Discrete-event Models: In the next few paragraphs a simple example is introduced to help the reader gain some appreciation for discrete-event simulation. Consider a situation where two loading shovels are serviced by a pooled fleet of four identical trucks (Fig. 9.4.5). Trucks wait in line at a shovel, first-come, first-served, if they arrive and find the shovel busy loading another truck. The material from each loading shovel is dumped at a distinct site, but trucks need not wait for trucks ahead of them to dump.

A dispatcher continuously keeps track of the trucks, and when a truck has finished dumping, it is assigned to return to one of the two shovels depending on the current situation. Specifically, assume the dispatcher keeps track of the number of trucks waiting in line at each shovel and the number in transit to that shovel from the dump site (previously dispatched). He calls this number "assigned transport capacity." He sends any truck that has just completed dumping to the shovel with the lower value of assigned transport capacity.

In evaluating system performance, assume one is interested in the production capacity of the system, that is, the amount of material dumped per unit time at each of the two dump sites, the utilization of each of the two shovels, and the amount of time the trucks spend waiting at the shovels.

In constructing a simulation model for this system, the following input data for the model might be established:

1. Combined time to spot and load a truck at the shovel.
2. Time to transport the loaded truck between each shovel and its respective dump site.
3. Time to transport the empty truck from each dump site to either loading shovel.

These data might come from time studies or from other sources (e.g., determination of haul cycle times using rimpull curves and data descriptive of haul road characteristics). Any or all of the input variables might be described as distributions rather than constant values. Depending on the detailed objectives of the study and needs for accuracy, it might be more appropriate to break the aggregate truck spotting/loading time into spotting and a sequence of swing cycles. But things will be kept simple here.

A set of state variables for the system might include:

1. Each shovel's operating status (idle or busy).
2. Assigned transport capacity (ATC) for each shovel.
3. The number of trucks waiting in line at each shovel.

The state variables for a given simulation are not unique; alternatives often exist. Moreover, the state variables employed depend on the objectives of the study. Progressing through the section, it should become clear to the reader that the shovel operating status is necessary as a state variable here only because of the interest in utilization of the shovels.

In constructing the model, the objective is to generate a run, that is, an artificial history of the behavior of the loading/haulage system as it progresses forward in time.

In general terms, the overall operation of a simulation model is described in Fig. 9.4.6. The *initial conditions* provide the starting point. They include, among other items, a specification of the initial state of the system. In the example, one might specify that one truck is waiting in line at each loader, loading by the shovel has just started for the second truck, ATC is two, and both shovels are busy. Time is subsequently advanced and state is updated as appropriate. Next, a check is made to see if it is time to stop the run. This might be ascertained by checking the current state with some terminating condition or by checking to see if the simulated time exceeds some predetermined stopping time specified by the analyst. If not, time is advanced and state is updated again as shown in the figure.

The key issue is time advance. Changes in the values of the state variables for the example only occur at discrete points in time. In such a situation, it is clear that one knows the behavior of the system completely if a sequence of "snapshots" of the system at those points in time where state changes can be generated. For generating a run efficiently, time should advance from the time of occurrence of one event to the time of occurrence of the next event.

Note, however, that some simulation models for mining systems advance time in fixed increments of short duration. Events and state changes may or may not occur at the end of these increments. Though appropriate for systems where continuous state variables are required for the analysis, for most discrete-event simulations, this technique loses not only in speed of execution but also in accuracy since state is not permitted to change, as it would in the real world, at arbitrary points in time.

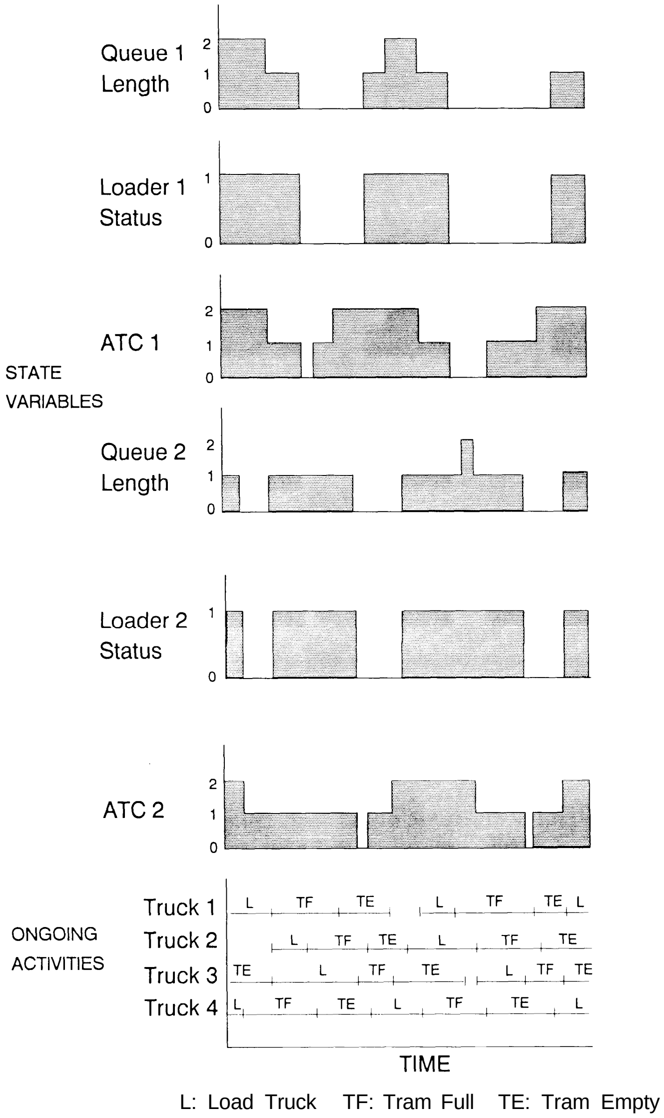

Fig. 9.4.7. Possible run for truck/shovel example.

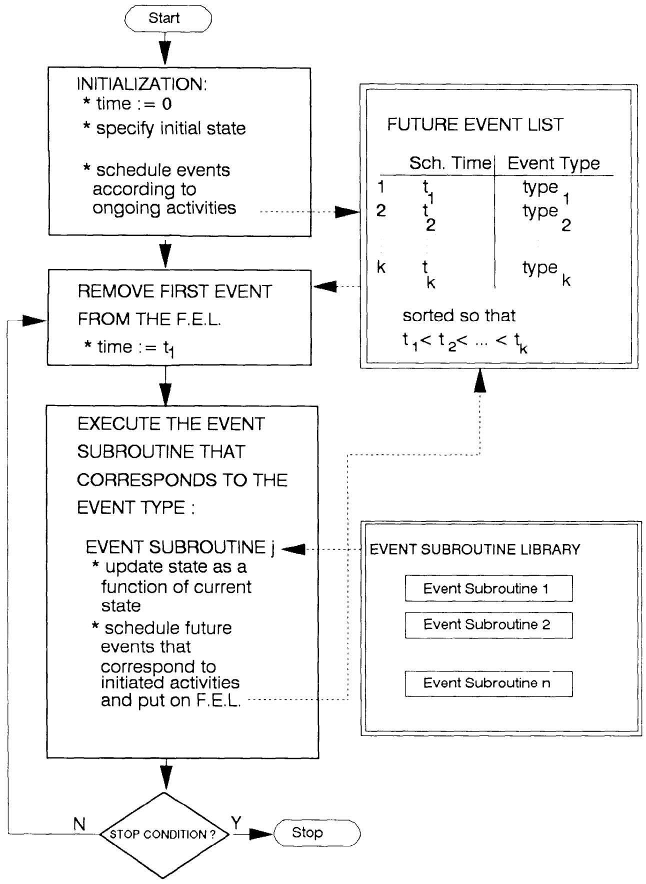

Fig. 9.4.8. Flowchart for the event scheduling approach to discrete-event simulation and corresponding program structure.

In discrete-event simulation, those input variables that specify a time duration are called *activities.* For the example, all three inputs—spotting/loading time, transport empty time, transport full time—are activities. Fig. 9.4.7 shows how the state variables might change with time for an example run of the truck haulage system. Referring to this figure, one sees that:

1. All events (an *event* corresponds to any change in the value of any of the state variables) occur upon the termination of activities. For instance, whenever a "transport empty" activity is terminated, an event occurs where the queue length increases by one and, if not already in the busy mode, shovel status changes to busy.

2. Upon termination of an activity, one might, using the external input to the model, be able to forecast the termination of some future activity. If this can be done, a point in time when some future event will occur has been identified. For instance, when the truck loading activity is finished, one can forecast, using the model input, when that particular truck will finish dumping. If "transport loaded" times are random, a typical time that follows the input distribution of these times would have to be "drawn" from this distribution. Nonetheless, the forecast can be made just using the *input* to the model.

Note that a future event cannot always be predicted upon termination of an activity. For instance, if a truck arrives and finds the shovel busy loading another truck, no activities are initiated, and no future events can be forecast. If the truck arrives and finds the shovel idle, a truck loading activity begins and the model input can be used to forecast when it will end. This illustrates that whether or not some future event can be forecast when the current event occurs is a function of the current state of the system.

The names for events are usually derived from the activities used to predict their occurrence. In the example, there are three events: (1) truck arrival at a shovel, (2) completion of truck loading at a shovel, and (3) completion of truck dumping at a dump site.

Now a position has been reached where it is possible to see how a computer might be programmed to execute a simulation run via what is known as the *event scheduling approach.* This is one of two major general purpose approaches for constructing discrete-event simulation models; the other is discussed later. Fig. 9.4.8 shows an overall flowchart for this approach. As noted previously, the initial conditions define the initial state of the system. In addition, they also give a few events for *priming* the model. For the example, if the initial state described above were to be used, a "completion of truck loading" event would have to

Table 9.4.1. Event Logic Tables for the Shovel Truck Problem

Definitions

State Variables:
- QL_i: queue length, shovel i.
- LS_i: status of shovel i, idle or busy.
- ATC_i: assigned transport capacity, shovel i.
- $TNOW$: current time

Activities:
- LT_{ik}: time to load truck k at shovel i.
- $TRAMF_{ik}$: time for truck k to tram full from shovel site i to dump site i.
- $TRAME_{ijk}$: time for truck k to tram empty from dump site i to shovel site j.

Event Logic Tables

Event 1. Truck k arrives at loader site i:

Condition	*Action*
Always	$QL_i \leftarrow QL_i + 1$
If LS_i = idle	$LS_i \leftarrow$ Busy Schedule a load completion event (type 2) for truck k at $TNOW + LT_{ik}$
If LS_i = busy	Put truck k at the end of the shovel i queue

Event 2. Truck k completes loading at shovel i

Condition	*Action*
Always	$QL_i \leftarrow QL_i - 1$ $ATC_i \leftarrow ATC_i - 1$ Schedule a dump completion event (type 3) for truck k at $TNOW + TRAMF_{ik}$
If $QL_i > 0$	Schedule a load completion event (type 2) at $TNOW + TRAMF_{ik'}$, where k' is the index of the truck at the front of the shovel queue
If $QL_i = 0$	$LS_i \leftarrow$ idle

Event 3. Truck k completes dumping at the dump site for shovel i

Condition	*Action*
If $ATC_1 \leq ATC_2$	$ATC_1 \leftarrow ATC_1 + 1$ Schedule a truck arrival event (type 1) for truck k at loader site 1 at $TNOW + TRAM_{i1k}$
IF $ATC_2 < ATC_1$	$ATC_2 \leftarrow ATC_2 + 1$ Schedule a truck arrival event (type 1) for truck k at loader site 2 at $TNOW + TRAM_{i2k}$

be specified for each shovel. In general, one priming event should be specified for each ongoing activity as the simulation run begins.

The priming events, both their identity and time of occurrence, are stored on the *future event list* (FEL). The events on this list are kept in order from earliest to latest. The computer then removes the most imminent event from the list, advances simulated time to the time of occurrence of that event and executes an *event subroutine* (there is one for each type of event). The event subroutine does two things:

1. It updates state.
2. It forecasts any new events due to activities initiated at the time of the current event and puts these new events on the FEL.

The results of both of these operations are determined strictly by the event type and the current value of the state variables using known functional relationships regarding the behavior of the system. No other information is required. Table 9.4.1 gives *event logic tables* for the three events of the example. These tables effectively describe the action of the event subroutines that one would incorporate with the event scheduling algorithm shown previously in Fig. 9.4.8 when coding the model.

Note that at any point in time, the content of the FEL is determined by the ongoing activities. A new event placed on the FEL would not necessarily go at the bottom of the list. For example, when truck 3 finished loading at shovel 1, its dump completion event would be placed on the FEL. While it is traveling loaded to the dump site, truck 4 may have begun loading at shovel 2. Its load completion event would then be placed on the FEL, and it may be placed ahead of the dump completion event for truck 3. Further, in general, events may be removed from the FEL before they occur. This would happen if activities exist that preempt ongoing activities.

Two new concepts, *entities* and *attributes*, useful for coding simulation models, are now introduced. Entities correspond to those dynamic objects in the physical system that require explicit representation in the model. In the example, entities might be used to represent the trucks and the shovels. Attributes are properties of a given entity, for example the operational status of the shovel, the size of the material load in a truck.

In the computer program, entities are often represented as records and order is maintained using files. For example, a sorted first-in, first-out (FIFO) file of records representing truck entities might be used for the waiting lines at each of the shovels. When an end of loading event occurs, the top record of this list is removed to identify the next truck to be loaded by the shovel. Discrete-event simulation programs have much in common with standard data processing routines. Good codes (i.e., codes that are efficient in their use of computer memory and in speed of execution) written from scratch in a general purpose language such as FORTRAN or Pascal require the use of list processing techniques and search algorithms to handle properly dynamic representations of the system using entities and attributes.

The event scheduling approach, discussed previously, is primarily an approach for organizing the simulation program. A quite different organization of simulation programs called the *process interaction approach* will now be discussed. Here coding is based on what are called *process routines.* One process routine is written for each type of entity in the system. In the example, two process routines would exist, one for truck entities and one for shovel entities.

The process routine describes everything that can happen to the entity as it passes sequentially through the system. Fig. 9.4.9 gives a process routine for the truck entities in the example. To understand how a process interaction simulation program works, it is useful to imagine that each entity is given, as it enters the system, a copy of the process routine that corresponds to the type of entity it happens to be. The entity then executes the routine sequentially in a fashion described below until it exits the system or the run otherwise is terminated.

The entity's process routine is activated. It starts at some point in the routine and executes as many steps in the routine as possible with zero time advance. These steps might change the value of global state variables, change the value of attributes of the entity, or schedule future events and put them on the FEL. Note that the FEL is common to both the event scheduling and process interaction approaches. Both are variable time increment techniques that advance the clock from the time of one event to the next.

Execution of the routine is temporarily suspended once time advance is required for the entity to take an additional step. These stop points correspond to the blocks before the dashed connection lines in the flowchart of Fig. 9.4.9. Note that some of the suspensions correspond to the beginning of activities. Here a future event will be placed on the FEL. Initiation of truck loading, block 6, is an example of this. Other stops correspond to indefinite delays, for example, wait in the queue at the shovel until removed, block 4.

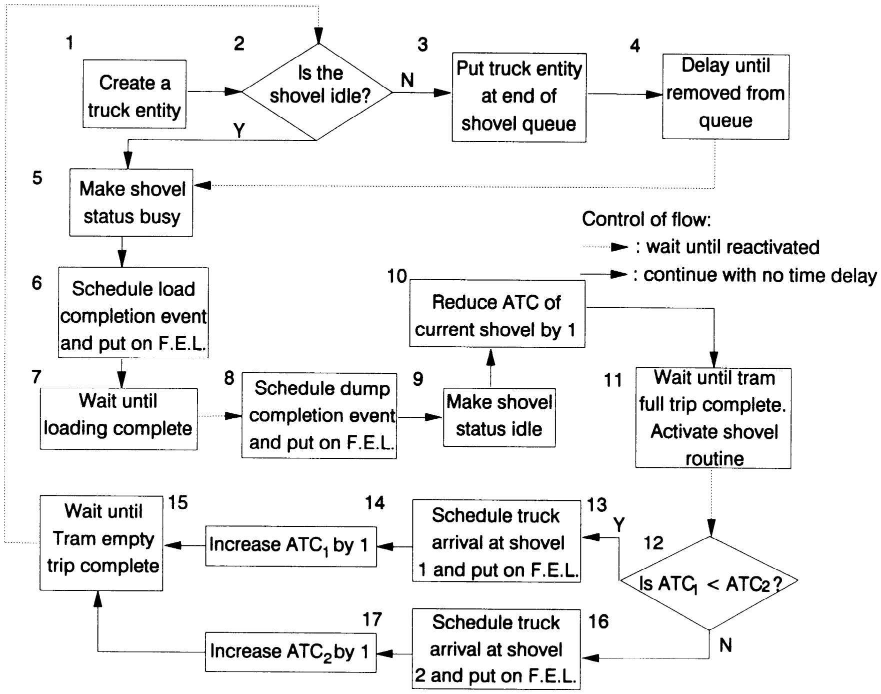

Fig. 9.4.9. Process routine for truck entity.

Once the process interaction routine stops, the process routines for other entities may be activated to see if they can also be advanced with zero time delay. In the example, a shovel entity's process routine would at some point in time remove a particular truck entity from the queue and subsequently stop execution. Before time advances, execution of that truck's process routine would resume from block 5 in Fig. 9.4.9.

Once all of the process routines have been advanced as far as possible with zero time advance, the most imminent event is removed from the FEL and time is advanced to the time of occurrence of that event. This corresponds to conclusion of an activity, and it reactivates the process routine of the entity that scheduled the event. The process routine of that entity is then executed sequentially starting from the block following the previous stop point.

If one writes a simulation model in a general programming language such as FORTRAN, the event scheduling approach should be used rather than process interaction. If the program writer must take care of all details, process interaction routines become very complex and the organization of the code is not natural. However, most of the special purpose *simulation languages,* including all of the more recent languages, are based on the process interaction approach.

When writing a program in these languages, one effectively defines a process interaction routine for the system entities. However, the statements available are at a macro level; a single statement may take care of many detailed operations automatically. These statements are geared to common situations that arise again and again in simulation models, and they are very powerful. Also some complete process interaction routines for common situations are built into these languages. In the example problem, one probably would not have to write any code for the shovel's process routine, just one for the trucks.

With these macro statements, writing a process interaction routine is often quite natural and is typically much less involved than writing an event routine for the event scheduling approach. Table 9.4.2 gives a process interaction routine for the example problem written in the SIMAN simulation language. Note that only 18 lines of code were required for this model, and one need not explicitly write such a routine for the shovel. The use of simulation languages in mine systems simulation is discussed in more detail in a later section.

Continuous Simulation Models: Continuous simulation differs from discrete-event simulation in that the state variables do not change strictly at discrete points in time. Rather, they change continuously with respect to time. Simulation is not required if a closed-form relation that gives the value of the state variable for any time and any specification of initial state can be established. However, often one can only specify the rate of change of the state variable with respect to time as a function of the current state.

For instance, from basic mechanics, one can specify a differential equation relating the state variable x, position of the vehicle, to equipment performance data that describe acceleration a_v of the vehicle:

$$\frac{d^2x}{dt^2} = a_v \qquad (9.4.1)$$

If a_v were a constant, it would be simple to establish a closed-form expression of x as a function of time and initial position. However, a_v is determined by the the rimpull characteristic (a measure of available force for acceleration) and the motion resistance of the vehicle, both of which, for a given vehicle and operating conditions, change as a function of the vehicle's velocity (see 9.4.2.4).

If the rate of change of the state variable is described as a first-order ordinary differential equation (i.e., the highest-order derivative is one, and all derivatives are taken with respect to the same variable, e.g., time), then a first-order Taylor's series expansion of x about t yields:

$$x(t + \Delta t) = x(t) + dx/dt(\Delta t) + O(\Delta t^2) \qquad (9.4.2)$$

Ignoring higher order terms, this expansion suggests a simple

```

numerical approach to computing $x(t)$. Start with $x(t_0)$, the initial state at time t_0, then, ignoring the higher-order terms, use the expression and the expression for dx/dt as a function of the state variables to estimate $x(t_0 + \Delta t)$ for some small increment Δt. Repeat this procedure to estimate $x(t_0 + 2\Delta t)$, $x(t_0 + 3\Delta t)$, etc. The magnitude of Δt is called the step size. The error in computing x for a single step is given by the unknown term $O(\Delta t^2)$, which can be made small by selecting a small step size.

This approach is seldom used directly because, relative to other available approaches, errors are large and computational efficiency is poor. However, this illustrates the basic idea behind a class of algorithms called Runge-Kutta methods that are routinely applied for this type of application. With minor extensions, these techniques can be applied to higher-order ordinary differential equations like the second-order one given previously to describe vehicle motion.

9.4.3.3 Coding Options for Mine Simulation Models

One has three options for establishing a model for use in mine production systems analysis: (1) write the code from scratch in a general purpose programming language, (2) select an appropriate and existing, often commercial, mining simulation software package, or (3) write the code from scratch in a simulation language. The issues one should consider in selecting from among these alternatives are now briefly discussed.

The first option is probably one that should only be considered by research institutions or engineering firms. The justification for considering this option is that a general purpose language offers complete flexibility in constructing the model. In contrast, the other two options might be constrained in the type of process they can model and/or in the efficiency with which they can execute a particular type of simulation run. These constraints do not exist for a general purpose language.

However, this option is often a time-consuming one. These models typically involve thousands of line of code and have, in the past, taken months, even years, to code. One should become very familiar with list-processing techniques and data structures prior to attempting such programming. Note that execution speed for models written in a general purpose language should, if proper data processing routines are employed, at least equal that achieved by the simulation languages. Often these speeds can be exceeded because the situation being modeled may allow use of more specialized routines than those implemented by the simulation language.

If one elects to code in FORTRAN, one might consider use of the GASP language. Though often referred to as a simulation language, GASP is a collection of FORTRAN subroutines that can be used to organize filing structure for the program, handle filing operations, handle input and output, and provide a clock-advance mechanism. The program would be coded using event scheduling. Several other simulation language packages also offer such utility routines for user-written FORTRAN codes.

However, writing simulation models in general languages other than FORTRAN that have better data structures and dynamic storage allocation (e.g., Pascal or C) is often more natural. FORTRAN is only prominent in simulation because of tradition, not because of any special suitability of the language itself.

Numerous simulation software packages exist for mine production systems, such as conveyor network models, truck/shovel models, surface mine simulators, continuous mining section simulators, longwall simulators, etc. Some of the more prominent of these packages are discussed in the next segment of this chapter.

These packages provide the core routines necessary for simulating these types of operations, and they accept alternative user specifications on system structure. The main advantage of such packages is that the user need not generate the code. Further, some of these packages have an impressive range of capability. For example, the General Purpose Surface Mining Simulator (GPSMS) package incorporates detailed ore body and spatial description of the mine along with capability to simulate a wide range of production operations and their interaction on this property (Albert, 1989).

There are some limitations of these packages, however, that should also be kept in mind. Input requirements can be extensive and learning these requirements can be quite time consuming. The better packages have given considerable attention to simplifying the user interface. For packages with broad scope, one may not be interested in using all this capability, but the package may, regardless, require extensive input description. Many of the existing packages use discrete increment time advance. Though necessary for simulating systems with continuous state variables, this approach leads to very slow execution times and inaccuracy for discrete-event simulations, and is inappropriate for some of the systems modeled.

Perhaps the most serious limitation of this class of software is that it is nearly impossible for the package developer to foresee all the systems alternatives that users might like to model. The scope of available options may not meet user needs. Moreover, since the software is written in general purpose languages with thousands of lines of code, major modifications of the package to accommodate user needs, other than by the original developer, is often a forbidding task.

The third option is the use of simulation languages. Here the user must write his own code. However, because of the powerful nature of the statements of these languages, the amount of code required to write the model is typically dramatically reduced relative to that required when writing the model in a general purpose language. This is especially true when the process interaction approach is employed.

For instance, a simulation model was developed by the author of a surface mine where a truck fleet serves as an intermediate transport link between a pair of loading shovels and two skip hoists. Features addressed in the model included a detailed description of the truck loading cycle, haul road segmentation with different operating conditions, pooled use of the truck fleet with special dispatch rules, modeling of truck failures, use of standby trucks that are activated when breakdowns occur, interfacing with a fixed capacity bunker at the hoist stations with special control logic for skip loading, and shift start-up and shutdown routines. Using a simulation language, a model for this system was written with fewer than 130 lines of code. This is substantially less than 5% of the amount of code that would be required to construct the same model using a general purpose programming language.

The proficient programmer in these languages can write reasonably complex models in a matter of hours or days, not months. In the course of developing the code, the programmer becomes intimately familiar with how the process is being modeled. The level of model validity can be judged better relative to judgments made when using a package developed by others. Most importantly, the programmer has considerable flexibility in customizing the model and the output it provides to suit needs and analytical objectives.

Simulation languages possess what is called a *world view*. This reflects the scope of the macro-statements used in the model and the type of real-world processes to which they are oriented. This is an important factor to consider since it influences the ease with which one might model a given situation or the ability to model it at all using the language. Many simulation languages are oriented toward modeling queueing systems. The SIMAN language, developed for manufacturing applications, has a number of features useful for mine systems modeling. These include material handling modules for discrete vehicle and conveyor transport and special features for accommodating spatial aspects of the system. Other languages have recently started to introduce such features.

It is not likely that one will find the world view of most simulation languages too restrictive or awkward for mining applications; most situations can be modeled using these languages. General constructs in the language can usually be combined to model specialized processes when the specialized constructs are absent. Differences may exist in the facility with which various situations can be modeled. Moreover, to overcome restrictions in scope, most of the modern simulation languages allow the user to interface routines written in a general purpose language with the routines written in the simulation language. One can thereby accomplish operations that the language cannot perform itself directly. At least in principle, one is not constrained in the scope of processes that may be modeled if user-defined routines can be integrated with the code.

If possible, it is suggested that someone interested in modeling a particular process contact users of the various simulation languages to see if example codes they have developed for various mining applications are available. Because of their brevity, these codes can be readily "digested" by individuals familiar with the simulation language. These examples can aid the learning process and greatly speed development of a custom model for a particular application.

The major simulation languages currently available include GPSS (GPSS/PC, GPSS/H), SLAM, SIMAN, and SIMSCRIPT II. Since these languages and their supporting software packages have been undergoing extensive updating and improvements in recent years and these trends are likely to continue for the foreseeable future, detailed comparisons of features will not be undertaken here. The following issues, however, should be considered when purchasing a license for a simulation language.

1. *Availability of the package in a PC version.* The computing power of today's personal computers is adequate for many (but certainly not all) applications. OS/2 packages that are now becoming available will increase the size of model that can be investigated using a microcomputer.

2. *Available modeling orientations supported by the language.* Preferably the language should support process interaction, event scheduling, and continuous simulation. Process interaction is typically the main approach employed for discrete-event simulation using the language. User-written event routines may often be interfaced with the process routines to increase flexibility and scope of the language; the package will typically have utility subroutines available to the user for creating these programs. If modeling of systems with continuous state variables is supported, mixed continuous/discrete systems can be represented. Detailed examination of the approach used for interfacing user-written routines and for mixing discrete/continuous representations should be undertaken if one believes there will be need to use these capabilities.

3. *Special application orientations for the language.* Some languages are directed especially toward queuing systems simulations, which is a major aspect of many real-world simulations, including mining systems (see 9.4.5). Some packages have built in features to make the simulation of materials handling systems easy.

4. *Output analysis software.* Custom reporting capability should be provided, and it should be easy to gather a wide range of system performance statistics. Many packages enable one to create files with detailed performance data generated during a run and include rather sophisticated statistical software for analyses using these data.

5. *Capability of animation of the simulation run.* This includes a graphics interface to the simulation package that provides a dynamic display of the system state using symbolic representations that the user designs. Effectively, it provides an opportunity to obtain a dynamic, global view of system operation at a faster or slower pace than could be observed in the real world. The importance of this capability depends on user needs. It may provide a means for gaining insights into system operation and can be an effective communication tool when presenting results to management or clients. At present, costs for animation capability can be high.

6. *Availability of good documentation with example programs to illustrate modeling approaches.* A well-written manual with illustrative examples can greatly speed the process of learning the code.

7. *Quality of debugging facilities.* The language package should have convenient facilities for debugging with abilities to generate program traces, set break points, etc. Debugging effort for programs in a simulation language is, relative to typical computer programming applications, slightly disproportionate to the size of the programs because of the powerful nature of the statements. Animation capability can also aid the debugging process.

9.4.3.4 Using the Models in Systems Analysis

The capability of simulation models to accommodate inputs that are described as random variables is most useful. Mining engineers are well aware of the ramifications such randomness has on the performance of real-world mine production systems. One might attempt to answer questions such as

1. How do truck breakdown rates and repair team performance influence the preferred size of a truck fleet?

2. How do different belt sizes and speeds influence the amount of spilled material at a transfer point, given the stochastic patterns of loaded material on the intersecting belts?

3. How much increased production can be expected if a bunker of a particular size is installed in the belt network to provide a storage buffer when outby belts fail?

4. What are the implications of the randomness in truck loading and haulage cycle times on the way a dispatcher should control the truck fleet so that production rate is maximized and blend qualities are maintained?

In answering questions such as these, there is a key issue to recognize (an issue that, unfortunately, is often ignored by practitioners). If the input variables are random variables, the performance variable(s) also is a random variable. The proper goal, therefore, is to know the probability distribution for the performance variable as a function of the input variables and specification of the decision variables.

However, the simulation model, because it is based on a run mechanism, does not give us this distribution directly. Rather, a single run gives one possible *realization* of this process. For example, it describes the way production might go for a particular shift. One must use multiple and/or extended runs and statistical inference to infer properties of the distribution of the performance variable (e.g., the mean level of the variable). Drawing conclusions on performance of a system from a single, short simulation run can be as misleading as management using, say, one shift's production figures for evaluating a field-implemented system.

The first issue of output analysis is to establish a clear definition of the performance variable(s) of interest. There is usually opportunity to collect observations on a large number of variables of interest during the simulation run. In the truck haulage model of 9.4.3.2, one might be interested in utilization of each loader, the average waiting time of the truck in the loader queue, the average production rate from each loader, the average total cycle time for the trucks, and perhaps others. Although any or all of these data are readily obtained from a simulation run of this system model, one is strongly discouraged from considering more than one or two variables in formal comparisons between alternative specifications of the decision variables.

There are two reasons for this statement. First, as will become more clear in the discussion that follows, there is uncertainty involved in any estimate of performance from a stochastic simulation run. If one wants to ascertain the value of several performance variables with high accuracy, often an extreme amount of computer time will be required.

Second, one is faced with difficulties in comparing alternative systems when multiple performance criteria are involved. In the example, if system A has higher loader utilization but higher average total truck cycle time than system B, how does one trade off a unit of loader utilization vs. a unit of total truck cycle time to decide which system is preferred? Multi-criteria decision making, that is, ranking alternatives while considering multiple performance variables of distinctly different natures, is an area of active research interest. However, most results from this field are not yet considered very practical.

It should be noted that one can often aggregate many performance variables in terms of their contribution to cost or profit from the operation. In the truck haulage example, a revenue might be associated with each ton of ore produced, a cost might be imposed for each hour the vehicle is operated and for each failure incident. In turn, a single criterion such as net profit becomes the performance variable of interest in comparing alternative system design or control options.

Other criteria might become performance constraints that all system designs must satisfy if they are to be considered true candidates for implementation. For instance, one might wish to select the production system alternative that produces at the lowest cost per ton subject to the constraint that the alternative produces at an minimum average rate of X tons per month. Here the performance variable "production rate" is not used directly in comparing alternatives. One just ensures that all candidates produce at the minimum acceptable level.

Though it is strongly encouraged that the analyst establish a single performance criterion for formally comparing system alternatives, this is not to say that one should ignore the other criteria. Ad hoc, intuitive experiments with a simulation model can often provide considerable insight into system operation and often suggests useful design and control options. Within reason, such experimentation is strongly encouraged. Indeed, it is here where the animation of the simulation run can often serve a useful role in the analysis. Nonetheless, the study should conclude with formal, scientific comparisons.

A final point must be emphasized regarding selection of performance criteria. Most of the literature discusses basing system comparisons on the value of the mean or average level of the performance variable (e.g., mean rate of production, mean availability). The mean is often, but not always, an appropriate basis for comparisons. The mean is so useful because it "boils down" the entire distribution to a single value. This value can be directly used in making comparisons in cases where total rewards or costs are proportional to the accumulated value of the performance variable over repeated or extended runs of the system. For example, total production revenues are likely proportional to the sum of individual tonnages produced during

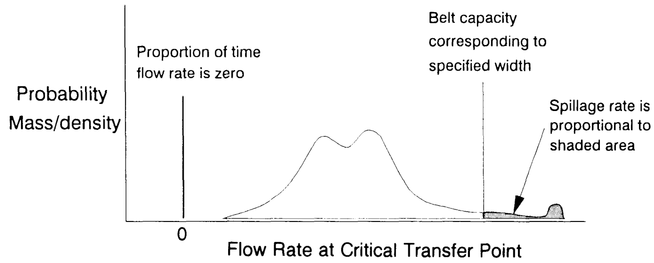

Fig. 9.4.10. Performance variable of interest for conveyor spillage example.

future shifts. Here the mean is a reasonable basis for comparing two or more system designs.

However, often other properties of the distribution of the performance variable, such as its variance, are also of interest. Consider the following example.

In simulating material flows in a conveyor network, flow rate (cubic yards or cubic meters per hour) at each of the transfer points might be included among the system state variables. Belt width effects on flow rate at some critical intersection in the model might not be explicitly incorporated in the model (a fixed conveyor width would simply truncate the flow rate when it exceeds some fixed level). Rather, one might attempt to size the belt, ex post facto, once the model output has been obtained. Here one is using what some might call a *functional model*—a model where unit sizing or capacity effects on its operation are ignored. Such models are often appropriate when designing a system since unit size is typically a decision variable.

What kind of performance variable would be of interest here? One that comes to mind is that time-persistent statistics might be gathered on the flow rate variable for the critical intersection. These data could be used, for instance, to generate a histogram (Fig. 9.4.10), where the magnitude of the vertical bars is equal to the proportion of time the flow rate is at any particular observed value. This histogram, assuming it accurately portrays long-run performance, could be used to provide information on expected spillage for any particular belt width. One would simply truncate the distribution at some fixed capacity level corresponding to a particular belt size; spillage rate would be proportional to the area above the point of truncation.

Here it is clear that one would like to know the *entire distribution* of the performance variable. The information provided by the mean flow rate is insufficient for and, in fact, has little relevance to the needs of this analysis.

As noted previously, simulation output does not give the distribution of the performance variable directly. Rather, this distribution, or properties of the distribution, must be inferred from data generated during a run using statistical techniques.

There are some interesting complications that arise when applying statistical methods to simulation output. Consider again the truck haulage example. Assume that truck delay time in the loader queue is the primary performance variable of interest. It is quite clear that the delay times of individual trucks will be related to one another. If the delay time of one truck is long, it is very likely that the delay of the next truck will also be long. Similarly, if the delay for one truck is short, the delay of the next truck is also likely to be short. This illustrates a key feature of simulation output. Individual observations of output variables are likely to be correlated (positive correlation in this case). Classical methods of statistical inference that are based on assumptions that successive observations are independent and follow the same distribution, that is, they are independent and identically distributed random variables (IIDRV), do not apply to simulation output.

Two distinct cases can be identified for analysis of output: *terminating simulations* and *steady-state simulations.* Such distinction arises not from the nature of the simulated process itself but from the nature of the performance variable of interest to the analyst when evaluating that process. With terminating simulations, the desired measure of performance is defined relative to a specific interval of simulated time. With steady state simulation, the desired measure of performance is defined relative to the limiting distribution of the variable as simulated time goes to infinity.

As an example of a terminating simulation, one might be interested in the volume of material moved *for a production shift* in the truck haulage example. A terminating simulation must have well-defined start-up conditions and terminating conditions. In the example, one might start as previously described in 9.4.3.2. One might terminate using a rule such that if a truck dumps its material within 10 min of quitting time, it returns to the service area.

Often one might be interested in system performance only during periods of "peak demands" on the system. For example, for some performance variable, one might simulate a track haulage system only during the period around shift changes, say, from 3 pm to 5 pm. Such simulations are also terminating; however, definition of initial conditions may be more difficult than in the previous example since activities of the system that are in progress when the simulation run begins may not be known and might be random.

As an example of a steady-state simulation, one might study, using a simulation model that accommodates unit failures, the availability of the furthest inby face conveyors as influenced by the size and location of surge storage bins in the belt network. If contemplating incorporating such buffer capacity in the network, one would certainly want to know implications on mine production over an extended time horizon. However, there are no natural starting or terminating conditions for considering performance of this system. Steady-state simulations are frequently employed where performance measures are long-term in nature and where there are no natural events to terminate the run.

An inherent characteristic of steady-state simulation is that the initial state of the system influences the early observations of the performance variable. For instance, in the truck haulage example, assume that for some reason one is interested in the steady state value of the mean delay of the trucks at the loader queue. The simulation might be started with all trucks queued up at the two loaders. Under such circumstances, the early delays will be longer than they typically would be. If data from the early portion of the run are used in estimating the mean steady-state delay, the estimate will be biased high because of these long delays. Any other starting condition is also arbitrary and will introduce some type of bias. This is called *initialization bias,* and it should be dealt with carefully.

The distributions for the exogenous input variables for steady-state simulations must remain constant throughout the simulation run. In contrast, terminating simulations are by nature transient. These distributions may change over simulated time. Moreover, no effort is made to eliminate the effect of initial state on the performance observations. In fact, one wants to explicitly capture the effects of initial state on performance. It is considered a fundamental aspect of the process under study.

Terminating simulations are much easier to analyze than steady-state simulations. Assume interest is focused on the mean value of some performance variable. The analytical procedure is to make multiple runs of the simulation model, each spanning the performance period of interest. Each of these runs, or replications, would use a different sequence of random numbers. Then the mean value of performance variable, $\overline{X}_i$, observed for each individual replication $i^i = 1,2, \ldots, r$, where r is the total number of replications, is calculated. Though the individual observations of the performance variable *within* a replication are not statistically independent, the $\overline{X}_i$, $i = 1,2, \ldots, r$, since they are generated using independent random number streams, clearly may be treated as IIDRV, and classical statistical techniques may be applied. Since the $\overline{X}_i$ are averages, they will tend to be normally distributed in many applications. (There are central limit theorems for correlated random variables.) The data can be used to compute a confidence interval for the performance interval as follows. Let

$$\overline{X} = \sum_{i=1}^{r} \overline{X}_i \tag{9.4.3}$$

and

$$S_{\overline{X}} = \left[\frac{\sum_{i=1}^{n} (\overline{X}_i - \overline{\mathrm{X}})^2}{r(r-1)}\right]^{1/2} \tag{9.4.4}$$

Then compute a $(100 - a)\%$ confidence interval for the mean value of the performance variable $\mu_{\overline{x}}$ as

$$\overline{X} \pm t_{a/2,r-1}\, S_{\overline{X}} \tag{9.4.5}$$

where $t_{\beta,k}$ is the value such that the $Pr\{U < t_{\beta,k}\} = \beta$ if U has a t distribution with k degrees of freedom.

What has been discussed is a procedure that has high probability, specifically $100 - a$, of constructing an interval that contains the unknown value of $\mu_{\overline{x}}$. Preferably, the interval will be small in width, but this depends on the innate variability of X. One can overcome wide intervals by increasing the r, as is evident from the previous formulas. In using this approach to compute a confidence interval, one does not say that $\mu_{\overline{x}}$ is contained in the interval with probability $1 - a$. The probability statement is about the procedure. A probability statement about $\mu_{\overline{x}}$ is inappropriate since it is a constant (though unknown), not a random variable.

Fig. 9.4.11 illustrates two major approaches for characterizing the mean value of a performance variable in a steady-state simulation. The first illustrated approach is similar to that used in terminating simulations. One makes several replications of the model using different random number sequences. Like the terminating case, the mean level for each replication will be IIDRV. However, since interest is in steady-state performance, observations from the early part of each run are eliminated to prevent these observations from biasing the estimator.

The second approach is called the batch approach. Rather than making several replications, a single long run is made. This long run is divided into a number of batches. For example, if 4000 truck delays are observed in the simulation run, the run might be divided into 40 batches of 100 observations each. (There is little incentive to ever create more than 40 batches.) Although consecutive individual observations of the performance variables are correlated, intuition suggests that if the batches are big enough, the means for each batch will tend to be uncorrelated. This is frequently observed to be true. These means will also tend to be normally distributed. The batch observations might thereby be treated as IIDRV.

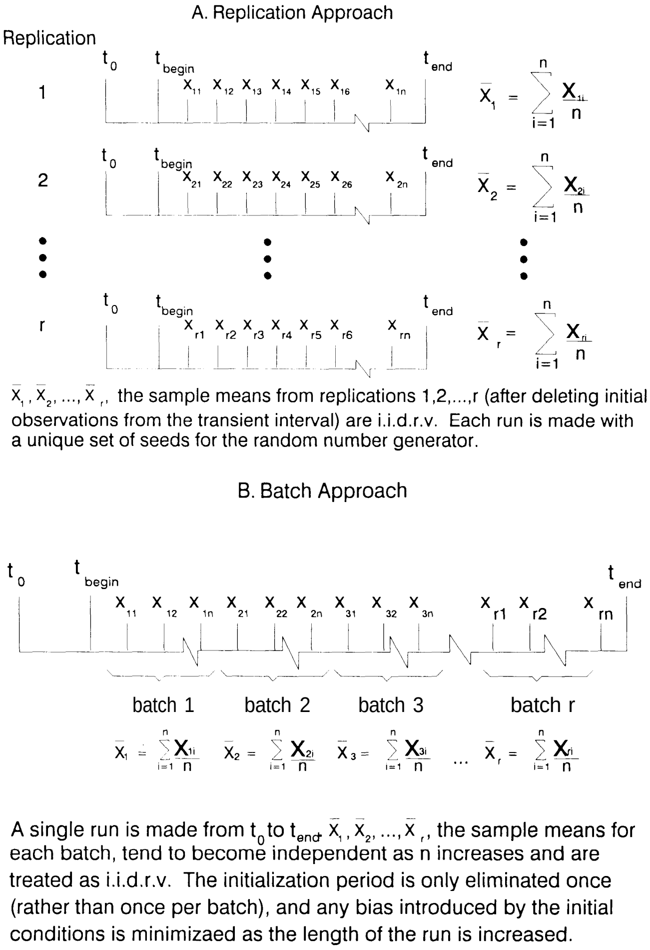

Fig. 9.4.11. Two approaches to estimating a performance variable for a steady-state simulation.

The batch approach has the advantage over the replication approach in more efficient use of data since one only throws data away for the initial transient period once, not *r* times. Moreover, it is difficult to ascertain how many data should be eliminated to eliminate initialization bias. This differs from one system to the next. In the batch approach, initialization bias becomes less and less significant as more data are collected by extending the length of the run. However, with the replication approach, one might collect more data by adding replications. If the length of the initialization period has been underestimated, a narrow confidence interval might be constructed around a biased estimator of performance and such an interval can be very misleading. Both the batch and the replication approach would use the same formulas given previously for terminating simulations in the numerical computation of the confidence interval.

Room exists here only to highlight some of the major points in analysis of output from simulation models. Hopefully, it is clear to the reader that simulation models with stochastic input variables do not directly describe performance of the system. Rather, they give data from which performance can be inferred with appropriate use of statistical techniques. Failure to consider formally these techniques is a weak point of many applications of simulation to mining problems. The reader is referred to the texts Law and Kelton (1982), Banks and Carson (1984), and Fishman (1978) for more detailed discussions of output data analysis. These texts address additional topics as follows:

1. How to determine how many replications of a terminating simulation are necessary to characterize a performance variable with a level of precision specified by the analyst.

2. Procedures to determine how long the initialization period lasts for a steady-state simulation. However, these procedures can only be viewed as giving approximate answers to this difficult question.

3. Procedures for determining the batch size and run length necessary for determining the mean level of a steady-state performance variable with a certain level of precision using the batch approach.

4. Procedures for comparing system alternatives. These include techniques for computing confidence intervals on the difference between the mean levels of performance in two systems, for selecting the best of a number of distinct system alternatives, and the use of formal experimental design in characterizing system response to the adjustments of the decision variables.

5. Procedures for reducing the variance of the response variables by manipulations of the input data to the model. With these procedures, response variables can often be estimated with greater precision, and comparisons between alternatives can often be more easily made.

9.4.3.5 Discussion of Specific Applications

The objective of this segment is to identify typical applications of simulation modeling in mine production systems engineering, to discuss some of the key technical issues in structuring these models, and to identify software packages that might be applied to these problems. Major differences in structure exist between models involving continuous material handling systems and discrete vehicle transportation systems, and this forms the basis for organizing this section.

Continuous Material Handling Systems: The major continuous material handling application involves conveyor network modeling. Some of the problems that might be addressed using simulation models of these systems are as follows.

1. *Design of systems for throughput capacity.* When a belt handles the output from several production sections, designing capacity to meet the combined peak loads from all of the sections can lead to unneedful expense in terms of capital and operating costs. Simulators can describe the distribution of material flow rates into any belt transfer point. This in turn can be used to evaluate a particular system configuration—specified in terms of network structure, belt speeds, use of surge bins to trim peak flow rates, use of limit switches and other operating controls, etc.—for its ability to handle material flows without excessive spillage or curtailments of availability of the network to the production sections.

2. *Assessment of network configuration impacts on availability of the transportation system to the production systems.* In many applications the production section and belt system form an extensive serial chain of operations. Belt system failures frequently provide a major constraint on production output. The simulators provide a means for testing alternative configuration options to assess their impact on network availability. This includes assessing the impact of buffer storage capacity (e.g., bunkers), appropriately sized and inserted at strategic locations, which are a means to temporarily breaking the serial dependence of one portion of the network on other portions.

3. *Testing control strategies for belt monitoring and control systems.* The potential for computer-based monitoring and control in underground mines is now just becoming evident, with the belt system a major focus of attention. A variety of means for real-time control of the dynamic material flows potentially exist, such as variable speed belts and feeders and feedback to

the production operations. Simulation will no doubt play an important role in development of these strategies.

Turning the discussion to highlight some of the key technical aspects of modeling these systems, there are two major approaches used to represent material flows. In the first approach, a conveyor is viewed as a collection of small adjacent cells, which is represented in the computer as an array. Attributes associated with each cell can denote properties of the material, for example, thickness on the belt or type of material. Time is advanced in small discrete time increments and, effectively, the attributes are shifted ahead a single register, representing material flow in the outby direction. At junctions or transfer points, cell attributes are combined in an appropriate fashion to represent superposition of material flows. For example, if the outby belt travels at the same speed as the inby belts, thickness attributes are simply added. This is, effectively, a simple form of continuous simulation. These models execute slowly relative to the approach discussed in the following, especially if one physically shifts records in the array to model material movement. It is much more efficient to shift a pointer to the array location that corresponds to the cell at the head of the belt, as done in some packages, than it is to move all of the records for each time advance.

The second approach employs discrete-event simulation. For many analytical purposes, one obtains adequate information if the *flow rates* are known at each transfer point, into and out of each bin or feeder, and out of each discharge point. For example, spillage and throughflows can be ascertained directly using these rates. Though knowledge of position of material along the conveyor at any point in time requires continuous representation as discussed previously, flow rates may be modeled as variables that only undergo changes at discrete points in time. If a change in flow rate occurs at one transfer point, one simply uses belt speed to forecast the time when a resulting change in flow rate will occur at the next outby transfer point. The magnitude of this future rate change is determined by multiplying the ratio of the speed of the incoming belt to the outgoing belt times the current rate change. A change of flow rate into a feeder/bin can be used to schedule a feeder bin overflow event if the new input flow rate exceeds the maximum discharge rate of the feeder, an event that may be preempted if rates decrease in the future before the scheduled event occurs. It may also schedule an increase in discharge rate if the current outflow rate is not currently at maximum. Further, such a change in flow rate can be used to schedule a future decrease in the outflow rate of the feeder if the input rate is less than the current outflow rate. Models using this representation may be coded using the event-scheduling algorithm mentioned previously. Since a variable time increment approach is used, they operate much faster than the other class of models. The BELTSIM program uses an approach similar to this (Bucklen et al., 1969).

Perhaps the most critical aspect of conveyor network modeling is obtaining a realistic representation of material arrival to the system. Exceeding the throughput capacity of units in a reasonably designed conveyor network will typically be a "rare event." Predicting accurately, with a reasonable amount of run time, the incidence of rare events via stochastic simulation can be difficult. For this reason, it is important that the description of material arrivals accurately portray the real-world situation.

For example, one might represent material arrivals from a continuous miner section in a coal mine using a sequence of discrete arrivals to the system. Shuttle car interarrivals would be random, but the parameters of the interarrival distribution would not be held constant through the simulation run. Rather, these parameters would be changed in a cyclic fashion to reflect the underlying cut sequence. A random place-change delay would also be allowed between each cut. The entire sequence of interarrivals may be preempted from time to time with delays representing major equipment failures. If additional realism is desired, interarrival times might alternate between high and low values for the two cars for those cuts where the tram paths differ substantially in length. One might also provide for shuttle car failure, changing the interarrival pattern when this event occurs. For a longwall unit, material arrivals would be continuous, but rates would vary for different portions of the cut. The overall arrival pattern would be cyclic and interruptions might be allowed to represent equipment failures. Available conveyor simulation packages vary in their ability to accommodate such detail. Some are quite flexible.

A number of packages for simulation of conveyor networks exist. These include BELTSIM (Bucklen et al., 1969), Continuous Material Handling Simulator (CMHS) (Tan and Ramani, 1988), Coal Mine Belt Capacity Simulator (CMBCS) (Thompson and Adler, 1988), BETHBELT- (Newhart, 1977), and UnderGround Materials Handling Simulator (UGMHS), (Manula, 1974). The recent paper by Sturgul (1989), discusses the use of a simulation language to construct a belt simulator.

Discrete Vehicle Transportation Systems: Simulation also provides a basis for analysis of many detailed aspects of mining systems employing discrete vehicle haulage in combination with excavation/loading equipment. Some of the issues one might attempt to address follow.

1. *Design of haul road profiles.* For example, should required climbs be achieved through use of short steep road segments or extended segments of lesser grade?

2. *Fleet makeup of transporters.* This addresses the determination of the best structure of a fleet of haulage vehicles at a mine, including the number of vehicles, their size, the number of units kept on standby in the event of breakdowns, and static allocation of the transport units among multiple loaders in order to maintain desired production ratios among the loaders.

3. *Analysis of real-time fleet control strategies.* Modern computer-based dispatching and fleet management systems often employ sophisticated computational schemes for improving the effectiveness of equipment utilization and maintaining control of quality of the mined product. However, the schemes are based on heuristic approaches (see 9.4.4). Simulation provides a technical basis for testing the quality of these heuristics and comparing alternative tactics.

4. *Detailed analysis of equipment interactions on overall system performance.* For example, one might consider modifications of the loading site to change maneuvering required for truck spotting or to allow double-sided loading at a shovel.

5. *Analysis of working section and pit layout options.* Examples of such analyses include where should an in-pit crusher be located to best serve multiple load sites and what are the ramifications of alternative cut sequences for a room and pillar section?

The detailed description of vehicle motion may require use of continuous simulation. A basic differential equation (9.4.1) can be used to describe the spatial position of a vehicle. When the vehicle is increasing in speed, a_v is typically determined from the expression,

$$a_v = \frac{F_r - F_m}{M_c} \tag{9.4.6}$$

In this relation, F_r is the rimpull force at the current velocity, which may be taken directly from the rimpull chart for the vehicle. F_m is the resistance force offered by the vehicle, which depends on rolling resistance, air resistance, and grade resistance. Corrections for rolling and air resistance are usually incorporated as a function of current velocity of the vehicle when making such simulations. M_c is the corrected mass that accounts not only for the actual mass of the vehicle, but incorporates a corrective term, which is also a function of current velocity, to account for losses in the drive system of the vehicle. It is seen that a_v can be known given a collection of state variables that includes the current velocity of the vehicle, grade, and rolling resistance of the haul road. Given a_v, Eq. 9.4.6 can be integrated to forecast the velocity and position of the vehicle at the end of a subsequent time increment.

Other factors taken into account in such simulations are speed limits for the road segment, which restrict maximum attainable speed, braking/retardation, and losses for the "dead time" when shifting gears (depending on the nature of the drive system). The VEHSIM package (Anon., 1984) is widely used for such simulations. It incorporates performance parameters of many Caterpillar vehicles and allows users to input parameters for other vehicles.

Recall that the selection of state variables, in part, depends on the the objectives of the simulation study and is not directly defined by the physical nature of the system. In simulations of material excavation and handling systems, performance is typically addressed in terms such as material production or throughput rates, equipment utilization, average cycle or delay times, etc. Performance measures such as these may be reliably obtained from simulation runs that do not provide knowledge of vehicle position at each instant of time. If one is in a situation where travel times are not available for various hauls (e.g., from time study data), it is often a good practice to use a vehicle motion simulator to provide data descriptive of haulage times for various segments of the haulage cycle. Subsequently, one uses these data as a basis for the input to a discrete event simulation model of the mining operation. The discrete-event model will operate much more efficiently, will not be repetitively computing deterministic haulage times, will readily accommodate stochastic aspects of the process, and can flexibly handle detailed aspects of the process relevant to the performance variables of interest.

A number of software packages have been developed for modeling these systems for both surface and underground mining. They include:

1. GPSMS, General Purpose Surface Mine Simulator (Albert, 1989), couples ore body modeling with operations simulation. Block models may be constructed to describe local geology and mine property boundaries. Operations descriptions are input to the package via a two-level structure. The first, "Equipment Face Activity Description," details excavation operations. The second, "Equipment Deployment Description" describes equipment operations and activities spatially and sequentially (i.e., the overall mining plan) and ties extraction with materials handling. Support modules are incorporated for simulating dragline operation, truck haulage (continuous simulation using rimpull curves), and conveyor haulage. This package extends the capability of its predecessors, the Total System Surface Mine Simulator (Albert, 1979) and Open Pit Materials Handling Simulator (O'Neil, 1966), although these packages have unique modules that may be of value and are not supported in GPSMS.

2. FACESIM (Prelaz, et al., 1968; Suboleski and Lucas, 1969) and UnderGround Material Handling Simulator (UGMHS) (Manula, 1979) can be used to simulate room and pillar mining operations, including ancillary operations. The input structure for UGMHS is similar to that for GPSMS. Motion of haulage vehicles may be established using continuous simulation in UGMHS, whereas distributions or constant values are input using FACESIM. The paper by Bise and Albert (1984) compares these packages and the use of simpler deterministic models of the mining cycle.

3. LHDSIM (Beckett et al., 1979) is a package for simulating a load-haul-dump system for room and pillar mining operations.

4. SCSMLT (Peng et al., 1988), simulates haulage in open pit mines and has features for interfacing discrete vehicle haulage systems to a crusher/continuous haulage system.

Examples of applications where the modeling was executed using a simulation language include Sturgul (1987), where alternative locations for an in-pit crusher were investigated; Mutmansky and Mwasinga (1988), who examined the general applicability of SIMAN to modeling mine production systems and applied the language to model a truck/loader system; Weyher (1976) who modeled room and pillar operations using GPSS; and Harrison and Sturgul (1988), who examined the main haulage system for a large underground mine and modeled several alternative transportation systems mixing both truck and train transport.

9.4.3.6 Simulation Case Study

A case study will illustrate the process of conducting a simulation study. The study has been "manufactured" by the author, but it is intended to portray major aspects of the execution of a simulation study in a realistic fashion.

Statement of Problem: A multi-mine coal operator has recently experienced some difficulty in meeting sulfur specifications for one of its major clients. Although construction work will begin shortly for new operations in a low-sulfur reserve owned by the company, in the interim, a greater quantity of low-sulfur coal is being obtained through the addition of two continuous miner sections at one of its existing operations working a low-sulfur seam. The addition of the two units brings the total number of working sections at the mine to four. A problem has been experienced because of the inadequate size of mainline belts to handle the peak production capacity of the four units. Several overload-related spills have occurred in the past few weeks since the new units have come on-line, and action needs to be taken so that this situation does not continue.

Decision Alternatives: The mine is nearing the end of its life, and since the belt line carrying the combined flow from the four units is quite long, the capital expenditure for modifying the existing conveyors so that they have higher capacity cannot be justified.

However, one option that is easy to implement and is believed to have potential for alleviating this problem is fine tuning the feeder discharge rates at the production sections. By slowing the feeders from their current levels, the discharge of an individual shuttle car is spread on longer, thinner layers on the conveyor belt. This, in turn, directly reduces the magnitude of the load observed at the transfer point where flows from the four units converge. Such a modification is expected to reduce the incidence and severity of spills. Note that it may not be desirable, from the perspective of overall production output from the mine, to set all of the feeders at the same speed. Hence the decision alternatives considered in this case study may be expressed in terms of four setpoint values, one for each of the four section feeders.

Of course, there are other control options that probably should be considered. With minor modifications, the model presented in the following is flexible enough to consider many other decision alternatives that one might conceive such as, for example, staggering start-up times of the production units so that the duration of the periods when all four units are active is minimized. However, for the purpose of this study, only feeder discharge rates will be considered.

Structure of the Simulation Model: The simulation model will incorporate (1) face operations for the four production units, (2) the feeders, and (3) the belt network to the transfer point where the material flow from the four units converges. The third component of the model is actually quite trivial for this study.

A fairly detailed model of face operations is necessary for two reasons. First, for the units where feeder speed will be reduced from current values, there is no direct way of predicting what the shuttle car interarrival times will be after the change is implemented. Certainly, there is a chance that on some cycles, the car dumping time will be increased from its current value if the material from the previous car has not cleared the feeder, but there is no direct way of knowing how often this will occur and what the net effect will be on total shuttle car cycle time.

Second, for this particular problem, there is a coupling between the belt network and face operations that should be considered. Changing feeder speeds has potential for both positive and negative impact on overall economics at the mine. By increasing shuttle car dump times on occasion, the short-term rate of production output from the mine will be negatively affected. On the other hand, if a major spill is avoided, one prevents shutting down the face units while the spill is cleaned up and production is increased through the increase in available operating time. As discussed in more detail in the following, the average rate of production output is employed to compare decision alternatives. To accurately reflect the coal output, the serial dependency of the face units on the operation of the belt should be incorporated in the model. It is interesting to note that the coupling exists in this case due to the nature of the performance criterion that is used in making the comparisons.

An issue that is believed to be important for the study is the effect of cut sequence. The variable distance between the cut and the feeder might have a pronounced influence on the effect of changing feeder speeds. If the cuts are close to the feeder, shuttle car interarrivals will be short and the feeder is likely to have more surge when the arrival occurs. Short hauls also have more dead time, and a delay in dumping is not as likely to turn into an overall delay in cycle time. For this reason, the model was constructed to incorporate the cut sequence followed by each section.

The model was coded in the SIMAN simulation language. Process interaction routines (in SIMAN, these are called "block models") were written to describe operation of the face units and the belts. Coal flow through the feeders and belts were modeled using flow rates as state variables since this approach has considerable advantages when modeling bulk material flows on continuous haulage systems (see 9.4.3.4). The SIMAN language does not readily accommodate such a representation for a surge storage device like a feeder, and for this reason the following event routines were written: (1) shuttle car arrival at feeder event, (2) feeder full event, (3) shuttle car empty event, and (4) feeder surge depletion event. Table 9.4.3 gives, as an example, the event logic table for event 1.

There are several interesting features of the block model. First, as one might expect, a separate process routine is not required for each face unit. The sequence of operations undertaken by a continuous miner, a shuttle car, and a roof bolter is very similar among the four units. The SIMAN macro concept (similar mechanisms are available in other simulation languages) allows entities from each of the four units to share the same process routines that describe the overall sequence of operations. Moreover, details necessary for describing spatial aspects of the process are readily decoupled from the process routine. In the model that has been developed, the shuttle car routine is roughly defined as follows:

1. Wait at the miner change point if the other shuttle car has not cleared the change point.
2. Once access to the miner is possible, seize a resource to block entry of the other shuttle car and tram to miner.

Table 9.4.3. Event Logic Table for Event – Shuttle Car Arrival at Feeder

First compute the current surge level in the feeder, E, as

$$E = \begin{cases} (T_e - t)\,D & D > 0 \\ 0 & D = 0 \end{cases}$$

where D is the current discharge rate of the feeder, t is the current time, and T_e is the time that the next surge depletion event (event 4) has been scheduled. (If $D > 0$ such an event is always scheduled.)

Condition	*Action*
Always	Set feeder input rate I to the shuttle car discharge rate R.
	Schedule a shuttle car empty event (event 3) at time
	$t + L/I$
	where L is the payload of the shuttle car.
If $D < I$ (feeder filling)	Schedule a feeder full event (event 2) at time
	$t + (K - E)/(I - D)$
	where K is feeder surge capacity. Also, delete any previously scheduled surge depletion event (event 4).
If $D > I$ (emptying) and $E > 0$	Schedule a surge depletion event (event 4) at time
	$t + E/(D - I)$

3. Wait while loaded.
4. Tram to miner change point and release the resource that allows the other shuttle car to enter.
5. Tram along a sequence of stations until arriving at the feeder change point.
6. Seize a feeder access resource and tram to feeder.
7. Activate a shuttle car arrival event (user-written event routine 1) and wait.
8. Release the shuttle car from the wait state when shuttle car empty event (user-written event routine 3) has occurred.
9. Return to the feeder change point and release the feeder access resource.
10. Tram along a sequence of stations until returning to the current miner change point.

Externally defined input data to the model define stations that correspond to physical locations of the crosscuts and entries. In addition, sequences of these stations are defined that control vehicle movements. Equipment moves along the cut sequence are handled in similar fashion. Only a few statements were required to model the four continuous miner units and movement of material along the belts.

Input data to the program, in addition to the station layouts and tram sequences noted above, are as follows:

1. Feeder discharge rates and surge capacity.
2. Belt transit times from the section feeder to the point of convergence.
3. Tonnage per cut.
4. Distribution of shuttle car, miner, and bolter tram rates.
5. Distribution of shuttle car payload size.
6. Distribution of time to load a shuttle car.
7. Distribution of time to bolt a cut.
8. Distribution of downtime when an overload spill occurs.
9. Distribution of time between unscheduled delays in the face production cycle and duration of such delays.

As can be seen, the amount of field work to obtain the various input distributions required by the model is not excessive. Simulation can usually proceed with a rather small investment in time studies. Moreover, these studies typically should focus on the various elemental times of the production operation, spending perhaps a few hours observing each of the major parts of the operation. Simulation is a means of synthesizing time study data and drawing meaningful conclusions from this data that otherwise cannot be obtained. In this case, perhaps the most difficult data to obtain would be the distributions involving unscheduled delays in the face production cycles. For the purpose of relative comparisons among the decision alternatives that have been studied, it might be reasonable to ignore such delays. Ignoring such delays would, however, be inappropriate if one hoped to obtain accurate cost figures from the simulation study.

Application of the Model: From examination of the capacity of the belts handling the combined flow from the four units, it is clear that the overload incidents occur at this mine only when peak loads from all four units meet simultaneously. In such a situation, reducing the frequency of overloading incidents can only be accomplished by reducing the sum of the discharge rates of the feeders to the minimum capacity of the belts handling the combined flow of the four units. Moreover, there is clearly no incentive to reduce the discharge rates below this level since this will only reduce the rate of production from the working faces. These questions remain:

1. Will the reduction in feeder discharge rates cause an excessive decrease in the rate of production that cannot be offset by the gains in operating time?

2. How should one best go about allocating the discharge rate reductions among the four units?

To help answer these questions, four alternative strategies have been investigated. Alternative 1 represents the status quo. Alternatives 2, 3, and 4 all specify the same combined feeder discharge capacities equal to the capacity of the belts handling the combined flows. With alternative 2, the rate reduction is split equally among the four units; with 3, it is split equally among three units; and with 4, it is split among just two units. Allocating all of the reduction to one unit was not considered since this would clearly be an excessive choke on output from that unit.

Though there is some cost associated with cleaning up a spill, the costs are an order of magnitude less than the lost production costs associated with any belt shutdowns that might occur. These shutdowns are reflected directly in the simulation model. Ignoring cleanup costs, the alternatives have been compared in terms of the time average flow rate on the mainline belts, a measure of total production output from the mine.

Simulation runs were made for a single production shift since this represents a natural termination point for the run, and the output is analyzed as realizations from a terminating simulation. To deal with the potentially significant influence of cut locations and the cut sequence, the starting cuts were randomized for each run. (One could perhaps find better ways to handle the influence of the cut sequence, which introduces a long cycle into the operations, than through randomization; this appears to be a rather complex issue from a technical perspective.) A total of 20 runs was made for each alternative and the results are given in Table 9.4.4. As the histogram for the performance variable for alternative 1 in Fig. 9.4.12 shows, there is considerable variability of the output response. The sample mean production rate for each alternative is shown in the table along with a 95% confidence interval for the mean.

The results appear to imply that a reduction in feeder speed is desirable and that it is best to allocate the reduction equally among the four units (alternative 2). An equal allocation in this case is not surprising, but such a result probably would not hold if there were significant differences in the production cycle among the four units. Though a comparison of sample means is the device for selecting the best alternative, such a selection cannot be made with certainty. The sample means only represent estimates of the true, but unknown, mean. The fact that the confidence intervals of several alternatives overlap provides an indication that one might expect some difficulty when coming to a decision about the best alternative.

Table 9.4.4. Output for the Four Alternatives Considered in the Case Study

	Alternative			
Run	1	2	3	4
1	4.15	4.46	4.44	4.74
2	3.32	4.09	4.10	4.18

In this problem, one might apply a procedure where the results of the first 20 runs are used as a basis for determining how many more runs to make before making a final decision on which alternative is best. These initial runs give considerable information in the inherent variability of system performance for each alternative. Using these measures of variability, the number of additional runs might be established on the basis of (1) the level of probability of a wrong decision that one is willing to accept, and (2) the minimum difference in performance among alternatives that one considers to be of significance. Once these additional runs are made, a final decision could be made by comparing the means, and one would have assurance that the two stated conditions on uncertainty are satisfied when making the decision. Further discussion of the nature of such procedures are beyond the scope of this presentation; interested readers are referred to the texts cited at the end of 9.4.3.4.

9.4.4 FLEET DYNAMICS AND DISPATCH

The stochastic aspects of mine operations—an equipment failure incident, variation in tram times or loading rates, etc.,—preclude development and field implementation of a fully prescriptive plan for operations. Rather than attempt to follow a rigid sequence of operations, often much can be gained from ongoing, real-time analysis of the current status and recent history of the operations. This analysis might then be used as a basis for taking control actions to improve subsequent performance of the system. This is perhaps most evident, and the technology is most fully developed and accepted, for real-time management (dispatch) of pooled truck fleets serving multiple loading units. Ideas similar to these might be applied to any type of mine production system employing discrete vehicles, although a large size of operations and the ability to allocate flexibly the transport vehicles among multiple excavators/loaders enhances the potential utility of such approaches.

The field is one with little theory; the basis for control actions involves application of heuristic approaches. Though innately heuristic, some procedures prescribe control actions on the basis of solutions to quite sophisticated mathematical models. The proof of the pudding is in the eating, and though heuristic, these techniques have been reported to be quite effective in increasing the rate of production from these mines for a given level of loading and transport equipment (Clevenger, 1983). Some approaches have also helped in simultaneously meeting a number of additional operational objectives such as better control of ore-grade targets.

An opportunity one has in certain discrete vehicle material transport systems involves the fact that the vehicle may be flexibly routed. Rather than running the vehicle in a locked cycle between a particular loader and dump site, one may use the vehicle to service multiple loaders and dump sites. Moreover, rather than following a predetermined, rigid sequence of movements, routing can be dynamically controlled, switching the sequence that loader and dump sites are visited by the truck from one cycle to the next.

The underlying reasons why advantages in system performance can be gained by such dynamic control include:

1. One can respond to information on the current state of the system that reflects the realization of particular random variables (e.g., the observed cycle time to load a particular truck) that could not have been predicted exactly ahead of time;

2. One can appropriately respond to deviations from the expected levels of performance that were used to develop the operational plan (e.g., one shovel is having an easy time digging and is completing its load cycle more quickly than expected and this provides opportunity for increased production over what was expected if levels of truck capacity allocated to the shovel are increased).

In examining truck dispatch strategies that have been employed, distinctions among them can be made with respect to two major factors as follows.

1. *The extent a forecast of future states of the system is employed to make the current dispatch decision.* Some approaches consider only the current truck (e.g., immediately upon completion of dumping) when making the dispatch decision prescribing where the truck should next be routed. Others attempt to forecast the state of the system for a number of future dispatches and make the current dispatch while cognizant of this forecast. For instance, one might send the current truck to its "best" shovel (e.g., the one that will be ready to load the truck at the earliest future point in time), but there is a good second choice for this truck. The next truck that will complete dumping also has the same "best" shovel but no second choice that is very good. Considering performance of the two trucks together, it would be better to send the current truck to its second-best choice.

2. *The scope of the operational objectives that drive the selection of dispatch assignment.* Some strategies base dispatch decisions on narrow criteria (e.g., send the truck to the shovel where it is expected to be loaded first). Other strategies base dispatch decisions in accordance with how well the decision contributes to conformance with a production plan. The plan is developed to enhance specific performance criteria such as overall mine production rate. It may also recognize various operational constraints such as achievement of grade targets with the ore blend from the multiple loading sites and desirable ore/gangue production ratios. These production plans are typically short term in nature, are routinely updated, and are frequently based on solution to math programming models for short-term production scheduling and equipment allocations.

Two examples of some simple "one truck at a time" dispatch heuristics are as follows:

1. As mentioned before, "send the current truck to be dispatched to the loader where it is expected to be loaded first." One would use figures on average load times and tram rates and current positions of previously dispatched trucks headed to the loader in question to forecast when the loader will have serviced all of these previously assigned trucks. Then travel time to this loader for the truck to be dispatched is compared to the forecast time when the loader will be free to estimate the future point in time that truck loading for the dispatch vehicle would begin. This is done for all loaders and the truck is sent on the shortest path to the one that is expected to load it at the earliest point in time.

2. "Send the current truck to be dispatched to the loader that is next expected to become idle (after servicing all previous trucks assigned to that loader)." One would forecast the time each loader is expected to become idle as discussed in the first example, and without consideration of the distance to that loader, the current truck is sent to the loader expected to become idle at the earliest point in time.

These rules are very simple and have some intuitive appeal. Note that one may use recent history on load time and tram rates to obtain better forecasts as operating conditions change at the mine. The first rule is noted to cause loader utilizations to become unbalanced (Lizotte and Bonate, 1987), since trucks tend frequently to be sent to the closest shovels, ignoring the remote ones. In the second case, production ratios will be more controlled but are primarily influenced by allocation of the shovel to the available loading sites. Both rules may result in shortsighted decisions because the current decision may be unfavorable when considered in conjunction with dispatches that might be made in the near future. Further, the objective criteria for both rules are very narrow and may not conform to overall operating objectives for the operations.

To see how one might approach overcoming the shortcomings of these simple rules, the operation of one of the more sophisticated dispatching systems, DISPATCH, which has been developed recently and is described by White and Olson (1986), is now discussed.

The DISPATCH system first solves a sequence of two linear programming problems to establish a short-term production plan. This plan is updated routinely as will be discussed in the following. When the plan is established, it is based on the current status of mine operations, reflecting siting and current availability of the loading shovels, estimates of quality characteristics of ore at working faces and stockpiles, and operational status of the process plant.

The first linear programming (LP) model defines "optimum" production rates for the various shovels, including those operating from stockpiles. The objective function of this optimization accounts for penalties associated with failure to meet process-plant input demands and violations of blend-quality constraints, and weights established by management reflecting the current relative desirability that plant feed originate from stockpiles or from active faces.

Given these overall flows from the material sources (stockpiles and working faces), a second LP is solved to determine the allocation of truck resources to move material flows efficiently along available haulageways. The model prescribes how many cubic yards (cubic meters) of haulage capacity should be allocated to all "paths" in the system. The second model is set up to maximize production rate from the system. It is loosely coupled to the first model in that the first model prescribes minimum production from working faces and stockpiles for the second model. Any excess production from working faces that can be achieved would be stockpiled.

The use of the output of the second model is to provide a criterion for truck assignments in real-time dispatch. Roughly speaking, the objective of the dispatch will be to implement and maintain the "optimum" haulage allocation determined by the second model, which is given in terms of the volume of haulage capacity that should be allocated to each path. Contrast this to the objectives of dispatch decisions for the two simple heuristics cited.

As mentioned previously, the two LP models form a short-term production plan. Whenever a major upset such as a shovel breakdown or process plant outage occurs, the models are solved again to establish a new short-term plan. Moreover, blend constraints in the first-level model are structured to allow some slack in conformance to rigid bounds on ore grade. An estimate of the moving average quality of the ore feed to the process plant is continuously maintained. There is a bound imposed on the maximum period of time that can pass without replanning so that excessive and sustained deviations from target grades do not occur. The more slack permitted in complying with grade requirements when solving the first-level model, the more frequently operating plans must be updated.

The actual dispatching procedure uses the deviation between actual current assignment of trucks to a path and the optimum assignment levels determined by the second stage LP as a basis for evaluating dispatch decision alternatives. All trucks that are in transit from a loader to a dumpsite are considered collectively with the current truck to be dispatched when making assignments. At the time of a dispatch, the time each loader will "need" a truck assignment (typically in the future) is forecast. "Need" is determined by the LP haulage capacity prescription. The loader with the earliest need is considered first. The truck closest to this shovel is nominally assigned to it. Eliminating this loader and truck from consideration, the shovel with the second earliest need is considered in the same fashion, etc., until all loaders have been considered. This will typically result in an assignment for the current truck to be dispatched.

The point of this discussion is to illustrate a way that dynamic dispatch systems can be used to (1) help achieve a goal-oriented production plan that, because of its short-term nature, is itself responsive to changing conditions at the mine, and (2) make decisions using updated forecasts of expected future states of the system rather than making each truck assignment independent of such forecasts.

The overall logical structure of most of the more recently developed dispatch systems will resemble the one discussed here. However, they will vary considerably in details. Although the mathematical models are described rather than explicitly reported, the system at the Mount Wright mine (Soumis et al., 1989) apparently differs from DISPATCH in a number of respects. Some of these include (1) consideration of alternative loader site locations when making preliminary equipment assignments, (2) use of a nonlinear objective function in determining optimum haulage allocation, which results in a more balanced distribution of truck capacity assignments, (3) use of a simple process-plant model for estimating the actual costs of deviations from blend targets (in the previous procedure these were, more or less, guesses), and (4) solution of a classical assignment model for dispatch decisions where the objective function minimizes the squared difference between current forecast waiting times for the shovels and trucks and average waiting times expected for implementing the operational plan.

This segment is concluded with two additional notes. First, the dispatch algorithm (but not the planning models) for these systems must be able to execute in a very short period of time (a matter a few seconds). With careful consideration of the mathematical techniques employed, one can use rather extensive models, as evidenced by the Mount Wright system, for making dispatch decisions. Second is a reminder that the procedures are heuristics, and many modifications are conceivable. Simulation, as discussed in the previous section, can serve to evaluate alternative dispatch heuristics and tactics for a given mining operation.

9.4.5 STOCHASTIC PROCESS MODELS OF MINE PRODUCTION SYSTEMS

The weakness of simulation as a tool for systems analysis should be evident from the discussion of 9.4.3. One wants to know the distribution of performance variables, perhaps, even how these distributions change as a function of time, but simulation only gives data from which one may infer some of the major properties of these distributions. It does not give the distributions directly. Moreover, it is typically quite cumbersome to make generalizations regarding system performance and its response to the decision variables on the basis of simulation output.

On the other hand, the theory of *stochastic processes* provides a basis for analytical modeling of these processes. The field is comprised of a number of basic topics including Poisson processes, Markov chains, renewal theory, continuous-time Markov processes, semi-Markov processes, Brownian motion, etc. These, in turn, service many applications including results in queuing theory, inventory theory, reliability theory, sampling plans for quality control, and inference-based measurements using signals gathered by sensing instruments, among many others.

The analytical results may, in some cases, give the distributions of the performance variables directly. They may also facilitate comparisons among alternative values of the decision variables, perhaps permitting mathematical optimization. Often they give valuable insights in to the nature of system operation that would not have otherwise been obtained. An example of this for a mining application is given in the following.

Typically, more assumptions are required in order to progress with this approach to systems analysis than are required when using simulation. If one is not careful, the result of the modeling effort may be an abstraction of little relevance to the real-world system. One is cautioned against "pulling a formula from a book" without understanding the assumptions and nature of the result. Nonetheless, the results that can be obtained by using these approaches often justify the efforts.

Subsequently, some examples of the more recent work in mining-related applications of stochastic process models that have resulted in—or with more work may lead to—practical achievements are discussed. These applications are in the area of modeling of continuous material handling systems and queueing theory applications. Space exists here only to present a descriptive discussion. Readers interested in learning about fundamental aspects of these techniques are referred to the well-known texts by Ross (1983), Cinlar (1975), and Karlin and Taylor (1975).

9.4.5.1 Stochastic Process Models of Continuous Material Handling Systems

As examples of the type of issues that can be addressed in applying this technology to analysis of continuous material handling systems, the work of Baral et al. (1987) and Sevim (1987) are discussed.

Baral et al. Model: This work addresses the implications of installing a bunker as a storage buffer in a serial arrangement of conveyors to increase the availability of that system to the production section it services. The role of such bunkers is to hold production for intervals of time when outby conveyors have failed, temporarily isolating the production section from its dependence on the outby transport network. They must be larger than bins used to reduce surge loading on an outby belt to control spillage. The service of the system depends on the availability of the conveyors between the face and the bunker and between the bunker and the end of the conveyor line. For the bunker to increase production, the inby belts must be available to haul material to the bunker when the outby belts fail. Moreover, the outby belts must be capable of clearing a substantial portion of the stored material between successive failures of the outby belts, else the effective capacity of the bunker might be reduced to the point where it provides little isolation. The availabilities of the bunker inflow and outflow belts are a function of where the bunker is located in the sequence of belts. Thus both the size of the bin and its location in the network are decision variables with important ramifications on performance of such a system.

It was assumed by the authors that the time between failures and time to repair the belts are exponentially distributed random variables. This permits the system to be modeled as a continuous-time Markov process. For a simple two-conveyor system with a bunker between the first and second conveyor, state is described by the triplet (up/down status of the inby conveyor, up/down status of the outby conveyor, and proportion of bin volume currently filled). It is clear that one can assess the availability of the system to the production section given the value of these variables. For larger networks, it was shown that the belts inby the bunker and the belts outby the bunker may be considered in aggregate analogous to the two-belt system to reduce the state space and simplify computations. Expressions were derived for steady-state availability of the conveyor/bunker system to the production system as a function of the bunker volume, and the time to failure and the time to repair distributions for the individual conveyors.

Analysis of these expressions suggested the following strategy for optimal specification of bunker storage. The bunker should be located at the location where the differential between the availability of the inby belts and the outby belts is the smallest, that is, at the location where these availabilities are closest to being equal. (Simple expressions can be used to compute the availability for an arbitrary serial chain of belts.) It is shown that the rate of increase of availability decreases and reaches an asymptote as bunker volume increases. Volume should be set prior to reaching the asymptote. Plots can be constructed to aid this decision.

Perhaps the most serious criticism of this work might be the assumption of constant flow on the belt when the system is up. The ramifications of this assumption are not known. It appears that additional work might also be done on how one combines multiple production sections serviced by the same network, although this was addressed by the authors to a limited extent.

Sevim Model: The work of Sevim (1987) focused on a different aspect of performance: the use of a bin to smooth outflow from multiple production sections that operate in a discontinuous fashion. Here, in contrast to the work just discussed, greater attention was given to modeling the production sections. Output from the face was modeled as a semi-Markov process, which allows for an arbitrary form of distribution of the times between up and down states as well as different classes of up and down states. It was assumed that the rate of production was constant during the up periods. Transient distributions of the probability of coal flow from a section were established for the first half-shift (from arrival at the section until the lunch break). It was also shown how these could be combined for multiple sections serviced by the same belt network. One thereby has knowledge of the probabilities (as a function of time of day) associated with the various aggregate levels of material flow on a belt. These distributions were then used to describe the inflow into a bin installed for the purpose of smoothing flow. A heuristic approach was established for sizing this bin. Both constant and controlled outflow rates from the bin were considered. Similar work applied to control of flow in slurry transport systems is presented in Sevim and Yegulalp (1984).

9.4.5.2 Queuing Models of Mine Production Systems

The basic structure of queuing systems is as follows. A *calling population* provides a source of *customers* who request service at some *service station.* One should take a broad interpretation of the term customers; in a mining context it might refer to shuttle cars waiting to be filled, belts needing repair, or even, as will be seen in an example that follows, working faces requesting an operation in the cut, drill, blast, load, roof-bolt sequence of coal mining operations. The calling population may either be finite or infinite. The latter is most common in queuing models and is simpler analytically. It typically refers to a large source of customers external to the system such as the body of potential customers for a fast food restaurant. In each of the three mining cases discussed before, and probably in most queuing systems of interest in mining, the calling population is finite and fixed.

The service station referred to previously contains one or more parallel *service channels;* each such channel is called a *server.* If the number of channels is finite, there is a limit in the number of customers that can be serviced simultaneously. Arriving customers finding all channels filled must wait for service in a *queue.* The queue may or may not correspond to a waiting line in the real-world system being modeled. For instance, broken machines (customers) may have to wait for the repair crew (servers) to finish a number of jobs before being serviced. But the machines are never "lined up" physically.

The queue itself provides an opportunity for controlling the system. It may be desirable to service some waiting customers ahead of others independent of their order of arrival to the queue. For example, one might load 80-ton (72-t) trucks ahead of 50-ton (45-t) trucks regardless of which truck arrived first. These controls are specified in terms of a *queue discipline,* which gives rules for determining the priority for removing customers from the queue when a service channel becomes available.

The queue may have limited capacity, and customers arriving when the queue is full may be balked from the system or sent to another service station. Each server is typically assumed able to service only one customer at a time. This customer is retained and occupies the server for a period of time called the *service time.* For example, an empty, spotted truck ties up the loading shovel until it is filled. Once service is completed, the server is now available to service another customer and the customer is released.

The system may consist of multiple service stations. A single customer may progress from one service station to the next in a fixed or a flexible sequence. This arrangement is frequently called a *queuing network.* In many mining systems, the customer is cycled among a number of service stations. For example, the truck goes from a loader to a dump site and back again. When multiple services stations are involved, state is often described in terms of the number of customers at each station.

Overall, the structure of queuing models is quite broad and flexible. Hopefully this brief discussion of structure has left the reader with the impression that a number of mining processes might potentially be modeled in this framework.

Two assumptions are frequently made to make queuing models more tractable analytically. First is that one is interested in equilibrium probabilities at steady state as opposed to transient performance of the system. As explained in 9.4.3.4, the acceptability of this assumption depends on the objectives of the study, not the system itself. Second is that the temporal variables of the system—customer interarrival times, customer service times, interstation transfer times—are exponentially distributed. This allows the theory of continuous-time Markov processes to be applied to compute the steady-state probabilities.

The latter assumption is a restrictive one. Though the exponential distribution is an excellent model for many situations such as time between failures of certain types of components, time between arrivals to a system from a large external calling population where customers act independently, it is not a good model for service times (e.g., time to load a truck) and interstation transit times (e.g., time to travel from the loader site to the dump-site) in many mining applications.

An approach that may be used to overcome this limitation is to employ what are called *generalized Erlangian distributions* or *phase-type distributions.* The general idea is to view a temporal variable with an arbitrary distribution, such as a service time, as being executed in a sequence of phases. The order of the phases is defined by either series or parallel structures or a combination of both. A serial structure implies that one phase is executed sequentially after another until the required number of phases in the series is completed. A parallel structure implies that multiple serial structures are available and one of these is selected with a specified probability then executed as just described. Time for each phase in the sequence is exponentially distributed. The phase structure and parameters of these exponential distributions may be determined so that as customers pass through the sequence of phases, the distribution of total elapsed time closely matches the arbitrary distribution that the modeler wants. Since all times are now exponentially distributed, the result is that a continuous-time Markov process model can be employed, with accompanying advantages in tractability. This, however, comes at the expense of an expansion of the state space relative to the initial problem. The theory of stochastic networks (Kelly, 1979) provides means for computing the steady state probabilities for the various states of the system.

Recently, this approach has been applied to mining systems in the work by Kappas and Yegulalp (1987). In their model of a room and pillar coal mining operation, working faces are viewed as customers that transit through a fixed series of service stations corresponding to the undercutting, drilling, blasting, loading, and roof-bolting operations of the conventional mining cycle. Distributions of general form were fitted to field data on the time required to complete each of these operations. A phase structure was fitted for each service station that resulted in a distribution of total elapsed time that matched the first two moments of the general distribution exactly (mean and variance) and was close to the third moment (skewness). They used specialized versions of computational algorithms for computing steady-state probabilities of the various states, which were given in terms of the number of faces undergoing each operation of the mining cycle. From these probabilities, various aspects of performance, such as steady-state production rate, could be obtained. They compared the effect of various numbers of working faces on production rates. Though a number of shortcomings were noted by the authors, including the uncertain utility of steady-state measures and inadequacies in accommodating spatial aspects of entry layouts when comparing system alternatives, the work certainly shows promise in bridging the major gaps in applying queuing theory to mining systems over previous applications where exponential times for activities were assumed.

Section 10 Geomechanics

MADAN M. SINGH ASSOCIATE EDITOR
Z.T. BIENIAWSKI, SECTION COORDINATOR

Chapter 10.0
INTRODUCTION

Z.T. BIENIAWSKI

Geomechanics signifies the science and engineering of soil and rock materials and of rock masses. It is a field of professional practice and research that draws heavily on the elements of soil and rock mechanics.

Geomechanics contributes to a number of disciplines: mining engineering, civil engineering, geological engineering, petroleum and natural gas engineering, and engineering geology (including the elements of geohydrology and geophysics). These disciplines are involved in the design and construction of such projects as mines, tunnels, foundations for structures, excavated rock slopes, dams, shafts, boreholes, oil reservoir wells, underground storage facilities for oil and gas, and hazardous waste repositories. Geomechanics allows us to improve both our environment and our quality of life.

In the context of this *Handbook*, the scope of geomechanics is discussed mainly from the point of view of applications to mining engineering. However, the coverage of the subject material is so comprehensive that it is relevant to other disciplines as well.

Section 10 covers the field of geomechanics in a structured fashion, beginning with the fundamental principles and leading into practical applications in mining engineering. Throughout the treatment of the subject, knowledge of geologic conditions is assumed since this is discussed in other sections of the *Handbook*.

An important feature of this section is a series of practical examples illustrating the various aspects of geomechanics.

Since geomechanics is concerned with both soil and rock mechanics, Chapter 10.1 introduces the fundamentals of soil mechanics while Chapter 10.2 does the same for rock mechanics. In these two chapters, the relevant principles of mechanics are given, and the properties of soil and rock are discussed together with the methods of their determination. Chapter 10.1 discusses such practical aspects as the bearing capacity and slope stability of soil and weak rock, while Chapter 10.2 emphasizes approaches for solution of problems in rock mechanics.

Chapter 10.3 deals with geomechanics instrumentation, which is of vital importance for assessing the stability of surface and underground excavations as well as in determining rock mass properties. For this purpose, the principles of rock instrumentation are treated at some length, but comprehensive information is also provided on the multitude of instruments currently available to the mining engineer.

Slope stability is the next applied topic, covered in Chapter 10.4, which is most relevant to surface mining. It includes the discussion of economic optimization of slopes and treats stability criteria as well as various modes of slope failure. Next, stresses in a slope and geologic data collection are discussed, and the reader is led through the design methods for slopes and the management of slope operations.

Chapter 10.5 deals with ground control mainly in underground mining. It presents methods for geologic site characterization and engineering rock mass classifications, together with determination of rock mass properties and in situ stresses. This is followed by practical design considerations of rock bolt reinforcement, design of pillars, and assessment of mine floor stability. The chapter concludes with a detailed treatment of ground control in longwall mining.

This last subject leads logically to a discussion of surface subsidence, which is presented in Chapter 10.6. Principles of subsidence as well as control and prevention of damage are dealt with in detail. Issues pertinent to abandoned mined lands and the legal aspects of mining subsidence are also included.

To ensure that all major applications of geomechanics are covered in this section, Chapter 10.7 is a potpourri of geomechanics applications not covered in other chapters of the section, such as nuclear waste disposal in mined underground repositories. The chapter also focuses on preserving rock mass integrity and deals with special topics that may face the mining engineer.

Overall, this section on geomechanics should enable the reader, already armed with geologic information, to determine soil and rock mass properties, establish in situ stresses, and design safe and economic excavations for surface and underground mining operations.

Chapter 10.1
SOIL MECHANICS

E.J. CORDING AND A.F. CEPEDA-DÍAZ

10.1.1. DEFINITIONS

Soil is a three-phase (solid, liquid, and gaseous) medium consisting of weakly bonded or unbonded mineral grains and voids filled with water and air. Mineral grains are more strongly bonded in rock than in soil, although in reality, there is no sharp boundary between soil and rock. In particular, properties of weak rock bear many similarities to those of soil and are included in the discussion in this chapter. *Soil mechanics* refers to the fundamental principles that govern the behavior of soils as related to the design, construction, and performance of engineering works. The most significant engineering properties of soil and rock are permeability, compressibility, strength, and durability.

Principles of soil mechanics are applied toward the solution of a variety of problems including seepage or water flow through soils; settlement of foundations and fills on compressible soils; swelling and slaking of clay-shales in foundations, slopes, and underground openings; earth pressures against retaining walls; stability of slopes and excavations; design of earth dams and retention ponds; bearing capacity of foundations and mine pillars on weak soils; and tunneling in soils, weak rock, or fault zones.

10.1.2. SOIL AND ROCK PROPERTIES

10.1.2.1 Characteristics of Soil

Soil and weak rock possess several characteristics that differentiate them from other engineering materials.

Fine-grained soils interact with water in such a way that there is no resemblance between their dry and wet behavior, and their properties are largely influenced by the physicochemistry of the soil-water system. Fine-grained saturated soils are generally cohesive as a result of the net balance between attractive and repulsive inter-particle forces.

Soft or weak sedimentary rocks, such as shale, and other *rock-soil transitional materials,* such as weathered rock or residual soils, not only have strengths that may approach those of highly overconsolidated soils but also have behavior similar to soils, inasmuch as it is influenced by the physicochemistry of the solid-water system. Thus the principles of soil mechanics can be also used to explain the behavior of so-called *weak rock* whose pore water response, volume change behavior (e.g., swelling), and shear strength characteristics are similar to those of soil.

Stiff soils and weak rocks commonly contain fissures and joints that affect permeability, compressibility, strength, and durability of the soil/rock mass. Thus the principles used in rock mechanics for evaluating a discontinuous medium are also applicable to these materials.

The *concept of effective stress* is one of the most important principles of soil mechanics. Both compressibility and strength of soil are controlled by effective stress. The concept establishes that for a saturated soil-water system, the effective stress σ' applied to the soil skeleton is equal to the total stress σ externally applied minus the existing pore water pressure u:

$$\sigma' = \sigma - u \tag{10.1.1}$$

The maximum shearing resistance (shear strength) that a soil can develop is a function of the effective stress acting on the soil. The pore water pressure is positive when u is in compression (greater than atmospheric pressure). An increase in the pore water pressure for a given total stress will reduce the effective stress and, consequently, the shear strength of the soil. The pore water pressure is negative, on the other hand, when u is in tension (less than atmospheric pressure). In the latter case, which occurs for saturated and partially saturated soils above the groundwater table, $\sigma' \geq \sigma$. The concept of effective stress applies not only to soils but to rock and other materials with continuous voids formed by pore spaces or joints.

Saturated materials that are soft enough to undergo significant volume change upon application or removal of pressure (soil and many weak rocks) exhibit time-dependent consolidation or swelling, which is a manifestation of the principle of effective stress. Upon application of an increment of pressure $\Delta\sigma$ to a saturated soil, its volume will not decrease significantly until water is expelled from the pore spaces. Because the soil skeleton is more compressible than water, the pressure increment is initially applied to the water, thus $\Delta u \approx \Delta\sigma$, the excess pore-water pressure. With time, as the water is squeezed from the pore spaces, the volume decreases, and the water pressure reduces to its original value ($\Delta u = 0$). The pressure increment is progressively transferred from the water to the soil skeleton, until finally the pressure increment becomes fully an effective pressure, $\Delta\sigma' = \Delta\sigma$. This time-dependent process is termed *consolidation* for the volume decrease resulting from an increase in effective stress, and *swelling* for the volume increase resulting from a decrease in effective stress. Excess pore-water pressure dissipates rapidly for permeable materials such as sands, and slowly for low permeability soils such as clay.

For a large mass of low permeability soil, the process is so slow that significant changes in volume or water content may not occur over the period of loading, so that the material remains undrained, and its strength and stiffness can be assumed to be unchanged from the initial condition, before the load increment was applied. Upon application of load and over a long period of time, drainage occurs and the soil consolidates, with corresponding increase in strength and stiffness. Upon unloading, however, the soil swells with time, and strength and stiffness decrease.

In contrast, most sandy soils subjected to static loads are assumed to be loaded slowly enough that significant excess pore water pressure Δu does not build up; therefore the soil is drained, and the pressure increment is applied directly to the soil skeleton throughout the loading increment ($\Delta\sigma' = \Delta\sigma$; $\Delta u = 0$).

10.1.2.2 Index Properties of Soil and Weak Rock

The spatial distribution and properties of soil, rock, fluids, and gas at a site are investigated utilizing a knowledge of the local geology and the information gathered from strategically located boreholes, test pits, and test shafts. These borings and excavations are used to log the distribution and changes in material properties, to index the soil properties by means of in situ tests such as standard penetration resistance and water pressure tests, and to collect either disturbed (or remolded) samples for laboratory index testing, such as water content and soil plasticity, or undisturbed samples for unconfined compressive strength and more elaborate laboratory tests.

Soil and weak rock are classified for engineering purposes in terms of *index properties,* which are by definition significant (i.e., engineering behavior can be inferred from them), simple and quick to measure, reproducible, and easy to express (e.g., with a numerical value).

Properties of the Disturbed Material: A soil is considered *fine grained* (clay and silt) or *coarse grained* (sand and gravel) if its predominant grain size is smaller or greater, respectively, than the smallest particle diameter that can be identified with the naked eye (i.e., 74 *m*m or US No. 200 Standard sieve).

With little to no clay or silt, coarse-grained soils are generally cohesionless, and their properties remain practically unchanged whether the soil is unsaturated or fully saturated with water. Coarse-grained soils are indexed in terms of their grain size and grain size distribution.

The Atterberg limits serve as an index test for measuring the cohesive characteristics of fine-grained soils, referred to as *soil plasticity.* The Atterberg limits (Anon., 1985a) define the range of water contents (percentage ratio between the weight of water and the weight of solids) in which the disaggregated finer soil fraction can deform without running like a liquid (liquid limit) and without rupturing (plastic limit) under the standard test conditions. The *shrinkage limit* is defined as the water content at which the fully saturated soil cake stops decreasing in volume. Any further moisture loss simply starts emptying the soil pores. High plasticity soils, having a large plastic range, are subject to high swelling and shrinkage.

Both grain size and plasticity form the basis for the categories in the Unified Soil Classification System shown in Table 10.1.1 (Anon., 1953). These index tests are performed on disturbed samples, which do not retain the structure and density of the soil or rock in situ.

Undisturbed Properties of the Material: In order to evaluate in situ permeability, compressibility, or strength, it is necessary to test the undisturbed material, either with field tests performed on the in-place material or with laboratory tests performed on relatively undisturbed samples collected from the field.

The structure and density of a soil, and therefore its strength and compressibility, are related to its past stress history as well as to the present stresses existing in the ground. The past stress history is largely summarized in terms of the preconsolidation pressures σ_p, which in some cases is equal to the maximum previous effective overburden pressure that acted on the soil but is also influenced by other diagenetic processes (such as bonding and cementation) to which the soil has been subjected in its geologic past. These processes create an overconsolidated material, that has a greater density, higher strength, and lower compressibility than would be obtained for a normally consolidated material, which has never been subjected to a pressure greater than the existing effective overburden pressure.

Standard penetration resistance in granular cohesionless soils and shear vane resistance in cohesive soils are in situ-measured index properties typically included in subsurface exploration programs to identify and characterize the strength and compressibility of various soil sublayers. The laboratory unconfined compressive strength also serves as an index of the strength and compressibility of cohesive soils. The natural water content relative to the plastic and liquid limits is also used to infer the strength and stiffness of cohesive soils.

Standard penetration resistance (Anon., 1985b) is defined as the number of blows N required to drive a standard 2-in. (50.8-mm) OD split spoon sampler 12 in. (305 mm) long under a weight of 140 lb (63.6 kg) falling 30 in. (762 mm). The N-blow count is used as an index of the density of granular soils and is correlated with relative density in Table 10.1.2. Relative density is defined as

$$D_r = 100\% \times (e_{\max} - e)/(e_{\max} - e_{\min}) \qquad (10.1.2)$$

where $e_{\min}$ is void ratio of soil in its densest condition, $e_{\max}$ is void ratio of soil in its loosest condition, and e is in-place void ratio. There is also a rough correlation between the standard penetration resistance and the unconfined compressive strength of clay, as shown in Table 10.1.2.

High blow counts (N > 100/ft) are usually indicative of boulders or weak rock. It is possible to drive the split spoon sampler into weak rock, such as a poorly cemented sandstone, or a weathered rock. The material obtained in the sampler is usually broken and even completely disaggregated in the process of sampling, so that the original structure of the rock is lost. In such a case, it is desirable to obtain additional samples using a double- or triple-tube rock core bit, perhaps one that has a thin-walled inner liner to protect the sample, in order to recover a sample that allows the structure of the rock to be retained. It is often difficult to obtain representative samples from small-diameter boreholes and samples (2 in. or 50.8 mm) in such materials. The use of large-diameter core samples (Adachi, 1989) or drilled shafts large enough for access for inspection and mapping has proven quite valuable in such conditions (Cording, et al., 1989).

10.1.2.3 Permeability

Permeability k is expressed in units of length/time and indicates the discharge velocity with which water under a unit hydraulic gradient flows through soil and rock. Procedures are available for measuring permeability in the field and in the laboratory. Results will depend on the direction of the water flow during the test because soil and rock generally have a direction-dependent permeability or anisotropy. In a bedded deposit, horizontal permeability k_h usually exceeds vertical permeability k_v. For example, for homogeneous soft clay, typical ranges for horizontal permeability are k_h = 1.0 to 1.5 k_v, whereas for varved clay typical ranges are k_h = 1.5 to 5.0 k_v. Much greater ratios of k_h/k_v will apply to bedded deposits having alternating layers of clay and sand.

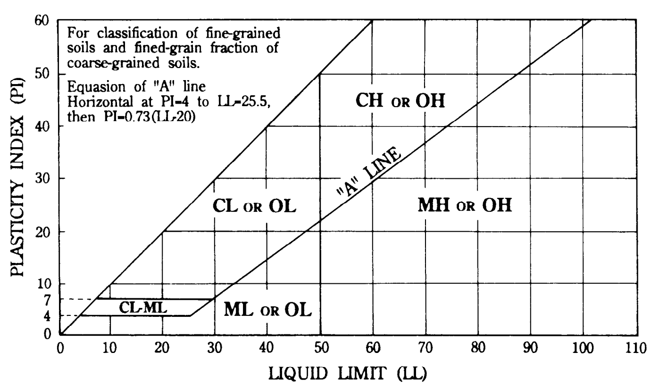
The coefficient of permeability k is a function of the size, shape (*tortuosity*), and number of the pores or joints (channels) in the soil/rock mass. Table 10.1.3 presents typical values for k for various soil and weak-rock materials. For a given soil or weak rock, k decreases with decreasing values of void ratio e (volume of voids /volume of solids) and therefore with increasing effective stress. The slope of the e-log k relationship is generally referred to as $C_k = \Delta e/\Delta \log k$. For soft clays C_k = 0.5 to 2.0, whereas for shales C_k < 0.5.

Permeability is particularly sensitive to heterogeneities such as stratification, fissures, and joints, and thus their presence determines either the minimum specimen size required in the laboratory to have a representative sample or the need for in situ testing to obtain a valid measurement. Disturbance of the soil during boring or sampling can also have a strong effect on the measurement of permeability. In many cases, laboratory determination of permeability does not give results comparable to the in situ permeability. In the field, the local permeability surrounding a borehole can be assessed by a water pressure test in which a quantity of water is pumped into or extracted from a section of a borehole under a given pressure. More comprehensive results, indicative of the performance of a larger portion of an aquifer, are obtained by pump tests in which piezometric

Table 10.1.1. Soil Classification Chart

Criteria for Assigning Group Symbols and Names Using Laboratory Tests[a]			Soil Classification Group Symbol, Name[b]	
Coarse-grained soils: > 50% retained on #200 sieve:				
Gravels: > 50% of coarse fraction retained on #200 sieve	Clean gravels > 5% fines[c]	Cu ≥ 4 and 1 ≤ Cc ≤ 3[e]	GW	Well-graded gravel[f]
		Cu < 4 and/or 1 > Cc > 3[e]	GW	Poorly graded gravel[f]
	Gravels with Fines > 12% fines[c]	Fines classed as ML or MH	GM	Silty gravel[f,g,h]
		Fines classed as CL or CH	GC	Clayey gravel[f,g,h]
Sands: > 50% of coarse fraction passes #200 sieve	Clean Sands <5% fines[d]	$C_u \geq 6$ and $1 \leq C_c \leq 3$[e]	SW	Well-graded sand[i]
		$C_u < 6$ &/or $1 > C_c > 3$[e]	SP	Poorly graded sand[i]
	Sands with fines > 12% fines[d]	Fines classed as ML or MH	SM	Silty sand[g,h,i]
		Fines classed as CL or CH	SC	Clayey sand[g,h,i]
Fine-grained soils: <50% retained on #200 sieve:				
Silts & clays: liquid limit, $L_w < 50$	Inorganic	PI > 7 & above "A" line	CL	Lean clay[k,l,m]
		PI < 4 or below "A" line	ML	Silt[k,l,m]
	Organic	$\dfrac{L_w\text{, oven dried}}{L_w\text{, not dried}} < 0.75$	OL	Organic clay[k,l,m,n] or silt[k,l,m,o]
Silts & clays: $L_w < 50$	Inorganic	PI on or above "A" line	CH	Fat clay[k,l,n]
		PI below "A" line	MH	Elastic silt[k,l,m]
	Organic	$\dfrac{L_w\text{, oven dried}}{L_w\text{, not dried}} < 0.75$	OH	Organic clay[k,l,m,p] or silt[k,l,m,q]
Highly organic soils		Dark organic matter, odor	PT	Peat

[a]Based on the material passing the 3-in. (75-mm) sieve.
[b]If field sample contained cobbles or boulders, or both, add "with cobbles or boulders, or both" to group name.
[c,d]Gravels or sands with 5 to 12% fines require dual symbols, such as: GW-GM well-graded gravel with silt, SP-SC poorly graded sand with clay.
[e]$C_u = D_{60}/D_{10}$ $C_c = \dfrac{(D_{30})^2}{D_{10} \times D_{60}}$
[f]If soil contains ≥ 15% sand, add "with sand" to group name.
[g]If fines classify as CL-ML, use dual symbol GC-GM, or SC-SM.
[h]If fines are organic, add "with organic fines" to group name.
[i]If soil contains ≥ 15% gravel, add "with gravel" to group name.
[j]If Atterberg limits plot in hatched area, soil is a CL-ML, silty clay.
[k]If soil contains 15 to 29% plus #200, add "with sand" or "with gravel."
[l]If soil contains ≥ 30% plus #200, predominantly sand, add "sandy."
[m]If soil contains ≥ 30% plus #200, predominantly gravel, add "gravelly."
[n]PI ≥ 4 and on or above "A" line.
[o]PI < 4 or plots below "A" line.
[p]PI on or above "A" line.
[q]PI plots below "A" line.



PLASTICITY CHART

Table 10.1.2. Characterization of Relative Density and Strength

Relative Density of Sand			Strength of Clay		
N^a	Relative Density %	Descriptive Term	N^a	Unconfined Compressive, tons/ft^2	Consistency
0–4	0–15	Very loose	<2	<0.25	Very soft
4–10	15–35	Loose	2–4	0.25–0.50	Soft
10–30	35–65	Medium	4–8	0.50–1.00	Medium
30–50	65–85	Dense	8–15	1.00–2.00	Stiff
>50	85–100	Very dense	15–30	2.00–	Very stiff
			>30	>4.00	Hard

[a]Standard Penetration Resistance, blows/ft
Conversion factor: 1 ton/ft^2 = 1.05 MPa.

Table 10.1.3. Coefficient of Permeability

Material Description	k, cm/s
Clean gravel	$1–10^2$
Coarse to medium sand	$10^{-2}–1$
Fine sand	$10^{-4}–10^{-2}$
Silt	$10^{-6}–10^{-4}$
Natural clays	$10^{-8}–10^{-6}$
Highly overconsolidated clays and shales	$10^{-12}–10^{-8}$

Conversion factor: 1 in. = 2.54 cm

levels are monitored in several borings, with time, as a nearby well is pumped.

Darcy's empirical equation (c. 1856), initially established for the flow of water through coarse-grained soils, has also proven to be valid for water flow through fine-grained soils including heavily overconsolidated clays and shales (Mesri and Cepeda-Díaz, 1987). *Darcy's law* states that the discharge velocity v_s in a direction s is equal to the coefficient of permeability in the s direction k_s times the hydraulic gradient i, or

$$v_s = k_s\, i \qquad (10.1.3)$$

where the dimensionless parameter i is equal to the change of total hydraulic head dh in the distance interval ds along the macroscopic or apparent flow path $s(i = dh/ds)$. Therefore, the time-rate of flow q (volume flow rate) through an area A perpendicular to the direction of the flow is given by

$$q = k_s i A \qquad (10.1.4)$$

which is used to directly evaluate one-dimensional *steady-state flow*.

A modified version of the previous equation is used to calculate the quantity of flow for two-dimensional steady-state flow through soil. The solution to the mathematical problem can be obtained graphically in the form of a scaled flow net (Cedergren, 1967) that, in the case of a homogeneous and isotropic medium ($k_h = k_v$), consists of two mutually orthogonal families of curves (flow lines and equipotential lines) forming curvilinear "square" cells within the boundaries of the problem and thus also forming both a number of flow channels n_f and a number of equipotential drops n_d, for a given head loss h_ℓ (Fig. 10.1.1). Since each flow channel carries the same flow rate as the others and continuity of flow (conservation of mass) must be satisfied, the fluid motion can be described at the individual square cell level where the hydraulic gradient i times the discharge area of the channel is equal to h_ℓ/n_d per unit of width and thus iA (per unit of width for the entire flow net) $= (h_\ell \cdot n_f)/n_d$. For two-dimensional steady-state flow, therefore, the time-rate of flow ($q = k_s iA$) is given by

$$q = k_s(n_f/n_d)h_\ell \qquad (10.1.5)$$

per unit of width perpendicular to the plane of the flow net. A flow net solution enables the hydraulic gradient and the pore water pressure to be calculated at any location within the hydraulic boundaries considered, and thus the pore water pressures as a result of water seepage can be determined along potential surfaces of sliding in order to evaluate the stability of a soil mass.

In many materials, such as jointed rock or bedded soils, permeabilities are not uniform. As a result, the flow net will be distorted, with flow lines and equipotential lines not forming squares.

10.1.2.4 Compressibility and Volume Change Characteristics

Components of Compressibility: The compressibility or expansibility of a soil or weak rock can be separated into several components. They are (1) initial "elastic" deformation, (2) time-dependent hydrodynamic volume change (primary consolidation or swelling), and (3) time-dependent volume change (secondary consolidation or swelling) and/or time-dependent deformation (creep).

Initial "Elastic" Deformation: Immediately after the application or removal of load, a fine-grained saturated soil will deform without any change in volume or water content, referred to as the "undrained condition." In an unsaturated soil or in a coarse-grained soil, the initial elastic deformations may include some volume changes as well as a distortional component.

Assuming that the material has not yet failed, the amount of strain for a given pressure increment can be estimated using a modulus of deformation, that is equivalent to a modulus of elasticity E but represents a tangent or secant to a stress-strain curve that is usually nonlinear. The deformation modulus E_u of a sample is determined in the laboratory from unconfined or triaxial compression tests, in which the specimen is subjected to an increasing axial stress σ_1, while the all-round confining pressure σ_3 is maintained constant. The slope of the curve relating the stress-difference, $\sigma_1 - \sigma_3$, vs. axial strain ϵ represents the modulus of the sample, and $(\sigma_1 - \sigma_3)_{\max}$ is the compressive strength. The unconfined compressive strength is generally referred to as q_u. For most soils and weak rocks, E_u = (50 to 300) q_u.

The in situ modulus of deformation is expected to differ from that determined on a laboratory specimen. For most soils, sample disturbance causes a significant reduction in soil stiffness, and

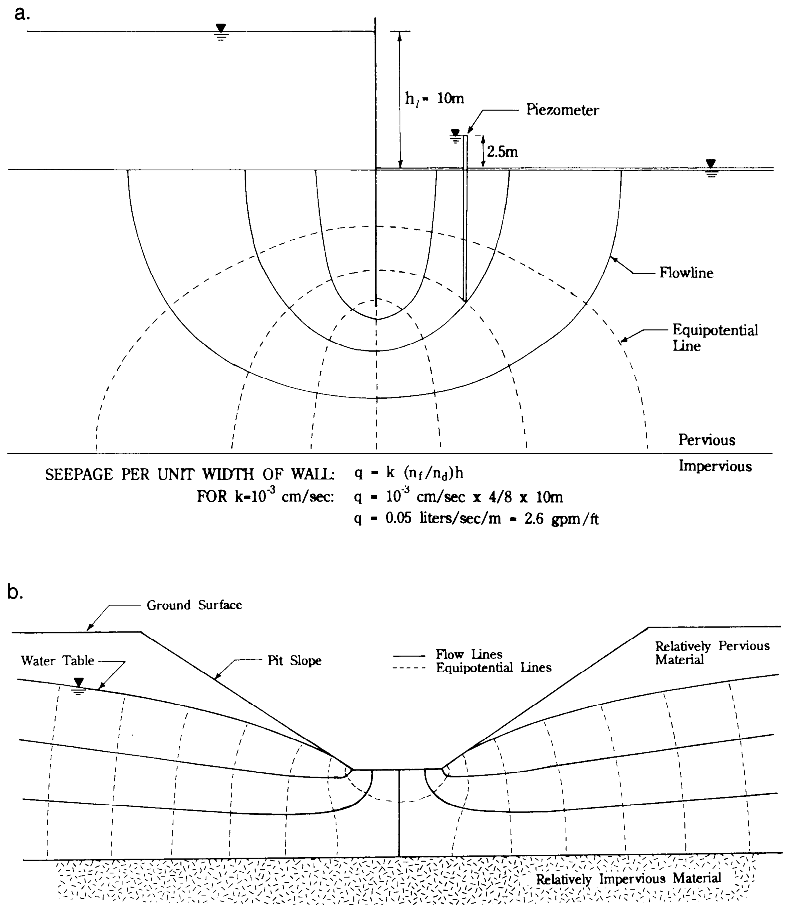


Fig. 10.1.1. Flow nets for medium soil with homogeneous, isotropic permeability. Conversion factors: 1 in. = 2.54 cm, 1 ft = 0.3048 m.

thus the laboratory test generally underestimates the in situ modulus of deformation. On the other hand, soil and rock masses that contain fissures or joints usually have a lower modulus than that of the intact laboratory sample, which does not contain a representative amount of the fissures or joints that are present in situ. In this case, the laboratory modulus would overestimate the in situ modulus of deformation.

The greater the stiffness of the soil or rock, the more significant is the initial deformation with respect to the overall deformation experienced with time by the soil or rock mass.

Time-dependent Volume Change: In a saturated fine-grained soil, the initial elastic deformations described previously occur with very little volume change in the soil matrix. With time, as the load remains in place, water is squeezed out of the soil matrix and the volume of the soil decreases. This process is referred to as *primary consolidation.* In soft clays, primary consolidation is the cause of most of the settlement that the clay will undergo upon application of a load. Compression that occurs with time, after the effective stress σ' has reached a final value under either isotropic loading or one-dimensional deformation conditions, is called *secondary consolidation,* and is a creep phenomenon.

Upon unloading, as water is sucked into the soil, the volume increases and the effective stress decreases. This time-dependent process is called *primary swelling.* Swelling that occurs with time after σ' has reached a final value (under either isotropic unloading or one-dimensional deformation conditions) is called *secondary swelling.*

For fine-grained soils, the magnitude of settlement or heave occurring during primary consolidation or swelling is determined in the laboratory by means of the one-dimensional consolidation test in which the specimen is restrained so that lateral strains are zero as vertical load is applied to the sample. As each load decrement or increment is applied, water is allowed to flow into or out of the soil through porous stones at the top and bottom of the sample, and the vertical deformation of the specimen is measured with time. The change in void ratio of the sample is proportional to the vertical displacement. The end of the primary consolidation or swelling, at time = t_p, occurs when the excess pore pressure, generated upon application of each load increment, has completely dissipated. This can be determined graphically.

For a homogeneous soil layer of thickness H and initial void ratio e_o, settlement or heave ΔH is given by

$$\Delta H = \{(e - e_o)/(1 + e_o)\} \times H \qquad (10.1.6)$$

where e is the void ratio at any particular vertical stress σ'_v and/or time t. The *magnitude of settlement* or heave at the end of primary consolidation or swelling for fine-grained soils is generally obtained from a plot of void ratio e vs. the logarithm of the effective stress σ'_v applied to the sample. Fig. 10.1.2 shows the typical e-log σ'_v relationship consisting of three parts: recompression, compression, and rebound for a heavily overconsolidated clay (Patapsco shale) with a preconsolidation pressure σ'_p of 38 tons/ft^2 or 40 MPa. The slope of the curve, $\Delta e/\Delta \log \sigma'_v$, for each distinct portion is identified as the recompression index C_r, compression index C_c, and swelling index C_s. Note that in the recompression range, the corresponding settlement is significantly smaller than that resulting when σ'_{vf} (final σ'_v) is in the compression range. Loading of soft clays, whose preconsolida-

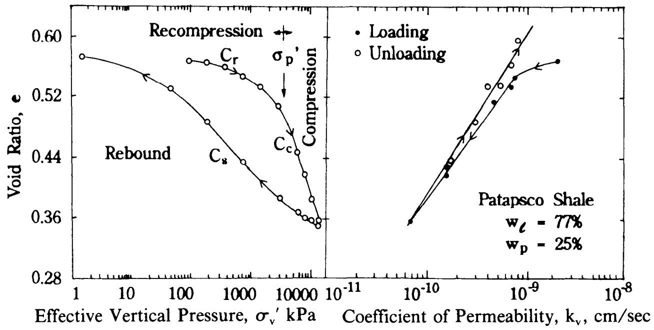

Fig. 10.1.2. Typical stress-volume change and permeability characteristics of soil and weak rock (after Cepeda-Díaz, 1987). Conversion factors: 1 in. = 2.54 cm, 1 psi^2 = 6.895 kPa.

tion pressure σ'_p is relatively small and the compression index C_c relatively large, can result in large settlements when the pressures applied cause the preconsolidation pressure to be exceeded. Magnitude of heave can be estimated using the rebound curve whose slope is C_s. Fig. 10.1.2 also presents direct measured permeability data at various σ'_v and corresponding e in the form of an e-log k_v plot, for parallel examination with the e-log σ'_v relationship.

The *time-rate of settlement* (*or heave*), which is controlled by the rate at which pore water can be expelled (or taken in), is a function of the permeability k and the compressibility (or swellability) of the soil, $a_v = \Delta e/\Delta\sigma'_v$, as expressed by the coefficient of consolidation (or swelling), $c_v = k(1+e)/a_v\gamma_w$, according to the Terzaghi theory of consolidation (Terzaghi and Peck, 1967). The mathematical solution of the latter theory provides the relationship between the average degree of consolidation (or swelling), U in % $= \Delta H/\Delta H_p$, and a dimensionless time factor T whose numerical value is equal to $c_v t/H^2$, where t is real time and H is the maximum drainage distance. Therefore, once c_v is evaluated (usually, by fitting Terzaghi's theory to the observed deformation-time data in the one-dimensional consolidation test), the settlement ΔH at any time $t < t_p$ during the consolidation process can be predicted. For example, according to the Terzaghi theory of consolidation (or swelling), the time factor for U = 95% *is* T_{95} = 1.12. Therefore, the (real) time for 95% average degree of consolidation (or swelling) to occur is given by $t_{95} = 1.12\ H^2/c_{cv}$. For a maximum drainage distance H = 20 ft (6.1 m) and a coefficient of consolidation (or swelling) of 10 ft^2/yr (0.93 m^2/s), the time for end-of-primary to occur can be approximated as $t_p \approx t_{95}$ = 1.12 (20 ft)^2/(10 ft^2/yr) = 45 yr. In soils containing lenses of sand with a clay or silt, the effective drainage distance is difficult to determine, and hence the time to achieve consolidation or swelling is difficult to estimate. One of the most effective means is to monitor the settlement of test fills.

Secondary Compression and Swelling: The slope of the observed e-log t curve for $t > t_p$ is called the secondary compression index C_α in the case of consolidation and the secondary swelling index $C_{\alpha s}$ in the case of swelling. Since C_α/C_c is a constant for any one soil, including shales, its value can be used in combination with the e-log σ'_v relationship to compute the secondary settlement at any $t > t_p$ (Mesri and Godlewski, 1977). The $C_{\alpha s}$-*OCR* (final overconsolidation ratio after swelling $\sigma'_{max}/\sigma'_{vf}$) relationship can be also obtained and used to compute the secondary swelling at any time $t > t_p$.

10.1.2.5 Shear Strength

The *shear strength s* or shearing resistance of a soil or rock is a function of the normal effective stress on the shear plane at failure σ'_{nf}. Thus s is controlled by the existing normal effective stress before shear ($\sigma'_n = \sigma_n - u$) and the excess pore water pressure induced during shearing up to failure u_{sf}, $\sigma'_{nf} = \sigma'_n - u_{sf}$. For $u_f = u + u_{sf}$, σ'_{nf} can be expressed as

$$\sigma'_{nf} = \sigma - u_f \tag{10.1.7}$$

During shearing, loose coarse-grained cohesionless soils and normally consolidated clays tend to compress, whereas dense cohesionless soils and overconsolidated clays and shales tend to increase in volume (dilate), as a result of particle rearrangement. Excess pore water pressures develop when water cannot move in or out of the pores fast enough to accommodate the volume changes induced during the shearing process. In this case, the soil is sheared under so-called undrained conditions.

Effective stress analyses can be used to evaluate the strength of a soil for either drained or undrained conditions. However, to use an effective stress analysis in the undrained case, the pore-water pressures generated at failure must be known. This information is difficult to obtain or predict. Therefore, for soft clays subjected to short term loadings, an undrained analysis is used, in which the undrained shear strength s_u is determined from unconfined compression tests, undrained triaxial tests, or in situ vane shear tests.

Sand: With the exception of dynamic loading, clean coarse-grained cohesionless soils can be treated as shearing under drained conditions as a result of their high permeability. Their shear strength can be expressed as

$$s = \sigma'_{nf} \tan \phi' \tag{10.1.8}$$

where ϕ' is drained friction angle (or friction angle in terms of σ' at failure). For granular soils, ϕ' is primarily a function of the relative density of the soil, and thus $\phi' \approx 28°$ for loose sand and $\phi' \approx 44°$ for very dense sand.

Loose saturated sands subject to dynamic loads, such as earthquakes, are susceptible to development of positive pore-water pressures that reduce the effective stresses to zero and liquify the sand.

Fine-grained Soils: In the case of fine-grained soils, their relatively low permeability is such that significant build-up of excess pore water pressure is expected to occur during the loading and unloading operations associated with construction. In a short period of time, the excess pore water pressures that are generated will not have dissipated, and the clay will not have undergone changes in volume or water content. Thus soft clays can be treated as being undrained, with an undrained shear strength s_u that has not changed from its original value. The condition is described in following paragraphs under the heading of undrained shear strength.

Use of the undrained shear strength is simple, and it has application to several significant engineering problems. However, many failures have resulted from using the undrained shear strength when it was not appropriate, particularly in situations in which negative pore-water pressures were generated initially, but then dissipated to cause a reduction in the strength of the soil during the period the undrained shear strength was assumed to be applicable. This is most likely to occur for stiff, overconsolidated clays. In addition, the presence of sand seams or fissures in a clay can cause a more rapid dissipation of negative pore-water pressures than would be otherwise anticipated, leading to an earlier failure during the construction period than expected. Thus, when using the undrained shear strength, it is important to recognize those conditions for which it is unconservative.

For these reasons, it is always a good practice to investigate the stability of fine-grained soils for both the short-term period (during and after the end of construction) when undrained conditions prevail and the long-term period when the material is drained.

Peak, Fully Softened, and Residual Shear Strength: The drained shear strength that a given clay or shale can actually mobilize (peak, fully softened, or residual strength) depends on whether the in situ material is intact, fissured, or contains discontinuities (e.g., bedding planes, shear planes) along which significant movements have occurred or will occur under the displacements imposed on the soil mass.

Peak Shear Strength—If the in situ fine-grained material is relatively intact, the peak shear strength is expected to be mobilized, and thus the failure envelope for the effective stress range considered can be characterized in terms of the "effective" strength parameters c' and ϕ',

$$s = c' + \sigma'_{nf} \tan \phi' \qquad (10.1.9)$$

where c' is the "cohesion" intercept. The greater the magnitude of the preconsolidation pressure σ'_p, the greater is the cohesion intercept c'. For normally consolidated clays, $c' = 0$. Values of ϕ' are typically in the range of 22° ± 10° and reflect the ability of a random arrangement of clay particles (of particular size and shape) to interact and interlock with each other.

In the case of overconsolidated clays, the typical shear stress-strain and strength curves presented in Fig. 10.1.3a show that the peak shearing resistance is mobilized with no major structural rearrangement. Near the maximum shearing resistance, the changes in volumetric strain v are small and mainly in compression.

Fully Softened Shear Strength—Additional shear displacement beyond the *peak (intact) shear strength* is accompanied by softening (volume increase as the disaggregated clay takes up water) and corresponding decrease in shearing resistance as c' decreases. By the time the softening process has been completed, only the *fully softened shear strength* is mobilized ($c' \approx 0$), and the material behaves as a normally consolidated clay (Eq. 10.1.8). Long-term stability of cuts in overconsolidated, fissured clays has been determined to be related to the fully softened shear strength.

The typical shear stress-strain and strength curves for a given sand in both dense and loose states, presented in Fig. 10.1.3b, show to what extent the behavior of dense and loose granular soils is similar to that of overconsolidated clays and normally consolidated clays, respectively. For the nonplaty granular soils, there is no possibility of particle alignment during shear, and thus the *ultimate shear strength* for the dense sand (which loosens after reaching its peak strength) corresponds to the maximum shear strength of the loose sand (which densifies during shear).

Residual Shear Strength—Additional shear displacement, if concentrated along a narrow shear zone, causes further decrease in shearing resistance, below that of the fully softened case, as the plate-shaped particles in the relatively narrow shear zone become increasingly aligned in the direction of shear. In this configuration, the soil or rock is only able to mobilize the *residual shear strength* or minimum s it can ever have, or

$$s = \sigma'_{nf} \tan \phi'_r \qquad (10.1.10)$$

The residual friction angle ϕ'_r is an index property of the natural soil composition, and it reflects the size and shape of the soil particles (Mesri and Cepeda-Díaz, 1986). As shown in Fig. 10.1.4a, for low plasticity clays and shales liquid limit w_ℓ < 50%), ϕ'_r can be as high as 30°, whereas for clays and shales with w_ℓ > 100%, ϕ'_r can be as low as 4 to 5°.

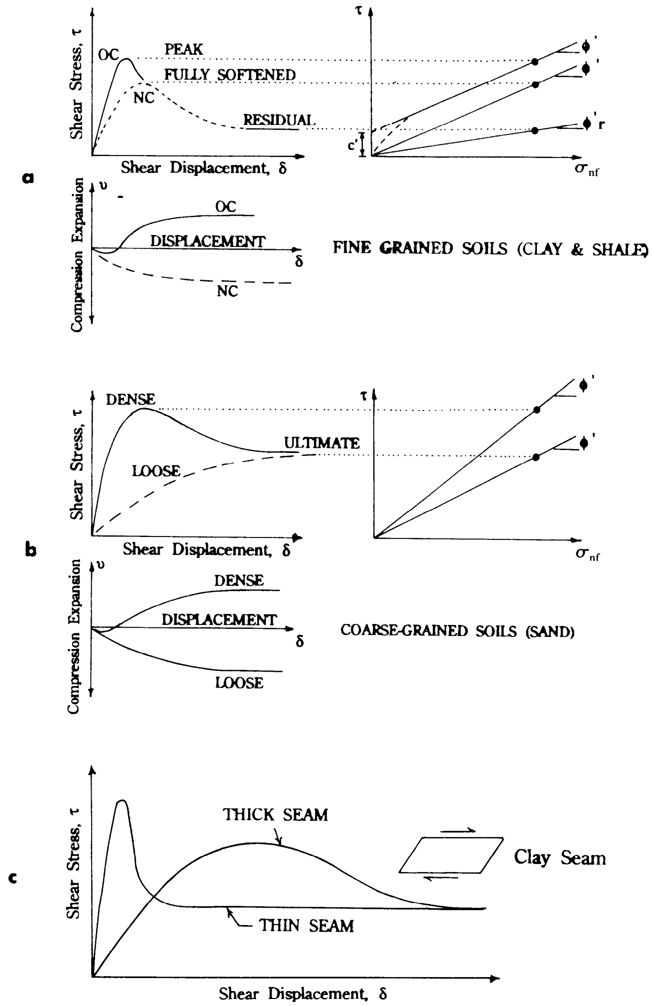

Fig. 10.1.3. Typical stress-strain and strength characteristics of soils and weak rock.

A correlation between the peak friction angle ϕ' and clay mineralogy also exists, and thus there is a correlation between ϕ' and ϕ'_r as shown in Fig. 10.1.4b.

In materials that contain thin seams of soft material or preexisting planes of weakness, such as bedded shales or shear zones, residual shear strengths are reached with much smaller displacements than the displacements required to reach residual strength for a thicker material. Fig. 10.1.3c illustrates the difference in shear displacements observed in direct shear tests on thick and thin seams of clay (Nieto, 1974). In practice, residual strengths are more likely to be representative of thin-bedded materials, such as a bedded shale, in contrast to a massive clay with indistinct bedding. Small displacements along the bedding planes can cause a rapid reduction of the peak strength to the residual. Additionally, any excess pore-water pressures generated in the bedding seam during shear are rapidly dissipated, so that drained conditions may prevail. If the mass of soil or rock presents evidence of discontinuities along which significant movements have already occurred, such as bedding or shear planes, then only the residual shear strength is expected to be mobilized and the failure envelope can be characterized in terms of the residual friction angle ϕ'_r.

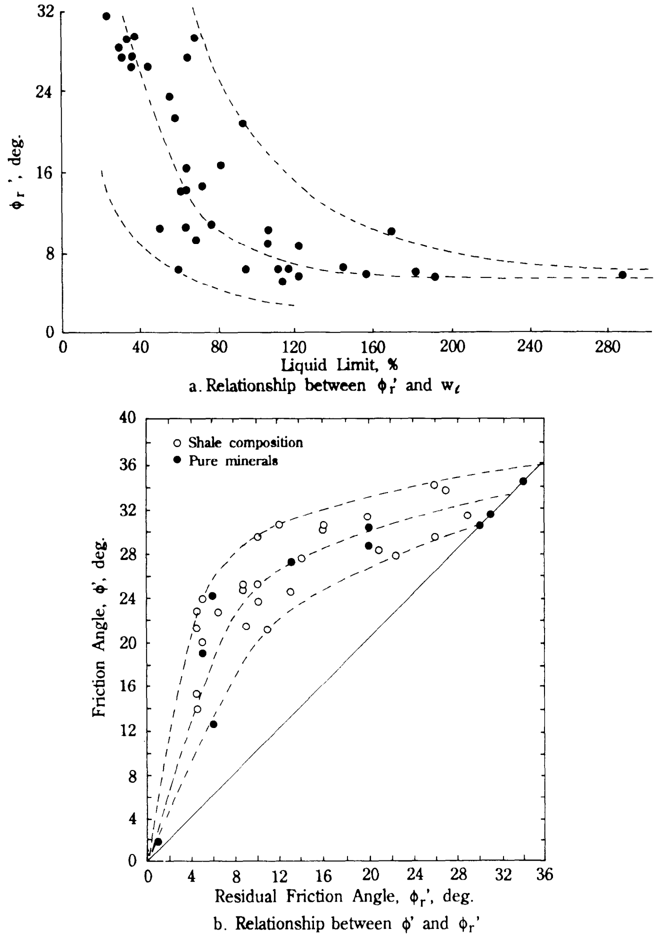

Fig. 10.1.4. Relationship between ϕ_r', ϕ', and *Lw* (after Cepeda-Díaz, 1987).

Undrained Shear Strength: The undrained shear strength of a clay can be obtained in terms of c' and ϕ' as long as u_f can be determined; however, this is often difficult in the field and sometimes infeasible in the laboratory. Therefore, the undrained shear strength s_u is usually determined or approximated from direct and simpler measurements, such as field vane tests, laboratory unconfined compression tests, or unconsolidated undrained triaxial tests on undisturbed samples. The *unconfined compressive strength* ($q_u \approx 2s_u$) is a measure of the consistency of fine-grained cohesive soils, and as such it has been used for classification purposes (Table 10.1.2).

Back-calculation of the mobilized shear strength $(s_u)_{\text{mob}}$ in a number of slope and foundation failures in various soft clay deposits indicates that for the cases investigated, $(s_u)_{\text{mob}} \approx 0.22\ \sigma_p'$ (Mesri and Godlewski, 1977). Typically, s_u determined from laboratory unconfined compression tests is less than $(s_u)_{\text{mob}}$ largely because of sample disturbance. Corrections are also applied to the measured laboratory undrained shear strength to account for field conditions that are not exactly duplicated in the tests, such as strength anisotropy, influence of shearing rate, and progressive failure.

The relationship between the undrained shear strength and the effective stress before shear can also be investigated using triaxial compression tests on undisturbed samples that are first consolidated to the various effective stresses selected and then sheared under undrained conditions. Such tests are usually referred to as consolidated-undrained triaxial tests, or briefly, CU tests.

Drainage Conditions and Shear Strength Parameters in the Field: The undrained shearing of highly overconsolidated clays and shales leads to a decrease in *s* with time as the induced excess negative pore-water pressures gradually dissipate, and thus for this type of material the long-term drained condition is generally the least favorable condition. For normally consolidated clays, on the other hand, the *undrained shear strength* (corresponding to a given σ_n' before shear) may be considerably lower than the corresponding drained shear strength as a result of the positive excess pore water pressures induced during undrained shearing. During foundation loading, for example, the least favorable condition for normally consolidated clays and slightly overconsolidated clays ($OCR < 2$) is generally the short-term undrained condition, and thus using the undrained shear strength for this latter type of materials is usually conservative.

In the case of unloading of slope cuts and other excavations, excess pore water pressures resulting from unloading are superimposed on the excess pore water pressure generated by undrained shearing. This can result in a net negative excess pore water pressure, even for normally or slightly overconsolidated clays. With time, as the excess negative pore water pressure is dissipated, the shear strength will decrease. Thus the undrained shear strength will be unconservative if used to estimate long term strength of excavations, particularly in the case of highly overconsolidated clays or shales.

In the case of bedded shales or weak rock with joints, the strength along the discontinuity, rather than the unconfined compressive strength of the material, will control many of the failures. In some cases, the strength along the bedding surface or other discontinuity can be estimated using a peak friction angle, which may include a dilatant component to account for irregularities on the surface. However, the residual friction angle should be used if irregularities have already been sheared off, or if they will be lost with small displacements. In the case of failure surfaces that cut at an angle to the discontinuity, the peak strength of the intact material may be applicable. However, combined failures, through both intact material and along discontinuities, will often occur in shale and other weak rock, and the interaction of the discontinuity with the intact portion of the weak rock will cause strengths to be less than would be predicted for failure of the intact material alone.

10.1.2.6 Creep

Creep refers to the time-dependent deformation of soil or rock resulting from internal rearrangement of particles in response to the application of a sustained stress difference = $(\sigma_1 - \sigma_3)$, generally smaller than the stress difference of the soil at failure = $(\sigma_1 - \sigma_3)_f$, where σ_1 and σ_3 are the major and minor compressive principal stresses, respectively. Deformation during undrained creep results from shape distortion as the soil mobilizes a constant shearing resistance in response to the shear stresses applied upon loading or unloading.

Creep models have been applied toward the solution of a variety of engineering problems, such as the closure of and loads on tunnels, chambers, and pillars in creep-sensitive materials, such as salt, shale, and fault zones. Highly stressed and creep-sensitive ground encountered in underground excavations is described in tunnelman's terminology as squeezing ground, inasmuch as it leads to a gradual closing of the opening under practically undrained conditions.

Undrained creep behavior is closely related to the *drained creep* phenomenon associated with secondary consolidation and swelling inasmuch as the mechanisms that cause volume change in the drained case (at a constant effective stress) correspondingly lead to the development of excess pore-water pressures for undrained (constant volume) loadings.

A fundamental approach to creep behavior involving the response of soil to isotropic and deviatoric stresses is quite complex and still in the development stage. For this reason, creep predictions have been traditionally based on semi-empirical creep models obtained through attempts to best-fit the observed laboratory creep data of a variety of soils. In this way, Singh and Mitchell (1968, 1969) developed the interrelationship among creep strain rate $\dot{\epsilon} = d\epsilon/dt$, stress level with respect to a reference strength $D = (\sigma_1 - \sigma_3)/(\sigma_1 - \sigma_3)$ and time t, which is widely applicable to both drained and undrained creep, and expressed by

$$\dot{\epsilon} = \frac{d\epsilon}{dt} = A_1 \, e^{\alpha D} \left(\frac{t_1}{t}\right)^m \tag{10.1.11}$$

where t_1 is the reference time. The m parameter is the slope of the linear $\log \dot{\epsilon}$-$\log t$ relationship existing for any intermediate stress level D ($\approx$ 30 to 90%) for which m is also a constant. In other words, m establishes the rate of decrease of the strain rate with time. The a parameter gives the dependency of strain rate on stress level in the range of $D \approx$ 30 to 90% for a given time ($t_1 < t_2 < \ldots t_n$) for which a is also a constant. The parameter A_1 is the extrapolated value of strain rate at the reference time t_1 for $D = 0$. The creep potential of a clay is closely related to the value of m, which is in the range of 0.5 to 1.3 for a variety of soils. As m decreases, creep deformations become more significant, and the soil is more susceptible to creep rupture under sustained loads. For any one soil, there seems to be a maximum shear stress the soil can sustain without creep rupture, called the upper yield strength.

Expressing the strain-stress model as a hyperbola provides a better physical meaning for the creep parameters. The parameters in the hyperbolic model are the ratio of undrained modulus to undrained shear strength E_u/s_u and the axial strain at failure ϵ_f (Mesri et al, 1981).

$$\epsilon = \frac{2}{(E_u/s_u)_1} \frac{D_1}{1 - (R_f)_1 \, D_1} \left(\frac{t}{t_1}\right)^{\lambda} \tag{10.1.12}$$

where $R_f = 1 - \dfrac{2}{(E_u/s_u)\epsilon_f}$ and all the pertinent parameters are evaluated at an initial time t_1.

The creep parameter λ that controls time or strain rate effects also correlates very roughly with E_u/s_u: $\lambda \approx$ (l/6000) E_u/s_u. Typical values of E_u/s_u are in the range of 100 to 600 for clays and shales, and thus the values of λ are typically in the range of 0.01 to 0.10. (Note that $\lambda = 1 - m$).

Laboratory creep tests on samples of clay gouge can be used to determine the creep rates and pressures anticipated around a tunnel in squeezing ground, as discussed in 10.1.6.

10.1.2.7 Deterioration

Deterioration of overconsolidated clays and weak argillaceous rocks in response to weathering, swelling, and associated softening is perhaps one of their most important engineering characteristics. Unstable shales, for example, have plagued the petroleum industry for many years; the washout experienced by shale formations in response to borehole drilling can be tolerable in some wells but uncontrollable in others. Deterioration of shale mine roofs have been a major cause of the time-dependent roof collapses that have troubled the coal mining industry.

Table 10.1.4. Shale Slake-Durability Classification

Slake-Durability Index	Descriptive Term
98	Very high
95-98	High
85-95	Medium high
60-85	Medium
30-60	Low
30	Very low

Disintegration of shale into relatively small pieces upon exposure to different humidity-moisture environments, including submersion, is usually referred to as *slaking.* For tunnels and other underground excavations, the slaking characteristics of shale affect stand-up time, overbreak, support loads, and construction and support procedures required to minimize deterioration. Successive disintegration and breaking away of loose material from the tunnel crown section results in a fresh rock surface which is exposed each time to a further cycle of weathering. Slaking also progresses along surfaces of fractures behind rock slabs, contributing to time-dependent instability of large blocks.

Wetting and drying are also known to significantly increase the expansion of exposed clay and shale strata (and thus the heaving of overlying structures) as compared to the magnitude of swell and associated softening caused only by unloading with access to water. The additional heave and expansion occurs in response to the further breakdown of diagenetic bonds and alteration of the shale structure. The rate of disintegration of the upper shale layers also controls the rate at which shale slopes are "worked down." The colluvium of disintegrated shale (which could be tens of feet or meters thick) often forms an unstable mass that slides along its contact with the underlying intact shale. Thus the overall strength and stability of slopes is frequently controlled by the strength of the softened and deteriorated material.

During drying, shale is often subjected to inhomogeneous and anisotropic shrinkage that can cause cracks or microfissures to open, providing the conduits for future moisture redistribution. Upon access to water, shear stresses resulting from differential swelling may also cause local failures and shale disintegration. Moreover, pore air compression resulting from immersion of unsaturated shale in water can apply internal pressures that may eventually exceed the local tensile strength of the material and cause additional shale slaking.

The resistance of shale to deterioration upon exposure to drying and wetting cycles is frequently estimated by subjecting representative specimens to the standard *slake durability test* (Anon., 1978). In this test, 10 oven-dried lumps of shale 40 to 60 g each are rotated (20 rpm) for 10 min in a partly immersed drum of 2.0 mm mesh. The slake durability index is the oven-dried weight percentage retained in the drum after two (oven drying-wetting) standard cycles. Shale slake durability is characterized as described in Table 10.1.4.

The deterioration response of shales encompasses a broad range because of the broad range of shale compositions and the wide variety of field humidity and moisture environments to which they are subjected. As a result, index tests and classifications based on limited, often severe testing environments do not permit a full evaluation of the shale performance under field conditions, particularly in underground excavations in which moisture changes may be caused by relatively small humidity changes rather than alternate soaking and drying.

A study of the deterioration of two dozen natural shales exposed to controlled temperature and relative humidity conditions revealed the following (Cepeda-Díaz, 1987). In general, shales with natural water contents w_o smaller than the shrinkage limit w_s are fissile, whereas shales with natural water contents higher than w_s are massive. *Fissile* shales (group F) deteriorate by opening along weak planes of stratification, followed by separation of thin slabs perpendicular to the stratification. On the other hand, *massive* shales (group M) lack a preferred orientation of discontinuities and often break down to chunks and chips along random cracks, fractures, and slickensided surfaces. Fissile shales generally have natural water contents smaller than 15% and liquid limits w_ℓ not greater than 100% (using ball-mill disaggregated samples passing the US No. 200 standard sieve). Beyond this range of values for w_o and w_ℓ, shales are generally massive.

Fissile and massive shales can be further subdivided into three groups (1, 2, and 3) depending on the moisture change response and deterioration behavior upon exposure and thus related to their equilibrium relative humidity. *Equilibrium relative humidity ERH* is the *relative humidity RH* (at a given temperature) in which freshly exposed specimens of a given shale remain at their natural water content. At $RH > ERH$, intact shale gains moisture from the air environment, whereas at $RH < ERH$, intact shale loses water to the environment. Shales in group 1 deteriorate if subjected to relative humidities greater than *ERH* and include shales with $w_\ell > 40\%$ and $w_o < 0.2\,w_\ell - 8\%$ but with natural water contents not greater than 15%. On the other extreme, shales in group 3 (which have *ERH* greater than 97.5%) deteriorate when subjected to environments drier than *ERH* and include shales with $w_\ell > 10\%$ and $w_o > 0.2\,w_\ell - 2\%$. Shales in group 2 deteriorate in environments different than *ERH* and include shales with $w_\ell > 10\%$ and natural water contents other than those characteristics of groups 1 or 3.

Shales that deteriorate if subjected to *RH* greater than *ERH* (groups 1 and 2) generally have natural water contents lower than that corresponding to $w_o = 0.2w_\ell$. On the other hand, shales that deteriorate only if subjected to environments drier than *ERH* (group 3) generally have natural water contents higher than $w_o = 0.2\,w_\ell$. Thus it is consistent that shales with natural water contents equal to both $w_o = 0.2w_\ell = w_s$ remain intact upon exposure to any *RH* environment. At such moisture and structural state, the total volume change associated with moisture gain or loss upon environmental exposure may be relatively small, and thus the shale does not experience a significant amount of anisotropy and inhomogeneous deformation, that is, no deterioration.

For underground excavations such as tunnels and mines where field environmental control can be considered, the following guidelines are suggested for preventing the deterioration of various types of exposed shale strata (Cepeda-Díaz, 1987). Shales in group 1 should always be maintained at environments drier than *ERH* and preferably not wetter than 75% *RH*. Dry environments not only avoid the damaging effect of humidity fluctuations at the high *RH* range but also discourage the chemical alteration of iron sulfides, if present in the shale. Iron sulfides are known to oxidize in the presence of water and oxygen to form limonite and sulfuric acid. The sulfuric acid reacts with any calcite available in the rock to produce carbonic acid and gypsum with resulting large increase in volume and shale disintegration. Shales in group 2 should always be maintained at relative humidities near *ERH* and preferably not exceeding *ERH* ± 2%. For group 2 shales, *ERH* values are expected to be in the range of 75 to 97.5%. Shales in group 3 ($ERH > 97.5\%$) should always be maintained at environments wetter than *ERH*, and thus very often close to 100% *RH*.

Because shales in group 3 rarely deteriorate upon immersion in water at their natural water content, the use of sprayers to keep the exposed shale strata from drying may be a suitable alternative to the high humidity control of these shales. For shales in groups 1 and 2, any direct contact with water should be suppressed to avoid severe deterioration. It should be pointed out that, independent of the initial type of shale deterioration upon initial environmental exposure, wetting as a result of water inflow, immersion, or spraying (rain in the case of open cuts) is likely to induce severe deterioration if the exposed shale strata has been allowed to dry before wetting.

10.1.3. MECHANICS OF BEHAVIOR

In many problems, in both soil and rock mechanics, the stresses or the interrelation of stresses and deformations in the soil or rock mass must be determined. In these problems, the boundary conditions—the geometry of the mass and the distribution of loads or displacements applied to the mass—must be considered in obtaining a solution.

The problems have traditionally been divided into two groups (e.g., see Terzaghi, 1943): (1) those in which the stresses in a region or a surface in the mass has reached a limit or failure condition, and (2) those in which the stress levels are below the limit condition, and changes in stress within the medium are a function of the deformations.

1. *Limiting stress conditions.* The loads or the state of stress can be determined from the equilibrium of a portion of the mass, assuming that the stresses along a surface or region within the medium have reached their limit—the strength of the material. Slope stability analysis, earth pressure theory, and bearing capacity problems are all concerned with the evaluation of the loadings upon the soil or rock mass when certain surfaces within the mass are at a limiting level of stress.

2. *Stress-deformation conditions.* In many problems it is assumed that changes in stress are a function of deformations. The simplest assumption is that stresses are proportional to strain, in other words, the material is elastic. Closed elastic solutions are available for relatively simple boundary conditions, and often can be used to obtain a first approximation to the mechanics of the problem. More sophisticated stress-deformation models may assume that the material has a nonlinear stress-strain relationship, that may even approach a limit at some strain level, and that energy losses occur as loads are cycled. Solutions for these models, as well as for elastic models utilizing more complex boundary conditions, require the use of numerical methods, such as finite element or discrete element models, and relatively large computer capacity (usually a workstation computer rather than the current personal computers).

Stress-deformation relationships are used to evaluate not only foundation settlements but also the interaction between the soil medium and a structure—such as an anchored bulkhead, braced excavation, or tunnel lining—whose stresses and deformations are a function of its relative stiffness with respect to the soil mass.

Another group of stress-deformation problems are those in which settlements or heave occur with time as water flows into or out of the soil matrix in response to changes in the state of stress—the process of swelling or consolidation, respectively, discussed in 10.1.2.4. In soft soils, volume changes occurring as water flows into or out of the soil are the major cause of settlement, whereas deformation of the soil at constant water content is usually a minor portion of the total displacement.

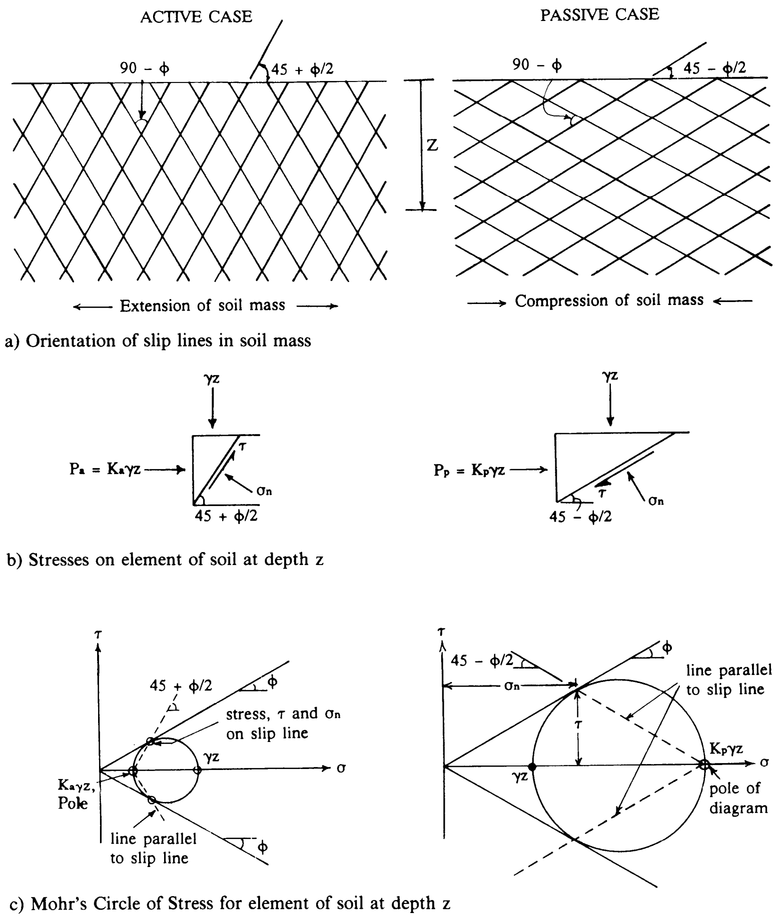

Fig. 10.1.5. Rankine active and passive earth pressures.

10.1.4. LIMITING EQUILIBRIUM

10.1.4.1 Active and Passive Earth Pressures

Lateral extension or compression of a soil mass will produce decreases or increases, respectively, in the lateral soil pressures until a limit is reached. The limits are termed the *active and passive earth pressures* and represent, respectively, the minimum and maximum possible natural lateral stresses that can exist in the ground. The active pressure P_a is used to represent the earth pressure acting behind retaining walls, while the passive pressure P_p is the maximum pressure that can act at the toe of a wall embedded in the soil.

Fig. 10.1.5 shows the active and passive pressures resulting from the extension and compression of an infinite soil mass with a horizontal ground surface.

The magnitude of the active and passive stresses acting on a vertical plane is obtained from Mohr's circle of stress, recognizing that the vertical stress is equal to the overburden pressure z, and the soil element is at its limit, and therefore the circle of stress is tangent to the strength envelope, which is assumed to be a straight line, $s = c + \sigma \tan \phi$. Rankine (1857) provided the first solution to this problem.

The principal stresses at the limit condition are related as follows:

$$\sigma_1 = \sigma_3 \tan^2 (45^\circ + \phi/2) + 2\, c \tan (45^\circ + \phi/2) \quad (10.1.13)$$

For the case of lateral extension of the soil mass, the lateral stresses are reduced to their minimum value, and s_3 will equal the lateral stress, which is the active earth pressure. The coefficient of active pressure K_a is equal to $1/\tan^2 (45 + \phi/2)$ for the case of a horizontal ground surface. For the case of lateral compression of the soil, the lateral stresses are increased to their maximum value, and σ_1 will equal the lateral stress, which is the passive earth pressure. The coefficient of passive pressure K_P is equal to $\tan^2 (45 + \phi/2)$ for the case of a horizontal ground surface.

The more general Rankine solution is for the active and passive pressures that develop in an infinite slope (Fig. 10.1.6). Assuming that the slope is infinite, the vertical force on a plane parallel to the ground surface is equal to the weight of the overburden. The active and passive earth pressures are the stresses acting on a vertical plane. They are oriented parallel to the ground surface and thus have both a normal and shear component. Fig. 10.1.6 illustrates the condition for the active earth pressure. The magnitude and direction of the active earth pressure and the orientation of the shear planes can be obtained from Mohr's circle.

If the entire soil mass is in a limiting state of equilibrium, as is assumed in the Rankine case, then the active and passive stresses acting on the vertical plane for a frictional material will increase linearly with depth, and the total active or passive force over a given height z will act at the lower third point and have a magnitude equal to $z/2$ times the active or passive pressure at the depth z. This condition is obtained for a retaining wall when

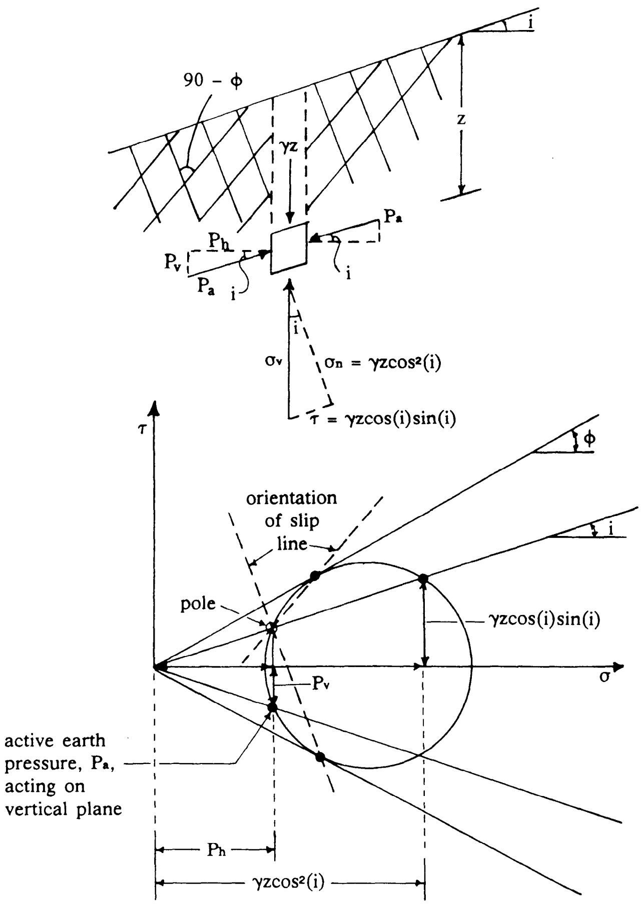

Fig. 10.1.6. Rankine active earth pressure for inclined surface.

outward deflections at the top of the wall are in the order of 0.1 to 0.5% of its height. Thus the validity of designs based on an assumed active state of stress behind the wall depends on the outward deflections that the retaining structure actually undergo.

For walls in which the upper portion of the wall is not allowed to deflect outward, the distribution of stresses on the wall will not increase linearly with depth, even though the movements of the lower portions of the wall may be sufficient to reduce the total forces on the wall to the active forces. This is the case with braced walls in which the upper portion of the wall is restrained early in the excavation process, usually in order to limit ground movements that could adversely affect structures and utilities adjacent to the wall. As a result, the center of pressure for the forces acting on the wall is at a higher elevation than the lower third point, although the total magnitude of the forces can be estimated using Rankine or Coulomb assumptions. Field measurement of strut loads for braced excavations are used to develop apparent earth pressure envelopes for design. The envelopes, which encompass the variations that can be expected in strut loads due to construction procedures, provide an almost rectangular (constant) pressure distribution with depth and a magnitude of the total force under the envelope that is approximately 1.3 to 1.75 times the active Rankine or Coulomb pressure (Peck et al., 1974).

The Rankine case, in which it is assumed that the ground surface is of infinite extent, either horizontal or sloping, can be applied to real problems in which the ground surface is not of infinite extent, as long as the stresses on the vertical plane can be assumed to act parallel to the ground surface. It usually produces a conservative estimate of either the active or passive pressures on a wall because it usually does not fully account for the shear stresses that act on the wall.

The magnitude and location of the total active or passive forces acting on the back of a retaining structure can also be determined using the assumptions involved in Coulomb wedge analysis, as described in the next section. The Coulomb analysis is more general than the Rankine method in that any orientation of the forces on the back of the retaining wall can be assumed, and surcharges and irregular backfill slopes can be handled.

10.1.4.2 Coulomb Wedge Analysis

A more general solution for limiting conditions in a soil mass can be obtained from the Coulomb (1776) analysis, which evaluates the forces acting on a wedge of soil. In this analysis, it is assumed that a planar failure surface has developed in the soil mass and that the soil wedge slides along a planar surface forming the back of the wall. The analysis is commonly used to evaluate active earth pressures behind retaining walls.

Fig. 10.1.7 illustrates the procedure for a frictional material. As in most limit equilibrium problems, the analysis is handled in a series of steps:

1. A free-body diagram of the wedge of soil is drawn, showing all forces acting on the boundaries of the wedge, as well as the body forces (weight W_s and acceleration forces) acting in the free body. A failure plane forms one of the wedge boundaries. A trial failure plane is selected, oriented at angle a to the horizontal.

2. A force polygon is constructed to include all the forces acting on the free-body diagram. The summation of forces can be obtained either graphically or by trigonometry, considering the geometry of the force polygon. Water pressures U_1 and U_2 acting on the boundaries of the wedge are included as external forces. Although the summation of forces equals zero, the assumption of a plane failure surface may result in the summation of moments not equaling zero.

3. Because the orientation of the failure surface is usually not known, several trial wedges are analyzed, each with a planar failure surface at a different orientation a. The largest value of the active force or the smallest value of the passive force represents the critical condition, in which the first planar failure surface would develop.

In the case of soil or rock containing preexisting planes of weakness of known orientation, the failure plane is selected parallel to the plane of weakness, for cases in which its orientation is close to the orientation of the critical failure plane. In this case, it is not necessary to search for the orientation of the critical failure plane by analyzing multiple trial wedges.

The Coulomb method described in the foregoing can be used for general retaining wall problems, but there are some limitations. For the passive pressure case, when there is a significant component of wall friction, a planar failure surface does not closely approximate the actual failure surface that occurs in the field, and thus the Coulomb method is unconservative (overestimation of the passive pressure). In such cases, the critical plane will be curved and the passive pressure can be analyzed by methods described in the following.

10.1.4.3 Application of Wedge Analysis to Slope Stability Problems

Fig. 10.1.8 illustrates the procedure for determining the stability of a slope by analyzing multiple wedges or slices of the

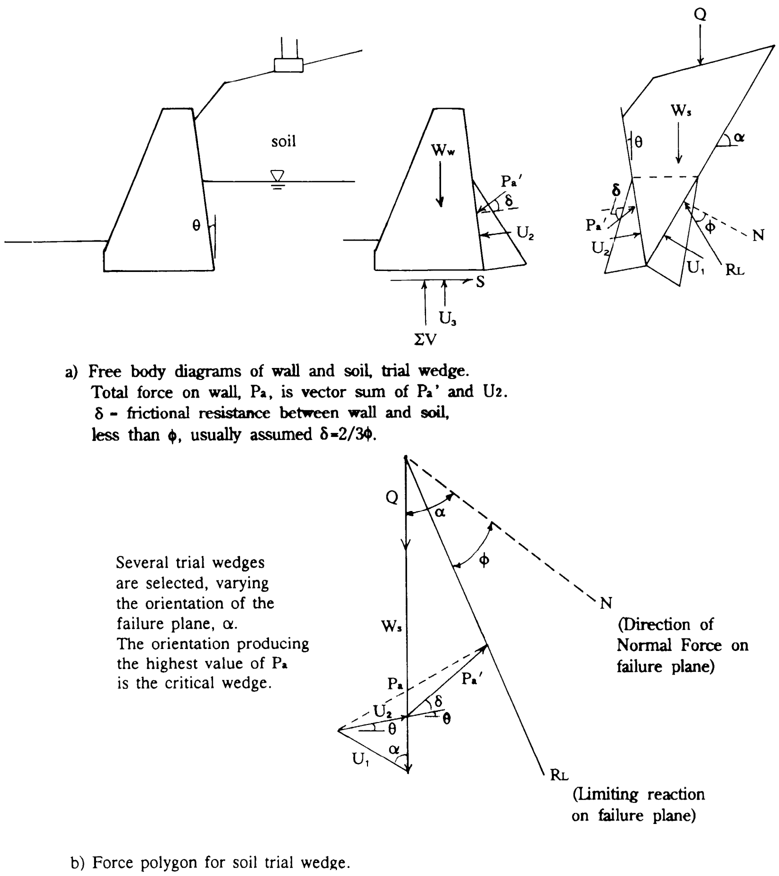

Fig. 10.1.7. Coulomb active earth pressure.

potential sliding mass. Multiple slices are treated by summing forces in the same manner as the Coulomb wedge in 10.1.4.2. A slice is related to the adjacent slice by equating the force acting between the two slices. There are several different techniques for evaluating the forces between slices. In general, forces acting between vertical slices are assumed to act parallel to the slope, as would be the case for an infinite slope. Where one slice or wedge has a significant vertical displacement with respect to an adjacent wedge or slice, the forces acting between the two may approach their maximum obliquity, at ϕ degrees to the normal. The mobilized or developed friction angle ϕ_D (required to produce a factor of safety of one) is determined from trials using the graphical construction for the composite force polygon of Fig. 10.1.8c. The factor of safety *FS* is the ratio of tan ϕ to tan ϕ_D.

In most slope stability analyses, the slope is assumed to be two-dimensional. In actual cases in which the slope does not extend a large distance in the third dimension, the actual factor of safety will be higher than would be computed for a two-dimensional slope having the same profile. The three-dimensional analysis of rock wedges (Chapter 10.4) shows a similar trend. Although the two-dimensional assumption would provide a conservative estimate of the factor of safety of a slope, making the assumption that a slope is two-dimensional in the back analysis of shear strength parameters would overestimate the shear strength if the slope is actually three-dimensional.

10.1.4.4 Circular Failure Surface for Stability of Cohesive Material

The maximum height of a slope or a cut in a cohesive material, in which the undrained shearing resistance s_u is assumed to apply, can be determined from the stability chart of Fig. 10.1.9 (Peck et al., 1974). The factor of safety *FS* of the slope is found from the expression,

$$FS = N_\sigma s_u/\gamma H \tag{10.1.14}$$

Use of the undrained shear strength s_u will be unconservative if the slope is excavated in overconsolidated or fissured clays, or clays containing sand and silt seams. In such cases, effective shear strength parameters should be used, which assume the material has frictional resistance and, in some cases, a small effective cohesion.

10.1.4.5 Curved Failure Surfaces for Passive Earth Pressures

The Coulomb analysis produces unconservative results for the passive case when the passive force on the wall acts at a significant angle δ to the normal. In this case, a curved failure surface should be assumed in order to determine the passive earth pressure. The failure zone will consist of a zone of radial shear and a passive Rankine zone (Fig. 10.1.10). For a frictional material, the shape of the failure surface in the zone of radial shear approximates a logarithmic spiral. Additionally, the log spiral simplifies the calculations because the limiting reactions acting on the log spiral failure surface will meet at a point and can be ignored in the analysis by summing moments about that point. Fig. 10.1.10 illustrates the pattern of slip lines for the case of the angle δ on the wall at its maximum value, equal to the angle of friction. In this case, the plane of the wall becomes a slip line for the soil mass.

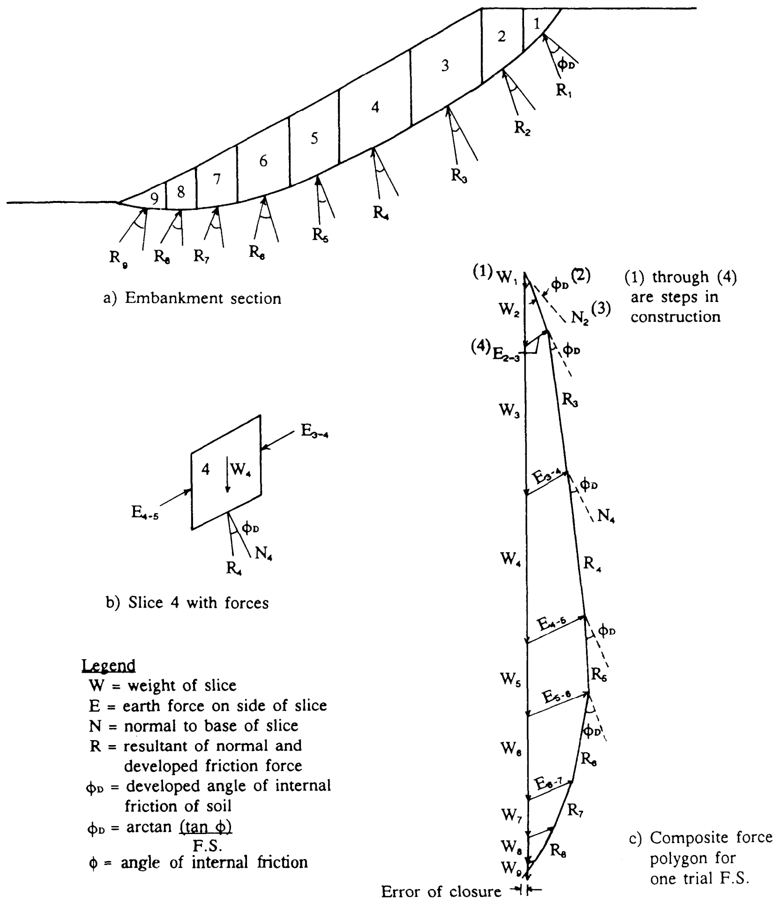

Fig. 10.1.8. Method of slices for analyzing slope stability.

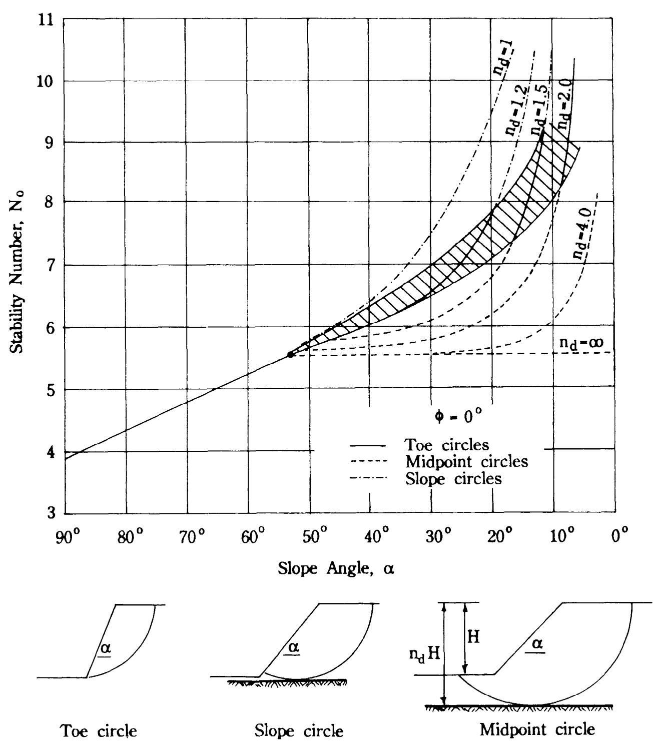

Fig. 10.1.9. Stability chart for slopes in cohesive soil (after Taylor, 1937).

10.1.4.6 General Bearing-capacity Relationship

Relationships for the bearing capacity of soils loaded by foundations have been developed from the theory of plasticity. The solutions of Prandtl (1921) and Reisner (1924) were obtained for a rough, rigid strip footing on the surface of a weightless, perfectly plastic material (Fig. 10.1.11). Note that the pattern of the failure surfaces is similar to the combined active and passive zones illustrated in Fig. 10.1.10. The ultimate bearing capacity q_{ult} is related to the undrained shear strength of the soil c and the surcharge pressure q as follows:

$$q_{ult} = cN_c + qN_q \tag{10.1.15}$$

where N_c and N_q are dimensionless bearing-capacity factors that are a function of the friction angle ϕ:

$$N_q = \exp(\pi \tan \phi) \text{ and } \tan^2(45° + \phi/2) \tag{10.1.16}$$

$$N_c = (N_q - 1) \cot \phi \tag{10.1.17}$$

The general bearing capacity relationship (Terzaghi, 1943) is an approximate solution that was obtained by superposing on Eq. 10.1.15 an additional relationship for a frictional soil with weight, but without cohesion intercept (c = 0) and without a surcharge (q = 0). The superposition produces an error on the safe side not exceeding 20% for friction angles of 30 to 40°, and, of course, no error for a friction angle of zero (Vesic, 1975). The additional term is proportional to the shear capacity developed from the normal stresses in the weighted soil mass below the footing, and is therefore proportional to the size of the mass B and is also a function of the friction angle ϕ.

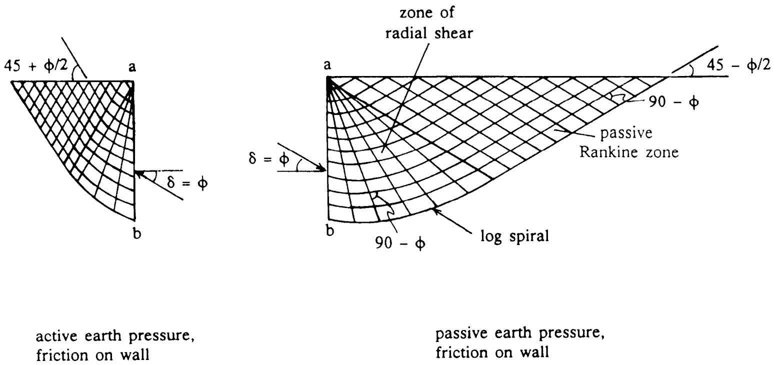

Fig.10.1.10. Active and passive earth pressures, friction on wall.

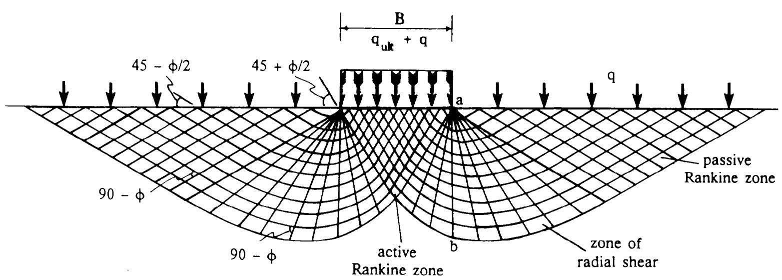

Fig. 10.1.11. Bearing capacity of a shallow footing; no friction on footing base.

The resulting general bearing-capacity relationship for a long strip footing of width B is

$$q_{\text{ult}} = cN_c + qN_q + 1/2B\gamma N_\gamma \qquad (10.1.18)$$

where N_g a dimensionless bearing capacity factor that is a function of ϕ and must be evaluated numerically. It can be approximated by the analytical expression,

$$N_\gamma = 2(N_q + 1)\tan\phi \qquad (10.1.19)$$

with an error on the safe side of 5 to 10% (Vesic, 1975).

Vesic (1975) notes, contrary to some of the earlier discussions in the literature, that the shape of the failure zone and the magnitude of the ultimate bearing capacity are not strongly affected by the presence or lack of friction at the base of the footing. He further notes that the ultimate bearing capacity is not strongly influenced by the stress distribution at the base of the footing, which could range from a uniform pressure for a flexible foundation to the variable stress distribution created by a rigid footing (or punch) displacing a constant amount into the soil mass. However, if the base of the footing rests on a thin soft layer above a stronger layer (such as the case of the bearing capacity of underclays beneath a mine pillar), significant reductions in bearing capacity can result by changing from a rough to smooth footing or by changing from a rigid punch to a uniform pressure acting at the base of the footing.

For foundations greater than approximately 4 ft (1.2 m) wide in sands and other frictional materials, the bearing capacity factors are quite high so that bearing capacity failures develop only for very high foundation loads. In these cases, the capacity of the foundations are controlled by allowable settlements.

Bearing Capacity of Cohesive Soils: Adjustments to the general bearing-capacity relationship have been made for other footing shapes and for the extension of the failure planes into the soil surcharge above the footing base. A linear approximation of the bearing capacity relationship for cohesive, frictionless materials (Skempton, 1951) is

$$q_{\text{ult}} = (1 + 0.2D_f/B)\,(1 + 0.2B/L)s_u N_c \qquad (10.1.20)$$

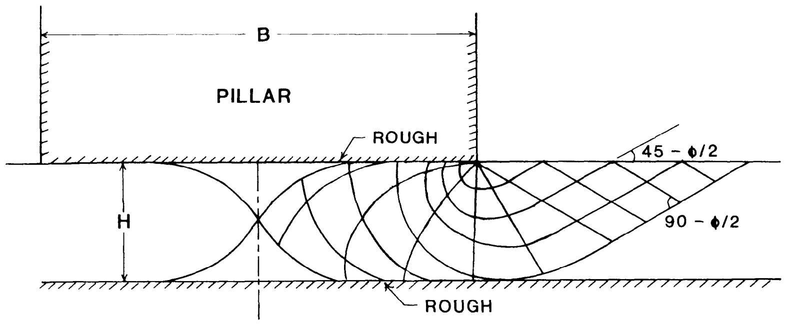
where N_c = 5.14; B is the footing width; D_f is the depth of the surcharge above the footing base, and is set equal to $2B$ for values of D_f greater than $2B$; and B/L is the ratio of width to length of the footing. The ultimate bearing capacity q_{ult}, is the pressure in excess of the pressure applied by the surrounding soil surcharge $g\ D_f$.

The foregoing relationship is used to estimate the allowable bearing capacity q_a for foundations on clay. The allowable bearing capacity is usually selected with a factor of safety of three against the ultimate bearing capacity q_{ult}. In addition, the foundation can accept a pressure equal to the surrounding soil surcharge pressure $g\ D_f$:

$$q_a = q_{\text{ult}}/3 + \gamma D_f \qquad (10.1.21)$$

10.1.4.7 Bearing Capacity of Mine Pillars on Underclays

In many coal mines, underclays are present beneath the coal pillar and the floor of the mine. Stresses in the pillars are often high enough to cause a bearing-capacity failure. Several types of bearing failure can occur. The pillar can punch into the underclay, or a general bearing-capacity failure can develop, with large heave occurring in the floor adjacent to the pillar. Typically, the underclays are in layers having a small thickness with respect to the pillar width. In such a case, the slip surfaces illustrated for the general bearing capacity relationship cannot form and the underclay will have to be squeezed out between the base of the pillar and underlying stronger rock layers, as illustrated in Fig. 10.1.12.



For φ = 0, Both Surfaces Rough:

B/H	0	1.4	5	10	15	20
Nc	5.14	5.14	6.4	9.2	11.8	13.4

$q_{ult} = S_u N_c$

Fig. 10.1.12. Squeeze of clay from thin zone beneath pillar (after Mandel and Salençon, 1972).

As a result, the magnitude of the ultimate bearing capacity is greater than would be obtained for a deep deposit of the same material. Vesic (1975) and Mandel and Salençon (1972) show that, as the ratio of the width of the pillar to the thickness of the soft layer increases, the ultimate bearing capacity for a cohesive, frictionless soil increases from 1 to approximately 2.5 times the ultimate bearing capacity that would be obtained for a deep deposit of the same soil.

Experience with coal pillars overlying underclays shows an interesting interaction between the pillar and the underclay. As the underclay is squeezed laterally outward from beneath the pillar, the pillar is subjected to tensile stresses, causing vertical fractures to develop in the pillar. Not only does closure of the opening result from the squeezing of the underclays, but the process can lead to collapse of the pillar and further closure of the mine opening. The formation of vertical tensile fractures in the pillar is a demonstration of the inability of the pillar to sustain the shear stresses that tend to develop between the pillar and the underclay as the clay squeezes outward. Mandel and Salençon show that the increase in bearing capacity factor N_c is much less significant if there is no shear resistance on one of the layers bounding the thin failing layer.

The shear stresses that develop at the base of the pillar have a much greater effect on the bearing capacity for a thin soil layer than they do for a deep layer. The failure of a footing above a deep layer is by a general downward movement of the soil beneath the footing whereas in the failure of a pillar overlying a thin weak layer, the soil is squeezed out laterally, between the pillar above and the stronger layer below. The presence of vertical fractures in a pillar effectively breaks the pillar into a group of narrow pillars, causing the effective ratio of pillar width to layer depth to decrease, and can lead to a reduction in the shear stresses along the pillar-underclay contact and a decrease in the bearing capacity.

Time effects also occur in the failure of coal pillars overlying underclays. Squeezing of the underclays will occur with time as a result of creep of the clay under high stress and the loss of strength of the underclay beneath the floor due to swelling in response to excavation unloading. Pillar settlement and floor heave may begin during active mining, but often the time-dependent effects cause continued failures, floor heave, and large settlements long after excavation has been completed. Large and relatively abrupt subsidence has taken place over abandoned room and pillar workings many years after the facilities were abandoned.

10.1.5. SETTLEMENT OF FOUNDATIONS

10.1.5.1 Soft Clays

Upon application of a load from a footing or fill placed upon a layer of soft clay, most of the settlement will take place with time, as water is squeezed from the soil pores and the volume of the voids decreases. The settlement of a foundation on a soft clay can be estimated by determining the change in effective stress on the clay layer as well as the effective stress existing before loading, and then determining the change in void ratio by using an appropriate slope on a plot of void ratio vs. change in effective pressure (e vs. log σ'_v). The slope to be used can be estimated from laboratory tests or other field tests. For a material loaded above its maximum previous consolidation pressure or preconsolidation pressure σ'_p, steeper slopes corresponding to C_c will apply. For stress changes below σ'_p, flatter slopes corresponding to C_r will apply (see 10.1.2.4).

The stresses resulting from a footing load will tend to spread out with depth below the footing, and thus the magnitude of the imposed stress will be reduced. In order to estimate the stresses at depth, an elastic distribution of stresses is usually assumed. Newmark charts, available in most soil mechanics texts, provide a means of graphically determining the stresses at any depth below the footing. An approximate estimate can be also obtained by assuming that the stresses spread on a $2V{:}1H$ slope from the edge of the footing.

10.1.5.2 Sands

The *standard penetration test* and its corresponding N-values are generally used to predict the allowable contact pressure to which a granular soil can be subjected by a foundation in order not to exceed tolerable settlements. Compression of saturated coarse-grained soils occurs rapidly as a result of their high permeability.

For footings with widths B greater than about 4 ft (1.2 m), the allowable pressure (q_a) expected to produce a total settlement smaller than 1 in. (25.4 mm) and corresponding differential settlements not exceeding 1/2 in. (12.7 mm) can be approximated by

$$q_a = 0.11\ N \qquad (10.1.22)$$

where q_a is in tons/ft^2, and N is the smallest average value of the standard penetration resistance. The value of N is located within a depth interval equal to B below the foundation level after corrections are made, if necessary, to take into account the effect of the overburden pressure and the position of the water table (Peck et al., 1974).

The ratio between the differential settlement and the total settlement is significantly less for very wide footings or raft foundations than for regular size footings, and thus the allowable pressure for rafts is that corresponding to a total settlement of 2 in. (50.8 mm), which can be approximated by $q_a = 0.22\ N$. For very narrow footings ($B < 4$ ft or 1.2 m), a small increase in pressure may lead to a significant enough settlement to consider it a bearing capacity failure. Therefore, the margin against bearing-capacity failure for these footings should also be investigated as explained in 10.1.4.6.

10.1.5.3 Weak Rock and Stiff Soils

The compressibility of foundations in weak rock and stiff soils can be evaluated using the theory of elasticity, assuming an appropriate deformation modulus for the material. The Boussinesq equation gives the displacements and stresses in an elastic mass due to a point load applied at the ground surface. The equation is integrated to determine the displacements and stresses due to loads distributed over some area at the ground surface. Newmark developed a graphical method for determining stresses or displacements for any assumed distribution of pressures at the ground surface. For the simple case of a uniform pressure p acting over a circular area of radius a, on the surface of an elastic medium, the surface displacement d at the center of the circle can be estimated as

$$d = 2pa(1 - \mu^2)/E \qquad (10.1.23)$$

where E and m are, respectively, in situ deformation modulus and Poissons ratio.

For rock containing natural fractures, the stiffness obtained in a laboratory test on an intact sample should be reduced in order to obtain the in situ deformation modulus. Parameters that index the degree of fracturing of the rock mass, such as the rock quality designation (RQD) or the ratio of field seismic velocity to laboratory sonic velocity, can be used to estimate the amount that the field deformation modulus should be reduced from the laboratory modulus. Plate bearing tests (typically with plate diameters of 3 ft or 1 m) can be used to determine the in situ modulus at selected locations in the field.

10.1.6. TUNNELING

10.1.6.1 Tunneling Conditions

The following should be considered in constructing a tunnel in soil or weak rock: (1) ability to safely excavate and support the tunnel; (2) ability to limit damage to third parties, in particular, to control ground movements that could affect nearby buildings and utilities; and (3) ability to perform its intended function over the life of the project, in particular, an adequate lining (Peck, 1969).

Commonly, long circular tunnels in soil are constructed using circular shields that are shoved through the ground, excavating the soil at the face of the shield, and providing initial support to the perimeter of the tunnel heading and permitting the initial tunnel lining to be erected in the tail section of the shield without exposing the soil surface.

Stability of the tunnel heading and prevention of damaging ground settlements are major concerns in soft ground tunneling. Design of the tunneling process is more difficult in cases in which the ground conditions vary across the tunnel face or vary along the length of the tunnel alignment. A single shield may not be able to accommodate all the conditions efficiently, and it may be necessary to change tunneling procedures or to use ground modification techniques, such as dewatering or grouting, to advance the tunnel.

Mixed-face conditions, in which rock and soil are encountered in a single tunnel face, create difficulties in excavating the rock while supporting the soils, which are often unstable. Bedding and layering of soils create variations in permeability that allow water to perch on top of low permeability layers and to flow into the tunnel. To minimize such flows requires placement of dewatering wells on very close spacings adjacent to the tunnel.

Soil tunneling procedures must also be employed when tunneling in rock, when a mixed face of soil and rock is encountered at the contact between rock and the overlying soil overburden, or when fault zones are encountered in the rock. Commonly, water in the soil and permeable rock fractures contributes to the instability of these zones. Although rapid and efficient tunneling may not be possible in the soil, it is desirable that the methods used to get through the soil zones allow safe, steady progress. This is more likely if it is anticipated in the design of the tunneling system that such conditions may be encountered.

The initial tunnel lining must be designed to accommodate the loads applied during construction, as well as the stresses produced by ground loads. In shielded tunnels, initial support commonly consists of steel ribs and lagging, steel liner plate segments, or concrete segments. Significant loads can develop during erection and subsequent grouting or expansion of the segments against the ground. If the ground has been excessively loosened or if it forms an irregular perimeter in poor contact with the lining, then nonuniform loadings and bending are produced that may result in significant damage and even buckling of the lining. As the shield advances, ground loads are transferred to the installed lining. Elastic analyses and experience show that there is significant interaction between the ground and the lining. If the lining is in full contact with the ground around its perimeter, then active ground loads applied to one portion of the lining perimeter will cause a small outward deflection and the build-up of a passive ground reaction on other portions of the perimeter that will support the lining and permit it to act as a stable arch. If the lining is relatively flexible with respect to the soil mass, then the bending moments that develop in the lining will be quite small.

10.1.6.2 Tunnelman's Ground Classification

Because the tunneling process may temporarily expose the ground over head or on vertical surfaces, soil characteristics that are of great concern to the tunneler are the ability of the soil to stand until the support can be placed. One of the major factors controlling the stand-up time of the soil is its short-term cohesion or cementing, as well as the amount of soil surface that is exposed ahead of the supports at one time. It is often difficult to determine the anticipated tunnel behavior from the standard index properties obtained in the soil exploration program. Often, in sampling, cohesive granular soils or partially cemented soils will be disturbed so that their in situ cohesive characteristics are lost. Another factor that strongly influences stand-up time is the groundwater flow. Flow occurring into the tunnel creates high seepage-pressure gradients near the tunnel face that can result in instability of the soil, causing it to flow into the tunnel.

The Tunnelman's Ground Classification is a qualitative description of the types of soil behavior encountered during tunnel-

Table 10.1.5. Tunnelman's Ground Classification

Classification		Behavior	Typical Soil Types
Firm		Heading can be advanced without initial support, and final lining can be constructed before ground starts to move.	Loess above water table; hard clay, marl, cemented sand and gravel when not highly overstressed.
Raveling	Slow raveling Fast raveling	Chunks or flakes of material begin to drop out of the arch or walls sometime after the ground has been exposed, due to loosening or to overstress and "brittle" fracture (ground separates or breaks along distinct surfaces, opposed to squeezing ground). In fast raveling ground, the process starts within a few minutes.	Residual soils or sand with small amounts of binder may be fast raveling below the water table, slow raveling above. Stiff fissured clays may be slow or fast raveling depending upon degree of overstress.
Squeezing		Ground squeezes or extrudes plastically into tunnel, without visible fracturing or loss of continuity, and without perceptible increase in water content. Ductile, plastic yield and flow due to overstress.	Ground with low frictional strength. Rate of squeeze depends on degree of overstress. Occurs at shallow to medium depth in clay of very soft to medium consistency. Stiff to hard clay under high cover may move in combination of raveling at excavation surface and squeezing at depth.
Running	Cohesive, running Running	Granular materials without cohesion are unstable at a slope greater than their angle of repose (± 30-35°). When exposed at steeper slopes, they run like granulated sugar or dune sand until the slope flattens to the angle of repose.	Clean, dry granular materials. Apparent cohesion in moist sand, or weak cementation in any granular soil, may allow the material to stand for a brief period of raveling before it breaks down and runs; termed cohesive running.
Flowing		A mixture of soil and water flows into the tunnel like a viscous fluid. The material can enter the tunnel from the invert as well as from the face, crown, and walls, and can flow for great distances, completely filling the tunnel in some cases.	Below the water table in silt, sand, or gravel without enough clay content to give significant cohesion and plasticity. May also occur in highly sensitive clay when such material is disturbed.
Swelling		Ground absorbs water, increases in volume, and expands slowly into the tunnel.	Highly preconsolidated clay with plasticity index 30, generally containing significant montmorillonite.

ing. Table 10.1.5 presents the classification, as proposed by Terzaghi (1950) and modified by Peck (1969) and Heuer (1974).

The classification is more than a description of the properties of the soil because it describes behavior under certain of the conditions encountered in a tunnel. Construction methods and equipment and tunnel geometry influence the ground behavior.

The stand-up characteristics of the soil are the primary factors that define the categories. The initial cohesion or cementing of the soil differentiates between *firm, raveling,* or *running* ground, whereas the presence of groundwater seepage can transform running ground into *flowing* ground. *Swelling* and *squeezing* ground are most likely in shales or clays of high plasticity. Protection of the shale from disturbance and access to water will minimize the swelling pressures that can develop. Thus early placement of a continuous lining against potentially swelling surfaces is usually desirable. If pressures still are high, then procedures to allow the ground to displace in a controlled manner can be devised.

10.1.6.3 Squeezing Ground

The severity of squeezing ground in a tunnel can be estimated from the ratio of overburden pressure gH to the undrained shear strength s_u of the clay (Peck, 1969). Ratios greater than 5 will produce the equivalent of a bearing capacity failure of the clay surrounding the tunnel, and result in rapid squeezing into unsupported areas in the tunnel face or into voids around the shield and lining. Compressed air pressures used in the tunnel are subtracted from the overburden pressure to reduce the ratio to acceptable levels. Although squeezing conditions are not as severe for ratios less than approximately 4, some time dependent movement and loading of supports will take place for ratios between 1 and 4.

Squeezing relationships cannot only be evaluated for soft clays in shallow tunnels but also for deep rock tunnels in shales and fault zones. In mine pillars or abutments where mining nearby has resulted in transfer of large stresses to the pillars, the stresses that cause failure or time-dependent movements will be greater than overburden and will be a function of the total stresses transferred to the pillar. The time rate of closure and build-up of pressures on linings in squeezing ground can be evaluated using creep relations, such as given in Eq. 10.1.12. Using this equation to describe the stress-strain-time relationships, the creep closure around a circular tunnel instantly excavated in a hydrostatic stress field was analyzed and compared with the results of field measurements of the Stillwater Tunnel in Utah, excavated at a depth of 2000 ft (600 m) in a shale containing fault zones and closely fractured zones subject to squeezing (Phienweja, 1987). Creep parameters were not only estimated from laboratory creep tests on shale and sheared clay gouge but were also estimated from measured closure and lining pressures in various rock mass classes. Table 10.1.6 illustrates the creep parameters and typical values of pressure and deforma-

Table 10.1.6. Back Calculated and Estimated Values of Strength and Creep Parameters for Various Classes of Shale

Ground Class	Description	ϕ, Degrees	q_u, psi	λ, %	$\dfrac{E_s}{(\sigma_1 - \sigma_3)_f}$	R_f	Diametral Closure, % at 3 months
CL I	Sandstone and siltstone, widely spaced joints	50	9000	—	200–500	0.1	
CL II	Siltstone to shale, moderately jointed	45	2000–4000	1–2	250–300	0.1–0.2	0.2 to 0.4 (steel ribs)
CL III	Shale, closely jointed with some thin shears	35	500–1000	5–7	250–300	0.5	1 to 2 (steel ribs)
CL IV	Shale, closely jointed and sheared, shear zones contain crushed and soft materials	25	200–300	7–10	200–250	0.8–0.9	0.8% (concrete segments)
CL IVb	Shale, wide shear zones of crushed and soft materials	25	0–100	12–15	150–200	0.9	4% (steel ribs)

Note: Steel ribs developed yield stresses (40 psi radial pressure) in Class III-IVb ground. Concrete segments were effectively stiffer and developed approximately 100 psi radial pressure. Conversion factor: 1 psi = 6.895 kPa.

tion that developed for the ground classes. The slope of the (log of tunnel closure) – (log time) plot was initially greater than λ as the headings advanced but approached λ with time. Pressures that develop on a lining installed soon after excavation are also strongly influenced by λ.

10.1.6.4 Estimating Ground Movements Around Shallow Tunnels.

In any tunnel, the ground in the heading must be kept under control to prevent instability prior to and during installation of the tunnel lining. When advancing shallow tunnels in soil in the vicinity of structures and utilities, a further requirement is to limit ground movements so that unacceptable movements and damage do not occur. Ground control measures must be selected with due consideration to the stand-up time of the soil. Two types of ground loss can occur: (1) large loss of ground, often in a sudden, uncontrolled, or catastrophic manner; and (2) the regular, smaller ground movements that occur throughout the length of the tunnel drive.

Large ground losses usually occur by means of running, flowing, or squeezing of soil into the tunnel face but can also occur due to flow of soil through the tunnel lining or by collapse of an unstable lining. Tunneling procedures should be selected to minimize the risk of large ground losses for the anticipated ground conditions.

Regular ground losses occur around the shield and around the lining, during excavation and installation of the lining, throughout the tunnel drive. For a shielded tunnel, a large portion of regular ground losses results when the shield cuts a perimeter that is several inches (tens of millimeters) outside the outer perimeter of the installed support. Ground losses are minimized by design of a shield that has minimum overcutting and is easily steered on line and grade, and by rapid and complete expansion or grouting of the lining behind the tail of the shield.

The volume of ground loss into the tunnel is distributed through the soil mass and results in a surface settlement trough of volume V_s that is less than the volume of ground loss V_1 by the amount of the volume expansion ΔV that takes place in the ground (Fig. 10.1.13). The denser the soil and the larger the ratio of tunnel-depth to diameter, the greater is the volume expansion, which reduces the volume of the surface settlement trough for a given volume of ground loss around the tunnel. In soft clays, V_s is approximately equal to V_l, but will exceed V_1 if drainage or disturbance of the clay surrounding the tunnel results in consolidation with time.

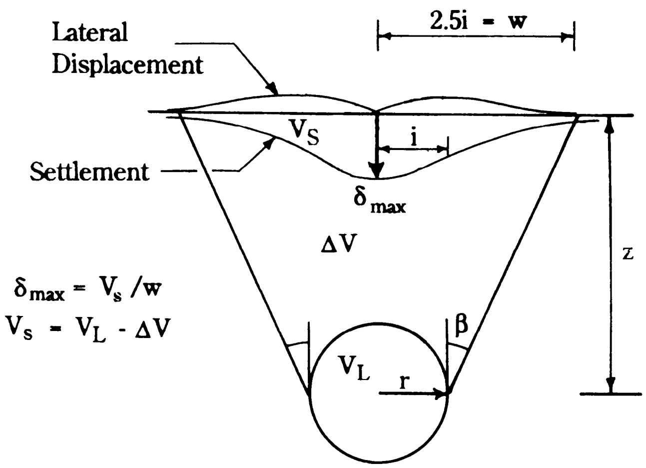


Fig. 10.1.13. Settlement trough for tunnel in soil.

The half width of the settlement trough *w* can be estimated using procedures described by Peck (1969) and Cording and Hansmire (1975). For a settlement trough shaped like a normal distribution curve with an inflection point *i*, then *w* is equal to 2.5 *i*. For sands, the angle *b* is in the range of 10 to 30°. For clays, the angle *b* is typically in the range of 25 to 45°. With these relationships, the magnitude and distribution of surface settlements and the damage to structures can be estimated for given volumes of ground loss.

10.1.6.5 Controlling Ground Movements.

A variety of tunneling procedures and shield designs can be used to control the face as well as limit movements around the shield and lining. Open face shields or shields using mechanical diggers support the face with the muck that is excavated and by additional breasting boards or plates positioned against the face. Wheeled excavators must control the face by only rotating the wheel sufficiently to excavate a volume of soil equivalent to the volume of the tunnel that is advanced. In both of these techniques, additional measures, such as compressed air or dewatering, may be used to prevent inflow of soil, and it may also be necessary to prevent running by use of techniques such as chemical grouting of the soils ahead of the face. Pressurized face shields may be used in lieu of compressed air to stabilize the face. They use air, water, a slurry, or the excavated muck to provide positive pressures in a chamber at the face of the shield to balance the water and earth pressures in the soil ahead of the face. Even with this technique, additional ground control measures may be necessary to prevent loss of ground in the face.

Procedures used to modify ground and groundwater conditions prior to tunneling include dewatering, chemical or cement grouting to penetrate the ground, jet grouting to form columns of soil-cement around the tunnel, and freezing. Structures that would be damaged by settlements can be directly supported by underpinning, or tied to reduce lateral extension of the structure. Compaction grouting is a process that can be used as required during tunneling to redensify the ground that has loosened above the tunnel before it causes surface settlement. It consists of a low slump grout placed at high pressures above the tunnel, usually after the shield has passed, in holes drilled down from the surface or up from the tunnel (Baker, et al., 1983).

Chapter 10.2
ROCK MECHANICS

WILLIAM G. PARISEAU

The fundamental objective of rock mechanics is to predict the motion of rock. In mine engineering, the rock of interest is the mass adjacent to the open cuts, shafts, adits, stopes, entries, rooms, panels, and so forth that are excavated in the course of mining. Equations that are available for the purpose of calculating the motion of a rock mass follow from consideration of three basic sets of laws:

1. Physical laws.
2. Kinematics.
3. Material laws.

The prediction of rock mass motion is a formidable task. A less ambitious but more practical objective that is often associated with engineering design is to determine whether the anticipated displacements are within some acceptable limit. The limit may be implied or restricted outright to the elastic range of response. The tacit assumption is that beyond the elastic limit, a large increase in displacement may become possible with little increase in load. Roof falls, pillar spalls, and rock slides are examples. Under these circumstances, design analysis is essentially an analysis of safety and stability. The fundamental objective is then to calculate a factor of safety appropriate to the problem at hand.

10.2.1 PHYSICAL LAWS

The physical laws of most importance to rock mechanics are:

1. Conservation of mass.
2. Balance of linear momentum.
3. Balance of angular momentum.
4. Balance of energy.
5. Balance of entropy.

These laws are applicable to all rock types and, indeed, are independent of the nature of the material considered. Other physical laws such as the balance of charge could be added to the list, and would be required, for example, if electro-mechanical phenomena were to be considered. Application of physical laws taken in basic form from particle mechanics to the mechanics of bodies of finite size requires the introduction of continuum concepts including that of stress.

10.2.1.1 Concept of a Continuum

The great generality and simple form of the equations that express basic physical laws tend to mask certain conceptual difficulties that arise in their application to bodies of finite size in contrast with particle mechanics. In rock mechanics, the concept of a continuum seems particularly troublesome.

In fact, the concept of a continuum is straightforward: matter is assumed to be continuous to an infinitesimal subdivision; the discrete nature of matter at the molecular level is ignored. A cube 25 mm on edge (about 1 in.^{3}) of a monatomic gas at room temperature and pressure contains about one hundred billion billion atoms (10e + 20). Dense solids of similar volume contain 100 to 1000 times more atoms. For comparison, the grain size in granitic laboratory test specimens of rock is of the order of millimeters. A single quartz grain 1 mm (0.04 in.) on edge then contains about the same number of atoms (10e + 20). Imperfections in the crystalline structure of a grain in the form of dislocations are several orders of magnitude smaller than grain size but still involve very large numbers of atoms and are certainly amenable to a continuum mechanics analysis.

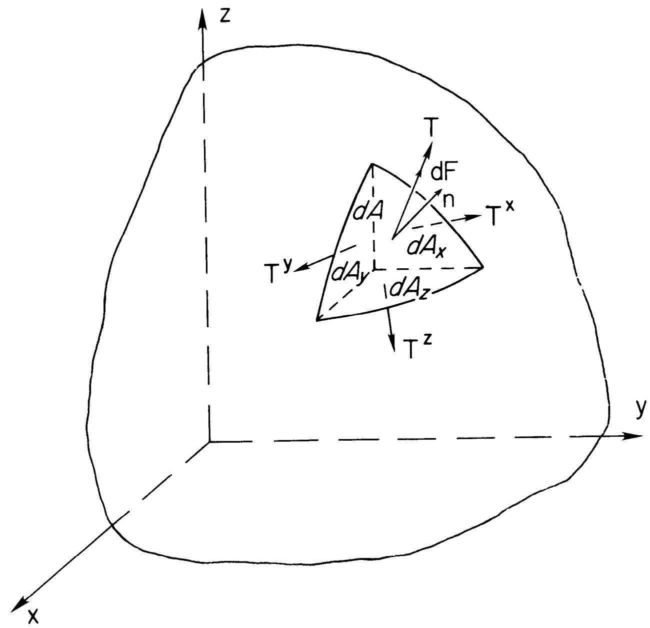

Fig. 10.2.1. Tetrahedral neighborhood of a surface point leading to the concept of stress.

The concept of a continuum does not require a uniform or even a smooth distribution of matter. Subgrain scale structural imperfections and heterogeneity in laboratory test specimens of rock are not excluded by the continuum concept. Geologic structures such as faults, joints, bedding planes, and so forth, and rock type variations at even larger scales of observations, are also entirely consistent with the continuum concept. The assumed continuous subdivision of matter does not preclude abrupt changes in its distribution.

10.2.1.2 Concept of Stress

The continuum concept of stress arises in consideration of the internal mechanical reaction of a body to deformation (Fung, 1965; Jaunzemis, 1967; Malvern, 1969). At the surface of a body in equilibrium, the external forces must be equal to the internal forces. Fig. 10.2.1 shows a small tetrahedral neighborhood of such a point. The external force dF is distributed over the surface dA of the tetrahedron to produce the traction T such that $dF = TdA$. The vectors dF and T have the same direction. The surface element dA has an associated outward unit normal vector n, as shown in Fig. 10.2.1. If the origin of coordinates is located at the internal vertex of the tetrahedron, then the internal surfaces of the tetrahedron are coordinate planes with areas dA_x, dA_y, dA_z. They are acted on by tractions T_x, T_y, T_z. Equilibrium requires

$$\begin{aligned} T_x &= \sigma_{xx}n_x + \tau_{yx}n_y + \tau_{zx}n_z \\ T_y &= \tau_{xy}n_x + \sigma_{yy}n_y + \tau_{zy}n_z \\ T_z &= \tau_{xz}n_x + \tau_{yz}n_y + \sigma_{zz}n_z \end{aligned} \tag{10.2.1}$$

where σ_{xx}, τ_{yx}, τ_{zx}, etc., are components of the tractions acting on the coordinate planes. The first subscript indicates the direction of the normal to the surface acted on, while the second subscript indicates the direction of action of the considered traction component. The direction cosines (components) of n are n_x, n_y, n_z.

When these three equations (10.2.1) are applied to all imaginary surfaces passing through an interior point of a body, the result is the famous Cauchy stress principle. By definition, the quantities σ_{xx}, τ_{yx}, etc., are the stresses. Stresses σ_{xx}, σ_{yy}, and σ_{zz} act normal to their associated surfaces and are direct stresses. The stresses τ_{xy}, τ_{yz}, τ_{zx}, etc., act parallel to their associated surfaces and are shear stresses.

For each direction n at a given point P, there corresponds a stress vector T with components given by Eq. 10.2.1. Formally, the set of stress vectors at P defines the state of stress at P. However, Eq. 10.2.1 shows that, as a practical matter, the stresses only need to be known relative to a given set of reference axes in order to specify the state of stress at a point.

The balance of angular momentum, in the absence of intrinsic angular momentum, shows an equality of shear stresses such that $\tau_{xy} = \tau_{yx}$, $\tau_{yz} = \tau_{zy}$, $\tau_{zx} = \tau_{xz}$. Thus the order of subscripts is not important, and only six stresses are necessary to define the state of stress at a point.

Introduction of the concept of stress into the balance of linear momentum leads to the stress equations of motion. Thus

$$\begin{aligned} \partial\sigma_{xx}/\partial x + \partial\tau_{yx}/\partial y + \partial\tau_{zx}/\partial z + \gamma_x &= \rho a_x \\ \partial\tau_{xy}/\partial x + \partial\sigma_{yy}/\partial y + \partial\tau_{zy}/\partial z + \gamma_y &= \rho a_y \\ \partial\tau_{xz}/\partial x + \partial\tau_{yz}/\partial y + \partial\sigma_{zz}/\partial z + \gamma_z &= \rho a_z \end{aligned} \tag{10.2.2}$$

Various representations of the state of stress are possible. The simplest is to use a list $(\sigma_{xx}, \sigma_{yy}, \sigma_{zz}, \tau_{xy}, \tau_{yz}, \tau_{zx})$. A one-by-six row vector is useful when matrix notation is convenient as is a six-by-one column vector. If the state of stress is represented by a row vector,

$$(\sigma) = (\sigma_{xx}\ \sigma_{yy}\ \sigma_{zz}\ \tau_{xy}\ \tau_{yz}\ \tau_{zx}), \tag{10.2.3}$$

then the same state is represented by the column vector,

$$\{\sigma\} = (\sigma)^t \tag{10.2.4}$$

where the superscript t means transpose. A three-by-three array is also a useful representation:

$$[\sigma] = \begin{bmatrix} \sigma_{xx} & \tau_{yx} & \tau_{zx} \\ \tau_{xy} & \sigma_{yy} & \tau_{zy} \\ \tau_{xz} & \tau_{yz} & \sigma_{zz} \end{bmatrix} \tag{10.25}$$

which represents the state of stress at a point referred to the (xyz) coordinate axes. It is often convenient to divide the stresses into spherical and deviatoric parts. The spherical part is the mean normal stress:

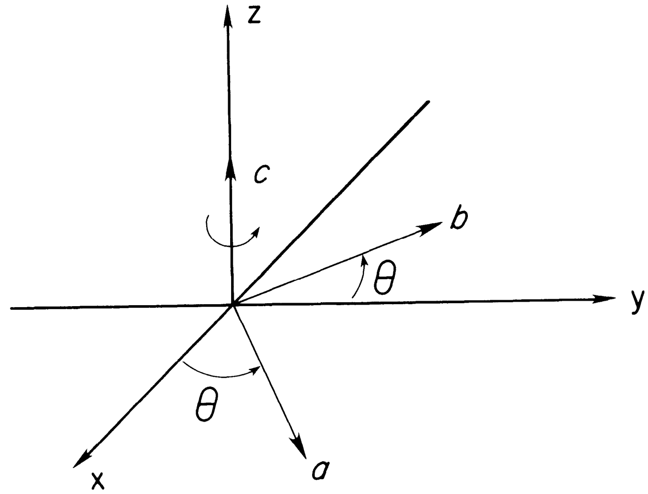

Fig. 10.2.2. Rotation of the reference axes about one of the given.

$$\sigma = (⅓)\,(\sigma_{xx} + \sigma_{yy} + \sigma_{zz}). \tag{10.2.6}$$

The deviatoric normal stresses are obtained by subtracting the mean normal stress, thus,

$$s_{xx} = \sigma_{xx} - \sigma,\ s_{yy} = \sigma_{yy} - \sigma,\ s_{zz} = \sigma_{zz} - \sigma, \tag{10.2.7}$$

are the deviatoric normal stresses. The deviatoric shear stresses are simply the given shear stresses; that is, $s_{xy} = \tau_{xy}$, etc. The state of stress in matrix form is then

$$[\sigma] = \begin{bmatrix} s_{xx} & s_{yx} & s_{zx} \\ s_{xy} & s_{yy} & s_{zy} \\ s_{xz} & s_{yz} & s_{zz} \end{bmatrix} + \begin{bmatrix} \sigma & 0 & 0 \\ 0 & \sigma & 0 \\ 0 & 0 & \sigma \end{bmatrix} \tag{10.2.8}$$

The spherical part of stress is also known as the hydrostatic component of stress in analogy with the pressure p at a point in a fluid at rest; that is, $p = \sigma$.

The symmetric array of real numbers (Eq. 10.2.5) can be transformed by a rotation of the reference axes to the diagonal form:

$$[\sigma(123)] = \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix} \tag{10.2.9}$$

where σ_1, σ_2, σ_3 are the major, intermediate, and minor principal stresses. The new reference axes (123) are the principal directions. Principal stresses are mutually perpendicular and act normal to principal planes. Principal planes are free of shear stresses; any plane free of shear stress is a principal plane. If any two principal stresses are equal, then the corresponding principal directions are not unique. The surfaces of naturally supported excavations in rock are free of shear stresses and are therefore principal surfaces. The normal to such a surface is a principal direction, and the associated normal stress is a principal stress whose value happens to be zero. If the excavation was an unlined water reservoir, the normal stress would still be a principal stress. However, its value would be equal to the water pressure.

Rotation of the reference axes about one of the given axes as shown in Fig. 10.2.2 is a very useful procedure. If the given axes are (xyz), and the new axes are (abc), then rotation through a positive counterclockwise angle Θ about the z axis is in matrix notation,

$$[\sigma(abc)] = [R][\sigma(xyz)][R]^t \tag{10.2.10}$$

where $[R]$ is the rotation matrix given by

$$[R] = \begin{bmatrix} \cos\Theta & \sin\Theta & 0 \\ -\sin\Theta & \cos\Theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{10.2.11}$$

After carrying out the multiplications in Eq. 10.2.10, the stresses referred to the (abc) axes are in algebraic form:

$$\begin{aligned}
\sigma_{aa} &= (\tfrac{1}{2})(\sigma_{xx} + \sigma_{yy}) + (\tfrac{1}{2})(\sigma_{xx} - \sigma_{yy})\cos(2\Theta) + \tau_{xy}\sin(2\Theta) \\
\sigma_{bb} &= (\tfrac{1}{2})(\sigma_{xx} + \sigma_{yy}) - (\tfrac{1}{2})(\sigma_{xx} - \sigma_{yy})\cos(2\Theta) - \tau_{xy}\sin(2\Theta) \\
\tau_{ab} &= -(\tfrac{1}{2})(\sigma_{xx} - \sigma_{yy}) + \tau_{xy}\sin(2\Theta) \qquad (10.2.12) \\
\sigma_{cc} &= \sigma_{zz} \\
\tau_{ca} &= \tau_{zx}\cos(\Theta) + \tau_{zy}\sin(\Theta) \\
\tau_{cb} &= -\tau_{zx}\sin(\Theta) + \tau_{zy}\cos(\Theta)
\end{aligned}$$

The first three equations of Eq. 10.2.12 are the usual two dimensional equations of stress transformation in the xy plane. The last three equations are the three dimensional part of the rotation about the z axis. Generally, three dimensional rotations can be obtained by a sequence of three simple rotations about an axis.

If the z direction is a principal direction, the z direction shear stresses vanish. The magnitudes of the principal stresses in the xy plane are then given by

$$\begin{aligned}
\sigma_1 &= (\tfrac{1}{2})(\sigma_{xx} + \sigma_{yy}) + [(\tfrac{1}{4})(\sigma_{xx} - \sigma_{yy})^2 + (\tau_{xy})^2]^{(1/2)} \\
\sigma_3 &= (\tfrac{1}{2})(\sigma_{xx} + \sigma_{yy}) - [(\tfrac{1}{4})(\sigma_{xx} - \sigma_{yy})^2 + (\tau_{xy})^2]^{(1/2)}
\end{aligned} \tag{10.2.13}$$

and the directions by

$$\tan(2\Theta) = \tau_{xy}/[(\tfrac{1}{2})(\sigma_{xx} - \sigma_{yy})]. \tag{10.2.14}$$

There are two solutions to Eq. 10.2.14. The solution that gives the direction of σ_1 can be decided by the fact that σ_1 will be nearest the largest given normal stress.

The xy shear stresses vanish on the principal planes associated with the xy principal stresses. In fact, rotation about the z axis through the angle given by Eq. 10.2.14 causes the xy shear stresses to vanish even if the z direction is not a principal direction. In that case, the stresses given by Eq. 10.2.13 are known as secondary principal stresses. Only if the z direction shear stresses are zero, are the stresses given by Eq. 10.2.13 true principal stresses. Since the z direction is arbitrary, there are an infinite number of secondary principal stresses at a point, but only three true principal stresses. A sequential determination of the secondary principal stresses allows for the determination of the true principal stresses, a fact that is used in the reduction of stress measurement data obtained in practice.

The shear stresses also have extremal values. There are six given in terms of the principal stresses by

$$\pm(\tfrac{1}{2})(\sigma_1 - \sigma_3), \quad \pm(\tfrac{1}{2})(\sigma_1 - \sigma_2), \quad \pm(\tfrac{1}{2})(\sigma_2 - \sigma_3) \tag{10.2.15}$$

The maximum and minimum shear stresses at a point are given by the first two equations of Eq. 10.2.15. They act on planes that are inclined at $\pm 45°$ to σ_1 and are parallel to the direction of σ_2.

Addition of stress is done by components. If the initial state of stress is $\{\sigma_i\}$, and stress changes $\{\Delta\sigma\}$ occur, the final state of stress $\{\sigma_f\}$ at the considered point is simply

$$\{\sigma_f\} = \{\sigma_i\} + \{\Delta\sigma\} \tag{10.2.16}$$

that is, $\sigma_{xx}(f) = \sigma_{xx}(i) + \Delta\sigma_{xx}$, $\tau_{xy}(f) = \tau_{xy}(i) + \Delta\tau_{xy}$, etc. It is important to note that all components are referred to the same reference axes. The principal stresses associated with the initial and final states are generally different and have different directions. It makes no sense, therefore, to write

$$\sigma_1(f) = \sigma_1(i) + \Delta\sigma_1 \tag{10.2.17}$$

In this regard, the stress changes also have principal components and directions; the latter are generally different from the principal directions associated with either the initial or final stress states. For example, in the gravity field, the vertical stress before mining is the major principal stress (compression considered positive). After excavation, say, of two stopes separated by a sill pillar in a vertical vein, the vertical stress on the sill floor is reduced to zero. The stress parallel to the sill floor remains compressive. The vertical stress thus becomes the minor principal stress after excavation, and the direction of the major principal stress rotates 90° from vertical to horizontal.

Closely associated with the concept of stress change is the concept of stress rate. If the state of stress is time dependent—that is, $\sigma = \sigma(x,y,z,t)$ where σ represents any particular component of stress, then the time rate of change of stress at a point in space is simply the partial derivative with respect to time, $\partial\sigma/\partial t$. However, if the stress rate for a given material element is desired, then the material derivative is used.

$$\begin{aligned} D\sigma/Dt = \partial\sigma/\partial t &+ (v_x\partial\sigma/\partial x) \\ &+ (v_y\partial\sigma/\partial y) + (v_z\partial\sigma/\partial z) \end{aligned} \tag{10.2.18}$$

Other stress rates are also of interest and are discussed in detailed treatments of continuum mechanics.

10.2.2 KINEMATICS

Kinematics deals with the geometry of motion. Like physical laws, kinematic relationships are independent of the constitution of the material and have great generality, especially when developed in general curvilinear coordinates. Only a brief outline of the more important kinematic relations including the concepts of motion, deformation, displacement, and strain are given here.

10.2.2.1 Motion of a Body

The concept of a motion of a material body in symbolic form relates the current position of all points in the body of interest to their initial position as a function of time. If x, y, z, and t denote the current position of a point that was initially at X, Y, Z, measured in the same Cartesian system, then the motion of the body may be described by

$$x = f(X,Y,Z,t), \quad y = g(X,Y,Z,t), \quad z = h(X,Y,Z,t) \tag{10.2.19}$$

where $X = f(X,Y,Z,0)$, $Y = g(X,Y,Z,0)$, and $Z = h(X,Y,Z,0)$. The functions f, g, and h are sufficiently smooth so that they can be inverted to give the initial positions as functions of the current positions. The motion described by Eq. 10.2.19 is a deformation of a body from an initial configuration to a final configuration. Spatial derivatives of Eq. 10.2.19 are deformation gradients.

Velocities and accelerations are the usual material time rates of change:

$$v_x = Dx/Dt, \quad v_y = Dy/Dt, \quad v_z = Dz/Dt, \qquad (10.2.20)$$
$$a_x = Dv_x/Dt, \quad a_y = Dv_y/Dt, \quad a_z = Dv_z/Dt.$$

The instantaneous motion in the neighborhood of a typical point in the body can be decomposed into two parts, a rigid body motion and a deformation. The length of a line segment between any two points of a body remains unchanged during rigid body motion, although its orientation may change. If x is the position vector with components (x,y,z), then the combination of rigid body translation and rotation in matrix rotation is

$$\{x(t)\} = \{a(t)\} + [R(t)]\,\{x(0)\} \qquad (10.2.21)$$

where $\{a(t)\}$ is the translation, $[R(t)]$ is the rotation matrix; $\{x(0)\}$ is the initial position, and $\{x(t)\}$ is the current position of a point of interest.

10.2.2.2 Displacements and Strains

Displacements relate the current positions of all points in the considered body to their initial positions:

$$x = X + u, \quad y = Y + v, \quad z = Z + w \qquad (10.2.22)$$

where u, v, and w are the time and position dependent Cartesian components of the displacement vector. Displacement should not be confused with distance traveled, which depends on the actual path followed between two points.

Elementary definitions of strains lead to complicated expressions in terms of displacement derivatives. However, when the strains are small in the sense that products of displacement derivatives are negligible, the usual definitions of infinitesimal strain apply. With reference to Fig. 10.2.3, if ϵ is the normal strain in the x-direction, then $\epsilon = \Delta L/L_0 \approx (\partial u/\partial x)$, or if γ is a shear strain in the xy-plane, then $\gamma = \tan(\alpha + \beta) \approx (\alpha + \beta) \approx (\partial u/\partial y + \partial v/\partial x)$, and in general,

$$\epsilon_{xx} = \partial u/\partial x, \qquad \epsilon_{yy} = \partial v/\partial y, \qquad \epsilon_{zz} = \partial \mathrm{w}/\partial \mathrm{z},$$
$$\gamma_{xy} = (\partial u/\partial y + \partial v/\partial x) = 2\epsilon_{xy},$$
$$\gamma_{yz} = (\partial v/\partial z + \partial w/\partial y) = 2\epsilon_{yz}, \qquad (10.2.23)$$
$$\gamma_{zx} = (\partial w/\partial x + \partial u/\partial z) = 2\epsilon_{zx},$$

where γ with double subscripts indicates the engineering shear strains. These are twice the tensorial shear strains indicated by ϵ with a double subscript.

In a rotation of the reference axes, the tensorial shear strains must be used. For example, if the state of strain is referred to a new set of axes (abc) rotated through an angle Θ about the z-axis, then

$$\epsilon_{aa} = (\tfrac{1}{2})(\epsilon_{xx} + \epsilon_{yy}) + (\tfrac{1}{2})(\epsilon_{xx} - \epsilon_{yy})\cos(2\Theta) + \epsilon_{xy}\sin(2\Theta)$$
$$\epsilon_{bb} = (\tfrac{1}{2})(\epsilon_{xx} + \epsilon_{yy}) - (\tfrac{1}{2})(\epsilon_{xx} - \epsilon_{yy})\cos(2\Theta) - \epsilon_{xy}\sin(2\Theta)$$
$$\epsilon_{ab} = -(\tfrac{1}{2})(\epsilon_{xx} - \epsilon_{xx}) + \epsilon_{xy}\sin(2\Theta)$$

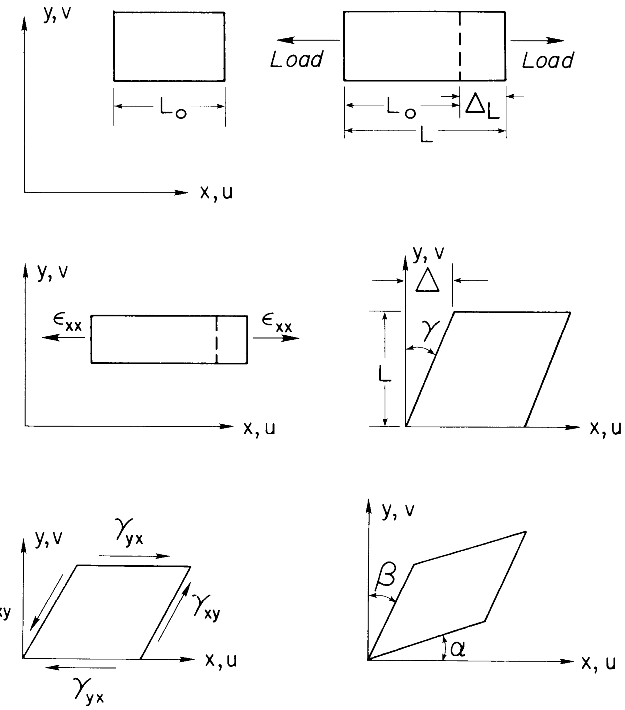

Fig. 10.2.3. Elementary concepts of normal and shear strain.

$$\epsilon_{cc} = \epsilon_{zz}$$
$$\epsilon_{ca} = \epsilon_{zx}\cos(\Theta) + \epsilon_{zy}\sin(\Theta)$$
$$\epsilon_{cb} = -\epsilon_{zx}\sin(\Theta) + \epsilon_{zy}\cos(\Theta) \qquad (10.2.24)$$

which are identical in form to the transformation of the stresses, Eq. 10.2.12.

The state of strain can be represented in the form of a symmetric three-by-three array:

$$[\epsilon] = \begin{bmatrix} \epsilon_{xx} & \epsilon_{yx} & \epsilon_{zx} \\ \epsilon_{xy} & \epsilon_{yy} & \epsilon_{zy} \\ \epsilon_{xz} & \epsilon_{yz} & \epsilon_{zz} \end{bmatrix} \qquad (10.2.25)$$

that has principal values ϵ_1, ϵ_2, and ϵ_3. In fact, the tensorial character of strain implies the same mathematical properties as for stress. All the formulas for principal stresses, directions, maximum and minimum shear stresses, stress changes, and so forth apply to the strains. The physical interpretation is quite different, of course. When the state of strain is decomposed into spherical and deviatoric parts, then the state of strain at a point has the representation,

$$[\epsilon] = \begin{bmatrix} e_{xx} & e_{yx} & e_{zx} \\ e_{xy} & e_{yy} & e_{zy} \\ e_{xz} & e_{yz} & e_{zz} \end{bmatrix} + \begin{bmatrix} \epsilon & 0 & 0 \\ 0 & \epsilon & 0 \\ 0 & 0 & \epsilon \end{bmatrix} \qquad (10.2.26)$$

where $\epsilon = (\tfrac{1}{3})(\epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz})$, $e_{xx} = \epsilon_{xx} - \epsilon$, etc., are the deviatoric normal strains. The deviatoric shear strains are just the tensorial shear strains. The spherical part of strain is related to the dilatation Δ or change in volume per unit of original volume of material. Thus

$$\Delta = 3\epsilon \qquad (10.2.27)$$

is the dilatation. The deviatoric part of strain is associated with a change in shape.

10.2.3 MATERIAL LAWS

Material laws include such well-known relationships as Hooke's Law in elasticity theory, Darcy's Law in seepage analysis, and Fourier's Law of heat conduction. The need for material laws arises from the fact that physical laws and kinematics alone do not provide as many independent equations as there are unknowns for the description of the motion of a material body. Material laws also express relationships between dependent variables, for example, stress and strain, that arise in the description of the rock mass motion. The independent variables are position and time. Material laws such as Hooke's Law express broad categories of material behavior. In this regard, a particular rock type may respond elastically to an initial application of load, but with increasing load, reach an elastic limit and subsequently fracture and flow. Beyond the elastic limit, a more complicated material law is necessary. Of course, not all materials behave elastically even over a limited range of loading. Thus material laws, unlike physical laws and kinematical relations, are restricted in application by the nature of the material and the range of conditions of stress, temperature, moisture, and so forth that are encountered in a given mining environment.

Material laws may alternatively be viewed as simplified models of real material behavior. The three classic idealizations of material behavior are the elastic, plastic, and viscous models. Questions naturally arise as to what simplifications should be made and, once made, how well the idealized model corresponds to reality. Questions of this type relate more to the art than to the science of engineering design and have no final answers. Of course, experience gained against a background of insight and clear understanding of the fundamental concepts can be a great help.

10.2.3.1 Elasticity

In the linear elastic case (Love, 1944; Sokolnikoff, 1956; Lekhnitskii, 1963), the material law is

$$\{\sigma\} - \{\sigma(0)\} = [a]\,\{\epsilon\} \tag{10.2.28}$$

where the stresses and strains are six-by-one column matrices, and $[a]$ is a six-by-six material properties matrix. If the unstrained states of stress and strain coincide, then the initial stresses vanish, and

$$\{\sigma\} = [a]\,\{\epsilon\} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} & a_{16} \\ a_{21} & a_{22} & a_{23} & a_{24} & a_{25} & a_{26} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} & a_{36} \\ a_{41} & a_{42} & a_{43} & a_{44} & a_{45} & a_{46} \\ a_{51} & a_{52} & a_{53} & a_{54} & a_{55} & a_{56} \\ a_{61} & a_{62} & a_{63} & a_{64} & a_{65} & a_{66} \end{bmatrix} \{\epsilon\} \tag{10.2.29}$$

or in inverted form,

$$\{\epsilon\} = [b]\,\{\sigma\}. \tag{10.2.30}$$

where $[b]$ is the inverse of $[a]$. If the material is elastic, then 10.2.29 is the generalized Hooke's law, and the strains are recoverable upon unloading of the test specimen. Symmetry of the stresses and strains shows that $[a]$ and $[b]$ are also symmetric, $a_{12} = a_{21}, \ldots, a_{56} = a_{65}, b_{12} = b_{21}, \ldots, b_{56} = b_{65}$, so that there are at most 21 independent elastic constants. Such a material is highly directional or anisotropic even under a uniaxial test strain.

With increasing material symmetry, the number of elastic constants is reduced. An orthotropic material has three material axes and nine independent elastic constants. A gneiss or schist may be orthotropic; the three material axes correspond to the rift, grain, and hardway in quarry terminology. Many sedimentary rocks show pronounced differences in properties of samples parallel and perpendicular to the bedding and are transversely isotropic. Five elastic constants are needed for the description of transversely isotropic rock. Only two independent elastic constants are needed for the description of isotropic rock, which by definition lacks directional mechanical properties.

In the isotropic case, Hooke's law in extended form may be written as

$$\begin{aligned} E\epsilon_{xx} &= \sigma_{xx} - \nu\sigma_{yy} - \nu\sigma_{zz},\ G\gamma_{xx} = \tau_{xy}, \\ E\epsilon_{yy} &= \sigma_{yy} - \nu\sigma_{zz} - \nu\sigma_{yy},\ G\gamma_{zz} = \tau_{yz}, \\ E\epsilon_{zz} &= \sigma_{zz} - \nu\sigma_{xx} - \nu\sigma_{yy},\ G\gamma_{zx} = \tau_{zx}, \end{aligned} \tag{10.2.31}$$

where E is Young's modulus, v is Poisson's ratio, and G is the shear modulus (also known as the modulus of rigidity). The shear modulus, Young's modulus, and Poisson's ratio are related by the simple formula,

$$E = 2G(1 + \nu). \tag{10.2.32}$$

A number of other elastic constants are in use including the bulk modulus K and the Lame constants λ and μ. Any two constants can be used to derive a third constant. Table 10.2.1 shows the relationships between the more frequently used elastic constants.

Elastic constants such as Young's modulus and Poisson's ratio are properties that must be determined by physical measurement. The most common laboratory test is done on cylindrical samples prepared from diamond drill core. Samples are usually *NX* size (2⅛ in. diameter, or 54 mm) and are cut to a length about twice the diameter (4¼ in., or 108 mm). Application of an axial stress, say, in the z direction and simultaneous recordation of the axial and transverse strains allows for the determination of E and v.

Because of the cylindrical geometry of the test specimen, Hooke's law referred to cylindrical coordinates $(r\Theta z)$ are most convenient. Thus

$$\begin{aligned} E\epsilon_{rr} &= \sigma_{rr} - \nu\sigma_{\Theta\Theta} - \nu\sigma_{zz}, G\gamma_{r\Theta} = \tau_{r\Theta}, \\ E\epsilon_{\Theta\Theta} &= \sigma_{\Theta\Theta} - \nu\sigma_{zz} - \nu\sigma_{rr}, G\gamma_{\Theta z} = \tau_{\Theta z}, \\ E\epsilon_{zz} &= \sigma_{zz} - \nu\sigma_{rr} - \nu\sigma_{\Theta\Theta}, G\gamma_{zr} = \tau_{zr}. \end{aligned} \tag{10.2.33}$$

Inspection of Eq. 10.2.33 shows that the slope of a plot of the axial stress σ_{zz} (vertical axis) as a function of axial strain ϵ_{zz} (horizontal axis) is E. A consequence of the cylindrical geometry is equality of the radial and circumferential strains $(\epsilon_{rr}, \epsilon_{\Theta\Theta})$, and hence, Poisson's ratio is simply the ratio of the circumferential to axial strains. Fig. 10.2.4 (a) illustrates the uniaxial compression test for elastic moduli. An important feature of the idealized stress strain curve shown in Fig.10.2.4 (a) is the linear relationship between stress and strain.

The elastic moduli of a nonlinear elastic material are not constant but depend on strain. However, the shape of the material is recovered after a cycle of load application and release. Fig.

Table 10.2.1. Some Relations Among Elastic Constants

$E =$	$3K(1-2\nu) =$	$2G(1+\nu) =$	$9KG/(3K+G) =$	$(\lambda/\nu)(1+\nu)(1-2\nu)$

E = Young's modulus G = shear modulus K = bulk modulus

ν = Poisson's ratio λ = Lame's constant

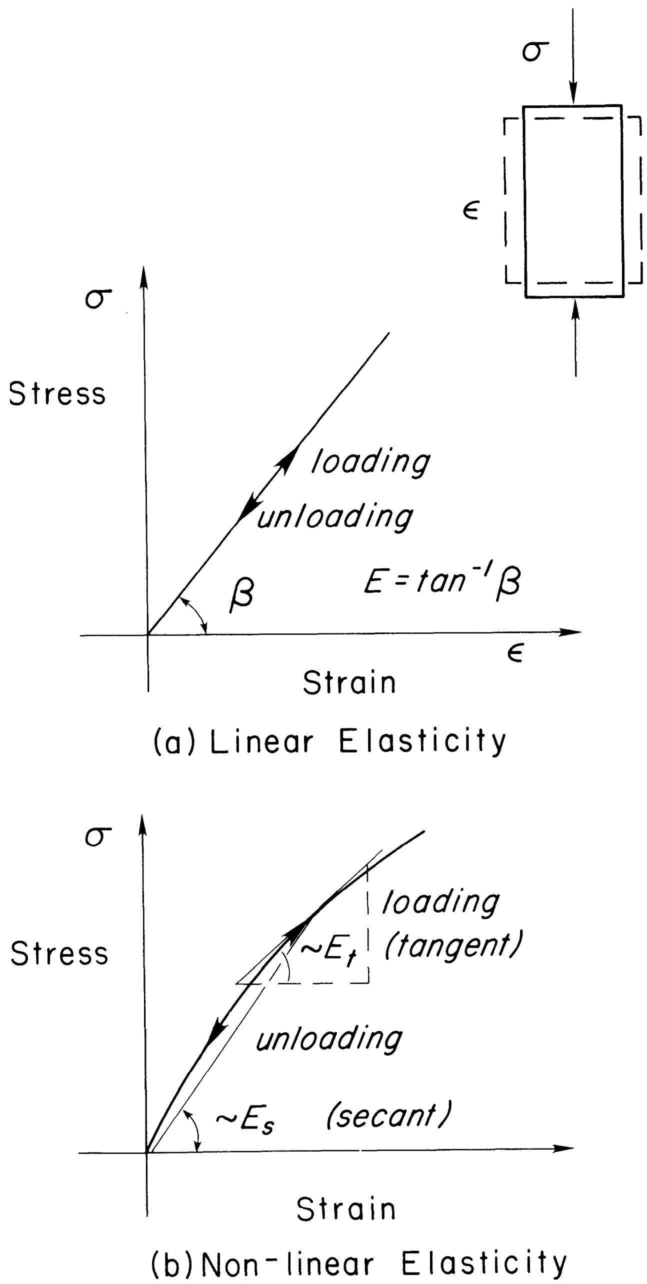

Fig. 10.2.4. Uniaxial compression test for elastic moduli (a) Linear elasticity, (b) Nonlinear elasticity.

10.2.4 (b) illustrates the concept of a nonlinear elastic material. The local slope of the uniaxial stress strain curve is known as the tangent modulus E_t. The slope of a straight line from the origin to a point on the uniaxial stress strain curve is the secant modulus, E_s.

STRAIN ENERGY. The work done on a body during deformation is stored in the body as strain energy. In one dimension, the area under the stress strain curve is the strain energy per unit volume of material. If A is the cross-sectional area of a prismatic bar and L is the length, then the stress $\sigma = F/A$ and the strain $\epsilon = (L - L_0)/L_0$, where L_0 is the original length of the sample. The work done $w = (\sigma^2/2E)$. In the case of one dimensional shear loading, $t = F/A$, and g is the corresponding shear strain. The work done $w = (t^2/2G)$. In three dimensions, the strain energy density may be written as a quadratic form,

$$W = (K\epsilon^2/2) + G[e^2_{xx} + e^2_{yy} + e^2_{zz}) + (1/2)(\gamma^2_{xy} + \gamma^2_{yz} + \gamma^2_{yz})] \qquad (10.2.34)$$

which partitions the strain energy into hydrostatic and deviatoric strain contributions. Use of the stress strain law allows for expression of the strain energy density as a quadratic form in terms of the stresses and as a bilinear form in terms of stresses and strain.

ELASTIC STIFFNESS. The concept of elastic stiffness is closely associated with the one dimensional stress-strain curve through a plot of force vs. displacement. From the one dimensional form of Hooke's law, $\sigma = E\epsilon$, the one dimensional force displacement relation, $F = K_nU$, may be obtained, where the normal stiffness $K_n = EA/L_0$. In the case of shear loading, the shear stiffness $K_s = GA/L_0$. Stiffnesses depend on the geometry of the structure and may be much less than the elastic moduli, especially when the structure is a frame or has holes in it. An example is a timber crib. Shear stiffness of a timber crib is likely to be much less than the shear modulus of individual timber pieces in the crib.

10.2.3.2 Plasticity

Plastic or permanent, irreversible strain occurs beyond the elastic limit. The simplest plasticity theory is an extension of time-independent elastic behavior. If the plastic deformation is time-dependent so that creep or relaxation phenomena occur, then a more complex plasticity theory is needed. In either case, a well-defined elastic limit is characteristic of the material. By contrast, viscous flow occurs in materials that lack a well-defined yield point, fluids, for example. However, compressible fluids may respond elastically to a uniform compression. Indeed, elastic, plastic, and viscous mechanisms of deformation may all be simultaneously present to a significant degree in some geologic media. Nevertheless, deformation beyond the elastic limit is plastic deformation (Hill, 1950; Kachanov, 1971).

Strength may be conceptually defined as the stress at the limit to a purely elastic response to load. Strength plays a central role in plasticity theories. While unloading from the elastic limit is an elastic process, continued loading at the elastic limit leads to inelastic deformation. The range of post-elastic deformation of a laboratory test specimen may be quite small and terminated by brittle rupture. However, ductile deformation of laboratory test specimens is observed as well as brittle failure. In this regard, post-elastic strain is composed of a recoverable elastic part and a nonrecoverable plastic part. Ductile deformation of rock is often associated with diffuse microcracking throughout a laboratory test specimen in contrast to the formation of a macroscopic rupture surface that transects the entire sample. In large rock masses, the formation of rupture surfaces localizes deformation onto the rupture surface but, of course, does not terminate the deformation process; motion of the rock mass must continue until a new equilibrium position is reached under the action of the applied loads. Thus jointed rock masses often appear to yield in a ductile manner, even though samples of intact rock between the joints may be brittle when tested in the laboratory at room temperature, pressure, and quasi-static loading rates.

EFFECTIVE STRESS. A concept that is essential to any discussion of rock strength is the concept of effective stress (Terzaghi and Peck, 1948; Taylor, 1948). The concept applies to porous media in general. Most rocks contain void spaces in the form of pores between grains and in the form of microcracks across grains and at grain boundaries. When the voids are interconnected, the presence of fluids changes the rock strength. By definition, the effective stress is just the difference between the total stress and the pore fluid pressure. The concept applies only to the normal stresses. Thus the effective stresses are

$$\sigma'_{xx} = \sigma_{xx} - p_f,\ \sigma'_{yy} = \sigma_{yy} - p_f,\quad \sigma'_{zz} = \sigma_{zz} - p_f \qquad (10.2.35)$$

where the prime indicates effective stress and compression is considered positive. According to the concept of effective stress, strength is a function of the effective stresses only, although the total stresses determine equilibrium. Effective stresses are also known as the intergranular stresses; that is, the stresses transmitted through the solid skeleton of the porous sample. The solid skeleton provides resistance to failure. For this reason, it is the effective stresses that determine the strength of porous media. If the material lacks interconnected void spaces or pore fluids are absent, then the effective and total stresses are the same. Effective stresses are implied in any discussion of rock strength.

PLASTIC POTENTIAL. The strength of rock formally enters plasticity theory in two ways: (1) as a plastic potential function and (2) as a loading criterion. In the first way, a yield function or failure criterion, when satisfied by the state of stress at a point, is differentiated with respect to the stresses obtained from the plastic contribution to the total strain. In the second way, the total differential of the failure criterion, when satisfied, is set equal to zero in order to maintain a smooth transition from one plastic state to a neighboring state. In this regard, the material properties may depend on the amount of plastic deformation that has occurred, so that the failure criterion may depend implicitly on the plastic strains as well as the stresses. If the plastic potential and loading function are the same, then the resulting plastic stress strain relations are known as associated rules of flow. However, the two need not be the same, and the rules of flow may be nonassociated. In either case, the stress strain relations have the incremental form,

$$\{d\sigma\} = ([E_e] - [E_p])\,\{d\epsilon\} \qquad (10.2.36)$$

where $[E_e]$ is the elastic material properties matrix, and $[E_p]$ is the plastic contribution to the overall material properties matrix. Generally, $[E_p]$ depends on the current state of stress and strain, so that Eq. 10.2.36 is nonlinear even when the plastic strains are

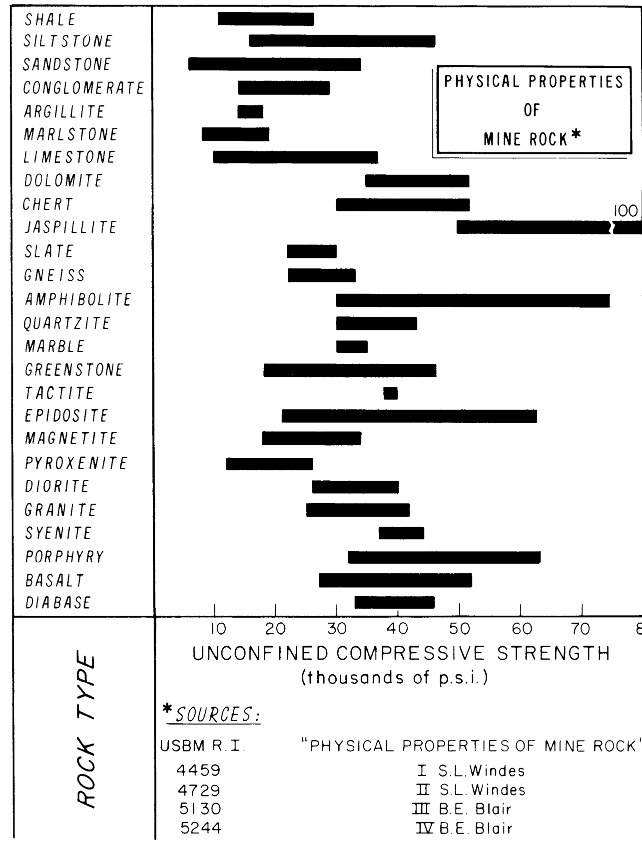

Fig. 10.2.5. Uniaxial strength data for several rock types. Conversion factor: 1 psi = 6.895 kPa.

the same order of magnitude as the elastic strains, which is often the case in rock mechanics.

In the realm of plasticity theory, care should be exercised in consulting the literature because of the frequent specialization of theory for applications to metals and the omission of a more general treatment applicable to geologic media. Ductile metals typically yield regardless of the hydrostatic component of stress; they are pressure-independent. Geologic media are characterized by pressure-dependent failure criteria.

STRENGTH OF INTACT ROCK. If a small test cube of rock is loaded to the elastic limit under a number of different combinations of principal stresses (σ_1, σ_2, σ_3), the resulting locus of points plotted in stress space defines the strength of the material. The strength of the rock is then given by the function $F(\sigma_1, \sigma_2, \sigma_3)$. The function F is a criterion for failure, and its form may be suggested according to some empirical rule (Nadai, 1950; Jaeger, 1967, 1969).

Any such rule should be consistent with experimental data and, for practical use, have a simple mathematical form. Fig. 10.2.5 shows some uniaxial strength data obtained from a variety of rock types. In this regard, the tensile strength of rock T_0 is generally only a small fraction of the unconfined compressive strength C_0, usually less than 10% of the compressive strength, and often much less. Fig. 10.25 shows there is a wide range of strengths for a given rock type; there appears to be no correlation with a genetic classification of rock types. Another feature is great variability within a given set of samples; the coefficient of variation often shows a standard deviation, that is, 30% of the mean strength. Variability is the rule rather than the exception.

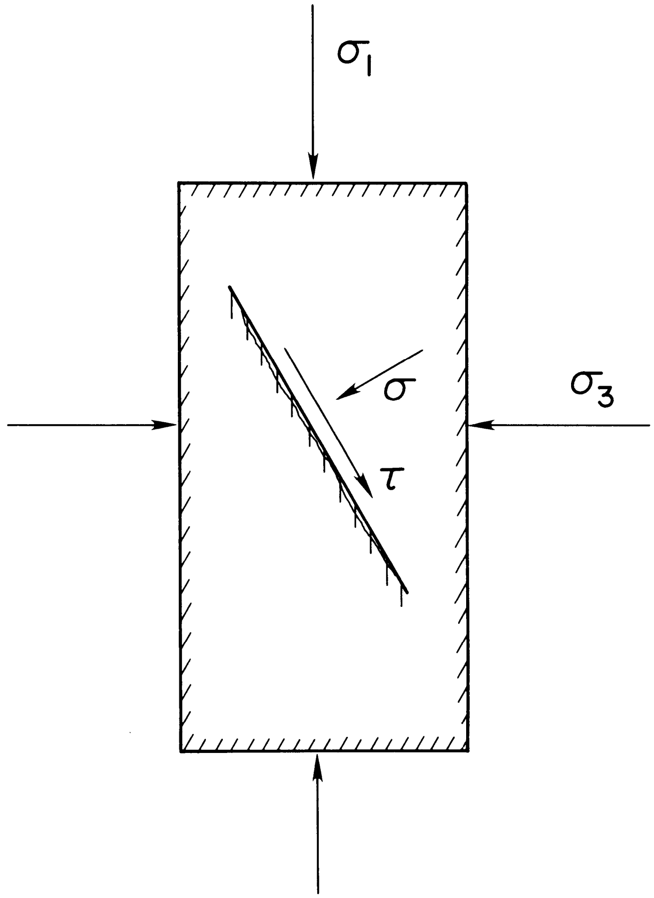

Fig. 10.2.6. Mohr concept of failure.

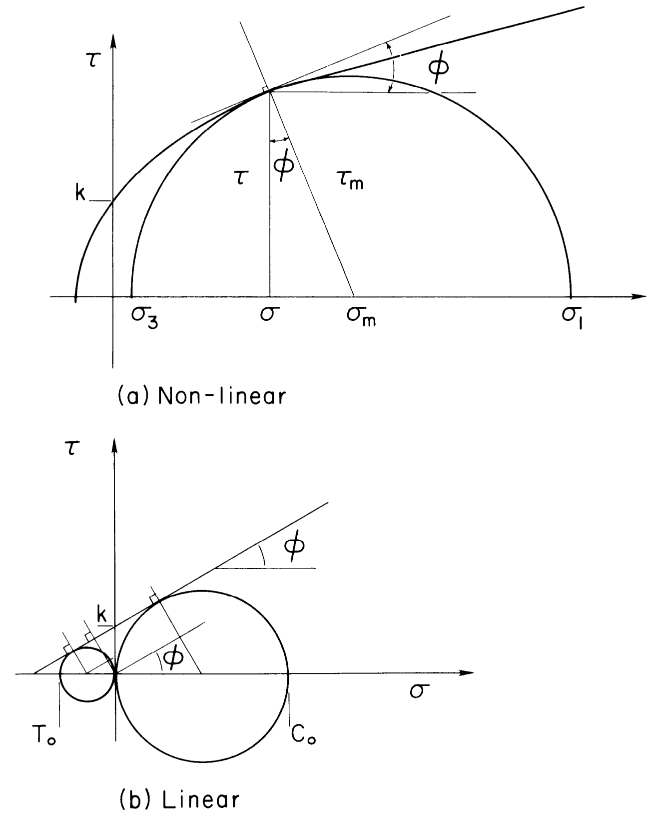

Fig. 10.2.7. Mohr failure criterion in graphical form (a) Non-linear, (b) Linear.

A number of failure criteria that have been suggested include (Nadai, 1950; Jaeger, 1969):

1. Maximum principal stress.
2. Maximum shear stress.
3. Maximum principal strain.
4. Maximum shear strain.
5. Maximum strain energy.
6. Maximum shear strain energy.
7. Maximum octahedral shear stress.
8. Griffith theory.
9. Mohr-Coulomb theory.
10. Drucker-Prager theory.
11. Nonlinear forms of (9) and (10).

None of the simple rules (1) to (7) are consistent with experiment, nor is the Griffith theory (8), and a more sophisticated approach to defining the form of a failure criterion for rock is needed.

According to the Mohr description (Nadai, 1950, 1963), there is a functional relationship between the normal and shear stresses acting on a potential failure surface, as shown in Fig. 10.2.6. Thus, at the onset of failure, $\tau = f(\sigma)$. When applied to the usual laboratory test for compressive strength under confining pressure, an extension of the Mohr criterion leads to $\tau_m = f(\sigma_m)$ where $\tau_m = (\frac{1}{2})(\sigma_1 - \sigma_3)$ and $\sigma_m = (\frac{1}{2})(\sigma_1 + \sigma_3)$. The simplest forms of $f(\sigma_m)$ are

1. Constant: $\tau_m = A$
2. Linear: $\tau_m = A + B\sigma_m$
3. Quadratic: $(\tau_m)^2 = A + B\sigma_m$
4. *n-type:* $(\tau_m)^n = A + B\sigma_m$

where *A*, *B*, and *n* are different experimental constants, depending on the form that best fits the data. They are the strength properties of the test specimen and are related to the uniaxial compressive strengths. Criterion 1 is the well-known Tresca criterion used in metal plasticity; 2 includes the famous Mohr-Coulomb criterion that finds great use in soil mechanics and to some extent in rock mechanics; and 3 is associated with the name of Torre, while the *n*-type condition is due to writer.

A plot of the Mohr-Coulomb criterion and a typical Mohr's circle representing the stress state at failure in the usual laboratory test for compressive strength under confining pressure is shown in Fig. 10.2.7, where compression is considered positive. Under these conditions, the intermediate and minor principal stresses are equal, and the Mohr-Coulomb criterion is

$$\tau = \sigma \tan(\phi) + k \qquad (10.2.37)$$

where k is the shear (t) axis intercept and is known as the cohesion; t is the inclination to the normal (σ) stress axis, and is the angle of internal friction. The criterion expressed by Eq. 10.2.37 has the interesting property of being an envelope of Mohr circles representing the stress states at failure. With a change in variables, Eq. 10.2.37 can be expressed as

$$\tau_m = k \cos(\phi) + \sigma_m \sin(\phi) \qquad (10.2.38)$$

The angle of internal friction is quite different from the ordinary friction angle associated with sliding surfaces in contact. In this regard, the failure surface referred to in Mohr theory is a virtual surface. If failure occurs by fracture, then an actual surface is created during the failure process. Subsequent slip on such a surface or on an existing failure surface would be analogous to frictional slip. However, if failure occurs by yielding, then the surface remains a virtual surface.

The strength parameters, cohesion k and angle of internal friction ϕ of the Mohr-Coulomb criterion, are related to the uniaxial compressive and tensile strengths C_0 and T_0 as can be seen from the geometry of the Mohr's circle representing the stress state at failure and the failure criterion. Inspection of Fig. 10.2.7 shows that in the linear case,

$$\begin{aligned} C_0 &= (2k\cos(\phi))/(1 - \sin(\phi)) \\ T_0 &= (2k\cos(\phi))/(1 + \sin(\phi)) \qquad (10.2.39) \\ \sin(\phi) &= [(C_0/T_0) - 1] \,/\, [(C_0/T_0) + 1] \\ k &= (\tfrac{1}{2})[C_0T_0]^2. \end{aligned}$$

The geometry of Fig. 10.2.7 also shows that the angle m between a Mohr-Coulomb failure surface and the major compression is $\pm(\pi/4 - \phi/2)$. In an actual test, the state of stress in the sample, while axially symmetric, is generally not uniform. As a consequence, the failure surface even when it manifests itself as a fracture is curved, and only a very rough measurement of m is possible. There is also a possibility that the Mohr envelope does not exist for some stress states near the origin.

Quadratic criteria lead to a variable failure surface angle and are generally more suitable for describing the failure of rock. There are several quadratic criteria that have been proposed in rock mechanics that are parabolas when plotted in the plane of (σ_3, σ_1) or in the plane of (σ_m, τ_m). These are (1) Fairhurst, (2) Hoek-Brown, (3) standard, and (4) n-type, (super-parabola). The first two have special properties and contain tacit assumptions about the material behavior. For example, No. 2 does not cross the σ_m axis at 90°, although close fits to strength data obtained under confining pressure are obtained.

A peculiarity of Mohr theory when applied to the standard laboratory test for strength is the absence of the intermediate principal stress in the failure criterion. A criterion that lacks one of the principal stresses leads to edges on the failure surface when plotted in principal stress space $(\sigma_1, \sigma_2, \sigma_3)$ that when combined with a difference in uniaxial compressive and tensile strengths leads to an irregular-shaped pyramid as shown in Fig. 10.2.8 (a) (Shield, 1955). There is a dearth of experimental data concerning the importance of the intermediate principal stress on the strength of rock because of the difficulties associated with the experimental access to arbitrary, three dimensional stress states.

However, there are alternatives to Mohr theory that also have the advantage of leading to smooth yield surfaces in stress space. The conical surface shown in Fig. 10.2.8 (b) is a graphical representation of the widely used Drucker-Prager criterion (Drucker and Prager, 1952):

$$(J_2)^{(1/2)} = A(I_1) + B \qquad (10.2.40)$$

where A and B are strength properties that are related to the uniaxial strengths by

$$\begin{aligned} A &= (1/\sqrt{3})(C_0 - T_0)/(C_0 + T_0), \\ B &= (2/\sqrt{3})(C_0T_0)/(C_0 + T_0), \end{aligned}$$

and (10.2.41)

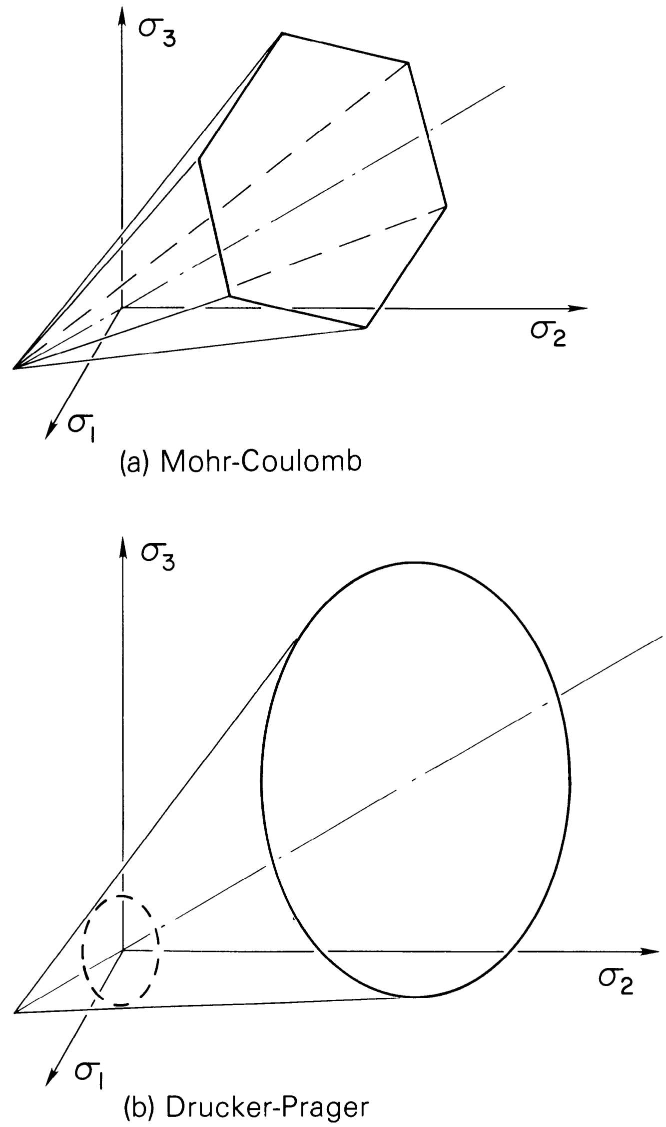

Fig. 10.2.8. Mohr-Coulomb and Drucker-Prager yield criteria in principal stress space.

$$\begin{aligned} (J_2)^{(1/2)} &= \{(\tfrac{1}{6})[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 \\ &\quad + (\sigma_3 - \sigma_1)^2]\}^{(1/2)}, \\ I_1 &= (\tfrac{1}{3})(\sigma_1 + \sigma_2 + \sigma_3). \end{aligned}$$

The quantity $(J_2)^{(1/2)}$ is akin to a root-mean-square measure of shear stress and is analogous to the maximum shear stress t_m, while I_1 is a true mean normal stress analogous to the average normal stress σ_m. In fact, J_2 and I_1 are invariant with respect to rotation of the reference axes, and thus meet a basic requirement for the description of failure criteria appropriate to isotropic materials. If the compressive and tensile strengths are equal, then $A = 0$, and the yield condition is independent of the hydrostatic component of stress. Eq. 10.2.40 then reduces to the famous Von Mises yield function that is in widespread use in metal plasticity.

Quadratic and n-type forms of $J_2 - I_1$ yield functions or failure criteria that include the effects of the intermediate principal stress are possible. The n-type form is

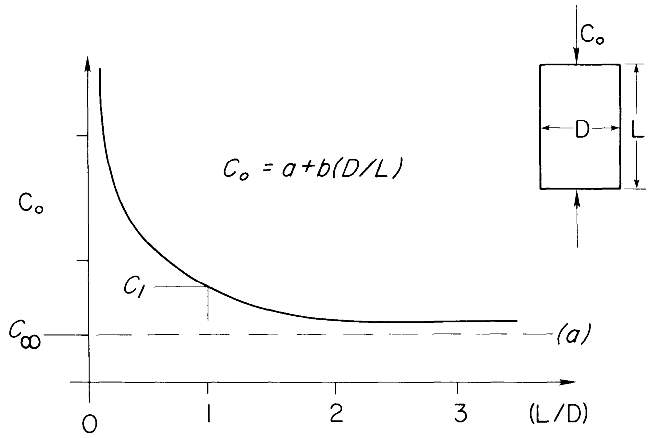

Fig. 10.2.9. Size effect on compressive strength.

$$(J_2)^{(n/2)} = A(I_1) + B \qquad (10.2.42)$$

and is a smooth surface in stress space.

Anisotropic forms that take into account directional properties of certain rock types are also in use (Pariseau, 1972). In this regard, shear properties that are distinctly different from values computed on the basis of isotropy play a major role in the analysis of ground motion where a distinct bedding, foliation, or schistosity is present. Examples include subsidence analysis or soft coal mines in flat-lying strata and the stability of underground excavations in metamorphic rocks such as phyllites and schists (Pariseau, Duan, and Schmuck, 1984; Pariseau et al., 1986). In this regard, all yield functions known to the writer are, in fact, polynomial functions of the stresses.

SIZE EFFECTS. An interesting feature of laboratory test results for compressive strength is a so-called size effect (Obert and Duvall, 1967; see also Chapter 10.5). The effect is most often observed in uniaxial compressive strength test data where the strength is computed by dividing the axial force at failure by the cross-sectional area of the test specimen. A different result is obtained depending on the height of the sample for a given diameter. The same phenomenon is observed in testing prisms. The compressive strength apparently depends on the "size" of the sample. Several simple formulas have been fit to such data; the most common one has the form,

$$C_0 = a + b(1/r) = a + b(D/L) \qquad (10.2.43)$$

where r is the ratio of sample height to diameter (L/D ratio). Fig. 10.2.9 shows a plot of Eq. 10.2.43. The curve is a hyperbola. According to the Eq. 10.2.43, the compressive strength approaches a minimum value a, as the height of the sample becomes very large at fixed diameter. This observation coupled with the presence of friction shear stresses across the ends of the specimen and the fact that rock compressive strength is generally confining-pressure dependent suggests an "end effects" explanation of the observed results. A simple equilibrium analysis shows this to be the case. With reference to Fig. 10.2.10, the shearing forces at the ends of the test specimen must be equilibrated by an equal but opposite horizontal force distributed over the midplane of the sample. The required force effectively confines the test specimen by a pressure p such that $P = (p)(LD)$. The average shear stress over the sample ends is $t = T/(pD^2/4)$. Hence $p = (tp/4)(D/L)$. According to the Mohr-Coulomb criterion,

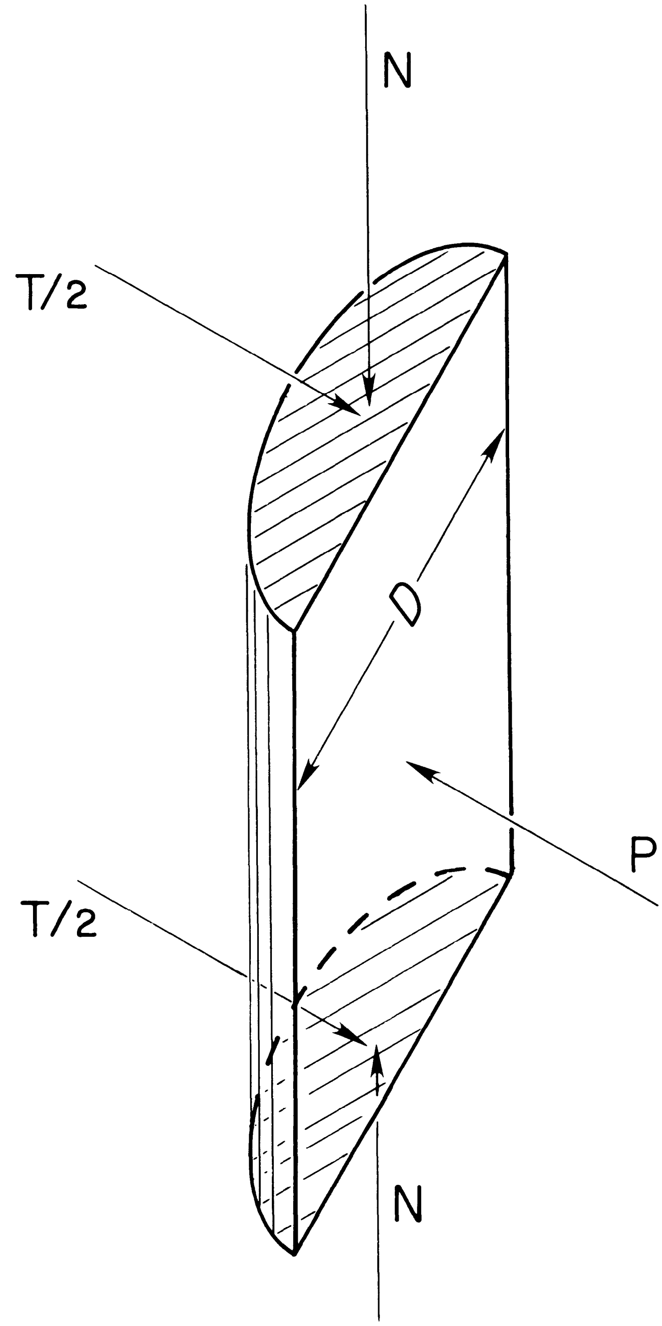

Fig. 10.2.10. End effects forces.

$$C = C_0 + (C_0/T_0)p \qquad (10.2.44)$$

and thus,

$$C = C_0 + (C_0/T_0)(\tau\pi/4)(D/L) \qquad (10.2.45)$$

which has the same form as the size-effects relation, Eq. 10.2.43. Since t is expected to be independent of the ratio L/D, Eq. 10.2.45 can be written as

$$C = C_1[a' + b'(D/L)] \qquad (10.2.46)$$

where $a' = (C_0/C_1)$, $b' = (1 - C_0/C_1)$, and C_1 = compressive

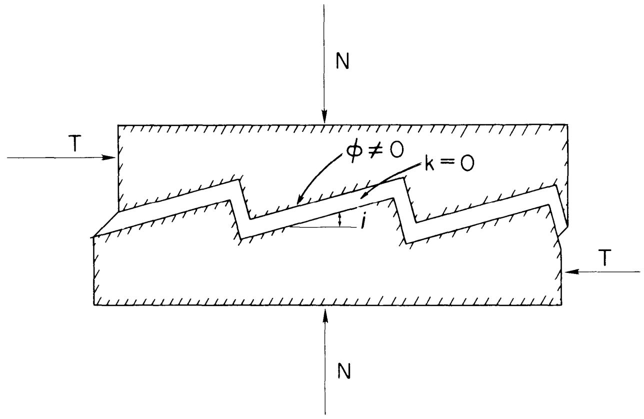

Fig. 10.2.11. Conceptual model of joint asperities.

strength at $L/D = 1$. Detailed computer simulations of the laboratory test for compressive strength support the end-effects explanation of Eq. 10.2.43 (Pariseau, 1979).

However, statistical theories of strength may also be used to explain size effects (Jaeger and Cook, 1969), although the evidence is not decisive because of the natural variability in rock, the need to test enormous numbers of samples, and the difficulties associated with test interpretation in the presence of end effects and possibly stress gradients as occur in a beam bending test for tensile strength. In any case, size effects in laboratory test data should not be extrapolated beyond the range of experiment, in particular, not to the scale of excavations in rock masses.

STRENGTH OF ROCK JOINTS. Joints refer to a large variety of discontinuities commonly present in rock masses. Examples are faults, bedding planes, and contacts between different rock types. The description of the strength of rock joints is similar in many respects to intact rock strength (Goodman, 1980; Brady and Brown, 1985; Einstein and Dowding, 1989). Both are based on experimental observations and the practical need for simple mathematical forms. Joints are solid surfaces in contact. Although referred to as surfaces, joints are not very smooth. Moreover, additional material may be present along a joint surface in the form of fault gouge or cementatious chemical precipitates of various kinds. Joint topography and filling suggests that they may be viewed as a thin layer of material whose properties differ from those of the adjacent intact rock. The thickness of a joint is intuitively related to joint roughness and to the height of the surface asperities. If the asperity height is δ, perhaps the joint thickness is 2δ. Thus joints may be assigned a thickness and a volume, and then described in a conventional manner. All the various failure criteria applied to intact rock may be used for the description of joint strength. However, there are phenomena associated with joint mechanics that are not observed in intact rock.

The strength of a clean tensile fracture that is free of extraneous material and lacks cohesion is entirely frictional. However, the topography of such a joint influences the apparent angle of friction (Patton, 1966) when first sheared. With reference to Fig. 10.2.11, if shearing loads are applied to the sawtooth-shaped joint surface, and the top block slides upwards parallel to the forward slope of the sawtooth-like asperities, which are in frictional contact, then resolution of forces parallel and perpendicular to the joint plane shows that

$$T = N \tan(\phi + i) \tag{10.2.47}$$

where ϕ is the angle of sliding friction, i is the inclination of the asperity face to the joint plane, and $(\phi + i)$ is the apparent angle of sliding friction on the joint. The expansion of the joint under the action of the shearing force is known as shear dilatancy. When several joints in parallel are tested simultaneously, any mismatch in the peaks and valleys of the asperities tends to obscure shear dilatancy (Brechtel, 1978).

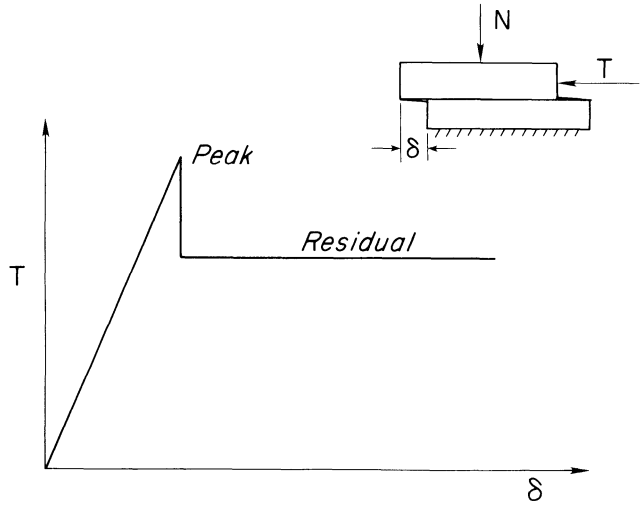

Fig. 10.2.12. Idealized shear force shear displacement test of a cohesionless joint showing peak-residual behavior.

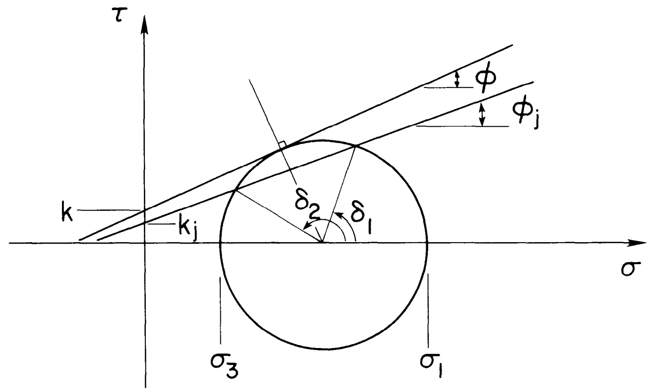

Fig. 10.2.13. Mohr-Coulomb joint failure criterion when the joint strike is parallel to the intermediate principal stress.

Under continued shearing, the asperity tips will fail and form a gouge that tends to fill the valleys between asperity peaks. As a consequence, the joint surface friction angle tends to decrease towards a residual value. Fig. 10.2.12 shows an idealized plot of shear force as a function of shearing displacement obtained during a direct shear test of a cohesionless joint that shows peak residual behavior. Repetition of the test under higher normal loads changes the outcome of the test. The transition from peak to residual frictional sliding is potentially unstable. Peak residual behavior may be suppressed entirely at very high normal loads.

The most commonly used joint strength criterion in practice is the Mohr-Coulomb criterion, which attributes frictional and cohesive strengths to the joint. The frictional component is dependent on the normal stress, of course. Fig. 10.2.13 shows a plot of the Mohr-Coulomb criterion for a joint inclined at an

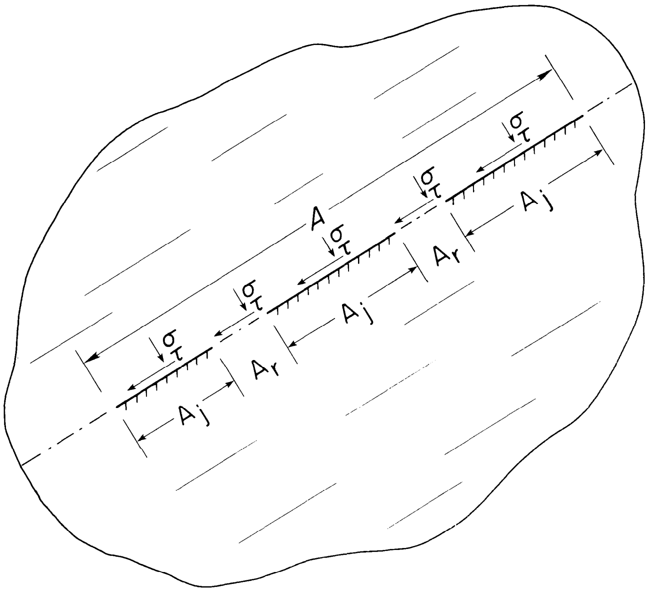

Fig. 10.2.14. Planar failure in a jointed rock mass.

angle δ to the horizontal and subject to applied stresses σ_1 and σ_3 (compression positive). The intermediate principal stress σ_2 is assumed to be parallel to the strike of the joint. The Mohr circle that represents that state of applied stress extends beyond the joint failure line. This is possible in the case of joints because the failure surface is fixed in advance of the test, unlike the case of intact rock where the failure surface is free to orient itself relative to the applied stresses. With reference to Fig. 10.2.13, only joints within the range (δ_1,δ_2) are liable to slippage and failure. In three dimensions where the principal stresses are not aligned with the joint plane geometry, the normal and shear stresses acting on the joint surface must be determined by a rotation of the reference axes before the strength of the joint can be determined. A comparison of joint shear strength with joint shear stress can then be made to determine the potential for slip.

STRENGTH OF WELL-JOINTED ROCK MASSES. Although the mechanics of well-jointed rock masses is an area of active research and is central to engineering design of excavations in rock, procedures for rational estimation of rock-mass strength from test data obtained on small samples of intact rock and rock joints remain to be firmly established within the context of plasticity theory (Pariseau, 1989). However, an empirical formula of longstanding can be obtained by combining the strength of intact rock and joints according to a simple area-weighting formula due to Terzaghi (1962).

Mohr-Coulomb failure criteria are assigned to the intact rock and the joint. Failure is assumed to occur along a plane as shown in Fig. 10.2.14. The failure surface area A is composed of joint area A_j and the area A_r of the intact rock bridges between the joints. The applied normal force N acts perpendicular to the failure surface; the resisting shear force T is parallel and composed of joint shear resistance T_j and rock shear resistance T_r. The forces are simply stresses multiplied by areas. Thus,

$$\tau = [\sigma_j \tan(\phi_j) + k_j](A_j/A) + [\sigma_r \tan(\phi_j) + k_r](A_r/A) \qquad (10.2.48)$$

where the subscripts j and r refer to joint and intact rock, respectively. If the assumption that the rock and joint friction angles are equal and the joint is cohesionless, then the composite strength is

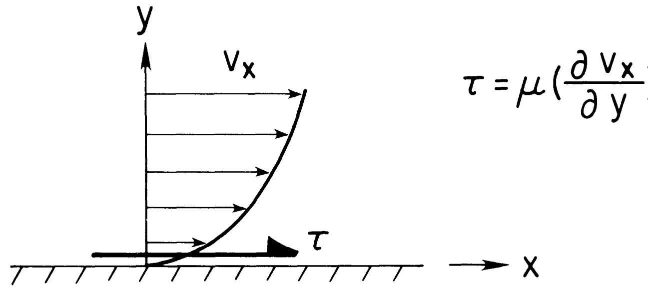

Fig. 10.2.15. Elementary viscous shear.

$$\tau = \sigma \tan(\phi) + (k_r)(A_r/A). \qquad (10.2.49)$$

Eq. 10.2.49 shows that the cohesion of a jointed rock mass is likely to be only a small fraction of the cohesion of the intact rock. Stress concentrations at joint ends and progressive failure are likely to lower the rock mass strength even more. Progressive failure is associated with extension of existing joint surfaces at the expense of the rock bridges and thus leads to a displacement dependent cohesion that decreases with successive episodes of motion associated with periodic blasting, cycles of rainfall, or even heating and cooling. The process may be unstable in the sense that it may lead to triggering of catastrophic motion (Pariseau and Voight, 1979).

10.2.3.3 Time-dependent Material Laws

Time may enter material laws in several ways. A material may age with time, meaning that its material properties change in time. The increase of strength as concrete cures is an example. The loss of strength by some shales upon exposure to air in coal mines is another. Properties that are sensitive to moisture content and variation of moisture content in time also may be interpreted as time dependent material behavior. Fluid flow in porous rock imparts a time dependency to the motion. Perhaps the most important source of time-dependent material behavior is the presence of viscous phenomena.

Although usually associated with fluid motion, viscous behavior is also observed in solids. A characteristic feature of purely viscous behavior is that flow occurs with the application of shear stress. Flow stops with the removal of shear stress. However, the material does not return to its original configuration; the deformation is not elastic. Incompressibility is often assumed with viscous behavior, although it is not necessary to do so; density may be allowed to depend on pressure. An elementary model of viscous behavior shown in Fig. 10.2.15 assumes a proportionality between the shear stress t and a derivative of the flow velocity taken normal to the shear surface. The latter is a shear strain rate (strictly speaking, a rate of deformation), and the constant of proportionality is the viscosity:

$$\tau = \mu d \qquad (10.2.50)$$

where m is viscosity of the material, and d is the engineering rate of shear deformation = $\partial v/\partial y$.

The viscosity of silicate glass at room temperature (68°F or 20°C) is about 10^{22} poise (dyne-sec-cm^{-2}) or about 10^{17} psi (kg/m^2) sec (Jaeger and Cook, 1969). An intact silicate rock having the same viscosity and subject to a 1000 psi (7-Mpa) load would creep about 10 microstrain units in 100 years. Thus true creep of intact hardrock is likely to be insignificant relative to engineering design. However, jointed rock masses may show significant creep

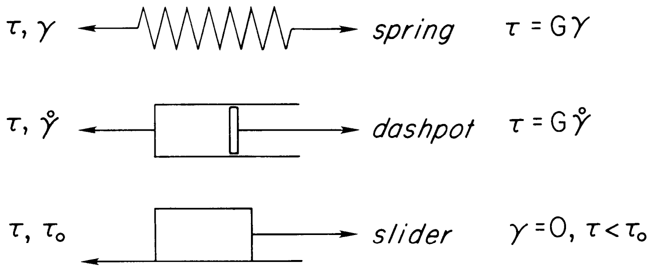

Fig. 10.2.16. Rheologic elements in time-dependent material models.

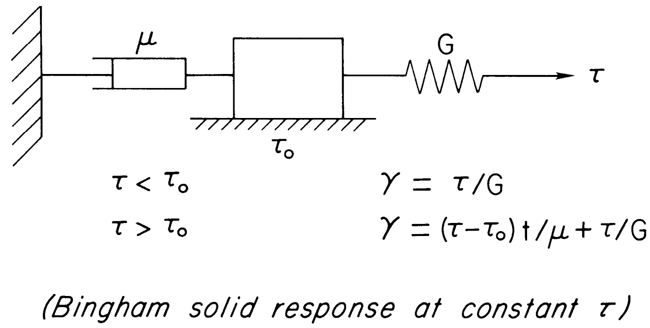

Fig. 10.2.17. Bingham solid response.

because of viscous joint filling or locally high stress on joint asperities which leads to fracture and flow. Soft rock such as shales and rock types that are composed of minerals that crystallize in the cubic system (e.g., evaporites) may also show significant creep.

The linear three dimensional case is obtained by applying Eq. 10.2.50 to the deviations of stress and rates of deformation (Malvern, 1969). Thus

$$\begin{aligned} s_{xx} &= 2\mu\, d_{xx}, \quad s_{xx} = 2\mu\, d_{xx}, \quad s_{xx} = 2\mu\, d_{xx}, \\ \tau_{xy} &= 2\mu\, d_{xy}, \quad \tau_{yz} = 2\mu\, d_{yz}, \quad \tau_{zx} = 2\mu\, d_{zx}, \end{aligned} \tag{10.2.51}$$

where the deviators of the deformation rates are

$$\begin{aligned} d_{xx} &= (\partial v_x/\partial x) - d, \\ d_{yy} &= (\partial v_y/\partial y) - d, \\ d_{zz} &= (\partial v_y/\partial z) - d \\ \tau_{xy} &= (\partial v_x/\partial y + \partial v_y/\partial x), \\ \tau_{yz} &= (\partial v_y/\partial z + \partial v_z/\partial y), \\ \tau_{zx} &= (\partial v_z/\partial x + \partial v_x/\partial z), \\ d &= (1/3)(\partial v_x/\partial x + \partial v_y/\partial y + \partial v_y/\partial z) \end{aligned} \tag{10.2.52}$$

and m is the shear viscosity of the material. Materials may also have a bulk viscosity that relates the departure of the mean pressure from the equilibrium pressure to the rate of change of volume.

The viscous deformation is still only part of the total deformation of a solid that shows significant time-dependent strain. In this regard, rheological models guide the development of material laws for such solids. There are many such models, but all are based on the behavior of just a few rheologic elements. One element is a spring that represents elastic behavior as shown in Fig. 10.2.16. Another element is a dashpot or shock absorber that represents viscous behavior described in Eq. 10.2.50. A third element is a slider that represents a yield point. These elements are combined in various one dimensional series and parallel arrangements. The three dimensional material law is then obtained by viewing the one dimensional result as being applicable to deviatoric relations. An example is the Bingham model shown in Fig. 10.2.17. The Bingham material is elastic until the yield point is reached; flow occurs beyond the yield point.

Unfortunately, most rocks that exhibit measurable viscous deformation also show nonlinearity with respect to viscosity. Creep of salt and potash are examples (Obert, 1964). Fig. 10.2.18 shows a model creep curve and three stages of creep. Creep is time-dependent deformation under constant load. Relaxation is

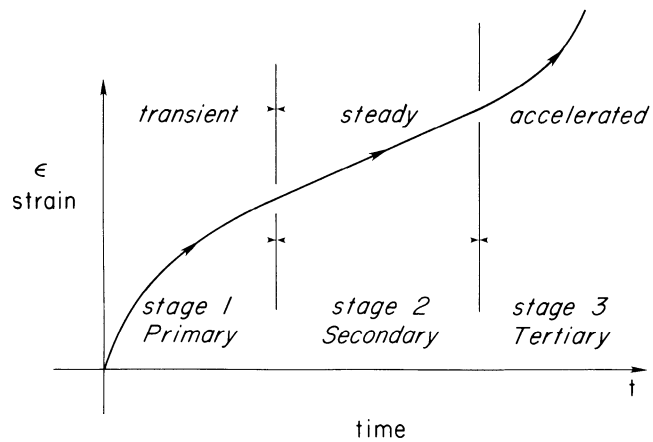

Fig. 10.2.18. Stages of creep.

time-dependent stress at constant strain. The first stage of creep shown in Fig. 10.2.18 is transient creep. The second stage is steady-state creep. Tertiary creep occurs prior to rupture. Elevated temperatures and pressures complicate the picture. A number of empirical relations have been proposed on the basis of experimental observations, but no generally accepted time-dependent material laws have been formulated. A simple form that fits much uniaxial steady state creep data is cited by Carter and Gnirk (1979):

$$(d) = A[\exp(-Q_c/RT)](s^n) \tag{10.2.53}$$

where A, Q_c, and R are constants, and T is the absolute temperature. The exponent n ranges between 1 and 9, but is usually between 3 and 6. Comparison of Eq. 10.2.53 and 10.2.50 suggests that the steady state viscosity is indeed stress dependent:

$$1/\mu = A\,[\exp(-Q_c/RT)](s^{n-1}). \tag{10.2.54}$$

Note that under uniaxial stress, say, in z-direction, deviations of stress and corresponding deformation rates are given by

$$s_{zz} = (2/3)\sigma_{zz}, \qquad d_{zz} = (2/3)(\partial v_z/\partial z) \tag{10.2.55}$$

In many cases, strain rates, for example, $(D\epsilon_{zz}/Dt)$ are used instead of deformation rates $(\partial v_z/\partial z)$.

10.2.4 SOLUTION APPROACHES

A proper combination of physical laws, kinematic relations, and material laws leads to a complete system that contains as many unknowns as equations, and therefore allows the motion of the rock mass to be estimated in advance of actual excavation. Excavation processes are equivalent to the application of load. Of course, there are other ways of loading a rock mass, for example, by the addition of heat. In the absence of inertia forces caused by wave propagation, the resulting system of differential equations is composed of the stress equations of equilibrium, the strain displacement equations, and the equations describing the material response. Integration of the system in the region of interest is generally subject to the specification of stresses and displacements at the boundary of the considered region and throughout the region at the beginning of the excavation processes being investigated. Analytical solutions obtained under a given set of specifications are functions that allow for the calculation of the displacements, strains, and stresses that would result if the excavation was carried out according to plan. Such solutions and associated calculations provide valuable design guidance in advance of actual excavation. However, analytic solutions to three dimensional problems in rock mechanics are generally not feasible. Even in two dimensional linear elasticity, analytic solutions, with few exceptions, are not easy to obtain.

Although there are relatively few analytic solutions available, they provide valuable insight concerning stress concentration about underground excavations such as tunnels and shafts and the bending and flexure of stratified ground. The results of analytic solutions to stress concentration problems and to beam and sheet bending analyses are immediately applicable to opening design based on safety factor criteria. Pillars between openings are amenable to analytic treatment based on average stresses. Approximate solutions to slope stability problems associated with surface mine excavations may be obtained from consideration of limiting equilibrium states. In this regard, the factor of safety is by definition the ratio of strength to stress. Of course, appropriate measures of strength and stress must be stated for the problem at hand. In all cases, numerical methods may be used for detailed study of stress distributions, strains, displacements, and safety factors.

10.2.4.1 Analytic Solutions

An example problem of great technological importance that demonstrates several interesting features of stress concentration about excavations in rock is that of determining the distribution of stress in a thick-walled cylinder subject to uniformly distributed radial pressures inside and outside the cylinder. As the outer radius of the cylinder becomes indefinitely large, the problem amounts to the determination of stress about a circular opening in an medium of indefinite extent. The latter is applicable to the analysis of unlined shaft wall safety, while the first is applicable to the analysis of shaft liners.

Another example problem amenable to analytic study and of considerable importance is beam analysis. In stratified ground where the immediate roof layers tend to separate from strata in the remote roof, analytic solutions are readily obtained from technical beam bending theory.

STRESS CONCENTRATION CONCEPT. Cylindrical coordinates are a natural choice for the analysis of circular openings as shown in Fig. 10.2.19. The opening is considered long in the sense that variations with z are negligible, so that derivatives with respect to z are zero. In particular, the z direction strains are zero, and the analysis is plane strain.

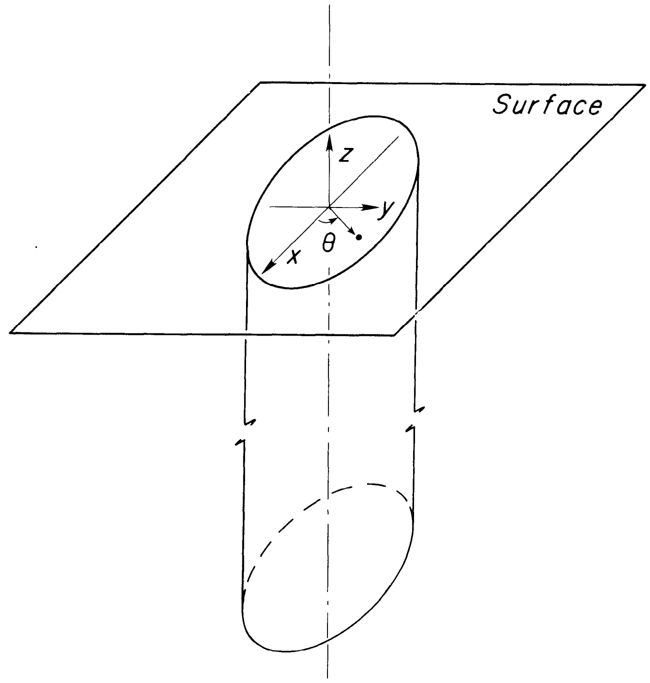

Fig. 10.2.19. Circular shaft analysis.

Use of Hooke's law for linearly elastic and isotropic rock in the stress equations of equilibrium together with the strain displacement relations and the axial symmetry of the problem leads to the solution for the radial displacement (Obert and Duvall, 1967):

$$u(r) = Ar + B/r \tag{10.2.56}$$

where the constants of integration A and B are determined from the applied loads.

The shaft in Fig. 10.2.19 is excavated in initially stressed ground, and the displacement given by Eq. 10.2.56 is the radial displacement of the shaft wall induced by excavation. The induced displacement decreases away from the shaft, so that as r becomes indefinitely large, A must be zero.

At the shaft wall, the change in radial stress caused by excavation must be equal but opposite to the preexcavation stress. The stresses about the shaft after excavation are simply the preexcavation stresses plus the stress changes. Hence

$$\begin{aligned} \sigma_{rr} &= (\sigma_h^0)[1 - (b/r)^2] \\ \sigma_{\Theta\Theta} &= (\sigma_h^0)]1 + (b/r)^2] \\ \sigma_{zz} &= \sigma_v^0 \\ \sigma_v^0 &= \gamma h \\ \sigma_h^0 &= K_0\sigma_v^0 \end{aligned} \tag{10.2.57}$$

where σ_{rr}, $\sigma_{\Theta\Theta}$, σ_{zz} are the post-excavation stresses in the radial, circumferential, and vertical directions, respectively; σ_h^0 and σ_v^0 are preexcavation horizontal and vertical stresses related by the constant K_0; h is depth; g is specific weight of rock; and b is the unlined shaft radius.

Stress concentration K is by definition the ratio of the actual stress $\sigma_{\Theta\Theta}$ to a reference stress. The reference stress is generally

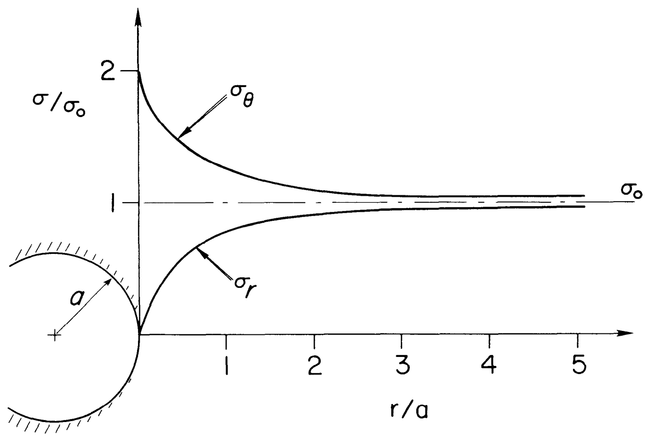

Fig. 10.2.20. Stress concentration around a circular hole.

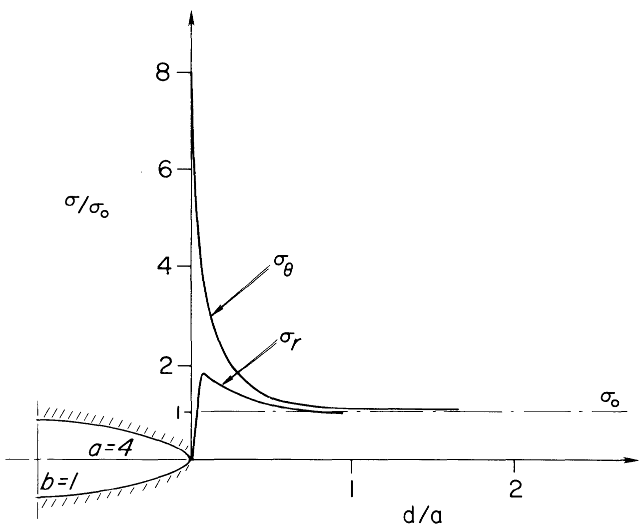

Fig. 10.2.21. Stress concentration around an elliptical hole.

the major principal stress before excavation σ_h^0. A plot of stress concentration vs. distance from the shaft wall is shown in Fig. 10.2.20. Inspection of Eq. 10.2.57 and Fig. 10.2.20 shows that the greatest concentration of stress in the horizontal direction occurs at the shaft wall. The compression at the shaft wall is double the preexcavation stress.

Eq. 10.2.57 and Fig. 10.2.20 demonstrate an important feature of stress concentration in two dimensional analyses and that is its rapid decrease with distance from the excavation wall. The stress concentration is within 4% of the preexcavation stress at a distance of two shaft diameters away from the shaft wall and within about 11% at a distance of only one shaft diameter. A rough rule of thumb is that excavations more than one-diameter (1D) apart do not interact to a significant degree.

In this regard, shaft diameter is the characteristic linear dimension of the excavation in the example analysis. Excavations of other shapes are characterized by the *greatest* dimension of the opening for the 1D rule of thumb. Fig. 10.2.21 shows the decrease of stress concentration with distance from the end of an elliptical excavation that has a ratio of major to minor axis of four and subject to the same initial state of stress as the circular shaft. Again the stress concentration decreases rapidly with distance from the excavation wall, and at about a distance equal to the length of the *major* axis of the excavation, the circumferential stress is within 10% of the preexcavation stress. The characteristic linear dimension of the opening in this case is indeed the greatest dimension of the opening.

The zone of significant stress concentration is the zone of influence of the excavation. An envelope extending a characteristic dimension from the excavation wall into the adjacent rock defines a zone of influence of the opening. The rock mass beyond the zone of influence is relatively unaffected by the excavation. However, if the wall of the opening is stressed to the elastic limit, plastic deformation may occur with the development of a yield zone in the vicinity of the opening. The effect of yield zone development is to reduce the peak stresses that would occur in a purely elastic response and to raise the average stress in the region of yielding. Beyond the yield zone, the rock is elastic where again the stress concentration decreases rapidly with distance (away from the elastic-plastic boundary).

Another important rule of thumb that arises from analysis of stress and the study of stress concentration around shaft, and tunnel-like excavations is that most favorable orientation of a single opening is with the long axis of the opening aligned parallel with the major compression. Such an orientation exposes the long dimension of the opening to the minimum preexcavation stress. A similar rule is appropriate to three dimensional, stope-like openings. Stated another way, the rule is as follows: orient the smallest dimension of the excavation perpendicular to the greatest compression, the largest dimension perpendicular to the least compression, and necessarily the intermediate dimension perpendicular to the intermediate preexcavation principal stress. This rule minimizes the exposure of a stope to stress concentration. Fig. 10.2.22 illustrates the most favorable opening orientation rule of thumb.

In the case of a row of openings of similar size and shape, the row axis should be aligned parallel to the major compression. The least compression is then perpendicular to the row axis. Spacing of the openings according to the zone of influence rule would require the pillars between the openings to be as wide or wider than the openings themselves, as shown in Fig. 10.2.22.

SHEET AND BEAM BENDING. Consideration of the equations of equilibrium, Hooke's law, and the geometry of strain under the assumption that sections perpendicular to the neutral surface of a sheet remain plane while deforming into a cylindrical shape leads to the equations of technical beam and sheet bending theory (Timoshenko and Woinowsky-Geiger, 1959). The two equations of most importance are the flexure formula,

$$\sigma_{max} = Mc/I, \tag{10.2.58}$$

where σ_{max} is peak stress in the sheet or beam, M is maximum moment, c is distance from the neutral axis to outermost fiber, and I second moment of area about the neutral axis; and the Euler-Bernoulli bending formula,

$$d^2w/dz^2 = M/EI \tag{10.2.59}$$

where $w(x,z)$ is displacement of the beam from its unloaded position, and E is Young's modulus. In the case of a sheet, E is replaced by $E/(1 - \nu^2)$, where ν is Poisson's ratio. The difference between sheet and beam bending in most cases is therefore small, about 4%. Mine roof strata are rectangular in cross section, and thus $I = bH^3/12$, where b is the breadth of the section and h is the stratum thickness.

Analytic solutions to the problem of a beam loaded on its upper surface by a uniformly distributed pressure p with built-

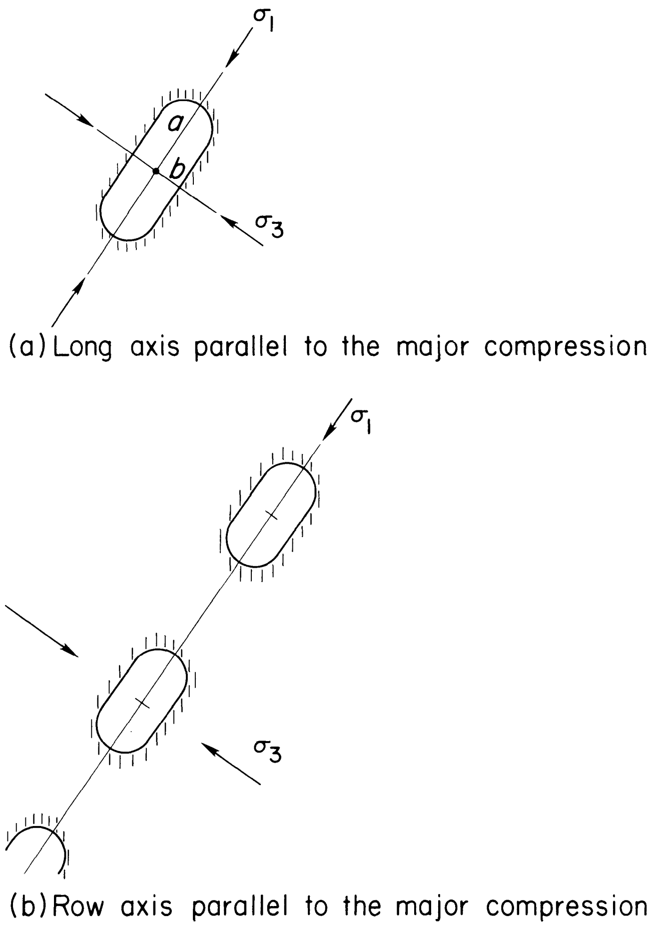

Fig. 10.2.22. Favorable orientation of holes and rows of holes (a) Long axis parallel to the major compression, (b) Row axis parallel to the major compression.

Table 10.2.2. Beam Analysis Results

Case	Max. Tension	Max. Sag
Simply supported	$(3/4)p(L/h)^2$ at center span beam bottom	$[5p(L/h)^2]/[32E]$ at center span
Built-in ends	$(1/2)p(L/h)^2$ at beam ends beam top	$[p(L/h)^2]/[32E]$ at center span

in ends and simply supported ends are given in Table 10.2.2, including the maximum tension and sag. The two cases in the table are extremes; all other cases that allow some rotation of the beam ends lead to stresses and displacements that are in between the simply supported and built-in end cases. Inspection of the results in Table 10.2.2 shows that the built-in end case is optimistic in the sense that the peak stress in the roof beam is less than in the simply supported case. The peak shear stresses are the same in both cases; the sag in the simply supported case is five times the sag in the built-in end case.

In some instances, several roof strata may separate in a cluster. The sag is the same for each stratum within a cluster,

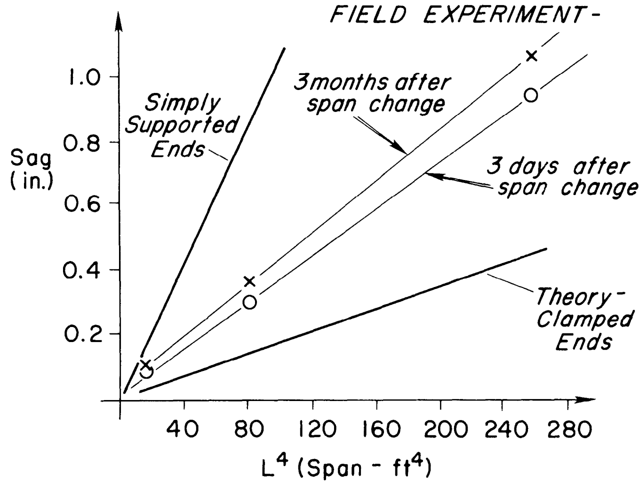

Fig. 10.2.23. Comparison of measured roof sag with beam theory (after Merrill, 1957). Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

and the net "pressure" $p(i,n)$ acting on the ith layer in a cluster of n layers is given by

$$p(i,n) = \{(E_i h_i)[p_g - p_b + \textstyle\sum(\gamma_j h_j)]\}/[\textstyle\sum(E_j h_j^3)] \tag{10.2.60}$$

where E_i, h_i, g, are Young's modulus, thickness, and unit weight of the ith roof layer, respectively; p_g and p_b are gas and bolting pressures; and summation is from the first to the nth roof layer in the separated cluster. The gas (or water) pressure term is included only if gas or water pressure develops at the separation horizon. Eq. 10.2.60 can be used to determine where bed separation may occur by a sequential computation of $p(1,n)$ that load on the first roof layer above the opening. As n is increased, $p(1,n)$ will increase up to the separation horizon where $p(1, n + 1)$ will be found to be less than $p(1,n)$. Separation occurs between the roof layer n and $n + 1$ counted up from the first roof layer.

Results of a full-scale test (Merrill, 1957) of the applicability of beam theory to mine roofs is shown in comparison with theory in Fig. 10.2.23. The measured data fall between the simply supported and built-in end cases, as might be expected in actual practice. In this regard, an essential feature of the analysis is the occurrence of bed separation. If bed separation occurs in the immediate roof, then beam analysis is applicable. The immediate roof strata are the layers within the zone of influence of the excavation. In this regard, a roof beam should have a span to thickness ratio greater than five and preferably eight to insure applicability of beam theory. Beam theory also finds application to cantilevered strata over longwall support.

PILLARS. Rock left between multiple openings forms pillars. There are many different types of pillars in hard-rock and soft-rock mines, for example, crown pillars, sill pillars, shaft pillars, rib pillars, chain pillars, and barrier pillars. Where pillars are numerous and occur in some repetitive pattern in a flat tabular ore body, a rigorous calculation of the average vertical stress in a typical pillar is possible. The calculation is based on the tributary area concept (Obert, Duvall, and Merrill, 1960). The tributary area A is simply the area defined by half the distance to the adjacent pillar. The ratio of the area mined A_m to the tributary area is the extraction ratio R, and the method is also known as extraction ratio pillar design. Excavation transfers to the pillar the weight of the overburden in an imaginary prism extending from seam to surface. Thus the force on the pillar after mining is equal to the overburden load, and the average vertical stress in the pillar is given by the formulas,

$$\text{(a) } S_p = S_v/(1 - R), \quad \text{(b) } R = A_m/(A_m + A_p) \qquad (10.2.61)$$

where $S_v = gH$, g is unit weight of overburden, H is seam depth, and R is extraction ratio.

In dipping seams, the average normal and shear stresses in the pillar are given by similar extraction ratio formulas (Pariseau, 1982):

$$\text{(a) } S_p = S_n/(1 - R), \quad \text{(b) } T_p = T_n/(1 - R) \qquad (10.2.62)$$

where S_n and T_n are the preexcavation normal and shear stresses, respectively, and are obtained through a rotation of the reference axes from the horizontal and vertical to directions parallel and perpendicular to the seam. Eq. 10.2.62 is valid at all seam dips. Pillar stresses S_p and T_p are the post-excavation stresses.

Where progressive failure of pillars needs to be taken into account in the design process, for example, in the design of yielding pillars, then a detailed analysis of the evolution of the stress distribution about the openings and in the pillars as time passes and mining progresses as necessary.

SLOPES. Surface excavation in rock masses generates slopes that must remain stable for safety of operations (see Chapter 10.4). Failure of slopes in rock masses almost always results from an unfavorable combination of slope height, slope angle, and geologic structure (Hoek and Bray, 1977). Water seepage is often an important contributing factor. From the kinematic viewpoint, there are four basic types of rock slope failures: (1) planar block slides, (2) wedge failures, (3) rotational, and (4) toppling, as shown in Fig. 10.2.24. The planar block slide is the simplest and serves as a conceptual model for more complicated failures.

With reference to Fig. 10.2.25, the downhill forces D tend to drive the slide mass, while the uphill forces R resist the motion. According to Newton's second law,

$$F = D - R = (W/g)a \qquad (10.2.63)$$

where W is slide weight, g is acceleration of gravity, and a is downhill acceleration. Since the slide mass is initially at rest, negative accelerations imply stability. Resisting forces arise from cohesion and friction on the slide failure surface and reinforcement, say, from pretensioned cable bolts. Frictional resistance depends on the effective or net normal force that is calculated from the requirement for equilibrium in the direction normal to the potential failure surface. The water force P is the integral of water pressure over the wetted portion of the failure surface. Provision is also made for seismic load S in Fig. 10.2.25, usually calculated as the product of slide mass (W/g) and a horizontal acceleration equal to a small fraction of g. For example, in a high-risk seismic zone, an acceleration of $0.15g$ may be dictated, so that $S = 0.15W$. Bolting forces in surface installations may range to over 1.8 MN (400,000 lb/ft) per bolt hole, but are generally quite small in relation to other forces acting on the slide mass (Seegmiller, 1975). An interesting feature of Eq. 10.2.63 is that it also describes the motion of the mass center of the slide mass even though the mass center is a point in space rather than a mass point. Mass center motion calculations are important for estimating dynamic features of rock slides, including mass center velocity and distance traveled. Such calculations are germane to practical questions such as zoning against geologic hazards.

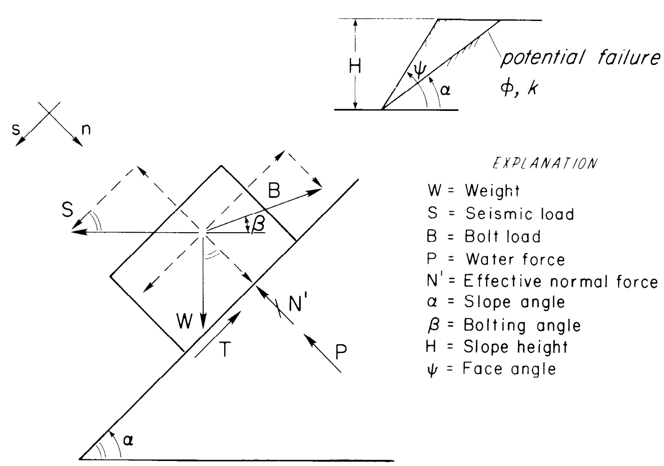

Fig. 10.2.25. Planar block slide model.

10.2.4.2 Factor of Safety Concept

The safety factor concept is a practical design criterion that has been in engineering use for many years. A global safety factor is used in design against collapse of a structure as a whole such as an open pit mine slope. A local factor of safety is more appropriate to elastic design of underground openings.

SAFETY FACTOR AGAINST COLLAPSE. The most commonly used safety factor FS in slope stability analysis is a ratio of resisting forces R to driving forces D:

$$FS = R/D \tag{10.2.64}$$

Safety and stability is indicated by $FS > 1$. If $FS < 1$, then the design is unsatisfactory—slope failure would occur if excavated accordingly to plan. Only the downhill forces enter into D; uphill forces are included in R. Negative resisting and driving forces are inappropriate concepts; R and D are strictly sums.

Eq. 10.2.64 is entirely equivalent to the negative acceleration criterion described previously as can be seen by substitution of Eq. 10.2.64 into Eq. 10.2.63. Thus

$$D(1 - FS) = (W/g)a \tag{10.2.65}$$

shows that stability is indeed achieved with $FS > 1$. Safety factors near one are common in open pit mines, but higher safety factors are needed for special cuts and embankments.

In the case of rotational failure, the global factor of safety is the ratio of resisting to driving moments. Thus

$$FS = (M_R/M_D) \tag{10.2.66}$$

where M_R and M_D are sums of the resisting and driving moments, respectively. When the potential failure surface is curved, then strictly speaking, the forces and moments must be obtained by integration of the stresses over the failure surface and throughout the slide mass volume. A detailed analysis of stress is required for such calculations. However, there are a number of approximate methods in use, many in computer code form, that allow for slope stability analysis and global safety factor estimation without the need for a rigorous stress analysis.

SAFETY FACTOR AGAINST LOCAL YIELDING. By definition, the local safety factor FS = "strength"/"stress." As a ratio of strength to stress, the local safety factor is a measure of the nearness of the stress state at a point to the elastic limit there.

In the problem of stress concentration at the wall of an excavation, in roof beam analysis, and in pillar stress calculation by the tributary area method, the stress state is essentially one dimensional. The appropriate measure of strength is then the unconfined compressive strength for compressive stress and tensile strength for tensile stress. The factors of safety in (a) compression, (b) tension, and (c) shear are

$$\text{(a) } FS_c = C_0/\sigma_c, \quad \text{(b) } FS_t = T_0/\sigma_t, \quad \text{(c) } FS_s = T_s/\sigma_s \tag{10.2.67}$$

where T_s and σ_s are shear strength and stress, respectively.

In the problem of stress concentration, the peak (a) compressive and (b) tensile stress are given by

$$\text{(a) } \sigma_c = K_c\sigma_1^0, \qquad \text{(b) } \sigma_t = K_t\sigma_1^0 \tag{10.2.68}$$

where K_c is peak compressive stress concentration factor, and K_t is peak tensile stress concentration factor.

In roof beam analysis, the peak tension for use in Eq. 10.2.67(b) is obtained from Table 10.2.2 in the case of a single, separated roof beam and from Eq. 10.2.60 for a multi-layered roof that has separated from the strata above.

In tributary area pillar design, the peak compression for use in Eq. 10.2.67(a) is obtained from the extraction ratio formula Eq. 10.2.62(a), while the peak shear stress is obtained from Eq. 10.2.62(b). The shear strength T_s is often calculated from the Mohr-Coulomb criterion.

10.2.4.3 Numerical Solutions

Declining costs of hardware and improved software for implementing advances in numerical solution techniques have made very powerful stress analysis tools available at the desk top of rock mechanics engineers. Where the complexities of excavation geometry, geology, and material behavior preclude analytic solutions, design guidance can often be obtained with the help of these new tools. The most important numerical methods are

1. Finite difference (FD).
2. Finite element (FE).
3. Boundary element (BE).
4. Distinct element (DE).

There are advantages and disadvantages associated with each, although in the hands of the sophisticated user, the distinctions tend to blur.

The finite difference method is a traditional approach to numerical solution of differential equations. The method is well developed and is especially suited for solution to problems in homogeneous rectangular domains that do not contain holes. Wave propagation analysis, temperature distribution calculations, and quasi static analysis of groundwater seepage are examples of problems often studied by finite difference methods. An advantage of finite difference methods is the large accumulation of knowledge about such techniques. A disadvantage is the difficulty often encountered in handling boundary conditions for regions containing holes of irregular shape. For this reason, the method is not popular for stress analysis of excavations in rock.

The finite element method (Cook, 1974; Zienkiewicz, 1977) is based on a spatial subdivision of the region or rock mass of interest. The method is well suited to analysis of irregularly shaped openings and is perhaps the most popular method in rock mechanics. It is relatively easy to use, and a number of engineering colleges now offer introductory finite element courses at the undergraduate level. The technique allows for a variety of rock types and material laws to be used in the same analysis and also allows for sequential excavation and filling of surface and underground excavations. The method has great versatility and has been used in the analysis of stress, temperature, and groundwater flows about mines. Analysis of two dimensional problems is almost routine. Three dimensional problems represent a sizable increase in computing effort; although feasible in principle, they are far from routine.

Boundary element methods are based on discretization of the bounding surface of the rock mass of interest (Crouch and Starfield, 1983; Banerjee and Butterfield, 1981). They are similar to finite element methods in some respects and have the advantage of reducing the dimensionality of the problem, say, from three (volume) to two (surface) dimensions. However, the apparent advantage of reduced dimensionality does not necessarily translate into reduced computer size and time requirements. The real advantage of boundary element methods relative to finite element methods is in the preparation of input data, especially in three dimensional analysis where volume discretization is a major task. An important disadvantage of the boundary element method is that it is difficult to apply to the analysis of other than linear, homogeneous, isotropic elastic rock masses.

The distinct element technique was originally developed by Cundall and treats rock masses as assemblages of rock blocks (Cundall, 1971). The emphasis in the distinct element technique is on the important role that rock mass discontinuities such as joints play in the mechanics of field-scale rock masses. In the distinct element method, individual blocks are defined by joint sets that are usually assumed to be continuous and persistent throughout the rock mass. Blocks may be rigid or deformable. A major advantage to the distinct element technique is the capability for following large displacements of rock blocks on joints. Applications range from conventional slope stability analysis, fault slip stability in an underground mine, and bin flow analysis, to throwout calculations associated with blasting of craters, to blast casting of overburden in a strip mine. An important disadvantage to the distinct element technique is the rather large amount of computer storage and time needed for problem analysis.

Chapter 10.3
GEOMECHANICS INSTRUMENTATION

W.A. HUSTRULID AND B.P. BOISEN

10.3.1 INTRODUCTION

Two geomechanics *instruments* used by miners throughout time to assess the state of their mine are their eyes and their ears. For many applications, these are still the most important and appropriate. These sensors have the unique feature of being able to scan a wide horizon and also to focus on a single place or event. They are connected to a powerful data acquisition system that provides interpretation and issues instructions based on that interpretation. However, just as one would not think of running a modern mill without a battery of instruments to provide quantitative data regarding the state of the process, the same is true—albeit to a lesser level—in a mining operation. A number of devices have been developed throughout the years that can be used to provide quantitative information regarding rock/soil behavior and/or the response of the mine structure. In this chapter, the major types of instruments for underground and surface applications are discussed.

Call (1982) has provided some very useful guidelines for the selection of geomechanics instrumentation. Although they deal specifically with the monitoring of slopes in open pits, they have general applicability. His general guidelines for decision making are

1. Measure the obvious things first. Surface displacement is the most direct and most critical aspect of slope instability.
2. Simpler is better. The reliability of a series system is the product of the reliability of the individual components. A complex electronic or mechanical device with a telemetered output to a computer has significantly less chance of being in operation when needed than do two stakes and a tape measure.
3. Precision costs money. The cost of a measuring device is often a power function of the level of precision. Measuring to ½ in. (10 mm) is inexpensive compared to measuring to 4×10^{-5} in. (0.001 mm). A micrometer is unnecessary for monitoring slope movement that has a velocity of 2 in. (50 mm)/day.
4. Redundancy is required. No single device or technique tells the complete story. A single extensometer or survey point cannot indicate the area involved in the instability, and, if it is destroyed, the continuity of the record is lost.
5. Timely reporting is essential. Data collection and analysis must be rapid enough to provide information in time to make decisions. Reducing last week's survey data and telling the mine superintendent that the slope was moving Thursday when a shovel was buried Sunday does not lead to pay raises!

The questions that must be asked—in sequence—in any instrumentation program are these:

1. Why measure?
2. What measure?
3. Where measure?
4. How measure?

If the question, "Why measure?", cannot be answered satisfactorily; then there is no reason to continue through the list. Some typical instrumentation uses include:

1. Determination of rock and soil mass properties such as strength, deformability, anisotropy, and resistance to some types of alteration.
2. Observation of the state of stress in the masses, including in situ stress and redistributed stress.
3. Observation of the response of the rock or soil masses due to disturbances induced by the excavation and operation of the structure.
4. Measurement of the reaction of the mine structure to conditions imposed by the geologic mass, and to conditions during subsequent operation.
5. Observation of the behavior of associated or adjacent structures or services either affected by or at risk as a result of mining.
6. Recognition of hazards, either actual or incipient.
7. Identification of remedial measures, i.e., reinforcement.
8. Verification of the effectiveness or ineffectiveness of remedial measures.
9. Evaluation of safety factors.
10. Short- and long-term monitoring, with alarm capability as required.

Regardless of the application, all instruments have certain requirements in common (Dutro, 1986).

1. *Range:* The provision of adequate range is a consideration often overlooked in choosing instruments for a specific application. On the other hand, excessive range should also be avoided, as it often can be obtained only at the expense of some other desirable characteristic, such as resolution.
2. *Resolution*: Resolution denotes the smallest numerical change an instrument can discriminate, but not necessarily repeat. Adequate resolution is important in identifying low-level phenomena, particularly those indicative of hazards. Excessive resolution, however, should also be avoided, as it is usually attainable only at the expense of other characteristics, and as it may lead to a degree of scatter in the data that obscures other trends and relationships.
3. *Repeatability*: Repeatability is a measure of the least reading which can be repeated consistently. Repeatability and resolution, together with range, indicate the general suitability of a particular instrument for a specific application.
4. *Accuracy*: Absolute accuracy is a difficult requirement to adequately define. All instruments are accurate under some conditions, but no instruments are likely to be absolutely accurate under all conditions. It is important to understand the advantages and limitations of the instruments proposed, and to relate these to the requirements of the proposed measurements. Accuracy is expensive and preoccupation with excessive accuracy may divert attention from other instrument characteristics and requirements. In a majority of instrument applications, the data obtained relate to a component of force, deflection or displacement, and not a resultant. Unless the other vector quantities are known with the same precision required of the instruments, the accuracy of the instruments is not at issue. Instrument accuracy should, therefore, be specified in terms of the probable overall precision of the entire application.
5. *Survivability*: The adversity of mining environments is usually underestimated. Instrument failures are not only expensive and inconvenient, but they typically result in lost data that are almost always irretrievable. Mining instruments must, therefore, have the highest order of survivability, if acceptable levels of operation and data continuity are to be maintained.

Many instrumentation programs ultimately are unsuccessful because the information was not acquired, processed, and transmitted in a timely manner. Readout intervals, levels of processing and interpretation, and chains of authority for the transmittal of data should be clearly established at the outset of programs. The usual tendency is to overdo at the outset, with too short an interval between readouts, too much data, and too elaborate initial processing and interpretation. Consequently, data do not become available to the appropriate personnel in time to be really useful.

When dealing with instrumentation data, several points should be kept in mind: (1) Significant measurement trends, particularly adverse trends, are generally evident in the raw data, without any processing. Readout personnel should scan all data as they are acquired, and take whatever action is indicated without awaiting further processing. (2) If potential hazards to life and property are involved, "timely" means right now! (3) In many situations and almost invariably in hazard situations, the appropriate personnel are the lowest level of authority for the necessary action, or the individual or individuals in danger.

Some of the advantages/disadvantages of automatic data acquisition and processing vs. manual readout are implicit in the foregoing comments. Manual instrument readout is costly and time consuming. On the other hand, a person is present, and that person can be trained to scan the data, recognize significant trends or deviations, and take the indicated action. The necessary skill can be readily developed by mine personnel. Automatic and semiautomatic readout apparatus are expensive, as is the extra cabling usually necessary to route the signals to common points. The systems, however, provide data at more frequent intervals and at lower unit readout cost, so the cost factors tend to balance out, particularly on programs of considerable duration. The ideal readout plan is an automatic system with an alarm capability, supplemented by periodic manual readout and data scan by qualified personnel. This would also relieve a persistent problem of automatic systems, whereby alarm thresholds are either set too low, resulting in annoying false alarms, or too high, resulting in increased hazard exposure.

There are a variety of costs involved in a geomechanics instrumentation program:

1. Hardware.
2. Installation.
3. Readout.
4. Data processing.
5. Interpretation.

Sometimes, there are also costs or at least lost savings by not having such a program. Presuming that such a cost-benefit analysis has been done and the decision has been made to measure, then the tendency is to try and minimize cost. The most obvious way is to economize on the hardware. Although "homemade" will sometimes suffice, there are many examples where this decision has turned out to be penny wise but pound foolish. The costs add up very quickly when trying to interpret "suspect" data. *Quality* hardware—whether homemade or "store bought"—is a good investment. Furthermore, quality installation is also a must. The acquisition of poor data is sometimes worse than having no data at all.

10.3.2 INSTRUMENTATION FOR SURFACE MINING APPLICATIONS

10.3.2.1 Introduction

The use of rock mechanics instrumentation in open pit mining can in general be placed in one of the following three categories:

1. Initial slope design.
2. Slope design assessment.
3. Slope monitoring.

Monitoring the condition of critical or suspect slopes in open pit mines is the most obvious and currently widespread use of rock mechanics instrumentation in open pit mines. Much of the available instrumentation, as a result, deals with this aspect. However, because of the large effect slope angle has both on short- and long-term pit economics, increasing emphasis is being placed upon the development of techniques upon which recommendations for optimum bench, inter-ramp, and overall slope angles can be based. Some instruments and instrumentation techniques for assisting in this assessment both prior to and during mining are available. The discussion in this segment will be organized along these lines of mining application.

10.3.2.2 Initial Slope Design

Generally, a major part of the evaluation of a mineral property is carried out through a development drilling program. Diamond drilling yielding core is common, although rotary drilling is used as well. The type of information that is sought according to Waterman and Hazen (1968) is

1. Geology of the mineralized zone.
2. Quantitative data on grade and tons.
3. Physical size and shape of the deposit.
4. Mineralogical and metallurgical characteristics of the ore.
5. Physical characteristics of the ore.
6. Data on other factors that could affect mining operations, such as groundwater, ground conditions, etc.

Unfortunately, the last category is sometimes added as more or less an afterthought. These factors, however, are extremely important in the design of today's surface mining operations. Maximum slope angles as determined by structural characteristics and groundwater have a very large impact on mining economics. A change in slope angle by 1° can mean millions of dollars in stripping cost (Stewart and Kennedy, 1971). Fig. 10.3.1 is a plan view of a large open pit in the design stage. As can be seen, there are 10 sectors in which the slope angle has been prescribed.

To be able to make such a detailed design requires a significant amount of information regarding rock structure, rock mass properties, and groundwater. Therefore, consideration must be given as to how to extract such information during the development and subsequent drilling phases of a property.

Core Orientation: The orientation of the structures that will make up the walls of a pit are important for design. Figs. 10.3.2 and 10.3.3 show one such device, the Craelius core orienter (CCO), that can be used (Seegmiller, 1979).

Originally, the device was fitted to a core barrel which in turn was attached to the drill string. The string is lowered down the hole without rotation. The pins make a multipoint impression of the bottom configuration. A marking ball dents a soft steel plate thereby indicating the vertical plane. The CCO slides up in the core barrel, undisturbed as drilling proceeds. Drilling continues as long as there is space in the core barrel to take both the CCO and the core. The string must then be removed from the hole to extract the oriented core. Seegmiller (1990) has modified the device to work in wireline systems.

The orienter can be used, in dipping, in upwards inclined, and in horizontal drillholes without having to orient the drill string. It can be used in vertical holes after the drill string has been oriented. Instructions for using the orienter and logging oriented core have been given by Seegmiller (1976).

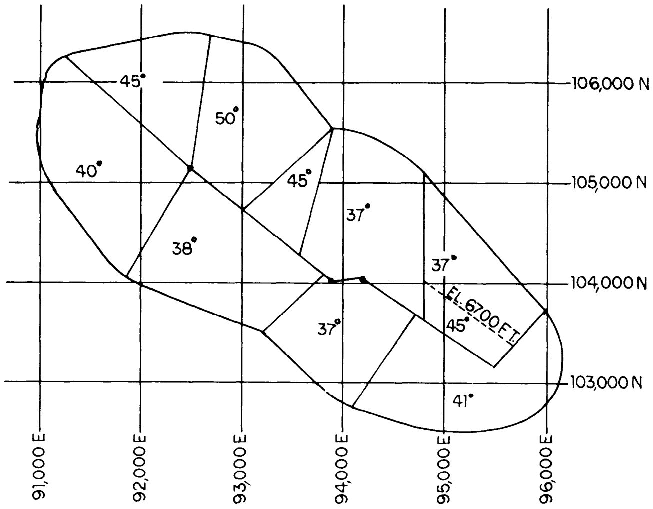

Fig. 10.3.1. Plan view of open pit showing slope sectors (after Crawford and Davey, 1979).

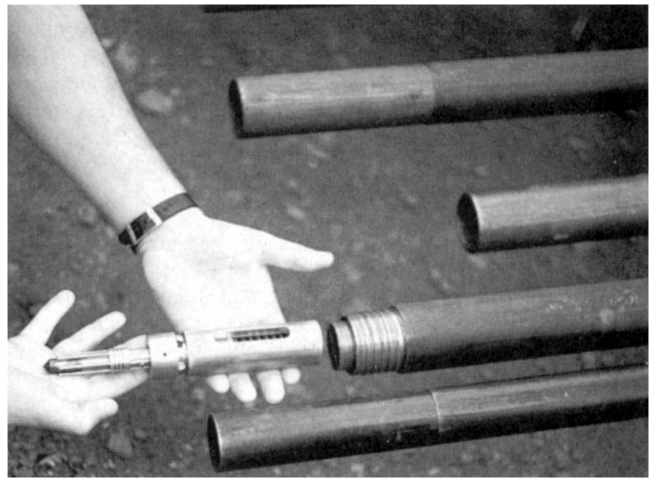

Fig. 10.3.3. CCO wireline orienter (*courtesy:* Seegmiller International).

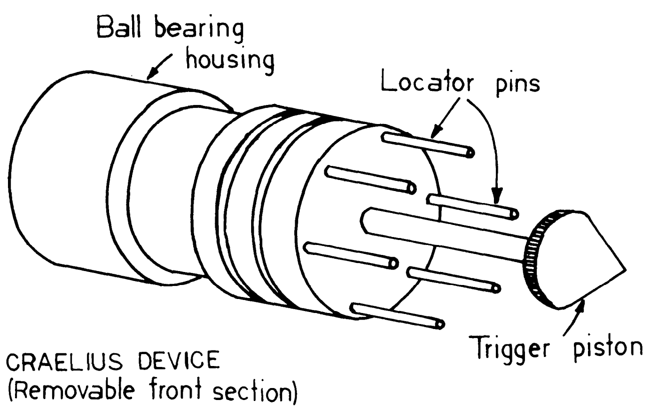

Fig. 10.3.2. Isometric drawing of Craelius core orienter (after Seegmiller, 1990).

The CORO, another core-orienting device operating along somewhat similar principles to the CCO, has been developed in Australia and Chile (Seegmiller, 1990).

Call et al. (1982a) have described another system for obtaining oriented core.

Borehole Television Cameras: The development of small-diameter, high-resolution television cameras over the past few years have made them into practical tools for viewing borehole walls. By observing the same structure at three known angular orientations in the borehole, the strike and dip can be calculated. The resolution is quite good even in water-filled holes.

Borehole television cameras are commercially available for lowering on a cable into vertical or near-vertical holes up to 1000 ft (300 m) deep. The smallest camera from one manufacturer (Fig. 10.3.4) has a diameter of 1 l/8 in. (29 mm) and can be used in boreholes with a length up to 500 ft (150 m). The image is transmitted through the lowering cable to the surface where it can be viewed and recorded. Various techniques are used for positioning purposes. Some systems use a rotating mirror or prism when viewing the side wall. In others, the camera is rotated (Stenning, 1990). Television borehole cameras producing both color and black and white images are available.

Borehole Seismic Tools: *Seismic Surveys*—Seismic surveys can be made in drillholes using commercially available equipment (Anon, 1977a). Because the strength of rock is roughly proportional to the sonic velocity, velocity surveys can provide estimates of the in situ strength of a slope wall or changes in the strength with time. In general, the higher the seismic velocity, the stronger the rock mass and vice versa. Large defects such as faults, massive discontinuities, or other large anomalies can be located through geophysical seismic techniques (Anon., 1988; Elkington et al., 1982). Fig. 10.3.5 shows the results of a series of different logs run in a borehole at a coal property (Kowalski and Fertl, 1976). Radar has recently been used to help define rock conditions (Holloway et al., 1990; Pittman et al., 1984; Anon., 1990l).

Borehole Radar—The borehole radar system (RAMAC), shown in Fig. 10.3.6, has recently been developed by the Swedish Geological Co. (Anon.,1990l) and applied to fracture detection in crystalline rock.

The system works in principle in the following manner: short current pulse is fed to a transmitter antenna, which generates a radar pulse. The pulse, made as short as possible to obtain high resolution, propagates through the rock. It is received by the same type of antenna, amplified, and registered as a function of time. From the full wave record of the signal, the distance (travel time) to a reflector, the strength of the reflection, and the attenuation and delay of the direct wave between transmitter and receiver may be deduced.

Optical fibers are used for transmission of the trigger signals from the computer to the borehole probes and for transmission of data from the receiver to the control unit. The advantages with optical fibers are (1) they have no electrical conductivity and will not support waves propagating along the borehole, and (2) they cannot pick up electrical noise. Since the signal is digitized down-hole there will be no deterioration of the signal along the cable. The quality of the results will thus be independent of cable length.

Borehole radar measurements can be performed as single-hole reflection measurements and/or cross-hole measurements. In single-hole reflection measurements, the transmitter and re-

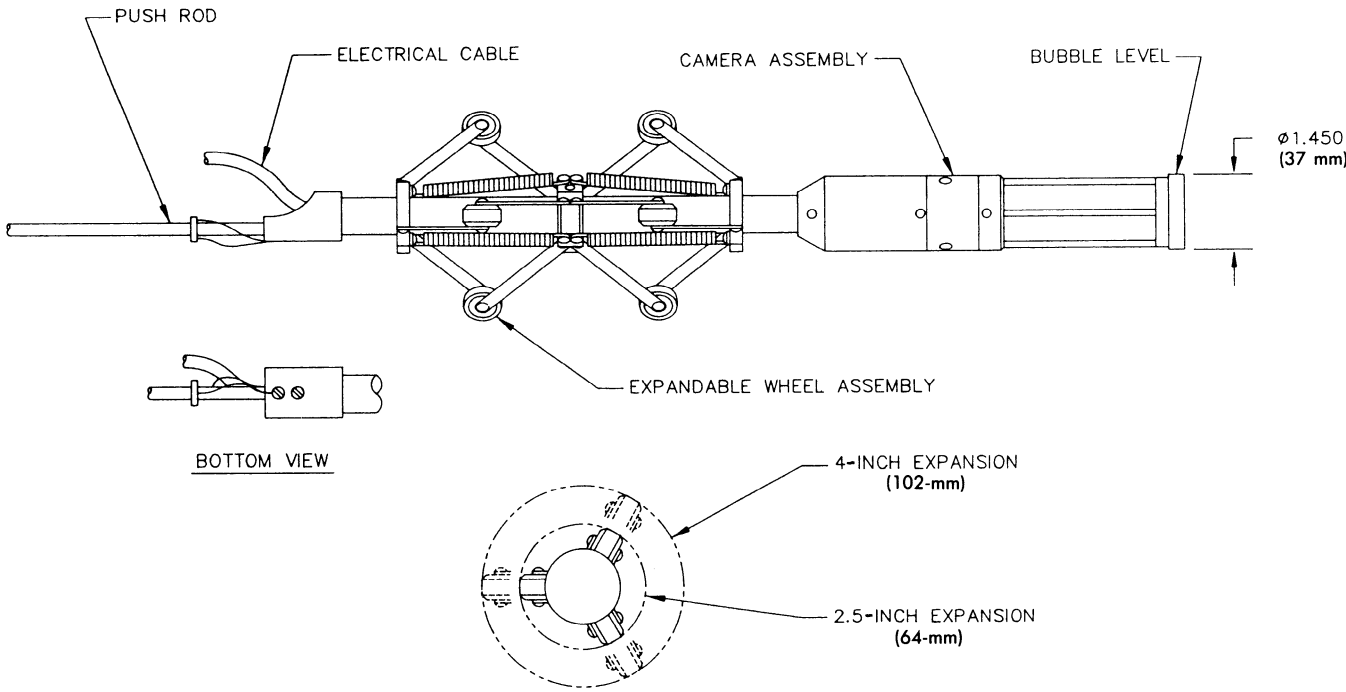

Fig. 10.3.4. Diagrammatic representation of small-diameter borehole television camera with guide arrangement (*courtesy:* Stenning Instruments).

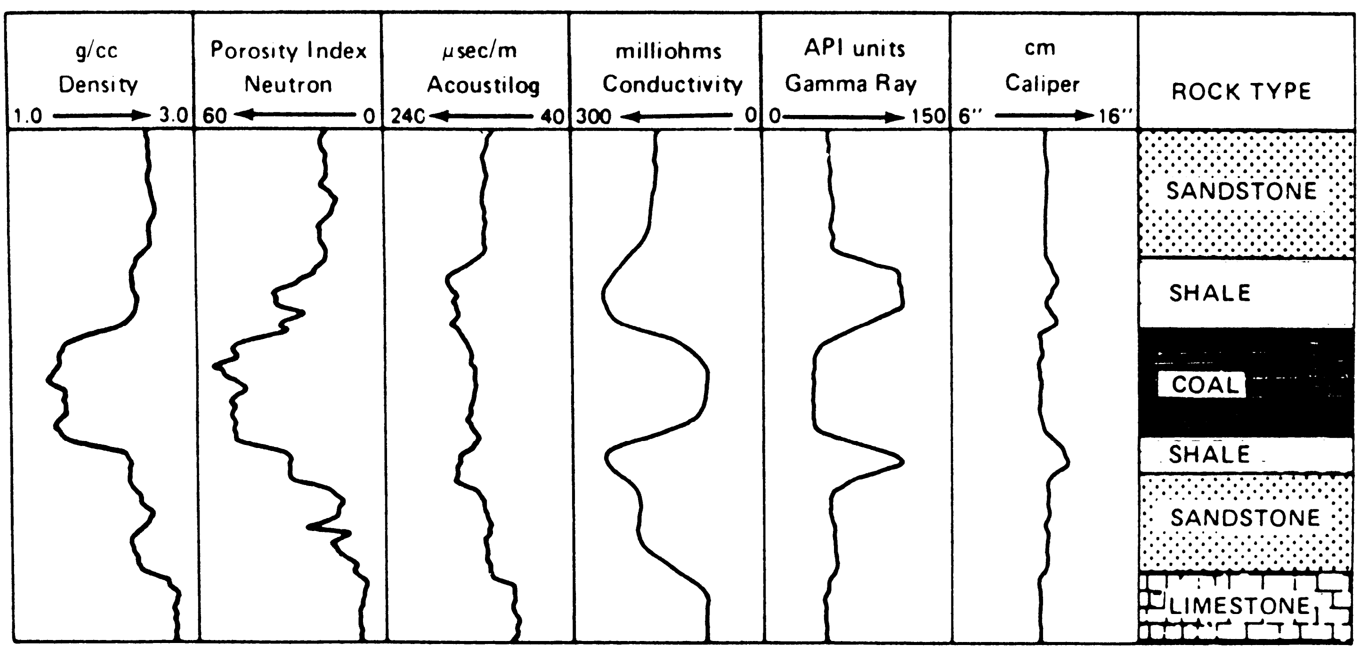

Fig. 10.3.5. Generalized response of geophysical logs in various lithologies (after Elkington et al., 1982). Conversion factors: 1 in. = 2.54 cm, 1 ft = 0.3048 m, 1 lb/ft^3 = 16.018 kg/m^3 = 0.016 g/cm^3.

ceiver are located in the same borehole, with the fixed separation distance maintained by glass fiber rods. The transmitter-receiver array is moved along the borehole and measurements are made at fixed intervals. Each measurement, including the movement to the next measuring position, takes about 30 to 50 seconds. Measurements can be performed with antennas ranging from 20 to 80 MHz. A large penetration (300 to 500 ft, or 100 to 150 m) from the borehole in combination with a high resolution (7 to 16 ft, or 2 to 5 m) is obtained.

In a cross-hole measurement, the transmitter and receiver are placed in separate boreholes. One of the probes is kept in a fixed position in one of the boreholes while the other probe is

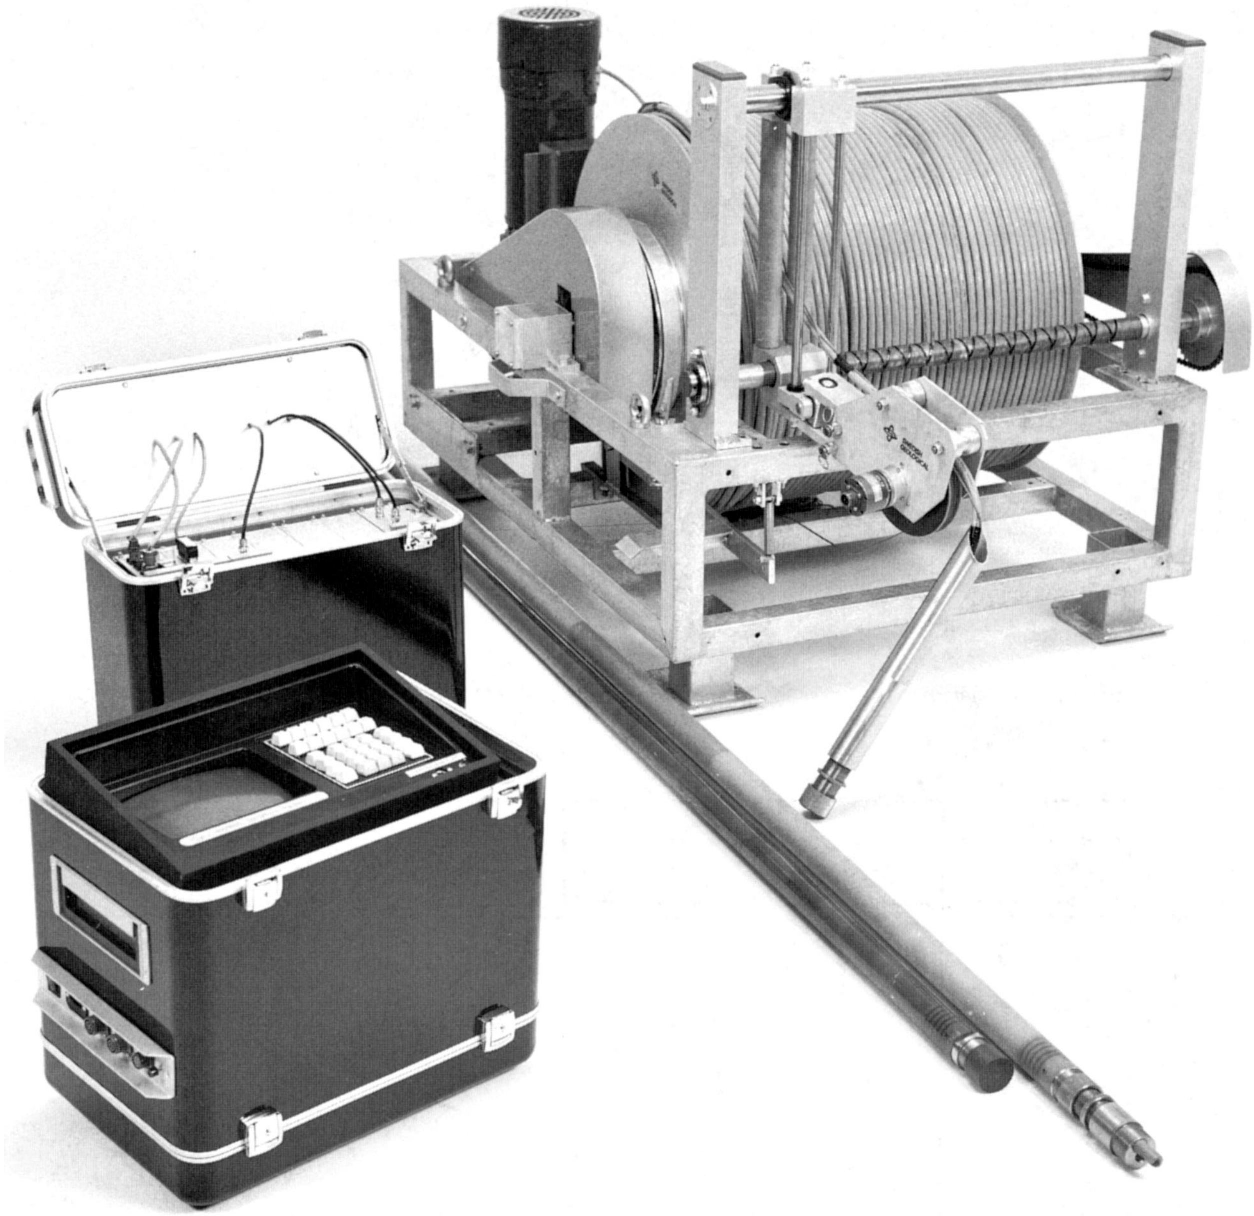

Fig. 10.3.6. Borehole radar equipment (*courtesy:* Swedish Geological Co., SGAB).

moved in the other hole where measurements are made at fixed intervals.

Fig. 10.3.7 is an example of a measurement made in granite. In the radar plot, fractures are shown as lineaments; the drift located about 130 ft (40 m) from the borehole is shown as a hyperbola, and a pair of 2.2-in. (56-mm) boreholes intersecting the measured borehole at 0 ft (0 m) are shown as line reflectors.

Borehole Water Level: The determination of water conditions is an important input (Anon., 1977b) into slope design as well as the evaluation of slope stability. The most common way of obtaining such information is simply through the observation of the water level in an uncased borehole or observation well. A disadvantage of this system is that a perched water table or an artisan pressure in one of the intersected strata can make the readings meaningless.

The simplest technique for determining the basic water table level in a drillhole is through the use of an open-well piezometer (Fig. 10.3.8). The hole is drilled to the layer of interest, a PVC casing with a filter tip at the lower end is installed, and the annulus between the PVC pipe and the hole wall is backfilled with bentonite to prevent flow of water into the filter from other locations along the hole. When the probe, shown in the figure, touches the water surface, an electrical circuit is completed, and the lamp lights. The depth to the surface is read from the cable tape. Knowing the difference in elevation between the water surface and the filter tip, the pressure at the tip can be calculated. Flow rate can also be calculated by pumping down the water level in the hole and observing the time of recharge.

Water Pressure Measurements: When the water pressure is to be measured directly, pneumatic and hydraulic piezometers

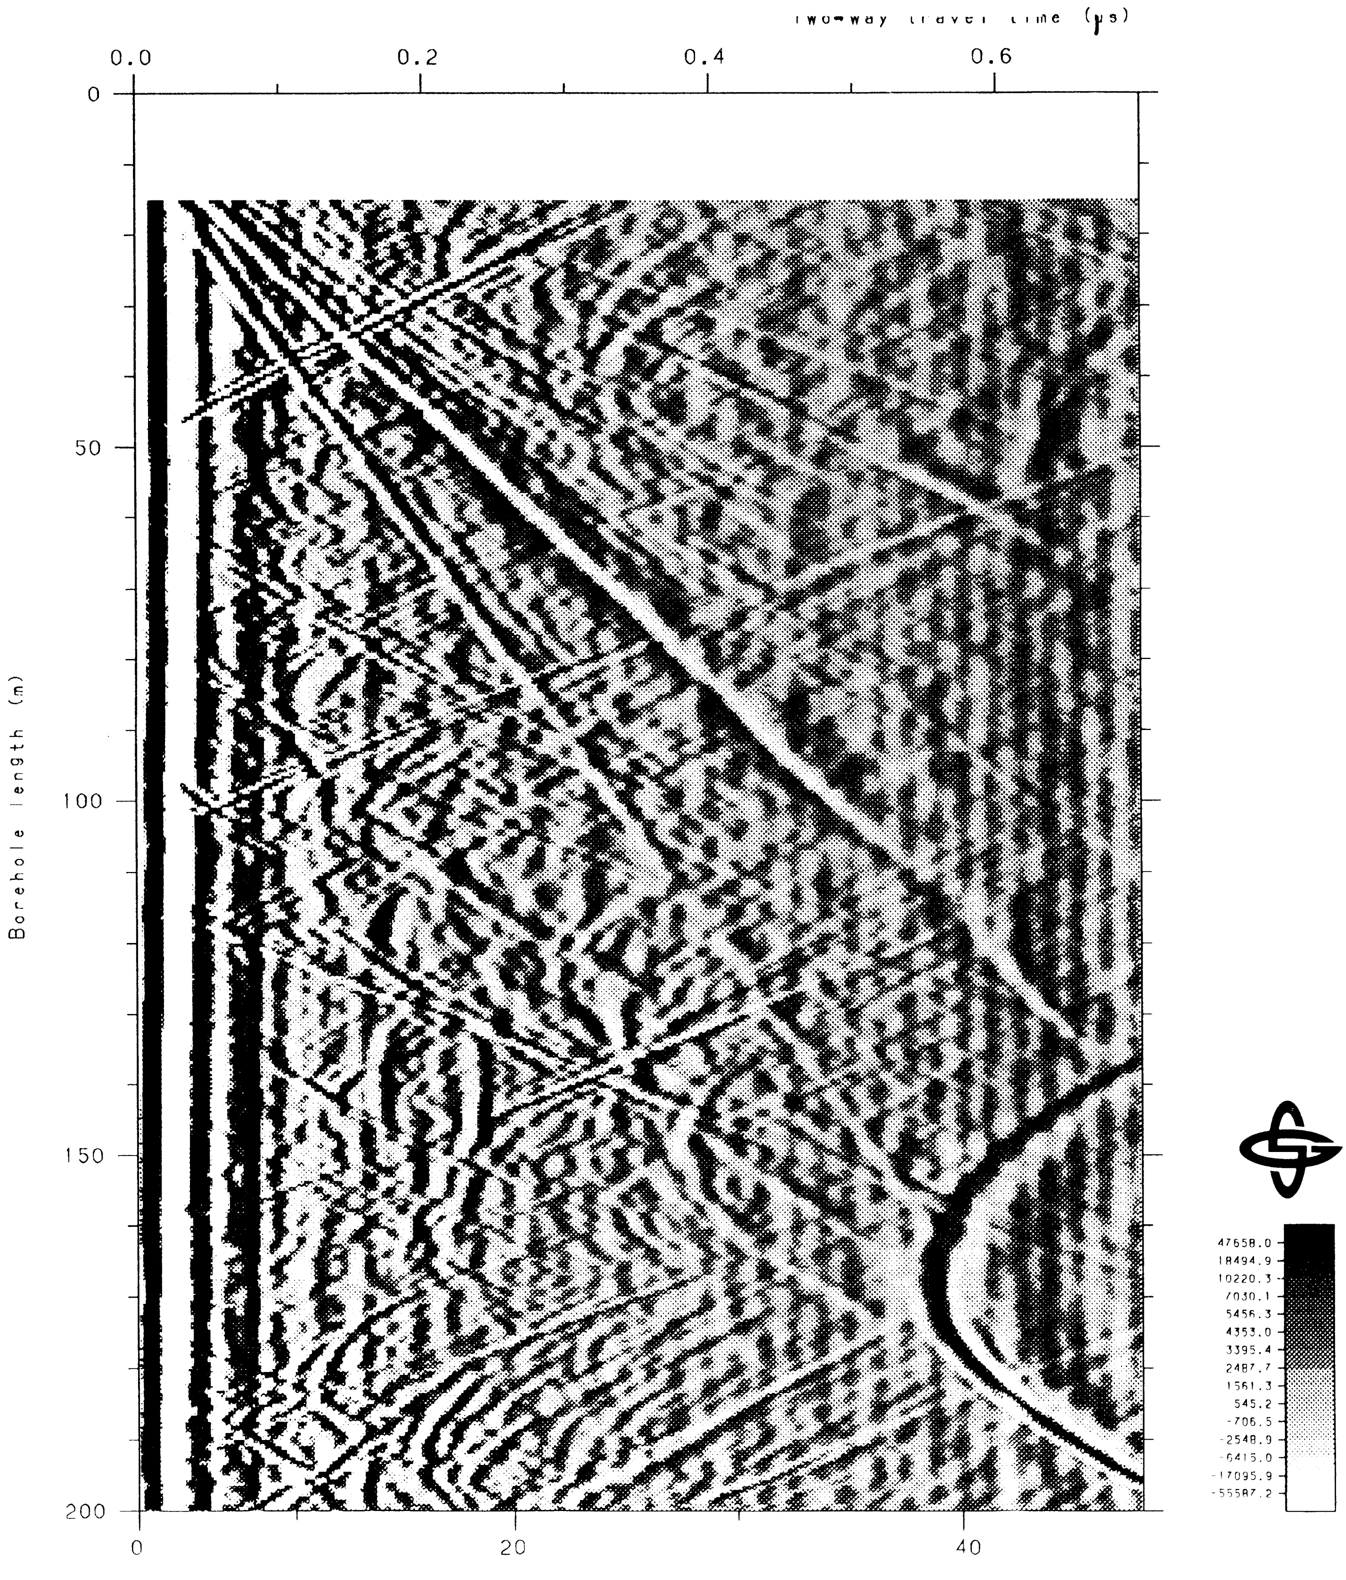

Fig. 10.3.7. Radar map produced in crystalline rock from borehole F4 60 MHz antenna (*courtesy:* Swedish Geological Co., SGAB). Conversion factor: 1 ft = 0.3048 m.

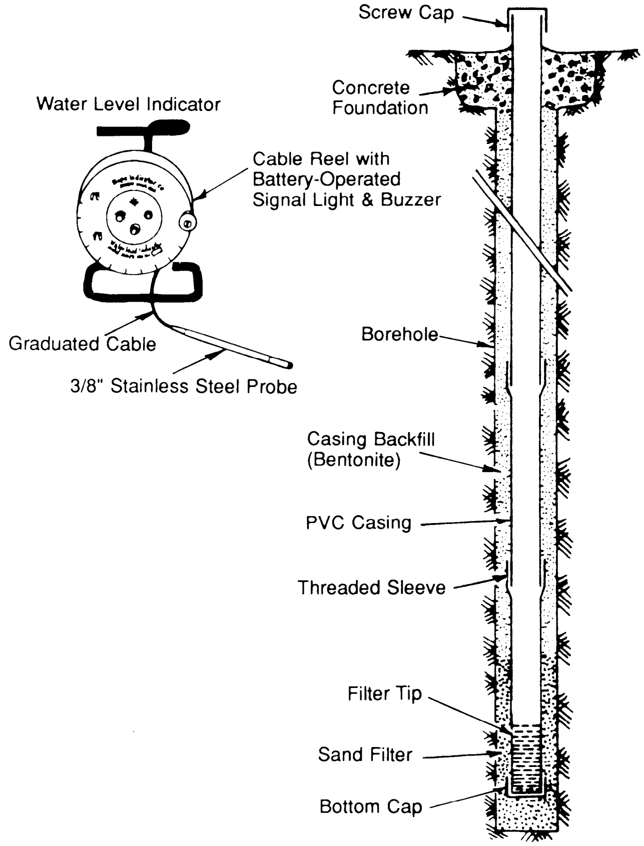

Fig. 10.3.8. Borehole water level device (*courtesy:* Slope Indicator Co.). Conversion factor: 1 in. = 25.4 mm.

employing a special sealed tip containing a pressure-sensitive valve are often used. The valve opens or closes the connection between two tubes that lead to the surface, the slope face, or any other convenient location and elevation. In the piezometer shown in Fig. 10.3.9, compressed nitrogen flow through the outlet tube is established as soon as the inlet-tube pressure equals the pore-water pressure. In the hydraulic piezometer, hydraulic fluid is used instead of gas, but the basic principle remains the same. Pneumatic piezometers have the following advantages: (1) negligible time lag because of the small volume change required to operate the valve, (2) simplicity of operation, (3) capability of purging the lines, (4) minimum interference with construction, and (5) long-term stability. Their main disadvantage is the absence of a de-airing facility.

Electric piezometers have a diaphragm that is deflected by the pore pressure against one face. The deflection of the diaphragm is proportional to the pressure and is measured by means of various electric transducers.

Because they may be effected by the environment or they may have various life spans, the longevity record of electric piezometers should be investigated prior to selection for installations in which reliable readings are required during an extended period of time.

10.3.2.3 Slope Design Assessment

Strike-dip Information: The collection of strike and dip information from exposed rock surfaces remains one of the most important tasks for the geologist/rock mechanician (Anon., 1978b). Fig. 10.3.10 shows a pocket transit that is commonly used for making such measurements (Anon., 1990k).

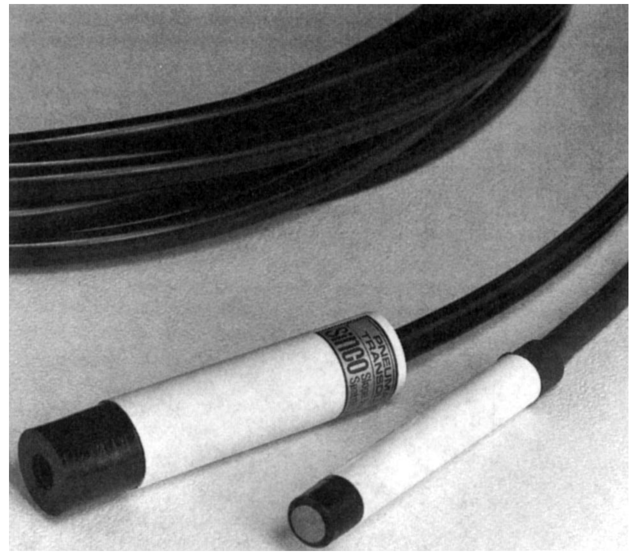

Fig. 10.3.9. Borehole piezometer for water pressure measurements (*courtesy:* Slope Indicator Co.).

Electronic Notebook: Although the data collected are generally still entered by hand into a paper notebook for later manual transfer onto maps or into a computer, electronic notebooks are available that greatly simplify the process. These notebooks can be programmed for data collection in the form desired, do some intermediate processing, and then transfer the contents of its memory to a personal computer, mainframe computer, or printer. Fig. 10.3.11 shows one such electronic notebook being used in the data collection mode (Anon., 1990b).

10.3.2.4 Slope Monitoring

Introduction: Stability monitoring of slopes and dumps is important at many open pits and strip mines (Barron et al., 1971; Call, 1982b; Stewart et al., 1971; Weir-Jones and Bumala, 1975; John, 1977). There are many techniques that can be used. Typical measurement objectives (Wilson et al., 1978) are

1. To determine absolute lateral and vertical movements of a sliding surface.
2. To determine the rate of sliding (accelerating or decelerating) and thus warn of impending dangers.
3. To determine the depth and shape of the sliding surfaces.
4. To determine the relative movements within a slope.
5. To monitor the effectiveness of various control measures.
6. To monitor groundwater levels and pore pressures so that analyses can be made.

There are a number of reasons why measurements are made. The obvious one is for safety. By monitoring the movements and the rate of change of movements, warning can be provided in advance of a slide. With such a warning, certain actions ranging from restricting area access to the unloading of the slope can be planned and taken. Design parameters such as friction angle, cohesion, groundwater levels, and pore pressures can be obtained through slope monitoring. These can lead to better slope designs. The measurement of groundwater parameters has already been discussed. The focus in this segment will be on the measurement of deformation.

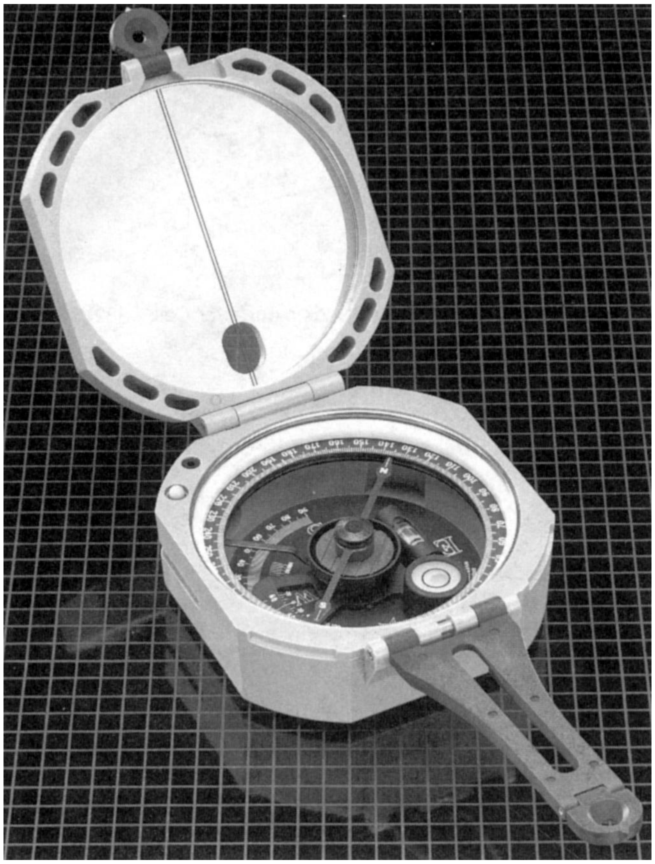

Fig. 10.3.10. Brunton compass (*courtesy:* Brunton, USA).

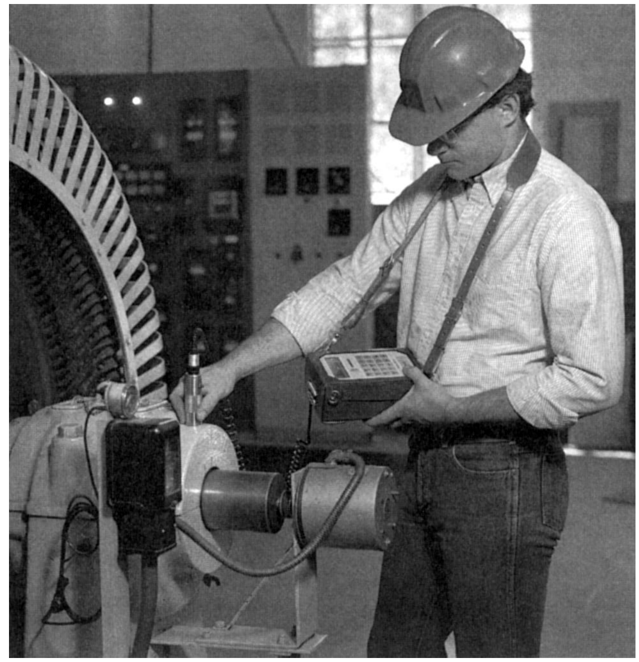

Fig. 10.3.11. Electronic notebook/recorder in use (*courtesy:* Omnidata).

The overall objectives of a pit slope monitoring program (Call, 1982) are

1. To maintain safe operational procedures for the protection of personnel and equipment.
2. To provide advance notice of instability so that mine plans can be modified to minimize the impact of slope displacement.
3. To provide geotechnical information for analyzing the slope failure mechanism, for designing appropriate remedial measures, and for conducting future redesign of the slope.

Conventional Survey Networks (Call, 1982): Surface displacement measurement using conventional survey equipment and extensometers has been and continues to be the most widely used and cost-effective technique.

Fig. 10.3.12 shows a survey network consisting of targets on the pit slopes and instrument stations from which angles and distances to the targets are measured. Either triangulation with a theodolite or trilateration with an electronic distance measuring (EDM) instrument can be used.

In planning the network, care should be taken to ensure that a sufficient number of targets are established for collecting the necessary data. If a total station EDM instrument is used, approximately 3 min will be required for each reading; thus about 30 to 40 prism targets can usually be surveyed in a half day. If a distance-meter EDM and a theodolite are used in combination, each reading would take about 5 min.

The survey network has several primary functions:

1. It establishes a surveillance system to detect initial stages of slope instability.

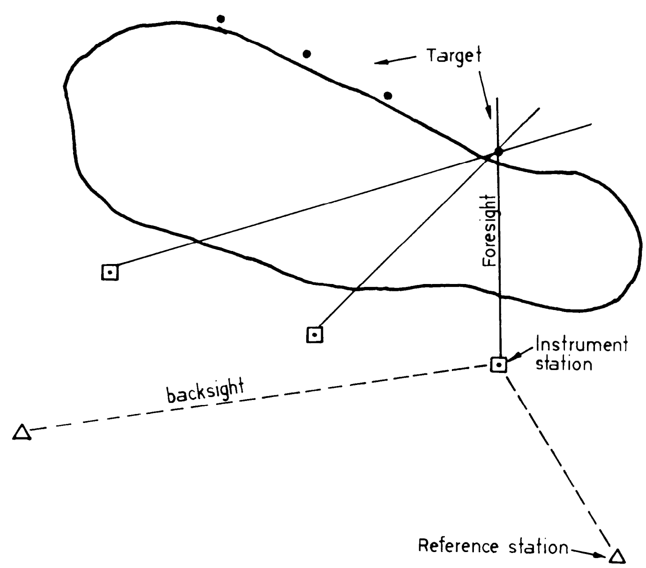

Fig. 10.3.12. Survey network for open pit mine (after Call, 1982).

2. It provides a detailed movement history in terms of displacement directions and rates in unstable areas.
3. It defines the extent of the failure areas.

Since deviations in survey data can result from the inability to repeatedly set up exactly in the same position at the stations, the observation (instrument) station should have stable bases. These are best established with concrete or metal monuments. An instrument base plate affixed to the top of the monument serves as an instrument platform.

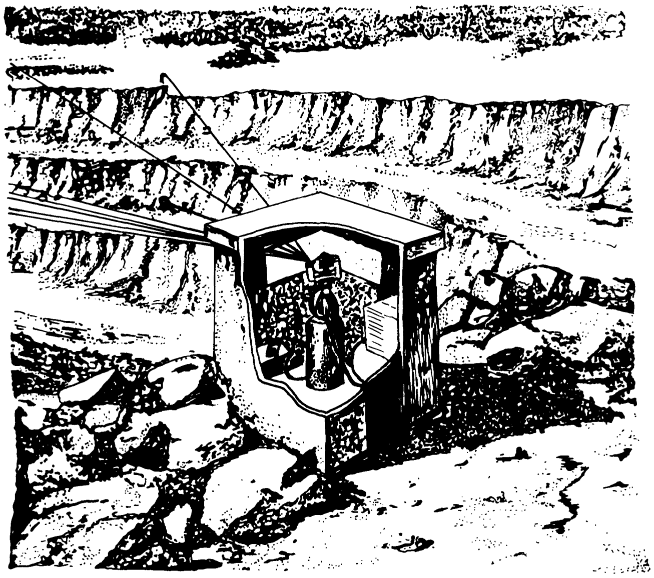

Fig. 10.3.13. Computer-directed surveying (*courtesy:* Geotronics).

Primary survey points, used to tie the observation stations to the mine grid baseline, should be located on stable ground, beyond the influence of the pit excavation.

Prism targets should be attached to bench faces, if possible. A location 6 to 8 ft (1.8 to 2.4 m) above the bench toe is usually preferred. Minor raveling may dislodge the prism if it is located near the crest. If the target is near the toe, it could be covered relatively quickly by raveled rock debris. In some areas, the prism reflectors will have to be mounted on sturdy tripods at selected monitoring points. It is best to allow newly installed targets to stabilize for one week before readings begin. Initially, the readings may be somewhat erratic, but an overall trend should soon become apparent.

An adjustment capability is usually needed for each target on a moving slope because it may be necessary to adjust the prism for proper instrument alignment if significant slope displacement occurs or if the instrument station is relocated. The prism can tolerate a misalignment up to 14º and still return the signal to the EDM.

Automated Surveying: A computer-controlled measurement system (Anon., 1989c) that can be programmed to measure distances and horizontal and vertical angles at predetermined intervals to a set of prism targets, anchored in the pit wall, is currently available (Fig. 10.3.13).

An analysis of the measurements can be performed by the computer and the results, in terms of target movement, velocity, and acceleration, can be presented numerically or graphically on the computer display or a printer. The measurement data can also be transferred to a mainframe computer over a data link for further processing.

Surface Mounted Extensometers: Surveying procedures can be used to obtain absolute displacements (with respect to a fixed reference) or relative movements. These may be considered as a type of surface extensometer on a very large scale. Other types of surface extensometers of varying ranges, precisions, and costs are also used for monitoring.

One early, obvious indication of slope instability is the development of tension cracks. By systematic mapping of these cracks, the extent of the unstable area can be established (Fig. 10.3.14).

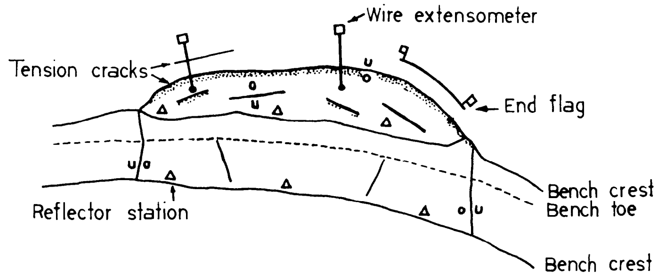

Fig. 10.3.14. Tension crack map (after Call, 1982).

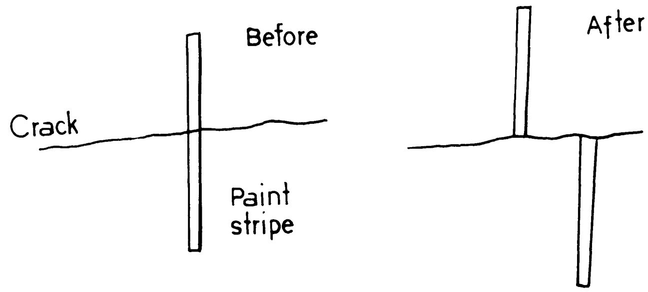

Fig. 10.3.15. Paint stripe technique (after Call, 1982).

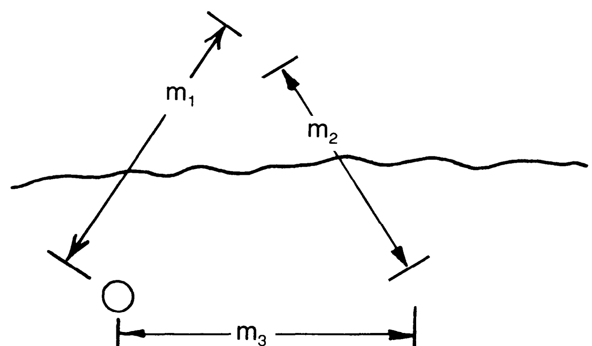

Fig. 10.3.16. Simple triangulation system for crack monitoring (after Call, 1982).

The ends of the cracks should be flagged so that on subsequent visits new cracks or extensions of existing cracks can be identified.

It is often useful to monitor on a very small scale (Anon., 1984), such as is shown in Fig. 10.3.15. The displacement of the simple paint stripe gives a good idea of movement.

The use of three rebar posts installed as shown in Fig. 10.3.16 provides triangulation possibilities. By measuring the distances between marks in the tops with a tape, one can determine relative motion and movement direction.

Another simple indicating device is a hardwood wedge lightly forced into the joint crack with a mark placed on it at the level of the rock. If the joint opens, then the wedge will fall to a deeper level in the rock. However, if the joint is closing or

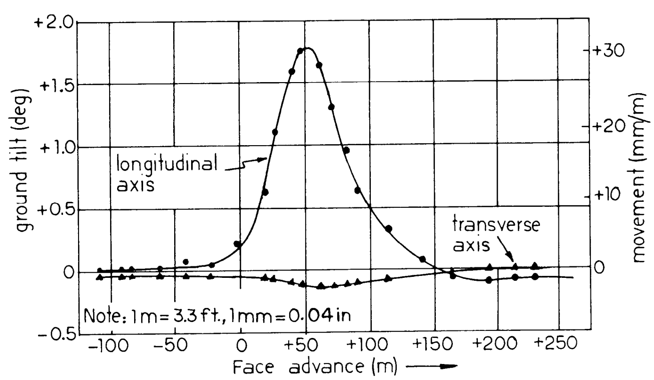

Fig. 10.3.20. Output from tiltmeter used in subsidence zone (after Wilson et al., 1978).

subject to shear movement, such a wedge indicator may not be helpful.

More elaborate systems (Fig. 10.3.17) are also available.

Portable wire extensometers can be used to provide monitoring in areas of active instability and to provide backup for the survey system. These monitors can be quickly positioned and easily moved. A simple extensometer, which can be fabricated in the mine shop, appears in Fig. 10.3.18.

For backup to the survey system, an extensometer should be positioned on stable ground behind the last visible tension crack, and the wire should extend out to the unstable area. Wire extensometers can be placed at strategic locations where anyone working in the area can make an immediate check on slope movement by inspecting the instruments.

A wire extensometer can be set up as a warning device by affixing a switch several inches (millimeters) above the displacement weight; significant displacement will trip the switch. Lights or sirens powered with a 6-V dry cell battery wired to the switch will warn of slope activity. A continuous drum-type recorder adapted to an extensometer can provide a continuous record of slope movement (Fig. 10.3.18). It will provide excellent data regarding the sensitivity of the slope to blasting, production, and rainfall.

The length of the extensometer wire should be limited to approximately 200 ft (60 m) because sag can produce inaccurate readings. Usually 35 to 50 lb (17 to 24 kg) of counterweight are needed for such a length, but this depends on the tensile strength of the wire. Aircraft control cable or similar wire, which is manufactured to have very little stretch, is recommended for this type of monitoring device. The flexibility and durability of steel cable, compared to the rigidity and brittleness of INVAR wire, outweigh the benefits of the thermal properties of INVAR wire. Temperature fluctuations can be measured, and corrections can be made if necessary (Call, 1982).

Tiltmeters: Tiltmeters provide another means of monitoring movement (Anon., 1977d; McCarter, 1976). They may be used in any area where the failure mode of a mass of soil or rock can be expected to contain a rotational component. One type of tiltmeter in which servo-accelerometer sensors are used is shown in Fig. 10.3.19. Sample tiltmeter data collected from a subsidence area overlying an underground mine appear in Fig. 10.3.20. A simpler tiltmeter contains a mercury switch which, when tilted,

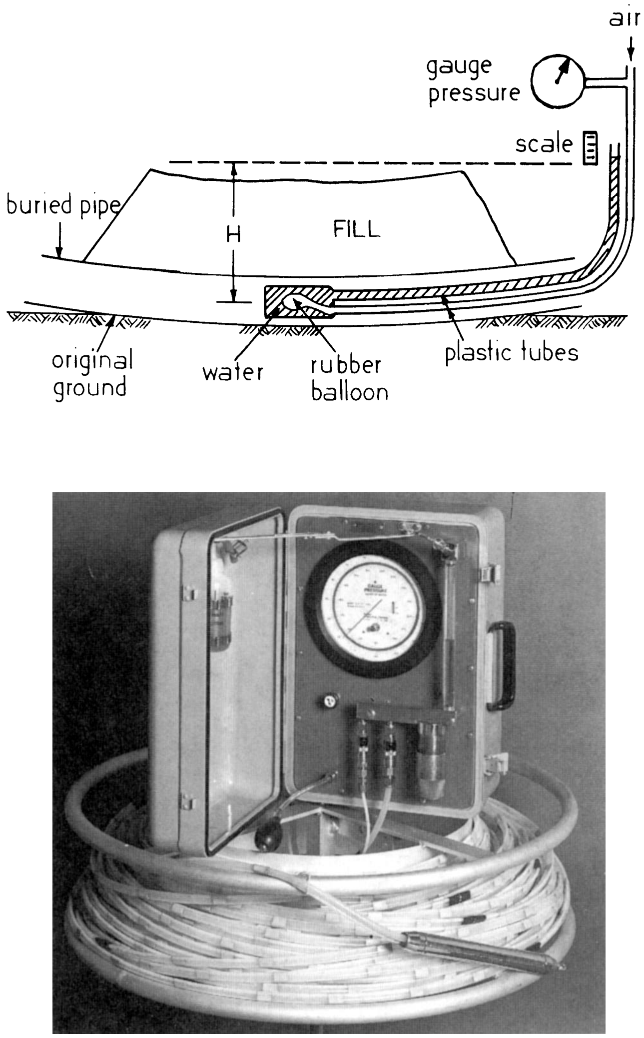

Fig. 10.3.21. Liquid-level displacement gage (*courtesy:* Walter Nold Co.).

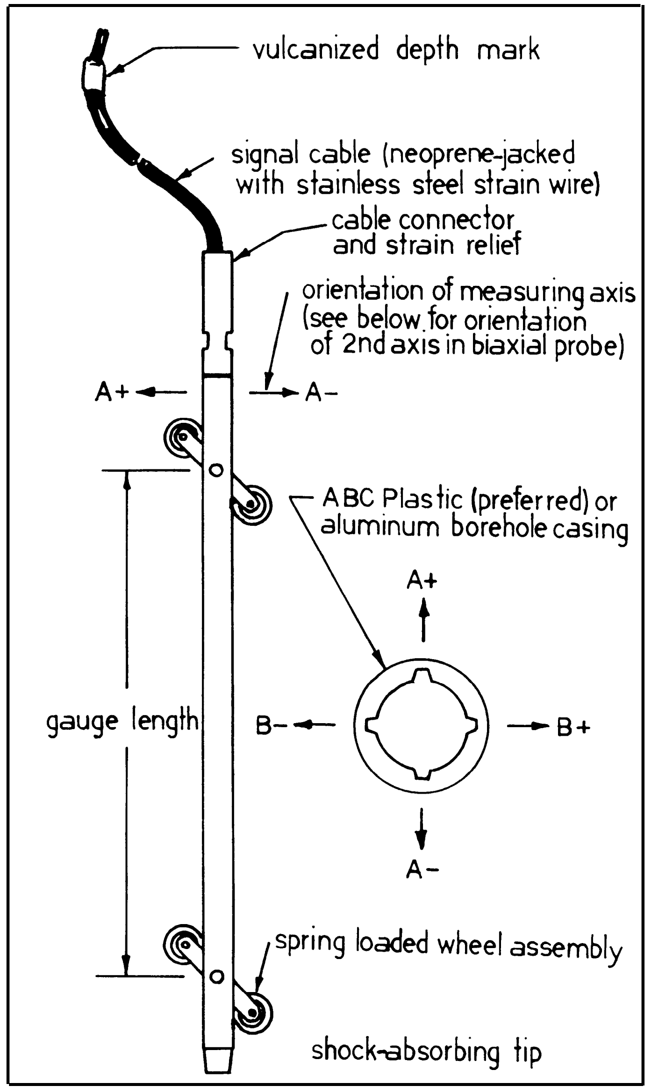

Fig. 10.3.22. Diagrammatic representation of inclinometer (after Wilson, 1970).

causes an electrical circuit to be closed. This is an off/on type of device that can be connected to a warning system. It does not provide information regarding rate of movement, etc.

When tension crack displacement is predominantly vertical, a tiltmeter, consisting of a bar across the crack with protractor and pendulum, can be used to measure displacement. A mercury switch on the bar can be attached to a warning light.

Liquid-level Displacement Gages: A liquid-level vertical displacement gage operates on the physical principle that the liquid level in two vessels joined by a connecting tube is at the same elevation, provided the pressure on the liquid surface is the same in both vessels. The change in elevation between the two reservoirs can be determined by micrometers attached to each reservoir.

Fig. 10.3.21 shows a diagrammatic, horizontal, full-profile settlement gage that works on a somewhat similar principle. A water-filled tube terminated by a torpedo is pulled or pushed through a 1 l/2-in. (38-mm) diameter PVC pipe. Elevation differences of up to 20 ft (6 m) can be evaluated over lengths of 500 ft (150 m). The settlement accuracy is from l/4 to 3/4 in. (6 to 19 mm), depending upon the amount of care used while taking a reading.

Sub-surface Instruments: Although it is possible to make inferences about the subsurface extent of instability from surface displacement measurements, there are situations where subsurface data are needed. Access is generally through the use of boreholes. Because of this, they involve considerably more expense. Four devices fall into this category:

1. Inclinometers.
2. Shear strips.
3. Time-domain reflectometry.
4. Borehole extensometers.

Only the first three are discussed here since extensometers are covered in the underground segment (10.3.3).

Inclinometers—An inclinometer (Anon., 1977d; Anon., 1981; Muller et al., 1977) measures the change in inclination (or tilt) of a casing in a borehole (Fig. 10.3.22) and thus allows the distribution of lateral movements to be determined as a function of depth below the ground surface and as a function of time. Application of the inclinometer to slides is readily apparent, namely, to define the slip surface or zones of movement relative to the stable zones. Inclinometers have undergone rapid develop-

Plotted Traverses of a Portable Borehole Inclinometer.

Fig. 10.3.23. Typical output from inclinometer installation (after Wilson, 1970).

ment to improve reliability and accuracy, reduce weight and bulk of instruments, lessen data acquisition and reduction time, and improve versatility of operations under adverse conditions. Automatic data-recording devices, power cable reels, and other features are now available.

Most inclinometers measure the inclination of the casing in two mutually perpendicular near-vertical planes. Thus horizontal components of movement, both transverse and parallel to any assumed direction of sliding, can be computed from the inclinometer measurements.

The function of the inclinometer is to detect the change in inclination of the casing from its original near-vertical position. Readings taken at regular preestablished depths inside the casing allow the change in slope at various points to be determined; integration of the slope changes between any two points yields the relative deflection between those points. Repeating such measurements periodically provides data on the location, magnitude, direction, and rate of casing movement (Fig. 10.3.23). The integration is normally performed from the bottom of the hole, since the bottom is assumed to be fixed in position and inclination.

Shear Strips—The shear-strip failure locator (Fig. 10.3.24) is a safety device used to detect and locate up to two failure zones in soil, rock, or concrete. It can be installed in boreholes as small as 1 1/2 in. (38 mm) in diameter, bonded to surfaces, or embedded in slots or trenches. The strip consists of a series of resistors mounted on a brittle substrate that breaks with shear movements. The shear-strip indicator is used to make the read-

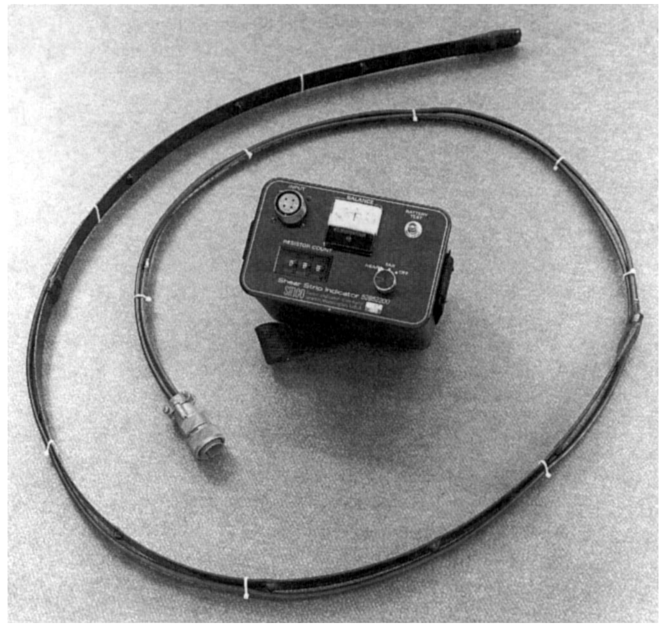

Fig. 10.3.24. Shear strip failure locator (*courtesy:* Slope Indicator Co.).

ings. These systems have the limitation of being go/no-go devices.

Time-Domain Reflectometry—This technique (Alexander, 1990; Anon., 1983; Anon., 1989e) was initially developed to locate discontinuities in coaxial transmission cables. In mining, the technique has been employed (Wade and Conroy, 1980; Panek and Tesch, 1981) to identify zones of rock mass deformation. When the ground deforms, a coaxial cable grouted into a borehole will also be deformed, thereby modifying cable impedance. A step voltage pulse transmitted along the cable experiences a partial reflection at the points where impedance changes exist. Pulse reflections from all changes in impedance along the cable are superimposed on the input pulse to form a series of TDR signatures. The composite signature observed on a TDR cable tester screen consists of many individual reflections generated by localized deformations along the cable.

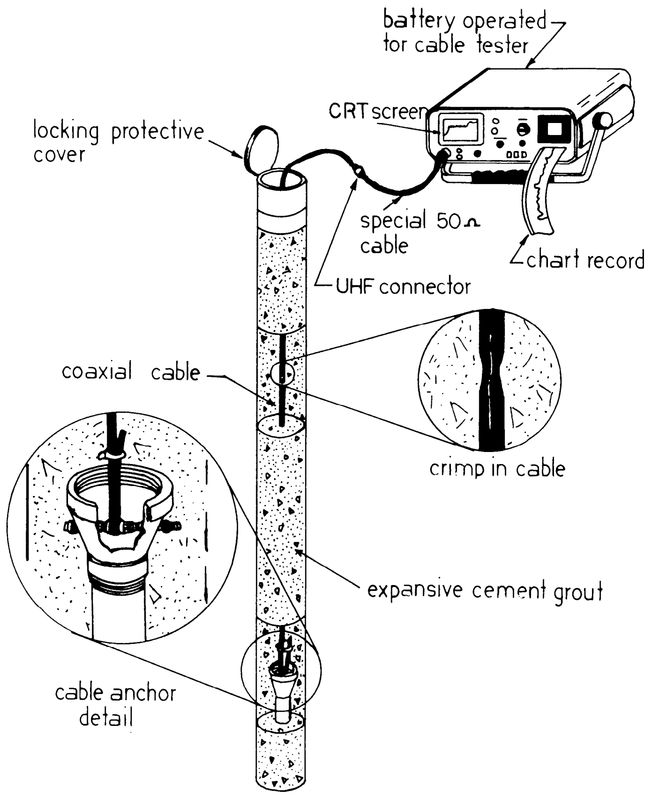
The time delay between a transmitted pulse and the reflection from a cable deformity (cable fault) uniquely determines the fault location. The time, sign, length, and amplitude of the individual reflection pulses define the location, type, and severity of the deformity.

Cable crimps are made at known distances during installation to serve as references for distance along the cable. A schematic TDR installation (Dowding et al., 1989; O'Connor and Dowding, 1984) is shown in Fig. 10.3.25. A readout instrument is shown in Fig. 10.3.26. Some results in which the TDR technique was used to monitor caving over a coal longwall face (Wade and Conroy, 1980) are shown in Fig. 10.3.27. Obviously, the technique can be used to monitor rock slopes and even the development of caving in underground mines.

10.3.3 INSTRUMENTATION FOR UNDERGROUND MINING APPLICATIONS

10.3.3.1 Introduction

Underground mining systems in the future will be based upon four fundamental concepts:



SCHEMATIC TDR INSTALLATION

Fig. 10.3.25. Time-domain reflectometry installation (after Dowding et al., 1989).

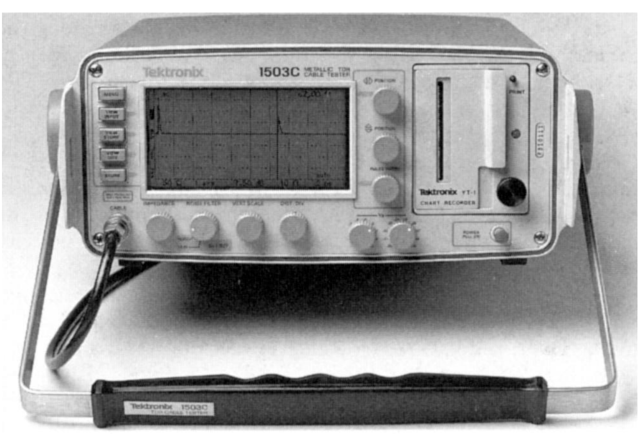


Fig. 10.3.26. Readout device for TDR (*courtesy:* Tektronix).

1. Low specific development.
2. High degree of automation.
3. High level of equipment utilization and availability.
4. Minimum time lag between development and production.

In order to achieve these objectives, a much greater emphasis and level of responsibility than in the past will be placed on mine engineering, and particularly on the mine design component. The engineering of underground openings requires a knowledge

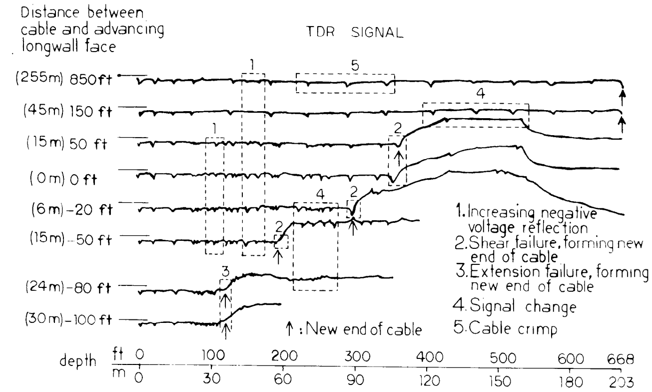

Fig. 10.3.27. Results from TDR monitoring of a longwall (after Wade et al., 1980).

of rock mass properties, the in situ stress state, the interaction between the rock mass and various stabilizing elements, etc. As in surface mining, instrumentation plays an important role in

1. Developing the basic underground design.
2. Developing design improvements.
3. Short- and long-term design monitoring.

Advances in underground mining have tended to outstrip the state of the art in the prediction of geologic conditions and rock behavior. It has often been necessary to evaluate conditions as they are encountered, and adjust mining procedures accordingly. It is in this area of timely identification and evaluation of unforeseen rock and soil mass conditions that field instrumentation can help improve both the safety and economy of underground mine.

Mining instrumentation involves measurements to (1) observe the behavior, and hopefully the stabilization, of geologic masses disturbed by operation, (2) evaluate the effectiveness and efficiency of support systems and structure designs, (3) provide early detection of hazards, (4) indicate remedial action for hazards, and (5) indicate the effectiveness of remedial measures. The measurements are typically of stress, load, pressure, strain, and displacement.

Measurements (Bauer, 1985; Boisen, 1990; Dunnicliff, 1988; Franklin, 1977) can be made on exposed surfaces of structures or masses, in drillholes, at interfaces, between surfaces (tunnel walls, roof/floor), and internally, typically in structures. Measurements distributed over an entire mass or structure are preferable to those at isolated locations or test sections. Instruments should be selected and distributed to provide a reasonable degree of data redundancy so that important interpretations are not made on the basis of single measurements. Other important considerations are that sample distribution and redundancy be achievable even under the conditions of limited site accessibility that are typical of most field locations, and that costs be tolerable.

Achieving any rational basis for designing an underground opening or system of openings requires knowledge of both the mechanical properties and the state of stress in the surrounding rock. This information, together with knowledge of the deformations produced by or following excavation, are essential for evaluating the stability of underground openings in rock. The development of instrumentation and procedures for measuring rock properties, the state of stress, and structural deformations has been the subject of many investigations. Some of the instruments and more generally accepted procedures are described in the following.

10.3.3.2 Absolute Stress Measurements

Over the years, a number of different techniques (Obert, 1962; Aggson and Hooker, 1982; Dunnicliff, 1988) for determining the state of stress in the ground have been developed. Under ideal conditions, many will give satisfactory results. Unfortunately, many mining applications are far from ideal, and hence the results obtained are commensurate. Even under the best circumstances, successful stress determinations require careful instrument installation and interpretation by experienced people. Available space allows no more than a brief introduction to some of the methods. The Commission on Stress Measurements of the International Society of Rock Mechanics has prepared detailed materials regarding the major techniques (Anon., 1987a).

When considering which of the stress determination techniques is best suited to a particular site or problem under investigation, attention should be given to the following selection factors: (1) the soundness of the theoretical basis of each of the available methods; (2) the limitations, practicability, or ease of use of each of the available methods in the particular situation; and (3) the direct cost of equipment and the time required (Aggson and Hooker, 1982). These three factors cannot be considered independently. For example, the rate at which data can be gathered using a particular method must be considered when evaluating both the second and third selection factors. Data are usually obtained at a slower rate when using techniques that require the use of epoxy or grout. Trade-offs between the various selection factors must also be considered. However, if stress information is a necessity, reliability of results should be a prime consideration (Aggson, 1972).

Hydraulic Fracturing: The hydraulic fracturing method of rock stress determination was first demonstrated in 1957 (Hubbert and Willis, 1957). Since then, numerous investigators (Haimson 1974, 1977, 1988; Kehle, 1964; Ljunggren, 1990) have examined hydraulic fracturing as a means of in situ rock stress determination. This method of rock stress determination consists of sealing off a section of borehole with packers and then increasing the fluid pressure in the section of the hole until the surrounding rock is fractured (Fig. 10.3.28).

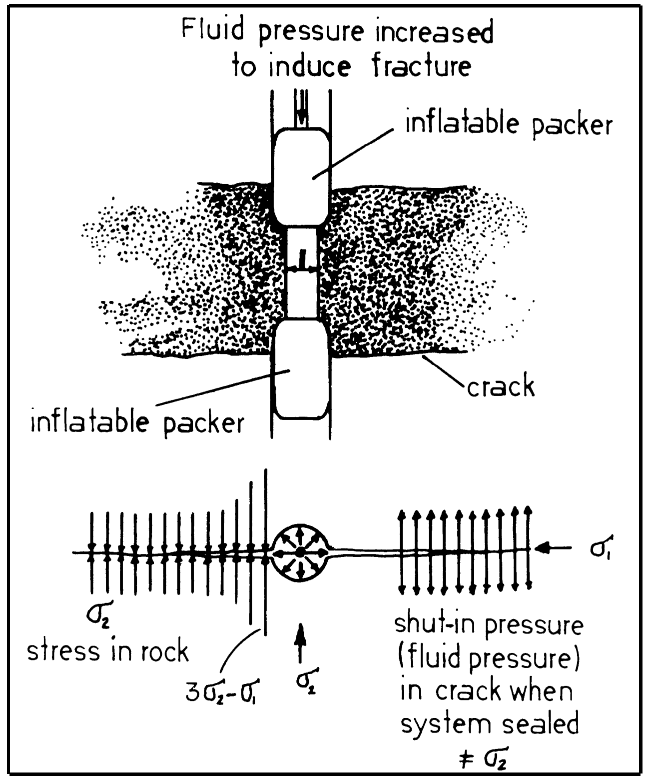

Fig. 10.3.28. Diagrammatic representation of hydraulic fracturing test (*courtesy:* Mindata).

The magnitude of the minor secondary principal stress component can be estimated directly from the shut-in pressure. The magnitude of the major secondary principal stress is calculated from relationships involving the crack initiation pressure, the crack reopening pressure, and the hydraulic fracture strength of the rock. The fracture strength can be determined from miniature hydraulic fracture tests carried out on the rock in question in the laboratory. The mini-frac equipment developed by the CSIRO (Anon., 1990d; Enever et al., 1989; Wold et al., 1989) is shown in Fig. 10.3.29.

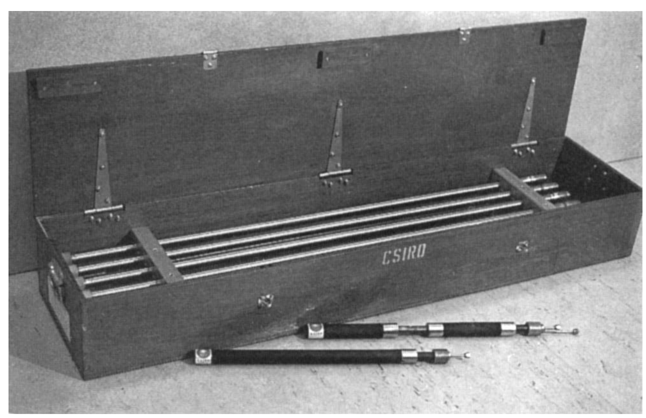

Fig. 10.3.29. Mini-frac equipment (*courtesy:* CSIRO).

An impression packer consisting of an inflatable element wrapped with a replaceable, soft rubber film can be used to determine the orientation of the fracture. This, in turn, gives the orientation of the major secondary principal stress in the plane normal to the hole axis. Recently there has been the commercial development of a small-diameter (1½-in. or 38-mm) cored-hole tool for mine use.

Because the hydraulic fracturing method of stress determination does not require some type of stress or strain relief by overcoring, this method is the only method that has been successful in deep (up to 6300 ft or 1920 m) boreholes (Haimson, 1974).

Borehole Deformation Gage: For many years, the most popular device for measuring in situ stresses has been the US Bureau of Mines (USBM) borehole deformation gage (Fig. 10.3.30) (Merrill and Peterson, 1961; Hooker et al., 1974; Hooker and Bickel, 1974; Bickel, 1985). This device consists of three pairs of strain-gaged cantilevers, each pair oriented at 120° to the next; these cantilevers are held within a sealed, stainless-steel housing, and their tips are deflected by means of tungsten-carbide-faced plungers.

The borehole gage is inserted inside an EX diamond drillhole so that the plungers are depressed. The initial deflection of the cantilevers is measured by connecting the signal cable to a conventional strain indicator readout box.

With the gage still in the EX borehole, a 6-in. (150-mm) concentric hole is drilled around the gage so that it is eventually isolated from the stressed rock mass inside a 5 5/8-in. (143-mm) diameter core about 12 in. (300 mm) long.

Fig. 10.3.30. USBM borehole deformation gage (*courtesy:* Geocon).

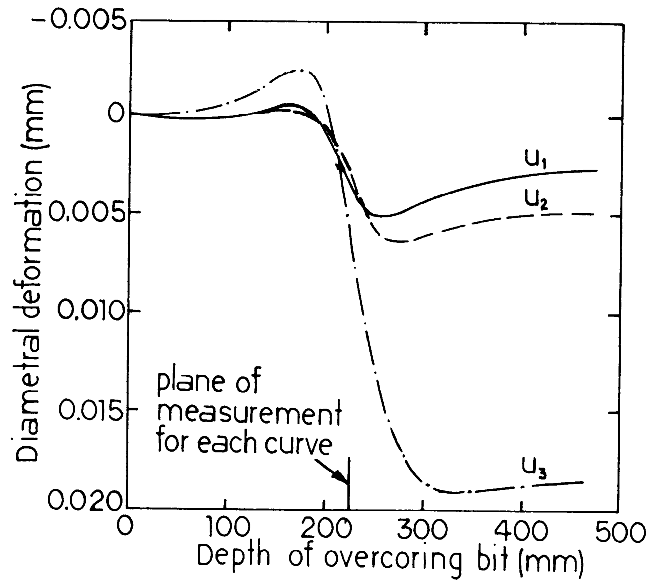

Fig. 10.3.31. Typical output from USBM gage (after Anon., 1987a). Conversion factor: 1 in. = 25.4 mm.

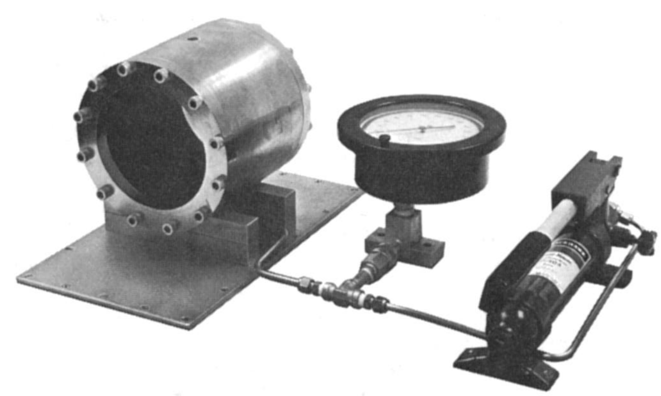

Fig. 10.3.32. Biaxial chamber for determining rock properties (*courtesy:* Geocon).

As this core is liberated from the stress field, it expands, and the resultant change in the diameter of the EX hole is measured by the strain-gaged cantilevers. Fig. 10.3.31 is a typical output.

After each overcore, the core is removed from the hole and placed inside a biaxial chamber (Fig. 10.3.32). This chamber incorporates a neoprene membrane that permits a hydraulic pressure to be exerted radially on the rock core while the resultant change in the EX borehole diameter is once again measured by means of the borehole gage. The stress/strain relationship so measured is used to calculate the elastic modulus of the rock, which then permits the rock stress to be computed from the strains measured during overcoring.

This procedure, repeated in three differently oriented boreholes, permits the magnitude and direction of the three principal stresses of the three dimensional state of stress to be calculated using an appropriate computer program.

In rock that tends to fracture easily, "disk," or "poker chip" during overcoring, the borehole gage can be modified by replacing the standard housing with a "reverse case" that allows the

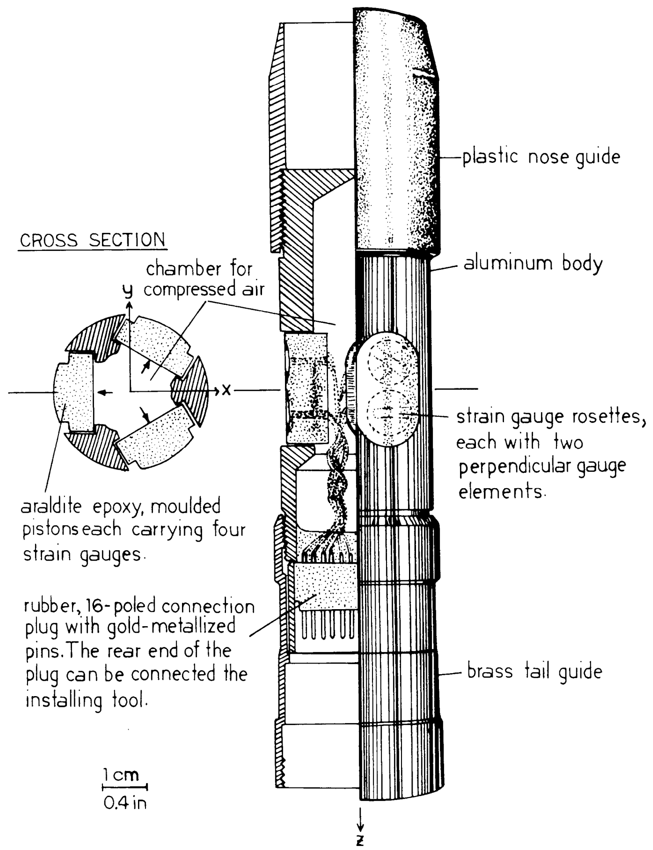

Fig. 10.3.33. Cross section through LuH cell (after Stillborg and Leijon, 1982).

Fig. 10.3.34. LuH cell (*courtesy:* Leijon, 1990).

cantilever plungers to be positioned very close to the start of the EX hole.

A calibration jig is available for periodic checks on the stability of the gage calibration.

CSIR Triaxial Strain Cell: The South African Council for Scientific and Industrial Research (CSIR) has developed a gage that can be used to obtain the complete stress tensor at one point in a borehole (Leeman 1964, 1969a, 1969b; Van Heerden, 1976). The triaxial strain cell consists of three groups of three strain gages mounted on the circumference of a tubular body.

A 1 l/2-in. (38-mm) diameter pilot hole is drilled and the gages glued directly to the borehole wall using a special positioning/installing tool. After the cement has dried, the initial strain readings are taken. The installing tool is then removed from the hole. After overcoring is completed, the installing tool is reconnected, and the new strains are read. The core, together with the included gage, is removed from the hole and placed in a biaxial chamber. From the pressure-strain readings, the elastic properties can be determined.

The strain changes induced by overcoring and the elastic properties of the rock are used to calculate the complete in situ state of stress from overcoring.

LuH Cell: Researchers at the University of Lulea (LuH) in Northern Sweden have made a number of improvements to the original CSIR triaxial strain cell (Stillborg and Leijon, 1982). Strain gages are attached to movable pistons contained in the body of the cell (Figs. 10.3.33 and 10.3.34). A rapid-setting cement is applied to the gages, and the cell is inserted in a small-diameter pilot hole. When the correct location and orientation is obtained, compressed air is used to force the pistons against the wall of the hole. After the cement has dried, initial strain readings are taken and the installing tool removed. The cell is then overcored and the resulting core removed from the hole. The installing tool is reattached and final strain readings are taken. The data acquisition system contains a computer which calculates the stresses from the measured strain changes. Elastic properties are determined using the biaxial chamber.

CSIRO Hollow Inclusion Cell: The "Hollow Inclusion" (HI) stress gage developed by the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO) can also be used to determine the complete stress tensor at a measuring site (Worotnicki and Walton, 1976; Walton, 1980).

The CSIRO cell incorporates nine (or twelve) strain gages in three rosettes (Fig. 10.3.35) encased within an epoxy shell attached to a 12-core readout cable.

The cell is grouted into a borehole and overcored.

Fig. 10.3.36 shows typical output from a good test. The retrieved core containing the cell is placed in a biaxial chamber. From the resulting strains the elastic properties can be calculated. The strain gage results and rock material properties are processed by computer to provide principal stress magnitudes and orientations plus resolved vertical and horizontal stresses and relevant statistical information.

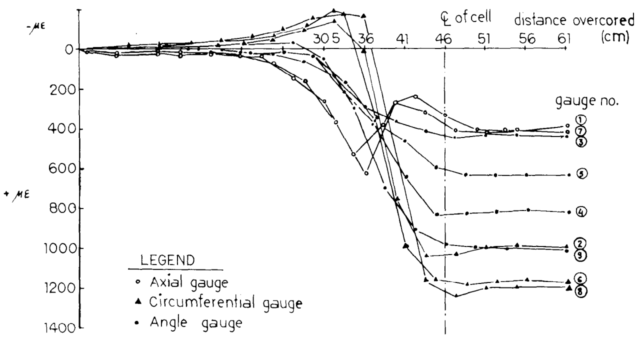

Fig. 10.3.36. Typical output from HI cell (after Walton, 1980). Conversion factor: 1 in. = 2.54 cm.

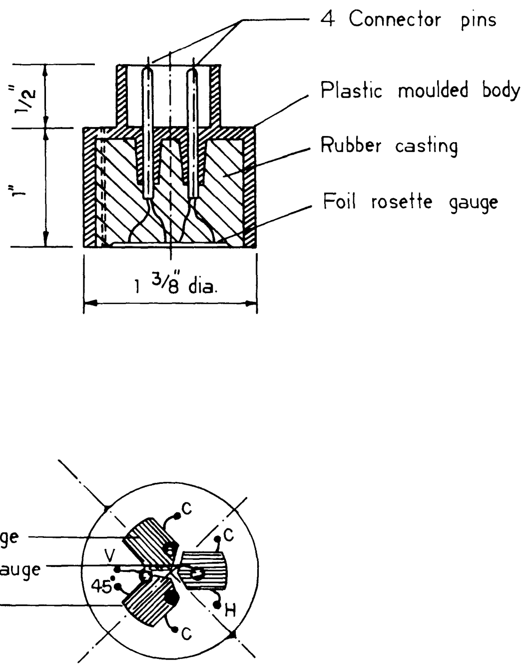

Fig. 10.3.37. Diagrammatic view of doorstopper (after Anon., 1966).

Doorstopper: The South African CSIR has also developed a device that has come to be known as the "doorstopper" (Leeman, 1964, 1969a, 1969b). It consists of a strain gage rosette potted in the base of a low-modulus cylindrical solid (Fig. 10.3.37 and 10.3.38). The doorstopper is glued to the end of a borehole that has been ground flat and smooth with a flat-faced, diamond-impregnated bit (Fig. 10.3.39). Strain readings taken before and after overcoring give a measure of the stress relief. The in situ state of stress within the rock mass is related to the stress relief measured at the end of the borehole through the use of stress concentration factors. Elastic properties (Young's modulus and Poisson's ratio) of the rock are used together with the overcoring data to calculate the stress. Readings in three boreholes are required to calculate the complete three dimensional stress field.

Flatjacks: The flat-jack method of rock stress determination was first described in 1952 by Habid and Marchand. This method basically consists of first installing strain devices oriented to measure in the line of intended stress determination (Merrill et al., 1964; Panek and Stock, 1964). An initial strain reading is made. A slot is cut between the strain gages, and a thin hydraulic cell called a flat jack is grouted into the slot. After the grout has cured, the flat jack is pressurized to a value such that the strain gages indicate their initial value. The flat-jack pressure is then considered to be equal to the rock stress that existed normal to the plane of the flat jack before the slot was cut. The flat-jack technique has the disadvantage of being limited to measurements near the surface of an underground opening and thus influenced by the geometry of the opening and resulting stress concentrations. However, it has the advantage of not requiring a knowledge of the elastic properties of the rock. The averaging effect due to the comparatively large area of the flat jack can also be a significant advantage. This method can be used in highly stressed

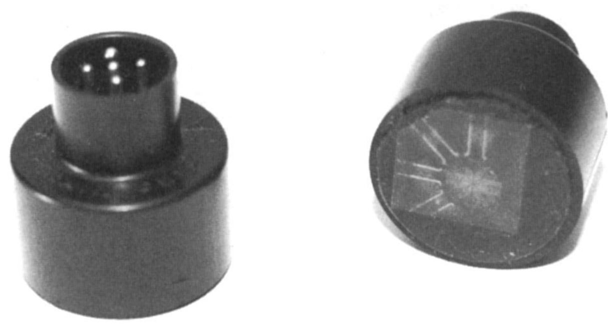

Fig. 10.3.38. Doorstopper (*courtesy;* Roctest).

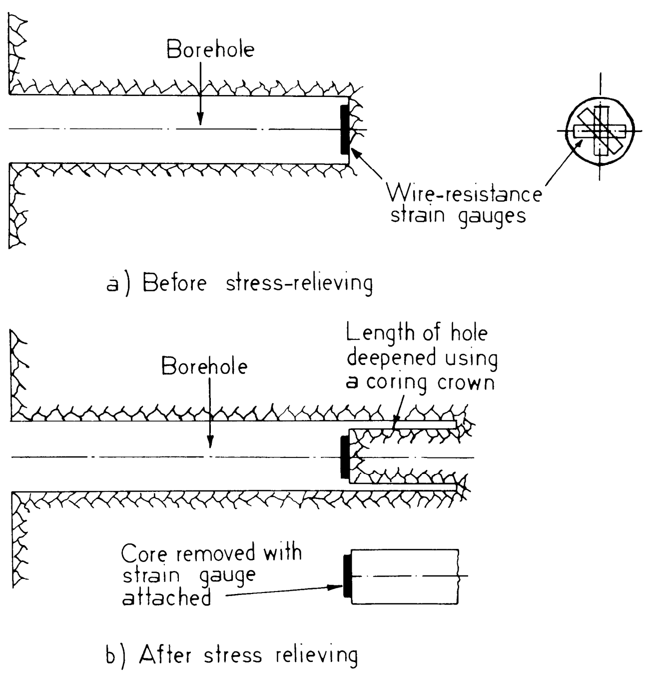

Fig. 10.3.39. Overcoring of doorstopper (after Leeman 1969a, 1969b).

areas or rock in which poor core recovery would eliminate those methods that require drill core recovery.

Core Disking (Aggson, 1982): The phenomenon known as core disking may be used to infer in situ rock stress magnitude. Core disking is the formation of disks or wafers of relatively uniform thickness that fracture or rupture on the surface approximately normal to the axis of the drill core. Usually, the surfaces of the disks are concave-convex, with the concave side toward the collar of the hole. Core disking is independent of core diameter and has been observed in drill cores 5 ft (1.5 m) in diameter down to less than 1 in. (25 mm). The presence of a center hole in the core, such as would be required for overcoring, does not influence the disking process.

Core disking, often called "poker chipping" by diamond drillers, occurs when the in situ stress field is high in relation to the strength properties of the rock involved. The relationships between the in situ stress field, the strength properties of the rock, and the stress concentrations caused by the borehole and the kerf of the drilling bit are rather complex. However, laboratory investigations (Obert and Stephenson, 1965), modeling studies (Durelli, Obert, and Parks, 1968), and field observations (Hooker, Bickel, and Aggson, 1972) have provided various relationships that allow estimation of the stress field magnitudes.

The drill core from a vertical hole near the earth's surface or from an underground borehole near the opening from which it is drilled will disk if the average compressive stress in the plane normal to the borehole is approximately equal to one-half of the unconfined compressive strength of the rock. At this threshold stress level, the thickness of the disks that are formed will be roughly one-fourth of the core diameter. As the magnitude of the stress field increases above the threshold stress, the disks will become thinner (shorter in the axial direction). At yet higher stress levels, the disks become very thin and may have sharp edges. Empirical relationships have been developed that allow stress field estimation from rock strength parameters and disking that occurs in deep holes under triaxial loading conditions (Obert and Stephenson, 1965). Core disking, when observed in exploration holes from the surface or in drillholes underground, should be taken as an indication that stress levels are high relative to rock strength and that ground control problems may be anticipated.

Explosive Fracturing (Aggson, 1982): The orientation of the maximum and minimum normal compressive stress in rock can be determined near a rock surface without the need of absolute stress measurement by one of the methods described previously. This can be done by drilling a hole to a depth that is below the critical crater depth and then detonating an explosive charge in the borehole. If the stress field components are of a biaxial nature, a fracture will propagate in the direction of the maximum normal compressive stress. The direction of fracture propagation is determined by the principle of least work. This process has been shown consistently to produce fractures that are in line with the measured maximum compressive stress (Hooker, Nicholls, and Duvall, 1964).

10.3.3.3 Stress Change Measurement

Investigations into the stability of underground structures often require the evaluation of stress changes. Stress change measurements are easier to perform than absolute measurements since overcoring is not required. They are often more difficult to interpret, however, due to uncertainties regarding rock properties. All of the techniques described under the heading of "absolute stress determination" can be used for examining stress changes (Myrvang and Hansen, 1990). The borehole deformation gage, for example, can be placed in a borehole, and as stress conditions change, the change in shape of the borehole, as measured by the gage, can be used to directly calculate stress change in the plane normal to the hole. Specialized instrumentation and techniques have been developed that are intended for use in those situations where stress change is of concern.

Borehole Pressure Cells (Sellers, 1990): Hydraulic borehole pressure cells have been in use for many years for the measurement of rock stress changes in both elastic and viscoelastic (i.e., plastic) rock types. A great deal of the development and use was a result of efforts made by the US Bureau of Mines (Panek, 1961).

The standard borehole pressure cell (BPC) is manufactured from two steel plates welded together around their periphery. The plates are deformed into a "dogbone" configuration so that they can be expanded easily without damage to the welds (Fig. 10.3.40).

The space between the two plates is filled with deaired antifreeze solution and is connected via a high-pressure stainless

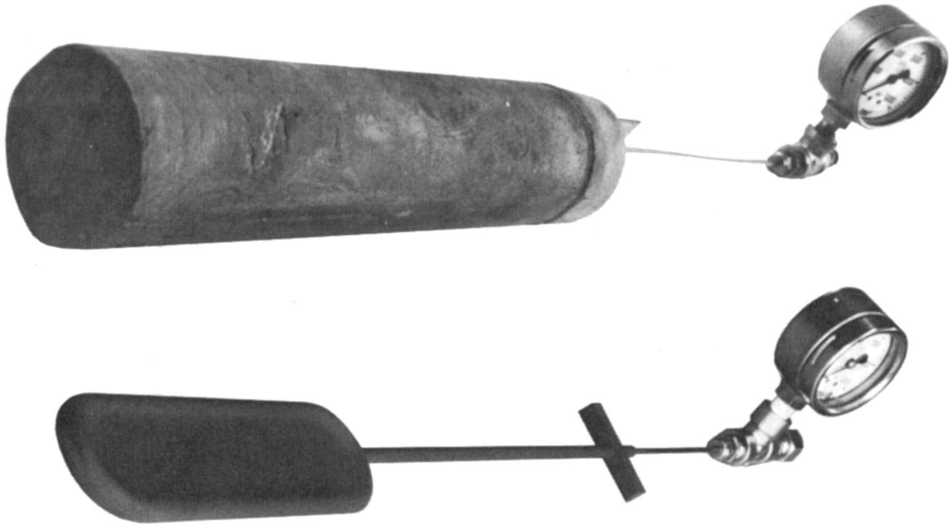

Fig. 10.3.40. Borehole pressure cell (*courtesy:* Geocon).

steel tube to a stainless steel pressure gage and/or a pressure transducer.

In use, the BPC is grouted inside a borehole drilled into the rock. The BPC is either pushed into a hole already filled with grout or grout is pumped in after the BPC has been positioned.

Alternatively, the BPC may be preencapsulated inside a cylinder of mortar of such size to permit it to slide inside the borehole and then to fit snugly when the BPC is pumped up.

Usually the BPC is pumped up until the initial hydraulic pressure is equal to the estimated rock stress. In elastic rocks, the relationship between observed fluid pressure change (as shown by the pressure gage) and the actual rock stress change can be calculated if a special pressurization technique is used and the elastic modulus of the rock is known (Sellers, 1970).

The BPC, because of its flat configuration, responds mainly to stresses acting at right angles to its plane. It is only slightly sensitive (about 6%) to stresses acting in the plane of the BPC.

In strongly biaxial stress fields, two BPCs oriented at right angles to each other in the same borehole will enable the principal stresses in the plane perpendicular to the borehole to be analyzed. In rocks which exhibit plastic creep, such as salt, potash, trona, etc., the BPC will measure not only rock stress changes but will also measure the actual in situ stress.

Vibrating Wire Stressmeter (Sellers, 1990): The stressmeter (Hawkes and Bailey, 1973; Hawkes and Hooker, 1974) consists essentially of a high-strength steel proving ring wedged tightly across one diameter inside a borehole drilled into the rock (Fig. 10.3.41). The distortion of the proving ring, caused by changing rock stresses, is measured by means of a vibrating wire that is tensioned across another diameter. Changes in rock stress cause changes in the resonant frequency of vibration of the tensioned wire. The two are related by means of calibration data supplied with each stressmeter.

The stressmeter is installed in boreholes up to 100 ft (30 m) long by means of a setting tool that is used to drive a wedge so that a platen is expanded against the side of the borehole (Fig. 10.3.42). Although diamond drillholes are preferable, those drilled percussively can be used. They should have their walls smoothed by incorporating a reaming shell with the bit.

The stressmeter behaves as a rigid inclusion in that the calibration varies by only a factor of 2 if the rock modulus varies

Fig. 10.3.41. Vibrating wire gage (*courtesy:* Geocon).

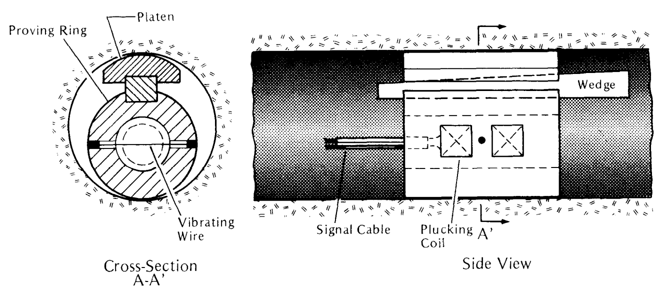

Fig. 10.3.42. Cross-section through vibrating wire gage (*courtesy:* Geocon).

by a factor of 10. The relationship between calibration factor and rock modulus is provided by the manufacturer. A thermistor can be incorporated in the stressmeter if temperatures are to be measured.

Several stressmeters can be installed in the same hole when both magnitude and orientation of the stress changes are re-

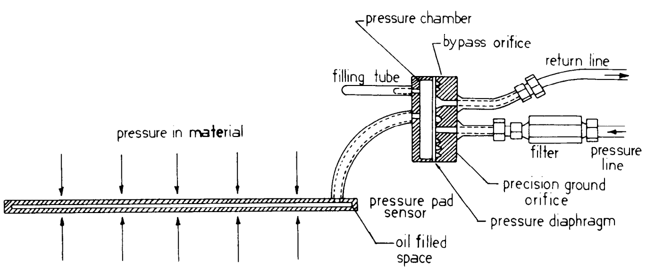

Fig. 10.3.43. Cross section through Glöztl cell (*courtesy:* Slope Indicator Co.).

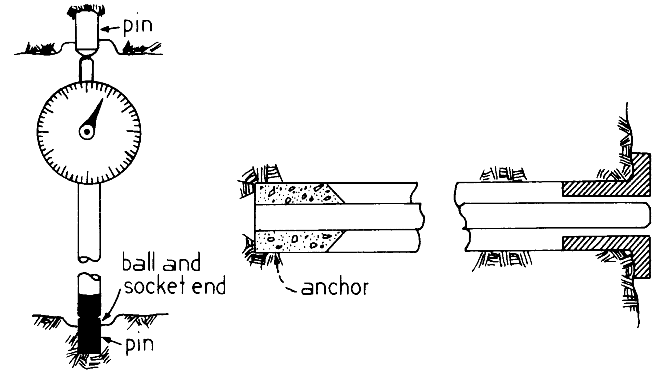

Fig. 10.3.44. Tube extensometer setup (after Obert, 1973).

quired. Special gages incorporating multiple vibrating wire sensors in one body are also available.

Glötzl-Type Pressure Cells: In underground mining, there are a number of applications in which it is of interest to measure ground pressure. Hydraulic-cemented rock fills are important ground control components in several mining systems. Although fill pressures can be measured using several different techniques, one of the most common devices is the Glötzl cell shown diagrammatically in Fig. 10.3.43.

All Glötzl cells utilize a unique bypass valve assembly which permits the isolation of the sensing system of the various cells from the measuring (readout) medium. Separating sensing and readout circuitry allows control of the sensing component characteristics to provide maximum response in diverse material types and applications.

The bypass valve's primary components are a stiff metal plate and a synthetic seal that is essentially undeformable. The plate supports the seal to create a diaphragm, which is loaded by pressure transmitted by the sensing system. When loaded, the diaphragm prevents circulation between the two sides (input line and return line) of the measuring system until the pressure introduced into the input line is sufficient to exceed the load pressure. When this slight excess pressure is reached, the diaphragm lifts slightly, permitting the measuring medium to circulate into the return line. The diaphragm will close the input-return line circuit at a pressure very closely approximating the pressure in the sensing system. Initial diaphragm lift approximates 5 µm, and the final pressure determination is made at a lift which approaches zero.

Glötzl earth pressure cells feature a standard thickness-to-width ratio of approximately 0.05.

Cells for the measurement of earth pressures are filled with oil, while those for the measurement of concrete stresses are filled with mercury. This ensures that the modulus of the cell assembly is higher than the modulus of the material surrounding the cell. The characteristics of the pad and the interaction of the pad and bypass valve assembly are such that the cell acts as a rigid inclusion in the pressure medium and thus responds directly to pressure changes in the medium.

The satisfactory operation of Glötzl cells requires that they be installed in a manner that (1) fully and continuously exposes them to material typical of the pressure medium, and (2) does not appreciably modify load or pressure conditions typical of the medium.

When in use, cells may be imbedded directly in the material in which measurements are to be made. In coarse fill, imbedment in a lens of finer-grained material allows proper load distribution of the measuring surfaces. Generally, the diameter of the largest grain bearing directly on the measuring surface should be 1/10 or less of the minimum plane dimension (length or width) of the cell.

Earth pressure cells may be installed in any attitude. They may also be installed in oriented arrays to provide data for complex pressure envelope analysis.

Readout facilities are usually remote from the cell locations, the cells being connected to the readout instrument by means of hydraulic tubes extending from the cell locations to the readout enclosure. The tube array for one Glötzl cell comprises an individual pressure (input) tube, and a zero pressure discharge (return) tube that may be shared in common by a number of cells.

This same principle has been used in pore water pressure cells and concrete stress cells.

10.3.3.4 Displacement Measurements/ Deformation Measurements

The deformeters described here are used for measuring both relative and absolute deformations produced by excavation, for example, roof-floor convergence, deformations in the walls, or structural parts of a mine. Included are optical levels and theodolites, as they can be used for deformation measurements over large distances.

Roof-Floor Convergence: *Tube Extensometer*—The tube extensometer (Haas, 1982; Obert, 1973) consists of telescoping tubes, a dial indicator, and contact seats on each end to measure the change in distance between anchor points in the roof and floor (Fig. 10.3.44). An initial zero reading is taken. Subsequent readings are taken at daily, weekly, or monthly intervals. The difference between one of the subsequent readings and the zero reading is the convergence during the intervening time period.

The indicator accuracy is approximately 0.001 in. (0.025 mm). The overall length of the telescoping tube is typically adjusted in l-ft (0.3-m) and l-in. (25-mm) increments by tapered pins that fit into a series of precisely spaced holes in the tubes. Instruments are available with measurement lengths of 3 to 6 ft (0.9 to 1.8 m), 6 to 11 ft (1.8 to 3.4 m), 11 to 17 ft (3.4 to 5.2 m), and 17 to 25 ft (5.2 to 7.6 m). Threaded hemispherical contact seats may be threaded into holes tapped into the heads of mine roof bolts, which results in an inexpensive anchor station. Floor stations must be protected by a pipe to prevent loose rock from contacting the sides of the bolt. The floor anchor points must be in solid rock or else the readings will be affected by movements of the floor due to subsequent blasting vibrations and possible movements of mine equipment near the station.

A necessary accessory for the tube extensometer is the master bar. The master bar is made of the same material as is the tube extensometer and is used as a reference standard against which the extensometer is checked periodically. The magnitudes of

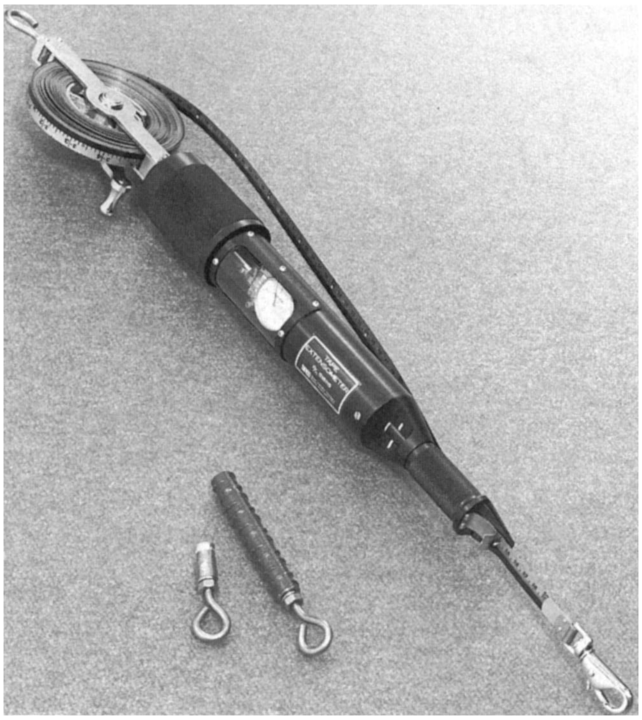

Fig. 10.3.45. Tape extensometer (*courtesy:* Slope Indicator Co.).

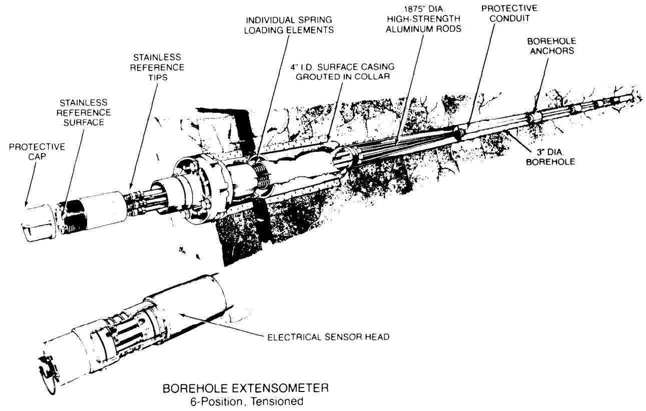
errors introduced by wear of the contact seats and tampering with the zero setting of the dial indicator are easily measured with the master bar. Errors due to temperature are not determined with the master bar, however. A thermometer on the side of the extensometer should be read at each measurement location in the mine. A temperature correction can then be made if necessary.

The two principal applications of the tube extensometer in underground mining are (1) to measure the convergence between roof and floor as a function of time (rate of convergence gives an indication of stability and instability of the roof), and (2) to measure separations between roof layers by placing anchors at several horizons in the roof.

While these two applications appear quite simple in concept, the technique gives reliable data that are easy for the mine engineer to interpret. Increasing rates of convergence or bed separation give warning of an approaching unstable condition so that preventive action may be taken to stabilize or withdraw from an area. On the other hand, convergence data showing little or no change between readings give some assurance that the opening will remain stable.

Tape Extensometer—The tape extensometer is a portable instrument which is hand-held while making readings (Fig. 10.3.45). It uses a steel engineer's tape with punched holes to measure changes in distance between two points with precision and speed. Measurements are made in any direction—vertical to horizontal—between the two reference points. The changes in distance between these two points over a period of time can be monitored with accuracy, reliability, and repeatability. These features are important to an instrumentation program measuring relative convergence of tunnels, mine roof sag, deformations in excavations and structures, or ground movements.

Tape tension is controlled by means of a compression spring. To adjust the tape tension, the knurled collar is rotated until the scribed lines are precisely aligned. This alignment causes a known force to be exerted on the tape.



Multiple Position Borehole Extensometer

Fig. 10.3.46. Components of borehole extensometer system (after Boisen, 1982).

The dial caliper often used as a readout has a resolution of 0.001 in. (or 0.025 mm).

The alignment and positioning of the anchor points for tape extensometer measurements are not critical. The hook fittings on the tape extensometer are not affected by the direction angle of the tape, or the positioning of the anchor.

Borehole Extensometers: *Mechanical Extensometer*—Measurement of rock deformation is essential to stability and behavioral monitoring of underground openings. The difficulties of obtaining adequate sample distribution, density, and orientation can frequently be overcome by the use of single- and multiple-position borehole extensometers (Boisen, 1982; Anon., 1978a; Windsor et al., 1987).

In its simplest form, a borehole extensometer consists of an instrument head, usually anchored in the collar of a borehole, and a number of in-hole anchors, each of which is fixed in place at a known distance from the collar. As rock adjacent to the borehole deforms, the component parallel to the borehole direction causes a distance change between adjacent in-hole anchors, as well as a distance change between individual anchors and the instrument head. These changes are measured by means of a mechanical link (usually wire or rod) extending to the instrument head from each anchor. The resulting data can be used to compute the distribution, magnitude, rate, and acceleration of deformation in the material intersected by the extensometer's borehole.

Borehole extensometers are made up of at least the following five principal components (Fig. 10.3.46): the instrument head, the collar anchor assembly, the downhole system of anchors and rods or wires, the signal cable if the head is equipped for electronic readout, and the readout apparatus, whether mechanical or electronic.

Extensometers are designed to measure axial strain components in the instrumented drillhole. As the drillhole is axially deformed, the distances between individual down-hole anchors and the instrument head change, as do the distances between adjacent anchors. The distance changes measured by a multiple position borehole extensometer, for example, are reduced to functions of time, hole depth, anchor position, or other parameters of significance in terms of the structure under investigation.

In order to establish an optimum plane of reference, the boreholes should be long enough to extend into rock zones (Fig.

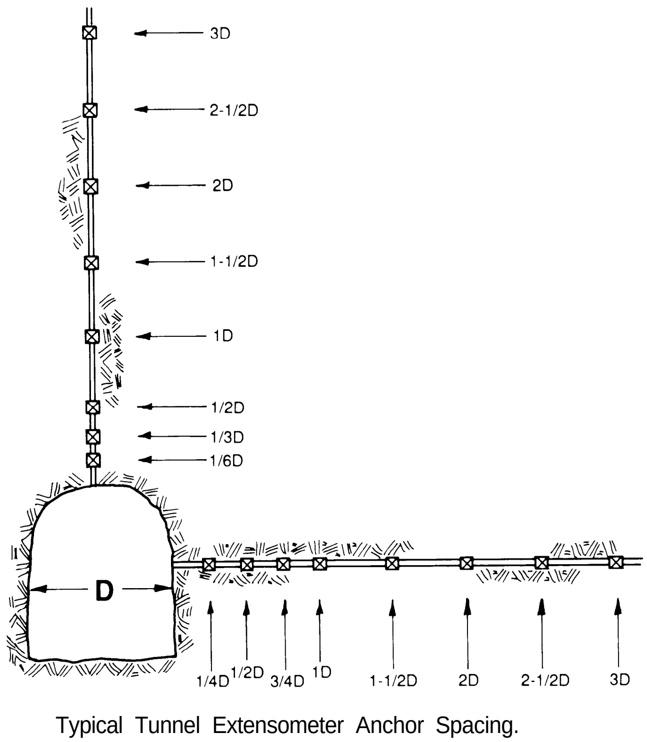


Fig. 10.3.47. Borehole extensometer anchor layout (after Boisen, 1982).

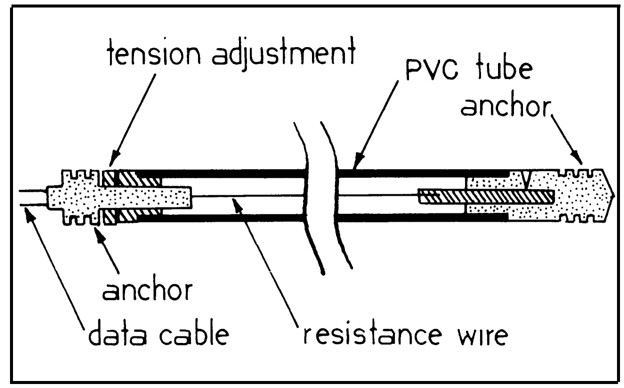

Fig. 10.3.48. Diagrammatic representation of resistance wire extensometer (*courtesy:* Carlson/RST).

10.3.47) in which the stress field is in an original state (i.e., where the stress field is relatively unaffected by the presence of the structure). Assuming that one or more of the deepest down-hole anchors is in substantially stable ground, the instrument head is analogous to a yo yo moving up and down, and in or out, at the end of a wire or rod fixed in place at a stable anchor. For interpretive purposes, the stable anchor occupies a point that is fixed, or relatively fixed, in space, and in relation to which the instrument head is displaced. The shallower anchors, on the other hand, are located in rock zones exhibiting varying degrees of instability, and may themselves be undergoing displacement at varying rates and in varying directions, relative to the instrument head, the stable anchor, and adjacent anchors. An analysis of the reduced data permits the identification of zones that are undergoing strain at varying rates and in varying directions in relation to the structure, and the measurement of axial strain rates and magnitudes.

Since the equipment is designed to measure rock strain components acting in an axial direction with respect to the borehole, the boreholes should be oriented to measure axial components that are meaningful to the problem or structure under investigation. In tunnel instrumentation, the normal orientation is in a plane transverse to the long axis of the tunnel. In fault-zone and slide-plane instrumentation, holes may be oriented either transverse to the principal planes of movement to measure separation or at a small angle to the principal planes of movement to measure a component of translatory displacement.

Data processing may consist of the reduction of field data to indicate displacement of the instrument head relative to each down-hole anchor, the displacement of each down-hole anchor relative to the deepest anchor, and rock strain acceleration either between adjacent down-hole anchors (and between the shallowest down-hole anchor and the instrument head) or between the deepest down-hole anchor and the instrument head, etc.

Intermediate computation steps involve the calculation of anchor-anchor displacement and anchor-anchor strain. Other parameters, such as anchor-instrument head strain, anchor-instrument head strain rate, anchor-instrument head strain acceleration, and displacement of each anchor relative to the instrument head, may be calculated as required.

Resistance Wire Extensometer—A resistance wire extensometer (RWE) is a simple extensometer (Anon., 1990m) for monitoring rock movement (Fig. 10.3.48). It basically consists of an electrical resistance wire element situated inside a 3- to 6-ft (l- to 2-m) long, PVC hollow tube. The wire is attached, under mild tension, to each end of the tube and is configured to have a resistance of 120 ohms. Thus configured, the RWE can be monitored with a resistance meter, conventional strain gage measuring equipment, or a data logger. No additional displacement transducer is required to convert movement of the extensometer into a proportional electrical signal. An RWE is installed by grouting into a percussive- or diamond-drilled borehole. A number of RWEs can be installed end-to-end into a borehole by attaching them to a suitable carrier (such as PVC conduit) to facilitate installation. The resistance wire is pretensioned within the hollow tube enabling up to 0.5% compressional strain to be measured. However, up to 18 to 20% tensile strain can be measured, with high sensitivity. Due to the hollow tube construction, the RWE has low sensitivity to moderate displacements across a borehole.

Magnetic Extensometer—In this design (Fig. 10.3.49), ring magnets sliding on a central access tube and within a collapsible outer tube are fixed in the ground at locations where movement is to be monitored (Anon., 1990j). These magnets may be installed in a borehole or placed subsequently during construction of earth works. Location of the targets is accomplished by passing a reed switch probe through the access tube. When the probe enters the magnetic field generated by the target, an audible signal is emitted at ground level. Measurements made with a steel tape may then be related to any convenient datum. The targets are designed to move independently of the access tube and within the protection of the outer collapsible tube. Features of this type of extensometer are

1. Reliable, accurate, simple to install and read.
2. No limits to number of points that can be located in the one borehole, with little extra cost.
3. Can be extended simply.

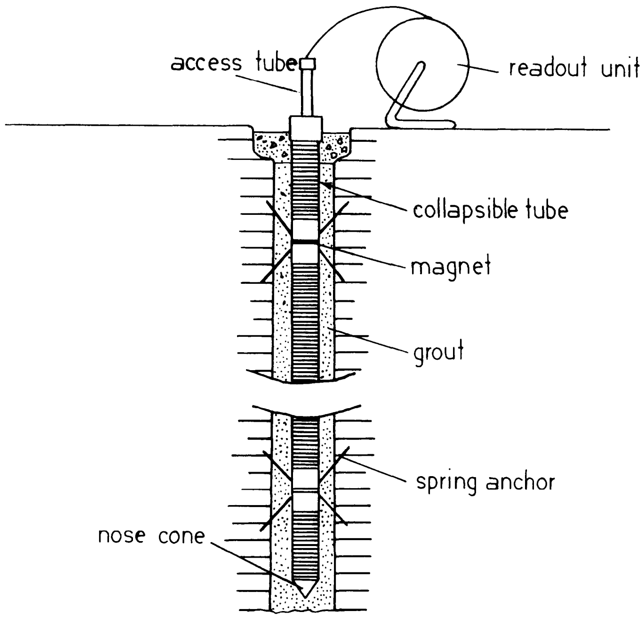

Fig. 10.3.49. Diagrammatic representation of magnetic extensometer (*courtesy:* Geotechnical Systems).

Fig. 10.3.50. Sonic probe extensometer (*courtesy:* Geocon).

4. Only one probe required for many installations.
5. Very economical.

Sonic Probe Extensometers—The advantage of sonic probe extensometers (Sellers, 1990) lies in their ability to provide electronic readout with maximum simplicity at minimum cost (Fig. 10.3.50). They are particularly suited to the measurement of rock movements around mines and underground openings.

Rigid sonic probe types use a portable sonic probe in the form of a "wand." The probe can be inserted into each extensometer head in turn to measure the relative position of a series of magnets attached to the ends of the measurement rods leading to each of the borehole anchors. A readout box, when connected to the probe, displays movements of the magnets. Various types of borehole anchors are available. The sonic probe may be left permanently in position for remote readout.

A probe 10, 20, or 25 ft (3, 6, or 7.5 m) long is inserted inside a guide tube that is located along the borehole axis and that passes through from 1 to 20 snap-ring, or hydraulic, borehole anchors. A magnet is located within each anchor. The position of each of the magnets relative to either the head of the extensometer, or to a neighboring anchor, is measured and displayed directly on the readout box.

The principle of the sonic probe relies on the magnetostrictive properties of the probe material. An electrical pulse in the probe creates a magnetic field that interacts with the field of a permanent magnet located either in a borehole anchor (flexible probe) or on the end of a rod attached to the borehole anchor (rigid probe). The change in the magnetic field generates, in the probe material, a torsional stress pulse that travels along the probe at the speed of sound. The arrival time of the stress pulse at the end of the probe is detected and becomes a measure of magnet position. Changes in position of as little as 0.001 in. (0.025 mm) can be detected. A switch determines whether movements are measured between each anchor and the mouth of the borehole or between each succeeding pair of anchors.

The maximum cable length between readout box and probe should not exceed 800 ft (244 m). Distances greater than this require the use of an in-line repeater to boost the signal.

Differential Sag Stations (Haas, 1982): The measurement system shown in Fig. 10.3.51 was developed by the Mine Safety and Health Administration (MSHA). Several spring anchors are installed at various depths in a single drillhole in the roof of the mine. Movement of the anchor is transmitted to the hole collar by a wire and is measured relative to the collar anchor. A 5-lb (2.3-kg) weight is used to keep the wire taut as the measurement is being taken. A dial indicator with 0.001-in. (0.025-mm) graduations measures between a brass button attached to the wire and a brass pipe cap secured to the anchored collar pipe. The system has the advantage of having several measurement points in one hole.

The two principal applications of the wire-type differential sag station in underground mining are

1. To measure strata separations in a mine roof as a function of time. Usually one anchor is placed quite deep, say 15 ft (4.6 m). Other anchors are placed at 2, 4, and 8 ft (0.6, 1.2, and 2.4 m), or as desired to span expected separation planes.

2. Measurement of roof deflection when, because of unstable floor conditions or vehicular traffic, one cannot install floor stations for use with a tube extensometer. In this application, the uppermost anchor should be placed above the zone of influence of the opening. The zone of influence above the opening normally extends a distance of at least one opening width.

Precision Leveling: Targets such as shown in Fig. 10.3.52 can be suspended from the roof of a drift on the ball-headed measuring bolts. This facilitates precision level surveys. If the same type of bolts are installed in the floor, the convergence surveys can also be run.

Stope and Drift Profilers: Over the past several years there have been some remarkable developments in surveying instruments (see Chapter 8.2) (Anon., 1989d; Anon., 1990e; Anon., 1990h; Anon., 1990i; Darling, 1988). Today there are instruments that can provide profiles of both drifts and stopes without the need for reflecting targets other than the rock wall itself. The obvious application is for improved mine surveying. However, as stope dimensions are increased, stability evaluation and control will require the use of such instruments on a routine basis. Stope roofs and pillar walls can be examined to determine their locations, dimensions, and gross deformations.

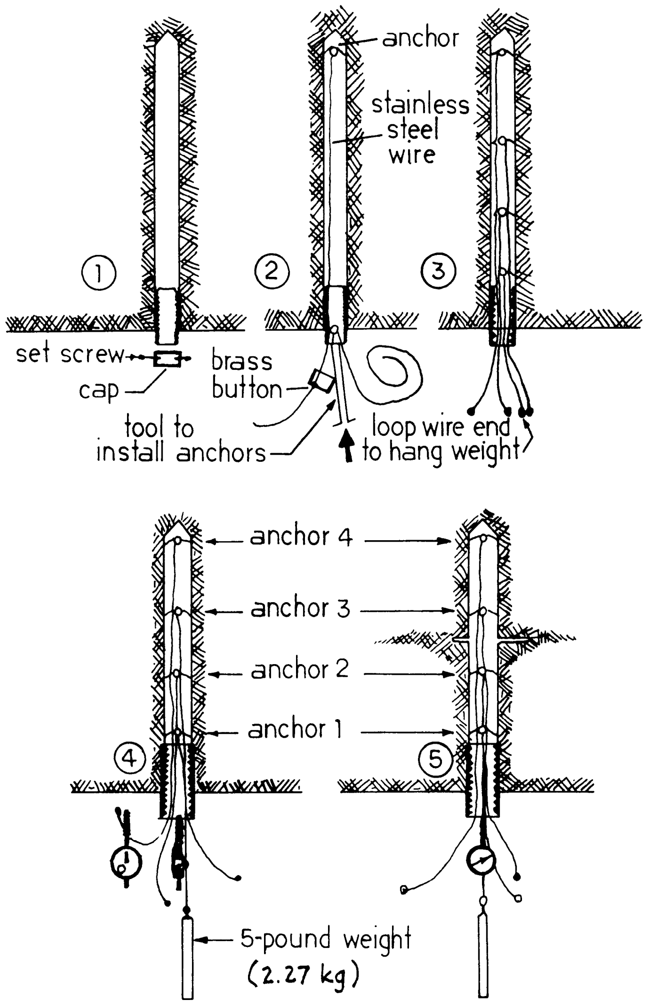

Fig. 10.3.51. Differential sag measurement system (after Haas, 1982).

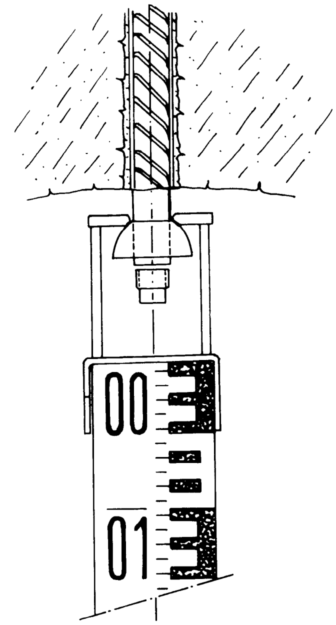

Fig. 10.3.52. Precision leveling (*courtesy:* Interfels).

Fig. 10.3.53. Distance measuring system using two laser beams (*courtesy:* Afgen).

In one technique, developed specifically for mine use (Anon., 1990e), two laser beams are emitted from the measuring unit. One beam is fixed and the other movable. The movable spot is adjusted to coincide with the fixed line at the point to be measured. The distance is read off from the instrument scale. By using the horizontal and vertical circles, outlines can be plotted.

The accuracy for this very inexpensive system, shown in Fig. 10.3.53, is dependent on the preset operating range. Some typical published values are given below:

Preset range		Typical accuracy at full range	
(ft)	(m)	(in.)	(mm)
1.5 to 15	0.5 to 5	±0.2	±5
3 to 30	1 to 10	±0.5	±10
6 to 60	2 to 20	±1.5	±40
10 to 100	3 to 30	±4	±100
15 to 150	5 to 50	±10	±250

Recent results for the 5- to 150-ft (5- to 50-m) range have suggested accuracies of the order of ± 1 in. (± 30 mm). For very rapid distance measurements, where the plotting facility is not required, the unit may be hung from a strap around the user's shoulders.

Other units of varying levels of sophistication and prices are available from several manufacturers.

10.3.3.5 Visual Inspection in Boreholes (Emmanuel, 1990)

There are several methods for visual examination of boreholes (Anon., 1990f; Anon., 1990g).

Fiberoptic Borescopes (Flexible): These instruments are manufactured in lengths to 200 ft (60 m). Some can be equipped to provide a scan capability at right angles to the shaft axis. These devices transport illuminating light to the distal or insertion end and present an image to the operator that is transmitted through a spatially correlated bundle of glass or quartz fibers. In the longer lengths, diameters generally run about 0.4 in. (10 mm). Cost of these devices typically runs between $500 and $1000/ft ($1500 to $3000/m).

The flexible fiber optic borescope is relatively portable, requiring only a light source as additional equipment. High-powered sources at about $3000 are recommended at long lengths, and cameras may be adapted to the eyepiece for recording purposes. Color video cameras are probably of marginal utility due to low light conditions at the eyepiece. Resolution is limited to the pixel count of the image bundle which is typically about 10,000. The instruments are relatively delicate and should not be torqued or kinked.

Video Borescopes (Flexible): Currently available instruments include devices of 0.25-in. (6-mm) diameter to lengths of 50 ft (15 m). These systems carry a charge-coupled-device sensor in the distal end that is sequentially illuminated with red, green, and blue reflection from the scene. This light is transmitted through the instrument shaft. The resulting fields are combined in a digital processor and presented as color video. Prices are typically about $1000/ft ($3000/m).

The video borescope typically offers improved resolution, over that of the fiberoptic technique, with 30,000 pixels a typical resolution. The optical path is very short, thus providing much greater latitude as regard lighting conditions. The video format permits all kinds of recording capabilities, and the video screen allows group observation. It is, however, both expensive and "high tech."

Geometric Borescopes (Rigid): The long-established rigid borescope technology, which transmits light through a carefully designed series of refractive (lens) elements, enables observation to depths of about 65 ft (20 m). These instruments are constructed in sections 3 to 5 ft (1.0 to 1.5 m) in length. Light is furnished by a halogen lamp which is carried in the head and powered through the body of the scope. They are relatively heavy, and unwieldy at long lengths. Cost is typically about $300/ft ($1000/m).

The rigid extendable borescope provides excellent resolution, is modest in cost, but is difficult to use at lengths exceeding the dimensions of the work space, since the operator must unscrew the assembly to add additional 3- to 5-ft (1.0- to 1.5-m) extension sections. Lighting tends to become a problem with added length as the losses increase with the addition of every lens section. This may make it extremely difficult to recover data in video format.

Direct Video Imaging: The current generation of commercially available remote head video cameras has permitted the construction of direct imaging color video systems that easily operate up to insertion depths of about 100 ft (30 m). Units with head diameters of 1.10 in. (28 mm), remote focus, remotely controlled lighting, and a remotely switchable directions of view (forward and side) have been provided. Cost (for a 100-ft, or 30-m, system) is about $300/ft ($1,000/m). Longer reaches are attainable for small incremental cost increases; shorter lengths do not change significantly from the 100-ft (30-m) baseline numbers.

Direct video imaging offers an excellent compromise in all characteristics, since resolution is typically about 330 to 350 thousand pixels (400 line horizontal resolution), insertion depth is limited by cable length, which is comfortable at 100 ft (30 m) and may, with current technology, extend to twice that distance. Much longer distances are possible but require different transmission approaches if the system is constrained to fit the 1 l/4-in. (32-mm) borehole. Care must be taken with the cable since it is a complex assembly. The system shown in Fig. 10.3.54 features an environmentally sealed 1.1-in. (28-mm)-diameter optical head with remote focus and light control supported by a 100-ft (30-m) cable.

10.3.3.6 Microseismic Monitoring (Brady, 1990)

Literally, a microseism is a "small earthquake." (The word is derived from the Greek words "micros," meaning small, and "seismos," meaning earthquake.) As detected in a mine, a microseism is sometimes an audible, sometimes subaudible, noise resulting from vibrations introduced into the mine structure by rock fracturing or by slippage along preexisting planes of weakness (joints, faults) in the rock mass.

The microseismic method to detect regions of structural instability and high-stress zones in underground mines was developed in the early 1940s by the USBM. Since that time, the microseismic method has been improved upon and it has been used throughout the world by mining and construction companies as well as by governments in assessing the stability of underground and surface excavations (Blake, 1982; Leighton, 1982; McMahon, 1988).

Microseisms or acoustic emissions are readily detected in mines by securely attaching velocity gages or accelerometers to the rock mass surrounding the area of interest within the mine. These are transducers that "listen" for rock vibrations, and they are known as "geophones." Acoustic vibrations travel through the mine at the speed of sound in rock, typically several miles (kilometers) per second, which usually varies along the path of the sound wave. When a rock noise is detected by several geophones, the origin of the noise can be calculated from relative arrival times of the signal at different geophones. Plots of event locations are superimposed on mine maps for given periods of time. Events in a given area are counted to produce rate plots. For example, the number of microseismic events per day may be plotted against the days of the month. An anomalous increase in the daily event rate may forecast a failure. However, mining progress must also be considered because there is normally more microseismic activity during drilling, blasting, and extraction than during nonmining cycles.

There are three types of microseismic monitoring systems currently in use. In the first type, a surface seismograph, similar to those used by the US Geological Survey in worldwide seismic networks, is installed with its sensor in a quiet area of the mine near the surface in competent rock. Its usefulness lies in allowing mine management to determine that a large event of an approximate magnitude occurred somewhere in the mine at a given time. For location purposes, an observer using only one surface seismograph can differentiate between an event in the host mine, an event in a nearby mine, or a distant earthquake.

A mine-wide system whose geophone spacings are at intervals of 1000 ft (300 m) or more is the second type of system. A typical mine-wide system will detect and locate, within 100 ft (30 m), events whose magnitudes are on the order of routine blasting or larger. These systems are useful for determining the approximate location of large events and what the physical mechanism is that is causing these events. An auxiliary use for a mine-wide system is the identification of unstable areas that warrant detailed investigation.

The third type of system is a local microseismic system where geophone spacings are as close as 30 ft (10 m). Such a network is designed to monitor a small section of a mine. In a mine with several working sections, complete coverage requires several local systems which can be networked such that data can be shared, effectively making a mine-wide system. These data can then be transmitted to central surface analysis stations via phone modem or satellite.

10.3.3.7 Remote Sensing (Peters, 1990)

Remote sensing data and analysis methods have proven to be useful for identification of zones of rock mass instability in both underground and open pit mines (see Chapter 4.4).

Lineaments are linear or curvilinear features of the earth's surface that are definable on aerial and satellite photographs and images. A number of researchers (e.g., Dimick and Barnum, 1978; Elder et al., 1974; Hylbert, 1981; Jansky and Valane, 1983; Milici et al., 1982; Overbey et al., 1973; Peters and Speirer, 1986; Peters et al., 1988) have demonstrated the ability to define geologic structures (faults, joints, and fracture zones) that extend to at least the depth of the mine (as deep as 2000 ft or 670 m) through use of lineament analysis. Figs. 10.355 through 10.357 provide an example of a site at an underground coal mine in central Utah where such structures have created instability in the roof rock. For this small mine, it was found that 82% (27 out of 33) of the ground-control problems (primarily roof falls, bad roof, and water inflows) were within the lineament-related, potential-hazard zones defined through interpretation of a Landsat Multispectral Scanner image (Peters et al., 1988). Although remote sensing analysis has proven useful in many cases, some researchers have had difficulty in using and/or verifying lineaments (e.g., Peng and Haddad, 1981; Moebs and Sames, 1987). Therefore, lineament analysis can be useful as an indication of degree of risk for potential ground control problems, but such analysis is not a panacea and must be backed up by further surface and underground (where possible) geologic investigations and by monitoring of mine and rock mass conditions over time.

Some work also has been done using remote sensing analysis for surface mine stability and subsidence monitoring. For example, Stahl (1983) gives examples of the use of aerial photography for lineament analysis for identification of structures that can destabilize pit walls in uranium mines. Structures or other unstable areas so identified then could be instrumented to focus monitoring efforts on the areas most likely to have slope stability problems. Lineament analysis of a Landsat Thematic Mapper image also was used to define areas of potential adverse breakage and material property changes (such as clay and iron content) in a propant and glass sand quarry in western Wisconsin. Advances in the spatial resolution of satellite systems (e.g., the 30-ft, or 10-m, ground resolution with stereo capability of the French SPOT satellite imagery, and the 15-ft, or 5-m, or better resolution of the Soviet KFA-1000 satellite photography) hold promise for the use of these systems for slope monitoring of surface mines or of glory holes above caving mines.

Modern photogrammetric techniques and instruments, in conjunction with aerial photography, have been shown to be usable in place of ground surveying to monitor subsidence over coal longwall mines (Cousins, 1986). Using aerial photographs from 1980, prior to mining of the underlying panel, and from 1984, following mining of the panel and during subsidence activity, and known control points from surface monuments surveyed over the same period, Cousins was able to derive an elevation stereomodel (through use of an analytical stereoplotter) of the subsiding area for both 1980 and 1984 that matched the ground surveys to within 2 in. or 50 mm. The Office of Surface Mining Reclamation and Enforcement subsequently approved the use of this subsidence monitoring technique, in place of repetitive ground surveys, for a few coal mines on an experimental basis. The method promises to be a less costly monitoring method for rugged and relatively inaccessible sites where ground surveys would be time-consuming and overly labor intensive.

Current and improving Global Positioning Satellite (GPS) techniques of vertical and horizontal location determination also offer the possibility of continuous, automatic monitoring of slopes and subsidence. This technique takes advantage of a carefully arranged array of Navy satellites to determine the latitude, longitude, and elevation (relative to the orbit of the satellite) of a GPS ground station to within as little as 0.5 in. (10 mm). Automated GPS stations (probably solar-powered) would allow both accessible and inaccessible sites to be monitored for ground movement with minimal labor.

10.3.4 SUMMARY

As in all measuring programs, the overall effectiveness of the instrumentation depends primarily on the care with which the instruments are installed and the measurements made, processed, and interpreted.

The distribution of instruments in each measurement station, and the exact nature of the instruments, is also an extremely important consideration and one that usually involves a considerable amount of judgment based on good geologic and engineering information. As a rule, an appreciable degree of redundancy should be designed into the measurement program whenever and wherever possible. In other words, each measurement should serve not only to provide specific information, but also to at least partially substantiate some other measurement. The end result should be an accumulation of measurements, which, by virtue of their redundancy, comprise an aggregate of information to which a high intrinsic level of practical value both for construction and for information relative to the subsequent operation and maintenance of the completed structure.

In conclusion, it should be noted that measurements without purpose are without value. The value of the data obtained can be realized only in proportion to the extent that the data are ultimately applied to the interpretation or solution of actual problems.

Chapter 10.4
SLOPE STABILITY

RICHARD D. CALL

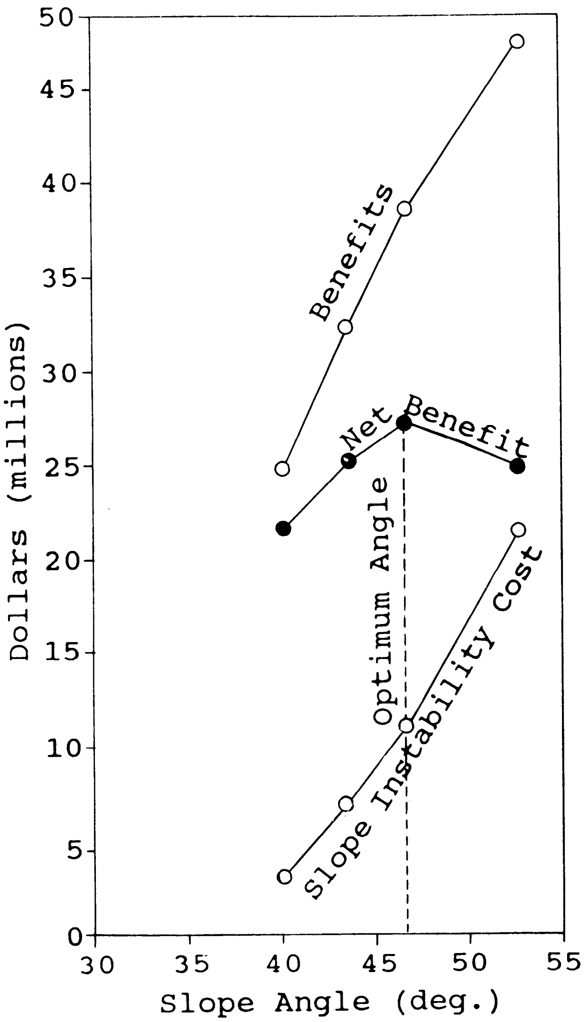

Fig. 10.4.1. Cost benefit curves.

10.4.1 INTRODUCTION

10.4.1.1 Design Approach

In the design of a typical open pit, increasing the slope angle decreases the stripping and/or increases the recoverable ore, which produces a higher benefit or return on investment (Fig. 10.4.1). However, increasing the slope angle decreases the stability of the slope. Because of the variability of geologic structure and rock properties, there is not a unique angle below which there is no slope instability and above which massive failure occurs. More typically, as the slope angle is increased, the number, size, and movement rate of slope failures increases. These slope failures result in operating costs such as the expense of cleaning up failed material, lost production, and unrecovered ore.

At steeper slope angles, the cost of slope instability increases more rapidly than the benefits. Thus the net benefit curve obtained by subtracting the cost of instability from the gross benefit has a maximum. The slope angle at which this maximum occurs is the *optimum angle,* since mining at a flatter angle results in higher stripping costs and reduced ore recovery. Conversely, mining steeper than the optimum results in slope instability costs greater than the increased ore recovery.

Slope design is the process of determining this optimum angle for input into pit design. The slope stability portion of slope design is the prediction of the slope instability as a function of slope angle.

10.4.1.2 Stability Criteria

From the standpoint of simple mechanics, the *stability of a slope* is the ratio of the strength of the material to the stresses in the slope. If the stress exceeds the strength, the slope is unstable; conversely, if the strength exceeds the stress, the slope is stable. This ratio is termed the *safety factor* and has been the basis for stability analysis in civil engineering for many years. Because of the variability of rock properties, uncertainty in the measurement of these properties, and the influence of quasi-random events, such as earthquakes and rainfall, the stresses and strengths used in stability are estimates of populations with significant distributions rather than single values. For this reason, safety factors greater than one have been used for slope design. An alternate approach to defining stability is to use the reliability method, whereby the probability of whether or not a slope will be stable is calculated from the distribution of input values.

Slope instability does not necessarily mean slope failure from the operational standpoint. It is not uncommon for a slope to become unstable, with the resulting displacement being less than 3 ft (1 m). Whether an unstable slope results in significant cost to the operation depends on the rate of movement, the type of mining operation, and the relationship of the unstable material to the mining operation. Unstable areas with displacement rates of over 4 in. (100 mm)/day have been successfully mined by truck and shovel operations. On the other hand, a few inches (millimeters) of displacement of the rock under a crusher, conveyor, or building may require extensive repair. When the rate of displacement is such that it disrupts the operation or the movement produces damage to mining facilities, it is considered an operational slope failure. A similar economic concept was used by Varnes (1958) to distinguish between creep and landslides. He restricts the lower limit of the rate of movement of landslide material "..to that actual or potential rate of movement which provokes correction or maintenance."

10.4.1.3 Safety

Another aspect of slope stability is *slope management.* In an optimized slope, some slope failure can be expected but the specific location and time of instability cannot be predicted with any certainty. Also the stability analyses utilized in design, with very few exceptions, are static solutions that do not provide

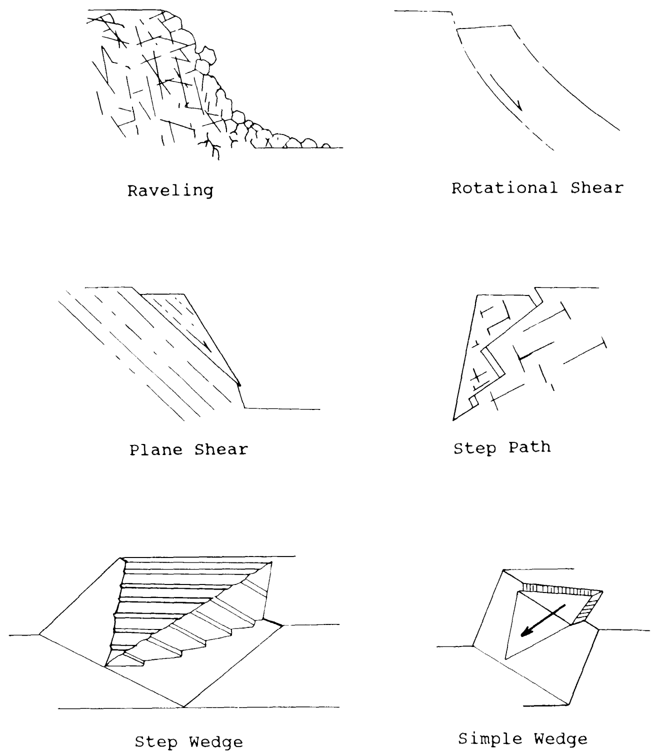

Fig. 10.4.3. Typical failure models.

estimates of the rate or magnitude of displacement. Therefore, to provide safe working conditions and minimize the economic impact of slope instability, there should be a program of displacement monitoring to provide advance warning of major slope displacement, accompanied by design of remedial measures. In spite of the uncertainty in slope stability, the safety record has been excellent compared with mining in general and other activities (Table 10.4.1). With an appropriate slope management program, it should be possible to mine steep slopes with an equal or greater safety record.

10.4.1.4 Slope Geometry

There are three major components of a pit slope: bench configuration, interramp slope, and overall slope (Fig. 10.4.2). The *bench configuration* is defined by the bench face angle, the bench height, and bench width. The *interramp angle* is the slope angle produced by a number of benches. Where there are haul roads, working levels, or other wide benches, the *overall slope angle* is the angle of the line from the toe to the crest of the pit; the slope angle will be flatter than the interramp angle. It is important in slope design to consider these components. For example, in the case of bedding dipping into the pit at 40°, the daylighting plane shear criteria would result in a design angle of 40°. If this angle were used for the overall slope angle, haul roads cut into the slope would undercut the bedding and result in interramp instability. In addition, there would be almost no catch benches left, as the bench face angle would be steeper than the bedding.

10.4.2 INSTABILITY MODELS

In order to make a quantitative estimate of the stability of a slope, analytical models amenable to mathematical solutions must be used. The requirements of these models are the failure geometry and assumptions regarding material properties and stress distributions. (In the following discussion the term "failure" is used for simplicity and to be consistent with prior usage.)

10.4.2.1 Geologic Model

The rock of a slope can be considered to consist of the following components.

Intact Rock: The primary unbroken rock as determined from a piece of core cut for compression testing. The term rock substance has also been used for the unbroken rock.

Fractures: The geologic structures such as joints, bedding, foliation, and minor faults that break the intact rock into more or less discrete blocks. *Discontinuity* is a term that is also used for fractures.

Rock Mass: The combination of intact rock and fractures considered as a unit. Soil could be considered a special case of rock mass.

Major Structures: Geologic features such as faults that are large enough to be mapped and located as individual structures. There is actually a continuum between fractures and major structures, but the differentiation is useful for design purposes.

10.4.2.2 Sliding Block Geometries

The sliding block failure mode refers to a situation in which displacement occurs along one or more geologic structures, and the failure mass is considered to be a rigid block or a number of blocks. These geometries are shown in Fig. 10.4.3.

Plane Shear: The plane shear is the simplest geometry consisting of a single plane striking nearly parallel to the slope. The structure must have a dip flatter than the slope angle (daylighted) and must be long enough to reach the surface or a tension crack. Since the stability analysis is two dimensional, the width of the failure must be great enough that the end results are negligible or there are boundary structures that define the lateral extent of the failure.

Step Path: The step path geometry occurs where there is a fracture set dipping into the pit in the plane shear orientation, but no individual fracture is long enough to form a plane shear geometry. Sliding is assumed to occur along fractures in the plane shear orientation (the master joint set) and separation along fractures approximately perpendicular to the master joint set or tensile failure of the rock between the master joints.

Wedge: The wedge failure geometry is the result of two planar geologic structures intersecting to form a detached prism of material. Sliding can occur down the intersection or on one plane with separation on the other plane. In some cases the sliding on one plane will be a rotation rather than simple translation.

Step Wedge: The step wedge is similar to the simple wedge except that one or both of the failure surfaces are step paths.

Two-block: The two-block is a two dimensional plane shear geometry where there are two plane shear structures dipping into the pit, with a third structure dipping back into the wall that divides the failure into an active and a passive block.

Slab: Where there is bedding or foliation parallel to the pit, slope instability can occur even though the structures are not daylighted. The possible failure mechanisms are crushing at the toe, a two-block geometry formed by joints at the toe, and buckling.

10.4.2.3 Nonplanar Failure Surfaces

Rotational Shear: In a soil or weak rock mass slope where there are no geologic structures that control the failure, the most unstable failure surface is approximately a circular arc. The radius and location of the most unstable circle (the critical circle) depends on the material properties and must be found by iterative solutions of trial circles. The stability of the circular arc is usually analyzed by the method of slices. The failure is divided into a series of vertical slices so that the failure surface can be approximated by planar segments. The driving forces and resisting forces on the failure surface at the base of the slice, as well as the interslice, forces are summed up over the slices. The method of slices is normally a two-dimensional analysis.

General Surface: The general surface is a mixed mode failure in which part of the failure surface is structurally controlled and part is failure through the rock mass. An example would be a nondaylighted plane shear. The method of slices can be used to analyze the stability of the general surface.

10.4.2.4 Other Models

Block Flow: Compared with underground rock mechanics, the stresses in a pit slope are low and do not exceed the rock mass strength. Thus most slope instability is controlled by geologic structure. However, in deep pits, there is the possibility that the stresses in the toe of the slope would be sufficient to result in the crushing failure of the rock mass, particularly if there was a high horizontal stress. This mode of instability was referred to as *block flow* by Coates (1981).

A conceptually possible variation of the block flow would be a situation where the rock mass under confinement in the slope wall yields plasticly. The resulting deformation would be plastic flow such as occurs in a glacier. At the surface of the pit slope, where there is no confinement, secondary sliding block failure would occur similar to the calving of a glacier. This is a possible explanation for situations where instability occurs in a relatively flat slope, and the back analysis indicates an anomalously low shear strength.

Toppling: Where there are steeply dipping structures that result in blocks with a large height-to-thickness ratio, the *toppling* failure mode has been postulated. For toppling to occur, the center of gravity of the block must be outside the toe of the block. Therefore, sliding or crushing of the toe must occur before toppling is initiated unless the slope is mined steeper than 90º. Because of this, toppling is most commonly observed as a secondary failure mechanism resulting from displacement caused by another mode of instability.

An exception to this generalization is where ice wedging or pressure from water-filled cracks causes toppling, as in the case of the Hells Gate Bluffs failure in Fraser Canyon, British Columbia (Piteau et al., 1976).

Rockfalls and Raveling: Bench faces are normally cut as steeply as the loading equipment can dig them. As a result, individual blocks in the face are at or close to limiting equilibrium, and disturbing forces can dislodge them. The primary disturbing forces are freeze/thaw and water from rainfall. The action of these disturbing forces can dislodge individual blocks, producing a rockfall. The dislodging of large numbers of blocks is termed *raveling.* Weathering can also produce raveling by the deterioration of the material supporting the blocks. Although in principle, the stability of individual blocks could be analyzed, there is no practical method of conducting stability analyses for raveling on a pit scale. The design approach is to provide for adequate catch benches.

10.4.3 STRESSES IN A SLOPE

Although most stability analyses assume simple gravitational body loading to calculate the stress on a failure surface, it is recognized that the actual stress magnitude and orientation is affected by the in situ stress field, the geometry of the pit, and the variation in material properties.

10.4.3.1 In Situ Stress

Simple gravitational loading would produce a vertical stress equal to the weight of the overlying material, and according to elastic theory, the horizontal stress would be a function of the vertical stress and Poisson's ratio. For the common value of 0.25 for Poisson's ratio, the horizontal stress would be 1/3 the vertical stress. Measurements of in situ stress in underground mines have demonstrated that the horizontal stress can be greater than the vertical stress, as a result of active or residual tectonic stress. The horizontal stress is not equal in all directions, either. In the absence of in situ stress measurements or other indications of a high horizontal stress, the most reasonable assumption is that the horizontal stress is equal to the vertical stress.

10.4.3.2 Slope Geometry

There is a stress concentration at the toe of a slope that is a result of the deflection of stresses around the toe. A high horizontal stress produces a greater toe stress than simple gravity loading. The effect of in situ stress and slope geometry for a plane strain analysis is shown in Fig. 10.4.4. It should be noted that the toe stress is much more dependent on the pit depth and the ratio of horizontal to vertical stress than on the slope angle.

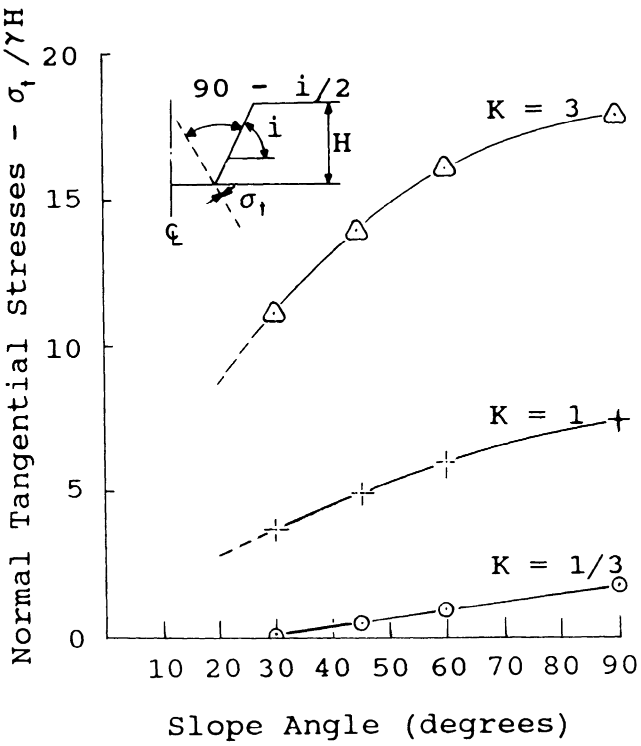

Fig. 10.4.4. Variation in plane strain of the toe stress.

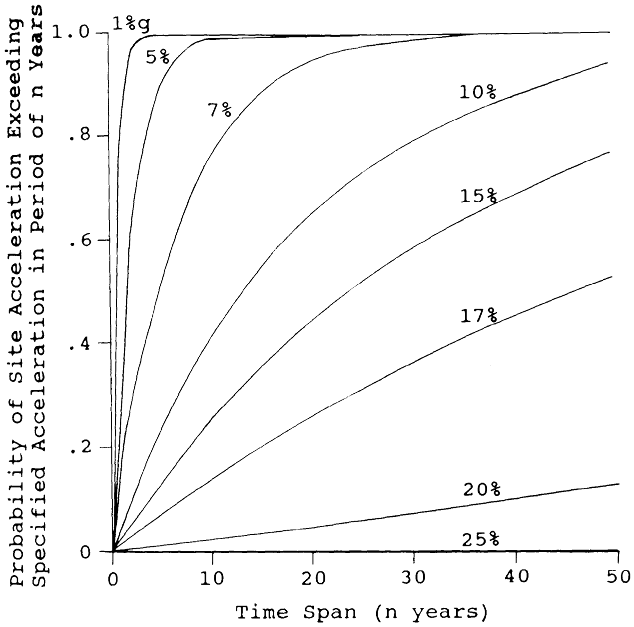

Fig. 10.4.5. Site acceleration probabilities as a function of time. Attenuation calculated according to Patwardhan (1978).

10.4.3.3 Material Properties

Finite element analyses have shown that major stress concentrations can be produced where there are rocks of differing stiffness in the slope. Stiffer rock units carry more load and thus have a stress concentration. Of particular concern for slope stability is the development of high shear stresses in the vicinity of the contact between rocks of differing stiffness.

10.4.3.4 Seismic Acceleration

The shock wave from an earthquake exerts a temporary additional stress on a slope that can cause instability. This has been demonstrated by the number of landslides triggered by earthquakes (Glass, 1982), although this record is misleading with regard to rock slopes; as saturated soil slopes are subjected to liquefaction, which would result in much greater displacement at lower seismic loading. Thus it is appropriate to include the affect of dynamic stresses in the stability analysis of slopes.

The classic method of including the effect of earthquakes in stability analysis is the pseudo-static approach whereby the maximum site acceleration that could be produced by an earthquake is input into the stability analysis as a horizontal force. This approach is excessively conservative when applied to pit slopes, for the reasons listed in the following.

Probability of Occurrence: The maximum earthquake may have a very low probability of occurrence during the critical exposure time of a pit slope. Although the life of a pit may be 20 years or more, the maximum height and angle only exists at the end of the mine life. Therefore, when analyzing the stability of the final slope, the exposure time for that slope geometry is only a few years.

For the cost-benefit approach to slope design, a probabilistic risk analysis of seismic dynamic loading can be used. From the historical earthquake record, a time history of acceleration at the site can be obtained by using empirical attenuation relationships to convert the magnitude and distance for each earthquake to a site acceleration, and calculating the probability of occurrence of site accelerations for time intervals with Gumbel's extreme value theory (Fig. 10.4.5).

Slope Response: The response of a specific failure geometry is a function of the frequency and duration of the ground motion as well as the maximum acceleration. Even if a failure geometry is unstable at an acceleration below the maximum, resulting from ground motion, the amount of total movement may be only a few inches (tens of millimeters). Although a pseudo-static stability analysis would give a safety factor less than one, the displacement would be below the range of what would be considered an operational slope failure.

To estimate the displacement resulting from seismic acceleration, the linear acceleration dynamic response (LADRS) technique developed by Glass (1982) can be used. In this technique the displacement is calculated for small time steps using a digitized model accelerogram and the displacement summed over the duration of the accelerogram. The failure criteria can be expressed as a maximum permissible displacement specific to the slope situation being analyzed. For slopes without facilities such as crushers or conveyors, a maximum displacement of 8 to 12 in. (200 to 300 mm) would be appropriate. Where facilities are present, the displacement tolerance of the structure would be the criteria.

10.4.4 DATA COLLECTION

Collecting adequate and appropriate data for stability analysis is a key aspect of slope design. Obtaining incorrect results from slope stability analysis is predominantly the result of failing to analyze the critical failure mode or not having the suitable estimates of the input parameters such as rock strength or the geometry of geologic structures. With the use of computers, our ability to construct mathematical models and perform the calculations exceeds our ability to collect adequate input data for the models. There are two aspects to the problem of data collection: sampling and measurement.

To illustrate the problem, let us take the specific task of determining compressive strength. This is usually measured by conducting a compressive test on a cylinder of rock 2 to 3 in. (50 to 75 mm) in diameter and 5 to 8 in. (125 to 200 mm) in length. The population of interest (referred to as the target population by statisticians) includes all the cylinders in the volume of rock that could be involved in slope instability. Based on slope behavior and stress considerations, this volume would extend one pit depth back from the design pit and one half the pit depth below the bottom of the design pit. It is obvious that all of the target population could not possibly be tested, so the strength distribution must be estimated by inference, using the test results from some small, hopefully representative, fraction of the target population.

The availability of samples for testing is determined by access, which would be the ground surface, the pit wall, underground workings, and drillholes. Where there is no preexisting pit or underground workings, and the ground surface is covered by alluvium, access to samples is restricted to drillholes. These accessible samples are referred to as the sampled population. The samples that are actually collected and tested are referred to as the sample population. To make valid statistical inferences about a population, every member of the population in question must have an equal likelihood of being sampled, and the tested samples must be an unbiased representation of the population. This can be true regarding the sampled population, but making the step from the sampled population to the target population is more difficult. Because of the restricted access, not all members of the target population are available for sampling even if a specific rock mechanics drilling program is conducted, as there are surface topographic restrictions on locating drill sites, and holes may not be completed because of bad ground. As pointed out by Cochran et al. (1954), "No statistical processes can make the step from sampled population to target population. It can only be done by judgment, intuition, and subject matter knowledge."

Sample disturbance and the difficulty of reproducing the in situ field conditions introduce measurement uncertainties. In the case of rock mass strength, the sample size required makes direct testing prohibitive. Indirect methods, such as modeling the rock mass by compositing the intact rock strength and joint strength, or a rock mass classification with subsequent correlation to empirical behavior are generally employed.

In the case of geologic structure data collection, parameters such as orientation, length, and spacing are geometric rather than scalar, and cannot be measured at a point. This results in a window problem, particularly in the case of fracture length. If the fracture is larger than the observation window, such as a bench face, the length cannot be directly measured. This is why surface mapping is preferable to drillhole data where the core diameter is the window. There is also an orientation bias, as a linear sampling window such as a drillhole does not intersect fractures parallel to the window.

Data collection should be well organized, with specific objectives regarding the use of the data and the quantity required (Table 10.4.2). Collecting data for data's sake should be avoided, as it will result not only in information that is not used, but the possible omission of information needed. Ongoing data reduction is important in order to determine whether a sufficient quantity of appropriate data is being collected.

10.4.4.1 Geology and Major Structure

Conventional geology provides the distribution of rock types and alteration, and the location of major structures. Geologic data should be in the form of a surface map, cross sections, and level maps. It is preferable to have two sets of documents—the factual sheets that show only the actual observations and a set of interpreted maps and cross sections.

For the design of final pits, a geologic map of a trial pit design and cross sections normal to the pit wall should be constructed.

10.4.4.2 Rock Fabric

Rock fabric is the orientation, length, and spacing of fractures. These are the geometric attributes used in stability analysis and in characterizing the rock mass. On a pit scale, the number of fractures such as joints are too numerous to map. Fracture mapping, therefore, consists of measuring the attributes of a subset of the total fractures and characterizing the population with distributions of the attributes.

It has been found from detailed mapping that the orientation of fracture sets has a normal or bivariate normal distribution. Since the orientation is vector quantity, it is properly a spherical normal distribution. However, for the limited range of attitude for a specific fracture set (100), the simple normal distribution is adequate. In the case of folded rock, the poles of the bedding planes fall along a great circle.

The measurable aspect of joint size is the trace length, which is the intersection of the joint and the mapping surface. The negative exponential appears to be the best distribution for trace lengths on the basis of fit to mapping data and theoretical considerations. Models such as the circular disc and the Poisson flat have been postulated to describe joints in three dimensions. These models can be used to correct for the observation window limitation.

Several common mapping methods are available.

Fracture Set Mapping: This is a modification of conventional joint mapping where fracture sets are identified by eye, and the orientation, length, and spacing are recorded. If joints or other structure orientations have been recorded during regular geologic mapping, they can be compiled and used in slope design.

Detail Line: The detail line method is a systematic spot-sampling method in which a measuring tape is stretched along the bench face or outcrop to be measured. For all the fractures along the tape, the point of intersection with the tape, orientation, length, roughness, filling type, and thickness are recorded. To get an adequate representation of the fabric, 100 to 150 fractures need to be mapped. This is the least subjective method, as individual fractures are recorded, and it provides the most detailed length and spacing data. It is relatively inefficient, however, as more observations are made on closely spaced fracture sets than are required for adequate statistical representation.

Cell Mapping: In this method, mapping surfaces such as a bench face are divided into cells. Normally, the width of the cells is made equal to the height of the cells. Within each cell, the fracture sets are identified by eye, and the orientation, length, and spacing, characteristics are recorded. Cell mapping is a combination of fracture set mapping and detail line, with the efficiency of visual identification of fracture sets and some of the more rigorous measurements of detail line.

Oriented Core: To obtain subsurface fabric, oriented core can be used. In inclined holes excentrically weighted, imprinting devices can be used to determine the orientation. In vertical holes, a scribing technique coupled with a downhole compass must be used. Oriented core provides information on fracture

orientation and spacing, but the length of fractures cannot be directly measured.

10.4.4.3 Rock Properties

Since the spatial variability of rock properties is large, the potential for sampling error is greater than the measurement error. For this reason, it is preferable to use simple test methods for a number of samples than to use an expensive precise method on one sample.

For the shear strength of fractures and fault gouge, the direct shear test is recommended as it is a simulator of field conditions. Since the shear/normal failure curve may be nonlinear, it is important to use normals that represent the expected range of normals for potential failure geometries in the slope. The tests at each normal should be run with sufficient displacement to obtain a residual shear strength, as the residual shear strength usually is a better estimate of in situ strength than the peak strength. To obtain the shear/normal relationship, a curve can be fitted to the shear normal values for a range of normals. Some stability analyses, such as the modified Bishop method of slices, require a linear failure curve of the classic relation,

$$S = c + n \tan \phi \tag{10.4.1}$$

where ϕ is friction angle, c is cohesion, n is normal stress, and S is shear stress. This is a linear failure curve and is often a good fit, particularly for fault gouge. The more general curve is the power with an intercept, that is

$$S = c + kn^m \tag{10.4.2}$$

where c, k, and m are constants.

Commonly, fractures have the simple power curve,

$$S = kn^m \tag{10.4.3}$$

The linear is a special case of the power with intercept where

$m = 1$, in which case k becomes tan and c is cohesion. The linear fit to an actual power curve can be an adequate predictor of shear strength except at low and high normals where the curves diverge. When using these strength estimates, it is useful to think of cohesion as a mathematical intercept rather than an intrinsic property of the material.

For intact rock, unconfined compression and Brazilian disc tension tests are recommended. In addition to obtaining the compression and tension strengths, the intact rock shear strength can be approximated by a fit to the tension and compression Mohr circles using the relationships,

$$\phi = \arcsin[(U\text{-}T)/(U+T)](0.85) \qquad (10.4.4)$$

$$C = 0.5T\tan\phi(1/\sin\phi + 1)(0.98) \qquad (10.4.5)$$

where U is uniaxial compression, and T is tensile strength.

The constants 0.85 and 0.98 are factors developed from comparison between triaxial testing and the simple linear fit to the uniaxial and disc tension strengths. For most stability analyses, the failure surface is not under high confinement, so triaxial testing is not necessary.

The uniaxial compression tests can be gaged to obtain the Young's modulus and Poisson's ratio for the intact rock.

Index tests such as the point load can also be used to evaluate the spacial variability of intact rock strength.

For the rock mass where direct testing is not possible, indirect methods such as the rock mass rating (RMR) classification and back analysis must be used.

10.4.4.4 Hydrology

Standard hydrologic procedures such as piezometers and pump tests can be used to obtain the current pore pressure distribution and the permeability for predicting changes in pore pressure with time and changes in pit geometry. Simple techniques, such as measuring the water level in drillholes, are effective procedures. Two factors need to be considered, however:

1. Water behavior in rock slopes is a fracture flow phenomenon, and porous media analysis, while useful at a regional scale, may be a poor predictor of pore pressure at pit slope scale.

2. The critical factor in slope design is the pore pressure rather than the quantity of water. A low permeability rock mass may yield very little water and appear "dry," yet have significant pore pressure.

10.4.4.5 Stress Measurements

The most cost-effective stress measurement techniques are overcoring methods such as the "door stopper" or the triaxial gage. Because of the practical limitation of most current overcoring techniques to hole depths of 100 ft (30 m), underground openings are needed to penetrate far enough into the slope to get away from the surface effects. Also overcoring is usually not successful where the rock quality designation (RQD) is less than 50%, which is often the case with deposits such as porphyry copper. Alternates to current overcoring techniques, such as hydrofracturing, have potential where overcoring is not feasible.

It is useful to conduct a finite element analysis using assumed stress to evaluate the mud for in situ stress.

Detailed measurement techniques are discussed in Chapter 10.3.

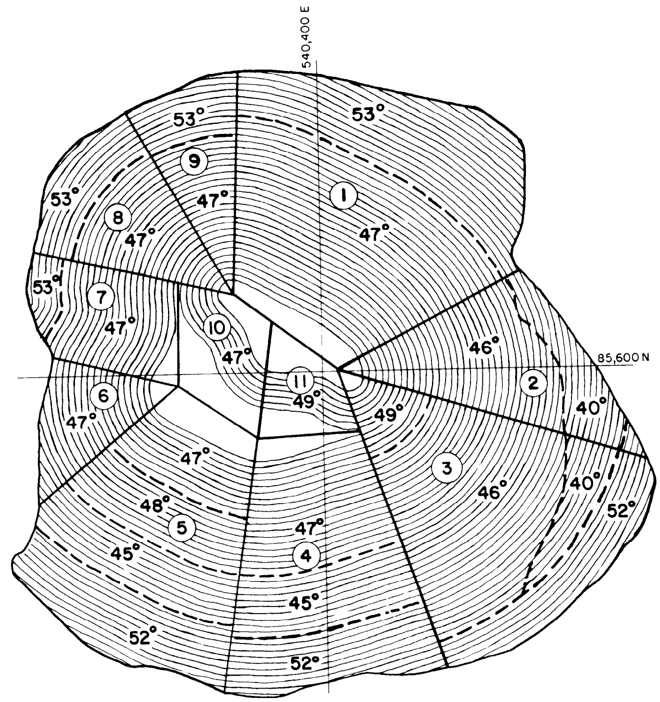

Fig. 10.4.6. Cuajone design sectors and recommended interramp angles.

10.4.5 DESIGN

Steps in slope design are the following:

1. Define design sectors.

2. Conduct a bench design analysis to determine the maximum interramp slope.

3. Conduct interramp design analysis using economic criteria for the selection of interramp angles.

4. Evaluate the resulting overall slope for potential instability, and modify the design if required.

Slope design is an interactive process as a trial pit is required to select design sectors, but the development of a trial pit requires slope angles.

10.4.5.1 Design Sectors

To conduct stability analyses and develop optimum slope angles for input into pit design, the proposed pit must be divided into design sectors that are sections of the pit with similar geologic and operational characteristics (Fig. 10.4.6).

The first criterion for the selection of design sectors is the structural domain, which is an area within which the rock properties and fabric are consistent. Typical structural domain boundaries are lithologic contacts and major structures which separate areas of dissimilar fabric.

The second criterion is wall orientation. Since rock is usually anisotropic, different wall orientations within the same structural domain can have significantly different modes of instability and different optimum angles. An extreme example of this is a dipping coal deposit where slab slides occur in the footwall at a slope angle of 18°, whereas 150-ft (45-m) high benches in the same lithologic sequence in the highwall orientation are stable at 70° with only minor step path raveling.

A third criterion for defining design sectors is operational considerations. Because of the higher cost of slope failure, sections of the pit wall that will contain in-pit crushers, conveyors, or haul roads require different stability criteria than the same wall orientation in the same structural domain.

Since a pit geometry is required to define design sectors, slope design is iterative with mine planning. A preliminary set of slope angles must be provided so that a trial pit can be developed. After the optimum angles are selected and a pit designed, the pit plan must be reevaluated to determine whether the design sectors need to be changed because of changes in the pit geometry.

For each of the design sectors, the rock fabric and major structure orientation data can be plotted on a stereographic projection. This diagram is used to determine failure modes and select structure sets for stability analyses.

10.4.5.2 Bench Design

Bench faces are normally mined as steeply as possible so that some bench-scale rockfalls and raveling can be expected. Thus it is customary, and in many cases mandated by mining regulations, that catch benches be left in the pit wall to retain rockfalls and raveling. Bench design is the process of conducting stability analyses to estimate the minable bench face angles, selecting the bench width, and, to a limited extent, the bench height. The bench height is controlled by the height of the mining levels, but it is possible to increase the height by leaving catch benches on every other level (double benching) or every third level (triple benching).

Based on an analysis of rockfall mechanics, Ritchie (1963) developed width and depth criteria for a ditch at the toe of a slope to protect highways from rockfalls. Falling rocks impact close to the toe of the slope, but, because of horizontal momentum and spin, can roll considerable distances from the toe. The concept of Ritchie's design was that the rock would impact in the ditch, and the side of the ditch would stop the horizontal roll.

It is not practical to excavate a ditch in an open pit catch bench, but a berm can be substituted for the ditch. A modification of Ritchie's design that can be used to determine the minimum bench width for bench heights from 30 to 100 ft (9 to 30 m) is

$$\text{minimum bench width} = 4.5 \text{ ft} + 0.2 \text{ bench height} \qquad (10.4.6)$$

with a minimum 4-ft (1.2-m) high berm on the edge of the bench.

Recent work with mathematical simulation of rockfalls has indicated that this criterion may be conservative, and the simulation method has the potential for more site-specific bench width criteria (Evans, 1989).

For a given bench height and corresponding bench width, the upper limit of the interramp angle becomes a function of the bench face angle. The bench face angle, however, is not a unique value, as variability of the rock fabric results in varying amounts of backbreak. Backbreak is defined as the distance from the design crest to the as-mined crest. Because of this variability, it is preferable to use a reliability approach rather than using the mean bench face angle. (Calculating an interramp slope using the minimum bench width and the mean bench face angle results in 50% of the benches being too narrow.) The procedure is to select a percentage reliability and use the cumulative frequency distribution of the bench face angle to find the angle where the percentage greater is equal to the reliability (Fig. 10.4.7). This gives the design bench face angle to use, with the minimum bench width and the bench height, to calculate the interramp slope angle.

The percent reliability represents the percentage of the bench along a given level that would be wider than the minimum required bench width to catch rockfalls. The reliability should be selected on the basis of the potential for rock fall and the exposure of personnel and equipment. For example, the catch bench in raveling ground above a haul road requires a greater reliability than catch benches in a stripping area with more competent ground. In practice, reliabilities from 60 to 90% have been satisfactory.

In an operating property, the actual bench faces can be measured, and the measured bench face angle distribution can be used in design. Where existing bench faces are not available, a bench-face angle distribution can be obtained by running a stability analysis of a vertical face. For this analysis, the plane shear, wedge, and step path analyses are run using the fracture data. The height analysis should be incremented in steps up to the bench height, and the resulting backbreak composited, as short fractures that would not result in full bench failure can still cause crest backbreak. This bench face angle distribution is referred to as the theoretical bench face distribution, as the effect of blasting and digging is not included. If there is a strong geologic control such as bedding or foliation, the measured and theoretical bench face angles are the same. Where no strong structure exists, the theoretical bench face angles should be reduced to include the effect of blasting. Based on comparisons that have been made between measured and theoretical angles, the reduction should be between 10 and 20°, depending on the controlled blasting to be used.

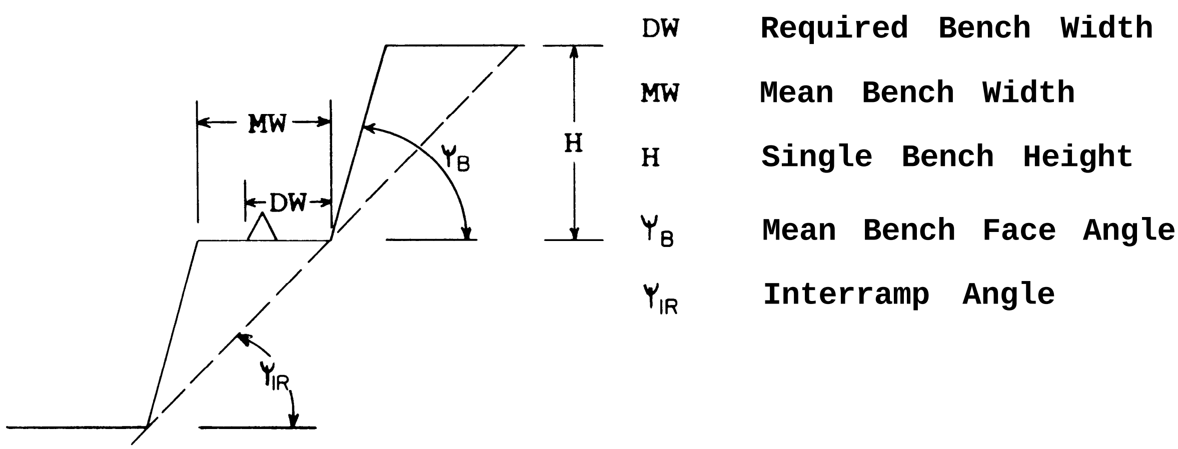
10.4.5.3 Interramp Design

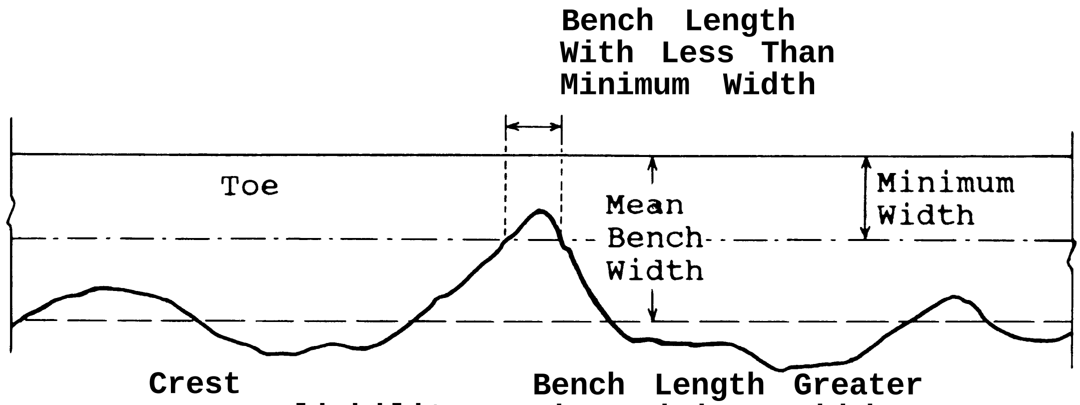
The stability of interramp slopes is primarily controlled by intermediate and major structure failure geometry. Where major structures can be specifically located in space, the geometry relative to the slope can be defined and a discrete stability analysis can be conducted. Commonly, however, the number of mapped structures is large and the distance between the mapping sites and the design wall is greater than the length of the structures. In this case, the structural data must be considered a statistical representation of the structures that will occur in the design slope, and a probabilistic analysis is required.

To obtain the input for stability analysis, the wall orientation can be plotted on a lower hemisphere stereographic plot of the poles of the fractures and the major structures. The fractures and major structures are sorted into design sets based on their orientation relative to the orientations for failure modes, as shown on Fig. 10.4.8; and the distribution of orientation, length, and spacing can be computed for the design set. These design sets may not correspond to geologic sets, although the boundaries of the sets may be adjusted to avoid splitting a geologic set. An advantage of this approach is that it is based on kinematic tests for viable failure geometry and makes it unnecessary to test all the structures for each failure mode.

Major Structures: In the case of through-going major structures, where the geometry is known, a safety factor can be calculated for specific slope angles and slope heights using analytical models described in the references for the appropriate failure model. For a deterministic design, the slope angle with the desired safety factor would be selected.

In the reliability method, the probability of sliding can be calculated by Monte Carlo sampling of the shear strength distribution to obtain a distribution of safety factors; and computing the area of the safety factor distribution that is less than one (Fig. 10.4.9). Other techniques can be used, such as the point estimate method (Harr, 1984) or calculating the probability that





$$\text{Reliability} = \frac{\text{Bench Length Greater Than Minimum Width}}{\text{Total Bench Length}}$$

Fig. 10.4.8. Design set determination.

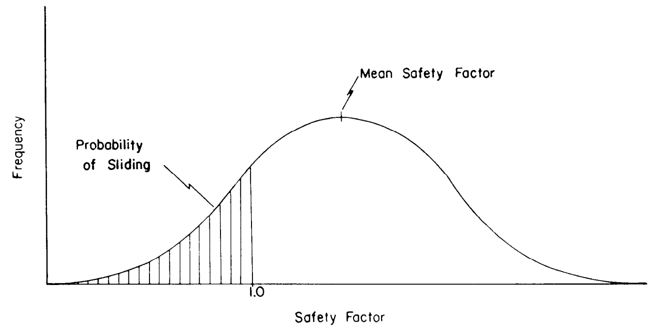

Fig. 10.4.9. Example distribution of safety factors used to calculate probability of sliding.

the shear strength is less that the strength required for a safety factor of one.

Because of the variability of the shear strength, a safety factor greater than one is used to reduce the risk of instability to an acceptable level. One problem with this is that a given safety factor will have a different level of risk depending on the dispersion of the input parameters. The advantage of the reliability approach is that it deals directly with the risk.

Failure Volume Estimation: Where the geologic structures compose a statistical population, the probability of failure for the single occurrence of a specified failure mode is a function of the probability that the structures exist and form a viable failure geometry, as well as the probability of sliding. The probability of existence is calculated from the orientation, length, and spacing of the structures.

To calculate the expected number of failures and the expected failure volume for input to a cost-benefit analysis, the probability of failure for the possible failure modes must be calculated for a range of heights and angles and then composited.

Fig. 10.4.10 is an example of the number of failures and failure volume as a function of slope angle for the design sector of a large pit.

Cost of Failure: Given the expected number of failures and the expected failure tonnage, the cost of slope failure can be estimated. Failure costs consist of cleaning up failure material, repairing haul roads, repair of facilities, lost production due to disruption of operations, the value of lost ore buried by a failure, and engineering costs. The method used to estimate failure cost is a "what if" mine planning procedure. A failure is postulated for a design sector, a plan for responding to the failure is made, and the cost of the plan is estimated. These exercises are useful whether or not a full cost-benefit optimization is done, as they can lead to modifications of the mine plan that will reduce the impact of slope instability.

10.4.5.4 Overall Slope

The overall slope is usually flatter than the interramp slope because of ramps or other step-outs. Thus the overall slope normally will be more stable than the interramp except for stress-induced failure or failure modes not analyzed for the interramp.

Block flow potential can be analyzed by the finite element technique. Finite element has been a time-consuming and expensive analysis in the past. However, with the faster computers and better software currently available, it has become more feasible. A quick check can be made for block flow potential using the charts developed by Coates (1981) (see Fig. 10.4.4). If the charts do not indicate block flow potential with any regional stress assumption, finite element is not needed unless there is a high contrast in stiffness between adjacent materials in the slope. The charts assume a homogenous material and would therefore not indicate stress concentrations produced by stiffness contrasts.

Changes in the overall slope angle have relatively little effect on the stress concentration at the toe of the slope, where a greater concentration could produce block flow. Therefore, block flow potential would not be a suitable method for selecting overall slope angles. A more effective design approach would be to design the slope based on other criteria, and to make provision in the mine plan for step-outs, if needed in the toe area of the pit to reduce the stress concentration produced by the notch effect of the bottom of the slope. The loss of ore from step-outs at the toe would have less economic impact than the amount of stripping required to have the same effect on block flow potential.

Rotational shear analysis should be run for the overall slope, even on rock slopes, to verify that it would not be a critical failure mode. Rotational shear would be a primary method of analysis for both interramp and overall slopes in alluvium and low rock-mass strength slopes such as soft coal measures.

The general surface analysis should be used for the overall slope to evaluate mixed mode failure types where part of the failure is structurally controlled and part is failure of low rock-mass strength. Nondaylighted wedge and plane shear failures in which the weak rock at the toe fails are becoming recognized as a more significant failure mode. This is in part because pits are becoming steeper and deeper, and partly because more pits have been designed for the simpler sliding block failure modes.

10.4.5.5 Slope Support

Ground support techniques such as cable bolting have not had wide application in open pit mining, although the effectiveness is well established in underground mining and in civil construction. One reason is the uncertainty of the ultimate pit geometry. Where the ultimate pit is defined by an economic cutoff, changes in the price of the commodity or in operating costs change the location of the pit slope. It is difficult to justify the expense of cable bolting when there is a reasonable chance that the there will be a new pushback and the bolts will have to be mined out. Corrosion is another problem with bolting, particularly in copper mines where acid mine water is very corrosive. In large pits where the bolt length would have to be in excess of 500 ft (150 m) to include potential failure surfaces, bolting would be difficult and expensive.

A current application of support, employed in Australia in particular, is the bolting of bench faces to reduce ravel and steepen the faces. By reducing raveling, catch benches can be made narrower, which can increase the interramp angle if multibench failure geometries are stable. In some cases, catch benches could be eliminated by using a combination of bolting and meshing to prevent raveling.

There are special situations where bolting is warranted. Even small-scale failures could damage in-pit facilities such as crushers and conveyors, resulting in expensive repair costs and a long period of lost production while the equipment is being repaired or replaced. In this case, bolting to improve the reliability of the slopes that affect the facility would be appropriate. An example of this is the bolting of the haul road in the Ertsberg Pit (Mealey and Nicholas, 1986). The haul road was the only access to ore, and a bench-scale wedge failure of the haul road would stop production. Because of the steep interramp slope, repair of the haul road would have been difficult, so the face below was cable-bolted to increase the reliability of the haul road.

The contribution of a bolt to the shear resistance is composed of three parts:

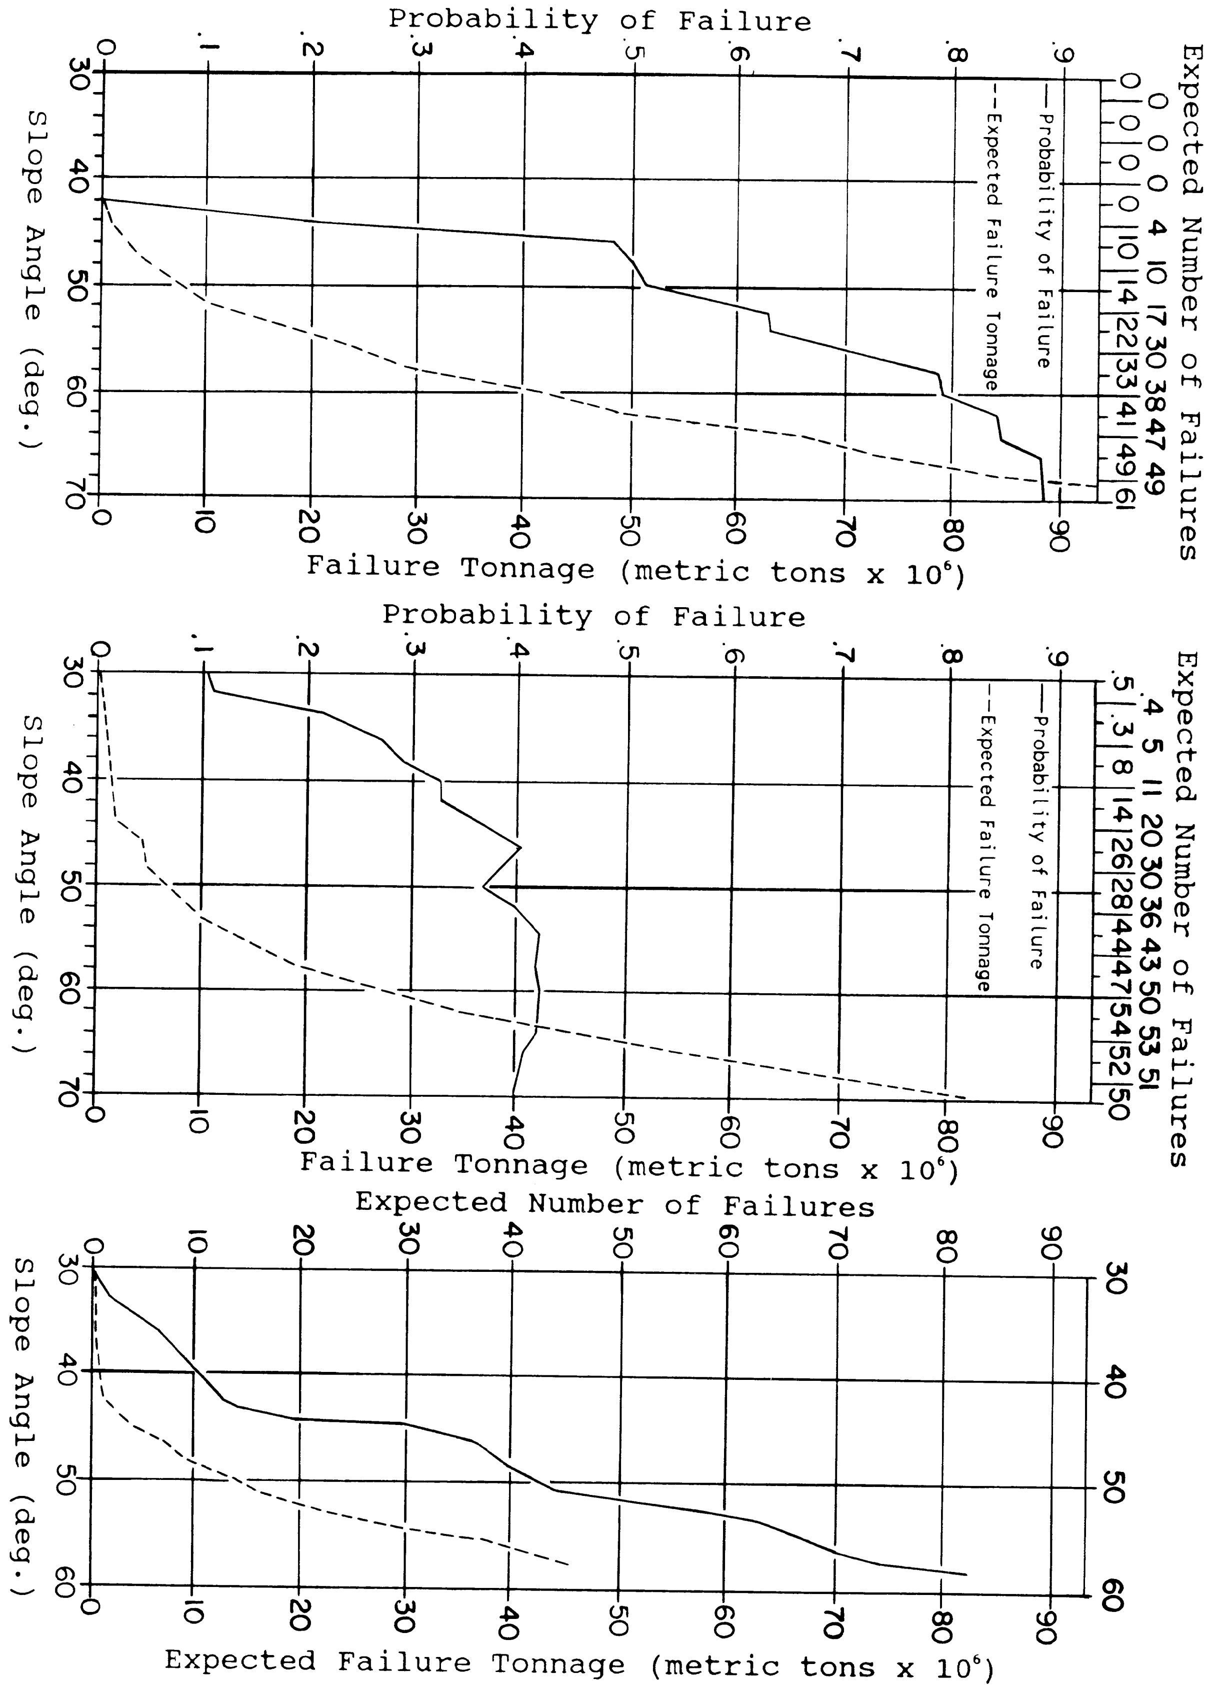

Fig. 10.4.10. Expected failure tonnage curves. Conversion factor: 1 ton = 0.9072 t.

$$\text{tension} = B\cos\alpha \quad (10.4.7)$$

$$\text{dowel} = 0.5B \quad (10.4.8)$$

$$\text{friction} = B\sin\alpha\ \tan\phi \quad (10.4.9)$$

where B is the bolt tensile strength, and a is the angle between the bolt and the shear surface. The dowel strength, which is the strength of the bolt in shear, is taken as one-half the tensile strength. Assuming the bolt acts as a Tresca material (Dight, 1982), the tensile and dowel strengths are not mutually exclusive, and the net shearing resistance of the bolt is

$$\text{net resistance} = (\text{tensile}^2 + \text{dowel}^2)^{1/2} + \text{friction} \quad (10.4.10)$$

Untensioned, fully grouted bolts are easier to install and less expensive than tensioned bolts, and there is considerable evidence that a fully grouted bolt reaches full tension with a very small displacement. The argument for tensioned bolts is that displacement required to tension an untensioned bolt may result in loss of the peak shear strength of the rock and may cause cracking of the grout, which would expose the bolt to corrosion. It is doubtful, however, that the benefit of tensioned bolts justifies the additional cost.

Shotcrete has also been used successfully on a small scale to stabilize progressive raveling failure affecting haul roads.

10.4.5.6 Controlled Blasting

Production blasting is designed to fragment rock for loading. At the slope wall, this fragmentation results in backbreak, which reduces the bench face angle and results in flatter slope angles or narrower catch benches. To reduce this backbreak the fragmentation of the final wall must be reduced by controlled blasting.

It has been found that a blast shock wave with a peak particle velocity greater than 25 in./sec (625 mm/s) initiates cracks in rock and produces significant damage above 100 in./sec (2.5 m/s). The peak particle velocity is a function of the charge weight and the distance from the charge. The relationship is

$$V = k(D/W)^b \quad (10.4.11)$$

where V is peak partial velocity, D is distance, and W is instantaneous charge weight (see Chapter 9.2.2). The constants k and b are a function of the rock and the type of blasting, so are site specific. Typical values for open pit blasting are $b = -1.6$ and $k = 26$ to 260 (Oriard, 1982). This relationship can be used to determine the maximum charge weight per delay required to keep the peak particle velocity below 25 in./sec. (625 mm/s).

Reducing the number of holes per delay will reduce the peak particle velocity, but for the perimeter row of holes and the buffer row, a production hole charge is usually too large, and must be reduced. To maintain the same powder factor, the hole spacing must be reduced concurrently with the reduction in hole charge. In practice, this method of controlled blasting has been shown to increase the measured bench face angle by 5° (Savely, 1986).

Presplitting, where a closely spaced line of holes with a light powder charge is shot before the main blast, can produce a smooth face with minimum damage. Presplitting is usually not necessary and is not effective in closely jointed rock.

10.4.6 SLOPE MANAGEMENT

With an economically optimized slope design, some degree of slope instability can be expected. Minimization of the adverse effects of slope instability must be accomplished through judicious mine planning and the establishment of operational contingencies.

There are several principles of slope mechanics that should be kept in mind when dealing with slope instability.

1. *Slope failures do not occur spontaneously.* A rock mass does not move unless there is a change in the forces acting on it. The common changes that lead to instability in an open pit are removal of support by mining, increased pore pressure, and earthquakes.

2. *Most slope failures tend toward equilibrium.* It is an observed phenomenon that as a slide displaces, the toe pushes out and the crest recedes. Such displacement reduces the driving force and increases the resistance force so that the displacement rate is reduced until movement stops. When high pore pressures are involved, a similar balance is attained. Displacement causes dilation of the rock mass. As a result, pore pressures drop, and the effective shear strength increases. This mechanism explains the stick slip movement of some slides, in which recharge increases the pore pressure in tension cracks, resulting in renewed displacement. There are exceptions to this generalization, but they are usually the result of reduction of shear strength due to shearing of asperities or changes in the forces acting on the rock mass.

3. *A slope failure does not occur without warning.* Prior to major movement, measurable deformation and other observable phenomena such as development of tension cracks occur. These phenomena occur from hours to years before major displacement. However, single bench sloughing directly associated with mining does occur rapidly. While a slope failure does not occur without warning, the converse is not always the case. Deformation and tension cracks can occur without major displacement.

10.4.6.1 Detection of Instability/Monitoring

The first step in slope management is the identification of potential failure areas such as faults, breccia dikes, and/or jointing with attitudes that would form a failure geometry. Data for this identification would come from geologic pit mapping. Areas of higher water levels are also potentially unstable and should be identified.

The second step is monitoring areas that are potentially unstable and/or show evidence of instability by displacement and tension cracks. On the basis of monitoring and mapping, the geometry of a failure can be determined and predictions made of future behavior.

The objectives of a pit slope monitoring program should be

1. To maintain safe operational procedures for the protection of personnel and equipment.

2. To provide advance notice of instability so that mine plans can be modified to minimize the impact of slope displacement.

3. To provide geotechnical information for analyzing the slope failure mechanism, for designing appropriate remedial measures, and for conducting future redesign of the slope.

An effective slope monitoring program consists of the systematic detection, measurement, interpretation, and reporting of evidences of slope instability. Measurements are normally made of both surface and subsurface displacement in order to provide an accurate assessment of slope instability (see Chapter 10.3).

Surface Displacement: Surface displacement measurement by means of tension crack mapping, extensometers, and survey points is still the most cost-effective monitoring method. All three procedures should be used as no one method would give the entire picture. Fig. 10.4.11 shows a typical surface monitoring layout.

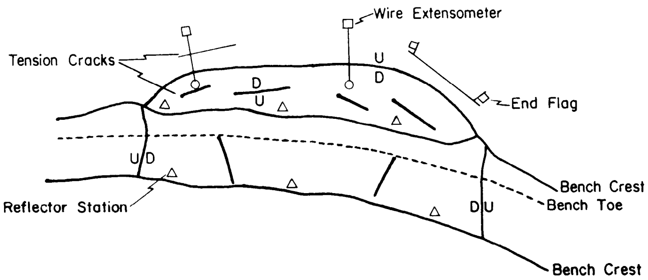

Fig. 10.4.11. Tension crack map.

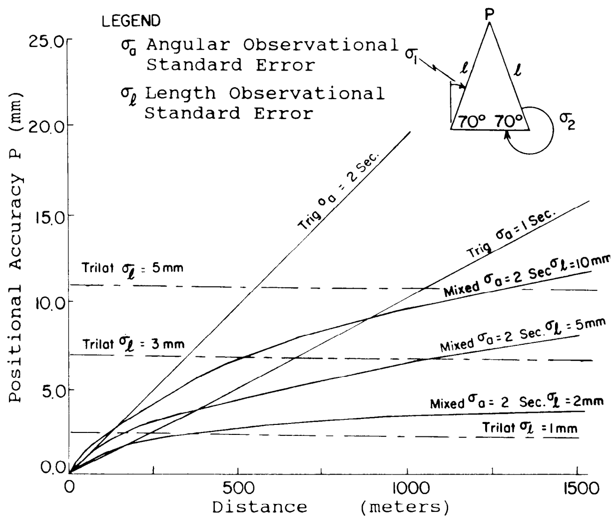

Fig. 10.4.12. Positional accuracy of P by triangulation, trilateration, and triangulateration (Ashkenazi, 1973). Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

1. Tension crack mapping: Tension cracks are an early, obvious indication of instability. By systematically mapping the cracks, the geometry of a failure can be better defined. All cracks should be mapped regardless of apparent cause. Often cracks which appear to be the result of local bench failure or blasting form a pattern showing an impending larger failure when plotted on a pit map.

The ends of the cracks should be flagged or marked so that on subsequent visits new cracks or extensions of existing cracks can be identified.

2. Extensometers: Portable wire extensometers should be used to provide monitoring in areas of active instability across tension cracks. These monitors can be quickly positioned and easily moved. The extensometer should be positioned on stable ground behind the last visible tension crack, and the wire should extend out to the unstable area. For warning devices, or for information on deformation within a sliding mass, wire extensometers can be placed at any strategic location. Anyone working in the area can make an immediate check on slope movement by inspecting the instruments.

3. Survey monitoring: Monitoring prism targets with the geodimeter total station continues to provide the most detailed movement history in terms of displacement directions and rates in the unstable areas. To keep within an accuracy of 0.05 ft (15 mm), the two-second geodimeter should have a maximum range of 5000 ft (1500 m) (Fig. 10.4.12).

Backsights can be taken on other instrument stations or on reference points outside the pit for calibration. In addition to a backsight, each instrument station should have a reference point on stable ground. This reference point is used to check the stability of the instrument station and to calibrate the EDM. Since the displacement measurements are relative, reproducibility is often more important than absolute distances.

Subsurface Displacement: Surface displacement measurements do not determine the subsurface extent of instability, although it is possible to make inferences from displacement vectors. There are many situations where measurement of subsurface displacement is needed. These measurements are commonly made utilizing shear strips, borehole inclinometers, and borehole extensometers.

1. Shear strips: Shear strips in a borehole will help to locate the position where the hole is cut off. Either commercial segmented strips or a coaxial cable with a fault finder can be used. These systems have the limitation of being go/no-go devices.

2. Borehole inclinometers: A borehole inclinometer that measures the angular deflection of the hole will give the deformation normal to the hole.

3. Borehole extensometers: Borehole extensometers will give the deformation parallel to the borehole.

Precision, Reliability, and Cost: The number of different devices that can be used for monitoring, as well as the precision and sophistication of the devices, are a function of the ingenuity, time, and budget of the engineer in charge of monitoring. Since none of these factors is infinite, hard choices must be made. Some general guidelines for decision making follow.

1. Measure the obvious things first: Surface displacement is the most direct and most critical aspect of slope instability.

2. Simpler is better: The reliability of a series system is the product of the reliability of the individual components. A complex electronic or mechanical device with a telemetered output to a computer has significantly less chance of being in operation when needed than do two stakes and a tape measure.

3. Precision costs money: The cost of a measuring device is often a power function of the level of precision. Measuring to 0.4 in. (10 mm) is inexpensive compared to measuring to 0.0004 in. (0.001 mm). A micrometer is unnecessary for monitoring slope movement that has a velocity of 2 in. (50 mm)/day.

4. Redundancy is required: No single device or technique tells the complete story. A single extensometer or survey point cannot indicate the area involved in the instability, and, if it is destroyed, the continuity of the record is lost.

5. Timely reporting is essential: Data collection and analysis must be rapid enough to provide information in time to make decisions.

Monitoring Schedule: A definite monitoring schedule should be established. The frequency of monitoring is a function of the precision of the system, the rate of movement, and how critical the area is. Table 10.4.3 is a suggested schedule. If there is heavy rain or a large blast in the area, additional measurements should be made.

Cooperation between operations and engineering is important. Equipment operators often have an intuitive feel for ground conditions. Any changes in the condition of an area observed by operators should be reported to engineering for followup.

Data Reduction and Reporting: The following measurements or calculations should be made for each survey reading:

1. Date of reading, incremental days between readings, and total number of days the survey point has been established.
2. Coordinates and elevation.
3. Magnitude and direction of horizontal displacement.
4. Magnitude and plunge of vertical displacement.

Table 10.4.3. Suggested Monitoring Schedule

Mining	Velocity Ft/Day	Velocity Mm/day	Visual Inspection	Extension	Crack Map	Survey[3]	Piezometers
Active	0	0	Daily[1]	—	Monthly	Monthly	Monthly
	< 0.05	<15	Daily[1]	Daily[2]	Weekly	Monthly	Weekly
	0.05–0.17	15–50	Each Shift[1]	Each Shift[2]	Daily	Weekly	Daily
	0.17–0.30	50–100	2 × Shift	2 × Shift	Daily	Daily	Daily
Inactive	0	0	Monthly	—	Monthly	Quarterly	Monthly
	< 0.05	<15	Monthly	Monthly	Monthly	Monthly	Monthly
	0.05–0.17	15–50	Daily	Daily[2]	Weekly	Weekly	Weekly
	0.17–0.30	50–100	Daily	Daily[2]	Daily	2 × Week	Daily
	< 0.30	<100	2 × Day	2 × Day[2]	Daily	2 × Day	Daily

Note:
1. Some mining codes require inspection of working face at beginning of each shift.
2. Extensometers should have warning lights.
3. If extensometers are not installed, survey observations should be on extensometer schedule.

5. Magnitude, bearing, and plunge of resultant (total) displacements.

Both incremental and cumulative displacement values should be determined. Calculating the cumulative displacement from initial values rather than from summing incremental displacements minimizes the effects of occasional survey aberrations.

Slope displacements are best understood and analyzed when the monitoring data are graphically displayed. For engineering purposes, the most useful plots are

1. Horizontal position.
2. Vertical position (elevation vs. change in horizontal position, plotted on a section oriented in the mean direction of horizontal displacement).
3. Displacement vectors.
4. Cumulative total displacement vs. time.
5. Incremental total displacement rate (velocity, usually in ft or m/day) vs. time.

All graphics should be kept up-to-date and should be easily reproducible, for ease of distribution. By studying several graphs simultaneously, the movement history of a particular slope can be determined.

Precipitation data should also be recorded in order to evaluate possible correlations with slope displacement. A gage located at the mine site can be used to measure occurrences and amounts of precipitation. In addition, measurement of the average daily temperatures will provide some indication of freeze and thaw periods.

The location of mining areas and the number of tons mined should also be recorded on a regular basis, because slope displacements are often associated with specific mining activity. One method of cataloging this information is to plot the mining area and then note the number of tons mined and the date on a plan map of the pit. A histogram can be made of tons mined vs. time, and this plot can then be compared to the total displacement graphs.

A formal monthly slope stability report should be prepared, containing the data listed in Table 10.4.4 and recommendations on the appropriate response to current instability. This ensures that mine management receives the appropriate information and provides the discipline to document slope behavior. Direct informal communication should also be maintained with pit operations on a daily basis.

10.4.6.2 Slide Management

When instability occurs, there are a number of response options:

Table 10.4.4. Monitoring Data Presentation

Graphs
Cumulative Displacement vs. Time
Velocity vs. Time (ft or m/day, semi-log plot)
Precipitation vs. Time
Water Levels vs. Time
Mining vs. Time
Maps and Sections
Pit Map with Location of Unstable Areas
Location of Monitoring Points with Displacement Vectors
Tension Crack Map
Horizontal Plot of Location with Time
Vertical Plot of Location with Time
Map of Piezometric Surface
Cross Section of Unstable Area

1. Leave the unstable area alone.
2. Continue mining without changing the mine plan.
3. Unload the slide through additional stripping.
4. Leave a step-out.
5. Partial cleanup.
6. Mine out the failure.
7. Support the unstable ground with cable bolts.
8. Dewater the unstable area.

The choice of options or combination of options depends on the nature of the instability and the operational impact. Each case should be evaluated individually and cost-benefit comparisons conducted. The following is a list of guidelines on the choice of options.

1. When instability is in an abandoned or inactive area, it can be left alone.

2. If the displacement rate is low and predictable and the area must be mined, living with the displacement while continuing to mine may be the best action.

3. Even though unloading has been a common response, in general it has been unsuccessful. In fact, there are situations involving high water pressure where unloading actually decreases stability.

4. Step-outs have been used successfully in several mines. The choice between step-out and cleanup is determined by the trade-off between the value of lost ore and the cost of cleanup.

5. Partial clean-up may be the best choice where a slide blocks a haul road or fails onto a working area. Only that material necessary to get back into operation need be cleaned up.

6. Where the failure is on a specific structure and there is competent rock behind the structure, mining out the failure may be the optimum choice.

7. Mechanical support may be the most cost-effective option when a crusher, conveyor, or haul road must be protected.

8. Where high water pressure exists, dewatering is an effective method of stabilization that may be used in conjunction with other options.

10.4.6.3 Contingency Planning

Mine planning should have the flexibility to respond to slope instability. Rather than an after-the-fact crisis response to forced deviation from a rigid mine plan, contingency plans should be prepared in advance so that the response to slope instability is well thought out.

Operational flexibility should be built into the mining plan. For example:

1. Adequate ore should be exposed and accessible so that production is not dependent on a single location.

2. There should be more than one access road into the pit for service vehicles.

3. Whenever possible, double access to working benches should be maintained.

4. Production scheduling should have a provision for slide cleanup.

Chapter 10.5
GROUND CONTROL

Z.T. BIENIAWSKI

The terms ground control and strata control, which here are used interchangeably, date back some 60 years to the early 1930s when the use of rock bolts was pioneered in the United States. Records show that in 1936, the St. Joseph Lead Co. in Missouri introduced rock bolting in its mines. But it was not until 1943 that systematic use of rock bolts for ground control was described by Weigel. The first international conference on rock pressure and ground control was held in Liege, Belgium, in 1951. Originally, ground/strata control were concerned primarily with coal mining in bedded rock formations (strata), but since the early 1960s, the term has been generalized and systematically applied in all types of underground mining and specifically also in hard-rock mining. More recently, ground control found its way to civil engineering tunneling, due particularly to the importance of mined underground repositories for nuclear waste storage, and to petroleum engineering with the emergence of the mining-for-oil concept (Bieniawski, 1987).

In essence, *ground control* means maintaining rock mass stability by controlling the movement of excavations in the ground, which can be either rock or soil. This is a specialty engineering field that is important because the design of underground excavation is, to a large extent, the design of underground support systems such as pillars and rock reinforcement (rock bolting).

Although today, ground control is no longer solely a mining art since much of it can qualify as an engineering science, the application of rock and soil mechanics principles and techniques in day-to-day mine planning and design is still not common. It is hoped that the up-to-date knowledge digest contained in this chapter will contribute to better dissemination and application of ground-control concepts and techniques, some of which have been available for many years but of which mining engineers have not availed themselves fully.

10.5.1 COMMON GROUND-CONTROL PROBLEMS IN UNDERGROUND MINES

Ground-control failures in underground mines are characteristic of the mining methods employed, opening shape, and support methods. Types of failure include pillar failure, roof falls, floor heave, rock bursts, strata cavings in longwall mining, and support failure.

Moreover, there are many types of failure mechanisms in underground excavations. These include loosening of the rock mass due to body forces and geologic conditions; in situ stresses exceeding the rock strength and resulting in slabbing, swelling, and squeezing of rock; or rock failure due to water, gas, and temperature effects. In essence, failure of an underground excavation may be caused by (1) movement of blocks or wedges of rock into an excavation under the action of gravity, water pressure or in situ stresses, and/or (2) failure of intact rock from overstressing. At shallower depths, the stability of an excavation is generally structurally controlled.

10.5.2 DESIGN PRINCIPLES FOR GROUND CONTROL IN UNDERGROUND MINING

The following definition of *engineering design* may be quoted after the Accreditation Board for Engineering and Technology (Anon., 1987): "Engineering design is the process of devising a system, component, or process to meet desired needs. It is a decision-making process (often iterative), in which the basic sciences, mathematics, and engineering science are applied to convert resources optimally to meet a stated objective. Among the fundamental elements of the design process are the establishment of objectives and criteria, analysis, synthesis, construction, testing and evaluation. Central to the process are the essential and complementary roles of analysis and synthesis. In addition, sociological, economic, aesthetic, legal and ethical considerations need be included in the design process."

The ten distinguishable stages in the design process are as follows (Bieniawski, 1984):

1. Recognition of a need or a problem.
2. Statement of the problem, including identification of performance objectives and design issues.
3. Collection of information.
4. Concept formulation in accordance with design criteria.
5. Analysis of solution components.
6. Synthesis to create alternative solutions.
7. Evaluation and testing of the solutions.
8. Optimization.
9. Recommendation and communication.
10. Implementation.

In mining, the process of designing an excavation may be conceptually visualized, as depicted in Fig. 10.5.1. The design methods available for assessing the stability of underground excavations can be broadly categorized as follows:

1. Analytical methods.
2. Observational methods.
3. Empirical methods.

Analytical methods utilize the analyses of stresses and deformations around openings and include numerical modeling techniques, such as the finite element method. They are effective in ground control because they enable comparisons of a few variations of a mining situation and serve as a relative design procedure.

Observational methods rely on actual monitoring of ground movement during excavation to detect measurable instability, and on the analysis of ground-support interaction.

Empirical methods assess the stability of mines and tunnels by the use of statistical analyses of underground observations and experience. Engineering rock mass classifications are the best known empirical methods.

Note that only some factors are within the control of the design engineer. In the case of coal mining these include opening width, pillar width and length, pillar layout, panel width and length, excavation sequence, panel sequencing, and orientation. Nevertheless, the range within which these factors may be varied is limited; for example, one cannot mine an opening narrower than that needed for operating mining machinery.

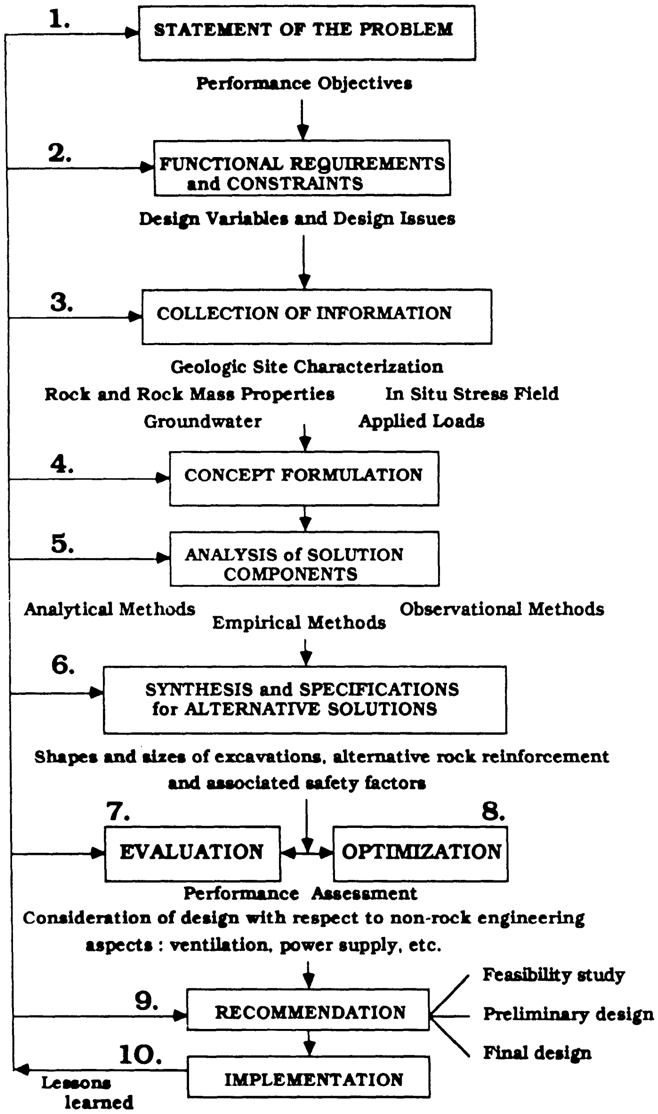

Fig. 10.5.1. Simplified chart of a design process in mining (Bieniawski, 1988).

10.5.3 GEOLOGIC SITE CHARACTERIZATION AND ENGINEERING CLASSIFICATIONS OF ROCK MASSES

Provision and interpretation of reliable input data for ground-control design is one of the most difficult tasks facing geologists and engineers. It is extremely important that the quality of the input data matches the sophistication of the design methods. It has been contended often that some design methods, such as numerical techniques, have outpaced our ability to provide the input data necessary for the application of these methods. Obviously, it must be realized that if incorrect input parameters are employed, incorrect design information will result.

The input information needed for design purposes generally includes geologic characterization of the rock masses and evaluation of the virgin ground stresses and the mechanical properties that characterize the rock mass in its natural state. Whatever procedures and techniques are employed to obtain the input parameters, it is necessary to emphasize that any such procedures and techniques should only be used if they can be fully justified for the purposes of a given project. In other words, measurements and investigations should be carefully planned and matched with the purpose of a project, full justification being given for any investigations and tests performed.

Furthermore, determination of the input parameters for design should be so planned that as much quantitative data as possible is obtained rather than relying on qualitative descriptions.

In essence, the following three important messages emerge:

1. The eventual quality of the engineering design is directly proportional to the quality of the input parameters.
2. Any procedures or methods employed in providing input data should be fully justified and carefully planned.
3. Quantitative rather than qualitative information is required for design purposes.

Determination of the input data for design, involving geologic site characterization, ground stress conditions, groundwater conditions, and mechanical properties of rock masses, is a wide subject. In particular, see Goodman (1976), Hoek and Brown (1980), and Hansen and Lachel (1980), with special reference to mining applications.

10.5.3.1 Geologic Site Characterization

"The first fact which must be recognized when planning a site investigation program is that there is no such thing as a standard site investigation" (Hoek, 1982). The scope of a detailed site exploration is outlined in Fig. 10.5.2. In essence, site characterization involves the discovery, correlation, and analysis of geologic data such as:

1. Rock types to be encountered.
2. Depth and character of overburden.
3. Microscopic scale discontinuities such as major faults.
4. Groundwater conditions.
5. Special problems, such as weak ground or swelling rock.

The initial site assessment can utilize a number of sources of information, of which two are particularly relevant:

1. Available geologic maps, published literature, and possibly local knowledge.
2. Photogeologic images (aerial photographs) of the area. The photogeologic study includes information on topography, drainage, lithology, geologic structures, and discontinuities.

One of the purposes of the initial site exploration is to determine the regional geology of the vicinity of the project. While determination of the regional geology is based mainly on studies of reports, maps, and publications involving the geologic history of the area, some limited investigations may also be conducted. These would include mapping of the surface outcrops, physical exploration, and a limited program of drilling and groundwater investigations. Some laboratory tests on rock samples and index field tests on rock cores may also be performed. Based on these investigations, preliminary geologic maps and sections should be prepared showing favorable and unfavorable regions in the rock mass. These maps and sections are important for planning the next stages of the site characterization program.

Where outcrops and geologic structures are not easily deduced by either photogeologic or ground investigations, geophysical methods may be used to locate large discontinuities such as faults. The most effective means of doing this would be by seismic or resistivity methods (see Chapter 4.4).

Based on initial site exploration, detailed site investigation will be conducted once the feasibility of the project has been established. This stage of site characterization will include detailed exploratory drilling, geologic mapping, geophysical surveys, and rock mechanics testing.

Drilling Investigations and Core Logging: The purpose of a drilling investigation is to

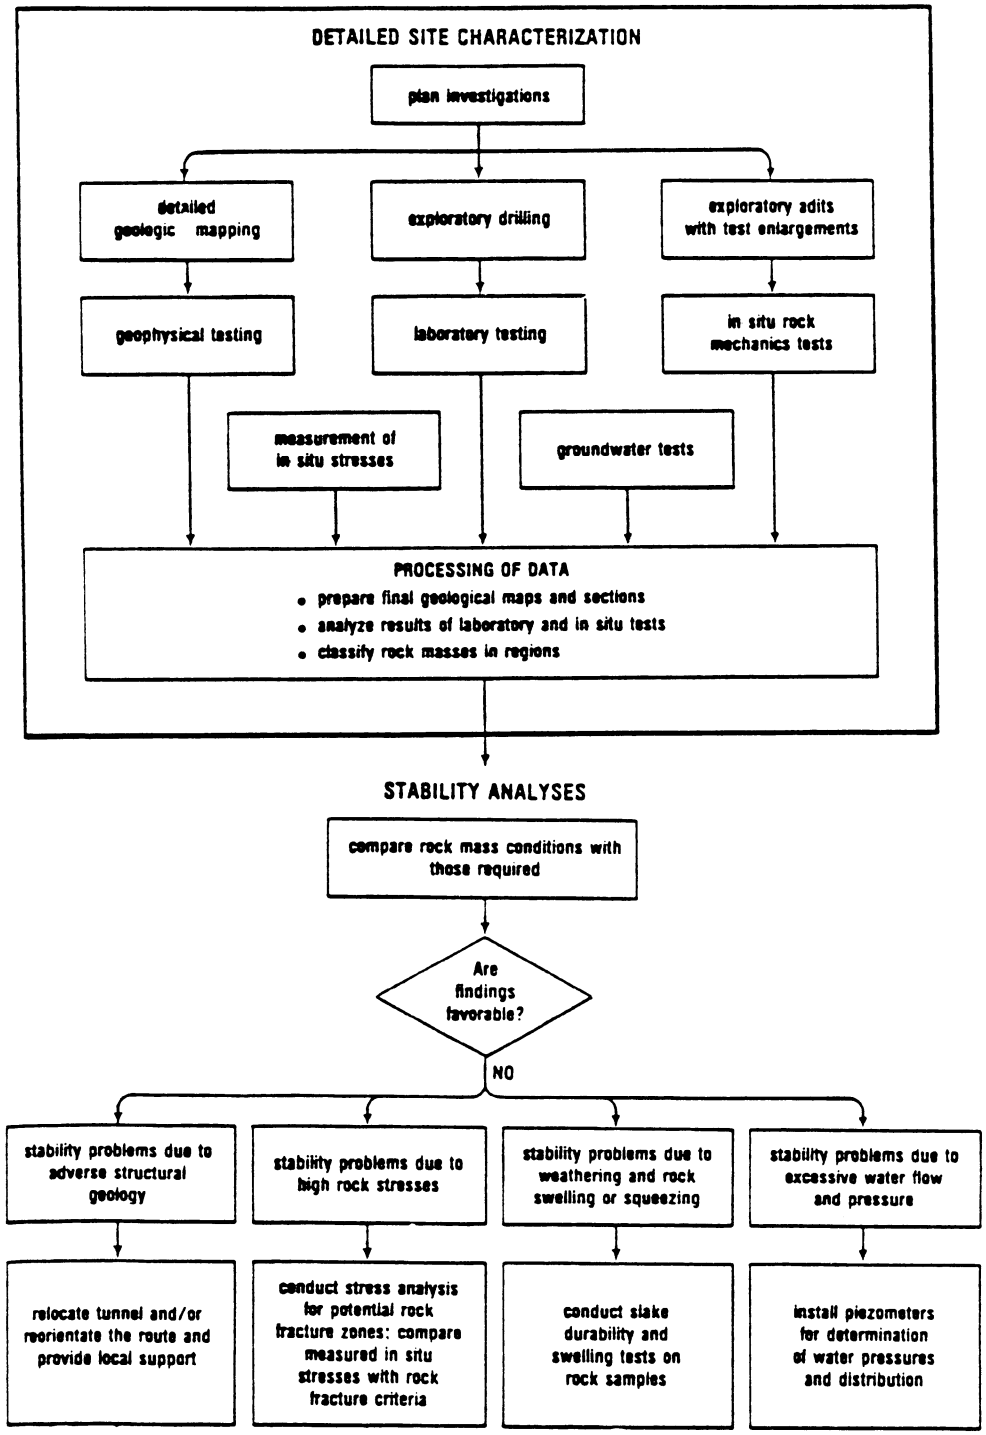

Fig. 10.5.2. Stages of a site characterization program (Bieniawski, 1984).

1. Confirm geologic interpretations.
2. Examine cores and boreholes to determine the quality and characteristics of the rock mass.
3. Study groundwater conditions.
4. Provide cores for rock mechanics testing and petrographic analyses.

As the object of drilling is to obtain cores for interpretation and testing, it is essential to obtain as near 100% core recovery as possible. To ensure a successful drilling operation, the following aspects should be remembered:

1. The cost of a drilling investigation for geotechnical purposes is much higher, sometimes by a factor of two, than the cost of drilling for mineral exploration purposes. Geotechnical drilling necessitates good-quality equipment and extra care, but it can provide high-quality information.

2. The drilling equipment should feature diamond core drilling facilities permitting core of at least NX size ($2\frac{1}{8}$ in. or 54 mm diameter) and featuring split double-tube core barrels to minimize drilling vibrations. Also included should be equipment for performing water pressure tests.

3. The purpose of drilling investigations is to obtain not only the core logs, but also the logging of the borehole itself. Hence examination of the borehole walls by borehole cameras or by other systems should be considered.

4. For meaningful interpretation of the orientation of geologic features, core orientation procedures may be employed during geotechnical drilling. A number of techniques are available for that purpose (see Chapter 5.2). Boreholes should be angled so that vertical discontinuities can be sampled.

5. Good care should be taken of the core recovered from the boreholes. This means that the cores should be photographed as soon as possible, should be carefully marked, placed in protective wrapping in the core boxes, and stored in properly provided storage sheds. Core samples removed for testing should be appropriately marked in the core boxes.

A systematic method should be used for geotechnical logging of the rock cores. There is a difference between a geologic core log for general purposes and a geotechnical core log for engineering purposes. The geotechnical core log provides a format to record both the geologic and engineering characteristics of the rock core and the results of any field tests. The core log should systematically record all the information available from the core. An example of a geotechnical core log is given in Fig. 10.53. It should be noted that there is no rigid standard format for a geotechnical core log, and the amount of detail used will depend on the actual purpose of the project.

Engineering Geologic Mapping: The purpose of engineering geologic mapping is to investigate the significant features of the rock mass, especially the discontinuities such as naturally occurring joints. It is also important to determine the geologic structure especially in stratified rock that may have been subjected to faulting. Detailed procedures for engineering geologic mapping have been described in a number of publications (e.g., see Chapter 5.2).

It should be noted that while engineering geologic mapping is fairly frequently found on tunneling projects, this is not the situation on mining projects. Engineering geologic mapping in underground mines is a fairly recent innovation in mapping procedures for mines (Chapters 5.2 and 5.5).

Finally, one should emphasize that one of the purposes of engineering geologic mapping is to provide input data for a rock mass classification to be used at the site for estimating the stability of underground structures and support requirements. Clearly, engineering geologic mapping will provide the most reliable input data for a rock mass classification, although it is also possible to obtain reasonable data from interpretations of the borehole and core logs.

Geophysical Investigations: Geophysical techniques involving seismic refraction and reflection, electrical resistivity, gravimetric, and magnetic measurements form an accepted part of engineering-geologic investigation procedures. Detailed descriptions of these methods, together with their applications, limitations, accuracy, and costs, may be found in many textbooks and articles (e.g., Hoek and Brown, 1980), as well as in Chapter 4.4.

Geologic Data Presentation: If determination of geologic data for site characterization is a difficult problem, presentation of these data for engineering purposes is sometimes even more difficult. Communication between the engineering geologist and the design engineer would be greatly enhanced if the format for data presentation could be established in the early stages of an engineering project. The following suggestions are useful:

1. Borehole data should be presented in well-executed geotechnical logs.

2. Mapping data derived from joint surveys should be presented as spherical projections, for example, of the Schmidt or Wolff type (Goodman, 1976; Hoek and Brown, 1980).

3. A summary of all geologic data, including groundwater conditions, should be entered in the input data sheets for rock-mass classification purposes, such as depicted in Fig. 10.5.4. One such sheet is required for each geologic zone in which certain rock-mass features are more or less uniform, for example, type of rock or discontinuity spacing.

4. Longitudinal and cross sections of structural geology at the site should form an integral part of a geologic report.

5. Consideration should be given to constructing a geologic model of the site.

In summary, the following geologic parameters are considered important in the stability of underground excavations and should be included in a site characterization report:

1. Orientation of discontinuities in the rock mass.
2. Spacing of discontinuities in the rock mass.
3. Condition of discontinuities, including roughness, separation, continuity, weathering, and infilling (gouge).
4. Groundwater conditions.
5. Major faults.
6. Properties of intact rock material.

10.5.3.2 Rock Mass Classifications

Empirical design methods relate practical experience gained on previous projects to the conditions anticipated at a proposed site.

Rock mass classifications form the backbone of the empirical design approach and are widely employed in rock engineering (Bieniawski, 1989). In fact, on many projects, the classification approach serves as the only practical basis for the design of complex underground structures. Most of the tunnels and mines constructed at present make use of some classification system. The most used and the best known of these is Terzaghi's rock load classification introduced over 45 years ago (Terzaghi, 1946). Since then, this classification has been modified (Deere et al., 1970), and new rock classification systems have been proposed. These systems took cognizance of the new advances in rock support technology, namely, rock bolts and shotcrete, as well as addressed different engineering projects: tunnels, chambers, mines, slopes, and foundations. Today there are so many different rock classification systems in existence that it is useful to tabulate the more common ones (Table 10.5.1).

Rock mass classifications have been applied throughout the world, in the United States (Deere et al., 1967; Wickham et al., 1972; Bieniawski, 1979); Canada (Franklin, 1976); Western Europe (Lauffer, 1958; Pacher et al., 1974; Barton et al., 1974); South Africa (Bieniawski, 1973; Laubscher, 1977; Olivier, 1979); Australia (Baczynski, 1980); New Zealand (Rutledge and Preston, 1978); Japan (Nakao et al., 1983); India (Ghose and Raju, 1981; Venkateswarlu, 1986); USSR (Protodyakonov, 1974); and Poland (Kidybinski, 1979).

Major Classifications Currently in Use: Of the many rock-mass classification systems in existence today, six should be cited because they are especially important contributions, namely, those proposed by Terzaghi (1946), Lauffer (1958), Deere et al. (1967), Wickham et al. (1972), Bieniawski (1973), and Barton et al. (1974).

The rock load classification of Terzaghi (1946) was the first practical classification system introduced and has been dominant in the United States for over 40 years, proving very successful for tunneling with steel supports. Lauffer's classification (1958) was based on the work of Stini (1950) and was a considerable step forward in the art of tunneling since it introduced the concept of the stand-up time of the active span in a tunnel, which is highly relevant in determining the type and amount of tunnel support. Deere's classification (1967) introduced the rock quality designa-

tion (RQD) index, which is a simple and practical method of describing the quality of rock core recovered from boreholes.

The concept of rock structure rating (RSR), developed in the United States by Wickham et al. (1972, 1974), was the first system featuring classification ratings for weighing the relative importance of classification parameters. The geomechanics classification (RMR system) proposed by Bieniawski (1973) and the Q system proposed by Barton et al. (1974) were developed independently; both provide quantitative data for the selection of modern tunnel reinforcement measures such as rock bolts and shotcrete. The Q system has been developed specifically for tunnels and chambers while the RMR system, although also

initially developed for tunnels, has been applied to rock slopes and foundations, ground rippability assessment, as well as to mining problems (Laubscher, 1977; Ghose and Raju, 1981; Kendorski et al., 1983).

Today the RMR system and the Q system are the two rock mass classifications most commonly used throughout the world, and they will be discussed in detail.

Geomechanics Classification (Rock Mass Rating System): The rock mass rating (RMR) system, otherwise known as the geomechanics classification, was developed during 1972–73 and modified over the years as more case histories became available and to conform with international standards and procedures (Bieniawski, 1973, 1979). Over the past 15 years, the RMR system has stood the test of time and benefited from extensions and applications by many authors throughout the world. These varied applications, contained in some 350 case histories, point to the acceptance of the system and its inherent ease of use and versatility in engineering practice, involving tunnels, chambers, mines, slopes, and foundations. Nevertheless, it is important that the RMR system is used for the purpose for which it was developed and not as the answer to all design problems.

Because the RMR system has been modified several times, it is important to note that the system has remained essentially the same in principle in spite of the changes. Thus any modifications and extensions were the outgrowth of the same basic method and should not be misconstrued as new systems. To avoid any confusion, the following extensions of the system were valuable new applications, but were still a part of the same overall RMR system: mining applications, Laubscher (1977, 1984); rippability, Weaver (1975); hard-rock mining, Kendorski et al. (1983); coal mining, Unal (1983), Newman (1984), Venkateswarlu (1986), Newman and Bieniawski (1987); dam foundations, Serafim and Pereira (1983); tunneling, Gonzales de Vallejo (1983); and slope stability, Romana (1985).

Classification Procedures—The following six parameters are used to classify a rock mass using the RMR system:

1. Uniaxial compressive strength of rock material.
2. Rock quality designation (RQD).
3. Spacing of discontinuities.
4. Condition of discontinuities.
5. Groundwater conditions.
6. Orientation of discontinuities.

To apply the RMR system, the rock mass is divided into a number of structural regions such that certain features are more or less uniform within each region. Although rock masses are discontinuous in nature, they may, nevertheless, be uniform in regions when, for example, the type of rock or the discontinuity spacings are the same throughout the region. In most cases, the boundaries of structural regions will coincide with major geologic features such as faults, dykes, shear zones, etc. After the structural regions have been identified, the classification parameters for each structural region are determined from measurements in the field and entered onto the input data sheet (Fig. 10.5.4).

The geomechanics classification (RMR system) is presented in Table 10.5.2. In section A, five parameters are grouped into five ranges of values. Since the various parameters are not equally important for the overall classification of a rock mass, importance ratings are allocated to the different value ranges of the parameters, a higher rating indicating better rock mass conditions. The importance ratings are assigned to each parameter, according to section A of Table 10.5.2. In this respect, the average typical conditions are evaluated for each discontinuity set and the ratings are interpolated, using the classification charts A through E. The charts are helpful for borderline cases and also remove an impression that abrupt changes in ratings occur between categories. Chart D is used if either RQD or discontinuity spacing data are lacking. Based on the correlation data from Priest and Hudson (1976), the chart enables an estimate to be made of the missing parameter. Furthermore, it should be noted that the importance ratings given for discontinuity spacings apply to rock masses having three sets of discontinuities. Thus, when only two sets of discontinuities are present, a conservative assessment is obtained. In this way, the number of discontinuity sets is considered indirectly. Laubscher (1977) presented a rating concept for discontinuity spacings as a function of the number of joint sets. It can be shown that when less than three sets of discontinuities are present, the rating for discontinuity spacing may be increased by 30%.

Very favorable	Favorable	Fair	Unfavorable

Strike Parallel to Tunnel Axis		Irrespective of Strike
Dip 20–45°	Dip 45–90°	Dip 0–20°
Fair	Very unfavorable	Fair

Source: Bieniawski, 1984.

After the importance ratings of the classification parameters are established, the ratings for the five parameters listed in section A of Table 10.5.2 are summed to yield the basic (unadjusted for discontinuity orientations) rock mass rating for the structural region under consideration.

The next step is to include the sixth parameter, namely, the influence of strike and dip orientation of discontinuities by adjusting the basic rock mass rating according to section B of Table 10.5.2. This step is treated separately because the influence of discontinuity orientations depends upon the engineering applications, for example, tunnel, mine, slope or foundation. It will be noted that the value of the parameter, *discontinuity orientation,* is not given in quantitative terms but by qualitative descriptions such as "favorable." To facilitate a decision whether strike and dip orientations in mining and tunneling are favorable or not, reference should be made to Table 10.5.3(a), which is based on studies by Wickham et al. (1972). For slopes and foundations, the reader is referred to appropriate papers by Romana (1985) and by Bieniawski and Orr (1976).

The parameter discontinuity orientation reflects on the significance of the various discontinuity sets present in a rock mass. The main set is usually designated as set number 1 and controls the stability of an excavation; for example, in tunneling it will be the set whose strike is parallel to the tunnel axis. The summed up ratings of the classification parameters for this discontinuity set will constitute the overall rock mass rating. On the other hand, in situations where no one discontinuity set is dominant and of critical importance, or when estimating rock mass strength and deformability, the ratings from each discontinuity set are averaged for the appropriate individual classification parameter.

In the case of civil engineering projects, an adjustment for discontinuity orientations will generally suffice. For mining applications, other adjustments may be called for, such as the stress at depth or a change in stress, and these were discussed by Laubscher (1977) and by Kendorski et al. (1983). The procedure for these adjustments is depicted in Table 10.5.3(b).

After adjustment for discontinuity orientations, the rock mass is classified according to section C of Table 10.5.2, which groups the final (adjusted) rock mass rating into five rock mass classes, the full range of the possible RMR values varying from 0 to 100. Note that the rock mass classes are in groups of 20 ratings each. This concept of rating a rock mass on a maximum value of 100 has a distinct advantage over an open-ended system in that it allows the engineer or geologist to get the sense of a relative quality, or the lack of it, of a given rock mass in terms of its maximum potential.

Next, section D of Table 10.5.2 gives the practical meaning of each rock mass class by relating it to specific engineering problems. In the case of tunnels, chambers, and mines, the output from the geomechanics classification is the stand-up time and the maximum stable rock span for a given rock mass rating, as shown in Fig. 10.5.5 (a) and (b).

When mixed-quality rock conditions are encountered at the excavated rock face, such as good quality and poor quality being present in one exposed area, it is essential to identify the most critical condition for the assessment of the rock strata. This means that the geologic features that are most significant for stability purposes will have an overriding influence. For example, a fault or a shear in high-quality rock face will play a dominant role irrespective of the high rock material strength in the surrounding strata.

It is recommended that when there are two or more clearly different zones in one rock face, one approach to adopt is to obtain RMR values for each zone and then compute the overall

Table 10.5.3(b). Adjustments to the Rock Mass Rating System for Mining Applications

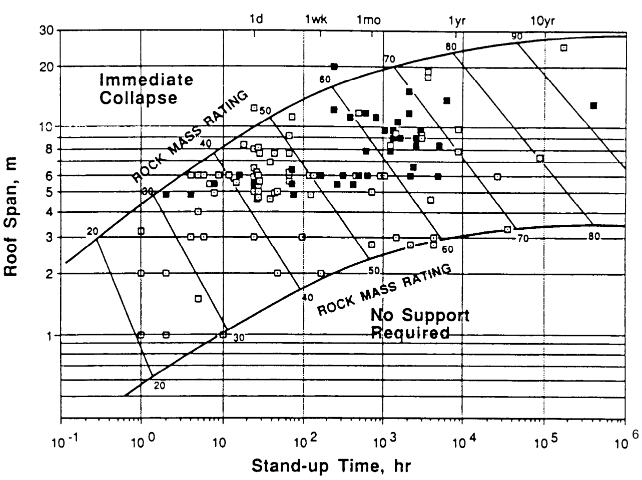

Fig. 10.5.5a. Relationship between the stand-up time and span for various rock mass classes, according to the RMR classification system—output for mining and tunneling. The plotted data points represent the roof falls studied: black squares for mines, open squares for tunnels. The contour lines are limits of applicability. (Bieniawski, 1989). Conversion factor: 1 ft = 0.3048 m.

weighted value by the surface area corresponding to each zone in relation to the whole area, as well as by the influence that each zone has on the stability of the whole excavation.

The RMR system provides guidelines for the selection of rock support for tunnels and mines, examples of which are given in Tables 10.5.4, 10.5.5, and 10.5.6. These guidelines depend on such factors as the depth below surface (in situ stress), tunnel size and shape, and the method of excavation. Note that the

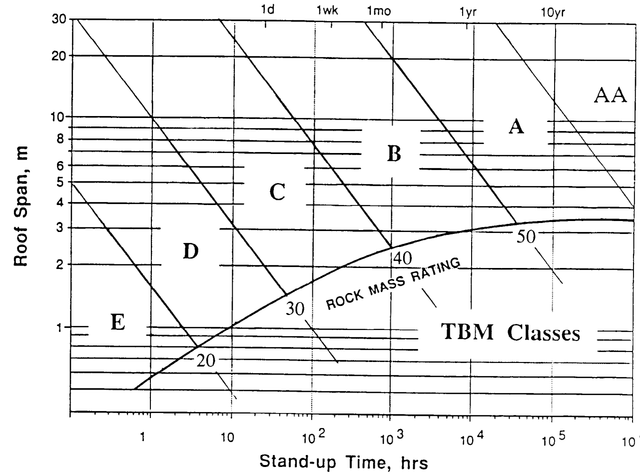

Fig. 10.5.5b. Modified 1988 Lauffer diagram depicting boundaries of rock mass classes for tunnel boring machine applications (Lauffer, 1988). Equivalent RMR values are estimates.

support measures given in Table 10.5.4 represent the permanent and not the primary support for tunnels. All these guidelines should be tested for applicability to the local mining conditions.

Support load can be determined from the RMR system as proposed by Unal (1983):

$$P = [(100 - \mathrm{RMR})/100]\gamma B \qquad (10.5.1)$$

where P is support load in lb (kN), B is tunnel width in ft (m), and g is rock density in lb/ft^3 (kg/m^3).

It must be emphasized that for all applications such as those involving the selection of rock reinforcement, determination of rock loads or rock mass strength and deformability, it is the actual RMR value that must be used and not the rock mass class in which this RMR value falls. In this way, the RMR system is very sensitive to individual parameters because within one rock mass class, for example, "good rock", there is much difference between RMR = 80 and RMR = 61.

Rock Mass Deformation—In the case of rock foundations, knowledge of the modulus of deformation of rock masses is of prime importance. The RMR system proved a useful method for estimating in situ deformability of rock masses (Bieniawski, 1978). As shown in Fig. 10.5.6, the following correlation was obtained:

$$E_M = 2\ \mathrm{RMR} - 100 \qquad (10.5.2)$$

where E_M is in situ modulus of deformation in GPa and RMR > 50.

More recently, Serafim and Pereira (1983) provided many results in the range RMR > 50 and proposed a new correlation:

$$E_M = 10^{(\mathrm{RMR}-10)/40} \qquad (10.5.3)$$

In the case of slopes, the output is given in section D of Table 10.5.2 as the cohesion and friction of the rock mass. Romana (1985) has applied the RMR system extensively for determination of rock slope stability.

Rock Mass Strength—Hoek and Brown (1980) proposed a method for estimating rock mass strength that makes use of the

Table 10.5.4. The RMR System Guidelines for Excavation and Support in Rock Tunnels

SHAPE: HORSESHOE, WIDTH: 10 m; VERTICAL STRESS: BELOW 25 MPa; CONSTRUCTION: DRILLING AND BLASTING

Rock mass class	Excavation	Support		
		Rock bolts (20 mm, dia., fully grouted)	Shotcrete	Steel sets
Very good rock I RMR:81–100	Full face 3 m advance.	Generally no support required except for occasional spot bolting.		
Good rock II RMR:61–80	Full face 1.0–1.5 m advance. Complete support 20 m from face.	Locally bolts in crown 3 m long, spaced 2.5 m with occasional wire mesh.	50 mm in crown where required.	None
Fair rock III RMR:41–60	Top heading and bench 1.5–3 m advance in top heading. Commence support after each blast. Complete support 10 m from face.	Systematic bolts 4 m long, spaced 1.5 m–2 m in crown and walls with wire mesh in crown.	50–100 mm in crown and 30 mm in sides.	None
Poor rock IV RMR:21–40	Top heading and bench 1.0–1.5 m advance in top heading. Install support concurrently with excavation 10 m from face.	Systematic bolts 4–5 m long, spaced 1–1.5 m in crown and walls with wire mesh.	100–150 mm in crown and 100 mm in sides.	Light to medium ribs spaced 1.5 m where required.
Very poor rock V RMR: <20	Multiple drifts. 0.5–1.5 m advance in top heading. Install support concurrently with excavation. Shotcrete as soon as after blasting.	Systematic bolts 5–6 m long, spaced 1–1.5 m in crown and walls with wire mesh. Bolt invert.	150–200 mm in crown, 150 mm in sides and 50 mm on face.	Medium to heavy ribs spaced 0.75 m with steel lagging and fore-poling if required. Close invert.

Source: Bieniawski, 1979. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

RMR classification. The criterion for rock mass strength is as follows:

$$\frac{\sigma_1}{\sigma_c} = \frac{\sigma_3}{\sigma_c} + \sqrt{m\frac{\sigma_3}{\sigma_c} + s} \qquad (10.5.4)$$

where σ_1 is major principal stress at failure, σ_3 is applied minor principal stress, σ_c is uniaxial compressive strength of the rock material, and m and s are constants dependent upon the properties of the rock and the extent to which it has been fractured by being subjected to σ_1 and σ_3. For intact rock, $m = m_i$ is determined from a fit of the above equation to triaxial test data from laboratory specimens, taking $s = 1$ for rock material.

For rock masses, the constants m and s are related to the basic (unadjusted) rock mass rating RMR, as follows (Hoek and Brown, 1988):

For *undisturbed rock masses* (smooth-blasted or machine-bored excavations):

$$m = m_i \exp[(\text{RMR} - 100)/28] \qquad (10.5.5)$$

$$s = \exp[(\text{RMR} - 100)/9]$$

For disturbed rock masses (slopes or blast-damaged excavations):

$$m = m_i \exp[(\text{RMR} - 100)/14] \qquad (10.56)$$

$$s = \exp[(\text{RMR} - 100)/6]$$

Significant values are summarized in Table 10.5.7.

An alternative criterion for estimating rock mass strength also involves the use of RMR. A rock failure criterion proposed by Bieniawski (1974) was modified by Yudhbir (1983) with respect to the constant A, as follows :

$$\frac{\sigma_1}{\sigma_c} = A + B\left[\frac{\sigma_3}{\sigma_c}\right]^{\alpha} \qquad (10.5.7)$$

where a = 0.75 and B depends on rock type as follows: shale and limestone, B = 2; siltstone and mudstone, B = 3; sandstone and quartzite, B = 4; norite and granite, B = 5.

In the Bieniawski criterion, A = 1 (for *intact rock*), but for *rock masses* Yudhbir determined that A is a function of the rock-mass quality as follows:

$$A = 20\,m\,(0.0765\ \text{RMR} - 7.65) \qquad (10.5.8)$$

Database: The database used for the development of a rock mass classification may indicate the range of its applicability. For example, the RMR system involved originally 49 case histories followed by 62 case histories added by Newman and Bieniawski (1987) and a further 78 cases collected between 1984 and 1987. For the database represented by all 351 case histories, see Bieniawski (1989).

Q System: This system of rock mass classification was developed in Norway in 1974 by Barton et al., all of the Norwegian Geotechnical Institute. Its development represented a major contribution to the subject of rock mass classification for a number of reasons: (1) the system was proposed on the basis of an analysis of 212 tunnel case histories, mostly from Scandinavia, (2) it is a quantitative classification system, and (3) it is an engineering system facilitating the design of tunnel supports.

The Q system is based on a numerical assessment of the rock mass quality using six different parameters: (1) RQD, (2) number

Table 10.5.5. Rock Support Selection Chart for Coal Entries 20 ft wide

Roof rock class	Rock mass rating (RMR)	Rock load height (ft)	Support specifications: Mechanical bolts	Support specifications: Resin bolts
I Very good	90	2.0	L: 2.5' S: 5' x 5' G: 40 ø: 5/8" C: 6.2 tons	
	80	4.0	L: 2.5' S: 5' x 4.5' G: 60(40) ø: 3/4"(7/8") C: 11 tons	L: 2.5' S: 5' x 5' G: 60 ø: 3/4" C: 12 tons
II Good	70	6.0	L: 3.0' S: 4' x 4' G: 60 ø: 3/4" C: 10 tons	L: 3.0' S: 5' x 5' G: 60 ø: 3/4" C: 18 tons

of joint sets, (3) roughness of the most unfavorable joint or discontinuity, (4) degree of alteration or filling along the weakest joint, (5) water inflow, and (6) stress condition. These six parameters are grouped into three quotients to give the overall rock mass quality Q as follows:

$$Q = \frac{RQD}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{SRF} \qquad (10.5.9)$$

where RQD is rock quality designation, J_n is joint set number, J_r is joint roughness number, J_a joint alteration number, J_w is joint water reduction number, and SRF is stress reduction factor.

The rock quality can range from Q = 0.001 to Q = 1000 on a logarithmic rock mass quality scale.

In Table 10.5.8, the numerical values of each of the classification parameters are given. They are interpreted as follows: the first two parameters represent the overall structure of the rock mass, and their quotient is a relative measure of the block size. The quotient of the third and the fourth parameters is said to be an indicator of the interblock shear strength (of the joints). The fifth parameter is a measure of water pressure, while the sixth parameter is a measure of (1) loosening load in the case of shear zones and clay bearing rock, (2) rock stress in competent rock, and (3) squeezing and swelling loads in plastic incompetent rock. This sixth parameter is regarded as the *total stress* parameter.

Table 10.5.6. Support Recommendations for Mine Drifts

Spot bolting: Bolting to restrain limited areas or individual blocks of loose rock, primarily for safety.

Wide pattern bolting: Bolt spacing on 1.5 m to 1.8 m, or wider in very large openings.

Medium pattern bolting, with or without mesh or straps: Bolts spaced 0.9 m to 1.5 m, 23 cm wide straps or 100 mm welded wire mesh.

Close pattern bolting mesh, or straps: Bolt spacing less than 0.9 m, 100 mm welded wire mesh, 0.3 m straps, or chain link.

Medium pattern bolting with shotcrete: Bolts spaced 0.9 m to 1.5 m and 80 mm (nominal) of shotcrete. Light mesh for wet rock to alleviate shotcrete adherence problems.

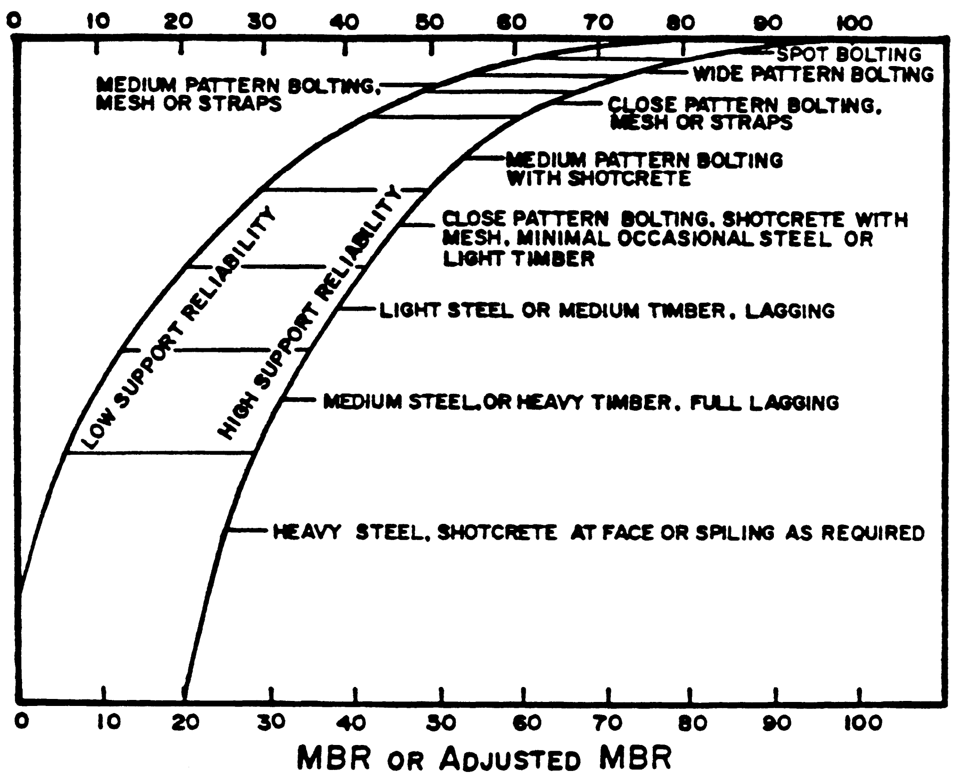
Close pattern bolting, shotcrete with mesh, minimal occasional steel or light timber: Bolt spacing less than 0.9 m with 100 mm welded wire mesh or chain link throughout, and nominal 100 mm of shotcrete. Localized conditions may require light wide-flange steel-sets or timber sets.

Light steel, medium timber, lagging: Bolting as required for safety at the face—full contact (grouted or Split Set) bolts only. Light wide-flange steel-sets or 0.25 m timber sets spaced 1.5 m, with full crown lagging and rib lagging in squeezing areas.

Medium steel, heavy timber, full lagging: Medium wide-flange steel-sets or 0.3 m timber sets spaced 1.5 m, fully lagged across the crown and ribs. Support to be installed as close to the face as possible.

Heavy steel, shotcrete at face or spilling as required: Heavy wide-flange steel-sets spaced 1.2 m, fully lagged on crown and ribs, carried directly to face. Spilling or shotcreting of face as necessary.

General: Bolting: bolts in spot bolting through close pattern bolting are considered to be 19 mm in diameter, fully grouted or resin-anchored standard rockbolts; mechanical anchors are acceptable in material of MBR > 60. Split-Set use is at the discretion of the operator.



Source: Kendorski et al., 1983. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

The quotient of the fifth and the sixth parameters describes the *active stress.*

Barton et al. (1974) consider the parameters, J_n, Jr, and J_a, as playing a more important role than joint orientation, and if joint orientation had been included, the classification would have been less general. However, orientation is implicit in parameters J_r and J_a, because they apply to the most unfavorable joints.

The Q value is related to tunnel support requirements by defining the equivalent dimensions of the excavation. This equivalent dimension, which is a function of both the size and the purpose of the excavation, is obtained by dividing the span, diameter, or the wall height of the excavation by a quantity called the excavation support ratio (ESR). Thus,

$$\text{equivalent dimension} = \text{span or height (meters)/ESR} \tag{10.5.10}$$

The ESR is related to the use for which the excavation is intended and the degree of safety demanded, as now shown:

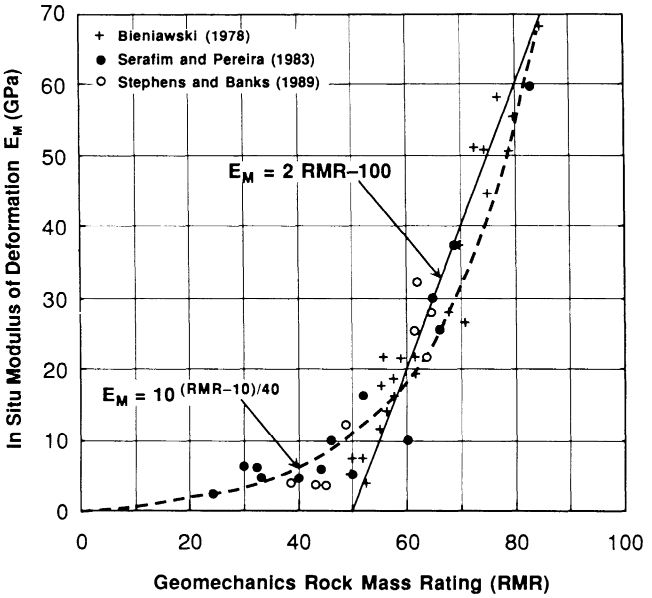


Fig. 10.5.6. Correlation between the in situ modulus of deformation and rock mass rating RMR (Serafim and Pereira, 1983). Conversion factor: 1 psi = 6.895 kPa.

Excavation category	*ESR*	*No. of cases*
A. Temporary mine openings	3–5	2
B. Vertical shafts:		
circular section	2.5	—
rectangular/square section	2.0	—
C. Permanent mine openings, water tunnels for hydropower (excluding high-pressure penstocks), pilot tunnels, drifts, headings for large excavations	1.6	83
D. Storage caverns, water treatment plants, minor highway and railroad tunnels, surge chambers, access tunnels	1.3	25
E. Power stations, major highway or railroad tunnels, civil defense chambers, portals, intersections	1.0	73
F. Underground nuclear power stations, railroad stations, factories	0.8	2

The relationship between the index Q and the equivalent dimension of an excavation determines the appropriate support measures, as depicted in Fig. 10.5.7 (a) and (b). These 38 support categories specify the estimates of permanent support. For temporary support determination, either Q is increased to 5 Q or ESR is increased to 1.5 ESR.

It should be noted that the length of rock bolts is not specified in the support guidelines in Fig.10.5.7, but the bolt length L is determined from the equation,

$$L = 2 + 0.15B/\mathrm{ESR} \qquad (10.5.11)$$

where B is the excavation width.

The maximum unsupported span can be obtained as follows:

$$\text{Maximum span (unsupported)} = 2(\mathrm{ESR})Q^{0.4} \qquad (10.5.12)$$

The relationship between the Q value and the permanent support pressure P_{roof} is calculated from the following relation:

$$P_{\mathrm{roof}} = (2.0/J_r)Q^{-1/3} \qquad (10.5.13)$$

If the number of joint sets is less than three, the equation is expressed as:

$$P_{\mathrm{roof}} = 2/3\, J_n^{1/2} J_r^{-1} Q^{-1/3} \qquad (10.5.14)$$

Case histories used to develop the Q system consisted mainly of tunnels and chambers from Scandinavia (Sweden and Norway), including 97 cases reported by Cecil (1970).

Correlations: A correlation was proposed between the RMR and the Q index (Bieniawski, 1976). Based on 111 case histories analyzed for this purpose (involving 62 Scandinavian cases, 28 South African cases, and 21 case histories from the United States, Canada, Australia, and Europe), the following relationship was found for civil engineering tunnels:

$$\mathrm{RMR} = 9\, \ln Q + 44 \qquad (10.5.15)$$

For mining tunnels, Abad et al. (1983) analyzed 187 coal mine roadways in Spain arriving at this correlation:

$$\mathrm{RMR} = 10.5\, \ln Q + 42 \qquad (10.5.16)$$

Moreno Tallon (1982) in Spain, Jethwa et al. (1982) in India, and Trunk and Honish (1989) in Germany further substantiated the correlation by Bieniawski (1976) on the basis of 59 projects.

Example 10.5.1. Find rock mass quality by a classification system.

Given: Rock mass in horizontal bedding, 500 ft (152 m) depth.
Rock material: shale.
Uniaxial compressive strength: 5800 psi (50 MPa).
Strata conditions: separation < 0.04 in. (1 mm); slightly weathered, slightly rough surfaces, no infilling.
RQD = 60%. Three discontinuity sets.
Spacing of main discontinuities: 6 in. (150 mm).
Groundwater conditions: damp.
In situ stresses: horizontal stress = 2.5 vertical stress.

Solution.

RMR System

Rating due to uniaxial compressive strength	5
Rating due to RQD	12
Rating due to discontinuity spacing	7
Rating due to condition of discontinuities	17
Rating due to ground water conditions	10
Rating due to strike and dip of discontinuities (Horizontal bedding = "fair" orientation)	− 5
Rock Mass Rating (RMR)	46
Factor due to in situ stresses: 0.9 Adjusted RMR is	41

Q system

RQD = 60
J_n = 9
J_r = 1.25
J_a = 2
J_w = 0.66
SRF = 1

Q = 60/9 × 1.25/2 × 0.66/l = 2.75

10.5.4 ROCK MASS PROPERTIES AND IN SITU STRESSES

The ground-control engineer is confronted with rock as a rock mass, that is, an assemblage of blocks of rock material separated by various types of geologic discontinuities such as joints, bedding planes, shears, and faults. Consequently, both the engineering properties of intact rock and of rock masses must be considered. The tests and properties for intact rock are dealt with in Chapter 10.2.

Unfortunately, laboratory-measured quantities obtained from tests conducted on small rock specimens generally do not yield data that are directly applicable to the in situ rock mass from which the specimens were taken. If laboratory test results could be scaled reliably to field conditions, then small scale, easily controllable tests would provide a convenient means for estimating rock mass characteristics.

10.5.4.1 Rock Mass Properties

Rock mass characteristics of particular significance in ground control are as follows:

1. Modulus of deformation or elasticity, essential for the design of drifts, chambers, entries, and mine floors.
2. Compressive strength, important in the design of mine pillars.
3. Shear strength, important in rock slopes, foundations, and tailings dams.
4. Tensile strength, important in mine roofs.
5. Frictional properties (cohesion and friction angle) important in fractured masses, yield zones, and mine floor design.
6. Bearing capacity, important for mine floors.

The concept of the *critical size* (Bieniawski, 1967; see also 10.2.3.2), depicted in Fig. 10.5.8, represents the phenomenon of strength reduction with increasing specimen size. It will be noted

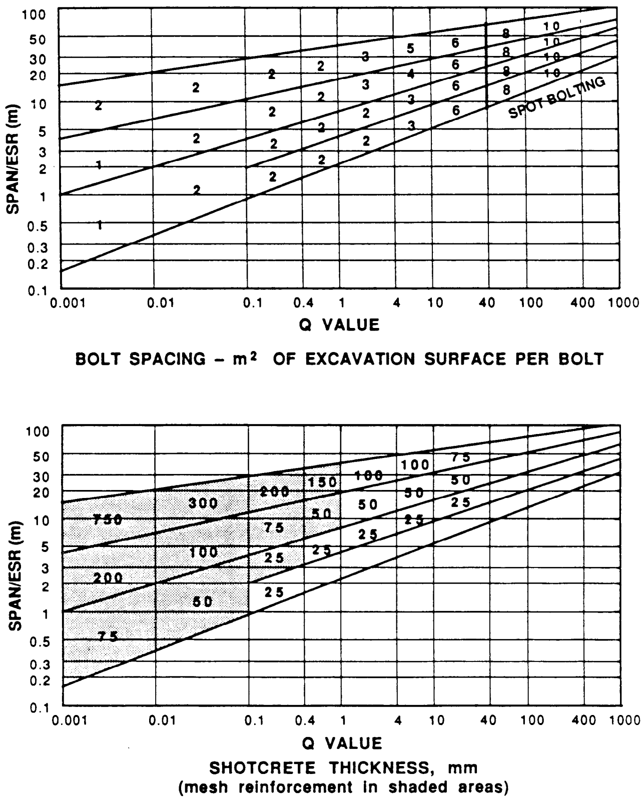

Fig. 10.5.7. Tunnel support requirements in accordance with the Q system (Barton et al., 1974). Conversion factor: 1 ft = 0.3048 m.

that from a certain size onward, the in situ strength remains constant, irrespective of specimen size. The significance of the phenomenon of critical size is that the strength values at the critical specimen size are directly applicable to full-size rock pillars.

10.5.4.2 In Situ Stresses

When an excavation is made in a rock mass, the initial in situ stresses are disturbed and redistributed in the vicinity of the excavation. In situ stresses can therefore be categorized into the virgin (original) stresses and induced (due to excavation) stresses.

The virgin stresses can be of gravitational, tectonic, or residual type. Gravitational stress is due to the effect of gravity on the overburden rock. Tectonic stress is due to previous or present day straining in the earth's crust, for example, regional faulting. Residual stress is the stress remaining after the cause has been removed, for example, thermal stresses or stresses caused by swelling or heat.

Rock stress measurements featuring a variety of techniques have been conducted throughout the world. These techniques may involve either overcoring methods, flat jack techniques, or the hydrofracturing method. Full details of these methods are given in Chapter 10.3.

Fig. 10.5.9 shows the accumulated results of stress measurements obtained in certain parts of the world, featuring a variation of the vertical stress with depth. A clear trend in the data is apparent. However, there is little consistency if a similar figure is constructed featuring the change of the horizontal stress with depth. As depicted in Fig. 10.5.10, there is no unique correlation between the ratio of the horizontal to vertical stresses and depth. It can also be seen that at a depth of about 1500 ft (450 m), the horizontal stresses are greater than the vertical stress. This is a worldwide phenomenon, but a difference of opinion exists as to the actual relationship governing the horizontal stresses. A conclusion that can be reached from this discussion is that while the vertical stresses may be predicted on the basis of the depth of the overburden with an accuracy sufficient for engineering purposes, no simple method exists for estimating the horizontal stresses. Consequently, in situations where such stresses are of great importance, stress measurements should be conducted. Note that Aggson (1978), Haimson (1978), and Linder and Halpern (1978) have compiled information on the principal stress magnitudes and directions in the United States.

10.5.5 DESIGN OF ROCK BOLTING REINFORCEMENT

Rock reinforcement must utilize the structural properties of the rock mass to improve the stability of underground excavations. The principal objective in the design of underground support is to help the rock mass support itself. The mechanics of rock reinforcement includes the concept of rock-support interaction as the main principle. The design of rock reinforcement systems depends on the geotechnical properties of the discontinuities and of the intact rock, the size and shape of the excavations, the magnitudes of redistributed stresses, and the degree of deformation acceptable in the completed excavation.

10.5.5.1 Mechanism of Rock-Support Interaction

The behavior of an opening and the performance of the support system depend upon the load-deformation characteristics of the rock and of the support, as well as of the manner and timing of support installation. The interaction between support and rock mass is qualitatively illustrated by the *ground reaction curve* given in Fig. 10.5.11. This concept was developed in detail by Deere et al. (1970), but was discussed by Fenner in Austria as early as 1938. More recently, the concept was studied by Brown et al. (1983).

When a tunnel is excavated, the rock moves inwards. The ground reaction curve displays the load that must be applied to the roof or the walls of the tunnel to prevent further movement. The movement which occurs before support can be installed is denoted by the line OA. If the support were perfectly incompressible, the load of the support would be represented by the line AA'. Support, however, deforms and, with the walls of the tunnel also deforming, an equilibrium is attained at point C at a radial displacement of the walls equal to OB and a support deformation equal to AB, at which stage the support load is BC.

However, the equilibrium at point C is only reached if the support is properly designed and placed timely. Line AeE in Fig. 10.5.11 depicts support that yields before stabilizing the opening, line AF represents support that is too flexible, while line GH is support too delayed in installation, hence ineffective. Accordingly, it is important to note that support should be installed as soon as possible so that the early rock deformation could stress the support at the same time as the rock mass is generating interior arching movement and shear stress in an attempt to be self-supporting. Furthermore, the less competent the rock, the earlier the support should be installed. Clearly, then, active rock reinforcement will be more effective and will require less capacity than passive support, but installation must take place as soon as possible after each face advance. Active rock reinforcement will require less support because the ability of the rock to support

Table 10.5.8. Classification of Individual Parameters Used in the Q System

	Description	*Value*	*Notes*
1.	**Rock Quality Designation**	(RQD)	
A.	Very poor	0– 25	(I) Where RQD is reported or measured as ≤ 10, (including 0) a nominal value of 10 is used to evaluate Q.
B.	Poor	25– 50	
C.	Fair	50– 75	
D.	Good	75– 90	
E.	Excellent	90–100	(II) RQD intervals of 5, i.e., 100,95,90, etc. are sufficiently accurate.
2.	**Joint Set Number**	(J_n)	
A.	Massive, no or few joints	0.5–1.0	
B.	One joint set	2	
C.	One joint set plus random	3	
D.	Two joint sets	4	
E.	Two joint sets plus random	6	
F.	Three joint sets	9	(I) For intersections use ($3.0 \times J_n$)
G.	Three joint sets plus random	12	(II) For portals use ($2.0 \times J_n$)
H.	Four or more joint sets, random, heavily jointed, "sugar cube" etc.	15	
J.	Crushed, rock, earthlike	20	
3.	**Joint Roughness Number**	(J_r)	
	(a) Rock wall contact and *(b) Rock wall contact before 10 cm shear*		
A.	Discontinuous joints	4	
B.	Rough or irregular, undulating	3	
C.	Smooth, undulating	2	
D.	Slickensided, undulating	1.5	(I) Descriptions refer to small scale features and intermediate scale features, in that order.
E.	Rough or irregular, planar	1.5	
F.	Smooth, planar	1.0	
G.	Slickensided, planar	0.5	(II) Add 1.0 if the mean spacing of the relevant joint set is greater than 3 m.
	(c) No rock wall contact when sheared		
H.	Zone containing clay minerals thick enough to prevent rock wall contact	1.0	(III) J_r = 0.5 can be used for planar slickensided joints having lineations, provided the lineations are orientated for minimum strength
J.	Sandy, gravelly or crushed zone thick enough to prevent rock wall contact	1.0	
4.	**Joint Alteration Number**	(J_a)	**(ϕ_r approx.)**
	(a) Rock wall contact		
A.	Tightly healed, hard non-softening, impermeable filling i.e. quartz or epidote.	0.75	(—)
B.	Unaltered joint wall, surface staining only.	1.0	(25–35°)
C.	Slightly altered joint walls. Non-softening mineral coatings, sandy particles, clay-free disintegrated rock etc.	2.0	(25–30°)
D.	Silty-, or sandy-clay coatings, small clay fraction (non-soft).	3.0	(20–25°)
E.	Softening or low friction clay mineral coatings, i.e. kaolinite or mica. Also chlorite, talc, gypsum, graphite etc., and small quantities of swelling clays.	4.0	(8–16°)
	(b) Rock wall contact before 10 cm shear		
F.	Sandy particles, clay-free disintegrated rock etc.	4.0	(25–30°)
G.	Strongly over-consolidated non-softening clay mineral fillings (continuous, but < 5mm thickness).	6.0	(16–24°)
H.	Medium or low over-consolidation, softening, clay mineral fillings, (continuous but < 5 mm thickness).	8.0	(12–16°)
J.	Swelling clay fillings, i.e. montmorillonite (continuous, but < 5 mm thickness) Value of J_a depends on percent of swelling clay-size particles, and access to water etc.	8–12	(6–12°)
	(c) No rock wall contact when sheared		
K. L. M.	Zones or bands of disintegrated or crushed rock. and clay (see G,H,J for description of clay condition).	6,8, or 8-12	(6–24°)
N.	Zones or bands of silty-or sandy-clay, small clay fraction (non-softening).	5.0	(—)
O,P. R.	Thick, continuous zones or bands of clay (see G,H,J, for description of clay condition).	10,13, or 13-20	(6–24°)

Table 10.5.8.—cont.

	Description	*Value*		*Notes*
5.	**Joint Water Reduction Factor**	(J_w)	**Approx. water pressure (kp/cm^2)**	
A.	Dry excavations or minor inflow, i.e. < 5 l/min. locally.	1.0	< 1.0	
B.	Medium inflow or pressure, occasional outwash of joint fillings.	0.66	1–2.5	
C.	Large inflow or high pressure in competent rock with unfilled joints	0.5	2.5–10	(I) Factors C to F are crude estimates. Increase J_w if drainage measures are installed.
D.	Large inflow or high pressure, considerable outwash of joint fillings	0.33	2.5–10	
E.	Exceptionally high inflow or water pressure at blasting, decaying with time	0.2–0.1	>10	(II) Special problems caused by ice formation are not considered.
F.	Exceptionally high inflow or water pressure continuing without noticeable decay	0.1–0.05	>10	

6.	**Stress Reduction Factor**		
	(a) Weakness zones intersecting excavation, which may cause loosening of rock mass when tunnel is excavated	(SRF)	
A.	Multiple occurrences of weakness zones containing clay or chemically disintegrated rock, very loose surrounding rock (any depth).	10	(I) Reduce these values of SRF by 25–50% if the relevant shear zones only influence but do not intersect the excavation.
B.	Single weakness zones containing clay or chemically disintegrated rock (depth of excavation < 50 m).	5	
C.	Single weakness zones containing clay or chemically disintegrated rock (depth of excavation > 50 m).	2.5	
D.	Multiple shear zones in competent rock (clay-free), loose surrounding rock (any depth).	7.5	
E.	Single shear zones in competent rock (clay-free) (depth of excavation < 50 m).	5.0	
F.	Single shear zones in competent rock (clay-free) (depth of excavation > 50 m).	2.5	
G.	Loose open joints, heavily jointed or "sugar cube" etc. (any depth).	5.0	

	(b) Competent rock, rock stress problems	σ_c/σ_1	σ_t/σ_1	(SRF)	
H.	Low stress, near surface	> 200	>13	2.5	(II) For strongly anisotropic virgin stress field (if measured): when $5 \leq \sigma_1/\sigma_3 \leq 10$, reduce σ_c and σ_t to 0.8 σ_c and 0.8 σ_t. When $\sigma_1/\sigma_3 > 10$, reduce σ_c and σ_t to 0.6 σ_c and 0.6 σ_t, where: σ_c = unconfined compression strength, and σ_t = tensile strength (point load), and σ_1 and σ_3 are the major and minor principal stresses.
J.	Medium stress	200–10	13–0.66	1.0	
K.	High stress, very tight structure (usually favourable to stability, may be unfavourable for wall stability)	10–5	0.66–0.33	0.5–2	
L.	Mild rock burst (massive rock)	5–2.5	0.33–0.16	5–10	
M	Heavy rock burst (massive rock)	2.5	0.16	10–20	(III) Few case records available where depth of crown below surface is less than span width. Suggest SRF increase from 2.5 to 5 for such cases (see H).

	(c) Squeezing rock: plastic flow of incompetent rock under the influence of high rock pressure	
N.	Mild squeezing rock pressure	5–10
O.	Heavy squeezing rock pressure	10–20
	(d) Swelling rock: chemical swelling activity depending on presence of water	
P.	Mild swelling rock pressure	5–10
R.	Heavy swelling rock pressure	10–15

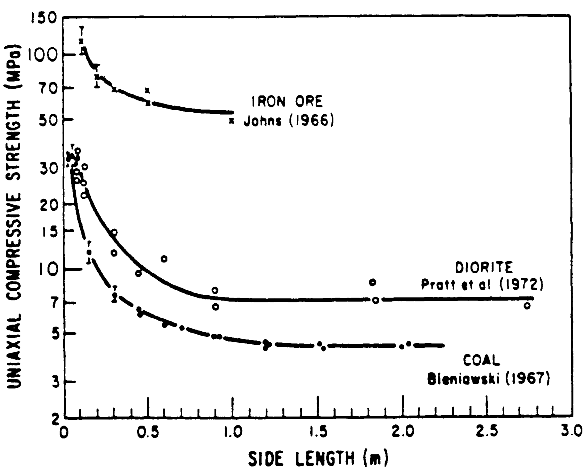
Table 10.5.8.—cont.

Additional Notes on the Use of the Above Table

When making estimates of the rock mass quality (Q) the following guidelines should be followed, in addition to the notes listed in the tables:

1. When borehole core is unavailable, RQD, can be estimated from the number of joints per unit volume, in which the number of joints per metre for each joint set are added. A simple relation can be used to convert this number to RQD for the case of clay free rock masses:
   $RQD = 115 - 3.3\ J_V$ (approx.) where J_V = total number of joints per m^3
   ($RQD = 100$ for $J_V < 4.5$)
2. The parameter J_n representing the number of joint sets will often be affected by foliation, schistosity, slaty cleavage or bedding etc. If strongly developed these parallel "joints" should obviously be counted as a complete joint set. However, if there are few "joints" visible, or only occasional breaks in the core due to these features, then it will be more appropriate to count them as "random joints" when evaluating J_n.
3. The parameters J_r and J_a (representing shear strength) should be relevant to the *weakest significant joint set or clay filled discontinuity* in the given zone. However, if the joint set or discontinuity with the minimum value of (J_r/J_a) is favourably oriented for stability, then a second, less favourably oriented joint set or discontinuity may sometimes be more significant, and its higher value of J_r/J_a should be used when evaluating Q. *The value of J_r/J_a should in fact relate to the surface most likely to allow failure to initiate.*
4. When a rock mass contains clay, the factor SRF appropriate to *loosening loads* should be evaluated. In such cases the strength of the intact rock is of little interest. However, when jointing is minimal and clay is completely absent the strength of the intact rock may become the weakest link, and the stability will then depend on the ratio rock-stress/rock-strength. A strongly anisotropic stress field is unfavourable for stability and is roughly accounted for as in note II in the table for stress reduction factor evaluation.
5. The compressive and tensile strengths (σ_c and σ_t) of the intact rock should be evaluated in the saturated condition if this is appropriate to present or future in situ conditions. A very conservative estimate of strength should be made for those rocks that deteriorate when exposed to moist or saturated conditions.

Source: Barton, Lien, and Lunde, 1974. Conversion factors: 1 in. = 25.4 mm = 2.54 cm, 1 ft = 0.3048 m, 1 psi = 6.895 kPa.



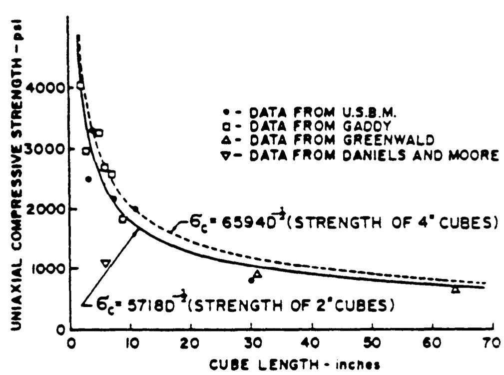


Fig. 10.5.8. Strength reduction in coal as a function of the size of cubical specimens tested in the laboratory and in situ (Bieniawski, 1967; Hustrulid, 1976). Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

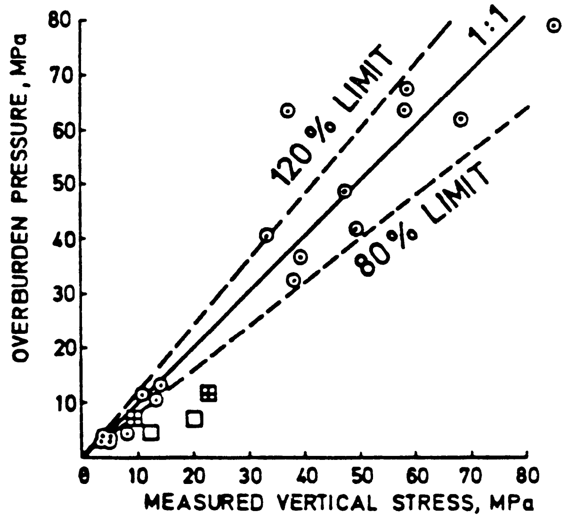
itself is being utilized, while with massive support the full weight of the rock is being supported.

Although the concept of the ground reaction curve has been studied extensively by Deere et al. (1970), Rabcewicz (1964), Pacher (1977), and Brown et al. (1983), the ground reaction curve cannot as yet be theoretically defined for rock masses. Furthermore, even if the theory could be used to predict the curve, Deere believes that the large local variations in construction procedures would inhibit the usefulness of the curve for the practical design of supports, not to mention that the load-deformation characteristics of some supports are also not clearly understood. The only possibility of obtaining quantitative data on the required support resistance and ground deformation behavior lies in measurements in situ. From measurements of the radial displacement of excavation surface and of the displacement inside the rock mass as a function of time during mining, the stabilization process as well as the load of the support can be established (Bieniawski, 1984).

Among the various methods of rock reinforcement, rock bolting stands out as the most effective technique. It was mechanical bolts that revolutionized to a great extent ground control in the American mining industry during the 1950s. The United States is credited with pioneering the use of rock bolts in underground excavations as early as 1930.

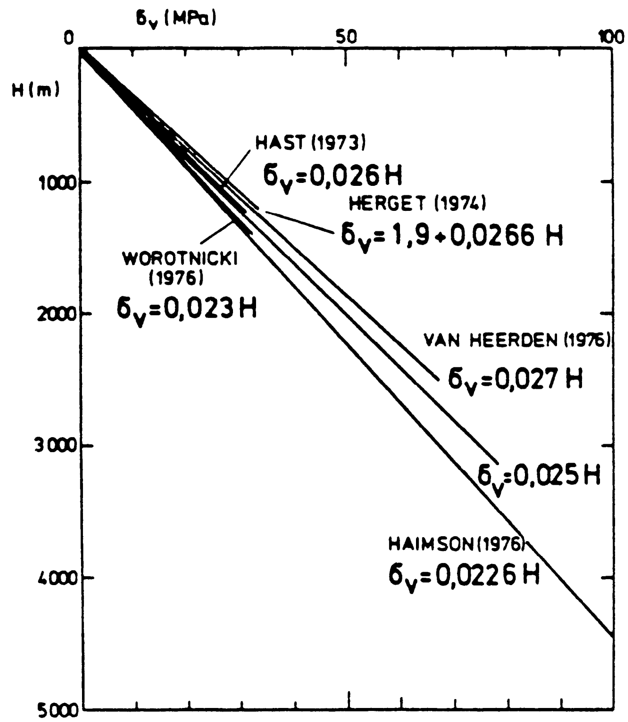
Although the first use of rock bolts is lost in antiquity, it was not until 1943 that their systematic use on a planned basis was recorded. Weigel (1943) described a system introduced by the St. Joseph Lead Co. in 1936 in Missouri (Panek, 1973).

Rock bolting first became popular in 1947 in the United States where it was promoted by the US Bureau of Mines (USBM) in an attempt to reduce the number of accidents caused by roof falls. In under two years, it had come into general use in the US mining industry. In 1949, the method was in use at over 200 mines, and by 1952, annual consumption had reached 25 million bolts. Growth of rock bolting was rapid. In 1968, the USBM reported that 912 coal mines used 55 million roof bolts annually and 60% of underground coal production was mined under bolted roof. In 1989, the Bureau of Mines estimated that about 120 million rock bolts were used annually in American mines, and over 90% of underground coal production was mined under bolted roof.



(a)

Correlation between calculated and measured vertical stresses.



(b)

Plot of vertical stresses versus depth below surface.

Fig. 10.5.9. Variations of vertical in situ stress with depth (Bieniawski, 1984). Conversion factors: 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

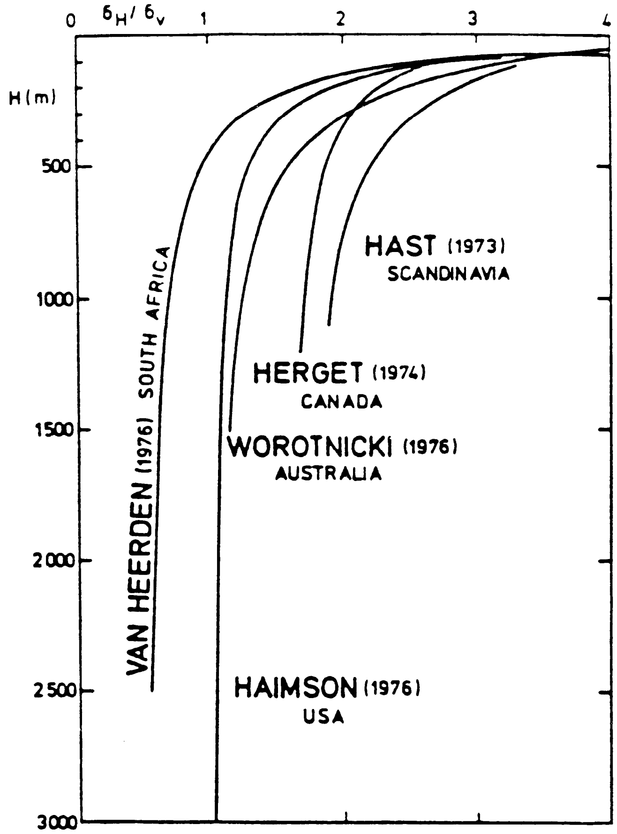
While there are many types of rock bolts, some of which are depicted in Fig. 10.5.12, it is estimated that the most popular type (in about 60% of mining) is the mechanical bolt, followed by a grouted bolt used for 30% of installations. The remaining 10% use other methods of rock bolting such as friction stabilizers (split sets), roof trusses, etc.

10.5.5.2 Mechanical Rock Bolts

Fig. 10.5.12 features a commonly used rock bolt that is mechanically anchored and tensioned. It should be noted that a large number of expansion-shell anchor designs are available, and these work well in all but very soft rocks. Failure of the system generally occurs in the threaded portions of the bolt at either the nut or the anchor ends.

Point anchors produce high stress concentrations against the rock. This results in rock fracture and a tendency for the anchor to slip or creep with time. This has led to the emergence of another version of mechanically anchored rock bolts, that is, one involving anchors imbedded in resin or grout. This system is similar to a standard mechanical rock bolt with the exception that the shell is embedded in resin which sets up around it, after which the bolt is tightened. Anchor creep is virtually eliminated with this system, and long-term anchorage is excellent.

After tensioning, grouting of mechanical rock bolts may be undertaken to ensure long-term corrosion protection.



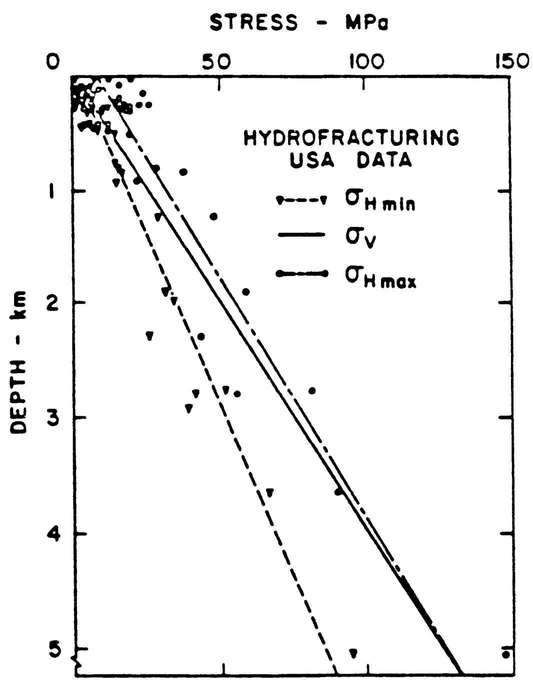


Fig. 10.5.10. Variations of horizontal in situ stresses with depth (Bieniawski, 1984). Conversion factors: 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

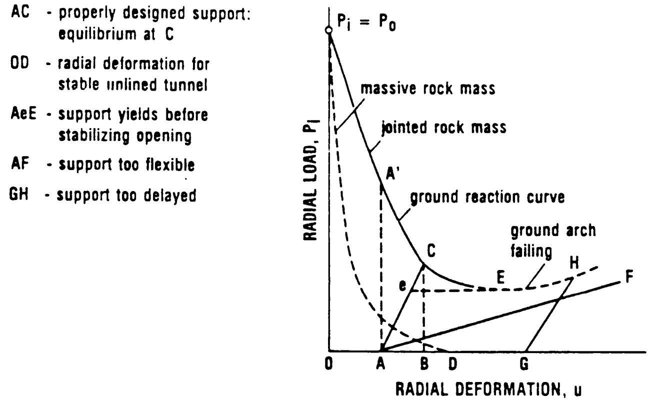

Fig 10.5.11. Concept of the ground reaction curve for rock tunnels (Deere et al., 1970).

Other Types of Mechanical Fixtures: The split-set rock reinforcement system (friction rock stabilizers), developed by Scott (1980) in conjunction with the Ingersoll-Rand Co., is widely used in American metal mines. The present range of usage is about 50% of the total fixtures in metal mines, or approximately 3.5 million bolts a year. The reinforcement element consists of a thin-walled steel tube of 1½-in. (38-mm) diameter, which is forced into a 1⅜-in. (35-mm) diameter drillhole. The spring action of the compressed steel tube induces a friction force along the length of the tube, and this frictional force anchors the reinforcing element in the rock. Assuming that the borehole diameter is accurately controlled, this system can be used very effectively. Installation is very rapid and support performance is good, provided that the split sets are installed close to a face and that stresses imposed are not very high. These devices have not been used to any significant extent in civil engineering tunnels because they cannot be grouted, are susceptible to corrosion, and hence cannot be considered as permanent support. They have also not been used much in coal mining because of problems with installing these rock bolts in low coal seams. However, equipment is under development for use in coal mines.

The "Swellex" rock reinforcement system, developed by Atlas Copco, is gaining popularity in Europe. This untensioned rock reinforcement system offers a number of advantages (Mattila and Boyd, 1985). The reinforcing element consists of a thin-walled tube of approximately 1⅝-in. (42-mm) diameter that has been folded into a collapsed shape of about l-in. (25-mm) diameter. This collapsed fixture can be inserted easily into a borehole of about 1½-in. (39-mm) diameter and, once in place, is expanded by injection of water at a pressure of about 3000 psi (20 MPa), which is generated by a small portable pump unit. Expansion of the fixture results in an overall length reduction, and this pulls the face plate right against the rock and induces a small tension in the device. The anchoring force is very high, and the strength of the system is limited by the strength of the tube. Although the system cannot be grouted, rusting is inhibited by the presence of a sealed volume of water inside the expanded fixture and by a protective coating that can be applied to the outside of the fixture.

Tensioning of Mechanical Rock Bolts: Mechanical bolts are always tensioned at the time of installation to a load level not exceeding 60% of their anchorage capacity or the yield strength of the bolt. With mechanical bolts, any differential rock sag stretches the bolt, introducing a tensile stress in the bolt and a compressive force on the rock countering the direction of movement. The magnitude of this force depends upon the length

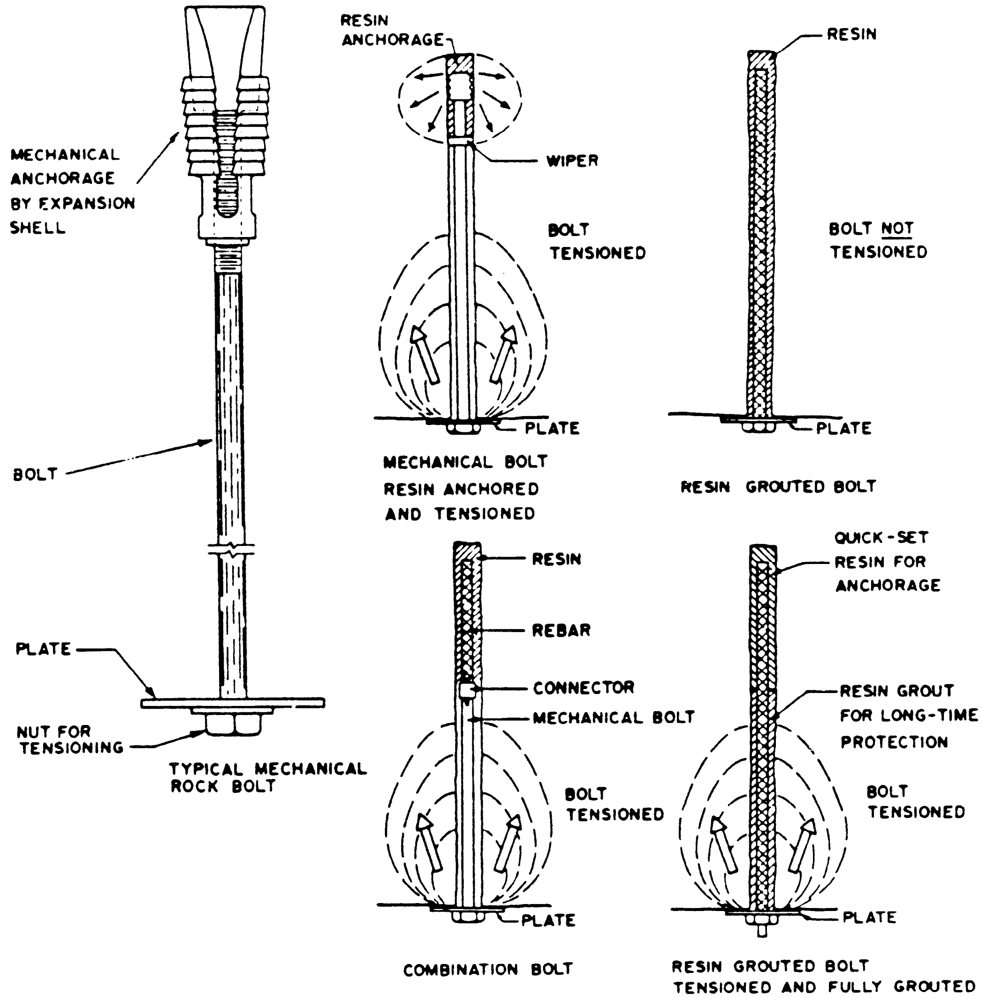

Fig. 10.5.12. Types of rock bolts commonly used (Peng and Tang, 1984).

of the bolt, and without tensioning, a large deformation would occur before the bolt mobilized sufficient support resistance. The purpose of tensioning is to prevent rock movement, and hence mechanical bolts are an active method of rock reinforcement. The bolts are tensioned to specified loads by means of a torque wrench or a hydraulic tensioning device. Grouting the bolt after tensioning ensures that the loads will be maintained in the bolts.

Mechanical bolts support the roof both by a suspension effect (Snyder et al., 1979) as well as through a friction effect (Panek, 1973). Lamination of the roof in coal mines requires that the individual layers slide across one another as they deform. This sliding action is opposed by friction, and the mechanical bolts act to increase the friction resistance by applying a compressive force normal to the friction surface.

10.5.5.3 Grouted Rock Bolts

If the circumstances are such that the installation of the rock reinforcement can take place before significant deformation of the excavation has occurred, the use of untensioned reinforcement is appropriate. With the introduction of fast-setting, high-strength resins in the early 1970s, it became possible to integrate fully grouted bolting into the high-speed mining cycle of US coal mines. Today approximately one-quarter of all rock bolts installed are resin-grouted bolts (Mahyera et al., 1981). Two other types of fully grouted nontensioned bolts are cement-grouted bolts and "pumpable" bolts (Zink and Wang, 1977; Serbousek and Bolstad, 1981). The grout may be either a resin or inorganic cement.

Grouted bolting is simple in concept (Fig. 10.5.12): a hole is drilled in the rock, and a rebar is inserted in it and grouted. The rebar should be threaded at one end, and the face plate should be fastened with a nut for added effectiveness. Grouted bolts are a passive reinforcement support since they apply little load to the rock unless movement occurs.

An advantage of resin bolts is their resistance to transverse shear (Fairhurst and Singh, 1974; Pells, 1974). The grouted bolt acts only where a crack in the rock tends to dilate, and all stretching in the bolt is confined to a very short section. Thus high unit stresses are developed in response to movement (Reed, 1974). In addition, resin bolts are effective in maintaining the initial friction between layers (Snyder et al., 1979).

The basic mechanism of resin bolting is a combination of the principles of suspension and beam building, although there is no consensus of opinions as to which effect is prevalent (Snyder et al., 1979).

Karabin and Debevec (1976) agree that the suspension mechanism applies to either a mechanical rock bolt or a grouted bar. Fully grouted resin bolts employ a full-length bond to bind the strata into an effective beam while mechanical bolts achieve this by relying on frictional interfaces developed through bolt tensioning. Moreover, an advantage of resin bolts is their resistance to transverse shear. They provide physical barriers to resist movement along the planes of discontinuities.

However, by comparison with mechanical bolts, untensioned resin-grouted bolts are a passive means of rock reinforcement. Hoek and Brown (1980) suggest that grouted rock bolts reinforce a rock mass in a fashion similar to that of steel bars in reinforced concrete.

In soft rock, the resin bolt assembly fails at the rock interface, indicating that the resin is stronger than the rock. In hard rock, a resin-grouted rebar fails by failure of the steel, but a smooth bolt pulls out, indicating that mechanical interlock is the primary means of bonding.

Types of Grouted Bolts: There are two main types of grouted bolts. The most common type features synthetic resin, which is introduced into the borehole in sealed capsules. These capsules contain the resin and a catalyst in two separate compartments, and mixing of these takes place when the plastic capsule is broken by insertion and rotation of the reinforcing steel rod. The chemical composition of the resin and catalyst can be varied to suit different ambient temperatures and to control setting times.

An advantage of resin bolts is that they are effective in weaker rock masses, but a disadvantage is that resin grouting is expensive. Recently, however, the USBM has developed an inorganic cement grout that is cost effective (Serbousek and Bolstad, 1981).

The other type is the Perfobolt system developed in Europe for grouting and anchoring rebars in boreholes. Perforated half tubes are packed with mortar, and the halves are wired together and inserted in the drillhole. The mortar is extruded when the rebar is pushed down the center of the tube. For a l-in. (25-mm) rebar diameter, the sleeve diameter is 1¼ in. (32 mm) while the borehole diameter is 1½ in. (38 mm).

The latest Mine Safety and Health Administration (MSHA) safety standards for rock bolts (MSHA Draft Regulation 1983-K75.202j) specify that if the tested grouted bolt does not withstand 150 ft-lb (203 N-m) of torque without rotating in the hole, corrective action must be taken or supplemental support installed.

10.5.5.4 Design Guidelines For Rock Bolt Systems

Design of rock bolt systems involves the selection of the following parameters: length of rock bolts, spacing of rock bolts, bolt capacity, bolt diameter, and bolt tension (if applicable).

Although the systematic use of rock bolts for strata stabilization in mining goes back nearly 50 years, the development of a rational basis for the design of rock-bolting systems proved to be elusive. Nevertheless, much progress has been made.

In early rock bolt research by the USBM, analytical studies and laboratory investigations with physical models were directed primarily towards clamping action incorporating the friction effect by tensioned bolts in laminated coal mine roof (Panek, 1973).

Concurrently with Panek, several rock behavior studies were conducted by Lang (1961). The emphasis was on heavily fractured ground rather than laminated mine roofs, and an extensive analysis of bolting patterns across various types of discontinuities was presented. It was found that even highly fragmented rock could be stabilized by rock bolting and form a load-carrying structural number that would span an opening. Bolts spaced closely enough produced a zone of uniform compression within the rock strata and were very effective at supporting the roof. The thickness of the beam of compressed rock was approximately the bolt length minus the spacing.

A major contribution to a rational design procedure for rock-bolt systems was provided by Lang and Bischoff (1982). They developed a rock bolting analysis to incorporate the shear strength developed by the rock mass on the vertical boundaries of the rock unit reinforced by a single rock bolt. The rock is assumed to be destressed to a zone width D, but variable vertical stresses σ_v and horizontal stresses $k\sigma_v$ are assumed to be induced with the destressed zone. Typically, k may be taken as 0.5. The shear strength developed at any point on the perimeter of the reinforced rock unit is given by $c + \mu k\sigma_v$, where c is the cohesion, and $\mu = \tan\phi$ is the coefficient of friction for the rock mass. Lang and Bischoff's analysis leads to the result,

$$\frac{T}{AR} = \frac{\alpha\gamma}{\mu k}\left(1 - \frac{c}{\gamma R}\right)\left[\frac{1 - exp(-\mu kD/R)}{1 - exp(-\mu kL/R)}\right] \qquad (10.5.17)$$

where T is rock bolt tension, A is area of roof carrying one bolt (equals s^2 for $s \times s$ bolt spacing), R is shear radius of the reinforced rock unit $= A/P$, where P is the shear perimeter (i.e., $4s$ for $s \times s$ bolt spacing), $a = 0.5$ for active support, and $a = 1.0$ for passive reinforcement, and L is bolt length that will often be less than D, the height of the destressed zone of rock, and g is rock density.

Lang and Bischoff suggest that, for preliminary analyses, the cohesion c should be taken as zero. Design charts based on Eq. 10.5.17 show that, particularly for low values of ϕ, the required bolt tension T increases significantly as L/s decreases below about two, but that no significant reduction in T is produced when L/s is increased above two. This result provides some corroboration of Lang's empirical rule that the bolt length should be at least twice the spacing for civil engineering applications.

In mining, the bolt length/bolt spacing ratio is acceptable between 1.2 and 1.5. The length of rock bolts may be selected as a function of the roof span, as depicted in Fig. 10.5.13.

Empirical Rules: Sources such as Hoek and Brown (1980), the US Corps of Engineers (Anon., 1980), and the USBM (Lang and Bischoff, 1982) provide information on general empirical rules that are useful as a check for bolt lengths and spacings. These rules are as follows:

1. *Minimum bolt length*
   Greatest of: (a) Twice the bolt spacing.
   (b) Three times the width of critical and potentially unstable rock blocks defined by the average discontinuity spacing in the rock mass.
   (c) For spans less than 20 ft (6 m), bolt length of one-half the span. For spans from 20 ft (6 m) to 60 ft (18 m), interpolate between 10 ft (3 m) and 15 ft (5 m) lengths, respectively. For excavations higher than 60 ft (18 m), sidewall bolts are one-fifth of wall height.
2. *Maximum bolt spacing*
   Least of: (a) One-half the bolt length.
   (b) One-and-one-half the width of critical and potentially unstable rock blocks.
   (c) 6 ft (2 m); greater spacing than 6 ft (2 m) makes attachment of wire mesh difficult.
3. *Minimum bolt spacing:* 3 ft (0.9 m).

NOTE: Where discontinuity spacing is close and the span is relatively large, the superposition of two bolting patterns may be appropriate, e.g., long heavy bolts on wide centers to support the span and shorter,

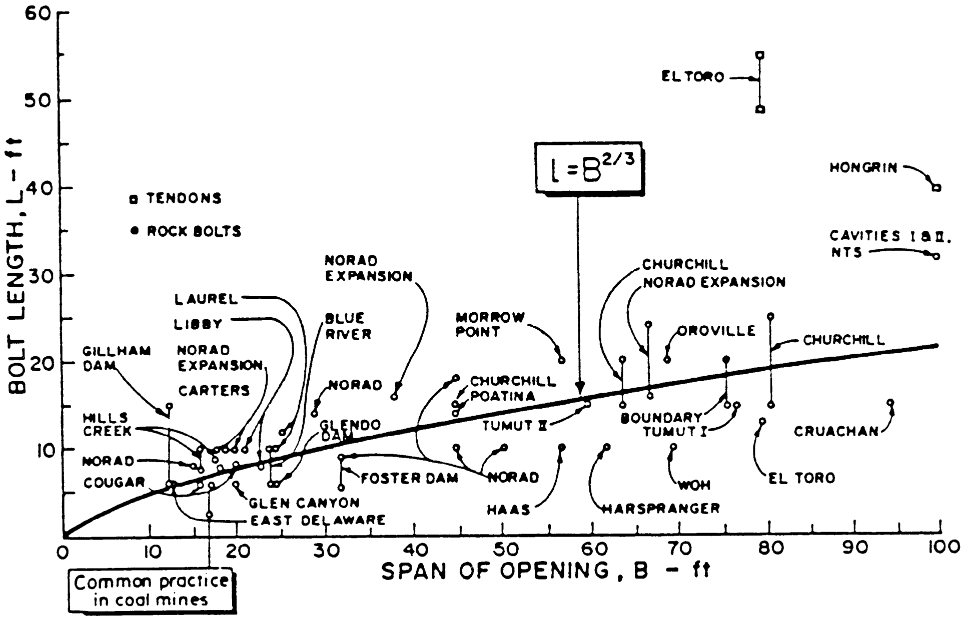

Fig. 10.5.13. Relationship between bolt length and roof span (Lang and Bischoff, 1982). Conversion factor: 1 ft = 0.3048 m.

thinner bolts on closer centers to stabilize the surface against raveling due to close jointing.

The above empirical rules should be considered only as general guidelines because the appropriate support system for a particular underground excavation depends on many factors such as the characteristics of the rock mass, in situ stress field, the expected loading history, safety regulations, availability, and cost of different types of support.

Hoek and Brown (1980) recommend that, once support estimates have been made, a working sketch should be prepared depicting the layout of rock bolting superimposed on the excavation cross section and the structural geologic features.

For coal mining applications, Title 30 of the *Code of Federal Regulations* (CFR) (Anon. 1989) states that openings should not exceed 20 ft (6.1 m) in width, where roof bolting is the sole means of support, nor should they exceed 30 ft (9.2 m) when roof bolts and other support, such as timber posts, are used. Section 75 of CFR 30 stipulates that in no case should the length of roofbolts be less than 30 in. (0.76 m) plus 1 ft (0.3 m) if anchored in the stronger strata to suspend the immediate roof. The bolt spacing and the distance between the bolt and the rib or the face should not be more than 5 ft (1.5 m). Mechanical bolts should be tensioned to 50% of the yield point of the bolt or the anchorage capacity. Miners may not work under an unsupported roof.

Support Selection Procedure: Hoek and Brown (1980) suggest the following procedure for estimating support requirements:

1. During site exploration, classify the rock mass by means of either the RMR system or the Q system. Check stability from Fig. 10.5.14.

2. Make a preliminary evaluation of the support system on the basis of the recommendations summarized in Tables 10.5.4, 10.5.5, or 10.5.6.

3. Estimate the in situ stress conditions from the measurements of stresses at the site or at adjacent sites in similar rock. If no measurements are available, obtain a crude first estimate

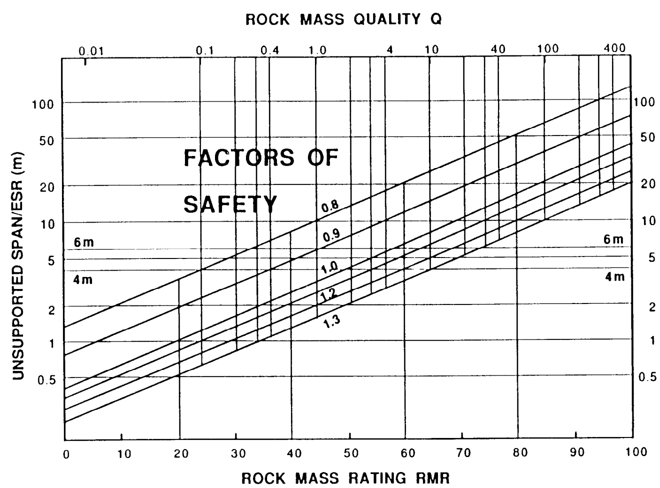

Fig. 10.5.14. Estimated factors of safety as a function of rock mass conditions and unsupported spans (Houghton and Stacey, 1980). Conversion factor: 1 ft = 0.3048 m.

based on the depth below surface and the compiled data, as shown in Fig. 10.5.9 and 10.5.10.

4. From analytical studies, estimate the maximum boundary stresses in the rock surrounding the proposed excavation.

5. If tensile stresses can occur on the excavation boundary, consider the extent of the tensile stress zone (from the minor principal stress contours), and explore the extent to which this zone could be eliminated or minimized by small changes in the excavation shape. If no such change is possible, consider the length of rock bolts that would be necessary to stabilize this zone, and estimate the capacity of this support from the volume of material subjected to tensile stress.

6. If only compressive stresses are present around the opening, compare the maximum boundary stress (excluding sharp corners) with the unconfined compressive strength of the rock mass given by $\sigma_{cM} = \sigma_c\sqrt{s}$ in accordance with Eq. 10.54. If the boundary stress exceeds the unconfined compressive strength of the rock mass, carry out a more detailed analysis of the extent of the potential failure zone and the directions of fracture propagation.

7. Whatever the outcome of the analyses described in steps 5 and 6, make an examination of the potential for structurally controlled instability. Using whatever geological information is available, examine the possibility of wedges or blocks forming by means of the sterographic techniques or the key-block theory recently developed by Goodman and Shi (1984). If the potential for this type of failure exists, consider the length and capacity of rock bolts required to stabilize the excavation.

8. Taking all these analyses into account, consider the consequences of excavation sequence and possible variations in the timing of support installation.

9. Check the rock bolt pattern design against preceding experience using the empirical rules described earlier and ensure that the various requirements do not conflict with one another.

10. Once these estimates have been made, prepare a drawing of a typical cross section of the excavation, superimposing an approximate pattern of structural features, the possible final excavation profile, the size and shape of the potential failure zone around the excavation, and the support system (draw to scale). Check to see if it appears correct and that there is enough room available to drill holes and install bolts.

Specifications: Peng and Tang (1984) offer these guidelines for mechanical bolts:

1. Bolt the roof as soon after mining as feasible to prevent strata separation.
2. Determine the optimum expansion shell and the optimum anchorage horizon through onsite pull-out tests.
3. Employ substantial structural components (i.e., high-strength bolts and plates with low deformation characteristics) to reinforce the strata effectively.
4. Ensure that all bolts work together by installing them with equal tension.

For fully grouted resin bolts, it is recommended to:

1. Employ quality components (i.e., resins, bolts, and bearing plates) that meet ASTM specifications.
2. Determine the optimum bolt-hole combinations and necessary length for best support.
3. Bolt newly exposed rock strata as soon as possible.
4. Closely follow the manufacturer's recommended installation procedures concerning borehole length, number of cartridges required, mix time, and holding time.
5. Conduct torque and pull-out tests to verify curing and system strength.
6. Store resin in cool places (underground) for maximum shelf life.

In general, a higher in situ horizontal stress improves the performance of roof bolts (Peng and Tang, 1984), which may be due to the apparent increased compressive strength of the rock with increased confining pressure and improved anchorage efficiency.

The spacing of the bolts should satisfy the criterion that the ratio of bolt length to bolt spacing should be about 1.5 generally in mining and 2.0 minimum in fractured rock and civil engineering tunneling (Lang and Bischoff, 1982). A bolt length-to-spacing ratio of 1:2 is considered the acceptable minimum for coal mine roofs reinforced by tensioned rock bolts.

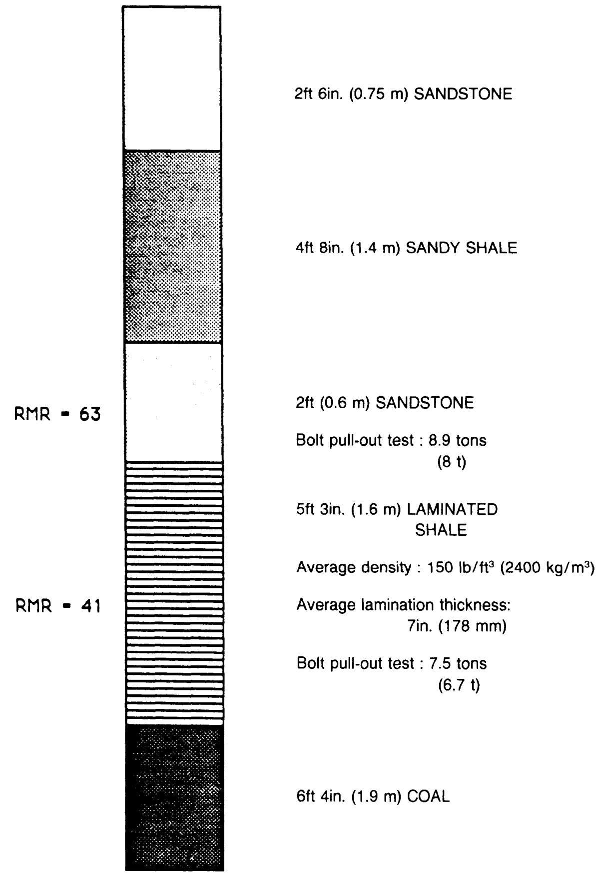

Fig. 10.5.15. Stratigraphic column (Ex. 10.5.2)

If roof bolting provides mainly a suspension effect, the roof bolts should be equally spaced. If there is no competent layer in the immediate roof, the function of roof bolting is to provide a friction effect and, in this case, the bolt density should be larger near the ribs with a smaller bolt density at the center of the excavation. The spacing between the bolt sets does not have to be on the usual square grid pattern but depends on the anchorage capacity of the anchoring layer.

Fully grouted resin bolts were suggested as being superior in ground control to mechanical bolts due to the following advantages (Peng and Tang, 1984): (1) anchorage is virtually guaranteed; (2) the bolt is permanently effective throughout its length; (3) fully grouted bolts resist both vertical and lateral strata movements; (4) the hole length is not critical; (5) fully grouted bolts seal wet holes and exclude air, thus reducing corrosion of the bolt assembly and weathering of rock; (6) resin-grouted bolts can absorb blast vibrations without bleed-off of the bolt load; and (7) time and labor for tensioning the bolts are not needed.

Example 10.5.2. A roof support system is to be designed for a 20-ft (6.1-m) wide coal mine entry. Consider the use of mechanical and resin-grouted bolts. The simplified stratigraphic column in Fig. 10.5.15 illustrates the coal seam and the overlying and underlying strata. The RMR value of the roof strata is 41. Depth of coal seam below surface is 500 ft (152 m).

Solution.

Step 1. Calculate the rock-load height.

The rock-load height h_t is given by:

$$h_t = \left(\frac{100 - \text{RMR}}{100}\right) B = \left(\frac{100 - 41}{100}\right) 20$$
$$= 11.8 \text{ ft} \cong 12 \text{ ft (3.7m)}$$

(If the RMR value is not known, the rock-load height can be estimated from roof-fall data by taking the roof-fall height as the rock-load height).

Step 2. Find the bolt length.

$$L = \frac{h_t}{2} = 6 \text{ ft}$$
$$\text{or } L = \text{SPAN}/3 = 20/3 = 6.7 \text{ ft}$$
$$\text{or } L = (\text{SPAN})^{2/3} = 7.2 \text{ ft}$$

Use L = 6 ft (1.78 m) as a practical bolt length. This would provide anchorage in the sandstone (Fig. 10.5.15).

Step 3. Find the bolt capacity.

The anchorage failure load P_f from pull-out tests is given as 8.9 tons (8.0 t). The yield load P_y of bolts can be checked for bolt diameter ϕ and grade of steel G from manufacturers' data, e.g.,

ϕ	G	P_y	G	P_y
⅝ in.	60	9.3 tons	40	6.2 tons
¾ in.	60	13.2 tons	40	8.8 tons

Select ¾-in. bolt, G = 60. Thus, bolt capacity is 8.9 tons.

Step 4. Calculate bolt spacing.

The bolt spacing is calculated using the suspension principle:

$$S = \sqrt{\frac{0.6\ P}{\gamma h}} = \sqrt{\frac{0.6 \times 17800}{150 \times 5.25}} = 3.68 \text{ ft}$$

Thus: S = 3 ft 7 in. (1.12 m). Use S = 4 ft (1.2 m).

Check: L/S = 1.5. Use four bolts per row.

Step 5. Find the bolt tension (mechanical bolts only) = 60% of bolt capacity.

Step 6. Compare mechanical bolting with resin bolting.

The final choice between the two types of roof bolting should be made on economic grounds. Select mechanical bolts.

Step 7. General considerations.

Always prepare a sketch of the rock bolt layout, to scale, to check whether it is practicable. It should be noted that in Ex. 10.5.2, no use is made either of the beam theory nor of the Panek chart for friction effect. Both these approaches are considered out of date: the first one because it needs the unrealistic assumption of the "modulus of rupture" (tensile strength), which is an unreliable parameter and rarely available at that; and the second, because it is oversimplified and has been abandoned by the Bureau of Mines where it was originally developed (Panek, 1973).

It should further be noted that no distinction is made in the example between the tensioned mechanical bolts and untensioned grouted bolts when it comes to the selection of the bolt length. This is so because the bolt length is the function of the excavation size and the rock mass quality. However, due to better anchorage characteristics, grouted bolts result in larger bolt spacing; they are also preferable for longer applications (e.g., in the main entries).

10.5.6 DETERMINATION OF PILLAR STRENGTH

Experimental results from tests on rock and coal show that there is a strength-reduction effect with increasing specimen size (Fig. 10.5.8).

The concept of *critical-size strength* (Bieniawski, 1968) for rock masses is very important in practical design. The critical size is defined as that specimen size at which a continued increase in specimen width causes no significant decrease in strength. Other authors (Jahns, 1966; Lama, 1971; Pratt et al., 1972) have confirmed that this critical-sized phenomenon exists in various rock types.

For coal, it was concluded by Bieniawski (1968) that 5-ft (1.5-m) cubic specimens constitute the critical-size value. Pariseau (1977) reported that the critical size for US western coal is 3 ft (0.9 m). Hustrulid (1976) pointed out that a critical size of 3 ft (0.9 m) would be generally applicable for coal for practical engineering purposes. This is evident from Fig. 10.5.8(b) where his data for the Pittsburgh coal seam are depicted.

The significance of the phenomenon of critical size is, of course, that the strength values at the critical size are directly applicable to full-sized pillars.

The size effect characterizes the difference in strength between the small-sized specimens tested in the laboratory and the large-sized pillars mined in situ. Research has shown (Hustrulid, 1976) that the scaling of coal properties from laboratory-measured data to field values can be satisfactorily achieved by the following equations (in customary English units):

$$\sigma_1 = \frac{k}{\sqrt{36}} \tag{10.5.18}$$

applicable to cubical pillars having a height h > 36 in. (0.9 m), or

$$\sigma_1 = \frac{k}{\sqrt{h}} \tag{10.5.19}$$

applicable to cubical pillars having a height less than 36 in. (0.9 m).

In the above equations, the constant k must be determined for the actual pillar material and is obtained as shown by Gaddy (1956):

$$k = \sigma_c \sqrt{D} \tag{10.5.20}$$

where σ_c is uniaxial compressive strength of rock specimens tested in the laboratory having a diameter or cube size dimension D (in inches). It should be noted that although there is a difference in laboratory results depending on whether cylindrical or cubical specimens are used, for practical engineering purposes this difference is not significant within the range of D between 2 to 4 in. (50 to 100 mm) (see Fig. 10.5.8b).

Typical k values for different coal seams are listed below:

Seam	k	Seam	k
Cameo (CO)	3200–7970	MaryLee (AL)	3000
Clintwood	4230–5200	Pittsburgh (PA, WV)	5550–5860(av.5580)
Elkhorn No. 4	6000–6250	Pocahontas	4310–4825
Harlan	8860–9460	Springfield #5 (IL)	4930
Herrin #6 (IL)	5500	Upper Freeport (PA)	1640
Marker	10120–10600	Winifrede (WV)	6510

10.5.6.1 Pillar Strength Formulas

Numerous pillar strength formulas have been proposed, but five formulas are used most commonly (Bieniawski, 1984; Peng, 1986). Each formula specifies its own appropriate factor of safety.

1. Obert-Duvall/Wang Formula: Obert and Duvall (1967) derived from laboratory tests on hard rock and elasticity considerations the same relationship as did Bunting in 1911. Greenwald et al. (1939) mention that this form of an expression for pillar strength was proposed in 1900 for anthracite after laboratory tests made for the Scranton Engineers Club. This formula is given as

$$\sigma_p = \sigma_1 \left(0.778 + 0.222 \frac{w}{h}\right) \qquad (10.5.21)$$

where σ_p is pillar strength, σ_1 is uniaxial compressive strength of a cubical specimen ($w/h = 1$), and w and h are pillar dimensions.

According to Obert and Duvall, this equation is valid for w/h ratios of 0.25 to 4.0, assuming gravity-loading conditions. Through back calculations from mining case histories and utilization of laboratory rock properties, safety factors of 2 to 4 were derived for short- and long-term pillar stability, respectively. Essentially, this safety factor accounts for strength scaling from laboratory (or rock-material) strength to in situ (or rock-mass) strength for hard rock.

In 1975, Wang, Skelly, and Wolgamott of the Colorado School of Mines (CSM) conducted in situ tests on a coal pillar located in West Virginia (Wang et al., 1977). The tests consisted of reducing pillar dimensions until failure occurred and then determining the pillar strength. The authors proposed the same formula as above and defined σ_1 as the ultimate strength of a cubical specimen of critical size or greater. The recommended factor of safety is 2.0, although $F = 1.5$ is acceptable if mining conditions are well known.

The CSM research was important for a number of reasons. First, Eq. 10.5.21, was applied to coal strata. Second, the term σ_1 was defined acknowledging the existence of a critical sized phenomenon. Third, the equation was stated as being valid for w/h ratios up to 8.

2. Holland-Gaddy Formula: Holland (1964) extended the work by Gaddy (1956) and proposed the following formula:

$$\sigma_p = \frac{k\sqrt{w}}{h} \qquad (10.5.22)$$

where k is the Gaddy factor from equation 10.5.20, w and h are pillar dimensions in in., and σ_p is pillar strength in psi. Holland specified a safety factor between 1.8 and 2.2 for the design of coal pillars, with a recommended value of 2.0. The width-to-height ratio, for which the Holland formula is valid, ranges from 2 to 8. Although popular in the 1970s, the Holland-Gaddy formula is no longer recommended because it was found to be overly conservative at higher $\frac{w}{h}$ ratios (> 5).

3. Holland Formula: In a paper published in 1973, Holland provided a different expression for the strength of coal pillars, namely:

$$\sigma_p = \sigma_1 \sqrt{\frac{w}{h}} \qquad (10.5.23)$$

where σ_1 is the strength of cubical pillars ($w = h = 1$). In effect, σ_1 can be interpreted as the strength at the critical size of coal specimens and is to be determined from Eq. 10.5.18. The recommended factor of safety is 2.0.

4. Salamon-Munro Formula: Salamon and Munro (1967) conducted a survey of failed and standing coal pillars in South Africa. Based on the studies of Holland (1964) and Greenwald et al. (1939), they selected the following form of pillar strength to apply to square pillars:

$$\text{strength} = Kh^{\alpha}w^{\beta} \qquad (10.5.24)$$

The constants for the above equation were derived from a statistical survey of data reflecting actual mining experience. In all, 125 case histories were used, of which 98 were standing pillars and 27 were failed pillars (collapsed at the time of the analysis). In deriving a pillar strength formula, it was assumed that those pillars that were still intact had safe dimensions, while the collapsed pillars were too small. The following pillar strength formula was proposed:

$$\sigma_p = 1320\frac{w^{0.46}}{h^{0.66}} \qquad (10.5.25)$$

where the strength σ_p is in psi, and the pillar dimensions w and h are in feet. The recommended safety factor for this formula is 1.6, the range being 1.31 to 1.88.

In SI units, the above equation becomes:

$$\sigma_p = 7.2\,\frac{w^{0.46}}{h^{0.66}} \qquad (10.5.26)$$

where the strength σ_p is in MPa while w and h are in meters.

This statistical formula is applicable to South African conditions, and it represents the average strength data for coal pillars in that country. Since there are considerable variations in coal strength between the various mines in South Africa (Bieniawski and van Heerden, 1975), the Salamon-Munro formula is currently being modified in South Africa in two respects: (1) by incorporating the actual strength of coal in a mine rather than the average coal strength in the country, and (2) by extending its use for a w/h ratio of 5 and above (Wagner, 1982). The first aspect can be simply achieved by the use of Eq. 10.5.19 when working in English units or using Eq. 10.5.18 and converting σ_1 to SI units for substitution in place of factor 7.2 in Eq. 10.5.26. Thus in English units, the Salamon-Munro formula is of the form,

$$\sigma_p(\text{psi}) = \frac{k}{\sqrt{12}}\,\frac{w^{0.46}}{h^{0.66}} \qquad (10.5.27)$$

5. Bieniawski Formula: This formula is based on large-scale in situ tests on coal pillars. Such tests were first undertaken in the United States by Greenwald et al. (1939) during the period 1933–1941. Extensive tests were conducted in South Africa during 1965–1973 by Bieniawski (1968, 1969), Wagner (1974), and Bieniawski and van Heerden (1975). Wang et al. (1977) conducted in the United States the largest test of all involving one full-sized coal pillar measuring 80 ft (24 m) in width. All these investigations examined the various pillar-strength formulas.

To make the in situ test results generally applicable (i.e., not only to the locality where the actual tests were carried out), the pillar-strength formula can be expressed in a normalized form. For example, the original formula for the Witbank coalfield (Bieniawski, 1967) was of the form,

$$\sigma_p = 400 + 220\,\frac{w}{h} \qquad (10.5.28)$$

where σ_p is in units of psi. This can be represented dimensionlessly as

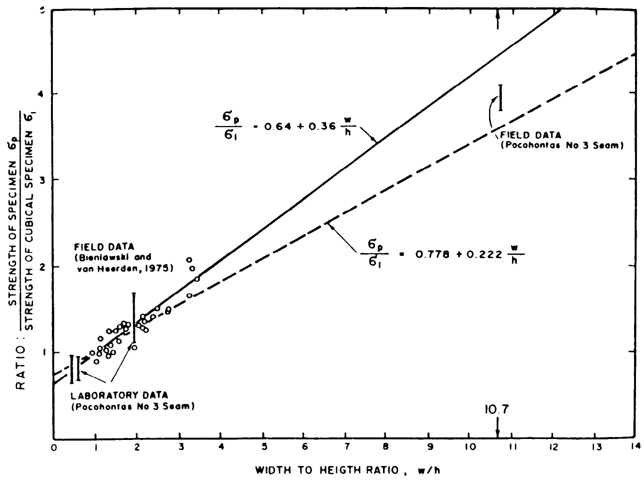

Fig. 10.5.16. The effect of specimen width-to-height ratio on the uniaxial compressive strength of coal pillars (Wang et al., 1977; Bieniawski and van Heerden, 1975).

$$\sigma_p = 620\left(0.64 + 0.36\frac{w}{h}\right) \tag{10.5.29}$$

where σ_1 = 620 psi is the critical-size strength for the Witbank coalfield. Thus the general normalized form of the Bieniawski equation is

$$\sigma_p = \sigma_1\left(0.64 + 0.36\frac{w}{h}\right) \tag{10.5.30}$$

where σ_p is pillar strength, w is pillar width, h is pillar height, and σ_1 is the strength of a cubical specimen of critical size or greater (e.g., about 3 ft or 1 m for coal).

Bieniawski (1969) and Bieniawski and van Heerden (1975) confirmed this relationship by large-scale in situ tests on 66 coal specimens of width-to-height ratios from 0.5 to 3.4.

The formula is particularly realistic for *w/h* ratios up to 10, after which it provides conservative estimates (Fig. 10.5.16). However, for high *w/h* ratios, it is the least conservative formula by comparison with the other four formulas. As this formula is applicable to any mine pillar with a value of σ_1 characterizing the in situ strength of the rock strata, Holland (1973) suggested that a safety factor of two would be generally adequate for US coal mining applications.

To clarify this point, a national survey of coal pillar and roof span dimensions and design procedures in the United States was reported by Bieniawski (1983) that features 171 cases of standing pillars, 23 cases of failed pillars, and 58 cases of roof failures (see Fig. 10.5.17). It was shown that factors of safety ranging from 1.5 to 2.0 would be applicable to coal mining in the United States using the Bieniawski pillar strength formula (Eq. 10.5.30). The value of F = 1.5 is recommended for short term applications (e.g., in the panels) while F = 2.0 should be used in the mains and when pillar recovery on retreat is contemplated. Nevertheless, these recommendations should be regarded as a guide only, and local mining experience should be taken into consideration.

The application for pillar strength formulas to room and pillar mining is covered in 10.5.6.4 and Chapter 18.1.

10.5.6.2. Pillar Load Determination

A number of approaches are available for estimating the *pillar load* or, more correctly, the average pillar stress. The

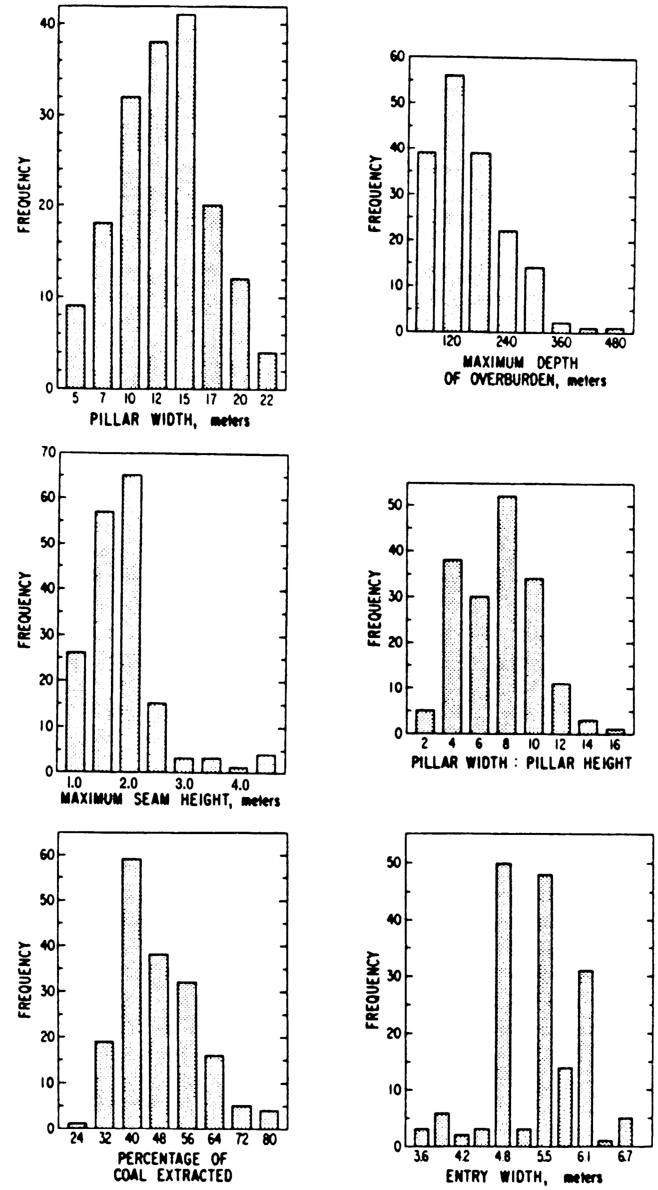

Fig. 10.5.17. Results of survey of room-and-pillar parameters in US coal mining (Bieniawski, 1984). Conversion factor: 1 ft = 0.3048 m.

two major ones are the tributary area approach and the elastic deflection theory.

The simplest approach to determine the pillar load is by the tributary area theory. If a number of well-known simplifying assumptions are made, the pillar load can be calculated from:

$$S_p = \frac{1.1\,H\,(w + B)\,(L + B)}{w \times L} \tag{10.5.31}$$

where S_p is pillar load or the average pillar stress in psi, H is depth below surface in ft, w is pillar width in ft, L is pillar length in ft, and B entry width in ft. The term 1.1 H can be replaced by the virgin vertical pressure S_v derived from the overburden weight above the seam gH, where g is the unit weight of the overburden. The pressure can be considered to increase at a rate of 1.1 psi/ft of depth.

For square pillars, that is, when $w = L$, Eq. 10.5.31 becomes

$$S_p = 1.1H \frac{[w + B]^2}{w} \tag{10.5.32}$$

If the term *extraction e* is introduced (100*e* is percentage extraction), which is defined as the ratio of the mined-out area to total area, then for rectangular pillars the extraction

$$e = 1 - \left[\frac{w}{w + B}\right]\left[\frac{L}{L + B}\right] \tag{10.5.33}$$

Thus Eq. 10.5.31 may also be rewritten as:

$$S_p = \frac{1.1H}{1 - e} \tag{10.5.34}$$

This approach incorporates the following assumptions:

1. The seam is subjected only to vertical pressure, which is constant over the mined area. However, stress transfer occurs where stiff abutments exist in underground workings. Thus this vertical pressure may be relieved partially.

2. Each pillar supports the column of rock over an area that is the sum of the cross-sectional area of the pillar plus a portion of the room area, the latter being equally shared by all neighboring pillars. However, this is certainly not valid if the area of development is small since the pillars in the center of the excavation are under more stress than the pillars near the sides. It is usually only accepted as valid if the mined-out area is greater than the depth below surface.

3. It is assumed that the load is uniformly distributed over the cross-sectional area of the pillar. However, research has shown that:

a) The stress is not evenly distributed over the cross section of an individual pillar, the maximum stress occurring at the corners formed by the intersection of three orthogonal planes, namely, two sidewalls of the pillar and the roof or the floor.

b) The stress on pillars increases with percentage extraction.

c) The stress distribution in pillars depends upon the ratio of pillar width to pillar height.

Clearly, the assumptions made in the formulation of this approach lead to a conservative estimate of the pillar load. Therefore, it represents the upper limit of the average pillar stress. In fact, measurements have shown (Hustrulid and Swanson, 1981) that this approach overestimates the pillar load by about 40%. The simplicity and conservatism of this approach results in its present popularity.

10.5.6.3 Comparisons of Pillar Strength Formulas

From all the available pillar strength formulas, five empirical expressions are most commonly used.

In Fig. 10.5.18, the five selected formulas are plotted (using the Pittsburgh coal seam properties) as the strength ratio vs. the width-to-height ratio. It is apparent from these figures that for higher width-to-height ratios, the Holland-Gaddy formula predicts the lowest strength while the Bieniawski formula predicts the highest strength. At the same time, the form of the Holland formula is such that it will become very conservative at large width-to-height ratios. The higher strength values predicted by the Bieniawski formula are consistent with the fact that for high width-to-height ratios, there is a very rapid strength increase. In fact, pillars are thought to be almost indestructible for width-to-height ratios greater than 10 (Cook and Hood, 1978).

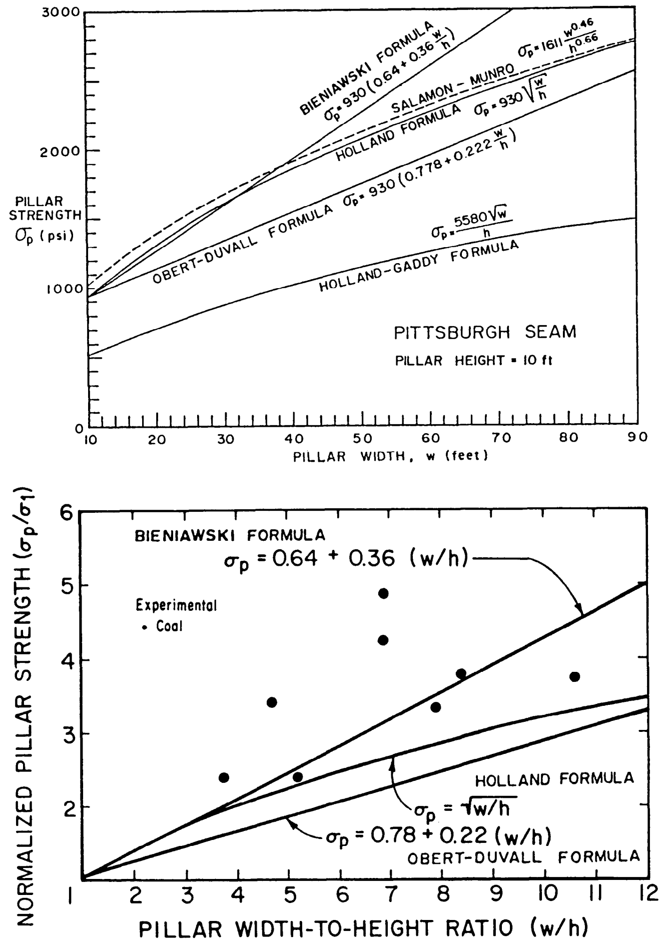

Fig. 10.5.18. Comparison of pillar strength formulas with respect to width-to-height ratio (Bieniawski, 1987). Conversion factor: 1 psi = 6.895 kPa.

A detailed study of this aspect (Bauer, 1980) revealed that the theoretical strength of coal pillars is considerably higher even than that predicted by the Bieniawski formula. Accordingly, it was proposed (Belesky, 1981) that an exponent could be added to the Bieniawski formula thus incorporating a higher rate of strength increase with increasing width-to-height ratios. Currently, the Salamon-Munro formula is being modified along this line (Madden, 1988).

In addition, it is also obvious from Fig. 10.5.18 that the Holland formula and Salamon and Munro formula are quite close in their predictions. This is not surprising since Salamon-Munro used the format of the Holland formula to derive their expression for the strength of coal pillars in South Africa. It is also evident that the Holland-Gaddy formula is very conservative by comparison with the original Holland formula as well as with the other three formulas.

An important point of consideration when comparing pillar strength formulas is the value of the recommended factor of safety, which varies for different formulas. This is demonstrated in Ex. 10.5.3.

10.5.6.4 Design Procedure

The following step-by-step pillar design procedure is recommended (Bieniawski, 1984) when planning new room and pillar coal mines (equations identified):

Step 1. From coal specimen testing $1\frac{1}{8}$-in. (54-mm) core or cubes, tabulate the uniaxial compressive strength of coal σ_c and specimen size (edge dimension or core diameter) D.
Step 2. Based on the uniaxial compressive strength of coal σ_c, determine the value of k for the pillar locality:

$$k = \sigma_c \sqrt{D} \tag{10.5.35}$$

where D is specimen diameter or cube size.
Step 3. Select a pillar strength formula to estimate the pillar width w for a known seam height h. For example, for best economy and safety use:

$$\sigma_p = \sigma_1 (0.64 + 0.36\, w/h) \tag{10.5.36}$$

where

$$\sigma_1 = \frac{k}{\sqrt{36}} \tag{10.5.37}$$

Step 4. Select the roof span B.
Step 5. Determine the pillar load (the average stress on the pillar). In the case of room and pillar coal mining, use the formula based on the tributary area approach:

$$S_p = 1.1H \left[\frac{w + B}{w}\right] \left[\frac{L + B}{w}\right] \tag{10.5.38}$$

where S_p is pillar load in psi, H is depth below the surface in ft, B is entry span in ft, w is width of pillars in ft, and L is length of pillars in ft. For longwall mining application, the pillar load is determined as discussed in 10.5.8.
Step 6. Select a factor of safety F (usually ranging between 1.5 and 2.0) and equate $\sigma_p/F = S_p$. Solve for pillar width w.
Step 7. For economic considerations, check whether the percentage extraction (100e) is acceptable for profitable mining:

$$e = 1 - \left[\frac{w}{w + B}\right] \left[\frac{L}{L + B}\right] \tag{10.5.39}$$

Step 8. If the percentage extraction is not acceptable and needs to be increased by decreasing the pillar width w, select from step 7 the pillar width and length that would give the required coal extraction and determine whether this is acceptable for mine stability. This requires calculation of the factor of safety,

$$F = \sigma_p/S_p \tag{10.5.40}$$

where σ_p is the pillar strength from step 3 while S_p is the pillar load from step 5. The safety factors should be F = 1.5 for short term pillars (in the panels) and F = 2.0 for long-term pillars (in the mains) and for panel pillars to be retreated.
Step 9. Exercise engineering judgment, by considering a range of mining and geologic parameters, to assess the various options for mine planning. Consider the effect of the floor condition.

The above design procedure is not only applicable to room and pillar coal mining but also facilitates the determination of the strength of rock pillars in other rock engineering applications, including longwall mining. In such cases, to establish pillar sizes, special consideration needs to be given to the pillar load since the tributary area formula will not be applicable to tailgate design in view of the abutment pressures. Accordingly, design procedures for chain pillars and yielding pillars are discussed under longwall mining in 10.5.8.

Example 10.5.3. Check an existing coal mining operation in the Pittsburgh seam and improve its performance. Given:

Depth	H =	500 ft (152 m)
Entry width	B =	18 ft (5.5 m)
Pillar width	w =	60 ft (18.3 m)
Pillar length	L =	80 ft (24.4 m) (L/w = 1.33)
Seam height	h =	7 ft (2.1 m)

Pittsburgh seam characteristics: k = 5580 based on σ_c = 3822 psi from NX cores.

Solution. First find σ_ℓ = 5580/6 = 930 psi
Then determine the current factor of safety:

$$F = \sigma_p/S_p = \frac{930\,(0.64 + 0.36 \times 60/7)}{1.1 \times 500 \times 78/60 \times 98/80} = 3.95$$

Clearly, this is not an efficient operation with $F \cong 4.0$ (w/h = 8.57), as evident from the low-percentage extraction:

$$e = 1 - 60/78 \times 80/98 = 0.372 = 37.2\%$$

To improve coal extraction, determine the minimum pillar sizes recommended by the five pillar strength formulas, retaining the ratio of pillar length to pillar width of 1.33.

The calculations provide these results for the appropriate factor of safety recommended by each formula:

Formula	Pillar width (ft)	Pillar length (ft)	Extraction e	Appropriate factor of safety, F
Obert-Duvall	44.2	58.8	0.46	2.0
Holland-Gaddy	52.8	70.2	0.41	1.8
Holland	38.6	51.3	0.50	2.0
Salamon-Munro	28.9	38.5	0.57	1.6
Bieniawski	28.8	38.3	0.58	1.5

Based on the above tabulation, pillar dimensions of 29 by 39 ft (8.8 by 11.9 m) are selected, resulting in an acceptable coal extraction of 59% with a factor of safety of 1.52.

Example 10.5.4. A coal mine in the Pittsburgh seam is mining at 500 ft (152 m) with stable pillars and roofs, and mining is planned at 1000 ft (305 m). What square pillar sizes should be selected at that depth?

Given: H = 500 ft (152 m)
h = 10 ft (3 m)
w = 40 ft (12.2 m)
B = 18 ft (5.5 m)

Solution. (a) Determine the factor of safety found satisfactory at the mine:

$$S_p = 1156 \text{ psi}$$
$$\sigma_p = 930\,(0.64 + 0.36\, w/h) = 1934 \text{ psi}$$
$$F = 1.67$$

(b) Check on the current percentage extraction:

$$e = 0.52 = 52\%$$

(c) At the planned depth of 1000 ft and the same roof span B = 18 ft, the new square pillar width is calculated as:

Equation:	Obert and Duvall	
F	Extraction	Width
2.0	0.26	109.6 ft (33.4 m)

Equation:	Holland	
F	Extraction	Width
2.0	0.27	105.3 ft (32.1 m)

Equation:	Holland and Gaddy	
F	Extraction	Width
1.8	0.15	210.2 ft (64.1 m)

Equation:	Salamon and Munro	
F	Extraction	Width
1.6	0.33	80.0 ft (24.4 m)

Equation:	Bieniawski	
F	Extraction	Width
1.5	0.39	63.5 ft (19.4 m)

10.5.7 ANALYSIS OF FLOOR STABILITY

The existence of floor stability problems in mines and tunnels has been recognized for many years, yet little effort has been made to develop a rational floor stability analysis. This neglect has led to numerous difficulties affecting miner safety, working area and equipment access, transportation, and ventilation. Knowledge of the bearing capacity of mine floors is also particularly important when designing face supports in longwall coal mining.

The bearing capacity approach as practiced in soil mechanics is applicable since room and pillar mining reduces the surcharge due to overburden pressure and leaves a pillar acting in a fashion similar to a vertically loaded shallow foundation. The term *bearing capacity* is defined as the maximum load that may be applied by a foundation to the surrounding soil without causing failure.

Brady and Brown (1985) recommend the following expressions for a cohesive, frictional material such as soft rock:

$$q_u = \frac{1}{2}\gamma\, BN_\gamma + cN_c \tag{10.5.41}$$

$$N_c = (N_q - 1)\cot\phi \tag{10.5.42}$$

$$N_\gamma = 1.5\,(N_q + 1)\tan\phi \tag{10.5.43}$$

$$N_q = e^{\pi\tan\phi}\tan^2\left(\frac{\pi}{4} + \frac{\phi}{2}\right) \tag{10.5.44}$$

where g is density, B is width of footing or pillar, L is length of footing or pillar, c is cohesion of floor strata, and ϕ is friction angle of the floor strata.

Eq. 10.5.41 is applicable to determining the bearing capacity developed under a long rib pillar. For pillars of length L, the bearing capacity is given by

$$q_u = \frac{1}{2}\gamma\, BN_\gamma S_\gamma + c\cot\phi\; N_q S_q - c\cot\phi \tag{10.5.45}$$

where S_y and S_q are shape factors defined as:

$$S_\gamma = 1.0 - 0.4\,(B/L) \tag{10.5.46}$$

$$S_q = 1.0 + \sin\phi\,(B/L) \tag{10.5.47}$$

The factor of safety against bearing capacity failure q_u/S_p should be greater than 2.0 in view of the uncertainty of assuming that the average pillar stress S_p is applied as a uniformly distributed normal load to the floor area (Eq. 10.5.31).

Example 10.5.5. Assess floor stability in a coal mine entry under the following conditions:

Longwall panel at the depth of 640 ft (195 m). The floor of the 18-ft (5.5-m) wide entry is next to a yield pillar with B = 22 ft (6.7 m) and L = 130 ft (39.7 m). Entry height h = 6 ft (1.8 m). The pillar load, as determined from the ALPS procedure, is σ_p = 2660 psi (18.3 MPa). The properties of the fractured grey shale, which is the floor material, are: density g = 70 lb/ ft^3, cohesion c = 30 psi (4320 psf) (0.2 MPa), friction angle ϕ = 19°, uniaxial compressive strength σ_c = 1680 psi (11.6 MPa). The rock mass rating RMR = 44.

Solution.

$$S_\gamma = 1 - 0.4 \times 0.169 = 0.932$$
$$S_q = 1 + 0.2789 \times 0.169 = 0.953$$
$$\gamma = 70\ \text{lb/ft}^3$$
$$N_q = 5.80 \text{ for } \phi = 19°$$
$$N_\gamma = 4.68 \text{ for } \phi = 19°$$
$$q_u = \tfrac{1}{2} \times 70 \times 22 \times 4.68 \times 0.932 + 4320 \times 2.31 \times 5.8 \times 0.953 - 4320 \times 2.91$$
$$= 3358.55 + 69486.0 - 12571.0 = 60{,}273 \text{ psf} = 418 \text{ psi}$$
$$\text{F} = 418/2660 = 0.16 < 2.00 \text{ (flcor failure expected).}$$

Following is a microcomputer program output (SI units) for an alternative determination of the ultimate stress on floor strata of underground coal mines (after Faria and Bieniawski, 1989).

Mine Data and Geomechanical Parameters of the Floor Strata:

Lithological type of the floor: sandy shale
Uniaxial compressive strength (in MPa): 11.6
Point of critical energy release (in MPa): 8.5
Tensile strength (in MPa): 1.5
Unit weight of the floor (in kN/m^3): 12
RMR (rock mass rating): 44
Depth of overburden (in meters): 195
Unit weight of the overburden (in kN/m^3): 25
Pillar width (in meters): 6.7
Pillar length (in meters): 40
Pillar stress (in MPa): 18.3
Entry width (in meters): 5.5
Entry height (in meters): 1.85
Value of m for intact rock: 12.5

Stability analysis—pillar punching into floor

Parameter m: 1.69
Parameter s: 0.002
Geostatic stress (in MPa): 4.88
Cohesion of floor strata (in MPa): 3
Equivalent angle of internal friction—floor: 19°
Ultimate stress on floor strata (in MPa): 15.34
Factor of safety of floor: 0.84. Expect floor failure.

10.5.8. GROUND CONTROL IN LONGWALL MINING

Good ground control is the most important element for successful longwall mining; proper roof control in longwall faces is needed not only to control effectively the immediate roof but also to control and adapt to the behavior of the main roof. This requires a complete understanding of the behavior of the overburden strata. Two of the more frequent problems encountered in US longwall mining are related to panel and entry design and to the development method used. These problems are (1) a panel can be mined out faster than a new one can be developed, and (2) strata control problems occurring in the tail entry, particularly shearing of the roof strata at the rib line, floor heave, and pillar sloughing.

10.5.8.1 Strata Mechanics

It has been observed from measurements of rock pressures around longwall faces that beyond a certain depth—approximately 1000 to 1150 ft (300 to 400 m)—one may achieve control of the roof at the face by using supports with a load-bearing capacity ranging from 220 to 550 tons/ft^2 (20 to 50 t/m^2) of exposed roof. This holds true even at depths down to 4600 ft (1400 m), as is the case in Europe. This figure of support capacity is very small when compared with the weight of the overlying strata; in fact, it is no more than 1 to 2% of that weight. An explanation lies in the rock strata transferring a considerable part of the load ahead of the face, thus creating a zone of high pressure which advances with the face. This creates a bridge over the mining area in which the abutment on one side is the mass of coal in situ and on the other side is the caved waste in the gob. Both "legs" of the bridge are being compressed, and the face supports are therefore carrying only a very small thickness of the rock strata of the order of 33 to 50 ft (10 to 15 m).

To understand this phenomenon better, it may be noted that a redistribution of the stress field in the presence of a longwall face causes high stress concentrations at various points around the longwall face. Three types of such abutment pressures can be categorized, namely, front abutment pressure, side abutment pressure and rear abutment pressure (Peng and Chiang, 1984; see also Chapter 20.1). The front abutment pressure may reach a peak pressure of up to five times the original overburden pressure at about 3 to 10 ft (1 to 3 m) in advance of the coal face. This peak pressure causes a significant strata control problem in both headgate and tailgate entries, even without the interaction with the adjacent previously mined-out panel. However, when interaction does occur, the tailgate entry suffers more than the headgate entry. This is due to the superposition of pressure from the old panel because the side abutment pressure of the previously mined panel meets with the front and side abutment pressures of the presently mined panel.

However, the location of the peak front abutment pressure varies from area to area due to differences in strata characteristics. For US conditions, measurements show that the peak front abutment pressure occurs at about 13 to 30 ft (4 to 9 m) ahead of the face line (Peng and Chiang, 1984).

It should be noted that the generalized positions of the front-abutment pressure profile for British and German coal measure rocks is different from that in the United States. The reason for this is that mining practices in America are different, necessitating a multiple entry tailgate and headgate as well as bleeder entries, which change the stress distributions.

The side abutment pressure, which occurs along both sides of the panel in the gob area, is the largest at the rib sides, reaching its peak some 10 to 30 ft (3 to 10 m) from the longwall side, decreasing exponentially with distance from the ribs to a maximum distance of one-fourth to one-third of the overburden thickness, or typically 200 ft (60 m).

Generally, the magnitudes of the side-abutment pressure for the first row of chain pillars range from 0.4 to 3.5 times the overburden pressure, depending on the location inside the pillar. Moreover, depending on the total pillar width and the zone of influence of side abutment, the stress change in the pillar when the face of the second panel is passing by may reach up to seven times that when the first panel is being mined. The magnitude due to second panel mining ranges from 1.6 to 10 times the overburden stress. As far as the rear abutment pressure is concerned, this is the pressure in the gob area, and its maximum can equal the overburden pressure.

10.5.8.2 Sizing of Chain Pillars

The optimum size of chain pillars is affected by such parameters as the overburden depth, stratigraphic thickness in the roof, working height, entry width, coal strength, and face width. The assessment of the chain pillar stability requires a knowledge of the pillar strength, the pillar stress, and the safety factor.

The strength of coal pillars can be determined using the procedures described in an earlier part of this chapter (10.5.6). Determination of the stress state in chain pillars is particularly crucial in longwall mining because of the presence of the abutment stresses. In the longwall retreating phase, the high abutment stresses can damage entries ahead of the longwall face and the tail entry for the next panel. An optimum arrangement of chain pillars can lead to favorable strata control conditions in the gate entries.

Choi and McCain (1980) reported on the use of the yield pillar concept in a coal mine in West Virginia at a depth of 700 to 800 ft (213 to 244 m). The longwall panels were 450 ft (137 m) wide and were developed using three-entry headings, 16 ft (4.9 m) wide on 100 ft and 50 ft (30.5 m and 15.2 m) centers. The width of the resulting chain pillars (stiff pillars) in the development headings was 80 ft (25.6 m). It was reported that the yield pillars of 34 ft (10.4 m) to 44 ft (13.4 m) width have been successfully used where the strength of the Pittsburgh coal was 2200 to 2500 psi (15.2 to 17.2 MPa). Note that the size of the yield pillars is determined by the strength of the roof in the tailgate, that is, the pillar must yield before the roof of the tailgate breaks. Because the yielding pillars are considered to be independent of supporting the abutment pressure, the size of the chain pillars is obtained from the pillar stress (including the abutment pressures) vs. pillar strength considerations. This is given by Choi and McCain, (1980) as

$$L = 0.6H - 1.2\left[\frac{H^2}{4} - \frac{5}{3}\left(\frac{AW}{W + C} \times \frac{\sigma_p}{24.9\ SF} - AH - \frac{SH}{2}\right)\right]^{0.5} \qquad (10.5.48)$$

where L is width of the panel, H is overburden depth, A is chain pillar width, S is entry width, C is crosscut width, W is chain pillar length, all in ft (m), and SF is safety factor for pillar strength.

Hsiung and Peng (1985) proposed a chain pillar design formula under weak roof conditions by analyzing statistically the results from the three-dimensional, finite-element, parametric analyses. The parameters such as mechanical properties of the roof and floor strata, overburden depth, panel width and length, and coal strength were incorporated. The formula was expressed as follows:

$$\begin{aligned}\log W_p = &-4.676 \times 10^{-3}\, E_i/E_c - 4.04 \times 10^{-3}\, E_m/E_c \\ &- 3.33 \times 10^{-2} \log (E_f/E_c) - 0.0789 \log \sigma_{oc} + 0.5144 \log h \\ &+ 0.0494 \log (L_p/2) + 0.1941 \log P_w\end{aligned} \qquad (10.5.49)$$

where W_p is pillar width in ft, h is overburden depth in ft, L_p is panel length in ft, P_w is panel width in ft, σ_{cc} is uniaxial compressive strength of coal in situ in psi, E_i is Young's modulus of the immediate roof in psi, E_c is modulus of the coal in psi, E_m is modulus of the main roof in psi, and E_f is modulus of the floor in psi.

More recently, Mark and Bieniawski (1986) developed at Penn State a new method for the design of longwall chain pillars, called ALPS (analysis of longwall pillar stability). The method provides estimates of the pillar abutment loads during all stages of their service life. The key issue addressed by ALPS is the magnitude and time-of-arrival of the longwall abutment loads applied to chain pillars as demonstrated in the example which follows. Field studies were conducted, and over 100 case histories were analyzed to verify the method.

10.5.8.3 Analysis of Longwall Pillar Stability (ALPS)

The Penn State ALPS method is a *stiff pillar* design approach. Its goal is to size longwall pillars capable of carrying the abutment loads to which they will be subjected. ALPS consists of three basic elements:

1. Estimation of the load applied to the pillar system.
2. Estimation of the strength of the pillar system.
3. Application of a safety factor.

Before using ALPS, it is necessary to collect mine and coal-strength data used in the design:

1. Maximum depth of cover (H).
2. Unit weight of the overburden (g, typically 162 lb/ft^3).
3. Width of the panel, or face length (P).
4. Entry width (B).
5. Pillar length (L).
6. Height of the coal seam (h).
7. In situ strength of the coal seam (σ_1).

Fig. 10.5.19 defines most of the geometric parameters listed above. The in situ coal strength σ_1 is the same parameter discussed in 10.5.61.

To use ALPS, it is also necessary to have estimates of the individual pillar widths w and the total width of the pillar system W_t. The pillar widths are needed because both the development load and pillar-strength equations are functions of w. If ALPS is being used to size pillars, it is necessary to perform several iterations, adjusting the pillar widths each time as required.

The length of the pillars is normally based on the requirements of ventilation and operations. From a strata control standpoint, the pillars should be as long as possible to increase the available load bearing area. It is particularly important that the pillar lengths equal or exceed the pillar widths. Pillar strength is determined by the least pillar dimension.

The heart of the ALPS method is the estimation of the load applied to longwall pillars. The load estimation procedure begins with an estimate of the development load per ft of gate entry L_t:

$$L_t = (H)\,(W_t)\,(\gamma) \tag{10.5.50}$$

The total pillar load is the sum of the development and the abutment loads. Three parameters are needed in order to estimate the magnitude of the abutment load. These are the magnitude of the side abutment (L_s or L_{ss}), the percentage of the side abutment applied to the chain pillars (R), and the front abutment factors (F_h and F_t). Two equations are available for calculating the side abutment. For critical and supercritical panels, where $P > 0.77\,H$, the magnitude of the side abutment per ft of gate entry L_s can be estimated as

$$L_s = 0.38\,(H^2)\,(\gamma/2) \tag{10.5.51}$$

For panels where $P < 0.77\,H$, the expression for the side abutment (L_{ss}) is

$$L_{ss} = \left(\frac{H\,P}{2} - \frac{P^2}{3.1}\right)\gamma \tag{10.5.52}$$

The percentage of the abutment load applied to the chain pillars is the *abutment fraction R:*

$$R = 1 - \left(\frac{D - W_t}{D}\right)^3 \tag{10.5.53}$$

In Eq. 10.5.53, D is the extent of the side abutment influence zone, which is equal to $9.3\sqrt{H}$.

The front abutment factor is used to estimate the fraction of the total side abutment that is present at the T-junctions. Two front abutment factors are necessary, one (F_h) for the first front abutment experienced in the headgates (and the first tailgate), and the other (F_t) for second front abutment applied to the tailgate. The proposed front abutment factors are F_h = 0.5 and F_t = 0.7, as determined from field measurements.

The maximum loading L_{max} to which the pillar system is subjected depends on the services for which the pillar system will be used. Three possible loading conditions may be defined.

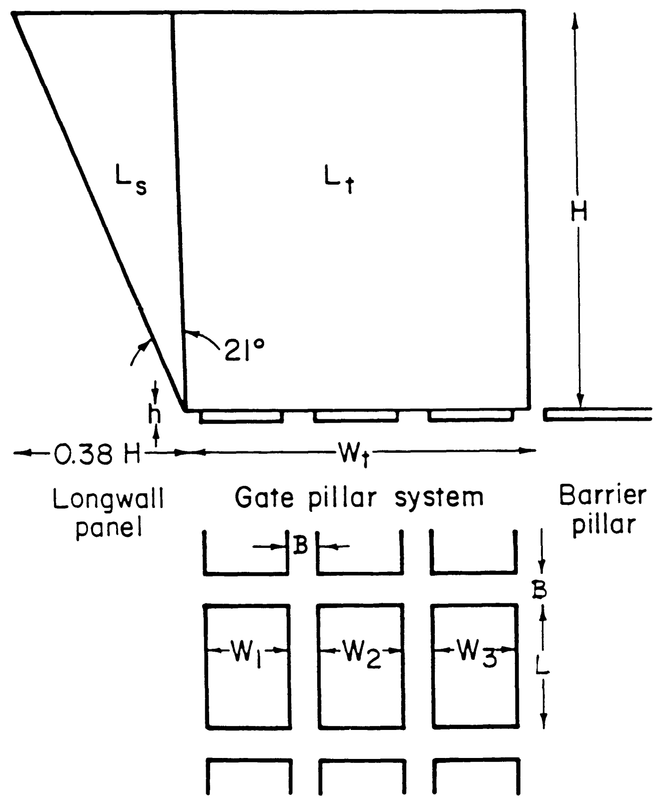

Fig. 10.5.19. Definition of geometric parameters used in the analysis of longwall pillar stability (Mark and Bieniawski, 1986).

The loading experienced by pillars at the T-junctions in the headgate, or in the tailgate during first panel mining, is called headgate loading. *Headgate loading* L_H consists of the development load plus the first front abutment:

$$L_H = L_t + (L_s)(F_h)(R) \tag{10.5.54}$$

Pillars which are expected to protect bleeder entries will be subjected to the development load and the first full side abutment or *bleeder loading* L_B:

$$L_B = L_t + (L_s)(R) \tag{10.5.55}$$

The loads on barrier pillars may also be determined from Eq. 10.5.55 by setting $R = 1$.

The most severe longwall loading is *tailgate loading* (L_T), experienced during the mining of the second and subsequent panels. Tailgate loading consists of the development load, the first side abutment, and the second front abutment:

$$L_T = L_t + (L_s)(1 + F_t) \tag{10.5.56}$$

Once the design pillar loading is established, the next stage is the estimation of the load-bearing capacity of the pillar system. First, the strength of each individual pillar is estimated using the Bieniawski formula:

$$\sigma_p = \sigma_1 (0.64 + 0.36\, w/h) \tag{10.5.57}$$

Then the load-bearing capacity of the pillar system per ft of entry LB is calculated as the sum of the individual pillar resistances:

$$LB = \Sigma[(\sigma_p)(w)(L)][144/(L + B_e)] \tag{10.5.58}$$

Once both the load and the resistance of the pillars have been determined, a safety factor SF may be calculated as:

$$SF = LB/L_{\max} \tag{10.5.59}$$

The final step in the analysis is the comparison of the safety factor determined in Eq. 10.5.59 to a recommended safety factor. If no previous longwall experience is available, $SF = 1.3$ is considered adequate for sizing chain pillars for the gate entries. For barrier pillars that are expected to protect the main entries for a long period of time, a higher safety factor should be used ($SF = 2.0$ to 2.5).

In many cases it is possible to calibrate ALPS with actual field experience. Where several case histories are available from a given mine or mining area, safety factor may be calculated for each pillar design and compared to the observed ground conditions. The SF which corresponds to acceptable conditions may then be used for sizing pillars in future panels.

One major advantage of the ALPS method is that it may be applied to two-, three-, and four-entry systems employing any combination of pillar widths. Although there does not appear to be sufficient justification for specific recommendations regarding the use of unequal size pillars, ALPS does predict that using a single large pillar flanked on one or both sides by small pillars results in a more efficient design. The reason that a design employing a combination of small and large pillars is more efficient than one using equal sized pillars is that the pillar strength increases rapidly as the w/h ratio increases. It appears that many mines could minimize the coal lost in chain pillars without compromising gate entry stability by shifting from equal to unequal sized longwall pillars.

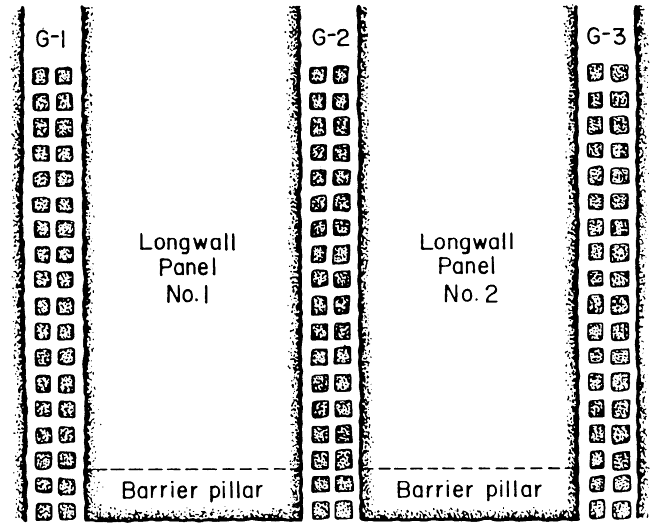

Fig. 10.5.20. Sample problem illustrating the Penn State ALPS method (Mark, 1987).

If small pillars are used in combination with large ones, it is suggested that they be sized to be weaker than either the roof or the floor to reduce stress concentration in the entries. Moreover, as shown in 10.5.7, information on pillar stresses is required for floor stability. The Penn State ALPS method may be used to estimate the average pillar stresses for this purpose.

Example 10.5.6. Chain Pillar Design by the ALPS method. A mine is developing its first two longwall panels in a block of coal reserves. The seam is known to be about 6 ft (1.8m) thick and is considered to be of an average strength for the Pittsburgh seam. The depth of cover over the proposed panels is 1000 ft (305 m). The face length is fixed by the available longwall equipment at 800 ft (244 m). The entries will be 18 ft (5.5 m) wide, and three-entry gate systems will be used. MSHA approval has been obtained to drive the crosscuts with a center-to-center spacing equal to 110 ft (33.5 m) or the entry spacing, whichever is greater. It is desired to size the chain pillars for the three sets of gate entry systems, numbered G-1, G-2, and G-3 in Fig. 10.5.20. Determine the required pillar sizes.

Solution. Each of the three-gate systems will be subjected to different maximum service loadings. Therefore, in order to minimize the total amount of coal used in the chain pillars, the pillars will be sized for each gate system separately. A step-by-step solution for G-1 is given below.

1. Collect the required data:

H = 1000 ft (305 m)
g = 162 lb/ft^3 (25.1 kg/m^3)
P = 800 ft (244 m)
B = 18 ft (5.5 m)
L = 92 ft (28 m) or the pillar width if w > 92 ft (28 m)
h = 6 ft (1.8 m)
σ_1 = 930 psi (6.4 MPa)

2. Provide initial estimates of the pillar width w and the total width of the pillar system W_t:

w = 72 ft
W_t = 180 ft

3. Estimate the development load using Eq. 10.5.50:

L_t = (1000) (180) (162)/2000
= 14,600 tons/ft

4. Estimate the side abutment load. Because the panel is supercritical ($P > 0.77\ H$), Eq. 10.5.51 is used:

L_s = (0.38) (1000^2) (162/2)/2000
= 15,500 tons/ft

5. Calculate the extent of the side-abutment influence zone D and the abutment fraction R, using Eq. 10.5.53.

$$D = 9.3\sqrt{1000} = 294 \text{ ft}$$

$$R = 1 - \left(\frac{294 - 180}{294}\right)^3 = 0.94$$

6. Estimate the maximum service loading L_{max}. Since gate system G-1 will be used as a bleeder system, the maximum pillar loading is L_B, represented by Eq. 10.5.55:

L_B = 14,600 + (0.94) (15,500)
= 29,170 tons/ft

7. Calculate the strength of the individual pillars in the system using Eq. 10.5.57. As the pillars in G-1 are of equal size, only one calculation is necessary:

σ_p = 930 [0.64 + 0.36 (72/6)]
= 4613 psi

8. Calculate the load bearing capacity of the pillar system using Eq. 10.5.58:

LB = (2) (4613) (72) (92) (144)/(110)(2000)
= 39,970 tons/ft

9. Calculate the safety factor (Eq. 10.5.59):

SF = 39,970/29,170
= 1.37

(Thus the maximum abutment pressure is 3367 psi).

10. Compare the SF to a design criterion. In this example, we assume longwall experience is available, and a criterion of SF = 1.5 is used. Since the SF calculated in step 9 is less than 1.5, another iteration of steps 2 to 10 is necessary using an increased pillar size. In order to obtain SF = 1.5, 82-ft (25-m) wide pillars must be used.

The same procedure must be followed to size the pillars for G-2 and G-3, considering the different loading conditions in each case. The pillars in G-2 must protect the tailgate of the second panel, and should be designed using the maximum load defined by Eq. 10.5.56. If the entries in GS-3 will not be used as bleeders for any length of time, then the headgate loading defined by Eq. 10.5.54 can be used. Otherwise, Eq. 10.5.55 would be more appropriate.

The advantage of using unequal-sized pillars may be illustrated by this example problem. If equal-sized pillars are used in G-2, each pillar must be 100 ft wide (30.5 m) for a total pillar width of 200 ft (61 m). The same SF of 1.5 could also be obtained using a 130 ft (40 m) pillar in combination with a 20 ft (6.1 m) pillar, thereby reducing the total pillar width by 25%.

Computer Program for ALPS: Although the application of the ALPS method is straightforward, it can be time-consuming if a number of designs must be analyzed. A computer program is available from Penn State and the USBM.

Longwall Chain Pillar Sizing by Different Methods: There are three approaches to longwall chain pillar design from the point of view of stress distribution/abutment pressure determination. In contrast, in room and pillar mining, only one method is used: the tributary area approach. In both room and pillar mining and longwall mining, the same pillar *strength* formulas are applicable: Obert-Duvall/Wang, Holland, Holland-Gaddy, and Bieniawski.

The three approaches to longwall chain-pillar design are

1) Analytical (Wilson).

2) Empirical, from field measurements (Mark and Bieniawski).

3) Numerical, from finite element method modeling (Hsiung and Peng).

The Wilson method provides an analytical solution of stress distribution due to abutment loading (see 10.5.8.4), and for pillar strength it simply assumes that the in situ coal strength is one-fifth of the laboratory strength. It also assumes that the horizontal and the vertical in situ stresses are equal.

The Mark-Bieniawski method (ALPS) is an empirical approach providing estimates of the abutment loads based on field measurements, for three phases of longwall mining: development, headgate loading, and tailgate loading. For pillar strength, the Bieniawski formula is used (Eq. 10.5.30).

The Hsiung-Peng method is based on finite element method modeling of abutment loading, but it is not directly comparable to the other two methods because it requires assumptions of the modulus of deformation of coal in pillars, mine roof (immediate and main), and mine floor. The pillar strength, like in the Wilson method, is again assumed to be one-fifth of the laboratory coal strength.

It is obvious that the determination of the pillar strength (as one-fifth of the laboratory strength) in the Wilson method and the Hsiung-Peng method is open to criticism. On the other hand, if one of the five common strength formulas is included, care must be exercised that the factor of safety appropriate to each formula is used because they are not the same, as discussed earlier.

Example 10.5.7. It is required to determine the relationship between the overburden depth and the resulting chain pillar sizes as predicted by the various design methods. The following input data are used from a base study by Peng (1986):

Longwall panel width	460 ft (140 m)
Longwall panel length	4000 ft (1219 m)
Entry width	20 ft (6.1 m)
Entry height	6.5 ft (2 m)
Laboratory strength of coal	4500 psi (31 MPa) = σ_c
Specimen size tested	$2\frac{1}{8}$ in. (54 mm) = D
Gaddy k factor	6560
Triaxial strength factor	3.75
Angle of draw	17°
Abutment angle	21°
E_i/E_c = 1	
E_m/E_c = 10	
E_f/E_c = 1	

Modulus of deformation of coal $E_c = 0.5 \times 10^6$ psi (3448 MPa).

Solution. In situ coal strength for the Wilson and Hsiung-Peng methods: $\sigma_o = \sigma_c/5 = 900$ psi (6.2 MPa).

In situ strength of coal for the Mark-Bieniawski method: $\sigma_1 = k/6 = 1093$ psi (7.5 MPa). Note that for comparison with the other two methods, factor of safety of unity will apply.

In situ strength of coal for the Bieniawski formula (also for Obert-Duvall/Wang and Holland formulas): $\sigma_1 = k/6 = 1093$ psi (7.5 MPa).

Pillar strength factor for the Salamon-Munro formula:

$$K = k/\sqrt{12} = 1893 \text{ psi (not convertible to SI units)}$$

In undertaking a comparison, it may be appropriate not only to compare the three main longwall chain pillar design approaches mentioned above but also to include the results of the Wilson stress distribution calculation combined with the common pillar strength formulas instead of the arbitrary assumption that $\sigma_o = \sigma_c/5$. In this case, each pillar strength formula must include its corresponding safety factor *F*, so that the appropriate values will be as follows:

Obert-Duvall/Wang formula: $F = 2.0$, thus $\sigma_o = \sigma_1/2 =$ 546 psi (3.77 MPa)
Holland-Gaddy formula: $F = 1.8$ thus $k_o = k/1.8 = 3644$ psi (2513 MPa)
Holland formula: $F = 2.0$ thus $\sigma_o = \sigma_1/2 = 546$ psi (3.77 MPa)
Salamon-Munro formula: $F = 1.6$ thus $K_o = K/1.6 = 1183$ psi (8.16 MPa)
Bieniawski formula: $F = 1.5$ thus $\sigma_o = \sigma_1/1.5 = 728$ psi (5.02 MPa)

If, in the above example, $F = 1.0$ is chosen for all five formulas, the results will be comparable with those predicted by the three main chain pillar design approaches.

Fig. 10.5.21 shows a comparison of the three main design approaches. It is concluded that the Mark-Bieniawski method provides the most economical, yet safe, pillar sizes.

Special Considerations: These considerations include chain pillars in multi-entry development, pillars at greater depths (over 1500 ft or 458 m), rectangular pillars, barrier pillars, and pillars exhibiting brittle behavior.

It should be noted that for *multi-entry development* as practiced in US longwall mining, one can use the Wilson method to obtain a "stress decay" profile over the entry, that is, stress decrease from the gob size to the unmined panel. Once this is done, pillar sizes may be selected, including yielding pillars, based on any of the five pillar strength formulas.

For *pillars at greater depths* (over 1500 ft or 458 m), which means higher width-to-height ratios, the formulas of Obert-Duvail/Wang, Holland-Gaddy, Holland, and Salamon-Munro are all too conservative and, in fact, were never intended for this purpose. Only the Bieniawski formula is still realistic up to width-to-height ratios of 10 to 12. Realizing this, Madden (1988) reported on a modified Salamon-Munro formula for squat pillars, which is of the following form:

$$\sigma_p = \sigma_1 \frac{5^{0.5933}}{V^{0.0667}} \left\{ \frac{0.5933}{2.5} \left[\left(\frac{w}{5h} \right)^{2.5} - 1 \right] + 1 \right\} \tag{10.5.60}$$

where σ_1 is in situ strength of coal = 7.2 MPa, *V* is pillar volume, *w* is pillar width, and *h* is pillar height, all in meters.

This formula should be compared with the Bieniawski formula as well as the original Salamon-Munro formula given in Fig. 10.5.18. Note that the factor $K = 7.2$ MPa is applicable to South African conditions and for US applications should be replaced by the value of σ_1 in MPa.

For *rectangular pillars,* three expressions are available. It is no longer accepted that the strength of rectangular pillars equals the strength of square pillars, the width of which is the same as the smallest dimension (width) of the rectangular pillars.

The expressions for the effective pillar width for rectangular pillars are as follows:

(Salamon and Oravecz, 1970)

$$w_{eff} = (w_w \times w_L)^{0.5} \tag{10.5.61}$$

(Wagner, 1974)

$$w_{eff} = 4A/C \tag{10.5.62}$$

(Peng, 1986)

$$w_{eff} = w_w^{0.85} \times w_L^{0.15} \tag{10.5.63}$$

where w_w is pillar width, w_L is pillar length, *A* is pillar area, and *C* is pillar circumference. It is believed that the Wagner formula has been most tested in practice.

For *barrier pillars*, the old "mine inspector's formula" of 1930 is considered too conservative. It is of the form, with units in ft,

$$W_{barrier} = 20 + 4h + 0.1H \tag{10.5.64}$$

A more realistic approach is to select a barrier on the basis of the width-to-height ratio being $w/h > 20$ since pillars with $w/h > 12$ are virtually indestructible, and hence $w/h > 20$ gives a sufficient margin of safety.

Finally, for *pillars exhibiting brittle behavior,* the elastic-plastic analysis of Wilson may not be applicable. Instead, a stress analysis incorporating the Hoek-Brown rock mass strength criterion could be more appropriate (Eq. 10.5.4). It should be noted that the Wilson method was developed for British soft-coal strata and, up to a depth of 2300 ft (700 m) and for $k = 3$, it conforms closely to a British empirical formulation that the rib pillar width should equal one-tenth of the depth below surface plus 15 yd (13.7 m). Note that in Britain, a single rib pillar separates longwalls mined on advance with single-way entries (called drivages or roadways).

Distribution of Vertical Stress Around a Longwall Face: Wilson (1977, 1983) has developed an instructive analysis of the distribution of vertical stress around a longwall extraction. This analysis uses a stress balance method in which the total vertical force applied over a large plan area must remain equal to that caused by the overburden, even after part of the seam has been removed. It is assumed that, compared with the total vertical force to be redistributed, the vertical forces transmitted by the roadway supports are small and may be ignored.

Fig. 10.5.22 shows Wilson's approximations to the vertical stress distributions acting at cross sections. The distribution of vertical stress postulated in the caved waste is based on an assumption, derived from field observations, that the stress reaches the overburden stress at a distance of 0.3h from the rib side (Fig. 10.5.22a). The distribution of stress within the yielded zone at the rib side is calculated using an elastic-plastic analysis. As shown in Fig. 10.5.22 c, the resulting nonlinear stress distribution is approximated by a triangular distribution. Table 10.5.9 sets out the values calculated by Wilson for the vertical stress, the peak abutment stress, the width of the rib-side yield zone, and the total vertical force carried by the yield zone for two sets of strata conditions. In Fig. 10.5.22 and Table 10.5.9, the following symbols are used:

σ_{zz} = vertical stress
σ_y = peak abutment or yield stress
p = vertical stress remote from the excavation = gh
C_o = in situ uniaxial compressive strength of the strata
b = a constant in the principal stress form of the Coulomb shear strength equation, $\sigma_y = C_o + b\sigma_3$

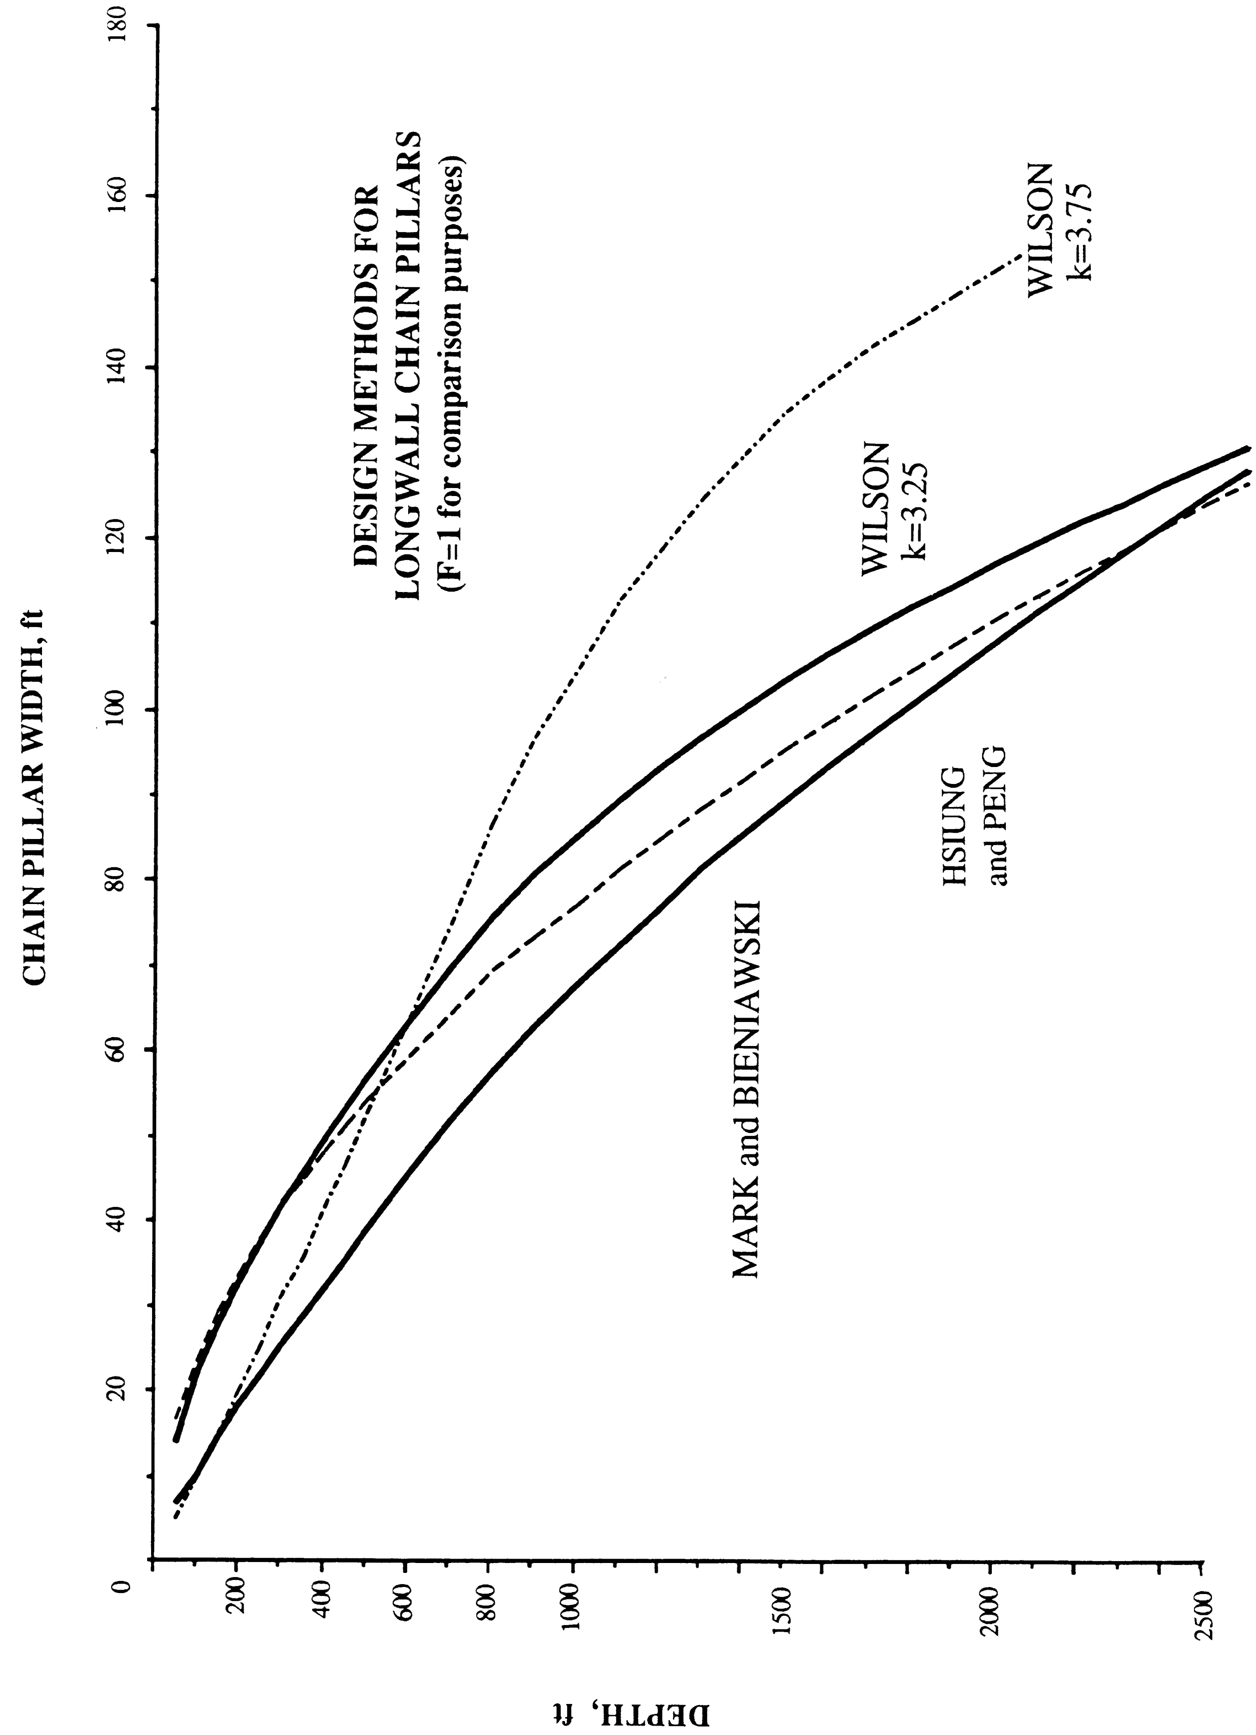

Fig. 10.5.21. Comparison of longwall pillar design methods. Conversion factor: 1 ft = 0.3048 m.

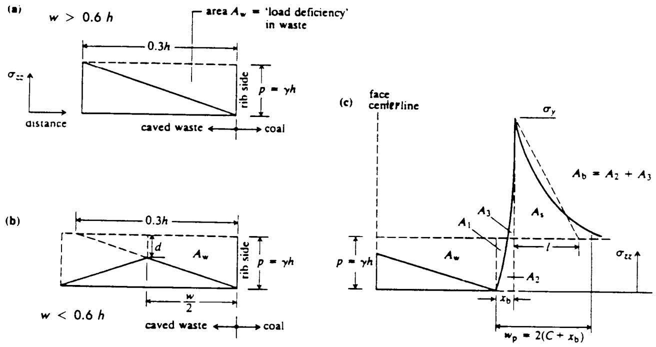

Fig. 10.5.22. Hypothetical decay of stress around a longwall face (Wilson, 1983).

Table 10.5.9. Expressions for Calculating Distributions of Vertical Stress at Rib Sides (Roof, seam and floor of similar strength).

vertical stress	$\sigma_{zz} = bp^*\left(\frac{2x}{m} + 1\right)^{b-1}$
peak abutment or yield stress	$\sigma_y = C_o + bp$
width of yield zone	$x_b = \frac{m}{2}\left[\left(\frac{p}{p^*}\right)^{1/(b-1)} - 1\right]$
vertical force carried by the yield zone	$A_b = \frac{m}{2}p^*\left[\left(\frac{p}{p^*}\right)^{b/(b-1)} - 1\right]$

Source: Wilson, 1983.

m = height of the extraction
x = distance from the rib side
x_b = width of yield zone
p^* = support pressure p_i plus the unconfined compressive strength of the broken material at the rib side, taken as 0.1 MPa, or $p^* = p_i + 0.1$ MPa
$F = \frac{b-1}{\sqrt{b}}\left(1 + \frac{b-1}{\sqrt{b}}\tan^{-1}\sqrt{b}\right)$, where $\tan^{-1}\sqrt{b}$ is expressed in radians

The stress in the zone beyond the peak stress decays asymptotically towards the overburden stress p. The stress decay curve is assumed to be of the form,

$$(\sigma_{zz} - p) = (\sigma_y - p)\exp\left(\frac{x_b - x}{C}\right)$$

where C is a constant having the units of distance. By equating areas under the curves in Fig. 10.5.22c so as to maintain a vertical stress balance, the value of C is calculated as

$$C = \frac{A_w + px_b - A_b}{\sigma_y - p} \tag{10.5.65}$$

where A_w is the *load deficiency* associated with each rib side as shown in Figs. 10.5.22 a and b.

For $w > 0.6h$,

$$A_w = 0.15\gamma h^2 \tag{10.5.66}$$

and for $w < 0.6h$,

$$A_w = \frac{1}{2}w\gamma\left(h - \frac{w}{1.2}\right) \tag{10.5.67}$$

where w is the width of the extracted area.

It must be emphasized that Wilson's method of calculating the distribution of vertical stress in the mining domain following extraction is mathematically not rigorous but is based on a number of assumptions and approximations.

Chapter 10.6
MINE SUBSIDENCE

MADAN M. SINGH

10.6.1 INTRODUCTION

Subsidence is an inevitable consequence of underground mining— it may be small and localized or extend over large areas, it may be immediate or delayed for many years. During recent years, with the expansion of urbanization and increased concern for the environment, it is no longer possible to ignore its aftermath. In the United States, mining companies have, therefore, begun to devote attention to the subject and study it in a methodical manner. Appropriate regulations have also been promulgated by various government agencies, depending on the needs of the region, in order to protect the public interest.

The problems associated with subsidence have been recognized since the inception of mining and mentioned in the literature as far back as Agricola's *De Re Metallica* in 1556. The initial "vertical theory" was modified by the researches of Coulomb, Toillez, Gonot, Rziha, and Fayol (Peele, 1952). Significant contributions may also be credited to Rucloux, Durmond, Callon, Goupilliere, Schulz, von Sparre, von Dechen, Hausse, and Jicinsky (Peele 1952). In the early part of the century, Briggs (1929) presented his comprehensive treatise on the subject. In the United States, the early investigations of Richardson (1907), Young and Stoek (1916), Rice (1923), Rutledge (1923), Crane (1925, 1929, 1931), and Allen (1934) are notable. The motivation behind these studies was the severe damage caused to structures, communications, and agricultural lands; the victims (mostly property owners) demanded compensation and restitution from the mine operators, and frequently resorted to court action. In order to defend against unjustified claims, measurements of ground movements were made. These data, along with theoretical concepts on the development of these movements, gradually evolved into the subject of *mine subsidence engineering.* Courses specifically devoted to the subject have been taught in German academies since 1931 and in US universities only since 1963. The major objectives of subsidence engineering are

1. Prediction of ground movements.
2. Determining the effects of such movements on structures and renewable resources.
3. Minimizing damage due to subsidence.

Thus it is evident that subsidence engineering not only entails the study of ground movements, structural geology, and geomechanics (both soil and rock mechanics), but also encompasses a knowledge of surveying, mining and property law, mining methods and techniques, construction procedures, communications technology, agricultural science, hydrology and hydrogeology, urban planning, and socioeconomic considerations.

Although the mining of all underground minerals may result in subsidence, most studies to date have concentrated on the extraction of flat bedded deposits—primarily coal. Hence throughout this discussion, reference to coal mining is made frequently. The information presented herein is, therefore, most pertinent to coal mining, although it generally applies to other bedded deposits. The principles may be also extrapolated to other mining methods, but the conclusions need validation by actual experience.

The pumping of geofluids, such as petroleum, natural gas, geothermal brines, and water, constitute "mining" in the strict sense and also cause subsidence. The effects of fluid withdrawal have been investigated at some length, although they are beyond the scope of this chapter. But the lowering of the water table in the region adjoining mining activity also induces ground movements, thereby causing surface damage, which must not be overlooked.

The term *subsidence,* as used in this chapter, implies the total phenomenon of surface effects associated with the mining of minerals and not only the vertical displacement of the surface as is sometimes inferred in the literature.

10.6.2 PRINCIPLES OF SUBSIDENCE

10.6.2.1 Development of Subsidence

Whenever a cavity is created underground, due to the mining of minerals or for any other reason, the stress field in the surrounding strata is disturbed. These stress changes produce deformations and displacements of the strata, the extent of which depends on the magnitude of the stresses and the cavity dimensions (Chapter 10.2). With time, supporting structures deteriorate and the cavity enlarges, resulting in instability. This induces the superjacent strata to move into the void. Gradually, these movements work up to the surface, manifesting themselves as a depression. This is commonly referred to as subsidence. Thus *mine subsidence* may be defined as ground movements that occur due to the collapse of the overlying strata into mine voids. Surface subsidence generally entails both vertical and lateral movements.

Surface subsidence manifests itself in three major ways:

1. Cracks, fissures, or step fractures.
2. Pits or sinkholes.
3. Troughs or sags.

Surface fractures may be in the form of open cracks, stepped slips, or cave-in pits and reflect tension or shear stresses in the ground surface.

When the area of surface collapse into the mine void is relatively small, the subsidence is termed a *pit* or *sinkhole;* generally, these are associated with shallow room and pillar mining. In Britain, the terms "crownholes," "chimneys," or "pipes" are also used to describe this phenomenon. In time, these pits may enlarge and coalesce to form trenches. Frequently, the walls of the pit intersect the surface precipitously, and the pit diameter increases with depth. The depth of pits is generally limited: 100 ft (30 m) in Pennsylvania (Gray et al., 1977), 165 ft (50 m) in Illinois (DuMontelle et al., 1981), or 10 to 15 times seam thickness, based on studies primarily in Colorado, Utah, and Wyoming (Dunrud and Osterwald, 1980).

When the mine void is of larger size due to longwall mining or eventual collapse of pillars, the collapsed strata fall into the excavation and bulk (i.e., broken material occupies a larger volume than in situ rock). This process continues until a height is reached of about three to six times the mined seam thickness (Singh and Kendorski, 1981), unless the material spreads or is transported to other parts of the mine by water. Cyclical wetting and drying of the debris could also induce greater compaction.

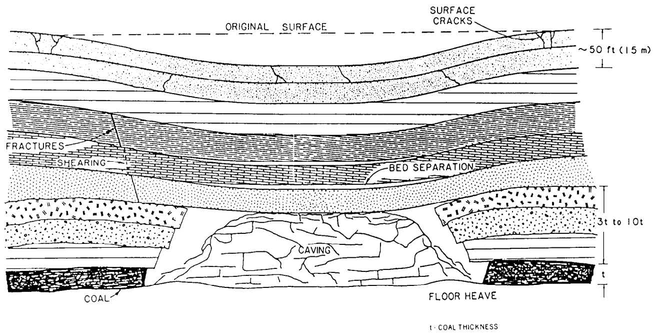

Fig. 10.6.1. Strata disturbance and subsidence caused by mining (Singh and Kendorski, 1981).

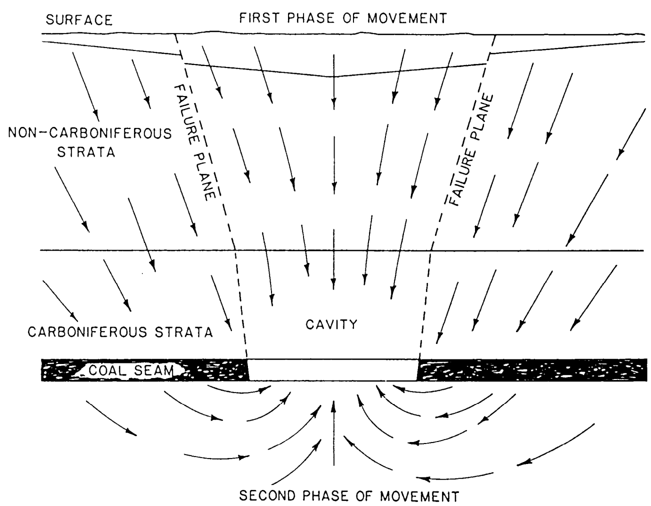

Fig. 10.6.2. Schematic representation of ground movements due to subsidence (Grond, 1957).

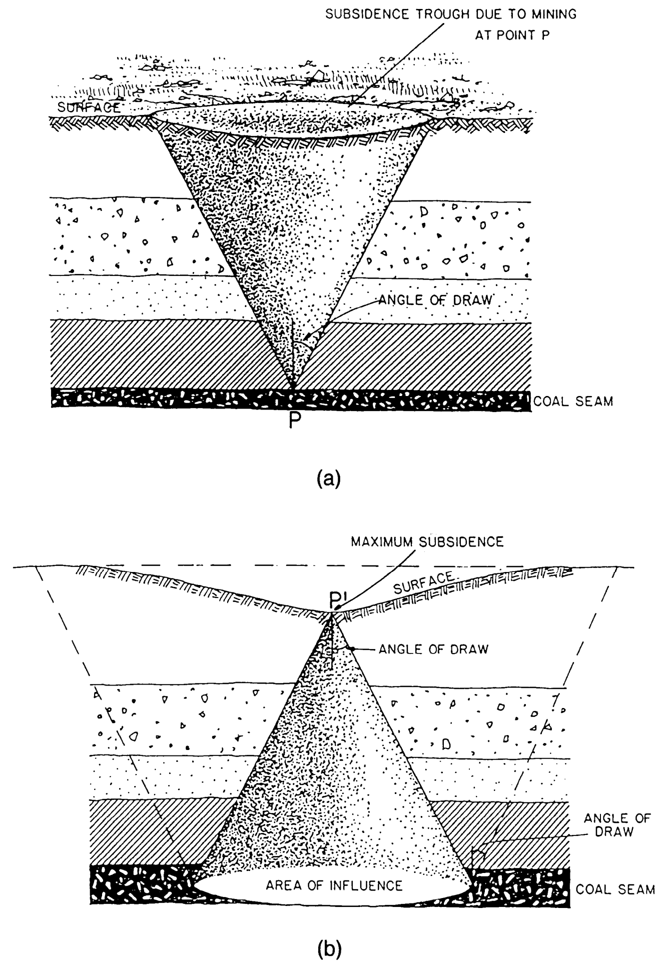

Fig. 10.6.3. Sketch depicting area of influence. (a) Effect on surface by mining at P. (b) Maximum subsidence at P′ by mining entire area of influence.

When the cavity is essentially filled with broken rock, the debris offers some support to the superjacent beds (Fig. 10.6.1). As these strata settle or sag, bed separation may occur because of the tendency for lower strata to subside more than the higher beds. Overall, as the various strata settle or subside, they sag rather than break and produce a dish- or trough-shaped depression on the surface. This type of feature normally covers a larger area than sinkholes, and is referred to as *trough* or *sag subsidence.* Trough subsidence may occur due to mining at any depth. The overall movements of the ground around the opening are depicted in Fig. 10.6.2; the direction of motion is not only vertically downward but also horizontal and, in some locations, upward.

The mining of a single point P (Fig. 10.6.3a) at seam level will affect a circular area on the surface, defined by the base of an inverted cone with P as the apex and the limit angle g as the semi-angle of the cone. If this cone is turned upright, then the mining of any part of its base will influence the subsidence of its apex P (Fig. 10.6.3b). Hence, this circular area is termed the *area of influence.* This implies that the diameter of the area of influence is given by $2D \tan g$, where D is the depth of the seam below the surface and g is the limit angle. (It may be noted that some authors use the complement of the limit angle, often termed the "angle of major influence.") This diameter also defines the *critical width* of the workings, which is the minimum width that needs to be mined before the maximum possible subsidence is observed at the center of the trough. If the mined width is less than critical, it is termed *subcritical,* and the amount of subsidence that occurs will be less than the maximum. If a *supercritical* (i.e., larger than critical) width is excavated, the central portion of the trough will attain maximum subsidence, and a flat-bottomed depression will be produced (see Fig. 10.6.4).

If the vein being extracted is relatively flat and nearly horizontal, as is generally the case with coal and potash, the overburden and surface collapses or subsides forming a *depression* or *trough.* The surface area affected by mining is generally larger than the vein area excavated. Hence the angle of inclination between the vertical at the edge of the workings and the point of zero vertical displacement at the edge of the trough is termed the *limit angle* or *angle of draw.* It is evident that the limit of surface subsidence depends upon the precision with which the subsidence is measured. By convention, this is taken to be the contour of points that have subsided vertically by 0.01 ft (3 mm). It is also a function of the vein dip and the geology of the area.

10.6.2.2 Movement of the Subsidence Curve

As subsidence occurs, there is a movement of surface points towards the center of the mined area. The amount of vertical

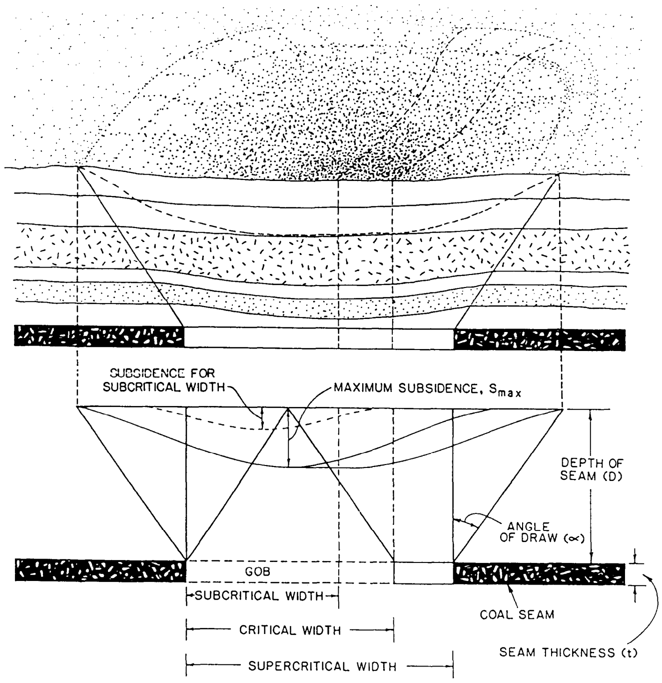

Fig. 10.6.4. Influence of extraction width on subsidence.

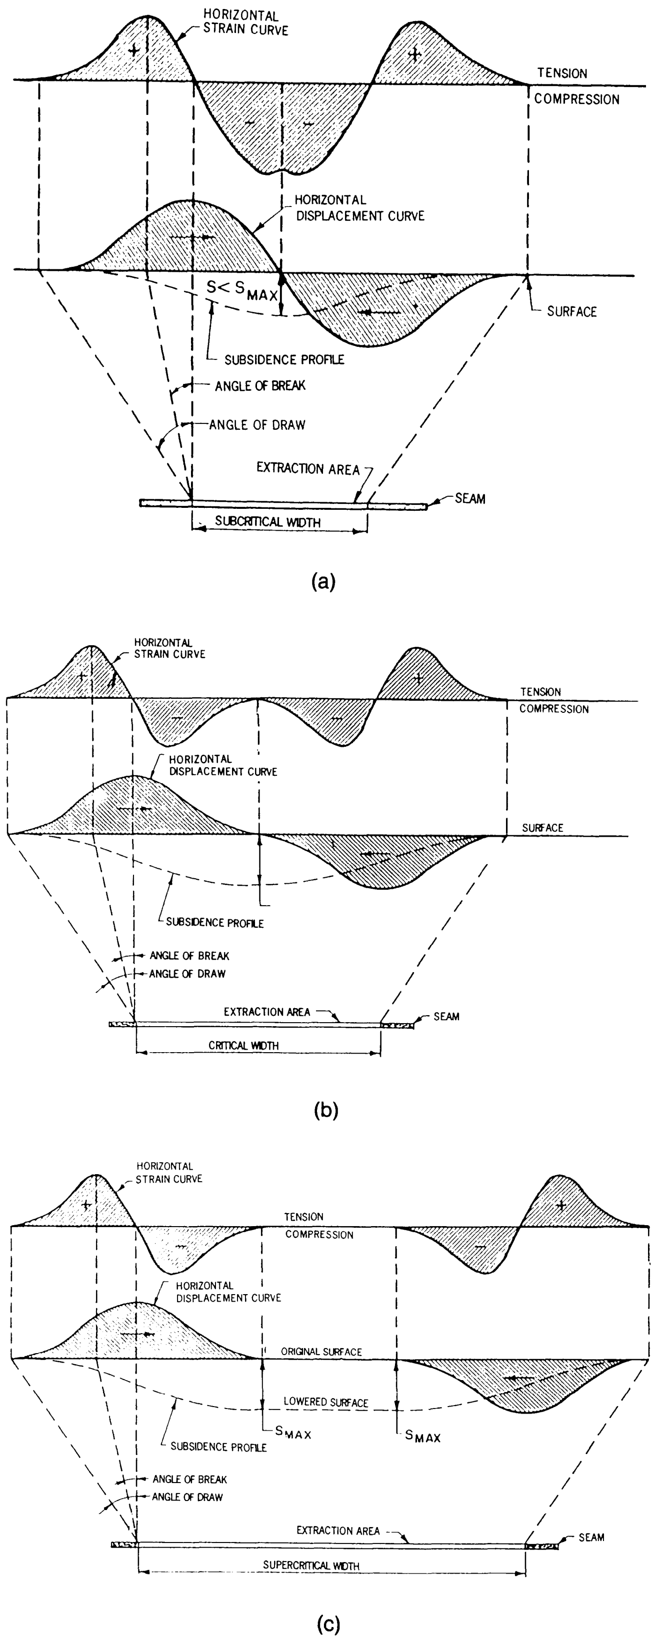

Fig. 10.6.5. Schematics of displacement and strain curves for various working widths. (a) Subcritical width. (b) Critical width. (c) Supercritical width.

displacement experienced is greatest at the center while the horizontal displacements are least at the center and edges of the trough and maximum at, or close to, the edges of the mined area. Since these lateral movements are not uniform, there are changes in the lengths per unit length (i.e., strains), along any cross section of the mined panel. These strains tend to stretch the surface near the edges of the trough (i.e., these are tensile), and push inward within the boundaries of the extracted area (compressive strains; see Fig. 10.6.5). Both the tensile and compressive horizontal strains disappear at the center of the subsidence trough in the case of critical- and supercritical-width workings. Fig. 10.6.6a shows the progressive development of the mine working and the subcritical, critical, and supercritical widths being formed. As the mine workings progress, the horizontal tensile and compressive strain regions also move along (Fig. 10.6.6b). Hence these are also referred to as traveling strains.

The inclination to the vertical of the line connecting the edge of the mined area with the surface point exhibiting the maximum tensile strain is called the *angle of break* or *angle of fracture* (Fig. 10.6.7). These terms should not be confused with the draw or limit angle defined earlier. Generally, the angle of break is somewhat higher with subcritical-width workings than with critical- or supercritical-width workings for a given region.

10.6.2.3 Components of Subsidence

Subsidence consists of five major components, which influence damage to surface structures and renewable resources (see Fig. 10.6.7):

1. *Vertical displacement* (settlement, sinking, or lowering).
2. *Horizontal displacement* (lateral movement).
3. *Slope* (or tilt), i.e., the derivative of the vertical displacement with respect to the horizontal.
4. *Horizontal strain,* i.e., the derivative of the horizontal displacement, with respect to the horizontal.

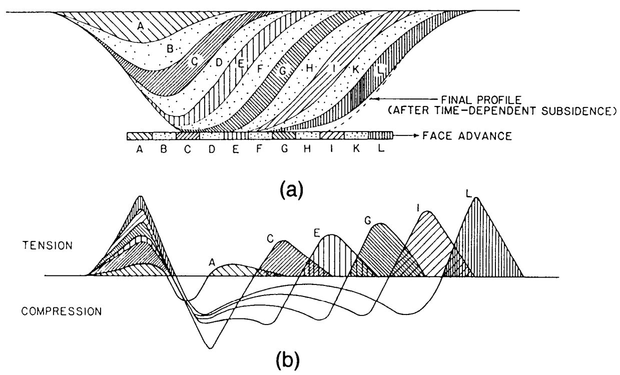

Fig. 10.6.6. Development of subsidence trough and strains with face advance (Rellensman and Wagner, 1957). (a) Subsidence development. (b) Traveling strain curve.

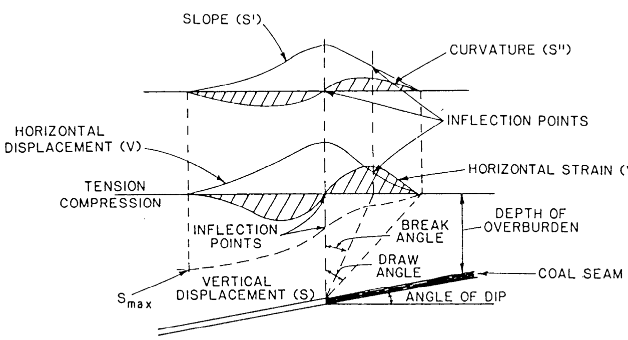

Fig. 10.6.7. Schematic of ground movements caused by subsidence (Singh, 1978).

5. *Vertical curvature* (or flexure), which may be approximated by the derivative of the slope, or the second derivative of the vertical displacement with respect to the horizontal.

Vertical displacements alone cause little structural damage. Examples of an observation tower having sunk 30 ft (9.2 m) in a coalfield, mining structures subsiding a similar amount around the sulfur mining areas off the coast of Louisiana, and a church in a potash mining district having settled 20 ft (6.2 m), all without significant damage, have been quoted in the literature. However, lowering of the land may cause some parts to be inundated, so that drainage patterns in agricultural areas may require redesign, flow through pipes may be disrupted or reversed, the groundwater circulation may be dislocated, and the grade of roads or railways may be altered.

Uniform horizontal movements of the ground surface also cause little damage to structures. But breaks in pipes, electric or communications lines, roads, and other features may occur.

Differential vertical settlements cause slopes to form and induce tilting. Maximum slopes in a subsidence trough generally range between 2×10^{-3} to 20×10^{-3}, but may reach 150×10^{-3} for multiple-seam extraction (Brauner, 1973). The formation of slopes may cause structures to tilt, the gradients of railroad tracks and highways to change, and tanks to overflow, and interfere with gravity drainage.

Surface horizontal strains cause most of the damage to structures located above mined areas. They cause tensile or shear cracks and buckling. Masonry structures withstand compression much better than tension. Strains may induce distortion, fractures, or failure. The weaker parts of the structure (e.g., openings) and the lower part of the frame are the first to show tension cracks. Pipes, cables, roads, railways, walls, and other building components buckle readily under compressive strains. Generally, the strains due to mining range between 1×10^{-6} and 10×10^{-6} (Brauner, 1973). The extent of strain transfer from the ground to foundations is not well established.

Curvature causes two types of distress on structures: (a) *shear strain,* which induces angular changes and tends to distort buildings out of square (distortion is generally proportional to structure height): and (b) *flexure* or *bending,* which causes strains in long load-bearing members. Concave curvature causes tension along the bottom and compression along the top of the building. The dimension of curvature is the inverse of length. Hence generally, the reciprocal of the curvature (i.e., radius of curvature) is quoted. For mine subsidence, this normally varies between 3200 ft (1000 m) and 6600 ft (2000 m), and seldom falls below 1600 ft (500 m) (Brauner, 1973).

10.6.2.4 Factors Affecting Mine Subsidence

Several geologic and mining parameters and the nature of the structure affect the magnitude and extent of subsidence that occur due to coal mining (Henry, 1956; King and Whetton, 1957; Sinclair, 1963; Cortis, 1969; Brauner, 1973; Chen et al., 1974; Anon., 1975).

Effective Seam Thickness: The thicker the seam extracted, the larger the amount of surface subsidence that is possible. In some cases, the entire seam may not be mined or some pillars or other nonminable coal may be left in place. Hence the effective seam thickness should be considered. In thick beds, the slenderness (height-to-width ratio) of the pillars is higher for a given extraction ratio. Slender pillars are normally more prone to failure.

Multiple Seams: Where multiple worked-out mining horizons exist, collapse could be initiated from any one of several levels, thereby increasing the likelihood of subsidence events, because the adjacent strata are disturbed. This is especially true when the prior mining was in an overlying seam.

Seam Depth: A school of thought exists that at greater depths, an arch is formed over the mine cavity, preventing surface subsidence. In recent years, this has been gradually refuted. Perhaps the time period that elapses before subsidence effects are observed at the surface is prolonged, but the total amount of subsidence does not appear to be changed; that is, subsidence is independent of depth (Orchard, 1964). Pit depths generally do not exceed certain limits, as discussed previously (see 10.6.2.1).

Dip of Seam: When the coal seam being mined is inclined, an asymmetric subsidence trough is formed that is skewed toward the rise; that is, the limit angle is greater on the dip side of the workings. The strains are also smaller toward the dip direction. Pillars in steeply dipping seams tend to be less stable.

Competence of Mine Roof and Floor: Since subsidence propagates from the mine level, the characteristics of the mine roof and floor are vital in the initiation of subsidence movements. Soft fireclay floors, especially if susceptible to further weakening due to moisture, induce pillar punching or heave. Weak roofs, composed of shales, siltstones, and limestones, permit falls that are accentuated if punching also occurs. Competent roof beds tend to support the overlying strata longer and hence delay the subsidence. Also, when these fracture, they occupy a greater bulk volume than weaker strata (which compact more). When both the roof and floor are strong, the pillars tend to spall and crush.

Nature of Overburden: Strong massive beds above the mine level tend to prop the overburden for a prolonged period and defer the occurrence of subsidence.

Near-surface Geology: The soils and unconsolidated rocks near the surface tend to accentuate subsidence effects. The geologic materials are less homogeneous and isotropic than the underlying strata, and often behave in an inconsistent manner. Cracks and fissures may initially form in a 50-ft (15-m) thick layer from the surface (Singh and Kendorski, 1981). Later, these may be filled by plastic deformation or material transportation by water. Occasionally, however, water flow may accentuate these fissures and form gullies. Structures and renewable resource lands are thereby adversely affected.

The composition of the rock/soil cover is important; if the material is of a fine, sandy nature containing large amounts of water, it may flow to a rock fracture and drop into the underground workings. Besides, water accumulating in the abandoned mine may seep upwards into the unconsolidated strata above through natural fissures and cracks in the rock and increase the potential for soil collapse.

Geologic Discontinuities: The existence of faults, folds, and the like may increase subsidence potential. Mining disturbs the equilibrium of forces in the strata and may trigger movement along a fault plane, due to ease of slippage, causing either settlement or upthrust at the surface, which may appear as a series of step fractures. The effects of the other parameters may need to be discounted in areas of adverse geological conditions.

Lateral movements concentrate near the fault, but the strains may become immeasurable on either side. Structures that straddle fault planes tend to be severely damaged, but nearby buildings remain relatively intact. Joints and fissures in the strata affect subsidence behavior in a manner similar to faults but on a smaller scale.

Fractures and Lineaments: Natural fractures and lineaments affect surface subsidence, but a strong correlation has not been established to date.

In Situ Stresses: High horizontal stresses tend to restrain surface subsidence by forming a ground arch in the immediate mine roof (Lee and Abel, 1983). The arch height and stability are sensitive to the ratio of vertical to horizontal stresses. Highly stressed arches may fail violently (e.g., the Urad molybdenum mine, Colorado). Roof instability and floor heave, resulting from high horizontal stresses and their orientation, need to be taken into account when laying out coal mines in the Allegheny Plateau (Aggson, 1978).

Degree of Extraction: Lower extraction ratios tend to delay subsidence. It is less prevalent in areas superjacent to first mining, since sufficient pillar support is generally available without crushing of pillars. In second mining, the cross section of the pillars is reduced by splitting and slicing. Localized stress buildups promote crushing, and excessively wide roof areas exposed between pillars stimulate roof failure. Third mining is almost invariably followed by roof collapse in the workings. Surface manifestations are a function of time, dependent on the rate of upward propagation of settlement.

Surface Topography: As may be anticipated, sloping ground tends to emphasize downward movements because of gravity. Tensile strains may become more marked on hilltops and decrease in valleys. Surface effects are influenced accordingly.

Groundwater: Deformation of the strata around mined areas may alter drainage gradients, resulting in the formation of surface or underground reservoirs (in aquifers). Low-lying areas, such as in central Illinois, may become flooded. Rocks may be weakened by saturation. Erosion patterns could change, and in limestone areas, caverns or karst areas may be created over a period of time.

Where surface runoffs from precipitation or water from leaky mains are allowed to accumulate, water may percolate down through the soil to the fractures and fissures in the bedrock, and finally into the mine openings. The erosion and lubrication effects induce failure.

Water Level Elevation and Fluctuations: Water reduces the strength and stiffness of pillars and the roof and floor markedly. Periodic changes in mine humidity promote deterioration of all these members. Floor softening permits punching, resulting in instability and subsidence. Flow through fissures cause seepage pressures, endangering the stability of the rock mass. Cleavage and bedding planes are lubricated by water, inducing movements.

Mined Area: The critical width needs to be exceeded along both the lateral and longitudinal axes to achieve maximum subsidence. This is especially important if competent strata present in the overburden tend to bridge across the panel and decrease subsidence when the panel width is less than the critical width, even though the length of the panel is greater.

Method of Working: The type of initial subsidence experienced, namely pit or trough, depends on whether room and pillar or longwall mining is being practiced. With room and pillar mining, the eventual collapse of pillars may lead to trenching or sagging of the surface. The displacements and strains over short distances, when they start appearing on the surface, are significant. Nearly immediate but predictable subsidence occurs with longwall mining. Harmonic mining, either by working adjacent longwalls in the same seam or superposed panels in different seams, can be effectively utilized to neutralize compressive and tensile strains and thereby protect surface structures. However, the method is not readily applied and is restricted for use only where mining costs become subservient to historical or social demands.

Rate of Face Advance: Surface subsidence follows the face as it progresses in the panel. If the coal extraction rate varies markedly, the traveling strains also fluctuate. This results in large differential settlements. A fairly rapid, even rate of face advance is best (Legget, 1972).

Backfilling of the Gob: Partial or complete backfilling of the gob reduces, but does not eliminate, subsidence. The amount of subsidence that occurs depends upon the type and extent of backfilling adopted. Thus, for example, hand packing is not as good as pneumatic stowing or hydraulic backfilling.

Time Elapse: The amount of subsidence observed is a function of time. In room and pillar operations, no surface effects may be noted for some time after the mining is complete until the pillars deteriorate or punch into the floor. In longwall mines, the surface may start sagging almost immediately after the face passes below an area. However, the occurrence of massive beds in the overburden could delay this. With longwalls, surface movements are complete within a few years, but when pillars are left intact for support, this may take decades. Room and pillar mining with removal of pillars may produce surface effects similar to longwall mining, with the degree of similarity dependent upon the amount of coal left as fenders or stumps (see also 10.6.3.4).

Structural Characteristics: The extent of damage to a structure is dependent on the type of structure and its size, shape, age, foundation design, construction materials and techniques used, standards of maintenance and repair, and purpose (Chen et al., 1974). The surcharge due to building loads may induce soil compaction, generating instability. Tall structures cannot tolerate much tilt, poorly constructed or older buildings are more readily damaged, and a large edifice is more liable to crack because of the strains and curvature induced by subsidence.

10.6.3 SUBSIDENCE PROFILES

10.6.3.1 Measurement of Subsidence

In order to make subsidence measurements, it is essential to erect monuments that will undergo the same vertical or horizontal displacements as the ground. Several designs of monuments have been used, some of which are depicted in Fig. 10.6.8. Whichever design is selected for use, it should be stable and firmly anchored about 5 ft (1.5 m) below the ground surface so as not to be affected by frost or other surface effects.

The choice of measuring instruments that may be used for subsidence measurements depends on a number of parameters (Panek, 1970):

1. Objectives of the investigation.
2. Area to be covered.
3. Topography of the region.
4. Profiles along which monuments are installed.
5. Spacing and number of monuments or observation stations.
6. Total cost that can be tolerated.
7. Duration of the investigation; survey frequency.
8. Labor requirements for surveying and data reduction.

The horizontal distance between monuments depends on the subsidence gradient. Generally, however, a compromise has to be reached between placing the monuments too close, which increases installation and measurement cost, and too far apart, which does not give enough readings to depict the measured variables adequately. The British National Coal Board (NCB) (Anon., 1975a) has recommended a monument spacing of $0.05D$, where D is the depth of the mined bed. In the United States, the tendency is to increase this distance (Deere, 1961; Gentry and Abel, 1978), and spacings of $0.05D$ to $0.1D$ have been advocated (Panek, 1970). The accuracy of the measurements should be such as to detect strains of 10^{-4}, which is about 1/10th the strain-level for structural damage. The method of measurement and the precautions necessary depends on the distance between monuments and may be obtained from any text on surveying (see also Chapter 8.2; Panek, 1970; O'Rourke et al., 1977).

Vertical displacements may be measured by trigonometric leveling (precision optical or laser), differential leveling, or tilt measurement. When using the theodolite, vertical angles must be measured correct to ½ second of arc. With precise leveling, a micrometer direct reading to about 0.005 ft (1.5 mm) should be employed. An inclinometer with a sensitivity of 10 seconds of arc is generally adequate for subsidence measurements. Second-order subsidence surveys with geodetic level and invar scale or equivalent, should close within $0.035(M)^{1/2}$ feet, where M is the circuit length in miles (Moffitt and Bouchard, 1975), an accuracy of 0.01 ft (3.3 mm) over a 1000-ft (305-m) line. In mountainous or swampy areas, third-order control with a closure of $0.052(M)^{1/2}$ ft may be used, an accuracy of 0.02 ft (6.5 mm) in 1000 ft (328 m). Tiltmeters for use in long-term (several years) subsidence surveys have been developed (e.g., Jacobsen et al., 1975; Holzhausen, 1986).

Automatic data acquisition systems (ADAS) for subsidence have also been used. One device employs one angular displacement transducer to measure tilt and another with an invar wire between monuments to ascertain linear displacement (Schmechel et al., 1977).

10.6.3.2 Subsidence Prediction

Existing subsidence prediction techniques fall under two basic categories, empirical and phenomenological (Voight and Pariseau, 1970; Brauner, 1973; Singh, 1978). The empirical theories are principally based on observations and experience from field subsidence studies. Some of the empirical methods have proved sufficiently reliable for subsidence prediction, at least for a given region. Many of these have been successfully applied in a number of countries, especially in Europe. Phenomenological techniques are based on equivalent material modeling principles where the subsiding strata are mathematically represented as idealized materials that obey the laws of continuum mechanics. Unlike empirical methods, the procedures used in the latter category have not achieved much success to date, mainly due to the difficulty of representing complex geologic properties of the strata in simple mathematical terms.

Promising empirical methods for prediction of subsidence over underground mines consist of the following:

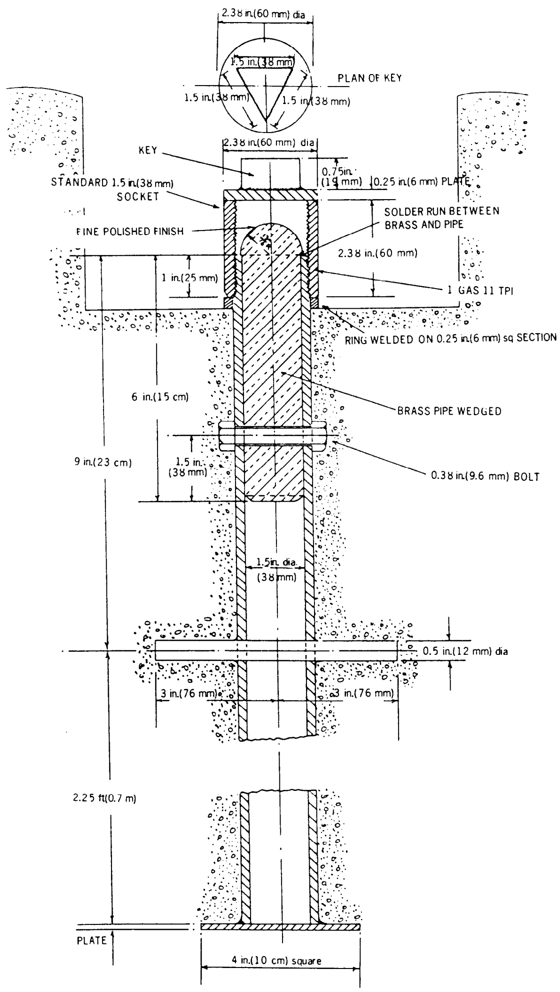
1. Graphical.
2. Profile functions.
3. Influence functions.

Graphical Method: This simply involves displaying subsidence data in the form of graphical charts or nomographs, whereby subsidence magnitude and the associated parameters may be directly obtained for a specified set of mine parameters. This method is adaptable in areas where considerable subsidence data exist, and its applicability is generally restricted to relatively few, geologically similar regions. This technique has seen considerable use in the United Kingdom (Anon., 1975a).

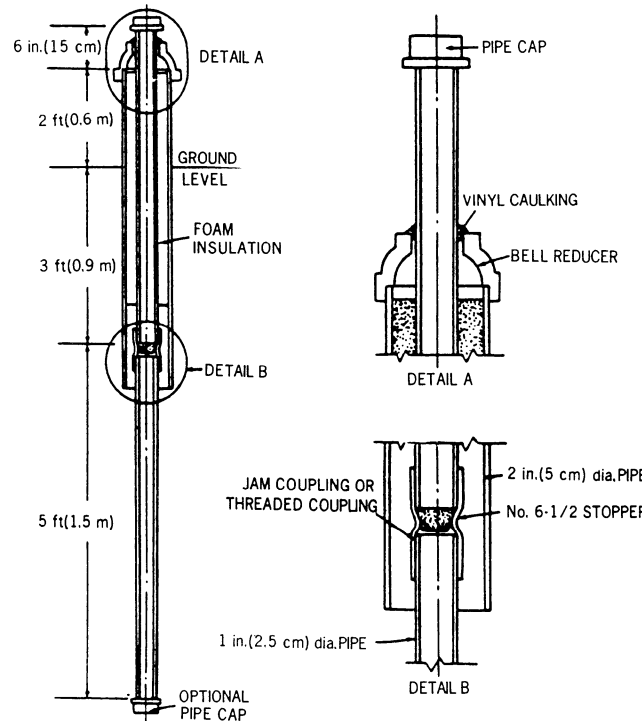
Profile Functions: This involves the derivation of a mathematical function that can be used to plot a complete profile of the subsidence trough at the surface. It differs from a phenomenological approach in that the constraints employed in the profile function are empirically derived from observed data. This method can be readily applied to geologically dissimilar conditions by modifying the constant values. Profile functions have been successfully applied in several countries abroad such as Poland, Hungary, the Soviet Union, and currently in the United States (Gill, 1971; Brauner, 1973; Munson and Eichfeld, 1980; Adamek and Jeran, 1981; Hood et al., 1981; Peng and Cheng, 1981; Wardell, 1982). Selected profile functions are given in Table 10.6.1.

Influence Functions: This principle for subsidence prediction is based on the extraction of infinitesimal elements of area. Subsidence at any point on the surface is obtained from the sum of the influence of each extracted element, using the principle of superposition. Unlike profile functions, influence functions cannot be found directly by measurement. In addition, this method assumes a homogeneous, isotropic overburden material and, therefore, has limited accuracy. In general, influence functions have been found to be especially suitable for subsidence prediction over underground workings with irregular or complex geometries. This method has received considerable attention in Europe, and to a limited extent in this country (Sinclair, 1963; Gill, 1971; Brauner, 1973; Adamek and Jeran, 1981; Hood et al., 1981; Karmis et al., 1981; Peng et al., 1986). Table 10.6.2 depicts a few influence functions.

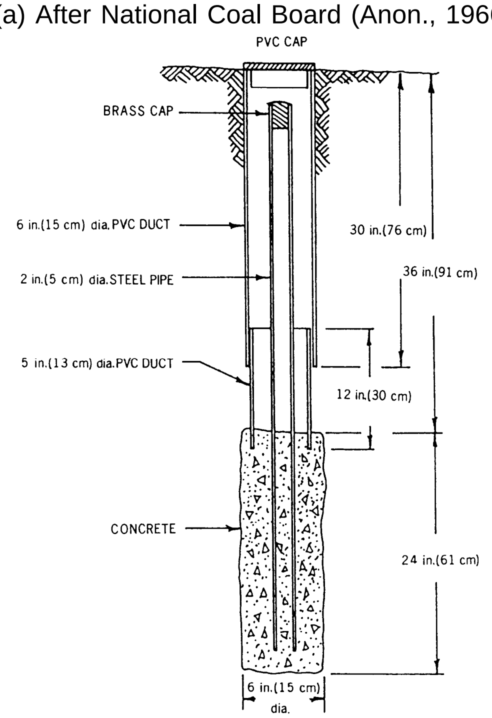
Phenomenological Methods: These are primarily based on the principles of continuum mechanics and assume the media to be elastic (Salamon 1963–4; Berry, 1969; Plewman et al., 1969; Crouch, 1973), viscoelastic (Marshall and Berry, 1967), plastic (Pariseau and Dahl, 1970), and elastic-elastoplastic (Dahl and Choi, 1974). Only the elastic-plastic model has been used with success in the United States (Dahl and Choi, 1974; 1981). Recently an elastic, frictionless, laminated model has been proposed (Salamon, 1989). Subsidence predictions using these various approaches are demonstrated in the following example.



(a) After National Coal Board (Anon., 1966)



(b) After Conroy and Gyarmaty (1982)



(c) After Huck and Bhattacharya (1988)

Table 10.6.1. Profile Functions

Name	Function	Country/Area	Reference
Critical Extraction:			
Hyperbolic	$S(x) = \frac{1}{2} S_{max} \left[1 - \tanh\left(\frac{cx}{B}\right)\right]$	UK	King and Whetton (1957) Wardell (1965) Cherny (1966)
Error	$S(x) = \frac{1}{2} S_{max} \left\{1 - \left[\frac{2}{(\pi)^{1/2}} \int_{O}^{(\pi x/B)} exp(-u^2)du\right]\right\}$	Poland/ Upper Silesia	Knothe (1953)
Exponential	$S(x) = S_{max}\, exp\left[-\left(\frac{1}{2}\right)\frac{(x+B)^2}{B^2}\right]$	Hungary	Martos (1958) Marr (1958–59)
	$S(x) = S_{max}\, exp\left[-\left(\frac{cx}{B}\right)^d\right]$	US/Appalachia	Peng and Cheng (1981)
Trignometric	$S(x) = \frac{1}{2} S_{max} \left[1 - \left(\frac{x}{B}\right) - \left(\frac{1}{\pi}\right)\sin\left(\frac{\pi x}{B}\right)\right]$	USSR/Donets	General Institute of Mine Surveying (Anon., 1958)
	$S(x) = S_{max} \sin^2\left[\left(\frac{\pi}{4}\right)\left(\frac{x}{B} - 1\right)\right]$		Hoffman (1964)
Subcritical Extraction:			
Trignometric	$S(x) = S_{max}\,(n_1, n_2)^{1/2}\left[n^2\left(1 - x + \frac{\sin 2\pi x}{2\pi}\right) + \frac{1-n^2}{4}(1 + \cos \pi x)^2\right]$	USSR/Donets	General Institute of Mine Surveying (Anon., 1958)
Hyperbolic	$S(x) = \frac{1}{2} S_{max}\left[\tanh\frac{2(x+w)}{B} - \tanh\frac{2x}{B}\right]$	Poland/ Upper Silesia	Knothe (1957) Wardell and Webster (1957)
		US/Appalachia	Peng (1978)

x = horizontal distance
c = arbitrary constant
B = radius of critical area of excavation
u = integration variable
w = panel width
$S(x)$ = profile function
S_{max} = maximum possible subsidence
n_1, n_2 = coefficients related to width/depth
n = n_1 or n_2 depending on side of panel

Source: Updated from Brauner (1973) and Hood et al. (1981).

Example 10.6.1. Mine M, located in the Appalachian coalfield, is worked by the longwall method and has the following dimensions for a panel:
Depth of seam D = 213 m (700 ft)
Extraction height of seam h = 1.83 m (6 ft)
Panel width w = 152 m (500 ft)
Panel length L = 1219 m (4000 ft)

Solution.

(1) *Graphical Method (NCB)*

The National Coal Board (NCB) procedure has been selected as an example of the graphical method because of its wide use in this country in the past. The method is, however, becoming less popular in the United States, and thus the graphs presented by the National Coal Board (Anon., 1975a) are not reproduced in the interest of space. Reference is made instead to the figures in the original publication.

Step 1: From NCB, p. 9, Fig. 3, for w = 152 m (500 ft) and D = 213 m (700 ft), the subsidence factor, a = 0.68.

Hence the maximum possible subsidence,

$$S_{max} = ah = 0.68 \times 1.83 \qquad (10.6.1)$$
$$= 1.24 \text{ m } (4.1 \text{ ft})$$

Step 2: Since $\frac{w}{D} = \frac{152}{213} = 0.71$, from NCB, p. 13, Fig. 5, the values of $\frac{x}{D}$ (i.e., distance x from the center of the panel, in terms of the depth D) can be read off at various subsidence ratios, 1.00 S, 0.95 S, 0.090 S, . . . (see Table 10.6.3a).

For D = 213 m (700 ft), the values of distance d may be computed, as in Table 10.6.3a.

Step 3: From these data, the subsidence profile, $S(x)$, may be plotted (Fig. 10.6.9).

Step 4: Based on prior experience, the method assumes that the point of inflection occurs at 0.5 S_{max} = 0.62 m (2.05 ft), i.e.,

Table 10.6.2. Influence Functions

Function	Reference
$\phi(r) = \dfrac{S_{max}}{\pi\{\sin\gamma \cos\gamma + [(\pi/2) - \gamma]\}} \dfrac{B^3 \tan^3 \gamma}{r(r^2 + B^2 \tan^2 \gamma)^2}$	Bals (1932–33)
$\phi(r) = \dfrac{3\, S_{max}}{\pi\, B^2}\left[1 - \left(\dfrac{r}{B}\right)^2\right]^2$	Beyer (1945)
$\phi(r) = \dfrac{n\,(2)^{\frac{1}{n}}\, S_{max}}{\pi B \Gamma\ (1/2n)\ r}\, exp\left[-4\left(\dfrac{r}{B}\right)^{2n}\right]$	Sann (1949)
$\phi(r) = \dfrac{2\, S_{max}}{(\pi)^{3/2}\, Br}\, exp\left[-4\left(\dfrac{r}{B}\right)^2\right]$ when $n = 1$	
$\phi(r) = 0.216\,\dfrac{S_{max}}{Br}\, exp\left[-4\left(\dfrac{r}{B}\right)^6\right]$ when $n = 3$	
$\phi(r) = \dfrac{n\, S_{max}}{B^2}\, exp\left[-n\,\pi\left(\dfrac{r}{B}\right)^2\right]$	Litwiniszyn (1957)
$\phi(r) = \dfrac{S_{max}}{B^2}\, exp\left[-\pi\left(\dfrac{r}{B}\right)^2\right]$ when $n = 1$	
$\phi(r) = \dfrac{2\, S_{max}}{B^2}\, exp\left[-2\,\pi\left(\dfrac{r}{B}\right)^2\right]$ when $n = 2$	
$\phi(r) = \dfrac{4.6\, S_{max}}{\pi\, B^2}\, exp\left[-4.6\left(\dfrac{r}{B}\right)^2\right]$	Ehrhardt and Sauer (1961)
$\phi(r) = \dfrac{n\, S_{max}}{2\pi\, r_o^2\, \Gamma(2/n)}\, exp\left(-\dfrac{r}{r_o}\right)^n$	Kochmanski (1959)
$\phi(r) = \dfrac{7\, S_{max}}{B^2}\, exp\left(-6.65\,\dfrac{r}{B}\right)$ when $n = 1$ and $B = 6.65\, r_o$	

r = radial distance from reference point
B = radius of critical area of excavation
γ = angle of draw
n = parameter for characterizing strata conditions
$\phi(r)$ = influence function
S_{max} = maximum possible subsidence
Γ = gamma function
r_o = independent parameter

Source: Brauner (1973); Hood et al. (1981).

from Table 10.6.3a (or NCB, p. 13, Fig. 5), $\dfrac{x}{D}$ 0.36 so x = 0.36 × 213 = 76.7 m (251.6 ft).

Step 5: The slope curve may be drawn from the subsidence profile by taking slopes at various points and plotting.

From NCB experience, the maximum slope is given by

$$2.75\,\frac{S_{max}}{D} = \frac{(2.75 \times 1.24)}{213} = 16.0 \times 10^{-3} \quad (10.6.2)$$

Step 6: The maximum values of extension and compression may be read off from NCB, p. 29, Fig. 15.

For $\dfrac{w}{D} = 0.71$, these are

$+E = 0.67\,\dfrac{S}{D}$, i.e.,

$$+E = \frac{(0.67 \times 1.24)}{213} = 3.90 \times 10^{-3}, \text{ and}$$

$$-E = 0.83\,\frac{S}{D} = -4.83 \times 10^{-3}. \quad (10.6.3)$$

Now from NCB, p. 25, Fig. 12, the values of horizontal strain may be read off in terms of $\dfrac{x}{D}$ and then converted to x, as in Table 10.6.3b.

Step 7:

$$\text{Curvature } r = \frac{(\text{bay length})^2}{\text{differential of the strain}} \quad (10.6.4)$$

(i.e. second differential of subsidence)

Bay length is generally the distance between monuments. These are computed along with the curvature in Table 10.6.3b.

NOTE: All of the above calculations assume that both the seam and the surface are flat. If the surface is sloping, the adjustment in horizontal strain may be obtained from a nomograph (NCB, p. 31, Fig. 18). If, however, the surface is level, but the seam is dipping, the correction in the tensile strain is given in a table (NCB, p. 32, Table 6). The tensile strain on the dip side increases and that on the rise side decreases.

(2) *Profile Function*

A hyperbolic function has been demonstrated to fit well the subsidence characteristics of US mines (Peng and Chyan, 1981; Hood et al., 1981; Karmis and Jarosz, 1988), i.e.,

$$S(x) = 0.5\, S_{max}\left[1 - tanh\left(\frac{cx}{B}\right)\right] \quad (10.6.5)$$

where c = 1.8 for critical and supercritical widths, and c = 1.4 for subcritical widths (Karmis et al., 1986), and

$$B = D \tan\gamma \quad (10.6.6)$$

the radius of major influence.

For mine M, take g = 25°; hence tan g = 0.4663, D = 213 m (700 ft). So B = 99.3 m (325.7 ft). Since the panel width is 152 m (500 ft), it is subcritical.

$$G(x) = S'(x) = -\frac{1}{2}\, S_{max}\,\frac{c}{B}\, sech^2\left(\frac{cx}{B}\right) \quad (10.6.7)$$

$$\rho(x) = S''(x) = \frac{c^2}{B^2}\, S_{max}\left[sech^2\left(\frac{cx}{B}\right)\, tanh\left(\frac{cx}{B}\right)\right] \quad (10.6.8)$$

For a flat seam, the horizontal displacement $u(x)$ and horizontal strain $\epsilon(x)$ are similar but related by a constant b, so that

$$u(x) = -\frac{1}{2}\,\frac{bc}{B}\, S_{max}\, sech^2\left(\frac{cx}{B}\right) \quad (10.6.9)$$

$$\text{and } \epsilon(x) = \frac{bc^2}{B^2}\, S_{max}\left[sech^2\left(\frac{cx}{B}\right)\, tanh\left(\frac{cx}{B}\right)\right] \quad (10.6.10)$$

(b) Strain and Curvature Data

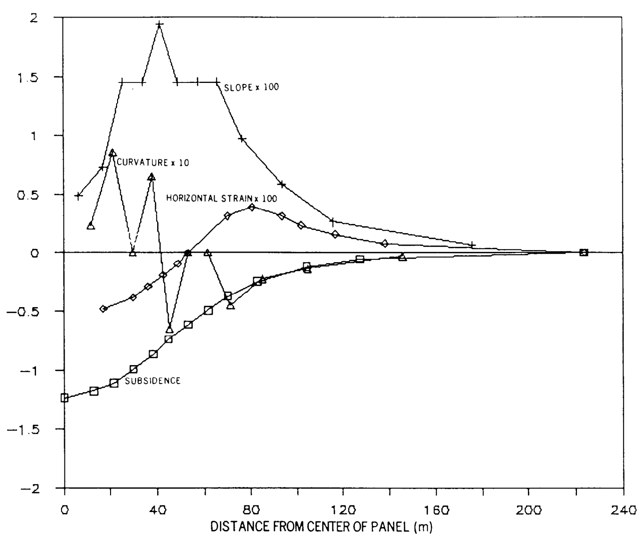

Fig. 10.6.9. Plots of results of Example 10.6.1, using the graphical method.

Peng et al. (1986) have found the horizontal displacement coefficient $b = 0.12$ in Appalachia.

Also, since $S_{max} = 1.24$ m (4.1 ft), $c = 1.4$, and $B = 99.3$ m (325.7 ft),

$$S(x) = 0.5\,(1.24)\left[1 - tanh\left(\frac{1.4x}{99.3}\right)\right]$$

$$G(x) = -0.5\left(\frac{1.4}{99.3}\right)(1.24)\, sech^2\left(\frac{1.4x}{99.3}\right)$$

$$\rho(x) = \left(\frac{1.4}{99.3}\right)(1.24)\, sech^2\left(\frac{1.4x}{99.3}\right) tanh\left(\frac{1.4x}{99.3}\right)$$

$$u(x) = -0.12 \times 0.5\left(\frac{1.4}{99.3}\right)(1.24)\ \mathrm{sech}^2\frac{1.4x}{99.3}$$

$$\epsilon(x) = 0.12\left(\frac{1.4}{99.3}\right)(1.24)\, sech^2\left(\frac{1.4x}{99.3}\right) tanh\left(\frac{1.4x}{99.3}\right)$$

These values are presented in Table 10.6.4 and plotted in Fig. 10.6.10.

(3) *Influence Function*

The influence function, commonly referred to as the Budryk-Knothe function (Knothe, 1957), has been successfully used in the United States for predicting mine subsidence, viz.,

$$f(x) = \frac{1}{B}\, exp\left[-\pi\left(\frac{x}{B}\right)^2\right] \tag{10.6.11}$$

where x is the distance from the origin, located at the inflection point, and B is the radius of major influence $= D \tan g$

Hence the subsidence at the surface point due to the extraction of a unit element Δx is

$$S_a = f(x) \cdot \Delta x \tag{10.6.12}$$

So when the extraction extends from $-x_1$ to $-x_2$ for an effective mining height h, the surface subsidence at any point A is given by

$$S_A = \frac{ah}{B}\int_{-x_1}^{+x_2} exp\left[-\pi\left(\frac{x}{B}\right)^2\right]dx \tag{10.6.13}$$

By definition, $S_{max} = ah$.

Integrating, using the probability density function, $\phi(x)$,

$$S\left(\frac{x}{B}\right) = \frac{S_{max}}{2}\left[\phi\left(\pi^{0.5}\,\frac{x}{B}\right) + 1\right] \tag{10.6.14}$$

Hence the surface slope

$$G\left(\frac{x}{B}\right) = S'\left(\frac{x}{B}\right) = \frac{S_{max}}{B}\, exp\left[-\pi\left(\frac{x}{B}\right)^2\right] \tag{10.6.15}$$

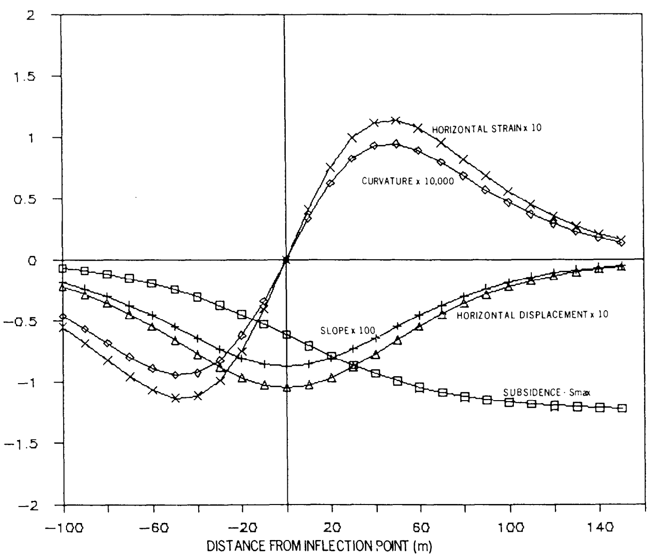

Fig. 10.6.10. Plots of results of Example 10.6.1, using the profile function method.

and the curvature

$$\rho\left(\frac{x}{B}\right) = S''\left(\frac{x}{B}\right)$$

$$= \frac{2\pi}{B^2} S_{max}\left(-\frac{x}{B}\right) exp\left[-\pi\left(\frac{x}{B}\right)^2\right] \qquad (10.6.16)$$

For a flat seam, the horizontal displacement profile $u(x)$ and the horizontal strain $\epsilon(x)$ are similar to the slope and curvature respectively, and related by the strain correlation coefficient b, i.e.,

$$u\left(\frac{x}{B}\right) = b\,\frac{S_{max}}{B}\,exp\left[-\pi\left(\frac{x}{B}\right)^2\right] \qquad (10.6.17)$$

$$\text{and } \epsilon\left(\frac{x}{B}\right) = b\,\frac{2\pi}{B^2}\left(-\frac{x}{B}\right) exp\left[-\pi\left(\frac{x}{B}\right)^2\right] \qquad (10.6.18)$$

Also we know that $B = D \tan g = 213 \tan 25° = 99.3$ m (325.7 ft) and $S_{max} = ah = 1.24$ m (4.1 ft).

For the Appalachian coalfield, $b = 0.12$ (Peng et al., 1986), so

$$S\left(\frac{x}{B}\right) = 0.5\,S_{max}\left[\phi\left(\pi^{0.5}\,\frac{x}{B}\right) + 1\right]$$

$$G\left(\frac{x}{B}\right) = \frac{1.24}{99.3}\,exp\left[-\pi\left(\frac{x}{B}\right)^2\right]$$

$$\rho\left(\frac{x}{B}\right) = \frac{2\pi}{(99.3)^2}\left(\frac{x}{B}\right) exp\left[-\pi\left(\frac{x}{B}\right)^2\right]$$

$$u\left(\frac{x}{B}\right) = 0.12 \times \frac{1.24}{99.3}\,exp\left[-\pi\left(\frac{x}{B}\right)^2\right]$$

$$\epsilon\left(\frac{x}{B}\right) = 0.12 \times \frac{2\pi}{(99.3)^2}\left(-\frac{x}{B}\right) exp\left[-\pi\left(\frac{x}{B}\right)^2\right] \qquad (10.6.19)$$

Since $B = 99.3$ m (325.7 ft), we generate Table 10.6.5 and plot these data as Fig. 10.6.11.

NOTE: In the NCB graphical method, the inflection point of the subsidence curve is assumed to be at the face. Generally, this is a short distance in the gob and can be empirically determined (Brauner, 1973; Kohli and Jones, 1986). In the solutions to the example above, subsidence is considered negative, extension is positive.

10.6.3.3 Prediction Methods Used in the United States

Many of the methods referred to in the earlier sections have been applied to US coalfields, yielding varying levels of success. The most favored technique until recently has been the use of the empirical charts developed by the National Coal Board (Anon., 1975a). Comparison of US subsidence data with NCB predictions highlight the following shortcomings:

1. With the possible exception of Illinois, maximum subsidence factors observed in US coalfields are less than predicted by NCB (O'Rourke and Turner, 1979; von Schonfeldt et al., 1979; Karmis et al., 1981). Probably the large proportion of competent strata in the overburden of most US coalfields is the cause of the discrepancy.

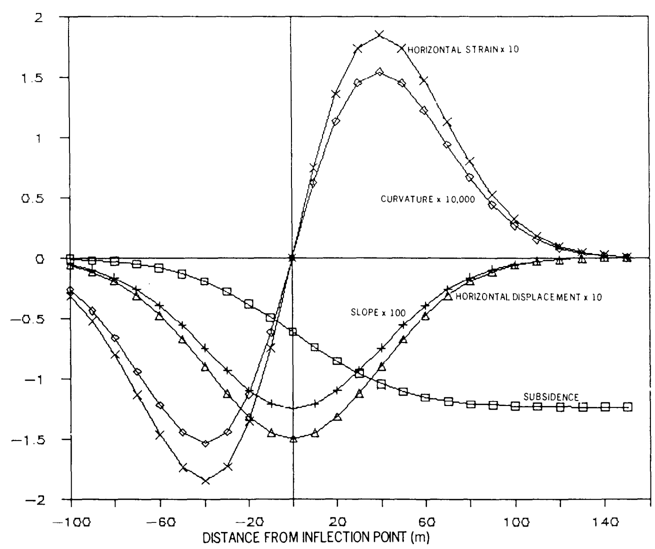

Fig. 10.6.11. Plots of results of Example 10.6.1, using the influence function method.

2. Limit (draw) angles in the US coalfields tend to be less than the 35º value generally accepted by NCB (Abel and Gentry, 1978; King and Gentry, 1979; von Schonfeldt et al., 1979; Bauer and Hunt, 1981; Karmis et al., 1981), because of the bridging effect of the strong strata in US coal measures. Typical draw angles for various countries and coalfields are given in Table 10.6.6.

3. The points of inflection of the subsidence profiles over US coal mines are generally closer to the panel centerline compared to the NCB profile (O'Rourke and Turner, 1981; Adamek and Jeran, 1981); this effect is dependent not only on the percentage of competent strata in the overburden but also on their locations relative to the ground surface and their thicknesses.

4. Surface strains and curvatures observed over US longwall panels have been shown to be significantly higher than NCB predictions, almost four times larger in many cases (O'Rourke and Turner, 1981; Adamek and Jeran, 1981; Moebs, 1982). It has been suggested that the presence of ancient workings, different in situ horizontal stress conditions, and the relatively unconsolidated nature of the surficial deposits above British mines may have resulted in the lower strain values (O'Rourke, 1983).

For the most part, the discrepancies in the observed values are a result of the differences in geologic characteristics between British and US coal measures. Most of the observations constituting the NCB charts were taken within relatively narrow geographical boundaries. Therefore, it may be expected that these data are inapplicable in the United States on a global basis. Only in areas where the geology is similar to that in the British coalfields can these charts apply. In other mining regions, these charts have to be modified prior to application.

In addition to the NCB-type subsidence predictive charts, studies have been undertaken to evaluate the potential of profile and influence functions for subsidence prediction in the United States. Among the profile functions that have been recommended (Munson and Eichfeld, 1980; Kohli et al., 1980a; Daemen, 1981; Hood et al., 1981; Adamek and Jeran, 1981), the hyperbolic tangent function appears the most promising. One drawback of profile functions is that their applicability is restricted to mine geometries that are simple, such as longwall panels. Most US coal mines are worked by room and pillar methods, rendering the profile function techniques less applicable. The use of influence functions is expedient in these instances since complex room and pillar layouts can be readily modeled. One application of influence functions is the zone area method, originally developed by Marr (1975). This method has been successfully used (Karmis and Haycocks, 1983; Karmis and Jarosz, 1988; Peng et al., 1986; Luo and Peng, 1989), since it lends itself to computer treatment.

Table 10.6.7 lists some computer programs currently available in the United States.

10.6.3.4 Time Effects

The duration of subsidence resulting from mining is composed of two distinct phases: (1) active and (2) residual. Active subsidence refers to all movements occurring simultaneously with the mining operations, while residual subsidence is that part of the surface deformation that occurs following the cessation of mining (or in the case of longwall mining, after an underground excavation has reached its critical width). The duration of residual subsidence is of particular importance from the standpoint of structural damage at the surface as well as from a legal perspective. The latter involves evaluating the extent of liability of underground mine operators for postmining subsidence.

Time spans during which surface subsidence may occur vary markedly with the mining method being used. Longwalls induce subsidence rapidly, beginning almost immediately after mining. With room and pillar systems, major occurrences of surface subsidence may be delayed for decades until the support pillars have substantially deteriorated and collapsed. The actual time involved depends on a number of factors such as the strengths of coal, roof, and floor; extent of fracturing; presence of water;

Table 10.6.6. Typical Values of Angle of Draw

Coalfield/Country	Reference	Angle of Draw (degrees)
Limburg/Netherlands	Brauner (1973)	35–45

depth of workings; pillar size; and percentage extraction. Hence prediction of when or how much damage may occur becomes difficult.

Longwall Mining: The duration of residual subsidence movements above longwall panels is relatively short, typically varying between a few weeks and about 10 years. Further, the magnitude of these movements rarely exceeds about 10% of the total subsidence. The time spans reported in the literature are summarized in Table 10.6.8.

Empirical relations proposed to estimate the duration of residual subsidence include:

1. United Kingdom (Institution of Municipal Engineers, Anon., 1947):

$$\text{Time (mo)} = 6 + \frac{\text{mining depth (yd)}}{100} + \frac{\text{face advance (yd)}}{\text{rate of face advance (yd/mo)}} \qquad (10.6.19)$$

2. USSR, Germany (Brauner, 1973; Kratzsch, 1983):

$$s = 1 - e^{-ct} \qquad (10.6.20)$$

where s is ratio of instantaneous subsidence to final subsidence, c is overburden strata characteristic, t is subsidence time span, and e is base of natural logarithms.

3. USSR (Shadrin and Zamotin, 1977):

$$t = c[(1/q) - 1]^{1/2} \qquad (10.6.21)$$

where t is subsidence time span, c is overburden strata characteristic, q is a constant relating mining depth, panel width, and structure and hardness of overlying rock, i.e., $1/[1 + (D/w)^n]$, D is mining depth, and w is width of workings. Nomograms have also been developed and used for this purpose.

None of the above quantitative relations are immediately applicable to US conditions because of the site-specific constants contained within each expression.

Room and Pillar Mining: *Mechanism of Subsidence Development*—In room and pillar mining without pillar recovery, the magnitude of active subsidence is generally small, and the ground surface may experience a variable frequency of subsidence incidents during this period. The coal pillars and the surrounding rock are usually relatively sound at this time with only minor deflections of the roof being transmitted to the surface.

Some time after mining, however, complete collapse of the abandoned pillars and the adjacent strata may occur as a result of natural causes or human activities. These processes are likely to continue until all the voids created by mining excavation have been filled by the caved strata. Consequently, in the case of room and pillar mining, the residual subsidence can be the major subsidence measured on the surface.

There have been some misconceptions among the US mining community that surface subsidence may be avoided if certain conditions are fulfilled:

1. Sufficient coal is left unworked to serve as load-bearing pillars (generally over 50%).
2. Mining is conducted at great depths.
3. Strata overlying the workings contain competent beds.

Recent studies, however, have shown that no matter how well-designed a room and pillar layout might be, the additional weight transmitted to the pillars due to excavations will cause measurable deformation on the pillars, and these movements will eventually be transmitted to the surface. Depending upon the extent of pillar loading and the characteristics of the pillars and the superincumbent material, the surface deflection may vary from considerable to negligible, and sometimes is nearly undetectable. The long-term stability of mine pillars is extremely difficult to determine.

Table 10.6.7. US Computer Programs for Subsidence Prediction

Program	Year	Developer	Basis	Output	Merits	Limitations	Comments
INTEX	1982	international Exploration, Inc.	Empirical—finite element	Max vert subsidence max horiz comp strain break angle draw angle	Accommodates joints and faults. Can model local conditions.	Requires knowledge of specific coal and rock properties, and mine layout.	Developed for anthracite coalfield
SPASID (subsidence prediction and system identification)	1983	Pennsylvania State University	Influence function (Knothe and elastic)	Vertical subsidence horizontal subsidence profile horizontal strain grid lines percentage subsidence with respect to face	Can determine optimum influence function from measurements. Usable as batch program. Permits modification of input to suit geology. Considers dip, gates, edge effects, time, asymmetric profiles of adjacent panels. 2-D and 3-D plots. Math co-processor not required.	Command-driven, slow. FORTRAN and subsidence knowledge required. Needs graphical software. Default parameters are from UK experience.	
SUBPRO (subsidence professional)	1985	USBM	Combined profile and influence functions	Vertical subsidence inclination curvature horizontal strain	Has variable coefficient to suit geology. Can accommodate actual overburden data or average. Computer or subsidence knowledge not required. Special hardware not needed.	Maximum profile is 300 ft on either side of panel edge. Cannot store input or computed data.	Restricted to northern Appalachian coalfield. Parameters cannot be modified. Requires BASIC software.
SUBSIDE 2.0	1986	Buelah Engineering	Influence function (Bals)	Subsidence strain profiles	Permits changing input. Different parameters for room-and-pillar, varied overburden, multiple seams, dip. Generates design load/safety factor for pillars. Panel/profile data interchangeable. Operates batch jobs. AUTOCAD tie-in. Menu driven. Works with limited input data.	Cannot accommodate discrete points. Automatically generated intermediate points may not align with input data. Knowledge of subsidence required.	Developed for Appalachia.
SDPS (surface deformation prediction system)	1987	Virginia Polytechnic Institute and State University	Profile function	Vertical subsidence location of inflection point panel subcritical, critical, supercritical	Easy to use. Plots profiles.	Cannot predict subsidence at specific points.	Developed for Appalachian coalfield, but used elsewhere.
			Influence function	Subsidence slope curvature strains at discrete points	Displays 2-D and 3-D plots. Can accommodate room-and-pillar mining, dip, flexibility in input parameter.	Need to exit program to access deformation indicies.	
			Zone area	Maximum subsidence	Cannot compute subsidence at discrete points. Cannot adjust subsidence parameter	Plots are 2-D and 3-D. Can adjust subsidence parameters. Needs math co-processor and knowledge of subsidence.	
CISPM (comprehensive, integrated subsidence prediction model)	1988	West Virginia University	Influence function	Subsidence horizontal displacement slope strain curvature	Can take data directly from total survey station or electronic distance meter. Parameters automatically recommended, but can be adjusted for geology. Can graph all solutions. Accommodates profiles and discrete points. Computer and subsidence knowledge not required. Menu-driven.	Needs math co-processor. Has six programs—LWSUB, SUBSDNC, DYNSUB, SURVEY, SUBDED, CONSULT.	Developed for Appalachian coalfield, but used elsewhere. Assumes surface subsidence complies with normal probability distribution.

Sources: Anon. (1982), Ingram et al. (1989), Luo and Peng (1989), Martin (1990). **Author's Note:** Subsidence computer programs are continually being revised, modified, and developed. This information may not reflect the latest version, nor does this table list all available programs.

Table 10.6.8. Residual Subsidence Duration Over Longwall Mines

Reference	Country/ Coalfield	Residual Subsidence Duration
Institution of Municipal Engineers (Anon., 1947)	UK	2 to 10 years
Orchard & Allen (1974)	UK	Several months to 3 to 6 years (strong overburden)
Collins (1977)	UK	2 to 4.5 years
Grard (1969)	France	6 to 12 months
Brauner (1973)	Germany	1 year (Cretaceous overburden) 2 years (sandstone overburden)
Brauner (1973)	USSR	2 years (shallow mines) 4 to 5 years (deep mines, > 1300 ft or 400m)
Shadrin and Zamotin (1977)	USSR	2 to 25 months
Gray et al. (1977)	US/Appalachian	Few months to few years
Hood et al. (1981)	US/Illinois	12 months

The three basic mechanisms responsible for residual subsidence over room and pillar mines include:

1. Collapse of roof beds spanning adjacent pillars.
2. Pillar failures.
3. Squeezes or crushes.

1. *Roof Collapse.* Over remnant pillars, this is perhaps the most prevalent failure mechanism associated with abandoned room and pillar mines. Depending on certain geometric and geotechnical factors, the caving process may be arrested at some point in the overburden or it may extend upwards to the surface. The surface expression of this process is generally in the form of a localized depression or pit.

The height to which the collapse process can take place is a function of

a. Volume of the original mine opening or room.
b. Bulking factor of the strata material.
c. Location and thickness of overlying competent strata.

Two basic modes of roof failure have been recognized, namely, shear and flexural failure (Morgan, 1973). The former usually initiates diagonal tension cracks near the junction of the mine pillar and the roof, and the latter causes tension cracks near the midspan of the roof. Both result in voids above the mine level. Dependent on the mechanism of failure of the individual roof beds and their tensile and shear strengths, a variety of geometric forms of collapse are possible, ranging from conical through wedge to rectangular. For a given width of mine opening, it can be demonstrated that, for each type of collapse, the height of collapse is a function of the overlying strata. The influence of competent strata in the overburden has been neglected in this analysis (Piggott and Eynon, 1977).

2. *Pillar Failures.* These occur due to changes in the environment or surcharged loading and may take place at the time of mining or after considerable delay. They result in trough-like subsidence.

In general, subject to pillar geometry, pillar failure does not ordinarily occur at shallow depths since the size of coal pillars left behind are usually much greater than that required to support the overlying strata or any additional loading from surface development. However, where very small pillars or "stubs" exist within a given mining section, these may fail and cause sufficient loads to be transferred to adjoining pillars by arching, resulting in extended failure.

In most instances, pillar failures coincide with some phase of mining, such as pillar robbing on the retreat, abandonment of a particular mining area, or working other seams in close proximity. Another common cause of pillar failure is the action of concentrated foundation loads, from pile foundations or otherwise, being transmitted onto the remnant pillars (Piggot and Eynon, 1977).

3. *Squeezes or Crushes.* When abandoned pillars punch into either the immediate roof or floor that might have been weakened or altered by the action of water or other weathering processes, squeezes (crushes) may result. Generally, the surface settles as a trough or basin.

The mechanism of failure in this case is not unlike the failure of building foundations as the load carried by the mine pillar is transferred to the floor (or roof). If the bearing capacity of either the roof or floor is exceeded, squeezing may occur. The following factors (Gray et al., 1977) favor bearing capacity failure:

a. Underclay mine floor.
b. High pillar stresses.
c. Flooded mine conditions.

Factors Influencing Duration of Residual Subsidence—The factors in room and pillar mines that govern the duration of residual subsidence have not been quantified as yet. Probably the following parameters play a role:

1. *Depth of Working:* Increased depth implies a longer duration for subsidence movements. Any instability caused at the mine level has to propagate through the overburden in order to reach the surface.

2. *Mine Geometry:* This may be expressed in terms of the following attributes:

a. Seam thickness.
b. Pillar width-to-height ratio.
c. Extraction ratio.
d. Presence of multiple panels.
e. Presence of multilevel workings.

Increased *seam thickness* increases the potential for instability of pillars and speeds up the subsidence process.

Both the *pillar width-to-height ratio* and *extraction ratio* reflect upon the safety factor built into the mine design. Pillar width-to-height ratios greater than 0.1 and extraction ratios of less than 50% have both been claimed to permit no surface subsidence. Although mines designed to these standards have been known to be stable for long periods of time, sometimes more than a hundred years, this is not strictly true.

Presence of multiple panels and *multilevel workings* generally result in a shorter residual subsidence phase since they increase the volume of underground voids.

3. *Strength and Deformation Characteristics of the Roof Floor, and Pillar:* Over the long term, these affect the duration of surface subsidence depending on the interrelationships of these structural members.

4. *Types of Roof Control:* Roof control practices in a mine influence the relative susceptibility of the roadways to collapse; for example, bolted mines tend to subside faster than those with cribs, steel supports, or other types of bracing.

5. *Character of the Overburden:* Significant aspects which profoundly govern the duration of subsidence movements are

a. Thickness of surficial soil beds.

b. Lithology.
c. Structural geology.

Soil thickness is important since the fractures propagate through it rapidly. Also granular materials (e.g., sands) offer less bridging capacity than fine-grained soils (i.e., clays).

Although the effect of *lithology* is poorly understood, weaker rocks (i.e., shales and siltstones) are generally unable to support their own weight and the strata above, and transmit subsidence movements to the surface in a short time span. Competent rocks (e.g., sandstones and limestones) effectively bridge over excavations and delay the residual subsidence period. Besides their relative competency, the thicknesses of these strata govern the duration of subsidence; massive beds inhibit the propagation of subsidence movements longer than thin, laminated formations. Also affecting the process are facies changes, lensing, pinchouts, and other lateral variations of geology that may alter the character of the overburden from one place to another. Joints occur even in competent strata, and some slippage along these may be expected with time. Thus even though some investigators suggest that a competent rock layer of thickness greater than 1.75 times the width of the workings will arrest the collapse (Piggott and Eynon, 1977), other studies (Thornburn and Reid, 1977; Gray et al., 1977) show that such competent beds merely delay the subsidence process.

Structural geology impacts subsidence in the same manner as lithology, by varying the ability to bridge excavated spans. Generally, surface geologic features (e.g., faults, photolineaments, stream valleys), and underground features (e.g., bedding planes, joints, fissures, cleat, folds, or other inhomogeneities) tend to shorten the subsidence period.

6. *Presence of Old Mined-out Workings:* Old workings in the vicinity of an active mine accelerate the rate of residual subsidence, since the surrounding strata are disturbed.

7. *In Situ Stress Field:* The existence of high horizontal stresses impacts the time for subsidence since the structural integrity of the mine supports is affected.

8. *Water:* The presence of water reduces the strength and stiffness of mine pillars, roof, and floor in flooded mines. Further, softening of the floor (e.g., underclay) encourages pillar punching, resulting in instability and subsidence. Flow of water through fissures causes seepage pressures in the rocks, endangering the rock mass stability. Generally, the formation of pits in shallow mines is promoted by these factors. Dewatering of flooded mines accelerates coal pillar deterioration by exposing submerged pillars to the damaging effects of air and removing the buoyant support afforded by the water.

Periodic *changes of humidity* cause the slow deterioration of pillars, roof, and floor, with similar results.

9. *Nonmining factors:* Those that affect subsidence include
a. Mine fires.
b. Earthquakes.
c. Tectonic movements.
d. Surface precipitation.

Although not common, *mine fires* accelerate the subsidence process due to degradation of abandoned pillars (Dunrud and Osterwald, 1980). *Earthquakes* and *tectonic movements* may destabilize otherwise stable areas. Experience indicates a direct relationship between increased *rainfall* and greater subsidence activity (Anon., 1975b; Gray et al., 1977).

Prediction of Time of Subsidence—The wide variety of interrelated factors that may affect the duration of residual subsidence over room and pillar workings renders the task of accurate prediction of the time of subsidence difficult. Field observations of the time period of residual subsidence is further complicated by the fact that these movements generally continue over prolonged periods of time. Thorburn and Reid (1977) reported a case study of a subsidence event occurring about 118 years following mine abandonment. Ivey (1978) observed subsidence in Colorado 73 years after cessation of mining. Dunrud and Osterwald (1980) concluded that surface subsidence is likely to occur for several years or several decades after mining and reported subsidence events over workings in Wyoming that were driven 25 to 80 years earlier. Mahar and Marino (1981) made similar observations in Illinois where mining had taken place several months to more than 100 years prior to the occurrence of subsidence. Based on data collected from subsidence incidents in Pennsylvania and Illinois, a common trend is not evident (Fig. 10.6.12). Investigations in Illinois (Bauer and Hunt, 1981) showed no direct relationship between depth of workings and the time period of subsidence; Pennsylvania data show similar scatter. Kratzsch (1983) developed an analytical relation between the time factor and parameters such as pillar size, shape, deformation behavior, and degree of backfilling, based on data from room and pillar salt mines. Its applicability to coal mines is unverified. A generalized model for subsidence prediction over partial-extraction mining is not currently available.

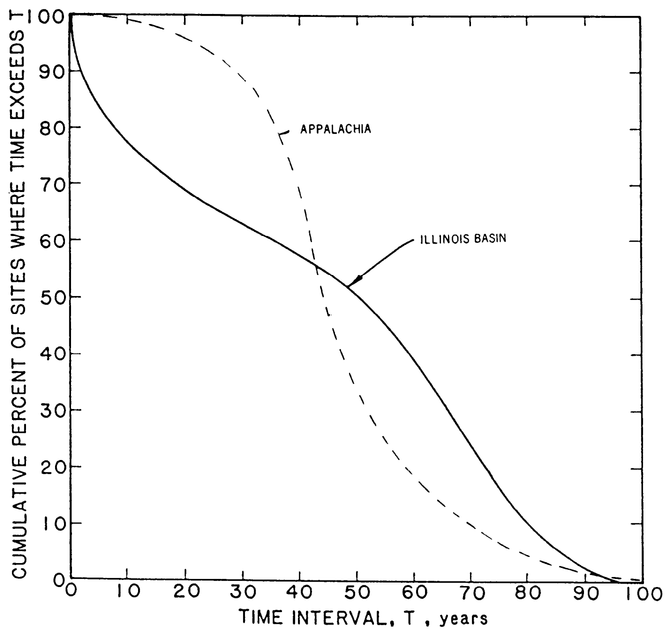

Fig. 10.6.12. Relationships for time interval between mining and subsidence. *Source:* Appalachia (Gray et al., 1977); Illinois data (Bauer and Hunt, 1981).

10.6.4 SUBSIDENCE-INDUCED DAMAGE

10.6.4.1 Surface Structures

Buildings: Damage to surface structures, especially buildings, is mainly caused by tilt, angular distortion, bending, and horizontal strain. Several distinct types of damage are evident as manifestations of tension, compression, angular distortion, shear, bending, and rigid body rotation and/or translation of the structure. Building deformations from ground movements usually begin at foundation level and propagate upward through the basement to the superstructure (Anon., 1975a; Bruhn et al., 1982). The transmission of the deformations from the foundation to the superstructure depends on the nature of the structure, in particular its continuity and attachment.

Tensile stresses developed by horizontal ground strain tend to produce vertical and steplike cracks in brickwalls, generally across and along the mortar-brick interfaces. Most of the extension cracks tend to be vertical, particularly near the base of the structure, and usually propagate from weak elements, such as doors, windows, or construction joints. These are generally uniformly open or more open at the bottom than the top. In the upper part of the structure, the cracks may become diagonal. Extension cracks on the basement floor are usually open and show little or no offset between the sides of the crack, usually appearing at right angles to the direction of the tensile stresses.

Compressive damage is characterized by bulging and bending failures of foundation cracks. Severe compression can cause the lower parts of the walls to move closer together and induce bending stresses in the structure that cause tensile cracks near the upper part of the walls and compressive failure at the lower part. In masonry structures, however, compressive stresses are usually not transmitted to the upper part of the walls due to the low shear resistance along mortar/brick contacts. In such cases, the induced cracks are generally restricted to the lower parts of the structure. Where the floor is especially weak, heaving of floor tiles or buckling failure may result.

Angular distortion related to differential settlement can cause vertical cracks in floor slabs that usually form closer to the side that has settled more. Walls subject to angular distortion exhibit diagonal cracks in the plaster or masonry walls which tend to extend toward the side with greater settlement. Angular distortion also causes binding of doors and windows.

Differential tilting or bending of a structure induces shear stresses in the walls and slabs. Under these circumstances, damage is characterized by horizontal and vertical cracks in the walls. Alternatively, shear and bending may act together to cause diagonal cracks in the walls.

These descriptions exemplify the effect of a single deformation mode acting alone on the structure. In actual practice, several of these forces may occur together and produce a complex pattern of cracking and distortion in various locations and directions. Furthermore, the damage descriptions provided above are limited to visible damage external to the structure. Damage caused to structural members or foundations is difficult to characterize in simple terms since the nature of the damage depends largely on the several variables including strength properties of the structural members, type of construction, zones of weakness, and previous deformation history.

In addition, the length of the structure has a major influence on the relative severity of the resulting damage. Studies have indicated that the longer the structure, the greater the damage severity (Anon., 1975a; Peng and Cheng, 1981a).

Damage Criteria—A number of damage classifications have been developed which correlate building damage to ground movements; only three are presented here. The scheme developed by the National Coal Board (Anon., 1975a) on the basis of direct observations of building damage in the United Kingdom is probably the best known (Table 10.6.9). A similar system has been developed for Northern Appalachian coalfields (Table 10.6.10), which relates damage to a severity index, based on the repairs required for building basements, instead of ground movements (Bruhn et al., 1982). Currently, a sufficient database does not exist to extend this nationwide. The results of a survey of a wide range of sources is presented in Table 10.6.11. A brief discussion of these and other classification systems is presented by Bhattacharya and Singh (1985).

Bridges: Damage may be caused to bridges by horizontal ground strain resulting in the movement of the supports of piers either towards or away from one another. Differential vertical settlement or distortions in the horizontal plane may bring about complex and often serious effects on the decking and arches (Anon., 1975a).

It is generally difficult to determine the location and nature of the ground movements based on visual observation of damage. Often compressive damage leads to crushing and spalling of concrete decks and plaster. Combined compression and extension due to bending may cause opening and closing of construction joints in abutments and plaster cracking. At the higher end of the scale, damage is characterized by distress in the superstructure, inward horizontal movement of abutments, jamming of beams and girders against the back wall of the abutments, and serious damage to the bearings (Moulton et al., 1982).

Damage Criteria—Few data on damage criteria for bridges are currently available. Results of a survey are presented in Table 10.6.12.

Miscellaneous Structures: Included in this category are dams, embankments, reservoirs, canals, locks, aqueducts, sewers, sewage disposal works, and other common types of structures. Very limited data are available on these structures.

Measurement of ground movements in the failure investigation of an earth dam due to extension cracks in the concrete embankment, revealed that the magnitude of horizontal strain developed was about 1×10^{-3} (Lee, 1976). Tensile strains greater than 1.5×10^{-3} resulted in damage to dams in the Kyushu coalfields of Japan (Nishida and Goto, 1969).

A failure criterion of 1×10^{-3} for limiting horizontal strain has been recommended in the design of two reservoirs at one location, and between 0.3 to 2.75×10^{-3} for another (Lackington and Robinson, 1973).

The consensus appears to converge upon a limiting horizontal ground strain of around 1×10^{-3}, applicable to a variety of surface structures. However, this should be regarded only as a first estimate, and site-specific analyses should be conducted prior to design recommendations.

10.6.4.2 Public Utilities and Communications

Roads and Airport Runways: The principal types of damage affecting roads and highways due to subsidence movements include:

1. Cracks on the road surface.
2. Deterioration of base course and/or subgrade.
3. Distortion of horizontal and vertical alignment.
4. Bumps or undulations on the road surface.
5. Damage to ancillary works such as sidewalks, drains, fences, curbs, and the like.
6. Water flooding.

Of these, the most common form of damage is the formation of tensile cracks on the road surface, usually coinciding with the position of the ribsides in the mine workings below. Altematively, compression ridges may occur near the center of the panels. Also common are severe local changes of gradient that may become a source of danger for high-speed traffic, especially if it causes surface water to stand in pools in affected areas.

Airport runways experience problems similar to those for high-speed highways.

Damage Criteria—It is generally accepted that highway bridges are more susceptible to ground movements than roadways. Hence damage criteria for bridges often are used to represent a conservative limit of such criteria for roads. Further, most public roads are protected by safety pillars and generate little interest for accumulating data. Besides, road damage can generally be repaired with tar or “cold patch” treatment, which is relatively inexpensive. Table 10.6.13 presents some available data.

Table 10.6.9. National Coal Board Classification of Subsidence Damage

Change of Length of Structure		Class of Damage	Description of Typical Damage
From	*To*		
	Up to 0.1 ft (30 mm)	Negligible or very slight	Hair cracks in plaster. Perhaps isolated slight fracture in the building, not visible on outside.
0.1 ft (30 mm)	0.2 ft (60 mm)	Slight	Several slight fractures showing inside the building. Doors and windows may stick slightly. Repairs to decoration probably necessary.
0.2 ft (60 mm)	0.4 ft (120 mm)	Appreciable	Slight fracture showing on outside of building (or one main fracture). Doors and windows sticking; service pipes may fracture.
0.4 ft (120 mm)	0.6 ft (180 mm)	Severe	Service pipes disrupted. Open fractures requiring rebonding and allowing weather into the structure. Window and door frames distorted; floors sloping noticeably; walls leaning or bulging noticeably. Some loss of bearing in beams. If compressive damage, overlapping of roof joints and lifting of brickwork with open horizontal fractures.
Over 0.6 ft (180 mm)		Very severe	As above, but worse, and requiring partial or complete rebuilding. Roof and floor beams lose bearing and need shoring up. Windows broken with distortion. Severe slopes on floors. If compressive damage, severe buckling and bulging of roof and walls.

Source: Anon., 1975a.

Table 10.6.10. Subsidence Damage Classification for Northern Appalachian Coalfield

Class	Characteristic Basement Damage	Severity Index
I Slight	• Hairline cracks in one or more basement walls and possibly floor slab. • Some cracks in perimeter walls causing loss of water tightness. • Repointing required in some or all walls.	0
II Moderate	• Cracks in one or more basement walls and floor slab. • Some wall/footing reconstruction and floor replacement required, as well as local repointing.	1
III Severe	• Cracks in one or more basement walls and floor slab. • Possible wall instability and loss of superstructure support, requiring shoring and bracing. • Extensive repair work involving wall/footing reconstruction and floor slab replacement.	2
IV Very severe	• Cracks typically in all basement walls, as well as floor slab. • Possible instability of several walls and loss of superstructure support, requiring extensive shoring and bracing. • Possible significant tilt to home.	4
	• General reconstruction of basement walls, footings and floor slab required.	5

Severity Index is the relative cost of repairing basement. *Source:* Bruhn et al. (1982).

Railroads: One of the first effects of subsidence on railroad tracks is rider discomfort, which sometimes requires the reduction of maximum permissible speeds. At higher levels of ground strain, rail tracks have a tendency to "snake" or bend, and in more extreme cases, entire rails may be forced out of the track. Sometimes where the mine workings are located on one side of the track, differential lateral strains may occur and cause displacement of the tracks relative to one another. Changes in ground slope may adversely affect track performance by formation of localized depressions, or creating gradients greater than permissible for a given type of traffic.

One effect commonly observed over longwall panels is that, depending on the location of the coal working faces, reversals of stress and strain occur on the surface. A railway line might be subjected to tensile stresses at first, followed by a neutral stress period, and then by compressive stresses. This transition is generally the most damaging phase of movements from the point of view of rail tracks (Anon., 1977).

The extent to which a railway line is affected by ground movements is related to

1. Types of traffic involved.
2. Speed limits.
3. Types and construction of track.
4. Preventive and remedial works.
5. Nature and magnitude of ground movements.

Damage Criteria—Damage to railroads may be classified in terms of interruption of use or failure. Interruptions of use would refer to excessive track gradients or bumps on the track resulting in rider discomfort, reduction of permissible speeds, increased propulsion and braking forces, reduced payloads and train lengths, or impairment of orderly traction and shunting operations. Quantitative limits for this level of damage are difficult to assign due to the many variables involved. A railroad track may be deemed to have failed if the deformations are of such magnitude that it is incapable of sustaining traffic due to risk of derailment. Available data are given in Table 10.6.14.

Pipelines. Generally, pipelines are laid some distance below the ground surface. Buried pipelines are known to be more susceptible to damage from ground movement than those laid above ground. These move in response to ground movements due to friction and soil pressure between the pipe material and the

Legend:

Architectural: Small scale cracking of plaster and sticking of doors and windows.
Functional: Instability of some structural elements, jammed doors and windows, broken window panes, building services restricted.
Structural: Impairment of primary structural members, possibility of collapse of members, complete or large-scale rebuilding necessary, may be unsafe for habitation.

No data available on rigid, massive structures/central core design.

Table 10.6.12. Damage Criteria for Highway Bridges

Damage Severity Level	Allowable Movement: Type of Movement	Allowable Magnitude	Source	Suggested
Architectural	Angular distortion	1.0×10^{-3}	Moulton et al. (1982)	1.0×10^{-3}
Functional	Angular distortion	$4.0–5.0 \times 10^{-3}$	Moulton et al. (1982)	3.0×10^{-3}

Functional (undulations and water accumulation)	Slope	5.0×10^{-3}	Kratzsch (1983)	5.0×10^{-3}
Structural (adverse effects on driving dynamics—large-scale cracking affecting base/subgrade; severe local gradients; potholes)	Slope	10×10^{-3} 10×10^{-3} $10.0–20.0 \times 10^{-3}$	Maize et al. (1941) Sowers (1962) Kratzsch (1983)	10×10^{-3}

Table 10.6.14. Damage Criteria for Railroads

Damage Severity Level	Movement Limits: Type of Movement	Movement Limits: Tolerable Range	Source	Suggested Value
Risk of derailment and rider discomfort	Horizontal strain	2.0×10^{-3} 3.0×10^{-3}	Kratzsch (1983) Saxena and Singh (1980)	2.0×10^{-3}
Risk of derailment and rider discomfort	Slope	12.5×10^{-3}* 10.0×10^{-3} *2.5×10^{-3} (for railway stations)	Kratzsch (1983) Saxena and Singh (1980) Kratzsch (1983)	10.0×10^{-3} or maximum permissible track gradient specified by design

ground. If the magnitude of the ground movements are such that either the pipeline or its joints (or couplings) are unable to accommodate the deflection or strain which is developed, they may fracture or fail.

Damage may be caused either by excessive strain along pipe lengths or excessive distortion at the joints or both. Three basic modes of failure may be identified (O'Rourke and Trautmann, 1982):

1. Strain in pipe material leading to rupture or intolerable deformation.
2. Rotation of the joints leading to leakage or loss of connectivity.
3. Axial slip at the joints leading to leakage or disengagement of adjacent pipe lengths.

The first two failure modes may be caused by differential settlement, and the first and third by lateral displacement.

The largest percentage of pipe failures are caused by compressional forces causing excessive telescoping at joints. Tensile failures are the next major mode, whereas failures due to ending or shearing rarely occur (Tilton, 1966). British experience recognizes the following types of fractures: beam, pull, shear, thrust, and leverage (Anon., 1975a).

The extent to which a pipeline can absorb ground deformations is said to be dependent upon the stress/strain behavior of the pipe material, the rotation and pull-out capacity of the couplings, connections to other structural elements, corrosion resistance of pipe and joints, and other general factors such as state of repair and installation technique (O'Rourke and Trautmann, 1980). The location of the joints with respect to the subsidence profile and the degree of rigidity of the pipeline will also significantly affect the nature and extent of damage. At times the joints constitute the weakest link in a pipeline system and are usually affected by ground movements long before the pipe length.

Couplings in water and gas distribution mains increase pipeline flexibility. Flexible couplings are generally equipped with a gasket that is compressed to prevent leakage. These joints are capable of sustaining rotations that vary from 1 to 7º. Mechanical joints can tolerate about 2 in. (50 mm) of horizontal slippage before leakage. When both horizontal strains and differential settlements must be sustained, pipeline joints can be designed to rotate and telescope. Welded pipelines are most susceptible to damage by compression because ground movements cause local wrinkling or buckling of the pipe wall. Once local wrinkling has initiated, all subsequent deformations will tend to concentrate at the location of the wrinkle. Local wrinkling may occur at compressive strains on the order of 0.4 to 0.6% (Bouwkamp and Stephen, 1973). Butt-welded steel pipelines are most capable of sustaining the differential soil movements caused by mining subsidence, but these must be high quality welds, free of significant corrosion.

Damage Criteria—Ground movement limits may be prescribed for two basic damage levels:

1. Interruption of use.
2. Failure or loss of use.

Pipelines are usually laid under fairly stringent grade requirements. A change of ground slope may affect power costs in the form of greater pumping requirements or may cause inconvenience to the users. These constitute impaired use of the application. Ground movement limits for this level are difficult to assign because of its site-specific nature. However, utility companies sometimes provide standards for a given type of application. If these are known, appropriate criteria can be developed for a given area. Gas line leaks pose a special hazard, because of the

Table 10.6.15. Damage Criteria for Pipelines

Type of Pipe	Damage Severity Level	Movement Limits: Type of Movement	Movement Limits: Range	Source	Suggested Value
Cast iron pipe with lead-caulked joints	Failure of pipes or couplings	Angular distortion	4.0×10^{-3}	O'Rourke and Trautman (1982)	4.0×10^{-3}
Cast iron pipe with lead-caulked joints	Failure of pipes or couplings	Horizontal strain	$0.5–2.0 \times 10^{-3}$	Grard (1969)	1.0×10^{-3}

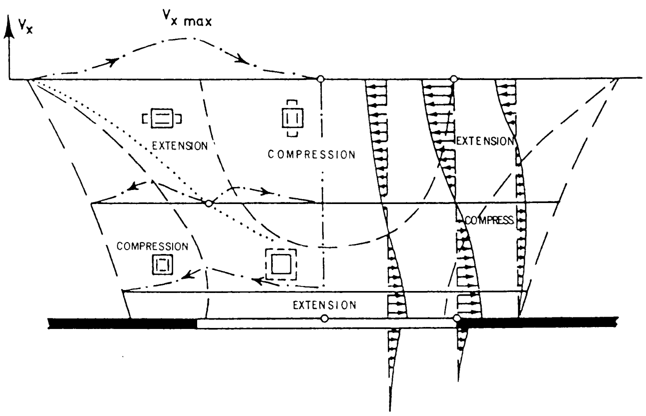

Fig. 10.6.13. Horizontal deformation of a continuum over workings in a bedded deposit (Kratzsch, 1983).

toxic and/or explosive effects of the constituents. Available data for failure are shown in Table 10.6.15.

10.6.4.3 Shafts and Subsurface Structures

Shafts: Mine subsidence damage affects not only surface structures but also those located within the rock mass. With shallow workings, it is possible to leave a protective shaft pillar, which is not mined. However, in deep mines, the size of pillars becomes excessive, and large amounts of ore tend to become sterilized within them. Hence it is impractical not to mine within the safety zone.

Fig. 10.6.13 depicts movements of the strata above the mine openings as if it were a continuum and not bedded. If the entire mine pillar were mined, a shaft through these strata would be subjected to compression near the surface and tension near the mine floor. If the pillar were partially retained, the type and magnitude of the ground strains experienced by the shaft would depend upon location of the shaft within the pillar, and would vary along the length of the shaft. Generally, the horizontal movements of the shaft tend to be towards the center of the workings near the surface and away from them near the floor and immediate roof. The net result is that the shaft tends to lean towards the gob as the face approaches the shaft, and then reverses itself as the face goes past. Finally, the shaft may become vertical again with time. During this period, hoisting equipment experiences increased wear in the inclined shaft. Rupture of the shaft, however, does not normally occur, since assuming the shaft experiences a compressive strain of 2×10^{-3}, the walls of a 20-ft (6-m)-diameter shaft close by only ½ in. (12 mm). The horizontal compression is largely absorbed by the pressure arch in the rock and compressible material surrounding the shaft. Although bending of the shaft is not large, bending stresses need to be considered in the design of rigid linings. Fractures in the shaft lining invariably accompany shear movements in severely bent strata.

With appropriate mining techniques, it is possible to use the shaft for hoisting as well as maintain integrity through water-bearing zones. Principles to follow include (Kratzsch, 1983):

1. *Compensating* axial tension and compression stresses along the shaft with the use of two or more faces.
2. *Working symmetrically* around the shaft, minimizing shaft tilt and shear.
3. *Minimizing subsidence* by backfilling or leaving a core pillar.
4. *Designing* the shaft lining to accommodate movements.
5. *Observation* of axial deformation, tilt, and bending regularly during the operation.

Designing flexible shaft linings implies

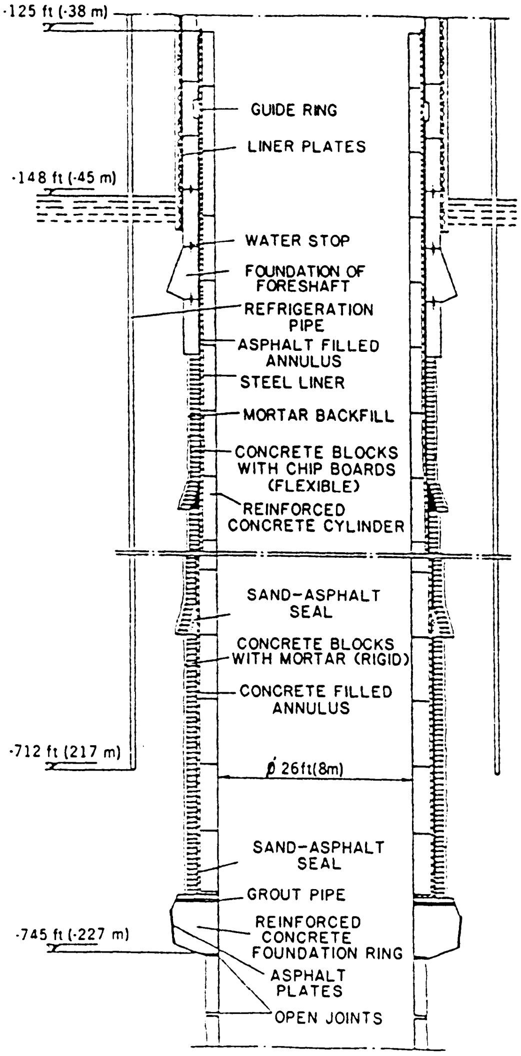
1. Introducing a *sliding joint,* which reduces friction and seals the shaft through water-bearing zones.
2. Providing an *expansion joint* in the lining at the mining horizon, which absorbs axial compression.
3. Placing *compressible courses,* 100 to 150 ft (30 to 50 m) apart, so that the shaft can yield or bend, but the shaft loses watertightness.
4. Using a *weak mortar,* which serves as a compressible course, and facilitates masonry repair.
5. Furnishing an *annular cushion* of fly ash at the mining horizon; this absorbs lateral expansion of the seam, and vertical compression.
6. Constructing an *outer ring of concrete,* which seals fractured strata and prevents shear movements from intersecting faults.
7. *Monitoring* movements so as to recognize danger in a timely manner.

A cross section of a shaft through water-bearing strata designed to absorb ground movements is shown in Fig. 10.6.14.

Damage Criteria—No specific values for damage can be provided, since this is dependent on the design of the lining, but the horizontal and vertical stresses in the shaft lining can be computed and checked against the strength values of the lining materials.

Subsurface Structures: The degree of damage experienced by subsurface structures depends upon their location with respect to the mine workings. These may be sited at various horizons:

1. *Below mine level:* the extent of damage incurred should be small, even if these are within the zone affected by movements.
2. *At mine level:* adequately designed and supported chambers should remain open, but the passageways leading to these may be difficult to maintain unobstructed, unless they are located in the shaft pillar. Openings sited in the shaft pillar would be subjected to minor movements.



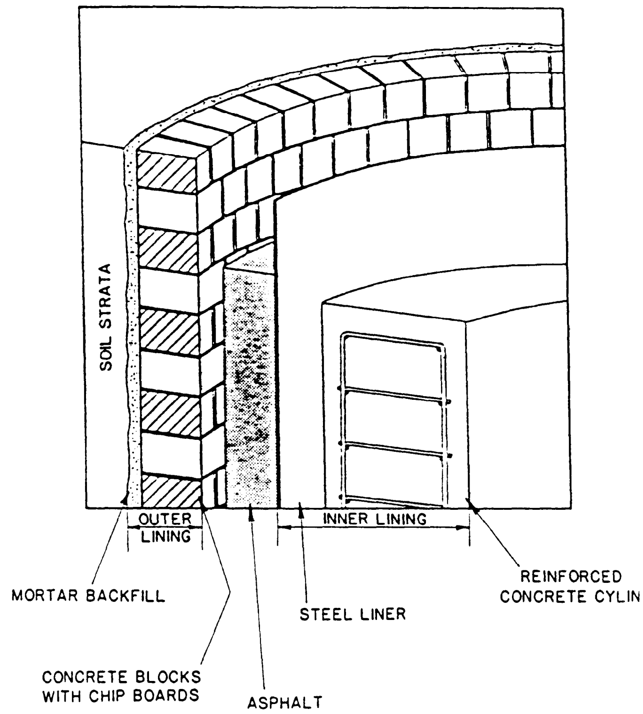


Fig. 10.6.14. Cross section through a shaft lining through water-bearing strata, designed to tolerate subsidence (Stoss and Braun, 1983).

3. *Above mine level, in the rock strata:* openings situated in this region may be subjected to large movements, and occasional shock loads or sudden falls; thus these would be costly to design and keep open. Structures located at a height above 60 times the seam thickness, and surrounded by thick plastic or viscoelastic strata (e.g., shales) may not experience sudden movements and could survive the subsidence effects with slight damage.

4. *Above mine level, in unconsolidated materials:* these openings are close to the surface and in deep mines, if properly designed and lined, may endure the ground movements due to the flow of the surrounding soils; some repairs would probably be required.

There are no data on structures within mine overburdens; validation of the above scenarios is needed.

10.6.4.4. Renewable Resource Lands

Renewable resource lands include aquifers and areas for the recharge of aquifers and other underground waters, areas for agricultural and silvicultural production of food and fiber, and grazing lands (Anon., 1979). In addition, significant springs, perennial streams, and other surface waters that support aquatic life or supply water to any public water system may be classed as renewable resources.

Agricultural Lands: Adverse effects of subsidence movements on agricultural lands include

1. *Formation of surface fissures* in the zones subjected to tensile stresses, which form pathways to drain the water away from the topsoil, thus being detrimental to plant growth. Flow of water in the cracks also causes erosion, thereby widening them (Schumann and Poland, 1970).

2. *Alteration in the ground slope.* Steepening increases flow velocity, which in turn enhances surface runoff and erodibility, whereas gradient reduction could lead to waterlogging of the soil. Crop yields may tend to decrease in either case.

3. *Disruption of surface drainage patterns* resulting from changes in ground elevation or slope. Lowering the topographic barriers to flow increases the potential for flooding (Moore and Nawrocki, 1980). In flat terrain, ponding may occur, especially if the water table is shallow and underlain by an impermeable stratum (Wohlrab, 1969). Changes in slope disturb the existing hydraulic regime.

4. *Modification of the subsurface hydrology* due to generally downward migration of the groundwater through cracks, and consequent decrease in soil fertility.

5. *Deterioration of groundwater quality* due to contact with sulfides and other minerals (Temple and Koehler, 1954; Lovell,

Table 10.6.16. Damage Criteria for Prime Farmlands

Damage Severity Level	Movement Limits		Source	Suggested Value
	Type of Movement	Tolerable Range		
Moderately reduced productivity	Horizontal strain	$2.0–3.0 \times 10^{-3}$	Inferred	$2.0–3.0 \times 10^{-3}$
Severely reduced productivity	Horizontal strain	5.0×10^{-3} 5.0×10^{-3} $<10.0 \times 10^{-3}$	Orchard (1969) Voight and Pariseau (1970) Jachens and Holzer (1982)	5.0×10^{-3}
Moderately reduced productivity	Slope	$2.0–3.0 \times 10^{-3}$	Inferred	$2.0–3.0 \times 10^{-3}$
Severely reduced productivity	Slope	6.0×10^{-3} $6.0–8.0 \times 10^{-3}$ $5.0–8.0 \times 10^{-3}$	Pierce et al. (1983) Fehrenbacher et al. (1978) U.S. Dept. Agriculture (Anon., 1951)	6.0×10^{-3}

1973; Kim et al., 1982) or changes in sediment loads (Moore and Nawrocki, 1980).

6. *Occurrence of subsidence pits* (sinkholes), which may result in upsetting the drainage system by either accumulation or loss of water and, in extreme cases, damage to equipment and life.

The effect of mine subsidence on farming depends on the type of crops, soil character, hydrology, topography, and other environmental factors. Essentially, subsidence damage caused to agricultural lands is characterized by the loss of use or reduced productivity. Increasing ground movements generally cause a decline in productivity, but the precise amount of decline is site specific and, thus, difficult to quantify in general terms.

Agricultural lands may be classified in various ways, but one that is commonly used in relation to mine subsidence is dividing such property into prime and nonprime farmlands. Prime farmland has "the best combination of physical and chemical characteristics for producing food, feed, forage, fiber, and oilseed crops. It is the land that gives the highest agricultural yield with minimum input when managed according to modern farming methods" (Guernsey et al., 1979). Generally, soils constituting prime farmland have slopes of less than 8 to 10×10^{-2} (Fehrenbacher et al., 1978; Guernsey et al., 1979). All lands not classed as prime farmland fall into the nonprime category.

Damage Criteria—Essentially, subsidence damage caused to agricultural lands is characterized by the loss of use or reduced productivity. Increasing ground movements generally cause a decline in productivity, but the precise amount is site-specific. In some instances, the extent of damage severely jeopardizes the capability of the land to economically produce crops, labeled "severely reduced productivity." Another level of damage, termed "moderately reduced productivity," accounts for less severe damage, such as decreased crop production potential because of loss of soil fertility. Ranges for these are presented in Table 10.6.16.

Forests and Grazing Lands: The types of damage caused by mine subsidence to forests and grazing lands is similar in nature to that for agricultural lands, but they are generally less susceptible to the damaging effects of subsidence movements than farmlands.

Damage Criteria—Table 10.6.17 depicts the current information. Small changes in slope are not likely to cause appreciable damage to forests and grazing lands.

10.6.4.5 Hydrologic Effects

Surface Water Bodies: The formation of open cracks, fissures, or pits at the bottom of surface bodies of water (streams, lakes, ponds) may lead to partial or complete loss of water by its drainage to lower strata or mine workings. Depletion of such water resources seriously impact public water systems and aquatic life forms. In extreme cases, catastrophic inundations of underground mine workings may occur.

Damage Criteria—Available data are given in Table 10.6.18; further guidance on the minimum depth required to maintain levels below the recommended limits is presented in Table 10.6.19.

Groundwater Aquifers: Mine subsidence affects groundwater aquifers in several ways:

1. *Lowering of groundwater* levels or hydrostatic head due to the formation of breaks and fractures in the strata above underground mine workings may decrease the groundwater supply.

2. *Changes in streamflow rates;* increases may occur due to faster movement through fractured strata, water accumulations in subsidence troughs, or reduced evapotranspiration because of a drop in the water table, whereas decreases are caused by water diversion.

3. *Alteration in water quality* produced by chemical interaction with the minerals or adjoining strata.

The prevailing hydrogeologic environment is significantly affected by subsidence-induced fissuring. Cessation of mining could bring about reconsolidation of the strata, but this may or may not result in the rebound of groundwater to premining levels. Water table depression is generally localized near the mine workings (Anon., 1981; Hill and Price, 1983), but the effects on the hydrologic regime could be highly variable and complex. Local structural features (e.g., faults, synclines, or anticlines) and the nature, continuity, and dip of the beds have a profound influence on subsidence damage. The significant presence of impermeable clay layers in the overburden inhibits groundwater drainage (Singh and Kendorski, 1981). The adverse impacts of water table lowering can be significant, especially in arid regions (Piper, 1933; Ward and Wilmoth, 1968; Subitzky, 1976; Rauch, 1978), and can reduce plant growth (Anon., 1981). Subsidence-induced streamflow rate variations have been noted (Growitz, 1978; Sgambat et al., 1980) as has the deterioration of water quality (Sgambat et al., 1980; Anon., 1981; Stoner, 1983), which is detrimental to water usability.

Damage Criteria—There is significant likelihood of damage to a water-bearing stratum if it is located within the caving or bed separation zones of an underground excavation. The strain limit suggested in Table 10.6.20 may be conservative since these strata are subjected to horizontal constraints, increasing their resistance to fracturing.

Example 10.6.2. Mine S is planning to develop several longwall panels and needs to obtain a permit, and hence to predict

Table 10.6.17. Damage Criteria for Forests and Grazing Lands

Surface Features	Damage Severity Level	Movement Limits: Type of Movement	Movement Limits: Tolerable Range	Source	Suggested Value
Pasture, woodland, range, or wildlife food and cover	Severe	Horizontal strain	$5.0–10.0 \times 10^{-3}$		5.0×10^{-3}
Wetlands	Severe	Horizontal strain	5.0×10^{-3}	Inferred	5.0×10^{-3}
Pasture, woodland, range, or wildlife food and cover	Severe	Slope	$450–660 \times 10^{-3}$ $250–350 \times 10^{-3}$	U.S. Dept. Agriculture (Anon., 1951; 1973) (Griffin, 1977)	300×10^{-3}
Wetlands	Severe	Slope	$30–80 \times 10^{-3}$	Griffin (1977)	30×10^{-3}

Table 10.6.18. Damage Criteria for Surface Water Bodies

Surface Features	Damage Severity Level	Movement Limits: Type of Movement	Movement Limits: Range	Source	Suggested Value
Natural: Sea or tidal waters, lakes, ponds, marshes, rivers, streams *Artificial:* Canals, impounded waters	Severe (implies partial or complete loss of water)	Horizontal strain	$5.0–10.0 \times 10^{-3}$	Wardell (1976)	5.0×10^{-3}

Suggested Vertical Distance Between Mine and Water Body = > 60 × (Mining Height)

Table 10.6.19. Minimum Cover For Total Extraction Under Water Bodies (with potential for causing catastrophic damage)

Seam Thickness (t): Feet	Seam Thickness (t): Meters	Minimum Cover Thickness (D): In terms of t	Minimum Cover Thickness (D): Feet	Minimum Cover Thickness (D): Meters
3	0.9	117 t	351	107.0
4	1.2	95 t	380	115.8
5	1.5	80 t	400	121.9
6	1.8	71 t	426	129.8
7	2.1	63 t	441	134.4
7.5	2.3	60 t	450	137.2
>7.5	>2.3	60 t	450	137.2

the surface damage expected due to subsidence. The mining height is 7.6 ft (2.3 m) and the depth of cover varies between 478 and 1022 ft (146 and 312 m). The mining company assumes that the angle of draw is 15° (probably low). Panel widths are expected to range between 500 and 700 ft (152 and 213 m).

Surface structures present in the permit area include buildings (e.g., a school), roads, and pipelines. Surface land use within the plan area is primarily pasture and woodland. There are no major aquifers or streams that serve as a significant water source for public water supply. There is one perennial spring fed by a perched aquifer, which is presently used for watering stock. This spring can be expected to have low flow rates during times of low precipitation or go completely dry during times of drought. The only persistent regional aquifer in the plan area is a sandstone, approximately 50 ft (15 m) below the valley level.

Solution: The extent of subsidence $S(x)$, slope $G(x)$, and horizontal strain $e(x)$ at the locations of the structures, and the expected worst-case sites for the renewable resource lands, may be determined by any of the methods discussed in Example 10.6.1 or by using one of the prevalent computer programs (see Table 10.6.7). These values are then compared with the ranges of slope and strains for various damage levels given in Tables 10.6.11 through 10.6.18 and 10.6.20. The expected damage levels can thus be obtained, as shown in Table 10.6.21. This information may be then provided in the permit application.

10.6.4.6 Nonmining Damage

When the time span for surface damage is prolonged, accounting for subsidence generated by nonmining causes is important and needs attention. In mining areas, local inhabitants have a tendency to blame mining activity for any damage that may be observed in local structures or lands. Such claims may not be justified in many instances. Types of nonmining damage that have been noted include the following.

Soil Settlement: Differential settlement of buildings can occur on fill material, especially when the fill is improperly compacted or part of the structure is on the fill and the rest on virgin ground. Such effects are also noted if some of the foundations are old and have already settled, whereas the rest of the foundation is relatively new. Inadequate bearing capacity of foundation soil and consolidation of soft clayey soil could also result in uneven settlement. The extent of damage caused depends upon the amount of settlement that develops and the orientation of the structure with respect to the settlement pattern.

Shrinking/Swelling of Soils: When soils shrink or swell due to the influence of water, damage may occur in surface structures that appears to be similar to subsidence damage. The change in moisture content could occur because of seasonal precipitation or drying, from leaks in water lines or sewers, or by trees and other vegetation in the vicinity. Roots tend to drain the clay; this is especially noticeable under paved areas since these areas are otherwise protected from precipitation and drying effects.

Table 10.6.20. Damage Criteria for Groundwater Aquifers

Features	Damage Severity Level	Movement Limits: Type of Movement	Movement Limits: Tolerable Range	Source	Suggested Value
Aquifers	Severe (implies partial or complete loss of water)	Horizontal strain	5.0×10^{-3}	Inferred	5.0×10^{-3}

Suggested Vertical Distance Between Mine and Aquifer = > 60 $\times$ (Mining Height)

Table 10.6.21. Damage Level Assessment for Ex. 10.6.2

Structure/ Resource	Overburden Depth m (ft)	Expected Strains ($\times 10^{-3}$) (Knothe)	Expected Strains ($\times 10^{-3}$) (NCB)	Expected Slopes ($\times 10^{-3}$) (NCB)	Strain Limit ($\times 10^{-3}$)	Slope Limit ($\times 10^{-3}$)	Expected Damage Level
Buildings	152–174 (500–570)	16.5–18.8	5.5–6.3	20.5–23.1	3.0	NA	Major structural damage
Roads	152–174 (500–570)	16.5–18.8	5.5–6.3	20.2–23.1	1.0	5.0–10.0	Surface cracking and considerable grade changes
Pipeline	152–274 (500–900)	10.4–18.8	3.5–6.3	12.9–20.2	1.0	NA	Widespread failure of pipe or couplings
Surface water	152–174 (500–570)	16.5–18.8	5.5–6.3	20.2–23.1	5.0	NA	Fissuring beneath stream bed, significant water loss
Aquifer	137 (450)	21.0	7.0	25.7	5.0	NA	Partial or complete dewatering
Forests/ grazing lands	146–311 (480–1,020)	9.2–19.6	3.0–6.6	11.3–24.0	5.0	300.0	Localized surface fissuring, little drainage effects

NA = Not available

Soil shrinkage generally induces vertical strains in the structure rather than the horizontal strains that commonly damage buildings due to subsidence. The building itself tends to shelter the inner portions so the outer walls are generally affected. These walls depict a tendency to pivot outward about the foundation. Swelling of the soil reverses the movement partially, but the cracks remain.

In cold areas, freezing and thawing effects may also cause expansion and contraction of poorly drained fine-grained soils in a manner similar to moisture-sensitive soils (DuMontelle et al., 1981).

Groundwater and Precipitation: Deviations in groundwater flows or significant changes in precipitation could cause damage to structures. Such changes may be a result of mining or due to other reasons. The effects of water drainage into mined excavations, leading to surface subsidence, must be recognized as mining-related and treated accordingly. However, alterations in groundwater flow may also be caused by building activity in the area, installation of wells for farm irrigation, or major excavations some distance away which affect an aquifer. These are entirely unrelated to the mining activities.

Inadequate Drainage or Waterway Regulation: Waterlogging occurs near buildings if proper drainage is not provided. This can induce seepage into building basements and general deterioration of structures, especially if these are made of wood or other materials susceptible to damage by water. Sometimes this type of damage is blamed on mining subsidence.

Faulty Construction, Inferior Materials, or Inferior Subsoil: Poor quality building materials and construction may increase the likelihood of damage to structures. Buildings on poor soil or improperly compacted fill may also suffer disastrous effects. Roof spread is a common form of damage that may occur due to an inadequate number of cross-ties or due to timber decay in older buildings. This permits the external walls to push outward at the top and induce cracking in them. This type of damage may be distinguished from subsidence damage when observed movements are in a direction opposite to that anticipated from mining.

Chemical Attack: Masonry or stone structures show cracking when embedded iron or steel members (such as dowels, hooks, or frames) begin to rust and corrode. Glass panes in metal frames may crack because of the pressure exerted on them by rust. This probably is the case when the window can still be opened, but the glass is cracked.

Dissolved sodium, calcium, or magnesium sulfates in surface water tend to react with Portland cement or lime causing the mortar to expand and deteriorate into a powder. The moisture initially affects the shrinkage cracks, but later induces further splitting. Chimneys with sulfurous gases make easy targets for such damage. If sulfur-containing shales (which are common in coal mining areas) are used for fill or as a foundation for buildings, the concrete floor is liable to show signs of distress from sulfate attack (Anon., 1975a).

Thermal Effects: The differential thermal expansion characteristics between tiles and the concrete surface to which they are bonded may cause them to separate or become loose (such as on the floor). Joints between different materials may also be affected (e.g., plaster board joints, wood and concrete or brick interfaces, concrete/brick and steel contacts). Pavements may crack or buckle because of thermal effects. Pipelines and railroad tracks show marked effects.

Natural Wear and Tear: All structures undergo wear and tear during normal usage, and sometimes it is difficult to isolate damage due to these causes, especially if the maintenance is not regular.

Vibrations: Industrial plants in the vicinity or heavy traffic on nearby roads may generate vibrations, which could induce cracking or cause settling of structures. This may be especially true if blasting is done for construction or seismic investigations.

Minor Earthquakes: Major earthquakes are readily noted and any damage resulting therefrom is clearly evident. In earthquake-prone areas where numerous minor earthquakes occur, however, this may not be the case. The cumulative effect of these can be seen as cracks in walls or other impairment to structures, which may be confused with subsidence damage.

Minor Landslides or Creep: As with earthquakes, the effects of major landslides are noticed. However, a number of small slides or gradual creep, especially on slopes, may induce deterioration that may not be readily visible for some time.

Tectonic Movements: Structural damage can result from long-term movements of the earth's crust. Such gradual motion has lifted pipelines in California and caused measurable vertical and horizontal displacements in Upper Silesia, Poland (Brauner, 1973).

Fluid Withdrawal: As mentioned in 10.6.1, this is considered a nonmining source of subsidence in this chapter. Notable instances include the withdrawal of water for industrial and public use in the Houston-Galveston area in Texas, for agricultural purposes in the San Joaquin Valley in California, land reclamation around New Orleans in Louisiana, production of oil from the Wilmington field near Long Beach, California, and geothermal fluid extraction near the geysers in California.

Nonmining Cavities: In situ coal gasification near Rawlins, WY, tunneling for infrastructure in several urban areas (e.g., Washington, DC; San Francisco, CA; Chicago, IL; Milwaukee, WI), and natural cavity formation in the karst areas of Florida and Tennessee have also resulted in subsidence.

These are, of course, well-publicized examples, but smaller amounts of subsidence continue to occur throughout the country as a result of these mechanisms. Coal mine operators and regulators need to be particularly aware of water and oil/natural gas withdrawal in the vicinity of their mines so that the correct cause of subsidence can be identified.

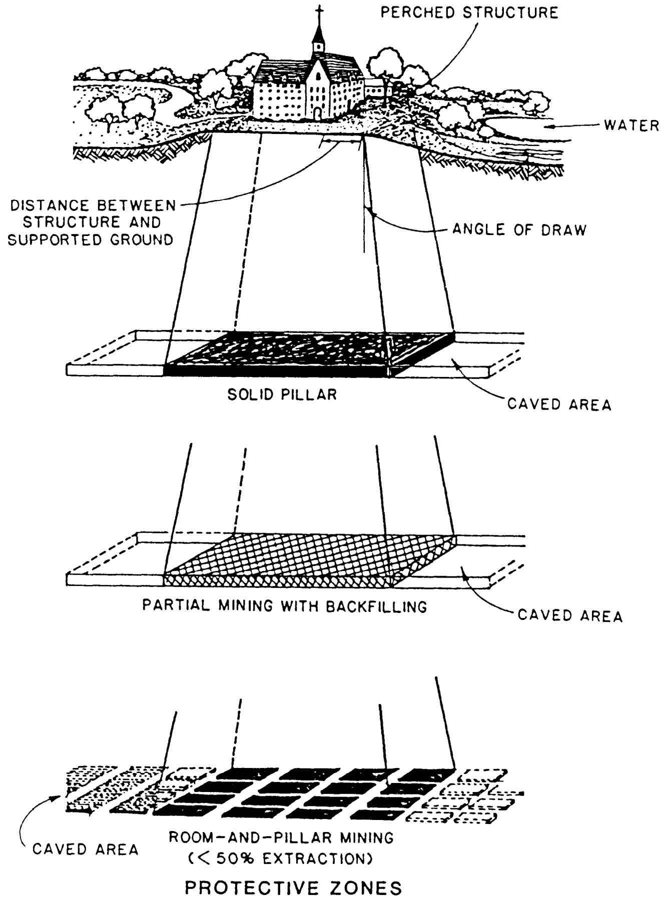

Fig. 10.6.15. Protective zones for surface structures (Singh, 1985).

10.6.5 CONTROL AND PREVENTION OF DAMAGE

There are four types of measures that may be adopted to control subsidence damage (Singh, 1985):

1. Alteration in mining techniques.
2. Postmining stabilization.
3. Architectural and structural design.
4. Comprehensive planning.

Each of these encompasses several methods.

10.6.5.1 Alteration in Mining Techniques

Partial Mining: This may be accomplished in a number of ways:

1. Leaving *protective zones,* which is the most commonly used procedure (Fig. 10.6.15). The zone may entail:

a. Leaving the *entire pillar unmined* beneath structures, such as factories, railroads, major highways, and bodies of water.

b. *Partially extracting the pillar* and backfilling

c. *Room and pillar mining,* with up to 50% extraction; a practice recommended in some states (e.g., Pennsylvania) by regulation. This method does not account for pillars deteriorating with time, especially if the mine is flooded.

It should be borne in mind that any structure supported by a protective zone is liable to become perched at a higher level than the surrounding ground, after it subsides. This may not affect the railroad or highway being protected, but could disturb the utilities to a building. An island may form if the water table is high.

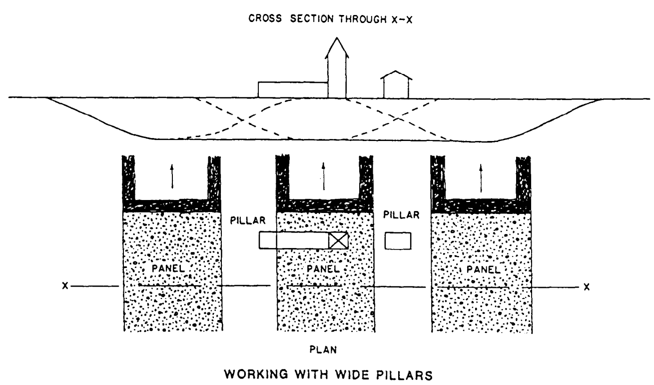

Fig. 10.6.16. Use of sized pillars for protecting surface structures (Singh, 1985).

2. Use of *sized pillars,* that is, the pillar width between panels is adjusted so as to uniformly lower the ground surface (Fig. 10.6.16)

3. *Mining subcritical widths,* so that the maximum subsidence is reduced.

Backfilling: This may be done using hydraulic or pneumatic techniques, which reduce the amount of subsidence, but do not eliminate it entirely. It is a very effective method of mitigating subsidence effects, since it not only minimizes the ground-defor-

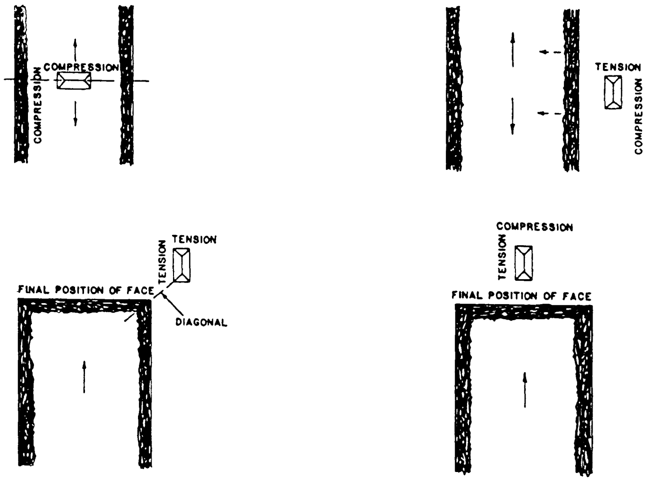

Fig. 10.6.17. Structural strains produced by basic face layouts (Kratzsch, 1983).

mation forces but also conserves the hydrologic regime. Cost effectiveness studies should consider the beneficial effect on the environment such as reduced acid-water drainage, savings in waste disposal and reforestation, prevention of refuse fires, reduced ground fissuring and escape of mine gases, as well as the advantages of long-term strata stability and decreased roof support. Railroads, canals, sewers, and streams experience smaller gradient changes. Hydraulic flushing may also cool the mine air, which is desirable in deep mines. Backfilling may become essential in flat regions with a high water table to prevent flooding, and in areas reclaimed from water bodies (e.g., in The Netherlands).

Harmonious Mining: The technique entails superimposing compressive surface strains on the tensile strains induced by another longwall face in a manner that they move along together. This may be accomplished by staggering two simultaneously worked faces that advance at the same rate, with (1) multiple seams, in which one face is superjacent over another, and (2) single seams, where the panels adjoin.

It is evident, of course, that total cancellation of the traveling strains can only occur if the displacement curves are congruent and symmetrical (i.e., the seam thickness, influence factors, width of compressive and tensile zones, and stowage density, if backfilling is adopted, are identical). Time factors for the mining sequence must also be available from prior experience.

Mine Layout or Configuration: Layout controls the strains experienced by the structure. It may be possible to locate the panel with respect to the building in such a manner as to expose it to deformations that it can withstand (Fig.10.6.17). In some cases, it may be best to stop short of taking all the coal; the loss may not be excessive if the seam is shallow.

Extraction Rate: Face advance cannot be readily altered in mining, and its range is generally limited with the available equipment. A faster rate is desirable in unfractured, viscoelastic strata because it lowers the tensile peak and moves it closer toward the working face. However, in fractured, clastic rocks (such as over previously mined beds), rapid face advance may accentuate displacements and strains and thus induce greater damage.

10.6.5.2 Postmining Stabilization

These techniques have been used in the United States and may extend over large areas (tens of acres or hectares) or be restricted to support a specific structure.

Areal: The four main methods used include:

1. *Backfilling*, which may be conducted
   a. Hydraulically.
   b. Pneumatically.

In either case the procedure may be (1) controlled, when the mine is accessible and barricades can be manually built, or (2) remote (blind), through boreholes when the openings cannot be entered, such as in abandoned mines.

With hydraulic stowing, the water level may rise temporarily in dry mines, acid water may be flushed out into the hydrologic system, and surface drainage may be affected by siltation, pollution, or flooding (especially in shallow mines). The technique is even usable in water-filled mines.

The Dowel1 process (Gray et al., 1974) is a special hydraulic blind-flushing technique, in which the slurry is pumped at a high velocity. The mixture deposits its load when the velocity drops on entering the mine cavity, forming a doughnut-shaped pile. As the pile height nears the mine roof the slurry velocity in the gap increases, keeping the solids in suspension longer, so that the pile grows outward.

Pneumatic stowing causes considerable sparking and may pose a hazard because of the potential for gas ignition.

A commonly used material for backfilling, both hydraulic and pneumatic, is fly ash because of its abundance at coal-fired power plants.

2. *Grouting* entails using a cementitious mixture and thus provides a stronger support. Additives used include Portland cement, pozzolanic mixtures, or organic compounds.

a. *Gravity grouting* is used to simply fill the mine void to whatever extent possible. There is little control, although a perimeter wall may first be built with a thick grout, which is then filled with an expansive grout to achieve good roof contact.

b. *Pressure grouting* is needed if a number of joints need to be filled or roof caving has occurred.

c. *Bag grouting* is a new development (Singh, 1985), and entails lowering a bag through a 6-in. (150-mm)-diameter borehole and filling that with grout until roof contact is obtained.

Grouting under important buildings requires special care (Scott, 1957).

3. *Excavation and fill placement* is only feasible in shallow abandoned mines, with no surface obstructions to excavation. The entire overburden and coal are removed and replaced with compacted fill. Flooded mines may yield large quantities of acid water.

4. *Blasting* of the roof and floor to fill the cavity is a patented technique (Patent No. 1 004 419), which has not been used recently (Gray et al., 1974). Over time, the broken rock compresses, but the movements may be expected to be gradual and evenly distributed.

Site Specific: These techniques are mostly used to support isolated structures.

1. *Grout columns* may be built remotely, but floor and column strengths are variable. Water may impede construction.

2. *Piers and cribs* may be constructed in mine openings that are accessible, if the mine floor and roof are competent.

3. *Deep foundations* may be used with shallow workings. They are, however, liable to damage by lateral shear forces that may be experienced.

4. *Groutcase supports* entail placing casing between the mine roof and floor and filling it with grout. These supplement existing coal pillars.

10.6.5.3 Architectural and Structural Design

Orientation: It is preferable to have the long axis of the building parallel to the subsidence contours. If a fault exists nearby, the shorter axis should be oriented perpendicular to the fault.

Location: Faults tend to concentrate ground strains, hence structures should be located at least 50 ft (15 m) away.

A single building should not be constructed on dissimilar soils, owing to the possibility of differential deformations or settlements.

Subsidence-Resistant Construction: This technique has received considerable attention in the literature. It may be discussed under four major construction categories:

1. *Rigid* in which both the foundation and superstructure are rigid in design. Often the foundations are highly reinforced concrete rafts or beams, capable of withstanding ground displacements and curvature. The structures generally span or cantilever over a subsidence wave. Foundations are of small plan area. Elevator shafts and the like are designed with extra clearances.

2. *Flexible design* permits slab foundations for small buildings such as houses. The slab should preferably be less than 60 ft (18 m) along the side, poured in a single operation, without joints, and finished close to ground level. It is generally underlain by granular material. Reinforcement should be near both the top and bottom so as to accommodate tensile and compressive strains.

If the building has a basement, there should be an open gap around it or filled with a compressible or granular material. Larger buildings may have rollers or slip-joints between the superstructure and foundation. Trenches around structures absorb some of the strains.

Flexible structures are designed to track the traveling subsidence wave without cantilevering, permit free ground movement below the foundation, provide sufficient superstructure support in spite of the ground flexing, and accommodate subsidence deformations that are larger than anticipated without jeopardizing structural stability.

3. *Semi-flexible designs* are used in instances where the structures can tolerate minor damage, such as some warehouses. These do not strictly adhere to the rigid or flexible criteria outlined above. It may be more cost effective to perform minor repairs as required than employ these more expensive designs.

4. *Use of releveling devices,* such as jacks, to prevent tilting. Excessive tilt may cause the gap between adjacent buildings to be reduced to the extent that they touch.

Gaps need to be provided between all buildings to allow for both compression and tilt. Other precautions that are helpful, depending on design philosophy, are (Chen et al., 1974; Anon., 1977)

a. Provide expansion joints to accommodate ground movements and thermal expansion.

b. Minimize the number of door and window openings and use flexible frames; their location should not significantly weaken the structure; do not position front and back doors opposite each other.

c. Avoid weak skin materials within rooms; partitions between building segments should be strong; instead of plaster on ceilings and walls, use plaster board.

d. Floors and roof should be secured to the walls.

e. Allow for tensile strains at all structural connections; movements should be possible for staircases.

f. Exclude masonry arches.

g. Do not have comer or bay windows or porches.

h. Detach outbuildings from the main building

i. Provide excessive falls for gutters.

j. Do not pave immediately adjoining buildings; use bituminous type materials for paving where necessary (e.g., driveways).

k. Employ flexible damp-proof courses (e.g., bitumen).

l. Use light fences around properties rather than walls.

m. Replace rigid retaining walls with earth banks.

Modification of Existing Structures: Total repair expenses may sometimes be reduced if a building is suitably modified prior to its experiencing ground movements. Possible alterations include (Chen et al., 1974; Kratzsch, 1983)

1. Cutting out a part of a house or removing an entire house from a row of buildings; unit lengths should be about 60 ft (18 m), with cuts extending into trenches, and gaps bridged with flexible materials; preferably locate cuts in connection corridors or unit divisions.

2. Digging trenches around a building (and filling with compressive material weaker than the surrounding soil) to below foundation level, without disturbing the foundation; trenches may be covered, if desired, with concrete slabs that do not butt.

3. Slotting rigid pavements or floors, and even superstructures (generally wood, brick, or stone do not present difficulties; concrete may).

4. Introducing slip planes, especially in new buildings.

5. Providing temporary supports and/or strengthening to parts susceptible to damage; support screens, partitions, and ornaments independently of the walls and floor.

6. Using tie rods, if it is anticipated that the roof trusses will be pulled out from their seats; however, indiscriminate use of tie rods may needlessly disfigure the building; stress concentrations at tie-rod bearing plates may pull these through the walls; often temporary corbels provide adequate support for trusses.

7. Installing pretensioned steel mesh around the exterior walls (this could be dismantled and reused later).

8. Taping windows, (especially with metal frames), to avoid flying glass.

9. Removing and storing stained glass windows, until subsidence is complete.

Remedial and Restorative Measures: Increasingly, structures are being constructed so as to be easily repaired after subsidence damage. Since a tension wave is usually followed by a compression wave, cracks should not be patched until all movements have stopped. Debris in the fractures should, however, be removed prior to the compression cycle.

In low-lying areas, the water table may create difficulties, necessitating the installation of drains and pumps.

10.6.5.4 Comprehensive Planning

It is desirable to plan both the surface land use and the mine with full knowledge of the requirements of each. Deep cuts for highways, railroads, or other structures, or excavations for utility tunnels or basements, may reduce the competent overburden thickness above the old workings to induce subsidence. This type of situation can be prevented with planning.

For planning or any other measure to be successfully implemented, it is paramount that everyone affected by subsidence fully comprehend what is being done and why. Therefore, an intensive effort of public education about the subject is in order. This should not only be directed towards the general populace, but also the mine operating personnel, builders and developers, government officials at all levels, and civic groups.

Four situations (Anon., 1977) may be identified, each of which requires a slightly different approach to planning:

1. Existing subsidence potential, existing development.
2. Existing subsidence potential, future development.

3. Future mining area, existing development.
4. Future mining area, future development.

Essentially all these approaches entail either coordination or control of both the surface and subsurface development.

Coordination of Surface/Underground Development: Although not a comprehensive list, typical of the principles that may be followed are

1. Avoid construction near outcrops or faults.
2. Build only specially designed structures over shallow workings; surface effects are magnified as the depth decreases.
3. Locate buildings above steeply dipping seams since the strains induced are reduced.
4. Erect communications or other significant structures in unmined or completely subsided areas.
5. Alter routes of highways, railroads, canals, and other structures to suit coal conditions (e.g., over want areas or near fault planes); subsequent costs for lowering may be thereby reduced.
6. Site linear structures (e.g., canals, railroads) so that they can be uniformly lowered along their entire length; locks may be located over unminable zones, although massive lock structures can be dropped without significant damage.
7. Avoid building important structures near mine boundaries since coordination with several mine operators and surface land owners is onerous; also boundary pillars may introduce higher stresses.

Collaboration between the mining companies and surface owners and developers is essential in regional or zonal planning, otherwise problems will arise.

Land Use/Development Control: Development of land areas overlying mines must be economically justifiable as well as socially and culturally acceptable. This implies that often regional plans should not only be discussed with mine and surface owners, but also be open to public comment prior to adoption. Changes in these plans also deserve an equally protracted treatment.

Federal, state, regional, county, and local government authorities exert considerable control over development of land that is potentially liable to damage due to subsidence through these means:

1. Surface Mining Reclamation and Control Act (SMRCA) of 1977 (Public Law 95-87).
2. Environmental impact requirements.
3. Zoning and subdivision regulations.
4. Building provisions (issuance of permits).
5. Mining regulations.
6. Safety requirements.
7. Insurance needs.
8. Investigative requirements for public buildings (e.g., Pennsylvania's Act 17 of 1972).
9. Special local ordinances.
10. Interagency coordination.

Perhaps in the future, it will be mandated that mine operators prepare plans that depict predicted subsidence locations, extent, trough centers, maximum subsidence, values and direction of tilt, compression and extension zones, and other pertinent data. These could then be circulated to building authorities, highway commissions, railroads, water supply and other utility agencies, pipeline operators, and others who may be affected for comments and suggestions (within strict time limitations). On the other hand, these groups as well as builders/developers should be required to incorporate proper precautions in the design of their respective structures. In extreme cases, construction may be barred from particularly risky areas, and these lands used for parks, forest preserves, and open spaces.

ACKNOWLEDGMENT

The author would like to thank Peter J. Huck of Engineers International, Inc. for his comments on the text and help with Example 10.6.1.

Chapter 10.7
OTHER APPLICATIONS OF GEOMECHANICS

FRANCIS S. KENDORSKI AND DOUGLAS F. HAMBLEY

Many areas of geomechanics are not covered elsewhere in this *Handbook.* In addition, there are uses for geomechanics that are peripheral to many other mining endeavors. This chapter introduces these peripheral areas and as yet uncovered topics. Applications of geomechanics should be discussed in a systematic fashion, so that the users can directly apply the concepts, principles, and information to their particular problems. In this chapter, geomechanics is discussed with respect to design at a planned, developing, or operating mine. Design as used here can include remediation of problem areas in the mine, design of a prototype mining method or layout, conceptualization of layout or support system alternatives, and calculation of stresses and deformations in an attempt to understand the behavior related to a particular observation, for example, pillar hour-glassing.

Application of geomechanics principles must follow a logical thought process; however, in solving particular problems, designers should not limit themselves to conventional techniques or design practices but should also consider findings in other disciplines, results of research and development, and conclusions from brainstorming sessions. A design philosophy and approach in geomechanics based on multiple working hypotheses has been found to be successful and workable in many cases. This approach has developed in response to the need for safe working conditions, sound design (consistent with precedent and accepted practice), cost effectiveness (to maintain profitability in economic downturns such as the early 1980s), and innovation (to maintain and enhance utility in the future). These four needs are driven by the respective requirements of (1) society and labor; (2) regulatory agencies (Mine Safety and Health Administration [MSHA], Office of Surface Mining, Reclamation, and Enforcement [OSMRE]); (3) the owner (mine management and shareholders); and (4) the design engineers themselves (for preservation, enhancement, and effective utilization of their skills).

In practice, this approach is achieved by developing an understanding of the true nature of the problem—for example, is the raveling slope a safety problem, or, more critically, the harbinger of an impending major failure—and by planning an effective step-by-step approach to the solution. Project management techniques (Martin, 1976) can aid in developing a systematic approach and have been found useful here. To Bieniawski's (1988) ten stages in the engineering design process (see Chapter 10.5) should be added another stage: observation and re-analysis.

Innovation can be included in the above process (Bieniawski, 1984a, 1988) through the use of brainstorming (a group throws out ideas for general consideration with no idea initially dismissed, no matter how fanciful, impractical, or illogical it may seem); programmed invention (Edison realized that a highly resistive filament would provide light when energized, and then his research group concentrated on either making the concept practicable or demonstrating its impracticability); or cross-fertilization (bringing together elements from different specialties).

Geomechanics design should be obtained from multiple analysis methods that converge to a desirable and mutually supportable conclusion. When the same solution is given by different analysis techniques, the engineer can have greater confidence in the result. Conversely, if the different techniques provide vastly different solutions, it is necessary to evaluate the data, methodology, and assumptions for the various techniques used. For instance, numerous formulas have been proposed for designing pillars in room and pillar mines: Holland and Gaddy (1957), Obert and Duvall (1967), Hedley and Grant (1972), Wilson (1972), Abel and Hoskins (1976), Bieniawski (1984b), Sheorey et al. (1987), and Salamon (1967). When designing a layout, try them all, determine which are most appropriate—some apply strictly for coal, some for hard rock, and some only to specific geometries —and optimize the results. For design in rock, one can use (1) basic statics methods (resisting forces vs. driving forces); (2) finite element, finite difference, boundary element, or discrete element numerical modeling methods; (3) physical models; (4) empirical methods (rules of thumb); or (5) whatever else can be brought to bear on the problem. In the design of a new level for a deep caving-method mine, the rock mass can be classified and support requirements estimated, load-shedding and driving forces can be calculated, numerical modeling can be performed to determine the strains to be accommodated, and lining requirements can be determined empirically based on comparisons of practices at other mines. The answer will be found from proper consideration of all these possibilities. No single method should be considered in preference to the others for it may be inapplicable or misleading.

10.7.1 GEOMECHANICS AS A TOOL

Like economics, time, labor, and other considerations such as personal or operational preferences, geomechanics is but one tool in a mine plan or design. It cannot be used in isolation, and must be used properly, with full awareness of the assumptions and limitations.

10.7.1.1 The Mine as a Structure

A mine is a system not only of functional components (mine, mill, shops, offices, transport) but also of structural components. For an open pit mine, these components could be benches, pit haul road, conveyor line, crusher station, and sump. Underground, they could be stopes, drifts, adits, ventilation drifts, crushing chambers, conveyor galleries, shafts, access and ventilation raises, orepasses and ore pockets, and the surface. These all interact structurally, and a failure in one could be catastrophic to the mine as a whole. Table 10.7.1 indicates the structural interactions likely for various components. These components cannot be designed in isolation, and the structural interactions of one on another must be considered.

10.7.1.2 Use in Mine Planning

Geomechanics is fundamental to mine planning. An open-pit or strip mine must have designed slopes and highwalls. Opening and stope stability are critical to any underground operation. At the exploration stage of a mining project or mine expansion project, geomechanical data must be collected to provide information for planning and design. For each core drilled, rock

Table 10.7.1 Mine Structure Interactions

Component	Interacts with
	SURFACE
Benches	Pit slope—bench stability dictates overall slope stability
	Haul roads—bench stability affects utilization of haul road above and below it
	Conveyor line—same as for haul roads
Pit slopes	Fundamental interaction with all components if located above, on, or near an unstable slope
	UNDERGROUND
Drifts	Stopes—instability in drifts may restrict access to stopes or lead to failure of overlying stopes
	Ventilation drifts—separate drifts for ventilation, common in some mining types, may be damaged or closed at intersections with unstable drifts
Stopes	Drifts—failure in stopes will lead to distress in overlying and underlying drifts of all types
	Shafts—instability in stopes may progress to ground around shafts, resulting in deformation or failure of the liner
	Surface—sinkholes or other subsidence features may develop at surface
Conveyor galleries	Crushing chambers at start or end of galleries may be impacted
	Shafts—the tail ends of galleries are often near shafts so that instability may lead to deformation or distress of shaft components
Ore pockets	Conveyor galleries, which often lead to or from ore pockets, may suffer distress from ore pocket failures
	Shafts may also suffer distress due to failure in nearby ore pockets
Surface	Stope—in caving or near-surface mines, surface deformations (slides, subsidence) may cause failure or filling of stopes
	Shafts—surface movements will distress shafts
Pillars	Drifts (rooms)—unstable pillars will result in closure of rooms or drifts
	Shafts—unstable pillars can lead to deformed and distressed shaft linings if the shaft is within the area of subsidence resulting from the unstable pillars
	Surface—failed pillars can lead to sinkholes or other subsidence effects

quality designation (RQD), fracture data, strength data (such as from a field point-load tester), core recovery, and a detailed geomechanical description must be provided. At large mines with aggressive exploration programs, two logging efforts are often made on all core—the first, geologic for ore control, the second, geomechanical. Separate logging forms are used to minimize clutter, and the core may be logged by different individuals. The geomechanical logging is usually performed before any splitting or sampling of the core, so it is often first. Obtaining correct and accurate geomechanical data early in the exploration phase is critical, because, as exploration proceeds and the prospect becomes a project, any redrilling required to obtain geomechanical data will be rushed. Moreover, it is very difficult to extract sufficient geomechanical information from split and assayed core (split core cannot be run in testing machines).

As mine plans are conceptualized, the geomechanical abilities of the rock mass to accommodate the plan must be assessed, as must the geomechanical consequences of the plan. For example, in room and pillar mining, the span of the rooms will initially be dictated by equipment clearance requirements and drilling equipment face coverage capabilities, whereas pillar size will be dictated by rock mass strength and deformation characteristics. After pillar size has been selected, room span, and crosscut span and spacing may be adjusted to meet the extraction ratio limits dictated by the pillar size and rock-mass characteristics. However, the limiting factor in room spans is the ability to support or reinforce the roof. It may be necessary to down-size equipment or put more effort into roof control to produce a safe design. Economic considerations of geomechanical designs (cost of rock reinforcement) must be balanced with equipment and with loading and haulage costs (size of units).

In caving mining systems, the geomechanical properties of the rock mass are all-important to the success of the system. Stewart (1981) contains numerous papers on rock mass descriptions for caving.

In open pit and strip mines, the required slope angle obviously dictates the stripping ratio.

10.7.1.3 Use in Mine Operations

Geomechanics programs should actively continue during mine operations, because more ground is now opened up, which facilitates sampling and mapping. In both underground and open pit mining, ongoing geomechanical programs should collect data on (among other things):

1. Rock strength properties and variations in strength.
2. Characteristics of fractures and faults.
3. Support performance (underground, and, where necessary, in open pits).
4. Slope performance (open pit).
5. Stress indicators (usually a greater concern underground).
6. Blasting performance.

The initial mine design should be fine-tuned to optimize return on investment and recovery of ore. Such data as listed above will allow reconsideration of the design and redesign, where necessary, to address changing and unforeseen conditions.

A balance must be struck between having, on one hand, a tailor-made design for every small mine section and, on the other hand, a standard design for the entire mine that is based on the expected worst conditions. A better solution is to design for average conditions, while making provision for alteration where necessary. For instance, a slope design that can accommodate wider benches or catch benches can have great flexibility for optimizing stability. In room and pillar mining, if pillars are initially left as ribs, crosscuts can be placed where roof or pillar conditions are best, rather than at the locations required by a regular, checkerboard pattern. In caving, design changes in small areas are difficult to achieve, and a redesign in an already-developed area is a disaster—once the drawpoints and undercuts are established, the mine is committed. (This is also true for stoping blocks in massive, steeply dipping ore bodies where methods other than caving—open stoping, shrinkage stoping, cut and fill, or vertical crater retreat mining—are used.)

10.7.1.4 When Things Go Wrong

It is all too common for geomechanics programs to be established only after serious problems have arisen. However, increasing requirements for regulatory permits are driving a demand for prediction of mining consequences. To do so requires the use of geomechanics. In any profitable mine, the very nature of natural geologic materials or human error will create a problem sooner or later. If a mine is designed to completely avoid any stability problems, or to be idiot-proof, it is probably uneconomic. (In jurisdictions where mines are government-owned, the economic viability of the mines may be secondary to other considerations; however, when mines are privately owned, mines will be operated or developed only if they can return a profit.)

The sorts of things that can go wrong geomechanically are

1. Surface: slope failures, bench failures, oversize in the blasts, poor road conditions, excess water.
2. Underground: roof falls, stope failures, pillar instability, drift closure, unsuccessful blasts (misfires, cutoff holes or short pulls), surface subsidence, runs of loose ore.

When such conditions occur, the original data collected must be reviewed carefully for the following

1. Was something missed (an unknown fault, a dike)?
2. Was something misinterpreted (why was that core lost)?
3. Was the laboratory testing independently verified?
4. Was the minimum core segment length changed when RQD was calculated for core diameters other than NX? (Four in.-long pieces apply to NX core [Deere, 1964] but not BX [Heuze, 1971], AX, or EXT.)
5. Were all holes drilled at the same orientation so that structures parallel or nearly parallel to the holes were missed? (Although this problem was recognized by Terzaghi [1965], it continues to be a major cause of incorrect structural interpretation.)
6. Were two distinct rock masses lumped in the same structural domain?
7. Is the stress field substantially different from that estimated or does it vary? (Changes in the orientation of the stress field within a mine can be inferred from the distribution and orientation of major structural features such as faults, folds, or dikes.)

All the design data and assumptions must be reconsidered. If there is no apparent cause for a problem, other investigations must be performed

1. Monitor deformations.
2. Instrument rock bolts.
3. Re-map the structural geology.
4. Monitor water levels.
5. Install pressure cells.
6. Install microseismic networks.
7. Drill additional exploratory coreholes.
8. Examine timing and sequencing of excavation steps (for example, in a stoping block with simultaneously mined parallel overhand stopes, the center stope should lead.
9. Determine whether support materials are appropriate and sufficiently long-lived.
10. Determine whether opening or bench use has changed from what was planned so that the opening or bench environment has altered.

Careful analyses of these and similar features and information will usually reveal the nature of the problem. Instrumentation is available that can monitor almost anything. Geophysical probing can be helpful, but low-velocity media will be obscured by adjacent high-velocity media when seismic methods are used (problem areas are usually low-velocity areas). All geomechanical aspects must be addressed before blaming operations personnel for problems, or accusing them of not doing their share. Unfortunately, human errors or errors in judgment cannot be overcome solely through improved geomechanical design. The operating problems that can (and have) led to mine failures include

1. Using rock bolts of incorrect length (usually too short, but roof failures can occur if bolts are all anchored at a uniform depth although the length is otherwise adequate).
2. Using insufficient (or all the same) delays for blasting rounds.
3. Using additional blastholes (or overloading holes) to use up powder.
4. Delaying or omitting roof support because "the roof always stands well."
5. Running drainage on the wrong bench.
6. Robbing pillars until they are grossly undersized, in order to get cheap muck.
7. Ignoring big voids discovered when blastholes are loaded.

10.7.2 IMPORTANCE OF PRESERVING ROCK INTEGRITY

The rock mass in which a mine is constructed is capable of great strength if its original strength is preserved in some way. "Weak" rocks are often considered to be those 8000 psi (50 MPa) or less in strength, whereas "strong" rocks are those with strengths in excess of 20,000 psi (140 MPa). Concrete for most purposes seldom exceeds 8000 psi (50 MPa) in strength, and in underground applications concrete strength is generally 3000 to 4000 psi (20 to 25 MPa). Hence concrete is usually weaker than the rocks encountered in most mining. Why then is it common (especially in tunnels and underground hydroelectric machine halls) to over-excavate and replace the rock with concrete? (Putting it another way, why tear out 20,000 psi, or 140 MPa, rock to replace it with 4000 psi, or 25 MPa, concrete?) There are two reasons:

1. The rock is flawed with joints, bedding, and other discontinuities, and, even when supported by passive external supports such as timber or steel sets, tends to detach or fall out as blocks.
2. Concrete can be engineered to give predictable properties and behavior, whereas the rock mass cannot.

Because of the greater inherent strength of the rock mass, any effort that preserves this strength is beneficial.

10.7.2.1 Rock Substance Compared to Rock Jointing

The strength of the rock substance is conventionally described in terms of the Mohr-Coulomb criterion (see Chapter 10.2):

$$\sigma_1 = S_c + \sigma_3 \tan^2\psi \qquad (10.7.1)$$

where σ_1 is maximum principal stress, σ_3 is minimum principal stress, S_c is uniaxial (unconfined) compressive strength, and ψ is failure angle (= 45° + $\phi/2$, where ϕ is the angle of internal friction). Failure is considered to occur if the actual maximum principal stress exceeds the value calculated from Eq. 10.7.1 when the actual minimum principal stress is substituted. The intermediate principal stress σ_2 is considered not to affect the strength. (This results from the fact that, in conventional "triaxial" testing, the intermediate principal stress is the same as the minimum principal stress. However, recent research with "true triaxial" testing machines has shown that the strength is affected by the magnitude of σ_2. Moreover, in real situations, σ_2 and σ_3 are usually different. Thus a failure criterion that incorporates all three principal stresses would be more applicable. Nevertheless, because the Mohr-Coulomb and other strength criteria that neglect the effect of σ_2 have been shown to give reasonable predictions, and because of their simplicity compared to triaxial failure criteria, their use is retained in these discussions.)

A "strength envelope" is obtained by plotting the results of several tests at different confining stresses on a graph of shear

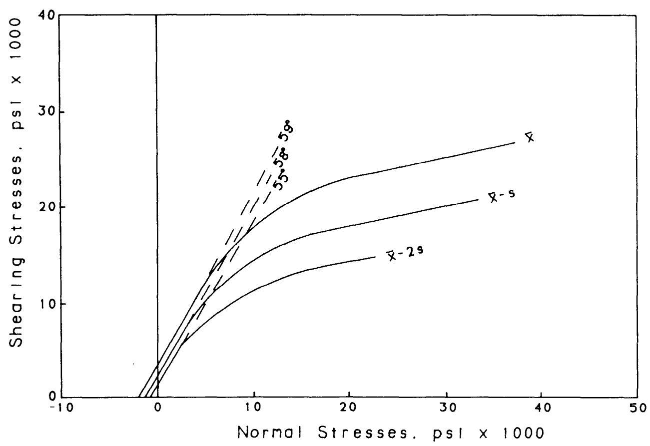

Fig. 10.7.1. Results of strength tests at various confining stresses for intact rock. Conversion factor: 1000 psi = 6.895 MPa.

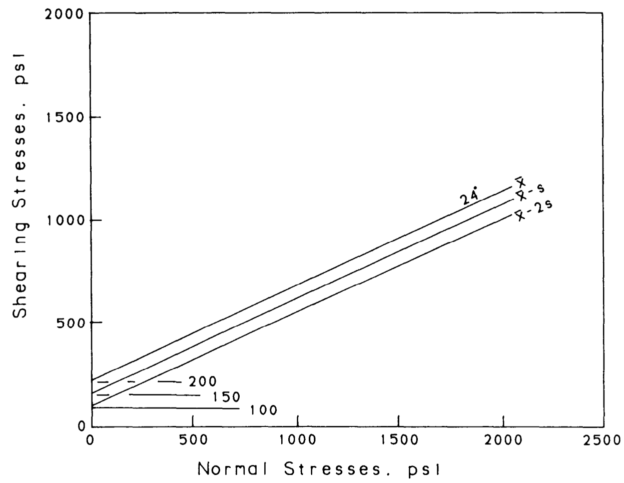

Fig. 10.7.2. Results of shear tests at various normal stresses for rock joints. Conversion factor: 1 psi = 6.895 kPa.

vs. normal stress (Fig. 10.7.1). The Mohr-Coulomb criterion gives a linear strength envelope. However, as shown, the strength envelope is actually curvilinear (parabolic) and approximately linear only for small confining stresses. Jaeger and Cook (1976) combine the Mohr circle construction for strength with a Griffith failure criterion to obtain the following parabolic failure criterion:

$$\tau^2 = 4T_o(\sigma + T_o) \tag{10.7.2}$$

where τ is shear stress, σ is normal stress, and T_o is tensile strength. Flaws or discontinuities can be tested to determine a similar strength envelope that will also usually be linear in the low-stress portion that is typically of interest. Fig. 10.7.2 illustrates a shear strength envelope for discontinuities.

Fig. 10.7.3 shows a graph of the combined rock substance (or intact rock) and discontinuities envelopes (Kendorski, 1977). In laboratory testing of intact rock, or in situations where the rock is not flawed by discontinuities, the mine rock will follow the upper envelope. When discontinuities totally control failure, such as the rock mass sliding along a large joint into a pit, the lower envelope is followed. Most rock masses, however, will behave in some intermediate fashion, with some failure along discontinuities, and some failure through intact rock. Fig. 10.7.3 also shows such an intermediate case where the rock has been restrained in some way to prevent loosening and block movement that would result in progressive failure along discontinuities only.

10.7.2.2 Rock Mass Strength

One of the greatest continuing problems in geomechanics is the manner in which to describe the strength properties of a rock mass consisting of intact rock (or rock substance) and pervasive discontinuities. Unfortunately, such rock masses are the norm in rock excavations. There is often considered to be a scale effect in rock mass strength—that is, the strength decreases as the volume of the rock mass increases. However, this scale effect is really a reflection of the fact that as the volume increases, the probability of discontinuities being incorporated into it increases. (Using the weakest link principle, the larger the number of discontinuities, the smaller the rock mass strength is likely to be.) A number of methods have been proposed for characterizing the rock mass strength (see Chapter 10.5 for a full discussion of these). They can be summarized as follows:

1. *Semi-empirical Scaling.*

For massive, elastic rock:

$$S_p = S_1(0.778 + 0.222\ W/H) \tag{10.7.3}$$

(Obert and Duvall, 1967)

For massive, brittle rock:

$$S_p = S_1 W^{0.5}/H^{0.75} \tag{10.7.4}$$

(Hedley and Grant, 1972)

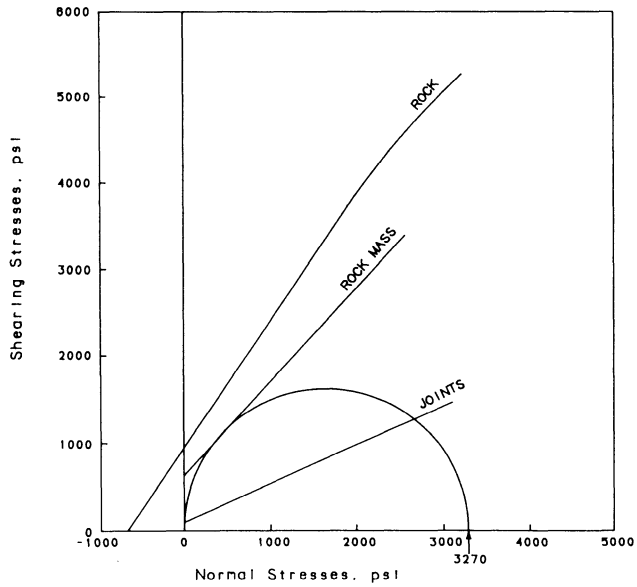

Fig. 10.7.3. Failure envelopes for intact rock and discontinuities and for failure intermediate between intact rock and discontinuities. Conversion factor: 1 psi = 6.895 kPa.

For coal:

$$S_p = S_1 W^{0.5}/H \qquad (10.7.5)$$
(Holland, 1974)

$$S_p = S_1 W^{0.46}/H^{0.66} \qquad (10.7.6)$$
(Salamon and Munro, 1967)

$$S_p = S_1(0.64 + 0.36W/H) \qquad (10.7.7)$$
(Bieniawski, 1984b)

$$S_p = S_1/H^{0.36} + amc\gamma h(W/H\text{-}1) \qquad (10.7.8)$$
(Sheorey et al., 1987)

where S_p is rock mass strength, S_1, is strength of a cube of intact rock (usually of a specified edge dimension), W is pillar width, H is pillar height, h is depth of cover, g is unit weight of the rock, m is ratio of the primitive stresses, c is a constant accounting for end effects, and a is a triaxial parameter. (Note that the formula given by Obert and Duvall for massive, elastic rock was initially applied by Bunting (1911) to design of pillars in anthracite coal mines.)

2. *Confinement Effect* (Wilson, 1972).

$$L = \sigma_v[WL - (W + L)y + 4y^2/3] \qquad (10.7.9)$$

a. $\sigma_v = \sigma_o + m\gamma h \tan\beta$
b. $y = H \ln(\sigma_v/\sigma_o)/[(\tan\beta)^{0.5}(\tan\beta\text{-}1)]$
c. $\tan\beta = (1 + \sin\phi)/(1\text{-}\sin\phi)$

where W is pillar width, H is pillar height, h is depth of cover, g is unit weight of the rock, ϕ is angle of internal friction of intact rock, m is ratio of the primitive stresses, L is length of the longer side of a rectangular pillar (= W for a square pillar), and σ_o is unconfined compressive strength.

3. *Partitioning* (Kendorski, 1977).

$$S_r = 2(c_f + R(c_r - c_f))\tan(45 + \phi_m/2) + \sigma_3\tan^2(45 + \phi_m/2) \qquad (10.7.10)$$

in which

$$\phi_m = \arctan(\tan\phi_r + R(\tan\phi_r - \tan\phi_f))$$

and where c_r is cohesion of intact rock, c_f is cohesion of discontinuity, ϕ_r is angle of internal friction of intact rock, ϕ_f is angle of internal friction of discontinuity, R is the fraction of intact rock present on a potential failure surface (balance is discontinuity), σ_3 is minimum principal stress, and S_r is rock mass strength.

(Note: The serious reader is strongly advised to consult the original references, or Chapter 10.5, before using these formulas.)

For some purposes, especially numerical modeling, it has been found useful and reasonable to "arbitrarily" discount the rock strength and other laboratory-derived properties, such as elastic moduli, by 40 to 60% to accommodate the rock-mass field situation. Models where this has been done give a reasonable approximation to the measured behavior in the field. The methods given here (Eqs. 10.7.3 through 10.7.10) also usually result in a discounted strength in the 40 to 60% range.

This discussion highlights the importance to the rock mass strength of the intact rock. The frictional properties of the discontinuities impart little strength to the rock mass and represent the lower bound to the rock mass strength. The rock mass integrity must be preserved as much as possible if the rock mass strength is to be effectively mobilized. The deterioration of rock-mass strength as the rock mass deforms is a time-dependent phenomenon, so that the integrity of the rock mass can be preserved by early application of reinforcement, restraint, support, or other measures. As the rock mass deformation increases in response to imposed loads or strains, the strength lessens, and it is essentially impossible to regain the lost strength or undo the deformations. Ultimately, an unrestrained rock mass will progressively deteriorate until it is composed of detached or loosened blocks bounded by discontinuities, and has reached the lower bound of its strength.

The so-called "New Austrian Tunneling Method" (NATM) uses this concept as its key in order to apply exactly the restraint needed at the right time, as determined by field measurements and observation. The "key block" concept (Shi and Goodman, 1981; Goodman, Shi, and Boyle, 1982) shown in Fig. 10.7.4 also uses the principle of preserving the rock mass integrity by determining the location and orientation of key blocks that, when restrained, prevent progressive deformation in the rock mass. The beauty of this concept is that the restraining effort is minimized, but the drawback is that it must be accurately determined at the moment of excavation. Yow (1985) discusses

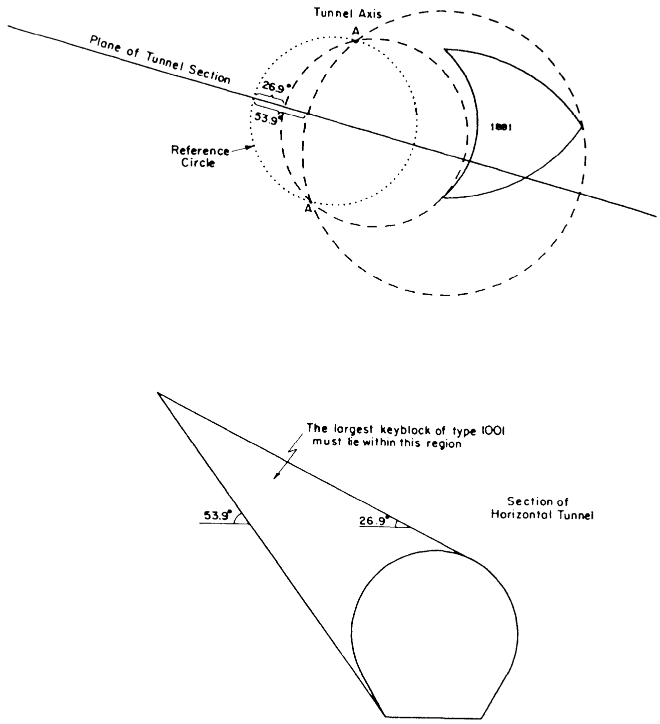

Fig. 10.7.4. The "key block" concept (Shi and Goodman, 1981).

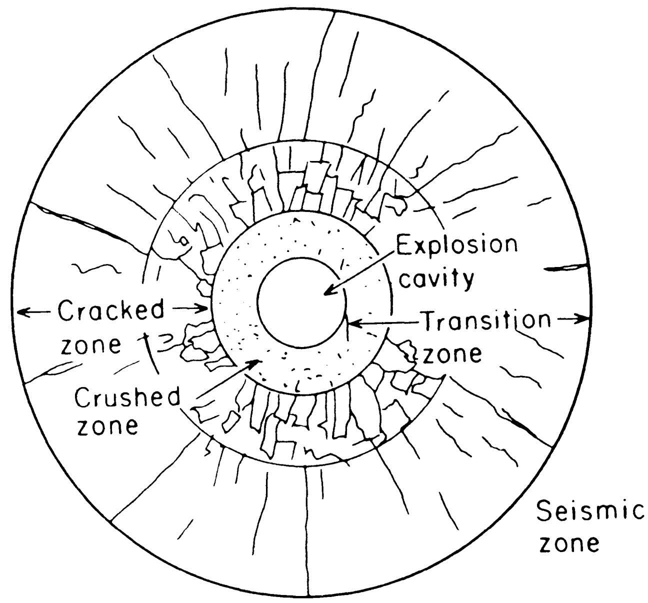

Fig. 10.7.5. Crushing of the rock mass adjacent to a blasthole by the blast-generated shock wave (Atchison, 1968).

key block stability calculations and presents computer programs for two- and three-dimensional analyses.

In underground situations, rock reinforcement restrains the rock mass and preserves its integrity through several mechanisms: pressure to keep loosening blocks in place, suspension of loosening strata, and reinforcement across discontinuities tending to slip. In surface excavations, rock anchors or tendons act in a similar manner, although long bars or tendons can also apply active forces to decrease sliding (Hoek and Bray, 1974; Seegmiller, 1982).

10.7.2.3 Blasting Effects

Mechanism of Fracture. The blasting process consists of several events that can damage the rock mass and lead to a loss of its integrity. When explosives or blasting agents are detonated, a shock wave is generated that progresses out from the blast location into the surrounding rock (see Chapter 9.2.1). This shock wave will locally crush the rock (Fig. 10.7.5) and was once thought to be solely responsible for fracturing near free surfaces. However, recent research has shown that such fracturing is caused by the expansion of compressed gases formed from the explosive reaction. The gases expand as they depressurize and, in doing so, create cracks and expand existing ones. Atchison (1968) has explained (Fig. 10.7.5) how the rock adjacent to the blasthole is damaged. Holmberg and Persson (1979) have shown how the rock much further away can be damaged by confined shots. The rock mass integrity can be preserved, when blasting, by two methods: presplitting and trim blasting.

Presplitting. In presplitting, small-diameter, lightly loaded holes are detonated at the perimeter of the desired excavation prior to the remainder of the blast, in order to presplit the rock mass and to provide a plane that the rock failure can progress to but not pass. The holes must be sufficiently loaded to allow gas-produced cracks from adjacent holes to connect. Cracks will, of course, extend in other directions, and damage to the rock mass from presplitting has been observed on numerous occasions—Hoek and Bray (1974), Herget (1972), and Oriard (1972) have all reported such instances. Thus great care must be taken in its design and application.

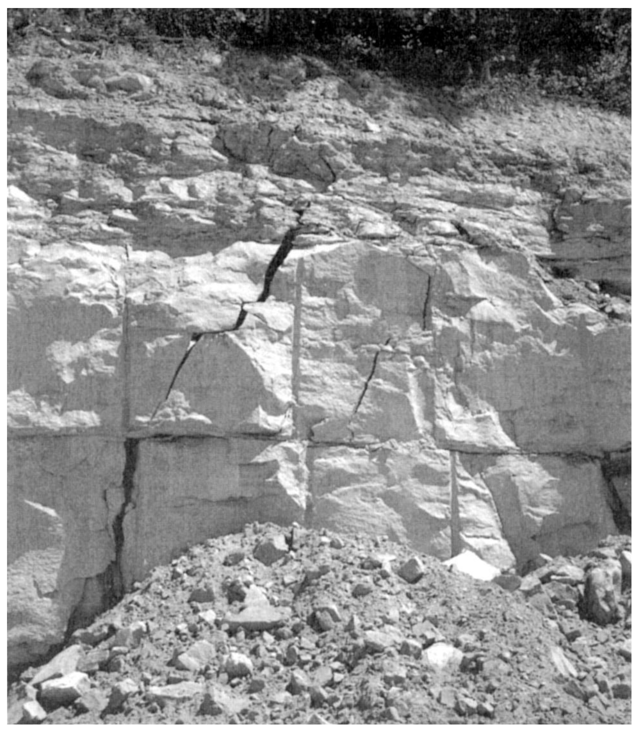

Fig. 10.7.6. Coal strip mine highwall severely damaged by blasting.

Trim Blasting. Trim blasting is essentially the reverse of presplitting. Perimeter holes (smaller or the same size as the holes for the main blast) are drilled and loaded, but are not detonated until after the main round. The holes are more closely spaced than in the main round; however, the explosives load in the holes is reduced and may be partially decoupled from the rock mass. Because of the light load, decoupling, and late firing, the rock slabs off the excavation perimeter, minimizing the damage to the surrounding rock.

Movement of Blasted Rock. The movement of the blasted rock can also damage the remaining rock mass, especially in surface mining. Fig. 10.7.6 shows a coal strip mine highwall severely damaged by the rock being forced to move along the slope face, rather than away from it. The dragging and tearing action has pulled apart the rock mass, weakening it, and causing it to lose its integrity.

10.7.3 STATE OF STRESS IN SITU

10.7.3.1 Causes and Estimation

The state of stress in the rock mass is extremely important, as it drives the rock deformations in response to excavation (see Chapter 10.2). Rock stress is a consequence of gravity, tectonic activity, or post-glacial isostatic rebound. The rock stress will be perturbed by excavation activity, and by rock damage from blasting or other destructive activities (e.g., hydraulic fracture stimulation for solution mining and oil and gas production).

Vertical Stress. In general, rock has a unit weight of about 160 lb/ft^3 (2560 kg/m^3), which results in a superincumbent load of 1.1 psi/ft of depth below the surface (0.025 MPa/m of depth). This relation provides a good estimator for the vertical stress in most cases—exceptions are areas with hill-and-valley topography, and, in some cases, areas of tectonic activity.

Horizontal Stress. For the horizontal, or confining, stress, the situation is considerably more complicated. According to elasticity theory, the confining stress is related to the superincumbent load (vertical stress) through the following formula:

$$\sigma_h = [\nu/(1 - \nu)]\sigma_v \qquad (10.7.11)$$

where ν is Poisson's ratio, σ_v is vertical stress, and σ_h is horizontal or confining stress. Although Eq. 10.7.11 has traditionally been used to estimate the horizontal stress, its use should be limited to areas where tectonic activity, post-glacial isostatic rebound, and major faulting are absent. Where tectonic activity or post-glacial isostatic uplift has occurred (or is occurring), and in areas where there is faulting, the horizontal stresses can considerably exceed the vertical stress. In bowl-shaped sedimentary basins, although the horizontal stress may be less than the vertical, it can, at the same time, be greater than the stress predicted by the above formula. Thus the situation assumed by Eq. 10.7.11 is the exception rather than the rule, and indiscriminate use of that formula, especially in designing tunnel supports, can lead to failures.

General Guidelines for In Situ Stress Estimation. Abel (1983) has provided a general guide for estimating the stress state in rock masses from which the following is synopsized:

1. Igneous and metamorphic rock types: high horizontal stresses probable.
2. Sedimentary rock type: high horizontal stresses possible.
3. Faulting nearby in igneous rocks: maximum stress approximately parallel to fault strike.
4. Faulting in nearby sedimentary rocks: maximum stress parallel to line of intersection between fault plane and bedding.
5. One dominant joint set: maximum stress lies in plane of joint set; minimum stress perpendicular to it.
6. Orthogonal joint sets: maximum stress parallel to line of intersection of the two most prominent joint sets; minimum stress perpendicular to most prominent set.
7. Pervasive foliation in metamorphic rocks: maximum stress lies in the plane of the foliation.

Formulas for In Situ Stress Estimation. Hoek and Brown (1980) have provided limits for the ratio of the horizontal to vertical stresses based on numerous field measurements in several continents, as follows:

$$100/h + 0.3 \leq K \leq 1500/h + 0.5 \qquad (10.7.12)$$

where K is ratio of horizontal to vertical stress, and h is depth in meters.

For the Canadian Shield, Herget (1980) has found the following relationships for the vertical and horizontal stresses:

$$\sigma_v = 0.0243h \text{ MPa } [\sigma_v = 1.074H \text{ psi}] \qquad (10.7.13)$$

a. 0-900 m depth: $\sigma_{ha} = 9.86 + 0.0371h$ MPa
[0-2953 ft depth: $\sigma_{ha} = 1430 + 1.64H$ psi]
b. 900-2200 m depth: $\sigma_{ha} = 33.41 + 0.0111(h\text{-}900)$ MPa
[2953-7218 ft depth: $\sigma_{ha} = 4844 + 0.486(H\text{-}2953)$ psi]

where h is depth in meters, H is depth in ft, σ_v is vertical stress, and σ_{ha} is average horizontal stress. Measurements by others have shown that Herget's relations are generally valid for formerly glaciated portions of eastern North America, including the Great Lakes Basin. (Note: Herget's relationship for vertical stress approximates the value using the superincumbent load. Also the lower limit for depth for the horizontal stress relations is the greatest depth at which measurements have been made.)

In situ stress is difficult to measure accurately, due to the basic physical principle that the act of measurement disturbs the measuring environment. The drilling of a hole to access the rock mass disturbs it and perturbs the stress field, as would driving a drift for access, or excavating a cut. Further, the fracturing usually present in a rock mass results in local rearrangements and variations in the stress field that are being measured by small instruments. Measurement of the in situ stress in the rock mass is, nevertheless, important for mine design.

Methods of measurement consist of (1) measuring the change in dimension of a stress-relieved rock mass, (2) measuring the pressure required to restore the rock mass to its near-initial position, or (3) measuring the pressure required to overcome the stress and fail the rock internally. The different methods include flat-jacks, borehole deformation strain cells, doorstopper gages, inclusion strain cells, inclusion stress meters, and hydraulic fracturing.

In situ stress measurements are dealt with in Chapter 10.3.

10.7.3.2 Effects in Surface Mines

Effects of in situ stress in surface mines arise from abnormally high stresses. As the rock is excavated, the weight of the rock is removed, and the remaining rock in the walls and the floor rebounds and deforms into the excavation. The result is loosening of the rock and, in competent strata, uplift and detachment of the immediate floor. The effect on the rock mass has also been noted as an increase in water-well yield near surface mines that is attributable to stress relief in the rock mass and the consequent opening of fractures in aquifers (Robertson et al., 1980). In mid-continental United States, it is common for the floors of quarries to be humped up and fractured in the center, due to this rebound effect. In New England granite quarries, the

Table 10.7.2. Stress Concentrations Around Openings Under Uniaxial Vertical Stress

		Stress Concentration (σ/σ_v)	
Shape	Height/Width	Roof	Side
Ellipse	0.5	−1.0	5.0
Oval	0.5	−0.9	3.4
Rectangle (round corners)	0.5	−0.9	2.5
Circle	1.0	−1.0	3.0
Ellipse	2.0	−1.0	2.0
Oval	2.0	−0.9	1.6
Rectangle	2.0	−1.0	1.7

floor may suddenly pop up due to high horizontal stresses and the relief of overlying weight (Obert and Duvall, 1967).

10.7.3.3 Effects in Underground Mines

In unsupported mines, particularly room and pillar mines, stress effects are manifested by stress-relief phenomena such as pillar slabbing and floor heave. In a 1200-ft (370-m) deep Gulf Coast underground salt mine, where the senior author was once employed, when subjected to little traffic, the floors of rooms would spring up, and a salt layer about 3 in. (7.5 mm) thick would detach leaving a small air-gap beneath. Walking on the floor was similar to walking on the skin of a drum, complete with booming steps and vibrations. High horizontal stresses can result in the roof failing by popping down or shearing—the roof strata act similar to a fixed-end beam subject to a lateral load, and deflect downward and fail.

Lack of stress due to the topographic or tectonic setting, or shallowness, can also lead to problems in unsupported mine roofs because roof strata tend to sag under their own weight when unsupported, and the stress level may be insufficient to counteract this downward movement. Natural fractures in the roof (or new fractures) will open because they are not held together, resulting in a roof fall. If stress is lacking in one direction, such as perpendicular to a mountainside, the roof fractures parallel to this direction will open and lead to failures.

In more highly stressed rock, or in rock that has had its stress increased by a high extraction ratio, deformation and failure will eventually occur. This is especially true near the corners of square and rectangular openings whose corners are sharp. Goodman (1980) and Duvall (1976) provide stress concentration factors for some typical opening shapes under a uniaxial, vertical stress. Although this stress state is unrealistic, it is, at the same time, instructive; hence, these factors are presented in Table 10.7.2.

Bray (1967) and Goodman (1980) provide a means of calculating the distance from the center of a circular opening in weak or ubiquitously fractured rock (subjected to an isotropically lithostatic stress field) to the boundary between the "plastic zone" of failed rock and the intact rock beyond, as follows:

$$R = a[(2\sigma_o - S_c + (1 + \tan^2(45 + \phi/2))S_j\cot\phi_j)/[1 + \tan^2(45 + \phi/2)(p_i + S_j\cot\phi_j)]^{1/Q} \qquad (10.7.14)$$

in which:

$$Q = [\tan(45 + \phi/2)/\tan((45 + \phi/2) - \phi_j)] - 1$$

and where a is radius of the circular opening, σ_o is primitive stress ($= \sigma_v$), S_c is unconfined compressive strength of the intact rock, S_j is cohesion of the joints, p_i is the support pressure provided to the walls of the opening by internal supports, ϕ is angle of internal friction of the intact rock, and ϕ_j is angle of internal friction of the joints. Although there are many idealized assumptions inherent in Eq. 10.7.14, it is useful for approximating the effects of stress state, rock strength, support pressure, and rock bolt lengths in fractured ground. Goodman (1980) provides estimates of support pressure p_i for typical support methods, as follows:

1. Rock bolts: 0 to 80 psi (0 to 0.6 MPa)
2. Shotcrete: 50 to 200 psi (0.3 to 1.4 MPa)
3. Steel sets: 0 to 400 psi (0 to 2.8 MPa)
4. Concrete lining: 100 to 500 psi (0.7 to 3.5 MPa)
5. Steel liner plates: 500 to 3000 psi (3.5 to 21 MPa)

Rock-bolt support pressures may be found by determining the yield strength of the chosen bolt in pounds and dividing by the square of the bolt spacing in inches (if a square pattern). For instance, number 5 (5/8-in. or 16-mm diameter), grade 36 rebar has a yield strength of 11,000 lb (76 MPa) ($36{,}000[\pi(0.625)^2/4]$) and with a 5-ft- (1.5-m-) square spacing has a support pressure of $11{,}000/(5 \times 12)^2$ or 3.06 psi (21 kPa).

10.7.4 SOIL/ROCK INTERACTIONS

10.7.4.1 Mixed Failure Modes

Soil and rock are very different materials. The key differences lie in the physical properties. Soils are generally unfractured—exceptions are near-surface clays. Most soils are cohesionless, or have small amounts of cohesion. Unlike rocks, soils do not "bulk" to a significant extent when disaggregated or dug. On the other hand, some "rocks" behave much as do soils. Deeply weathered rocks—sedimentary, igneous, or metamorphic—can behave just as soils do. Indeed, the authors are familiar with a "granite gneiss" in northwestern New Jersey that failed as a soil slope, but examination of the failure area backwall revealed all of the "crystal structure," "joints," and "veins" (Kendorski and Pincomb, 1991). In another instance in Colorado, triple-tube coring successfully cored highly altered rhyolite porphyry sills that looked just like wet rock cores when removed from the inner barrel, but could be squeezed in the hand like mud. Kendorski, Myers, and Grenot (1990) describe a highly weathered soil-like shale that underlies unaltered quartzite, yielding a mixed-mode situation.

The line between rock and soil is blurred. Neither properties alone nor genesis decide, because sedimentary rocks are consolidated soils whereas soils are decomposed or disaggregated rock. Farmer (1983) makes a distinction as follows:

> "Both rocks and soils are made up of mineral and organic particles. In the former, the particles are generally bonded or cemented together and an initial yield resistance must be overcome before they shear in an unconfined state. Soils exhibit no *real* resistance to shear in an unconfined state, and a very small energy input is required to precipitate breakdown." [emphasis in original]

Where soils overlie rock (the usual case), rock slope failures can trigger soil failures or extend into soil slopes. A wedge-type failure in rock becomes a slip-circle or single-plane failure when extended into soil.

In a streetcar tunnel in San Francisco, Kendorski (1982) found that a concrete-timber lining had failed in a peculiar way at the quarter-point on the upper arch as a result of a sloping rock/soil interface that dipped across the tunnel while the tunnel followed its strike. The two different materials applied two entirely different loads to the tunnel lining, which had been "designed" in 1913 to accept uniform loads. The failure occurred shortly after construction, but did not hinder the tunnel performance until federal funding in 1975 required the structure to be upgraded to current standards.

The case presented by Kendorski, Myers, and Grenot (1990) is an interesting one in that the formations dipped at 70° with quartzite overlying deeply weathered shale. When the quartzite was exposed, the rock slope behaved as a slope in rock, with planar failures. When the shale was exposed, usually after collapse of the quartzite, the rock slope behaved as a soil slope, with slip-circle failures. With both materials present, a certain minimum thickness of quartzite must be left in place to prevent the shale behind it from pushing out the quartzite and causing failure in both.

When drawing ore underground, or in sinkhole development during subsidence, the soil properties of minimal bulking and little or no shear strength lead to flooding of soil downward, because soil flow will not stop until the collapsed area has been filled. In rock, the 40% or so volume increase upon breakage will limit progressive collapse because the bulked rock fills the void, providing support against further collapse.

Mixed failure modes result from rock and soil in contact subjected to the same excavation or to the consequences of failure of one material affecting the other. Rock will behave as a rock; soil will behave as a soil. The effects of minimal bulking and little or no shear strength in soil as compared to substantial bulking and significant shear strength in rock is profound. As the previous case histories illustrate, the designer must recognize the likely failure modes and consequences of failure in the design. Recognition of the failure mode (or modes) is the key, because then design can proceed rationally.

10.7.4.2 Mixed-face Excavation

Mixed-face excavation represents an important problem because a combination of excavation and support techniques must be employed. The magnitude of the problem depends on the relative proportions of hard and soft materials encountered, and whether the soft material lies above or below the hard material. Moreover, the problems facing a geomechanics practitioner are different for surface and underground excavations, and will, in what follows, be dealt with separately.

Mixed-face Surface Excavations, In surface excavations, the critical factor is the stability of the excavated slope. In general, the soil will overlie the rock in the excavated face (unless the "soil" is gouge in a shear zone), in which case, the simplest strategy is to excavate the soil before beginning rock excavation.

The best method for excavating the soil in a given situation depends on a number of factors including the topography, type of soil, and groundwater conditions. A detailed discussion of the types of excavating equipment available and the advantages and disadvantages of each is beyond the present scope. For such information, the reader is referred to Nichols (1976), Church (1981), or Peurifoy and Ledbetter (1985). Design slopes should not exceed 1.5:1 (horizontal to vertical). In addition, a 50-ft (15-m) berm should be left between the toe of the soil slope and the crest of the rock slope at the top of rock.

In cases where the soil layer underlies a rock stratum, the situation is more complex, and a detailed slope stability investigation is advisable. The critical elements are the attitude and shear properties of the soil layer and the inclination of the final slope (Kendorski, Myers, and Grenot, 1990). For methods of slope stability analysis the reader is referred to Chapter 10.4 and to slope stability monographs such as *Rock Slope Engineering* (Hoek and Bray, 1974).

Mixed-face Underground Excavations. The underground excavations most likely to encounter mixed-face conditions are shallow tunnels. Mixed faces occur as a result of intersecting (1) seams of decomposed rock, (2) ancient erosion surfaces (usually river or stream beds that have filled with sand, gravel, or clay), (3) fault zones, and (4) different strata (if the dip of the strata is in the direction of tunnel advance). If the top of the excavation is in soft ground and the bottom is in rock, the result is one of the most difficult excavation situations that can be encountered—considerably more difficult than if the excavation were completely in soft or hard ground (Wilbur, 1982).

When a mixed face is encountered in a rock tunnel, excavation and support methods must usually be radically revised. The most difficult problems arise when a mixed face is encountered in a machine-driven excavation, because machines designed for hard rock generally do not work in soft ground. Furthermore, the very fact that a machine is being used implies that the mixed-face conditions were unexpected. As a result, long delays can be expected while the machine is removed and other methods of excavation are substituted. Worse, if the tunnel is being excavated by a contractor, large claims for changed conditions can be expected.

The situation is considerably simpler if mixed-face conditions are anticipated during the exploration phase. In this case, borings should be used to attempt to locate potential mixed-face zones. During excavation, exploratory drillholes should be carried ahead of the face as suspected mixed-face zones are approached.

Excavation and support of soft ground in the crown of a mixed-face tunnel should utilize the same techniques that would be used if the complete face were in soft ground. The critical consideration is whether the soft ground is dry or wet. If the ground is dry, temporary support consisting of steel poling plates, spiling, or a shield can be used to hold the crown until more permanent support such as liner plates or ribs and tight lagging can be installed. If the ground is wet, such methods can also be used if the soil can be consolidated by dewatering or grouting. Freezing may be practical in wet, running sands, whereas in wet, running, fine sands and silts, shield tunneling under compressed air may be necessary. In all cases, care must be taken when excavating the rock portion to ensure that the integrity of the soft-ground and its support is not compromised.

10.7.5 SPECIAL TOPICS

10.7.5.1 Problems at Great Depth

Definition of Great Depth. From a geomechanics standpoint, *great depth* refers to distances below surface where creation of an opening results in an overstressed condition in the surrounding rock, resulting in failure or yield. Thus the depth at which a mine may be considered deep depends on the strength of the rock mass. In very strong, brittle rocks such as metaquartzites or granites, mines are not generally considered deep until their workings extend 6000 ft (1800 m) or more below surface. Mines in this category include gold mines in South Africa, India, and Ontario, silver mines in Idaho, and nickel mines in Ontario. By contrast, coal and salt rock mines can be considered deep when they extend more than 1500 ft (450 m) below the surface. For mines in rock intermediate in strength, the criterion for a deep mine lies somewhere between these two extremes.

Geomechanics Behavior in Deep Mines. Openings in "deep" mines in weak, ductile (or pseudo-ductile) rocks, such as salt rock, shale, or bituminous coal, are characterized by viscoplastic (or pseudo-viscoplastic) deformation of the surrounding rock. This behavior serves to mitigate the effects of the high stresses. In strong, brittle rocks, however, strain energy resulting from excavation is not dissipated through viscous flow, but is stored in the rock until a limit is reached at which failure occurs in an explosive manner. Such explosive failures, which are called rockbursts, are small-scale seismic events—micro-earthquakes, if you like—and, like earthquakes, are accompanied by emission of acoustic energy. It is this behavior of strong, brittle rocks under large stresses that is generally associated with the phrase "problems at great depth." (Note: where extraction ratios approach 100%, rockbursts can occur at relatively shallow depths due to catastrophic failure of improperly designed pillars.) Hence the discussion hereafter will concern the causes and control of rockbursts.

Brief History of Rockburst Problems. As early as 1900, rockbursts had become a serious problem on the Kolar Gold Fields in India (Taylor, 1963). In South Africa, the first instance of earth tremors attributed to mining occurred in 1908 (Anon., 1977), although doubtless small bursts that were not felt at surface had occurred in the mines at a somewhat earlier date. Commissions were appointed to study the problem in South Africa in 1908, 1915, and 1924. The 1908 and 1915 Commissions attributed the cause to failures in support pillars and remnants. The 1924 Committee did not discuss the causes but rather directed attention to control methods and potential mechanisms. Even at such early dates, there was an awareness that the problem was related to the sudden release of strain energy (Anon., 1977).

In Ontario, rockbursts first occurred in 1928 or 1929, but their occurrence did not become a cause of anxiety until 1934. In 1940, R.G.K. Morrison, then superintendent of a Kolar gold mine in India, was engaged by the Ontario Mining Association to study the rockburst situation in Ontario. His report (Morrison, 1942) remains a classic discussion of the problem. In the Coeur d'Alene district in Idaho, rockbursting was first reported in 1956 (Blake, 1972a).

In spite of the early recognition of the problem, and the evident early qualitative understanding of the mechanism, it is only in the past 25 years that numerical stress analysis methods have been developed to evaluate the problem. Nevertheless, the early attempts to develop rockburst mitigation and control methods demonstrate considerable insight. The salient features of these attempts are the recommended modifications to mining methods and layouts, many of which remain valid. The use of longwall mining, and the minimization of the number of pillars and remnants, practices useful in mines having flat-lying or shallow-dipping orebodies, were proposed in South Africa as early as 1924 (Anon., 1977), and longwall mining was introduced on Crown Mines about 1930 (Pretorius, 1975) and on East Rand Proprietary Mines about 1940 (Ortlepp and Steele, 1975). For steeply dipping ore bodies, longwall mining is impractical, and other measures related to stope sequencing were proposed. These latter recommendations can be found in Morrison (1942). Oliver (1975) has demonstrated the effectiveness of these practical measures over a period of more than 30 years in the mines of INCO Metals Ltd. in the Sudbury District, Ontario.

Prediction of Rockburst Potential. The most important consideration in evaluating rockburst potential is the amount of energy released in connection with specific changes in mining geometry (Salamon, 1974, 1983). The energy quantity to be expended is the sum of the change of potential energy due to displacement of the perimeter of the opening, and the strain energy stored in the rock removed in the particular mining step. Part of this energy is accounted for by an increase in the energy stored in the surrounding rock. In supported excavations, some of this energy is also dissipated in deforming the supports. The change in excess energy due to a particular change in mining geometry is given by (Salamon, 1974, 1983):

$$\Delta W_r = \Delta U_m = (\textstyle\int_{\Delta A} T_i^{(p)} \Delta s_i dA)/2 \tag{10.7.15}$$

where ΔW_r is change in excess energy, ΔU_m is change in strain energy stored in rock removed by mining, $T_i^{(p)}$ is traction vector in the initial state acting on the surface A_m to be exposed by mining, Δs_i is change in the relative displacement (closure or ride) vector, and A is mined-out area of the stope.

The potential for rockbursting is minimized by minimizing the energy release rate, which is defined by (Salamon, 1984) as:

$$ERR = \Delta U_m/\Delta A \tag{10.7.16}$$

where ERR is the energy release rate, and the other variables are as defined previously. From Eq. 10.7.16, it is apparent that for a fixed volume of rock broken per round (ΔA), reduction in the energy release rate requires reduction of the change in excess energy associated with the mining step. From Eq. 10.7.15, this reduction can be accomplished by reducing either (1) the relative displacement or (2) the stress concentration at the surface to be exposed. The first step, therefore, is to evaluate the stresses and displacements due to several alternative mining sequences, choosing the one that minimizes the change in excess energy. Further reduction can be obtained through the use of backfill (provided the backfill is kept close to the face) as fill reduces the closure. In theory, the stiffer the fill (i.e., the higher the deformation modulus), the greater is the effectiveness; and a number of papers have been published (Van Eeckhout, 1984; Stout and Friel, 1980) that advocate stiff fills that are essentially lean, unreinforced concretes. Nevertheless, a contrast exists between the deformation modulus of the fill and that of the surrounding rock, and because of this contrast, very little of the stress is transferred from the surrounding rock to the fill, regardless of the stiffness of the fill. (A significant stress transfer might only occur if the opening were backfilled with fitted blocks of the original rock, as was once the practice in Cornwall, England, and on the Kolar Gold Fields). Moreover, because the rocks are elastic and brittle, the deformations are small unless failure has occurred so that greater reductions in energy are likely through reduction of the stress concentration by destressing. Destressing is as yet an art rather than a science, and is generally accomplished by extending drillholes some distance beyond the mining face, and blasting with spherical charges at the bottom of the holes. This practice has been used with apparent success at a number of mines including the Galena mine on the Coeur d'Alene (Blake, 1972b; Anon., 1979) and deep gold and nickel mines in Ontario (Anon., 1979). For more information on rockburst control, consult the various *Proceedings of the Symposium on Rockbursts: Prediction and Control.*

Detection of Strain Energy Buildup. Buildup of stored strain energy is accompanied by acoustic emissions. Thus microseismic monitoring systems can indicate if energy is building to potentially unsafe levels. Through the use of a multichannel system with accelerometers arrayed throughout the mine, the location of events can be determined. Event location algorithms have been discussed by Eccles and Ryder (1984), and recently a different approach based on the simplex algorithm has been proposed by Riefenberg (1989). Design criteria for monitoring systems have been discussed by Blake (1979, 1984), among others. For more information on rockburst detection, see the *Proceedings of the First International Symposium on Rock Bursts and Seismicity in Mines.*

10.7.5.2 Effects of Method of Excavation

The process of excavation results not only in the removal of rock, thereby creating an opening, but also in damage to the surrounding rock. Different methods of excavation have varying effects, and in situations where preservation of the integrity of the adjacent rock is of paramount importance, the method of excavation must be selected with the consequent damage in mind.

With normal blasting practices, the rock can be damaged (i.e., fractured and weakened) to a depth of 10 to 15 ft (3 to 4 m). This damage is caused by compressed gases in the blastholes that propagate cracks in the surrounding rock. By partially or fully decoupling the explosive from the blasthole, the detonation pressure is reduced, with a consequent reduction in the thickness of the damaged skin of rock. Blasting studies have shown (Hansen, 1976) that complete fracturing of a rock mass occurs for peak particle velocities (ppvs) in excess of 100 in./sec (2.54 m/s). For depths into the rock greater than about 3 ft (1 m), the ppv can be found from scaled-distance relationships. The following relationship has been found to give an upper bound to the ppv for blasts using cylindrical charges (Hendron and Oriard, 1972):

$$v = 130\ (R/W^{1/2})^{-1.57} \qquad (10.7.17)$$

where R is distance from the blasthole in ft, and W is charge weight per delay in lb. Similarly, a lower bound for ppvs from blasts in cylindrical holes is given by Dowding (1985):

$$v = 25\ (R/W^{1/2})^{-1.57} \qquad (10.7.18)$$

For most rocks, the actual ppv will fall within these limits. Substituting v = 100 in./sec (2.54 m/s) into Eqs. 10.7.17 and 10.7.18, and rearranging, we obtain a range of:

$$0.11\ W^{1/2} \leq R \leq 1.51\ W^{1/2} \qquad (10.7.19)$$

for the predicted limit of the depth of damaged rock. By substituting the charge weight per delay (in lb) for a particular blast into equation 10.7.19, the predicted depths of failed rock (in ft) for that blast can be found.

With mechanical excavation, the depth to which damage extends is much smaller. The reason is that the pressure applied to the rock is much smaller than the explosive detonation pressure, and there are no gases that need to expand to reduce their pressure. For roadheaders, the stress on the wall can be calculated from the Boussinesq solution for a force applied normal to a semi-infinite plane, if the normal component of the cutter thrust is known. In the case of tunnel boring machines (TBMs), and full-face and transverse drum continuous miners, the stress on the wall can be calculated from the Cerruti solution for a tangential force on a semi-infinite plane, if the cutter thrust is known. (The Boussinesq and Cerruti solutions can be found in elasticity texts such as Timoshenko and Goodier [1970] or Boresi and Chong [1987].) In either case, the depth to which the thrust results in significant stress is no more than a few inches (tens of millimeters). Moreover, the stress dissipates as soon as the cutterhead has advanced as little as 1 to 2 in. (25 to 50 mm). More important in the case of mechanically excavated openings is the limit of failed rock that results from the redistribution of stress around the opening. This limit can be found from elastic/plastic stress analysis, in the case of circular openings (see Eq. 10.7.14), if the failure criterion and failure parameters are known.

From the above discussions, it is clear that mechanical excavation is preferable to blasting from a geomechanics standpoint. However, the practicability of mechanical excavation depends upon other factors such as the rock strength, the size of the opening, and the length of the heading. With the exception of TBMs, mechanical miners are limited to rocks having compressive strengths less than 15,000 psi (100 MPa). Conversely, TBMs can excavate even the strongest rocks but are not cost-effective for headings shorter than about 3000 ft (900 m). Strong but fractured rock is very difficult to excavate by TBM because rock blocks tend to fall out of the face and get caught in the cutterhead, breaking cutters off. Thus drill-and-blast excavation may be the only practical alternative. However, controlled blasting techniques can be used to minimize damage. The available controlled blasting techniques include:

1. Presplitting.
2. Post-splitting.
3. Smooth blasting (using trim powder in the perimeter holes).
4. Dental excavation (blasting small, specially designed rounds over partial faces) in extreme cases.

These techniques were discussed in 10.7.2.3, and descriptions of some or all of these techniques are readily found in blasting handbooks as well as Chapter 9.2.1. In cases of contract mining, the use of these techniques will require close supervision of the contractor in order to assure that the desired result is achieved. (One can also hedge one's bets by putting close tolerances on the pay-line that defines payment for excavation.)

10.7.5.3 Evaporites

Before discussing the behavior of evaporites and the design of openings in evaporites, we shall first define what evaporites are, and introduce the minerals that fall into this classification.

Evaporites comprise all mineral deposits that are precipitated from solutions concentrated by evaporation. Although about 80 minerals have been identified in evaporite deposits, only about a dozen are sufficiently common to constitute important rock-formers (Boggs, 1987). Evaporites can be subdivided into those of marine origin and those of nonmarine origin. If carbonates are excluded, the most common marine evaporite minerals are anhydrite and gypsum. Halite is next in abundance followed by the potash salts sylvite, carnallite, langbeinite, polyhalite, and kainite, and the magnesium salt kieserite. The order of abundance derives directly from the order in which the minerals are precipitated.

Nonmarine evaporites are characterized by minerals not commonly found in marine evaporite deposits, although anhydrite, gypsum, and halite may also be present. The nonmarine evaporite minerals include trona, mirabilite, glauberite, borax, epsonite, thenardite, gaylussite, bloedite, and nahcolite (Boggs, 1987).

Design of Openings in Salt Rock. In the limited space available here, it is not possible to provide an exhaustive discussion of the rationale for, or derivations of, the design equations that are presented in this segment. For such information, the reader is referred to the references provided as well as references cited therein. It must also be noted that all the design equations in what follows assume that the primitive stress is uniform in all directions. This assumption is reasonable in the interiors of salt domes and thick, uniform, bedded deposits, but may not be accurate near contacts with surrounding strata in such deposits or in thin bedded deposits overlain and underlain by non-salt rocks.

To begin with, salt rocks are relatively weak. The compressive strength of halite in laboratory specimens—a meaningless parameter for design, but a useful parameter for comparisons with other rocks—typically ranges from 3000 to 6000 psi (20 to 40 MPa). Sylvite and carnallite, the most common potash minerals, are weaker still. Thus openings in salt rocks are surrounded by the following four zones (in order of increasing distance from the opening):

1. Brittle failed zone resulting from dynamic excavation stresses.
2. Yielded viscoplastic zone that may not exist at shallow depths.
3. Viscoelastic zone.
4. Undisturbed quasi-elastic zone.

Isolated single openings will be surrounded by all four zones. Properly designed yielding pillars contain the first two zones, and conventional pillars (and abutment pillars bordering panels with yielding pillars) contain the first three zones. The failed zone eventually separates from the surrounding rock and thus does not contribute to the stability. Mraz (1973, 1980, 1984) has shown that this failed zone can be ignored for calculation purposes if the opening is replaced by an effective equivalent elliptical opening that circumscribes the actual opening. The semi-width and semi-height of the ellipse is given by (Hambley, 1991):

$$d^2 = x^2 + xy \tag{10.7.20}$$

$$b^2 = xy + y^2 \tag{10.7.21}$$

where d is semi-width of the effective ellipse, b is the semi-height of the effective ellipse, and x and y are coordinates of a selected "corner point." The so-called corner point is either a point on the corner of the actual opening, or a point taken a small distance radially into the rock from it to account for the damaged zone. For a rectangular opening with rounded corners, the coordinates of the corner point on the perimeter of the opening are given by (Hambley, 1991):

$$x = (W/2) - R(1 - 1/\sqrt{2}) \tag{10.7.22}$$

$$y = (H/2) - R(1 - 1/\sqrt{2}) \tag{10.7.23}$$

where H is the height of the opening, W is the width of the opening, and R is the radius of curvature of the corner.

Considering a von Mises yield criterion (von Mises, 1913; Jaeger, 1969), which assumes that the deviatoric stresses are responsible for yield, the depth of the yielded zone in the roof is given by (Hambley, 1989):

$$M_{pv} = a_v\{\exp[(3^{1/2}\sigma_o/2k - 1)/2] - 1\} + b - H/2 \tag{10.7.24}$$

where σ_o is primitive stress, k is shear strength at zero mean stress (Prandtl limit), m_{pv} is depth of the yielded zone at the midpoint of the roof, and a_v is vertical radius of curvature of the ellipse. The formula for the vertical radius of curvature of the ellipse is given in mathematics handbooks (e.g., Tuma, 1987). The above formulas assume that the opening is in an infinite mass of salt rock. If there is a competent layer in the roof at a depth less than the depth of the yielded zone calculated from Eq. 10.7.24, it will be necessary to modify the shape of the effective ellipse. Procedures for so doing are given by Hambley (1989). The stress distributions along horizontal and vertical planes are estimated using a circular approximation to the effective ellipse.

In the yielded, viscoplastic zone, the radial and tangential stresses are given by the following expressions, assuming that the von Mises yield criterion is valid (Hambley, 1989):

$$\sigma_r = (4k/\sqrt{3})\ln(r/a) \tag{10.7.25}$$

$$\sigma_t = (4k/\sqrt{3})[1 + \ln(r/a)] \tag{10.7.26}$$

where σ_r is radial stress, σ_t is tangential stress, k is the Prandtl limit (shear stress at zero mean stress), a is radius of curvature of the ellipse, and r is radius to point at which stress calculated. The Prandtl limit can be estimated from laboratory creep tests but should be confirmed by underground stress and deformation measurements. For descriptions of laboratory creep testing procedures, Dusseault et al. (1985) should be consulted. For a description of the underground verification of the Prandtl limit, the reader is referred to Mraz and Dusseault (1986).

For a single opening, the stresses in the viscoelastic zone are given by (Hambley, 1989):

$$\sigma_r = \sigma_o(1 - r_f^2/r^2) + (4k/\sqrt{3})(r_f/r)^2 \ln(r_f/a) \tag{10.7.27}$$

$$\sigma_t = \sigma_o(1 + r_f^2/r^2) - (4k/\sqrt{3})(r_f/r)^2 \ln(r_f/a) \tag{10.7.28}$$

where r_f is the radius of the viscoelastic/viscoplastic interface. Other variables are as defined previously. The radius of the interface is found from:

$$r_f = a \exp[(3^{1/2}\sigma_o/2k - 1)/2] \tag{10.7.29}$$

where all variables are as defined previously.

For pillars between openings, the size should be selected so that the viscoplastic zones around the two openings just meet at the center of the pillar if a panel mining system with yielding pillars and bordered by barrier pillars is employed. If a conventional room and pillar system without barrier pillars is employed, then there should be viscoelastic cores in the pillars. Assuming that a viscoelastic core exists and that the steady-state value of Poisson's ratio is 0.5, the stresses in the viscoelastic zone are given by (Hambley, 1989):

$$\sigma_r = [\sigma'_v\, b^2/(b^2 - r_f^2)](1 - r_f^2/r^2) + 4k\ln(r_f/a)(b^2 - r^2)r_f^2/[3^{1/2}(b^2 - r_f^2)r^2] \tag{10.7.30}$$

$$\sigma_t = [\sigma'_v\, b^2/(b^2 - r_f^2)](1 + r_f^2/r^2) - 4k\ln(r_f/a)(b^2 + r^2)r_f^2/[3^{1/2}(b^2 - r_f^2)r^2] \tag{10.7.31}$$

where b is radius from the center of curvature to the center of the pillar, and σ'_v is average pillar stress determined by tributary area (Bieniawski, 1984b):

$$\sigma'_v = \sigma_v^0\,(W + B)(L + B)/(WL) \tag{10.7.32}$$

where σ'_v is average pillar stress, σ_v^0 is primitive vertical stress, W is pillar width, L is pillar length, and B is width of the opening.

In the case of pillars, the radius of the viscoplastic/viscoelastic interface must be found by trial and error or successive approximation, using the formulas for the tangential stresses in Eqs. 10.7.26 and 10.7.31. Some researchers claim that the Tresca criterion is more representative of yield in salt rock. If the Tresca criterion (Tresca, 1868; Jaeger, 1969), which assumes that yield occurs at a critical value of the maximum shearing stress($\sigma_1 - \sigma_3$), is chosen, Eqs. 10.7.24 through 10.7.31 do not apply. Instead, equations given by Hambley and Mraz (1987) can be used for single openings.

The equations presented above strictly apply only for long rib pillars. For rectangular or square pillars, some modifications are required as shown by Hambley (1989).

Steady-State Strain Rates. At steady state, the rate-controlling mechanism in the viscoelastic and viscoplastic zones appears to be Pressure-Solution creep. The strain rate is given by (Hambley, 1991a):

$$\dot{\epsilon}_{ij} = 21\ \pi\delta D_1\Omega s_{ij}/[kTd^3] \qquad (10.7.33)$$

where $\dot{\epsilon}_{ij}$ is strain rate in the *ij* direction, δ is grain boundary width, D, is effective diffusivity of solute in the fluid, Ω is molecular volume, s_{ij} is deviatoric stress in the *ij* direction, *k* is Boltzmann's constant, *T* is absolute temperature, and *d* is grain size (diameter).

Transient Creep Behavior. During transient creep, the strain rate decreases so that a plot of cumulative closure vs. time has a logarithmic shape (see Fig. 10.7.7). Empirical relationships can be used to estimate the closure once closure data from a prototype opening having identical dimensions are available. Conversely, predictions of closure behavior based on laboratory creep tests are unreliable. Hambley (1990b) has developed a method of predicting closures that provides reasonable agreement with measured values for opening perimeters but progressively poorer agreement with borehole extensometer data as the depth into the rock increases. Because of the similarity between physical properties of salt rocks from widely different locations, this method can be used even when parameter data for a specific location are unavailable. (There is insufficient space here to present the salient features of the method. The interested reader is referred instead to Hambley [1990b].) Closure predictions are not, however, a substitute for in situ measurements; however, after closure predictions for a given opening geometry have been confirmed by measurements, the prediction equations can be used with some confidence to predict the behavior of openings of other geometries.

Design of Shafts for Mines in Salt Rock. To this point, we have concerned ourselves with the design of rooms and pillars in salt rock. However, because of the behavior and properties of salt rock, shaft design also differs considerably from that in other rocks.

In the first place, because salt rocks are soluble in water, water must not be allowed to reach the salt rock via the shafts. Hence shafts must be watertight, especially because salt rocks are generally overlain by water-bearing sedimentary rock or sediments. The most effective linings for water-bearing zones consist of either (1) concrete-backed cast iron tubbing rings, or (2) a steel-and-concrete sandwich, which is sometimes separated from a primary lining of concrete blocks by a bitumen membrane. In both cases, the lining should be supplemented by curtain grouting behind it. Procedures for designing these linings are found in Ostrowski (1972) and Link et al. (1968). One note of caution, however: the design procedures of Link et al. are based on thin-shell theory and should be checked using thick-walled cylinder formulas for composite materials if the thickness of the lining exceeds 10% of the outside radius of the excavation.

If freezing is employed during shaft sinking, the temporary primary lining must be capable of resisting the deformations and stresses in the frozen material. Failure to ensure this can have tragic consequences if the material to be frozen consists of silts or clays.

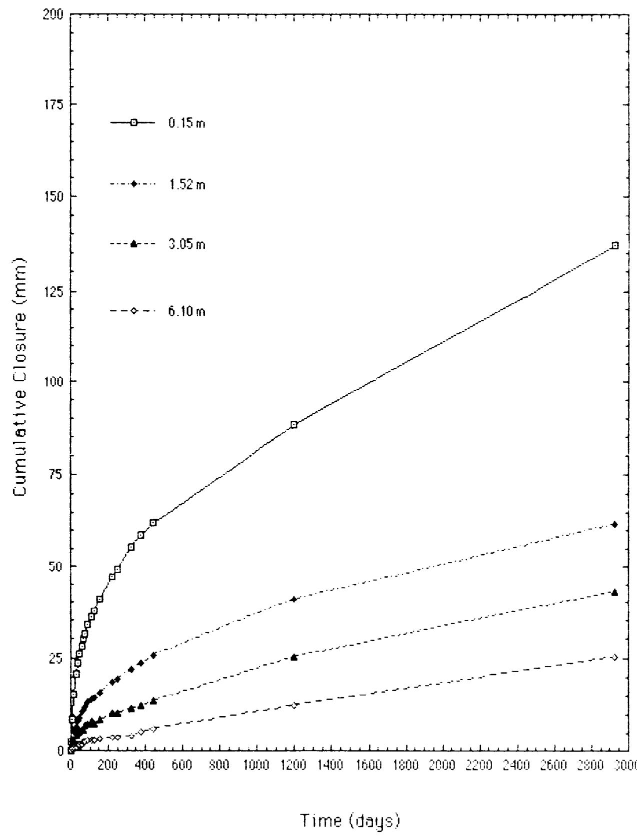

Fig. 10.7.7. Typical cumulative closure vs. time curves for extensometers in the wall of a single opening. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

10.7.5.4 Nuclear Waste Repositories

The high-level nuclear waste repositories currently under consideration in the United States resemble room and pillar mines and should be considered under these special topics. The construction and initial high-level waste placement period will extend for about 60 to 80 years. However, the engineered barrier systems must perform their functions for more than 1000 years. From a geomechanics standpoint, the critical issues are the long-term performance of the backfill and seals and the integrity of the host rock. (Design of the waste packages and their integrity under repository conditions are problems for materials scientists and corrosion engineers.) The process of predicting the behavior of the barriers under repository conditions is called *performance assessment.*

Prior to licensing of a repository, performance assessments must be able to show with "reasonable assurance" that the barrier system will provide the containment and isolation required by the regulatory authorities. Because of the time periods involved, performance assessment necessarily entails numerical modeling. The use of numerical modeling in turn spawns other issues such as the validity of the models used. The biggest problem, however, is the need to run models in which thermomechanical, hydrogeological, and geochemical effects are coupled. Moreover, our understanding of the processes in each of these areas is incomplete. Thus even with decoupled models that address thermomechanical, hydrogeological, and geochemical conditions individually, there is considerable uncertainty regarding the validity of the predictions. In spite of all efforts and progress that have been made to improve our knowledge, research needs in these areas remain considerable.

Waste repository design is discussed in Chapter 24.3.

10.7.5.5 Design Uncertainty and Risk

Unlike structural engineers who can engineer a material to provide the properties required for a particular application, an engineer designing facilities in natural materials must utilize the host rock to best advantage, taking into account its properties. He or she must design around what nature has provided, which requires, first and foremost, a thorough knowledge and understanding of the properties of the material. This requirement is further complicated by the fact that natural materials are not homogeneous— the properties will vary spatially and even temporally. (Conversely, this lack of homogeneity is the origin for economic mineral deposits. If all the elements in the earth's crust were homogeneously mixed, mining would consist solely of stone quarrying.) As a result, uncertainty and risk always exist concerning the stability of facilities in soil and rock. Thus design involves reducing uncertainty and risk to an acceptable level.

Acceptable uncertainty and risk will vary according to the purpose of the facility. Nuclear waste repositories, for example, must be designed with very low consequent risk. In mine design, use of this same principle could result in inefficient exploitation of reserves and excessive cost, thus reducing the economic viability of an operation. Nevertheless, a well-conceived exploration and design strategy will reduce uncertainty and risk to a level appropriate for the particular facility.

Design Strategy for Reducing Risk and Uncertainty. A well-conceived design strategy comprises the following steps:

1. Site exploration.
2. Physical property testing.
3. Definition of property variability limits.
4. Identification of structural domains.
5. Development of competing designs.
6. Use of multiple support calculation methods.
7. Comparison of alternatives.

Site Exploration: A site exploration program is necessary to determine the range of geologic conditions that can be expected and should include core drilling, outcrop mapping, and possibly geophysical surveys. If there are existing facilities in the strata of interest, they, too, should be examined. For example, in the case of design of a highway tunnel in Colorado, detailed examination of the 50-year-old lining of a railway tunnel a few hundred yards (meters) away facilitated the calculation of the expected loads for the highway tunnel.

Core drilling should include sufficient holes and hole locations to characterize the complete area of the proposed facility. If the facility includes shafts, a core hole should be drilled along the centerline of each proposed shaft to the full depth to be reached by the shaft. Logging of the cores should include not only the stratigraphy but also locations and inclinations of joints, type of joint filling (if any), and the RQD. In the case of tunnels under large bodies of water, core drilling may not be feasible for the underwater sections. However, seismic reflection surveys can be used to provide the necessary information in conjunction with the available cores.

Any available outcroppings of formations traversed by the core drilling should be mapped. This mapping should include detail line surveys (Robertson and Piteau, 1970) in both horizontal and vertical directions within the member to sample the attitudes of the joints. At least 120 observations should be obtained along each detail line.

Another useful exploration technique is excavation of an exploratory adit into the formations of interest. Use of an adit allows a designer to test proposed support techniques and gives a better indication of expected conditions than either cores or outcrop mapping. Detail line surveys should be performed in the adit and compared with the results from outcrop mapping. (Care should be taken to ensure that blast fractures are ignored in the detail mine surveys in the adit.)

Physical Property Testing: Sufficient property tests should be performed on core samples from all formations of interest that the range of property values is determined. The properties of interest are the tensile strength and uniaxial and triaxial compressive strength of the rock substance as well as the shear properties of joints. In some rock types, special properties such as slake durability and creep deformation must also be determined. In porous rocks, permeability or hydraulic conductivity will also be important so that water inflows can be predicted. Sufficient tests of each type should be performed on each rock type that the mean and standard deviation (or perhaps range) of property values is established. It is very unusual in most rocks to have a coefficient of variation (the ratio of the standard deviation to the mean) of less than 25%. (For further information on physical property testing, see Chapters 10.2 and 10.3).

Definition of Property Variability Limits: Because design of rock support or reinforcement systems depends on the properties of the rock itself, it is important that the limits of the variability of the rock properties be known. Specifically, statistical parameters should be determined for each property for each geologic member. Strength properties and permeabilities have generally been found to be log-normally distributed. Spatial properties of the rock mass obey other distributions—joint lengths and apertures follow a negative exponential distribution, joint attitudes obey a Fisher or Bingham distribution, and joint spacings are Poisson-distributed.

After the various statistical parameters have been calculated, expected values and limits can be placed on the properties for design purposes. Design values for the properties can then be chosen to minimize the risk that the design does not perform to expectation. A method of tunnel design using such statistical principles has been used successfully by the authors (Kendorski, 1980; Hambley and Kendorski, 1984).

In slope-stability design practice, probabilistic design methods are widely accepted, and many papers have been presented regarding such techniques. Examples include Call, Savely, and Nicholas (1977); McMahon (1975); Major, Ross-Brown, and Kim (1978); and Glynn, Veneziano, and Einstein (1978).

Identification of Structural Domains: Structural domains are areas of the rock mass that have sufficiently similar properties that they can be considered to behave in a uniform manner. Also the boundaries of the structural domains need not coincide with stratigraphic boundaries—a shear zone that cuts across several different strata might constitute a structural domain. Structural domains may also repeat. For example, for a pumped storage project in Georgia, it was found that the 17 stratigraphic units could be lumped into just two structural domains: one for the stronger members, and another for the weaker members (Grainger et al., 1986).

Development of Competing Designs: A first stage in developing designs is a thorough literature search for case histories exposed to similar conditions. A simpler means of achieving the same end is to designate the rock using rock classification systems. Although a number of classifications have been developed over the years beginning with Terzaghi (1946), two systems are most commonly used: the Q System of the Norwegian Geotechnical Institute (Barton, Lien, and Lunde, 1974) and the rock mass rating (RMR) system developed by Bieniawski (1974, 1989). Both systems are based on a number of case histories (Chapter 10.5). However, the rock types represented by the case histories are quite different. Thus the classification based on the Q System may be more reliable for strong rocks such as gneisses, granites, and quartzites, whereas the RMR system is generally superior for weaker rock types. However, both provide estimates of support requirements for different classes of rock mass.

In many cases, several different support systems could be considered (e.g., rock bolts and wire mesh vs. shotcrete vs. rock bolts, mesh, and shotcrete). Also different types of bolts might be considered: mechanical bolts, grouted bolts, or grouted cables.

Another type of alternative that arises with tunnels, but not usually in mines, is different vertical alignments within the rock mass. For example, the initial alignment of a highway tunnel was located in a claystone with the crown about 10 to 12 ft (3 to 3.6 m) below a massive sandstone. For this alignment, a horseshoe tunnel with steel sets on 4-ft (1.2-m) spacings was considered viable. However, if the alignment were raised so that the crown fell at the base of the sandstone, a rectangular tunnel with rock bolt support was feasible. Based on these alternative alignments, a number of alternative excavation and support sequences were identified.

Another type of alternative design strategy is incorporated in the New Austrian Tunneling Method, discussed in 10.7.2.2.

Use of Multiple Support Calculation Methods: If the use of rock bolts is contemplated, the spacings suggested by the classification systems can be checked against empirical guidelines based on the RQD index developed by Deere et al. (1969). Bolt design is covered in Chapter 10.5.

Rock bolts are commonly installed on standard patterns, the most common being radial bolts where the roof is arched and bolts perpendicular to the roof where the roof is flat. However, such standard patterns may not effectively reinforce critical joint sets. Alternatively, the direction of the bolts can be based on the directions of the critical joint sets, using a kinematic analysis on a Schmidt equal-area stereonet containing joint attitude probabilities calculated by the method given in Goodman (1976). Bolts should also be checked for their resistance to sliding forces on the worst case joint inclination, and to en echelon failure along a series of joints. Examples of such analyses are given in Hambley and Kendorski (1984).

Comparison of Alternatives: A comparative examination of all the design calculations and support predictions should demonstrate a convergence of the designs. If not, discrepancies need to be critically examined and resolved. Upon achievement of the sought-after convergence of the designs, the designer can be reasonably certain that the risk of inadequacy of the selected design has been minimized. As a contingency against unforeseen conditions, designers should always prepare backup designs for poorer rock conditions than expected, and, in the case of facilities driven under contract, include these designs in the contract documents.

Because of the inherent variability of natural materials, risk and uncertainty can never be eliminated; however, through the use of a comprehensive design strategy, they can be reduced to an acceptable level.

Chapter 11.0
ENVIRONMENTAL ISSUES

RAJA V. RAMANI

11.0.1 INTRODUCTION

Discussion in this section of the *Handbook* is limited to the working environment of miners, the mine workers themselves, and the machines used in mining (Fig. 11.0.1). The contents emphasize personnel health and safety aspects and engineering design and control practices to ensure a productive health and safety environment. Reference is to the health and safety of the individual miners as well as to the safety of the working environment. This *Handbook* also contains references to health and safety regulations in Chapter 3.2 and environmental protection in Chapters 3.4 and 7.3.

11.0.2 HEALTH AND SAFETY ISSUES

Conditions which have the potential to damage both the health and safety of the miners and the mining environment are numerous. In discussing occupational risks in the mining industry, it is common practice to identify health and safety hazards separately. Among possible threats to the health of miners are the following: exposure to toxic gases and dusts, exposure to excessive heat and humidity, inadequate illumination, noise and vibration problems, and oxygen-deficient atmospheres. Some of these environmental stresses may interact to produce a greater overall effect. For example, excessive vibration combined with low illumination may lead to a higher-order stress than either one being present alone. In combination or alone, if environmental stresses exceed human tolerance levels for prolonged periods of time, feelings of discomfort will arise, alertness will decrease, accidents will occur, and performance and productivity will drop. Threats to a miner's safety may arise from many sources: from falls of roof, face, rib, or side; from haulage or other machinery; from electrical equipment, explosives, or ignitions or explosions of gases and dust; from sudden inundations of water and gas; or from mine fires. Health and safety aspects are not necessarily unrelated; for example, a mine fire or an explosion is a safety problem that may pose a serious threat to the health of miners due to the resultant high concentrations of toxic gases in the mine atmosphere.

The importance of maintaining environmental stresses under control at all times cannot be overemphasized. Consequences of inadequate control can be sudden and catastrophic—such as injuries and loss of life through suffocation, heat strokes, and explosions—or slow and long-enduring—such as lung diseases including coal worker's pneumoconiosis (CWP) or black lung. The debilitation can be permanent. In addition to the toll of human suffering, environmental stresses are associated with insidious increases in social costs (see Chapter 3.1).

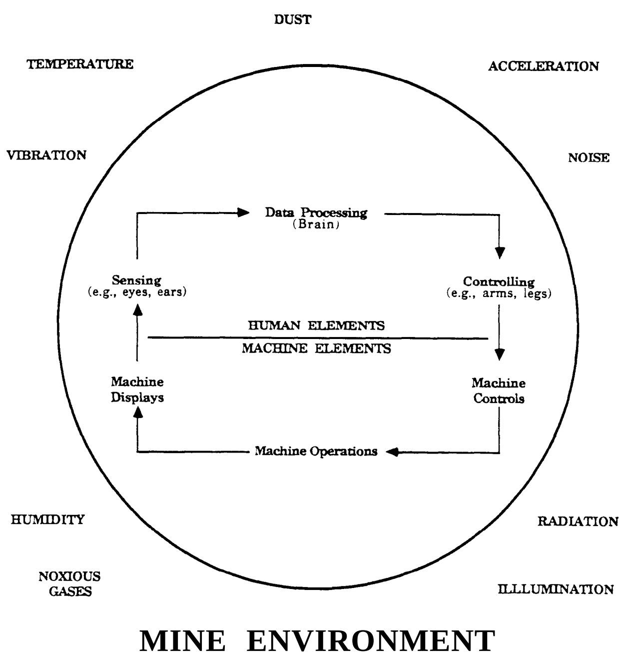

Fig. 11.0.1. Health and safety environment in mining operations.

11.0.3 ROLE OF GOVERNMENT

Today there is a strong measure of government control and inspection of mines under legislation specific to the mining industry that is intended to safeguard the health and safety of the miners (Anon., 1969; Anon., 1977). In general, however, mining laws have resulted due to the introduction of new and better mining methods by the industry and the development and implementation of new knowledge through research into the principles of accident prevention (Kenzy and Ramani, 1980). In this context, the establishment of the US Bureau of Mines in 1910, nearly 45 years after the first proposal to create one, is an event of major significance in the annals of health and safety. The Bureau's pioneering contributions in such areas as explosions, explosives, fires, and ventilation are widely credited for improved health and safety in mines worldwide.

Changes in the federal government's responsibility for mine safety have developed through a series of legislative actions in 1865, 1910, 1941, 1946, 1947, and 1952, culminating with the passage of the Federal Metal and Nonmetallic Mine Safety Act of 1966 (the 1966 Metal Act), the Federal Coal Mine Health and Safety Act of 1969 (the 1969 Coal Act), and the Federal Mine Safety and Health Amendments Act of 1977 (the 1977 Mine Act). The 1969 Coal Act represents yet another significant marker on the road to improved mine health and safety. In passing this Act, Congress declared that "the first priority and concern of all in the coal mining industry must be the health and safety of its most precious resource—the miner." According to Congress, the purpose of the Act is "to establish interim mandatory health and safety standards . . . to protect the health and safety of the Nation's coal miners."

Within eight short years of the enactment of the 1969 Coal Act, Congress passed the 1977 Mine Act by combining the health and safety programs of the 1966 Metal Act and 1969 Coal Act into one Act, and transferring the responsibility for enforcement

Table 11.0.1. Work Accidents in 1988 in the US

Industry	No. of workers	Fatalities	Disabling injuries
Agriculture	3,100,000	1,500	140,000
Mining, quarrying	800,000	200	30,000
Construction	6,500,000	2,200	210,000
Manufacturing	19,500,000	1,100	350,000
Transportation and public utilities	5,800,000	1,400	140,000
Trade	27,000,000	1,100	320,000
Services	34,600,000	1,500	330,000
Government	17,000,000	1,600	280,000
TOTAL	114,300,000	10,600	1,800,000

Source: Anon., 1989.

of the provisions to the Department of Labor from the Department of the Interior. Furthermore, new provisions were enacted to provide mandatory health and safety training to new miners and refresher training to all miners. The 1977 Mine Act is purported to have adopted the stronger features of the Occupational Health and Safety Act of 1970, perhaps the most significant piece of legislation with reference to workman's occupational health and safety in US history. The Mine Safety and Health Administration (MSHA) is the major federal agency responsible for the enforcement of the 1977 Mine Act. The agency also has provisions for technical support of the enforcement branch, training support for mining personnel, and testing and certification of new equipment for the mining industry.

11.0.4 ACCIDENT STATISTICS

According to the National Safety Council (NSC), in 1988, there were over 10,000 deaths on the job and 1.8 million disabling work-related injuries in the United States (Table 11.0.1). The total time lost due to these work-related injuries and fatalities was 35 million days. The total cost was estimated at $47.1 billion. The value of goods and services each worker must produce to offset the cost was approximately $410. These statistics vividly portray an enormous waste of talent and effort. In 1988, according to NSC figures, the mining and quarrying industry employed nearly 800,000 workers. There were 200 deaths and 30,000 disabling injuries (Anon., 1989). Despite these intolerable numbers and the need for higher safety, the 1988 statistics reflect an encouraging improvement over those of a few years ago.

The collection of mine accident statistics on an industry-wide basis and publication of reports of injury experiences, safety investigations, recommended practices, etc., are among the major functions of MSHA. Information reports on mining industry injury experiences and occupational illnesses are published on an annual basis. Separate reports are published for the coal, metallic mineral mining, nonmetallic mineral mining, sand and gravel, and stone segments of the mineral industry. Data used for the compilation of these reports are obtained from mine plant operators who are required to report the occurrences of injuries, occupational illnesses, and related data. The reported data are summarized by work location, accident classification, part of body injured, nature of injury, occupation, and principal type of mineral. Related information on employment, worktime, and operating activity also is presented. Data reported by independent contractors performing certain work at mining locations are also depicted separately in these reports. For ease of comparison with other segments of the mining industry, summary reference tabulations of other segments are included at the end of each report.

11.0.4.1 Definition of Terms

Detailed information on the source of data, scope of statistics, and definition of terms used can be found in the MSHA Information Reports on injury experiences (Anon., 1989a, 1989b, 1989c, 1989d, 1989e). Definitions of some of the important terms used in the Informational Report follow.

Occupational Injury: An occupational injury is any injury to a mine worker that occurs at a mine and for which medical treatment is administered, or which results in death or loss of consciousness, restriction of work or motion, inability to perform all job duties on any day after an injury, lost workdays, temporary assignment to other duties, transfer to another job, or termination. The injury must result from a recognizable single incident. For example, an explosion of a battery which splattered a worker with sulfuric acid would be a single incident, and the worker would be considered to have suffered an injury. Another example would be an injury where a worker was overcome by hydrogen sulfide gas released from an exploding vessel.

Occupational Illness: An occupational illness is an illness or disease of a mine worker that may have resulted from work at a mine or for which an award of compensation is made. To be classified as an occupational illness, the disability must result from repeated exposure to the condition or substance that caused the disability. A classic illness example is a pneumoconiosis disability that may have been induced by repeated exposure to the causative dusty condition. Dermatitis resulting from repeated exposure to lime dust or other material in the work environment also should be reported as an illness. In cases where the time of onset of illness is in doubt, the day of diagnosis of illness can be considered as the first day of illness.

Worktime: Worktime includes number of workers and number of employee-hours worked. "Average number of workers" is a summary of the average number of persons working at individual establishments during calendar quarters of active operations. "Employee-hours" is a summary of employee-hours reported.

Degree of Injury: Degree of injury indicates the seriousness of injuries. FATAL injuries are those occurrences resulting in death, NFDL (Non Fatal with Days Lost) injuries are nonfatal occurrences that result in days away from work, statutory days charged, or days of restricted work activity. NDL (No Days Lost) injuries are occurrences having no lost workdays, that is, nonfatal injury occurrences resulting only in temporary loss of consciousness or medical treatment other than first aid.

A *permanent total disability* is caused by work injury or illness other than death that permanently and totally incapacitates a worker from following any gainful occupation, or that results in the loss, or the complete loss of use, of both or any combination of: hands, arms, legs, feet, or eyes.

A *permanent partial disability* is caused by any work injury or illness other than death or permanent total disability that results in the loss, or the complete loss of use, of any member or part of a member of the body, or any permanent impairment of functions of the body or part thereof, regardless of any preexisting disability of the injured member of impaired body function.

Incidence Rate: Incidence rate is defined as the number of injuries per 200,000 employee-hours, rounded to two decimal places. The standard incidence rate formula is

$$\text{IR} = \frac{\text{number of injuries} \times 200{,}000}{\text{number of employee-hours}} \qquad (11.0.1)$$

The highest rate given is 99.99 even if the calculated rate is greater than 99.99.

Lost Workdays (LWD): Lost workdays consist of days away from work (DAW) and days of restricted work activity (DRA),

Table 11.0.2. Statutory Days Charged to Accidents

Disability	Lost Workdays Charged*
Death	6000
Permanent total disability	6000
Dismemberment or total loss of use	
Arm above elbow	4500
Arm at or below elbow and above wrist	3600
Hand at wrist	3000
Leg above knee	4500
Leg at or below knee and above ankle	3000
Foot at ankle	2400
Loss of sight:	
One eye (whether or not there is sight in the other eye)	1800
Both eyes (in one accident)	6000
Complete industrial loss of hearing:	
One ear (whether or not there is hearing in the other ear)	600
Both ears (in one accident)	3000
Unrepaired hernia	50

* Not more than 6000 lost workdays will be charged in a single accident that results in multiple injuries to a mine worker.
Source: Anon., 1989a.

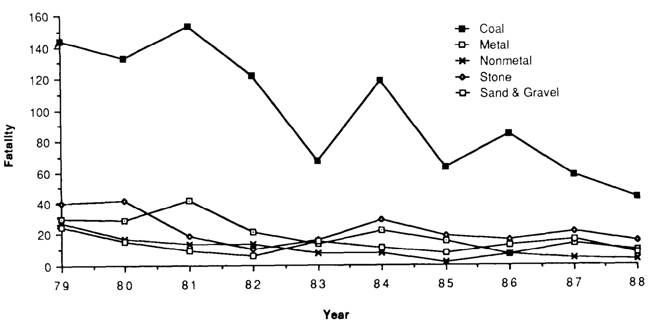

Fig. 11.0.2. Fatalities in coal, metal, nonmetal, stone, and sand and gravel over the period 1979–1988.

or statutory days charged as prescribed from a table of standard charges (see Table 11.0.2). For example, 6000 days are charged for a fatality or permanent total disability.

Severity Measure: Severity measure is the number of lost workdays per 200,000 employee-hours, rounded to whole numbers. The standard severity measure formula is

$$SM = \frac{\text{number of lost workdays} \times 200{,}000}{\text{number of employee-hours}} \qquad (11.0.2)$$

The highest rate given is 99,999 even if the computed rate is greater than 99,999.

Computer files of raw accident information data are available from MSHA. The raw data can be analyzed for studying the yearly variations in accident injury experiences for a particular mining commodity, job location, worker occupation, etc., as well as for several other comparative or absolute analyses.

11.0.4.2 Injury Experience

Summary statistics on the number of fatalities for each segment of the industry for the ten-year period 1979 to 1988 are presented in Fig. 11.0.2. While there have been fluctuations on a year-to-year basis, the long-term trend is characterized by a steady decrease in the number of deaths. Further, the frequency rates of incidences that involve lost working days (LWD injuries) and severity rates also show steady improvement for all segments of the mineral industry (Fig. 11.0.3 to 11.0.7). Even though there are year-to-year variations in either direction, the long-term trends are of decreasing incidence and severity rates. There is little doubt that mines are safer today than ever before. It is important to note that, each year, coal mining has experienced more fatalities than the other mining sectors. Also the incidence and the severity rates of the coal mining segment are the highest.

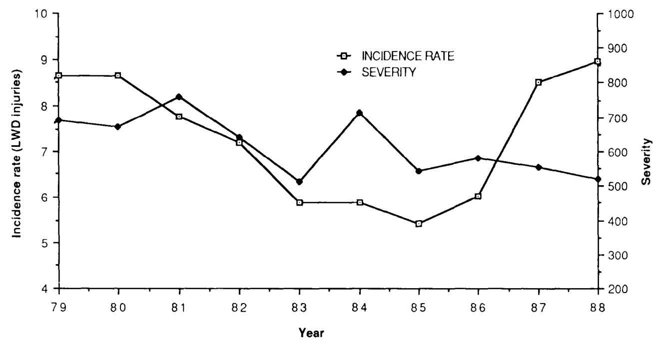

Fig. 11.0.3. Incidence rate and severity in coal mines over the period 1979–1988.

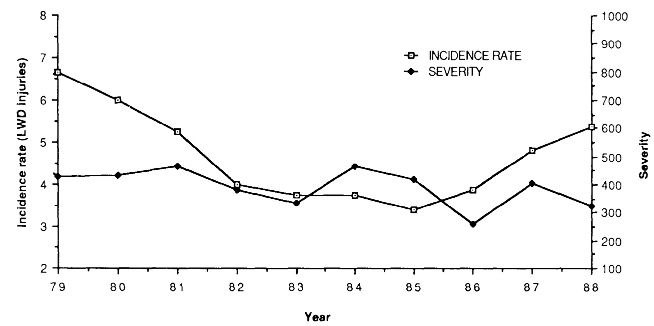

Fig. 11.0.4. Incidence rate and severity in metal mines over the period 1979–1988.

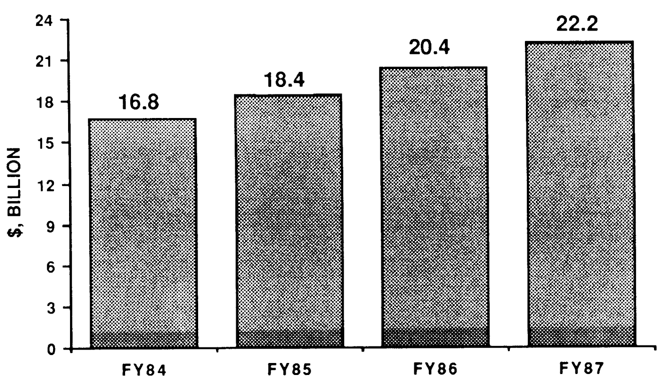

Fig. 11.0.8. Total compensation for black lung benefits.

sphere has been recognized from earliest times. Diseases such as silicosis, asbestosis, and pneumoconiosis are associated with long-term exposure to high concentrations of silica, asbestos, and coal dust, respectively. Bad water quality and the lack of adequate lighting have also been associated with such diseases as dermatitis and miners nystagmus, respectively. The payment of benefits to miners who suffer from occupational illness is a common practice. One such program is the black lung benefits program. Under this program, miners who are suffering from CWP are paid compensation. The cumulative benefits paid out of the program from 1969 until now total over $25 billion (Fig. 11.0.8). The number of claims processed in 1987 was nearly 300,000. The number of new claims per year averages between 400 to 500.

11.0.5 SECTION OUTLINE

It is now over two decades since the enactment of the 1969 Coal Act. This Act and the regulations contained therein defined in great specificity many standards for healthful and safe operation of a mine and, in some cases, what constitutes a good practice. Stringent standards have been presented for, among other things, respirable dust, noise, illumination, ventilation, roof control, electrical equipment, and escapeways. These have necessitated changes in mining layouts, mining operations, mine equipment, and miner training. Provisions for government inspection of mines and for assessment of penalties for violations have been revamped. Yet the fundamental requirements for a safe mining system continue to be (1) a well-engineered system in which all known hazards that can be eliminated by design are, in fact, eliminated; (2) a motivated work force that is trained to recognize hazards and to ensure that all operations are carried out in the safest manner; and (3) an effective management that not only maintains the safety integrity of the system but is constantly searching to improve on existing standards. Miner training must emphasize both general and job-specific health and safety aspects and improvement of production and maintenance skills. Management training must develop in its managers an ability to interpret safety statistics, perform cost benefit analyses on investments promising health and safety improvements, and understand human behavioral patterns. These are important issues in personnel health and safety (Chapter 11.1).

For maximum success, mine design must be compatible with sound engineering principles and practices and must incorporate the requirements of health and safety regulations. Tremendous changes have taken place in work procedures and practices to control mine atmospheric contamination from gases, dusts, heat and humidity, and radiation (Chapters 11.2, 11.3, and 11.4). Improved methods for controlling the hazards from diesel engine exhaust are also being actively pursued. The combination of better quality diesel fuel, well-maintained engines, new exhaust treatment systems, and changes in operational procedures has the potential to greatly reduce the gaseous and particulate components in the exhaust (Chapter 11.5). Ventilation is an important common denominator in most health and safety design considerations in mines. In addition to the supply of fresh air to the miners, the overall control of gas, dust, heat, and humidity problems is achieved through the proper design of the ventilation system (Chapters 11.6 and 11.7). Problems of noise and illumination, always a matter of concern in underground workings, are being addressed through the identification, development, and incorporation of specific design requirements for mine machinery and mining environment. All these have resulted in improved noise control and better lighting conditions (Chapters 11.8 and 11.9). A significant advance in aiding planning, designing, and controlling complex mining systems is the wide availability of computer-oriented mine atmospheric design simulators and mine-wide monitoring systems (Chapter 11.10).

The design of mines and mining equipment, and operational procedures that fit the mold of today's industrial and social environment is, however, a continuously evolving process. Experience world-over is that engineering controls and a knowledgable work force are the most effective preventive measures for occupation-related health and safety hazards. In fact, research and development of engineering solutions to the emerging problems along with enlightened legislation are the only realistic avenues to reach the goal of the complete elimination of health and safety hazards in the mine environment.

Chapter 11.1
PERSONNEL HEALTH AND SAFETY

RAJA V. RAMANI

11.1.1 INTRODUCTION

The single most valuable asset in any organization is human resources. It is the ingenuity and creativity of people that lead to the effective and efficient utilization of all other available resources to achieve the economic and societal goals of the organization. Protection of the health and safety of employees from excessive or undesirable stresses in the occupational environment is all important. This must be so from both the humanitarian point of view and the overall welfare of the enterprise itself.

The enhancement of personnel health and safety in mines requires an understanding of the hazards and the requirements for their control. Further, it requires a critical evaluation and application of the various approaches to hazard control. In addition to the learning experience from the lamentable history of accidents and disasters in mines, there is a critical need to reduce the risks of mine hazards and resulting accidents through the application of such proactive analysis techniques as systems safety analysis and disaster simulations for the identification of new hazards. For rapid progress towards a hazard-free environment for the miners, combinations of several hazard control approaches need to be utilized. The vital role of management in focusing the miner's attention to personnel health and safety must be recognized. Finally, the search for new tools and techniques for mining hazard control must go hand in hand with transfer of successful practices from other industries.

11.1 2 HAZARDS, ACCIDENTS, AND DISASTERS

Unless there is a common understanding of terms, there can be considerable confusion in transmitting information and knowledge. This can be particularly vexing in the understanding of safety literature in which such terms as "injury" and "accident" are often (and mistakenly) used interchangeably. Furthermore, definitions of accidents and hazards adopted for classification purposes may not be detailed enough to use as a basis for hazard control.

The term *hazard* is used here to describe an unsafe situation in a mine (Anon., 1981). This may be an unsafe physical condition or unsafe acts of miners. Perception of a hazard is essential. If a hazard is not perceived, no action can be taken to remove it. A *hazard source* is the background condition which, while not posing a danger in itself, may give rise to a hazard. For example, methane is a source of hazard. An *accident* is the realization of a hazard. An accident of major proportions representing a substantial threat to human life may be said to have *disaster potential.* If a large number of people are in fact killed, it is deemed a *disaster.* Disasters command tremendous attention, due to their infrequent occurrence and the extent of human suffering involved, even though the number of deaths from non-disaster accidents may be many times higher.

Fortunately, many mine accidents that have disaster potential do not become disasters, either because the accidents occur at a time when no or few workers are in the mine, or because the response is effective and all the threatened miners are evacuated safely. For those involved in health and safety management, the

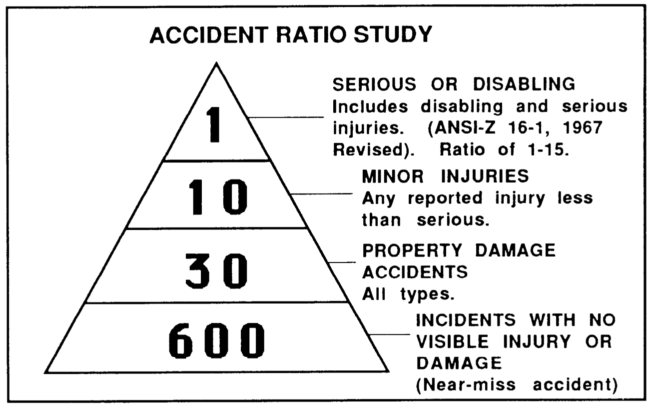

Fig. 11.1.1. Foundation of major accidents/injuries (Bird and Loftus, 1982).

distinction between accidents and disasters is not significant, and the aim is to identify, eliminate, or control the hazards.

11.1.3 HAZARD CONTROL REQUIREMENTS

The first requirement of *hazard control* is to recognize that any unintended occurrence is an accident whether such a happening results in injury or not. For example, if the objective of a study of mine explosions is to unearth the underlying causes of explosions and prevent their occurrence, the analysis of excessive gas accumulations, excessive frictional sparkings, and electrical arcings as well as any ignitions that did not result in injury or property damage can be just as significant as an incident (ignition or explosion) that resulted in injury. In fact, all these occur more frequently in a coal mine than explosions and provide a much larger basis for the analyses and determination of causative factors. This, in turn, can provide valuable information for developing more effective control strategies. According to a study by Heinrich (1959), the ratio of no injury to minor injury to major injury is 300:29:1. Underlying these minor injuries are numerous unsafe practices and unsafe conditions which fortunately may not result in any incident. Bird and Loftus (1982) have updated this ratio with further information on property damage accidents (Fig. 11.1.1). The moral of these ratio studies is that accident prevention must start with prevention of unsafe practices and unsafe conditions as well as of minor injuries.

A second requirement for an effective accident control program is a good index of safety performance. Many attempts have been made to develop comparative standards for safety measurement. Routine and surprise inspections, accident investigations, compensation costs, and injury ratings have all been used at one time or another. The number and severity of disabling injuries and the number of employee-hours lost can be compared with production and total employee-hours worked to judge safety performance between mines in the same company and between companies in the mining industry (see Chapter 11.0.4). The tremendous value of these statistics to focus attention on

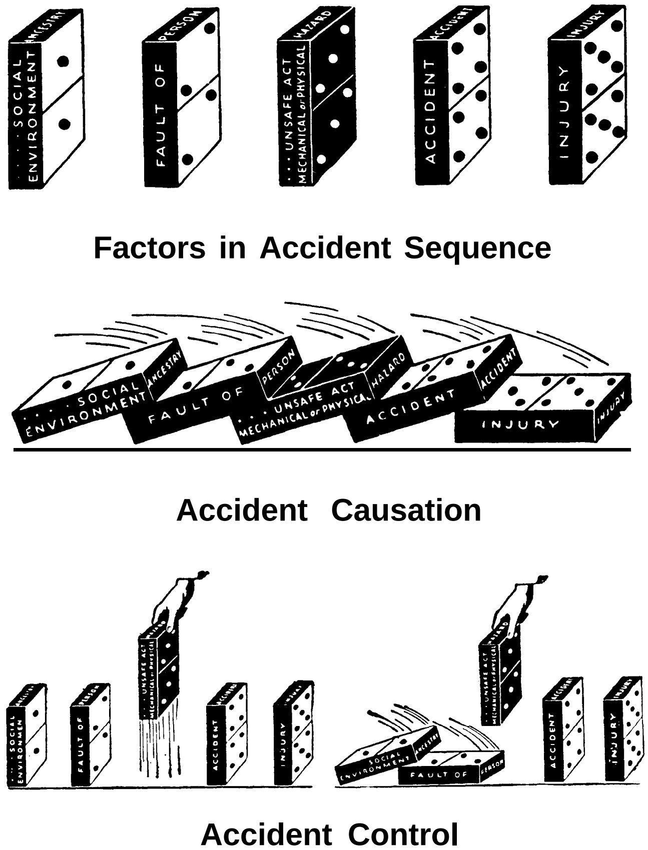

Fig. 11.1.2. Accident causation and control (Heinrich, 1959).

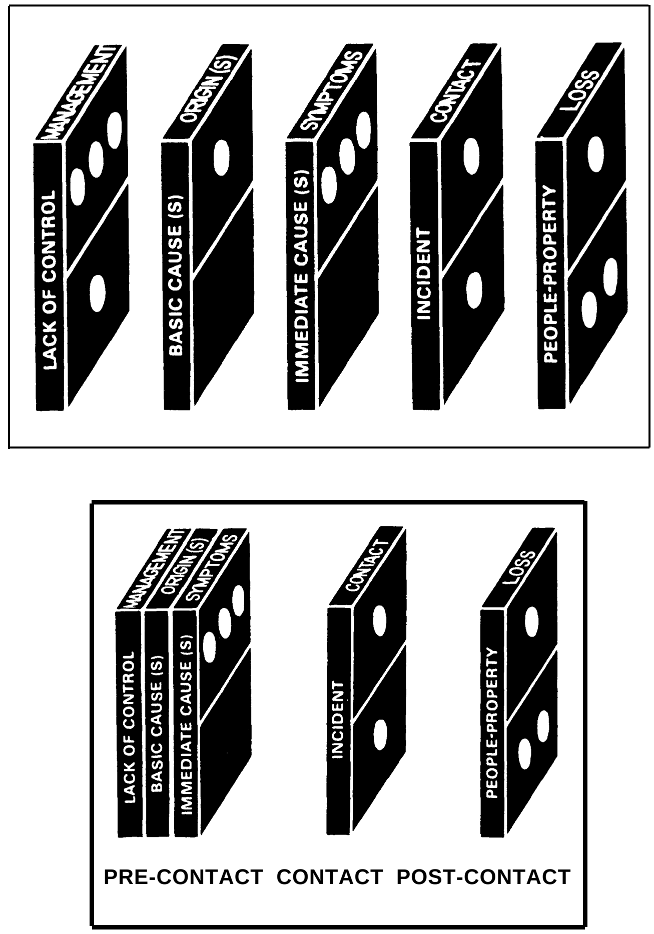

Fig. 11.1.3. Accident causation and control (Bird and Loftus, 1982).

health and safety issues must be recognized. But it is obvious that these performance ratings have a limited value in hazard control since they are still tied only to injury experience and lost employee hours. The ability to identify actual health and safety conditions by combining quantitative aspects of the existing indices with qualitative aspects is important.

A third area is the critical evaluation of the relative contributions made by the environment, human beings, and mechanical elements to an accident. The traditional method to assess their contribution has been through mandatory investigations and inspections. There are state and federal government inspection agencies with powers to ensure compliance with existing laws and for promulgating new regulations for safer performance. In many instances, mine personnel have to be certified by government regulatory agencies to be employed in certain categories (e.g., mine foreman) and these officials have a certain number of prescribed inspections to make. Inspections can be made to check operations against the prescribed standards, to detect deviations, and to suggest remedial actions. The chain of events leading to the causation of an accident or injury has been compared to a line of dominos, each domino in the sequence knocking down the one next to it (Heinrich, 1959). In this concept, the accident can be avoided by intervention to prevent an earlier domino from falling down such that the chain of events does not proceed to the last domino that represents losses to human resources and property (Fig. 11.1.2). This concept has been modified by Bird and Loftus (1982) to focus attention on the lack of control (Fig. 11.1.3) which is the first domino in the sequence. Also the highlighting of the key role of management in accident prevention by ensuring all aspects are under control at all times is to be noted. However, the causes of accidents are manifold and can result from unsafe acts of employees or unsafe mechanical and/or physical conditions, or both. It is comparatively easier to detect and spotlight physical hazards than unsafe acts of workers. However mechanically safe a system is designed to be, built-in safety can be jeopardized by an unsafe act. Maintenance and preservation of the safety features depend on compliance with many rules and regulations by the workers in the system. Miners must be well trained in these rules of safe operation and behavior. Further, during inspections, supervisors must spend more time studying the worker to discover possible acts of commission and omission beyond that required to ensure compliance.

In any case, compliance with laws and elimination of known unsafe practices are in mathematical terms "necessary" rather than "sufficient" conditions to consider a place safe. For instance, with the increasing ability to measure and characterize the elements of the mine atmospheric environment has come an awareness of factors, hitherto unknown, that may pose new threats to health and safety (Ramani, 1988). Recent examples here include, but are not limited to, the high concentrations of quartz in respirable airborne dust in coal mines, the large proportion of submicrometer particles in diesel engine exhaust and their impacts on mine air quality, the presence of asbestos-type fibers in mined products, and the adequacy of existing standards for radiation exposure in mines. These observations have enabled focusing attention to the need for increasing research on the health effects and developing more effective engineering controls. In other words, vigilance can never be relaxed in the search for new hazard sources and their control.

Finally, the collection, analysis, and use of accident statistics for developing hazard control programs must be a continuing endeavor. While controlled experimentation is difficult, the development of a theoretical framework for investigating hazard and accident phenomena is necessary. If accident statistics on an industry-wide basis are general and descriptive, they can result in conclusions and recommendations that are also of a broad and general nature. For developing specific programs for specific mines, the data collection activities and the analysis procedures must be focused to address the specific issues. For example, specific studies must be undertaken to achieve definite, realistic, and quantitative objectives, such as identifying the cause of specific accident types, initiating a new accident control program, or decreasing accident severity and injury rates.

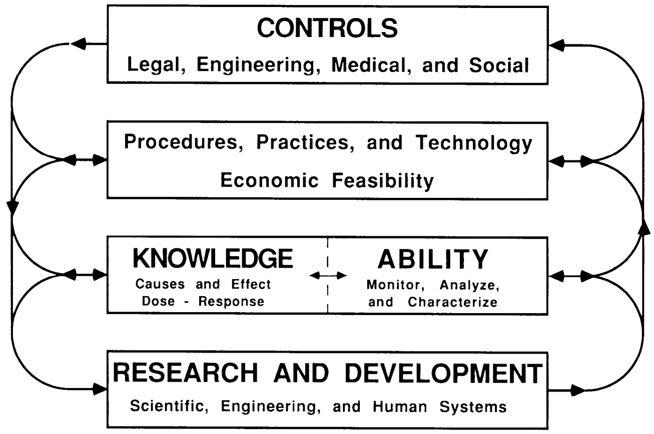

Fig. 11.1.4. Development paths for control mechanisms.

11.1.4 HAZARD CONTROL APPROACHES

Mining is one of the oldest of human occupations (Chapter 1.1). The awareness of occupational illness associated with mining is evident from the writings of Hippocrates (460–370 BC), Pliny the Elder (AD 23–79), and Galen (AD 131–210). Therefore, hazards associated with mining were known from ancient times. Georgius Agricola (1494–1535), in his *De Re Metallica,* refers to the diseases of miners and the need for their control through good planning and operating practices and responsible management. This early recognition of the occupational hazards has undoubtedly contributed to the development of occupational medicine and health care systems (Schwerha, 1989).

In assessing health and safety problems in the mining industry, there is no room for complacency or fatalistic attitudes. Yet one must recognize that mining is hazardous, and vigilance can never be relaxed. As distinct from practices in many other industries, the mine working environment cannot be precisely controlled. Also the environment is constantly changing. It is virtually impossible to foresee all the possible hazards and therefore, to take precautions against each of them. However, the control of the threats to health and safety of the miners has been a major concern for management, labor, and government alike. This concern has manifested itself in four primary mechanisms of control: (1) regulatory control through the passage of mine health and safety laws that set minimum standards of performance, (2) legal and social control through workmen's compensation laws for occupation-related injuries and health deterioration, (3) medical control through periodic physical examination, wearing of personnel protective devices, etc., and (4) engineering control through design and operation of mines according to the best recommended practices.

11.1.4.1 Health and Safety Regulations

It is only within the last 250 years that government regulation of mines and the promulgation of health and safety standards were initiated. France and Germany took a lead in this direction with the creation of inspectorates and schools of mines (Bryan, 1985). In England, statutes governing industrial working conditions were beginning to be debated by 1800. Initially, these efforts were spurred by the evils and excesses of the employment of women and children and increasing concerns to protect the community from the dangerous and unsanitary conditions in the mines. A major aspect of the early literature calling for legislation of mines was the recognition of the importance of adequate ventilation to health and safety and the need for better education and training of those responsible for the management of coal mines. Legislation specific to the mining industry was first enacted in England in 1842, and by 1850, a bill establishing a mine inspectorate was passed.

In the United States, Pennsylvania should be credited with the first formal move to legislate safety measures in its anthracite mines. In 1858, a bill was introduced in the Pennsylvania legislature authorizing state supervision of the mines in Schuylkill County. The bill failed that year and again in 1868, but in 1869 it became law, the first state mining statute in the United States (Core, Ramani, and Frantz, 1983). A bituminous mining law was not passed by Pennsylvania until 1877. As a matter of interest, the American Institute of Mining Engineers (AIME) was founded in Wilkes Barre, PA, in 1871, and one of its primary goals was the development of safer coal mines. Enactment of significant mine health and safety legislation in the United States has closely followed in the footsteps of major disasters (Table 11.1.1).

Prior to 1969, the federal government was extremely reluctant to intrude into the areas of health and safety, particularly the enforcement of standards, which was viewed as a state responsibility. The situation since 1969, as discussed in Chapter 11.0, has changed significantly. For a more detailed discussion of mine health and safety regulations, see Chapter 3.3 in this *Handbook.* It is worth emphasizing again that health and safety legislation, at any level, provides only a minimum framework for the engineering and operations of mines, and should rarely go beyond what is generally accepted as a good practice. Legal controls cannot solve problems of health and safety if they are not supported by sufficient technical clarity and feasibility. Otherwise, they will be no more than statements of good intent and may even frustrate professional progress towards safer work environments. The desirable process for developing effective control is better understanding of the cause and effect, dose-response relationships, feasible engineering designs and practices, and good professional judgment. These must be the foundations on which the legal control of health and safety is built (Fig. 11.1.4). However, advances in technology, good practices in other industries, and increases in knowledge provide sufficient grounds for the loop to run in the opposite direction. The danger to avoid is legislation that may restrict the alternatives available to the industry or does not fully consider the uniqueness of the mining operations and environment.

Table 11.1.1. Development of Federal and State Mine Safety Laws in the United States

Date	Disaster	Significant State and Federal Legislation	Proposals for or Enactment of Other Legislation
1842			Pennsylvania Mine Safety Act *Proposed*
1865			Federal Bureau of Mines *Proposed*

11.1.4.2 Workmen's Compensation Laws

The use of penalties to control occupational illnesses and injuries has been in practice from the earliest of times. However, specific approaches to indemnifying workers through worker's compensation laws began in Germany in 1885, Great Britain in 1897, and the United States in 1902 (Grimaldi and Simonds, 1975). These laws required the employer to compensate the injured employee whether or not negligence could be proved. The cost incurred due to accident insurance and compensation is considered, in the framework of control, as a part of operating the business. Workmen's compensation cost is viewed as a deterrent since it is, in effect, an after-the-fact penalty whose magnitude can be so high that it encourages management to take many positive actions to avoid it. Workmen's compensation insurance is required in each of the 50 states. This insurance is carried through an insurance firm or a state-operated insurance fund. In the event of a health or an injury problem, compensation is paid to the worker. For example, in 1985 the average annual compensation cost per covered employee (benefits paid ÷ covered workers) in the 50 states varied from a low of $90 (Indiana) to a high of $618 (Alaska). The national average for all 50 states was approximately $290.

The 1969 Coal Mine Act considered the plight of miners suffering from coal worker's pneumoconiosis (CWP) arising out of employment in underground coal mines and provided for the payment of black lung benefits. This compensation program is funded by a charge on every ton of coal mined. At the present time, the charge is $1.10/ton ($1.22/t) of underground mined coal and $0.55/ton ($0.62/t) of surface mined coal. The cumulative annual benefits paid out of this fund, thus far, total over $25 billion. The number of claims processed in 1987 totalled nearly 300,000 and the amount expended nearly $1.8 billion. The number of new claims per year in the late 1980s averaged between 400 to 500. For professionals engaged in health and safety of mines, no compensation should be enough to equalize the dangers to health and safety, particularly if these can be avoided through design and operational procedures.

11.1.4.3 Medical Examinations

In recent years, increasing financial responsibility for occupation-related health problems and accident-injuries cases has been placed on employers. Pre-employment physical examinations and periodic continuing examinations are required to assure that employees' health and physical conditions are routinely monitored and documented. These examinations may reveal the on-set of physical problems such as hearing loss, loss of vision, heart problems, arthritic conditions, lung impairment, etc. Whether required by law or not, examinations provide medical evidence for job switching and settlement of claims.

Under the 1969 Coal Mine Act, there are two activities focused on the prevention of CWP: (1) the National Coal Workers' Health Surveillance Program, and (2) the Coal Mine Respirable Dust Sampling Program. Both these activities have been pursued since 1970 by federal government agencies. The two together combine both primary and secondary methods for CWP prevention: the dust control program by environmental control and the surveillance program by protecting the health of the coal miner (Attfield, 1984). The health surveillance program has several significant purposes: (1) the protection of health of the individual miner; (2) the monitoring of prevalence and progression of CWP; and (3) the identification of mines with high incidences of CWP for closer dust control monitoring. If a miner shows signs of CWP on a chest X-ray, then the miner has the option to transfer to a less dusty work area. In addition, the surveillance program provides a means to monitor the incidence and prevalence of CWP under the dust control program. The medical control provides a useful evaluation of the individual miner's health status through early detection of abnormal conditions and prescription of preventative action.

11.1.4.4 Engineering Control

Engineering control encompasses design of mines, selection of appropriate equipment, selection and training of the human resources into a knowledgeable work force, and management of these resources to achieve the goals of health, safety, and productivity. The specific aspects of designing mining engineering systems with effective control over hazards from mine atmospheric contaminants such as gases and dust, and environmental aspects such as radiation, heat, humidity, noise, and illumination, are the topics of coverage in the subsequent chapters of this section and therefore will not be amplified here. It is, however, important to stress that the greatest positive effect on the health and safety of miners can be achieved through proper application of engineering controls during the planning, designing, and operating phases of the mine.

11.1.4.5 Human Factors Engineering

During the last two decades, the application of human factors to mining engineering problems has been growing to enhance operational efficiency and health and safety of the miners. *Human factors engineering* is the systematic application of relevant information about human characteristics, abilities, expectations, and behaviors to the design of machines, tools, facilities, procedures, and environments that miners use (Sanders and Peay, 1988). There is a large body of human factor data, principles, and methods developed outside the mining industry that can be brought to bear on problems encountered within the industry. Increased activity in the human factors area has resulted in the documentation of human-factor-related mining problems and their solutions. The objective of all these efforts is to ensure that human factors engineering is an inherent component of the mining engineering design and that a mining system of greater safety and reliability is designed.

11.1.4.6 Systems Safety Analysis

Systems safety analysis methods provide a proactive approach to analyze systems for potential hazards that may threaten the health and safety of miners. This approach, developed specifically for the space program in the early sixties, made it possible to generate safety statistics *before* the deployment of new products and systems—that is, to ensure safety on the basis of analysis of the system rather than on the basis of past history. In the space program, this involved (1) making products of unexcelled quality and reliability, (2) identifying the failure characteristics of each unit and the impact of the unit's failure on the total system, (3) increasing system reliability by providing alternatives to permit safe functioning of the system in the face of failures of individual units, and (4) developing emergency procedures for contingencies. While the objectives of the space program permitted incurring larger costs in the interest of safety than may be practical in other programs, much of the systems safety approach is applicable to other industries, mining among them.

The *systems approach* to the safety problem focuses on the system taken as a whole, and not on its parts separately. It involves the interaction of people, machines, and environment within procedural constraints. It does not imply that the system must be risk-free, but rather that risk can be identified, quantified, managed, and controlled (Hammer, 1972). This systematic approach as applied to mine safety should include all phases from conceptual formulation of the system through analysis, synthesis, design, testing, evaluation, construction, training, approval, operation, and maintenance of the system. It requires: (1) a logical examination of all the elements of the system and their interactions; (2) identification of all sources of hazards; (3) calculation of the probability of hazard occurrence; (4) a search for the available options for hazard elimination or minimization, and in the extreme case, provisions for evacuation, escape, survival, and rescue; and (5) an analysis of costs and of problems associated with implementation and other procedural aspects of the various alternatives.

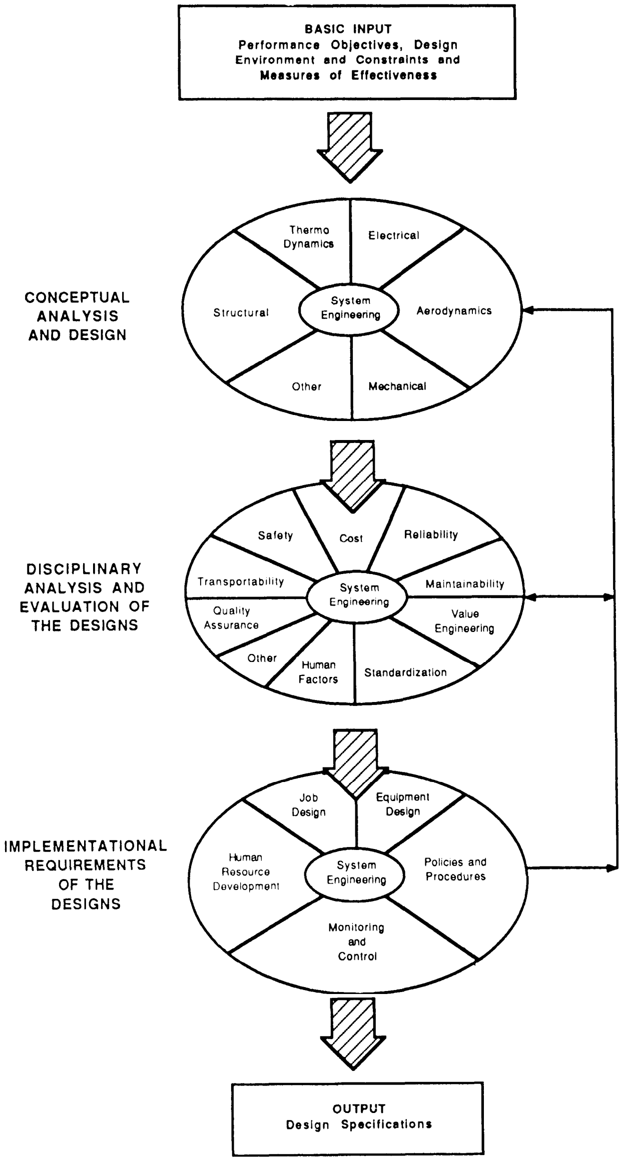

Fig. 11.1.5. System engineering process (after Anon., 1973).

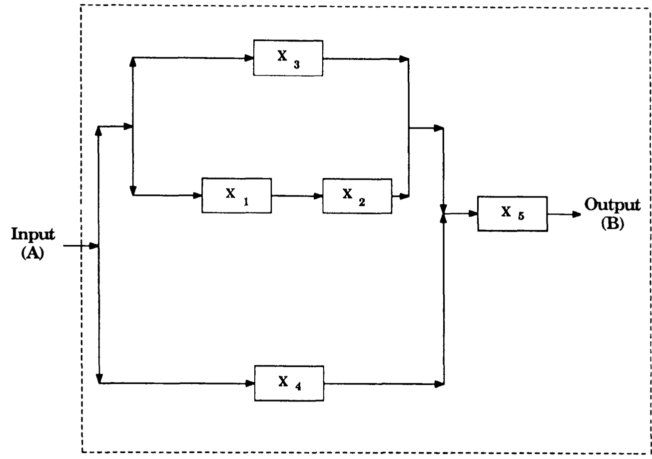
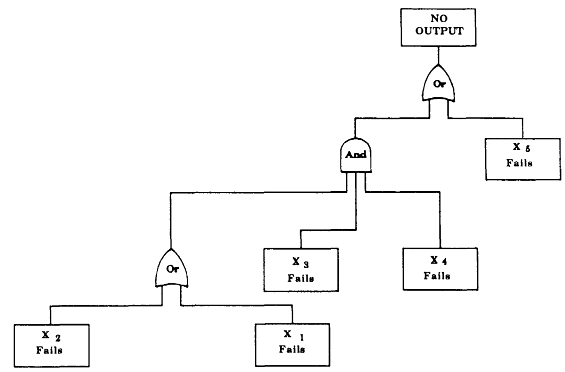


(a) System Schematic



(b) Fault Tree of the System for the Top Event "No Output"

Fig. 11.1.6. Illustration of the fault tree analysis technique (after Anon., 1973).

The system engineering process is outlined in Fig. 11.1.5 as a three-step sequential process with iterative feedback loops to earlier steps from the later ones. The first step is conceptual analysis and design, which is often subject to constraints on input resources and to performance requirements of the final design. In the second step, these designs are evaluated for compatibility and technical and cost effectiveness through a number of speciality disciplines. In the third step, the implementational aspects are analyzed and developed. In this three-step process, the system designer moves from analysis to synthesis, pulling together parts into a system (Anon., 1973).

The systems safety approach is a composite of elements from a number of diverse disciplines including systems engineering, statistics, reliability theory, information theory, control theory, management, and behavioral psychology. It uses a number of techniques (Hammer, 1972). For example, the *technique of operations review* (TOR) is a tracing technique for identifying and defining a health and safety problem by searching for the root causes. In the *failure mode and effects analysis technique* (FME), the possible modes of failure of each component in a system are listed, and the effects of this failure on other components and the total system are analyzed. The outcome of the failure may be stated in qualitative terms for hazard potential as safe, marginal, critical, or catastrophic; and for frequency of occurrence, as probable, reasonably probable, remote, or extremely remote. In the *fault tree analysis technique* (FTA), all events and combinations of events that can lead to an undesirable event are arranged in a logic flow chart (or diagram) with the undesirable event on the top. A simple application of the technique is shown in Fig. 11.1.6 where for the system schematic shown, the undesired event is the loss of output B. The bottom level of a fault tree represents failures that cannot be further broken down meaningfully, that is, these failures are basic. Probabilities can be attached to these basic failures, and the probability of the top event occurring can be calculated as a function of these basic probabilities. The use of fault tree analysis technique to evaluate the reliability of escapeways in the event of a mine fire is provided by Goodman and Kissell (1989). More importantly, the very intensive nature of the inquiry required to apply TOR, FME, and FTA techniques to complex systems meaningfully will focus attention on potential weak links in the design and operations and provide the opportunity to solve them prior to implementation.

There are several aspects of mining in which the systems safety approach can be applied. It can be used by regulatory agencies to evaluate mine plans and procedures before approval and to conduct *post-audits* of disasters and accidents. It can be used by research organizations to unearth new sources of hazards in existing systems, to conduct *pre-design* audits for developing specifications and standards, and through *post-design* audits, to evaluate the developed product or system for effectiveness. It can be used by mine operators to evaluate existing systems, suggest modifications to operations or equipment or both, and develop training programs.

11.1.4.7 Miner Training

Manpower is the most precious investment made in a mine. The right person for the job is not just "born" but created by meticulous selection and adequate training and job orientation (Craig and Bittel, 1967). The past two decades have seen considerable progress in miner training. The fuel crisis of the early seventies, which highlighted a need for increased coal production, also focused attention on the alarming shortage of trained workers to achieve the new production goals. This in turn led to a reappraisal of the role of training in the health and safety of all personnel associated with mines and culminated in two documents that have had far-reaching effects on miner training. The first of these was the 1974 contract between the United Mine Workers of America and the Bituminous Coal Operators Association (UMWA-BCOA), in which an agreement for the development of health and safety training and retraining programs for all union bituminous coal mines was outlined. The second document was the 1977 Federal Mine Safety and Health Amendments Act which mandated training for the entire mineral industry and also required that several of the training programs be conducted by instructors certified by the Mine Safety and Health Administration (MSHA).

The federal regulations for new underground miners set forth a minimum of 40 hours of training, of which 32 hours is classroom training and eight hours is at the jobsite. Eight hours of training must be received before a new miner can go underground. For new surface miners, the regulations specify only a minimum of 32 hours of training, of which eight hours occurs before miners begin their actual work assignments. In addition, eight hours of annual refresher training is required of all miners. The topics required for training new miners, newly employed experienced miners, and annual refresher training under the federal regulations are listed in Table 11.1.2 for both underground and surface coal mining. Several coal producing states have additional training requirements, and in some states, these exceed the federal provisions. Included among the latter states are Illinois, Indiana, Kentucky, Pennsylvania, and West Virginia (Sanders and Peay, 1988). Finally, several mining companies have training programs for their personnel which go beyond the mandated state and federal levels (Masutomi, 1990).

The National Mine Health and Safety Academy, established in 1976 as an educational and training arm of MSHA, offers a wide variety of training products and services to the mining industry. Among these are films and videotapes, instructional programs, mine emergency simulation exercises, pre-shift inspection programs, self-study books on health and safety problems, safety manuals, and other important health and safety reference documents (Anon., 1990). As a result of these actions, there has been an accelerated development of mine health and safety training programs and increased emphasis on mine safety training and procedures by the industry. Mechanization, automation, and remote control technology are now changing the working environment and job functions within the mines. Determining how such innovative changes create hazards, affect accidents, and cause injuries for different occupations and how much the safety conditions will change is complicated. The need for new training and increased training to meet these technological changes poses a new challenge to the industry. A conceptual framework for the evaluation and development of effective training and job design strategies is presented in Fig. 11.1.7. The framework incorporates the tools and techniques from systems safety, and loss control procedures to identify and eliminate weak links in the human, machine, and environmental components of the system and their interactions.

Table 11.1.2. Elements of Underground and Surface Mine Health and Safety Training Programs.

	Introductory for		
	New miners	Newly employed experienced miners	Annual refresher for working miners

11.1.5 ROLE OF MANAGEMENT

Management's role in health and safety is ubiquitous. It is reflected in the development of well-engineered systems, the choice of personnel for specific jobs, the provisions for education

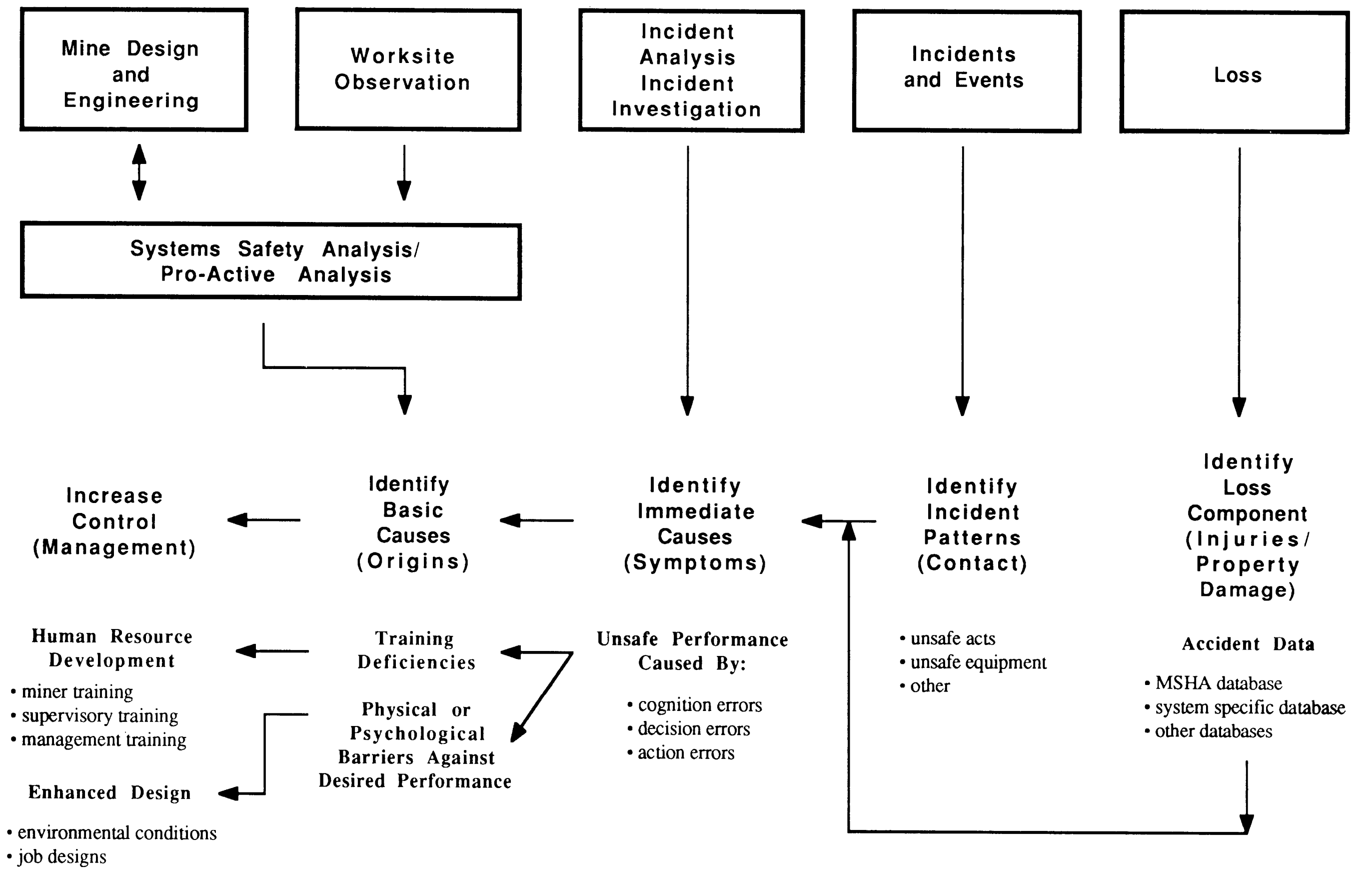

Fig. 11.1.7. Conceptual framework for evaluation and development of effective training and job-design strategies (Masutomi, 1990; Anon., 1981).

and training, and the continuing search for improvement in health and safety. Management has the sole authority to establish policies and priorities, to initiate and implement safety programs, to commit resources, and to reward managers and employees for achieving goals within the larger framework of its overall responsibilities (see Chapter 8.6).

The importance of management's commitment to safety was underscored in a National Academy of Sciences' mine safety study (Anon., 1982), which found that it was not possible to explain through statistical analyses of accident data the large and persistent differences between the injury rates of several mining companies as a function of physical, technological, or geographical factors. Instead, the differences were attributed to factors internal to the companies, particularly management's commitment, cooperation between management and labor, and quality of training of employees and manager.

It may even be worthwhile to side-step traditional concepts in mine management in favor of new ideas and principles for improving health, safety, and productivity. This was the case in a central Pennsylvania coal mine where a one-year test of the autonomous work group concept was conducted (Goodman, 1979; Trist, Susman, and Brown, 1977). In simplistic terms, the workers were responsible for planning and scheduling their own work, while the section foreman was responsible for ensuring that work practices adhered to applicable health and safety rules and regulations. An independent evaluation team analyzed the data and found a definite improvement with regard to safety. Mine safety violations had decreased; the miners felt that safety had improved; onsite observers noted better practices and habits in the autonomous work group than in the control group; and the responsibility given to the miners had the effect of reinforcing and creating better safety attitudes. Positive changes in attitudes and increased competency in job performance were also noticed. Although the study cannot be conclusive due to the small sample and short experimental period, it does point to the importance of teamwork, and suggests that closer cooperation between workers and management may be a way to achieve improved health and safety in mines.

The objectives of management, from the top executive to the first-line supervisor, must be to

1. Provide leadership in safety with clear definition of the goals and means to achieve them.
2. Ensure effective management through a safety organization that has clear lines of responsibility and support for managerial decision-making.
3. Promote and seek highest standards of safety performance at work through consistent and persistent development and use of knowledge and skill.
4. Provide a working environment for the miners in which the equipment, processes, and procedures are so reliable, well-defined, and understood as to eliminate hazards to the miners in the face of system failures.
5. Exemplify through actions at every available opportunity its deepest commitment to safety.

The major success of the 1969 Coal Mine Act rests on such strong foundations as methane concentration control, dust control, intrinsic safety and explosion-proof enclosures, minimum air quantity and quality standards, and escapeway provisions. These requirements drastically impacted mine ventilation planning, engineering, and practice, leading to both greater expectations and fulfillment of safe working conditions. The Act recognized the need for increased scientific, engineering, biomedical, and medical research studies to support not only the new legislation but also the development of new equipment and methods. A systems approach to the eradication of the problems of health and safety was prescribed through increased health and safety standards, inspections, personal protective devices, miner training, medical examinations, black lung benefits, and development of more effective engineering controls through increased research. Since the passage of the 1969 Coal Mine Act and the 1977 Mine Act, significant progress has been made in all aspects of health and safety. The vital role played by mine management and mine workers in achieving this improved record should not be overlooked or underestimated. The cooperative and coordinated efforts of the mining companies and miners, along with significant commitment of corporate financial resources, were among the major reasons for the rapid development and absorption of the newly developed technology. Much remains to be accomplished in achieving a hazard-free health and safety environment for the miners. There is little doubt, however, that mining in the United States has become less hazardous.

Chapter 11.10
COMPUTER APPLICATIONS IN MINE VENTILATION AND THE ENVIRONMENT

SUKUMAR BANDOPADHYAY

11.10.1 INTRODUCTION

Over the past three decades, the role of the digital computer has expanded in an unprecedented manner. As mainframes and personal computers became cheaper and grew to astounding size, and the FORTRAN programming language became more sophisticated and less core bound, the general use of computers spread to more mining companies and, more importantly, to more engineers. Present-day utilization of computers in the mining industry varies across a wide spectrum of activities: from operations research techniques to aid mine management through payroll processing to mine design and monitoring and control.

During the last years, efforts have been made with encouraging results towards planning of ventilation systems with computers. Computers have played a greater role in evaluating ventilation parameters and processes, largely because they can be used conveniently to relieve the ventilation engineer of repetitive calculations and to reduce voluminous ventilation data often collected for analysis of trends and their statistical significance. While these are basically data-reduction applications, the tremendous advantage of the computer for more sophisticated utilization is not fully realized. The great power of a computer lies in its ability to store, recall, manipulate, and modify data for analysis as well as generate copious information records, all in a fraction of a second. The application of energy and mass transport phenomena to the quantification of ventilation engineering parameters for quality and quantity control is not new. However, the solution of complex nonlinear systems of equations has taken a great leap forward since the advent of digital computers that permit complex ventilation problems to be solved numerically (Stefanko and Ramani, 1977).

General mine ventilation theory and practice are discussed in Chapters 11.6 and 11.7.

11.10.2 COMPUTER APPLICATIONS IN VENTILATION PLANNING

Most ventilation problems associated with the mine planning environment are essentially engineering problems and can be scientifically analyzed. Ventilation requirements and system structure can be defined only on the basis of a production plan. However, the iterative and feedback nature of this process must be noted since production planning must consider the services required to support an operation. Thus all ventilation problems are associated with the mine planning environment, and this in turn is usually related to the determination of the ability of existing ventilation plant to maintain certain legal standards. Legal standards defined in the Federal Coal Mine Health and Safety Act of 1969, which dictated major changes in mine ventilation with regards to both air quantity and quality requirements, have also been placed on the ventilation of belt lines, gob, and face areas. These and other similar requirements have not only precipitated several modifications to existing ventilation systems but also have greatly increased the complexities of ventilation planning in new mines. It is apparent that the use of computers in ventilation system analysis and design is a necessity.

A computer-oriented approach to mine ventilation planning began essentially in the late 1950s with the development of network simulation programs. For this reason, major developments in computer programming have taken place in the field of mine ventilation planning.

In designing the future ventilation system of a mine that is already in existence, two procedures are involved: (1) obtaining the physical details and specifications of the existing layout by means of ventilation surveys, and (2) the reduction and utilization of these data to study the effect of changes in some parameter on the characteristics of airflow in the existing layout, such as ventilation network analysis. The computer can provide powerful assistance in both these stages.

11.10.2.1 Data Reduction In Pressure Survey

An altimeter measures the instantaneous static pressure at a point underground in terms of the height of a theoretical air column of 50°F (10°C) dry air at the existing station atmosphere pressure. Assuming measurements were made simultaneously at two locations or corrected to the same time frame through the use of a stationary base instrument, corrections can be made for difference in elevation, air density, and airstream velocity to give the absolute pressure difference between two points. Calculation methods used have been described in the literature by several authors (Williamson, 1932; Krickovic, 1945–46; Mancha, 1946; Hall, 1951; McElroy and Kingery, 1957; and Hartman, 1961). The method developed at the US Bureau of Mines and described by McElroy and Kingery (1957) is probably the most commonly used method and has been adapted for use on a programable desk calculator by Harris et al. (1973) and for a hand-held calculator by Anderson and Nugent (1977). Several computer programs for the treatment of pressure survey data using digital computers have been described by Luxbacher et al. (1977). A sample data input for a pressure survey calculation identical to that used in McElroy and Kingery (1957) is listed in Table 11.10.1. The output of a program using this sample data is reproduced in Table 11.10.2.

11.10.2.2 Mine Ventilation System Network Analysis

A *mine ventilation system* is essentially a set of interconnected airways. The system includes the fan(s), airways, and regulatory devices. With added legal requirements placed on the ventilation of belt lines, gob and face areas, and air velocities on trolley haulage roads, the ventilation system can be quite complex, and all but simple problems require computational aids to ease and speed their solution.

The structural flow model constructed from a physical flow system such as the mine ventilation system can be conceptualized as a connected-directed graph. The term network is commonly used instead of graph, especially when quantitative characteristics such as flow, capacity, and resistances are assigned to the points and interconnections. A *ventilation network* consists of an interconnected group of branches and nodes. Branches or airways are the roadways, shafts, etc., through which the air flows

and in which the state of the air can be measured. A branch begins and ends at a node, which is defined as a position at which two or more branches meet. A mesh is defined as two or more branches connected in series and forming a closed loop.

Basically, the solution of mine ventilation network problems satisfies the well-known Kirchhoff's laws. The techniques for numerically calculating the conditions laid down by these laws were established by Hardy Cross (1936). The procedure to be followed for the manual application of the Hardy Cross (1936) method can be summarized as follows:

1. Estimate the air quantity flowing through each branch of the network and the pressures developed by the fans. The estimated airflows should normally satisfy Kirchhoff's first law at each junction.

2. Examine the network and decide upon a pattern of closed meshes. The minimum number of meshes is given by

$$\text{number of branches} - \text{number of junctions} + 1 \qquad (11.10.1)$$

3. For each mesh, evaluate the mesh correction factor from the equation given below:

$$\Delta Q_m = \frac{-Fm}{2\Sigma\ R_i \mid Q_i \mid} \qquad (11.10.2)$$

where F_m is pressure drop around the mth mesh, ΔQ_m is the correction for the mth mesh branches, and R_i and Q_i are the resistances and the quantities, respectively, in branches constituting the mth mesh.

4. Correct the flow in each branch.

Repeat steps 4 and 5 until all values of ΔQ_m are below a specified level. A satisfactory flow balance will then be reached.

Consider a simple example of a mine ventilation system, as shown in Fig. 11.10.1, where the total quantity flowing and the resistances in the branches are given. There are two meshes, BCFEB and CDGFC, in the network. Fig. 11.10.2 represents a simplified sketch of the meshes. Initially, let the quantities flowing through the branches be estimated to satisfy Kirchhoff's first law, as shown in the Fig. 11.10.2. Kirchhoff's second law now can be applied to the two meshes, BCFB and CDFC. Identify mesh BCFB as mesh I and CDFC as mesh II. In all the calculations, the clockwise flow has been considered as positive. Calculation is terminated whenever the value of corrections for all the meshes is 100 cfm (0.047 m^3/s) or lower. Calculations for the first iteration are presented in Table 11.10.3, and the flow distribution at the end of the iteration is shown in Fig. 11.10.3. Note that the junction laws still remain satisfied (Ramani, 1980).

Because the correction quantities are greater than 100 cfm (0.047 m^3/s), the calculations are continued. Iteration 2 with its associated correction quantities and flows is presented both in Table 11.10.4 and Fig. 11.10.4. At this stage, both ΔQ_{I} and ΔQ_{II} are greater than 100 cfm (0.047 m^3/s) and therefore the iterations are continued. The calculations of the third iteration are shown in Table 11.10.5, and the flows are presented in Fig. 11.10.5. Now the correction quantities ΔQ_{I} and ΔQ_{II} are smaller than 100 cfm (0.047 m^3/s) and therefore the iterations are terminated since the desired accuracy has been reached. Note that in these calculations, it has been assumed that the fan pressure remains the same during the variations in Q_i. Such an assumption will hold only if the fan is operating on the flat portion of its characteristics. However, Scott and Hinsley (1951) have considered the changes in fan pressure due to quantity changes and have modified the iterative equation:

$$\Delta Q_m = \frac{-Fm}{2\Sigma\ R_i \mid Q_i \mid} - dF\,(Q_i)/dQ_i \qquad (11.10.3)$$

where $dF\,(Q_i)/dQ_i$ is the slope of the fan characteristic at the operating point $(F(Q_i),\ Q_i)$. With knowledge of iterative solutions, attention can now be directed towards the solution of multi-mesh networks.

Solutions to network problems required extensive time on mechanical calculators, and even with modern electronic digital calculators, they still can be very tedious and time consuming. As a result, in the 1950s, there was a move to electrical analogue computers. The normal square-law relationship between flow and pressure was initially accommodated in the variable resistance of electric light bulbs (Maas, 1950). The method has a major advantage of onsite availability that was emphasized by Kline and Suboleski (1972), but it is not very flexible when several networks are to be solved simultaneously.

The situation has changed again with the increased use of digital computers. Modern machines have high calculating speed and adequate storage capacity for solving ventilation network problems economically. The digital computer offers the best available method for solution of mine ventilation networks, and it can easily provide a high degree of accuracy for network solutions.

11.10.2.3 Computer Solution for Mine Ventilation Problems

The Hardy Cross method of network solution, explained in detail in the earlier section, lends itself particularly well to programming for digital computers. To illustrate the use of the digital computer for mine ventilation analysis, a network of moderate complexity solved previously by Trafton and Hartman (1964) is used. The ventilation system shown in Figs. 11.10.6 and 11.10.7 is representative of a coal mine being worked from two shafts and employing bleeders for methane drainage through the gob. Although the network may appear to be an uncomplicated one, it consists of 42 airways, 32 junctions, and 11 loops. Each junction in the network is numbered, and airways are designated by these numbers. The loops comprised by the airways are given letter-number combinations. The directions of

flow indicated by arrows were assumed initially and are not necessarily the correct directions. The input data necessary in the problem, in the form in which they are read to the computer, appear in Tables 11.10.6 and 11.10.7.

The assumed flows that appear in Table 11.10.8 are those flows in each airway if 100,000 cfm (47.2 m^3/s) quantity of air is assumed to be entering the mine. This is demonstrated in Table 11.10.8 by the flow in airway 1-2. This assumed air input could be any, but some assumed amount of air must be going into the mine in order to solve the network problem. A quantity of 100,000 cfm (47.2 m^3/s) was chosen since this shows what percentage of the total amount of air input is distributed to the

Table 11.10.3. First Iteration (11.10.2.2)

Mesh I	Branch	*Q*	*R*	*R/Q/*	*R/Q/Q*

				8.34×10^5	-2.68×10^9

$$\Delta Q\ \text{II} = \frac{-(-2.68 \times 10^9)}{2\ (8.34 \times 10^5)} = 1.59 \times 10^3$$

Balance the network:

$Q_{bc} = 44300 + 2450 = 46750$
$Q_{cf} = 4800 - 2450 + 1590 = 3940$
$Q_{fb} = 55700 - 2450 = 53250$
$Q_{cd} = 49100 + 1590 = 50690$
$Q_{df} = 50900 - 1590 = 49310$

Table 11.10.5. Third Iteration (11.10.2.2)

Mesh I	Branch	Q	R	$R/Q/$	$R/Q/Q$
	bc	46,750	4.25	1.99×10^5	9.30×10^9
	cf	−3,940	9.45	0.372×10^5	-0.147×10^9
	fb	−53,250	3.25	1.730×10^5	-9.20×10^9
				4.09×10^5	-0.05×10^9

$$\Delta Q\ \text{I} = \frac{-(-0.05 \times 10^9)}{2\ (4.09 \times 10^5)} = 60$$

Mesh II	Branch	Q	R	$R/Q/$	$R/Q/Q$
	cd	50,690	7.60	3.86×10^5	19.60×10^9
	df	−49,310	8.20	4.30×10^5	-19.80×10^9
	fc	3,940	9.45	0.37×10^5	0.15×10^9
				8.53×10^5	-0.05×10^9

$$\Delta Q\ \text{II} = \frac{-(-0.05 \times 10^9)}{2\ (8.53 \times 10^5)} = 30$$

Balance the network:

$Q_{bc} = 46750 + 60 = 46810$
$Q_{cf} = 3940 - 60 + 30 = 3910$
$Q_{fb} = 53250 - 60 = 53190$
$Q_{cd} = 50690 + 30 = 50720$
$Q_{df} = 49310 - 30 = 49280$

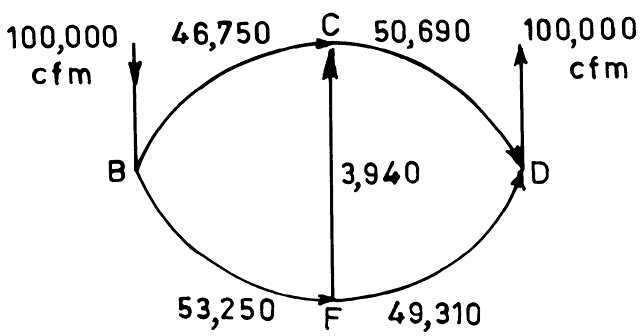

Fig. 11.10.4. Flows at the end of the second iteration. Conversion factor: 1 cfm = 0.472 × 10^{-3} m^3/s.

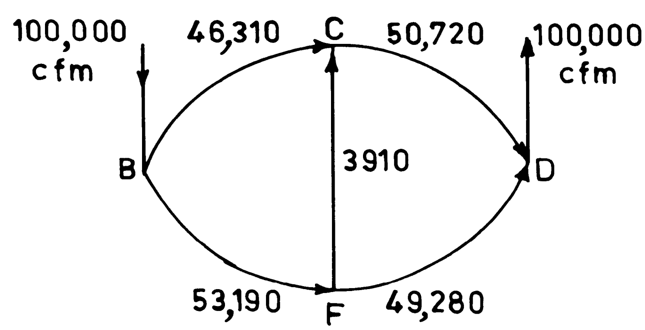

Fig. 11.10.5. Final flows in the network. Conversion factor: 1 cfm = 0.472 × 10^{-3} m^3/s.

various airways within the mine system. As an example, 40.3% of the total air input passes through airway 3–6, while 19.8% passes through airway 6–7. Of course, each mine air input varies, with the l00,000-cfm (47.2-m^3/s) value an input parameter, and a computer program is usually designed to allow any value to be used.

The adjusted values are those values of airflow through each airway that have been computed if a fan with the given characteristics had been installed externally to the mine ventilation network. In order to clarify this, airway 1–2 in Table 11.10.8, which as shown in Fig. 11.10.7, has 100,000 cfm (47.2 m^3/s) flowing within it if 100,000 cfm (47.2 m^3/s) is assumed to be entering the mine. However, if a fan of those given characteristics (Table 11.10.9) was installed, the fan H–Q characteristic curve and the mine characteristic curve is found by the computer to intersect at 265,608 cfm (125.4 m^3/s). This means that this fan is generating 265,608 cfm (125.4 m^3/s), which would be the mine air intake. Therefore, airway 1–2 has 265,608 cfm (125.4 m^3/s) of air flowing through it since 100% of the air input has to pass through this airway. Thus the value 265,608 cfm (125.4 m^3/s) is given as the adjusted flow with the fan in Table 11.10.8. Since airway 3–6 only has 40.3% of the air passing through it, then with a mine input of 265,608 cfm (125.4 m^3/s), only 106,995 cfm (50.5 m^3/s) will pass though airway 3–6.

From an original assumed mine quantity of 100,000 cfm (47.2 m^3/s) and a flow route 1–2–3–4–15–17–21–22–28–29–30–31–32, iterations were performed to correct the airway quantities until the cumulative error was reduced to 210 cfm (0.099 m^3/s). The total number of iterations required were 107. Then pressure losses were computed; values of H and Q, based on the assumed mine quantity, are given in Table 11.10.8. Direction of flow is indicated by the sequence of numbers designating each airway. The corresponding overall mine pressure loss is 0.37493 in. water (93.3 Pa). At the intersection point of the system curves, the

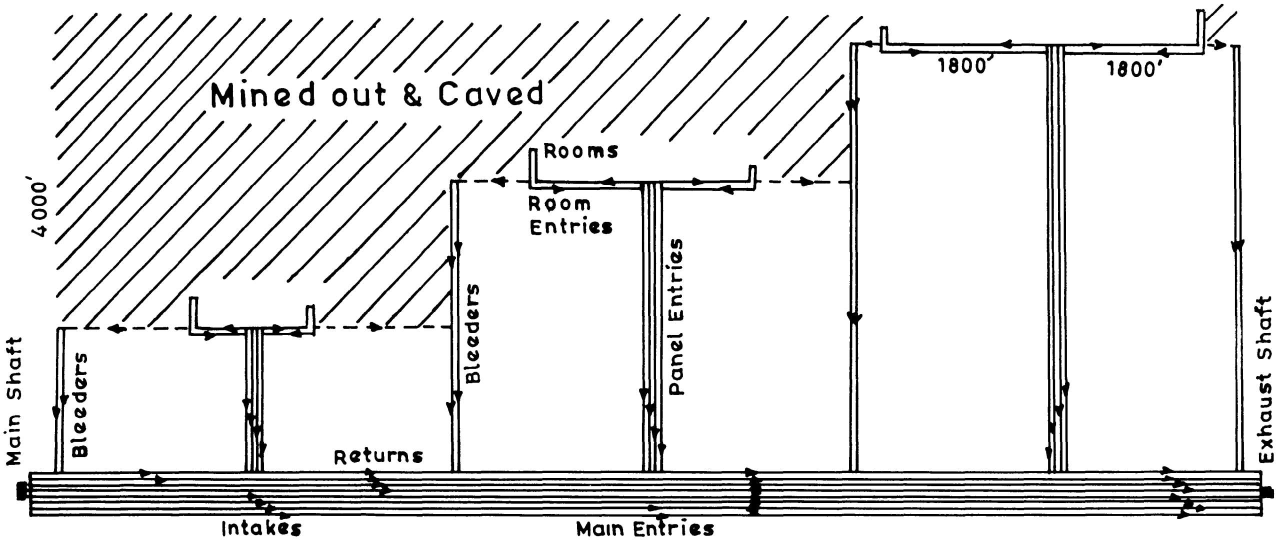

Fig. 11.10.6. Plan of room and pillar coal mine being worked with continuous equipment (Trafton and Hartman, 1964).

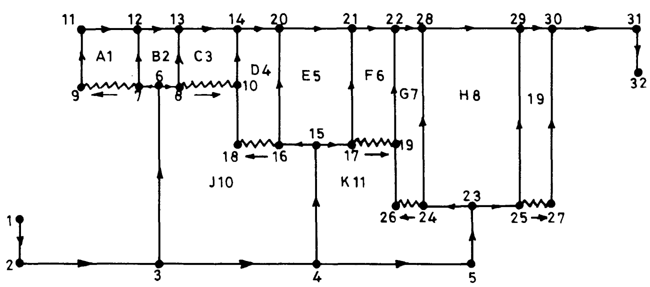

Fig. 11.10.7. Ventilation schematic of coal mine in Fig. 11.10.6. Complex network employing natural splitting with loops, airways, and junctions labeled and directions of flow indicated (Trafton and Hartman, 1964).

Table 11.10.6. Characteristics of Airways

Airway	Size, ft	Friction Factor $K \times 10^{10}$ lb-min^2/ft^4
main shaft	12 × 24	40
entries, rooms, crosscuts	6 × 15	60
caved ground	1 × 10	150
air shaft (31-32)	10 × 10	25

Conversion factor: 1 ft = 0.3048 m, 1 lb-min^2/ft^4 = 10^6 kg/m^3.

actual mine quantity was read as 265,608 cfm (125.4 m^3/s) and the mine pressure loss as 2.645 in. water (658 Pa). Using the proportion 265,608/100,000, new values of airway flows were computed. From the square of this proportion (since $H = RQ^2$), new values of airway head losses were likewise computed. These also appear in Table 11.10.8 and are the actual airway quantities and pressure losses that result when the given fan is installed in this mine. The computer program can be adapted to perform all calculations without intervention.

As expected, leakage through the gob is small (e.g., from 2081 cfm [0.98 m^3/s] in 7–9 to 6536 cfm [3.08 m^3/s] in 25–27). To increase the exhaust flow through the bleeders, room entries could be maintained open rather than caved; this may be desirable and would also serve to reduce the mine head somewhat.

The practical application of such a solution to the problem of natural splitting in a network may not be great, since practically every coal mine today employs controlled splitting. However, a rapid, simple means of obtaining accurate solutions by digital computer means that limits can be determined easily and a wide range of design variables can be explored readily.

11.10.2.4 Computer Programs For Solution Of Mine Ventilation Networks

Several computer programs have been developed in the United States (Hartman and Trafton, 1963; Wang and Hartman, 1967; Greurer, 1977; Hall et al., 1977; Stefanko and Ramani, 1972) and abroad (Hashimoto, 1961; Hitchcock and Hoover, 1976; McPherson, 1966) with the capabilities to solve complex ventilation networks and have been successfully used by many mining companies (Tien and Bjork, 1976; Mishra, 1973; Press and Johnston, 1976) and government organizations for analysis of complex ventilation systems. The use of ventilation network programs enables many more future situations to be investigated than would otherwise be practicable. It should perhaps be emphasized that the utilization of these programs does not require knowledge of their mode of operation. The ventilation engineer is intimately concerned with the preparation of his/her input data and analysis of the simulated results, but not with the mathematical and programming aspects of the network program. With these simulators, the mine ventilation engineer is provided with maximum information retrieval from the simulated network. In short, each possible ventilation alternative or situation can be easily tried on paper and evaluated before a final decision is taken. The general aspects of the information flow and logical structure of the mine ventilation simulator are shown in Fig. 11.10.8. For a detailed discussion of network solutions, see Wang (1982).

Table 11.10.7. Input Data (11.10.2.3)

Airway	Size, ft.	No.	Length, ft.	K_x 10^{10}	Airway	Size, ft.	No.	Length, ft.	K_x 10^{10}

11.10.3 COMPUTER APPLICATION TO FLOW PROBLEMS IN MINE VENTILATION

Most mine air pollutants, such as respirable dust, methane, diesel exhaust, and blasting fumes, are produced in face areas and haulageways. Their dispersal in mine airways contribute to interesting flow or transfer problems. Knowledge about sources, emission, and transport of these pollutants is essential for ventilation planning and design to ensure good engineering control over air quality, quantity, and environmental conditions. These physical phenomena in mine ventilation involve transient heat

Table 11.10.9. Fan Characteristics (11.10.2.3)

and mass transfer and can be described by parabolic differential equations (PDEs). Solution of these equations in the past was normally attempted using analytic approaches such as Laplace transforms. Even for simple problems, when account is taken of only one of the variable factors such as harmonic oscillations, stepwise changes, etc., calculations become complex. The advent of digital computers and advances in applied mathematics has made it possible to describe emission, dilution, and dispersion of contaminants into the mine atmosphere. The theoretical investigations into pollutant flow and diesel exhaust to be presented here are examples of ventilation problems that are completely computer-dependent. The computer is programmed to solve mathematical models, thereby enabling the flow phenomena to be simulated by varying parameters such as the characteristics of the gas source, boundary conditions, and air velocities (see Chapters 11.2, 11.3, and 11.5 for general coverage of contaminants).

11.10.3.1 Simulation Of Gas Emission And Transport

The major classifications of gases that enter a mine ventilation system are (1) flow through airways (herein, fully developed laminar or turbulent transfer of air, gas, and dust takes place in the airways, the geometry and surface properties of which are well defined); (2) flow through caved workings (flow through caved working can be laminar or turbulent, depending on the degree of consolidation of the broken strata and the pressure difference across the area); and (3) flow through porous media (an example is the seepage of methane from coal beds and adjacent strata in situ). The transport of dust, methane, and diesel exhaust in mine airways is but a variant of a diffusion-dilution problems relevant to underground mining practice.

Modeling of mass transfer phenomena in mine ventilation is largely based on extensive studies of turbulent dispersion in wind tunnels and the lower atmosphere of the earth. The general approach in the formulation of models lies in the recognition that these mass transfer phenomena can be conceptualized as a flow problem that can be solved by the general application of Taylor's theory (1954) of turbulent flow and diffusion with modification appropriate to the relevant static and dynamic parameters. If the face zone is initially contaminated by a pollutant over a long section (e.g., instantaneous exposure of large gas accumulations, rapid methane release, etc.), the process of decontaminating the mine workings can be regarded as displacement and diffusion of the trailing edge of the cloud of contami-

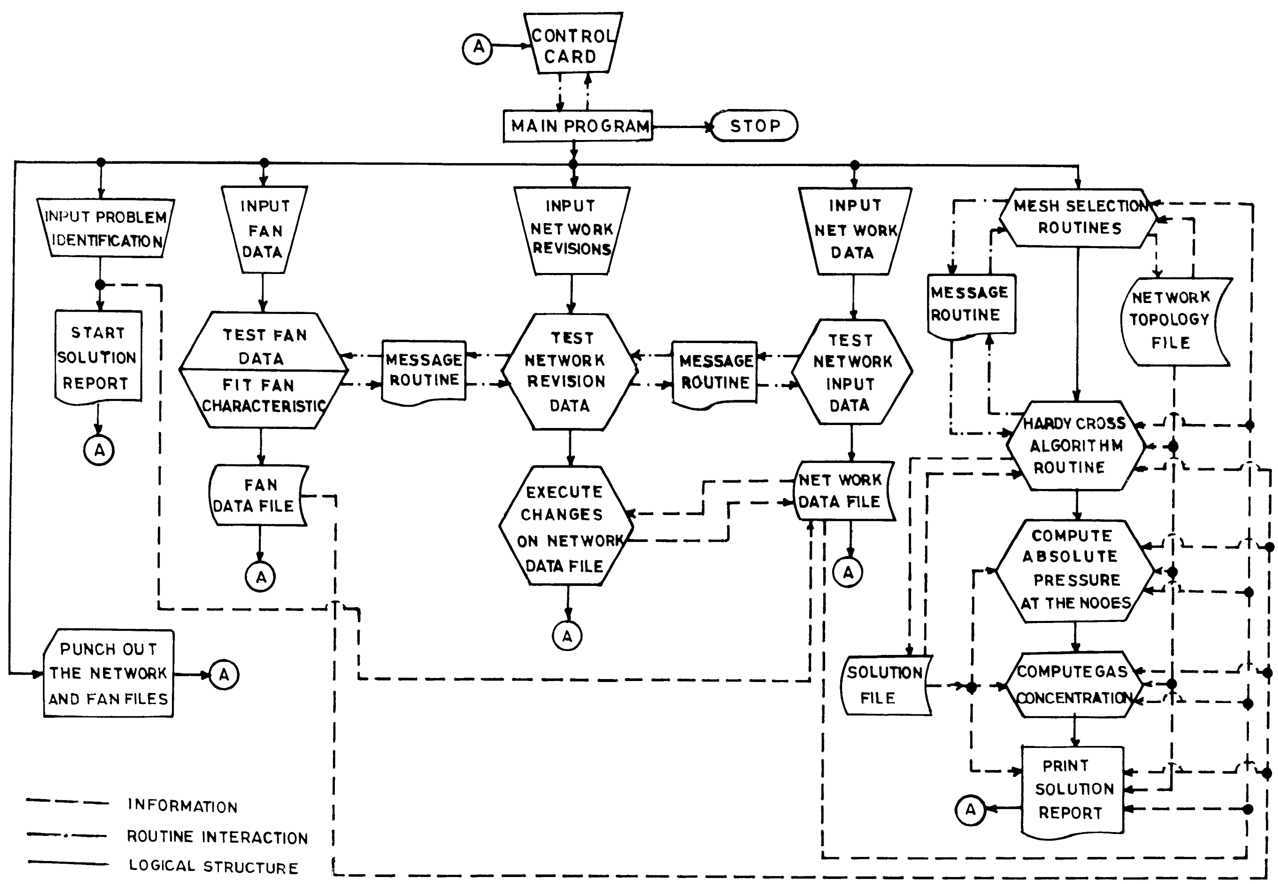

Fig. 11.10.8. Information and logical structure of the mine ventilation simulator (Didyk et al., 1979).

nants in the form of a semi-infinite gas body, for which a one-dimensional mass transfer equation is represented by:

$$\frac{\delta C}{\delta t} + \frac{u\delta C}{\delta x} = Ex\,\frac{\delta^2 C}{\delta x^2} + f(x,t) \qquad (11.10.4)$$

In Eq. 11.10.4, the term $\delta C/\delta t$ is the rate of growth of the concentration in the differential element, while $u(\delta C/\delta x)$ is the net gain of material due to convective transfer. The two terms balance the total loss of material due to turbulent dispersion that is represented by $Ex\,\frac{\delta^2 C}{\delta x^2}$, and $f(x,t)$, the source term for the pollutant in the roadway.

The approach in modeling is to use the above partial differential equation to predict the concentration growth in an airway.

Equations containing first-order spatial derivatives, such as the equation shown above, are known as "convection-diffusion" equations because of the physical processes that they describe. Typically, a suspended material (such as diesel exhaust pollutant) is carried along (convected) by a fluid at the same time as its concentration is being attenuated (diffused) within the flow. Numerically, more interesting problems arise when the first-order (convection) spatial derivatives are large in relation to the second-order (diffusion) derivative; that is, the solution behaves like the solution to the limiting hyperbolic (purely convective) case. In the converse situation, when diffusion is dominant, ordinary methods of parabolic equations can be used.

By employing numerical methods of solving partial differential equations for turbulent dispersal, the concentration of pollutants can be determined for any given source configuration, mine geometry, and air distribution (Bandopadhyay and Ramani, 1988). The option of various numerical solution techniques that are available to an analyst to the convection-diffusion equation for cases in which convection is dominant include

space discretization	finite difference finite element (consistent) finite element (lumped)
time discretization	implicit explicit
"tricks"	slope continuity elements upwinding penalty functions dispersion correction higher-order time scheme

11.10.3.2 Simulation of Diesel Exhaust Dispersion and Transport

The application of Taylor's theory (1954) to the study of diesel exhaust dispersion in mine airways appears to be an extension of the Russian work on dispersal of methane, blasting fumes, and dust. Skobunov (1970) recognized that ventilation calculations based on traditional dilution formulas did not adequately explain observed conditions. One reason was that multiple contaminations of the mine air could conceivably occur as a result of several vehicles operating in the same or parallel-connected entries. In addition, Holtz and Dalzell (l968) developed an effective ventilation concept for explaining the changes in concentration due to differential vehicle and air movement in mine entries. Models developed by Skobunov (1970) calculated the growth of contaminants in mine airways for single or multiple diesel vehicles. These models allowed consideration of the absorption of gases and air losses due to leakage. In later work, Skobunov (1974) examined the concept of turbulent flow across a mine entry cross section and developed a series of models based on transverse turbulent diffusion. These later models are applicable to moving axisymetric sources such as diesel vehicles, and linear sources such as a longwall plough.

Other Russian researchers (Osipov and Grekov, 1968) suggested the use of a convection-diffusion transport model to describe the transport of a gaseous pollutant in confined ventilation currents. Later, Grekov and Kalyusskii (1972) examined the concept of convection-diffusion transport of pollutants in which the current velocity varies with distance owing to air leakage.

The interest in increasing use of diesel-powered equipment in US coal mines has led to the development of mathematical models for the emission, dilution, and dispersion of gaseous pollutants from diesels. Stefanko et al. (1974, 1977) developed and evaluated diesel dispersion models through a grant from the US Bureau of Mines.

Diesel Exhaust Flow Models. When a diesel engine is traveling in an airway, load and speed change with time as a function of the engine duty cycle. The engine exhaust volume and composition are a function of engine speed and power, making it necessary to estimate the change in the pollutant volumes with time and location as a function of engine speed and load. To estimate the source function, it is necessary to know the engine speed, engine load, and vehicle speed at frequent intervals to account for variation in the pollutant flow rate. It would not be practical, however, to instrument every teletram or similar diesel-powered vehicle to acquire those data. It is possible, however, to generate the engine duty cycle and exhaust volumes and analyses on the basis of the simulation of a given production system (Ramani and Kenzy, 1978). One advantage of this approach is that several diesel-powered equipment deployments can be analyzed to generate values for the parameter of interest.

Generally, diesel engines move faster than air currents in the face areas and, consequently, the air that flows through the haulage road is contaminated several times before it is finally discharged into the return airways. This leads to a progressive rise in concentration in both the spatial and time axes owing to the superposition of contaminants. The concentration profile does not reach a steady-state situation because the velocity vector is not uniform. The concentration profile will not be fully developed in the face area because, when a moving plane source is used, the distance required to obtain adequate mixing to reach a steady-state situation is often greater than that found in the face area. The concentration gradient in the return airway, however, reaches steady-state. Air velocity affects the concentration growth in the return. The total contamination in the air at any point is the sum of the incremental contaminants from diesel engine(s) passed by the air. When the engine and the air are traveling in opposite directions, the predominant feature in the mass flow is the convective transfer, which causes deformation of both the front and rear profiles of the contaminant clouds. As the source moves further away from the face, the role of convective transfer gradually decreases along the length of the airway. In effect, the contaminant concentration front is an increasing function of distance and time from the face. Utilizing the conservative volume element methods, convection-diffusion mathematical models were developed for analyzing the growth of pollutant concentration for each of the following situations:

1. A single engine moving in an airway with or without considerable leakage.
2. Multiple engines in a single airway.
3. Multiple engines in a network of roadways.

The physical situation for the model in case 1 is operation of a diesel engine for face haulage. Operation of diesel engines for secondary and primary track haulage can be studied with the models for the other cases. Bandopadhyay and Ramani (1983, 1984, 1985) have detailed the finite difference approximation of the convective-diffusion equations and the boundary conditions used for the above model solutions.

11.10.3.3 Simulation of Methane Flow in Mine Airways

Much of the early work on the use of computers to simulate methane flow rates in mine airways was carried out during the 1960s, and only two are claimed to have been used with any success (Lidin, 1964; Airey, 1968).

Lidin's model is an empirical equation based on extensive research and compilation of actual gas emission data. Airey's model, on the other hand, was developed on the basis of the Darcian equation of gas migration through homogenous, permeable solids and can be solved numerically or analytically.

The quantity of methane emitted into the mine atmosphere and the movement of gas through solid coal and the adjoining country rock are dependent on the physical properties of the medium, boundary conditions, the initial gas pressure distribution, and the combination of natural and mining factors. Functional relationships among the factors are not yet known (Ramani and Owili-Eger, 1974). Consequently, the development of rigorous mathematical models to predict methane flow into mine air is difficult, and to date no model has been reported that is capable of such a function. The mathematical model that Ramani and Owili-Eger used is given in Eqs. 11.10.5 and 11.10.6, which are further attempts in presenting practical models for predicting the quantity of methane emission into the mine environment. Eq. 11.10.5 is the steady-state model and Eq. 11.10.6 is the unsteady state model:

$$\delta/\delta x \left\{K_x \frac{\delta P^2}{\delta x}\right\} + \delta/\delta y \left\{K_y \frac{\delta P^2}{\delta y}\right\} + W(x,y) = 0 \qquad (11.10.5)$$

$$\frac{\delta}{\delta x}\left\{KxA_x \frac{\delta P^2}{\delta x}\right\}\Delta x + \delta/\delta y\left\{K_yA_y \frac{\delta P^2}{\delta y}\right\}\Delta y + 0.1\ MZTq = \frac{M\phi CV_b}{5.615}\frac{\delta P^2}{\delta t} \qquad (11.10.6)$$

where P is gas pressure; $W(X,Y)$ is the source term for the steady-state model; x and y are the coordinate axes; K_x and K_Y are the directional permeabilites; A_x and A_y are the cross-sectional areas of the medium or block in the x direction and y direction, respectively; x and y are the dimensions of the block in the x direction and y direction, respectively; M is fluid viscosity; Z is gas deviation factor; q is gas flow rate; T is absolute temperature (in °R); ϕ is medium porosity; C is the gas compressibility coefficient; and V_b is volume of the block or medium. The variable t is the time. The source term is expressed as

$$W(X,Y) = \frac{0.1MZT}{V_b}q \qquad (11.10.7)$$

A finite difference analysis is used for solution of the above equations, each node being allocated initial rock properties and gas pressure. The model reacts to the changes that take place with respect to time. The flow of methane from block to block towards the ventilated airways is thus simulated. The simulation program provides output information on pressure distribution and methane flow rate at each block. The flow diagram for the methane generator program is shown in Fig. 11.10.9.

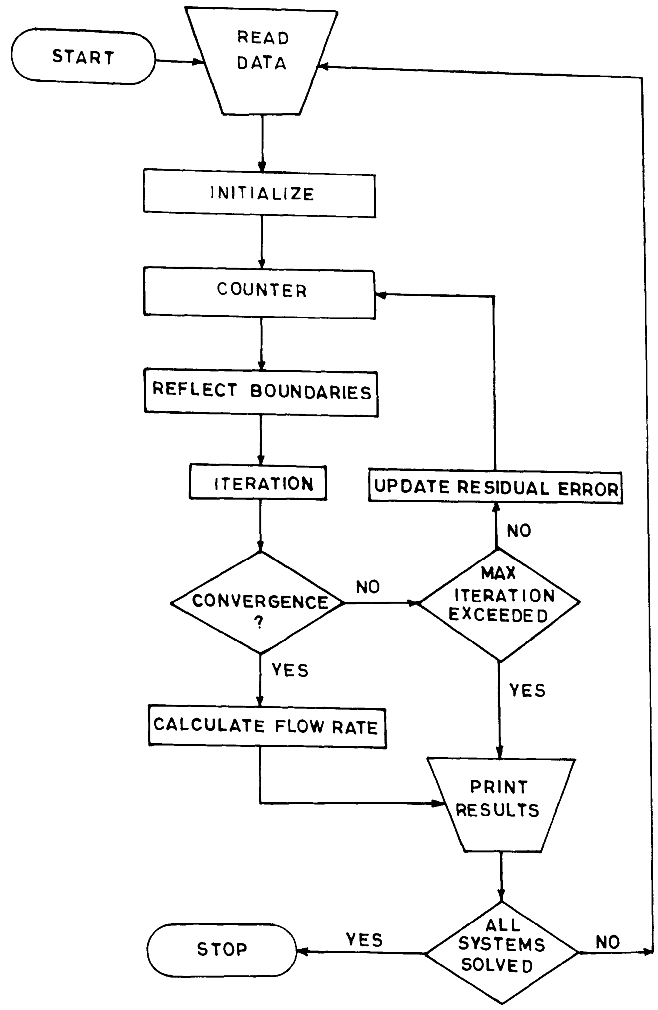

Fig. 11.10.9. Methane simulator flow diagram (Ramani and Owili-Eger, 1974).

In the United Kingdom, a method is being developed for prediction of methane emission into longwall workings. The method is based on the theoretical treatment of gas emission from coal seams (Airey, 1968; Dunmore, 1980). The method permits calculation of the emission rate from knowledge of the depth of the working, the sequence of gas-bearing coal seams in the disturbed strata, the initial gas content of these strata, and the proposed dimensions and the advance of the face. The National Coal Board's Mining Research and Development Establishment (MRDE) has developed a computer program to enable the emission rate to be calculated as a function of time (Curl, 1978). The program considers the shift-by-shift changes in the face advance, gives the required airflow to dilute methane concentrations to acceptable levels, and allows for the peaking of methane emission during the production periods. The program also enables the amount of gas liberated to be calculated at various positions in the gate roadways.

11.10.4 COMPUTER-AIDED MONITORING AND CONTROL SYSTEM

Recent advances and changes in requirements and philosophy have led to added emphasis being placed on remote control and monitoring in mines, particularly in relation to the underground environmental quality in mines worldwide. Hitherto, methods of monitoring the mine environment have been based on periodic spot observations by hand-held instruments. Such methods are labor-intensive, are expensive, provide only limited amounts of information, and sometimes suffer from the disadvantage that a comparatively long time may elapse between measurements and availability of results. The changing and varying characteristics of some hazards and the recent successful development of suitable sensors and transducers and monitoring systems have emphasized the need for, and benefits to be derived from, monitoring environments mine-wide.

Computer-based mine monitoring and control systems are the mining industry's state-of-the art use of specialized computer technology—both hardware and software—to "automate" a mine. It is a computerized data acquisition and analysis facility with the capability of controlling underground electrically powered equipment. These systems lend themselves readily to remote monitoring of the mine environment for continuous indication of state and early warning of abnormal conditions and adverse environmental trends. In addition, such systems can be applied to monitor and control machinery forming part of a mine environmental system, such as booster, auxiliary, and surface mine fans. Characteristics that can be sensed by the system include temperature, pressure, velocity flow rate, vibrations, and essentially any other parameters that can be measured and presented as electrical signals to the monitoring and control system. Environmental factors such as methane concentrations, carbon monoxide, diesel exhaust, oxygen, smoke, air velocity, and dust are sensed using available instruments.

For a general discussion of monitoring and control, see Chapter 12.6.

11.10.4.1 Monitoring System

Remote environmental monitoring enables continuous interrogation of selected parameters at one or more strategic positions to be made so that current values can be determined, variations detected and evaluated, and early warning given of abnormalities and adverse trends. Action can then be considered and, if necessary, taken more quickly than at present to correct the effects of an abnormal condition. Situations prior to, during and after abnormal events such as spontaneous methane emission, can be evaluated and factual information provided on trends, analysis, and potential remedies. Continuous monitoring of the underground environment involves interrogation and overall surveillance of certain parameters at strategic environmental positions at predetermined time intervals. A large number of on-off (digital or binary) signals are now available (Table 11.10.10) through two-state switches, relay instruments, instrument alarms, and the like. Analog functions, on the other hand, vary continuously to provide precise measurements of gas concentrations, pressures, velocities, flows, temperatures, etc.

Available environmental monitoring equipment includes

1. Methane monitors.
2. Smoke monitors.
3. Air velocity monitors.
4. Carbon monoxide monitors.
5. Carbon dioxide monitors.
6. Oxides of nitrogen monitors.
7. Relative humidity monitors.
8. Pressure monitors.
9. Temperature monitors.
10. Vibration monitors.

These digital and/or analog sensors are connected to "central station" input circuits. The central station contains electronics to perform processing of sensor signals, and reduce the data to digital form. The total number of sensors employed underground can range from one to hundreds, depending on the size of the system and layout philosophy of the mining operation. Various aspects of data collection and processing information are discussed with reference to Fig. 11.10.10, shows the physical configuration of the Conspec mine-wide monitoring and control system.

11.10.4.2 Conspec Senturion System

Specially designed accessor cards are the backbone of the Conspec system. The accessor is a single-point data transmittor/receiver processor and "intelligent," allowing the central computer to monitor and control all the connected equipment. The major advantage of the accessor is that it reduces the installation wiring cost and increases system reliability. The central microcomputer station communicates over four accessor trunks. The accessors have specially designed chips that multiplex the data for communication to the central station. The accessors are in the form of printed circuit cards upon which all the necessary logic circuitry is mounted. Reprogrammable rocker switches on the accessor allow address selection and point-data transmission.

Accessors are available that control equipment from simple start/stop functions to linear devices requiring proper feedback for control.

The primary means of displaying information is a CRT screen. The screen and its keyboard are the link from the system to the operator. Through this, the operator programs the system, receives a visual description of device status, and transmits signals to required accessors.

To set up the system, it is a simple matter of knowing what code each individual accessor was assigned and on which trunkline it is communicating. From here, the processor prompts the operator into entering information such as identification number, type of accessor and device being monitored, limits of operation and scaling factors, and a description of the device. Once a device is coded and entered in the system, it is ready to transmit information.

The central station can also be equipped with a variety of CRTs and printers. The use of two printers allows regular alarm and status change events to be printed simultaneously.

The CRT and printers can interact in a variety of ways. When a point is assigned to the system, it is given a code which dictates which way it appears on the screen and printers, and whether or not an alarm is sounded. In this way, repetitious events such as opening and closing of a ventilation door can be coded not to appear on the CRT or printer but to sound an alarm if opened too long. In all cases, an alarm will sound if a problem arises in the hardware of the system.

Environmental monitoring with a mine-wide monitoring and control system has provided specific benefits in US mines in relation to existing and potential hazards. Specific problems, for example, floor and roof methane emissions, high emission rates, etc., have been assessed and countered.

Mine-wide monitoring systems offer considerable potential and scope for continuous, essential, and factual information on particular aspects of the environment in relation to other parameters such as the incidence of methane peak flows or significant changes in methane emission rates. Computer programs are be-

Table 11.10.10. Selected Remote Environmental Monitors Used In British Mines

Parameter	Monitor and/or Switch	States
General body firedamp concentration in airways	BM.1 Single-head methane	Analog and/or ON/OFF
General body mine gases	Tube bundle	Analog and/or ON/OFF
Carbon monoxide	Tube bundle	Analog and/or ON/OFF
Air velocity in roadways	BA.1 Single-headed air velocity monitor	Analog and/or ON/OFF
Smoke	Trolex mine smoke detector	ON/OFF
Vacuum in firedamp drainage pipes	Vacuum switch and indicating unit	Analog and/or ON/OFF
Combined vacuum and flow in firedamp drainage pipes	Combined vacuum differential switch and indicating units	Analog and/or ON/OFF
Purity of drained firedamp	Acoustic methanometer Tube bundle	Analog and/or ON/OFF Analog and/or ON/OFF
Vibration levels in operating fans and firedamp extractors	Vibration monitor	Analog and/or ON/OFF
Ventilation system pressures	Pressure switch and/or recorder	Analog and/or ON/OFF
Temperature of fan or extractor motor carcases or water	Surface or probe type temperature monitors	ON/OFF
Auxiliary fan or multi-unit booster fan clusters ducts air velocities	IS or flameproof air flow switch	Analog and/or ON/OFF
Multi-unit booster fan clusters isolation doors' position	Proximity switches	ON/OFF
Auxiliary ventilating duct air pressures (suction or pressure)	Pressure or vacuum switches or recorder	Analog and/or ON/OFF

ing developed to analyze such situations and determine interrelationships of variables. The results of such analysis are bound to lead to improved and safer working conditions.

11.10.5 EXPERT SYSTEMS IN MINE VENTILATION

Much has been discussed on the suggested use of on-line computer systems for monitoring and control of the underground environment (Chapter 22.2). The next logical step in the development of these systems is to add predictive capabilities to simple reporting functions, such as alerting the operator that signs of spontaneous combustion are beginning to show in a district. Also in the sensor technology, development of "intelligent" sensors capable of acting independently is also a possible step in the future. In an emergency, intelligent sensors would not wait for a command from the central computer but would act independently to shut down electrical power, sound alarm, etc., thus speeding up response time.

Work is in progress in several countries on software systems, commonly known as "expert systems," that would combine in a real-time basis (1) the expert knowledge and response in a decision situation; (2) the existing knowledge based on laws and regulations, mine layout, etc.; and (3) real-time information gathered by the mine monitoring systems. Ramani and Prasad (1987) reported on the essential elements of such a system (Fig. 11.10.11) that can be used for mine ventilation system design. Three major elements identified in the system are

1. The knowledge base and its input-output interfaces to the design and analysis program (DAP).

2. The design and analysis programs, consisting of a ventilation database and ventilation programs.

3. The actual mine system which is operated on by natural factors and from which data can be collected on a real-time basis.

Much of the internal knowledge in the knowledge base is experience-dependent and can be acquired from experienced mine ventilation practitioners and from public domain sources. An integration of the expert system and traditional algorithmic programs would yield a superior decision support system for mine ventilation design. Development of such system is possible with the current state of system technology.

Chapter 11.2
GAS AND DUST CONTROL

FRED N. KISSELL

11.2.1 METHANE CONTROL IN UNDERGROUND COAL MINES

The most common control method for methane gas and respirable coal mine dust is dilution ventilation. However, this chapter considers only face ventilation measures, which in practice must be integrated with overall mine ventilation planning to ensure delivery of an adequate amount of air (see Chapters 11.6 and 11.7).

All coalbeds contain methane, the amount of which can vary from 0.01 to more than 600 ft^3 /ton (0.0003 to 19 mL/g). Usually, the amount of methane in coal increases with higher rank and greater depth. The gas is both adsorbed on the micropore structure of the coal matrix and compressed in the fracture system of the coalbed. Wherever coal is exposed by erosion or mining, the equilibrium that exists in the coalbed under confining pressure is disturbed, and methane is emitted.

The methane emission from a prospective coal mine can be forecasted using the "direct method" test. This test employs coal cores taken during exploration drilling. Gas seeping from the core is measured and used to forecast the methane emission from the mine (Diamond, LaScola, and Hyman, 1986).

US underground bituminous coal mines emit more than 256 million ft^3 of methane (7.25 M) daily. Two hundred mines account for 98% of this, but they also account for 60% of underground coal production. In the early years of coal mining, inadequate ventilation, failure to test for gas (methane), use of open lights, smoking, failure to remove dust accumulations, and the improper use of black powder for blasting were the most frequently cited causes in explosions. Although both the number of explosions and the number of fatalities per million tons of coal produced has declined, approximately 10% of all underground coal mine fatalities are still due to explosions. Deul and Kim (1988) have provided a good general reference on methane control research up to about 1980. An expert system computer program to give advice on controlling methane is available from the US Bureau of Mines (USBM) (Kissell and King, 1988).

Noncoal mines, especially those located near carbonaceous deposits, may also emit methane.

11.2.1.1 Methane Control in Advance of Mining

Control in advance of mining is accomplished with vertical boreholes, horizontal boreholes, and directional slant holes. The common characteristic of these is that they are all implemented remote from mining operations.

VERTICAL BOREHOLES. Vertical boreholes are used to drain a large block of virgin coal. Essentially, they are gas wells that require continual removal of water from the gas-producing horizon. By lowering the coalbed's water saturation, its permeability to gas increases, thus enhancing methane flow rates.

Because of the inherently low permeability of many coalbeds, vertical boreholes also use hydraulic fracturing or stimulation treatments to create artificial permeability. This is accomplished by pumping a volume of fluid (usually water or foam) under high pressure down the vertical borehole to open up a fracture. A sand proppant is usually pumped along with the fluid to keep the fracture propped open after the injection pressure is released. The penetration of stimulation fluids into the mine roof, causing roof damage, has been a concern of the mining industry. However, 22 case studies of mine-throughs of stimulation treatments in coalbeds showed no evidence of adverse roof conditions that could be attributed to the well treatment (Diamond and Oyler, 1987).

Vertical wells drilled in advance of mining have proved to be an effective technique for removal of methane from coalbeds. Oyler and Stubbs (1985) examined a producing pattern of 23 wells after four years of production and found a 50% reduction in the in-place gas content within the pattern and a 29% reduction 500 ft (150 m) outside the pattern. The commercial use of vertical coalbed wells has been discussed by Dunn (1984).

HORIZONTAL BOREHOLES. Horizontal boreholes have proven to be a very effective technique for removing methane from a coalbed. One technique, horizontal boreholes from shaft bottoms, has also been shown to be an effective method for removal of methane from the coalbed in advance of mining. The biggest drawback to this technique is that it requires the sinking of a ventilation shaft or large-diameter borehole (a large capital expenditure) three to five years in advance of their use. The commercial use of horizontal boreholes has been discussed by Dixon (1987).

DIRECTIONAL SLANT HOLES. A directionally drilled slant hole is a small-diameter borehole that is drilled from the surface and intentionally deflected to intercept the coalbed horizon horizontally. After the coalbed is intercepted, the horizontal drilling is continued. This technique was developed to take advantage of the gas drainage efficiency of horizontal boreholes and the central collection of gas and use of nonpermissible drilling equipment common to vertical boreholes.

Two such holes have been drilled successfully; however, neither hole produced much gas from the coalbed. The problems were difficulty in dewatering the horizontal portion of the borehole and failure to case the borehole far enough into the coalbed.

11.2.1.2 Room and Pillar/Longwall Development

The control of methane during mining on continuous miner sections is accomplished with one or more of the following techniques: ventilation, horizontal boreholes, and water infusion. The common characteristic of these is that they are all implemented from within the mine.

VENTILATION. Ventilation is the universal method of controlling mine gases (Chapters 11.6 and 11.7). In US coal mines, the working place must have a minimum quantity of 3000 cfm (1.42 m^3/s) of air ventilating the face and 9000 cfm (4.25 m^3/s) at the last open crosscut. The purpose of mine ventilation air is to dilute and render harmless the methane emitted from the working face. Therefore, to stay within the statutory limits (1%) established by Mine Safety and Health Administration (MSHA), the mine operator must provide at least 100 cfm (0.047 m^3/s) of air for every 1 cfm (0.00047 m^3/s) of methane. The principles of

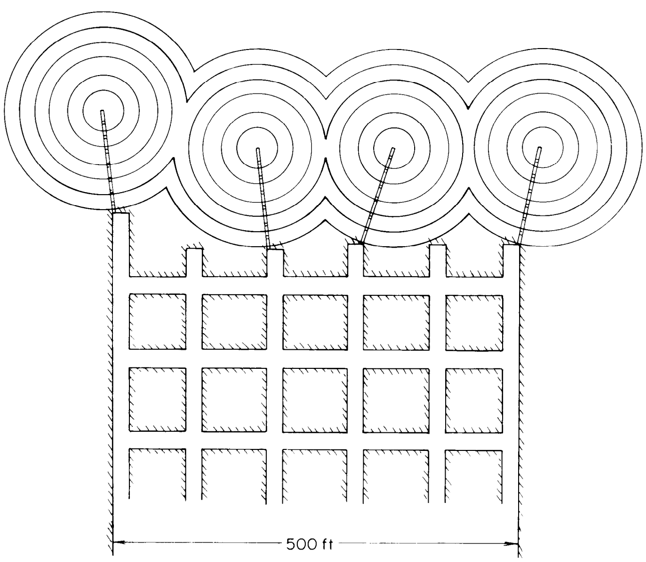

Fig. 11.2.1. Plan view of water infusing a development section.

ventilation are well understood and documented, and computer programs are available for analysis of mine ventilation systems.

HORIZONTAL BOREHOLES FOR METHANE DRAINAGE. The idea of drilling a horizontal borehole into a coalbed to remove methane has been known for at least 45 years; however, much of the technology to effectively drill these holes has only recently been developed (Kravits, Sainato, and Finfinger, 1985). For the mine ventilation engineer, the practical effects of horizontal methane drainage are a reduction in methane emissions during mining and a potential for selling the captured gas at a profit.

The use of horizontal boreholes has consistently reduced methane emissions by at least 50% (Prosser et al., 1981). Also on a longwall development section in an Alabama mine, a 50% increase in productivity was achieved in addition to a 54% decrease in methane emissions (Pate et al., 1983).

WATER INFUSION. Water infusion of coalbeds is a technique that can be used for methane control on working faces but also is beneficial for dust control. Fig. 11.2.1 illustrates a water infusion operation on a room and pillar section. The water that is infused into the coalbed flows through the fracture system displacing the methane that normally resides there. Infusing from the face area forces the methane from the face area and into the returns where the gas is safely diluted and carried from the mine. The result is a reduction in face emissions by as much as 70% (Deul and Kim, 1988).

Water infusion does not capture the methane displaced from the coalbed fracture system (like a drainage system), but just forces it out the ribline away from the working face. The net effect is to reduce methane emissions in the face area and increase methane emissions in the returns. Therefore, water infusion can only be considered as a possible control strategy for face emission problems.

11.2.1.3 Retreat Longwall

Methane problems on retreat longwall sections normally occur in one of five areas: the working place, returns, fresh air entry, bleeder system, or gob. When the immediate roof collapses and falls into the space created by the removal of the coal, fractures propagate up into the overlying strata. If there are methane-bearing rocks above the longwall panel, then methane gas can migrate from the roof and into the collapsed material comprising the gob. Control techniques to be discussed are gob holes and cross-measure boreholes (Baker, Garcia, and Cervik, 1988).

GOB HOLES. An effective method of removing methane from the gob is to drill a borehole from the surface to a point in the strata overlying the longwall panel. Then when mining passes beneath the gob hole, the methane can be drawn to the surface with the use of a surface exhauster installed on the borehole. Typically, three or four gob holes, drilled to within about 150 ft (45 m) of the top of the coalbed, are required on a longwall panel to provide effective control for the total length of the panel.

CROSS-MEASURE BOREHOLES. Although gob holes are normally used to control excess methane in bleeders and gobs, there are times when irregular surface topography, unavailability of surface right-of-ways, or costs prohibit their use. For these reasons, an alternative was developed, cross-measure boreholes.

In the cross-measure borehole system, small-diameter boreholes are drilled from the tailgate and out over the longwall panel. Each borehole is then connected to an underground pipeline that transports the captured gob gas to a vertical borehole for removal from the mine. The gas is captured because a partial vacuum is applied to the exhausting system and as the longwall retreats, the cross-measure boreholes intercept the fracture system over the caved gob and draw the gob gas into the system (Cervik and King, 1983).

11.2.1.4 Special Methane Situations

There are two situations that may arise for the mine ventilation engineer that may be considered special or extraordinary: frictional ignitions and gas outbursts.

FRICTIONAL IGNITIONS. When the bits on continuous miners or longwall shearers move across a hard surface such as sandstone in the mine floor, a streak of hot material will be left as a trail behind the bit. This streak is the source of frictional ignitions. Poor bit maintenance with tungsten carbide inserts lost or broken will aggravate the situation due to the higher incendivity of the steel shank (Courtney, 1981).

The first line of defense against frictional ignitions, as always, is good ventilation. Cecala (1985) has been able to show improved ventilation around a shearer with water sprays. One special area for emphasis that has been identified on longwalls is the headgate cutout area. In this area, several ideas for improving airflow have been identified for reducing frictional ignitions (Cecala et al., 1986). When improved ventilation is not able to solve a frictional ignition problem, then one of two machine-mounted techniques must be used: sprays directed to the back of the bit or modified bit design.

For a longwall shearer, the best machine-mounted solution is water sprays directed to the back of the bit to quench the hot streak. Field and laboratory tests have shown dramatic decreases in the number of frictional ignitions on shearer drums with the use of rear-directed water sprays (Agbede et al., 1982; Cecala et al., 1985). However, due to difficulties in developing a large-diameter water seal, this technique is not yet viable for continuous miners.

Frictional-ignition control technology is now available for longwalls and continuous miners in the form of a modified bit design (Cheng et al., 1983). Research has developed a "mushroom bit" that replaces the conventional plumb bob bit and

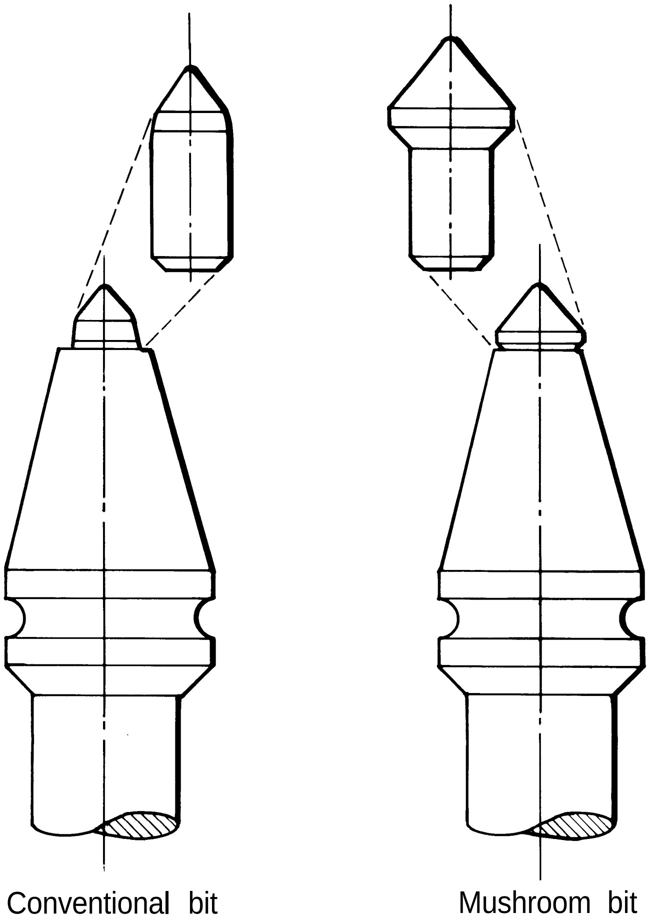

Fig. 11.2.2. Conventional and mushroom-type bits.

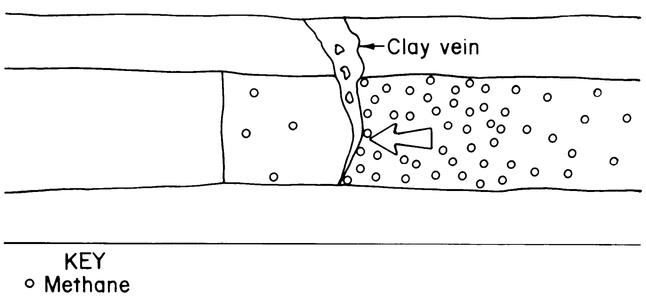

Fig. 11.2.3. Clay vein damming up gas flow.

provides added bit life and a reduction in the probability of frictional ignitions (Fig. 11.2.2).

GAS OUTBURSTS. The uncontrolled release of large volumes of methane into the working face is commonly referred to as a *gas outburst* and can be manifested in US coal mines in two manners. The first has been described by Campoli et al. (1985) as due to the inherent characteristics of the mined coalbed (e.g., gas content greater than 300 ft^3/ton or 9.4 mL/g), depth greater than 1300 ft (400 m), coalbed discontinuity present, etc. To safely mine coal prone to inherent gas outbursting, the mine operator must drain the methane from the coalbed to lower the gas content and reservoir pressure.

The other manifestation of gas outbursts has been described as being due to the formation of gas cells by intercepting clay veins. Fig. 11.2.3 illustrates how clay veins can form these cells from which methane is released into the working face when intercepted by mining. The clay veins are impermeable to the flow of methane and keep the gas confined within the cell at normal coalbed reservoir pressure, 0.44 psi/ft (9.95 kPa/m) of overburden. The method of controlling this problem is to drill a horizontal borehole in advance of mining to intercept the gas cell and reduce the pressure.

11.2.2 DUST CONTROL IN ROOM AND PILLAR COAL MINING

A good general reference to dust control for room and pillar coal mining has been written by Divers et al. (1987). A wealth of information on the health impacts of coal mine dust has been given by Lainhart et al. (1969).

Expert system computer programs that give advice on controlling dust are available from the USBM (Kissell and King, 1988).

11.2.2.1 Ventilation: Face Ventilation Equipment

The quantity of air and the distance from the end of the line brattice or tubing to the face are critical. Studies have shown that dust reductions are greater when the brattice or tubing is moved closer to the face; for this reason, the end of exhaust brattice or tubing should be maintained within 10 ft (3 m) of the face. Also mean entry air velocities above 60 fpm (0.3 m/s) will prevent face-dust rollback.

Brattice efficiency rapidly increases as the area between the tight rib and the brattice increases. The brattice should always be placed at a maximum distance from the rib, while allowing for machinery passage and placement of electrical cables and water hoses.

Because of leakage through and around permanent stoppings, more air must be forced into a mine than would otherwise be required for ventilation. As power costs increase, air leakage adds increasingly to the mine's operating costs. Most mines dry-stack the stopping blocks and trowel on a mortar coating to act as a sealant. Recent studies have shown that leakage can be significantly reduced if a modified mortar, supplemented with steel or fiberglass fibers, is used instead of a conventional troweling. Brushing with a plastic-bristle whitewash brush results in an even sealant coating and requires much less skill and experience than troweling.

As a general rule, especially in older mines, reducing stopping leakage is the most cost-effective technique to get more air to the face. Varying degrees of airtightness can be realized with different stoppings and the quality of construction used to erect the stoppings. Step-by-step instructions for building three types of stoppings, incorporating many of the procedures discussed, are available in a USBM handbook (Timko, 1983).

11.2.2.2 Water Sprays: Sizing Waterlines and Hoses

Consider a supply line for a continuous miner water-spray system that requires 40 gpm (2.5 L/s) at 100 psi (690 kPa). If the distance from the main tapping point is 500 ft (150 m) and a 1.25-in. (32-mm) inside diameter hose is used, the pressure loss is about 75 psi (518 kPa) for the entire length. Allowing an additional 10-psi (69-kPa) loss for fittings and the miner water circuit, a minimum of 185 psi (1280 kPa) should be available at the main tapping point. Selection of a hose only 0.25 in. (6.4 mm) wider (i.e., 1.5 in. or 38 mm) would reduce the pressure loss through the hose by approximately 67% (from 75 to 25 psi, or from 518 to 173 kPa).

WATER FILTRATION. A major problem associated with water-spray systems is the frequent clogging of spray nozzles caused mainly by particulate matter in the water line, including pipe scale, rock, and coal particles. Nozzle blockage can be minimized by using fewer nozzles, but with larger orifice diameters of at least 1/16 in. (1.6 mm).

The USBM developed a simple, nonclogging, water-filtration system to replace conventional spray filters (Divers et al., 1987). The system consists of an in-line Y-strainer to remove the plus 1/8-in. (3.2-mm) material, a hydrocyclone to remove virtually all of the remaining particulates, and a polishing filter to remove traces of particulates that are carried over the hydrocyclone overflow during the startup and shutdown of the spray system.

WATER SPRAY SYSTEMS FOR CONTINUOUS MINERS. Continuous miners are equipped with water systems designed to suppress dust, cool motors and bits, and serve as emergency fire-suppression systems. Spray nozzles mounted on the machine body deliver water to strategic areas for dust control. The purpose of these sprays is to wet the coal as it is cut. Once the liberated dust has been entrained in the ventilating air, the dust capture or "knockdown" afforded by these sprays is moderate. All spray systems should be turned on before cutting and should be left on for a short period after cutting. Tests have shown that the best spray systems can reduce respirable dust in the immediate return by 60%; typical reductions average 30 to 50%.

When mean entry air velocities are too low, an improper spray system can cause face-dust rollback to the machine operator's position. This can usually be determined by temporarily shutting off the sprays. If the rollback is reduced or eliminated, try the easiest of the following: (1) increase face airflow; (2) extend and tighten up the brattice or tubing; (3) if spray pressure is too high, reduce it; (4) if nozzle orientation is wrong, remove all nozzles pointed outby; or (5) install an anti-rollback spray system if mine is not gassy.

There are three types of spray systems recommended for continuous miners. The anti-rollback water spray system (Anon., 1985a) is recommended for nongassy sections with low airflow to the face. Spraying water sometimes can be self-defeating because the turbulence created by the sprays rolls the dust back toward the operator. High spray pressure (over 100 psi or 692 kPa) and the use of wide-angle top and side sprays that overspray the drum or are set too far from the drum promote this condition.

The anti-rollback spray system has alleviated this problem. With the new system, a moderate spray pressure of 100 psi (692 kPa), measured at the nozzle, is a practical maximum. Although higher pressure sprays have the potential to knock down more dust, they can increase the dust blown back to the operator. However, with severe dust problems, especially when cutting rock, water-flow rates should be as high as possible within a 25- to 35-gpm (1.6- to 2.2-L/s) range. As shown in Fig. 11.2.4, the top and side nozzles are arranged for "low" reach (about 12 in. or 300 mm) from the cutting head and no overspray that would increase rollback. Flat spray patterns, as opposed to cone spray patterns, are suitable because the entire flow from the nozzle can be directed to the cutting head. On the boom top, horizontal flat spray patterns near the cutting head cause the least air disturbance; on the sides, vertical flat spray patterns are best.

Efficiency of the anti-rollback system can be greatly improved through the use of underboom sprays. These are located on the rear corners of the shovel at the sides of the machine. They are aimed towards the front of the gathering arms (Fig. 11.2.5). Pressures can be as high as 200 psi (1380 kPa) and flow rates 4 to 5 gpm (0.25 to 0.31 L/s) (Anon., 1989).

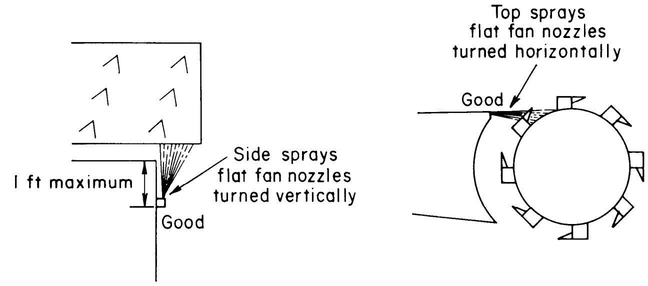

Fig. 11.2.4. Top and side nozzles arranged for low reach. Overspray causes rollback. Conversion factor: 1 ft = 0.3048 m.

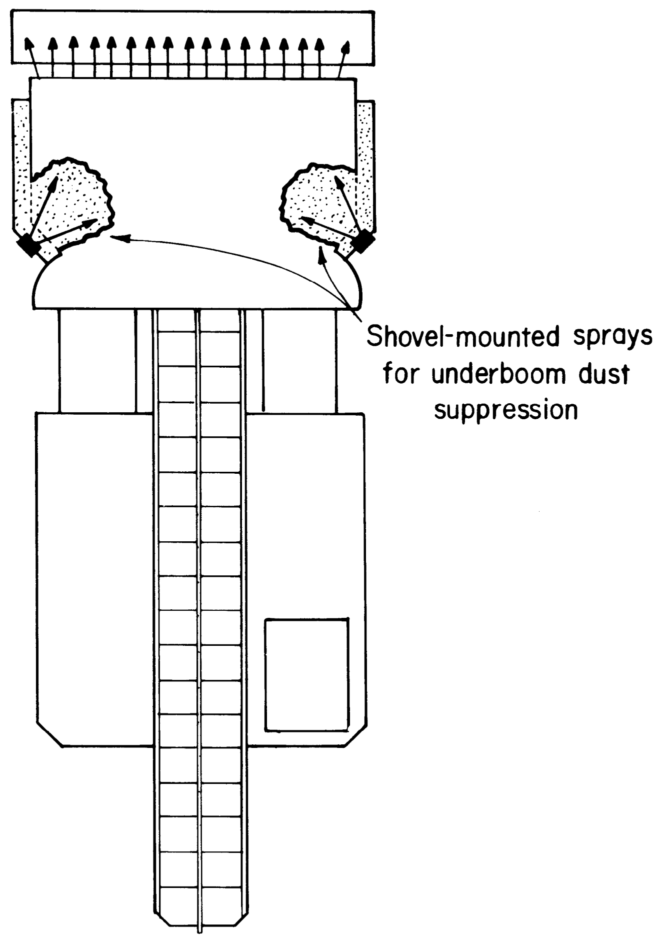

Fig. 11.2.5. Underboom sprays.

An anti-rollback system is particularly suited to faces without a gas problem and where dust standards are more stringent because of quartz. The conventional external water spray system is recommended for sections with good ventilation. The quantity of water needed depends upon the operating conditions of the individual section. Flowrates usually range from 20 to 30 gpm (1.3 to 1.9 L/s). Nozzles are typically located on top of the boom (directed at the top of the drum), beneath the boom (directed at the bottom of the drum and at the gathering arms), and in the conveyor throat. Sprays can also be located on both sides of the boom. Either full- or hollow-cone nozzles are used on the top to provide adequate coverage across the total width of the drum. These types of nozzles should also be used below the boom and should be uniformly spaced to maximize coverage of the area between the sprays and the bottom of the drum. Venturi sprays are suggested for the conveyor throat to prevent dust dispersion to the operator.

The spray fan system (Ruggieri, Babbitt, and Burnett, 1985) is primarily designed to reduce face methane concentrations, without stirring up more dust. It also provides water for bit lubrication and cooling and limited dust control. It is an auxiliary ventilation system consisting of several spray manifolds strategically placed on continuous miners to effectively ventilate the immediate face area. A series of water sprays direct the main ventilation flow to the face and sweep contaminated air and gas across the face toward the return. The spray fan system should only be used with good face ventilation (mean entry air velocities above 60 fpm or 0.3 m/s). It is also effective with curtain setback beyond 10 ft (3 m).

11.2.2.3 Mining Practices: Modified Cutting Cycle

Previous studies have shown that cutting rock can contribute five times the respirable dust compared with cutting coal. Rock cutting should be avoided if possible and should not be prolonged. The usual cutting pattern is to sump into the face at the roof and to shear down to the floor. An alternative is to sump into the face 1 to 2 ft (0.3 to 0.6 m) below the roof and to shear down to the floor. This should be continued for at least two sump-shear sequences (more if roof conditions and seam and/or miner height requirements allow). Then the machine is pulled back to cut the remaining top coal and roof rock. This procedure reduces respirable dust levels by allowing the roof rock to be cut to a free face.

BIT WEAR AND REPLACEMENT. Routine inspection of the cutting drum and replacement of dull, broken, or missing bits improves cutting efficiency and helps to minimize dust.

11.2.2.4 Roof Bolting Operations

The roof-bolter operator's dust exposure frequently comes from upwind dust sources, particularly the continuous miner. The use of a double-split ventilation system to provide the bolter operator with a clean split of air is the most effective way to combat this problem. In single-split sections, the mining-bolting cycle must be carefully designed to keep the roof bolter upwind of the continuous miner whenever possible. The roof-bolting machine can also contribute significantly to the respirable-dust problem, especially when the roof rock contains a high quartz content.

DUST COLLECTOR AND MAINTENANCE. Dust produced by roof-bolting operations can be easily detected and remedied with a few simple maintenance procedures. Dust in the collection system's blower exhaust is the most common problem encountered, a sign that dust is by passing the filters. Common causes of this are damaged or improperly seated filters. Cloth-bag-type filters are less efficient dust collectors than the pleated-paper cartridge-type and allow dust to bleed through the system and escape through the exhaust. Accumulations of dust between the filters and the blower (clean side) are a result of filter leaks. This dust can be removed by back-flushing the system with compressed air or by running the blower for several minutes. In either case, the filters should be removed and the access door opened. Finally, a visible dust plume from the collar of the drillhole is a sign of inadequate airflow to the chuck or bit and is often a result of air leaks within the system. These occur primarily through loose connections (especially at the chuck hose), air-pressure relief valves, poorly fitting dust-collector access doors, and worn and damaged hoses. Replacement of overloaded and clogged filters will generally increase airflow at the bit by more than 30%.

ROOF DRILLBITS. Studies have shown that a roof bolter's dust exposure can be substantially reduced by changing from a shank-type bit to a "dust hog" bit (air inlet port located on the bit instead of on the drill steel). Generally, this difference can be attributed to the initial few inches (millimeters) of bit penetration where the shank-type bit allows far more dust to become airborne. Underground evaluations of the two bit types showed that the dust hog bit reduced bolter dust exposure by over 80%, and it also drilled faster and cooler.

11.2.2.5 Auger Mining Operations

Face ventilation techniques applied on auger sections are generally limited to the push-pull type. Push-pull ventilation is more readily applied on auger mining sections because the wide entries permit construction of brattice lines on both sides of the entry without restricting machinery. The push-pull system has the advantage of delivering large quantities of ventilating air to the face while confining the dust cloud to the inby portion of the cut. When using the push-pull method, the return brattice line should always be maintained inby the intake line. Maintaining the exhaust brattice close to the face is particularly important.

Laboratory-model studies indicate that dust exposures for the jacksetters and machine operator may be reduced by as much as 95% if the exhaust-brattice setback distance is decreased from 20 to 10 ft (6 to 3 m). Air quantity should be maintained at about 4000 cfm (1.9 m^3/s) in the face return to reduce face dust concentrations. The distance of the return line curtain from the rib should be at least 5 ft (1.5 m) to obtain a large cross-sectional area for the face air. The blowing side can be closer to help ensure airflow towards the face. The airflow direction between the two curtains must be toward the face to keep the face workers in compliance. This is done by maintaining the return brattice tight against the roof and floor and keeping it at the maximum possible distance from the rib.

Wet augers that supply water to nozzles located along the auger shafts, in conjunction with external sprays mounted on the front of the machine frame, help to control dust in auger sections. If coal is not sufficiently wetted at the face, a significant amount of dust can be generated during transport by the machine conveyor and mobile bridge conveyors. An additional advantage of the wet auger system is the increased amount of water applied to the cutting and loading area, which provides more coal wetting and consequently lowers dust levels during transport.

11.2.2.6 Outby Dust Control: Conveyor Belts

The first step in minimizing the amount of dust generated during coal conveyance is to ensure that the coal is wetted adequately at the face. Rewetting the coal at intervals along the belt may also be necessary. This is best accomplished by uniformly wetting the coal stream with flat-fan sprays operating at 40 to 50 psi (280 to 350 kPa). The accumulation of coal and dust particles on the top and bottom sides of the returning belt can be controlled by mounting belt scrapers or wipers near the drive, or by spraying the belt with a low-quantity water nozzle. Maintaining the conveyor system (alignment, rollers, splices, etc.) in good working condition will also help reduce dust.

TRANSFER POINTS. Transfer points are the greatest source of dust in outby areas; these include shuttle-car-to-belt, belt-to-belt, and belt-to-mine-car transfer points. A major cause of dust at transfer points can be the dislodgement of dust adhering to the underside of the belt. Nozzles projecting a flat, fan-type spray directly at the underside of the belt have reduced dust levels in this area by as much as 60%; water quantities of 0.3 to 0.5 gpm (0.019 to 0.032 L/s) are typical for this application. It is also important that the coal be wet prior to reaching the transfer point. If rewetting of the coal is required, it should occur at a point far enough upstream of the transfer point to allow time for the coal and water to mix. Hoods and chutes may also be used to prevent the ventilating air from agitating dust and to reduce the amount of coal fragmentation and breakage associated with excessive free-fall distances.

HAUL ROADS. Good housekeeping (i.e., scooping up excess coal when a cut is finished, shoveling coal along the ribs to the middle of the entry where the machine can reach it, and minimizing shuttle car spillage) is a basic approach to this problem that can be very effective. Another method is to wet the roadway with water; however, this is usually a temporary measure because the water can rapidly evaporate, depending on air velocity and mine humidity. In order to keep the moisture content of the roadway dust at a desired 10% level, the use of a hygroscopic salt, like calcium chloride, is frequently required. It should be spread in two applications: three-quarters applied one hour after wetting the dust with water, and the remaining one-quarter applied about one week later. Retreatment of the roadway should not be necessary for about six months, but spraying the roadway with water after three months is recommended.

11.2.2.7 Techniques Requiring Machine Modification

Machine-mounted dust collectors consist of a fan to direct the dust-laden air into the scrubber, a wet dust-removal system to separate the dust particles from the airstream, and a de-mister unit to remove the water from the airstream. Scrubbers are primarily used with blowing face ventilation. Where seam height allows, the flooded-bed-type scrubber is becoming increasingly popular for use on continuous miners in room and pillar operations. Scrubbers are the only device that can remove most of the respirable dust from the airstream.

Remote control units allow the continuous miner operator to move farther back from the face area than the conventional cab location, thus reducing exposure when rollback of the dust cloud occurs. A growing application of these devices is in sections employing blowing ventilation, which utilize a scrubber-equipped miner to take deeper cuts (> 25 ft or 7.6 m) with extended face-brattice setback distances (> 25 ft or 7.6 m). Such cut depths and setback distances must first be approved by MSHA, and a reasonably good roof is essential.

Dust levels can be reduced through selection of proper cutting parameters, such as depth of cut, cutting speed, and bit spacing. Some options currently available for controlling primary-dust generation include: (1) bit spacing equal to two to three times two-thirds of the cut depth, (2) changing head gearing to reduce drum rpm, (3) increasing the advance (sump) rate, (4) using sharp bits, and (5) using a minimum number of gage cutters on the end ring.

Low-pressure wet drilling for roof bolting operations utilizes hollow drill steels to deliver water (5 to 6 gpm or 0.32 to 0.38 L/s per chuck) to the bits and offers the advantages of improved bit life, faster drilling, and excellent dust control. However, wet drilling can create problems in sections that cannot tolerate additional water accumulation on the mine floor.

11.2.3 DUST CONTROL IN LONGWALL COAL MINING

Longwall dust control techniques can be divided into the following:

1. Basic dust control techniques.
2. Additional necessary controls.
3. Optional supplementary controls.

A good source of information is the USBM *Dust Control Handbook for Longwall Mining Operations* (Shirey, Colinet, and Kost, 1985).

11.2.3.1 Basic Dust Control Techniques

There are three basic dust control techniques that should be implemented on all longwall mining operations:

1. A passive barrier or external water-spray system design that confines shearer-generated dust near the face and away from the operators.

2. Large quantities of water through the sprays, particularly the drum sprays, to aid in dust knockdown and prevent dust from becoming airborne.

3. A cutting sequence that allows the shearer operators to work primarily on the intake-air side of the lead cutting drum.

SHEARER CLEARER. There are some poorly designed shearer-mounted spray systems with nozzles directed upwind at the cutting and loading zone of the intake-side drum. These actually carry dust away from the face and upstream of the drum. Here it mixes with the clean intake air and is carried out into the walkway over the shearer operators.

The USBM has developed a novel shearer spray system, called the *shearer clearer*. It takes advantage of the air-moving capabilities of water sprays. The system consists of several shearer-mounted water sprays, oriented downwind, and one or more passive barriers, that split the airflow around the shearer into clean and contaminated air (Fig. 11.2.6). The air split is initiated by a splitter arm; conveyor belting hangs from the splitter arm down to the panline. This extends from the top gob side corner of the shearer body to 18 in. (460 mm) beyond the cutting edge of the upwind drum.

Spray manifolds mounted on the splitter arm confine the dust cloud generated by the cutting drum, further enhancing the air split. The dust-laden air is drawn over the shearer body and held against the face by two spray manifolds positioned between the drums, on the face side of the machine.

The air is then redirected around the downwind drum by a set of sprays located on the downwind splitter arm. Operating pressure must be about 150 psi (1034 kPa), measured at the nozzle, to assure effective air movement. Total water flow rate with all sprays operating is about 12 gpm (0.76 L/s).

In underground tests, the shearer clearer reduced operator exposure from shearer-generated dust by at least 50% when cutting against the ventilation, and 30% when cutting with the ventilation (Shirey, Colinet, and Kost, 1985).

COOLING WATER DISCHARGE. Shearer cooling water is often discharged through spray nozzles oriented against the primary airflow or directed into the face. This causes dust to be carried back into the walkway. An alternative for discharging cooling water is panline spray manifolds, mounted on both ends of the shearer, aimed down onto the panline. This minimizes the turbulence caused by face side sprays, and respirable dust reductions of up to 35% at the shearer operator's location can result.

DRUM SPRAY-WATER SUPPLY SYSTEMS. Dust generated by the shearer can also be reduced by increasing the quantity of

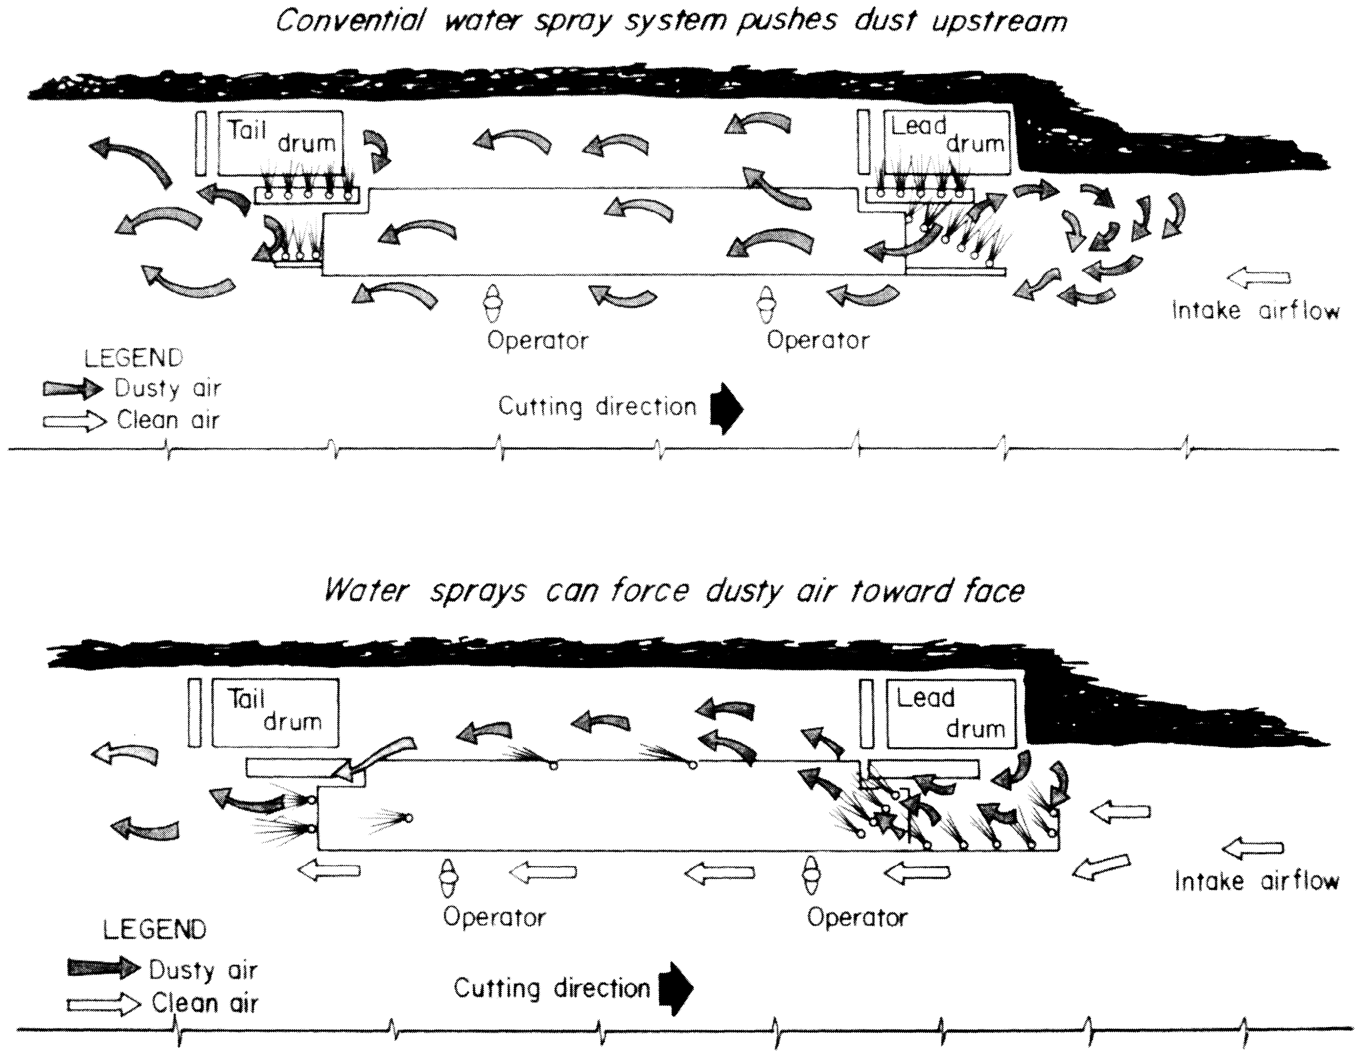

Fig. 11.2.6. Air currents with conventional sprays (top) and shearer-clearer system (bottom).

water supplied to the shearer. In two separate studies (Kost, Colinet, and Shirey, 1985; Ruggieri and Babbitt, 1986), water flow to the shearer was increased about 40 to 62 gpm and 45 to 65 gpm (2.5 to 3.9 and 2.8 to 4.1 L/s), respectively. In both cases, dust levels at the shearer were reduced 40%.

Dust exposure of the shearer operators may depend on the operating pressure of the water supplied to drum sprays. In two separate studies (Pimental, Adam, and Jankowski, 1984; Kok and Adam, 1986), water pressure to the drum sprays was increased about 50%, 75 to 150 psi and 80 to 150 psi, (517 to 1034 kPa and 552 to 1034 kPa), respectively. In both instances, dust exposure of the shearer operators increased 25%. Thus the maximum drum spray pressure appears to be from 70 to 100 psi (483 to 690 kPa). Water flow rate should be increased by increasing the nozzle orifice size, rather than the operating spray pressure.

All US longwall shearers use some type of internal water spray system. The pick-point flushing system uses nozzles mounted in the bit blocks or special blocks immediately in front of the bits. Cavity-filling systems use sprays installed in a pipe manifold mounted on the drum hub between the scrolls, or along the edge of the vanes. The water-through-the-bit concept is a new development. A channel through the bit directs water behind where the bit strikes the coal.

These three commonly used drum water-spray systems were compared on two longwall mining sections with very diverse geologic and mining conditions (Kost, Colinet, and Shirey, 1985). The pick-point flushing system with solid-stream (jet) nozzles was the most effective in suppressing respirable dust near the shearer operator's position. The pick-point system with cone-type sprays was only 70% as effective. The through-the-bit system with flat-fan sprays was only 60% as effective. The cavity-filling system was only 47% as effective as the pick-point-jet-spray system at reducing operators dust exposure. Down-wind concentrations were essentially the same for all systems.

Improved Cutting Sequence Designs. A primary means of controlling dust exposures on double-drum shearer longwall faces is to modify the cutting sequence to move workers upwind of dust sources. Currently, 75% of operating sections use a sequence where the shearer cuts coal in only one direction. In a bidirectional sequence, full cuts are taken in both directions. Typically, the lead drum takes a full cut in the raised position during the main cutting pass. The trailing drum cuts bottom

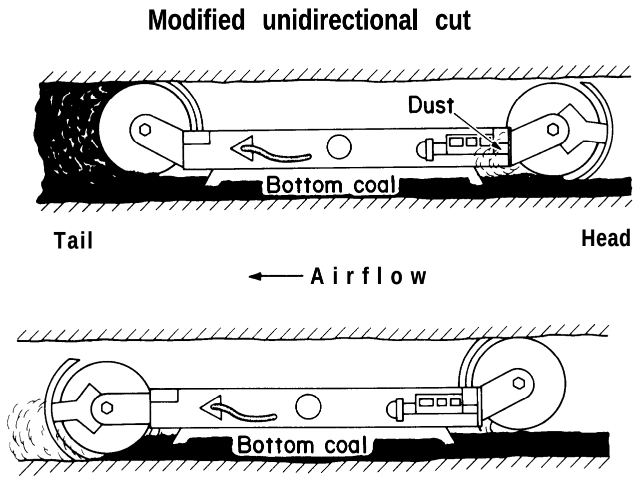

Fig. 11.2.7. Modified cutting sequence. Both directions shown.

coal. A minimal amount of coal is cut and loaded during the return cleanup pass.

On faces where the main cutting pass is taken upwind (typically from tail-to-head), both operators must remain at their controls. They are, therefore, positioned on the return-air side of the lead drum. An alternative method to reduce their dust exposure is to take the primary cut downwind (typically from head-to-tail), with the operators positioned upwind of the lead cutting drum.

Comparison of the instantaneous dust profiles for head-to-tail and tail-to-head cutting shows the large dust concentration gradient that can exist between the intake and return-air side of the lead cutting drum. Dust surveys conducted by the Bureau of Mines on 14 longwall faces (Anon., 1984) showed that the average shearer operator's exposure when cutting tail-to-head was 44% greater than when cutting head-to-tail.

One disadvantage of head-to-tail cutting is possible blockage beneath the machine underframe as material cut by the lead (tailgate) drum is loaded onto the face conveyor.

During a typical head-to-tail cut, the lead drum takes a full cut while the trailing drum cuts the remaining bottom coal. However, the dust generated by the trailing drum can spread into the walkway and increase the dust exposure of both operators. With a modified cutting sequence, the lead drum continues to take a full cut during the head-to-tail pass while the trailing drum is "free-wheeling" or cutting a minimal amount of coal (Fig. 11.2.7). During the tail-to-head cleanup pass, the trailing (return-side) drum cuts the remaining bottom coal. This enables both operators to remain on the intake-air side of the primary dust generating source, except when cutting out at the headgate.

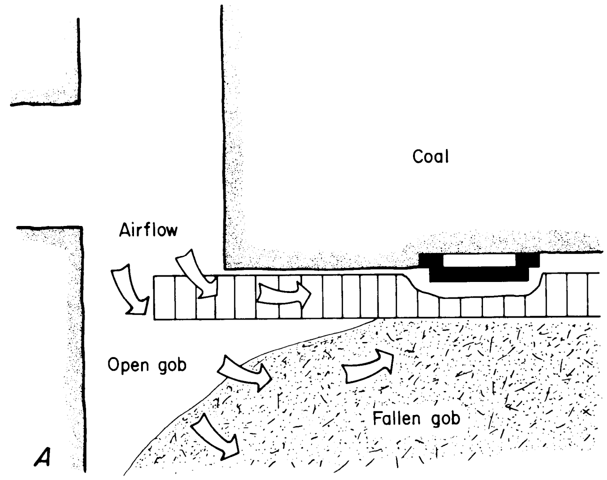
11.2.3.2 Additional Necessary Controls

The above control methods have proved to be effective on all longwall faces. Other techniques, however, are often required to bring a section into compliance with the federal dust standard.

VENTILATION. The primary function of any mine ventilation system is to dilute liberated methane to safe concentrations. However, it is also one of the principal methods used to control dust on longwalls. Face air velocities of 400 to 450 fpm (2.0 to 2.3 m/s) appear to be the most appropriate for longwall dust control.

Adequate longwall panel ventilation involves more than supplying the required volume of air to the headgate entry. Maintaining that airflow along the entire face is just as critical. Air leakage is greatest in the headgate area because there is often a large gap between the first shield and adjacent rib. Also the gob behind the first few shields remains open because the headgate entry is supported with roof bolts. This air loss prevents maximum use of the air available to ventilate the face. In addition, dust generated during gob falls may be entrained by this airflow and carried back into the face area. A gob curtain, installed from the roof to the floor between the first support and adjacent rib in the headgate entry, forces the ventilation airflow to make a 90º turn and stay on the face side of the supports (Fig. 11.2.8). During underground trials, the average face air velocity with the curtain installed was 35% greater than that without the curtain. The most significant improvement was seen for the first 25 to 30 supports.

However, misapplication of the primary ventilation airflow can increase dust exposure. Shearer operators are often exposed to very high concentrations as the headgate drum cuts into the headgate entry. The high-velocity primary airstream passing over and through the drum entrains and carries large quantities of dust out into the walkway and over both operators. An effective solution is to install a wing curtain between the panel-side rib and the stage loader (Fig. 11.2.9). This curtain shields the



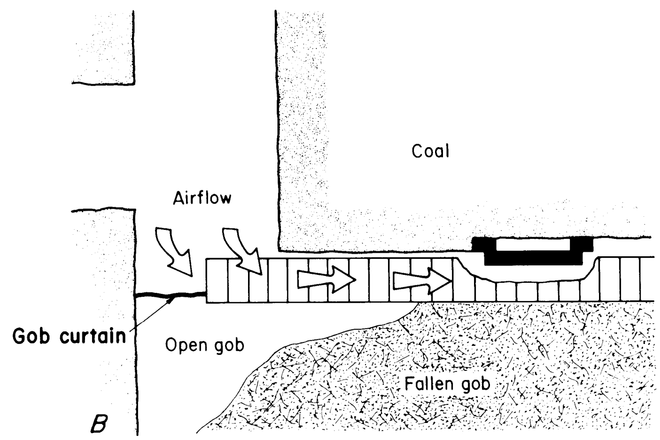


Fig. 11.2.8. Airflow at longwall headgate with a gob curtain (B) and without a gob curtain (A).

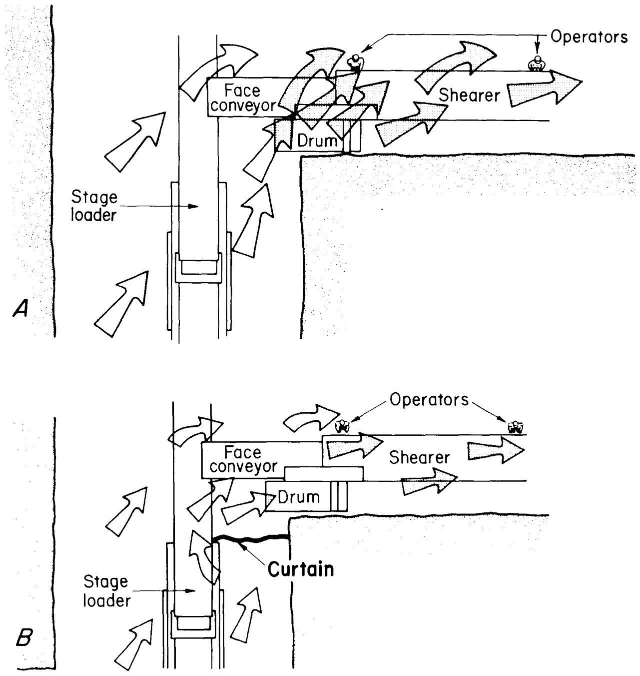

Fig. 11.2.9. Airflow at longwall headgate with (B) and without (A) a wing curtain.

headgate drum from the airstream as it cuts out into the headgate entry. It is typically located 4 to 6 ft (1.2 to 1.8 m) back from the corner of the face to provide maximum shielding without interfering with the drum. The curtain is only in place during the cutout operation, and is generally advanced every other pass. Dust concentrations monitored at the shearer operator positions indicate that the curtain can reduce their dust exposure by 50 to 60% during headgate cutout.

DEEP CUTTING. Reducing drum speed is one of only a few changes a longwall operator can make to increase output, reduce respirable dust, and decrease machine power consumption (Ludlow and Jankowski, 1984). Deep cutting is a function of drum speed and machine advance rate.

Pick spacing must be increased and gage length must be adjusted to take full advantage of deep cutting. The rotational speed of the drum is reduced (typically to 30 to 40 rpm). The depth of cut is increased by using large bits with wider spacing of the bit lines while maintaining the same advance rate used at higher rpm.

Field tests have confirmed the benefits of slow-speed deep cutting (Ludlow and Wilson, 1982). For these tests, the depth of cut was altered from a minimum of 1.7 in. (43 mm) to a maximum of 5.3 in. (135 mm) by varying drum speed and pick spacing while keeping the advance rate of the shearer constant. A 60% reduction in dust generation was achieved by reducing the drum speed from 70 to 35 rpm. This effectively increased bit penetration from 1.7 to 3.4 in. (43 to 86 mm).

11.2.3.3 Optional Supplementary Controls

There are several control techniques that are site specific, and therefore, cannot be successfully applied at every longwall installation.

HEADGATE STAGE LOADER AND CRUSHER. Dust generated at the stage loader is often overlooked, but warrants greater attention. This dust remains airborne across the entire face. It can have a significant impact on the full-shift dust exposure of all face personnel. The major source of dust in the headgate entry is the stage loader/crusher. A basic approach is to mount water sprays along the stage loader. Several sprays are mounted in spray bars, which usually span the width of the conveyor to ensure uniform spray coverage of the coal stream. Recommended spray bar locations inside the crusher include the area just inby and at the point where the stage loader dumps on the belt. The dust capture efficiency of these sprays may be enhanced by enclosing the stage loader, either with steel plates or strips of conveyor belting. The enclosure also isolates the conveyed material from the airstream, thus reducing dust entrainment. During underground trials with a fully covered stage loader and additional water-spray manifolds, improvements at the headgate operator and at support 20 locations were 80 and 45% respectively (Anon., 1985b).

WATER PROPORTIONING. Increasing the water flow to the drums usually reduces airborne dust levels produced by the shearer. Some operations, though, cannot tolerate an increase in water flow because of clay floors. Excess water in the coal reduces the run-of-mine Btu value. It can also cause problems in the coal transport system and in the coal preparation plant. For these operations, supplying larger quantities of water only to the upwind drum can have a significant impact on the amount of water used while still reducing the operator dust exposure.

A study was conducted to assess the effect of proportioning the water flows to the drum (Kok and Adam, 1986). Exposure of the downwind shearer operator and the total amount of respirable dust generated (as indicated by a tailgate measurement) were measured with the shearer cutting downwind. When water was shifted from the downwind drum to the upwind drum, both the operator dust exposure and total dust generated were reduced. The switch from a low flow on the upwind drum and a high flow on the downwind drum to the reverse situation resulted in an average 63% reduction in the operator dust exposure and a 32% reduction in the tailgate concentration.

SUPPORT MOVEMENT PRACTICES. Cutting and support movement practices are designed to minimize the time that jacksetters work downwind from the shearer and to maintain shearer operator dust exposure as low as possible. One such practice involves support advance on the downwind side of the shearer, keeping the shearer operators in uncontaminated air. When the pass cycle against the airflow is used as a clean-up pass, the dust levels generated by the shearer are typically low. The dust exposure of the jacksetters downwind of the shearer remains relatively low as long as no significant amount of rock is cut during the cleanup pass.

When the primary cut is taken against the airflow, a properly designed external shearer water-spray system can adequately confine shearer-generated dust against the face for about 40 ft (12 m) downwind from the shearer. This provides an acceptable environment for jacksetters working immediately downwind.

It is sometimes not feasible to move the supports on the downwind side of the shearer during the cleanup pass. Roof conditions require support advance immediately after the primary cut. In this case, supports are moved on the intake-air side of the shearer as it cuts head-to-tail (downwind). Shearer operators are then exposed to any dust generated by support movement. Under these circumstances, some mine operators find that support-generated dust can be effectively diluted before it reaches the shearer operators by increasing the distance between support advance and the shearer from 20 to 50 ft (6 to 15 m).

Water application on the immediate roof may also help to suppress some of the support dust generated during lowering, advancing, and resetting the roof supports. The immediate roof can be wetted adequately by

1. Maintaining enough water pressure at the drum sprays to wet the roof while the face is being cut.
2. Free wheeling the lead drum near the roof during the clean-up pass so that the water sprays wet the roof.
3. Spraying the roof with one or more water sprays mounted on top of the shearer body, directing water downwind, at an upward 45º angle.

Roof support automation will greatly help to reduce dust exposure, depending on the degree to which jacksetters are moved upwind of dust sources.

SHEARER REMOTE CONTROL. Longwall automation, specifically the remote control of the shearer, can significantly reduce dust exposure of the machine operators. Operators control the machine from positions along the face less contaminated than their normal work positions. A survey shows that exposure was reduced 68% by moving the operator (20 ft or 6 m) upwind of the normal work position (Anon., 1984).

Most manufacturers now offer either radio or umbilical (hard-wire) remote control (see Chapter 22.2). The greatest potential for remote control may be in high coal, where face spalls can seriously injure the operators. Umbilical remote controls are easy to retrofit to modern shearers. They are more common in the United States than radio controls.

11.2.4 PERSONAL PROTECTIVE EQUIPMENT

The Federal Coal Mine Health and Safety Act of 1969 mandated that approved respiratory equipment be made available to personnel when exposed to respirable dust concentrations greater than 2.0 mg/m^3. However, this equipment cannot be used in lieu of achieving the 2.0 mg/m^3 standard.

11.2.4.1 Replaceable Filter Respirators

The replaceable filter respirator consists of a filter-holding unit, typically fabricated from plastic, metal, or hard rubber, that also contains intake and exhaust valves. The filtering efficiency of approved filters is 98% or more. Soft rubber or cloth is used to form a face piece around the filter-holding unit that forms a seal against the wearer's face in an attempt to prevent dust-laden air from bypassing the filter. With a reasonably leak-tight face piece fit, the respirator should remove approximately 95% of the respirable dust.

During one respirator evaluation program (Cole, 1984), two models of face-mask respirators were tested on four longwall sections to determine the protection afforded to the wearer when worn in the tailgate area for an entire shift. The dust exposure of the tailgate worker was 80 to 92% less when wearing either one of the respirators.

Although the respirator does an excellent job of dust removal when properly fitted, some personal discomforts may arise, including increased breathing resistance, aggravated by dust loading on the filter, facial irritation caused by the face seal, interference with normal voice communication, and interference with eye glasses or goggles.

SINGLE-USE RESPIRATORS. The single-use respirator is a much lighter and simpler design. The entire mask is fabricated from filter material and covers the mouth and nose, similar to a surgical mask. The single-use respirator offers the following advantages when compared to the replaceable-filter respirator:

1. Lighter and thus more comfortable to the wearer.
2. Provides greater filtering area and, consequently, has lower breathing resistance.
3. Filter material contacts face and generally is less irritating than rubber or cloth.
4. Requires no maintenance.

However, single-use respirators usually do not form as tight a seal against the wearer's face as replaceable-filter types, thus allowing more leakage, Also single-use respirators provide no protection for the filter material, and, as a result, are not as durable as the replaceable filter type.

AIR HELMET. The air helmet is a redesigned hard hat equipped with a battery-powered fan, filtering system, and face visor, thus providing protection for the head, lungs, and eyes in one unit. Although the air helmet is slightly larger and heavier than conventional hard hats, weighing approximately 3 lb (1.4 kg), wearer acceptance has been quite favorable.

A small fan is mounted in the rear of the helmet to draw dust-laden air through a filtering system; the resulting cleaned air is directed behind a full-face visor and over the wearer's face. Seals are provided along both sides so that exhaled air and excess clean air are allowed to exit the helmet at the bottom of the visor. Also these face seals and additional seals inside the helmet limit contamination from unfiltered air. The fan is externally powered by a rechargeable battery smaller than a conventional cap-lamp battery to be worn on the miner's belt.

Studies were conducted to test the effect of air velocity and helmet position in the airflow on the effectiveness of the air helmet (Cecala et al., 1981). They showed that air velocity and position can have a major impact on the effectiveness of the helmet.

Underground tests on four longwall double-drum shearer faces were also conducted. For three of the four mines, the air velocity in the face walkway was less than 400 fpm (2.0 m/s), and the air helmets reduced respirable dust in the wearers' (shearer operator, jacksetter, and two researchers) breathing zones by an average of 84%. At the fourth mine, the air velocity was approximately 1200 fpm (6.0 m/s), and as a result, the air helmet was not as effective, with an average reduction of 49%. The underground sampling included periods when the face visor was lowered and periods when it was raised, according to normal underground use; this would tend to minimize differences between inside and outside samples, thus reducing the apparent effectiveness of the helmet.

11.2.5 UNDERGROUND METAL MINE DUST CONTROL

The exposure of workers to respirable dust in hard-rock mines, including both metal and nonmetal mines, may be reduced by a systematic approach that includes all or some of the following:

1. Prevention of formation at its source.
2. Preventing dispersal of the dust cloud.
3. Providing dilution ventilation.
4. Avoiding the dust.

11.2.5.1 Preventing Formation

Every effort should be made to prevent both the formation of dust at its source and its liberation into the atmosphere.

WATER. To improve the effectiveness of water when wetting down, a spray nozzle ensures an adequate spread of water over a greater area and prevents the settled dust from being stirred up. A moisture content of the rock of only 1% produces a very significant reduction in dust production when compared with dry rock. As it is difficult to maintain a moisture content of

1% under conditions encountered underground, the optimum moisture content should be maintained at about 5%.

The water used for dust suppression, particularly in drilling and in water-blasts, should be as clean as possible as the evaporation of dirty water can release considerable quantities of dust.

DRILLING. Adequate water suppresses drilling dust. Provide enough to keep the rock surface wet all the time, so that the rock is actually broken under a film of water.

This does not, however, prevent dust from entering the air during the initial collaring period. Various means have been tried to prevent the escape of dust during collaring, ranging from simple hand-held sprays to elaborate types of suction traps around the end of the drill steel, but no single method has been found to be very efficient.

If some of the compressed air operating the drill leaks into the front head of the drill and escapes down the drill steel, it will cause dry drilling and carry dust out of the hole. Also some of this compressed air will escape through the front head release ports and atomize some of the water in the front head. This atomized water, which forms a fog at the front head release ports of many rock drills, evaporates rapidly; and if the water is dirty, as it often is, many dust particles will remain in the air.

For dry drilling methods, the generated dust is collected. The air and dust drawn off must be exhausted into unoccupied return airways or filtered.

BLASTING. Blasting is unlike other mining operations, since it produces not only dust but other contaminants, such as carbon monoxide and nitrogen dioxide fumes. Since little can be done to prevent the production of dust during a blast, the emphasis should be on means to control the resultant contaminants.

The first step in controlling dust produced by blasting is to ensure that the area surrounding the blast (walls, floor, and back) is thoroughly wetted beforehand. This precaution will prevent dust settled out during previous operations from becoming airborne. Furthermore, some of the dust created by the blast will adhere to the wet surfaces in the area, thereby reducing the concentration in the airstream. The second step is to use a two-phase fog spray nozzle that employs both water and compressed air. These nozzles are effective in reducing dust and the amount of nitrous fumes (because of their solubility in water).

Proper ventilation is critical since water alone is inadequate. Blasting dust and fumes should be diluted and exhausted to surface via an untraveled route, preferably an upcast raise designed for that purpose. If this is not feasible, the blasting schedule should be arranged so that the contaminated air will pass through working places when the miners are absent.

11.2.5.2 Preventing Dispersal

The dispersal of respirable dust from crushers, conveyors, and similar equipment can be eliminated in most instances by confining the dust-producing operation within an enclosure and controlling the air contained therein. The air from within the enclosure can be exhausted directly to the upcast airway or, if this is not feasible, it can be filtered. Segment 11.2.8 on minerals processing dust control gives guidelines.

ORE AND WASTE PASSES. Ore and waste passes produce large quantities of airborne dust. The broken rock delivered to the passes contains a considerable amount of inherent dust as a result of preceding operations, such as blasting and loading. Furthermore, the autogenous grinding action of the rock as it is dumped and falls down the pass produces more dust. The first line of defense is to ensure that the rock is thoroughly wetted before delivery to the dump. More wetting can be obtained at the dump site by installing a mist-type atomizer to spray the rock as it falls into the pass. Excessive use of water at the orepass can be objectionable for many reasons: (1) adverse impact on crushing and milling, (2) a large quantity of water may accumulate on top of the material in the chute, creating a hazard for workers on the lower levels, and (3) plugging of clay minerals.

The second step in providing a good environment at ore and waste passes is to prevent the escape and dispersal of dust into working areas by confining it within the passes. This can be accomplished by a system of stoppings and airtight doors over the dumps or "tipping" points. The maintenance of these doors is of prime importance, since their main purpose is to prevent the escape of dust-laden air.

A third step, difficult to accomplish in practice, is providing means to keep the confined ore or waste pass under negative pressure to ensure that all leakage paths are indraft, and to capture the air displaced when rock enters the raise. A suitable fan exhausts from a convenient point in the raise. The contaminated air is filtered or sent via a direct untraveled route to the return air raise.

11.2.5.3 Providing Dilution Ventilation

Ventilation is the best method of controlling contaminants at underground operations. This is carried out in producing areas, such as stopes, scraper drifts, etc. by directing an air split from the main ventilating stream through the workings. The design criterion is 30 to 50 fpm (0.15 to 0.25 m/s), depending upon the type of operation and other local conditions. In some instances, volume may have to be increased greatly—for example, high-speed drives or scraper drifts, where the severe dust-producing operations may require as much as 150 fpm (0.75 m/s).

In headings and raises, the design volume also is based on providing an air velocity of 30 to 50 fpm (0.15 to 0.25 m/s). The type of auxiliary ventilating system employed will be governed by the local conditions at the mine. In most cases, the push-pull (or overlap system) will provide the most satisfactory environment although it is difficult to control in practice. This system consists of a main ventilating duct which exhausts dusty air, and a small blowing line kept to within 20 to 30 ft (6 to 9 m) of the face. The length of the overlap of the exhaust and blowing lines depends upon the size of the drift and, in any case, should be not less than 30 ft (9 m). The blowing volume should not exceed approximately 60% of the exhaust volume in order to avoid recirculation.

The overlap system should not be adopted for those working areas subject to a high virgin rock temperature. Under these conditions, the cool fresh air is heated and becomes saturated with moisture during the time it takes to reach the working face. To avoid this, the forcing or blowing system of auxiliary ventilation should be installed so that the fresh air can be kept dry and delivered to the face with a reserve of cooling power.

The exclusive use of exhaust systems for auxiliary ventilation should be discouraged, since it is impractical to keep the end of the duct near the dust-producing operation, particularly when blasting.

11.2.5.4 Avoiding Dust

This is an effective way of preventing exposure to respirable dust. It is applied mainly after blasting by the insistence on a minimum re-entry period, by arranging a fixed blasting time for each working place so that other workers are not exposed to the blasting dust and fumes, and by ensuring that blasting takes place only at the end of the shift when most other workers have already been withdrawn.

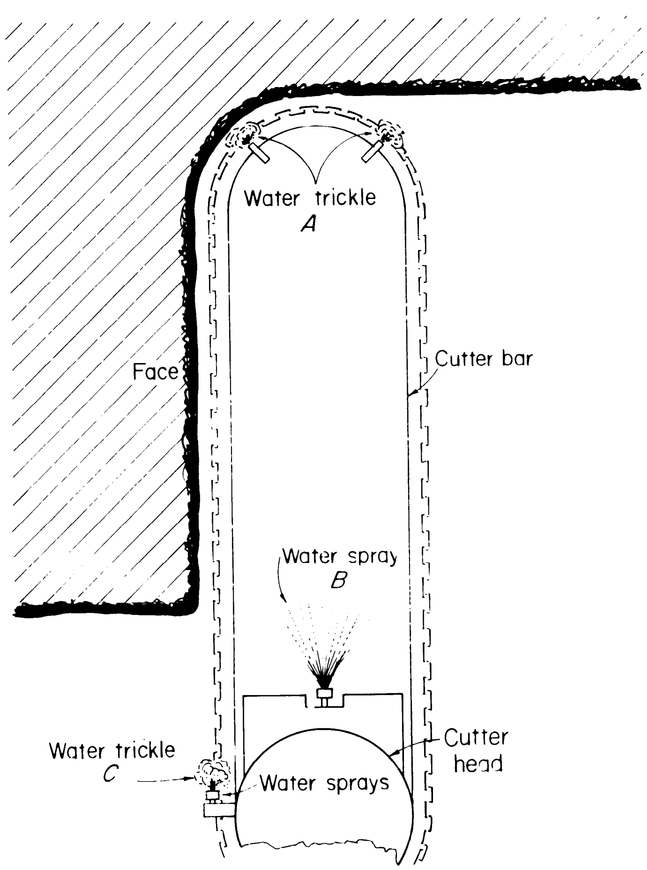

Fig. 11.2.10. Wet-bar water spray systems.

Other ways in which workers are kept out of dusty air are by arranging that men travel in downcast shafts and by having all underground waiting places in fresh air. Work may be scheduled in such a way as to reduce dusty operations upstream of a designated location.

11.2.6 DUST CONTROL IN WATER-SOLUBLE ORES

This segment reviews strategies to suppress and collect dust on cutter machines and face drills where water usage must be restricted to very low flow rates because the ore is water-soluble. Typical flow rates are 1 gpm (0.063 L/s).

11.2.6.1 Cutting Machine Dust Control

Achieving effective dust control on cutter machines can be difficult. Complications arise from the five major dust sources on a cutter machine: (1) the cutter chain during cutting, (2) the star wheel, (3) the cutter chain reentering the kerf, (4) the bugduster, and (5) a recirculation loop that develops within the kerf. The cutter chain during cutting and the recirculation loop are probably the most severe.

Wet bar type cutting techniques are used to help control mine dust by keeping the cutting chain wet. As the chain cuts the kerf, it dampens the dust produced by the cutting action at the point of generation.

Three basic wet-bar techniques, are used (Fig. 11.2.10). Water-trickle system A uses a gravity-feed or low-pressure (less than 50 psi or 345 kPa) pump to send water through the bar and to discharge it at the bar tip. Water-spray system B uses a low-pressure spray nozzle located at the front of the cutter head. For protection, the nozzle can be located within the cutter head. Water-trickle system C uses a gravity-feed or low-pressure pump to discharge water onto the cutter chain on either or both sides of the cutter head.

Tests on all three designs conducted in two salt mines showed there was no significant difference in the dust control performance. While there are many variations of the three designs, it is not expected that any one type will be more effective in controlling dust. Also the performance of the three systems is independent of water flow rate when operated between 0.25 and 1.0 gpm (0.016 and 0.063 L/s). At these water flow rates, the average total dust reduction of the three systems is 60 to 70%.

Dust control efficiency deteriorates significantly when water flow is cut to less than 0.25 gpm (0.016 L/s). Higher water flow rates (more than 0.5 to 1.0 gpm, or 0.032 to 0.063 L/s) are not likely to improve the performance of the wet bar system significantly. Also, excess water causes the dust to cake and solidify on the bit blocks, increasing bit-changing times from 10 to 15 minutes to 45 minutes or more. However, cutting the last few feet (meters) of the kerf dry will help clean the bit blocks without producing a significant amount of dust.

Several dry collection systems on cutter machines have been tried but have been generally unsuccessful. The reasons are (1) the large number of nonlocalized dust sources, (2) the tremendous amounts of dust produced are more than a machine-mounted collector can handle, and (3) the size of a suitable collector is not practical for machine mounting. More information on cutter machine dry collection systems is available in the literature (e.g., Page, 1983).

11.2.6.2 Face-Drill Dust Control

Dust control on face drills used in water-soluble ores is generally easier to accomplish than on cutter machines because there are fewer sources. Techniques tried by the mining industry to control the dust produced by face drilling includes both wet and dry systems.

Wet dust suppression systems include external water sprays, water injection through the drill, and foam injection through the drill. External boom mounted systems are typically homemade and reduce dust about 50%. Water-mist injection through the drill is available from several manufacturers. Dust reduction is much better, typically 90% or more. A homemade foam system has been used successfully (Anon., 1982). It achieved 95% dust reduction at lower water flow rates.

Dry collection systems are generally inferior to wet suppression systems. This is due primarily to the inability of dry collection systems to maintain effective intake dust capture because of face irregularities. The overall dust reduction is a product of the inlet capture efficiency and the filtration efficiency of the collector. Therefore, high filtration efficiency is pointless unless the inlet dust capture efficiency is also very high. An additional reason why dry systems are generally inferior to wet systems is maintenance. Dry systems require that the dust collected be disposed of in some convenient manner. Wet systems require no material handling; the wetted material merely dribbles down the face.

One dry collector tested has shown 76% respirable dust efficiency (Page, 1983).

11.2.7 SURFACE MINE DUST CONTROL

Personal exposure to respirable dust at surface mines primarily results from overburden drilling. Both wet and dry methods are available to suppress dust from this source. Haul road dust control is also important.

11.2.7.1 Overburden Drilling: Wet Suppression

Wet drilling systems consist of a water tank mounted on the drill from which water is pumped into the downhole airline. The water droplets in the bail air conglomerate dust particles as they travel up the annular space of the drilled hole, thus controlling dust as the air bails the cuttings from the hole.

Typical water flow rates are 0.1 to 2.0 gpm (0.0063 to 0.126 L/s) depending upon the size and type of drill, as well as the condition of the material being drilled. Flow rate is controlled manually by the drill operator by means of a control valve located in the cab. Some drills may also be equipped with a flow meter to give the operator visual indication of the flow rate. The operator simply watches the cuttings as they are bailed from the hole and adjusts the flow rate according to how moist the cuttings appear to be. This technique can be effective; however, the delay between the time the valve is opened and the time the cuttings are expelled from the hole can be several seconds. This makes it difficult for the operator to find the proper flow setting. This is especially true if the drill is drilling through alternating dry and wet strata.

Too much water pumped into the bail air wets the drill cuttings to a point where they are too heavy to be bailed up the hole. This results in the drillbit and lower part of the drill stem being seized in the hole. Freeing the drill stem is a time-consuming and costly procedure. Excessive water in the hole may also result in plugging the air orifices of the bit. The most obvious drawback to a wet system occurs when outside temperatures drop below freezing. The entire system must then be heated while the drill is in operation, and during downtime the system must be drained. The use of antifreeze compounds is prohibitively expensive because of the amount of water used.

Tests show that wet suppression systems can control respirable dust with up to 97% efficiency (Anon., 1987). Control efficiencies for 8-in. (200-mm) holes varied from a low of 9.1% at a flow of 0.2 gpm (0.013 L/s) to a high of 96.3% at a flow of 1.2 gpm (0.076 L/s). The control-efficiency vs. flow-rate curve shows a significant increase in efficiency generally between 0.2 and 0.6 gpm (0.013 to 0.038 L/s). The rate of increase of efficiency then decreases until the drill's upper flow limit is reached. In the case of the drills tested, a flow rate approaching 1.0 gpm (0.063 L/s) began to cause operational problems.

A practical and simple operational guideline can be provided to all mine operators who perform wet drilling. The guide also automatically accounts for various operating conditions such as different drills, changes in bit size, and different strata. In order to operate at close to the optimum water flow rate, the operator should slowly increase the amount of water just to the point where visible dust emissions abate. Due to the initial sharp increase of dust control effectiveness, the visible dust abatement point will be easy to identify. Increasing water flow beyond this point will not yield any significant improvements in dust control but will most likely cause seizing of the drill stem. It is important that the water flow be increased slowly to account for lag time as the air/water/dust mixture travels from the bottom to the top of the hole.

11.2.7.2 Overburden Drilling: Dry Collection

The use of a dry system involves enclosing the area where the drill stem enters the ground. This enclosure is usually accomplished by hanging a rubber or cloth "shroud" from the underside of the drill deck. This enclosure is ducted to a filtering device, the clean side of which is equipped with a fan. The fan creates a negative pressure inside the entire system, thus capturing dust as it exits the hole during drilling. The dust is removed in the filtering device and clean air is exhausted through the fan.

The integrity of the drill stem shroud, including how well it seals to the ground, is probably the single most important factor contributing to the effectiveness of a dry collection system. The shroud volume should be 1.8 times the volume of the hole and should be at a negative pressure of at least 0.2 in. of water (50 Pa). The length and width of the shroud should be 2.5 times its height. The air is ducted out of the drill stem shroud either from the top of the shroud near the outside edge or from the side of the shroud near the top. Varying the open area of the shroud will change the shroud's dust capture efficiency. As the open area is reduced, the velocity in the open area will increase. The most common open area is the gap between the bottom of the shroud and the ground, which is called the shroud height. With a shroud height of 6 to 9 in. (150 to 225 mm) or lower, it is apparent that the control system works well. However, as the height increases, the control efficiencies decrease.

During drilling, it is sometimes necessary to raise the drill shroud. This is done for two reasons: (1) to prevent large cuttings from falling back into the hole, and (2) so the operator can observe when the coal seam has been reached and stop drilling. As a result, there are times when a broken seal between the shroud and the ground or cutting cannot be avoided. Therefore, it is important for the driller to keep the open area to a minimum. This will involve raising the drill shroud more frequently.

11.2.7.3 Haul Road Dust Control

Many methods are available for haul road dust control. Water is the most obvious, but there are many others, including:

Salts—Hygroscopic compounds, i.e., calcium chloride, magnesium chloride, hydrated lime, sodium silicates, etc.

Surfactants—Substances capable of reducing the surface tension of the transport liquid, i.e., soaps, detergents, dust-set monawet, etc.

Soil cements—Compounds that are mixed with the native soils to form a new surface, i.e., calcium lignon sulphonate, sodium lignon sulfonate, ammonium lignon sulphonate, portland cement, etc.

Bitumens—Compounds derived from coal or petroleum, i.e., coherex peneprime, asphalt, oils, etc.

Films—Polymers which form discrete tissues, layers or membranes, i.e., latexes, acrylics, vinyls, fabrics, etc.

Salts increase roadway surface moisture by hygroscopically extracting moisture from the atmosphere. Surfactants decrease the surface tension of water, which allows the available moisture to wet more particles per unit volume. Soil cements, bitumens, and films generally form coherent surface layers that seal the road surface and thereby reduce the quantity of dust generated.

A recent study (Rosbury and Zimmer, 1983) showed that the highest control efficiency measured for a chemical dust suppressant, 82%, was for calcium chloride two weeks after application. Generally, however, the control efficiencies hovered in the 40 to 60% range over the first two weeks after application, and then decreased with time. After the fifth week, the limited number of data points suggest a control efficiency of less than 20%. Composite watering data were fairly uniform. Watering once per hour resulted in a control efficiency of approximately 40%. Doubling the application rate increased the control effectiveness by about 15 to 55%. Chemical dust suppressants (primarily salts and lignons) can be shown to be more cost-effective than watering under some conditions.

Table 11.2.1. Control Type vs. Proper Road Aggregate Size Gradation

Road Surface	Suppressant With Best Potential for Control
Gravel	Water
Sand	Bitumens
Good gradation	Any
Silt	Rebuild road

The cost of using a dust suppressant is very site specific. Shipping costs to. the mine are a major part of the product cost and may exceed product cost. Although sufficient test data is not yet available to conclusively prove the factor, it is apparent that certain types of dust suppressants work better in certain types of road aggregate. Recommendations appear in Table 11.2.1. They are based on the following:

1. In road surfaces with too much gravel, only watering will be effective. Chemical dust suppressants can neither compact the surface because of the poor size gradation, nor form a new surface, and water-soluble suppressants will leach.

2. In compact sandy soils, bitumens, which are not water-soluble, will be the most effective. Water-soluble suppressants such as salts, lignons, and acrylics will leach from the upper road surface. However, in loose, medium, and fine sands, bearing capacity will not be adequate for the bitumen to maintain a new surface.

3. In road surfaces with a good surface gradation, all chemical suppressant types offer potential for equal control.

4. In road surfaces with too much silt (greater than about 20 to 25% as determined from a scoop sample, not a vacuum or swept sample), no dust suppression program will be effective, and the road should be rebuilt. In high silt locations, the chemical suppressants will tend to make the road slippery, will not be able to compact the surface, or maintain a new road surface because of poor bearing capacity. Further, rutting under high moisture conditions will require that the road be regraded, which almost completely destroys chemical dust suppressant effectiveness. If the road cannot be rebuilt, watering is the best program.

All chemical dust suppressants (with infrequent watering) share one common failing as compared with frequent watering. Material spillage on roadways is extremely common in mines, particularly if ash haulers are also using haul roads. Material spilled is subject to reentrainment. With frequent watering, the spilled material is moistened at approximately hourly intervals. With chemicals, the spilled material could go 8 to 24 hours before being moistened, and the material would again redry. Therefore, in mines where spillage cannot be effectively controlled, watering will probably be more effective for dust control. In locations where trackout from an unpaved road to a paved road is a problem, chemical suppressants will generally be a better choice. Watering aggravates the trackout problem with moisture and mud, whereas a chemical suppressant, particularly bitumens and adhesives, leaves the road dry. Some mines have a dust problem in winter when temperatures are subfreezing but little moisture is present. The case for chemical suppressants over water in this case is clear.

11.2.8 MINERALS PROCESSING DUST CONTROL

A good general reference for minerals processing dust control is the *Dust Control Handbook for Minerals Processing* (Mody and Jakhete, 1987). For a discussion of the processes involved, see Chapter 25.3 in this *Handbook.*

11.2.8.1 Preventing Dust Formation

BELT CONVEYORS. The material should be loaded onto the center of the belt. Also the material and the belt should travel in the same direction and at the same speed whenever possible. The belt conveyor should be designed to operate at 75% of its full rated capacity.

LOADING POINTS. Closely spaced impact idlers (1-ft or 0.3-m centers) should be located at transfer points. These will absorb the force of impact and prevent deflection of the belt between the idlers, thus preventing dust leakage under the skirting rubber seal.

Skirtboards are used to keep the material on the belt after it leaves the loading chute. They are equipped with flat rubber strips that provide a dust seal between the skirtboards and the moving belt. Improved skirtboard designs are available (Mody and Jakhete, 1987). Muckshelves can be installed in the belt conveyor's material impact zone to load the material centrally on the belt.

A belt scraper should be installed at the head pulley to dislodge fine dust particles that may adhere to the belt surface. A scrapings chute should also be provided to redirect the material removed by the belt scraper into the process stream or container. A V-plow installed on the noncarrying side of the belt will clean the belt and prevent buildup of material and dust on the tail pulley, thus keeping the belt properly aligned.

TRANSFER CHUTES. Transfer chutes transport ore from one piece of equipment to another. When designing a transfer chute: (1) the chute depth should be at least three times the maximum lump size to avoid jamming; (2) the chute should be designed so the material falls on the sloping bottom of the chute and not on the succeeding equipment; (3) wherever possible, the material should fall on a local rockbox or stonebox rather than on the metal surfaces; (4) abrupt changes of direction must be avoided to reduce the possibility of material buildup, material jamming, and dust generation; (5) curved, perforated, or grizzly chute bottoms should be used when the product stream consists of fines and lumps; placing a layer of fines ahead of the lumps on the belt helps prevent heavy impact of material on the belt, which reduces belt wear and dust generation; (6) spiral chutes are used to prevent breakage of fragile or soft material; and (7) bin-lowering chutes are used to feed bins and hoppers without generating large amounts of dust.

ENCLOSURES. Enclosures are used to contain dust emissions around a dust source. When designing an enclosure for a dust source: (1) enclosures should be spacious enough to permit internal circulation of the dust-laden air; (2) enclosures should be arranged in removable sections for easy maintenance; (3) a hinged access door should be provided to aid routine inspection and maintenance; and (4) dust curtains should be installed at the open ends of the enclosures to contain dust and reduce airflow.

CRUSHERS. Crushers emit dust primarily from two points, the discharge and the feed. Dust control measures are not usually considered in the design of a crusher. However, the use of shrouds or enclosures for crushers can contain the dust so that a dust control system can operate more efficiently. The following measures are recommended: (1) a crusher feedbox with a minimum number of openings should be installed, and rubber curtains should be used to minimize dust escape and airflow, and (2) the crusher should be choke fed to reduce air entrainment and dust emission. Dust escape at the crusher discharge end can be minimized by properly designed and installed transfer chutes.

SCREENS. The rate of dust generated by screens cannot be altered. However, properly enclosing the screen can reduce dust emissions. A complete enclosure that can be easily removed for maintenance and inspection should be used. Some screen manufacturers provide sheet-metal covers to enclose the top of the screen. These covers are effective when properly maintained. However, they do not provide a dust seal between the moving screen surfaces and the stationary chutes.

STORAGE BINS AND HOPPERS. Dust emissions during feeding operations can be minimized by installing a bin-lowering chute and by completely enclosing the bin or hopper. Dust emissions can be minimized by installing a telescopic chute or by installing a loading spout. Such spouts are sophisticated versions of the telescopic chute and are used to load and stack ore into barges, trucks, and railroad cars. The falling material is enclosed by a flexible duct, acting as a chute, which retracts as the height of the material pile increases. The duct also prevents airflow during free fall of material between the chute and stockpile. The generated dust is captured by the same flexible duct and is conveyed, countercurrent to the material flow, to a dust collector.

BUCKET ELEVATORS. Bucket elevators emit dust from two points, the boot where material is fed and the head wheel where material is discharged. The steel casing that enclose the buckets and chain assembly contains dust effectively unless there are holes or openings in the casing. Emissions at the boot of the bucket elevator can be reduced by proper design of a transfer chute between the feeding equipment and the elevator. Dust production can be reduced significantly by keeping the height of material fall to a minimum and by gently loading material into the boot of the elevator. Proper venting to a dust collector will control dust emission at the discharge end of the bucket elevator.

SCREW CONVEYORS. Normally, screw conveyors are totally enclosed except at the ends, where emissions can be controlled by proper transfer chute design. To maintain a proper dust seal, a neoprene rubber gasket should be installed on the trough cover. Many manufacturers provide two-bar flanges and formed-channel cross members that make a continuous pocket around the trough. The flange-cover sections are set in this channel. Once the channel section is filled with dust, an effective dust seal is created.

STOCKPILES. All types of stockpiles can be a significant dust source. Generation of dust emissions from stockpiles is due to the formation of new stockpiles and wind erosion of previously formed piles. During formation of stockpiles by conveyors, dust is generated by wind blowing across the stream of falling material and separating fine from course particles. Additional dust is generated when the material hits the stockpile.

Dust from stockpiles can be reduced through the following measures:

1. Minimizing height of free fall of material and providing wind protection using

   a. Stone ladders, which consist of a section of vertical pipe into which stone is discharged from the conveyor. At different levels, the pipe has square or rectangular openings through which the material flows to form the stockpile. In addition to reducing the height of free fall of material, stone ladders also provide protection against wind.

   b. Telescopic chutes, in which the material is discharged to a retractable chute. As the height of the stockpile increases or decreases, the chute is raised or lowered accordingly. Proper design of the chute can keep the drop to a minimum.

   c. Stacker conveyors, which operate on the same principle as telescopic chutes.

2. Minimizing wind erosion of the stockpile by locating stockpiles behind natural or manufactured windbreaks, locating the working area on the leeward side of the active piles, and covering inactive piles with tarps or other inexpensive materials.

3. Minimizing vehicle traffic on or around the stockpile.

4. Using specialized equipment such as a reclaimer to minimize the disturbance of the stockpile or providing a tunnel underneath to reclaim the material.

11.2.8.2 Dust Control Systems

A dust collection system, also known as the local exhaust ventilation system, is one of the most effective ways to reduce dust emissions.

EXHAUST HOODS. The rate of airflow through the exhaust hood (i.e., the exhaust volume rate) is the most important factor for all types of hoods. For local, side, downdraft, and canopy hoods, the location is also important because the rate of airflow is based on the relative distance between the hood and the source. The shape of the exhaust hood is another design consideration. If the hood shape is not selected properly, considerable static pressure losses may result.

DUCTWORK. Ductwork design includes the selection of duct sizes based on the velocity necessary to carry the dust to the collector without settling in the duct. To prevent dust from settling and blocking the ductwork, transport velocities should range from 3500 to 4000 fpm (17.5 to 20 m/s) for most industrial dust (such as granite, silica flour, limestone, coal, asbestos, and clay) and from 4000 to 5000 fpm (20 to 25 m/s) for heavy or moist dust, such as lead, cement, and quick lime. Following are recommended minimum transport velocities for different characteristics of dust:

Material	Minimum Design Velocity, fpm (m/s)	
Very fine, light dusts	2000	(10)
Fine, dry dusts and powders	3000	(15)
Average industrial dusts	3500	(17.5)
Coarse dusts	4000-4500	(20–22.5)
Heavy or moist dust loading	4500 and up	(22.5 and up)

11.2.8.3 Wet Dust Suppression Systems

Wet suppression systems fall into three categories: (1) Plain water sprays. This method uses plain water to wet the material. However, it is sometimes difficult to wet surfaces with plain water due to its high surface tension. (2) Water sprays with surfactant. This method uses surfactants to lower the surface tension of water. The droplets spread further and penetrate deeper into the material pile. (3) Foam. Water and a special blend of surfactant make the foam. The foam increases the surface area per unit volume, which increases wetting efficiency.

The advantages and disadvantages of each are shown in Table 11.2.2.

11.2.8.4 Background Dust Sources

Background dust sources can expose workers at mineral processing facilities to more significant dust concentrations than from their normal job functions. These background dust sources include such things as soiled work clothes, blowing clothes off with compressed air, broken bags of product material both at the fill station and during the conveying process, bag hoppers overflowing with product, improper housekeeping techniques such as dry sweeping of floors, and dusty makeup air which many times flows into the mill buildings from outside sources.

The best way to truly detect and measure these background dust sources is through the use of an instantaneous dust monitor,

Table 11.2.2.
Comparison of Water Sprays

Advantages	Disadvantages
Plain Water Sprays	
It is probably the least expensive method of dust control.	Water sprays cannot be used for products that cannot tolerate excessive moisture.
The system is simple to design and operate.	Water sprays cannot be used when temperatures fall below freezing.
A limited carryover effect at subsequent transfer points is possible.	Usually, dust control efficiency is low, unless large quantities of water are used.
When good mixing of water and material can be achieved, dust generation can be reduced effectively.	Freeze protection of all hardware is necessary.
Enclosure tightness is not essential.	Careful application at transfer points that precede a screen is required to prevent blinding.
Water Sprays With Surfactants	
This method is used when surfactants are tolerated but excessive moisture is not acceptable.	Capital and operating costs are higher than water-spray systems.
In some cases, dust control efficiency is higher than with plain water sprays.	Careful application at transfer points that precede a screen is required to prevent blinding.
Equivalent efficiency is possible with less water.	Equipment such as the pump and the proportioning equipment used to meter the flow of surfactant requires maintenance.
	Freeze protection of all hardware is necessary.
Foam	
When good mixing of foam and product stream can be achieved, dust control efficiency is greater than water with surfactants.	Operating costs are higher than with finely atomized water-spray systems.
	The product is contaminated with surfactants.
Moisture addition is usually less than 0.1% of the material weight.	Careful application at transfer points that precede a screen is required to prevent blinding.

such as the MIE Model RAM-1 unit. By monitoring the worker's exposure throughout the entire workday, significant dust producing events can be identified and controlled.

Chapter 11.3
RADIATION CONTROL

ROBERT C. BATES

Providing a mining environment that is as safe and healthful as possible concerns everyone in the mining industry. Radon, thoron, and their respective daughter products create airborne radiation problems, but with proper safety precautions, these hazards can be minimized.

Although always associated with uranium mining, radioactive contaminants are not confined to uranium mines alone, and significant radon daughter concentrations have been measured in copper, gold, lead/zinc, phosphate, limestone, coal, and over 20 other types of mines (Anon., 1987; Rock et al., 1975). A review of Mine Safety and Health Administration (MSHA) data for 1985 through 1987 revealed that 139 mines in the United States, extracting 18 commodities, had radon daughter concentrations at a working level of 0.1 or more (Anon., 1988). (See 11.3.5 for a more detailed definition of working level.) Table 11.3.1 summarizes information on five commodities.

11.3.1 RADIATION SOURCES

Ionizing radiation damages any material it passes through, and any excessive exposure is a hazard. Three types of ionizing radiation occur naturally: alpha, beta, and gamma. Alpha particles consist of two protons and two neutrons and can travel only 1 to 3 in. (25 to 75 mm) in air. Although they cannot penetrate a piece of paper or a layer of skin, they cause the greatest amount of damage per unit length of path, and internally they can be quite damaging.

Beta particles are negatively charged electrons and are much smaller than alpha particles. They can travel several yards (meters) in air and about 0.4 in. (10 mm) in water or tissue. Actual travel distances depend on the energy of the particle and density of the absorbing material.

Gamma photons have no mass or charge and do not have a definite range. They interact directly with orbital electrons to ionize atoms, and all or part of their energy is transferred during an interaction.

Two radioactive decay chains, that is, uranium and thorium, are of concern in mining. Uranium is found throughout the earth's crust; its decay chain includes radium (^{226}Ra), which is the parent of radon (^{222}Rn) (Table 11.3.2). Radon is a chemically inert gas that easily escapes from the material in which it is formed and decays into the particulate daughter products RaA, RaB, RaC, and RaC′ (Fig. 11.3.1). Complete descriptions of radon and radon daughter build-up and decay are available in Evans (1969). When radon daughters are inhaled, they may be deposited on exposed tissues of the tracheobronchial airways, where subsequent decay of RaA and RaC′ (alpha radiation) poses a cancer risk (Anon., 1987).

The thorium decay chain (Table 11.3.3) involves another isotope of radon (^{220}Rn) called thoron. It also is chemically inert and behaves in the same manner as radon. Thoron is common in some uranium mines in Canada (Bigu, 1981) and is a factor in UK mines (Dixon et al., 1984), but it is infrequently found in US mines (Rock, 1975). It can become a problem in any mine where thorium minerals exist because alpha radiation from thoron daughters ThA, ThC, and ThC′ (Fig. 11.3.2) poses the same cancer risk as radon daughters.

Probably the best-known fact about radon and thoron concentrations in mine atmospheres is their variability in space and time. Many parameters, including ore particle size and radium content, influence the escape of radon and thoron atoms from their points of origin. The smallest grains and largest concentrations of radium release the most radon atoms (Pogorski, Busigin, and Phillips, 1981). Only a fraction of the radon escapes the mineral grain in which it is formed, however; this fraction is defined by the coefficient of emanation, which might range from 0% to near 100% (Austin and Droullard, 1978). Once in interstitial spaces, movement of radon is controlled by porosity, permeability, pressure changes, interstitial fluid, and fractures (Tanner, 1964). An excellent summary of the radon literature, including a review of steady-state diffusion and convection equations, is given in Tanner (1964).

However, conditions in mines are far from steady state; mining activities, such as blasting and slushing, influence concentrations (Fig. 11.3.3) (Franklin, 1981). Even if all mining ceases and other factors remain stable, large changes in radon concentrations can be caused by changes in barometric pressure (Fig. 11.3.4) (Franklin, 1981). Water has also been shown to be a carrier of radon in Newfoundland fluorspar mines (Morrison et al., 1984).

Table 11.3.1. Number of Mines Having Radon Daughter Concentrations in Excess of 0.1 WL

11.3.2 TECHNICAL CONTROL

Control of airborne radiation starts with preventing or retarding the flow of radon and thoron into a mine ventilating system. Since a radioactive decay process is involved, time is a factor in ventilation design. Methods that confine radon or thoron, such as bulkheading or sealing, provide the time necessary to allow radioactive particles to decay through their short half-life isotopes to less hazardous lead isotopes. However, once radon, thoron, and their daughters reach a mine atmosphere, then dilution and removal are the only control measures.

11.3.2.1 Confinement

The purpose behind confinement is to prevent radon and thoron from reaching the atmosphere of a mine. Even if the flow

Table 11.3.2. Uranium Disintegration Series

cannot be totally stopped, there is benefit in slowing it to allow some radioactive decay to take place.

Newly produced RaA and ThA are free (unattached) atoms, and they are attracted very quickly to rock surfaces, mine aerosols, or other materials. If trapped on surfaces such as mine walls or grain boundaries within the rock, they are no longer a hazard unless they are redistributed by blasting. Confinement methods include the use of bulkheads, backfill, overpressure, and sealants.

BULKHEADS. The most important method of confining radon, thoron, and their daughters is to seal mined-out stopes or other inactive areas (raises, shafts, and drifts) with good ventilation bulkheads. Many tests have demonstrated that effective bulkheads must be either leak-proof (which is almost impossible in a mine environment) or designed so that any leakage is from an active part of a mine into the bulkhead area. Even a small amount of highly contaminated air leaking from behind a faulty bulkhead can make otherwise good ventilating air unusable. Leakage can be prevented, even against barometric pressure changes, by establishing a negative pressure behind the bulkhead. Such pressure can be developed as part of the main ventilation system if the area behind the bulkhead is connected to exhaust airways. For a deadend area, negative pressure can be assured by running bleeder pipes through the bulkhead and placing a fan at the exhaust end to maintain a flow out of the bulkhead area into an exhaust airway (Franklin, 1981).

BACKFILL. The use of mill tailings and other materials in metal mines to backfill for ground support has been practiced for many years. The trend seems to be increasing, and more mines, including uranium mines, will be using backfill in the future. If use of uranium mill tailings is planned, then, in addition to standard properties determinations, some evaluation of radiation properties is needed (Nantel and Archibald, 1981). Radium content, emanating power at different grain-size fractions, and effects of cements can be tested in a laboratory before fill is placed underground.

Backfilling mined-out stopes can be of use in radiation control as well as ground control. The sheer bulk of backfill material inhibits radon and thoron flow from stope surfaces. Also the physical barrier prevents loss of ventilating air through inactive areas and recirculation of contaminated air. During a field test in a uranium mine in Grants, NM, there was an 87% reduction in radon flow from a stope after the stope was filled with plus 200–mesh uranium mill tailings. A temporary increase in downstream radon concentrations occurred while placing sand slurry, but concentrations quickly returned to normal after pouring stopped (Franklin, 1981).

Some questions have been raised concerning possible environmental problems associated with small quantities of radium in uranium mill tailings. In the Franklin study, measurements taken from a localized drainage ditch at the point where slurry water drained from the stope indicated increased radium concentrations, but measurements taken farther downstream (that is, where the water left the mine) showed no detectable increases in radium.

Table 11.3.3. Thorium Disintegration Series

Isotope	Symbol	Historical Name	Half-Life	Radiation	α Energy, Mev
Thorium 232	^{232}Th		1.41×10^{10} yr	α	4.01 (76%) 3.95 (24%)

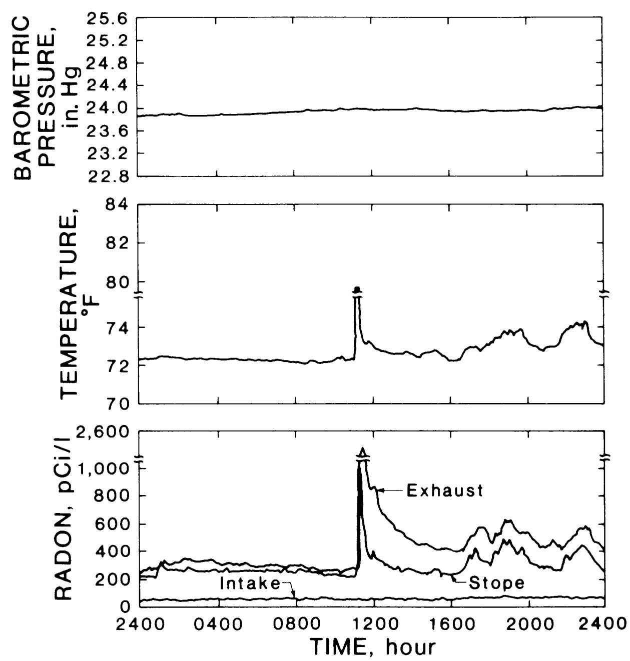

Fig. 11.3.3. Effects of blasting (highest peak) and slushing on radon concentrations.

OVERPRESSURE. Several research projects have examined the potential of reducing radon concentrations through the use of pressurization. In the earliest overpressure experiment, radon concentrations in a small underground room were lowered significantly by increasing pressure inside the room (Schroeder, Evans, and Kramer, 1966). A more recent test of blowing vs. exhaust ventilation was performed in a small, shallow uranium mine. Total radon production from the mine was reduced 20% by changing the ventilation pressure from –2.1 to +1.6 in. water (–523 to 398 Pa) (Franklin, 1981).

Three conditions are needed to make pressurization feasible: porous rock, permeable rock, and a sink to receive the radon. A mathematical study (Edwards and Bates, 1980) indicated that a large, permeable mass is not an effective sink, because eventually the sink is pressurized and diffusion rebuilds the flux to original levels. However, another study indicated that a mine opening less than 330 ft (100 m) away could serve as a sink (Bates and Edwards, 1981). Greater degrees of porosity and permeability allow more flow of interstitial gases toward a sink, and thereby permit larger reductions in radon flux for a given pressure. The calculations also project a large radon flux increase in the sink; therefore, personnel should be kept out of the low-pressure, exhaust side of a mine.

SEALANT. It would appear that an ideal way to prevent radon from escaping from the rock would be to seal the surface with a barrier coating. Laboratory tests on over 100 potential sealants demonstrated that some materials could stop 85 to 100% of the radon loss (Franklin, Nuzum, and Hill, 1975), but

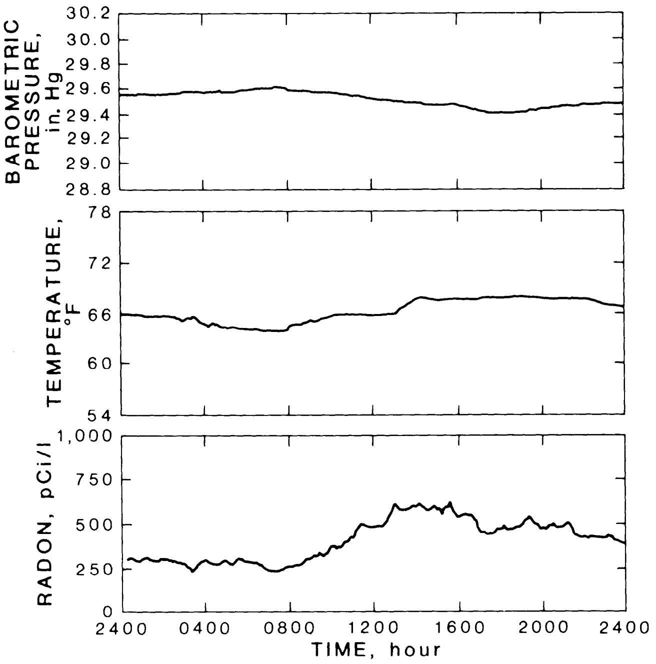

Fig. 11.3.4. Effects of diurnal changes on radon concentration in a shallow mine.

many sealants were rejected because they were poor barriers or were not safe to use underground. Water-based epoxy and acrylic latex sealants were safe for underground use. In one underground uranium mine test, radon concentrations were reduced from 80 to 100 picocuries per liter (pCi/L) to 25 to 30 pCi/L after the walls had been coated, which is about a 70% reduction (Lindsay, Schroeder, and Summers, 1981). Laboratory tests in West Germany found several materials that stopped over 93% of the radon exhalation from drill cores (Reim, Thome, and Haupt, 1984). Even though sealants can reduce the amount of radon escaping from rocks, there are two factors that limit their use: (1) ease of application and (2) cost. If the rock surface is rough or fractured, a smoothing layer of shotcrete is needed before two coats of the sealant are applied. Such multistep process is usually not compatible with mining activities in stopes. Material costs in 1981 ranged from \$0.30 to \$1.10/ft^2 (\$3 to \$12/m^2 (Franklin, 1981), and labor costs to place and maintain sealants raise the costs even more. Total application costs limit the use of sealants to special cases, such as permanent airways.

11.3.2.2 Dilution and Removal

By far the most common and important means of controlling radon and thoron is mechanical ventilation (see Chapters 11.6 and 11.7). Radon and thoron daughter concentrations start increasing as soon as fresh air is contaminated with the parent gas. In about 20 minutes, radon daughters have reached a little over 30% of their final equilibrium concentrations with the parent radon. In many cases, this is enough to make the air unusable. Therefore, moving the ventilating air through the work areas efficiently and into the exhaust airways is important.

General Ventilation. The general concepts for ventilating mines where radon and thoron are present are the same as for any mine (Rock and Walker, 1970). Air enters the mine through one or more fresh air openings, circulates through active workings, and returns to the surface through exhaust airways. Ideally, mining starts near return airways and progresses toward intake airways. Fans for a blowing system are located in the fresh air openings and keep the entire mine under positive pressure. For an exhaust system, fans are located in the return airways; consequently, the mine is under a negative pressure.

In a shallow underground mine, radon and thoron control might benefit from a blowing system whereas an exhaust system might exacerbate the problem (Franklin, 1981). In deep mines, however, other factors become more important. Many ventilation engineers prefer a combination push-pull system. Fans are installed in both intake and return airways. Fresh air is delivered to active areas under positive pressures. After the air is used, it is exhausted through inactive areas under negative pressures. Pressures across air doors and stoppings can be lower with these combination systems than with either blowing or exhaust systems.

To prevent contamination from radioactive products, openings for fresh air should be in nonradioactive waste rock. This is a major difference between ventilating a typical metal or nonmetal mine and any mine containing radon or thoron. Low-grade lead mineralization does not affect ventilating air passing through it; however, air passing through a zone of low-grade uranium mineralization can be so extensively contaminated that the only solution is to increase the airflow to dilute the contamination. In mines with radon and thoron, it is important to deliver fresh air to workers as quickly as possible and then quickly direct it away from them. If the air must be used in more than one work area, then the velocities must be maintained at high levels to keep the travel times and daughter growths low. Additional references on the use of ventilation to control radon and thoron are found in Dory (1981) and Schroeder and Evans (1969).

Daughter products continue to be generated as long as there is radon or thoron available, and any recirculation of ventilating air results in unwanted residence times. During such delays, the daughters can increase to unacceptable levels. Causes of recirculation include (1) fans or fan inlet pipes that are installed in the wrong locations, (2) flow through interconnecting openings that permits exhaust from one part of a mine to mix with fresh air from another, and (3) higher pressures on the exhaust side of an air door or stopping that forces contaminated air through any leakage points into fresh air. Less obvious are situations where high-velocity air passes the entrance of a dead-end side drift and sets up an eddy. Eddies are also sometimes created as air enters a stope or by ventilation tubing directed to sweep only part of a stope.

In the writer's opinion, the most insidious recirculation problem stems from temperature differentials. Natural drafts and convection currents can complicate an otherwise well-designed system. Airflow on the floor of a drift or stope may be opposite to flow along the back. In an unreported field test, warm air from a stope moved more than 20 ft (6 m) upstream along the back of a colder intake airway and was recirculated by an auxiliary ventilation fan.

There is at least one computer program available to identify recirculation loops (Notely, Wheeler, and Fytas, 1984) but the best tool an engineer can have to identify most recirculation problems is a smoke tube. With smoke, directions of low-velocity airflow, differences in direction from floor to back, and eddies can be seen. Careful measurements of airflow in all branches of a ventilation system will help the engineer identify where there are gains and losses in air quality.

Auxiliary Ventilation. All development openings and some stopes must be ventilated with auxiliary fans, pipes, and/or flexible tubing. Blowing systems are the most effective in supplying clean air to miners, provided fans and ducts are installed properly and sufficient air is supplied to dilute and move away any airborne contaminants. High-velocity air at the discharge end of a duct or tube can be directed to sweep a work area clean, and as with any system, contaminated air should be directed toward exhaust airways as efficiently as possible. Auxiliary ventilation systems are always in active workings where they are exposed to moving equipment and possibly flyrock; therefore, these systems should be inspected frequently and repaired.

ESTIMATING VENTILATION REQUIREMENTS. Experience and information collected from other mines in the same area are usually the best approach to developing ventilation requirements for a new mine. If practical information is not available, a more theoretical approach might be useful (Chakravatti, 1981). However, it is much easier to estimate the type and degree of ventilation needed to reduce existing radon daughter levels in a stope or small mine. In 1964, Harris and Bales published their derivation of a ventilation equation,

$$V_2 = V_1\ (WL_1/WL_2)^{0.56} \qquad (11.3.1)$$

where V_2 is new ventilation quantity, V_1 is initial ventilation quantity, WL_1 is initial radon daughter working level, and WL_2 is desired radon daughter working level.

Successful application of Eq. 11.3.1 requires that (1) the intake air is not contaminated, and (2) the air change per minute is between 0.03 and 0.30. (Air change per minute is stope or mine volume divided by air quantity.) If these two conditions are met, the predicted volume, V_2, should be within 5%. However, if these conditions are not met, the equation underestimates the amount of required ventilation.

Using contaminated intake air drastically increases the quantity needed. Obviously, if contamination of intake air is equal to the desired level, then effective ventilation is impossible. In a study of uranium-mine ventilation costs for both current and low-exposure limits, there were some mines that could not meet the low-exposure standards because of contaminated intake air (Bloomster et al., 1984).

11.3.2.3 Air Cleaning

Removing daughter products from mine air for reuse in other areas is one way of reducing overall ventilation costs. A study of possible systems established an effectiveness criterion of 90% reduction with throughput capacity between 4500 and 60,000 cfm (2.1 to 28.3 m^3/s) (Lawter, Lindsay, and Jashani, 1981). Of the many industrial cleaning systems examined, only filtration and electrostatic precipitation were judged to have the necessary capabilities for mine use. Any filtration system must have efficient filters, and the system must be cleaned frequently to maintain a reasonable pressure drop across the filter. Electrostatic precipitators also need to be maintained, but the main caution is to keep airflow within design limits. Forcing too much air through a precipitator severely impairs collection efficiency.

A pulse-cleaning filter system was designed as part of a US Bureau of Mines contract research effort (Schroeder, Muldoon, and Babbitt, 1984). During tests of the system, radon daughter and dust concentration reductions averaged 95% with an airflow of 11,000 to 12,000 cfm (5.2 to 5.7 m^3/s). Filter cartridge life was greater than six months, and pulse cleaning effectively removed dust and diesel contaminants. During a six-month follow-up test in an active mine (Holub, 1987), radon daughters were reduced 98% and condensation nuclei were reduced only 60%. This is an important result, as there are many nuclei left in the filtered air for attachment for newly formed RaA.

Radon is not removed by these systems; therefore, radon daughters will be created at predictable rates. Depending on incoming radon concentrations, air might be unusable in 1 to 10 minutes. Thoron, with a 55-second half-life, does not present the problems of radon, with a 3.825-day half-life. About 97% of the thoron released into a mine atmosphere decays within 4.6 minutes.

11.3.3 MONITORING

Ventilation patterns can be changed as result of relatively minor damage to a bulkhead. Even without mining-related activities, concentrations can change in response to barometric pressure (Fig. 11.3.4). Therefore, for any control program to be effective, there must be an effective monitoring program.

11.3.3.1 Grab Sampling

At a minimum, radon and thoron daughters must be sampled. While there are several methods for measuring airborne radon daughters (Borak et al., 1981), the method most frequently used in the United States is the Kusnetz method (Kusnetz, 1956), in which a known volume of mine air is filtered for a 5-minute period and the alpha radioactivity from the filter is measured 40 to 90 minutes later. If information on individual radon daughters (RaA, RaB, and RaC) is needed, alpha measurements must be taken on each filter at several designated times, for example, at 5, 15, and 30 minutes after sampling. More convenient is the Thomas (1972) method, which involves scalar measurements taken 2 to 5, 6 to 20, and 21 to 30 minutes after the end of sampling.

Thoron daughters can be measured on the same filter used for the radon daughter measurement. However, at least 50 L of air should be filtered, and in contrast to the five-minute sampling period needed for radon daughters, thoron daughter samples can be collected during a one-hour sampling period (Rock, 1975). The filter is counted five hours or more after sampling and the daughter concentration calculated using the appropriate instrument calibration and tables of decay factors. If both radon and thoron daughters are present, then a correction is needed to calculate radon daughters.

Information on radon concentrations is sometimes needed. Point sources, such as fractures or water, can be identified more precisely with radon measurements than they can with radon daughter measurements because radon daughters require time to build. Radon information is also useful for age-of-air calculations, because older-than-expected age-of-air might indicate recirculation in a ventilation system. The easiest method uses a phosphor-lined flask as first described in Lucas (1957). A description of flask calibration procedures is given in Beckman (1975).

11.3.3.2 Continuous Monitors

Continuous monitors provide the ventilation engineer with timely information on conditions underground and may include sensors to measure air velocity, temperature, relative humidity, barometric pressure, fan status, and air-door status, in addition to measuring radon and radon daughters. Several continuous monitoring systems have been described in the literature (Briggs, King, and Franklin, 1984; Franklin and Droullard, 1983; Kawaji, Pai, and Phillips, 1981). Some continuous radon daughter monitors measure the beta and gamma radiation from filtered RaB and RaC, while others use alpha counts to calculate thoron daughter concentrations in addition to radon daughter concentrations. None of the continuous monitors give an instantaneous reading of true concentrations because there is always some buildup and decay of radon daughters within the device to consider. Various schemes, such as polynomial and binomial filtering (Roze, Raz, and Bigu, 1984), have been proposed to show short-term fluctuations in radon daughter concentrations and to correct for the time lags inherent in the instruments. Even without special data-handling techniques, continuous monitors have a place in radiation control. They can warn mine management of control problems much earlier than can a human sampler, thereby decreasing exposure time or preventing any overexposure at all.

11.3.4 BETA AND GAMMA RADIATION EXPOSURES

In past years, uranium ore grades in the United States and Canada were between 0.1 to 1.0% U_3O_8. At these grades, the Federal Radiation Council (Anon., 1967) noted that it was unlikely that external whole-body radiation doses would exceed the 5 rem annual exposure level. However, the council expressed some concern with ore grades over 1 to 5% U_3O_8. A reevaluation of beta radiation exposure during the mining and milling of high-grade uranium ore suggested that such exposures might become important (Mernagh and Chambers, 1984). In four Canadian mines, the exposure limit for gamma radiation and radon daughters individually was not exceeded (Ching, Ho, and Bayne, 1984); however, it was likely that some miners would exceed a proposed standard for a combination of gamma and radon daughters. If beta and gamma radiation becomes a concern, as indicated by these papers, then moving individuals away from high-exposure areas is probably the main control option.

11.3.5 REGULATIONS

Permissible radon daughter concentrations and exposures are expressed in terms of *working levels*, or WL. One WL is defined as 1.3×10^5 mev of potential alpha energy per liter of air resulting from the decay of short-lived radon daughters (RaA through RaC). (Radon daughters in equilibrium with 100 pCi of radon will yield approximately 1 WL.) Originally, exposure to 1 WL of radon daughters was thought to be safe. However, with additional epidemiological data available, exposure limits were lowered and redefined to 4 working-level months (WLM) of exposure per year (Anon., 1989). WLM is calculated by adding each individual WL exposure $\times$ hours exposed $\div$ 173 hours. An average radon daughter concentration of 0.33 WL will yield about 4 WLM of exposure per year. Presently, recommendations are being considered to make the regulations more stringent by decreasing the permitted exposure levels (Anon., 1987).

If any individual is accidentally exposed to higher concentrations that will cause the cumulative radon or thoron daughter exposure to approach the limit, then that individual should be moved to a location where concentrations are lower. This is administrative control of total exposure, and it does not permit deliberate overexposure.

Personal respirators, properly fitted, are required in environments exceeding 1.0 WL (Anon., 1989, 30 CFR 57.5044). This is a temporary measure to protect individuals while establishing controls or to allow occasional entry into hazardous areas. Where radon daughter concentrations exceed 10 WL, then a respirator that removes radon as well as its daughter products or that supplies fresh air must be worn (Anon., 1989, 30 CFR 57.5046).

Finally, at least one radon daughter sample must be taken in the exhaust airway of each mine in the United States. If the concentration is over 0.1 WL, then additional samples must be collected. Additional studies and sampling are needed if active working places have high concentrations. The regulations require records to be kept where radon daughter concentrations are above 0.3 WL.

11.3.6 COORDINATING PRODUCTION AND RADIATION CONTROL

Control of airborne contaminants is an important factor in supplying underground workers with an environment that facilitates productivity. Production decisions, both short- (daily) and long-range, should involve ventilation and radiation control personnel in addition to management people, planning engineers, and foremen. Continuing education of everyone at each mine is needed to keep all aware of the importance of maintaining the integrity of the radiation control system and reporting any observed problems. Removing a bulkhead on the night shift to get extra room for broken ore can ruin a manager's day, especially if an inspector arrives.

Chapter 11.4
HEAT, HUMIDITY, AND AIR CONDITIONING

BRUCE JOHNSON

11.4.1 SYMBOL CONVENTION

AHP Air horsepower, hp (kW)
BHP Brake horsepower, bhp (kW), of a fan motor
c Humid specific heat of humid air, Btu/lb-ºF (kJ/kg-°C)
d_a Density of dry air, lb/ft^3 (Kg/m^3)
d_h Density of humid air, lb/ft^3 (Kg/m^3)
h_a Enthalpy of dry air, Btu/lb (kJ/kg)
h_h Enthalpy of water vapor, Btu/lb (kJ/kg)
h_v Enthalpy of humid air, Btu/lb (kJ/kg)
h_w Enthalpy of liquid water present as vapor, Btu/lb (kJ/kg)
P Barometric pressure, in. Hg (kPa)
p_s Saturation vapor pressure at the dry-bulb temperature, in. Hg (Pa)
p_s' Saturation vapor pressure at the wet-bulb temperature, in. Hg (Pa)
p_v Vapor pressure of the humid air, in. Hg (Pa)
Δp Fan static pressure rise, in. water (Pa)
Q Quantity flow of humid air, cfm (m^3/s)
q Heat transfer, Btu/hr (kJ/h)
RH Relative humidity, %
S Sigma heat of humid air, Btu/lb (kJ/kg)
Sl Slope of the wet-bulb temperature change
T Absolute temperature, °F (°C)
t Dry-bulb (DB) temperature, °F (°C)
t' Wet-bulb (WB) temperature, °F (°C)
t'' Dew-point temperature, °F (°C)
t_{isen} Isentropic temperature, °F (°C)
V Air velocity, fpm (m/s)
v Specific volume of humid air, ft^3/lb (m^3/kg)
W Specific humidity, lb water vapor/lb dry air (g water vapor/g dry air)
η Fan efficiency, decimal or percentage

11.4.2 PSYCHROMETRY

Psychrometry is the study of air-water vapor mixtures under normal atmospheric conditions. The equations given in this chapter for calculation of psychrometric properties are only valid when English system units are used; in the SI system different coefficients are needed. For brevity and to minimize confusion, only the equations using English system units will be given. To work in SI units, simply make the calculations in English system units, then convert the solution to SI units.

11.4.2.1 Temperatures

There are four temperatures that characterize any air-water vapor mixture. These are the dry-bulb temperature, dew-point temperature, temperature of adiabatic saturation, and the wet-bulb temperature.

The *dry-bulb temperature*, normally understood by the term "temperature," is characteristic of the kinetic energy of the gas molecules; it is measured with a thermometer in the usual manner.

The *dew-point temperature* is the temperature at which the water vapor present in any given mixture of air and water vapor will condense. It is only dependent on the gas pressure of the water vapor. Addition of more water vapor will cause the dew-point temperature to rise. There would also be a dew point for, say, ethyl alcohol in a gas mixture containing this substance. However, since water is the only gas normally present that condenses in the normal temperature range, dew point always refers to water vapor.

The *temperature of adiabatic saturation* is the temperature at which an air-water vapor mixture will be saturated if water is added adiabatically (i.e., without extraneous heat) to the mixture and allowed to evaporate. The evaporating water has to get from somewhere the heat needed for evaporation, and the only available source is the mixture. There will be no addition of heat, but the temperature of the mixture will drop until saturation is reached.

The *wet-bulb temperature* is the temperature at which water evaporates adiabatically into an air-vapor mixture. Since the rate at which evaporating water removes heat from a mass of water is practically the same as the rate at which the air-vapor mixture adds heat to the mass of water, the wet-bulb temperature and temperature of adiabatic saturation of water into air are, for all practical purposes, the same.

It is important to remember that the wet-bulb temperature, or more correctly, temperature of adiabatic saturation, of any air-vapor mixture is dependent only on the heat content of the mixture and not on the water vapor present in the air. Perfectly dry air has a wet-bulb temperature, and the heat contents of two mixtures of dry air and vapor with the same wet-bulb temperature but with different dry-bulb temperatures are nearly identical, as is explained in the following.

11.4.2.2 Dry Air

In actuality, the substance called air consists mostly of empty space, with a gas molecule here and there. All the gaseous constituents of air except one are of such uniform properties at normal conditions and are of such constant proportion that they can be lumped together as if they were a single gas, and this uniform mixture of gases is called *air*. The constituent that does not follow the properties of the others, as its concentration varies widely and because it can condense at normal temperatures, is gaseous water, here referred to as "water vapor," although "steam" is more correct, as other gases can also be called vapor.

Dry air is air in the absence of vapor, and *saturated air* is air containing so much vapor that no more can exist; an attempt to add any more will result in condensation of the added vapor to liquid water. *Saturated air* is also a confusing term, as there is a tendency to think of dry air as soaking up water vapor, like a sponge. This is absurd—the vapor and other gases are as independent from each other as the oxygen is from the nitrogen. Condensation would occur at the same temperature for a given quantity of vapor even if no other gases at all were present. When air is at saturation, its temperature is the dew-point temperature. *Humid air* is air containing water vapor up to the saturation point.

11.4.2.3 Humid Air

Now any gas follows a temperature-pressure relationship to saturation; that is, for every temperature, there is a corresponding pressure of the gas at which condensation will occur. All the other gases in the air condense at such high pressures and at such low temperatures that there is no use to worry about them under normal conditions. Water vapor is the exception. When the temperature is reached that corresponds to the dew-point temperature for the pressure of water vapor present, condensation will occur. Actually, condensation can begin before this temperature is reached because of the effect of water condensing onto dust particles, but this effect is difficult to analyze and is normally ignored in psychrometry.

The only sure way of determining saturation vapor pressures at various temperatures is experimentally, and tables of saturation vapor pressures exist (Goff and Gratch, 1945). However, an empirical equation exists for calculating *saturation vapor pressure* at any temperature *t*. The formula is

$$p_s = 0.18079 \exp \frac{17.27t - 552.64}{t + 395.14} \tag{11.4.1}$$

which yields results correct to within less than 1/2% error of the values given in standard tables.

All the psychrometric properties of air can be calculated from wet- and dry-bulb temperatures, measured with a sling psychrometer or other instruments, and from the barometric pressure, which is normally measured with a portable aneroid barometer. The first property calculated is the saturation vapor pressure (p'_s) at the wet-bulb temperature (t') by substituting t' for t in Eq. 11.4.1. From this, the *actual vapor pressure* p_v of the air is calculated by

$$p_v = p'_s - \frac{(p - p'_s)(t - t')}{2800 - 1.3t'} \tag{11.4.2}$$

The density of the *dry* air, ignoring the vapor present, is

$$d_a = \frac{P - p_v}{0.754\,(t + 460)} \tag{11.4.3}$$

where d_a is in lb/ft^3 (kg/m^3).

The *density of the humid air,* including the vapor present, is

$$d_h = \frac{1.325\,(P - 0.378p_v)}{t + 460} \tag{11.4.4}$$

where d_h is also in lb/ft^3 (kg/m^3).

Sometimes one density is used, sometimes the other, depending on the process. In air conditioning problems, the dry-air density is normally used, as the humidity is included in the sigma heat, as shown below.

Specific humidity is the weight of vapor per weight of dry air and is given by

$$W = 0.622 \frac{p_v}{p - p_v} \tag{11.4.5}$$

It is measured in units of lb vapor/lb dry air (g vapor/g dry air).

Relative humidity is the ratio between actual vapor pressure and what the vapor pressure would be if the air were saturated at the dry-bulb temperature, or

$$RH = \frac{p_v}{p_s} \times 100 \tag{11.4.6}$$

where p_s is calculated from Eq. 11.4.1 but with the dry-bulb rather than wet-bulb temperature. Relative humidity is normally not used in calculations, but is the way of expressing humidity most understood by lay persons. It is expressed as a percentage.

Specific volume is the reciprocal of humid air density:

$$v = 1/d_h \tag{11.4.7}$$

where v is in units of ft^3/lb (m^3/kg).

Dew-point temperature can be measured or calculated from the vapor pressure in a rearrangement of Eq. 11.4.1

$$t'' = \frac{-395.14 \ln p_v - 1228.495}{\ln p_v - 15.5596} \tag{11.4.8}$$

11.4.2.4 Heat Content of Air

Enthalpy is the heat content of the air expressed in Btu/lb (kJ/kg) dry air. In air conditioning practice, it is common to use 0°F (also taken as 0°C; see below) as the base starting point for enthalpy of air and vapor, since air is usually above this temperature. Of course, there is actually always heat present above absolute zero.

Some authorities arbitrarily either add or subtract 10 Btu/lb to the dry-air enthalpy in English units, so tables and charts do not always agree on enthalpy values. In the SI system, it is common to use 0°C as the starting point to simplify the equations, so conversion of enthalpy values from one system to the other will not agree, either. However, the important quantity is the change in enthalpy in a heating or cooling process, not the actual enthalpy value at any one point.

When calculating the enthalpy of humid air, it is necessary to consider three components:

1. Since the specific heat of dry air is 0.24 at normal temperatures, the *enthalpy of dry air* is given by

$$h_a = 0.24t \tag{11.4.9}$$

2. *Enthalpy of water vapor* is a little more complicated, since water condenses in the normal temperature range, and many processes involve condensation and evaporation, so the latent heat of vaporization must be taken into account. The formula for the enthalpy of water vapor is

$$h_v = 0.45t + 1061 \tag{11.4.10}$$

in which 0.45 is the specific heat of vapor and 1061 the latent heat of vaporization.

3. The third component of enthalpy is the *heat of liquid water* present in the air as vapor between 0°F and the wet-bulb temperature of the air:

$$h_w = Wt' \tag{11.4.11}$$

Finally, since the usual manner of handling air conditioning calculations is to express everything in terms of pounds (grams) dry air, and the term W is specific humidity in terms of pounds vapor/pound dry air (grams/gram), the formula for the *enthalpy of humid air* (h_h) *is*

$$h_h = 0.24t + W(0.45t + 1061 + t') \qquad (11.4.12)$$

The enthalpy of the liquid water is frequently disregarded as an unnecessary complication; in heating, the term drops out anyway, and in refrigeration, the liquid water is usually removed as it condenses, so it is not necessary to cool the liquid water below its condensation temperature. When the enthalpy of the liquid water is ignored, Eq. 11.4.12 simplifies to

$$S = 0.24t + W(0.45t + 1061) \qquad (11.4.13)$$

From Eq. 11.4.13 the following,

$$c = 0.24 + 0.45W \qquad (11.4.14)$$

can be extracted. This value c is the *humid specific heat* of air, and may be used in heat-exchange calculations when no evaporation or condensation takes place.

The value S calculated by Eq. 11.4.13 is called the *sigma heat* of the air. There is a complication here in that many writers, especially in this country, use the term enthalpy when they really mean sigma heat. That is, they use Eq. 11.4.13 but call it enthalpy anyway. In Commonwealth countries, the practice of using the correct form of sigma heat is more judiciously followed. In this chapter, sigma heat is used.

One thing that is very important is that sigma heat depends only upon the wet-bulb of the air, not the dry-bulb temperature. The reason is that as water evaporates adiabatically into dry air, it draws its latent heat of vaporization from the air-vapor mixture, whose temperature, of course, drops. However, the sensible heat of the air has been replaced by an equal amount of latent heat. While the heat is still present as latent heat, the latent heat often does not have the same physiological effect as does the sensible heat.

Therefore, if Eq. 11.4.13 is applied to an air-vapor mixture into which water is evaporating at successive times as the water evaporates, the dry-bulb temperature will drop as the specific humidity W increases. It is this increase of W with decrease of t that causes the sigma heat to remain constant.

If the psychrometric formulas are applied to various dry-bulb temperatures at the same wet-bulb and barometric pressure, and the resultant W values from Eq. 11.4.5 used in Eq. 11.4.13 at different dry-bulb temperatures, the resulting sigma heat values should be the same.

However, solving Eq. 11.4.13 for various dry-bulb temperatures in this manner will not yield exactly the same sigma heats; the reason is that the values given here for specific heats of both dry air and vapor are not exact, as they vary with temperature. Substitution of the exact specific heats in Eq. 11.4.13 would yield identical sigma heats.

Another problem frequently encountered in understanding this concept of sigma heat varying only with the wet-bulb temperature is the confusion of wet-bulb temperature and dew-point temperature. For instance, if a given air-vapor mixture is heated, both the dry-bulb and the wet-bulb temperatures will increase, although not at the same rate; the dew-point will remain the same.

For derivations of the foregoing equations, see Carrier (1904), Goodman (1941), Goff and Gratch (1945), and Hartman (1982).

Example 11.4.1. Calculate all properties of an air-vapor mixture whose temperatures are 60°F (16°C) WB, 80°F (27°C) DB, at a barometric pressure of 30.0 in. Hg (101.6 kPa).

Solution. First, calculate the saturation vapor pressure at the wet-bulb temperature from Eq. 11.4.1:

$$p_s' = 0.18079 \exp \frac{17.27(60) - 552.64}{60 + 395.14}$$

$$p_s' = 0.5212 \text{ in. Hg } (1.765 \text{ kPa})$$

and from this value, calculate the vapor pressure from Eq. 11.4.2:

$$p_v = 0.5212 - \frac{(30 - 0.5212)(80 - 60)}{2800 - 1.3(60)}$$

$$p_v = 0.3046 \text{ in. Hg } (1.031 \text{ kPa})$$

The density of the dry air, from Eq. 11.4.3 is

$$d_a = \frac{30.0 - 0.3046}{0.754(80 + 460)}$$

$$d_a = 0.0729 \text{ lb/ft}^3 \ (1.16 \text{ kg/m}^3)$$

The density of the humid air, from Eq. 11.4.4 is

$$d_h = \frac{1.325\ (30 - 0.378)\ (.3046)}{80 + 460}$$

$$d_h = 0.0733 \text{ lb/ft}^3 \ (1.17 \text{ kg/m}_3)$$

From Eq. 11.4.5, specific humidity is

$$W = 0.622 \frac{0.3046}{30 - 0.3046}$$

$$W = 0.0064 \text{ lb vapor/lb dry air (g vapor/g dry air).}$$

To calculate relative humidity, Eq. 11.4.1 must first again be used to calculate saturation vapor pressure at the dry-bulb temperature:

$$p_s = 0.18079 \exp \frac{17.27(80) - 552.64}{80 + 395.14}$$

$$p_s = 1.0348 \text{ in. Hg } (3.505 \text{ kPa})$$

Then Eq. 11.4.6 is used:

$$RH = \frac{0.3046}{1.0348} \times 100$$

$$RH = 29.6\%$$

Specific volume from Eq. 11.4.7 is

$$v = \frac{1}{0.0733}$$

$$v = 13.6 \text{ ft}^3\text{/lb } (0.852 \text{ m}^3\text{/kg})$$

Dew-point temperature from Eq. 11.4.8 is

$$t'' = \frac{-395.14\ ln\ 0.3065 - 1228.495}{ln\ 0.3065 - 15.5596}$$

$$t'' = 45°F\ (8°C)$$

Enthalpy, from Eq. 11.4.12 is

$$h_h = (0.24 \times 80) + 0.0064\ [(0.45 \times 80) + 1061 + 60]$$

$$h_h = 26.60\ \text{Btu/lb}\ (6.38\ \text{kJ/kg})\ \text{dry air}$$

From Eq. 11.4.13, sigma heat is

$$S = (0.24 \times 80) + 0.0064[(0.45 \times 80) + 1061]$$

$$S = 26.22\ \text{Btu/lb}\ (6.29\ \text{kJ/kg})\ \text{dry air}$$

and from Eq. 11.4.14 the humid specific heat is

$$c = 0.24 + 0.45(0.0064)$$

$$c = 0.2429\ \text{Btu/lb dry air-°F}\ (0.082\ \text{kJ/kg-°C}).$$

11.4.2.5 Heat Transfer Equations

Heat transfer between two media cannot be calculated by simple energy balance equations, as various coefficients of transfer are also involved. However, simplified equations can be used for the illustrative purposes here, as a complete treatment of the subject is beyond the scope of this chapter. See a standard handbook for details (e.g., Kern, 1950; Whillier, 1982).

If initial and final sigma heats are known, the heat transferred to moving air is given by

$$q = 60Qd_a\,(S_2 - S_1) \qquad (11.4.15)$$

where q is in Btu/h (kJ/hr), the normal manner of expressing heat flow in the English system, Q is airflow in cfm (m^3/s), d_a is dry air density in lb/ft^3 (kg/m^3), and S_2 and S_1 are final and initial sigma heats, respectively.

If the initial and final air dry-bulb temperatures are known, a formula that can be used is

$$q = 60Qd_ac(t_2 - t_1) \qquad (11.4.16)$$

where t_2 and t_1 are final and initial dry-bulbs. While Eq. 11.4.15 can also be used for calculating cooling by reversal of the sigma heat terms, Eq. 11.4.16 can not because it does not take into account condensation of vapor.

11.4.2.6 Psychrometric Chart

Prior to the advent of computers and electronic calculators, the psychrometric chart (Fig. 11.4.1) was indispensable as an aid to psychrometric calculations, as the formulas were too awkward for mechanical calculators, and slide rules were not accurate enough. Presently, direct calculation with electronic calculators and computers has obviated the need of the psychrometric chart for making calculations, but it is still invaluable as a visual aid to understanding the processes of changes of state, as the processes can be plotted on the chart. A psychrometric chart is accurate at only one barometric pressure, and correction factors (or a sheaf of charts) must be used for applying the chart at other pressures.

11.4.3 HEAT IN MINING AND THE NEED FOR COOLING

The cooling mechanism used by the bodies of all mammals, humans included, is that of evaporation of sweat from the skin. Therefore, wet-bulb temperature is an important factor as it limits the temperature to which the body can be lowered. A relatively high dry-bulb temperature can be tolerated as long as the wet-bulb temperature is sufficiently low. Air velocity is also a factor as it aids in evaporation by carrying away the evaporating moisture. The "cooling breeze" felt on a hot summer day is this effect of the evaporating moisture being dissipated; the air temperature is usually the same as before the breeze came up.

11.4.3.1 Human Comfort Indices

Several different indices for determining human comfort under hot conditions have been proposed over the years. Probably the oldest in this country, and one still widely used, is the *effective temperature* (ET). A nomograph for determining ET is given in Fig. 11.4.2. This nomograph relates wet-bulb temperature, dry-bulb temperature, and air velocity. A graph showing the effect of increasing ET on worker productivity is given in Fig. 11.4.3. This graph has been criticized as having been determined with experiments using unacclimatized men and therefore being overly conservative.

The *wet-kata thermometer* index (Stewart, 1982) has been used in South African mines for many years, although it has been criticized because the kata thermometer is so small compared to the surface of the human body. South African authorities have developed the *specific coolingpower* index in recent years (Mitchell and Whillier, 1972), which is more scientific and which employs graphs developed from experiments with acclimatized miners.

The *wet-bulb globe thermometer* (WBGT) index (Brief, 1973) is widely used by government agencies in this country, but because of its taking into account radiant heat, normally not a significant heat source in mines, and because of the time and the difficulty in measurement of WBGT, this index has not been well accepted in the mining industry.

A good standard to use is to try to maintain effective temperature between 70°F (21°C) and 80°F (26.5°C). Between 80°F and 85°F (26.5°C and 30°C), some means should be taken to provide cooling, and 85°F (30°C) should be the maximum ET allowed before cooling is provided. Effective temperatures lower than 70°F (21°C) are of little additional benefit, and air below 60°F (16°C) ET actually becomes uncomfortably cold. In mine cooling situations, 70°F (21°C) ET is a good goal temperature to use for the air that is leaving cooling apparatuses.

11.4.3.2 Heat Sources in Mining

The following are common sources of heat in mining:

1. Initially hot surface air.
2. Adiabatic compression of downcast air.
3. Heat added to air by fans; this is both from compression and from bearing friction in the motor and fan bearings.
4. Heat from other machinery, especially diesel engines.
5. Heat from water; this is both sensible (if the water is hotter than the ventilation air) and latent, from evaporation of the water.
6. Heat from blasting.
7. Heat generated in the friction of falling rock.
8. Wall rock heat.
9. Heat from human metabolism.

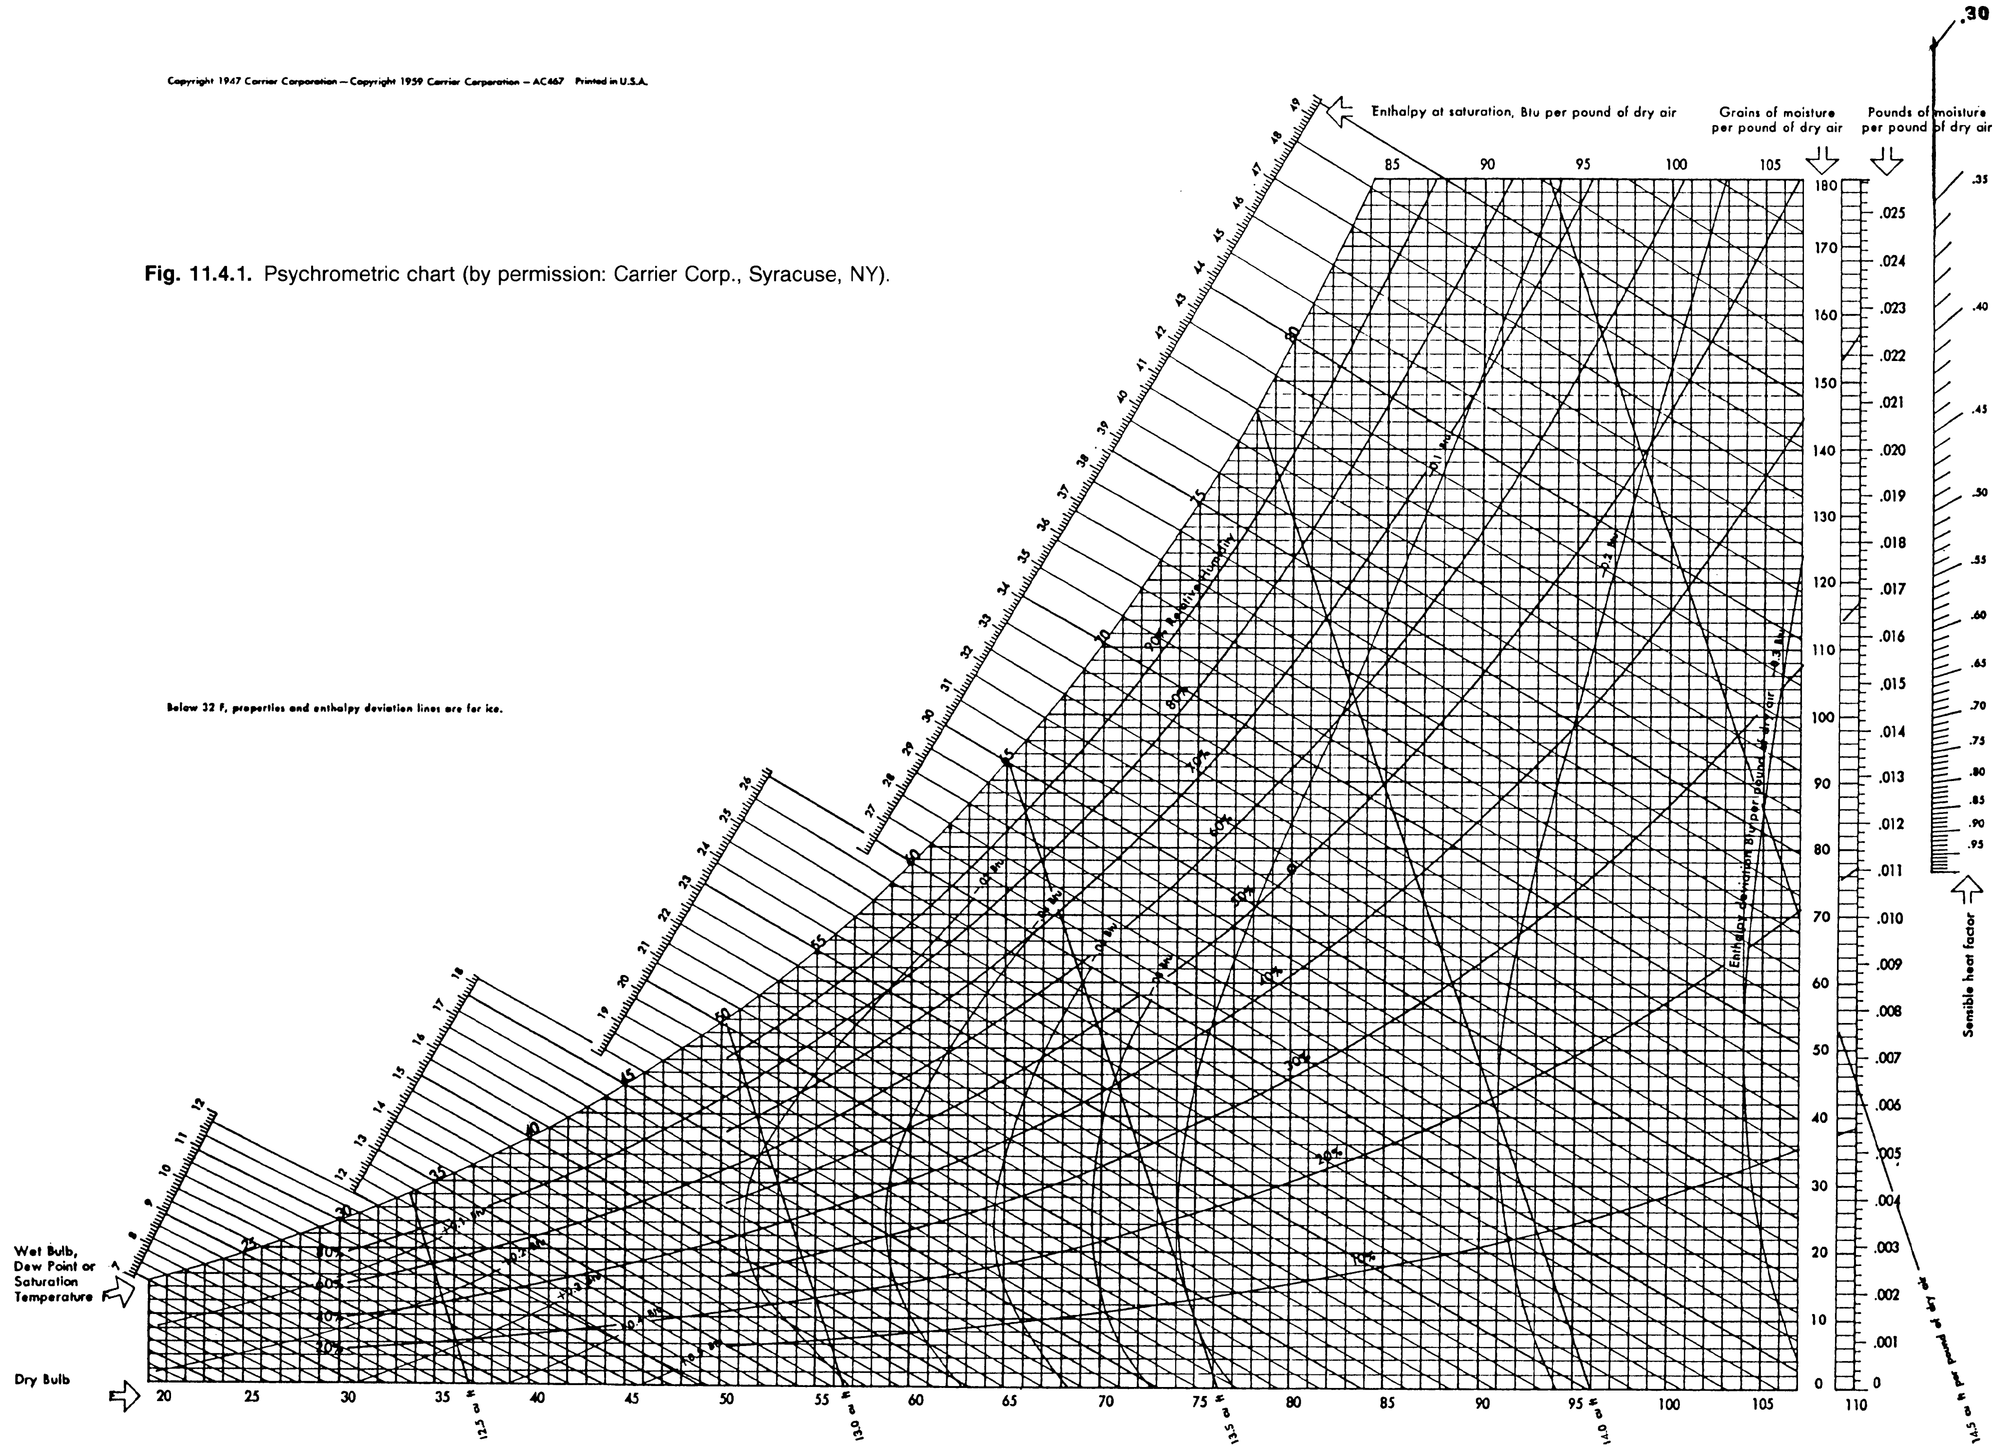

Fig. 11.4.1. Psychrometric chart (by permission: Carrier Corp., Syracuse, NY).

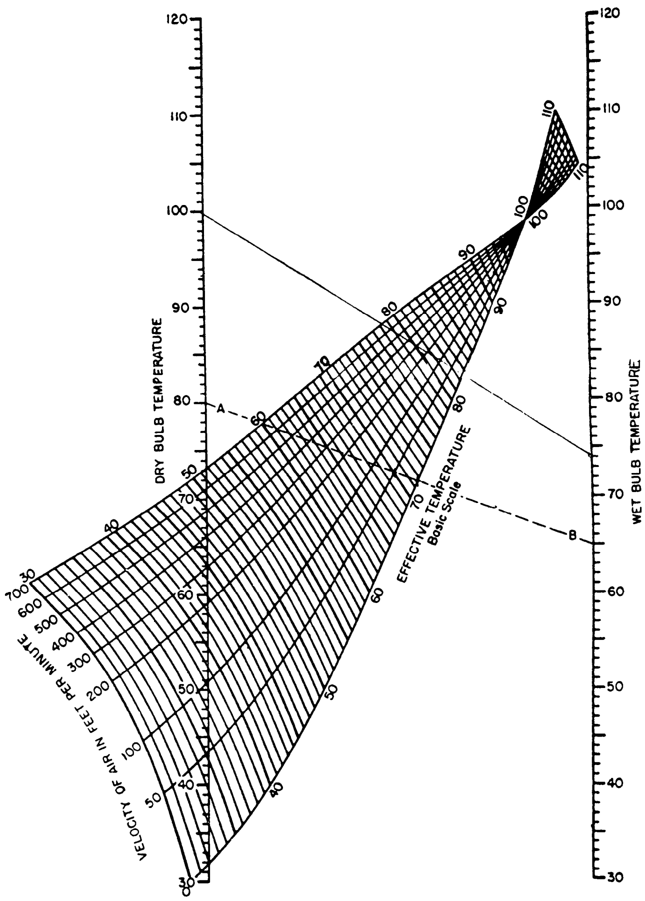

Fig. 11.4.2. Effective temperature chart at rest or doing light physical work in rooms heated by convection methods (Anon., 1988, Fig. 3.5; permission: ASHRAE).

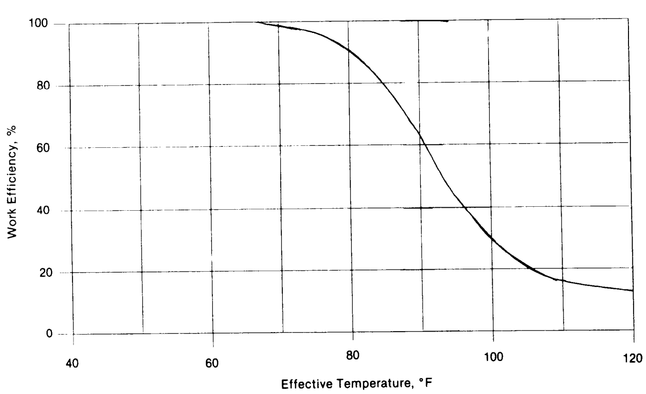

Fig. 11.4.3. Effect of effective temperature on work efficiency. (Carrier, 1950, p. 108; by permission: Penton Publishing Co., a division of Pittway Corp.)

10. Chemical heat, from oxidation of ore, curing of cement, etc.

Initially hot surface air: If this is the only significant heat problem, cooling is often a simple matter, as it can be done either as the air enters the shaft or on each level right off the shaft. However, if ground heat is present as well, the cooled air will absorb more heat than it would if it were carried nearer to the workings before being cooled.

Adiabatic compression of downcast air: This can be precisely calculated by the temperature-rise equation for adiabatic compression, but is usually estimated at 5.3°F/1000 ft (1°C/100 m) of shaft depth for the dry-bulb increase. Wet-bulb increase is taken to be half the dry-bulb increase. However, these figures are not completely accurate in practical situations due to the effect of shaft walls and steel absorbing heat during the hotter part of the day and then emanating heat during the cooler hours. No complete study of this effect is known to have been made; however, some empirical studies have been published (Vost, 1975).

Heat added by fans. Temperature rise in the air as it passes through a fan is considered to be an adiabatic process. Although there will be some heat added due to motor inefficiency and bearing friction, these sources are generally negligible. The procedure given here for estimating air temperature rise across a fan is from a paper by McPherson (1971).

1. Calculate the air horsepower of the fan at the anticipated quantity and fan pressure:

$$AHP = \frac{(Q)(\Delta p)}{6350} \tag{11.4.17}$$

2. From the power curve of the fan, determine the input brake horsepower at this operating point, and calculate the fan efficiency (or read the efficiency directly if the fan curve chart being used shows plotted efficiencies):

$$\eta = \frac{AHP}{BHP} \tag{11.4.18}$$

3. Calculate the isentropic temperature rise Δt_{isen} across the fan:

$$\Delta t_{isen} = 0.286 T_1 \times \frac{\Delta P}{13.6 P} \tag{11.4.19}$$

where T_1 is absolute temperature at fan inlet and P is barometric pressure of the air entering the fan in in. Hg (kPa).

4. Calculate the actual dry-bulb temperature rise from the isentropic temperature rise and fan efficiency:

$$\Delta t = \frac{\Delta t_{isen}}{\eta} \tag{11.4.20}$$

Wet-bulb temperature rise is estimated at half that of the dry-bulb temperature rise.

Heat from other machinery, especially diesel engines. All the energy used by machinery can be assumed to enter the ventilation air passing over the machinery. For diesel engines, 90% of the heat content of the fuel is assumed to enter the air as heat. For other machinery, such as electric motors, use the kW value of the machinery at full load.

Heat from water. Water evaporating can be assumed for estimation purposes to add 0.2°F dry-bulb/100 ft of drift length (0.4°C/100 m) in addition to the temperature rise caused by wall rock heat that is described below. If the water is very hot, an additional increase of 2°F/ 100 ft (3.6°C/100 m) up to a maximum temperature of 110°F (43°C) may be used. The wet-bulb temperature will be within 2°F (1.1°C) of the dry-bulb temperature at all times in very wet drifts (Johnson, 1988).

Heat from blasting. Blasting is generally done off shift, so much of the heat generated by the blast will have dissipated by the next shift, but a considerable amount will be retained in the muck pile and will be emanated during the mucking operation. Increase the predicted temperature in a working face by 2°F wet-bulb, 3°F dry-bulb (1°C wet-bulb, 1.7°C dry-bulb) temperature to allow for blasting heat.

Heat generated by the friction of falling rock. This is of some importance, especially in block cave mines. While no studies are known to have been made on this heat source, a rise of 1°F wet-bulb, 2°F dry-bulb temperature (0.5°C wet-bulb, 1°C dry-bulb) for a quantity of 6000 cfm (2.8 m^3/s) of ventilating air in an area where there is a good deal of falling rock can be used for a fair estimate.

Wall rock heat. The effect of this source is difficult to estimate accurately, as it varies not only with virgin rock temperature and rock type, but also with the time the area has been opened, size and shape of the opening, whether the area is wet or dry, the speed of the ventilating air, etc. There is far from universal agreement on the best way to estimate this effect, and the subject is currently being studied by various researchers. The method outlined by Johnson (1982) is fairly accurate although some of the assumptions are somewhat dated. Several computer programs are now commercially available that have been found to yield satisfactory results. This heat source is often the most important of all. For rough estimation purposes in hot rock mines, an increase of 0.5°F wet-bulb, 0.5°F dry-bulb per 100 ft of drift length (0.8°C wet-bulb, 1.7°C dry-bulb/ 100 m) is acceptable.

Heat from human metabolism. Unlike the air conditioning of buildings, this heat source is minor in mines due to the relatively large quantities of air being circulated, and can normally be ignored.

Chemical heat. This would have to be considered on an individual basis, but could be significant in mines where, for example, there is extensive oxidation of pyrite.

There are two errors frequently made in the estimation of mine heat loads for cooling system design:

1. The error of calculating the heat load as it would be done in a building, where air movement is very slight and most of the air is recirculated. In a mine, the air passes rapidly through the workings and heat added at, say, the end of the stope by an exhaust fan need not be added to the heat load of the stope, as the miners in the stope will not be affected by it. (Exception: If the air is being used in another stope, it is, of course, necessary to add it to the heat load of the other stope).

2. The error of grossly overestimating the cooling-system requirements by using intake air at the conditions of maximum heat load, say, at midsummer, for a condition that may only exist for a couple of weeks. Usually it is better to "tough it out" for the hotter season if this season does not last too long.

Mines contemplating the installation of major cooling facilities are advised to consult with mines that have such systems, or with knowledgeable consultants if there are no personnel on their own staffs with adequate background, as the planning of this type of installation requires a good deal of the "feel" of experience, at least at the present state of development of the art. In reality, most mines employing cooling systems use at least some empirical methods gained from experience for estimating their cooling needs (e.g., Lambrechts, 1950; Johnson, 1988).

Example 11.4.2. An air quantity of 100,000 cfm (47.2 m^3/s) at 60°F WB, 65°F DB (11°C WB, 18°C DB) downcasts a 1000-ft (300-m) deep shaft, and passes through a fan which develops 5 in. water (1250 Pa) of static pressure; fan inlet barometric pressure is 28 in. Hg (94.8 kPa), and efficiency of the fan is 75%. There is a 125-hp (93-kW) haulage motor operating on the level; this is a diesel motor that uses 8 gal (30.3 L) of fuel per hour; heat value of the fuel is 140,000 Btu/gal (38,780 kJ/L).

Air travels 600 ft (185 m) from the shaft and enters a stoping area, where the air is split among five stopes, each of which has a cross-sectional area of 12 × 15 ft (3.5 × 4.5 m). Heat emanating from each stope is 200,000 Btu/hr (210,800 kW). Calculate cooling requirements of cooling apparatus to be installed at the stoping area outlet so that the dry-bulb temperature of the air leaving the area will not exceed 80°F (21.5°C), as the air will be reused several times and it is desired to maintain it fairly cool.

Solution.

1. Adiabatic compression in the shaft:

$$\Delta t = 1000 \text{ ft} \times \frac{5°\text{F}}{1000 \text{ ft}} = 5°\text{F } (3°\text{C})$$

$$\Delta t' = \frac{5°\text{F}}{2} \simeq 2°\text{F } (1°\text{C})$$

Therefore, temperatures at the shaft station are

$$t = 65° + 5° = 70°\text{F } (21°\text{C})$$

$$t = 60° + 2° = 62°\text{F } (16.5°\text{C})$$

2. Fan heat.

$$AHP = \frac{(100{,}000)\ (5)}{6350} = 78 \text{ Hp } (58 \text{ kW})$$

Based on fan, h = 0.75,

$$t_{isen} = 0.286\ (70° + 460°) \times \frac{5}{(13.6)\ (28)}$$

$$\Delta t_{isen} = 2°\text{F } (1°\text{C})$$

$$\Delta t = \frac{2°}{0.75} = 2.7°\text{F, say } 3°\text{F } (1.5°\text{C})$$

$$\Delta t' = \frac{\Delta t}{2} = \frac{3°\text{F}}{2} = 1.5°\text{F, say } 2°\text{F } (1°\text{C})$$

Therefore, temperatures leaving the fan are

$$t = 70° + 3° = 73°\text{F } (23°\text{C})$$

$$t' = 62° + 2° = 64°\text{F } (18°\text{C})$$

3. Diesel haulage motor heat:

$$q = (0.9)\ (8)\ (140{,}000)$$
$$= 1{,}008{,}000 \text{ Btu/hr } (1{,}061{,}052 \text{ kJ/h}).$$

By rearrangement of Eq. 11.4.16,

$$\Delta t = \frac{q}{60\ Qd_a c}$$

$$\Delta t = \frac{1{,}008{,}000}{(60)\ (100{,}000)(0.075)(0.24)}$$

$$\Delta t = 9°\text{F } (5°\text{C})$$

$$\Delta t = \frac{9°}{2}\ 5°\text{F } (3°\text{C})$$

Therefore, temperatures after passing over the haulage motor are

$$t = 73° + 9° = 82°\text{F } (28°\text{C})$$
$$t' = 64° + 5° = 69°\text{F } (20.5°\text{C})$$

4. Wall rock heat transfer along the drift:

$$t = 600 \text{ ft} \times \frac{0.5°\text{F}}{100 \text{ ft}} = 3°\text{F } (2°\text{C})$$
$$t' = 600 \text{ ft} \times \frac{0.5°\text{F}}{100 \text{ ft}} = 3°\text{F } (2°\text{C})$$

Therefore, temperatures at the end of the drift entering the stoping area are

$$t = 80° + 3° = 85°\text{F } (29.5°\text{C})$$
$$t' = 69° + 3° = 72°\text{F } (22°\text{C})$$

5. Each stope uses 20,000 cfm (9.4 m^3/s). Barometric pressure can be taken as 28 in. Hg (94.8 kPa). From the psychrometric formulas above, d_a = 0.0667 lb/ft^3 (1.07 kg/m^3), c = 0.2465 Btu/lb-°F (1.85 kJ/kg-°C), S_1 = 35.96 Btu/lb (149.8 kJ/kg), q is 200,000 Btu/hr (210,800 kW), and by rearrangement of Eq. 11.4.16,

$$t_2 = t_1 + \frac{q}{60Qd_ac}$$
$$t_2 = 85° + \frac{200{,}000}{(60)\ (20{,}000)(0.0667)(0.2465)}$$
$$t_2 = 95.1°, \text{ say } 95°\text{F } (35°\text{C})$$

By rearrangement of Eq. 11.4.15,

$$S = \frac{q}{60Qd_a}$$
$$S = \frac{200{,}000}{(60)(20{,}000)(0.0667)}$$
$$S = 2.50 \text{ Btu/lb dry air } (10.41 \text{ kJ/kg})$$

At this point a method of estimating the final wet-bulb temperature will be given, as the actual wet-bulb cannot be calculated directly. However, McPherson (1983) has developed a method for calculation of the wet-bulb increase that utilizes the slope of the curve of the psychrometric chart. Since the slope varies over the chart, the slope must first be approximated at the original wet-bulb:

$$\frac{Sl}{\Delta t'} = 0.322 \exp(0.0237t_1' - 0.755)$$
$$= 0.322 \exp(0.0237\{72\} - 0.755) \qquad (11.4.21)$$
$$= 0.83$$

Rearrangement of Eq. 11.4.17 gives

$$\Delta t' = \frac{Sl}{1.03}$$
$$\Delta t' = \frac{2.50}{0.83} = 3.0°\text{F } (1.7°\text{C})$$
$$t'_2 = t'_1 + \Delta t'$$
$$t'_2 = 72° + 3° = 75°\text{F } (24°\text{C})$$

For large heat increases, the initial and final wet-bulb temperatures should be averaged and a second slope at this averaged wet-bulb calculated by Eq. 11.4.17. Then this slope should be used to compute a final t_2', which is more accurate. However, in this case the value of 75°F (24°C) is accurate enough. So the air leaving the stope will be 75°F WB (24°C WB), 95°F DB (35°C DB).

It is necessary to cool this air to 80°F DB (26.5°C). Normally in cooling, wet-bulb will decrease at about half the rate of dry-bulb, so calculate the needed drop in dry-bulb, and estimate the corresponding drop in wet-bulb:

$$\Delta t = 95°\text{F} - 80°\text{F} = 15°\text{F } (8.5°\text{C})$$
$$\Delta t' = \frac{15°\text{F}}{2} = 7.5°\text{F, say } 8°\text{F } (4.5°\text{C})$$
$$t' = 75° - 8°\text{F} = 67°\text{F } (19.5°\text{C})$$

Therefore, the cooling apparatus must cool 100,000 cfm (47.2 m^3/s) of air from 75°F wet-bulb, 95°F dry-bulb (24°C wet-bulb, 35°C dry-bulb) to 67°F wet-bulb, 80°F dry-bulb (19.5°C wet-bulb, 26.5°C dry-bulb). Assume barometric pressure to still be 28 in. Hg (94.8 kPa).

From the psychrometric formulas, calculate the entering and leaving sigma heat S_1 and S_2 at the cooling apparatus, and the dry air density entering the apparatus:

S_1 = 39.70 Btu/lb (165.4 kJ/kg), d_a = 0.0653 lb/ft^3 (1.06 kg/m^3) entering;

S_2 = 32.49 Btu/lb (135.4 kJ/kg) leaving.

From Eq. 11.4.15, rearranged for cooling calculations, calculate the cooling required at the cooling apparatus:

$$q = 60Qd_a(S_2 - S_1)$$
$$q = (60)(100{,}000)(0.0653)(39.70 - 32.49)$$
$$q = 2{,}824{,}878 \text{ Btu/hr } (823.9 \text{ kW})$$

or, since 1 ton refrigeration = 12,000 Btu/hr (3.5 kW),

q = 235.4 tons refrigeration

11.4.3.3 Mine Cooling Systems

The three techniques used to cool mine workings are

1. Increased air quantities.
2. Cooling of working areas with chilled service water.
3. Cooling of the ventilation air going to the workings.

Although alternative 1 is the first to be considered, it is frequently impractical. The air might already be at the maximum desired velocity anyway, and even if not, increase of air velocity might raise the air temperature because of additional fan heat.

Alternative 2 has met with a great deal of success in the South African mines, but it is not the panacea claimed by some authorities. It is necessary to maintain the cooling water below 60°F (15°C) as it enters the workings, and this means insulating the service water lines and frequently installing double lines so that the water can be kept circulating, in order that it not warm up while sitting in the pipes. The drawdown of service water is frequently so low that hours elapse between the time the water leaves the shaft and the time it reaches the face. Some mining systems consume so little service water that using very cold water does little good. However, where applicable, this approach can often be used to the exclusion of the much more complicated remaining alternative.

Alternative 3 is the most costly solution but is often the only practical one. Sometimes, cooling of the entire air mass is unnecessary; cooling of a portion of it and remixing with the uncooled air is best, as one of the principal problems in mine cooling is the passing of large amounts of air through cooling apparatuses.

Rejection of Mine Heat: It is of course necessary to reject the heat from the mine air to a heat sump somewhere. This can be done by

1. Rejection into mine drain water.
2. Rejection into upcast air.
3. Rejection into water circulating to the surface and back to underground.

Method 1 is the easiest to design, but often puts an intolerable additional burden on the mine dewatering system, and is costly because of the pumping power needed to lift the water out of the mine. It is only practical for small amounts of cooling, or for systems where drain water can be used as condenser water in cooling units located underground. Drain water is often so dirty that its use in condensers is impractical.

Method 2 is normally implemented through cooling towers built at the intakes to upcast shafts; the cooled water is then used in the condensers of underground refrigeration machinery. This system is still extensively used in the South African gold mines; it requires the availability of large amounts of unsaturated upcast air. No mine in this country has ever used the system on a large scale.

Method 3 is the most common method in most places, but is complicated by the water-handling systems needed, as is discussed below.

Ventilation air can be cooled at the surface or underground near the workings. Cooling at the surface, although the oldest system, was not commonly used for many years because of the poor positional efficiency, that is, the rewarming of air before it reached the areas where it was needed. However, this method is now finding new acceptance, as sometimes the rewarming effect is not significant. This is most true in areas where the main heat problem is caused by hot intake air.

Cooling of the Air Mass: This can be done in four ways:

1. By evaporative cooling of the air, if it is relatively dry.
2. By fin-and-tube cooling coils.
3. By spray chambers.
4. By direct expansion cooling coils working as part of a refrigeration apparatus.

Alternative 1 is restricted to very dry inlet air. Alternatives 2 and 3 are the most commonly used; alternative 4 is restricted to small local cooling units, commonly used in development headings.

Handling of Underground Cooling Water: There is a problem of high static head on water brought from the surface. This problem can be overcome by

1. Dumping the water into underground sumps that are then used as distribution points.
2. Reduction of the static head in turbines, which are then in turn used to generate part of the power needed to lift the water back out of the mine.
3. Using the water in the condensers of underground water cooling units, the chilled water from which is then circulated to air-cooling stations.
4. Using the water in the tubes of underground water-water heat exchangers; water circulating around the tubes of these exchangers, normally also in closed circuit, is then used in the air-cooling stations.
5. Using the water from the surface directly in air-cooling stations which are designed to handle high pressures.
6. Breaking and then recovering the head with a three-chamber pipe feeder system.

Alternative 1 is commonly used only for chilled service-water systems, where the water will be consumed anyway. It is uneconomical in loop-type systems because of the high cost of overcoming the static head to pump the water out of the mine.

Alternative 2 has been used in some South African mines, although there are often problems with balancing the flows into and out of the mine, as the system is normally used where the water to the air coolers is in open circuit.

Alternative 3 has been used in some German mines successfully. It, of course, necessitates ordering special machines equipped with condensers to handle the higher-pressure water. It also obviates the possibility of using evaporatively cooled water, as discussed in alternative (4) below.

Alternative 4 has been used in mines in the American Southwest, in the Soviet Union, and in South Africa. The problems here are the thermal limitations on heat transfer across the exchangers and the high pumping heads needed for the water circulating around the outside of the tubes (the “shell-side”) water. Water arriving at the surface can be cooled in cooling towers if conditions permit, in water chillers, or in towers first and then in water chillers.

Alternative 5 is known to have been used only in the Butte mines, and necessitates very high-pressure piping throughout the mine. It would be practical only where very few air-cooling stations near the shaft were needed.

Alternative (6) appears to be the overall best method (see Walker, 1986, for a description). This is a newly developed system, however, and operational data were not available at the time of this writing.

Use of Ice in Mine Cooling Systems: A recent South African development has been to transport ice underground in water slurries and then use it to cool water that is circulating in a closed loop underground to cooling stations. Heat exchange is initially being carried out by trickling the underground circuit water directly across an ice bed (Sheer, 1985).

If such a system proves practical, it would be a more propitious use of water, as it takes 6 Btu to melt a pound (14 kJ/kg) of ice, whereas only 1 Btu is absorbed in raising the temperature of a pound of water 1°F (1.3 kJ/kg-°C).

Other methods can sometimes be used in special instances, such as the utilization of cold stream water (where available) or an underground ice field in the summer that has been frozen the previous winter with cold winter downcast air (see Bossard and Stout, 1973, for a description of these and other possible systems).

11.4.4 CASE STUDIES

The cooling systems mentioned here are examples of various manners of effecting cooling; they are not necessarily “ideal” systems but have been proven in practice in the conditions for

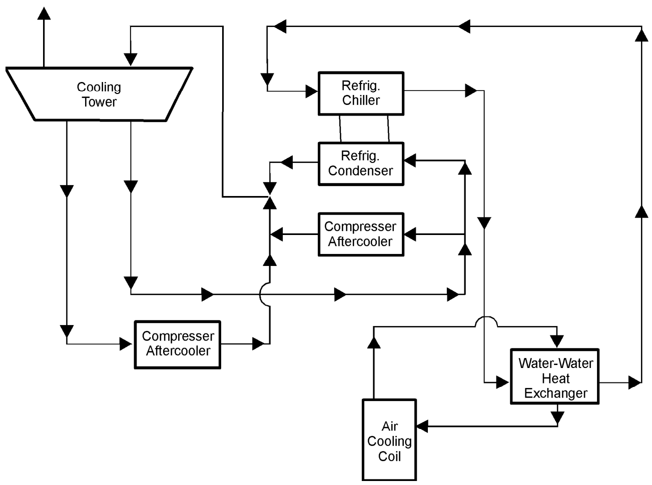

Fig. 11.4.4. San Manuel mine cooling system schematic.

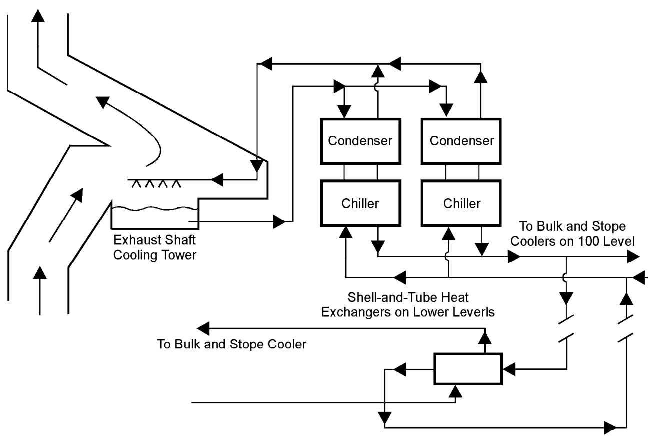

Fig. 11.4.5. Schematic of Western deep levels cooling system (Stroh, 1974).

their respective mines. Only general layouts are given with no specific figures on temperatures, cooling loads, etc.

11.4.4.1 San Manuel Mine, San Manuel, AZ

Main cooling is needed only during the summer months, although some development cooling with small air cooling units that have condensers utilizing service water is done year-round. The main cooling system consists of a cooling tower, surface water chillers, and underground water-water heat exchangers (Fig. 11.4.4). The heat exchangers can use water from the cooling tower directly, water from the surface water chillers that are in turn cooled by the cooling tower, or water cooled first in the tower, then in the water chillers.

Water circulating in the underground circuit through the heat exchangers is utilized principally in spray chambers; some is utilized in cooling coils near the working areas. Spray chambers are run as evaporative air-coolers, using only service water, in the early, dry part of the hot season.

11.4.2 Western Deep Levels, Johannesburg, South Africa

Water chilling units are located underground on several levels near exhaust shafts (Fig. 11.4.5). Condensers of the units are cooled by water circulating in closed circuit to cooling towers through which exhaust shaft air is routed. Chilled water is utilized in cooling coil stations and smaller, semiportable units at stope raises. Water for the deeper levels is run from a level where there are refrigeration units down through the tubes of water-water heat exchangers; shell water circulating through these exchangers is in turn circulated to air cooling stations.

The reference providing a description of this system is fairly old, and the system has since been somewhat modified.

11.4.3 Homestake Mine, Lead, SD

For a description of the mine's ventilation system, see Chapter 11.7. Cooling water is processed in water chillers on the 5000-ft (1.5-km) level for service in the deepest parts of the mine; the condensers are cooled by water that is dumped into the mine dewatering system. The chilled water is utilized in spray-chamber type coolers. Water from the spray chambers is rejected to the dewatering system. Some direct-expansion coil air chillers are also used; the condensers serving these units are cooled by service water that is rejected to the dewatering system.

11.4.4 Prosper Haniel, Germany

Air is cooled in fin-and-tube coils; the water for these coils is cooled in a series arrangement underground, first in water-water heat exchangers, then in evaporators of water chillers (Fig. 11.4.6). The water from the surface is run first through the tubes of the heat exchangers, then through high-pressure condensers serving the water chillers. Heat rejection on the surface occurs first through a cooling tower, then through the evaporators of water chillers; the condensers of these water chillers are cooled directly by surface air. However, in the winter, the tower and water chillers are unnecessary, as the water from underground can be cooled directly in fin-and-tube coils on the surface that utilize the cold air.

11.4.5 HEATING OF MINE AIR

In cold winter conditions, it is sometimes necessary to heat air entering the mine to avoid the problems caused by water freezing. This is a very different situation than cooling, as the problem is always caused only by cold surface air; underground conditions do not exacerbate the situation as they do in cooling situations.

Heating is generally best accomplished as the air enters the ventilation intakes from the surface. Usually the air is only heated to about 34°F (1°C).

11.4.5.1 Estimation of Heating Requirements

Eq. 11.4.15 or 11.4.16 can be used to calculate overall heating requirements, but manufacturers of the heating equipment being considered must be consulted for design of the actual system.

The system should be designed for average cold weather conditions, not for the maximum condition. For instance, if the average temperature is 0°F (– 18°C), but sometimes snaps down to – 40°F (– 40°C), a system designed for – 40°F (– 40°C) would be too large most of the time, and the needed equipment would be much more expensive than that needed for the average situation. In extreme cold conditions, it is better to reduce air quantities, or try to get along with the colder air for a short time.

11.4.5.2 Heating Systems

Cooling Tower. Sometimes, a cooling tower can be constructed over the exhaust shaft or portal; the tower extracts heat

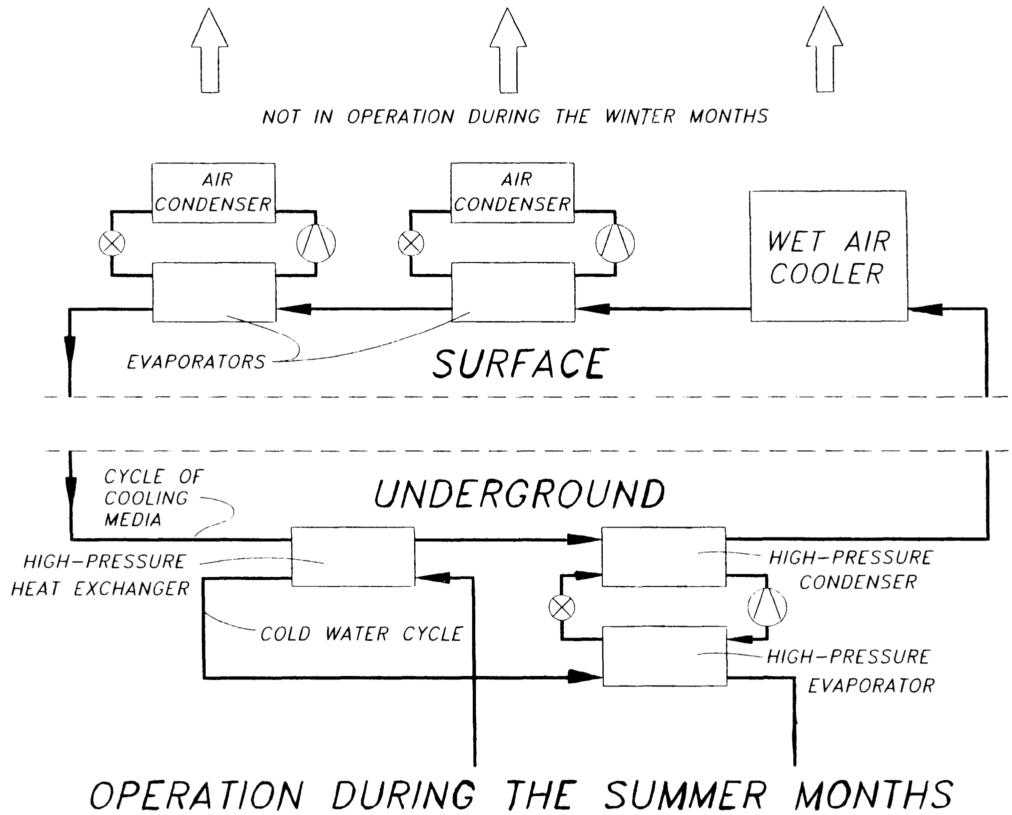

Fig. 11.4.6. Schematic of Prosper Hamel Colliery cooling system, German Federal Republic (Hamm, 1980, Fig. 10).

from the upcast air, and the warmed water is then pumped to heat exchanger coils at the fresh air inlet. This, of course, will only work if the upcast air is relatively warm to start with, about 70°F (21°C) dry-bulb. Since the water into the tower will be colder than the wet-bulb of the exhaust air, no unwanted cooling of the water will take place.

Waste Heat: If boilers are used in the area, the hot water from them may be circulated to heating coils at the mine inlet. Another possible heat source might be cooling water from compressors or generators that utilize diesel or gasoline engines. Sometimes, even geothermal energy may be used if the water from the mine is hot.

Indirect Heating with Furnaces: The furnaces used may be oil, gas, coal, or electric, depending on which is the cheapest power source in the area. If used in the indirect manner, whatever type furnace is utilized would heat water, or a glycol solution, and the solution would then be pumped in closed circuit through heating coils at the air inlet.

Direct Heating with Furnaces: In this system, the air is run directly through the furnace, as is the case in most buildings. Sometimes, the exhaust is even allowed to enter the airstream; this utilizes all the fuel consumed, as no heat is lost in exhaust gas. If the furnace is well maintained, no contamination problems should exist, as the amount of exhaust gas will be small compared to the amount of inlet air. However, this is not recommended, as potential disasters could occur if the furnace were to explode, or the air quantity suddenly drop drastically for some reason.

Chapter 11.5
DIESEL EXHAUST CONTROL

ROBERT W. WAYTULONIS

11.5.1 INTRODUCTION

This chapter deals with the control of exhaust emissions from diesel-powered equipment operated in confined spaces, such as mines.

The operation of diesel engines releases both gaseous and particulate pollutants into the atmosphere. The control of these emissions is necessary to ensure a healthful work environment. Several components of the gaseous fraction of the emissions can be toxic, asphyxiating, or strongly irritating at low concentrations. The particulate matter in the exhaust is entirely respirable and contains adsorbed substances, some of which are known carcinogens. The concentration and composition of the pollutant fraction of diesel exhaust depends on many interrelated factors that include fuel composition, engine type and its state-of-maintenance, duty cycle, and the operating environment.

Statutory safety and health requirements for diesel-powered equipment in the United States are found in Title 30, Mineral Resources, of the *Code of Federal Regulations* (CFR) (Anon., 1988). The Mine Safety and Health Administration (MSHA) of the US Department of Labor has the responsibility for establishing and enforcing standards concerning basic machinery design, safety features, ventilation requirements, and other criteria intended to minimize health and safety risks associated with use of diesel equipment. The exhaust pollutants upon which limits are placed are carbon dioxide (CO_2), carbon monoxide (CO), oxides of nitrogen (NO_x), sulfur dioxide (SO_2), sulfuric acid (H_2SO_4), and aldehydes. Hydrocarbons (HC), oxides of sulfur (SO_x), and odor are not specifically regulated. Diesel particulate matter (DPM) is currently regulated indirectly by limiting worker exposure to respirable dust. Diesel legislation worldwide is summarized elsewhere (Waytulonis and Johnson, 1987).

Diesel exhaust emissions are controlled by proper selection of fuel and engine, good maintenance and work practices, and exhaust aftertreatment. Controls are discussed in 11.5.3.

11.5.2 BACKGROUND

11.5.2.1 Engine Operation and Emissions

OPERATION. In a diesel engine, fuel is sprayed under high pressure into air heated by compression; typical compression ratios range between 16 and 22:1. The fuel ignites spontaneously, further heats the compressed air, and forces the piston downwards doing work. The fuel injection process is critical to ignition, efficiency, and emissions characteristics. Good mixing between fuel and air is essential and must occur over a period of a few milliseconds. The air induction and fuel injection systems, therefore, must be designed and maintained to achieve optimum interaction. Injection timing, pressure, spray geometry, and delivery rate are critical to good performance (Anon., 1982; Taylor, 1979). Engine speed and power are controlled by varying the amount of fuel injected into the combustion chamber. The intake airflow is unthrottled, allowing the engine to operate over a wide range of fuel-air ratios.

EMISSIONS. Emission of exhaust pollutants is due to incomplete combustion of fuel. Their concentrations in the exhaust are primarily related to fuel composition, combustion efficiency, and the fuel-air (F:A) ratio.

Diesel fuel (by weight) consists of about 85 to 86% carbon, 13 to 14% hydrogen, 0.00 to 0.9% sulfur, and traces of other elements. Air consists of essentially oxygen and nitrogen. If complete combustion occurred, all the fuel carbon would combust to CO_2, all the hydrogen to water vapor (H_2O), and all the sulfur to SO_2. However, because combustion is never complete, the exhaust also contains CO, HC, and particulate matter. Because of high temperatures during combustion, a small portion of the excess oxygen and nitrogen from the air reacts to form nitric oxide (NO) and nitrogen dioxide (NO_2). Essentially all of the fuel sulfur can be expected to be present as oxides (SO_x in the exhaust. If the engine is in proper mechanical adjustment, these pollutants are contained in diesel exhaust only in low concentrations over the normal operating range. The number of possible reactions in a combustion chamber is very large, and therefore, the exhaust contains thousands of different compounds. For practical reasons, a limited number of species are measured in emissions studies (Springer and Patterson, 1973).

The ratio of the mass of fuel to the mass of air in the combustion chamber is expressed as the *F:A ratio.* The value of this ratio dominates combustion and emissions characteristics. At the stoichiometric F:A ratio, the mixture contains the amount of air required to burn the fuel to CO_2 and water, with neither an excess nor deficiency of oxygen (Taylor, 1979).

For engineering purposes, the stoichiometric F:A ratio for typical diesel fuels is 0.067 (indicated by the arrow on Fig. 11.5.1). Ratios less than 0.067 identify lean mixtures containing more air than required for complete combustion. Ratios greater than 0.067 are rich and contain less air than is needed. In the normal operating range where there is excess air for combustion, useful power increases nearly in direct proportion to the F:A ratio. This relation ends rather abruptly near stoichiometry. In the rich range of F:A ratios, power is nearly constant despite greatly increased fuel consumption. Thus, in diesel engines overall, F:A ratios are lean. This results in good fuel economy and performance, particularly during low load operation (Anon., 1982).

Typical relationships between F:A ratio and changes in exhaust composition are shown in Fig. 11.5.1. Note that the vertical scale is logarithmic. This figure shows that diesel engines operated in the abnormally rich range can produce unacceptably high concentrations of certain exhaust pollutants. F:A ratios greater than about 0.058 indicate improper engine operation. Engines are operated in this abnormally rich region only for the purpose of obtaining laboratory data. It is particularly important that diesel engines used in mines be adjusted to prevent operation near stochiometry.

About 1.2 lb (0.54 kg) of water are produced from each pound of fuel burned. The H_2O curve in Fig. 11.5.1 is calculated from hydrogen balance during combustion. The nitrogen (N_2) curve represents not only N_2 in the intake air, but also argon and other inert constituents. Nitrogen is not toxic and is always

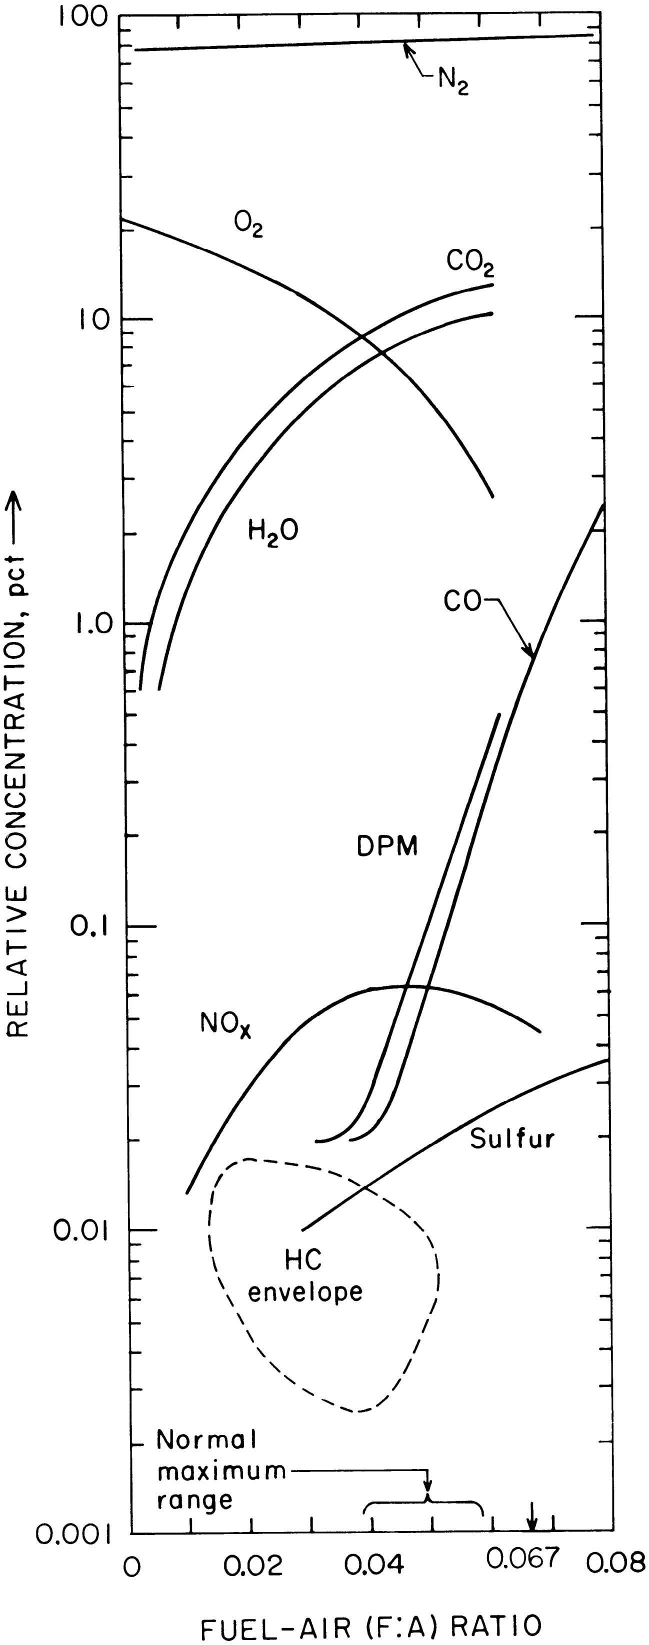

Fig. 11.5.1. Typical relationships of fuel-air ratio and relative concentration of diesel exhaust components.

present in exhaust gas in high concentrations. Although not shown, representative values of exhaust temperature are 260°F (127°C) for low F:A ratios to 1160°F (627°C) at stoichiometry.

Carbon Dioxide—Carbon dioxide is a non-poisonous, asphyxiating gas regarded as a hazard because of the large volumes produced and its tendency to layer at floor level. The emitted volume of CO_2 is directly related to the amount of fuel burned. The concentration of CO_2 increases almost directly with F:A ratio to a maximum at the stoichiometric F:A ratio.

Carbon Monoxide—Carbon monoxide results from incomplete combustion of carbon in the fuel. If sufficient oxygen is available, oxidation from CO to CO_2 will occur, but the reaction may be incomplete due to short residence time or low gas temperature (Watson and Janota, 1982).

Oxides of Nitrogen—Oxides of nitrogen (NO and NO_2) are always present in diesel exhaust gas, and concentrations of NO_x are generally greater in direct-injection (DI) engines than in equivalent indirect-injection (IDI) or divided-chamber engines (Holtz, 1960). The majority of NO_x formed in the combustion process is NO. Nitrogen dioxide is primarily a post-combustion product formed by oxidation of NO after the exhaust has been discharged (Marshall, 1975). As engine load and exhaust temperature increase, an IDI engine will typically emit up to 700 ppm NO_x. The concentration of NO_2 in raw exhaust is typically less than 10% of the total NO_x.

Oxides of Sulfur—Sulfur-containing species are emitted in diesel exhaust because sulfur is an impurity in the fuel. There are two sulfur oxides, SO_2 and sulfur trioxide (SO_3). The latter is normally collected as sulfuric acid since it reacts rapidly with water vapor in the exhaust. The gases SO_2 and SO_3 are strongly irritating at nontoxic concentrations and thus give considerable warning of their presence. Most fuel-bound sulfur is emitted as SO_2, less than 5% as sulfates (sulfuric acid and sulfate salts), and even smaller amounts as other organic sulfides (Anon., 1981). The sulfur curve in Fig. 11.5.1 is calculated for a fuel sulfur content of 0.5% by weight. It represents the total relative concentration of sulfur in the exhaust regardless of form: SO_2, sulfates, or other substances in gas, liquid, or solid phase.

Hydrocarbons— Some unburned and partially burned HCs are always present in diesel engine exhaust, both in the gas phase and adsorbed on DPM. The amount is usually small, but their presence is objectionable due to the odor of some species and their potential toxic or carcinogenic effects. They consist of some partially decomposed fuel molecules, some recombined intermediate compounds, and some HCs from the lubricating oil (Anon., 1981). Hydrocarbons in Fig. 11.5.1 are shown as carbon equivalent, measured by a flame ionization detector. Due to the great variability and absence of any trend, an envelope of realistic HC values is shown.

The major source of HC emissions in well-maintained engines results from fuel expansion and dripping from the injector sac volume (between the needle seat and injector holes) after the injector has closed (Watson and Janota, 1982). The sources of excessive HC emissions in poorly maintained engines includes misfires, poor injection, or raw fuel deposited on combustion chamber walls.

Aldehydes— Aldehydes are part of a broad group of partially oxidized HCs. Their concentrations in the exhaust are directly related to the unburned HC fraction.

Odor—Production of odorants is inherent in the diesel combustion process. There are two sources: (1) unburned fuel and its thermal breakdown products and (2) nitrogen compounds and other products of incomplete combustion (Marshall and Seizinger, 1978; Anon., 1982). Aldehydes contribute to odor, but there appears to be no single group of compounds that accounts for odor (Stewart, Dainty, and Mogan, 1976; Lilly, 1984). Since odor is not clearly defined, methods for reducing it are also not well defined. However, for a given engine, measures to reduce HC emissions also tend to reduce odor.

Diesel Particulate Matter—DPM has lately come under close scrutiny from a health effect viewpoint. For this reason, it will be discussed in more detail than the other diesel exhaust pollutants. Currently, there is no occupational exposure limit for DPM in the United States, but it may be regulated in the future due to the nature of the compounds it contains (Anon., 1988a, 1988b). Because DPM particles are predominantly less than 1 micrometer (μm) size, DPM is a component of respirable dust and thus indirectly regulated via compliance sampling for respirable dust (Cantrell, 1987).

Most particles result from the incomplete combustion of fuel and lubricating oil HCs. Engine oil contributes from 50 to 280 times as much material to the particulate emissions as does an equal amount of fuel consumed. So even though oil consumption is relatively small compared to that of the fuel, the oil can still have a significant effect on particulate emissions (Mayer, Lechman, and Hilden, 1980). Also leakage of fuel, hydraulic oil, etc., onto hot surfaces can add substantially to DPM in the atmosphere. Minor leakage rates on the order of 0.5 oz/hr (3.9 mg/s) of oil have been found to contribute about 0.5 to 2.5 mg/m^3 to the HCs in the air (Carlson, et al., 1986). Engine blowby (vapors that escape the combustion chamber into the crankcase) is a small source of DPM since the flow rate is typically about 1% of the air consumption rate of the engine. However, the concentration of HCs in crankcase vapors can be several times that found in the engine exhaust gases. Control systems are available to feed these gases to the intake system of the engine, where they are drawn into the combustion chamber (Adler et al., 1986). Typically in mining engines, these gases are released untreated into the atmosphere.

DPM is defined as the material, excluding water, that is collected on a filter after dilution of the exhaust with ambient air. Other terms related to DPM include smoke, particulates, and soot. For purposes of this discussion, *smoke* is defined as particles, either solid or liquid (aerosols), suspended in the exhaust gases, that obstruct, reflect, or scatter light. The term *particulates* refers to particles collected by filtration. *Soot* is defined as deposited DPM. The individual particles are carbonaceous solid chain aggregates with adsorbed or condensed organic compounds. These compounds include high-molecular-weight organic compounds such as unburned and oxygenated HCs, polyaromatic HCs (PAH), and inorganic species such as SO_2, NO_2, and sulfates (Khatri, Johnson, and Leddy, 1978; Vuk, Jones, and Johnson, 1976).

For discussion purposes, DPM can be subdivided into (1) non-gaseous oxides, (2) solid non-extractable carbonaceous material, and (3) a soluble organic fraction (SOF) (carbon-containing solvent-extractable material).

Non-gaseous Oxides—The oxide portion of DPM includes SO_4 and trace metal oxides (from lubrication oil and wear metals from engine components). In humid atmospheres, sulfates hydrate to form sulfuric acid and acid mists that can cause health and environmental hazards. Sulfates appear in diesel particulates as either acid droplets or more complex forms (Khatri, Johnson, and Leddy, 1978).

Carbonaceous Material—The carbonaceous portion of DPM results from incomplete combustion of fuel and lubrication oil, and is commonly called smoke. There are always some carbon particles present in the diesel exhaust under any operating conditions, and zero smoke emission is impossible (Taylor, 1979). Visible smoke is an indication of high DPM emissions. Diesel engines generate the highest DPM concentrations and visible smoke under high load and during cold-starting. Generally, smoke values above 4% opacity are visible to the human eye.

Smoke can be discussed in terms of observable colors. Diesel smoke is usually classified as either blue/white or grey/black in appearance. The blue component originates from an excess of lubricating oil in the combustion chamber. This results from deterioration of piston ring sealing, or valve-guide wear, and indicates a need for mechanical overhaul. However, unburned fuel can also appear as blue smoke if the droplet size is about 0.5 μm. The white component has a droplet size of about 1.3 μm and results from too low a temperature in the combustion chamber during fuel injection. White smoke can occur upon cold starting, at idle, and at low-loads. These conditions are made more obvious by low ambient temperatures and high altitude operation. Also white smoke can result from late fuel injection or low compression.

Grey/black smoke consists of solid particles of carbon from incomplete combustion. These particles are produced at or near full load if excess fuel is injected, or if the air intake is restricted. Main causes are poor maintenance of air filters and fuel injectors, or incorrect setting of the fuel injection pump (Lilly, 1984).

Soluble Organic Fraction—The *SOF* is the portion of the DPM that is extractable using a dichloromethane solution. The SOF originates from the fuel and lubrication oil. The soluble material is a complex mixture of raw fuel, cracked and partially oxidized fuel, and PAH. Because of their complexity, these mixtures must be fractionated before analysis (Anon., 1982).

The SOF can range from 2 to 70% by weight of the total DPM. Lubrication oil is the dominant source of the SOF. The remaining SOF is derived from fuel and typically makes up 10 to 30% of the total SOF on today's engines (Springer, 1988). The SOF portion of DPM contains mutagenic and carcinogenic substances, and it is important that any emission control technology under consideration be assessed with respect to its effects on the nature of the SOF (Anon., 1988b). Determination of the PAH gives an indication of the levels of known carcinogens. The Ames salmonella/microsomal test is the most popular short-term bioassay for measuring the activity of the SOF and its subfractions (Ames, McCann, and Yamasaki, 1975).

REGULATORY SCHEME. MSHA has the responsibility for establishing and enforcing mining regulations. CFR Title 30 describes requirements applicable to the emissions from diesel engines used in underground noncoal mines (Anon., 1988). Diesel-powered machines in gassy noncoal mines and tunnels are subject to several "parts" that are periodically revised. A part specifically for diesels in coal mines has not yet been established (adaptations of existing parts are used), but promulgation of such regulations have been recommended by an independent committee (Anon., 1988a).

MSHA generally uses the approved ventilation, methane, and respirable dust-control plans of individual mines to address some hazards of diesel use not specifically regulated. Some mine ventilation plans require minimum ventilation (volume flow) rates, ventilation requirements when multiple diesel units operate on the same ventilation current, environmental sampling, and specific work practices associated with the operation of diesel equipment. Air quality standards for some components of diesel exhaust are adopted from the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit values (TLV) (Anon., 1988c). These values are reviewed annually by ACGIH and revised as new research data warrant. MSHA regulations for coal and noncoal mines have cited different yearly issues, and thus compliance limits for substances may vary with mine type.

Dilution Ventilation—Ventilation is the principal means to control exhaust emissions. MSHA has established regulations limiting the concentrations of certain components in the raw exhaust and in mine air, and defining calculation methods to determine the "assigned" ventilating airflow which must pass over operating diesel machines. The rate of ventilation air is calculated from a combination of engine tests to determine the flow rate of exhaust gas, concentrations of pollutants, and their hygienically safe levels. From test data, the volume of fresh air to dilute the exhaust gas to a safe condition for the exposure of workers is calculated. When ventilation is calculated using a safety factor, concentrations of the exhaust pollutants will not exceed their limits (Holtz, 1960).

Currently, MSHA determines the maximum engine generation rate of the worst single gaseous pollutant, and the volume flow (quantity) of air to dilute that component to a safe level is calculated. Frequently, safe ventilation is based on the concentrations of NO_x in the exhaust; however, the specific gas varies for different engines. Sometimes maximum ventilation is based on either CO_2 or CO. DPM is not presently considered in measurements and calculation of safe ventilation.

Emission levels differ among engines and with different conditions of operation. The maximum exhaust dilution requirement does not always occur at maximum engine speed and load (Marshall and Hurn, 1968). Some time ago, 75 cfm/max hp (0.047 m^3/s/max kW) was suggested as enough ventilation for any diesel engine used underground. Experience has since indicated that safe dilution may range from about 90 to 250 cfm/max hp (0.057 to 0.158 m^3/s/max kW), provided the engine is adjusted to minimize CO (Holtz, 1960; Anon., 1985, 1985a). Because of these factors, no accurate empirical formula has been developed for estimating safe dilution ventilation for different types of diesel engines. For these reasons, no diesel engine should be placed in underground service until tests have been made to determine the safe ventilation rate. Both the maximum fuel injection rates at various altitudes and a safe ventilation rate are given in the approval or certification letter for each MSHA-approved diesel machine.

11.5.3 CONTROL OF EXHAUST EMISSIONS

11.5.3.1 Work Practices

Diesel engines were first used underground in the United States around 1937, mostly to drive locomotives. Guidelines for the safe use of diesel-powered equipment were subsequently developed. Results of research and practical experience have identified important work practices.

FUEL SELECTION. The American Society for Testing and Materials specifications for diesel fuels, ASTM D-975, is widely accepted. Number 1 diesel fuel is primarily produced for circumstances in which No. 2 causes cold-weather handling and engine starting problems. Some burner fuels meeting ASTM D-396 are also used in diesel operation (Anon., 1988d).

Fuel composition affects diesel emissions, and fuels with different properties do not necessarily respond the same way in engines with different combustion systems. Using fuel composition as an emission control technique will not significantly improve all diesel engine exhaust characteristics. Reasonable control of diesel fuel properties will, however, minimize operational, cold-start, and durability problems, along with some emission problems (primarily SO_x, HC, and DPM) (Ryan et al., 1981; Baranescu, 1988; Weidmann et al., 1988). Properties of diesel fuel of particular interest are cetane number, volatility, sulfur content, and hydrocarbon types.

The cetane number, sometimes estimated by the cetane index, describes the ignitability (ignition delay) of diesel fuel. Fuels with high cetane numbers have low self-ignition temperatures. Fuels with low cetane numbers cause engine roughness, but cetane numbers higher than the minimum requirement for a particular engine will not measurably improve engine performance. Cetane numbers range from 0 to 100; typical cetane numbers of diesel fuels used in the United States range from 40 to 57. Although the terms cetane number and cetane index both describe ignitability, they are sometimes erroneously used interchangeably. A cetane index can be calculated by a four-variable equation with density and volatility data from the particular fuel analysis (Dickson and Woodward, 1988).

Table 11.5.1. Optimum Property Limits for Diesel Fuel

Property	Limit
Cetane number	> 48
Aromatics	< 20%
90% dist. temp.	< 600°F (316°C)
Sulfur	< 0.10% by mass

Increased cetane number and volatility reduces the tendency to produce white smoke. Using a fuel with a cetane number greater than 48 and a seasonably adjusted cloud point reduces cold-start HC emissions, noise, odor, irritant, and fuel system wax separation problems.

Volatility is determined by distillation of a fuel at a prescribed rate, with observations of temperature vs. volume of distillate and amount of residue. The 10 and 90% distillation temperatures are frequently cited to give a concise indication of fuel volatility.

The most important emission-related fuel properties for controlling DPM are sulfur content and aromatic HC content. The ASTM standard for No. 2 diesel fuel sets a 0.5% by weight limit on sulfur content; many states have more restrictive standards. Reducing fuel sulfur reduces SO_2 emissions and the sulfate fraction of DPM. Reducing sulfur content of diesel fuels has the added benefit of reducing corrosive wear and oil fouling and extending engine life.

The HCs in diesel fuel are numerous, but mostly fall into three families: paraffins, naphthenes, and aromatics. Each series has its own molecular characteristics, and this has a strong influence on diesel fuel quality (Marshall and Hurn, 1968; Ryan et al., 1981; Weidmann et al., 1988). An important but usually unspecified property of diesel fuel is aromatic HC content. Typical commercial No. 2 diesel fuel has an aromatic HC content of 20 to 40% by weight. Reducing fuel aromatic content reduces HC and the carbonaceous fraction of DPM (Weaver et al., 1986).

Increasing aromatic content and the 90% distillation temperature will increase DPM and odor emissions (Lilly, 1984). However, some data indicate that changes in the distillation temperature have little potential for DPM emissions reduction (Weaver et al., 1986). These conflicting findings highlight the difficulties of isolating fuel effects on emissions when a number of fuel properties are interrelated.

High-quality fuels with low sulfur levels, low aromatic content, increased volatility, and cetane numbers greater than 48 have generally resulted in lower particulate emission levels. Optimum property limits for diesel fuel are shown in Table 11.5.1.

Fuel Additives—Fuel additives for smoke control modify ignition delay, catalyze the combustion of carbon, or improve the fuel-air mixing processes by assisting fuel atomization. Small quantities of additives, typically compounds of the alkaline earths, barium, and calcium, can reduce smoke opacity. These additives not only catalyze the conversion of carbon particles to CO_2, they also aid in the suppression of free carbon formation during the early stages of the combustion process. As a result, carbonaceous particles are replaced with emissions of oxides and sulfates of barium and calcium, and although smoke opacity is reduced, total particulate emissions are frequently increased (Kittleson et al., 1979).

The effectiveness of additives is load-dependent and variable. Using additives resulted in changes ranging from a 25% reduction to a 48% increase in DPM mass at steady-state operation (Roessler et al., 1980). A barium additive tested at the manufacturer's recommended concentration and at light engine loads, elevated DPM emissions by about 30%. The additive also produced statistically significant increases in both exhaust mutagenicity and PAH concentrations. In contrast, the same additive used at one-fourth the recommended level decreased DPM emissions at full load up to 74%. These results suggest that the barium additive should not be used for smoke suppression under light-duty operation, if at all (Zeller, 1987; Draper, Phillips, and Zeller, 1988).

Overall, experience with fuel additives for combustion modification and emission control is limited. The cost of additives as well as the fate and toxicity of their exhaust end products must be considered.

Commercial cetane improvers are available for diesel fuels and are mostly composed of mixtures of primary amyl nitrates or primary hexyl nitrates, which in concentrations near 1000 ppm in the fuel provide an increase of about four cetane numbers. Organic peroxides are also known to act as cetane improvers (Lilly, 1984). However, sensitivity to a cetane improver is fuel-dependent and generally causes particulate emissions to increase (Burley and Rosebrock, 1979).

Diesel fuel is sometimes modified with kerosene or gasoline to improve engine starting in cold weather. This modification can possibly lower the fuel flash point. Fuel flash point is an important parameter for evaluating fire hazards. Number 1 and 2 diesel fuels have minimum permissible flash points of 100°F (37.8°C) and 125°F (51.7°C), respectively. Users are advised that fuel additives to improve starting may result in lowering the flash point to less than 100°F (37.8°C). A gasoline content of only a few percent, for example, can reduce the flash point of diesel fuel to room temperature range, thus allowing the formation of explosive mixtures above the fuel in the tank (Adler et al., 1986). As a result, the fuel must be reclassified from a combustible liquid to a flammable liquid (Anon., 1988e).

ENGINE SELECTION. There are, as identified in 11.5.2.1, two types of diesel engine combustion systems, DI and IDI. In the DI system, the fuel is injected directly into a combustion chamber. The DI engine has about 10% lower fuel consumption, is less expensive, and offers a slightly better power-to-weight ratio than the IDI engines (Anon., 1982). In the IDI diesel engine, there is an additional chamber into which the fuel is injected. This prechamber is designed so that the intake air swirls as the piston rises. The air motion in the IDI combustion chamber is more violent than the movement in the DI type and promotes rapid fuel-air mixing for more complete combustion.

Comparison of emissions between DI and IDI diesel engines shows that the IDI engine produces the lowest CO, NO, HC, and aldehydes, but odor levels are not greatly different (Marshall and Fleming, 1971). The IDI diesel engine is one of the lowest emission internal-combustion engines available, and this has long been recognized in the underground mining industry.

ENGINE DERATING. Limiting engine power output by adjusting the maximum fuel rate, *derating,* reduces emission of pollutants. Reducing the maximum volume of fuel that can be injected makes excess oxygen available for combustion, limiting products of incomplete combustion. Combustion products are a sensitive function of the amount of excess oxygen, as shown in Fig. 11.5.1. *Derating is not a method to reduce excessive exhaust pollutants caused by deficient engine maintenance.* Derating requires the maximum fuel injection rate to be correctly adjusted and sealed. Consequently, *tampering with the fuel adjustment must not be tolerated.*

EFFECTS OF INTAKE AIR COMPOSITION. In mines using diesels, the atmosphere always will contain some exhaust gas. Blasting gases are similar in composition and at times may occur in relatively high concentrations in some locations. Naturally occurring methane may also be present. The presence of such contaminants, in addition to barometric conditions, will change the characteristics of the exhaust.

Operation in Gassy Atmospheres—Addition of methane to the engine intake air has the effect of supplying extra fuel. Thus, even with the fuel pump adjusted to operate in the normal range of F:A ratios, the natural gas can increase the F:A ratios into the rich range, increasing some pollutants in the exhaust. For example, 0.5% by volume (0.28% by mass) of methane in the intake air would have the effect of changing a F:A of 0.048 to 0.051.

Operation Without Ventilation—Diesel machines should never operate in areas with little or no ventilation. For example, operating a 50-hp (37.3-kW) diesel engine at full load in a 10 by 10 by 50-ft (3 by 3 by 15-m) entry without ventilation produces dangerous levels of CO_2 and depletes oxygen in a matter of minutes (Holtz, 1960). If such operation were continued, the concentration of CO would rapidly accumulate to dangerous levels. *All diesel equipment should be shut down immediately when positive ventilation is interrupted.*

When an engine rebreathes its own exhaust, the F:A ratio increases, which increases the CO and DPM emissions. Rebreathing can occur where ventilation is locally inadequate. Prolonged operation of diesel equipment in such an area causes hazardous conditions that deteriorate rapidly, particularly if the engine is operating at a high load. The effect of an engine rebreathing its exhaust on the composition of exhaust can be nearly the same as when a diesel engine is operated in normal air at F:A ratios in the rich range. The effect is countered by passing additional ventilation air over the diesel at a rate adequate to maintain the atmosphere hygienically safe (Berger et al., 1940).

Operation at Altitude—The effect of altitude on emissions is important when engines are operated in mountainous regions. The fuel rate must be decreased, as air density decreases, to maintain the maximum allowable F:A ratio. In naturally aspirated engines, a fixed maximum fuel rate setting is valid only over a moderate range of altitude if excessive emissions of CO and DPM are to be avoided.

The safe maximum fuel rate can be calculated for higher altitudes using CO emission data taken at any other barometric pressure. For example, the nominal fuel rate at full throttle for an engine at 1000 rpm is 12 lb/hr (5.4 kg/h) at 30 in. Hg (101.6 kPa) barometric pressure. For these conditions, the F:A ratio is about 0.054, and the concentration of CO in the exhaust is 0.09%. At a barometric pressure of 25 in. Hg (84.7 kPa), the maximum fuel rate should be reduced to 12(25/30) = 10 lb/hr (4.5 kg/h). This reduction would maintain the maximum F:A ratio at 0.054 and the concentration of CO at 0.09% in the exhaust. However, the maximum power output of the engine is reduced from 28 to 22 hp (20.9 to 16.4 kW) because of the reduced maximum fuel injection rate. When the engine is adjusted for the effects of barometric pressure in this way, the same volume of dilution air will provide safe ventilation at any altitude (Elliott, 1948; Holtz, 1960).

Fig. 11.5.2 shows how F:A ratio would change if an engine were not derated for altitude. For example, an engine adjusted for a F:A of 0.05 at sea level would operate with a F:A ratio of

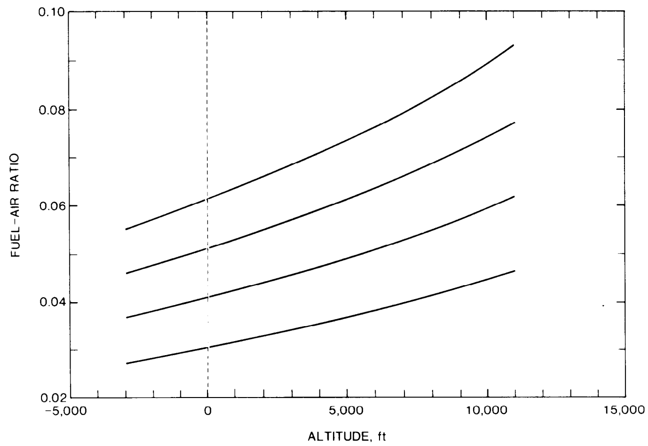

Fig. 11.5.2. Influence of altitude on fuel-air ratio for several constant fuel rate settings. Conversion factor: 1 ft = 0.3048 m.

about 0.07 at 9000 ft (2743 m) altitude. Typical exhaust emission levels for the uncompensated fueling condition from Fig. 11.5.1 indicate a significant increase in CO and DPM.

Supercharging (pressurizing the intake air) can compensate for loss of power at high altitude, and thus the maximum setting of the fuel injection pump can be increased (Watson and Janota, 1982). This increase in fuel adjustment results in more power while combustion conditions remain within the normal range of F:A ratios. Increasing the pressure of the engine intake air increases the oxygen available for combustion. The maximum fuel rates can be increased accordingly to yield increased maximum power at lower altitudes, or recovery of power lost from derating, at higher altitudes.

ENGINE MAINTENANCE. The objective of diesel engine maintenance is to keep engines in an optimum operating condition and extend useful engine life. Preventive maintenance, periodic repairs, and adjustments are all part of a basic maintenance program. Poor maintenance will result in increases in exhaust pollutants.

Table 11.5.2 shows the effects of faults or maladjustments on HC, CO, NO_x, and DPM emissions of an IDI engine, with the increase above baseline given in percent. For convenience, the percentage increases are given in groups (i.e., < 50, 50 to 200, and ≥ 200). These faults change the engine's F:A ratio and may result in increased pollutants in the exhaust. Also the level of emission caused by a pair of faults occurring individually is not as severe as the level when the same faults are combined (Branstetter, Burrahm, and Dietzmann, 1983; Waytulonis, 1985).

Of all the potential causes of excessive exhaust pollutants, overfueling is the most critical. Overfueling can result from improper injection-pump setting or improper altitude adjustment, worn injection system components, or improper injectors. For example, an engine adjusted for sea level, but operating at 4000 ft (12 19 m) is overfueled by 10%, and if operating at 7000 ft (2134 m), it is overfueled by 20%. Overfueling by 10% can increase CO by 50 to 200%, and 20% overfueling increases CO by more than 200%. Once set correctly, the fuel-injection setting does not require frequent adjustment.

Intake restriction, caused by a plugged intake air filter, will cause dramatic increases in CO and DPM. For example, 20% overfueling combined with 50 in. water (12.4 kPa) pressure drop across the air cleaner results in a ≥ 200% increase in CO and DPM. Proper and timely air cleaner maintenance can prevent such severe conditions.

Fuel injection timing increases CO at both an advanced or retarded position from the correct setting, and has mixed effects on HC and DPM. Timing advance is the primary engine fault that can lead to increased NO_x, while retarded timing will decrease it. Once properly set, injection timing does not require frequent adjustment.

Many premature engine failures are a result of ingestion of dust, fuel contamination, and cooling system irregularities. Internal engine parts must be kept free of dust to prevent accelerated wear of moving parts that have very close tolerances. Dual, paper-element air filters provide good protection. The inner (backup) filter element protects the engine against failure of the outer cartridge. Air filter cleaning intervals are difficult to predict, but a vacuum gage can effectively indicate excessive restriction. Reuse of filter cartridges is not recommended, nor is the practice of backflushing them with compressed air.

Using clean diesel fuel will contribute toward long engine life. Both dust and water in fuel will lead indirectly to higher pollutants in the exhaust by accelerating wear. Water collects in storage tanks and if allowed to enter the engine, will damage fuel injectors and pumps. Water and suspended matter can be removed from the fuel by filters and water separators. Minimizing fuel transfers and keeping storage tanks full helps to prevent contamination.

Overheating is a common cause of engine failure. A combination of several engine faults can result in overburdening the cooling system and cause permanent damage to the engine. Typically, overfueling and retarded timing will increase the exhaust-gas temperature, thus increasing the amount of heat rejected into the cooling system. Minerals in mine water form deposits on cooling surfaces and act as heat insulators. Damaged fans and shrouds reduce airflow through the radiator and over the engine, and slipping belts cause fans or coolant pumps to perform poorly. Proper and timely preventative maintenance can minimize these problems.

11.5.3.2 Exhaust Aftertreatment

The most important pollutants to control in confined spaces are probably CO, NO_2, and DPM. Exposure to high concentrations of CO and NO_2 eventually are fatal. DPM is important because of the known carcinogens adsorbed on exhaust particles. Discussion of exhaust aftertreatment therefore centers on these pollutants.

WATERBATH EXHAUST CONDITIONERS. These are also referred to as *water scrubbers* and are designed to cool the exhaust and to suppress flames and sparks in the exhaust. These safety functions are mandatory on diesel equipment operated in certain areas of gassy mines (Anon., 1988). A properly designed and maintained waterbath conditioner will not allow the exhaust temperature to exceed 170°F (77°C). Waterbath conditioners use the principle of adiabatic saturation of the hot exhaust by evaporation of water. Approximately 1100 Btu (1161 kJ) are required to vaporize 1 lb (0.45 kg) of water. The hot exhaust gas is bubbled through water to obtain the contact area necessary for rapid evaporation of the water and cooling of the exhaust. Under some conditions, a waterbath exhaust conditioner may create fog that can reduce visibility. About 3 lb (1.36 kg) of water are typically emitted/lb (0.45 kg) of fuel burned.

Waterbath exhaust conditioners may be batch- or a constant-level type. Batch-type conditioners contain all their operating water in one "batch" and operate with a variable level. Constant-level conditioners maintain a set water level controlled by a float valve or some other device. Water is supplied from an external

[b] Deviation from manufacturer's specification.

makeup tank. Fig. 11.5.3 shows a typical installation of a constant-level exhaust conditioner.

A waterbath exhaust conditioner can also act as a scrubber to remove some exhaust pollutants. The gases CO_2, SO_2, SO_3, and NO_2 are water soluble and are partially trapped, and some DPM is captured. Rapid corrosion from acid gases can occur unless the conditioner is constructed of stainless steel and flushed with fresh water regularly (Waytulonis, Smith, and Mejia, 1982). The gases CO and NO are practically insoluble in water and are not absorbed in any significant quantities. Also, because the conditioners cool the exhaust, some HCs are condensed and odor is reduced (Mogan, Dainty, and Lawson, 1986).

Most of the solid particles in the exhaust pass through the waterbath because a large proportion of the exhaust gas has no contact with the water. Internal baffles to breakup and distribute exhaust gas bubbles are thought to increase DPM and SO_2, removal. Total DPM is reduced 20 to 30% (Eccleston, Seizinger and Clingenpeel, 1981). Because of their design diversity, the effectiveness of waterbath exhaust conditioners to remove exhaust pollutants vary widely.

OXIDATION CATALYTIC CONVERTERS. These are sometimes referred to as *purifiers* and have been routinely used for many years for emission control on diesel engines used underground. During the early years of dieselization of underground mines, the functions performed by catalytic converters were considered more significant than they are today. Early work reported CO levels in the range of 800 to 2600 ppm and 100 ppm of aldehydes in some IDI engines used underground (Elliott, 1948; Holtz, 1960; Marshall and Hurn, 1968). Modern derated IDI engines in good mechanical condition typically have CO emissions less than 600 ppm and total HC emissions less than 200 ppm and, consequently, reduce the potential benefits of

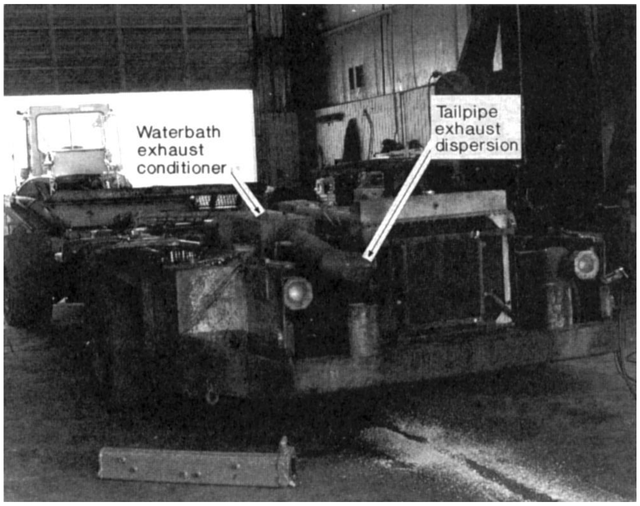

Fig. 11.5.3. Typical installation of a waterbath exhaust conditioner and tailpipe exhaust dispersion.

Fig. 11.5.4. Typical installation of an oxidation catalytic converter.

catalytic converters. In most instances, modem, well-maintained diesel engines operating in adequately ventilated areas do not need oxidation catalytic converters for emission control.

A *catalyst* is a substance that alters the rate of a chemical reaction without being consumed. In diesel exhaust, gas-phase reactions normally proceed at a very slow rate. On the catalyst, however, the rate is fast enough to be of practical value for controlling emissions. Noble metals (platinum and palladium) are typically used as the active components of the catalyst. The catalyst is deposited on a carrier or substrate and housed in a stainless steel container fitted into the exhaust system as shown in Fig. 11.5.4. There are two substrate configurations: pellets (alumina balls) and monoliths (ceramic or metallic honeycomb structure coated with alumina). Some configurations integrate a catalyst into a noise-reduction device. The monolith, shown schematically in Fig. 11.5.5, is the dominant type because it has better performance and stability than the pelleted alternatives and is generally smaller (Steel, 1988).

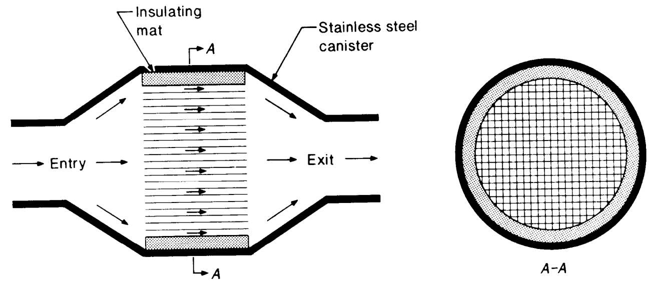

Fig. 11.5.5. Schematic of a monolithic oxidation catalytic converter.

Table 11.5.3. Effects of Oxidation Catalytic Converters on Some Diesel Exhaust Pollutants

Constituent	% Change
CO	−39 to −90%
HC	−2 to −68%
NO_2	0 to +25%
SO_4	+10 to + > 1000%
Aldehydes	up to −55%

The function of catalytic converters is to oxidize exhaust pollutants. This renders *some* of them less toxic. As hot exhaust gas passes over the catalyst, CO and HC (including aldehydes) are oxidized to CO_2 and water vapor, reducing the amount of CO, HC, and offensive odors in the exhaust (Marshall and Seizinger, 1978; Eccleston, Seizinger, and Clingenpeel, 1981). The catalyst formulation and its operating temperature are critical factors in converter performance (Rehnberg, 1981). The converter should be located as close as possible to the exhaust manifold to ensure maximum exhaust gas temperature. The temperatures required for 50% conversion of CO and HC are typically about 370°F (188°C) and 500°F (260°C), respectively. As higher exhaust-gas temperatures are attained, the conversion efficiency increases (McClure, Baumgard, and Watts, 1988).

Because specific catalyst formulations are proprietary, systematic studies of their effects on exhaust constituents cannot be made. However, the effects of current commercial catalytic converters on emissions are well documented. In addition to changing some exhaust pollutants to less toxic forms, properly functioning catalysts also have disadvantages dependent on fuel quality, catalyst formulation, and configuration. The disadvantages are conversion of SO_2 to SO_3 and H_2SO_4, conversion of NO to NO_2, and increasing mutagenicity of DPM. These effects are summarized in Table 11.5.3.

Catalysts are effective in reducing the SOF portion of DPM, but they increase the non-gaseous oxide portion (specifically sulfates). Almost all fuel sulfur emerges as SO_2 in raw exhaust. Upon passing over the catalyst, 5 to 90% of the fuel sulfur is oxidized to sulfate, depending on engine load and speed (Lawson et al., 1979; Hunter et al., 1981). However, a catalytic converter in service is likely to be coated and partially plugged with DPM so that the sulfur conversion to sulfate over a load cycle is probably in the 10 to 40% range (Johnson and Carlson, 1984).

Downstream in the exhaust, further reactions with water vapor form sulfuric acid mist. The lifetime of the acid mist in the mine environment is not known. Measurements in mine air have failed to identify any traces of SO_3 or H_2SO_4. One study reported measurements downstream of an operating vehicle and suggest that the acid mist quickly becomes an ore-related sulfate

(Dainty et al., 1987). Also at high exhaust temperatures, catalytic converters tend to oxidize NO to more toxic NO_2 (Lawson and Vergeer, 1977; Rhenberg, 1981).

Catalytic converters accumulate particulate material to varying degrees. This permits the DPM to be exposed to undiluted exhaust with subsequent nitration of organic compounds that can result in an increase in the concentrations of the biologically active SOF (Hunter et al., 1981). This enhanced mutagenic activity is probably due to nitration of the pyrene in the exhaust (Mogan et al., 1986a). Monolithic-type catalysts have little effect on PAH levels, while pelleted types cause a considerable increase. It has not been determined whether support configuration or catalyst formulation, both, or some other factor produces the increase in biological activity. These results suggest that any underground emission control device that permits the soot to be exposed to undiluted exhaust gas for significant periods of time should be carefully evaluated under actual working conditions before its use is considered (Mogan et al., 1983).

There may be special circumstances where catalytic converters could be beneficially used, for example, engines in good mechanical condition operated under moderate to heavy duty cycles and using fuel with sulfur less than 0.1% by weight. Also converters may reduce the incidence of false alarms where CO-based sensors are used for fire detection. *It might appear to be beneficial to use catalysts on diesel engines that are operated in inadequately ventilated spaces, or that are rebreathing their own exhaust, or on engines that do not receive regular preventive maintenance. However, these conditions violate basic safety principles in the use of diesel-powered equipment and must not be tolerated.*

In mine service, it must be remembered that catalytic devices deteriorate with use. Exhaust backpressure must be monitored and the converter replaced or cleaned at regular intervals to remain effective. Catalytic converters can maintain their performance up to 1000 hr with proper engine maintenance. Overall, current commercial oxidation catalytic converters appear to be counter-productive, but may have application in special circumstances. Developments by manufacturers are in progress to increase the range of applications where benefits outweigh the disadvantages.

DIESEL PARTICULATE FILTERS. It is difficult to trap the DPM contained in the exhaust stream because of its small aerodynamic diameter and tendency to plug filters. A number of filter materials have been tested including ceramic monoliths, wire mesh, ceramic foam, mat-like ceramic fibers, and woven silica fiber coils. To a lesser degree, paper and other fiber materials are under investigation, but the ceramic monolith filter or trap is thus far most promising for underground mining applications. The concept of a disposable trap is also possible, but has not yet been demonstrated for heavy-duty mining equipment. A typical installation of a ceramic monolith diesel particulate filter (DPF) is shown in Fig. 11.5.6.

Fig. 11.5.6. Typical installation of a diesel particulate filter.

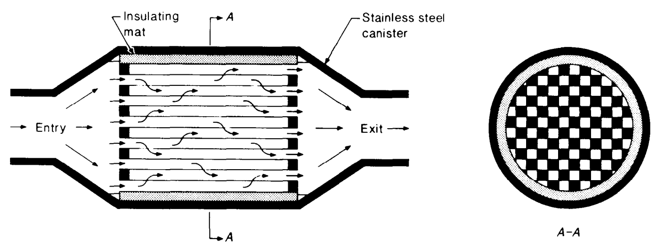

Fig. 11.5.7. Schematic of a ceramic monolith diesel particulate filter.

The ceramic monolith trap consists of a cellular substrate with square cells running the length of the filter, similar to monolithic catalyst supports used in most catalytic converters. On the inlet end, every other cell is plugged with ceramic material, with the adjacent cell plugged on the outlet end. This causes the exhaust to enter one cell, pass through the ceramic wall, and leave by an adjacent cell as shown in Fig. 11.5.7. This trap has a mass collection efficiency of 80 to 95%; however, it is less efficient at removing the SOF. This is because the carbonaceous portion of DPM is collected before the SOF has completely sorbed or condensed onto the surfaces of entrained particles and thus passes through as a gas or vapor (Baumgard and Kittleson, 1985). The SOF sampled downstream of the trap has a higher specific mutagenic activity than upstream samples, although the increased activity is largely offset by a decrease in the mass of SOF emitted (Draper et al., 1987). Only temporary reductions of SO_4 emissions are expected since much of the trapped SO_4 is released during regeneration (self-cleaning by combustion or evaporation of accumulated soot).

The most promising means of disposal of the collected soot is to burn or oxidize it in the trap, thus regenerating the filter. Regeneration depends upon the interaction between the deposited particulate material with oxygen, and varies with the temperature of the exhaust gases. About 5% of the sea level concentration of oxygen and exhaust temperature excursions in excess of 932°F (500°C) are necessary for regeneration. Soot regeneration (ignition) temperature can be lowered to about 750°F (399°C) by coating the substrate with noble metal catalysts and to 830°F (443°C) by coating with base metal catalysts. These catalytic traps also oxidize some exhaust components and are therefore termed trap oxidizers.

Regeneration of particulate traps is difficult to control on a diesel engine for a variety of reasons. One significant factor is that the diesel engine operating cycle can include periods with exhaust temperatures too low to start regeneration. Uncontrolled regeneration can occur when excessive amounts of soot have accumulated in the trap, and it is subsequently exposed to sufficient oxygen and heat to provide intense combustion. The result can damage the ceramic element, and also decrease efficiency. This type of failure is a potential safety hazard. Uncontrolled regeneration has resulted in melting of the ceramic element, CO excursions beyond 5000 ppm for several minutes, and surface temperatures in excess of 600°F (316°C) (Baumgard and Bickel, 1987).

The ability of particulate traps to store DPM over a useful operating period and to safely regenerate is necessary for their success. Methods to regenerate without creating safety hazards are being pursued. The first applications of particulate filters have been on mining machines that consistently generate high exhaust temperatures (those with moderate to heavy duty cycles) and operated at altitudes less than 2000 ft (610 m). Well-engineered systems have been used successfully in nongassy mine service (Dainty and Enga, 1988).

The key to safe operation is limiting the amount of soot in the filter. The amount of soot can be indicated by a pressure sensor mounted upstream of the trap and used to alert the operator to excess exhaust backpressure and the need for remedial action. Applications of traps in gassy mines are constrained by equipment-surface and exhaust-temperature limitations (Anon., 1988). Developments are underway to solve these problems (Waytulonis and Dvorznak, 1987).

11.5.3.3 Exhaust Dispersion Methods and Devices

After diesel exhaust leaves the tailpipe, it is diluted by the surrounding air and carried in the mine ventilation system. The gases CO and CO_2 are relatively stable, but some pollutants can undergo changes that may alter their chemical composition or their toxicological effects. In particular, water vapor and carbonaceous material react with gas-phase NO_2 (e.g., oxidation of NO to NO_2, adsorption of HC onto ambient particles). Conversion of NO to NO_2 can occur, especially in mines with large stopes, slow moving ventilation, and where no respirable dust standard is in force. Immediate dilution of NO from the tailpipe is effective in reducing its conversion to NO_2.

TAILPIPE LOCATION. To reduce exposure to raw exhaust, the exhaust should be dispersed immediately upon exiting the tailpipe. One effective means is to release the exhaust gas into the moving air from the radiator fan. This reduces the danger from local areas becoming contaminated and from the engine rebreathing exhaust. For liquid-cooled engines (with pusher fans), the exhaust flow can be directed into the airstream in front of the radiator, if the operator's position is favorable. See Fig. 11.5.3.

Another dispersion technique useful in headings with adequate roof clearance takes advantage of the lower density of hot exhaust, which tends to rise. Concentrations of exhaust often are higher near the roof, and cooler fresh air tends to enter deadened headings along the lower half of the drift (Janelid, 1976). The natural buoyancy effect can be enhanced by directing the exhaust upward and to the rear at about a 20 to 30° angle to horizontal. Machine operator's exposures to diesel exhaust were reduced up to 30 to 40% in a 150-ft (46-m) drift by this method (Johnson and Carlson, 1984).

FUME DILUTER. Jet-type exhaust dispersion devices entrain surrounding air and direct the diluted exhaust away from the machine operator's position. The exhaust gas is piped into the fume diluter manifold and released through a pre-set annular gap before it passes over an aerofoil surface. The high velocity of the jet creates an area of low pressure that inducts the surrounding air into the throat of the fume diluter. The secondary flow (which is about 10 to 12 times the volume of the primary flow) mixes with the exhaust causing rapid cooling and dilution. A jet of cool diluted exhaust is emitted from the fume diluter outlet at high velocity and mixes with surrounding air. A typical installation of a diesel fume diluter is shown in Fig. 11.5.8, with a schematic in Fig. 11.5.9.

In contrast with thermal convection, fume diluters do not rely on exhaust temperature but will dilute and cool under most engine conditions, low speed or idle being exceptions. Smoke opacity is reduced, and rapid dilution reduces the risk of NO to NO_2 conversion. The fume diluter has no moving parts. Periodic cleaning of the aerofoils and checking gap clearance is important to prevent plugging. The disadvantages of fume diluters are that there is no removal of exhaust pollutants, and they increase backpressure on the engine. Particularly appropriate applications are on diesel machines operated in tunnel development or dead-end headings.

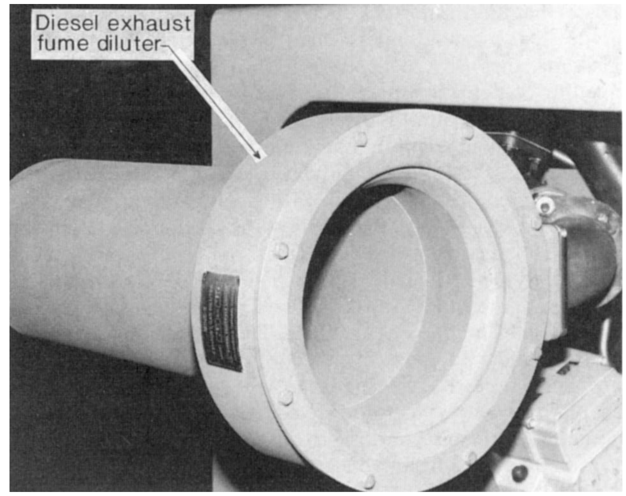

Fig. 11.5.8. Typical installation of diesel exhaust fume diluter.

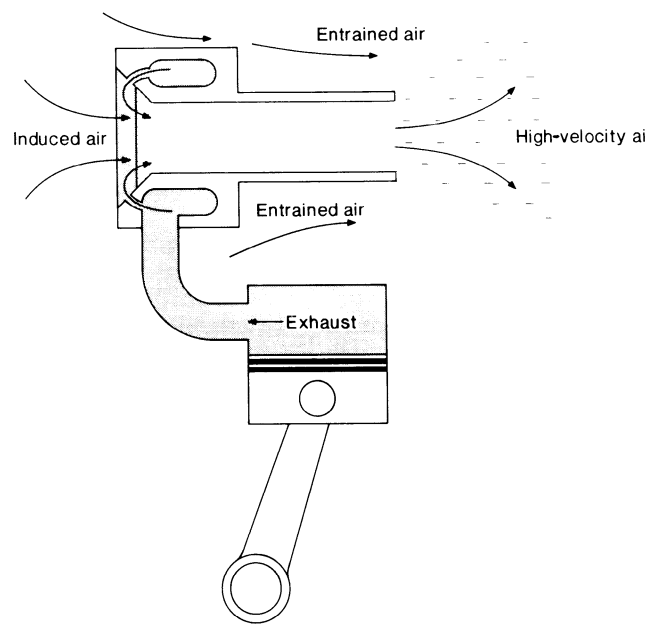

Fig. 11.5.9. Schematic of diesel exhaust fume diluter.

11.5.3.4 Future Exhaust Control Technology

The development of more effective emission controls will be driven by a lowering fuel quality and more stringent air quality standards. With conventional diesel fuels, the formation of particulates is fundamental to the combustion process. Projections indicate that the important fuel properties for emissions will degrade in the future unless there is regulatory intervention. Legislation to control fuel specifications (such as aromatic HCs and sulfur content) is already in effect in some states. Further, if a DPM exposure limit is established, MSHA will likely factor DPM emissions into dilution ventilation requirements.

Currently, the leading candidates for DPM aftertreatment are the trap oxidizer and the flow-through catalytic converter. The trap oxidizer is very effective in trapping the carbon portion of DPM and oxidizing the SOF. Trap material improvements could greatly benefit particulate trap system development. Applications of particulate traps could be increased if a safe, reliable regeneration technique was available. The performance of particulate traps and catalytic converters would improve with the use of low-sulfur diesel fuel. Catalysts, whether they are used on particulate traps or converters, are effective in reducing the SOF, and manufacturers are working to develop catalyst formulations that minimize their negative attributes.

DRY-TYPE EXHAUST CONDITIONING SYSTEMS. An alternative for waterbath exhaust conditioners is a dry-type exhaust conditioning system under development. This design does not require direct contact between the exhaust gas and water. Instead, the exhaust from the engine passes through a heat exchanger. The waste heat from the exhaust is dissipated by either the engine radiator or a separate cooling circuit. This heat load requires about 70% supplemental cooling capacity. A mechanical flame arrester and spark trap are used downstream of the heat exchanger. The dry system has the potential for requiring less maintenance than waterbath conditioners. Although this system does not alter pollutant concentrations, it can be used in tandem with a DPF, such as a trap oxidizer (Waytulonis and Dvorznak, 1987a).

INTEGRATED DPF AND DRY CONDITIONING SYSTEM. This is a combination of a DPF and the dry-type exhaust conditioner into a single, integrated control system for applications where permissible equipment is legislated. The integrated system simultaneously controls fire hazards and reduces DPM. As more efficient diesel exhaust control becomes necessary, integration of various devices into a system will become common.

Chapter 11.6
MINE VENTILATION

RAJA V. RAMANI

11.6.1 INTRODUCTION

Mine ventilation is essentially the application of the principles of fluid dynamics to the flow of air in mine openings. While air is a compressible fluid, airflow in mines is generally treated as steady state, turbulent, and incompressible. Airflow is induced from the atmosphere, through the mine, and back to the atmosphere by creating a differential pressure between the intake and return openings of the mine. This differential pressure is very small, of the order of 2 to 3% in most cases, when compared to the absolute pressure of the system. Therefore, volume and density changes are neglected without serious loss of accuracy or validity. However, in situations where the pressure, temperature, and humidity changes are large and air conditioning processes are involved, calculations must incorporate compressibility considerations. Standard references for mine ventilation include books by Hartman, Mutmansky, and Wang (1982) and Burrows et al. (1982).

The *mine ventilation* system consists of fans, airways (openings to surface and interconnections in the mine between the openings through the working areas), and control devices for air coursing. Quantity control in this system means achieving desired airflows through the optimal selection of openings to surface; the shape, size, and number of airways; location of control devices; and selection and location of fans. The term "optimal" as used here is global and not restricted to ventilation only. Very often, the airflow logistics problem is intertwined with miner and materials transport as well as with many other safety and productivity considerations. The mine airflow distribution is completely defined by (1) the physical parameters of the airways—shape, area, length, and characteristics of the airway surface; (2) the layout of the mine openings; (3) the pressure sources (e.g., fans) in the system, their location and characteristics; and (4) the interconnections between the airways, mine openings, and pressure sources.

This chapter addresses mine ventilation fundamentals while those following (11.7.1 and 11.7.2) are concerned with ventilation applications to metal and coal mining. Mine air conditioning is covered in Chapter 11.4 and computer applications in 11.10.

11.6.2 DENSITY OF MINE AIR

Mine air is a mixture of gases and water vapor. The density or the specific weight of the air is the weight per unit of volume of the air-water vapor mixture. It is a function of the barometric pressure and dry- and wet-bulb temperatures.

An approximate formula (the symbol "a" in the equation number indicates SI units) for calculating density for dry air conditions is (also see Eq. 11.4.3)

$$w = \frac{1.327B}{(460 + t_d)} \tag{11.6.1}$$

$$w = \frac{B}{0.287\ (273 + t_d)} \tag{11.6.1a}$$

where w is density of dry air in lb/ft^3 (kg/m^3), B is barometric pressure in in. mercury (Pa), and t_d is dry-bulb temperature in °F (°C). Table 11.6.1 provides values for w for t_d from 0 to 90°F (– 17.8 to 32.2°C) and B from 22.0 to 31.0 in. mercury (74.29 to 104.68 kPa).

Incorporating a correction for water vapor in the air, the general formula becomes (see Eq. 11.4.4)

$$w = \frac{1.327}{(460 + t_d)} (B - 0.378f) \tag{11.6.2}$$

$$w = \frac{1}{0.287\ (273 + t_d)} (B - 0.378f) \tag{11.6.2a}$$

where f is the vapor pressure at the dew-point temperature in in. mercury (kPa). Dew-point temperatures and vapor pressures can be obtained from Table 11.6.2. A convenient chart for determining air density is shown in Fig. 11.6.1.

Example 11.6.1. What is the air density under the following conditions: wet-bulb 60°F (15.56°C), dry-bulb 70°F (21.11°C), barometric pressure 28.75 in. Hg (97.13 kPa)?

Solution.

(a) Neglecting vapor considerations, the density can be read from Table 11.6.1:

$$w = 0.0740\ \text{lb/ft}^3\ (1.185\ \text{kg/m}^2)$$

(b) Using Eq. 11.6.1,

$$w = \frac{1.327}{460 + 70} (28.75) = 0.0720\ \text{lb/ft}^3\ (1.153\ \text{kg/m}^3)$$

(c) Using Table 11.6.2, determine the following dew-point temperature at 70°F dry-bulb (21.11°C), 60°F (15.56°C) wet-bulb (i.e., 10°F (5.55°C) wet-bulb depression), and the vapor pressure at the temperature.

Dew-point temperature = 53°F (11.66°C)

Vapor pressure at 53°F = 0.402 in. mercury (1.36 kPa)

$$\begin{aligned} w &= \frac{1.327}{460 + 70} (28.75 - 0.402) \\ &= 0.0710\ \text{lb/ft}^3\ (1.137\ \text{kg/m}^3) \end{aligned}$$

Method (c) is most accurate. The accompanying chart (Fig. 11.6.1) can also be used to estimate the densities of air/water vapor mixtures.

The density of dry air at sea level and 70°F (21.11°C) is the reference standard. This standard density value is 0.0750 lb/ft^3 (1.20 kg/m^3). The unit used in mine ventilation for pressure is in. water (Pa or kPa). The relationship between this unit and other units of pressure is

1 in. water (248.84 Pa) = 5.2 lb/ft^2 ≅ 70 ft air pressure at standard density

Table 11.6.1. Approximate Air Densities for Dry Air at Different Temperatures

Barometer, in. mercury	Dry-bulb Temperature 0° F	5° F	10° F	15° F	20° F	25° F	30° F	35° F	40° F	45° F	50° F	55° F	60° F	65° F	70° F	75° F	80° F	85° F	90° F

11.6.3 AIRFLOW FUNDAMENTALS

11.6.3.1 General Equation for Pressure Difference

The relationship of the total pressures (or heads) at two points between which airflow occurs is given by

$$H_{T_1} = H_{T_2} + H_{\ell_{1-2}} \tag{11.6.3}$$

where H_{T_1} and H_{T_2} are the total pressures at points 1 and 2, respectively, and $H_{\ell_{1-2}}$ is the head loss due to flow between 1 and 2.

The total head at a point is the sum of the absolute static head (atmospheric pressure H_{a_1} + the gage static pressure H_{s_1}), the velocity head H_{v_1}, and the elevation head at the point H_{z_1}:

$$H_T = (H_a + H_s) + H_v + H_z \tag{11.6.4}$$

Velocity Head—The velocity head at a point is given by

$$H_v = w\left(\frac{V}{1098}\right)^2 \tag{11.6.5}$$

$$H_v = \frac{wV^2}{2g} \tag{11.6.5a}$$

where H_v is velocity head in in. water (Pa) and V is air velocity in fpm (m/s). In Eq. 11.6.5a, w/g is the mass density in kg/m^3.

Under standard density conditions (w = 0.0750 lb/ft^3), Eq. 11.6.5 reduces to

$$H_v \cong \left(\frac{V}{4000}\right)^2 \tag{11.6.6}$$

Similarly, velocity,

$$V = 4000\sqrt{H_v} \tag{11.6.7}$$

Simplified Gage Pressure Equation—In mine ventilation, calculations are generally performed in gage pressures, in which case, the total head is defined as

$$H_T = H_s + H_v \tag{11.6.8}$$

and the head loss between two points 1 and 2, as

$$\begin{aligned} H_{\ell_{1-2}} &= H_{T_1} - H_{T_2} \\ &= (H_{s_1} - H_{s_2}) + (H_{v_1} - H_{v_2}) \end{aligned} \tag{11.6.9}$$

Air always flows from a point with higher total head to a point with lower total head. Because velocity heads and velocity head differences are very small, only static pressures are used in many mine ventilation calculations. However, where velocities are high and where there are major changes in cross-sectional areas (e.g., shafts, fan drifts, etc.), velocity pressures must be considered as well.

11.6.3.2 Resistance to Airflow

The resistance to the flow of a fluid in a pipe arises from several sources: (1) viscosity of the fluid (internal friction), (2) friction between the fluid and the pipe internal surface, (3) changes in area and direction of flow, and (4) obstructions in the path of flow. The pressure loss incurred in overcoming the resistance from the first two sources is *friction loss* and that in overcoming the last two is *shock loss.* Friction losses account for over 70% of the pressure loss in mine ventilation and is, by far, the most important. Friction loss due to viscosity of the fluid is generally neglected as the airflow in mine airways is virtually always turbulent. Shock losses, which may account for as much as 30% of the pressure losses, must be properly considered in mine ventilation design.

Friction Loss—The most widely used formula for friction pressure loss in a mine airway is the Atkinson formula:

$$H_f = \frac{KLOV^2}{5.2A} \tag{11.6.10}$$

$$H_f = \frac{KLOV^2}{A} \tag{11.6.10a}$$

where H_f is pressure (or head) loss in in. water (Pa), L is length of the airway in ft (m), O is perimeter of the airway in ft (m), A is a cross-sectional area of the airway in ft^2(m^2), and K is friction factor for the airway in lb-min^2/ft^4 (kg/m^3).

Since L, O, A, and K are constant for a given airway,

$$H_f \propto V^2$$

Atkinson's equation for head loss is similar to the Darcy-Weisbach formula for calculating the head loss for fluid flow in pipes and conduits.

Friction Factors—The coefficient K in the Atkinson equation is an empirical factor. Its value is determined by measuring the values for H_f, O, L, A, and V in an established airway:

English units

$$K = \frac{5.2AH_f}{LOV^2} \tag{11.6.11}$$

SI units

$$K = \frac{AH_f}{LOV^2} \tag{11.6.11a}$$

The value for K is a function of the type of flow (laminar or turbulent) in an airway. Therefore, it is a function of Reynold's number and, in turn, of the velocity V. The friction head loss varies with the velocity raised to a power between 1.75 and 2.0. In a mine airway, however, there are many minor variations in area and shape and in the velocity of the air. In view of this fact and that the flow in most cases is turbulent, no major error is committed by using Atkinson's equation for estimating head loss. Where more accurate calculations are needed or where the flow is not turbulent, the influence of Reynold's number on friction factors may be taken into consideration.

US Bureau of Mines Schedule of Friction Factors—McElroy and Richardson (1927) have developed a table of friction factors that can be applied to mine airways in both coal and metal mines (Table 11.6.3). The tabulated values apply to air of standard density. When working with air densities other than standard, the value of K should be corrected as follows:

$$K_{\text{actual}} = K_{\text{table}} \times \frac{w}{0.0750} \tag{11.6.12}$$

$$K_{\text{actual}} = K_{\text{table}} \times \frac{w}{1.201} \tag{11.6.12a}$$

Kharkar, Ramani, and Stefanko (1974) surveyed five coal mines in Pennsylvania, West Virginia, and Virginia and 108 roadway segments to find friction factor values for coal mine airways. The results of their survey are shown in Table 11.6.4.

Whenever possible, the friction factor of an airway should be determined from actual measurements. Such determinations may not be possible where the mine is in the planning stages or where new areas are being opened up. In these cases, it is a good idea to get an approximately correct value for the friction factor from measurements under mine airway conditions that are approximately the same.

Example 11.6.2. Consider a concrete-lined shaft 300 ft (9 1.44 m) deep, 18 ft (5.49 m) in diameter, and moderately obstructed. Calculate the head loss if a quantity of 400,000 cfm (188.78 m^3/s) is flowing in the shaft.

Solution.

$$L = 300 \text{ ft } (91.44 \text{ m})$$

$$O = \pi D = \pi 18 = 56.52 \text{ ft } (17.23 \text{ m})$$

$$A = \frac{\pi D^2}{4} = \frac{\pi\,(18)^2}{4} = 254.34 \text{ ft}^2\ (23.63 \text{ m}^2)$$

Air velocity can be found from this relation

$$V = \frac{Q}{A} \tag{11.6.13}$$

$$= \frac{400{,}000}{254.34} = 1572.70 \text{ fpm } (7.99 \text{ m/s})$$

The maximum value for K (from Table 11.6.3) for a smooth-lined, straight, moderately obstructed airway is 35×10^{-10} lb-min^2/ft^4 (0.0065 kg/m^3). Using Eq. 11.6.10,

$$H_f = \frac{KLOV^2}{5.2A}$$

$$H_f = \frac{35 \times 10^{-10} \times 300 \times 56.52 \times (1572.70)^2}{5.2 \times 254.34}$$

$$= 0.111 \text{ in. water } (27.67 \text{ Pa})$$

Using Eq. 11.6.10a, the head loss due to friction is H_f = 27.67 Pa.

Example 11.6.3. Consider a roadway 2400 ft (731.52 m) long with an area of 90 ft^2 (8.36 m^2) and a perimeter of 40 ft (12.19 m). A head loss of 1.5 in. water (373.26 Pa) is measured when the airflow is 54,000 cfm (25.29 m^3/s). Calculate the friction factor for the roadway.

Solution. Use Eq. 11.6.11, first finding V (Eq. 11.6.13):

$$V = \frac{Q}{A} = \frac{54{,}000}{90} = 600 \text{ fpm } (3.048 \text{ m/s})$$

$$K = \frac{5.2 \times 1.5 \times 90}{2400 \times 40 \times (600)^2 \times 600}$$

$$= 203 \times 10^{-10} \text{ lb-min}^2/\text{ft}^4\ (0.03767 \text{ kg/m}^3)$$

Head Loss Equations—Since $V = \dfrac{Q}{A}$, it is readily seen that

$$\text{H}_f = \frac{KLO(Q/A)^2}{5.2A} = \frac{KLOQ^2}{5.2A^3} \tag{11.6.14}$$

$$H_f = \frac{KLOQ^2}{A^3} \tag{11.6.14a}$$

It is a common practice in ventilation calculations to express the quantity in units of 100,000 cfm (i.e., $Q = Q \times 10^{-5}$), and use for the value of K the whole number given in Tables 11.6.3 and 11.6.4. Using this procedure, the 10^{-10} associated with K is compensated for by the 10^{10} associated with Q^2 :

$$H_f = \frac{[K]\ 10^{-10}\ L\ O\ [Q \times 10^5]^2}{5.2A^3} = \frac{KLOQ^2}{5.2A^3} \tag{11.6.15}$$

where K is the whole-number friction factor termed henceforth the airway friction factor, and Q is quantity flowing in units of 100,000 cfm (47.195 m^3/s).

For a given airway, K, L, O, and A do not vary. As such, the friction loss is proportional to the square of the quantity. Further, the *resistance* of the airway, defined below, is a constant:

Table 11.6.3. US Bureau of Mines Schedule of Friction Factors for Mine Airways

		Values of $K \times 10^{10}$, lb-min^2/ft^4

Source: Kharkar, Ramani, and Stefanko, 1974.

Notes: All values of K are for air weighing 0.0750 lb/ft^3. Values in the table are expressed in whole numbers but must be multiplied by 10^{-10} to obtain the proper K value. Units: lb-min^2/ft^4. Figures underlined are McElroy's min., avg., and mas values of friction factors from Table 11.6.3. Conversion Factors: 1 lb-min^2/ft^4 = 1.855×10^6 kg/m^3, 1 lb/ft^3 = 16.018 kg/m^3.

$$R = \frac{KLO}{5.2A^3} \quad (11.6.16)$$

$$R = \frac{KLO}{A^3} \quad (11.6.16a)$$

where R is resistance of the airway in in.-min^2/ft^6 (N-s^2/m^8). Similarly,

$$H_f = RQ^2 \quad (11.6.17)$$

Example 11.6.4. It is desired to pass 20,000 cfm (9.44 m^3/s) of air through a straight timbered drift measuring $4 \times 5 \times 2000$ ft ($1.22 \times 1.52 \times 609.6$ m). The density of air is 0.0500 lb/ft^3 (0.8000 kg/m^3). Calculate (a) the pressure difference that must be maintained between the ends of the drift, and (b) the resistance of the drift.

Solution .

(a) Find the air velocity by Eq. 11.6.13:

$$V = \frac{20{,}000}{20} = 1000 \text{ fpm } (5.08 \text{ m/s})$$

From Table 11.6.3, the value for K, assuming a clean airway, is 95×10^{-10} lb-min^2/ft^4 (0.0176 kg/m^3). Using Eq. 11.6.10,

$$H_f = \frac{95 \times 10^{-10} \times 2000 \times 18 \times (1000)^2}{5.2 \times 20}$$

= 3.29 in. water at w = 0.075 lb/ft^3 (818.68 Pa at w = 1.20 kg/m^3)

H_f at 0.0500 lb/ft^3 (0.8000 kg/m^3) density $= 3.29 \times \dfrac{0.0500}{0.0750} =$ 2.19 in. water (544.96 Pa)

(b) $H_f = RQ^2$ where Q is in units of 100,000 cfm and therefore 2.19 in. water = $R(0.2)^2$ or

R = 54.75 in.-min^2/ft^6(6.12 N-s^2/m^8) at w = 0.0500 lb/ft^3 (0.8000 kg/m^3)

$R = 54.75 \times \dfrac{0.0750}{0.0500} =$ 82.13 in.-min^2/ft^6 (9.1739 N-s^2/m^8) at w = 0.0750 lb/ft^3 (1.20 kg/m^3)

SHOCK LOSSES. *Shock losses* arise from changes in direction (e.g., bends), changes in cross-sectional areas (e.g., obstructions), or changes in both (e.g., junctions and splits). Shock losses are independent of the roughness of walls and therefore cannot be computed directly as friction losses. However, shock losses bear a constant ratio to the velocity pressure corresponding to the mean velocity of flow. This ratio is absolutely constant for most conditions of area changes and virtually constant for bends (McElroy, 1935). There are three methods for estimating shock losses.

1. *Calculate the shock loss as a function of the velocity head:*

$$H_x = XH_v \quad (11.6.18)$$

where H_x is head loss due to shock, and X is an empirical shock loss factor found by experiment.

2. *Account for shock losses by increasing the value of the friction factor K for that section of the airway where shock losses occur.* The US Bureau of Mines' friction factor table (Table 11.6.3) accounts for obstructions and sinuosity of airways.

3. *Account for shock loss by expressing a shock loss condition as an additional length of a straight airway to be added to the given length of the airway.* This length is known as the equivalent length, L_e. With the equivalent length method, the head loss in an airway H_L is obtained by including in the Atkinson equation the equivalent length:

$$H_L = H_f + H_x = \frac{K(L + L_e)\,O\,V^2}{5.2A} \quad (11.6.19)$$

$$H_L = H_f + H_x = \frac{K(L + L_e)\,OV^2}{A} \quad (11.6.19a)$$

where L_e is equivalent length in ft (m).

This method is recommended for all routine mine ventilation calculations. Hartman and Mutmansky (1982) provide values for equivalent length for various shock conditions based on an airway with $K = 100 \times 10^{-10}$ lb-min^2/ft^4 (0.01855 kg/m^3) and a hydraulic radius (area/perimeter) R_H = 2 ft (0.61 m) (Table 11.6.5). They also recommend the following procedure for its use:

1. Values of L_e from Table 11.6.5 need not be corrected for K or R_H.

Table 11.6.5. Equivalent Lengths for Various Sources of Shock Loss

Shock Loss Condition	Equivalent Length, ft
Bend, acute, round	3
Bend, acute, sharp	150
Bend, right, round	1
Bend, right, sharp	70
Bend, obtuse, round	0.5
Bend, obtuse, sharp	15
Doorway	70
Overcast	65
Entrance	3
Discharge	65
Contraction, gradual	1
Contraction, abrupt	10
Expansion, gradual	1
Expansion, abrupt	20
Splitting, straight branch	30
Splitting, deflected branch (90°)	200
Junction, straight branch	60
Junction, deflected branch (90°)	30
Mine car or skip (20% roadway)	100
Mine car or skip (40% roadway)	500

Source: Hartman and Mutmansky, 1982. Conversion Factor: 1 ft = 0.3048 m.

2. With a change in area (splitting not involved), shock loss is included in the airway section following the change. This also applies to a bend in conjunction with an area change. Separate values are provided for shock losses at entrance and discharge.

3. At splits and junctions in airways, only the portion of the total flow involved in a change of direction or area is used. Values from Table 11.6.5 assume an even division of flow and allow for bend and area change. Include the loss at a split or junction in the pressure drop for the particular branch.

4. Judgment must be exercised in making proper allowance for unusual sources of shock loss such as obstructions.

Values from Table 11.6.5 are sufficiently accurate for all routine work. For more precise calculations, such as would be required for research, the following formulas should be used (McElroy, 1935):

$$L_e = \frac{3240\ R_H X}{10^{10} K} \tag{11.6.20}$$

$$L_e = \frac{w R_H X}{2gK} \tag{11.6.20a}$$

where K is coefficient of friction in lb-min^2/ft^4 (kg/m^3) for a straight section of the airway with the same internal surface characteristics as that of the section for which shock loss is being determined. Values for the shock loss factor X (dimensionless) may be calculated using the methods suggested by McElroy (1935) or Hartman and Mutmansky (1982). Shock loss can be a significant factor in the total losses sustained in an airway. Irrespective of the method used to calculate shock loss, the underlying relationship is that shock loss is proportional to the square of the air velocity and therefore of the air quantity.

11.6.3.3 Power Considerations

The total head loss (H_L) is the sum of both frictional and shock losses in flow from one point to another, as determined

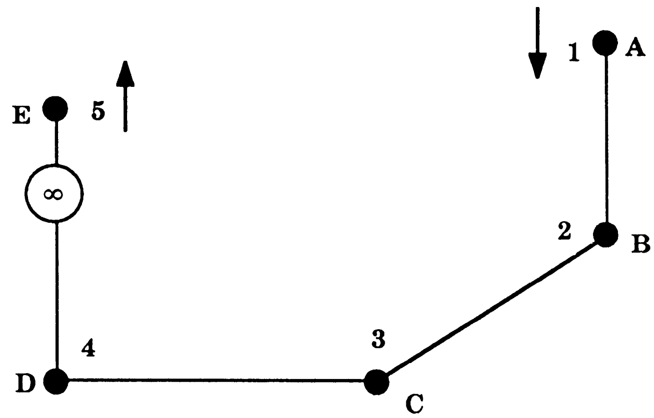

Fig. 11.6.2. Line diagram of the ventilation system (Ex. 11.6.5).

by Eq. 11.6.19. For flow to be continuous in the airway, the head H_L lost by the air must be compensated for by a continuous input of head H_L to the air. In other words, the loss of power due to friction and shock, must be compensated for by input of equivalent power. This power is known as the air horsepower and is given by

$$AHP = \frac{H_L Q}{6350} \tag{11.6.21}$$

$$AHP = \frac{H_L Q}{1000} \tag{11.6.21a}$$

where AHP is air horsepower (kW). Since H_L varies as Q^2, AHP varies as Q^3. The actual power input required to create the flow in the airway will be higher and will be determined by the efficiencies of the pressure generating source and its drive.

Example 11.6.5. Given the following data (see Fig. 11.6.2):

Airway	Width, W ft (m)	Height, H ft (m)	Length, L ft (m)	Friction Factor, k lb-min^2/ft^4 $\times$ 10^{10} (kg/m^3)
AB (shaft)	12 diameter (3.66)		600 (182.88)	25 (0.0046)
BC	20 (6.10)	6 (1.83)	2000 (609.60)	50 (0.0093)
CD	20 (6.10)	6 (1.83)	3000 (914.40)	50 (0.0093)
DE (shaft)	12 diameter (3.66)		600 (182.88)	25 (0.0046)

Calculate the friction and shock losses if the quantity through the fan is 40,000 cfm (18.88 m^2/s).

Solution. To be precise, it is necessary to calculate for each of the airways the value of hydraulic radius R_H and X, the shock loss factor, and then calculate the equivalent length L_e for each shock loss condition. However, values from Table 11.6.5 are acceptable:

Shock Loss Condition	Equivalent Length L_e, ft (m)
1. Entrance	3 (0.9144)
2. Gradual expansion	1 (0.3048)
3. Obtuse bend, sharp	15 (4.5720)
4. Sharp bend, right	70 (21.3360)
5. Discharge (fan)	0 (0.0000)

Using Eq. 11.6.15, and $Q = Q \times 10^{-5} = 40{,}000 \times 10^{-5} = 0.4$ cfm units (18.87 m^3/s) calculate the head loss for each airway:

Airway	L ft	Le ft	A ft^2	O ft	K lb-min^2/ft^6	H_L in. water (Pa)
AB	600	3	113.10	37.7	25	0.0121 (3.011)
BC	2000	1	120	52	50	0.0931 (23.167)
CD	3000	15	120	52	50	0.1396 (34.738)
DE	600	70	113.10	37.7	25	0.0134 (3.335)
					ΣH_L =	0.2582 (64.251)

let resistance of mine = R_m

$$H = R_m Q^2$$

$$(0.258)^2 = R_m (0.4)^2$$

$$R_m = 1.6138 \text{ in.-min}^2/\text{ft}^6 \ (0.1803\ N\text{-}s^2/\text{m}^8)$$

$$AHP = \frac{0.2582 \times 40{,}000}{6350}$$

$$= 1.6265 \text{ hp } (1.21 \text{ kW})$$

11.6.4 CONTROL DEVICES

Two distinct airstreams—intake and return air—are generally recognized in mine ventilation, particularly in coal mines. The fresh airstream or *intake air* is the air from the surface that is conducted directly to the workings and other desired locations to provide fresh air to the miners and to dilute and carry away gases and dust from the workings. After this air has served this purpose, it becomes *return air* to be conducted back to the surface. In general, intake and return airstreams must not be allowed to mix. This is always true for coal mines.

Control devices in mine ventilation serve to (1) separate the intake and return airstreams in adjacent airways (stoppings), (2) allow the crossing of the intake and return streams without mixing (overcasts), and (3) regulate the flow of air through the various airways in the desired manner when the quantity has to be split between the airways (regulators).

11.6.4.1 Stoppings

Stoppings are physical barriers erected between intake and return airways to prevent the air flowing in them from mixing with each other. Stoppings can be temporary or permanent.

Temporary stoppings are often constructed of fire-resistant jute fabric, plastic, rough lumber covered with plastic, or even various types of sheet metal sections. These are extensively used in areas where frequent adjustments to air directions are necessary, such as in the working panels. Where the stoppings are constructed of concrete, gravel, cinder, or slag blocks, the blocks are usually wedged in place with dry joints. This permits fast erection and even allows for the recovery of the blocks.

Permanent stoppings are installed in places where a permanent or a long-term control of flow is needed, such as between the main intakes and returns. They should be substantially built so that they are airtight and, if they are functioning as seals or bulkheads, they must resist the disruptive forces of explosions. For the latter purpose, the stoppings must be built according to specifications of the Coal Mine Health and Safety Act of 1969 as given in Title 30, *Code of Federal Regulations* (Anon., 1988).

Fig. 11.6.3. Well-constructed explosion-proof stopping.

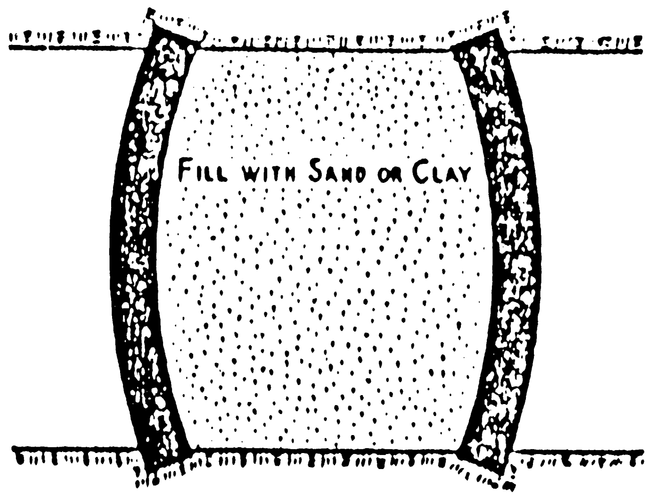

Fig. 11.6.4. Excellent construction for explosion-proof stopping.

Shown in Figs. 11.6.3 and 11.6.4 are two such constructions, the one in Fig. 11.6.4 being able to withstand greater pressures than the stopping in Fig. 11.6.3. The greater the distance between the two masonry walls, the more effective will be the stopping.

Stoppings utilizing such construction are rarely seen in mines. Most permanent stoppings generally consist of 8 by 8 by 16 in. (≅ 200 × 200 × 400 mm) solid or hollow blocks, laid with mortar joints. The entire block sides are then coated with cement or some type of block coating. The stopping is usually keyed into the roof, floor, and sides. It is common practice to provide a fire-resistant stringer or cushion across the top to prevent cracking due to strata pressure. Since stoppings must be accessible for inspection and repair, it is advisable that they be built where the roof and sides are secured. Additionally, gobbing rock against the stopping (Fig. 11.6.5) must be avoided as this makes both inspection and maintenance difficult.

A *door* is simply a hinged or movable partition within a stopping designed to permit the passage of men and equipment. Mine doors may be constructed of metal (required for doors between the intake and return) or of lumber covered with tarpaper, plastic, or other sealant material. They serve the same

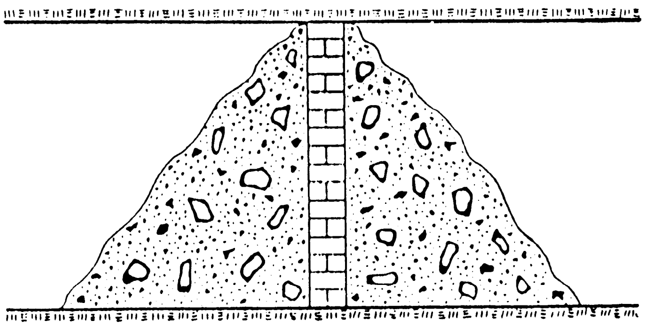

Fig. 11.6.5. Gobbing of rock against stopping.

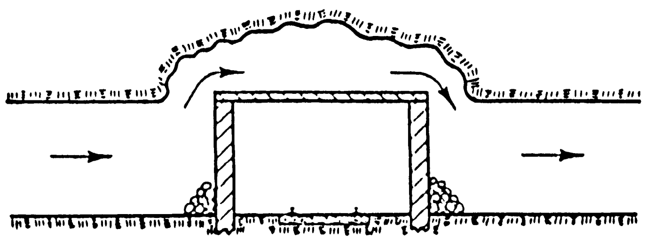

Fig. 11.6.6. Poor construction of overcast.

function as stoppings and are frequently used in haulageways. To avoid short circuiting between the return and intakes, doors should always be arranged in pairs to provide an *airlock*—one door will always be closed while the other is open. Automatic self-opening doors are especially useful along haulageways and equipment travelways. However, doors along the haulageways do not have sills, so that conveyor belting or brattice cloth should be attached to the bottom of the door.

Because the health and safety of underground employees may depend upon the ventilation doors, personnel should be trained in their proper use. They should be marked in bold letters, KEEP CLOSED or KEEP OPEN, so that they serve their ventilation purpose.

11.6.4.2 Overcasts

Overcasts or crossings are air bridges that allow the intake and return airways to cross one another without mixing. Undercasts are less frequently used since these are below the level of the surrounding openings, and water tends to accumulate in them. Shown in Fig. 11.6.6 is a very poorly constructed overcast. Shown in Fig. 11.6.7 is an ideal overcast with long sweeping curves at both the approach and discharge sides. The cross-sectional area of the overcast should be one-half the area of the approaching airway, if the approach is gradually contracted and the discharge is gradually expanded, as shown in Fig. 11.6.7.

The overcast should be properly built with high-quality material. In the area where an overcast is required, the roof is raised to the necessary height. Common practice where continuous miners are used is to ramp up at the spot where the overcast is to be located before returning to bench the coal (Stefanko, 1983). In constructing the overcast, solid blocks set in mortar should be used. The two wing walls must be anchored firmly in the ribs. Steel beams are then placed on the wing-walls over which the roof is built. Two walls are then built from this roof to the heightened roof line. An inexpensive but good-quality overcast,

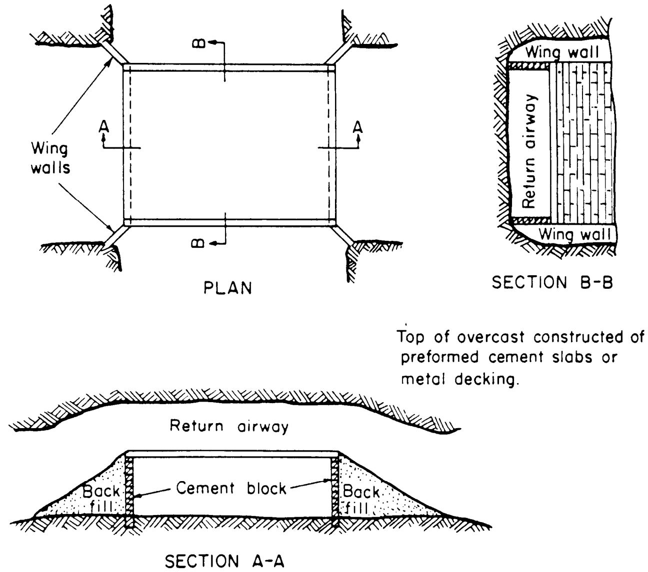

Fig. 11.6.7. Excellent construction for overcast.

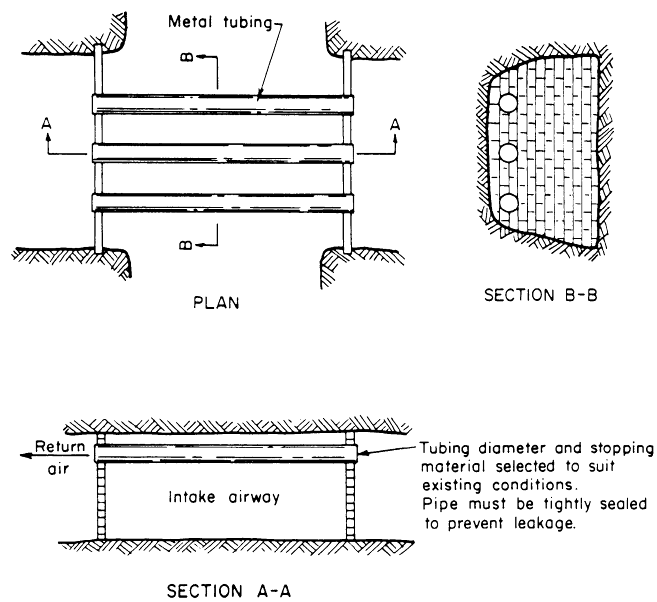

Fig. 11.6.8. Inexpensive but efficient overcast (Rock, Dalzell, and Harris, 1971).

most suitable for temporary use, is illustrated in Fig. 11.6.8. Here a solid (stopping) wall is built on either side of the airway, and a sufficient number of pipes of large diameter are laid on the top of the walls to carry the air across the main airway. It is possible to transport up to 25,000 cfm (11.8 m^3/s) with two 36-in. (914-mm) or three 30-in. (762-mm) pipes. The ends of the pipes should be embedded in the stopping and made air-tight.

11.6.4.3 Regulators

Regulators are used to control and redistribute the quantity of flow in each split of air. The regulator is an opening in a stopping in an airway and may be equipped with an adjustable

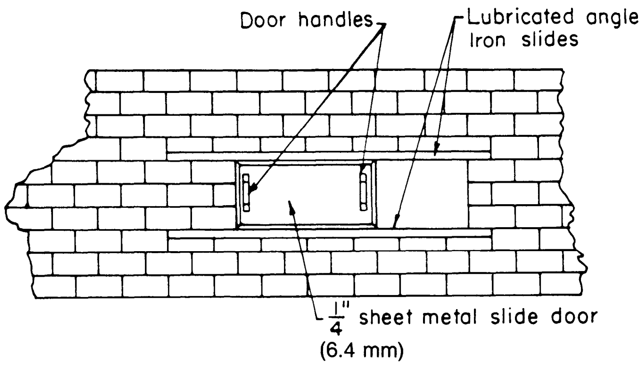

Fig. 11.6.9. Box-type regulator (Rock, Dalzell, and Harris, 1971).

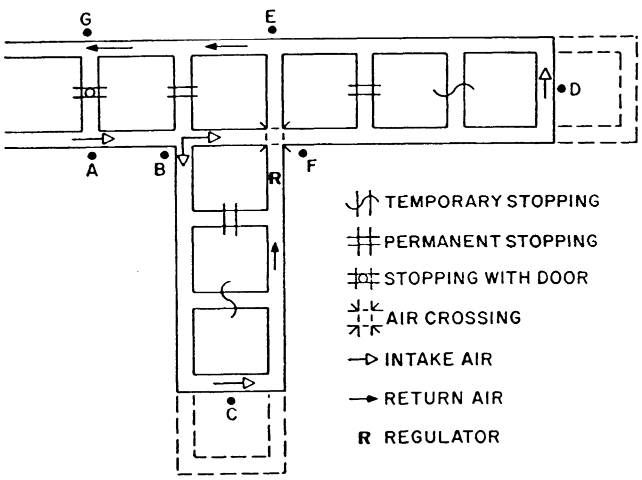

Fig. 11.6.10. Ventilation circuit with leakage sources.

or sliding door (Fig. 11.6.9). These are known as box regulators and are used almost exclusively in coal mines. Regulators should be easily accessible and located in places where roof and rib conditions are good. They should be kept clear of debris and obstructions. The ideal location for regulators in coal mines is in the return near the beginning of a ventilation split so as not to interfere with haulage and materials transport. In this location, it may not have to be moved for the life of the working section and it may be possible to use it even after the section is mined out or idled.

11.6.5 LEAKAGE CONSIDERATIONS

Consider a somewhat oversimplified diagram of a part of a mine ventilation system (Fig. 11.6.10). Fresh air to the workings is split at B. The roles of the stoppings, door, overcast, and regulators are evident. Stoppings are also built in the connecting entries between ABFD and DEG and in the connecting entries between BC and CF. The dotted lines show the mine advance projection; as the mine advances, the temporary stoppings will be replaced by permanent stoppings. The return from the workings at C must cross the intake in ABFD at F; an overcast is built at F to course the return air from C directly to E over the intake air to D. The two splits of air reunite at E. Since access to the return air may be needed, a door is built into the stopping in the connecting airway AG. A regulator R is placed in the return airway CF to regulate the flow into the workings at C. Since air always flows from a point of higher total head to one of lower total head, the head at every point on the intake side is higher than that at the return side. Consider the head across the stopping in the airway AG. On the side of the stopping towards A, the pressure head is higher than it is on the side of the stopping towards G. Because of the stopping, free flow of air from A to G is not possible. In practice, however, some air will flow through the cracks and crevices in the stopping due to the pressure difference. Such *unintended* losses of air directly to the return from the intake are known as *leakage.* Leakages occur, as explained before, through stoppings, overcasts, and doors. Leakages have also been known to occur through crushed pillars and improperly packed gob.

Leakage phenomena are complex, and the amount of leakage that occurs is a function of the pressure differential across the control devices, the construction and condition of the devices, and the area exposed. In the past, on the average, not more than 20% of the air quantity measured at the fans reached the working places. Conditions today are slightly better in that this figure is anywhere from 30 to 50%. Leakage through stoppings, doors, and regulators depends not only upon the pressure across the control device but also on the condition of the device itself. Ground pressures destroy control devices, and fugitive air losses become so great that it is almost impossible to provide adequate air at the face. Generally, leakage is most severe through old stoppings in the outby portion of the circuit. These are also subjected to higher pressure differences than the newer inby stoppings. Therefore, the circuit air quantity diminishes at a decreasing rate as the air progresses from outby to inby in the circuit. Painting and plastering a stopping decreases leakage, on the average, to around 2 or 3% of the leakage through a mortar-laid, unplastered, and unpainted stopping. The exact amount of leakage, however, is determined by how well the plastering and painting is done.

Kharkar, Ramani, and Stefanko (1974) carried out studies to determine leakage across stoppings under several different airflow conditions. Graphs were plotted for cumulative leakage against the number of stoppings (Fig. 11.6.11). The graphs show that the rate of air loss is variable over the length of the airway, the largest values being furthest from the working face with three-quarters of the total loss occurring in the first one-half of the air intake.

In ventilation planning, leakages have been handled by a system of rough allowances since they often cannot be measured accurately. There is very little information on leakage through overcasts, doors, and air locks. Table 11.6.6 lists some recommended figures for use in planning (Roberts, 1960). Where volume measurements can be made on either side of the leakage source, these measurements are not only more reliable than visual inspection, but may also serve as a base for estimating leakages. The leaking air does not help in the ventilation of the workings. Thus leakage is doubly disadvantageous—it does not improve health and safety conditions, and it increases the cost of getting the quantity of air needed into the main split. Leakage should be kept to a practical minimum.

11.6.6 AIRFLOW IN MINES

Two basic circuits or combinations of airways—series or parallel—are used to distribute air through the mine. A *mine ventilation network* is a combination of several series and parallel airways.

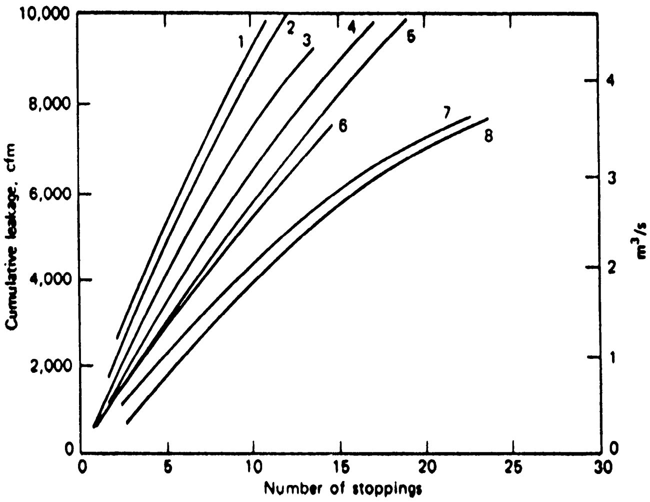

Fig. 11.6.11. Results of study to determine leakage vs. number of stoppings in several coal mines. (1) Mine 4, Section A: H = 1.7; L = 1530. (2) Mine 2, Section B: H = 2.8; L = 1520. (3) Mine 2, Section B: H = 2.3; L = 630. (4) Mine 3, Section A: H = 1.9; L = 1200. (5) Mine 2, Section C: H = .51; L = 1050. (6) Mine 4, Section B: H = .71; L = 990. (7) Mine 1, Section B: H = .78; L = 1360. (8) Mine 1, Section A: H = 1.32; L = 2125. L: Length in ft of roadway considered. H: Pressure drop in in. water across stoppings (*Source:* Kharkar, Ramani and Stefanko, 1974; Hartman, Mutmansky and Wang, 1982).

Table 11.6.6. Leakage Estimate in Coal Mines

1. Leakage across newly formed gobs (longwall faces)

Distance Between Intake and Return, ft	Leakage Across Gob as Percentage of the Air on the Face, %
150	20
300	10
600	5

No allowance made where solid stowing is done.

2. Separation doors: 3000 cfm
3. Overcasts: 3000 cfm
4. Surface Leakage: This is the air that leaks through the casing at the top of the upcast shaft. It is a function of fan head.

Fan Head in. water	Leakage cfm
5	25,000
10	35,000
15	45,000
20	50,000

5. Leakage through stoppings

   a. Explosion proof—None
   b. Temporary stoppings: 100–200 cfm dependent on the age, physical construction, maintenance, and head across the stopping.

Source: Roberts, 1960. Conversions Factors: 1 ft = 0.3048 m, 1 cfm = 0.47195 x 10^{-3} m^3/s, 1 in. water = 248.84 Pa.

11.6.6.1 Series Flow

In *series* combinations, the airways are connected end to end, and the same quantity flows through each of the airways. For a system of N airways in series, the following relationships hold:

$$Q = Q_1 = Q_2 = Q_3 = Q_4 = \cdots = Q_N \tag{11.6.22}$$

$$H_L = H_1 + H_2 + H_3 + H_4 + \cdots + H_N \tag{11.6.23}$$

$$R = R_1 + R_2 + R_3 + \cdots + R_N \tag{11.6.24}$$

where Q_i, H_i, and R_i are quantity, head, and resistance of the ith airway, and Q, H_L, and R are the quantity, head, and resistance of the system, respectively.

11.6.6.2 Parallel Flow

In *parallel* flow, all airways start at the same point and end at the same point. Therefore, the pressure difference between the ends of each airway is the same. For a system of N airways in parallel, the following relationships hold:

$$Q = Q_1 + Q_2 + Q_3 + \cdots + Q_N \tag{11.6.25}$$

$$H_L = H_1 = H_2 = H_3 = \cdots = H_N \tag{11.6.26}$$

$$\frac{1}{\sqrt{R}} = \frac{1}{\sqrt{R_1}} + \frac{1}{\sqrt{R_2}} + \frac{1}{\sqrt{R_3}} + \cdots + \frac{1}{\sqrt{R_N}} \tag{11.6.27}$$

Also the following relationships for quantity distribution in the parallel airways can be developed. This quantity distribution is called *natural splitting:*

$$Q_1 = Q\left(\frac{R}{R_i}\right)^{\frac{1}{2}}$$

or

$$\frac{Q_i}{Q_j} = \left(\frac{R_j}{R_i}\right)^{\frac{1}{2}} \tag{11.6.28}$$

In natural splitting, the highest quantity flows in the lowest resistance split; quantity flow in a split with higher resistance is lower than that in a lower-resistance split.

Example 11.6.6. Given three airways, 1, 2, and 3, in series, Q = 20,000 cfm (9.44 m^3/s), with head losses H_{L_1} = 2 in. water (497.68 Pa), H_{L_2} = 1 in. water (248.84 Pa), and H_{L_3} = 3 in. water (746.52 Pa). Find Q, *H,* and *R.*

Solution.

$$Q = Q_1 = Q_2 = Q_3 = 20{,}000 \text{ cfm } (9.44 \text{ m}^3/\text{s})$$

$$H = H_1 + H_2 + H_3 = 2 + 1 + 3 = 6 \text{ in. water } (1493.04 \text{ Pa})$$

$$R = H/Q^2 = 6/(0.2)^2 = 150 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6 \quad (16.755\ N\text{-}s^2/\text{m}^8)$$

$$\text{[Check: } R_1 = \frac{2}{(0.02)^2} = 50 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6;$$

$$R_2 = \frac{1}{(0.02)^2} = 25 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6;$$

$$R_3 = \frac{3}{(0.2)^2} = 75 \text{ in.-min}^2/\text{ft}^6;$$

$$R = R_1 + R_2 + R_3 = 150 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6\text{]}$$

Example 11.6.7. Given the three airways in the previous example with resistances $R_1 = 50 \times 10^{-10}$ (5.585), $R_2 = 25 \times 10^{-10}$ (2.793), and $R_3 = 75 \times 10^{-10}$ (8.378) in in.-min^2/ft^6 (N-s^2/m^8), arranged in parallel, with the total Q = 100,000 cfm (47.195 m^3/s); find system H and R and the quantities Q_1, Q_2, and Q_3.

Solution.

$$\frac{1}{\sqrt{R}} = \frac{1}{\sqrt{50}} + \frac{1}{\sqrt{25}} + \frac{1}{\sqrt{75}} = 0.141 + 0.200 + 0.116$$

$$= 0.457$$

$$R = 4.79 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6 \ (0.535\ Ns^2/\text{m}^8)$$

$$H = RQ^2 = (4.79)(1.00)^2 = 4.79 \text{ in. water (1.192 kPa)}$$

$$Q_1 = Q\left(\frac{R}{R_1}\right)^{\frac{1}{2}} = 100{,}000\left(\frac{4.79}{50}\right)^{\frac{1}{2}} = 30{,}952 \text{ cfm } (14.61 \text{ m}^3/\text{s})$$

$$Q_2 = 100{,}000\left(\frac{4.79}{25}\right)^{\frac{1}{2}} = 43{,}772 \text{ cfm } (20.66 \text{ m}^3/\text{s})$$

$$Q_3 = 100{,}000\left(\frac{4.79}{75}\right)^{\frac{1}{2}} = 25{,}272 \text{ cfm } (11.93 \text{ m}^3/\text{s})$$

[Check: $Q = Q_1 + Q_2 + Q_3 \cong 100{,}000$ cfm (47.2 m^3/s)]

11.6.6.3 Controlled Splitting

When airways are connected in parallel and the quantity required in each airway is specified, natural splitting generally will not result in the required distribution.

Example 11.6.8. Suppose for the airways in Ex. 11.6.7 that the required air distribution was Q_1 = 25,000 cfm (11.80 m^3/s), Q_2 = 35,000 cfm (16.52 m^3/s), and Q_3 = 40,000 cfm (18.88 m^3/s). Calculate the head loss and determine the amount of regulation in each airway.

Solution.

(1) Head losses in the airways.

$$H_1 = R_1Q_1^2 = 50(0.25)^2 = 3.13 \text{ in. water (778.87 Pa)}$$

$$H_2 = R_2Q_2^2 = 25(0.35)^2 = 3.06 \text{ in. water (761.45 Pa)}$$

$$H_3 = R_3Q_3^2 = 75(0.40)^2 = 12.00 \text{ in. water (2986.08 Pa)}$$

To obtain 75,000 cfm (35.4 m^3/s) in airway 3, 12 in. water (2986.08 Pa) pressure difference between the ends of airway 3 is needed. In *controlled splitting,* the airway with the highest head loss (in this case, airway 3), is known as the *free split.* In the other two airways, since only 3.13 in. (778.87 Pa) and 3.06 in. (761.45 Pa) are needed for the desired flows, when a head of 12 in. water (2986.08 Pa) is developed across airway 3, regulators are needed to restrict the flow to 25,000 (11.80 m^3/s) and 35,000 cfm (16.52 m^3/s), respectively.

(2) Regulator shock loss. The regulators are, in effect, resistances added in series to the airway to increase the head loss from 3.13 in. water (778.87 Pa) to 12.00 in. water (2986.08 Pa) in airway 1, and from 3.06 in. water (761.45 Pa) to 12.00 in. water (2986.08 Pa) in airway 2. The resistances to be added in series must create shock losses that are calculated as follows:

Airway 1: 12.00 – 3.13 = 8.87 in. water (2207.21 Pa)
Airway 2: 12.00 – 3.06 = 8.94 in. water (2224.63 Pa)

Regulators create shock loss conditions under which 8.87 in. water (2207.21 Pa) and 8.94 in. water (224.63 Pa) are dissipated as shock losses in the respective airways.

A number of formulas are available to calculate the size of regulators. A simple but approximate formula, known as the *equivalent orifice* formula, is as follows (Kingery, 1960):

$$A = \frac{0.0004Q}{\sqrt{H_x}} \tag{11.6.29}$$

$$A = \frac{1.2Q}{\sqrt{H_x}} \tag{11.6.29a}$$

where A is the area of the regulator in ft^2 (m^2), Q is quantity in the airway in cfm (m^3/s), and H_x is shock loss to be dissipated in the regulator in in. water (Pa).

Example 11.6.9. Calculate the areas of the regulators for airways 1 and 2 of Ex. 11.6.8.

Solution. The areas A_1 and A_2, respectively, of the regulators in airways 1 and 2 are calculated as follows:

$$A_1 = \frac{0.0004 \times 25{,}000}{\sqrt{8.87}} = 3.36 \text{ ft}^2 \ (0.312 \text{ m}^2)$$

$$A_2 = \frac{0.0004 \times 35{,}000}{\sqrt{8.94}} = 4.68 \text{ ft}^2 \ (0.435 \text{ m}^2)$$

In practice, a box-type regulator is placed in a stopping in the airway and the opening is adjusted until the desired quantity flow is obtained. For example, in airway 1, the regulator may be a 2 by 2 ft (0.186 by 0.186 m) opening, and in airway 2, 2.5 by 2 ft (0.232 by 0.186 m) opening. Based on flow conditions, the regulator size can be adjusted. There are alternative methods of ensuring the required distribution, including decreasing the resistance of airway 3 or by incorporating pressure sources (booster fans) in each airway to generate the required heads.

11.6.6.4 Mine Ventilation Networks

A mine ventilation network is defined as a *simple network* if the series and parallel airways can be combined through the equivalent resistance formulas into one airway with a resistance equal to the network resistance. Otherwise, the network is *complex.* Solutions for the flow and head for large ventilation networks, whether simple or complex, can be obtained through the use of computer programs that apply the mathematical theory of networks and physical laws of mass and energy conservation to solve the head-quantity distribution problem (Chapter 11.10; Wang, 1982; Ramani, 1988).

Example 11.6.10. Consider the ventilation of a mine with three production units (Fig. 11.6.12). AB is the intake shaft and is used as a man-materials shaft. EF is a return shaft used exclusively for ventilation purposes.

Characteristics of AB: $K = 35 \times 10^{-10}$ lb-min^2/ft^4(0.0065 kg/m^3); L = 1500 ft (457.2 m); cross section: rectangular, 16 × 6 ft (4.88 × 1.83 m)

Characteristics of EF: $K = 21 \times 10^{-10}$ lb-min^2/ft^4(0.0039 kg/m^3); L = 1000 ft (304.8 m); cross section: rectangular, 20 × 5 ft (6.1 m × 1.52 m)

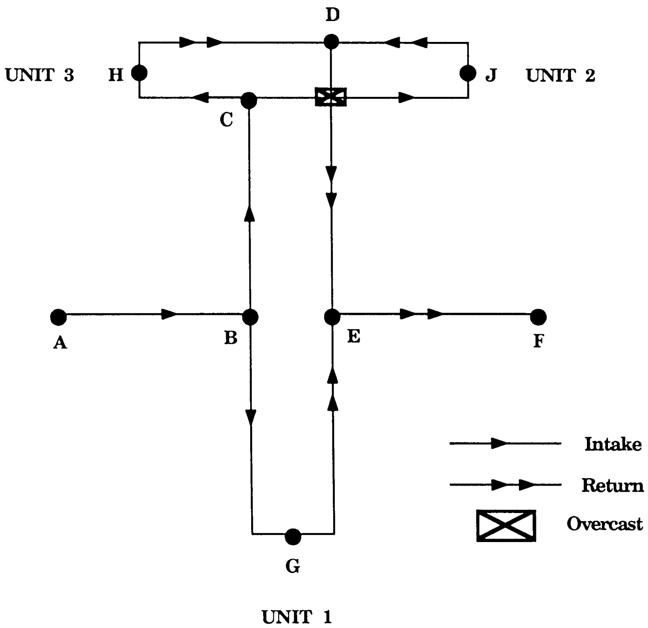

Fig. 11.6.12. Line diagram of mine ventilation system (Ex. 11.6.10).

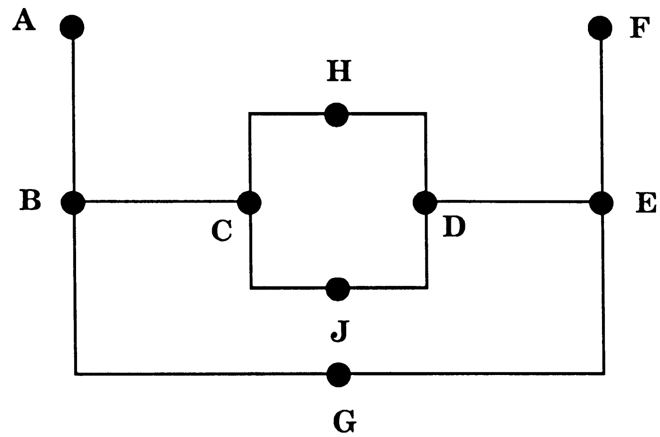

Fig. 11.6.13. Network schematic of mine ventilation system (Ex. 11.6.10).

The resistances in in.-min^2/ft^6 (N-s^2/m^8) of the other airways are as follows:

$$BGE = 2.0 \times 10^{-10}\ (0.2234) \quad CHD = 1.0 \times 10^{-10}\ (0.1117)$$
$$BC = 0.3 \times 10^{-10}\ (0.0335^8) \quad CJD = 2.0 \times 10^{-10}\ (0.2234)$$
$$DE = 0.36 \times 10^{-10}\ (0.0402)$$

Exactly 100,000 cfm (47.195 m^3/s) of air is flowing down the shaft AB.

(a) Calculate the following: the quantity flowing in airways *CHD* and *CJD* and head loss from A to F under natural splitting conditions.

(b) If the quantity required in the airways *CHD* and *CJD* is 40,000 cfm (18.878 m^3/s) each, and the total quantity entering the mine is 100,000 cfm (47.195 m^3/s) as before, calculate the head loss from A to F and the air horsepower. Also identify the free split and the required regulation airways.

Solution. First, draw a network schematic of the ventilation system (Fig. 11.6.13), and then calculate the resistances and proceed with reducing the network to a single airway.

$$R_{AB} = \frac{KLO}{5.2A^3} = \frac{35 \times 1500 \times 2(16 + 6)}{5.2 \times (96)^3}$$
$$= 0.5 \text{ in.-min}^2/\text{ft}^6\ (0.0559\ N\text{-}s^2/\text{m}^8)$$
$$R_{EF} = \frac{21 \times 1000 \times 2(20 + 5)}{5.2 \times (100)^3}$$
$$= 0.25 \text{ in.-min}^2/\text{ft}^6\ (0.0279\ N\text{-}s^2/\text{m}^8)$$
$$\frac{1}{\sqrt{R_{CD}}} = \frac{1}{\sqrt{R_{CHD}}} + \frac{1}{\sqrt{R_{CJD}}} = \frac{1}{\sqrt{1}} + \frac{1}{\sqrt{2}} = 1.71$$
$$R_{CD} = 0.34 \text{ in.-min}^2/\text{ft}^6\ (0.038\ N/s^2/\text{m}^8)$$
$$R_{BCDE} = R_{BC} + R_{CD} + R_{DE} = 0.3 + 0.34 + 0.36$$
$$= 1.0 \text{ in.-min}^2/\text{ft}^6\ (0.1117\ N\text{-}s^2/\text{m}^8)$$
$$\frac{1}{\sqrt{R_{BE}}} = \frac{1}{\sqrt{\mathrm{R}_{BCDE}}} + \frac{1}{\sqrt{R_{BGE}}} = \frac{1}{\sqrt{1}} + \frac{1}{\sqrt{2}} = 1.71$$
$$R_{BE} = 0.34 \text{ in.-min}^2/\text{ft}^6\ (0.038\ N\text{-}s^2/\text{m}^8)$$
$$R = R_M = R_{AB} + R_{BE} + R_{EF} = 0.5 + 0.34 + 0.25$$
$$= 1.09 \text{ in.-min}^2/\text{ft}^6\ (0.1218\ N\text{-}s^2/\text{m}^8)$$
$$H_S = R_M Q^2 = 1.09(1.0)^2 = 1.09 \text{ in. water (271.24 Pa)}$$
$$Q_{BCDE} = Q\left(\frac{R_{BE}}{R_{BCDE}}\right)^{\frac{1}{2}} = 100{,}000\left(\frac{0.34}{1.00}\right)^{\frac{1}{2}}$$
$$= 58{,}310 \text{ cfm } (27.52 \text{ m}^3/\text{s})$$
$$Q_{BGE} = \left(\frac{R_{BE}}{R_{BGE}}\right)^{\frac{1}{2}} = 100{,}000\left(\frac{0.34}{2.0}\right)^{\frac{1}{2}}$$
$$= 41{,}230 \text{ cfm } (19.46 \text{ m}^3/\text{s})$$

Check: total $Q \cong 100{,}000$ cfm (47.2 m^3/s)

$$Q_{CHD} = Q_{BCDE}\left(\frac{R_{CD}}{R_{CHD}}\right)^{\frac{1}{2}} = 58{,}310\left(\frac{0.34}{1.0}\right)^{\frac{1}{2}}$$
$$= 34{,}000 \text{ cfm } (16.05 \text{ m}^3/\text{s})$$
$$Q_{CJD} = Q_{BCDE}\left(\frac{R_{CD}}{R_{CJD}}\right)^{\frac{1}{2}} = 58{,}310\left(\frac{0.34}{2.0}\right)^{\frac{1}{2}}$$
$$= 24{,}042 \text{ cfm } (11.35 \text{ m}^3/\text{s})$$

Check: $Q_{BCDE} = 34{,}000 + 24{,}042 \cong 58{,}310$ (27.52 m^3/s)

The air distribution is summarized in Fig. 11.6.14.

CONTROLLED SPLITTING. In the network of the mine, first the quantities of flow in the various airways are calculated on the basis of the given data and the requirement that the quantity entering a junction must leave the junction (also known as Kirchhoff's first law). Secondly, the head loss for each airway is calculated using the airway resistance and the quantity flowing in it. The network is shown with the quantity and head loss in each airway (Fig. 11.6.15). The regulators required in branches that constitute parallel paths between two junctions is calculated

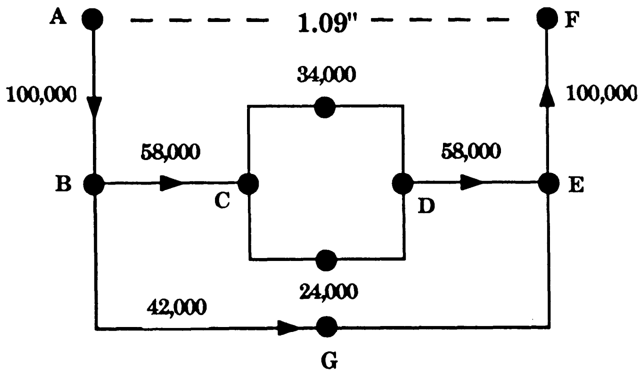

Fig. 11.6.14. Summary of air distribution under natural splitting conditions (Ex. 11.6.10). Conversion factors: 1 cfm = 0.47195 × 10^{-3} m^3/s, 1 in. water = 248.84 Pa.

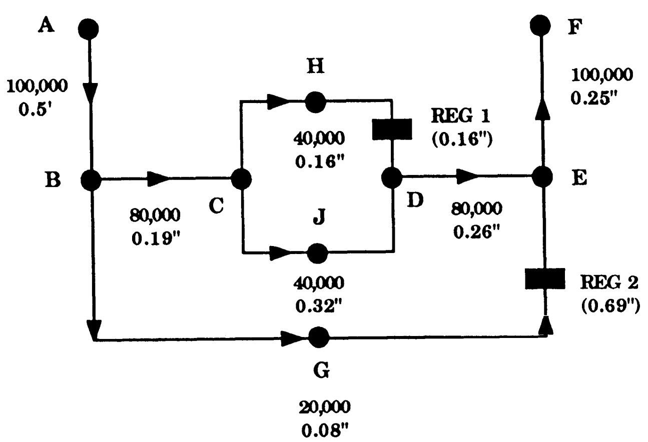

Fig. 11.6.15. Controlled splitting flow conditions (Ex. 11.6.10). Conversion factors: 1 cfm = 0.47195 × 10^{-3} m^3/s, 1 in. water = 248.84 Pa.

applying the requirement that the head loss across parallel splits must be the same (also known as Kirchhoff's second law). The splits are balanced starting from the innermost parallel splits and working to outer parallel splits.

Note that *CHD* and *CJD* are parallel airways and *CJD* is the airway with the higher pressure drop. *CHD* is therefore regulated (shown as REG1). Also *BCDE* and *BGE* are parallel airways. The pressure drop across *BCDE* is 0.19 + 0.32 + 0.26 = 0.77 in. water (191.61 Pa), whereas across *BGE* it is only 0.08 in. water (19.91 Pa). Therefore, *BGE* is regulated (shown as REG2) to lose (0.77 – 0.08) = 0.69 in. water (171.70 Pa). The only unregulated split from A to F consists of the airways AB, BC, CJD, DE, and EF. This is the free split, and the head loss in the mine is the sum of the head losses in the airways constituting the free split, which is 1.52 in. water (378.24 Pa). Finally,

$$AHP = \frac{HQ}{6350} = \frac{(1.52)(100{,}000)}{6350} \cong 23.94 \text{ hp } (17.85 \text{ kW})$$

11.6.7 MINE HEADS

By definition, three mine pressure heads are recognized: the static head H_{S_M}, the velocity head H_{V_D}, and the total head H_{T_M}. The *static head* is the sum of the friction and shock losses in the free split of the mine. The *velocity head* of the mine is the head due to the velocity of the air at the discharge of a mine. The *total head* is the sum of the static and velocity heads of the mine:

$$H_{S_M} = \sum_{i=1}^{N} (H_f + H_x)_i \tag{11.6.30}$$

$$H_{V_M} = w\left(\frac{V_D}{1098}\right)^2 \tag{11.6.31}$$

$$H_{V_M} = \frac{wV_D{}^2}{2g} \tag{11.6.31a}$$

$$H_{T_M} = H_{S_M} + H_{V_M} \tag{11.6.32}$$

where N is number of sections (or airways) in the free split, $(H_f + H_x)_i$ is friction and shock loss in section (or airway) i in in. water (Pa), and V_D is velocity at the discharge of the mine in fpm (m/s).

Example 11.6.11. In Ex. 11.6.10, consider that the return shaft is open to the atmosphere. Calculate the mine heads.

Solution. The velocity of the air at discharge

$$V_D = \frac{\text{Quantity discharged (cfm)}}{\text{Area at discharge (ft}^2\text{)}} = \frac{100{,}000}{100}$$
$$= 1000 \text{ fpm } (5.08 \text{ m/s})$$

Assuming standard air density,

$$H_V = w\left(\frac{V_D}{1098}\right)^2 = 0.0750\left(\frac{1000}{1098}\right)^2$$
$$= 0.0620 \text{ in. water } (15.43 \text{ Pa})$$

The static head of the mine (H_{S_M}) for the controlled splitting case has already been calculated as 1.520 in. water (378.24 Pa). Hence, the total mine head,

$$H_{T_M} = H_{S_M} + H_{V_M} = 1.520 + 0.062$$
$$= 1.582 \text{ in. water } (393.66 \text{ Pa})$$

11.6.7.1 Mine Characteristic Curves

The plotting of the mine head (static, total, or both) vs. the quantity results in curves called *mine characteristic curves.* Given

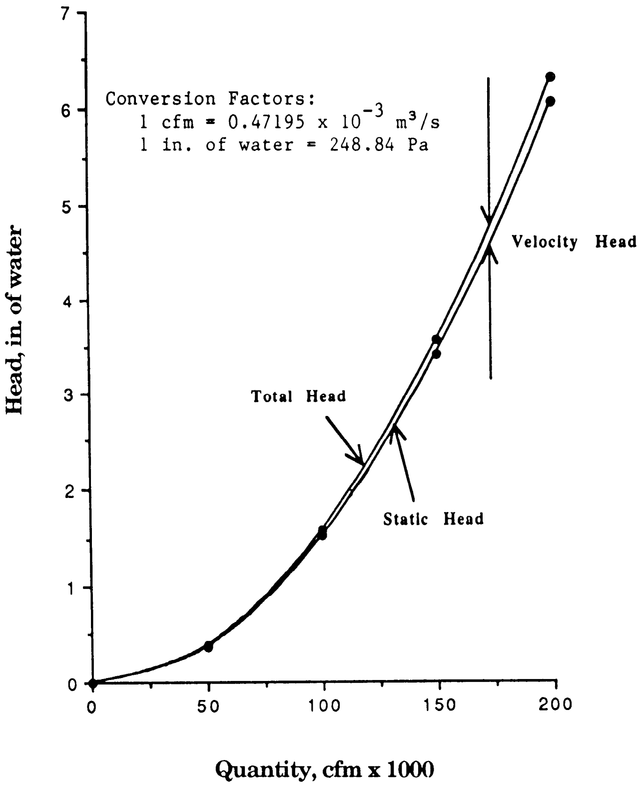

Fig. 11.6.16. Mine static and total head characteristics (Ex. 11.6.11).

one point on the characteristic (say, H_1, Q_1), the points on the characteristic can be calculated for any other quantity (say, Q_2) by repeated application of the head loss formula, $H = RQ^2$:

$$H_1 = RQ_1^2$$

$$H_2 = RQ_2^2$$

$$\frac{H_1}{H_2} = \left(\frac{Q_1}{Q_2}\right)^2$$

$$H_2 = H_1\left(\frac{Q_2}{Q_1}\right)^2 \tag{11.6.33}$$

Consider Ex. 11.6.11. The static and total heads for 100,000 cfm (47.12 m^3/s) are 1.52 (378.24 Pa) and 1.58 in. water (393.66 Pa). The mine characteristic curves for this mine can be calculated as follows:

Quantity, cfm (m^3/s)	Static Head, in. water (Pa)	Total Head, in. water (Pa)
0	0	0
50,000 (23.600)	0.38 (94.56)	0.40 (99.54)
100,000 (47.195)	1.52 (378.24)	1.58 (393.67)
150,000 (70.793)	3.42 (859.03)	3.56 (885.87)
200,000 (94.390)	6.08 (1512.95)	6.33 (1575.16)

Mine characteristics are useful to visualize the solutions to ventilation problems (Fig. 11.6.16) and to facilitate the selection of fans for mine ventilation systems.

11.6.8 MINE FANS

Fans provide the energy required to overcome the resistance to flow. They are mechanical devices which convert mechanical energy to fluid energy. By increasing the pressure of the air flowing through it, a fan creates a pressure difference in the system that causes the air to flow and the flowing air to overcome the pressure losses in the system. There are two main kinds of fans: *centrifugal* and *axial* flow. While centrifugal fans are still used in some mines and in other countries, the majority of modern mine fans in the United States are axial flow fans. Airflow established by fans is termed *mechanical ventilation.*

Measures of fan performance include the range of head and quantity delivered, power requirements, efficiency, noise characteristics, ease of changing operating points, etc. While most important among these is the head-quantity relationship, efficiency and noise characteristics are gaining importance from the economic and environmental points of view (Wang, 1982). Fan characteristics can be developed from the fundamentals using the theories of fluid dynamics. However, the practical or the actual characteristics—the useful output of fans—cannot be developed from theory. Instead, the actual head-quantity performance of a fan is developed empirically from fan test data of similar fans through the application of fan laws.

As with mine heads, three kinds of fan heads are defined. The *total head* H_{T_F} of a fan is the difference between the total head at fan outlet and the total head at the fan inlet. The *velocity head* H_{V_F} of the fan is the head due to the velocity at the discharge of the fan (fan outlet). The *static head* H_{S_F} of the fan is the difference between the fan total head and fan velocity head.

Mathematically,

$$H_{T_F} = \text{fan outlet total head} - \text{fan inlet total head} \tag{11.6.34}$$

$$H_{V_F} = \text{velocity head at the fan outlet} \tag{11.6.35}$$

$$H_{S_F} = H_{T_F} - H_{V_F} \tag{11.6.36}$$

Fan efficiency can be defined in several ways. The *static* η_s and *total efficiency* η_t of the fan are based on the static P_{as} and total power output P_{at} of the fan, respectively, and the power input to the fan P_F. P_{as} and P_{at} can be calculated using Eqs. 11.6.2 or 11.6.21a. P_F is measured during a fan test.

$$\eta_s = P_{as}/P_F \tag{11.6.37}$$

$$\eta_t = P_{at}/P_F \tag{11.6.38}$$

The *overall efficiency* η_o is the ratio of the total power output of the fan to the power input P_I supplied to the motor driving the fan:

$$\eta_o = (P_{at}/P_I) \tag{11.6.39}$$

The graphical method is the most useful way of presenting the performance curves of a fan. These curves are provided by the manufacturers and are for standard density conditions. The design type, diameter, and speed of the fan for which the characteristics are valid are specified. It is customary to plot the quantity as the independent variable with head (usually static), power, and efficiency as the dependent variables (Fig. 11.6.17). In most

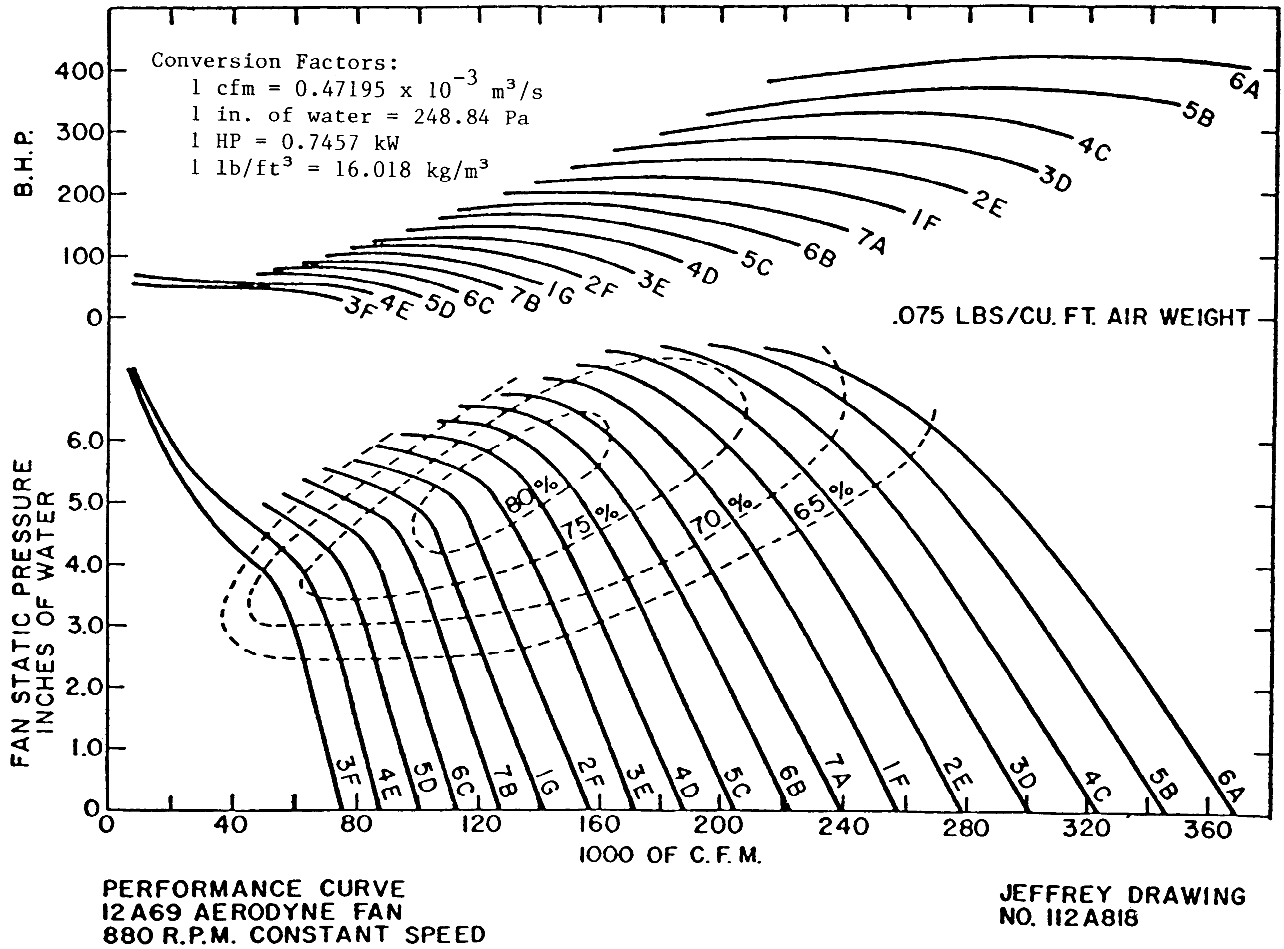

Fig. 11.6.17. Axial flow fan characteristics for various blade settings (*courtesy:* Jeffrey Mining Machine Division, Dresser Industries, Inc., Cumberland, OH).

mine ventilation calculations, the static head characteristics of the fans are used. As long as the fan velocity head is small or the difference between fan and mine velocity heads is small, this is acceptable. However, for precise calculations, total head characteristics should be used.

11.6.8.1 Fan Laws

Generalized. Fan rotational speed n, fan size (diameter) D, and air density w affect the performance of a fan. For geometrically similar fans and for a particular point of operation on the head quantity characteristic, the following relationships are valid:

$$\text{Quantity, } Q \propto nD^3 \tag{11.6.40}$$

$$\text{Head, } H \propto n^2D^2w \tag{11.6.41}$$

$$\text{Power, } P_m \propto n^3D^5w \tag{11.6.42}$$

The *fan laws* are derived from the above equations and are useful to predict the performance of the fans under new conditions of speed, size, and density.

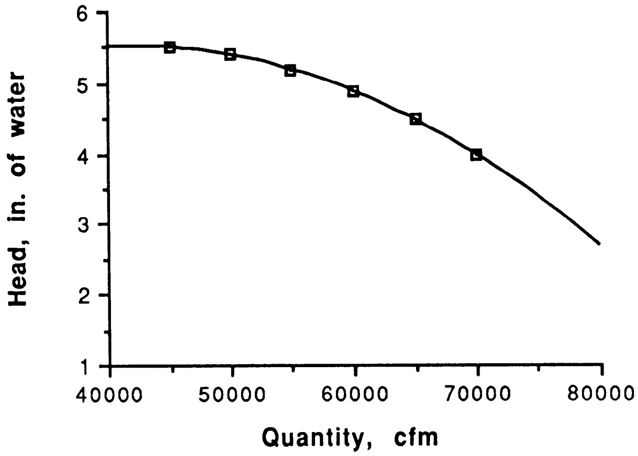
Fan Performance Variable	Law 1 Speed (n) changes w, D constant	Law 2 Size (D) changes w, nD constant	Law 3 Density (w) changes nD constant
Quantity, Q	directly	as square	no change
Head, H_{S_F}, H_{T_F}	as square	no change	directly
Power, P_a, P_F	as cube	as square	directly
Efficiency, η	no change	no change	no change

With axial flow fans, changes in the performance characteristics are obtained by varying the pitch of the blades over a limited range.

Example 11.6.12. The head-quantity characteristic of a 48-in. (1.22-m) fan operating at 1200 rpm and density of 0.0750 lb/ft^3 (1.2000 kg/m^3) is given below and in Fig. 11.6.18:

Point	1	2	3	4	5	6
H (in. water)	5.5	5.4	5.2	4.9	4.5	4.0
(kPa)	1.369	1.344	1.294	1.219	1.120	0.995
Q (cfm)	45,000	50,000	55,000	60,000	65,000	70,000
(m^3/s)	21.24	23.60	25.96	28.32	30.68	33.04

Calculate and plot the new head-quantity characteristic for each of the following conditions:



Conversion Factors:
1 cfm = 0.47195 x 10^{-3} m^3/s
1 in. of water = 248.84 Pa

Fig. 11.6.18. Head-quantity characteristic for fan (Ex. 11.6.12).

a. Speed is reduced to 800 rpm; *w* and *D* constant.

b. Diameter is increased to 60 in. (1.524 m); *nD* and *w* constant. What will be the new speed of the fan?

c. Density decreases to 0.0700 lb/ft^3 (1.12 kg/m^3); *nD* constant.

d. Speed, diameter and density are changed to 800, 60 in. (1.524 m) and 0.0700 lb/ft^3 (1.12 kg/m^3) simultaneously.

Solution. Using the subscript *O* for given conditions and *N* for new conditions, the following relationships are established.

a. *Speed change:* $Q_N = Q_O\left(\frac{N_N}{N_O}\right)$; $H_N = H_O\left(\frac{N_N}{N_O}\right)^2$

$$\frac{N_N}{N_O} = \frac{800}{1200} = 0.67; \left(\frac{N_N}{N_O}\right)^2 = 0.44$$

New Points	1	2	3	4	5	6
H_N (in. water)	2.42	2.38	2.29	2.16	1.98	1.76
(kPa)	0.602	0.592	0.570	0.537	0.493	0.438
Q_N (cfm)	30,150	33,500	36,850	40,200	43,550	46,900
(m^3/s)	14.23	15.81	17.39	18.97	20.55	22.13

b. *Diameter change:* $Q_N = Q_O\left(\frac{D_N}{D_O}\right)^2$, $H_N = H_O$

Constant tip speed: $D_N \times N_N = D_O \times N_O$

$$N_N = \frac{D_O \times N_O}{D_N}$$

$$\frac{D_N}{D_O} = \frac{60}{48} = 1.25; \left(\frac{D_N}{D_O}\right)^2 = 1.56; N_N = \frac{48 \times 1200}{60}$$
$$= 960 \text{ rpm}$$

The original characteristic and characteristics for the four cases are shown in Fig. 11.6.19.

Specialized.

In addition to the conventional fan characteristic curves, fan manufacturers provide special characteristic curves to aid in the initial selection of fans. In these curves, the performances of an entire series of fans is summarized using special parameters. For example, two such parameters are *specific speed* n_s and *specific volume* Q_s, defined as

$$n_s = \frac{Dn}{\sqrt{H}} \qquad (11.6.43)$$

$$Q_s = \frac{Q}{D^2\sqrt{H}} \qquad (11.6.44)$$

For constant density conditions, *H* and *Q* are the head and quantity developed by a fan with diameter *D* and rotational speed *n*. In Fig. 11.6.20 and Fig. 11.6.21 are shown typical specific volume-specific speed curves from two fan manufacturers.

11.6.8.2 Simplified Fan Selection Charts

Over the life of the mine, the demands for head and quantity will vary. When the mine is fully developed and all the units are in full operation, the demand for head and quantity may stabilize somewhat with only small variations due to mine extensions and

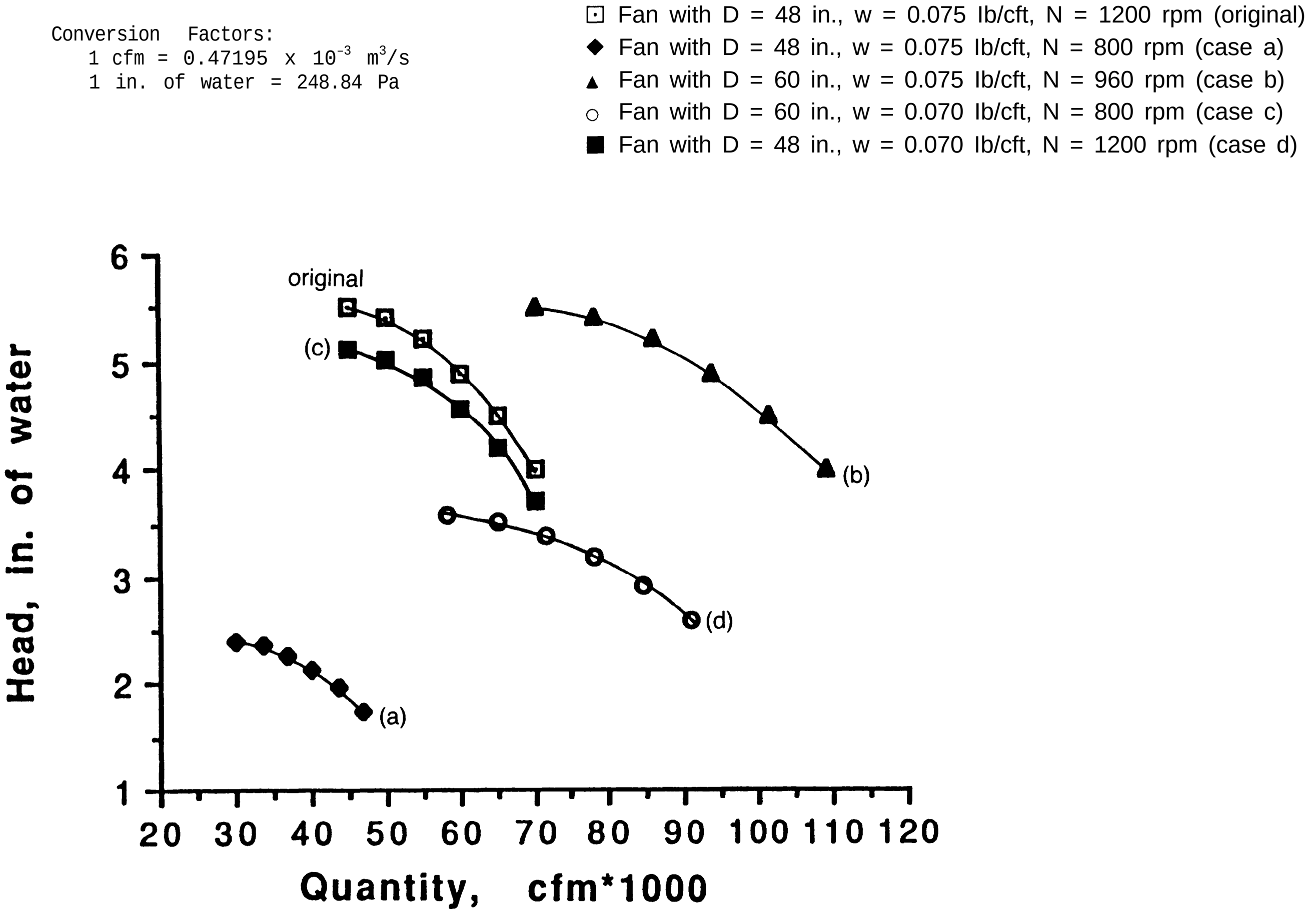

Fig. 11.6.19. Head-quantity characteristics for changing conditions (Ex. 11.6.12).

opening and closing of units. As the workings move away from the main fan shafts, as happens typically in coal mines, the duty on the fan may dramatically increase due to new operating sections or decrease due to addition of new shafts and fans. Fan selection procedure must consider these varying duties so that a fan with a range of heads and quantities at high efficiencies is selected. Further, multiple fans at different locations influence each other's performance and require careful selection to act with each other rather than act against each other. Some manufacturers provide simplified fan selection charts to aid in the selection of fans for given or anticipated mine conditions. These charts are useful for the initial selection of fans and for initial selection of fan curves for computer program inputs. Two such charts are shown in Figs. 11.6.22 and 11.6.23.

11.6.8.3 Fan Rating

An infinite number of combinations of pressure and volume can be obtained for a fan. *Fan rating,* on the other hand, is a statement of fan performance at one point of operation. Specifically, it is the head, quantity, power, and efficiency to be expected (fan diameter, speed, and air density remaining constant) when a fan is operating at peak mechanical efficiency. Manufacturers may provide a rating table with a fan that shows the complete range of capacities such as pressures, speeds, quantities, and horsepowers for a particular fan.

Since the static head developed by a fan cannot be mathematically calculated, the static head-quantity curve for a fan must be developed by running fan tests. A complete fan test provides the data for plotting its total and static head-quantity curves, and mechanical efficiency and horsepower curves (Mancha, 1940, 1942).

To test a fan, it must be operated at constant speed under varying conditions of resistance. Mancha (1940) described the procedures used by Jeffrey to rate their mine fans at the time that axial flow fans (as opposed to centrifugal fans) were coming into wide use in the United States. Most of the Jeffrey fans in use today were designed and their curves generated some 30 years ago, using a 48-in. (1.22-m) fan of each type. Characteristics for other sizes of fans were then developed through the application of fan laws. If at all possible, test arrangements and conditions, as well as all the curves developed, including total head-quantity characteristics, should be available to the ventilation engineer.

11.6.8.4 Fan and Mine Characteristics

When fan and mine characteristics are plotted on the same graph, they intersect, and their point of intersection is known as the *operating point.* Simply stated, when a fan is introduced into a mine circuit, the air quantity flowing through the mine and the head generated by the fan are completely determined by the fan and mine characteristics.

Consider the mine characteristic (B) shown in Fig. 11.6.24, and the fan characteristic (C) superimposed on it. These two characteristics intersect at the operating point (O). A fan whose

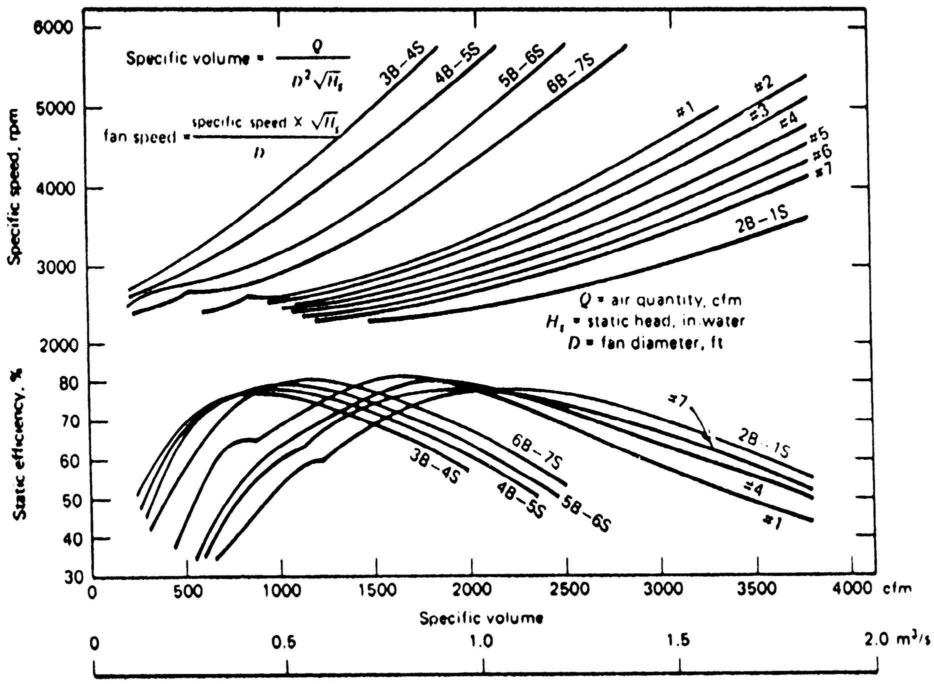

Fig. 11.6.20. Typical specific-volume vs. specific-speed plot for type 8H axial flow fans (*courtesy:* Jeffrey Mining Machine Division, Dresser Industries, Inc., Columbus, OH; Hartman, Mutmansky, and Wang, 1982).

head-quantity characteristic is defined by curve A will force through a mine for which the head-quantity characteristic is defined by curve B: 100,000 cfm (47.2 m^2/s) at 5 in. water (1.244 kPa). It should be noted that the true operating point is the point of intersection of the total head characteristics of the fan and the mine. The intersection of the two static head curves gives the operating point only if the mine and fan velocity heads are the same or if their difference is very small.

To avoid low efficiencies and/or unstable performance, the intersection of the mine and fan characteristics curves should lie along the upper part of the fan characteristic to the right of the fan stall point where unstable operation can occur, especially with axial flow fans. If the measured operating point of a fan does not fall on the fan characteristic curve supplied by the manufacturer, and the fan performance is stable, the fan is operating on the descending, low-efficiency portion of the curve. The importance of correctly matching the fan and mine characteristics is illustrated with an example in Fig. 11.6.25 (Rock, Dalzell, and Harris, 1971). Here, the head-quantity and power curves for an axial flow fan are shown for two blade positions. The dashed line indicates the portion of the curve that was not supplied by the manufacturer but was extrapolated.

The fan is presently operating in a mine in the No. 6 blade position supplying 40,000 cfm (18.88 m^3/s) of air at a pressure of 7.8 in. water (1.941 kPa) corrected to 0.0750 lb/ft^3 (1.2000 kg/m^3) density. The power consumed is 136 bhp (101.42 kW). To evaluate fan performance, the operating point and the mine characteristic are drawn on the same graph to the same scale. Since it is known that when H = 7.8 in. water (1.941 kPa), Q = 40,000 cfm (18.88 m^3/s) and $H = RQ^2$, the specific relationship between H and Q for this mine is

$$H = 48.8Q^2$$

Values for H are calculated for assumed values of Q (Table 11.6.7) leading to the mine characteristic shown in Fig. 11.6.25.

The operating point in blade position 6 is to the left of the stall point on the unstable and inefficient portion of the fan characteristic. On the other hand, if the fan were operated in blade position 12, the operating point would be to the right of the stall point in the high-efficiency portion of the curve. In fact, the power consumed is only 64 bhp (47.72 kW), and the fan will generate 39,000 cfm (18.41 m^3/s) at 7.4 in. water (1.841 kPa). This example clearly points out the need to match the fan and mine characteristic for efficient and economic operation.

11.6.8.5 Fan Applications

There are three distinct applications of fans in mine ventilation: main fans, booster fans, and auxiliary fans (Turcic and Banfield, 1982). *Main fans,* as the name implies, are the principal fans used to produce the general ventilation air current in mines. They are normally permanent in nature and large in capacity. According to the 1969 Federal Coal Mine Health and Safety Act, main fans must be located on the surface. *Booster fans* are usually installed to ventilate parts of the mine where the main fans may, by themselves, be inadequate. Booster fans are used extensively in metal mines but presently are not allowed in US coal mines. *Auxiliary fans* are usually of small size, portable, and temporarily installed to ventilate working places through which the general ventilating air may not otherwise pass (dead-end openings). It is a common practice to conduct the air from the auxiliary fan to the working place by a ventilation tube or duct.

MAIN FAN INSTALLATION. Main fans in coal mines must be placed on the surface. The primary advantages of locating a fan on the surface are

1. Accessibility—the fan is accessible in the event of underground disasters such as fires and flooding.

2. Safety—the fan is unlikely to be damaged in the event of underground disasters such as explosions and it is not subjected to ground movement or roof falls.

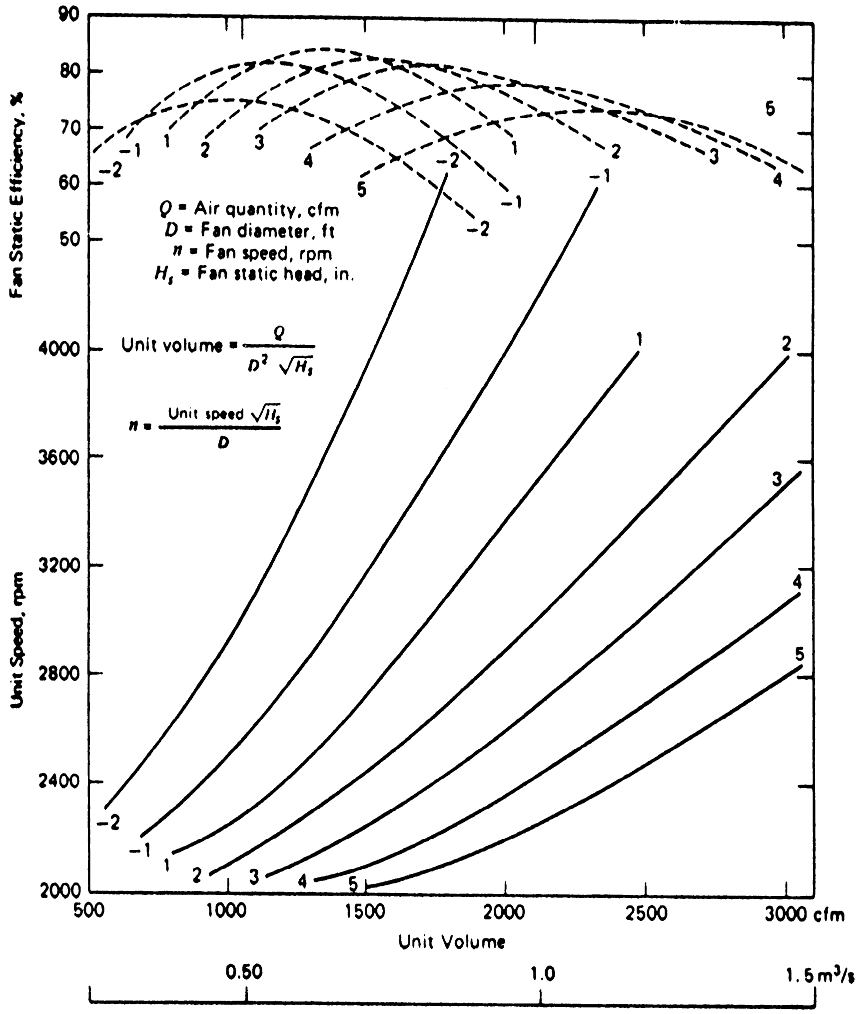

Fig. 11.6.21. Typical unit-volume, unit-speed plot for axial flow fans (by permission: Joy Technologies, Inc., Joy/Green Fan Division, New Philadelphia, OH; Hartman, Mutmansky, and Wang, 1982).

3. Ease of installation—installation of a fan underground requires that the workings be advanced; also the size of the fan to be used underground is constrained by space limitations, and a complicated network of airways is necessary to channel the air into the fan drift.

When installed on the surface, there can be a considerable leakage of air from the outlet side of the fan to the inlet side of the fan unless care is taken. As much as 20% of the air quantity handled by the fan may be air leakage through the surface air lock, fan housing, etc., in which case, only 80% circulates through the mine.

The placing of main fans underground is more common in metal mines. In underground metal mines, it is common to have separate fans for different underground levels (Chapter 11.7.1). In coal mines, when the workings are too far from the fan for efficient circulation, it is common practice to sink additional shafts and install additional surface fans (Chapter 11.7.2).

EXHAUSTING vs. FORCING FANS. Depending on the location of the fan in the mine circuit, the fan static and total pressures generated by it relative to the atmosphere can be positive or negative or both. When the fan is placed at the top of the intake shaft, it is known as a *forcing (blowing) fan.* Pressures in the mine are above atmospheric. When it is placed on the top of the return shaft, it is known as an *exhausting fan.* Pressures in the mine are below atmospheric. When it is placed in an underground location, it is known as a *booster fan.* In the booster location the mine pressure is negative from the intake shaft to the fan and is positive from the fan to the exhaust shaft.

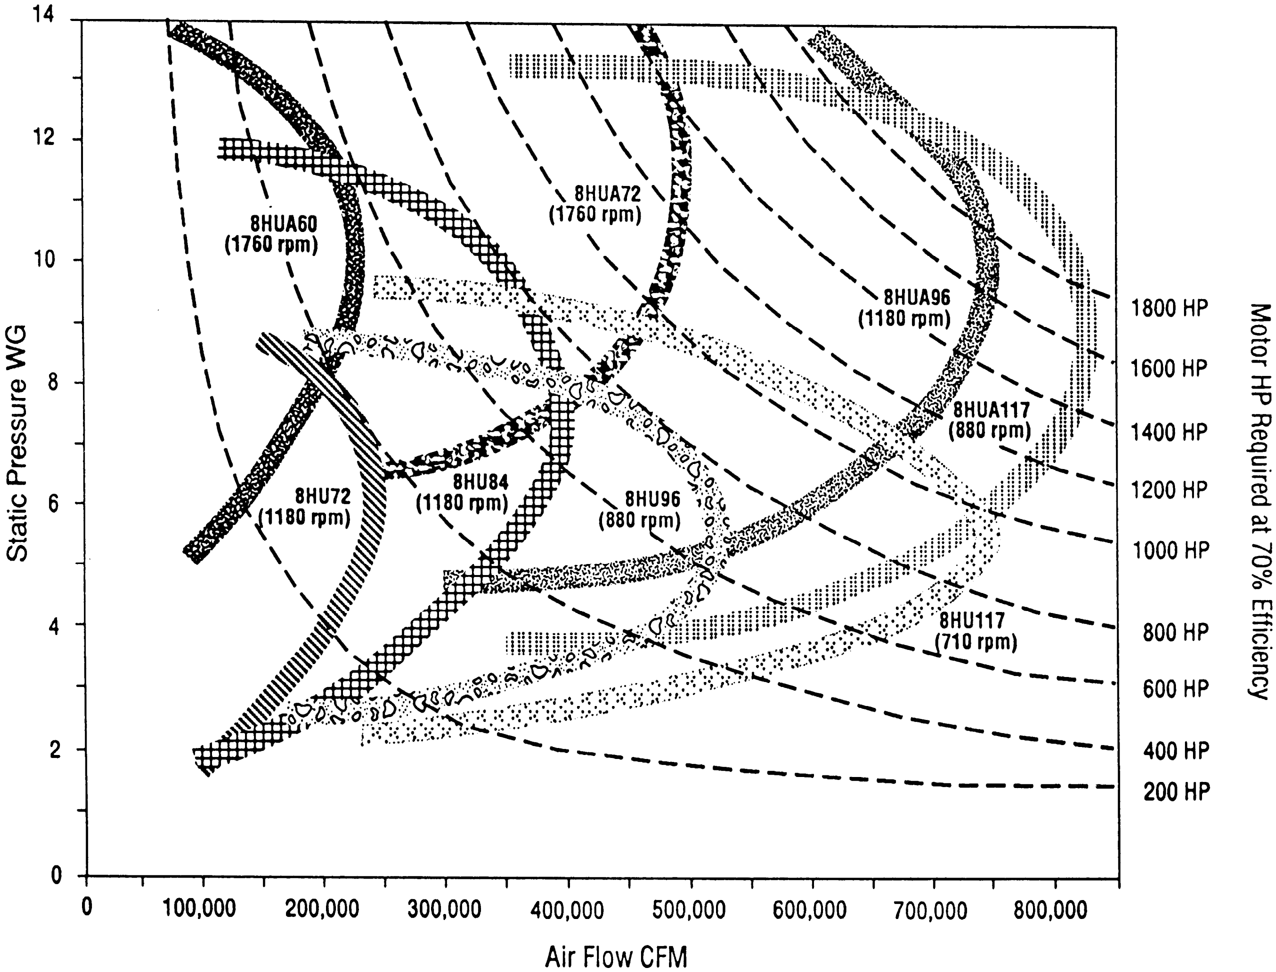
REVERSAL OF AIR CURRENT. In the event of a stoppage of the primary fan or one fan in a multi-fan system, the 1969 Coal Mine Health and Safety Act requires that provisions be taken to prevent adverse reversals of air currents. In some countries, it is required by law to provide arrangements for the reversal of air current if such a need arises. With centrifugal fans, reversal of the air current requires a complicated arrangement of doors and ducts. With axial flow fans, reversing the direction of the rotor movement ensure that air will flow in the opposite direction, though the air quantity is reduced by 50 to 60%.

11.6.8.6 Pressure Gradients for Fan Systems

Important points to remember in plotting the *pressure gradients,* the relationships of system pressures to system profile, for mine/fan systems are

1. The total pressure (H_s + H_v) is always zero at the entrance (atmospheric) to a system.

```
Conversion Factors:
  1 cfm = 0.47195 x 10^-3 m^3/s
  1 in. of water = 248.84 Pa
  1 HP = 0.7457 kw
```



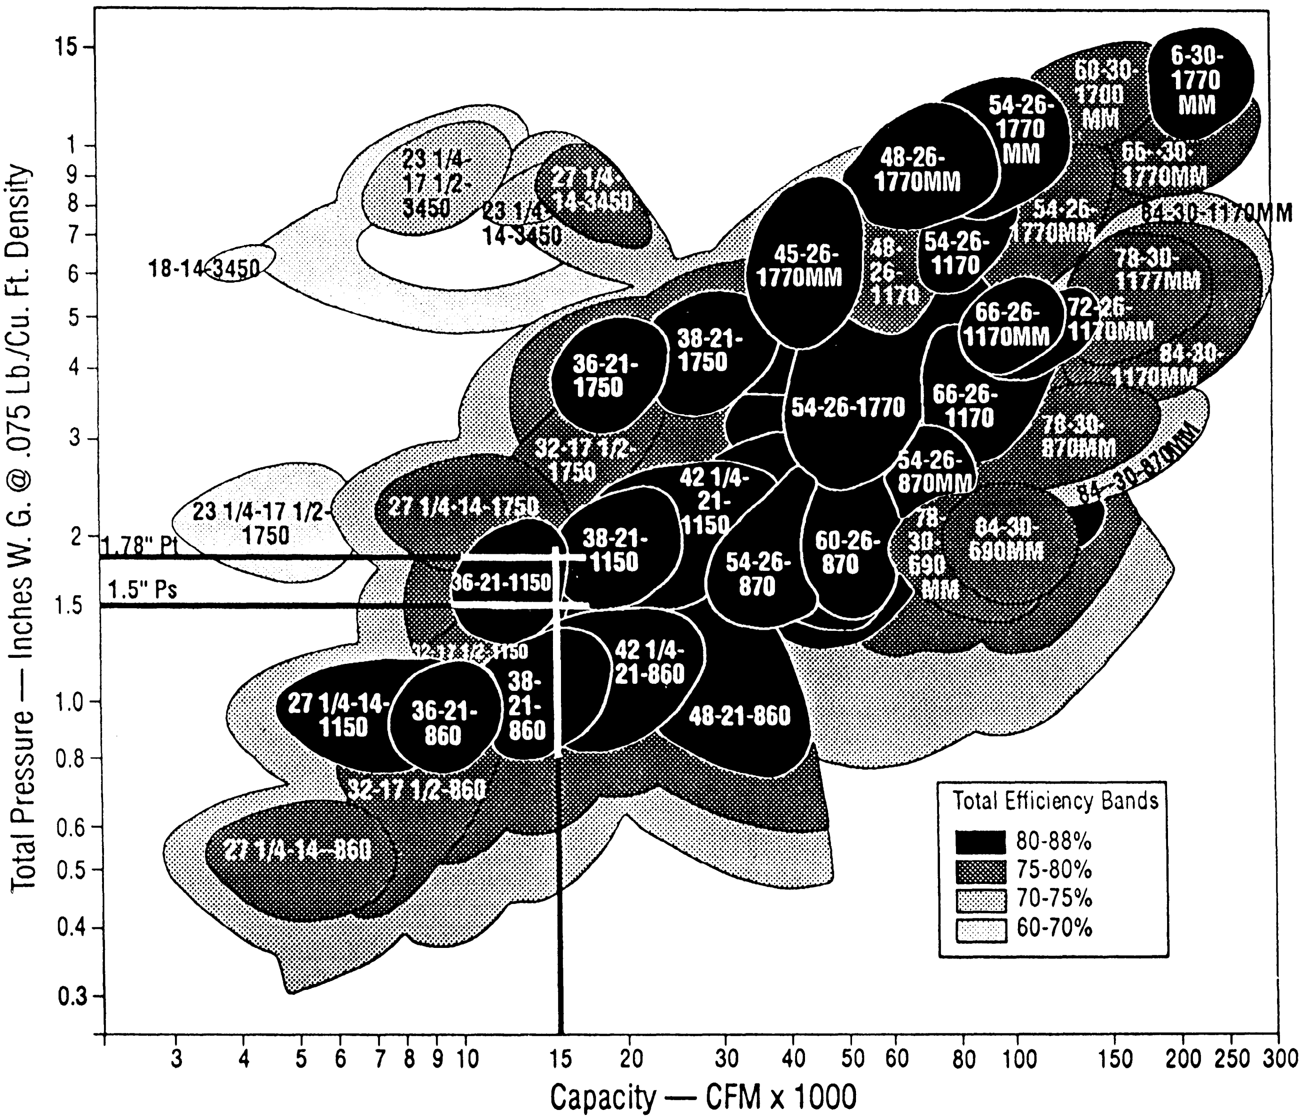
The curves show the approximate operating range of the Jeffrey eight-bladed fans. The area of maximum efficiency (over 80%) occurs at about 1/2 the maximum flow shown on the curves and over approximately the middle two thirds of the pressure range shown at the volume level. The horsepower lines correspond to a fan efficiency of approximately 70%.

Fig. 11.6.22. Jeffrey fan selection chart (by permission: Jeffrey Mining Machine Division, Dresser Industries, Inc., Columbus, OH).

2. The total pressure (H_s + H_v) is always positive and is equal to the velocity pressure at discharge to the atmosphere.

Since H_t = H_s + H_v at any point in the system and, by definition, at entrance, H_t = 0, then H_s at entrance must equal ($-H_v$). Similarly, H_t = H_v, at discharge, and H_s = 0. In effect, the static head is always zero at discharge, and is always negative and equals the velocity head at the entrance to the system. In drawing pressure gradients, a useful procedure is to start plotting the total pressure gradient from the point(s) away from the fan and work towards the fan. After plotting the total pressure gradient, mark off the velocity heads in straight sections of the airway, and draw the static pressure gradients parallel to the total gradient.

Forcing Systems. In the forcing system, the fan inlet is open to the atmosphere and the fan outlet to the mine intake shaft. The top of the intake shaft is equipped with an airlock. The air increases in velocity and static head as it flows through the fan. After flowing through the mine workings, it eventually returns to the surface through the return shaft. The absolute pressure measured at any point in the mine is higher than that of the atmosphere. The pressure gradient for a simple layout is shown in Fig. 11.6.26. The difference between the total pressure and static pressure gradients is the velocity pressure. Note that where there is an increase in area, there is an increase in static pressure at the expense of velocity pressure; but where the area decreases, there is drop in static pressure and velocity pressure



Conversion Factors:

1 cfm = 0.47195 x 10^{-3} m^3/s

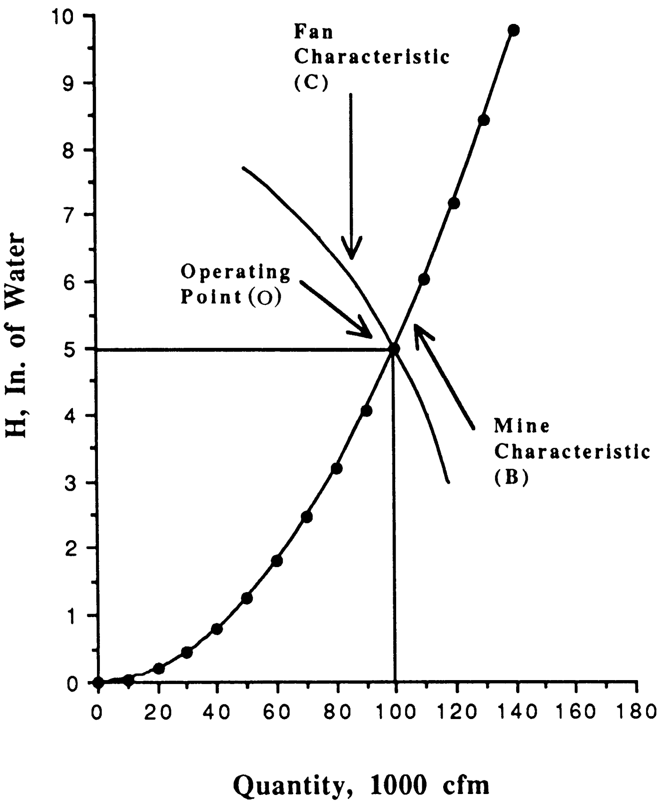
1 in. of water = 248.84 Pa

Fig. 11.6.23. Joy optimum efficiency fan selection chart (by permission: Joy Technologies, Inc., Joy/Green Fan Division, New Philadelphia, OH).

increases. In forcing systems, there is no shock loss at the entrance to the system as the fan absorbs this loss. The total pressure curve is above the static pressure curve and also above the atmospheric datum at all points except at the entrance.

Exhausting Systems. In an exhausting system, the fan inlet is open to the mine through the return shaft, and the fan outlet is open to the atmosphere, usually through an *evase,* a gradually expanding exhaust duct that recovers velocity head. The top of the return shaft has a weakwall or an airlock. When the fan is started, the air on the inlet side is drawn into it, increases in velocity and static heads, and flows through the evase into the atmosphere. The absolute pressure on the inlet side of the fan is lower than that of the atmosphere. Also there is reduced shock loss at the discharge of the system.

On theoretical grounds, there is very little difference between blowing and exhausting systems. Forcing fans handle clean air from the atmosphere that is denser than the hot return air. In a blowing system, gases are held back in the gobs. While this is an advantage when the fan is operating, if the fan is stopped due to any reason, the workings may be flooded by gases from the gob. On practical grounds, exhausting fans are preferred for coal mine ventilation. It is best not to locate the fan at the top of a shaft that is frequently used for personnel and material transport. This way, the surface airlock to the fan need not be disturbed at any time. Also the main access and exit to the mine must be through the fresh intake side. More importantly, the workers can escape through the intake escapeway. To protect the main fan on the surface from the force of an explosion, it should be offset from



Conversion factors: 1 cfm = 0.47195 × 10^{-3}/s, 1 in. of water = 248.84 Pa.

the nearest side of the mine opening with explosion doors (or a weak wall) installed in the direct line of the possible explosion force (Fig. 11.6.27). The fan must be equipped with a pressure-recording gage and an automatic signal device (audio and/or visual) to give an alarm should it slow down or stop. In the event of a fan stoppage, electrical power is disconnected from the mine and personnel are evacuated.

BOOSTER SYSTEM. The pressure gradient for a booster system is a combination of the gradients of the exhausting and forcing systems. The pressure gradient on the inlet side of the fan is similar to that of the exhausting system. After fan discharge, the pressure gradient is similar to that of the forcing system. The total pressure curve, as before, is always above the static pressure curve. However, the total and static pressures on the discharge side of the fan are greater than those on the inlet side. Because of this, unless the two sides of the fan are well separated, leakage can be severe, and air can recirculate from the outlet side of the fan to the inlet side or to the workings. Also there are shock losses at both entrance and discharge of the system.

Example 11.6.13. Draw the pressure gradients (total and static) and label all the relevant heads on the figure for the mine-fan system shown in Fig. 11.6.28 for (a) a forcing fan, (b) an exhausting fan, and (c) a booster fan located at the middle of section A.

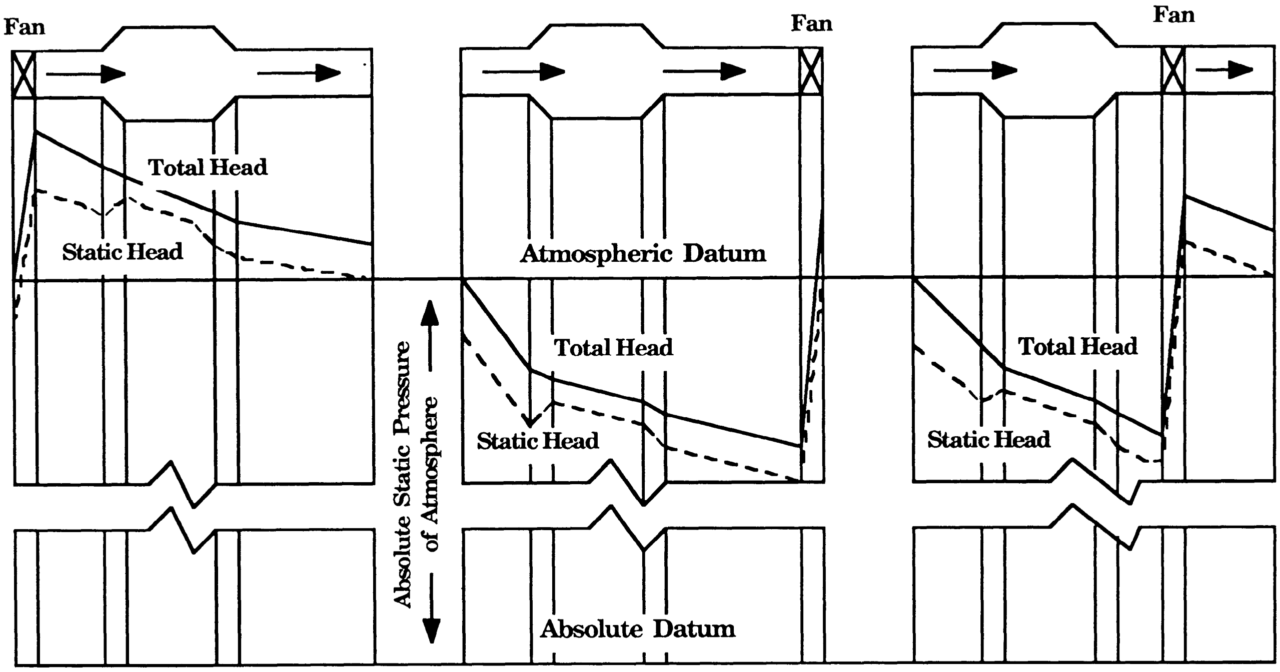

Fig. 11.6.26. Pressure gradients for fan-mine systems (McElroy, 1935).

Solution. Following the procedures outlined earlier, the pressure gradients are drawn for the three positions of the fan in the mine. See Figs. 11.6.28(a), (b), (c) for the forcing, exhausting, and booster fan locations.

FAN EVASE. In practice, all the theoretical head developed by a fan is not converted to static head. For example, in the radial-bladed fan, only half of the theoretical head is actually available as static head to generate the flow of air through the fan. The other half is in the form of kinetic energy in the air leaving the periphery of the fan. If this energy is to be recovered as static head, then the velocity of the air must be decreased. It is for this purpose that the fan is placed in a casing, and the air is then allowed to flow into a duct (Fig. 11.6.29) whose cross section is gradually increased from the fan outlet (DD) to the point of discharge. This duct is known as an evase. The gain in static head due to the evase can be mathematically stated as

$$H_g = \frac{w}{5.2}\left(\frac{V_1^2}{2g} - \frac{V_2^2}{2g}\right)\left(\frac{1}{3600}\right) \qquad (11.6.45)$$

$$H_g = \frac{w}{2g}(V_1^2 - V_2^2) \qquad (11.6.45a)$$

where H_g is static head gain due to evase in in. water (Pa), V_1 is velocity at the small end of the evase $= \frac{Q}{A_1}$ in fpm (m/s), V is velocity at the large end of the evase $= \frac{Q}{A_2}$ in fpm (m/s), Q is quantity flowing in cfm (m^3/s), A_1 and A_2 are area at the small and large ends of the evase, respectively, in ft^2 (m^2), w is density of air in lb/ft^3 (kg/m^3), and g is acceleration due to gravity = 32.2 ft/sec^2 (9.80665 m/s^2).

The evase must be properly shaped; if the expansion is abrupt, that is, the increase in area from the foot to the top is sudden, then eddy currents are set up, and the recovery is poor. A gentle slope of the evase sides allows for efficient conversion of the kinetic energy to static energy. According to Weeks (1926), the slopes should not be much over 6°. According to Briggs and Williamson (Penman, 1927), the ideal shape for vertical evases is one in which the walls nearest the fan and farthest from it slope at an angle of 7°, the side walls have an angle of 3.5°, and the area at discharge is about four times the area at the foot. Evases shaped as an expanding cone are commonly employed in mines. With forcing or booster fans, the intake shaft and the mine itself may serve the purpose of an evase. However, with exhaust fans, an evase is necessary to conserve as much energy as possible by decreasing the velocity at the discharge of the mine.

11.6.8.7 Multi-fan Arrangements

Increases in head, quantity, or both can be obtained by operating more than one fan. Multiple fans can be operated in series, parallel, or in combination as shown in Fig. 11.6.30. The analysis here neglects the velocity head of the fan; only static heads are considered.

SERIES ARRANGEMENT. Fans operating in series are on the same flow circuit, each handling the same airflow, and each generating a part of the total pressure required. Series operation of fans may be necessary when there is a need for increasing the pressure considerably without increasing the air quantity by the same proportion. Such conditions arise in high-resistance mines.

The combined fan characteristic for series operation is determined by plotting the sum of the pressures generated by each fan at a given quantity against that quantity. For example, consider fans A and B with the following characteristics (Table 11.6.8 and Fig. 11.6.31).

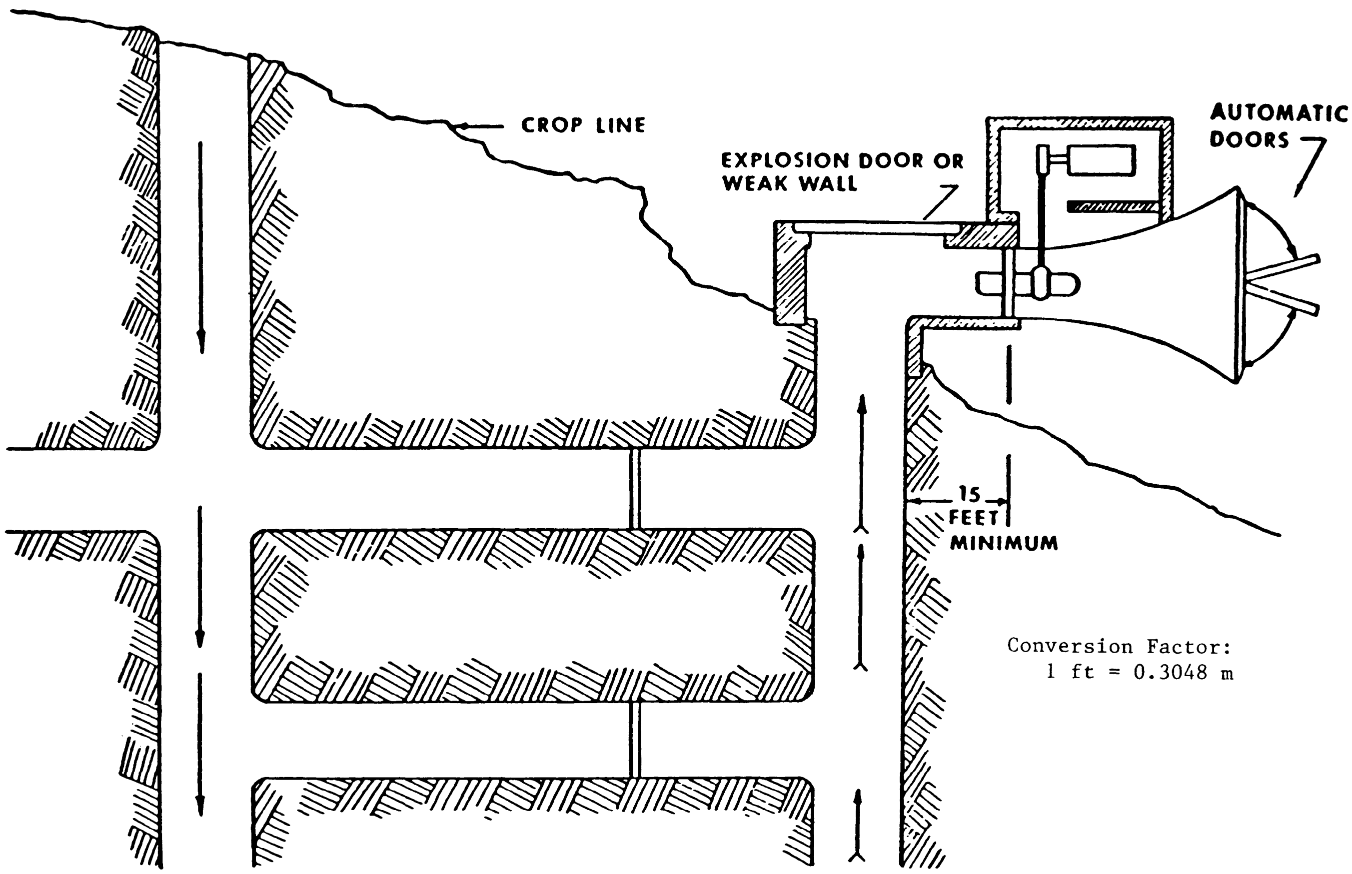

Fig. 11.6.27a. Diagram of main fan at drift or slope.

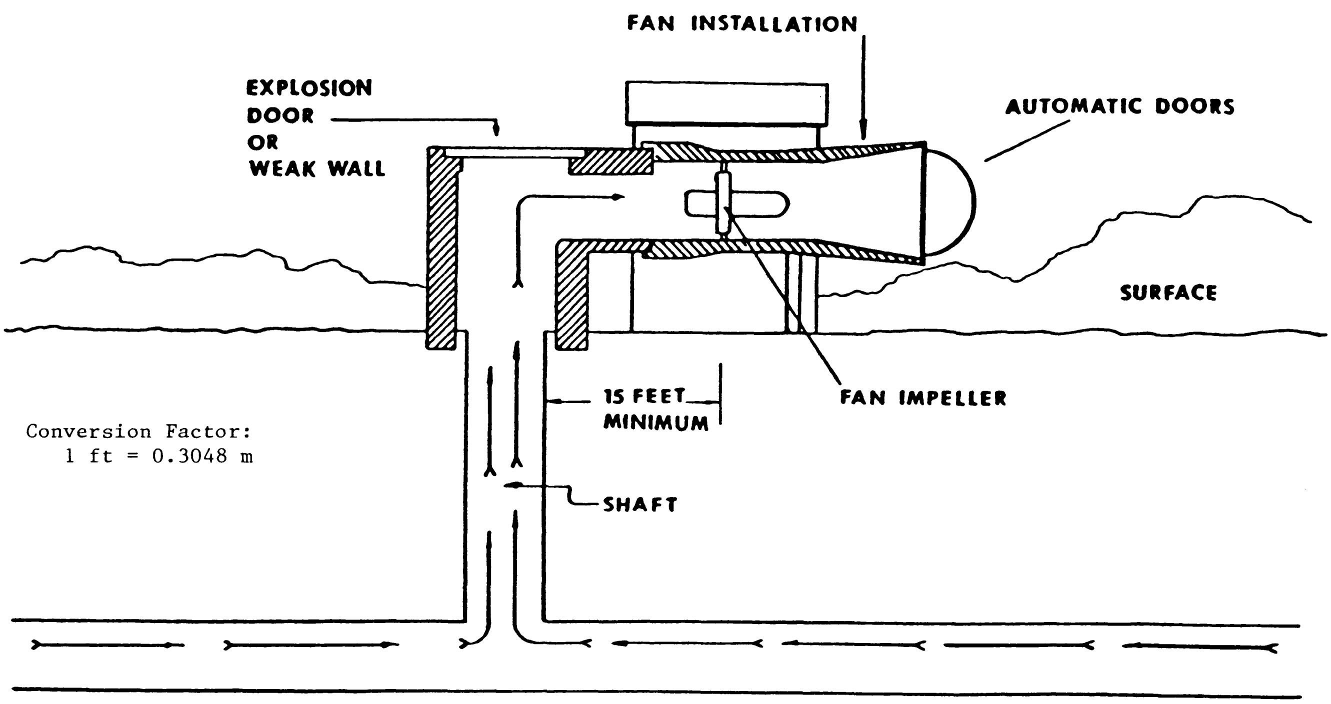

Fig. 11.6.27b. Diagram of main fan at shaft.

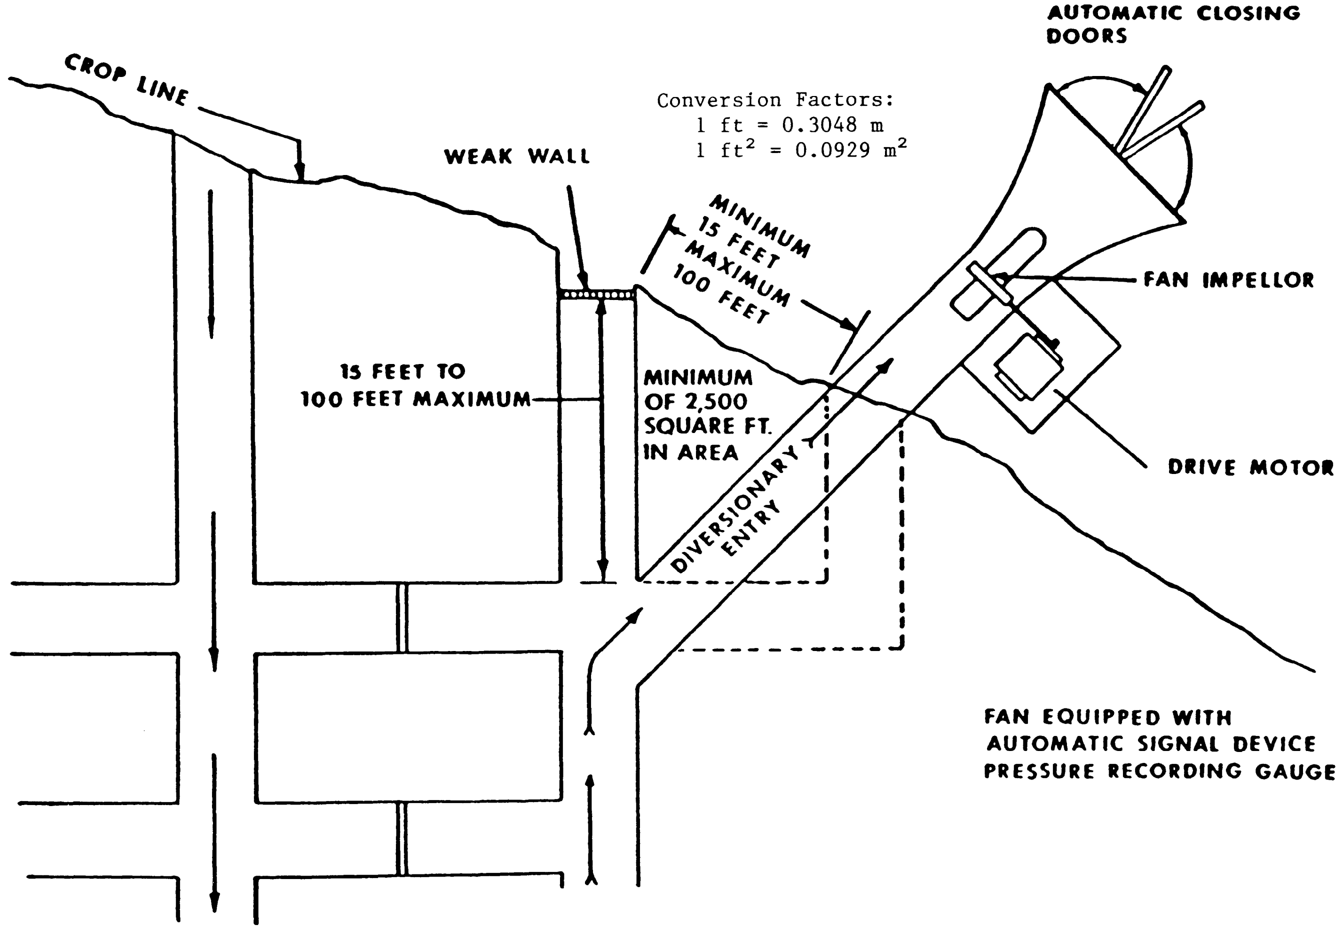

Fig. 11.6.27c. Diagram of main fan and diversionary entry.

When fan A and fan B are arranged in series, the combined characteristic is obtained as below:

Quantity, cfm (m^3/s)	Head, in. water (kPa)
0 (0)	3.0 + 1.75 = 4.75 (1.182)
10,000 (4.72)	2.5 + 1.5 = 4.0 (0.995)
20,000 (9.44)	0.5 + 1.0 = 1.5 (0.373)
22,500 (10.62)	0 + 0.8 = 0.8 (0.199)
30,000 (14.16)	0 + 0.25 = 0.25 (0.062)

Consider this arrangement in a mine whose characteristic is given by the curve C in Fig. 11.6.31. The operating point (O) is the intersection of the mine characteristic and the series characteristic. The quantity of air flowing through the mine and through each fan is approximately 17,000 cfm (8.02 m^3/s) at a head of approximately 2.63 in. water (654.45 Pa). A vertical line from O to the x axis intersects the fan curves for fans A and B at A_1 and B_1, respectively. Reading the pressure heads at A_1 and B_1, it is readily seen that fan A develops 1.5 in. water (373.26 Pa) and fan B, 1.13 in. water (281.20 Pa). Fan A does not generate any head when the quantity flowing through the fans exceeds 22,500 cfm (10.62 m^3/s), but will add a small amount of resistance to flow.

PARALLEL ARRANGEMENT. When two fans are installed in separate openings in such a way that they draw air from the same common point and deliver it to the same destination, they are said to be operating in parallel. Mine fans may be operated in parallel to increase the quantity of air flowing through the system when the pressure capacity of each fan is adequate. These conditions may arise in low-resistance mines. The combined fan characteristic for parallel operation is determined by plotting the sum of the quantities generated by each fan at a pressure against that pressure. For example, when fans A and B above are arranged in parallel, the combined characteristic is obtained as follows (Fig. 11.6.32). At 1.75 in. water (435.47 Pa), fan A delivers 15,000 cfm (7.08 m^3/s) and fan B delivers 0 cfm. At 1.5 in. water (373.26 Pa), fan A delivers 16,300 cfm (7.69 m^3/s) and fan B delivers 10,000 cfm (4.72 m^3/s). At 0.25 in. water (62.21 Pa), fan A handles 21,250 cfm (10.03 m^3/s), and fan B handles 30,000 cfm (14.16 m^3/s). The combined characteristic is calculated as follows:

Head, in. water (Pa)	Quantity, cfm (m^3/s)
1.75 (435.47)	15,000 + 0 = 15,000 (7.08)
1.5 (373.26)	16,300 + 10,000 = 26,300 (12.41)
0.25 (62.21)	21,250 + 30,000 = 51,250 (24.19)

If the mine characteristic is given by the curve C in Fig. 11.6.32, the head and quantity flowing are 1 in. water (248.84 Pa) and 38,000 cfm (17.93 m^3/s), respectively. Fan A develops 1 in. water (248.84 Pa) and 18,000 cfm (8.50 m^3/s). Fan B develops 1 in. water (248.48 Pa) and 20,000 cfm (9.43 m^3/s). If

3	0	1.75	0
2.5	10,000	1.5	10,000
0.5	20,000	1.0	20,000
0	22,500	0.8	22,500
		0.25	30,000

Conversion factors: 1 in. water = 248.84 Pa, 1 cfm = 0.47195 × 10^{-3} m^3/s.

the pressure required is above 1.75 in. water (435.47 Pa), fan B will not only be of no assistance, but will hinder the flow of air from the mine by recirculating some air through it back to fan A.

FANS IN COMBINATION. Many fans are operated in combination rather than in true series or parallel operation. Two possible applications are fans in semi-parallel and fans in semi-series (Fig. 11.6.33). In these arrangement, each fan shares a portion of the total mine resistance load, but retains its own specific zone

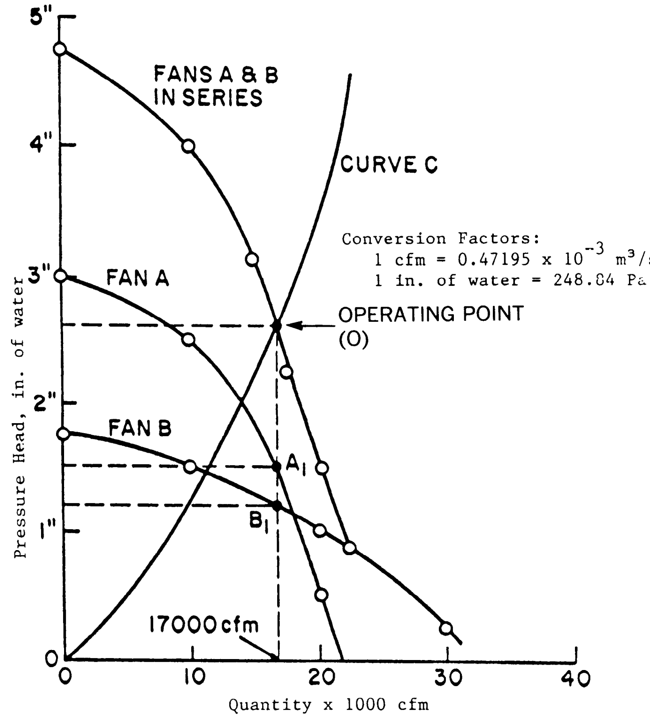

Fig. 11.6.31. Combined characteristics for series operation.

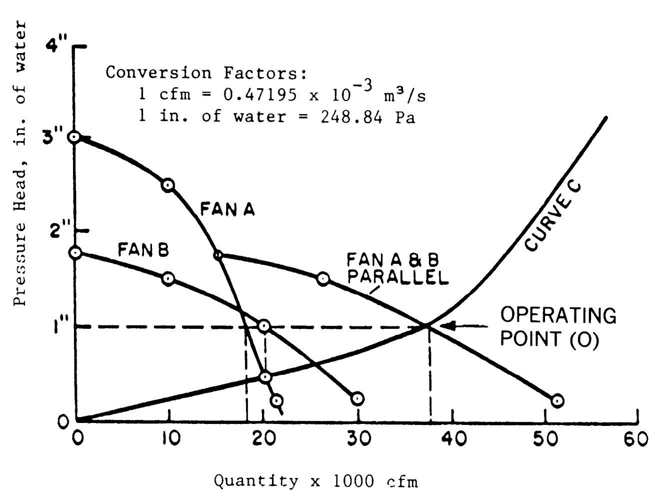

Fig. 11.6.32. Combined characteristics for parallel operation.

of influence. Thus the operation of each fan is influenced by the others in the system. The mathematical analysis of multiple-fan systems can become complex and is usually performed more rapidly and accurately with the use of computer-oriented mine ventilation network solution programs (Chapter 11.10). However, graphical techniques are available to solve simple problems (Rock, Dalzell, and Harris, 1971).

11.6.9 NATURAL VENTILATION

Natural ventilation is a result of the differences in elevation between mine openings and the addition of heat energy to the

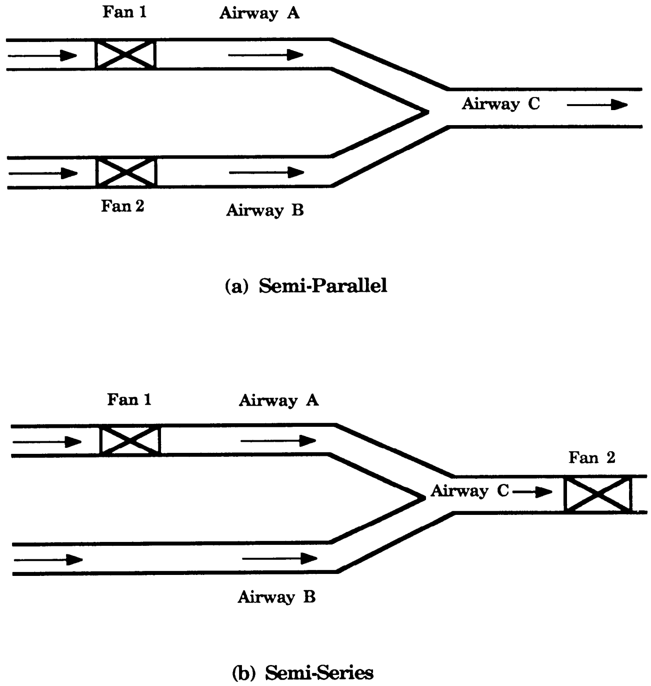

Fig. 11.6.33. Fans in combination. (a) Semi-parallel. (b) Semi-series.

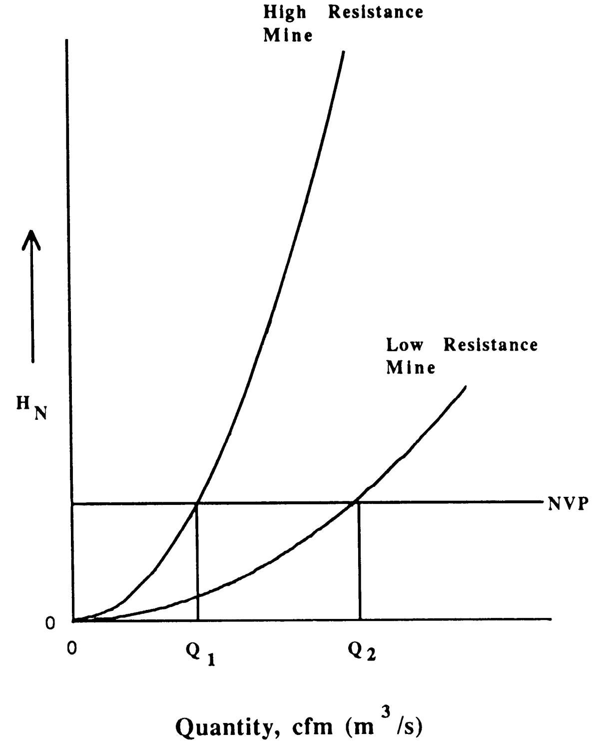

Fig. 11.6.34. Quantity of flow due to natural ventilation pressure.

air as it passes through the workings. Air, as it flows through a mine, gains in heat due to reasons such as the geothermal gradient, autocompression, and oxidation. Air may also be cooled due to contact with flowing water in the shafts or due to rock temperatures being colder than outside air. As a result, the displacement of a hot air column by a colder air columns ensues. Where the difference in the elevations of the openings is very small so that the columns of air do not have significant differences in density, flow will not occur naturally. If, on the other hand, flow is induced by some mechanical means such as a fan, the flow may continue as long as heat is added to the flowing air and the temperature difference between the two air columns exists. Even if the fan stops, this difference in temperature between the two air columns will continue to aid in the movement of air (assuming natural ventilation pressure was exerted in the same direction as the airflow) from the intake to the return although the quantity handled may fall off rapidly. Even if the elevations of the openings are the same, if local weather conditions cause a significant difference in the surface air temperatures above the openings, a flow of air can ensue.

11.6.9.1. Natural Ventilation Pressure

The rate of displacement of one column of air by another is proportional to the difference in the temperatures of the two columns. The differences in temperatures account for the density difference and the pressure head generated. This pressure head, because it arises due to natural conditions, is known as *natural ventilation pressure* (NVP). However, because the ventilation pressure provided by natural means is often inadequate, subject to variations, and difficult to control, ventilation by mechanical means is absolutely essential for most mines. On the other hand, natural ventilation affects the performance of the mechanical ventilator, so it is necessary to understand its effects on mechanical ventilation.

The magnitude and direction of NVP are not controllable. NVP is independent of the quantity flowing, depending only on the temperature difference and the height of the air column. NVP can be viewed as a fan with a characteristic parallel to the quantity axis (i.e., a constant head fan). Thus the amount of air flowing through a mine due to NVP is a function of the mine characteristic only. In a high-resistance mine, a lower quantity will flow than in a low-resistance mine (Fig. 11.6.34).

NVP ESTIMATION. The correct method of calculating the pressure generated by this addition of heat energy is the thermodynamic approach. The difference in temperature of the air in the intake and return air columns leads to a difference in the densities of the air columns. Calculations of the natural ventilating pressures using the densities of two columns of equal heights lead to results that are reasonably accurate for routine mine ventilation calculations.

Natural ventilation pressure changes frequently in magnitude. Its direction also changes, though this change can be seasonal or daily depending on the frequency and amount of temperature variations on the surface. In fact, due to the continual changes in temperature during a day, the NVP also continually changes. Fortunately, NVP tends to be small and, therefore, its calculation using one of several approximate formulas is adequate for routine mine ventilation calculations. On the other hand, where a detailed ventilation survey is being conducted, it is necessary to calculate NVP more accurately from detailed temperature and pressure surveys. For rapid estimates of NVP, the following approximate formulas can be employed (McElroy, 1935).

1.
$$H_n = \frac{1.325\ BL}{5.2}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) = 0.255\ BL\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \quad (11.6.46)$$

$$H_n = \frac{BL}{0.287}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \quad (11.6.46a)$$

where H_n is the natural ventilation pressure in in. water (Pa); B is the average absolute pressure in in. of mercury (Pa); L is the vertical height of the air columns in ft (m), and T_1 and T_2 are the average absolute temperatures of the columns in °F (°C).

The approximate average absolute pressure is obtained by direct measurement near the center of the columns or from a measurement at any elevation. In the latter case, the measurement must be corrected for difference in elevation from the center at the rate of 1 in. water change/1000 ft (816 Pa/1000 m), or more closely if the actual rate of change is known. The average absolute temperatures are obtained as weighted means according to the column lengths in the case of variable temperatures.

2. The intensity of natural-draft pressures may also be roughly estimated as about 0.03 in. water for each 10°F difference in average temperature for each 100 ft (100 m) difference in vertical elevation at standard air density (44 Pa/10°C/100 m), i.e.,

$$H_n = 0.03\left(\frac{T_2 - T_1}{10}\right)\left(\frac{L}{100}\right) \quad (11.6.47)$$

$$H_n = 44\left(\frac{T_2 - T_1}{10}\right)\left(\frac{L}{100}\right) \quad (11.6.47a)$$

3. A third approximation formula for calculating NVP is (Rees, 1950)

$$H_n = \left(\frac{T_2 - T_1}{5.2\ T_m}\right)(wL) \quad (11.6.48)$$

$$H_n = \left(\frac{T_2 - T_1}{T_m}\right)(wL) \quad (11.6.48a)$$

where T_2, T_1, and L are the same as above, w is density of the air, and $T_m = ½(T_2 + T_1)$.

4. Another approximate formula using the weights of the air columns is derived as follows. Let

$\overline{w}_d$ = average density of the air column in the downcast or intake shaft, lb/ft^3 (kg/m^3)

$\overline{w}_u$ = average density of an equivalent air column in the upcast or return shaft, lb/ft^3 (kg/m^3)

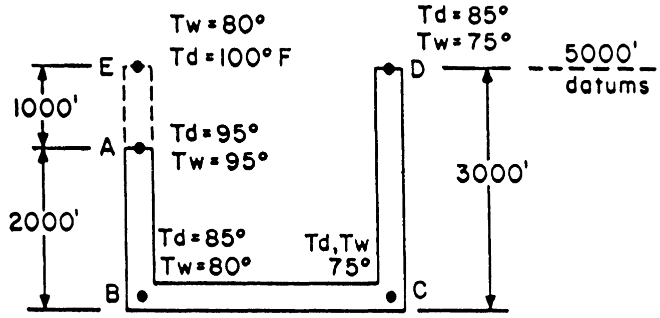
L = length of the air column, ft (m)

A column of air 1 ft^3 (0.02832 m^3) in volume and 1 ft (0.3048 m) in height in the intake shaft will exert a pressure of $(\overline{w}_d - \overline{w}_u)$ lb/ft^2 (kPa) on a similar volume of air in the return shaft. Therefore, the pressure exerted by the entire air column equals:

$$H_n = \frac{1}{5.2}(\overline{w}_d - \overline{w}_u)\,L \quad (11.6.49)$$

$$H_n = g\,(\overline{w}_d - \overline{w}_u)\,L \quad (11.6.49a)$$

in which $\overline{w}_d$ and $\overline{w}_u$ can be calculated by measuring the wet- and dry-bulb temperatures and the barometric pressure at different points in the intake and return shafts, and by averaging the calculated densities.



Conversion Factors:
1 ft = 0.3048 m
°C = 5/9 (°F-32)

Fig. 11.6.35. Results of a temperature survey (Ex. 11.6.14).

11.6.9.2. Quantity and Air Horsepower Due to NVP

Natural ventilation pressure is independent of the quantity of circulating air, and the quantity that will circulate is determined by the mine resistance only. However, Atkinson's equation still holds, i.e.,

$$H_n = \frac{KLOQ^2}{5.2A^3}$$

$$AHP = \frac{H_n Q}{6350}$$

Example 11.6.14. The application of the various formulas is illustrated with the following example. The results of a temperature survey are shown in the mine schematic (Fig. 11.6.35). The distance from B to C is 5 miles (8 km). All airways are 10 by 10 ft (3.048 × 3.048 m), and the K factor is 100×10^{-10} lb-min^2/ft^4 (0.0186 kg/m^3) at standard density. The elevation of the collar of the deeper shaft is 5000 ft (1524 m) above sea level.

Solution.

1. Since in all NVP calculations, columns of equal height have to be considered, an imaginary column AE is added to the shallower shaft.

2. The temperatures of the outside air at A are considered as the same at E.

3. Determine the barometric pressures at E, A, B, C, and D.

Point	Elevation, ft (m)	Barometric Pressure in. Hg (kPa)	Barometric Pressure psi
E	5000 (1524)	24.90 (84.6681)	12.28
A	4000 (1219)	25.84 (87.8398)	12.74
B	2000 (609.6)	27.82 (94.5277)	13.71
C	2000 (609.6)	27.82 (94.5277)	13.71
D	5000 (1524)	24.90 (84.6681)	12.28

4. Determine the density of air at E, A, B, C, and D using the chart (Fig. 11.6.1) and the given wet- and dry-bulb temperatures and the barometric pressure.

Point	Barometric Pressure in. Hg	t_d°F(°C)	t_w°F(°C)	Density Ratio* d_r	Density $0.0750 \times d_r$ (lb/ft^3) (kg/m^3)
E	24.90	100° (37.8)	80° (26.7)	0.77	0.0578 (0.925)
A (outside air)	25.84	100° (37.8)	80° (26.7)	0.805	0.0604 (0.966)
A (mine air)	25.84	95° (35)	95° (35.0)	0.800	0.0600 (0.960)
B	27.82	85° (29.4)	80° (26.7)	0.89	0.0668 (1.069)
C	27.82	75° (23.9)	75° (29.4)	0.91	0.0683 (1.093)
D	24.90	85° (29.4)	75° (29.4)	0.795	0.0596 (0.954)

*From Fig. 11.6.1.

5. Average the density, temperature, barometric pressure, taking into consideration the lengths of the air columns.

a. *Density*

Average density of the outside air in column EA =

$$\frac{0.0578 + 0.0604}{2} = 0.0591 \text{ lb/ft}^3 \ (0.946 \text{ kg/m}^3)$$

Average density of the air column AB in the mine =

$$\frac{0.0600 + 0.0668}{2} = 0.0634 \text{ lb/ft}^3 \ (1.010 \text{ kg/m}^3)$$

Average density of air column EB (weighted by length) =

$$\frac{1000 \times 0.0591 + 2000 \times 0.0634}{3000} = 0.0620 \text{ lb/ft}^3 \ (0.992 \text{ kg/m}^3)$$

Average density of air column CD =

$$\frac{0.0683 + 0.0596}{2} = 0.064 \text{ lb/ft}^3 \ (1.023 \text{ kg/m}^3)$$

Average density of the air in the two columns =

$$\frac{0.062 + 0.064}{2} = 0.063 \text{ lb/ft}^3 \ (1.008 \text{ kg/m}^3)$$

b. *Temperature*

Average dry-bulb temperature, column (outside) EA = 100°F (37.8°C)

Average dry-bulb temperature in mine, AB $= \dfrac{95 + 85}{2} =$ 90°F (32.2°C)

Average dry-bulb temperature of column EB =

$$\frac{1000 \times 100 + 2000 \times 90}{3000} = 93.3\text{°F} \ (54.1\text{°C})$$

Average dry-bulb temperature of column CD $= \dfrac{75 + 85}{2} =$ 80°F (26.7°C)

c. *Average Barometric Pressure*

Top of the air column = 5000 ft (1524 m) above sea level

Bottom of the air column = 2000 ft (609.6 m) above sea level

Average height of column $= \dfrac{5000 + 2000}{2} =$ 3500 ft (1066.8 m) above sea level

Barometric pressure at 3500 ft = 26.33 in. Hg = 12.94 psi (89.2187 kPa)

6. Natural ventilation pressure by various formulas:

a. $$H_n = 0.255\, BL \left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

$$= 0.255 \times 26.33 \times 3000 \left(\frac{1}{460 + 80} = \frac{1}{460 + 93.3}\right)$$

$$= 0.90 \text{ in. water (223.21 Pa)}$$

b. $$H_n = 0.03\, \frac{(T_2 - T_1)}{10} \times \frac{L}{100} \text{ at standard density}$$

$$H_n = 0.03\, \frac{(T_2 - T_1)}{10} \times \frac{L}{100} \times \frac{w}{0.075} \text{ at a density } w.$$

$$w = 0.03 \left(\frac{553.3 - 540}{10}\right) \times \frac{3000}{100} \times \frac{0.063}{0.075}$$

$$= 1.01 \text{ in. water (251.33 Pa)}$$

c. $$H = \frac{T_2 - T_1}{5.2 T_m}\, w\, L \quad \text{where } T_m = \frac{T_2 + T_1}{2};$$

$$= \frac{(553.3 - 540)}{5.2 \times 546.65} \times 0.063 \times 3000$$

$$= 0.88 \text{ in. water (218.98 Pa)}$$

d. $$H = \frac{1}{5.2}\,(\overline{w}_d - \overline{w}_u)\, L = \frac{1}{5.2}\,(0.064 - 0.062) \times 3000$$

$$= 1.15 \text{ in. water (287.11 Pa)}$$

The air will flow from C to B.

7. Calculate the airflow quantity and air horsepower.

$$H_n = \frac{KLOQ^2}{5.2A^3}$$

where $K = 100 \times 10$ in.-min^2/ft^4 (0.0186 kg/m^3) for standard air

The value of K must be corrected for the density of the air because the average density of the air varies during its flow through the mine.

average density of air in column AB = 0.0634 lb/ft^3 (1.010 kg/m^3)

average density of air in column CB = 0.0640 lb/ft^3 (1.023 kg/m^3)

average density of air in column BC = 0.0676 lb/ft^3 (1.082 kg/m^3)

(average of density at B and C)

The weighted average density of air

$$w = \frac{[0.0634 \times 2000] + [0.0676 \times 5 \times 5280] + [0.064 \times 3000]}{2000 + 5 \times 5280 + 3000}$$

$$= \frac{2103.44}{31400} = 0.0669 \text{ lb/ft}^3 \text{ (1.070 kg/m}^3\text{)}$$

Value of K to be used $= 100 \times 10^{-10} \times \dfrac{0.0669}{0.0750} = 89 \times 10^{-10}$ lb-min^2/ft^4 (0.0167 kg/m^3)

$$L = 31{,}400 \text{ ft (9571 m)}$$

$$A = 10 \times 10 = 100 \text{ ft}^2 \text{ (9.29 m}^2\text{)}$$

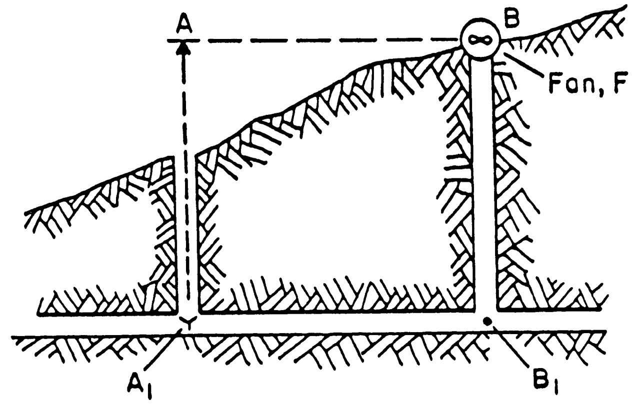
$$O = 2(10 + 10) = 40 \text{ ft (12.19 m)}$$

Using a value H = 1.1538 in. water (287.11 Pa) (calculation 2d) and $H = \dfrac{KLOQ^2}{5.2A^3}$,

$$1.1538 = \frac{89 \times 10^{-10} \times 31{,}400 \times 40 \times Q^2}{5.2 \times 100 \times 100 \times 100}$$

$$Q = 23{,}200 \text{ cfm (10.95 m}^3\text{/s)}$$

$$AHP = \frac{HQ}{6350} = \frac{1.1538 \times 23{,}200}{6350} = 4.22 \text{ hp (3.15 kW)}$$



11.6.9.3. Natural Ventilation Pressure and Fans

Since NVP acts on the same circuit as the fan, it can be treated as acting in series with the fan. However, it can act in the same direction as the fan and aid the fan or act in the opposite direction and hinder its performance. These effects can be demonstrated with the aid of mine, fan, and NVP characteristics.

Shown in Fig. 11.6.36 are the fan and mine characteristics without any NVP acting in the circuit. The head developed by the fan is H_1, and the quantity of air circulating is Q_1.

Fig. 11.6.37 shows the fan, NVP, and mine characteristics. When NVP is acting in the *same* direction as the fan, the combined characteristic is obtained by *adding* the NVP to the fan pressure at each quantity. The quantity circulating in the system is Q_2 with a head of H_2. However, the head developed by the fan is only H_f, which is lower than H_1.

Shown in Fig. 11.6.38 are the fan, NVP, and mine characteristics when NVP is acting in the *opposite* direction to the fan. In this case, the combined characteristic is obtained by *subtracting* the NVP from the fan pressure at each quantity. The quantity circulating is now Q_3 with a head of H_3. However, the head developed by the fan is H_f, which is higher than H_1. If NVP can significantly affect the operation of the fan, it is necessary to know its magnitude.

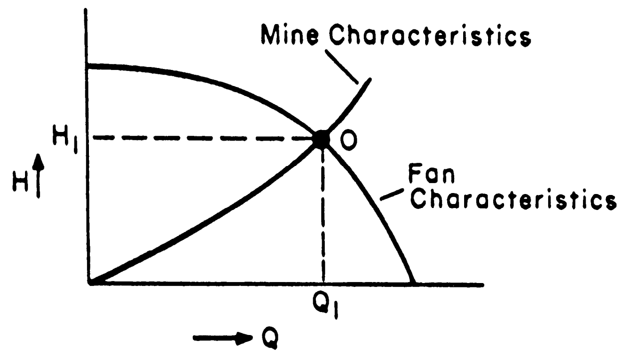


Fig. 11.6.36. Mine and fan characteristics for simple mine ventilation system without NVP.

11.6.9.4 Practical Application of Fan Laws and Air Densities

The application of the fan laws and the influence of air densities and NVP on fan performance is illustrated in the following example from Kingery (1960).

Example 11.6.15. The following data are available on the performance of two different fans:

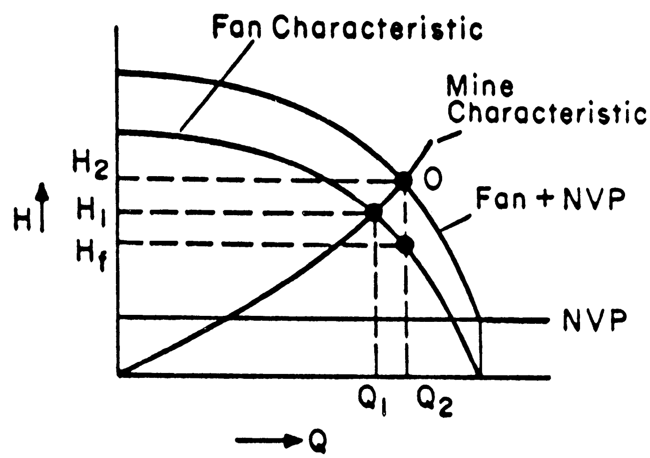

Fig. 11.6.37. Mine and fan characteristics with NVP acting in favor of the fan.

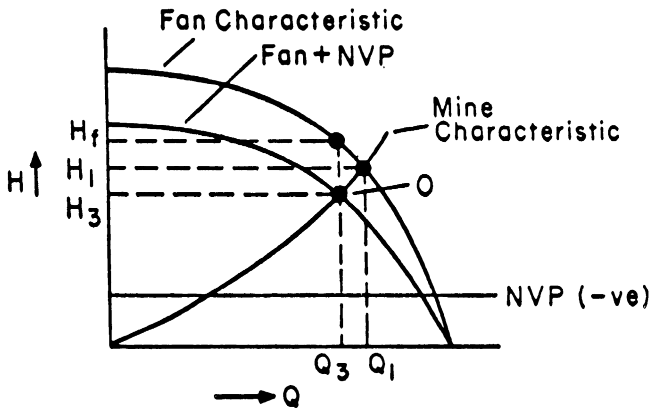

Fig. 11.6.38. Mine and fan characteristics with NVP acting against the fan.

	Fan A	Fan B
Speed, rpm	700	800
Density of air, lb/ft^3 (kg/m^3)	0.0700 (1.12)	0.0750 (1.20)
Head *H*, in. water (kPa) at following air quantities, cfm (m^3/s):		
150,000 (70.793)	4.90 (1.219)	6.55 (1.630)
160,000 (75.512)	4.62 (1.150)	6.05 (1.505)
170,000 (80.232)	4.16 (1.035)	5.45 (1.356)
180,000 (84.951)	3.64 (0.906)	4.70 (1.170)
190,000 (89.671)	3.04 (0.756)	3.85 (0.958)
200,000 (94.390)	2.29 (0.570)	2.80 (0.697)

These two fans are to be installed in series in a mine at an air density of 0.0700 lb/ft^3 (1.12 kg/m^3); both fans operate at speeds of 800 rpm. Mine resistance has been established at 3 in. water pressure (746.52 Pa) for 100,000 cfm (47.195 m^3/s) at a density of 0.0750 lb/ft^3 (1.2 kg/m^3). The natural ventilation pressure is 0.5 in. water (124.42 Pa) assisting fans.

What quantity will fans deliver? At what pressure will each fan operate?

Solution. The first step is to correct the pressure-quantity data for each fan to 800 rpm and a density of 0.0700 lb/ft^3 (1.12 kg/m^3). Fan A: No correction needed for density. The head-quantity characteristic for 800 rpm is developed using fan law 1.

$$Q_n = Q_o\left(\frac{800}{700}\right)$$

$$H_n = H_o\left(\frac{800}{700}\right)^2$$

Fan A: [Air density, 0.0700 lb/ft^3 (1.12 kg/m^3)].

Speed, 700 rpm		Speed, 800 rpm	
Quantity cfm (m^3/s)	Head in. water (kPa)	Quantity, cfm (m^3/s)	Head in. water (kPa)
150,000 (70.793)	4.90 (1.219)	171,500 (80.939)	6.40 (1.593)
160,000 (75.512)	4.62 (1.150)	183,000 (86,367)	6.03 (1.501)
170,000 (80.232)	4.16 (1.035)	194,300 (91,700)	5.43 (1.351)
180,000 (84.951)	3.64 (0.906)	206,000 (97.222)	4.75 (1.182)
190,000 (89.671)	3.04 (0.756)	217,000 (102.413)	3.97 (0.988)
200,000 (94.390)	2.29 (0.570)	229,000 (108.077)	2.99 (0.744)

Fan B: No correction necessary for speed. The head-quantity characteristic for w = 0.0700 lb/ft^3 (1.12 kg/m^3) is developed using fan law 3.

$$H_n = H_o\left(\frac{0.070}{0.075}\right)$$

Speed, 800 rpm; quantity, cfm (m^3/s)	Fan B Head, in. water (kPa) at density (kg/m^3) 0.0750 (1.20)	0.0700 (1.12)
		$\left(\frac{0.0700}{0.0750}\right) \times H_1$
150,000 (70.793)	6.55 (1.630)	6.11 (1.521)
160,000 (75.512)	6.05 (1.505)	5.65 (1.405)
170,000 (80.232)	5.45 (1.356)	5.09 (1.266)

200,000 (94.390)	5.12 (1.274)	—	—

* Pressure-quantity data, fan A, taken from curve of fan A plotted from calculated data.

Influence of natural draft at 0.5 in. water (124.42 Pa)

Quantity, cfm (m^3/s)	*H*, combined	*H*, NVP in in. water (kPa)	*H*, total
160,000 (75.5 12)	12.36 (3.076)	0.50 (0.124)	12.86 (3.200)
170,000 (80.232)	11.54 (2.072)	.50 (0.124)	12.04 (2.996)
180,000 (84.951)	10.51 (2.615)	.50 (0.124)	11.01 (2.740)
190,000 (89.671)	9.26 (2.304)	.50 (0.124)	9.76 (2.429)
200,000 (94.390)	—	—	—

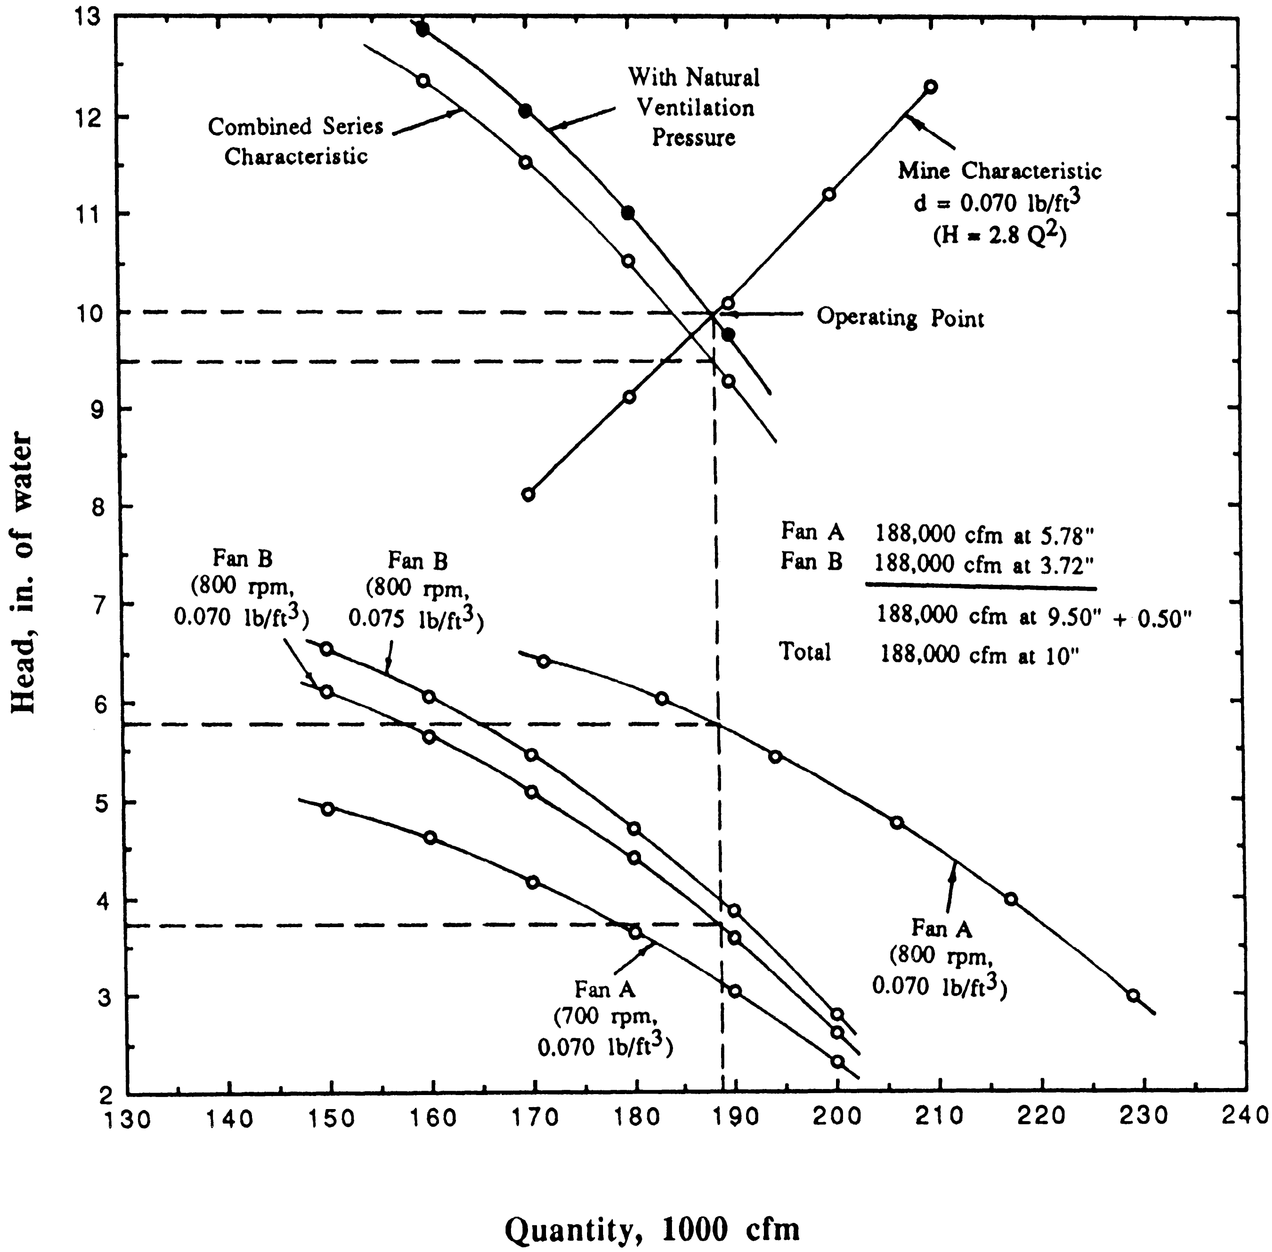
Plotting these data forms the total pressure-quantity relationship of all fans, plus natural draft (Fig. 11.6.39). The mine pressure *H* is 3 in. water (746.52 Pa) at 100,000 cfm (47.195 m^3/s) at standard density. Therefore, the pressure at a density of 0.0700 lb/ft^3 (1.12 kg/m^3) is $3 \times \dfrac{0.0700}{0.0750} = 2.8$ in. water (696.75 Pa).

$$R = \frac{H}{Q^2} = \frac{2.8}{(1.0)^2} = 2.8 \text{ in.-min}^2/\text{ft}^6 \ (0.313\ N\text{-}s^2/\text{m}^8)$$

The mine characteristic is calculated from the relationship $H = 2.8Q^2$.

Air quantity, cfm (m^3/s)	Head, in. water (kPa)
170,000 (80.232)	8.1 (2.016)
180,000 (84.951)	9.1 (2.264)
190,000 (89.671)	10.1 (2.513)
200,000 (94.390)	11.2 (2.787)
210,000 (99.110)	12.3 (3.061)

Plotting these data on Fig. 11.6.39, it is seen that the total air quantity of 188,000 cfm (88.73 m^3/s) at a combined pressure



Conversion factors: 1 cfm = 0.47195 × 10^{-3} m^3/s, 1 in. of water = 248.84 Pa, 1 lb/ft^3 = 16.018 kg/m^3.

Fig. 11.6.39. Fan, NVP, and mine characteristics for Ex. 11.6.15.

of 10.0 in. water (2.488 kPa) is flowing through the mine. The total pressure is distributed as follows:

	Head in. water (kPa)
Fan A	5.8 (1.443)
Fan B	3.7 (0.921)
Combined	9.5 (2.364)
Natural draft	0.5 (0.124)
Total head	10.0 (2.488)

11.6.10 VENTILATION SURVEYS

Comprehensive ventilation surveys are necessary to determine if the mine ventilation system meets statutory requirements, to decide what improvements in the current ventilation system are needed, and to enable planning for future expansion. Routine measurements made to check on the air quantity in a split or the amount of methane in the workings do not qualify as comprising a ventilation survey. Four major areas are included under the general heading of ventilation surveys: (1) air quantity survey, (2) pressure survey, (3) temperature survey, and (4) air quality survey (Luxbacher, 1977).

In the temperature survey, the measurements may include virgin rock temperatures and the dry- and wet-bulb temperatures. Often the operation of the fan must also be examined. In fact, the common practice is to conduct air quantity, pressure, and temperature surveys concurrently. Air quality and fan surveys are conducted as and when necessary along with these other surveys.

11.6.10.1. Air Quantity Surveys

In most cases in an air quantity survey, the volume flow rate of air is not measured directly but is calculated from velocity and area measurements at selected cross sections of the mine airway, using the relation (see Eq. 11.6.13),

$$Q = V \times A \tag{11.6.50}$$

where Q is quantity of air flowing in cfm (m^3/s), V is velocity of airflow in fpm (m/s), and A is area of the airway section in ft^2 (m^2).

To measure velocity, the physical effects of air in motion are used. Among these are (1) mechanical effects, (2) variations in air pressure, and (3) the cooling power of the air. Instruments that use mechanical effects to determine velocity include (1) the smoke tube, (2) the velometer, and (3) the anemometer, which is the principal instrument used since the early 1900s. Among the instruments that use pressure variations to determine velocity, the most common one is the pitot tube. Instruments such as kata thermometers and hot wire anemometers that use the cooling power of the air in motion to determine velocity are not generally used for that purpose in mines. The characteristics of several air-measuring devices are summarized in Table 11.6.9. The particular instrument chosen for velocity measurement is usually dictated by the range of air velocities anticipated [low < 150 fpm (0.76 m/s), medium 150 to 1000 fpm (0.76 to 5.08 m/s), or high > 1000 fpm (5.08 m/s)] and the accuracy desired. The accuracy of a quantity measurement is a function of the accuracy of the velocity and area measurements. Errors in velocity and area measurements can, of course, be compensating or compounding.

SINGLE- AND MULTI-POINT TRAVERSES. Whatever the instrument used, there are several methods by which the velocity of the air in an airway can be measured: (1) single-point centerline measurements, (2) multi-point measurements at predetermined points (fixed traversing), and (3) continuous traversing.

Because of the variation in velocity over the cross section of an airway, single-point measurements must be corrected to determine the average velocity of the air in an airway. This is usually found to be 80 to 90% of the measurement taken at the centerline. For day-to-day comparisons of velocity, single-point measurements taken at the same place (with no change in cross section) are satisfactory. For more accurate determinations, traversing methods, either multi-point (fixed) or continuous, must be employed.

Fixed-point traversing is warranted only when very precise ventilation surveys are needed such as for fan tests and shaft measurements. The total area of airflow is broken down into small equal areas for measurement purpose. Precise positioning of the instrument is then required at each of these measurement points. Fig. 11.6.40a shows the arrangement for fixed-point traversing in rectangular and circular airways. The rectangular airway is divided into 16 equal areas with more measurement points in the peripheral areas than in the areas in the center. Average velocity for each area is calculated and then the overall average velocity in the airway is taken as the average of the average velocities for all the areas. The number of areas should not be less than 24 for a section in which one dimension is twice the other.

For a circular airway or duct, the area is divided into a number of concentric but equal areas, and readings are taken at the center of each area along the horizontal and vertical diameters (i.e., four readings in an area). In Fig. 11.6.40b, the area is divided into five concentric areas with 20 measurement points. The velocity in the airway is the average of the 20 velocities.

INSTRUMENTS. Two of the most commonly used velocity instruments in mines are now described.

Vane Anemometer—The vane anemometer is a small windmill geared to a mechanical counter. The gearing converts the spindle revolution into a measure of lineal distance. The windmill is rotated by the moving air, and the air velocity is calculated by taking an observation over a measured period of time. To make a measurement, the gearing is engaged to the counter by a clutch. In some recent models, in place of a conventional clockwork mechanism, a low-friction digital counter is used. The common commercial anemometer is about 4 in. (100 mm) in diameter.

Anemometer readings are virtually unaffected by the air densities and air temperatures encountered in underground work. For routine measurements, the instrument may be handheld. However, for precise work, it should be mounted on an extension rod to reduce the effect of the hand, arm, and body of the observer on the airstream.

The anemometer registers a velocity somewhere within ± 10% of the true velocity. Calibrations furnished by the manufacturers are usually in the form of tables of plus or minus corrections to the observed velocity. Kingery (1960) recommends fitting a linear equation to the manufacturer's correction factors and using the equation to correct the observed velocity to true velocity. If the anemometer is to be used for very precise measurements, it is recommended that it be sent to the manufacturer for calibration prior to use.

The auxiliary equipment necessary to determine air quantity with the anemometer includes anemometer extension rods (if required), a stopwatch, and a tape measure. Measurements should be made at cross sections that are in straight lengths of airway. They should not be taken near sections where there are bends or changes in area.

Pitot Tube—The pitot tube is a primary standard instrument for determining velocities. It is made up of two coaxial tubes, one arranged to measure the total pressure and the other to measure the static pressure through small holes at right angles to the flow (Fig. 11.6.41). The head containing the holes for detecting total and static pressures is carried on a stem of suitable length set at right angles to the head. When the two tubes are connected across a manometer, the difference between the static and total pressure (i.e., the velocity pressure) is measured. The velocity of the air can then be found from solving Eq. 11.6.5 and 11.6.5a for:

$$V = 1098\sqrt{H_v/w}$$

$$V = \sqrt{2gH_v/w}$$

where V is air velocity in fpm (m/s), H_v is velocity pressure in in. water (Pa), and w is density of air in lb/ft^3. In Eq. 11.6.5a w/g is in kg/m^3.

While the facing holes reflect accurately the total pressure, the holes for static pressure are subject to some interference by the facing tube and stem, and have to be sized and located correctly (Drummond, 1974). Commercial types are generally accurate to within 1%, and specially made types can be accurate

Table 11.6.9. Characteristics of Air Velocity Measurement Instruments

Instruments	Range, fpm	Hole Size (for ducts)	Range, Temp. *	Dust, Fume Difficulty	Calibration Requirements	Rugged-ness	General Usefulness and Comments
PITOT TUBES with inclined manometer	600–up	3/8″	Wide	Some	None	Good	
Standard	600–up	3/8″	Wide	Some	None	Good	Good except at low velocities
Small Size	600–up	3/16″	Wide	Yes	Once	Good	Good except at low velocities
Double	500–up	3/4″	Wide	Small	Once	Good	Special
SWINGING VANE ANEMOMETERS							
Alnor Velometer	25–10,000	1/2″–1″	300°F	Some	Frequent	Fair	Good
ROTATING VANE ANEMOMETERS							
Conventional	30–10,000	Not for duct use	Narrow	Yes	Frequent	Poor	Special; limited use
Electronic (Airflow Development)	25–200 25–500 25–2000 25–5000	Not for duct use	Narrow	Yes	Frequent	Poor	Special; can record; direct reading
Digital (Airflow Development)	200–5000	Not for duct use	Narrow	Yes	Frequent	Poor	Special
BRIDLED VANE ANEMOMETERS							
Florite Air Velocity Meter	50–2500	Not for duct use	Narrow	Yes	Frequent	Fair	Special
HEATED WIRE ANEMOMETERS							
Anemotherm Model 60	10–8000	3/8″	Medium	Some	Frequent	Poor	Good
Anemotherm Gas Flow Meter	10–5000	1″	300°F	No	Frequent	Good	Not portable; for permanent station air flow
Flowtronic Air Meter 55A	0–1000 1000–2000 2000–4000	1/2″	Medium	Yes	Frequent	Poor	Good
HEATED THERMOCOUPLE ANEMOMETERS							
Alnor Thermo-anemometer Model 8500	10–2000 2 scales	5/16″	Narrow	Yes	Frequent	Poor	Good
Hasting Precision Air Meter B-22	10–500 500–10,000	5/16″	Narrow	Yes	Frequent	Poor	Good
Flow Corporation Series 800	10–4000	1/2″	Narrow	Yes		Poor	Good
Alnor Air Velocity Transducer System (AVT)	20–500 50–1000 100–2000	5/16″	Narrow	Yes	Frequent	Poor	Special; for permanent station use
VARIABLE AREA METER							
Airmeter F. W. Dwyer Co.	200–1200 1000–4000	Not for duct use	Narrow	Yes	Occasional (needs cleaning)	Good	Satisfactory for estimates of flow
VORTEX SHEDDING INSTRUMENT							
J-Tec (Mine Applications)	60–3000	Can be miniaturized	Wide	Occasional cleaning of the post	Twice a year or less	Good	Fixed-point automatic mine monitoring

to within 0.01%. Since velocity pressures in mines are ordinarily small, the use of the pitot tube is limited to high-velocity determinations at fans and in ducts and tubing. At velocities below 1500 fpm (2.5 m/s), the accuracy of pitot-tube measurements is not very high. However, anemometers can be used in this velocity range with satisfactory results.

11.6.10.2 Quantity Measurement by the Tracer Gas Technique

Using the tracer gas technique, the quantity of air flowing in an airway is calculated directly. The method is advantageous where areas are irregular and the flow is not steady. The test gas is usually selected on the basis of (1) the ease with which it can be detected and analyzed, (2) its not being present in the normal mine air, (3) its not being absorbed by chemical or physical means in the airway, (4) non-reactivity with other gases in mine air, and (5) non-toxicity or explosiveness. Gases which have been considered suitable include ozone, hydrogen, carbon dioxide, and sulfur hexafluoride (SF_6).

There are two methods of using the tracer gas technique. In the first method, the tracer gas is continuously metered into an airway. After thorough mixing has occurred and equilibrium has been established, air samples are taken at a point downstream. The concentration of the tracer gas is determined in the sample. The rate of airflow is calculated as

$$Q = \frac{Q_g}{C} \qquad (11.6.51)$$

where Q is quantity of air flowing in cfm (m^3/s), Q_g is feed rate of the tracer gas in cfm (m^3/s), and C is concentration of the tracer gas in $\left(\frac{\%}{100}\right)$.

In the second method, a known mass (or volume) of the gas is injected into the airstream, and its concentration at a downstream point is sampled either continuously or as often as possible until the concentration can no longer be measured. The quantity of tracer flowing through the sampling point at any time interval $(t,\ t + dt)$ is given by $QC_t \times d_t$, where C_t is concentration at time t, and Q is the airflow. Thus, over the time interval $(t_o,\ t_f)$,

$$Q_g = \int_{t_o}^{t_f} Q\, C_t\, dt \qquad (11.6.52)$$

where t_o is arrival time of first measurable concentration, and t_f is time after which the concentration is not measureable.

If C_t were plotted against t, the curve would look like that shown in Fig. 11.6.42 where

$$\int_{t_o}^{t_f} C_t\, dt$$

is the area under the curve and

$$Q = \frac{Q_g}{\int_{t_o}^{t_f} C_t\, dt}$$

On the other hand, the integration of $\int_{t_o}^{t_f} C_t\, dt$ can be done by simply taking the average of the measured concentrations (C_{ave}),

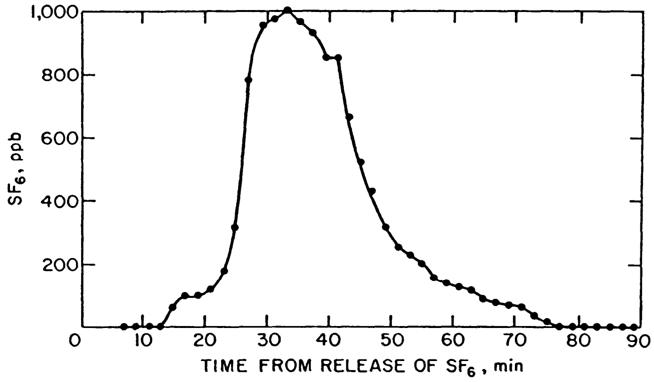

Fig. 11.6.42. Concentration of SF_6 at two-minute intervals (Ex. 11.6.16)

and multiplying the average by the total time $(T = t_f - t_o)$ which measurable amounts of concentration are found at the sampling point.
Then

$$Q_g = Q \int_{t_o}^{t_f} C_t \, dt = Q \times C_{ave} \times [t_f - t_o] = Q \times C_{ave} \times T$$

from which

$$Q = \frac{Q_g}{C_{ave} T} \qquad (11.6.53)$$

Example 11.6.16. Thimons and Kissell (1974) report that, when they released 0.371 ft^3 (0.011 m^3) of sulfur hexafluoride in a mine and monitored its concentration in the return, of the 45 samples taken at 2-min intervals, only 31 samples contained measurable quantities of the gas (Fig. 11.6.42). Average concentration in the 31 samples of the gas is calculated as 3.77×10^{-7} ft^3/ft^3 (m^3/m^3) of air. The total sampling time was 62 min. Therefore, the quantity of air flowing at the measurement point is calculated as

$$Q = \frac{0.371}{3.77 \times 10^{-7} \times 62} = 16{,}000 \text{ cfm } (7.55 \text{ m}^3/\text{s})$$

The tracer gas technique has potential applications in measuring air quantities in problem areas such as recirculation of return into intake air, leakage from adjacent mines, "lost" intake air, and unknown transit flow times through stoped or gobbed areas.

11.6.10.3 Pressure Surveys

Analysis of an existing mine ventilation system, including the evaluation of modifications to the system, requires accurate input data that can be developed *only* by a detailed pressure-quantity survey in the mine (McElroy and Kingery, 1957). The purposes of an accurate underground pressure survey are to: (1) obtain a pressure gradient along the circuit or circuits under investigation, and (2) determine the values of friction factor for various types of airways.

The pressure gradient aids in determining regions of excessive resistance and the feasibility of correcting the conditions causing them by cleaning airways, driving additional ones, or modifying existing ones. The pressure gradient is also useful for predicting the effect on other parts of the system when adjusting air regulation on any one split or when planning a new air shaft, slope, or drift. When projecting new mine development, high-precision work is required to establish these vital data for predicting the characteristics of mine pressure and air quantity.

Pressure measurements in underground mines can be made on either an absolute or a differential basis. Measurements made on an absolute basis at each station are subtracted, one from the other, to find the head loss between stations.

PRESSURE SURVEY INSTRUMENTS. There are several types of instruments available for measuring both absolute and differential pressures. Absolute pressures are generally measured by the use of altimeters or aneroid barometers while U-tubes or magnehelics are used to measure differential pressure.

Absolute Pressure Measurement—In making absolute pressure measurements with a barometer, the pressure reading obtained at a particular point, called the barometric pressure, is dependent upon the altitude and the gravitational force at that point and the prevailing atmospheric conditions. There are two common types of barometers, mercury and aneroid. Aneroid barometers are commonly used underground because mercury barometers are too bulky and fragile. An aneroid barometer calibrated in terms of elevation is called an altimeter. Since the response of each capsule to atmospheric pressure variations is slightly different from that of any other capsule, the reading scale for each instrument is unique to it. As a result, recalibration costs for aneroids tend to be high. Two types of aneroid barometers are widely used for mine pressure survey work, a direct-reading type manufactured by Wallace and Tiernan and an indirect-reading type manufactured by American Paulin System.

The equation used in all survey altimeter calibrations in the United States is taken from the Smithsonian Meteorological Table Number 51 (Anon., 1931):

$$H = 62583.6 \log (29.9/B) \qquad (11.6.54)$$

$$H = 19075 \log (101.3/B) \qquad (11.6.54a)$$

where H is elevation above sea level in ft (m), and B is barometric pressure in in. mercury (kPa). The formula assumes an air temperature of 50°F (10°C), no humidity (dry air), and a sea level atmospheric pressure of 29.92 in. mercury (101.325 kPa). Therefore, when readings are taken with an altimeter, corrections must be made for deviations from the assumption of dry air at 50°F (10°C). American Paulin System altimeters incorporate a correction for humidity in the dial of the instrument and use of volumetric gas expansion formula to correct for changes in temperature. Wallace and Tiernan altimeters utilize the density ratio of 50°F (10°C) dry air to the actual air density for this correction. The scale on the Wallace and Tiernan altimeter is offset by 1000 ft (304.8 m) to permit use below sea level. Charts for conversion of altimeter readings to direct units of pressure in in. mercury, and conversion factors for converting pressure differences due to flow from ft (m) of air column of altimeter scale density to in. water (pascals) are available.

Differential Pressure Measurement—Precision differential pressure measurements are usually made with a manometer. In this instrument, the difference between the pressure applied to two different surfaces of a liquid is balanced by the displacement of the liquid. Correct choice of the manometer liquid will avoid problems that may be encountered due to (1) a poorly formed meniscus, (2) poor surface tension, (3) poor visibility of the fluid level, and (4) changes in the density of the fluid.

The most important of the several types of manometers are the vertical U-tube manometer, the reservoir-type vertical manometer, and the inclined-tube manometer. The modern inclined-tube manometer comes with an adjustable limb that can be set at two or three different inclinations with alternative measuring scales for each inclination.

Among the devices available for measuring differential pressure underground, the magnehelic manometer is the most useful for underground spot surveys. The instrument is, strictly speaking, an aneroid barometer. It consists of a diaphragm across which the pressure difference is applied. This causes the diaphragm to move against a spring. At the end of the diaphragm is a magnet adjacent to which is a helix that is free to turn so as to maintain the minimum air gap between the magnet and helix. In effect, movement of the diaphragm through this magnetic linkage causes a rotation of the helix which can be read on a dial. Magnehelics are available with several different pressure ranges.

PRESSURE SURVEY METHODS. There are two methods of conducting pressure surveys. In the first method, the manometer survey, the differential pressure between two points is directly measured with a manometer. The basic requirements are two hoses connecting the two points to the limbs of a manometer. When the object is to measure the static pressure drop between the two points, a static-pressure measuring connection should be used at the extremities of the hoses. Manometer surveys are recommended where extreme precision is required such as for determining friction factor values and calculating pressure drops across doors or for surveys where handling of the hose would not be a problem. An essential precaution is guarding against the formation of condensate in the hose connections when they are moved from warm humid air to cold air. For friction factor determination, a sling psychrometer and a barometer should also be used to determine wet-bulb and dry-bulb temperatures and the barometric pressures. Additionally, velocity and area measurements are required for calculating the flow volume of air. Manometer surveys have found limited application in the United States due to the extensive size of most mines. In other countries, the use of the manometer is preferred over that of the altimeter for pressure surveys.

Altimeter Survey—Absolute pressure measurements made with an altimeter or barometer at the various stations in the mine must be compared to find the head loss or pressure differential between the stations. The instruments could be used to directly determine the pressure difference, in ft (m) of a theoretical 50°F (10°C) dry air column, in. mercury (pascals), or any other scale such as in. water (pascals) between any two points in a ventilation system if the two points were at the same elevation, had the same air density and airflow velocities (or velocity head), and the measurements were made simultaneously. Unfortunately, these conditions rarely exist during underground pressure surveys, and corrections must be applied. Two altimeter survey methods are used, differing only in the treatment of the time frame between measurements. These are the simultaneous measurement method and the fixed-base method, both of which require two altimeters.

In the simultaneous method, measurements are made simultaneously at two adjacent stations (stations 1 and 2). Immediately after the measurement, the observer at the rear instrument (station 1) moves past the other observer to the next forward station (station 3). The procedure is repeated for each successive station, and the technique has come to be known as "leap frogging" (Fig. 11.6.43).

The simultaneous method is more accurate than the fixed-base method as it avoids possible changes in air conditions and obviates the necessity of correcting readings for changes in atmospheric pressure. However, it is slow because two readings must be taken at each station. The logistics of alternate station moves

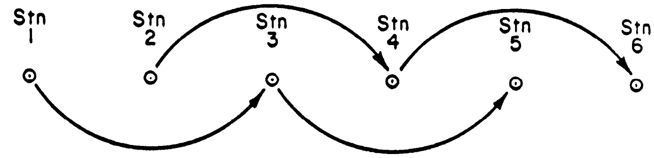

Fig. 11.6.43. Leap-frogging method of pressure surveying.

for the observer add difficulty to its use. It is still a useful procedure for small mines or portions of mines such as shafts.

In the fixed-base method, a base is established at which an altimeter (base instrument) is read at short intervals of time while readings are being taken with the other instrument (roving instrument) at all traverse stations in succession. The difference in the readings of the two instruments at adjacent stations is corrected for temperature, elevation, and atmospheric pressure differences that exist at the time of the measurements.

When the survey involves a closed pressure loop, starting and finishing at the same point, then in the absence of NVP and errors in the survey, the final pressure should be zero. However, a final instrument reading of 3 to 4 ft (0.9 to 1.2 m), representing the error of closure, can be expected. A small error of closure can result due to compensating errors in elevation measurements, altimeter readings, and velocity measurements. Therefore, accuracy of a survey can be established only by independent surveys and spot checks.

PRESSURE SURVEY CALCULATIONS. The method of calculating the survey results for the fixed-base method is explained in a US Bureau of Mines publication (McElroy and Kingery, 1957). With the results of the pressure survey, the following formula is used for calculating the difference in total pressure (head loss or head gain) between two stations:

$$DTP = \frac{-\left[(A_2 - A_1) - (B_2 - B_1) - \dfrac{(E_2 - E_1)}{DR}\right]}{CONFAC} + \frac{V_2^2 - V_1^2}{(4008)^2} \tag{11.6.55}$$

$$DTP = \frac{-\left[(A_2 - A_1) - (B_2 - B_1) - \dfrac{(E_2 - E_1)}{DR}\right]}{CONFAC} + \frac{w(V_2{}^2 - V_1{}^2)}{2g} \tag{11.6.55a}$$

where DTP is difference in total pressure between station 2 and station 1 in in. water (Pa); A_2, A_1 are roving altimeter readings, in ft (m) of air; B_2, B_1 are base altimeter readings in ft (m) of air; E_2, E_1 are elevations of stations in ft (m); V_2, V_1 are velocities of air in fpm (m/s); DR is average density ratio between stations 1 and 2; and $CONFAC$ is ft of air per in. water (m of air per Pa) pressure at the average altimeter reading between the two stations. Charts are available for the calculation of DR and $CONFAC$.

COMPUTER PROGRAMS. The altimeter survey calculations, though simple, are tedious and subject to arithmetical errors, particularly when extensive altimeter surveys are involved. Because of the sequential and repetitive nature of the calculations, the method can be easily programmed for a digital computer or a desk calculator and, for small surveys, for a hand-held calculator with small memory (Chapter 11.10). In view of the computer's ability to perform calculations at a very rapid rate and store information accurate to more than three or four decimal places, exact equations for conversion of velocity to velocity heads, for density determinations, and for conversion of ft (m) of air to in. water (Pa) can be used.

Chapter 11.7
MINE VENTILATION DESIGN

BRUCE JOHNSON AND RAJA V. RAMANI

11.7.1 METAL MINE VENTILATION

BRUCE JOHNSON

Metal mine (or noncoal mine) as used here refers to both metal and nonmetallic mines, including uranium mines. In most cases, these mines are not classified as gassy, that is, containing methane, although there may be other gases present such as radon or sulfur dioxide. The biggest differences in ventilation techniques between coal and nongassy metal mines in the United States are the permitted use of underground fans and recirculation or series utilization of air in metal mines.

Much of the discussion that follows is based on O'Neil and Johnson (1982). For coverage of ventilation principles, see Chapter 11.6; for air conditioning see Chapter 11.4.

11.7.1.1 General Considerations

AIR QUANTITIES. In most cases, air quantities are not determined by statute for metal mines, the exception being mines where radioactivity is present. Air quantities where diesels are used are determined from manufacturers' specifications or by testing and certification done on individual units by the US Bureau of Mines (USBM). For older uncertified units, it is generally satisfactory to allow 150 ft^3/min/bhp or cfm/bhp (1.0 m^3/s/kW) for each unit. For several units on the same split of air, the USBM recommends the full quantity requirement for the first unit, 75% of full quantity for the second unit, and 50% of the full quantity for each additional unit.

Otherwise, air quantities are usually determined by practical considerations and experience. Velocities even in main airways should not exceed 1500 ft/min or fpm (7.6 m/s) wherever possible, both for comfort and to reduce head losses due to friction, but this is not always possible where a large quantity of air may be needed to service an area.

Air velocities at a minimum always should be kept above 50 fpm (0.25 m/s), as this is about the lowest velocity at which air movement can be sensed; however, this requirement can be abrogated in large service bays.

In working places, air velocities should be 200 to 400 fpm (1.0 to 2.0 m/s) in stopes and 400 to 600 fpm (2.0 to 3.0 m/s) in drifts. These velocities are based on the author's experience in warm mines and may have to be reduced in cold mines.

OVERALL MINE LAYOUTS. In a shaft mine, intake air should be directed down the main man-materials shaft(s) and exhausted up some other shaft or shafts, preferably shafts sunk exclusively for exhaust. In an adit mine, the intake would normally be the adit(s) where people enter. Sometimes, a separate adit for exhaust would be used, which would be connected to the workings by raises and winzes. Some mines are close to the surface, and multiple boreholes can be used for ventilation.

AIR MOVING DEVICES. It is best, when possible, to have main fans located on the surface. This way, they can be accessed easily in emergencies, and routine maintenance or major repairs are facilitated. If the mine is hot, exhaust fans are preferred in order that the fans will not themselves add heat to the air. Where the mine is cold, the reverse would be true.

Generally, surface exhaust fans are preferred. However, where the mine contains numerous old open workings, exhaust fans will draw excessive air through areas where it is not needed. Sometimes the best solution is to have main surface exhaust fans supplemented by underground booster fans. If the exhaust shafts are also the hoisting shafts, surface location of the fans is impractical because of the design problem of moving skips through fan plenums. All things considered, though, the location of main fans on the surface is to be preferred.

BOOSTER FANS. Unlike coal mines, metal mines can usually use booster fans underground to either divert airflow or to give additional air moving power where needed. Booster fans are often needed in a situation where there are widely scattered areas being served by main fans. To facilitate distribution of air to remote areas, either a booster fan to move air to these areas is needed, or a larger main fan will have to be used to pressurize all areas. If a larger main fan is used, restrictions will then be needed in non-remote areas to waste the unneeded pressure to these areas and balance the system. Clearly, the second solution may be an unnecessary expense when boosters are applicable, although all possible solutions should be considered.

AUXILIARY FANS. These are relatively small fans used in directing air to individual faces or small areas. Where dead-end faces are to be ventilated, the air is delivered to (or exhausted from) the faces with duct connected to the fan.

In the case of large openings, auxiliary fans are often hung in main airstreams to divert the air into these openings with little or no duct connected to the fan. This is a common technique in room (stope) and pillar systems. A fan used in this manner is termed a "jet fan," as it not only moves the air that is passing through the fan but causes a vena contracta that sucks in additional air and moves it as well.

COMPRESSED AIR MOVERS. These work in the same manner as jet fans, but use a stream of compressed air emanating from an eductor to form the vena contracta. Compressed air movers are expensive from a power consumption point as it takes quite a bit of power to compress the air that they consume, but they are often applicable where only small amounts of air are needed and where fans may be impractical. At least one large American mine uses them extensively for secondary development and production ventilation.

REUSE OF VENTILATION AIR. Reuse of air is allowable in most metal mine situations, especially where the used air is mixed with fresh air, and this is normally preferred for economic reasons to using air only once. In most cases, there will not be much gas contamination, and oxygen depletion will be minimal. However, where dust or heat is a problem, filtration or cooling may first be needed. South African mines commonly use fume filters to extract nitrous oxide fumes from development blasting when blasting is done on shift, and also use baghouse filters at ore transfers located at intake shafts. However, these techniques are seldom employed in this country.

COURSING OF AIR. The normal way of coursing air is to direct the air to a stope raise and upcast it to the level above (a technique termed *ascentional ventilation).* This technique is used for two reasons: (1) most mines practice some sort of overhead mining method in which ore extraction is commenced at or just above the sill and proceeds upwards with successive cuts; and (2) in most mines, the rock is warmer than the ventilation air, so air is warmed as it rises, and this "chimney effect" aids airflow.

The design of ventilation for an individual stope is usually simple; the problem lies in the handling of air in a multilevel mine. An old practice, formerly used in the Coeur d'Alene, was to direct all air down the intake shaft to the lowest level of the mine, course it to the raises, and let it rise up throughout all the workings to the top active level, then direct it to the exhaust shaft(s).

This is an easy ventilation layout, but it has the obvious disadvantage of the upper stopes getting nothing but exhaust air from the lower stopes. While reuse of air is usually desirable for maximum utilization, there is also generally enough contamination with dust, gas, and heat that some addition of fresh air is necessary. Now if this addition is carried out on each level, with successive additions of fresh air, the upper stopes will have much more air than they need; besides, there are usually fewer stopes on the upper levels. This problem can be alleviated by directing some of the air up special exhaust raises or unused old stope raises.

Another solution is to have only alternate levels as intake levels, with the in-between levels serving as exhaust levels. This is a better method of handling air but necessitates special exhaust raises at the ends of the exhaust levels if the exhaust levels do not connect directly to the exhaust shaft(s). The disadvantage of the fresh air moving downward rather than upward in some areas is relatively slight and can easily be overcome with small exhaust fans.

11.7.1.2 Design Procedure

Generally, the design procedure for a metal mine is similar to that of a coal mine, except that devices such as booster fans are not presently allowed in American coal mines. For a design example, see 11.7.1.7.

1. Select main ventilation inlets and outlets.
2. From mining plans, determine the airflow requirements, and design tentative ventilation schematics. This must be done for various stages in the life of the mine.
3. Tentatively specify main and booster fan locations.
4. Determine airflow resistances for all branches, and build a computer model of the mine ventilation system.
5. Make simplified head loss calculations to initially determine fan characteristics.
6. Run a computer simulation of the ventilation system.
7. Adjust resistances, fans, etc., where needed, and rerun the model until computer output shows the model to be viable.
8. Consider alternate setups, and run alternate computer simulations on these alternates.
9. Review the planned setup with design personnel, and look over the plan from the standpoint of safety, for example, in case of fire in various areas, the time that would be needed for personnel working in remote parts of the mine to reach fresh air.

11.7.1.3 Ventilation Layouts for Specific Mining Systems

For details on the following mining methods, see Sections 18, 19, and 20.

OPEN STOPE: ROOM AND PILLAR MINING. Ventilation of this type of method is practically identical with that of coal mining. The main difference is the normally permitted use of underground fans in metal mining. Usually, diesels are employed and air quantities are predicated on the diesel units' requirements. Jet fans are frequently used to good advantage to direct air into rooms.

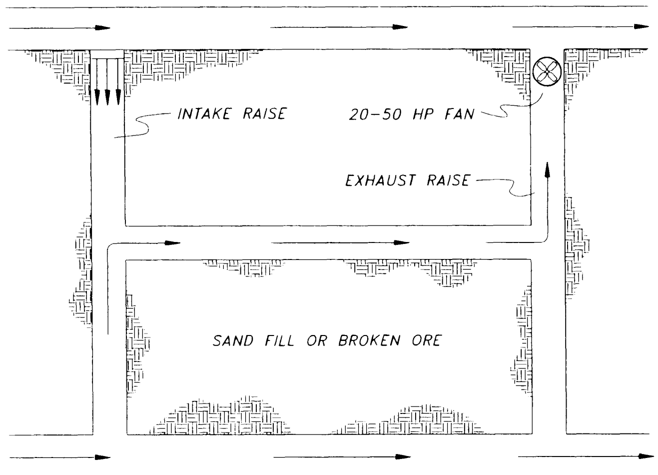

Fig. 11.7.1.1. Ventilation layout for horizontal cut-and-fill and shrinkage stopes. Conversion factor: 1 hp = 0.746 kW.

HORIZONTAL CUT AND FILL AND SHRINKAGE STOPES. This type of stope, at least theoretically, is the easiest to ventilate if developed in the normal manner (see Fig. 11.7.1.1) because there are raises on each end of the stope that are connected after the initial sill cut is made. The normal ventilation pattern is to bring air up one raise to the mining level of the current cut, direct it through the stope to the other raise, then up to the next level. Motive force for air movement between levels is best supplied by small exhaust fans, 20 to 50 hp (15 to 37 kW), at the tops of exhaust raises. Relying on brattices on the levels to maintain the desired pattern of airflow often results in poor distribution.

The initial sill cut will, of course, be dead-end until breakthrough into the next raise and must be ventilated as a breast stope, although if there are frequent open chutes that have already been driven up to the sill level, this will not be necessary.

BREAST STOPING METHODS: SQUARE SET, UNDERCUT AND FILL, SUBLEVEL CAVING. These methods are here classified as "breast stoping" because they all involve dead-end areas to be ventilated, as do drift headings, and these dead-end areas must be ventilated with auxiliary fans and ducts. Usually flexible rather than rigid duct is used because of the greater ease of handling of flexible dust and because of the brevity of life of the duct installation. If only one raise between levels is available, the air is directed up to the raise to an auxiliary fan at the sublevel being driven, coursed to the face, then exhausted back to the raise and up to the level above. Exhaust is preferably effected with an exhaust fan at the top of the raise.

Where multiple headings must be ventilated off the same raise, problems inevitably occur, especially if dust, heat, or exhaust gases are present (Fig. 11.7.1.2). Sometimes two compartments in the raise can be used, one dedicated to intake, the other to exhaust.

SUBLEVEL STOPES AND VERTICAL CRATER RETREAT (VCR) STOPES. These stopes are similar from a ventilation standpoint as they require sublevels. Air for the sublevels should be brought up the access raise, across the sublevel, and in the case of a sublevel stope, exhausted up through the open area. In a VCR stope, a second raise should be provided.

Draw in these systems is either from slusher trenches cut above the main level, or from extraction chambers crosscutting

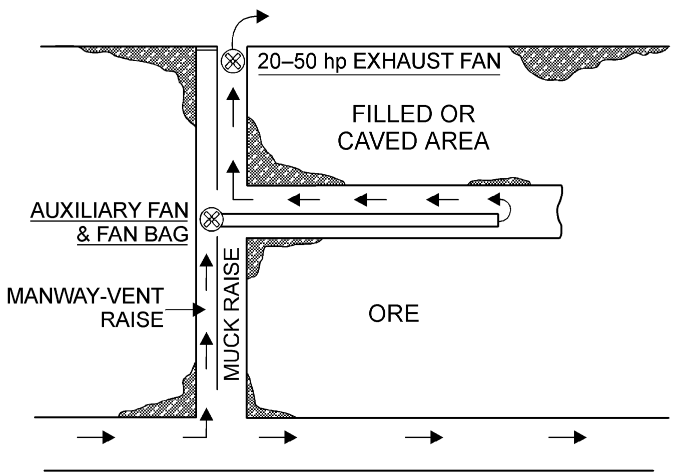

Fig. 11.7.1.2. Ventilation layout for breast stoping methods. Conversion factor: 1 hp = 0.746 kW.

into the ore body. The extraction chambers are located either on the main level or just above the main level. If the extraction area is above the main level, air should be brought up from the main level, directed across the trench or load-haul-dump (LHD) run, and then preferably up to the next level. In the case of sublevel stopes, exhaust can be through the open area. If extraction chambers are located on a main level, it is usually sufficient just to direct the air through the extraction area and back into the main drift.

BLOCK CAVING MINES. As far as ventilation is concerned, block cave mines are of two types: (1) both the ore control (grizzly) level and the haulage level are connected to the main shaft (or are separate adits); and (2) the haulage level is the only main level, and the control level is developed above the main level off raises from the main level.

In the first case, the air can either be brought across the control level into the blocks, then downcast to the haulage, or the two levels can be ventilated separately with an additional level or with special drifts serving for exhaust.

In the case where the haulage is the only main level, the air is brought across the haulage, up to the control level in each area by the mine, and is exhausted, preferably to a separate exhaust drift on the haulage level.

11.7.1.4 Control Devices

CONTROL DOORS. Control doors are installed in drifts and raises to divert air while permitting passage. These are best kept to a minimum as they are expensive to construct and maintain and tend to leak. Fire control doors are required by federal law to separate main intake shafts from possible contamination from mine fires. These must be fire-resistant and often require spray nozzles nearby. It is best to consult with Mine Safety and Health Administration (MSHA) inspectors before constructing them, as MSHA regulations governing these doors change frequently.

Where the pressure is more than about 1 in. water (250 Pa) across a door, an airlock composed of two doors in the drift is best, as opening a door against a lot of pressure is difficult, even with mechanical devices, and eventually results in damage to the door. The airlock should be long enough to accommodate a train of the length normally used at the particular mine. An airlock has the added advantage of always having one door in service if the other is damaged, and thus minimizes sometimes intolerable reversal of air currents.

Doors in small drifts can be made of double layers of ¾-in. (19-mm) plywood suspended on long steel hinges. The cracks around the door can be sealed with brattice cloth.

Wooden doors have the advantages of being cheap, easy to build, and fitting perfectly to the frame so that there is practically no leakage. But they have the disadvantages of soon wearing out and of usually being damaged beyond repair if struck by a locomotive.

Where drifts are wider, 12 ft (3.6 m) or greater, steel double doors or sometimes roll-up doors are better. Steel double doors can be fabricated from ⅛-in. (3-mm), mild steel plate with pipe or angle iron braces on one side. They are commercially available. Steel doors usually have to be opened with mechanical devices; these are often compressed air cylinders, although electric motors can also be used.

A compressed air cylinder is often mounted at the top of the door; the cylinder arm pushes the door closed and pulls it open. Another method is to mount the cylinder upright and connect the arm to a cable that goes through a pulley and then to the top of the door. The door is pulled open by the cable when the arm is retracted. When the arm is extended, the door is pulled closed by a counterweight attached via a cable and pulley to the other side of the door. This latter arrangement is sometimes better, as it is often difficult to properly maintain alignment when the door is pushed directly by the cylinder arm, and the cylinder will be badly damaged if the door is struck severely by a locomotive.

Roll-up doors can sometimes be used, but they are impractical for differential pressures greater than 1 in. water (250 Pa). Steel sectional roll-up doors can be used for fire control doors only if the anticipated differential pressure is sufficiently low. But steel roll-up doors will be completely ruined if struck by a motor (and, inevitably, they are), so are often impractical for normal air control doors.

Rubber roll-up doors are available, and these will not be damaged if struck; they will simply be pushed out of their guides and will have to be snapped back into the guides. But again, these are impractical for differential pressures greater than 1 in. water (250 Pa).

DOOR ACTUATING DEVICES. Steel-hinged doors are commonly opened by compressed air cylinders as described above or by electric motors, although electric motors open the doors rather slowly. Activation of either is best done by a remote device as the motorman approaches the door. These devices should be manually operated pull cords or pushbuttons. While such things as photoelectric cells or switches in the track will work, they are often difficult to keep maintained properly in the adverse conditions of underground mines.

Usually the electrically actuated valve that controls the air cylinders at a door is activated by a pull cord in the back of the drift, or by a pushbutton mounted on the rib. The latter arrangement is preferable as motor crews are forced to stop the train to reach the button. If the door is opened by a pull cord, there is just too much temptation to yank the cord on the fly instead of stopping. A missed cord, or a malfunctioning switch, and there is much likelihood of a wreck.

The worst disadvantage of automatic devices is that they are not "miner-proof." A motorman approaching a door activated by a remote device will expect it to open, and if there is a delay, or the device is malfunctioning, or speed is misjudged, a smashed door and possible human injury might result. Even a manually activated device should have overrides at the door itself so the door can always be opened.

Manway doors at the sides of main doors are also desirable in case the main door cannot be opened for some reason, as well as to minimize wear and tear on the door by not having to open it for foot traffic.

BRATTICES AND STOPPINGS. Brattices or stoppings to divert airflow can be built in a variety of ways. Cement block construction as used in coal mines is one technique, and is often preferable if the stoppings are permanent and the spaces to be crossed are wide, but their construction is labor intensive.

Poured concrete bulkheads can also be constructed if the mine is one that uses concrete in its operations and is therefore set up to handle concrete. Mines that do not would have to bring in the dry cement and gravel and employ mixers to mix the cement on the spot, which would be labor intensive. Of course, forms must first be constructed.

The simplest brattice is one made by stretching brattice cloth across an opening. The cloth may be fastened to the rock by studs shot into the rock, by constructing a timber set around the periphery, or by rock-bolting wooden plates to the ground around the periphery and fastening the brattice cloth to the plates. Velcro-fastened brattice cloth is available and has the advantages of permitting passage of personnel and of the velcro fasteners opening in case of a nearby blast, rather than having the brattice cloth tear. Of course, this type of brattice is leaky and easily damaged and is not recommended for long-term applications.

Wooden brattices can be quickly constructed if the openings are not too high. Such brattices can be better sealed by tacking brattice cloth over them, or, if more permanent use is desired, by covering the brattice with metal lath and plastering or shotcreting the brattice. The lath can be run back along the rock for a few inches (tens of millimeters) and the plaster or shotcrete applied over onto the rock to make a good seal. However, these seals will crack with ground movement. Plasters specially developed for mines are available; normal gypsum plaster used in house interiors will not work, as it is not waterproof. The plaster can either be troweled on or applied with guns.

Covering a wooden brattice with polyurethane foam is another method of minimizing air leakage, although the foam itself does permit some air passage. However, regulatory agencies sometimes prohibit the use of polyurethane foam.

There are some commercially available temporary brattices that are made of light cloth that balloon out with the ventilation air pressure and fill the opening. These are limited to areas where there is a sufficient differential pressure to fill the brattice.

11.7.1.5 Development Ventilation

This segment describes ventilation methods for drift headings, raises, shaft sinking, and other areas where ventilation of a dead-end face is necessary. Some manner of directing air to the face, or exhausting it from the face, must be provided.

DRIFT HEADINGS—GENERAL CONSIDERATIONS. Drift faces are often far removed from fresh air sources and require several fans working in series to provide ventilation. The fans are best placed along the length of the duct at about the points where static pressures in the dust have dropped back to atmospheric (in the case of fans blowing to the face) or where the pressures at fan discharges will be just below atmospheric (in the case of suction systems).

Ventilation of headings is greatly facilitated if two parallel drifts are being driven. In this case, crosscuts can be cut every few hundred feet (about 30 meters) between the drifts; auxiliary fans will then only be needed from the last crosscut to the headings, as air can be coursed in through one drift and out through the other. Of course, this type of ventilation is feasible only if it

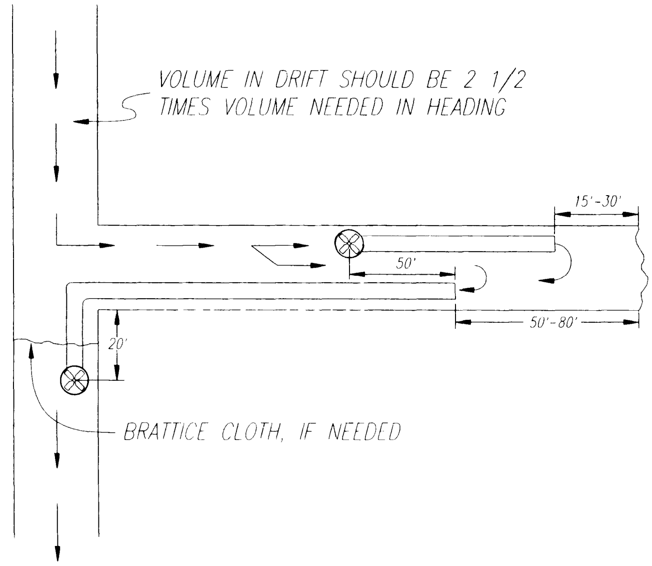

Fig.11.7.1.3. Exhaust overlap ventilation for development headings. Conversion factor: 1 ft = 0.3048 m.

is necessary to drive the two drifts anyway. It is usually not economical to drive a second drift just to facilitate development ventilation.

A similar plan can be used if two levels are parallel and are being advanced simultaneously; raises can be cut between the two levels at frequent intervals.

It is usually impossible to maintain the optimum air velocities in development that are given at the beginning of this chapter; the ventilation engineer does well to have 50 fpm (0.25 m/s) moving through most drifts. The reason, of course, is the difficulty of moving the larger quantities of air through a duct. A compromise, when blowing ventilation is used, is to have the duct discharging near the face and directing fairly high-velocity air onto the worker near the face. Ventilation in this manner is optimum when the air velocity emanating from the duct is between 600 and 1000 fpm (3 and 5 m/s).

EXHAUST vs. BLOWING VENTILATION. Air can be drawn away from the face, in which case it travels through the drift and out through an exhaust duct carried about 15 ft (4.6 m) from the advancing face, or the air can be directed to the face with a duct, in which case the air leaves the face through the drift. The former is preferable when dust and/or gases at the face are problems, the latter when heat at the face is a problem. A combination of the two methods is the exhaust overlap system (Fig. 11.7.1.3) in which prime motivation is supplied through the exhaust duct, but a portion of the air moving along the drift toward the face is drawn out with a small fan and directed to the face. This is usually done about 50 ft (15 m) from the exhaust duct inlet.

In blowing (forcing) ventilation, the advantages are those of having a positive airblast on the miners at the face, the possibility of using flexible duct with its greater versatility and lower cost, and of being able to cool the inlet air if needed.

LOCATION OF AUXILIARY FANS. When auxiliary fans are utilized to divert air from a moving airstream to a dead-end face, the fan should be located about 20 ft (6 m) from the upstream side of the turnout. The air quantity moving in the main airstream should be 2.5 times that being diverted by the auxiliary fan to minimize the possibility of exhaust air from the face being recirculated back to the fan. This is not always possible, as sufficient air is often not available. If not, a brattice curtain across the main airstream between the turnout and auxiliary fan should be used (Fig. 11.7.1.3).

VENTILATION DUCT. Duct or tubing used in mines is commonly of fiberglass, corrugated iron, or plastic-impregnated cloth; the latter is usually referred to as "fan bag" or "vent bag." Fiberglass has the advantages of being light, having low resistance to airflow, and being easily repaired if damaged; it is flexible to some extent, and will maintain its shape under light to medium impact. The fiberglass duct is usually suspended from the back with light cables wrapped around the duct, which are attached to caps or roof bolts. The small rings attached to the duct by the manufacturer are to facilitate handling and are not for suspending the duct.

Fiberglass duct is either of the bell-and-spigot type or is straight; when straight, lengths are connected with rubber connectors. This duct is commonly supplied in 10-ft (3-m) lengths. The bell-and-spigot type is generally better, as it is quicker to install and the joints are tighter. Tees, laterals, and elbows are available for all sizes; tees and laterals can be purchased with contained dampers to facilitate directing the airflow. Oval duct is available as well as round; oval is more expensive than round, but is sometimes better where clearance is a problem.

Corrugated galvanized-iron duct is cheaper than fiberglass but is heavier and more difficult to install. It can either be fastened together with the metal sleeves that are supplied with the duct or with short sewn lengths of brattice cloth that are clamped onto each length of duct with metal bands. Corrugated iron is easily knocked out of shape when being moved and is therefore not as reusable as fiberglass; it is adversely affected by wet conditions.

Plastic-impregnated cloth fan bag is available from several manufacturers. This can, of course, only be used for blowing applications although spiral wire-reinforced tubing can be used at low exhaust pressures. This duct is easy to transport as it can be contracted for handling, is very easy to install, and is relatively cheap. It can be purchased with suspension hooks fastened to the duct. The material is fairly resistant to tearing and to damage from flying rock, but cannot be compared to the solid ducts for durability. However, this is sometimes an advantage, as drops can be sewed into already installed duct when it is desired to split some air off at a certain point.

Flexible duct is more resistant to airflow than is rigid duct, and often is not reusable, especially if it has been in place more than a few months, as it becomes hard and brittle. Another problem is that flexible duct needs a certain amount of retained static pressure all the way to its discharge point to remain distended, usually about ½ in. water (125 Pa). The retained static pressure is turned into a shock loss at the end of the duct. This disadvantage can be minimized by stretching the duct taut and by using flexible duct with a ring sewn in at the ends.

Flexible duct is fastened together with various devices available from the manufacturers. Tees and laterals are also available, although some mines using large amounts of this material find it more economical to sew their own. This sewing can be done with sailcloth needles and light hemp or nylon twine. The work is best done by a person specially assigned to this work, usually an older miner, as it requires some practice and patience to do a good job.

Another type of flexible duct has wire sewn into it in a spiral, and usually comes in 10-ft and 20-ft (3-m) lengths. This accordion-type duct is rather awkward to handle, is very resistant to airflow, and should only be used occasionally where a short suction duct is needed, to turn flexible duct around a corner, or to direct air over some obstruction.

The size of duct used, whether rigid or flexible, varies with the airflow desired and the clearance available. Charts giving resistance values of various duct sizes are available from manufacturers. In general, it is best to use the largest-diameter duct possible for the headroom available in order to maximize airflow and minimize resistance; however, mines should standardize on no more than four sizes for simplification of supply. When planning an installation, be sure to determine the pressure to which the duct will be subjected and whether it will be blowing or exhausting so that the manufacturer can select the material accordingly.

QUANTITY REQUIREMENTS IN DRIFT DEVELOPMENT. Quantity requirements vary, of course, with the situation. If diesels are being used, or if radon or other gases are being emitted from the face, minimum air quantities are determined by statute. However, where such situations do not exist, the following quantities may be used as guidelines.

In relatively small headings, say 10 ft (3 m) square, air quantities should be between 3000 and 10,000 cfm (1.4 and 4.7 m^3/s). In larger headings, say 15 ft (4.6 m) square, increase the quantity to 20,000 cfm (9.4 m^3/s). Very large headings may require up to 30,000 cfm (14.2 m^3/s), but quantities greater than this are seldom necessary.

RAISES AND SMALL HEADINGS. Raises are usually small in cross section, and ventilation is simple; just use flexible ducting from an auxiliary fan and carry the duct near the face; quantity should be about 6000 cfm (2.8 m^3/s). At blast time, draw the duct back from the face to avoid damage, but keep air blowing to facilitate smoke dispersal.

Other small development headings, like block cave undercuts, are ventilated in the same manner as raises.

SHAFTS. Shaft sinking operations are best ventilated by the exhaust overlap system, as for drifts. Normally, when only one duct is to be used, suction ventilation is preferable. However, where heat is a problem and only one duct is to be used, it is a good idea to install the fan into the duct at the collar as a blowing fan, with a reversal system so as to have the duct on suction at blast time, and to have it blowing when personnel are at the bottom. Air quantity in a large shaft should be 30,000 to 40,000 cfm (14.2 to 18.9 m^3/s).

11.7.1.6 Case Studies of Ventilation Systems

The ventilation systems described in this segment are typical of those used by modern mines. They are not necessarily to be construed as "ideal" systems, but usually represent the best layout obtainable within operating and cost constraints.

BLOCK CAVING MINES: *San Manuel Mine*—This mine is developed by driving pairs of grizzly and haulage levels 60 ft (18.3 m) apart; there is a 300-ft (91.5-m) elevation between level pairs (Fig. 11.7.1.4). Intake is by a pair of man-materials shafts on the east end of the mine; these intake shafts are connected to all levels. Exhaust is via the four hoisting shafts on the west end of the mine; the exhaust shafts are only connected to the haulage levels. Motivation for airflow is by main intake fans near the intake shafts on the grizzly levels.

Air leaving the intake fan on each grizzly level is coursed along the north periphery of the ore body and enters through panel drifts driven into the ore body and along the strike. The air then is directed through the grizzly lines to 20-hp (15-kW) exhaust fans which are located in raises connecting the grizzly level to the haulage level; these raises hole into intermediate drifts that are driven between panel drifts. Additional boosting for ventilation air through individual grizzly lines is provided by compressed air movers that are used only when muck is running; inactive grizzly lines are bratticed off. A quantity of 3000 to

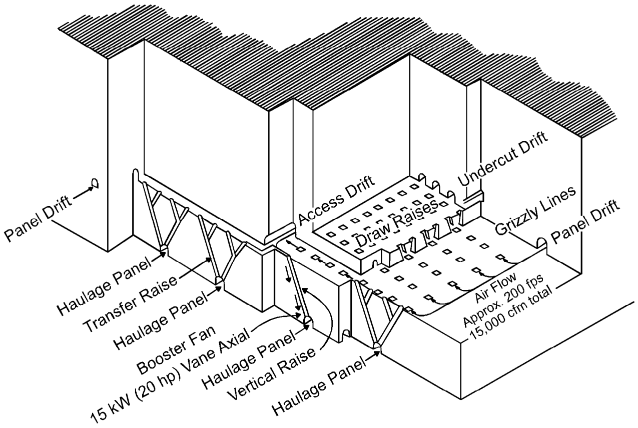

Fig. 11.7.1.4. Ventilation layout of San Manuel mine. Conversion factors: 1 fpm = 0.0051 m/s, 1 cfm = 0.472×10^{-3} m^3/s.

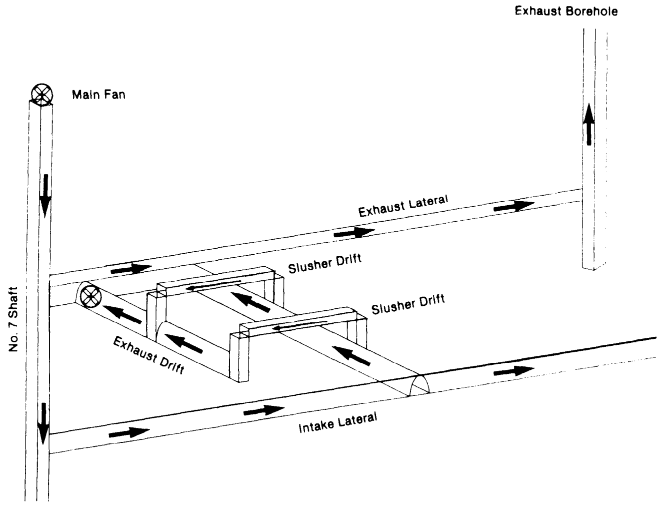

Fig. 11.7.1.6. Ventilation layout of Climax mine (after Smith, 1988).

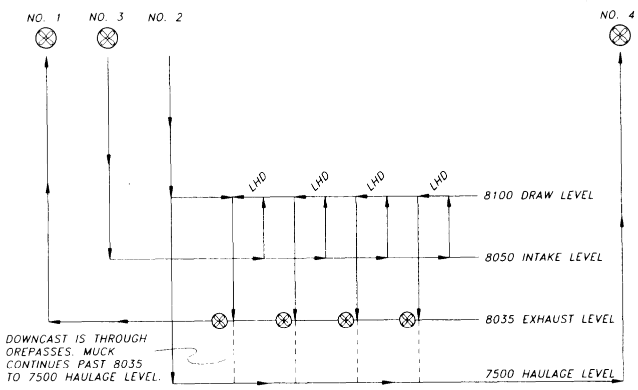

Fig. 11.7.1.5. Ventilation layout of Henderson mine (Knape, 1985).

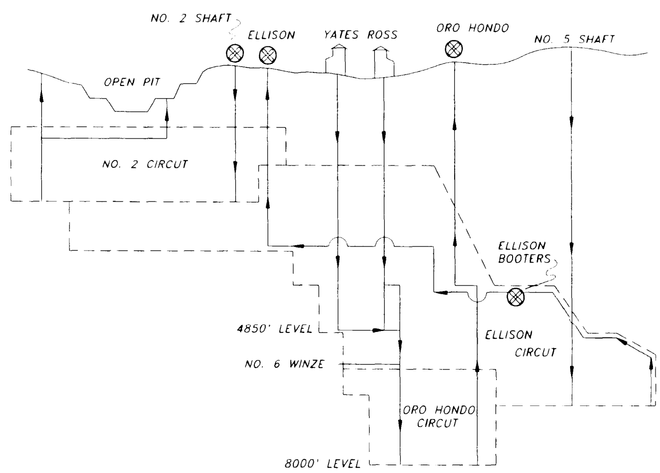

Fig. 11.7.1.7. Ventilation layout of Homestake mine (Marks, Struble and Brown, 1987, by permission: SME).

6000 cfm (1.4 to 2.8 m/s) is provided for each grizzly line being worked.

In areas where LHDs are used, grizzly lines are replaced by draw drifts that access the caving ore via chambers driven at the sides of the draw drifts. Here one exhaust raise fan to the haulage level is provided for each draw drift, and jet fans are used for moving the air rather than compressed air movers.

Henderson Mine—Air is downcast through No. 3 shaft and directed across the 8050 intake level to the production area (Fig. 11.7.1.5). Air is then upcast to individual draw drifts on the 8100 level where LHDs are in use. Fresh air travels past the LHD and downcasts the ore pass in which the LHD is dumping and is drawn off the orepass on the 8035 exhaust level by booster fans; the muck continues down the ore pass to the 7500 haulage level. Air travels across the 8035 level to exhaust at No. 1 shaft. Main intake fans are located at the collar of No. 3 shaft, and main exhaust fans at the collar of No. 1.

The 7500 haulage level is ventilated by a separate intake shaft, No. 2, and a separate exhaust shaft, No. 4. Motivation for this system is by exhaust fans at the collar of No. 4.

Climax Mine—This was the older type of block cave that did not have separate connections to the main openings for the draw-control and haulage levels (Fig. 11.7.1.6). In the latter days, production was from the 600 level, which was below surface level, and from the Storke level, which was accessed by an adit. Air was downcast through No. 7 shaft via intake fans located at the collar, then traveled through a ventilation intake lateral and into the haulage drifts.

Air upcast to each scraper drift from the haulage drift; scraper drifts were driven just above and at right angles to the haulage drifts. Air traveled to the end of the scraper drifts and downcast to exhaust drifts, one of which was driven between each pair of haulage drifts and parallel to them; motivation was provided by exhaust fans in the exhaust drifts. Air was then gathered into exhaust laterals and conducted to raises that exhausted up into the open pit. There were also some exhaust fans in the main exhaust laterals.

Underground operations at Climax ceased in 1987.

STOPE MINES: *Homestake Mine*—The mine is ventilated by three relatively independent circuits (Fig. 11.7.1.7). For the upper part, No. 2 shaft is the intake; there is an intake fan at the collar of this shaft, and exhaust is via raises that break into an open-cut mine. The mid-depth part of the mine intakes via No. 5 shaft with exhaust up Ellison Shaft; fans are underground boosters and an exhaust fan at the collar of the Ellison. The deepest part of the mine is designated the Oro Hondo Circuit; intake is via Ross Shaft, and exhaust is up Oro Hondo Shaft,

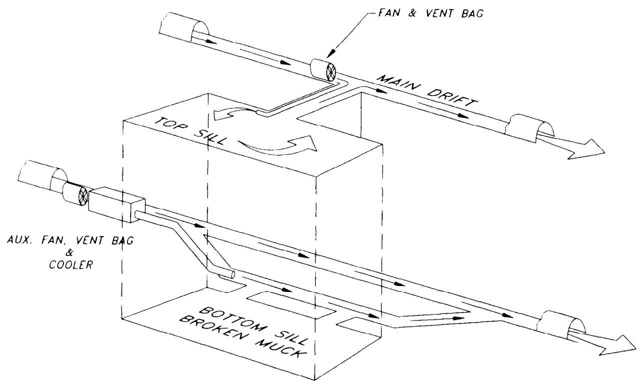

Fig. 11.7.1.8. VCR stope ventilation at Homestake mine (after Lappin-Randolph, 1987; Marks, 1988).

with main air motivation supplied by an exhaust fan at the collar of the Oro Hondo.

Most mining nowadays is with overhand cut and fill or vertical crater retreat (VCR) stoping systems. In the cut and fill system, air is directed into the stope with auxiliary fans from the drift on the bottom level of the stope; air is often blown through a cooler before entering the stope. Exhaust is through ventilation boreholes that are sunk from the upper main level of the stope along the strike of the stope in its early days of development. A quantity of 25,000 cfm (11.8 m^3/s) is provided for each cut and fill stope that uses extensive diesel equipment; smaller stopes that employ only compressed air machinery need 7000 cfm (3.3 m^3/s).

In the VCR method (see Fig. 11.7.1.8), it is necessary to provide ventilation for the top sill of the stope, from whence downholes are drilled to the bottom sill and loaded, and to the bottom sill of the stope where the muck is picked up; both these sills are driven by crosscutting from main level drifts. In the top sill, air is directed through an auxiliary fan to the face through vent bag. In the bottom sill, ventilation is flow-through since there are crosscuts in either end of the sill to the drift; air is directed through an auxiliary fan and ventbag to the muck bays that connect into the broken muck area; coolers are often used in line with the auxiliary fans. An airflow of 7000 cfm (3.3 m^3/s) is allowed for top sills, and 9000 to 15,000 cfm (9.9 to 7.1 m^3/s) for bottom sills.

Sunshine Mine—Air intakes the Jewell shaft and is divided into east and west ventilation districts. Initial motivation power is provided by underground boosters near the Jewell (Fig. 11.7.1.9). Air is then coursed through a series of winzes and raises to be distributed to the workings. Main exhaust is up the Bighole shaft, which is furnished with surface exhaust fans. Some supplementary exhaust is through the Sunshine tunnel and Silver Summit shaft. Details on stope ventilation were not available.

Mount Isa Mine—The overall ventilation layout of this mine is complex and beyond the scope of this article. However, stope ventilation can be described.

Footwall and hanging wall drifts are driven on each sublevel around the periphery of the ore body; these drifts either connect directly to shafts or to inclines between main sublevels. Stopes do not extend along the full width of the ore body, so several crosscuts connect the drifts, and air is supplied off these crosscuts to individual stopes (Fig. 11.7.1.10).

The stoping method used is sublevel stoping with ring drilling. Initial development is to bore a cutoff raise in the middle of the stope and slash this out to the stope width. Sublevels are driven along the stope length to intersect the cutoff raise. The raise connects to an exhaust horizon above the top of the stope, and to a fill conveyor level above the exhaust horizon. Air is supplied to the sublevels either directly via footwall pressure shafts, or via access ramps and fresh air raises. Air courses through sublevels and exhausts up the stope cutoff raise through an exhaust fan on the exhaust horizon. In stope development, auxiliary fans supply the faces of the sublevels before they connect to the cutoff raise; sometimes these fans continue to be used once hole-through to the cutoff raise is effected. About 15,000 cfm (7 m^3/s) of air per sublevel is needed.

Magma Mine—Ventilation is by downcasting No. 9 shaft, the main men-materials hoisting shaft, and upcasting No. 6 shaft, which is located west of the active workings (Fig. 11.7.1.11). Supplemental exhaust is supplied through a series of raises that connect to No. 4 shaft in the old western portion of the mine. Three of the shafts in the western portion supply intake ventilation for the older, inactive part of the mine. Motive power is provided by intake fans near No. 9 shaft that blow through cooling coils, and by main exhaust fans at the collars of both exhaust shafts. Some large underground exhaust booster fans are also used.

The ventilation pattern is to intake alternate levels from No. 9, upcast and downcast the air to the levels between the intake levels through mining raises, and then direct the air to the exhaust shafts. This is the ideal situation, although not always possible.

The mining method employed is undercut and fill stoping, principally in a replacement deposit that dips at a 30° angle. A raise was driven between levels, and two stopes started off each raise. One stope was just below the top sill, the other about halfway between levels. Stoping proceeds downward, with cuts on each sublevel being filled before the cut on the sublevel below is begun. Extraction of the ore on each sublevel is by an initial sublevel crosscut being driven along with the footwall, then by parallel cuts (termed panels) being driven across the dip of the ore from the crosscut to the hanging wall. About three panels are driven at a time; the panels are then sand-filled, and new panels driven. This sequence continues until the sublevel is mined out. Ventilation is supplied by drawing air off the raise and directing it to the faces of the various panels with auxiliary fans, then exhausting up another raise to the level above. The exhaust raise is often furnished with an exhaust fan at the exhaust level. A quantity of 6000 cfm (2.8 m^3/s) per active panel in each stope is allowed.

11.7.1.7 Design Calculations

Example 11.7.1.1. A gold mine is to be developed to an ultimate depth of 1500 ft (457 m). Levels are to be 100 ft (30 m) apart, starting with the uppermost level at a depth of 1000 ft (305 m). Two stopes per level pair are normally in production, with a total of five to six stopes at any one time.

The main hoisting and intake air shafts are circular, with a diameter of 15 ft (4.6 m). Exhaust is by an 8-ft (2.4-m) diameter bored shaft on the other end of the ore body from the intake shaft. Drifts are to be 10 by 10 ft (3 by 3 m) in cross section and timbered. Stoping is by the shrinkage method, with a raise at either end of each stope; ventilation of individual stopes is by upcasting one raise and exhausting up the raise at the other end. Raises have 3 by 3 ft (1 by 1 m) available for air passage. Stopes are 100 ft (30 m) long between raises, and have the same cross-sectional area as the drifts. Layout of the mine at its ultimate extent is as shown in Fig. 11.7.1.12.

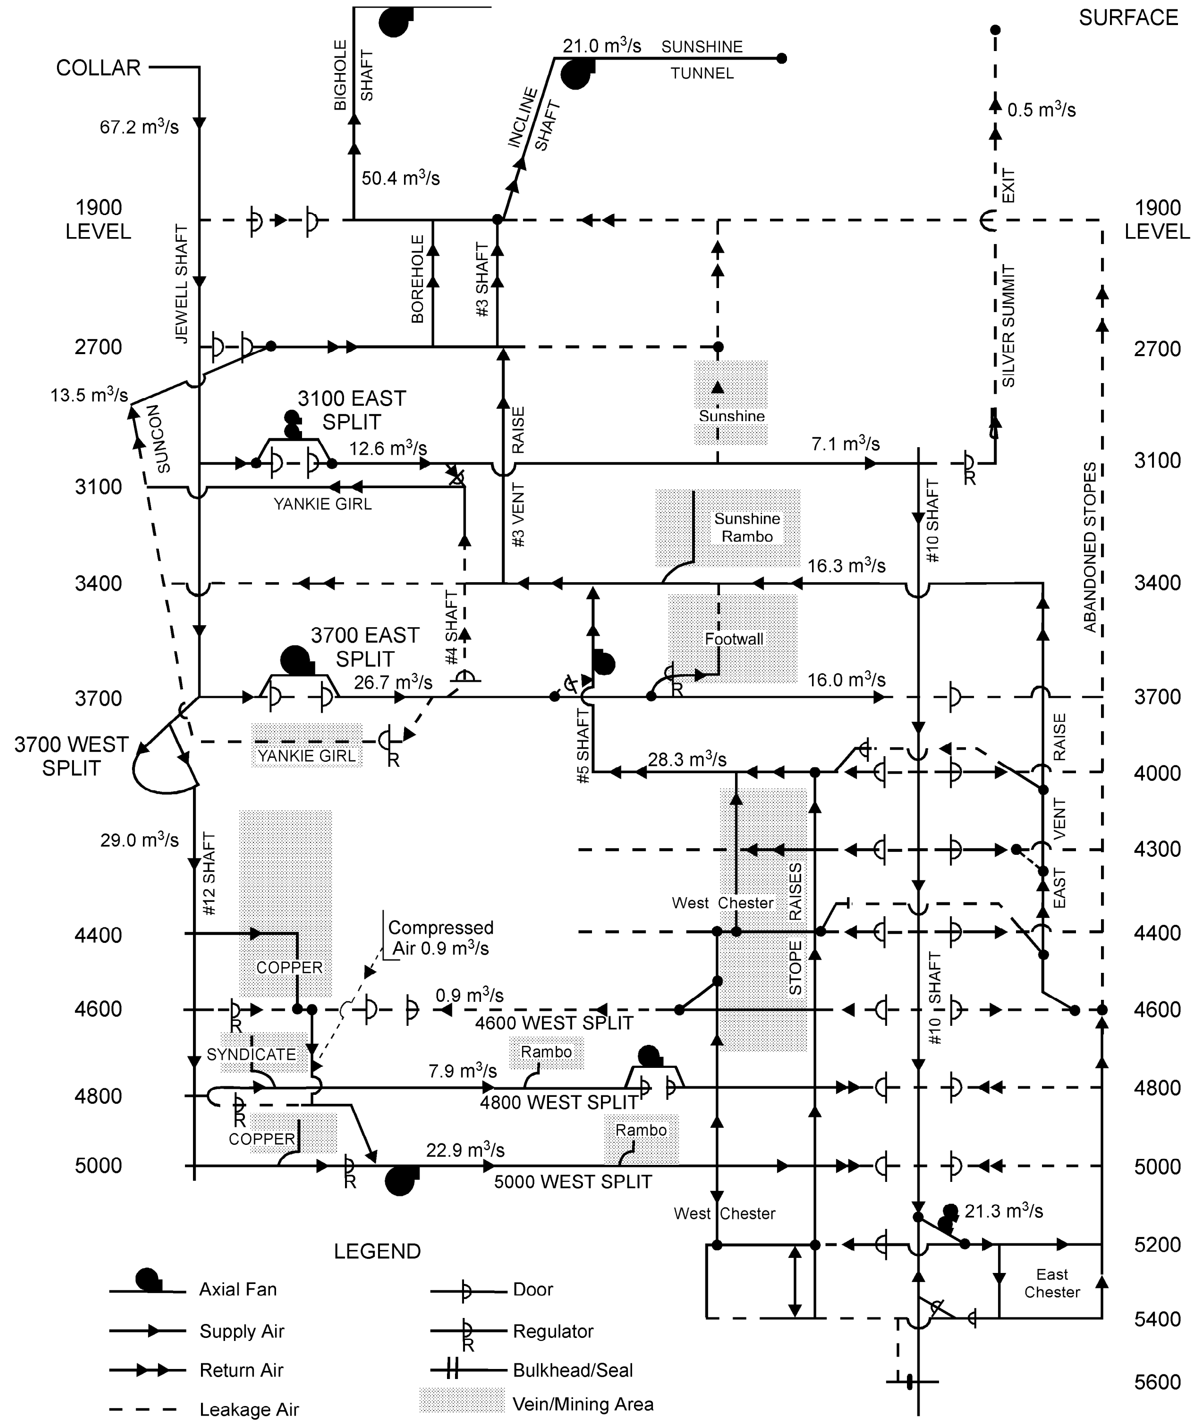

Fig. 11.7.1.9. Ventilation layout of the Sunshine mine (Jurani, 1977, by permission: SME). Conversion factor: 1 cfm = 0.472×10^{-3} m³/s.

Following the procedure given in 11.7.2, a ventilation system is designed as follows:

1. Select main ventilation inlets and outlets. This has already been done.

2. From mining plans, determine the airflow requirements, and design tentative ventilation schematics. An intake on alternate levels, with upcast to the level above, is to be used. Airflows are shown on the schematic, with no reuse of air. A velocity of 100 fpm (0.5 m/s) is used for airflow in the stopes and a minimum airflow of 200 fpm (1.0 m/s) on the levels.

3. Specify main and booster fan locations. A main exhaust fan at the top of the exhaust shaft is specified. Initially, booster fans are not being considered.

4. Determine airflow resistances for all branches, and build a computer model of the ventilation system. The resistances R in

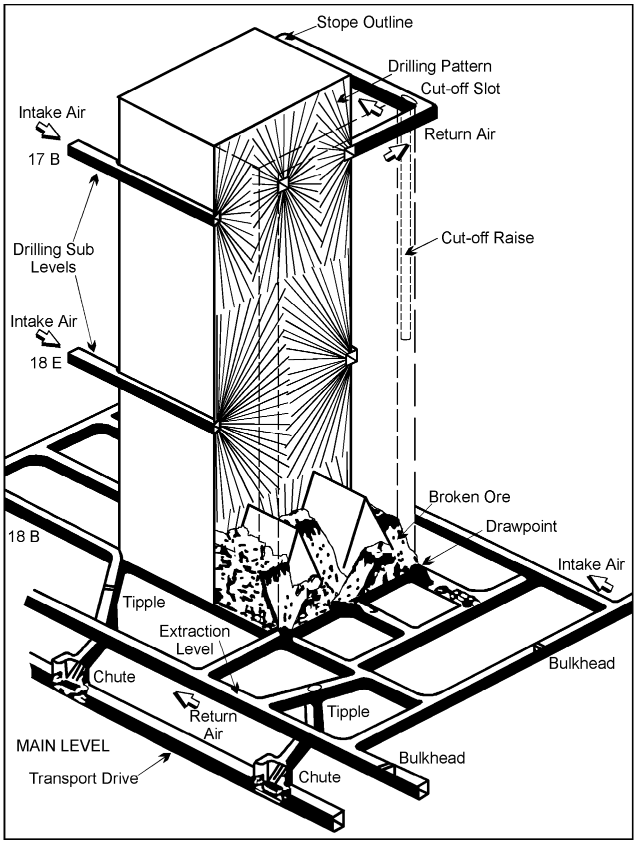

Fig. 11.7.1.10. Stope ventilation at Mt. Isa mine (Allen, 1976. By permission of the Mine Ventilation Society of South Africa, Johannesburg).

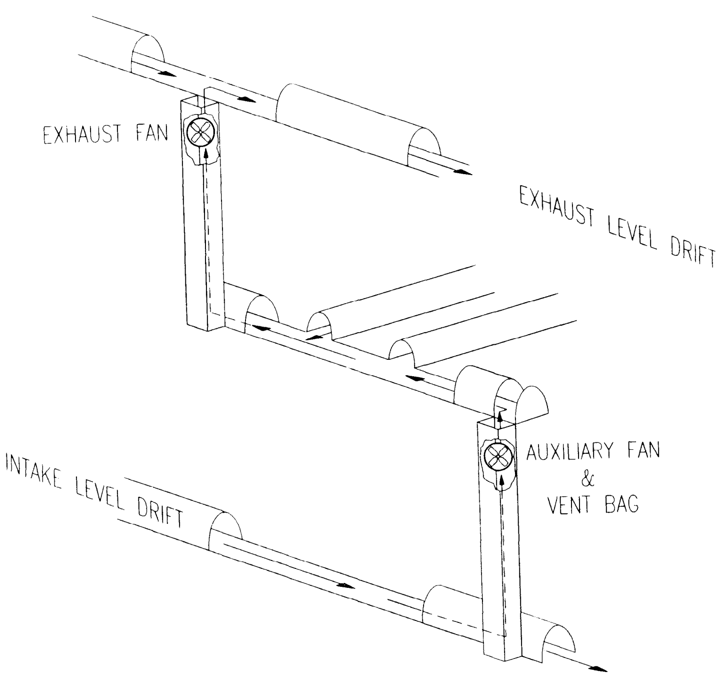

Fig. 11.7.1.11. Stope ventilation at Magma mine.

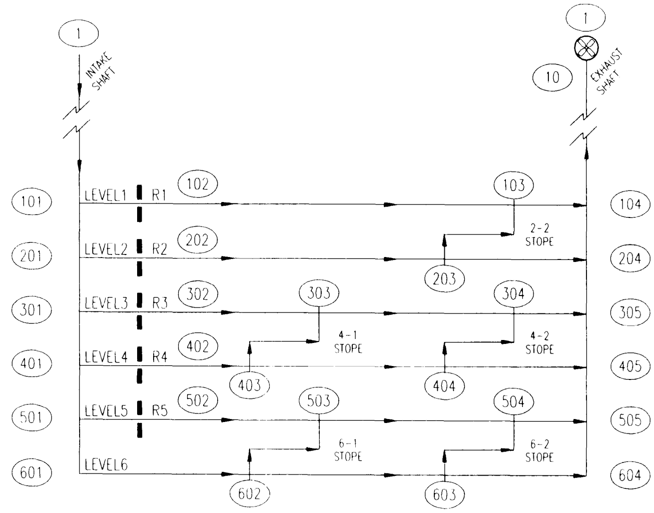

Fig. 11.7.1.12. Schematic of mine, Ex. 11.7.1.1.

in.-min^2/ft^6 (N-s^2/m^8) are calculated from the familiar Atkinson equation (see Eq. 11.6.15):

$$R = \frac{KLP}{5.2A^3} \tag{11.7.1.1}$$

in which K is friction factor in lb-min^2/ft^4 (kg/m^3), P is the airway perimeter in ft (m), L is airway length in ft (m), and A is airway area in ft^2 (m^2).

Resistances are calculated in terms of resistance/l00 ft (30 m), except for stopes; the stopes all have practically the same dimensions, so the same resistance for each suffices.

Equations employed in these calculations were derived and demonstrated in Chapter 11.6.

Solution.

A. Intake Shaft. Resistance calculation here is somewhat difficult, as the moving conveyances have some effect on the resistance, and the shaft fixtures must be taken into account. However, the procedure is simplified in this case by calculating the resistance as if the shaft were unobstructed and then increasing the resistance by 25% to allow for the shaft fixtures and conveyances. Use a K factor of 30×10^{-10} lb-min^2/ft^4 (5.6×10^{-3} kg/m^3) from Table 11.6.3 (see Chapter 11.6):

$$R = \frac{(30 \times 10^{-10})(15\pi)(100)}{5.2\left(\frac{15^2}{4} \times \pi\right)^3} \times 1.25$$

$$= 0.062 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6/100 \text{ ft } (0.0069\ N\text{-}s^2/\text{m}^8)$$

B. Calculate the R factor of the timbered drifts. Use a K factor of 100×10^{-10} lb-min^2/ft^4 (18.6×10^{-3} kg/m^3):

$$R = \frac{(100 \times 10^{-10})(4 \times 10)(100)}{5.2(10 \times 10)^3}$$

$$= 0.0769 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6/100 \text{ ft } (0.0086\ N\text{-}s^2/\text{m}^8)$$

C. Calculate the R factor of the exhaust shaft. Use a K factor of 15×10^{-10} lb-min^2/ft^4 (2.8×10^{-3} kg/m^3):

Table 11.7.1.1. Calculation of Head Loss for the Most Resistant Circuit of Ex. 11.7.1.1

Node 1	Node 2	Length, ft	$R \times 10^{-10}$/100 ft	Air Quant, kcfm	Hd. loss in. water
1	101	1000	0.0620	170	0.179
101	201	100	″	150	0.140
201	301	100	″	120	0.089
301	401	100	″	100	0.062
401	501	100	″	60	0.022
501	601	100	″	40	0.010
601	503	—	34.9749 (total)	1	0.350
503	504	300	0.0769	30	0.021
504	505	300	″	40	0.037
505	405	100	0.0571	60	0.021
405	305	100	″	80	0.036
305	204	100	″	120	0.082
204	104	100	″	140	0.112
104	10	1000	″	170	1.650
TOTAL					2.81

Conversion factors: 1 ft = 0.3048 m, 1 kcfm = 0.472 m^3/s, 1 in. water = 250 Pa, 1 in.-min^2/ft^6 = 11.17×10^{10} N-s^2/m^8.

$$R = \frac{(15 \times 10^{-10})(8\pi)(100)}{5.2\left(\frac{8^2}{4}\pi\right)^3}$$

$$= 0.0571 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6/100 \text{ ft } (0.0064\ N\text{-}s^2/\text{m}^8)$$

D. Calculate the R factor of each slope. Use $K = 110 \times 10^{-10}$ lb-min^2/ft^4 (20.4×10^{-3} kg/m^3) for the raises and $K = 200 \times 10^{-10}$ lb-min^2/ft^4 (37.1×10^{-3} kg/ms^3) for the sublevel.

(1) Raises:

$$R = \frac{(110 \times 10^{-10})(4 \times 3)(100)}{5.2(3 \times 3)^3}$$

$$= 34.8211 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6\ (3.890\ N\text{-}s^2/\text{m}^8)$$

(2) Sublevel:

$$R = \frac{(200 \times 10^{-10})(4 \times 10)(100)}{5.2\ (10 \times 10)^3}$$

$$= 0.1538 \times 10^{-10} \text{ in.-min}^2/\text{ft}^6\ (0.0172\ N\text{-}s^2/\text{m}^8)$$

(3) Total: $R = 34.9749 \times 10^{-10}$ in.-min^2/ft^6 (3.907 N-s^2/m^8)

E. Calculate the head loss of the most resistant circuit of the mine, using Eq. 11.6.16. This, from inspection, will probably be the airflow path of nodes 1-601-602-503-505-10. The calculation is shown in Table 11.7.1.1. Quantities are expressed in 1000 cfm (kcfm). One of several mine ventilation computer programs can be used for head-loss calculations and to balance the circuits.

Use, say, 3.0 in. water (750 Pa), as the total static head. Then a fan capable of supplying 170,000 cfm at 3.0 in. water (80.2 m^3/s at 750 Pa) will be needed. The fan selected will tentatively be one whose curves are shown in Fig. 11.7.1.13. Note that these are static pressure curves; were they total pressure curves, the fan's evase velocity pressure would have to be added to the static pressure to read the curves correctly. The estimated quantity and static pressure fall on the midpoint of the #2 setting of the fan, so the #2 setting will be that whose points will be input to the computer simulation.

An inspection of Fig. 11.7.1.12 leads to the conclusion that resistors (regulators) may be required on all levels except level 6; therefore, for the initial simulation run, resistors will be specified at the intake shaft, with arbitrary resistances of 0.5 in.-min^2/ft^6 (0.056 N-s^2/m^8) per resistor. The computer will calculate any increase or decrease in resistance needed.

Input quantities and output quantities are shown in Table 11.7.1.2, along with additional resistances calculated for the fixed branches. Resistances are calculated in the same manner as those shown in Table 11.7.1.1 (not shown). The fan is computed to be moving 178,900 cfm at 2.4 in. water (84.4 m^3/s at 600 Pa).

The 1-10 branch is necessary to close the mesh around the fan and is the fan brattice leakage. A very high resistance is input, as leakage should be minimal with a good installation. The resistance used in this run is 1000×10^{-10} in.-min^2/ft^6 (111.7 N-s^2/m^8).

The first computer run shows that expected outputs on the variable branches are about the same as input quantities, except for the stopes, where the quantities are too low. The simplest way to solve this problem in a metal mine is with the use of booster fans, at the exhaust raise of each stope, that will overcome the entire stope resistance. This is the solution that is used here.

For the fixed-quantity branches, an examination of the computer printout reveals that the only place where resistance really is needed is on level 4.

A second computer run is now made, with booster fans installed at each stope. Small fans like those needed at the stopes can be entered into a computer model, but the solution with them entered into the model is suspect due to the difficulty of realistically calculating the resistance of each stope. A more practical method is simply to eliminate the stope branches from the model and assume that the booster fans can take care of the stopes, with perhaps some field adjustments. This particular computer program does not require airflow branches, so airflow quantities can be added and subtracted at nodes without specifying the paths of those quantities.

The fixed branches are changed to variable branches, except for the required 401–402 resistor. These former resistors are assigned resistances of 0, as the branches no longer really exist; however, they remain in the model in case they are needed later, and to save the trouble of renumbering some nodes. Input quantities and output quantities for the second computer model

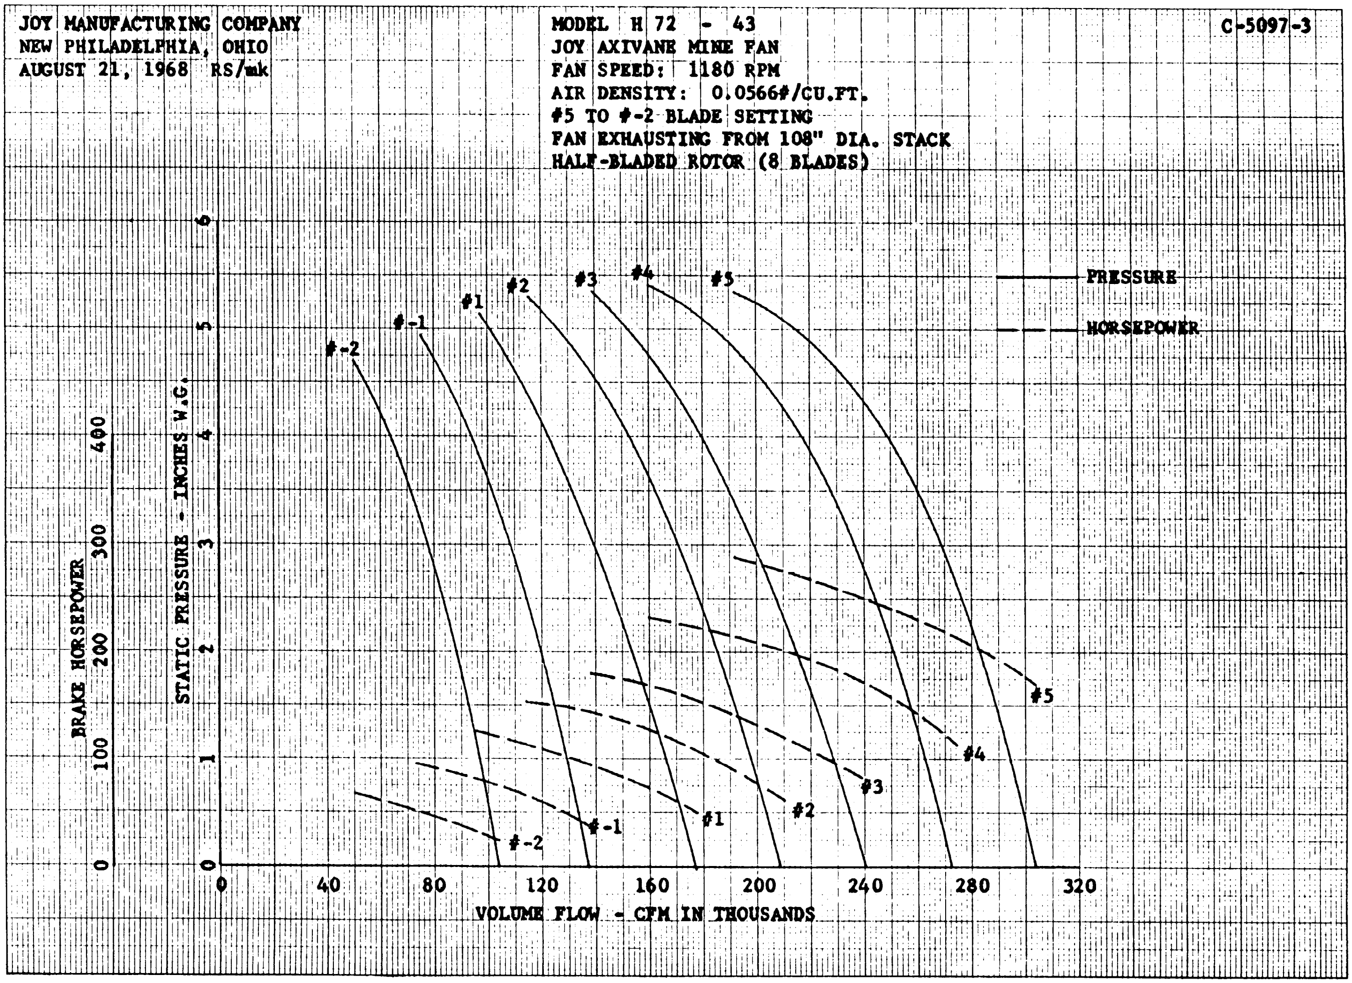

Fig. 11.7.1.13. Curve of fan for mine of Ex. 11.7.1.1 (by permission: Joy Mfg. Co., New Philadelphia, OH).

are shown in Table 11.7.1.3. The fan is computed to be moving 178,900 cfm at 2.4 in. water (84.4 m^3/s at 600 Pa).

The second computer model shows the airflows to be generally as desired, so no more modeling is needed for this example. Of course, in an actual problem, a good many more runs would be made with varying changes in order to obtain the optimum solution.

However, one point to be noted is that the fan develops 178,900 cfm at 2.4 in. water (84.4 m^3/s at 600 Pa). From this, the air horsepower and efficiency can be calculated (see Eqs. 11.6.17 and 11.6.31).

$$\text{Air power } AHP = \frac{H_L Q}{6350} = \frac{(178{,}900)(2.4)}{6350}$$
$$= 67.6 \text{ hp } (50.4 \text{ kW})$$

From the horsepower curve of the fan at a #2 setting and a quantity of 178,900 cfm (84.4 m^3/s), the fan develops 105 bhp (78.2 kW). The fan efficiency η therefore is

$$\eta = \frac{P_{as}}{P_f} = \frac{67.6}{105} \times 100 = 64\%$$

One notes that 64% is not a good efficiency; fans in their normal operating range should develop 70 to 75% efficiency. Therefore, further search should be made for a more suitable fan, even if the output quantities are considered adequate.

Some variation in method of solution may also be dictated according to the computer algorithm used. The algorithm used in this solution requires desired air quantities to be input, but does not require a balance in air quantities at any node; therefore, the stopes could simply be eliminated from the network as was done for simplification of the problem after the first run. Other algorithms would not permit this, and other solutions would have to be sought in the modeling that included the stopes.

11.7.1.8 Ventilation Department Organization

Personnel Requirements. At mines where there are many fans and much ventilation construction work is done, there should be at least one full-time engineer employed in ventilation. At mines where a full-time ventilation engineer cannot be justified, ventilation responsibilities should be assigned to one staff engineer— the old saw that ventilation is “everybody’s job and nobody’s responsibility” just cannot apply in this day and age.

Professional Development. When a person is assigned to ventilation, that person should at first train under someone who is familiar with ventilation. If nobody familiar with ventilation is available, the person assigned should be sent to one of the short courses in ventilation taught from time to time at the

various mining engineering institutions. Relying on knowledge acquired as an undergraduate in a university mine ventilation course is often insufficient, unless the course was just recently completed, as this type of subject matter is easily forgotten unless used.

Ventilation personnel should understand both the theoretical and practical sides of their field. At least one of the ventilation textbooks listed in the references of this chapter should be acquired. A subscription to the *Journal of the Mine Ventilation Society of South Africa* is recommended as this it the only English language journal devoted exclusively to mine ventilation.

The SME Underground Ventilation Committee holds biannual symposia (in odd-numbered years) and attendance is encouraged for all engaged in mine ventilation. This Committee sponsors technical sessions at the annual SME meeting as well. Proceedings of past symposia and preprints of papers from the annual meetings are available from SME.

There are also International Mine Ventilation Congresses held every four years (in even-numbered years, divisible by four) in different parts of the world. Information on these congresses is always provided in the various mining journals.

VENTILATION INSTRUMENTS. Every mine ventilation department should have at least one ball-bearing vane anemometer equipped with extension rods for velocity measurements. These are better for average flow measurements than thermal or vortex-shedding anemometers as they permit integration of air velocities over the cross section of an opening. The other instruments are accurate but are only good for instantaneous readings and spot checks.

A mine ventilation department should also have at least one aneroid barometer accurate to within 0.005 in. Hg (1.7 Pa) (two barometers are needed for traverses), chemical smoke tubes and aspirator bulbs, sling psychrometers (or equivalent electronic instruments), and gages for reading differential water gage pressures—dial-type indicators are handy here, although for reading very small differences such as for making trailing-tube pressure traverses, inclined oil-filled manometers are better.

Gas detection instruments are necessary in many mines, especially those using diesels. Portable electronic instruments for measuring many gases are available, and stain tube indicators are available for virtually all gases found in mining. Dust measuring instruments are also necessary to maintain air quality.

VENTILATION SURVEYS. Mine-wide surveys should be made as often as necessary to determine the overall air distribution

Table 11.7.1.4. Sample Computer-Generated Report on Weekly Face Ventilation Conditions at a Western Metal Mine

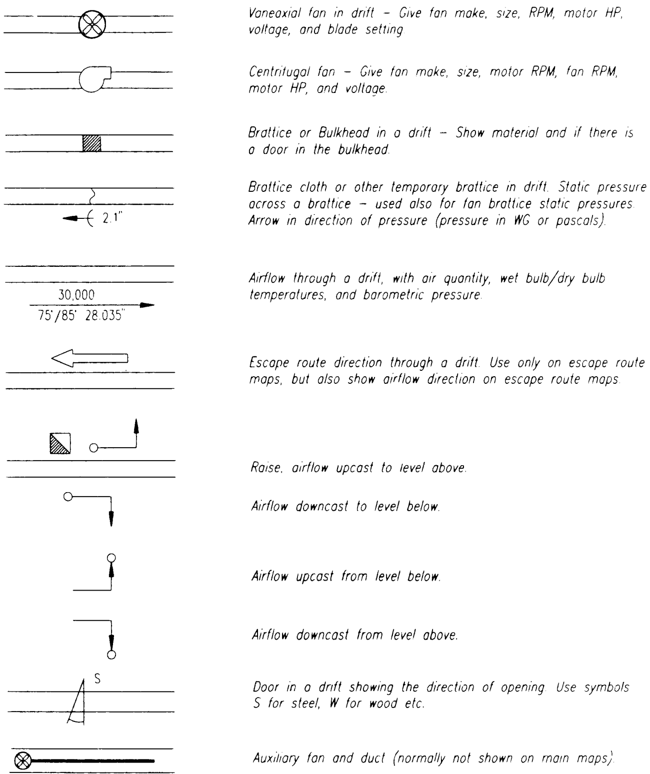

Fig. 11.7.1.14. Suggested ventilation map symbols.

pattern and to evaluate the performance of fans. The minimum frequency for doing this is annually, and some mines do it as often as monthly, although this is seldom justifiable unless ventilation changes radically from month to month. Once every three months is about right for most mines.

Results of overall surveys should be entered on maps and/or ventilation schematics, and calculated air quantities should be stored on computer printouts. There is really no standardized method of mapping ventilation beyond the obvious one of using arrows to indicate airflow direction. Some mines use solid arrows to indicate fresh air and dashed arrows to indicate exhaust air; some prefer to do this with colored arrows. Some places, where heat is a problem, use different colored arrows according to the temperature. Airflows, preferably corrected to standardized density of 0.075 lb/ft³ (1.20 kg/m³), should be logged on the maps or schematics along with wet- and dry-bulb temperatures and fan pressures. See Fig. 11.7.1.14 for a set of suggested ventilation mapping symbols.

Avoid putting too much detail on overall ventilation maps or schematics. If details of flow in a certain area must be shown, use a blown-up detail of the area.

In addition to overall surveys, checks should be frequently made of ventilation conditions at the working faces. This is really the most important type of measurement, as the "business end" of ventilation is where the rock is being broken. These measurements will vary according to the mining method and conditions. For instance, in diesel headings, measurements should be made to assure that adequate airflows are supplied and noxious gas levels are within legal limits. In mines with heat problems, temperature-velocity measurements are needed. Where dust is a problem, dust levels and air velocities are important.

Working face measurements should be made at least monthly; often semi-weekly or even weekly observations are better, especially if potentially hazardous conditions requiring constant surveillance exist. Results of these surveys should be logged on reports and distributed—the computer is a great aid in doing this type of work. Table 11.7.1.4 illustrates a computerized weekly report used at a western metal mine.

Airflow resistance factors of the mine for use in computer simulations should be kept either on schematics, maps, or in computer files. These factors should be updated from time to time with pressure surveys as new areas open up and old ones close down. For determination of mine friction and resistance factors, see Chapter 11.6.

CONSTRUCTION CREWS. Ventilation departments that are responsible for getting much construction work done are advised to have a few timbermen under their direct control. Larger operations may need a full crew with a full-time supervisor. General repair crews with other work to do often tend to leave ventilation work to the last.

11.7.2 COAL MINE VENTILATION

RAJA V. RAMANI

Coal mine ventilation systems must be designed so as to maintain at all times healthy and safe atmospheric working conditions. The main purposes of a coal mine ventilation system are to provide adequate quantities of fresh air to the miners in the workings and to render harmless toxic, noxious, and explosive gases and dusts and carry them out of the mine through dilution by fresh air.

For coverage of ventilation principles, see Chapter 11.6.

11.7.2.1 General Considerations

Correct estimation of the required air quantity at each of the workings is vital. This quantity should be determined on the basis of number of workers in the workings, kinds of machinery used, and the make up of gases, dust, heat, and humidity. The required quantities of fresh air at the faces and other places must be increased in proportion to the amount of leakage anticipated in the airways. Leakage estimation may be problematical, but an allowance of 100% of the estimated quantities for faces is common. Quantity estimation is critical as head losses and power are proportional to the square and cube of quantity, respectively. Small errors in quantity estimates can therefore lead to large errors in pressure head and power estimates and affect the total mine ventilation, health, safety, and production performance.

The number of airways required to course the various quantities through the mine is important as this number influences the velocity of the air in the airway. Air velocities are critical from two points of view. From the safety viewpoint, inadequate air velocities can cause undesirable accumulations and layering of gases; very high velocities, on the other hand, can raise dust clouds. From the economic viewpoint, the head loss in a mine airway is proportional to the square of the velocity, and high velocities will entail large horsepower dissipation. Thus velocities must be carefully chosen so that the safety and economic factors are not compromised. Since velocity is a function of the area of an airway and of the number of airways in parallel, definition of the velocity and quantity requirements will automatically determine the number of airways once the shape and size of an airway are determined by mining machine and ground control conditions.

The head loss in individual splits can be calculated once the resistances of the airways and the volumes of air circulating in them are known. The head loss in the individual splits can be accumulated using series or parallel circuit laws as applicable until the total head loss in the system is calculated. Knowing the quantity and head required for a mine, selection of a suitable mine fan can be made. This is not to imply that mine ventilation system planning and designing is a simple straightforward process but to emphasize that it is an ordered process with many interactions with other aspects of mine planning and designing (Stefanko, 1983; Suboleski and Kalasky, 1982; Luxbacher and Ramani, 1980). Factors such as ground control, production requirements, and equipment limitations may often have great bearing on the mine design. In fact, mine ventilation planning is quite complicated when data on strata gases, mining methods, and mine openings are not readily available or estimates of these have large variances. Therefore, the final ventilation design selected must be flexible in order to adapt to changing conditions.

11.7.2.2 Coal Mine Ventilation Design

The flow diagram in Fig. 11.7.2.1a illustrates the planning and design of the ventilation system as it relates to the overall mine planning problem. At the exploration stage, data must be collected on those specific geological factors that may affect the ventilation system. Mine design also includes many other geological data and, as indicated, is affected by rules and regulations on health and safety. The end result is the development of a mining method and a mine infrastructure. Mine ventilation considerations play an important role at this initial design stage. However, a more detailed ventilation analysis is required as more definite plans are made to mine the coal seam (Fig. 11.7.2. lb). This analysis must be very specific with respect to quantity and quality control of the mine air, and should include a sensitivity analysis covering factors such as methane and leakage that cannot be accurately estimated. Once a suitable plan has been selected, it must be examined with relation to such factors as performance in case of emergencies (e.g., fires and explosions) and adaptability to changing mining plans (e.g., from room and pillar to longwall).

On the basis of such an analysis, the plan may be accepted as presented or modifications may be required in the ventilation plan or even in mine design. Early liaison between mine planning and ventilation staffs can prevent many problems and shorten the length of planning time by revealing the need for additional investigations or new calculations on engineering revisions. In effect, mine development schemes should incorporate full details of ventilation arrangements and the means of achieving effective ventilation at each stage of the mine life. The design of the ventilation system, therefore, should be considered in relation to the long-, medium-, and short-range plans of the mining plan (Anon., 1971). While safety is the prime consideration, to maintain or to increase production and productivity levels, good ventilation planning is essential.

LONG-RANGE PLAN. A long-range plan is defined 10 to 20 years in advance. The general layout of airways underground should be decided by ventilation considerations as well as by other considerations. The sizes of the underground entries must be sufficient for their varying duties as airways at different stages of development. Since production plans may change with changing geologic and/or market conditions, the ventilation plan must be based on a split system that will give some flexibility to blocking off old or opening new sections as the need arises. The evaluation of specific details related to ventilation should be made as early as possible. Though there may be uncertainty with regard to geologic and market data, decisions regarding development of access to the seams (e.g., slopes, shafts, adits, etc.) and method of mining, for instance, cannot be deferred indefinitely. Such decisions as those pertaining to main and sub-

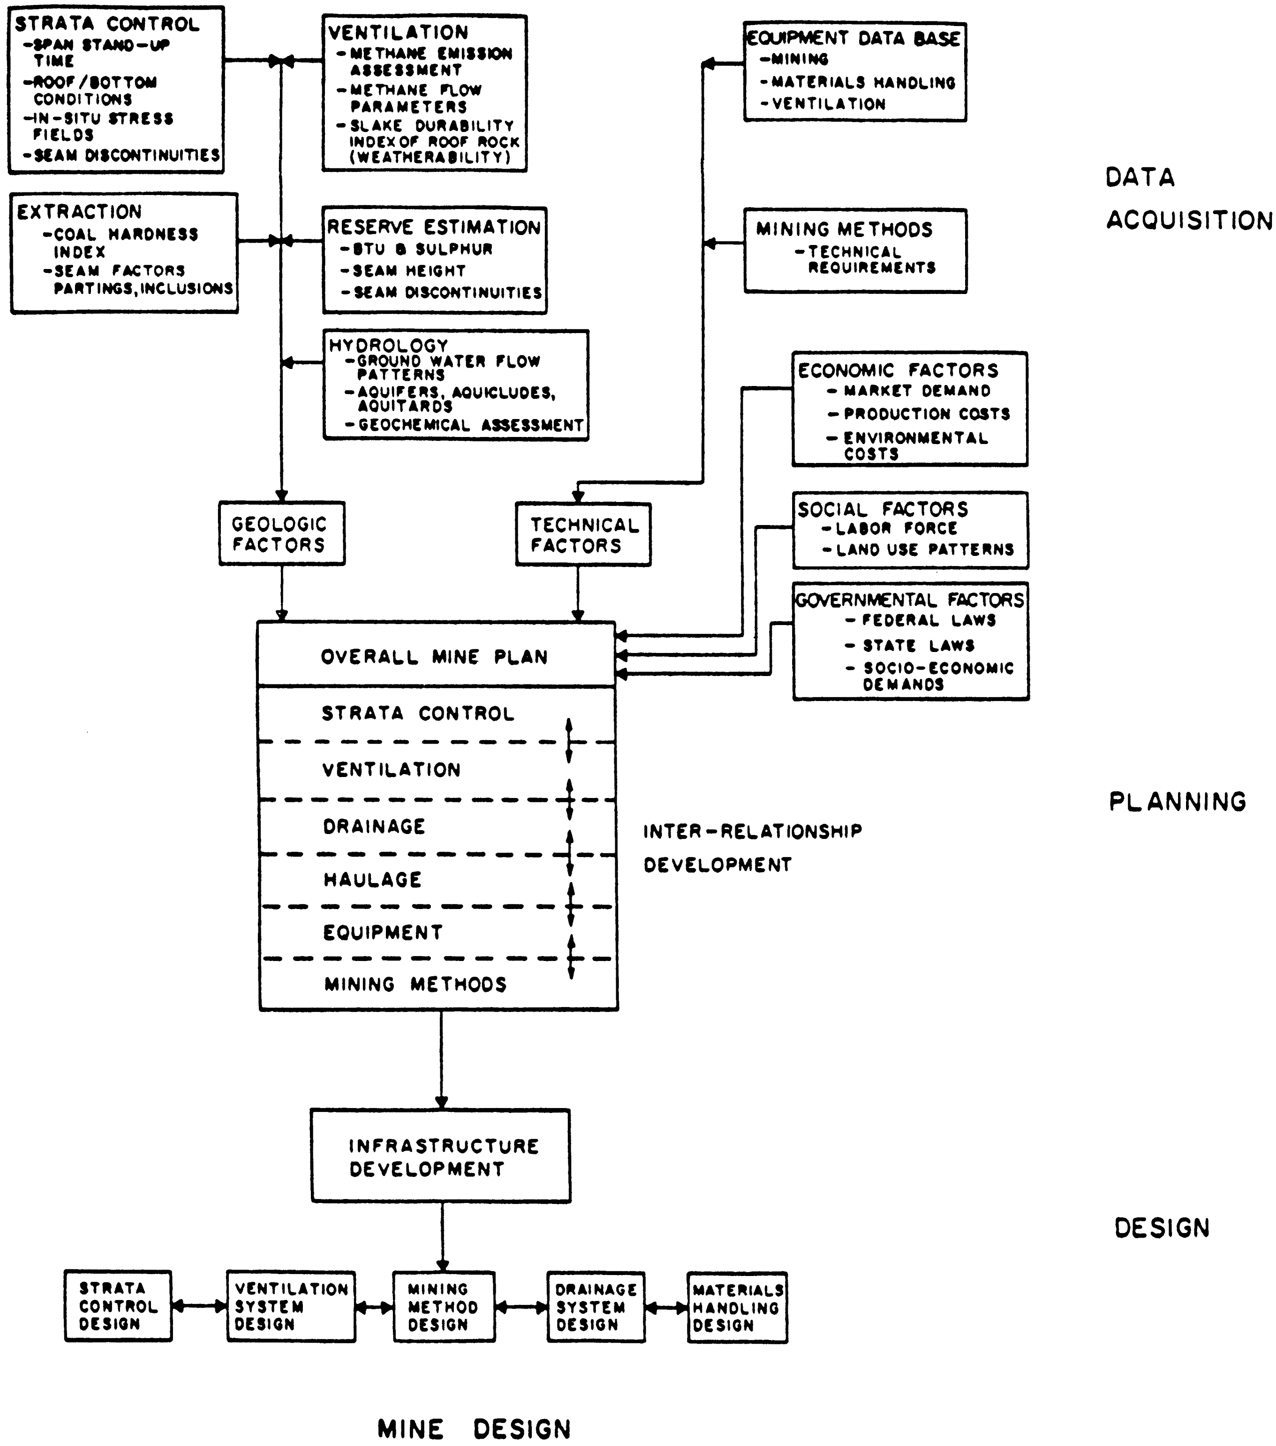

Fig. 11.7.2.1a. Mine design and ventilation system design (Luxbacher and Ramani, 1980).

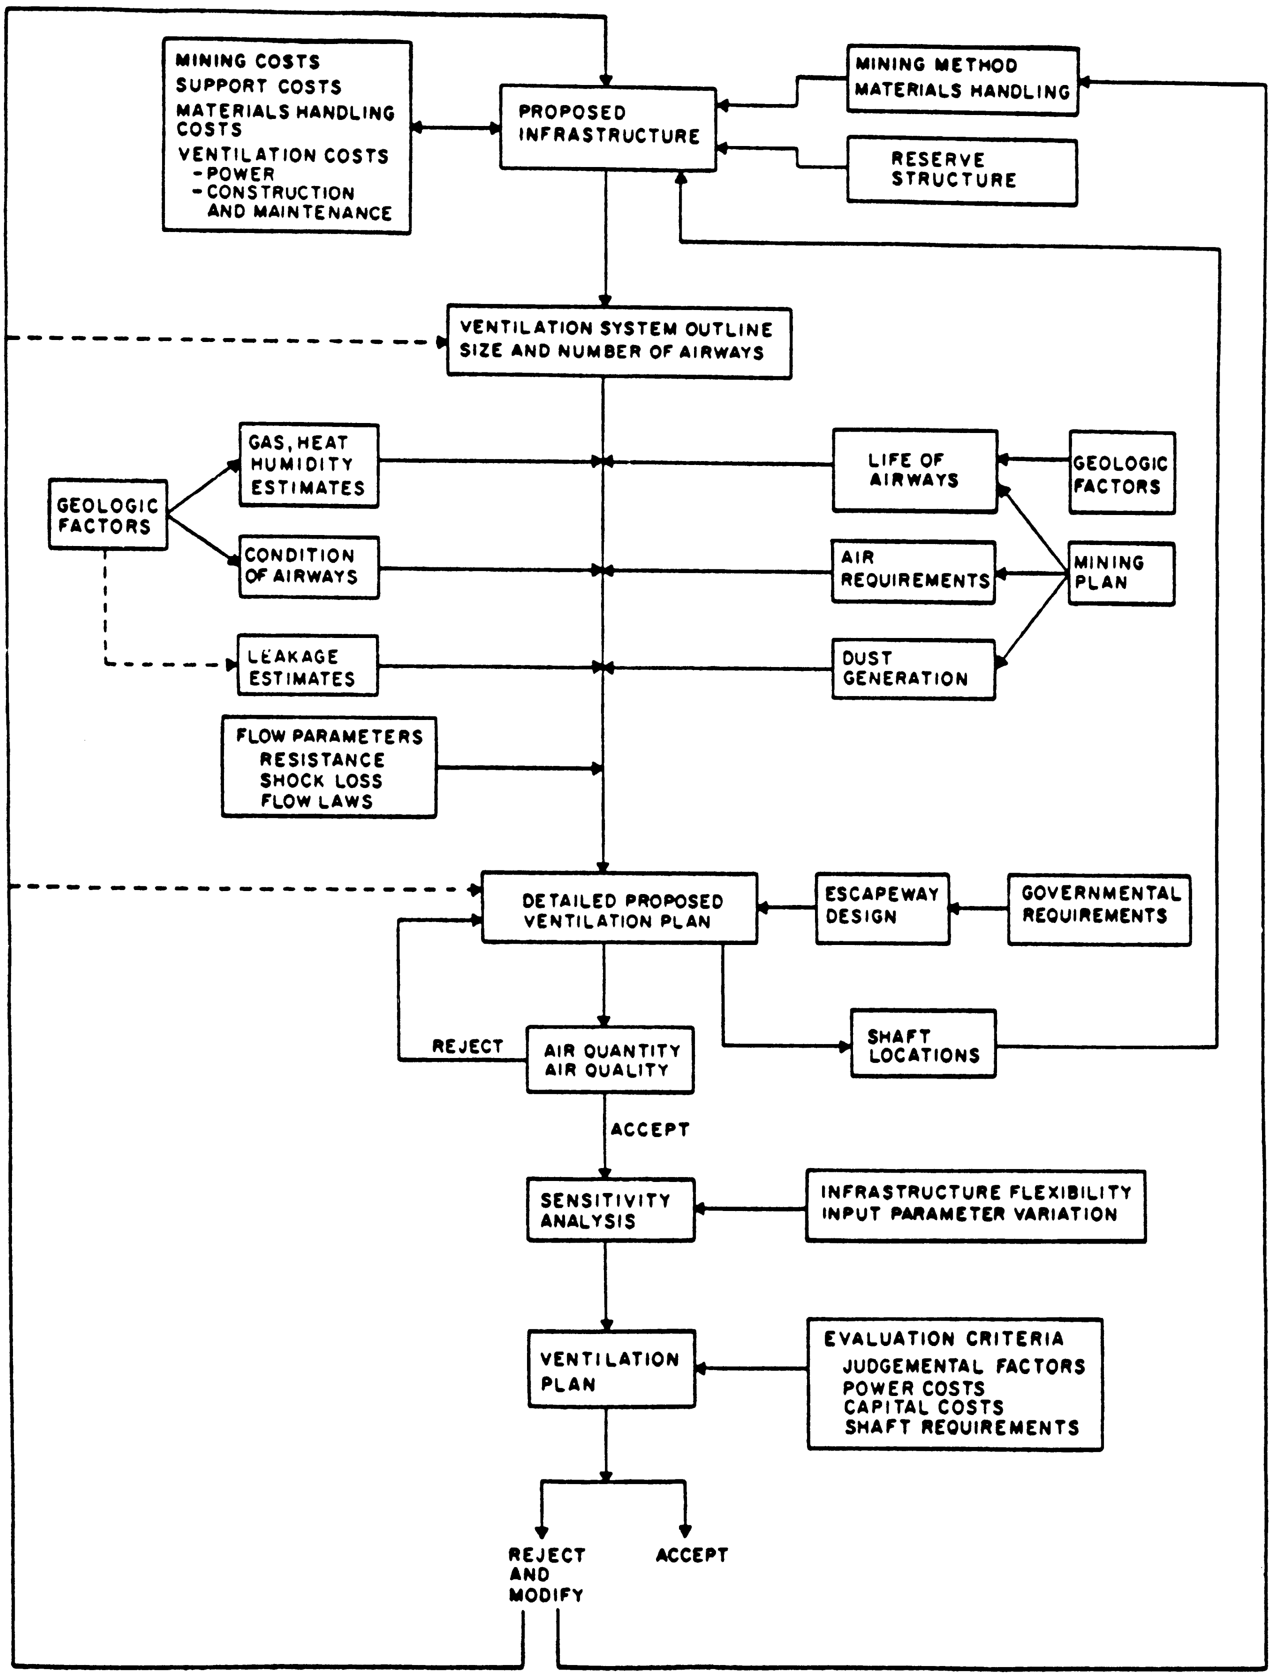
main layouts, cross-sectional areas, and lining of the airways must be made. Since mine openings and fans normally function for the life of a mine, they should be selected carefully taking into account their life cycle duties. Such total system considerations can reveal the need for relocation of shafts or the opportunities for eliminating shafts in the preliminary plan. Further, they will amplify the sequencing needs for these critical ventilation-related activities.

MEDIUM-RANGE PLAN. Medium-range plans must show the projected method of working and the general method of ventilation to be used for at least three to five years into the future. These projections should be updated at least once a year to include changes and variations from the plan. These plans must be available to the operational staff to schedule ventilation-related actions in their operational plans. Medium-range plans should be based on underground pressure/quantity, methane,



VENTILATION SYSTEM DESIGN

Fig. 11.7.2.1b. Mine design and ventilation system design.

and temperature surveys except in cases where the workings are entering virgin areas. In the latter case, use of good estimation techniques for parameter values and of extensive sensitivity analysis cannot be overemphasized.

SHORT-TERM PLAN. The short-term plan, as the name implies, is for the immediate future, usually a year or so, and is based on the projected long- and medium-range plans. Short-range planning of ventilation is necessary to maintain control of the nature and timing of ventilation construction and activities. It must include at least the following: (1) layout of development work with a time sequence, (2) air quantities, (3) ventilation arrangement at the working faces, (4) schedule for ventilation changes, (5) schedule for the construction of air crossings, doors, etc., (6) special precautions for firefighting, and (7) emergency escapeways.

11.7.2.3 Quantity Distribution

Success in providing adequate ventilation to the active workings of a mine for any method of mining depends on adequate fan capacities and good air distribution (primary ventilation) and, when the air reaches the face area, good control and distribution of the air at that location (face ventilation). An acceptable system provides overcasts, airlocks, regulators, and bleeders arranged so that air is coursed in the desired manner in the desired quantities.

MAIN ENTRIES. The main entries that extend from the shafts and slopes carry the major volume of air to the splits and are usually required to last throughout the life of the mine. These two aspects make their design with regard to number, size, support, and lining material important. Since material (coal and supplies) is usually conveyed through one or more of the entries, limitations such as isolation of the belt and maximum velocity in trolley haulage airways must be considered in determining the number of airways. The air quantity flowing in the airway will be a function of the air velocity range desirable in the airway.

Example 11.7.2.1. Given these ventilation and haulage specifications, calculate the number of entries in the mains:

Mainline haulage:	belt
Supply haulage:	battery-powered scoops
Range of maximum velocity:	600 to 800 fpm (3.05 to 4.06 m/s)
Minimum quantity to be carried:	300,000 cfm (141.6 m^3/s)
Seam height:	6 ft (1.82 m)
Width of entry:	20 ft (6.1 m)

Solution. (a) In the above case, the area of an airway is 6 × 20 ft = 120 ft^2 (11.15 m^2). But it is possible that this entire area may not always be available for airflow since there may be some obstructions in the form of stationary equipment and supplies that are either required or left in the entries. Additionally, due to convergence, the actual height of the entry may be less than 6 ft (1.82 m). Assuming the actual area for airflow at 100 ft^2 (9.29 m^2) and an air velocity of 800 fpm (4.06 m/s), the number of airways needed to convey 300,000 cfm (141.6 m^3/s) will be

$$\frac{300{,}000}{800 \times 100} = 3.75 \simeq 4 \text{ entries}$$

$$\frac{141.6}{4.06 \times 9.29} = 3.75 \text{ entries}$$

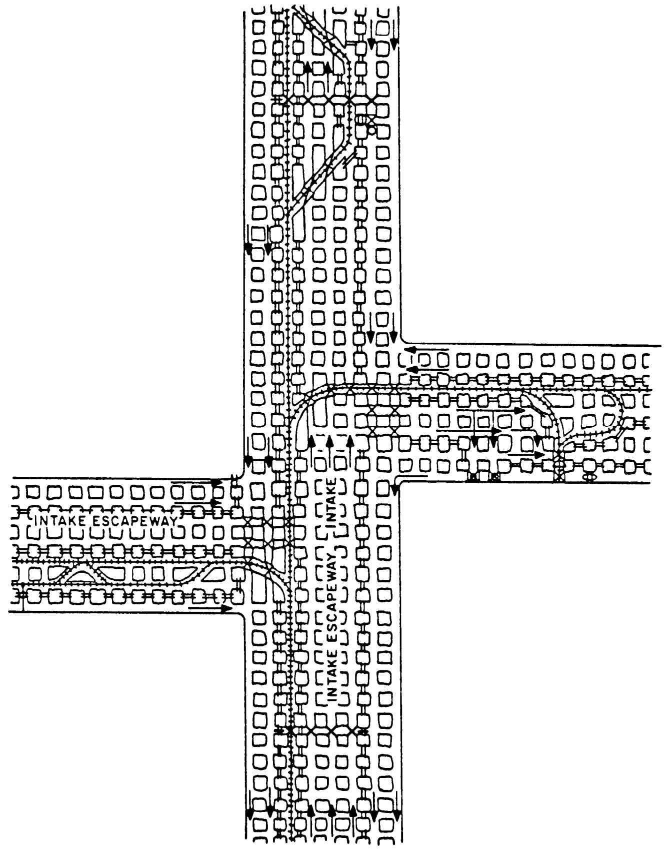


Fig. 11.7.2.2. Eight-entry main development with track haulage.

At a velocity of 600 fpm (3.05 m/s), the number of airways needed will be

$$\frac{300{,}000}{600 \times 100} = 5 \text{ entries}$$

$$\frac{141.6}{3.05 \times 9.29} = 5 \text{ entries}$$

(b) It can be assumed that the main entries will be carrying the entire quantity over only a short distance and that air from the main entries splits to the submains and panels at frequent intervals. Thus, from the velocity point of view, at least four intakes and four returns (i.e., a total of eight entries) are necessary.

(c) Because a belt entry must be isolated, an additional entry is needed to accommodate the belt, making nine the total number of entries required. If trolley haulage is used for men and material transport, then the intake escapeway must be isolated from the trolley entry. Additionally, the velocity in the trolley entry must not exceed 250 fpm (1.27 m/s). This may increase the number of entries in the mains by at least one.

If, instead of a belt, trolley haulage is used for men, supplies, and coal transport, then only the intake escapeway must be isolated from the entry in which the trolley operates. However, the velocity restriction still demands that the trolley be isolated and regulated. In this case, however, eight-entry mains may be sufficient.

Shown in Fig. 11.7.2.2 is an eight-entry mains development. In this example, the two outside entries on each side are the

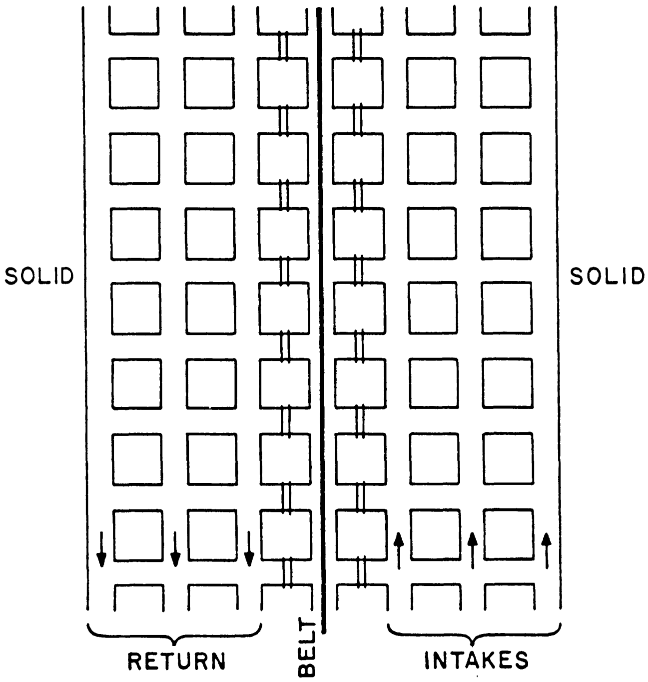

Fig. 11.7.2.3. Mains development with belt haulage to minimize number of stoppings.

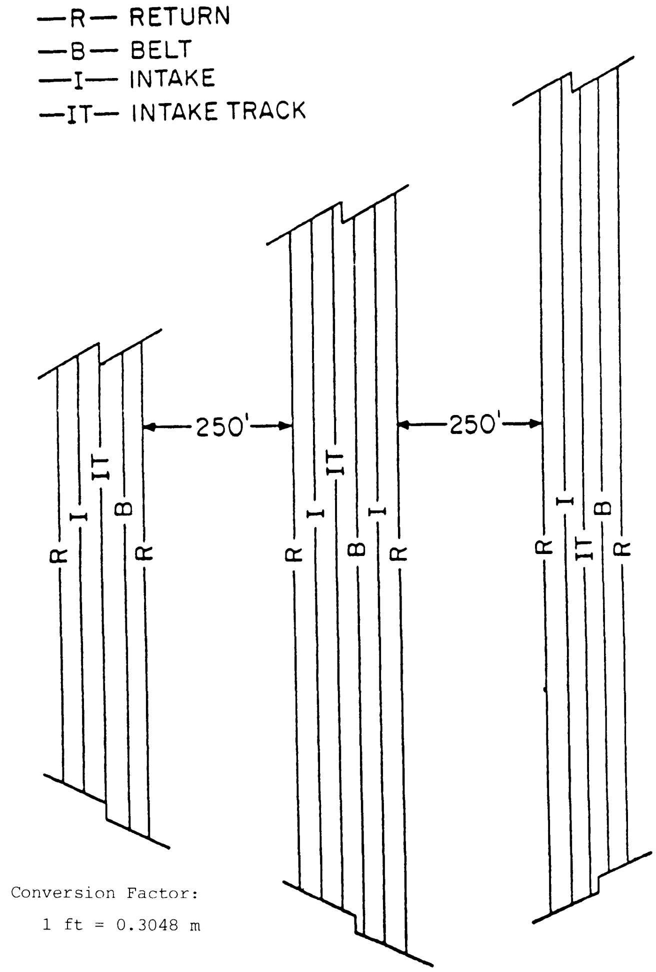

Fig. 11.7.2.4. Mains development for achieving high production and for reducing leakage. Conversion factor: 1 ft = 0.3048 m.

returns. The No. 3 entry (always counting from the left facing inby) contains the tracks for trolley haulage. The trolley entry is isolated and followed by the three intake entries. One of these is designated as the intake escapeway. Whenever the trolley haulage has to be carried into the splits, the trolley entry needs to be isolated from the other intakes and returns by a set of overcasts. It is also a good practice to connect the returns on either side by a set of overcasts every 2000 ft (600 m). These are known as "equalizers." Thus, if there is a fall on the returns blocking any set of overcasts completely, the air can cross over and back without unduly affecting the overall resistance of the returns. The idea of putting the returns adjacent to the solid rib of coal is advantageous because of any gas that bleeds off the solid coal will not be carried to the face. If symmetry with regard to the haulage is required, the trolley or belt can be moved to the fourth or fifth entry. In this case, however, an additional row of stoppings will be required (i.e., two rows of stoppings to isolate the intakes from the return on each side, and two rows to isolate the trolley or belt from the intakes on either side).

There are several other possible layouts for the mains. For example, to minimize the number of stoppings, one side could be made intake and the other return as shown in Fig. 11.7.2.3. The disadvantage of this layout is the contamination of the intake air from the solid rib bleedoff and worked-out panels. Because of ventilation economics, some mines with low methane emissions use such an arrangement (Stefanko, 1983).

Shown in Fig. 11.7.2.4 is a standard set of mains in a high-methane, high-production mine (Stefanko et al., 1977). Sixteen entries divided into three groups are laid out so that, during development, each group has its own belt (B), track (IT), intakes (I) and returns (R). Once development is complete, the outlying groups, which consist of five parallel entries, will be used as returns. The central group, which consists of six entries, will utilize five entries as intakes and an isolated belt will be placed in the No. 4 entry. The eventual isolation of the three groups into returns and intakes with 250-ft (75-m) barriers between them reduces both leakage and resistance. Furthermore, this type of mains development is suitable for use when large tonnages are being produced during first mining. Figure 11.7.2.5 shows a scheme employed at a mine employing eight entries per section with two sections paralleling each other. The two sets of entries are connected at convenient intervals and have the same advantages as listed above.

SUBMAINS. The submains or panel entries have a much shorter life than the mains and carry much less air. For example, according to the 1969 Coal Mine Health and Safety Act, the minimum volume of air required is only 9000 cfm (4.25 m^3/s) at the last open crosscut. In practice, however, the quantity of air required at the last open crosscut is a function of the methane liberation rate and the number of machine units and workers in the section. It is good ventilation practice to place the miner operator on one split of air that will be conveyed directly to the return, and the roof bolter operator (or other machine units) on another split of air. This type of face ventilation, called dual-split or fishtail arrangement, is very common in gassy mines as well. The air in the face areas is coursed by line brattice and check curtains. Here leakage losses will be severe. For example, the air quantity on the basis of the above considerations at the last open crosscut is, say, 40,000 cfm (18.88 m^3/s) (20,000 cfm, or 9.94 m^3/s, on each side). The air at the entrance to the panel

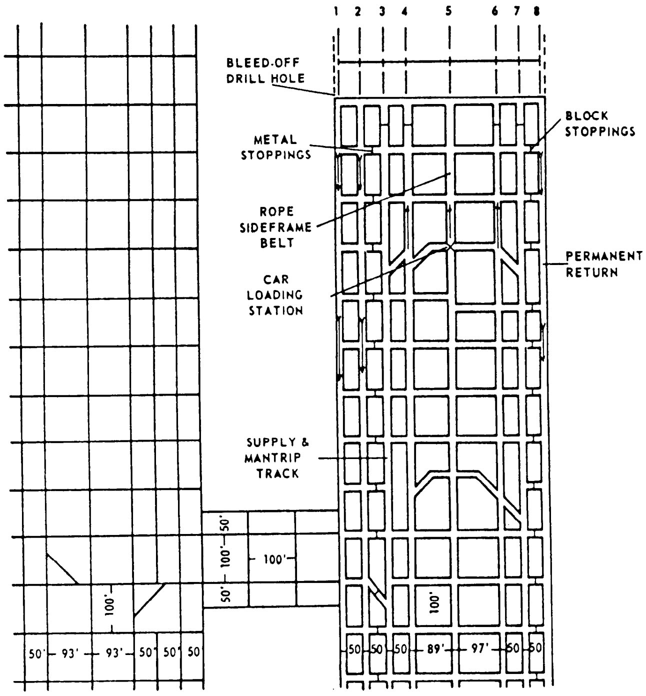

Fig. 11.7.2.5. Design of mine entries according to pressure-arch theory and reflecting future ventilation expansion (Belton, 1962). Conversion factor: 1 ft = 0.3048 m.

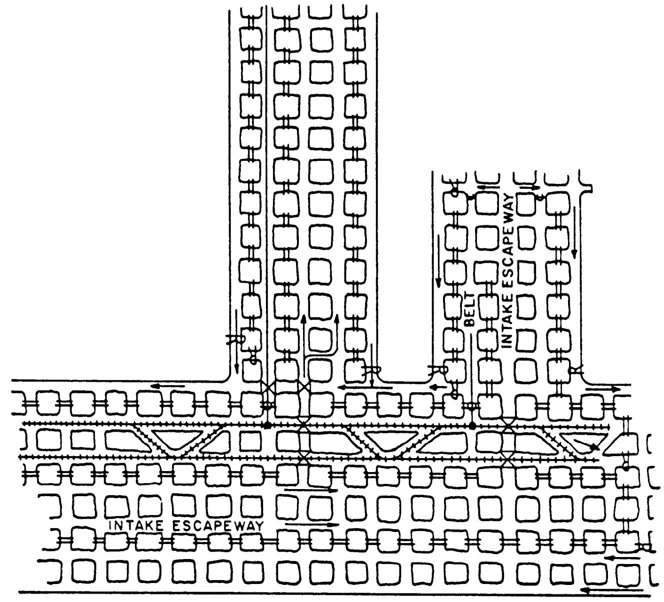

Fig. 11.7.2.6. Five-entry submains development.

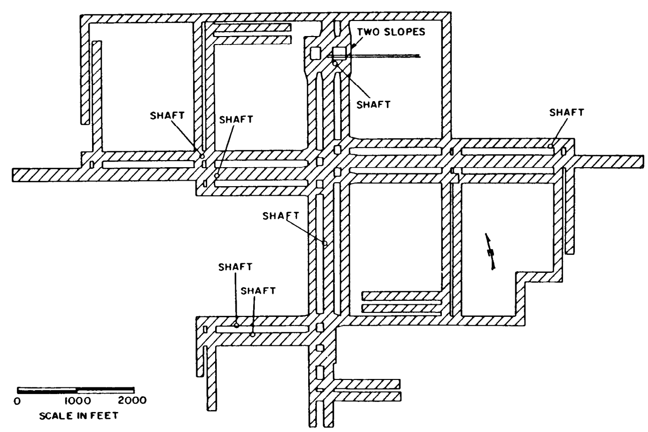

Fig. 11.7.2.7. Mine plan for high-development production and degasification—development after 36 months. Conversion factor: 1 ft = 0.3048 m.

will have to be much more than this quantity to account for the leakage from the intake into the returns all along the panel length. This can be estimated on the basis of the number of stoppings and the stopping construction. For the purposes of illustration, the air at the panel entrance is assumed to be 60,000 cfm (28.32 m^3/s). The air velocity in the submains (or panel entries) is considerably less than that in the mains.

Example 11.7.2. Given the following ventilation and haulage considerations, calculate the number of panel entries.

1. Maximum velocity: 300 fpm (1.52 m/s)
2. Width of entries: 20 ft (6.1 m)
3. Height of entries: 6 ft (1.8 m)
4. Belt for coal transportation
5. Battery haulage for men and materials
6. Minimum quantity to be carried: 50,000 cfm (23.6 m^3/s)

Solution. The cross-sectional area of an airway, although 120 ft^2 (11.15 m^2), is rounded off to 100 ft^2 (9.29 m^2) as before for the same reasons. Using the maximum velocity of 300 fpm (1.52 m/s), it is obvious that one airway can convey 30,000 cfm (14.16 m^3/s). Thus two intakes and two returns will be enough from the ventilation point of view. However, a separate entry must be driven for the isolated belt. In summary, a five-entry development is adequate.

Shown in Fig. 11.7.2.6 is an example of a five-entry development taking off from a seven-entry submain with trolley haulage. Notice that in the submains, two entries are isolated from the intakes and returns for the trolley.

Studies by the US Bureau of Mines have shown that isolating a large block of coal by developing sets of headings around it to allow bleedoff for at least one year prior to mining can provide safety and production advantages. An example of such a panel development is shown in Fig. 11.7.2.7 where several blocks have been isolated before extraction within any one block begins. From an economic point of view, this practice is not most desirable due to the high investment in the mine, the high cost of development coal and the delay caused in the start of second mining (i.e., pillaring or longwalling). Methane drainage ahead of mining through vertical boreholes from the surface or horizontal holes in the seam is a preferred method (Deul and Kim, 1986).

11.7.2.4 Longwall Ventilation Planning

The development for a longwall face consists of two sets of parallel entries with two, three, or four entries in each set. The most common in the eastern United States is the three- or four-entry development, accounting for over 80% of the longwalls in operation. In the western United States, two-entry developments are widely used. The distance between the two sets (i.e., the face length) is variable and can be anywhere from 450 to 1000 ft (137.2 to 304.8 m). These entries may be driven 6000 to 10,000 ft (1829 to 3048 m) in length.

The amount of air required in a longwall face is dictated by the methane emission rate during mining and conveying. The area available for the air to travel from the intake entries to the return entries is limited. The total cross-sectional area of the face is determined by the height of coal cut (usually the thickness of the coal seam), and the distance from the face to the gob line (usually, 12 ft (3.7 m)). However, the area occupied by the machine, roof support equipment, and conveyor must be subtracted from the total area to calculate the effective area available for ventilation. This area may be as little as 50% of the total face area. The net result of such a low area for ventilation is high air velocities at the face. While it is advantageous from the methane point of view to have high velocities, from the dust point of view, velocities over 500 fpm (2.54 m/s) are undesirable. Assuming a 5-ft (1.5 m) coal seam and a 12-ft (3.66 m) distance from the face to the gob line, the maximum cross-sectional area for airflow is 60 ft^2 (5.57 m^2). Assuming that only 75% of this area is available for ventilation, the remaining 25% being covered by obstructions such as the machine, conveyors, and support, the maximum velocity in the face for a flow of 22,500 cfm (10.62 m^3/s) will be about 500 fpm (2.54 m/s). A limit on the face velocity, somewhat on the high side, is 600 fpm (3.05 m/s). Thus, if the methane emission rate per ton of coal mined is high, then the emission of methane can be reduced only by mining at a lower rate, by degasifying the seam prior to longwalling by isolated panels and/or by drainage through vertical or horizontal holes, or by water infusion.

As an illustration, consider a gas emission rate of 10 ft^3/ton (0.31 m^3/t) of coal mined and a maximum production rate of 10 tpm (9 t/m). The amount of gas liberated is 100 cfm (0.047 m/s), requiring nearly 10,000 cfm (4.72 m^3/s) of fresh air for dilution at the face. An additional 5000 cfm (2.36 m^3/s) can be assumed to directly enter the gob from the face. Therefore, at the entrance to the face, there must be 15,000 cfm (7.08 m^3/s). Providing for leakage, say, 5000 cfm (2.36 m^3/s), in conveying the air from the main intakes to the face through the panel entries for ventilating the panel belt, say, 3000 cfm (1.42 m^3/s) is needed; and for other purposes (5000 cfm, or 2.36 m^3/s); a total of approximately 28,000 cfm (13.21 m^3/s) must be obtained from the main intake. This quantity can be easily handled by a single entry whose cross-sectional area is 100 ft^2 (9.29 m^2). However, requirements of a neutral belt, bleeding from the solid coal, and the entries to serve the adjacent longwall face, demand a two-, three- or even a four-entry longwall development. In modern high-production longwalls, the air quantity traversing the face can be as much as 30,000 to 50,000 cfm (14.16 to 23.60 m^3/s).

RETREATING LONGWALL VENTILATION. A four-entry layout for longwall mining is shown in Fig. 11.7.2.8. The ventilation system consists of the following: two butts, labeled l-Butt and 2-Butt in Fig. 11.7.2.8, each consisting of four entries, are driven the length of the panel; the butts are connected by four entries in the back (three rows of pillars). The three most inby entries form the bleeder (and the rib of the 4th entry forms the retreating longwall face). Entry No. 4 of 2-Butt is the isolated belt entry. Entries 2 and 3 of 2-Butt carry the major portion of the intake air (about 20,000 cfm or 9.45 m^3/s) of which about 18,000 cfm (8.50 m^3/s) will reach the headgate. At this point, about 15,000 cfm (7.08 m^3/s) will enter the face, and 3000 cfm (1.42 m^3/s) will be allowed to return through the belt into the main returns. A small quantity of air, say, 3000 cfm (1.42 m^3/s), will be allowed to enter entry 1 of 2-Butt and be directly conveyed to the bleeder. This will enable bleeding of the solid block to the left. A small amount of intake air (say, 5000 cfm, or 2.36 m^3/s), will enter through entry No. 1 of l-Butt that will be used to ventilate the A entries and the tail end of the face. Entries 2 and 3 of 1-Butt serve as the returns for the panel. Fig. 11.7.2.9 shows the ventilation plan for a three-entry longwall layout in a 5-ft (1.5-m) thick seam.

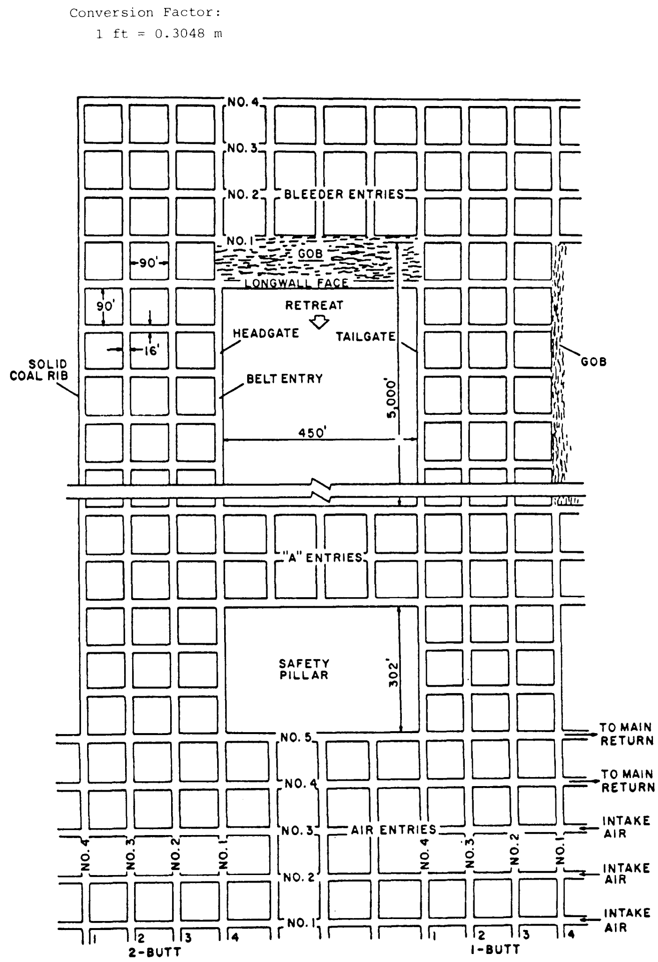

Fig. 11.7.2.8. Four-entry longwall ventilation scheme (Anon., 1976).

Dust control in longwalls is a problem, particularly when the face is mined in both directions (see Chapter 11.2). In bidirectional cutting, when cutting in the direction of the flow of air, the dust generated by the machine is blown away from the operator. However, when cutting in the reverse direction, the operator and other workers are in the downwind side.

ADVANCING LONGWALL VENTILATION. Fig. 11.7.2.10 illustrates the ventilation system of an advancing longwall face (Dalzell, 1972). In this system, the five-entry panel is advanced by a continuous miner ventilated by 17,000 cfm (8.02 m^3/s) of air while the longwall face is ventilated by a separate split of 18,000 cfm (8.50 m^3/s). The No. 4 entry in the panel serves as a common intake to the development section and the longwall face up to the crosscut inby the longwall face where the air is split to provide separate air currents to each unit. The longwall and the development utilize a common belt in the No. 3 entry of the panel. The belt entry is ventilated by low-velocity air traveling in by along it to a regulator installed on the third crosscut outby the No. 1 butt development faces where it enters the No. 1 and No. 2 entry return air courses.

The bleeder system for the advancing gob is developed by converting into bleeders the No. 5 entry, of the active panel (adjacent to the gob) and No. 1 and 2 entries of the previously mined panel which is the tailgate for the advancing longwall. Bleeder flow is controlled by checks and regulators. The return air from the longwall face is directed to the main returns through

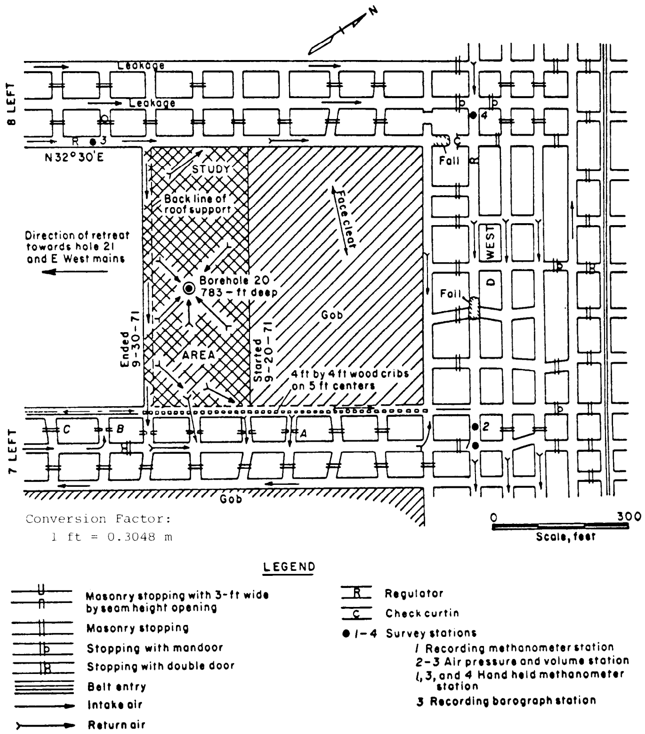

Fig. 11.7.2.9. Three-entry longwall ventilation scheme (Moore, Deul, and Kissell, 1976).

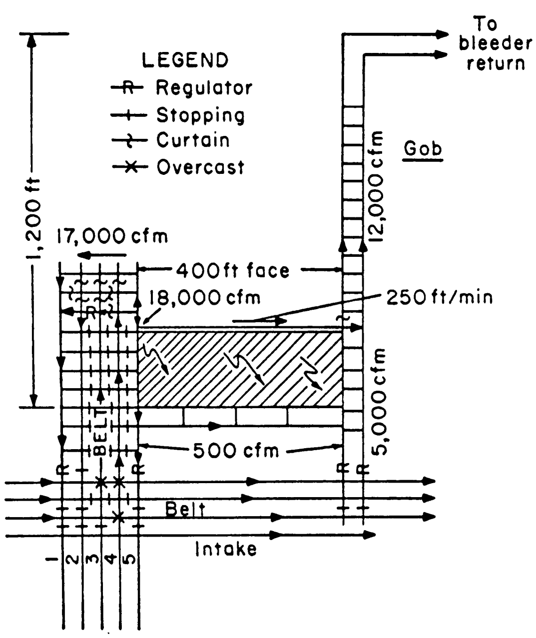

Fig. 11.7.2.10. Advancing longwall face ventilation (Dalzell, 1972). Conversion factors: 1 ft = 0.3048 m, 1 cfm = 0.47195 × 10^{-3} m^3/s.

No. 1 and No. 2 entries of the previously mined panel (5000 cfm or 2.36 m^3/s) with the remainder diverted to the bleeder entries (12,000 cfm or 5.66 m^3/s), allowing 1000 cfm (0.472 m^3/s) leakage through the active gob to the No. 5 entry to the active panel. The advancing longwall system is not commonly practiced in the United States.

11.7.2.5 Shortwall Ventilation

The shortwall layout, as shown in Fig. 11.7.2.11, is very similar to that of a longwall (Stefanko, 1983). The primary difference is that the shortwall face is generally 150 to 250 ft (45.7 to 76.2 m) wide. The web depth is about 10 ft (3.0 m), as opposed to a maximum of about 30 in. (0.76 m) in a longwall. The minimum operating height of a shortwall face is about 54 in. (1.37 m). Thus the face area open for ventilating air is much larger than that for a longwall.

The shortwall face shown in Fig. 11.7.2.11 was located in Eastern Kentucky in the Elkhorn No. 3 seam that averages 44 in. (1.12 m) in thickness, ranging from 42 to 48 in.(1.07 to 1.22 m). The main entries, which are not shown in the figure, consist of five intakes and four returns in a two-split arrangement with two returns on each side. The submains, represented by 10 Left in the figure, consist of three intakes, one controlled belt-track intake, and five returns in a two-split or fishtail arrangement. One Right Flats, off 10 Left Submain, has a similar configuration but consist of only seven entries. The panel entries perpendicular to One Right Flats consist of an intake on the right side (No. 3 entry) with a return in No. 1 entry and a neutral belt-track entry in No. 2. A bleeder system is shown in use with panel production. This ventilation system is very effective in maintaining the methane below the 1% level.

In shortwall, the continuous miner cuts only in one direction. Then it is backed up to the headgate and another cut is started. Therefore, by arranging the ventilation flow from headgate to tailgate, the miner operator and the jack setters are always in fresh air and are not exposed to the dust generated by the machine. Other than this, there is essentially little difference between the ventilation of longwall and shortwall faces.

11.7.2.6 Bleeders

Methane control during development, although requiring constant and careful attention, is easier than methane control during pillaring. During development, frequent inspections and regular monitoring are possible. However, as soon as conventional pillaring or retreat of longwall is started, it is impossible to inspect the gob areas. To keep the gob clear of gases, a controlled flow of air across it must be established. This is known as bleeding the gob (Kalasky and Krikovic, 1973). It is usually achieved by placing regulators at strategic locations at both panel ends and utilizing whatever permeability has been established in the gob. The location of the regulators should be chosen to provide as much flow across the gob as is needed to sweep away gases and avoid dangerous accumulations in the gob. These regulators should be accessible since, as retreat mining increases, adjustment regulator is needed to compensate for the increased natural resistance of the developing gob. To accomplish “bleeding,” an adequate pressure differential from the front to the back of the pillar line, as well as to both sides, is required.

Effective bleeding should remove the methane sufficiently far from the active pillar line or face so that a temporary ventilation interruption or sudden atmospheric pressure drop due to an approaching storm will not cause a large influx of gas from the gob.

Supplementary degasification through vertical boreholes drilled from the surface ahead of approaching pillaring lines or in the longwall gob is also practiced. However, effective bleeding systems should still be used to reduce the methane problem in the gob.

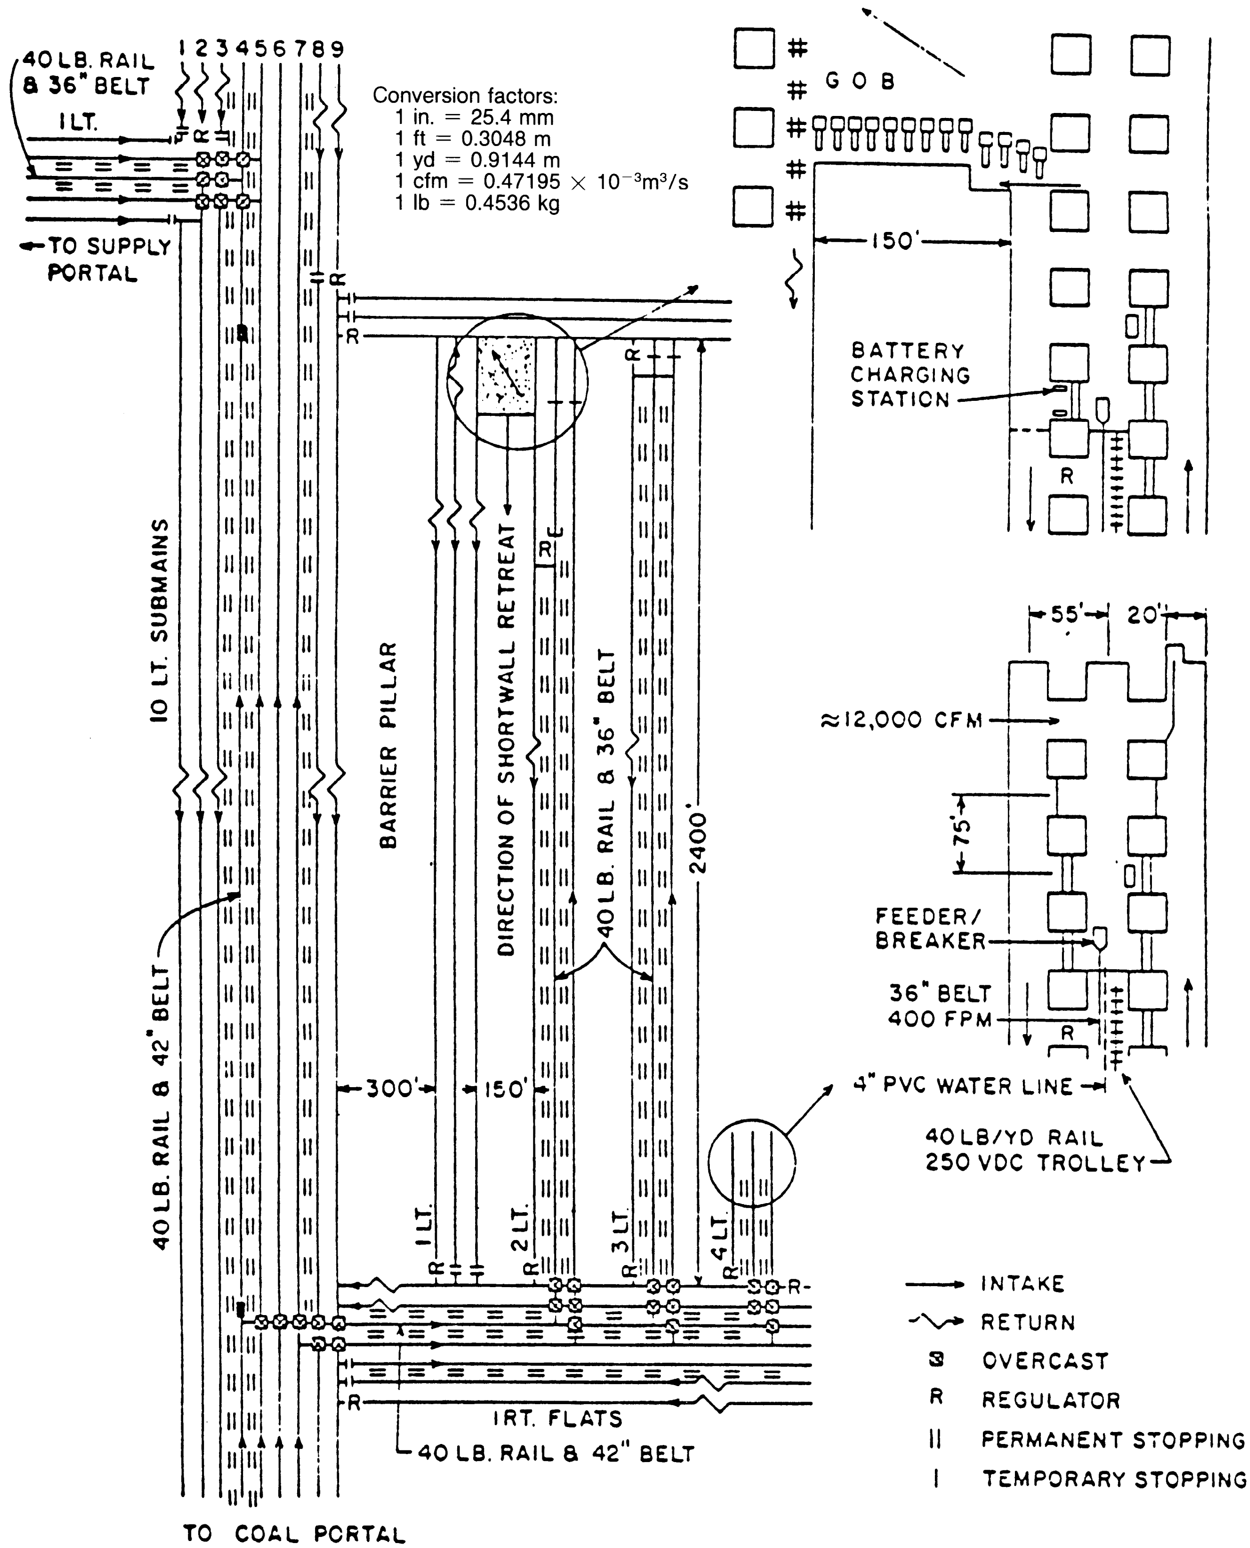

Fig. 11.7.2.11. Shortwall ventilation scheme (Stefanko, 1983).

Bleeders for Room and Pillar Systems. A simple bleeder entry system for room and pillar mining is shown in Fig. 11.7.2.12. Here the mining method involves mining panel headings usually advancing from one side of a set of submains to another set, that is, from 6 North to 7 North, and from 7 North to 8 North, as shown. When the panel headings approach the submains, 7 North and 8 North, they are reduced to a single heading that acts as the bleeder. Regulation is provided in the

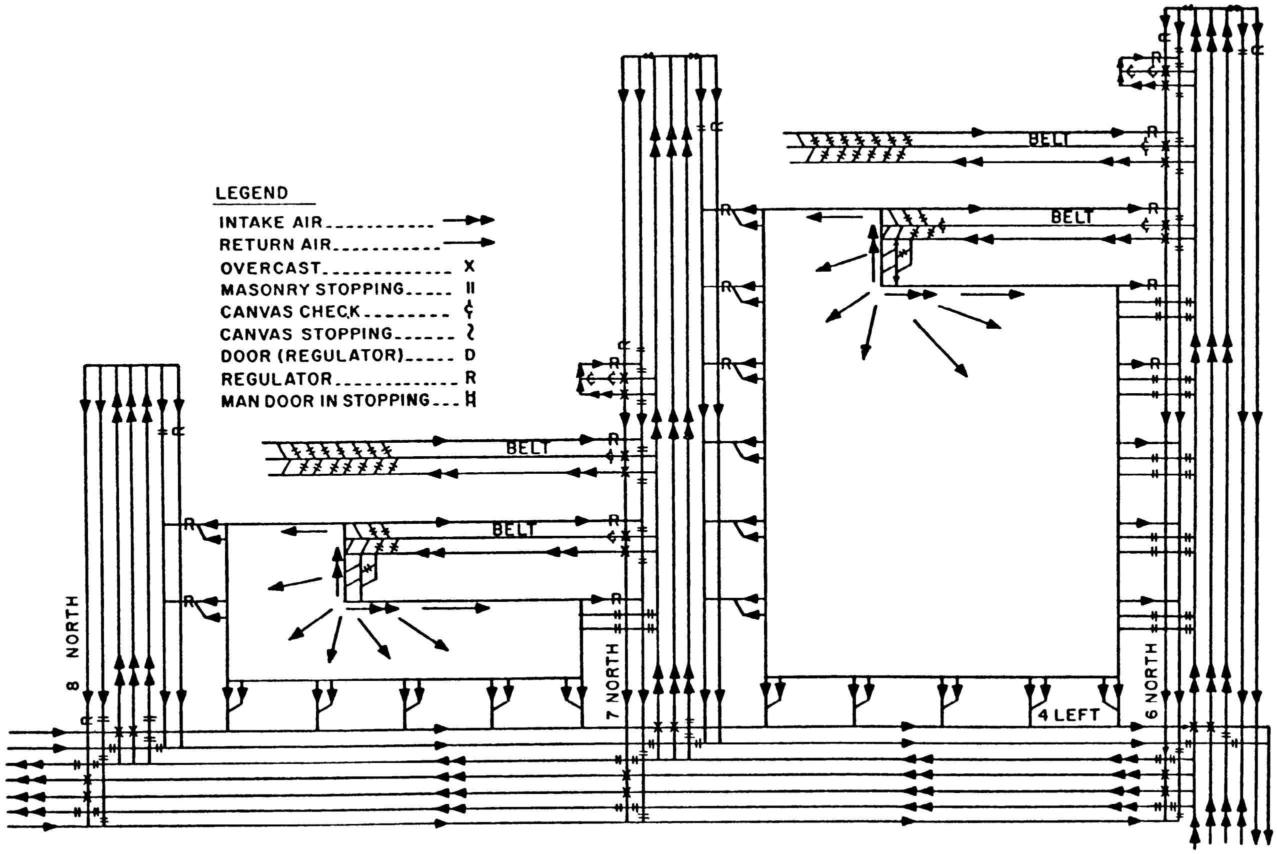

Fig. 11.7.2.12. Bleeder system for room and pillar workings (Kalasky and Krikovic, 1973).

bleeder system as the gob becomes larger in size; regulators in the bleeders are closed to provide greater resistance to flow through the more permeable areas of the gob, and opened to provide more flow through the less permeable areas. If the pressure differential across the gob is not adequate, the fan pressure may have to be increased, and, if that proves impractical, vertical boreholes must be drilled from the surface and a high-pressure exhauster installed on the top. One significant advantage of this arrangement is that the bleeders are accessible from the intake airway. This facilitates cleanup of falls and pumping of water accumulations. Otherwise, such conditions would cause restrictions to adequate bleeding.

In the plan of mining shown in Fig. 11.7.2.13, panel headings are driven to mine the block of coal on the left side of the 6 North submains, and retreated on an adjacent side (from 7 North submains) with intermediate bleeders. In this case, the distance between the submains is double the panel length, minimizing the number of submains required for development. In this method of extraction, the same bleeder headings utilized in mining the first group of panels are also utilized for the second group. This arrangement may be unsatisfactory, particularly in very gassy mines, since it is difficult, if not impossible, to maintain the bleeder headings between the two gobs, especially during the final retreating cycle. In any case, all bleeders in this arrangement must be adequately supported. For pools of water that might block the bleeders, one remedy is to drive panel headings in advance and provide pumping facilities to remove water and, of course, avoid placement of bleeders in the low spot of a seam.

An alternative method of providing bleeders for the mining plan is shown in Fig. 11.7.2.14. Here a four-entry system is developed in between the submains with two intakes in the center and a return on either side. The butt drivage at the end is reduced to a single heading (bleeder) and is connected to the nearest return with regulation in the bleeder. This plan provides an effective and flexible bleeder system, approachable from the intake side for cleaning the bleeders and adjusting the regulators.

BLEEDER ENTRIES FOR LONGWALL SYSTEMS. Bleeder entry development for longwall mining calls for careful planning. A good method consists of providing a set of four or five entries as main bleeder returns with solid barriers on each side (Fig. 11.7.2.15). The head and tailgate development for the longwall will be connected at the back end by four or five entries that form the backend bleeder.

Initially, at one mine, the longwall block was retreated from the outside heading of the backend bleeder. Present design (Fig. 11.7.2.16) provides for a protective barrier of 200 ft (61 m) where three rooms on narrow centers are provided when the longwall is started. Extremely gaseous conditions encountered when the immediate roof and overlying strata collapse here necessitated the use of vertical degasification boreholes equipped with exhausters, in some cases to supplement the underground bleeder system.

The problems involved in bleeding and bleeder system development are extremely difficult ones, and deserve critical attention in the planning stage.

11.7.2.7 Ventilation Planning Example

Example 11.7.2.1. To illustrate the complete procedure involved in designing a coal mine ventilation system, the mine

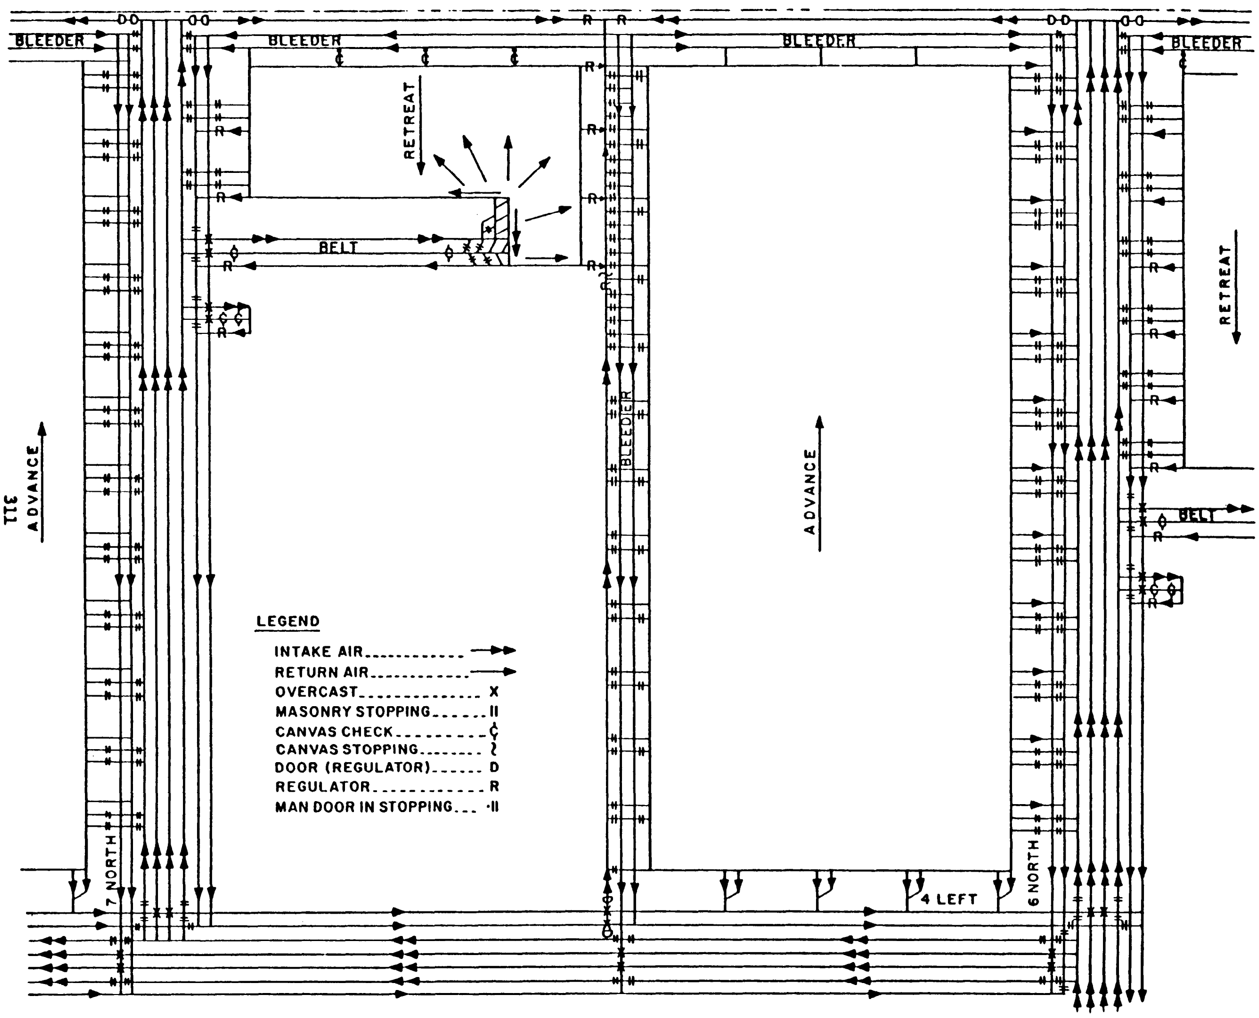

Fig. 11.7.2.13. Central bleeder system (Kalasky and Krikovic, 1973).

shown in Fig. 11.7.2.17 is used (Stefanko, 1983). It is located on a property 1 by 3 miles (1.6 by 4.8 km) in area at a depth of 1000 ft (305 m) in a highly gaseous seam. The mains are driven in the north-south direction (3 m or 4.8 km) along the center of the property. The property will be mined on a half-advance, half-retreat arrangement. Panels (2000 ft or 610 m long) will be driven and mined to the left on advance until the property line is reached; panels will then be driven on the right on retreat. Only the northern half of the mine on advance is shown as the southern half is a mirror image of the northern half. All entries are 16 ft (4.9 m) wide on 100-ft (30.5 m) centers. It is assumed that six machine units (four on development and two on pillaring) are required to meet the production tonnage of 2000 tons (1814 t)/ shift. Panel belts will transfer coal to a main belt.

Solution.

QUANTITY CALCULATIONS—MINING UNIT. Assuming a gas liberation rate of 40 ft^3/ton (1.25 m^3/t) of coal mined and a mining rate of 5 tpm (4.54 t/min), the amount of gas liberated per minute during cutting is 200 ft^3 (5.66 m^3). The amount of fresh air required to dilute the gas to a methane content below 1% is 20,000 cfm (9.44 m^3/s).

It is good practice from the health point of view to provide two splits of air in a panel, one for the continuous miner and another for the roof bolter. In this arrangement, the dust-laden air from the continuous miner is placed directly in the return. Further, there is no line brattice through which shuttle cars must tram, reducing leakage which otherwise adversely affects the air distribution in the face area. Thus two splits of air, 20,000 cfm (9.44 m^3/s) for the miner and another 20,000 cfm (9.44 m^3/s) for the other machine units, are utilized in a section.

BELT VENTILATION. Belts may not be placed in main intakes or returns but must be isolated in order to prevent the spreading of a fire, and only that amount of air is to circulate in them that is necessary to maintain methane concentrations below 1%. The air passing over the belt must be placed directly into the return rather than being transported to working faces. Since there is a certain amount of air leakage where the belt passes through the doors near the head end, belt air travel direction is usually into the panel to utilize the leakage. Normally, a temporary stopping will be placed across the belt entry just outby the belt-loading point with a regulator in the outby crosscut that regulates the belt air directly to the return.

In the sample calculation, a small quantity of air (5000 cfm or 2.36 m^3/s) will be split from the main intakes at the head of the belt and dumped directly into the returns near the tail of the belt.

LEAKAGE CONSIDERATIONS. There will be leakage through the stoppings in the panel from intake to return. The quantity

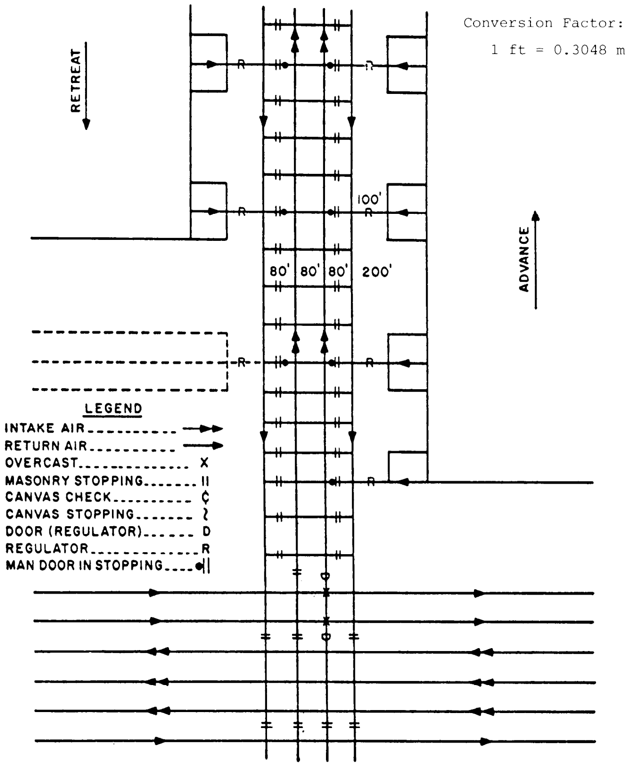

Fig. 11.7.2.14. Better design for a central bleeder (Kalasky and Krikovic, 1973).

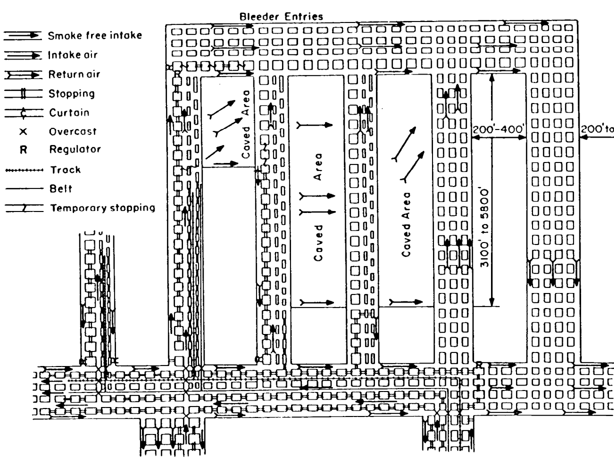

Fig. 11.7.2.15. Bleeder system for longwall workings—Case A (Kalasky and Krikovic, 1973). Conversion factor: 1 ft = 0.3048 m.

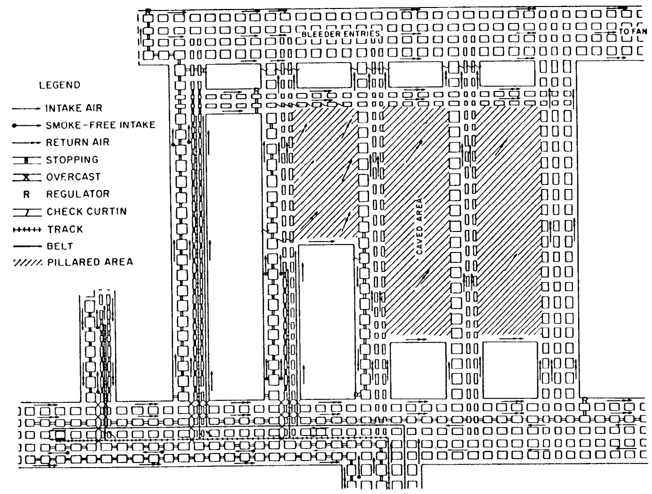

Fig. 11.7.2.16. Bleeder system for longwall workings—Case B (Kalasky and Krikovic, 1973).

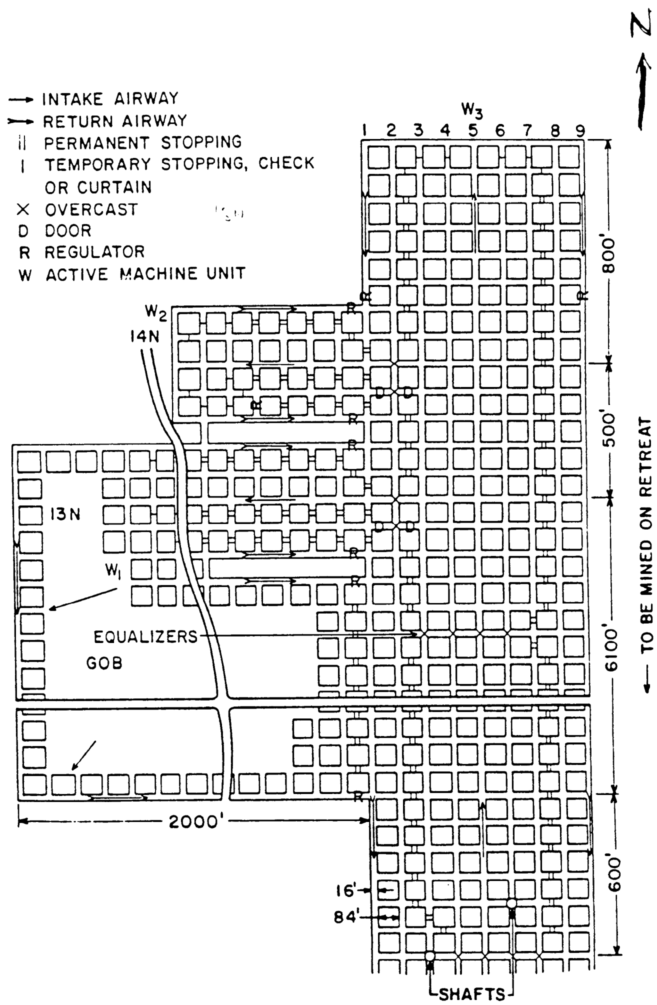

Fig. 11.7.2.17. Double-split system of mine ventilation. (Stefanko, 1983). Conversion factor: 1 ft = 0.3048 m.

of air required at the entrance to the panel will be much higher than the 40,000 cfm (18.88 m^3/s) calculated as required at the last open crosscut. When the panel is fully developed (i.e., 2000 ft or 610 m, with 20 crosscuts), there will be two rows of stoppings between the intakes and the returns on either side of the intakes, and one additional row of stoppings for the isolated belt. Assuming a maximum leakage of 1000 cfm (0.472 m^3/s) through the stoppings in each crosscut, a total leakage quantity of 20,000 cfm (9.44 m^3/s) is estimated, making the air required at the panel entrance 65,000 cfm (30.68 m^3/s) (60,000 cfm, or 28.32 m^3/s, for the unit + 5000 cfm, or 2.36 m^3/s, for the belt).

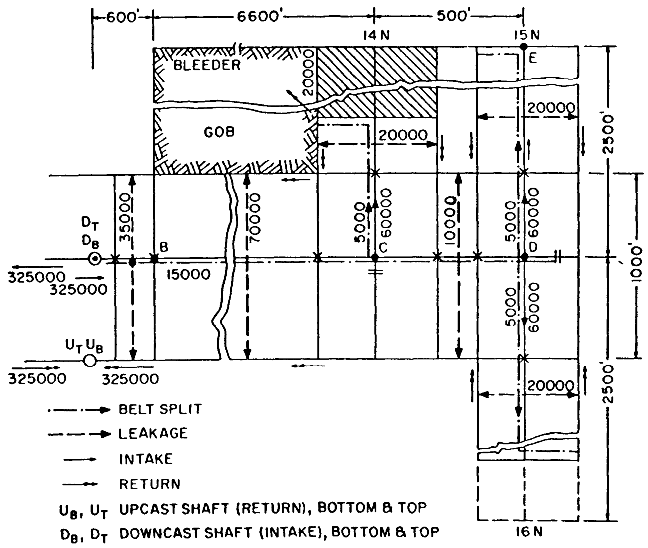

Fig. 11.7.2.18. Ventilation schematic for mine in Fig. 11.7.2.17. Conversion factors: 1 ft = 0.3048 m, 1 cfm = 0.47195 × 10^{-3} m^3/s.

The air quantity that must be apportioned at the fan for a panel must provide for air leakage between the main intakes and returns through the stoppings, overcasts and mandoors. The farthest panel (i.e., the one at the property line) will be approximately 8000 ft (2438 m) or 80 crosscuts away from the fan shaft. Fortunately, control devices in the mains are built more substantially than those in panels because they have to be in service through the life of the mine. Assuming 500 cfm (0.236 m^3/s) leakage of air per stopping through each crosscut, a total leakage of 40,000 cfm (18.88 m^3/s) is estimated, making the air required at the fan 105,000 cfm (49.55 m^3/s) for a panel. Thus, with three active panels in the north, the total air required for the panels will be 315,000 cfm (148.66 m^3/s). To this must be added the air required for the main belt, which is estimated at 10,000 to 15,000 cfm (4.72 to 7.078 m^3/s), making the total air required for the north side 325,000 cfm (153.38 m^3/s). The air required for the south side will be another 325,000 cfm (153.38 m^3/s), making a total fan quantity of 650,000 cfm (306.76 m^3/s).

HEAD LOSS CALCULATIONS—MAIN ENTRIES. The cross-sectional area of an entry is 16 by 6 ft (4.88 by 1.83 m) = 96 ft^2 (8.92 m^2). The maximum velocity permitted in the mains is, say, 800 fpm (4.06 m/s). Then one entry can carry 76,800 cfm (36.25 m^3/s) of air. The number of entries needed to carry 315,000 cfm (148.66 m^3/s) (10,000 cfm, or 4.72 m^3/s, will be carried by the belt entry) is just over four entries (315,000 ÷ 76,800). Because the air from the mains is split into the submains and panels, and leakages occur between the main intakes and returns, in practice, the mains handle progressively lower quantities. On the other hand, the entire 96-ft^2 (89.2-m^2) area of an entry may not be available for airflow. Therefore, for this example, the number of intake entries is set at five, the number of return entries at four and one isolated belt entry is provided, making a 10-entry main.

PANEL ENTRIES. Since the panel entries have to carry only 60,000 cfm (28.32 m^3/s), a three-entry development—one intake entry, one return and one isolated belt entry—can suffice. However, for providing a separate intake escapeway and greater production potential, a five-entry development is adequate.

BLEEDER. The quantity of air to be regulated into the bleeder from the active pillaring section is 20,000 cfm (9.44 m^3/s). The air flows through the gob and joins the main return at a distance of 600 ft (183 m) away from the return shaft.

LEAKAGE. For the purpose of head loss calculation, unless it is definitely known that an inordinate quantity of air is leaking through a particular airway, it is assumed that leakage air is uniformly distributed over the entire airway. Thus the quantity flowing in an airway is the average of the quantity flowing in the beginning and end of the roadway. In the ventilation schematic shown in Fig. 11.7.2.18, the North mains have been developed to the property limits. The most critical situation with regard to ventilation will arise when the unit in 14-N panel will be pillaring, 15-N panel is nearing completion of development to the boundary to the west prior to pillaring, and 16-N panel (the first panel to the east of the mains) will be on development. Examination of the ventilation schematic reveals that the free split is the path from the downcast shaft through the 15-N panel to the upcast shaft.

FRICTION FACTORS. The values for friction factors must always be chosen on the basis of field measurements under conditions that are similar to the mine conditions. For new mine projections in virgin areas, the following general values can be used.

Concrete-lined shaft:	15 × 10^{-10} lb-min^2/ft^4	(0.00278 kg/m^3)
Intake airways:	80 × 10^{-10} lb-min^2/ft^4	(0.0148 kg/m^3)
Return airways:	100 × 10^{-10} lb-min^2/ft^4	(0.0186 kg/m^3)

SHOCK LOSS CONSIDERATIONS. In the calculation of head loss in each segment of the airway, consideration must be made for shock losses that may be encountered due to such conditions as splitting, changes in areas, overcasts, and changes in direction. Shock losses can be minimized by gradual changes in area and direction, but can never be eliminated. The longest segment in the example mine is from the bleeder junction (B) to the 14N entrance (C). Considerations for shock loss on the basis of the number of overcasts, doorways, obstructions, and area changes must be made for this segment. The second largest segment is the panel mains in 15N from D to E. Here also, considerations for shock loss on the basis of the number of doorways and obstructions must be made. In the calculations in Table 11.7.2.1, therefore, equivalent lengths of 1000 ft (305 m) for the segment BC and 200 ft (61 m) for the segment DE have been assumed.

TOTAL HEAD LOSS. It is convenient to calculate the head loss in each segment of the airways and add the head losses in series to calculate the total head loss. It is also preferable to use a tabular format for the calculations. The following formulas are used for calculating head loss (see Chapter 11.6):

$$H = RQ^2 \tag{11.7.2.1}$$

where R is resistance of the airways in parallel

$$R = \frac{R_1}{n^2}, \tag{11.7.2.2}$$

where R_1 is resistance of one airway, n = number of identical airways in parallel.

$$R_1 = \frac{K(L + L_e)O}{5.2A^3} \tag{11.7.2.3}$$

$$R_1 = \frac{K(L + L_e)O}{A^3} \tag{11.7.2.3a}$$

Table 11.7.2.1. Resistance Calculations for the Mine Segments

						Σ = 5.6797

Notes:
1. A split of 15,000 cfm is taken for the main belt.
2. A split of 65,000 cfm is taken for the 14-N section and panel.
3. The leakage into return also includes the belt return.
4. This includes return from 15N, 16N and main belt.
5. Return from 14-N is 45,000 cfm.
6. Return from the bleeder 20,000 cfm.

Conversion factors: 1 cfm = 0.47195 × 10⁻³ m³/s, 1 in.-min²/ft⁶ = 1.117 × 10⁹ N-s²/m⁸, 1 in. water = 248.84 Pa.

where R is the resistance in in.-min²/ft⁶ (N-s^2/m⁸), K is friction factor in lb-min²/ft⁴ (kg/m³), L is length of airway in ft (m), L_e is equivalent length to account for shock conditions in the airway in ft (m), O is perimeter of the airway in ft (m), and A is cross sectional area of the airway in ft² (m²).

Table 11.7.2.1 shows the calculation of mine resistance for each segment, and Table 11.7.2.2 shows the calculation of head loss for each segment. The head loss in the circuit is calculated as 5.68 in. water (1.413 kPa). Adding about 0.32 in. water pressure (79.63 Pa) for losses across the face in 15-N on a line brattice, the fan must develop a static head of nearly 6 in. water (1.493 kPa).

FAN SELECTION. A fan that can develop static head of 6 in. (1.493 kPa) water and 650,000 cfm (306.77 m³/s) is needed, and it must be able to handle this quantity with high efficiency. The fan motor selected to provide adequate horsepower for the total mine/fan head, and the fan must operate in an adequate range of capacities since it must be operated during the life of the mine during which time the mine requirements for quantity and head will increase.

Using the Jeffrey fan selection chart (see Fig. 11.6.22, Chapter 11.6), an initial selection of a fan can be made. It can be seen that a 8HU117 fan operating at 710 to 880 rpm can provide the required head and quantity. However, the efficiency of this fan at this high quantity is rather low. To increase the efficiency, a possible combination may be two 8HU117 fans operating in parallel at 710 rpm, each producing 350,000 cfm (165.18 m³/s) at 6 in. (1.493 kPa) static head. The operating point of each fan is nearly at the middle of its quantity capacity (≅ 750,000 cfm, 353.96 m³/s), and the head is within the range of 2 to 10 in. water (0.498 to 2.488 kPa) . At this operating point, the fan efficiency is well above 80%. The horsepower of the motor (from the curve) at 70% efficiency is 500 (373 kW). At 80% efficiency, the fan motor will be sized at 440 hp (328 kW). The static air horsepower at the operating point is given by $\frac{6 \times 350{,}000}{6350} \cong 331$ (247 kW), resulting in an overall static efficiency of approximately 75% [= (331/440) × 100].

Yet another method for initial selection can be the use of charts of specific speeds and specific volumes. Assume a specific volume Qs = 2000 cfm (0.94 m^3/s); then from Eq. 11.6.44 (Chapter 11.6),

$$D^2 = \frac{Q}{Q_s\sqrt{H}} = \frac{650{,}000}{2000 \times \sqrt{6.0}} = 132.68 \text{ ft}^2 \ (12.33 \text{ m}^2)$$

$$D \cong 11.52 \text{ ft } (3.35 \text{ m})$$

Choose a fan 12 ft (3.66 m) diameter. The specific volume for a 12-ft (3.66-m) fan is

$$Q_S = \frac{650{,}000}{(12 \times 12)\sqrt{6.0}} = 1850 \text{ cfm } (0.87 \text{ m}^3/\text{s})$$

Enter chart (Fig. 11.6.20, Chapter 11.6) at 1850 cfm (0.87 m^3/s), and note that several blade settings (#1, #4, #7, and 2B-1S) have efficiencies approaching 80% at $Q_s \cong 1850$ cfm (0.87 m^3/s). The specific speed n_s for the (2B-1S) blade setting is approximately 2500, and for the #1 blade setting is approximately 3000. Choosing the lower specific speed, the fan speed can be calculated from Eq. 11.6.43 (Chapter 11.6) as

$$n = \frac{n_s\sqrt{H}}{D} = \frac{2500 \times \sqrt{6}}{12} = 510 \text{ rpm}$$

$$P_m = \frac{650{,}000 \times 6}{6350 \times 0.8} \cong 768 \text{ bhp } (573 \text{ kW})$$

A 12-ft (3.66-m) diameter fan connected to a 768-hp (573-kW) motor operating at 510 rpm may be an initial choice.

For a lower Q_s, say, Q_s = 1500 cfm (0.71 m^3/s),

$$D^2 = \frac{650{,}000}{1500 \times \sqrt{6.0}} = 176.91 \text{ ft}^2 \ (16.43 \text{ m}^2)$$

$$D = 13.50 \text{ ft} \cong 14 \text{ ft } (4.27 \text{ m})$$

This is a very large-diameter fan. Assuming that two smaller fans will be placed in parallel, to divide the quantity between them equally, the diameter of the fan for the same specific volume (i.e., Q_s = 1500, or 0.71 m^3/s),

$$D^2 = \frac{325{,}000}{1500 \times \sqrt{6.0}} = 88.45 \text{ ft}^2 \ (8.22 \text{ m}^2)$$

$$D = 9.3 \text{ ft} \cong 10 \text{ ft } (3.05 \text{ m})$$

Assume two 10-ft fans in parallel:

$$Q_s = \frac{325{,}000}{100 \times \sqrt{6.0}} = 1327 \cong 1400 \text{ cfm } (0.66 \text{ m}^3/\text{s})$$

Enter chart (Fig. 11.6.20) at 1400 cfm (0.66 m^3/s) and note that peak efficiency (80%) occurs at blade setting No. 1 and that specific speed is 2800.

$$n = \frac{2800 \times \sqrt{6}}{10} = 685.86 \cong 700 \text{ rpm}$$

$$P_m = \frac{325{,}000 \times 6.0}{6350 \times 0.80} = 384 \text{ bhp } (286.35 \text{ kW})$$

Thus two 10-ft (3.05-m) diameter fans in parallel, each operating at 700 rpm and connected to a 384-hp (286.35-kW) motor, may be another choice.

Each of these alternatives is associated with quantifiable factors such as capital and operating costs, and non-quantifiable but important qualitative factors such as flexibility, availability, standardization, and future mine extensions. The actual selection of a fan will be the result of the judgmental evaluation by the engineer of these factors. Economics in mine ventilation costs must be accomplished by reducing the static and total heads of the mine. The reductions are achieved by having straight, clean, and unobstructed airways and, wherever possible, a number of airways in parallel; by reducing the leakage through stoppings, overcasts, and airlocks; by selecting and operating fans with high efficiency for the desired mine quantity and head. In addition to the extreme care in the design of the system, frequent mine ventilation surveys and regular maintenance of the components of the ventilation system—airways, control devices, and fans—are required to assure continued safe performance of the ventilation system. The modern automatic monitoring techniques—for gases, quantities, pressures, temperatures, power, etc.—can be effectively applied to the ventilation system to aid managers and engineers in maintaining the integrity of the health and safety aspects of the system (Ramani, 1982) (also see Chapter 12.6).

The example just developed is for a relatively small mine. In large mines, it is impractical to take in all the air through one shaft and return it through another, and so a multiple-fan-and-shaft arrangement becomes necessary. In such a situation, each fan has a zone of influence, and all the zones are interconnected. Difficult ventilation problems may arise at zone interfaces where there may be no airflow (i.e., neutral zones) or air directions may be the reverse of those desired. The areas of influence of each fan vary as a complex function of such factors as the advance rates of the interconnected zones, distances from the main intakes, and the fans and their blade settings (Mishra, Ramani and Wang, 1978).

Mine ventilation planning must include provisions for future expansion and exigencies that must be incorporated into the initial design. When planning with computer-oriented mine ventilation network analysis programs, it is possible to try out various alternatives with regard to factors such as fans, shafts, and mains (Wang, 1982; Ramani, 1988). Stefanko and Ramani (1972) present the application of a mine ventilation network analysis program to the ventilation planning example discussed in this chapter. The complex calculations involved with multiple-fan, multiple-shaft ventilation systems are best carried out on a mine ventilation network analysis digital computer program (see Chapter 11.10).

Chapter 11.8
NOISE ABATEMENT

LEONARD MARRACCINI

11.8.1 INTRODUCTION

In the United States, mining activities began in the 1700s. This was strictly manual, labor-intensive type of mining. By the late 1800s, mechanization began to replace manual labor. Today mechanization in the mining area involves state-of-the-art technology, including lasers, computer-operated equipment, etc. However, along with mechanization has come one byproduct—the generation of *noise.* Various types of mining equipment generate noise levels for different lengths of time, depending upon the mining operation. This results in employee noise exposure. Many times, this exposure is in excess of the federal mining noise regulations. Over exposure to excessive noise levels has resulted in hearing loss.

Depending on the situation, noise can be a significant problem, particularly in view of the large number of mines and miners. In the beginning of 1988, there were 17,778 mines in operation in the United States. Of this total, 6276 were coal mines, and 11,502 were noncoal (metal or nonmetal) mines. A total of 330,871 people were employed in the industry, 145,096 in coal mining, and 185,775 in noncoal mining.

Due to the high degree of mechanization involved in the industry, and the number of operations and people employed, noise is one problem that must be addressed. Throughout this chapter, various concepts will be presented regarding noise and noise abatement. Some of the key terminology and definitions that are used repeatedly are listed as follows:

1. Noise—unwanted sound.
2. dBA noise level—the overall noise level, measured in decibels, A-weighted.
3. Frequency distribution—the range of frequencies that compose the noise spectrum, typically in the audible range of 20 to 16,000 Hz.
4. Acoustical materials—any material specifically designed for or used to reduce the noise levels.
5. Retrofit—to modify existing equipment that is already in service.
6. Noise dose—the amount of noise exposure that an employee is exposed to for a given amount of time.

This chapter briefly summarizes mining noise regulations, noise measurement instrumentation, survey procedures, and noise abatement techniques.

11.8.2 NOISE REGULATIONS

Regulations dealing with noise exposure in the mining industry fall into two categories, state, and federal. Essentially, the various states that have mining noise regulations refer to or mirror the federal regulations. Thus this discussion focuses on the federal regulations. The Mine Safety and Health Administration (MSHA) has jurisdiction of the enforcement activities for the mining industry. The Federal Coal Mine Safety and Health Act of 1969 contained the first noise regulations pertaining to mining in the United States. This Act prescribed noise levels as stated in the Walsh-Healy Public Contracts Act. The Walsh-Healy criteria for noise are shown in Table 11.8.1.

Table 11.8.1. Walsh-Healy Noise Criteria

Maximum Noise Level, dBA	Maximum Exposure Time, min.
90	480
95	240
100	120
105	60
110	30
115	15

No noise level shall exceed 115 dBA for any period of time.
Source: Anon., 1989.

Basically, these criteria involve exposure to specific levels of noise for specific time intervals. For each 5-dBA increase in the noise level, the maximum exposure time is halved.

The Occupational Safety and Health Administration (OSHA) standards differ from MSHA limits by assigning 85 dBA for 8 hours for hearing conservation purposes. For enforcement purposes, OSHA also uses 90 dBA for 8 hours.

The Federal Metal and Nonmetallic Mine Safety Act of 1974 incorporated the same Walsh-Healy criteria. Several years later, the Federal Mine Safety and Health Act of 1977 amended the Federal Coal Mine Safety and Health Act of 1969 to include all mines, coal and metal and nonmetal. The 1977 Act also repealed the Federal Metal and Nonmetallic Mine Safety Act of 1974.

The current regulations concerning noise in the mining industry can be found in Title 30, *Code of Federal Regulations* (CFR), Chapter 1 (Anon., 1989). In the Code, regulations pertaining to noise in metal and nonmetal facilities can be found in Subchapter N, Part 56, Subpart D (surface operations), and Part 57, Subpart D (underground operations). Regulations pertaining to noise in coal facilities are found in Subchapter O, Part 70, Subpart F (underground operations), and Part 71, Subpart I (surface operations). These regulations still contain the same criteria as in the Walsh-Healy Act. The regulations also specify noise measurement instrumentation, instrument calibration, measurement procedure, etc.

11.8.3 NOISE INSTRUMENTATION/SURVEY PROCEDURES

Before undertaking any noise abatement work, the trained investigator should utilize appropriate instrumentation to make various noise measurements. A wide range of instrumentation is commercially available to measure noise. The specific type of noise instrumentation chosen depends upon what type of data is required. All instrumentation, regardless of its usage, does have to meet specific standards, primarily those of the Acoustical Society of America (ASA) or American National Standards Institute (ANSI). Additionally, when noise measurement instrumentation is used in an underground gassy mine, the instrumentation must also meet the MSHA permissibility requirements. The permissibility requirement essentially safeguards against the ignition of methane gas by electrical equipment.

Fig. 11.8.1. Sound level meter.

Fig. 11.8.2. Noise dosimeter.

Some of the more common types of noise instrumentation and their associated functions are described as follows. One of the most basic instruments is the *sound level meter* (SLM), which is used to measure the overall noise level. With various electronic weighting networks built into the instrument, the SLM can respond to noise in the same way the human ear responds (A-weighting), or it can have an almost flat or linear response (C-weighting). A typical sound level meter is shown in Fig. 11.8.1.[1]

Another instrument frequently used is the *personal noise dosimeter*. This instrument, worn by the employee, measures the noise exposure for an employee and cumulates this information for up to 8 hours. This noise dose is based upon either OSHA, MSHA, or other regulatory specifications. For an example of this device, see Fig. 11.8.2.

The sound level meter and personal noise dosimeter are instruments that yield information primarily used in noise regulation work. However, to obtain specific acoustical engineering data, other types of instrumentation are required. One is a *portable noise analyzer* that measures the frequency components of the noise in either octave or third-octave bands (Fig. 11.8.3).

Another instrumentation system is a *precision tape recorder and microphone system* (Fig. 11.8.4). This system is used to tape record the noise in field situations. The tape recorded data can then be returned to the laboratory where it is analyzed by means of an analyzer, either octave band, third-octave band, narrow band, or even fast fourier transform analyzer.

By using the data from the portable noise analyzer or the analyzed tape data, the investigator can develop a graph illustrating the frequency distribution of the noise levels. As stated before, this is an important piece of engineering data needed for noise control work. An example of a graph illustrating the frequency distribution of noise is shown in Fig. 11.8.5.

Thus, depending upon the type of noise data required, various types of instrumentation are available to conduct a noise survey.

Noise surveys can have a wide range of descriptors; however, they basically are considered as either a health survey or an engineering survey. Although the bottom line of the work is to protect the employees' hearing, there are distinct differences between the health and engineering survey. The health survey is conducted to determine if an employee receives an overexposure to noise. The survey involves the use of either a sound level meter or personal noise dosimeter. Regardless of the instrumentation used, this type of survey requires that the investigator follow the employee for the entire shift, using a stop watch to accurately note work duties and locations. These times are then correlated with the starting time of the employee and the instrumentation measurements. Thus, at the end of the shift, the investigator can determine the employee's noise exposure on an overall basis, and more importantly, on a work duty or work location basis.

The engineering survey is conducted to determine what mechanical component, or components, on a piece of noisy mine equipment is creating the problem. The investigator already knows that the mine equipment is the source of the employee's overexposure to noise. It is his job then to determine which component, or components, on the equipment need to be treated with acoustical materials, etc. To do this, the investigator obtains data using either a microphone-tape recorder system or portable noise analyzer. Diagnostic tests are conducted on the various machine components, or operating modes, of the machine. The resulting noise spectra (frequency distribution of the noise) can be used to pinpoint the machine component or operating mode that is causing the problem. Engineering noise control techniques can then be instituted.

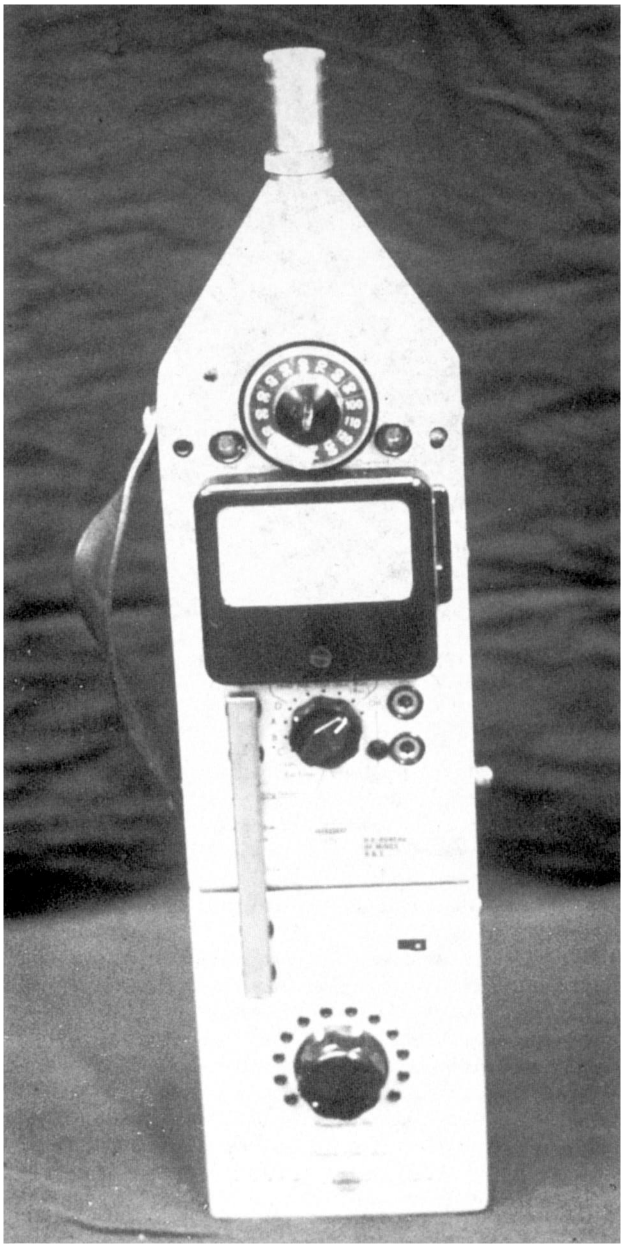

Fig. 11.8.3. Portable noise analyzer.

11.8.4 BASIC NOISE ABATEMENT

When noise abatement work is anticipated, the investigator has to decide the most appropriate approach. In classical noise abatement, this involves either the treatment of the noise *source,* interrupting the *path* or route the noise travels, or isolating the *receiver* or employee who is overexposed to the noise. With regard to each of these approaches, various questions must be answered such as the anticipated length of time the mine equipment will be out of production, the economics of the approach, and whether the equipment will be retained or shortly phased out.

In deciding the most appropriate approach to noise abatement, the mine operator may be confronted with certain situations that may involve a newly purchased or soon-to-be purchased piece of equipment. In the best interest of the mining company, it has been shown that noise controls designed and installed at the manufacturing site are more effective than noise controls installed at the mine site as a retrofit approach after the equipment has been purchased. Also many mining companies have begun to specify in the purchase agreements that the new equipment meet current noise regulations. This puts the burden of effective noise control on the manufacturer as opposed to the mine operator.

If the mine operator decides that the noise abatement work will be done at the mine site as a retrofit program, he must realize that the most important factors in achieving maximum noise reduction are the selection of the *proper* acoustical materials and the quality of the installation. This has been proven time after time. The selection of acoustical materials has to be tied very closely with the frequency range of the noise involved. If, for example, the noise is predominately high frequency, then the acoustical material chosen should be the one that has characteristics that operate most effectively at the same high frequency range. Similarly, if the noise is predominantly mid-frequency, then the acoustical material chosen should be most effective in the mid-frequency range. With the current cost of acoustical materials and the large number of materials available, it is senseless to have an “any material will do” attitude.

Acoustical materials, in addition to the frequency characteristics, can be classified into three groups. Each group performs somewhat differently. *Absorptive materials,* composed of a lightweight open cell or fiber structure, absorb sound energy, similar to a sponge absorbing water. Some common examples of absorption materials include fiberglass, various foams, and mineral wool. *Transmission-loss (barrier) material,* being a high-density material, actually reflects sound energy, thus preventing the sound from passing through it. Some common examples of transmission-loss material include brick, lead, and plywood. Finally, the *composite materials* are composed of a high-density material sandwiched between two layers of absorptive material. Fabricated in this manner, the composite material has both absorptive and transmission-loss properties. There is one other category of materials, not commonly thought of as acoustical material, that deals with vibration isolation and damping. These vibration materials are used to prevent one vibrating component from transmitting vibrational energy to another component by isolation, or to dampen a vibrating plate. As mentioned previously, each category of material has different properties and should be used accordingly.

One other item should be discussed regarding any type of acoustical or vibrational material. This is the flammability of the material. At the present time, MSHA does not have regulations pertaining to flammability of acoustical materials. However, it does have guidelines. These guidelines refer to the flame-spread index as measured by either ASTM E-162 or E-84 test standards. The investigator and mine operator should be very aware of the flammability properties of the acoustical materials that are intended for use. This is particularly important during any maintenance work where burning, welding, or any open flame is present near the installed acoustical materials.

After the proper acoustical materials have been selected, one more matter needs to be addressed for the most effective noise reduction to occur. This last item involves the quality of the installation, and it can be summarized as follows: *Regardless of how good the acoustical material is, maximum noise reduction will not be achieved by shoddy installation practices.* The proper installation of these acoustical materials requires forethought, planning, and last but not least, patience. To rush through an installation almost always results in unsealed holes or cracks,

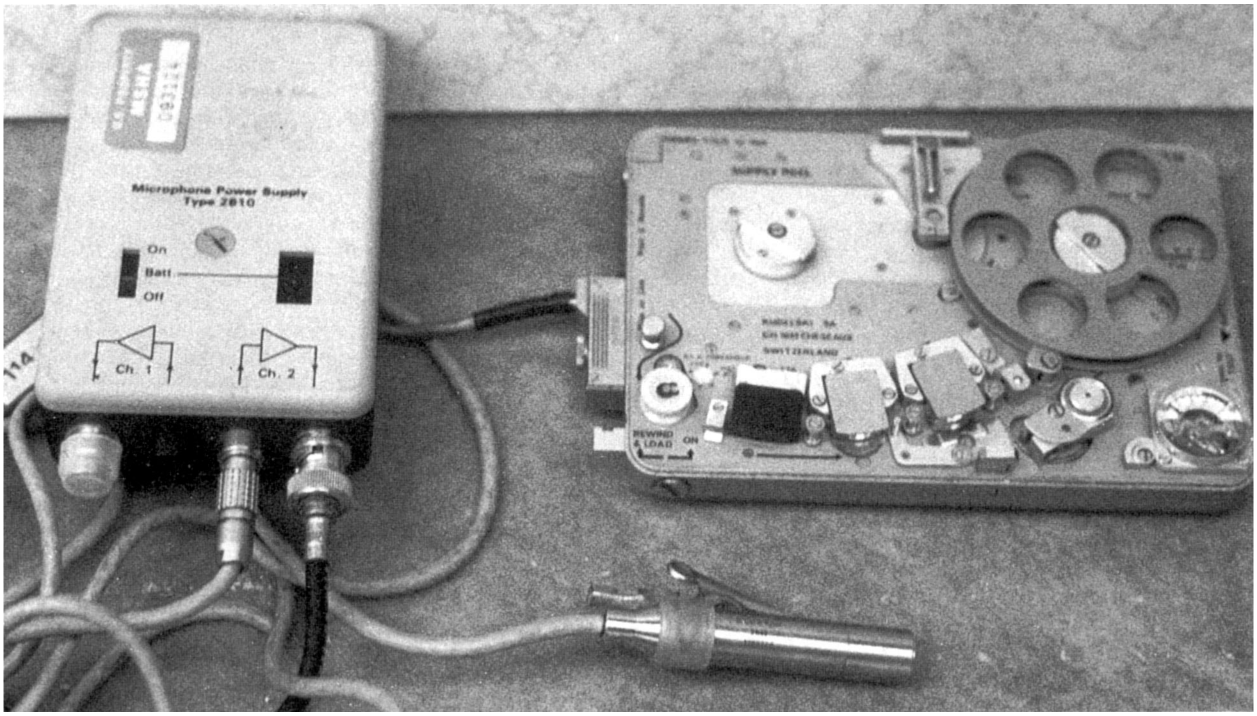

Fig. 11.8.4. Tape recorder and microphone system.

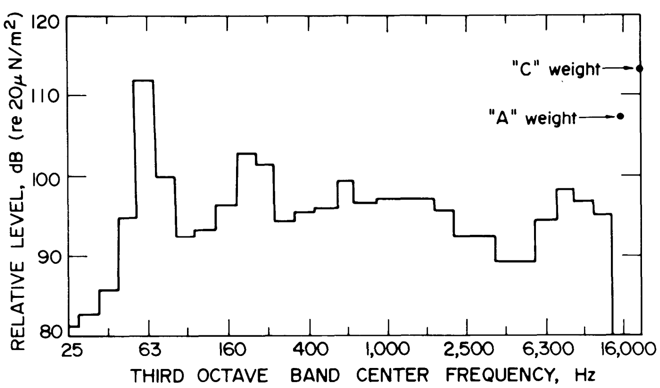

Fig. 11.8.5. Graph of frequency distribution of noise.

poorly fitted materials, etc. The end result is that the maximum noise reduction will not be achieved regardless of the quality of the acoustical materials used.

11.8.5 EXAMPLES OF NOISE CONTROL

Space requirements do not permit an in-depth discussion of noise controls for the wide range of mining equipment in use today. Instead, the discussion here is limited to "generic" machine types that can be characterized as mobile surface and underground equipment and preparation plants. It must be emphasized that these noise controls are general in content.

11.8.5.1 Mobile Surface Equipment

Most mobile surface equipment, such as bulldozers, front-end loaders, haulage trucks, etc., are diesel-powered. As such, the noise controls associated with this type of equipment are very similar, particularly from a retrofit aspect. Typical noise sources may include the diesel engine, exhaust, drive train, and torque converter. One of the most common techniques for noise control involves the installation of an exhaust muffler (properly matched to the engine specifications) to reduce the exhaust noise, and the isolation of the operator from various noise sources by installing acoustical materials to the inside surfaces of the operator's cab.

On equipment such as cranes, shovels, and draglines, a common noise control technique involves the installation of a barrier (flexible or rigid) between the operator and the engine area. This is done to prevent engine and gear noise from reaching the operator. In addition to this barrier, acoustical materials are installed in the area around the operator to absorb any noise that leaks through the barrier.

With most mobile equipment types, one of the more favorable aspects of retrofit noise control work is the availability of the equipment. The equipment can be taken out of production and relocated if needed to a shop area or adjacent to a shop area for the installation of the noise controls.

11.8.5.2 Underground Equipment

The task of performing retrofit noise control work on underground mining equipment is by far the most difficult in comparison to mobile surface equipment or preparation plant. One of the reasons for this is that in many situations, once the equipment is placed underground, it does not return to the surface unless it is scheduled for overhaul or rebuild. This time period may be as long as four or five years. However, in some cases, underground shops are available, thus making retrofit noise-control installation easier.

Many equipment types operating in the working face area incorporate cutting heads to extract the material and chain conveyors to move the mined material. Such equipment includes auger miners, continuous drum miners, and longwall shearers. Typically, the cutting head and chain conveyor system are two of the primary noise sources. Vibration isolation and vibration damping techniques have proven effective in reducing noise levels. Specially designed cutting heads incorporating vibration damping materials have been effective. Constraint-layer damping of the conveyor pans has also been effective.

In some of the larger pieces of equipment, such as drill jumbos, an acoustically treated operator's cab has been used successfully. Where several employees are working in close proximity to a noisy piece of equipment, treatment of the various sources or troublesome components is important because of reverberant conditions found in underground mines.

11.8.5.3 Preparation Plants

Noise control work in a mineral preparation plant or processing operation can present some very challenging situations. This can be due to the potentially large number of noise sources and the movement of people throughout the operation. For a plant or systems operator, the utilization of an acoustically treated booth is essential. In some situations, where an operator periodically walks a beltline or observes material levels in bins, he may feel that he must leave the treated booth. However, this need not be the case because economical video systems can be used along the belt lines or near the bins. The operator can remain in the treated booth and observe the operations on the video screens. Also numerous bin level indicators are commercially available that can also be incorporated with the booth. For employees who must move from one location to another throughout the day, small acoustically treated booths can be placed at various locations to create "quiet" areas where the employee can go for brief periods of time. Other noise controls available include chute liners, bin liners, treated screen decking, impact pads, and partial barrier curtains.

Regardless of the situation, be it either mobile surface equipment, underground equipment, or preparation plant equipment, a wide range of noise controls is available to reduce employee noise exposure.

11.8.6 PERSONAL PROTECTIVE DEVICES (HEARING PROTECTION)

When engineering noise controls and/or administrative controls such as changing work routines fail to bring employee noise exposures into compliance with regulations, personal hearing protection can be utilized. These devices are commercially available in a wide range of styles, models, and configurations. These include earplug devices, earmuff devices, and cap-mounted earmuff devices. All of these should be tested according to the latest ANSI standard. This standard is used to evaluate hearing protectors under optimum (laboratory) conditions. From these test data, a noise reduction rating (NRR) value is calculated. This rating value can give an estimation of the expected effectiveness of the devices. However, numerous organizations have conducted research that indicates that when the hearing protector is used in an actual work environment, the effectiveness of the device can be significantly less than that measured in the laboratory. There is a wide range of variables that can contribute to this difference, such as the various noise spectra of the equipment encountered, poor fit on the individual, use of other safety equipment such as safety glasses and hard hats, improper maintenance of the hearing protector, etc. Thus, individuals should not consider hearing protector devices as the complete "cure-all" from noise exposure. If the employee must depend upon hearing protectors, then that person should be properly trained, and be made aware of the limitations of the hearing protectors.

Chapter 11.9
MINE ILLUMINATION

KENNETH WHITEHEAD AND GEORGE R. BOCKOSH

11.9.1 INTRODUCTION

The mining environment poses unique challenges to the illuminating engineer. It is unlike most other industrial settings, in that conditions cannot be designed but rather must be accommodated. Specifically, room dimensions and surface reflectance in underground mines are defined by the deposit mined and can only be modified at great expense. A potentially explosive atmosphere, dust, and the ever-changing nature of the underground environment further complicate the illumination task.

In surface mining operations, vast areas are active 24 hours a day, and large equipment confronts operators with poor visibility. In addition, reflectivity, weather, and task variations adversely affect visual performance and impose difficult demands on illumination system design.

It is these predetermined, and often adverse, conditions that cause extreme difficulty in providing adequate *illumination in mines.* The concerns that need to be addressed include adequate illumination for hazard and operational cue recognition, the quality of lighting, and health maintenance.

11.9.2 LIGHT PHYSICS

Two major systems of units are currently used for the quantification of light: Illumination Engineering Society (IES) and International System of Units (SI). The primary difference between IES and SI systems is that the IES system uses US standard measures for linear dimensions in the unit definitions while the SI system uses metric measures. Current US coal mine lighting regulations customarily use IES units; therefore, these will be adopted primarily in this chapter.

Systems of lighting units are unique in that they explicitly apply a human weighting function to the physical energy quantity they measure. That is, all unit systems take into account how the eye exhibits different sensitivities to various light wavelengths in terms of perceived brightness and weight the energy measurements according to the spectral luminous efficiency curve (Fig. 11.9.1).

All standard systems of light units employ certain fundamental concepts that are based on convenient and meaningful approaches to light energy measurement and quantification. These basic concepts are luminous flux, illumination (illuminance), luminous intensity, and luminance.

11.9.2.1 Luminous Flux

The luminous flux symbol is ϕ, and the lumen (lm) is the flux unit used in both the IES and the SI systems.

Luminous flux is the time flow rate of light energy. Flux is a power quantity in the same manner as horsepower or Btu per hour. The unit of luminous flux, the lumen, is most frequently used to describe the total lighting power of light sources. Other light energy concepts (e.g., illumination, luminous intensity, and luminance) use the lumen in conjunction with various geometric quantities to describe the distribution of light energy flow to the surroundings. Light sources are often evaluated for their total lumen output. For example, a 100-W incandescent lamp produces about 1740 lm.

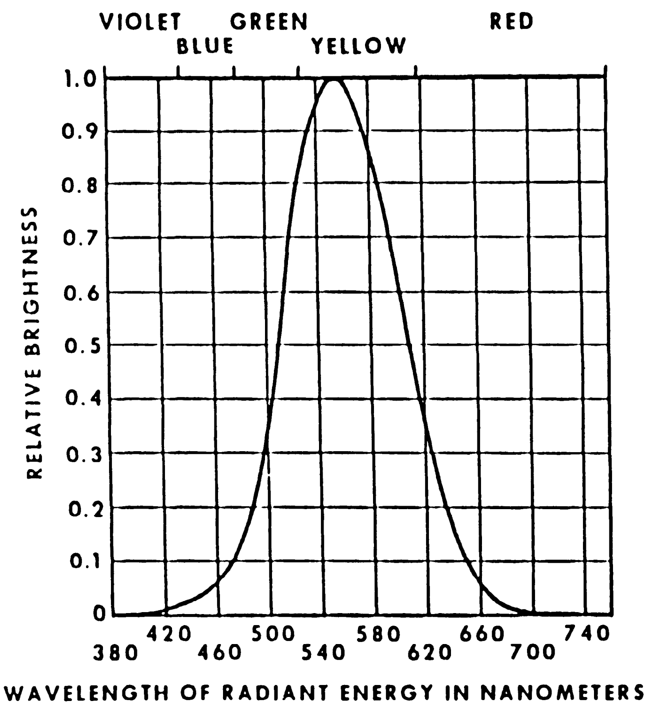

Fig. 11.9.1. Brightness sensitivity of the eye as a function of light wavelength.

Total lumen ratings of light sources, usually available from hardware manufacturers, are valuable for use in making preliminary approximations in lighting design problems. The number of lumens needed in a given situation will help determine the size and/or number of lighting fixtures necessary.

11.9.2.2 Illuminance

Illumination (illuminance) E is a measure of the density of luminous flux striking a surface. Its units are the footcandle (fc) and lumen/ft^2 in the IES system, and lux (lx) and lumen/m^2 in the SI system. Mathematically, illumination may be defined as

$$E = \phi/A_R, \tag{11.9.1}$$

where E is illumination produced by the luminous flux ϕ falling on a light-receiving surface of area A_R (Fig. 11.9.2).

As an example of the illumination concept, if light energy flowing at the rate of 9 lm is distributed over an area A of 1 ft^2, the illumination of area A is 9 fc. If the same energy is subsequently distributed over a larger area B of 3 ft^2, then the average illumination of area B is 3 fc, one-third as great as area A. The total illumination levels from two or more light sources shining on a surface are obtained by adding the illumination level produced by each source separately.

When determining illumination, ϕ in Eq. 11.9.1 concerns the total lumens striking the receiving surface area, regardless

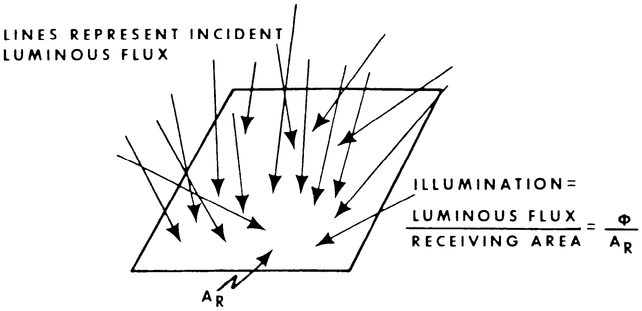

Fig. 11.9.2. Illumination.

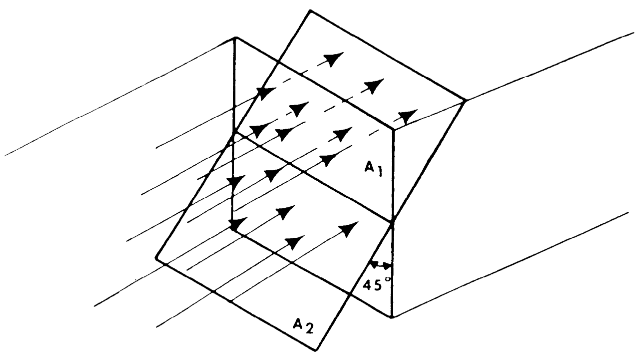

Fig. 11.9.3. Basis of the cosine law.

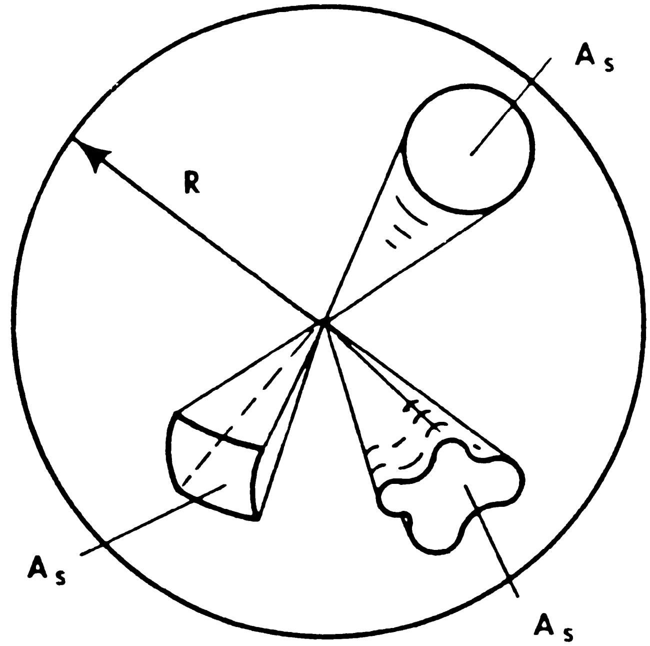

Fig. 11.9.4. Solid angle forms.

of the originating direction of the luminous flux and represents an average value. The illumination at any point on the receiving surface is determined by considering a very small area around the point as the receiving area. Point illumination for all points on a surface equals *average* illumination if the luminous flux is uniformly distributed over a surface. If the illumination is nonuniformly distributed, point illumination E_P would vary for each point on the surface.

Average illumination is an easy quantity to measure. The significance of the fact that illumination is an easy quantity to measure is that illumination measurements can be converted to other light quantities (e.g., luminous intensity), which are meaningful but more difficult to measure directly. Lighting design specifications, which are often presented in terms of illumination (footcandle or lux) levels, do not consider how a receiving surface reflects light. This is a definite shortcoming because reflected light determines what is seen. Various properties of light-receiving surfaces can affect reflectivity.

11.9.2.3 Illumination and the Cosine Law

The *cosine law* and the *inverse square law* (discussed later) are two very useful lighting laws. The cosine law states that the illumination of a surface varies as the cosine of the angle between an imaginary perpendicular line to the surface (i.e., the normal) and the actual direction of the incident light. To illustrate the cosine law, imagine a light beam consisting of uniformly distributed parallel rays traveling in a particular direction. Assume that 10 lm is incident upon surface A, with a surface area of 1 ft^2 in Fig. 11.9.3. Note that surface A is perpendicular (normal) to the direction in which the light is traveling. The average illumination of this surface could be calculated according to the discussion in the previous segment as follows: $E_1 = \phi/A$, or 10 lm divided by 1 ft^2 equals 10 fc.

Now imagine that instead of intersecting a surface perpendicular to the light's direction of travel, this same 10-lm beam intersects a surface rotated 45°, as surface A, is in Fig. 11.9.3. The illumination is now uniformly distributed over a larger area (A_2), which is equal to A_1 divided by the cosine of q.

Therefore, $E_2 = \phi/A_2$, which equals $\phi/A_1 X \cos q$ – or $E_1 X \cos q$. If q is 45°, $E_2 = E_1 \cos 45° = 10\ (0.5) = 5$ fc.

Although the cosine law derived was for average illumination, the law also applies equally to point illumination.

11.9.2.4 Luminous Intensity

Luminous intensity I is a concept used to describe how a light source (e.g., a lamp or luminaire) distributes the total luminous flux, or lumens, it emits into various portions of the space surrounding the source. Both the IES and SI unit is the candela c. The geometric concept of the *solid angle* is used to define the particular portion of surrounding space in question. Before luminous intensity is discussed, the geometric concept of solid angle must be explained.

A solid angle is simply a three-dimensional angle. It is formed by a point at the center of a sphere and a surface, of any shape, that comprises a part of the surface of the sphere. Fig. 11.9.4 illustrates various forms of solid angles.

The dimension of a solid angle w is determinated by finding the area A of the sphere subtended, or enclosed, by the angle divided by the radius R of the sphere squared. Hence,

$$w = A_s/R^2 \qquad (11.9.2)$$

The unit of the solid angle is the steradian (sr). A subtended surface area of 1 ft^2 on a sphere of l-ft radius forms a solid angle of 1 sr. Note that the spherical area subtended by a solid angle varies with the radius squared.

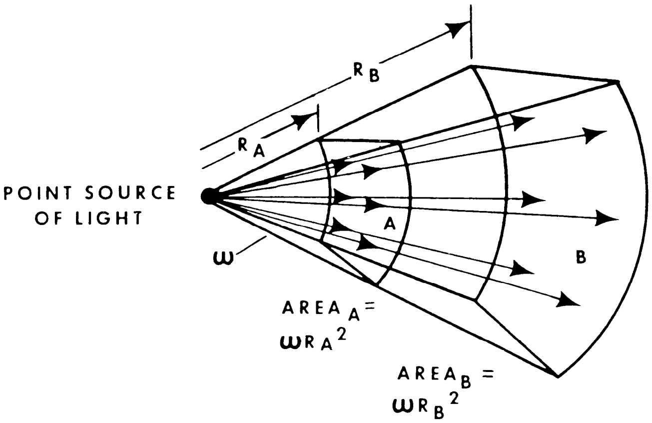

Fig. 11.9.5. Basis of the inverse square law.

Luminous intensity is defined mathematically as follows:

$$I = \phi/w \tag{11.9.3}$$

where I is equal to the luminous intensity of a point source of light in a direction defined by a particular solid angle, f is the total luminous flux (lumens) emanating from the point source within the specified solid angle, and w is the dimension of that solid angle in steradians. The candela c is the luminous intensity unit (both the SI and IES systems) and equals 1 lm/sr.

Intensity is a directional quantity, with the direction in question being defined by the line that forms the axis of the solid angle. The intensity of the light source may, indeed, vary with direction. Intensity, as calculated from Eq. 11.9.3, is an average intensity over the entire solid angle w. As w is subdivided into smaller and smaller solid angles, the direction of the intensity is better defined, and the distribution of light from the source is more accurately established.

11.9.2.5 Inverse Square Law

A common problem in lighting system design is determining the illumination on surfaces at various distances from a light source. This problem can be handled using the inverse square law.

Given the intensity of the light source depicted in Fig. 11.9.5 in the direction defined by the illustrated solid angle, the flow of luminous flux within that solid angle can be calculated using Eq. 11.9.3. The illumination of the depicted surface subtended by the solid angle would be the flux within the solid angle divided by the area subtended, as defined in Eq. 11.9.1. Since the flux is the same in both equations, we can solve for the flux and set the resulting expressions equal:

$$\phi = Iw\phi = EA_s \tag{11.9.4}$$

Solving for illumination gives

$$E = \frac{Iw}{A_s} \tag{11.9.5}$$

Since by definition, $w = A_s/R^2$, substituting this in the illumination equation gives

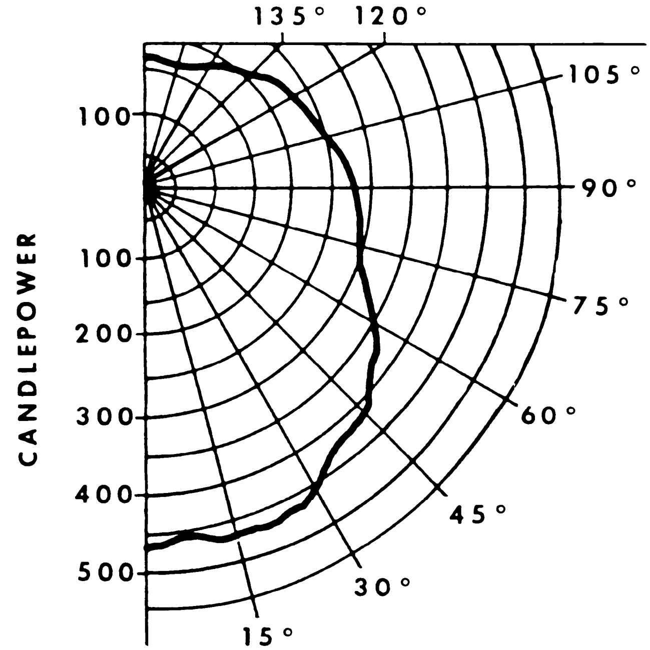

Fig. 11.9.6. Candlepower curve for a typical incandescent fixture. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

$$E = \frac{IA_s}{A_sR^2} = \frac{I}{R^2} \tag{11.9.6}$$

This equation relating illumination, intensity, and the distance between the source and light-receiving surface is known as the inverse square law. It enables illumination of a surface to be calculated if the intensity of the light source and the distance between the light source and the surface are known.

In general practice, it is common to calculate the illumination at a point on a surface rather than an area on a sphere. The inverse square law can then be modified to use the distance D between the light source and the point rather than the radius R of the sphere. Eq. 11.9.6 then becomes:

$$E = I/D^2 \tag{11.9.7}$$

The inverse square law assumes a point source of light. Most real light sources are not point sources, however. Nevertheless, the law can be applied, with negligible error, if the distance between the light source and the illuminated area is greater than five times the maximum dimension of the light source. Consequently, using the law is practical for most purposes encountered in lighting design, except where long, tubular light sources (e.g., fluorescent lamps) are used.

A second assumption inherent in the inverse square law is that the surface area is perpendicular to the direction of light flow. When this is not the case, the inverse square law can be combined with the cosine law as follows:

$$E = E_{\text{normal}} \times \cos\theta = \frac{I\cos\theta}{D^2} \tag{11.9.8}$$

11.9.2.6 Candlepower Curves and Their Uses

The most common way of presenting lighting data on luminaries and lamps is by the candlepower curve or some variation of this curve. A candlepower curve is a plot of the intensities of a light source in a particular plane, at all angles around it. Fig. 11.9.6 illustrates a candlepower curve for a household incandes-

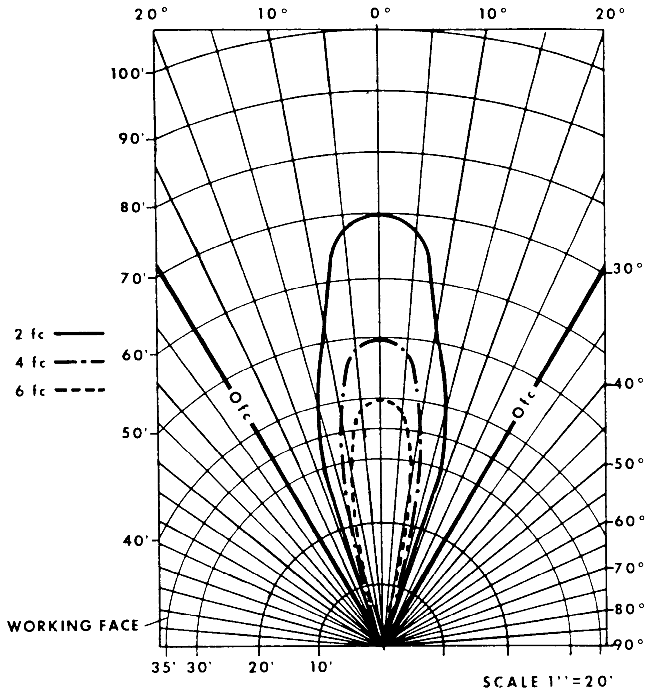

Fig. 11.9.7. Isofootcandle curve for a mining vehicle headlight.

cent fixture. As shown, these curves are usually plotted using polar coordinates.

Candlepower curves are extremely valuable for various design calculations. They depict how a light fixture distributes its total luminous flux into the surrounding space. Also, because of the relationship between illumination and intensity—the inverse square law—these curves may be viewed as depicting a light fixture's ability to illuminate in various directions. The higher the intensity in a given direction, the greater the ability of that source to illuminate surfaces in that direction. The curves are obtained by making *illumination* (fc) measurements at various orientations with respect to the lighting fixture and utilizing the inverse square law to calculate the intensity at that orientation.

A candlepower curve applies only to the intensities in a single plane that passes through the light fixture. To fully describe a fixture's light distribution, several candlepower curves in different planes may be necessary, depending on the symmetry of the light distribution.

One of the primary uses of candlepower curves is to utilize these data to calculate the surface illumination that the fixture would provide, given the geometry and dimensions of a particular setting.

Depending upon their intended use, candlepower curves can be converted to other forms for the sake of convenience. A commonly used alternative form is the isofootcandle curve shown in Fig. 11.9.7.

An isofootcandle curve shows the distance a source will illuminate to a certain footcandle level in the various directions around the source. A typical drawing includes a family of curves at different footcandle levels.

The ease of using candlepower and isofootcandle curves in the design process is described in detail by Lewis (1986), and an example of this process is given in 11.9.8.

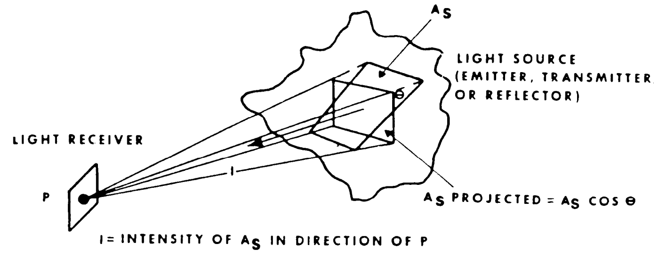

Fig. 11.9.8. Concept of luminance.

11.9.2.7 Luminance

In physical terms, luminance is a concept used to quantify the density of luminous flux emitted by an *area* of a light source in a particular direction toward a light receiver such as a human eye. The area of a light source, in practice, may be an area of a light reflecting surface, such as a wall or desk top; an area of a light emitter, such as a lamp; or an area of a light transmitter, such as a diffusing lens on a luminaire. The most common definition of luminance L is

$$L = \frac{I}{A_s \text{ projected}} = \frac{I}{A_s \cos\theta} \tag{11.9.9}$$

and its IES unit is candela per square inch (cd/in.^{2}) also referred to as foot lambert (fL), while its SI unit is candela per square meter. Referring to Fig. 11.9.8, I is the intensity of light produced by area A_s of the source in the direction of the receiver P, and A_s projected is the projected area of the source when viewed from the receiver. A, projected is equal to A_s cos where q is the angle between the normal to A_s and the angle of observation. Fig. 11.9.8 illustrates the concept. When A_s is large, L is the *average* luminance of A_s; as A_s decreases, L approaches a value of point luminance.

The luminance concept is extremely important in illumination design because it is a physically measurable quantity that correlates with the subjective evaluation of "brightness" when viewing a surface or object. By manipulating the variables (L, I, A_s) in the luminance equation, the subjective evaluation of "brightness" becomes apparent as light intensity (I) and area (A_s) are changed.

When applying the luminance concept, the principles to remember are that luminance (1) varies directly with the intensity (I) of a light source of constant area, (2) varies inversely with the area (A_s) of a light source of given intensity, (3) is independent of distance of observation, and (4) is affected by the angle of observation of the lighted surface.

11.9.2.8 Relationship Among Reflectance, Illumination, and Luminance

Reflectance p is the ratio of reflected to incident light energy, which may be defined as lumens emitted per unit area divided by lumens incident per unit area.

For perfectly diffuse reflectors, lumens emitted per unit area is luminance L', and lumens incident per unit area is illumination E. Therefore,

$$\rho = L'/E \tag{11.9.10}$$

This is an extremely important equation for illumination design because it can be used to determine the illumination that should be provided for an environment, given the desired luminance (i.e., brightness) level and the reflectance of the environment.

The simple relationship among luminance, illumination, and reflectance represented by Eq. 11.9.10 applies only to perfectly diffuse reflectors. Although no surface exactly meets this criterion, such a relationship often applies over a wide range of viewing angles making the use of the formula a practical matter in many cases. Although coal has a specular component in its reflection, the cleaved surfaces are generally not well oriented. In the main, coal can be considered a diffusing surface, and for practical purposes of analysis, perfectly diffusing. In some design problems, detailed reflectance measurements from many angles of observation are often made to assess the limits to which this equation may be applied.

11.9.3 LIGHT MEASURING TECHNIQUES AND INSTRUMENTATION

Instruments are required to evaluate lighting systems and components. The field of light measurement is called *photometry*, and the instruments used to measure lighting are called photometers.

Many types of photometers are available to measure light energy and related quantities, including illumination, luminance, luminous intensity, luminous flux, contrast, color, and visibility. The discussion in this chapter is limited to photometers used to measure illumination E and luminance L from which other quantities, such as reflectivity and luminous intensity, may be computed.

In underground mine lighting applications, the photometer is used to verify compliance with Mine Safety and Health Administration (MSHA) lighting regulations and in the design and evaluation of lighting systems.

Before taking measurements with a photometer, care must be taken to insure that a luminaire or illumination system is in the proper condition to satisfy the purpose of the measurements. An adequate warmup period should be allowed for fluorescent, sodium vapor, and mercury vapor luminaires; line voltage should be stable; and dirty luminaires, obstructions, or deviations in luminaire mountings and orientations from specifications should be avoided.

11.9.3.1 Portable Photoelectric Photometers

The portable photoelectric photometer consists of a photocell that receives light and converts it into an electrical signal that is conditioned through an electrical circuit and is displayed on a visual meter. The meter reading is proportional to the light energy level received by the photocell.

Even the more simple and durable photometers are delicate instruments that can give highly erroneous results when improperly used or calibrated. Proper instruction in the use and calibration of photometers cannot be overstressed. Many factors can cause significant errors in the measurements in the very low light levels typical of underground coal mines. Photometers are available in a variety of models ranging from the low-cost, hand-held units, which are very convenient but have limited accuracy and range, to more expensive, and more accurate but less portable units.

The following major factors affecting the accuracy of photometers should be understood and considered before purchasing and using a unit.

11.9.3.2 Photocell Characteristics

Photocells used in portable photometers have been improved significantly in the past few years. New design photometers that utilize silicon photocell technology have distinct advantages when compared with selenium photocell photometers. Silicon photocells are more stable and exhibit a more uniform (linear) response in output with a change in light level. Selenium photocells are more prone to change in calibration with time and also can exhibit a memory (hysteresis) effect when measured light levels vary significantly. When exposed to illumination, the output of photocells decreases over a period of time because of fatigue. Therefore, the meter should be exposed to the light level being measured for as long an adaptation period as necessary, that is until the meter reading stabilizes.

11.9.3.3 Color Correction

The color response of a typical photocell differs from that of the human eye. This difference would cause a significant error in the measurement of visible light if the cell were not color corrected. Thus photometers must be color corrected by filters to ensure accurate measurements.

11.9.3.4 Cosine Correction

The response of a photocell changes as the angle of light impinging on its surface changes. Errors in light measurement caused by this factor alone may be as much as 25%. Cosine correction is provided by placement of a diffusing cover over the photocell.

11.9.3.5 Sensitivity

Illumination and luminance levels in underground coal mines are very low. Regulations call for an average luminance of 0.06 fL and incident illumination levels in the range of 2.0 fc. For the engineering design and evaluation of underground coal mine illumination systems, it is recommended that the photometer sensitivity be such that a full-scale range of no more than 0 to 3 fc is available. The meter should, of course, have other selectable ranges for higher level measurements, perhaps to 50 fc or greater. A meter with high sensitivity and accuracy permits the very necessary fine tuning of lighting systems needed to meet the stringent lighting regulations.

In designing mine lighting systems, luminance measurements are often required to determine the reflectance of the simulated mine surfaces. For luminance measurements, meters with an available full-scale setting of approximately 0 to 0.1 fL are recommended.

Use of inadequate meters in the design and/or evaluation of mine lighting can result in overdesign of the system, which could be unnecessarily expensive due to the high cost of illumination system components.

11.9.3.6 Calibration

Calibration is a method by which the response of a photometer is set to match a working standard. Probably the most significant source of error in illumination measurements is inaccurate instrument calibration. Photometers are particularly susceptible to loss of calibration and should always be checked both before and after any series of light measurements. The meter can be calculated with a reference standard specifically designed by the manufacturer for the specific instrument. Whatever standards are used, they must be traceable to a primary lighting standard in a national physical laboratory.

11.9.3.7 Photometer Zeroing

It is important to check photometer zeroing prior to taking measurements. If an analog meter is used, this requires setting the meter reading to zero with the photocell completely covered. It should be verified that the meter remains correctly zeroed, when the photometer scale selector is changed. A photometer that cannot be properly zeroed on all scale ranges should be repaired and recalibrated. Improper zeroing can be the source of significant error in the low coal-mine illumination levels.

11.9.3.8 Temperature and Humidity Effects

Wide temperature variations affect the performance of photocells. Prolonged exposure of selenium photocells at temperatures above 120°F (49°C) will permanently damage them. Silicon photocells are less susceptible to temperature variation when compared with selenium photocells. Exposure of a photometer to corrosive high-humidity conditions should be kept to a minimum. Photometers should certainly never be stored underground. Hermetically sealed cells provide greater protection from the effects of both temperature and humidity. It is recommended that a desiccator be packed with meters taken underground.

11.9.3.9 Contamination

In mines, dust can rapidly accumulate on the photodetector surface and diminish measurement accuracy. Moisture and dust can enter photometer enclosures and cause component corrosion or wear. These factors can easily affect the accuracy and useful life of an instrument. Photometers should be kept in a well-sealed case and, to avoid contamination, should be removed only when they are to be used. The photodetector surface should be kept very clean, and care taken to use a cleaning method that will not scratch the surface.

11.9.3.10 Making Illuminance Measurements

Considerable error in measurements can occur if the light meter photocell is not positioned correctly for the type of illuminance measurement being taken. In mine lighting, illuminance measurements are typically taken for the following purposes:

1. To determine the incident luminous energy (footcandles) on a surface.
2. To determine the light output characteristics of a luminaire.
3. To determine if illuminance levels are sufficient to qualify the illumination system for MSHA approval.

First of all, it is important to recognize that the photocell is designed to generate an output signal that is proportional to all the light impinging on it and passing through an imagined hemisphere below which the photocell is placed with the lens facing directly up. Therefore, if a measure of illuminance impinging on a surface is required, the photocell should be placed flat against the surface, as shown in Fig. 11.9.9A. This reading will yield the footcandles (lumens per square foot) of luminous energy that is intercepted by the surface.

When determining the candlepower distribution of a luminaire, the photocell should be pointed directly at the luminaire, as shown in Fig. 11.9.9B. The candlepower curve can then be computed using the inverse square law, $E = I/D^2$ where E is measured illuminance, D is distance to the luminaire in ft, and I is luminous intensity in candelas. Remember, when the distance from the photometer to the luminaire is less than five times the maximum luminaire dimension, this method rapidly becomes inaccurate.

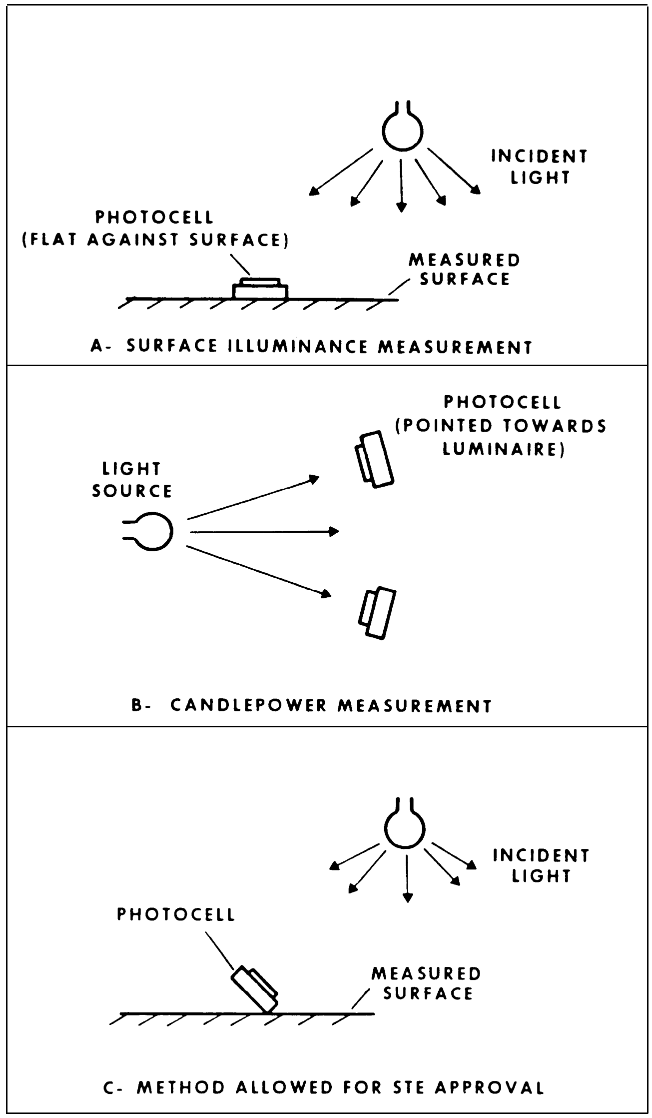

Fig. 11.9.9. Photocell orientation for making illumination measurements. STE—Statement of Test and Evaluation.

When illuminance measurements are made to qualify a lighting system for a statement of test and evaluation (STE, which will be discussed later in 11.9.6), MSHA allows them to be made by pointing the photocell in the direction that results in the highest measured value. This special case of measurement, as illustrated in Fig. 11.9.9C, yields the level of illuminance emanating in the direction of the photometer only. This measured illuminance does include the effect of the cosine law, and therefore, the values cannot be used for the computation of surface reflectance. This procedure is useful for STE measurements only.

11.9.3.11 Making Luminance Measurements

Luminance can be measured directly with photometers designed for this purpose. Typically, photometers have a luminance adapter, which allows light within a specific cone angle to be sensed by the photocell.

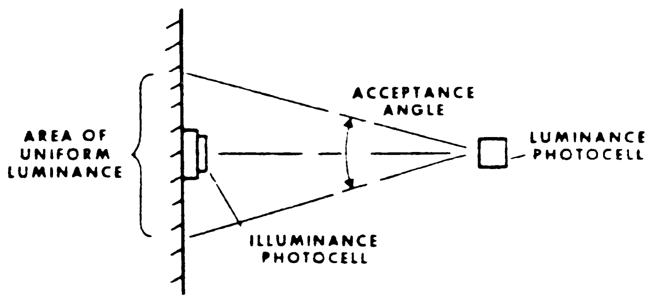

Fig. 11.9.10. Reflected-incident light comparison method for measuring reflectivity.

One method specified for making luminance measurements of the face, roof, ribs, and floor with a photometer is specified in the *Code of Federal Regulations* (CFR), Title 30, part 75.1719-3 (Anon., 1988). Luminance measurements specified in these regulations state that the photometer shall be held approximately perpendicular to the surface being measured. They also require that the sensing element be at a sufficient distance from the surface to allow the light sensing element to receive reflected light from a field not less than 3 ft^2 ($0.27m^2$) nor more than 5 ft^2 ($0.45m^2$). In areas where a photometer cannot be held sufficient distance from the surface to encompass at least 3 ft^2 ($0.27m^2$), the luminance can be computed by averaging four uniformly spaced readings taken at the corners and within a square field of approximately 4 ft^2 ($0.36m^2$). In the evaluation of large surface areas, the meter can be used in a scanning mode, which requires the meter be held 4 to 5 ft (1.2m to 1.5m) from the surface being measured and moved in a direction parallel to the surface. The scan rate must be less than 3 ft/sec (0.9m/s) to allow sufficient time for the sensor to react to changes in surface luminance. Such a procedure might be useful to mine operators to determine if they are in compliance with the lighting standards. The detailed regulations and procedures are discussed later in this chapter and should be reviewed when luminance measurements are to be taken to establish compliance of a mine lighting system.

11.9.3.12 Making Reflectance Measurements

The total reflectance of a surface was defined as $\rho = \phi$ reflected light/ϕ incident light, where ϕ reflected is the total reflected flux and ϕ incident is the total incident luminous flux.

Accurate measurements of the reflectance of surfaces such as a coal face can be a complex task because, when a surface is not a diffuser, the reflected flux can be scattered nonuniformly. Methods for the measurement of the reflectance of coal surfaces are briefly discussed in the following paragraphs. No standard method has been established for the measurement of coal reflectance.

The *reflected-incident light comparison method* is a convenient and simple means to measure reflectance if a surface is a good diffuser. For a perfect diffuser, reflectance can be computed using Eq. 11.9.10, $r = L'/E$. Although coal has a specular component in its reflective characteristics, the cleaved surfaces are often not well oriented and, therefore, it may be considered a diffusing surface and for some purposes perfectly diffusing. A standard portable photometer equipped to measure both illuminance and luminance can be used in this method of reflectance measurement. Illuminance is measured by placing the photocell flat on a uniformly illuminated surface as shown in Fig. 11.9.10.

With the photometer in the luminance measurement mode, the surface luminance is measured and care is taken that the area being measured is within the conical acceptance angle of the luminance photodetector. Surface reflectance can then be computed with the preceding equation. This is the method utilized by MSHA to approve coal mine simulators, which must have a surface reflectance no greater than 5%. Note that measurement error is introduced when the surface is not a perfect diffuser. Also care must be taken to insure that the presence of instrumentation or the operator does not interfere with the actual light levels.

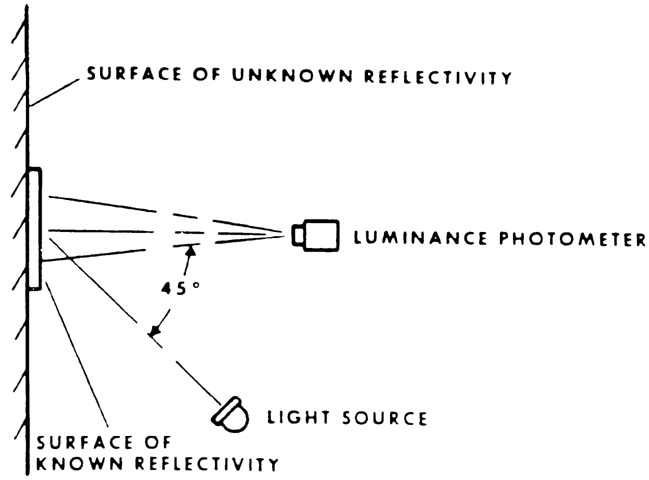

Fig. 11.9.11. Luminance standard comparison technique for measuring reflectivity.

The *reflectance standard comparison method* is a method by which the reflectance of an unknown surface is determined by comparing the luminance of a standard of known reflectivity to the luminance of the surface being tested. The reflectance of the surface being tested can be computed with the equation $r = r_s (L/L_s)$, where r_s is reflectance of the known standard surface, L is the luminance of surface being tested, and L_s is measured luminance of the standard surface. This method is depicted in Fig. 11.9.11. The acceptance angle of the photometer must be sufficiently small to insure that the measured luminance is within the area of the standard surface.

This method is adaptable to controlled laboratory measurement conditions because sample sizes need not be large. Commission International del'Eclairage (CIE) (Anon., 1981) standard conditions for using this method state that the source of illumination shall be at an angle of 45° from the perpendicular to the surface to be tested and that viewing should be perpendicular to the surface.

11.9.4 PHYSIOLOGICAL REQUIREMENTS FOR HUMAN VISION

Vision and the effect of illumination levels on visual perception is an extremely complicated process by which the brain receives the vast majority of information about the outside world. The operation of the eye has been described in great detail by many authors (Halldane, 1970); for this review, the most relevant information concerns the operation of the eye at low light levels. Light enters the eye through the lens and is focused on the retina. The retina contains a large number of light-sensing organs called rods and cones. The rods operate at low light levels and do not detect color; the cones can detect color but require higher levels of luminance to function. The distribution of these sensors is not uniform across the retina. Cones are dense at the center of the retina, and each is individually connected to the brain by a separate nerve fiber. As the distance from the retina's center increases, the density of cones decreases and rods predominate. The rods are not individually connected to the brain; instead, several transmit their information via a single nerve fiber. This characteristic causes the eye to see detail only in the center of the retina, utilizing predominately cone receptors. At luminance levels below the photopic or daylight vision threshold, the eye is night-adapted and is said to be in the scotopic or rod-dominate mode of operation. At these levels, cones do not receive enough energy to function, and the ability to see detail and color is lost. At luminance levels above the photopic threshold, cone vision is restored. A transitional mode of operation, between the photopic and scotopic range where the cones are not completely operational, has been defined as the mesopic region. Halldane (1970) reports that this transitional region lies between 10^{-3} to 10^{-1} fL, with the greatest changes occurring below 10^{-2} fL. Thus, at light levels above this value, the majority of photoreceptors are operational.

While it is difficult to precisely determine, the cone vision threshold lies between 0.03 fL and 0.05 fL, and it is generally agreed that illumination levels must maintain the eye above the scotopic, or night, vision range. Merritt et al. (1983) recommended 0.06 fL as a luminance level for reasonable response times in the detection of hazards. The reasons for this recommendation include not only maintenance of detail and color vision, but also the prevention of miners' nystagmus, a disease common to underground miners before 1940. Miner's nystagmus is caused by long periods of conditioning to low light levels and results in the individual's inability to look directly at an object, resulting in constant eye movement and nausea.

The introduction of the modern electric cap lamp eliminated miners' nystagmus and provided adequate illumination for detailed, near field tasks. However, the cap lamp's photometric distribution is very narrow (typically 5 to 10°) and in low-reflectivity environments does not provide enough illumination to ensure adequate peripheral vision. Standards that maintain levels above the scotopic threshold and provide adequate peripheral vision have been established in many countries (including the United States) to provide for area illumination in various high-activity locations in underground mines. International standards have been drafted by the Commission International de L'Eclairage TC 4.10 Committee (Anon., 1981) that follow these principles.

11.9.5 SURFACE MINE ILLUMINATION AND ILLUMINATION OF THE SURFACE AREAS OF UNDERGROUND MINES

Surface mining operations occupy vast areas, and activity is dispersed throughout the property, typically continuing 24 hours a day. It is the continuous operation throughout the night that demands consideration of adequate illumination. Federal standards that address illumination of these areas are general in nature and are published in the CFR, Title 30, parts 56.17001 and 77.207 (Anon., 1988.) These sections state, "Illumination sufficient to provide safe working conditions shall be provided in and on all surface structures, paths, walkways, stairways, switch panels, loading and dumping sites, and work areas."

The problem of providing adequate illumination for surface mining operations can be said to address a number of generic situations. These include the areas surrounding various slow-moving machines that typically perform their functions in a stationary mode such as draglines and highwall drills, high-speed machines such as haulers and front-end loaders, and finally, specialized task and area illumination for locations such as the interiors of large equipment and maintenance activities.

Table 11.9.1. Draglines, Shovels, and Bucket Wheel Excavators: Illumination Intensities While Equipment Is Operated

Location	Average illumination intensity in fc	Uniformity ratio
1. Interior walkways while persons are present.	10	10/1
2. All other interior areas, except operating cabs while persons are present.	10	10/1
3. All areas 20 ft (6m) in all directions from the main frame, including all work or travel areas beneath the main frame.	5	10/1
4. Exterior walkways on board draglines, shovels, and wheel excavators.	5	10/1
5. The area beneath the boom from 20 ft (6m) from the main frame to the farthest point the equipment is capable of excavating or discharging material.	1	10/1

Source: Anon., 1977.

Dragline, power shovel, and bucket wheel excavator illumination recommendations were published in the US Federal Register and are listed in Table 11.9.1.

Illumination levels for other self-propelled surface mining equipment are listed in Table 11.9.2.

Research to define appropriate illumination levels for other surface mining activities has not progressed to the extent that permits specific levels to be defined for all major tasks or situations, and so in many cases, the illumination engineer can only refer to standards that address similar but not identical conditions.

As an example, the IES Lighting Handbook (Kaufman and Haynes, 1981) lists recommended illumination levels for a large number of situations and therefore provides a good reference source. A specific example would be IES's recommendation of an illuminance level of 2 FC for building excavation. This condition is analogous to bench preparation activity. Until such time as definitive studies are completed, the reader should view these values as approximate, and consideration should be given to the local conditions, especially the contrast level between the overburden and ore.

11.9.6 UNDERGROUND COAL MINE ILLUMINATION

The lumination requirements for underground coal mines are defined in detail by CFR in Title 30, Section 75.1719 (Anon., 1988). This section consolidates and explains the regulations, interpretations, and official enforcement policies that govern the implementation of lighting in underground coal mines in the United States, including:

1. Specification of required illumination levels and the particular areas of the mine that must meet these levels. (75.1719-1)

2. Specification of standards (primarily electrical) to be observed when implementing lighting systems to prevent the sys-

Table 11.9.2. Self-propelled Equipment: Illumination Intensities While Equipment Is Operated

Location	Average illumination intensity in fc	Uniformity ratio
1. An area to the front and to the rear of all rubber-tired or crawler-mounted scrapers, front-end loaders, dozers, graders, loaders, and tractors. The areas shall start at the point the operator can normally see the ground surface and extend for a distance of 20 ft (6m) and for a width equal to the machine width.	1	10/1
2. An area to the side of equipment where operating visibility is normally to the side. The area shall start at the side edge of the blade or bucket and extend to the side and rear of the blade or bucket for a distance of 5 ft (1.5m).	1	10/1
3. All areas within 10 ft (3m) of the hole being drilled by vertical drills, except small pneumatic drills.	5	10/1
4. All areas within 10 ft (3m) of horizontal drills and coal augers. On-board work areas of horizontal drills and coal augers.	5	10/1

terns from posing additional hazard to worker or machine. (75.1719-2)

3. Specification of procedures for making light measurements to verify compliance with the illumination standards. (75.1719-3)

4. Specification of requirements, in addition to illumination, to increase visibility in the mine environment. (75.1719-4)

11.9.6.1 Primary Illumination Standard

Published lighting values are not the complete answer to the problem they are meant to help solve, for whenever a stage of knowledge is reached upon which a code is based, unsolved problems still remain.

This statement applies, of course, to US lighting regulations. Anyone implementing a lighting system on the basis of these regulations should not view the standards as a "cookbook prescription" for optimum lighting. Rather, these standards are only intended to specify *minimum* requirements for meeting the *priority* visual needs of the mine-face situation. The status of current knowledge and the necessary accommodations to account for variability of mining circumstances make specification of more extensive standards, at least for the present, inappropriate. To realize the optimum benefit from mine lighting, it may be desirable to exceed these minimum requirements in some instances and to consider additional factors.

The "cornerstone" of the US lighting code is expressed in provision 75.1719-1(d) of the *CFR* (Anon., 1988). "The luminous intensity (surface brightness) of surfaces that are in a miner's normal field of vision of areas in working places that are required to be lighted shall be not less than 0.06 foot-lamberts . . ."

The following points should be noted about this specification:

1. The requirement is expressed in terms of luminance rather than illuminance. This is the preferred method of expressing standards since only the physical measure of luminance correlates what the eye sees. Moreover, by specifying luminance rather than illuminance, the standard is, theoretically, uniform regardless of variability on environmental reflectivity. The disadvantages of expression of standards in luminance terms is that (a) luminance measurements are more difficult to make, and (b) design requires accurate knowledge of reflectivity.

2. The statement that 0.06 fL applies to "surfaces that are in a miner's normal field of vision" is an explicit recognition that mine lighting should accommodate peripheral vision. Peripheral vision is important in mining for (a) early recognition of conditions that might give prewarning of potential safety hazards in the peripheral field, and (b) performance of tasks that require knowledge of the relative spatial relationships among objects separated by significant distance in the surroundings. Light on all surfaces in a miners' normal field of vision eliminates the "tunnel vision" effect of the narrow cap lamp beam and overcomes beam cutoff by machine structure or posts. Provision that this light illuminates these surfaces to 0.06 fL insures response of all the eye's photoreceptors to light impulses in observer's field of view, particularly in the peripheral field.

3. Research shows that the 0.06-fL level is adequate for performance of a major portion of mining tasks (fine perception of details is generally not required). Most of those tasks where greater levels are desirable are performed at close range, and the cap lamp acts as a supplement to the general lighting for adequately meeting these lighting requirements.

4. The 0.06-fL general level of luminance is low enough that adaptation problems in going from the illuminated area to darker areas of the mine are not severe.

11.9.6.2 Applying Illumination Standards in the Mine Environment

The federal coal mine lighting standards apply to all self-propelled mining machines utilized inby the last open crosscut. The reason for requiring illumination around these machines and in this area of the mine—as opposed to other machines and other areas of the mine—is because here is where (1) machine-worker activity is most concentrated, and (2) hazards are most serious and most likely to develop.

The standards are expressed in terms of specific machine vicinities to be lighted to a surface brightness of at least 0.06 fL. These vicinities vary, depending upon machine type, mining method, and seam height. They have been selected primarily on the basis of the objectives stated previously; that is, lighting needs for adequate peripheral vision and adequate visibility for task performance and hazard identification.

The specific machine vicinities to be illuminated to the 0.06 fL standard are identified in CFR 75.1719-1(e)(1) through (e)(6) (Anon., 1988). In enforcing these standards, certain accommodations have been made by the MSHA so that the effective standards are consistent with the current status of mine lighting technology. The accommodations are in recognition of problems with discomfort glare, hardware maintenance, efficient utilization of fixture candlepower, etc., that currently cannot be alleviated through system design and installation with available hardware and techniques. Policy in enforcing the illumination standards is based upon extensive and continuing post audit of the impact of the standards and reflects a commitment by MSHA as a proponent of both good and practical lighting within the intent of scope of CFR 75.1719.

As an alternative to evaluating an illumination system in an underground coal mine, MSHA has established a program that permits the surface certification of a coal mine illumination system and the issuing of a *statement of test and evaluation* (STE).

The STE program is administered by MSHA's Approval and Certification Center (A&CC) group by system designers, including manufacturers and mine operators. This information is reviewed to determine system compliance with relevant requirements of the CFR and, if these requirements are satisfactorily met, A&CC issues an approval called a STE to the party submitting the design for review.

Mine operators may then implement the design in their mines and be guaranteed compliance with the illumination standards as long as the approved design and application specifications are initially and continually met in the actual installation. This includes proper maintenance of the system with respect to permissibility, cleanliness, and operativeness of system components.

The primary advantage of a STE-approved design over a non-STE-approved design is that the STE is a substitute for onsite light measurements in determining whether the system is in compliance with the illumination requirements. An inspector will not take light measurements as long as the system meets the design specified in the STE and is properly maintained.

The standards that apply to the various machines and environments, the latest enforcement policies for these standards, and details of STE application are described in USBM IC 9074, "Underground Coal Mine Lighting Handbook" (Lewis, W.H., 1986).

In complying with these standards, the mine operator has the option of mounting luminaires on the machine or separate from the machine, for example, temporarily mounting them along roof and ribs. The latter option is typically referred to as "area lighting." Because of practical difficulties with area lighting systems, nearly all systems now utilized employ machine-mounted fixtures.

The seam height used for lighting application requirements at a mine is equal to the normal extracted height. In cases where entry dimensions vary across the entries of a working section, the lowest dimension may be used to determine the lighting requirements that apply to that situation. On sections where the seam is extracted in two or more lifts (e.g., the upper 10 ft or 3m and lower 10 ft or 3m of a 20-ft or 6-m back seam), the lighting system must meet the requirements for both seam heights.

In addition to the illumination of face machine vicinities, it is a federal requirement that each person who goes underground wear an approved personal cap lamp.

11.9.7 ILLUMINATION FOR UNDERGROUND METAL AND NONMETAL MINES

Illumination requirements for underground metal and nonmetal mines are addressed in the CFR, Title 30, part 57.17010 (Anon., 1988). This section specifies lighting (requirements) only in general terms as follows: "Individual electric cap lamps shall be carried for illumination by all persons underground."

The metal and nonmetal mine environment offers a large variation in conditions that affect illumination requirements. The physical dimensions of the mine void and the reflectivity of the underground surfaces are of primary concern. Physical dimensions of worksites vary from a 4 by 4-ft (1.2 by 1.2-m) by 10-ft (3-m) development raise to a 124 by 148-ft (37.5 by 45-m) by 200-ft (60-m) open stope. Reflectivity varies from less than 2 to over 90%.

Table 11.9.3. Minimum Luminance Recommendations for Metal and Nonmetal Mines

Visual task	Luminance, fL Age, 40	Luminance, fL Age, 55	Maximum luminance ratio
Cracks			
Wide	0.029	0.058	27:1
Narrow	0.064	0.13	12:1
Rock Motion	0.066	0.13	12:1
Floor hazard			
Near holes	0.025	0.050	55:1
Far holes	0.014	0.028	13:1
Near rubble	0.019	0.038	72:1
Far rubble	0.014	0.028	36:1
Floor hazard			
Far holes	0.050	0.10	N.A.
Far rubble	0.024	0.048	N.A.
Peripheral			
Motion on foot	0.0026	0.0052	85:1
Mach. op.	0.013	0.025	N.A.

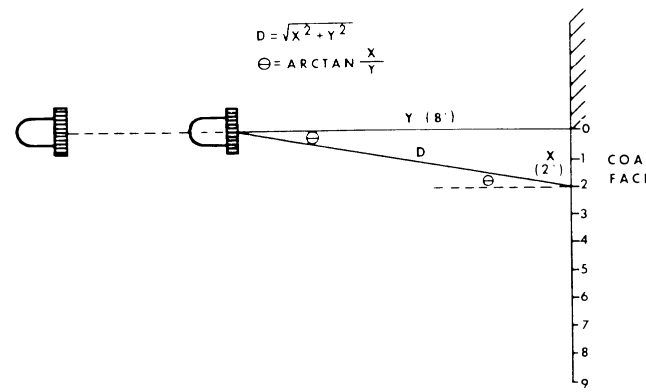

Fig. 11.9.12. Geometry for performing illumination calculations.

Merritt et al. (1983) studied the illumination requirements of the metal and nonmetal mine environment and determined minimum luminance requirements for a number of generic visual tasks as listed in Table 11.9.3. These values closely agree with other findings of a general minimum luminance value of 0.06 fL.

Research to establish appropriate illumination levels for other specific activities has not progressed to the extent that permits specific levels to be defined for all major tasks or situations. Therefore, the illumination engineer can only refer to standards that address similar but not identical conditions. The IES Illumination Handbook (Anon., 1981) lists recommended illumination levels for a large number of situations and, therefore, provides a good reference source.

11.9.8 EXAMPLE OF USE OF LIGHTING EQUATIONS AND RELATIONSHIPS

The following example illustrates the application of candlepower and isofootcandle curves in defining the illumination levels and light distribution produced by a typical mine headlight fixture, and the use of the cosine and inverse square laws, in conjunction with these curves, to calculate the illumination level at any point on the coal face.

Example 11.9.1. In this example the headlight is mounted on the inby end of a cutting machine that is assumed to be located 8, 12, and 16 ft (2.43, 3.65, and 4.87m) from the face. Calculation of illumination levels is made at 1-ft (0.3-m) intervals from the beam axis as shown in Fig. 11.9.12.

Table 11.9.4. Footcandle Values for Different Distances From Lamp Axis and Specified Distances From Coal Face

Distance from lamp axis, ft	Distance from headlight to face, ft		
	8	12	16
0	150	67	38
1	121	64	38
2	33	38	34
3	6	15	18
4	2	5	8
5	0	2	5
6	0	1	2
7	0	0	1
8	0	0	1
9	0	0	0

Conversion factor: 1 ft = 0.3048 m.

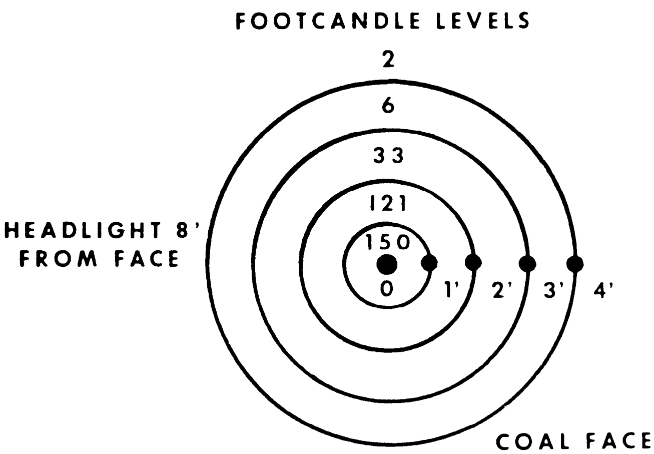

Fig. 11.9.13. Pattern of illumination with headlight 8 ft (2.4m) from mine face.

Solution. Illumination on the face normal to the direction of light travel is given by Eq. 11.9.7

$$E = I/D^2$$

For D = 8 ft and I = 2300 c (from candlepower curve),

$$E = 2300/64 = 36 \text{ fc}$$

Illumination on the face at points not normal to the direction of light flow is given by Eq. 11.9.8:

$$E = \frac{I \cos \theta}{D^2}$$

For a point 2 ft from the axis of the light,
$D^2 = 8^2 + 2^2 = 68$
θ = arc tan x/y = arc tan 2/8 = 14°
I = 2300 c
E = (2300/68) cos 14° = 33 fc

Using these relationships, the footcandle distribution on the face was calculated for the specified lamp distances from the face and different distances from the lamp axis. The results are presented in Table 11.9.4. Because the candlepower curve for the headlight is symmetric about the lamp axis, lines of equal illumination will form concentric rings on the face as shown in Fig. 11.9.13.

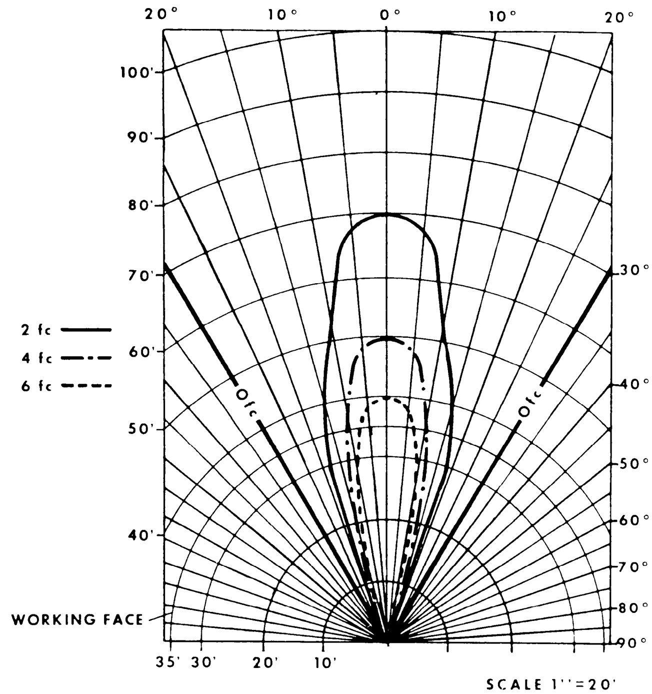

Fig. 11.9.14. Isofootcandle curve by a mining vehicle headlight.

When lamp candlepower curves are not symmetrical, similar calculations can be performed using candlepower curves for different planes and then drawing lines to connect points of equal footcandle levels.

The candlepower curve can be converted to an isofootcandle curve by using the following procedure:

Read the candela values from headlamp candlepower curve for a sampling of angles measured from the lamp axis, say, every 5° interval. For more accurate curves, smaller intervals are used.

Using the inverse square law, substitute values for the candlepower (read from the curve) and the desired isofootcandle curve level. Solve the equation for the distance at which the lamp will light to the desired footcandle level (Eq. 11.9.7):

$$E = I/D^2$$

Solving for D and substituting values for I and E,

$$D^2 = I/E = 2300/6 = 19.5 \text{ ft } (5.9 \text{ m})$$

Repeat this calculation for other candlepower/footcandle combinations and plot the results on polar-coordinate paper as shown in Fig. 11.9.14.

Illumination at any surface along the lamp axis and normal to the axis can be determined simply by drawing such a surface on the isofootcandle curve. Distances from the axis where the isolines intersect the surface may be scaled from the drawing and the isofootcandle curves plotted as shown in Fig. 11.9.15.

Section 12 Auxiliary Operations

JAN M. MUTMANSKY, ASSOCIATE EDITOR
CHRISTOPHER J. BISE, SECTION COORDINATOR

Chapter 12.0
INTRODUCTION

CHRISTOPHER J. BISE

Although production operations at mines, representing the extraction and removal of the mined material, often appear to receive the greatest amount of attention, the emphasis given to auxiliary operations is continually increasing. This is due to the changing economic, social, and environmental climate in which modern mines must operate. *Auxiliary operations* can best be described as those activities that are not directly related to the extraction and removal of the mined material, but must receive proper attention if recovery is to take place in a safe, efficient, and socially responsible manner. In fact, certain mining auxiliary operations, such as strata control and ventilation, are considered to be of such importance that they warrant separate sections in this *Handbook*. Judging from a mine-personnel standpoint, it is not uncommon for a mine to hire the same number or more individuals responsible for auxiliary operations as the number assigned to production.

This section is organized into eight diverse chapters which are related to each other solely in their impact as auxiliary operations.

Chapter 12.1 deals with the design and management of water and sediment control systems. The proper design and implementation of a comprehensive stormwater and sediment control system can enhance overall mining productivity, meet regulatory requirements, and reduce time delays in permitting. Many cost-effective design procedures are illustrated throughout this chapter. Emphasis is placed on the types of control that are frequently utilized in water conveyance, retention, and energy dissipation. Likewise, current and innovative sediment control structure design procedures are explained. Methodologies needed to develop peak flow, a hydrograph, and sediment load are provided. Since sediment basins are the predominant stormwater and sediment control devices, cost-effective techniques, such as internal check dams and passive dewatering systems, are discussed in detail with respect to sediment trap efficiency. Various types of diversions and culvert design methods are described. Selection, design considerations, and troubleshooting procedures for pumps are illustrated through a dewatering design.

Chapter 12.2 focuses on the handling, transportation, and placement of mine waste, such as overburden, waste rock, low-grade and ore-grade stockpiles, refuse, mill tailings, leach heaps and dumps, slags, process sludge and residues, acid mine drainage, and seepage water. Designing waste disposal facilities that meet environmental goals is a complex task, resulting from a large number and variability of factors influencing waste, the many disciplines involved, the general inexperience of meeting environmental goals, and the inherent geotechnical uncertainty that must be managed. The intent of this chapter is to identify the basic design considerations for meeting both traditional structural goals and emerging environmental goals. Low-volume special wastes or stack effluent are not discussed; neither are methods for addressing many reclamation and environmental issues (these are covered elsewhere in the *Handbook*). The enormous potential for liability, the quick evolution of technology and regulations, and the complexity of factors make it imperative for a design engineer to develop the specific components of a design based on current information from the many disciplines involved.

Chapter 12.3 deals with the broad subject of reclamation. The scope of reclamation is addressed initially in order to establish the bounds of the text that follows. One issue addressed specifically is the regulatory framework related to reclamation. A major portion of the chapter focuses on reclamation planning since forethought can often lessen the burden placed upon operators and produce superior results. A general reclamation process is described in detail. Finally, several specific reclamation problems are considered, including such issues as mine waste disposal, soil-related problems, and stability of fills in mountainous terrain.

Chapter 12.4 provides an introduction and overview of electric-power components and systems commonly used in the mining industry. The intent is to familiarize the mining engineer with the importance, history, terminology, basic design criteria, types of equipment and protection, and system arrangements of mine power systems. To enhance coverage, many guidelines are included for this broad and complex subject. Even if the mining engineer is not directly responsible or involved with the power system, a basic understanding of its safety aspects, operation, and limitations is essential since the power system affects many other unit and auxiliary operations within the mine.

Chapter 12.5 deals with proper design of compressed air systems. This topic is approached from the perspective that the most cost-effective compressed air system requires careful design. To achieve the lowest cost system, this chapter uses a series of examples to lead the reader through the design of a network for a small mine. The lowest-cost system requires assessment of alternatives, which is facilitated with a computer program.

Mine monitoring, control, and communications are covered in Chapter 12.6. Effective communications among mine employees is crucial to the achievement of management goals for the safe and efficient operation of a mine. Technology has advanced considerably since the days of the crank-ringer phone to modern systems that often include computer-controlled private branch exchanges and hybrid wired/wireless systems. Second only to the need for good communications is management's need for information to improve the decision-making process. Mine monitoring systems are playing a pivotal role in providing timely information and allowing for operating economies. Traditionally, the mining engineer has had little exposure to this auxiliary aspect, but is now being called upon to utilize this technology. This chapter presents the necessary background to understand the technology and its appropriate uses, and suggests procedures that can be used to help insure that the technology will yield maximum benefit.

Chapter 12.7 addresses the topic of vehicles used in surface and underground mines for the purpose of transporting supplies and personnel. Both track-mounted and trackless applications are considered, and surface and underground applications are further subdivided into coal and noncoal. A selection procedure is included and encompasses suitability, safety, operating experience, and overall cost. Finally, a detailed example of the calculations required for analyzing the capital and operating costs for a vehicle is included.

Finally, Chapter 12.8 addresses the most direct method of increasing machine availabilities: equipment maintenance. This topic is approached from the perspective that the best maintenance program is one that anticipates and acts on impending problems rather than reacts to existing problems, and that the role of maintenance in mining is to provide the lowest possible cost to a mine in terms of maintenance labor, and material and production loss resulting from the maintenance program. To achieve these goals, strategies are proposed for productivity control, preventive maintenance, and predictive maintenance. As a recordkeeping aid for equipment repair histories and accountability, concepts and considerations for computerized management information systems for mine equipment maintenance are discussed.

Chapter 12.1
DESIGN AND MANAGEMENT OF WATER AND SEDIMENT CONTROL SYSTEMS

RICHARD C. WARNER

12.1.1 INTEGRATING ENVIRONMENTAL COSTS

During past decades, industry has sometimes been viewed by the public as an insensitive steward of the environment. Preoccupation with mineral and energy resource extraction caused the mining industry to neglect the integration of environmental cost into their companies' business plans and developmental policies. The results of this missed opportunity are mandated regulations, leaving many critical decisions outside the control of companies. With the passage of the Surface Mining Control and Reclamation Act of 1977 (SMCRA), Public Law 95-87, the goal of minimizing hydrologic impacts to offsite areas was enacted.

Specific interpretations of this law in the form of changing regulations do not provide for regional differences with respect to the quality of receiving waters and climatologic regimes. Regulations focus on many specific criteria, yet neglect the benefits/costs associated with an integrated overall strategy. For instance, sediment standards are set for a peak concentration associated with a design storm (the specified size of storm for which the strategy is designed), yet neglect the sediment duration-concentration relationship that influences aquatic invertebrates and disregards the water quality and multiple use of receiving waters. Criteria quite appropriate for some locales may be entirely unjustified, both environmentally and economically, for mine sites in other regions. Despite regulatory constraints, opportunities still exist to implement innovative approaches to achieving the goal of minimizing hydrologic impacts.

What is meant by minimizing the hydrologic impact of a mining operation? Surface mining and surface disturbance from underground mining create changes to the hydrologic regime, usually in the form of increased storm runoff and generated sediment loads. If minesite stormwater and sediment discharge can approximate predevelopment conditions, then no significant adverse offsite impacts are expected. The determination of predevelopment conditions should consider both onsite factors and the quality of receiving waters. A stormwater and sediment control plan is created to detain excess stormwater, reduce peak flow, and remove the higher sediment load caused by disturbing stable landforms. Similar to stormwater, the control of nuisance water is particularly important to mining operations.

For general coverage of environmental regulations, see Chapters 3.4 and 7.3.

12.1.2 TYPES OF CONTROLS

A comprehensive multifaceted approach to *storm water, nuisance water, erosion,* and *sediment control,* thoroughly integrated throughout the entire planned life of the mine, can reduce potential environmental impacts, increase mine productivity, and be achieved in a cost-effective manner. The types of controls frequently utilized are (1) water conveyance structures, (2) retention facilities, (3) energy dissipators, and (4) pumps. A wide spectrum of water and sediment controls is listed in Table 12.1.1.

Table 12.1.1. Stormwater and Sediment Controls

- Stormwater conveyance
  - Diversions
    - Temporary
      - Earthen
      - Mats of straw, nylon, etc.
      - Geotextiles
      - Flexible membrane liners
    - Permanent
      - Rock riprap
      - Gabion mattress
      - Concrete-filled geotextiles
      - Concrete
      - Asphalt
      - Grassed waterways
  - Culverts
    - Corrugated metal
    - Concrete
    - PVC
    - Polyethylene (PE)
    - Steel
  - Energy dissipators
    - Plunge pools
    - Rock aprons
    - Gabions
    - Concrete-filled geotextiles
    - Check dams
    - Filter fabric fences
    - Brush barriers
  - Dewatering
    - Sumps
    - System of wells
  - Sediment controls
    - Sediment basins
      - Contour
      - Dugouts
      - Embankment
      - Permanent pool
      - Passively dewatered
      - Infiltration
    - Sediment separators
      - Swirl concentrators
      - Inertial separators
    - Sediment traps and check dams
      - Excavation pits
      - Dozer basins
      - Filter fabric fences
      - Brush barriers
      - Vegetative filters

As can be seen from this list, numerous options exist for designing an integrated water and sediment control plan. Although not explicitly enumerated in this section, two other control methods are crucial to a program that is successful overall: (1) limiting temporal and spatial exposure of highly erodible areas, and (2) the implementation of onsite controls for concurrent reclamation through use of grading, terraces, mulches, soil amendments, grasses, etc.

The most common structures designed to minimize the hydrologic impact of mining are sediment basins, diversions, culverts, energy dissipators, and dewatering systems. Methods, equations, and discussions are provided to illustrate design procedures for these controls.

12.1.3 HYDROLOGY

12.1.3.1 Selection of Analysis Method

Stormwater and sediment control facilities are often based on a design storm of a specified frequency. For simple controls such as diversions or culverts, only a peak flow may be necessary. In contrast, the design of a sediment basin, which involves storage routing, requires a complete hydrograph. Thus the required control defines the complexity of the hydrologic analysis.

The rational equation (Anon., 1969a; Rossmiller, 1982) is widely used for peak flow estimation due to its simplicity. Development of a design storm hydrograph is more complex but has been greatly simplified through user-friendly application programs (Schwab and Warner, 1987; Anon., 1986b; Anon., 1970).

Numerous hydrology texts describe, in detail, all facets of peak flow estimation and hydrograph development (Hjelmfelt, 1975; Linsley et al., 1949; Overton and Meadows, 1976; Viessman et al., 1977; Eagleson, 1970; Barfield et al., 1981).

12.1.3.2 Design Rainfall Event

Stormwater management designs are based on a specified design storm (e.g., 10 yr–24 hr) precipitation amount, temporal distribution of precipitation, and the infiltration characteristics of watersheds. The design storm is normally specified by regulations. Storm depth-duration-frequency values are provided in HYDRO-35 (Frederick et al., 1977) and US Weather Bureau TP40 (Hershfield, 1961) for the eastern United States and in a series of National Oceanic and Atmospheric Administration (NOAA) Atlases for the 11 western states.

Where design situations require maximum assurance of safety, the probable maximum precipitation (PMP) events are utilized. PMPs represent the theoretically greatest depth of precipitation for a given duration that is physically possible over a given size area at a specific location at a given time of the year (Anon., 1985).

To develop a hydrograph, it is necessary to know the design storm depth-duration-frequency (e.g., 4.2 in. or 107 mm, 10 yr-24 hr) and the temporal pattern of rainfall throughout the duration of the storm. The rainfall pattern is usually associated with a synthetic rainfall distribution. The Soil Conservation Service (SCS) has developed four rainfall distribution curves, defined as SCS type curves, applicable to specific regions throughout the United States (Anon., 1986b).

12.1.3.3 Peak Flow Determination

For design of diversions and culverts, only the design storm peak flow is needed. The most widely used method for peak flow determination is the rational method (Anon., 1969a). The rational formula is

English units

$$q = CIA \tag{12.1.1}$$

SI units

$$q = 0.0028\ CIA \tag{12.1.la}$$

where q is peak flow in cfs (m^3/s), C is a dimensionless runoff coefficient, I is rainfall intensity in in./hr (mm/h) with a duration equal to the time of concentration t_c, and A is the watershed area in acres or ac (hectares or ha). The runoff coefficient accounts for all hydrologic factors such as rainfall interception, infiltration, antecedent moisture conditions, etc. Representative C coefficients are given in Table 12.1.2 for urban and rural areas. The rainfall amount is found in HYDRO 35 (Frederick et al., 1977).

Table 12.1.2. Runoff Coefficients for the Rational Method

Description of Area	Runoff Coefficients
Residential	
Single-family areas	0.30–0.50
Suburban	0.25–0.40
Industrial	
Light areas	0.50–0.80
Heavy areas	0.60–0.90
Unimproved areas	0.10–0.30
Lawns; sandy soil	
Flat, ≤ 2%	0.05–0.10
Average, 2–7%	0.10–0.15
Steep, > 7%	0.15–0.20
Rural Areas (clay and silt loam)	
Woodland	
Flat 0–5%	0.30
Rolling 5–10%	0.35
Hilly 10–30%	0.50
Pasture	
Flat 0–5%	0.30
Rolling 5–10%	0.36
Hilly 10–30%	0.42
Cultivated	
Flat 0–5%	0.50
Rolling 5–10%	0.60
Hilly 10–30%	0.72

Source: Adapted from Anon., 1969a; Schwab et al., 1962.

Time of concentration t_c, is the length of time for runoff from the hydraulically most remote point in the watershed to reach the watershed outlet. Several methods exist to estimate t_c, such as the SCS upland method (Anon., 1973), kinematic wave analogy (Ragan and Duru, 1972), and Kirpich (1940). The Ragan and Duru equation is

$$t_c = C_1\ (nL)^{0.6}/(i_e^{0.4}S^{0.3}) \tag{12.1.2}$$

where t_c is time in minutes, n is Manning's N, L is length in ft (m), i_e is rainfall excess intensity in in./hr (mm/h), S is slope in ft/ft (m/m), and C_1 = 0.928 in English units (C_1 = 1.977 in SI units). Note the equation is valid only when the product of i_e and L is greater than 500 ft (152 m). The Kirpich equation for estimating t_c is

$$t_c = C_2\ L_1^{0.77}\ (L_1/H)^{0.385} \tag{12.1.3}$$

where L_1 is the maximum flow length in ft (m), H is elevation difference in ft (m) between the hydraulically most remote point in the watershed and the watershed outlet, and C_2 = 0.0078 in English units (C_2 = 0.0195 in SI units).

12.1.3.4 Storm Hydrograph Development

A *storm hydrograph* is a graph of flow rate vs. time. It is necessary for evaluating alternative designs of basins, since routing of incremental storm volumes is used in determining peak

Table 12.1.3. Typical Topsoil *K* Factors for the USLE

Texture	Estimated *K* value (ton/ac/*R* unit)	(Mg/ha/*R* unit)
Clay, clay loam, loam, silty clay	0.32	0.72
Fine sandy loam, loamy very fine sand, sandy loam	0.24	0.54
Loamy fine sand, loamy sand	0.17	0.38
Sand	0.15	0.34

Source: Adapted from Anon., 1978.

stage, flow through principal and emergency spillways, detention time, and sediment trap efficiency. A description of hydrograph developmental methods is beyond the scope of this chapter, but many excellent texts provide detailed methodologies and illustrative examples (Barfield et al., 1981; Linsley et al., 1975; Overton and Meadows, 1976). Also computer programs are available that greatly simplify hydrograph development: SEDCAD+—Sediment, Erosion, Discharge by Computer-Aided Design (Warner and Schwab, 1990); SEDIMOT II (Wilson et al., 1982; Warner et al., 1982); TR-55 (Anon., 1986b); and HEC-1 (Anon., 1970).

12.1.4 SEDIMENTOLOGY

12.1.4.1 Quantity of Sediment Determination

The quantity of sediment eroded from a slope depends on the erosive power of rainfall, soil characteristics, slope length and gradient, and type and amount of soil cover and conservation practices. These parameters have been combined into the *universal soil loss equation* (USLE) (Wischmeier and Smith, 1965, 1978):

$$A = R\ K\ LS\ C\ P \qquad (12.1.4)$$

where *A* is soil loss per unit area in tons/ac (Mg/ha or metric tons/ha); *R* is a rainfall factor; *K* is soil erodibility in tons/ac/*R* unit (Mg/ha/R units); *LS* is a dimensionless length-slope factor that accounts for the actual length and slope compared to a standard slope of 9% and 72.6 ft (22.1 m) in length; *C* is a factor that accounts for the effectiveness of vegetal cover, mulches, etc.; and *P* is a factor that accounts for the effectiveness of conservation practices such as terraces. Values for these parameters may be found in Wischmier and Smith (1978).

A prediction of soil loss from a regraded spoil that has been recently topsoiled, seeded, and mulched at 2 tons/ac (4.5 Mg/ha) will be used to illustrate the applicability of the USLE. The design 10 yr–24 hr storm for western Kentucky (Hershfield, 1961) is 4.2 in. (107 mm). Assuming an SCS Type II rainfall distribution and applying Eq. 12.1.5 (Barfield et al., 1981),

$$R_{st} = 19.25\ P^{2.2}/D^{0.47} \qquad (12.1.5)$$

$$R_{st} = 2.48\ P^{2.2}/D^{0.47} \qquad (12.1.5a)$$

yields R_{st} of 101.6, where R_{st} is the rainfall factor on a storm basis, *P* is precipitation depth in in. (mm), and *D* is storm duration in hr.

A fine sandy loam topsoil has been used during reclamation. Table 12.1.3 lists estimated soil erodibility *K* values as a function of soil texture. The *K* value for this example topsoil is 0.24 (0.54).

Table 12.1.4. Selected *C* Factors for the USLE

Surface Conditions	*C* Factor
Bare soil, seed bed prepared, racked smooth	0.9
Bare soil, seed bed prepared, rough graded	0.8
Bare soil, compacted by a bulldozer	0.9–1.2
Undisturbed forest with > 90% ground litter and > 75% effective canopy	0.0001–0.001
Undisturbed forest with 75 to 85% ground litter and 40 to 70% effective canopy	0.002–0.004
Undisturbed forest with 40–70% ground litter and 20–25% effective canopy	0.003–0.009
Rangeland/idle land, no appreciable canopy, 0% groundcover	0.45
Rangeland/idle land, no appreciable canopy, 40% ground cover	0.10–0.15
Rangeland/idle land, no appreciable canopy, 80% ground cover	0.01
Rangeland/idle land, 50% tall weed or short brush canopy, 0% ground cover	0.26
Rangeland/idle land, 50% tall weed or short brush canopy, 40% ground cover	0.07–0.11
Rangeland/idle land, 50% tall weed or short brush canopy, 80% ground cover	0.01–0.04
Clear cut woodland, 20% residue on soil surface	0.06–0.44
Clear cut woodland, 60% residue on soil surface	0.05–0.20
Straw mulch at 1 ton/ac (2.26 Mg/ha)	0.1–0.2
Straw mulch at 2 tons/ac (4.52 Mg/ha)	0.02–0.08
Woodchip mulch at 2 tons/ac (4.52 Mg/ha)	0.65
Woodchip mulch at 4 tons/ac (9.04 Mg/ha)	0.4
Woodchip mulch at 8 tons/ac (18.08 Mg/ha)	0.1
Grass cover < 60 days after emergence	0.1–0.4
Grass cover > 60 days after emergence	0.05

Source: Adapted from Wischmeier and Smith, 1978.

The approximate original contour of a representative slope has a gradient of 12% and is 200 ft (70 m) in length. Applying these values to Eq. 12.1.6,

$$LS = (l/72.6)^{m}\ (0.043s^{2} + 0.30s + 0.43)/6.574 \qquad (12.1.6)$$

$$LS = (l/22)^{m}\ (0.043s^{2} + 0.30s + 0.43)/6.574 \qquad (12.1.6a)$$

where λ is slope length in ft (m); *m* is an exponential factor that equals 0.6, 0.5, 0.4, and 0.3 for slopes of > l0%, >4 to l0%, 4%, and < 4%, respectively; and *S* is sin *q*, *q* is the slope angle in degrees; an *LS* value of 2.8 is calculated.

Table 12.1.4 lists selected *C* factors reported in the literature (Barfield et al., 1981). Since the example problem has a regraded topsoil that has been recently seeded and mulched at 2 tons/ac (4.5 Mg/ha), the *C* factor ranges from 0.02 to 0.08. An average value of 0.04 is selected. Since no conservation practices such as terracing were included, P = 1. Applying Eq. 12.1.4 yields

$$A = (101.6)(0.24)(2.8)(.04)(l) = 2.7 \text{ tons/ac}$$

$$(A = (101.6)(0.54)(2.8)(.04)(l) = 6.1 \text{ Mg/ha})$$

If mulch was not applied, and rough-grade bare-soil conditions were predominant, the *C* factor would be 0.8, and the quantity of eroded sediment would be increased by the ratio of *C* factors (that is, 0.8/0.04), or by a factor of 20. Thus 54.6 tons/ac (122 Mg/ha) of eroded sediment would be predicted by the USLE.

The USLE provides an estimate of sediment delivered from a field size area. To determine the sediment yield at some point beyond the base of the field, the eroded sediment needs to be routed to the point of interest. As such, the USLE provides an estimate of the quantity of sediment eroded from a representative area within a relatively homogeneous subwatershed. A delivery ratio may be used to transfer eroded sediment to a point of interest such as a sediment basin (Barfield et al., 1981). A delivery ratio is simply the ratio of the quantity of sediment that reaches a structure to that quantity of sediment predicted by the USLE. It is a rough approximation often based on drainage area. As with hydrology, computer techniques have expanded predictive capabilities well beyond delivery ratio estimates by applying sediment detachment, transport, and deposition methodologies. Popular programs include SEDCAD$^+$ (Warner and Schwab, 1990) and CREAMS (Chemical, Runoff, Erosion from Agricultural Management Systems) (Knisel, 1980).

12.1.5 SEDIMENT CONTROLS

12.1.5.1 Sediment Basins

A wide variety of sediment basins has been used throughout the mining industry. Small elongated basins are often located along benches near the highwall in contour mining. Dugouts, which are primarily excavated basins with 4- to 8-ft (1.2- to 2.4-m) berms, are prevalent in area mining and mountaintop removal. The most common basins consist of a dam embankment 12 to 19 ft (3.6 to 5.8 m) in height with added storage capacity provided through excavation of soils in the pool area. These basins often use trickle tube (a straight pipe through the embankment) or drop inlet principal spillways, and an emergency spillway. The principal spillway of a dugout is often a trapezoidal channel that may also function as the emergency spillway. Contour basins often have trickle tube principal spillways and an emergency spillway.

Sediment basins are used to reduce peak flow and trap sediment. The efficiency of basins to accomplish these two functions is directly related to the basin design with respect to (1) location and gradient of inflow channel(s); (2) selection of type, size, and location of principal and emergency spillways; (3) length-to-width ratio of the pool measured at the crest of the principal spillway; (4) basin shape; (5) percentage of basin capacity allocated to sediment and permanent pool storage; (6) dewatering method(s); (7) detention storage; (8) inlet baffles, turbidity curtains, and internal check dams; (9) use of flocculation additives; etc. As can be seen from this list of engineering considerations, the performance of a sediment basin in reducing the incoming peak storm flow and retaining sediment is directly achieved through design rigor.

The objective of minimizing the hydrologic impact can be assured if the peak discharge emanating from the basin is reduced to near premining conditions and a significant percentage of the incoming sediment load is captured. To achieve this objective, consider the application of each of the design factors as explained in Table 12.1.5.

A cost-effective sediment basin design that is expected to minimize the hydrologic impact to offsite streams is illustrated in Figs. 12.1.1 through 12.1.5. (Warner and Schwab, 1989). The function of the identified features in these figures is described. The length-to-width ratio is approximately 2:1. It may be smaller than the recommended ratio due to the internal check dam. Incoming flow energy is dissipated by the rock impact pool at the basin entrance. The internal check dam is used to accomplish many functions. It further slows and spreads out the incoming flow by rapidly creating a pool of water in the primary chamber. The larger-sized sediments rapidly settle out in this forward chamber, which, in combination with the access road and/or a check dam wide enough for a backhoe, facilitates sediment cleanout.

Small storm runoff is contained in the primary chamber and is slowly dewatered by either a small drop-inlet perforated riser and/or a wide rock riprap French drain (see Figs. 12.1.2 and 12.1.3). As the primary chamber fills with the larger-sized sediment, it also acts as a slow sand filter that greatly increases the quality of discharged water. For larger storms, short circuiting and dead storage are substantially reduced since the internal check dam evenly distributes flow across the width of pool. The check dam is protected by a geotextile fabric and rock riprap or equivalent.

Optional principal spillway configurations are shown in Fig. 12.1.1 and detailed in Figs. 12.1.4 and 12.1.5. The drop-inlet perforated riser should be sized to reduce peak flow to near premining conditions. The tapered riser perforations slowly dewater the storm pool, thereby providing additional storage for subsequent storms. This also reduces the peak stage, compared to the permanent pool option, thus reducing embankment construction cost. Dewatering reduces peak discharge, increases sediment trap efficiency with respect to total sediment load, and reduces peak and average effluent sediment concentrations. The floating siphon tube (Fig. 12.1.5) provides an added advantage by dewatering only the uppermost water level, thus increasing sediment trap efficiency. Stationary or floating siphon tubes can be used in conjunction with either trickle tubes or drop-inlet principal spillways (Warner and Schwab, 1989, 1990).

Impact pools with depressed outlet channels dissipate the energy of concentrated pipe discharge to reduce downstream impacts (Warner and Schwab, 1990).

Design of stormwater retention basins is facilitated by using computer programs such as DAMS2 that routes water through principal and emergency spillways (Putnam et al., 1982; Anon., 1965). Principal and emergency spillway designs, stormwater and sediment routing, inflow and outflow hydrographs and sedimentgraphs, dewatering options, impact pools, sediment trap efficiency, embankment earthwork volumes, etc., can be calculated through use of the SEDCAD$^+$-Version 3.0 Model (Warner and Schwab, 1990).

12.1.5.2 Infiltration Basins

An infiltration basin has no direct discharge for surface waters and is used to recharge an aquifer constructed during mountaintop or area mining (Dinger et al., 1988). A vertical durable rock core is constructed during spoil placement to facilitate the rapid downward movement of stormwater. Infiltration basins have the advantages of recharging groundwater, complete containment of stormwater and sediment, relatively simple construction, avoidance of potential embankment stability problems, and allowance of a large degree of flexibility in a spatial siting.

12.1.5.3 Sediment Basin Hydraulics

Design aspects of basin hydraulics encompass (1) principal spillway design, (2) emergency spillway design, (3) pond stage-area-capacity, and (4) routing the inflow hydrograph. The basic steps in developing an outflow hydrograph for a sediment basin are listed in Table 12.1.6.

12.1.6 SEDIMENT SEPARATORS

The swirl concentrator and inertial separator have both been designed to intercept sediment-laden inflow. The swirl concentrator separates sediment from the incoming flow through the

Table 12.15 Application of Sediment Basin Design Principles

Design Consideration	Implementation
1. Location of inflow channels	Locate inlet(s) to provide the hydraulically longest flow path between inlet(s) and outlet(s). This will help reduce short circuiting of flow.
2. Inlet flow channel gradient	Provide a wide, shallow slope entrance. Stabilize steeper slopes with rock riprap or equivalent protection to avoid severe gully formation.
3. Size of principal spillway	Size to significantly reduce the incoming peak flow to near premining conditions.
4. Location of principal spillway	Depending on size, and associated flow rate, locate a minimum of at least 2 to 3 ft (0.6 to 0.9 m) above the sediment storage level. Also, locate farthest point away from inlet(s).
5. Pool length to width ratio (L/W)	The L/W ratio measured at the crest of the principal spillway should be 2:1 or greater.
6. Basin shape	Provide a L/W ratio of 2:1 or greater and the basin deep enough such that resuspension of settled sediment is avoided. Refer to design considerations 4 and 5.
7. Sediment storage	Base sediment storage needs depend on (1) estimated loads for at least the life of the project or (2) for the expected sediment load associated with the 10-yr, 24-hr design storm. Sediment storage volumes, based on project life, may be reduced dependent upon a sediment approval plan.
8. Permanent pool storage	Both advantages and disadvantages exist for permanent pools in contrast to a dewatered or partially dewatered pool. The major advantage is dilution of the incoming sediment concentration. Disadvantages are (1) higher peak flow discharged and greater peak stage, (2) increased fall depth of incoming sediment prior to retention in the sediment storage area, (3) shorter detention time, and (4) discharge of warm, low-oxygen water during summer months.
9. Pool dewatering (gated risers, perforated risers, stationary and floating siphon tubes, small trickle tubes)	Dewatering provides numerous advantages when compared to the permanent pool option—(1) lower peak discharge, (2) lower storage volume, (3) higher sediment trap efficiency.
10. Detention storage (time difference between inflow and outflow hydrograph peaks or hydrograph centroids.)	Detention storage is an indicator of basin performance. Longer detention times indicate reduced peak flow and poentially more efficient sediment trapping.
11. Inlet baffles, turbidity curtains, and internal check dams	All of these devices increase the flow path between inlet(s) and outlet(s). In addition, they decrease dead storage which improves sediment trap efficiency.
12. Flocculation additives	Long chain polymers create flocs, a group of soil particles, which settle at rates significantly faster than individual soil particles, thus increasing sediment trap efficiency.
13. Outlet stabilization	The outlet of principal and emergency spillways should be stabilized by energy dissipators such as impact pools constructed of rock riprap, gabions, or concrete-slurry-filled geotextiles to avoid downstream bed scour.

centrifugal force generated by the inherent inertia of the flow (Warner and Dysart, 1983). Effluent with a high sediment load is transmitted to a small sediment trap while the clearer flow is discharged directly to a stream. Fig. 12.1.6 shows a schematic of the swirl concentrator. The inertial separator is designed to retain incoming sediment in a tank between a series of V-cut bottom-slotted troughs (Sterling and Warner, 1984). The sediment-laden influent is transferred from shallow influent troughs into the tank, and clearer flow is withdrawn by deep troughs. Plan and elevation cross section of the inertial separator are shown in Fig. 12.1.7.

The numerous advantages of these devices call attention to their use as primary sediment control structures on surface-mined lands. Both devices are relatively simple, containing no moving mechanical parts, and no onsite energy requirements are needed. Since the devices are relatively small, they can be easily transported on flat-bed trucks and modularized to facilitate rapid installation and relocation once reclamation and bond release have been accomplished. The added advantage of the swirl concentrator is that no sediment maintenance is needed since it is self-cleaning; that is, the concentrated sediment-laden flow, which represents 5 to 15% of the incoming flow, is automatically discharged to a small sediment basin.

12.1.7 DIVERSIONS

Diversions are designed to be stable and convey a specified peak flow. Stability is usually interpreted as avoidance of significant erosion of the channel bed or sidewalls. Diversions can be classified as temporary or permanent structures. Temporary diversions may be constructed of soil and/or a soil/spoil mixture, and protected by straw or nylon blankets, geotextiles, and flexible membrane liners. For these diversions, the determination of stability is based on either a permissible velocity or a critical tractive force, the assumption being that if the specified velocity or tractive force is not exceeded, the diversion will remain stable. Conveyance capacity is calculated using $Q = VA$ and Manning's

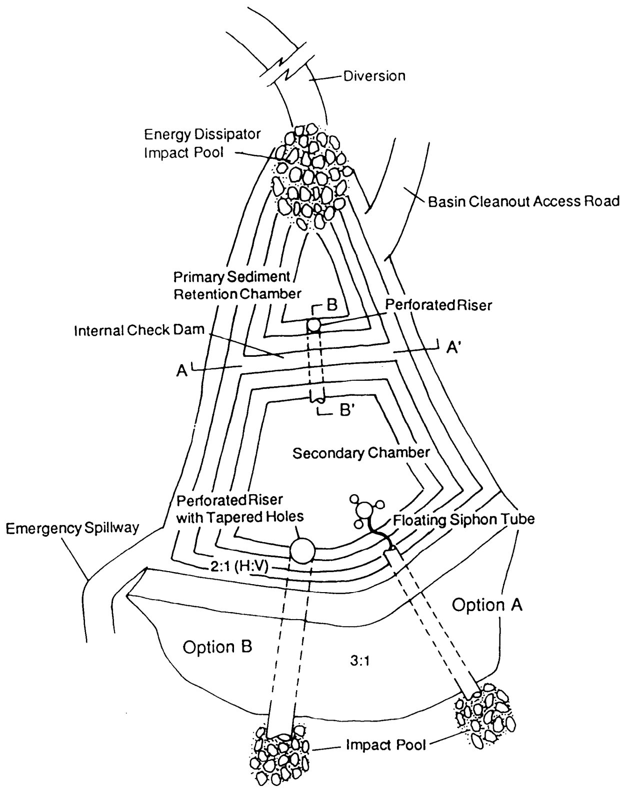

Fig. 12.1.1. Efficient and cost-effective sediment basins.

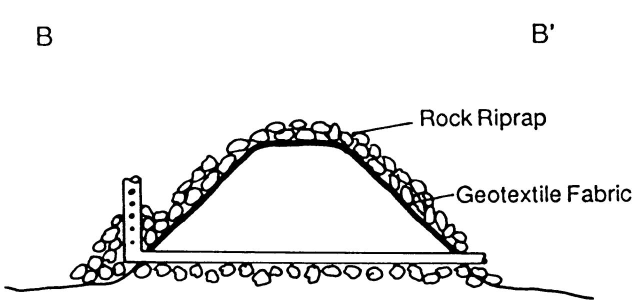

Fig. 12.1.3. Cross section B-B[1] of dewatering type of internal check dam.

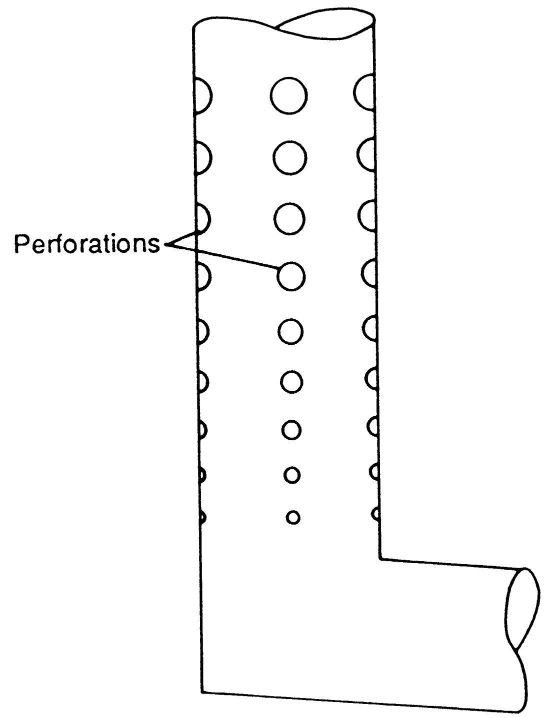

Fig. 12.1.4. Schematic of perforated riser with tapered holes for dewatering.

equation (12.1.7) where Q is discharge in cfs (m^3/s), V is the average channel velocity in fps (m/s), and A is the cross-sectional area in ft^2 (m^2), and Manning's equation is

$$V = 1.49\, R^{2/3}\, S^{1/2}/n \tag{12.1.7}$$

$$V = R^{2/3} S^{1/2}/n \tag{12.1.7a}$$

where R is the hydraulic radius in ft (m), which is the cross-sectional area divided by the wetted perimeter, and s is the hydraulic gradient (channel slope) in ft/ft (m/m).

Permanent diversions are often constructed of rock riprap, gabion mattresses, grass, asphalt, concrete, concrete slurry-filled, double-layer geotextile forms, and interlocking concrete blocks. Stability of these products is often related to discharge, diversion gradient, or velocity (Maccaferri, undated; Anon., 1989; Anon., 1982.) Rock riprap stability is based on selecting riprap that is large enough such that the gravitational force exceeds the overturning forces (Anon., 1982). Also an underlying rock filter, consisting of a range of smaller rocks, is required to avoid erosion of the base soil. The design of grassed waterways is a function of grass type and height, permissible velocity, slope, Manning's n, and hydraulic radius. Use of retardance classes simplifies the design process (Anon., 1969b). Computer programs, such as SEDCAD$^+$ Version 3.0 (Warner and Schwab, 1990), simplify design procedures.

12.1.8 CULVERTS

The selection of a properly sized culvert is based on design discharge, type of culvert, entrance configuration, pipe length and slope, headwater constraints, and tailwater condition (Fig. 12.1.8). Two of three primary design parameters must be known.

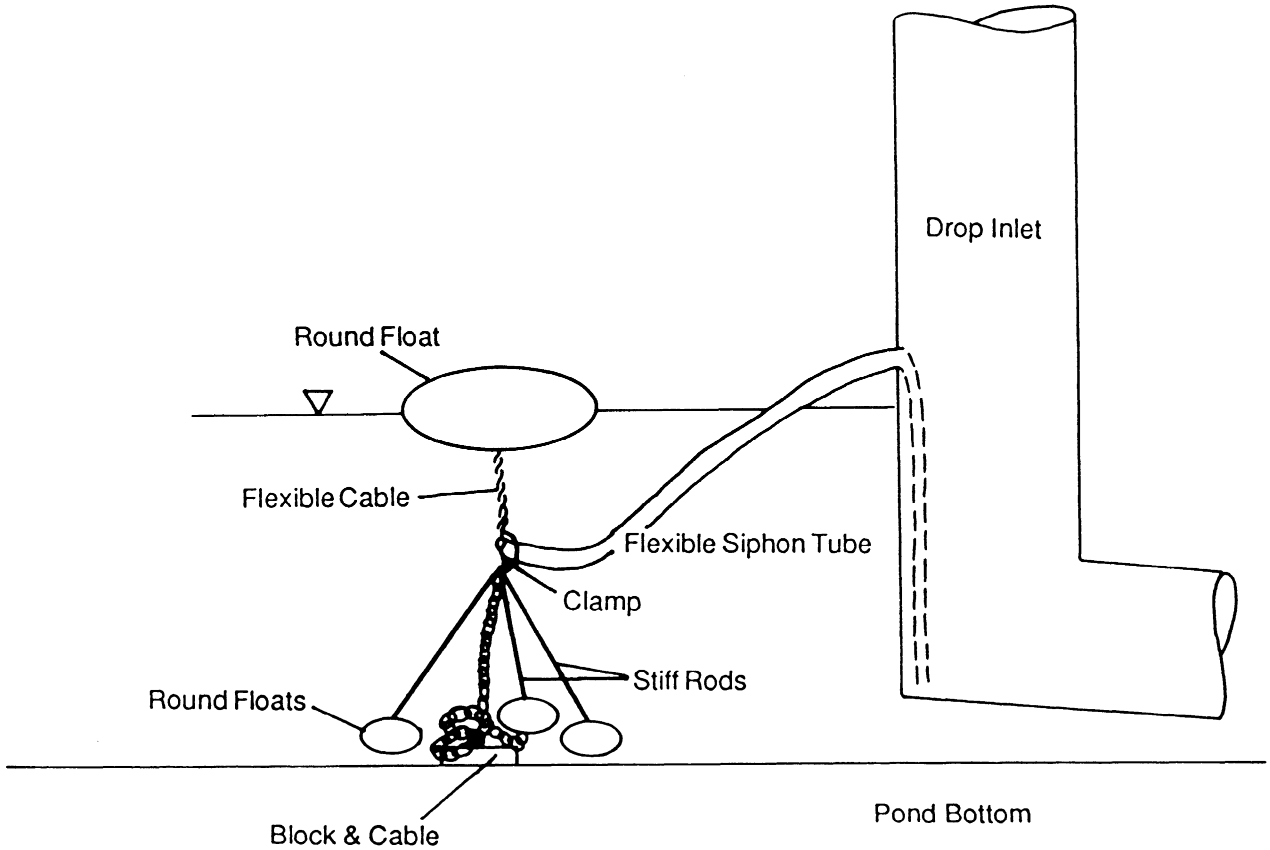

Fig. 12.1.5. Schematic of floating siphon tube used for dewatering.

The primary parameters are (1) discharge, (2) pipe size, and (3) headwater. Thus, if discharge is known, the headwater can be determined for a specific size of culvert. Depending on these parameters, the culvert may function with inlet, outlet, or full-pipe flow control.

Design procedures have been somewhat simplified through the development of culvert capacity charts (Anon., 1962). Such a chart is illustrated in Fig. 12.1.9. Headwater values are indicated on this chart on the ordinate and discharge values on the abscissa. The solid curves designate inlet control and the dashed curves indicate outlet control. Also listed is an index value I, defined as

$$I = \frac{L}{100S_o} \tag{12.1.8}$$

$$L = \frac{3.28L}{100\ S_o} \tag{12.1.8a}$$

where L is pipe length in ft (m), and S_o, is pipe gradient in ft/ft (m/m).

Example 12.1.1. Use of the culvert capacity chart is illustrated by a design example. Inputs are (1) a design discharge of 70 cfs (2m^3/s), (2) concrete culvert, (3) grooved-edge entrance, (4) culvert length of 200 ft (61 m), and (5) a slope of 0.02 and 0.002 ft/ft (m/m), respectively.

Solution. The solution procedure begins with the calculation of the index value. When the calculated index value is less than or equal to the index value of a specified culvert, the culvert will be in inlet control, and the solid line will describe culvert performance. Applying Eq. 12.1.8 to the design input values mentioned above and using a 0.02-ft/ft (m/m) slope yields an I of 100. A vertical line at 70 cfs (2 m^3/s) intersects the solid 300 index value for the 36-in. (910-mm) culvert (Fig. 12.1.9). Since the calculated index value is less than the 300 solid line, inlet control is specified, and the headwater height of 5.2 ft (1.6 m) is determined by extending a horizontal line to the ordinate. In a similar manner for the 0.002 ft/ft (m/m) culvert gradient, an index value I of 1000 is calculated. Since the calculated index value lies between the solid and dashed curve of the 36-in. (9l-cm) culvert, outlet control is specified. Referring to Fig. 12.1.9, a headwater of 6.1 ft (1.9 m) is determined from the interpolated index value. A calculated index value greater than the dotted curve indicates full pipe flow, and an applicable nomograph should be used. A detailed analysis of culvert design procedures is available (Normann et al., 1985).

The user of these culvert analysis charts should be cautioned that neither the open-channel flow regime nor submerged outlet conditions are accommodated by the culvert capacity charts. Computer programs for culvert designs are available (Anon., 1986; Warner and Schwab, 1990). The SEDCAD$^+$ Version 3.0 program provides complete performance curves of headwater versus discharge for all culvert flow regimes.

12.1.9 PUMPS

Pumps are widely used throughout the mining industry for dewatering deep mine operations, an active pit, and predraining

Table 12.1.6. Development of an Outflow Hydrograph for a Sediment Basin

Item	Method
Principal spillway relationship	1. Drop-inlet riser stage-discharge (Barfield et al., 1981) —Weir flow equation —Orifice flow equation —Pipe flow equation 2. adjacent areas prior to pit excavation. Control of groundwater and surface water can alleviate numerous production problems and provide safer working conditions. For example, a series of wells installed adjacent to an area to be mined can decrease groundwater migration, reduce construction of large sumps, and enhance slope stability.

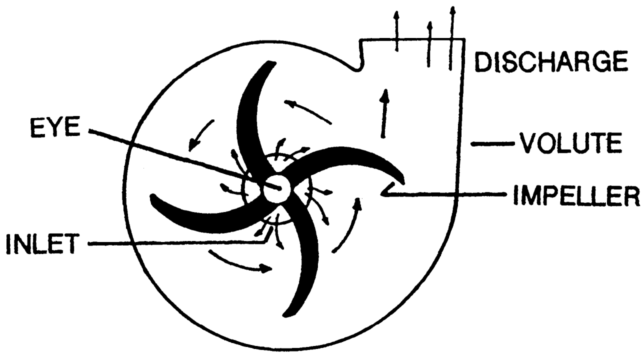

Fig. 12.1.10. Centrifugal pump components.

12.1.9.1 Basic Principles of a Centrifugal Pump

Centrifugal pumps are probably the most popular type in mining (Bise, 1986). The basic components of a centrifugal pump as illustrated in Fig. 12.1.10 are an inlet, the eye of the rotating impeller, curved impeller vanes, volute, and discharge connection. A centrifugal pump is a simple device with the only moving part being the impeller which is attached to the shaft of a motor or engine. Assuming that the suction pipe and pump housing (volute) is filled with water to the level of the eye (i.e. primed), as the impellers rotate, a partial vacuum is created that allows atmospheric pressure to lift more water into the pump housing. The water, which entered the inlet opening at the eye of the impeller, is set in rotation by the impeller and creates centrifugal force resulting in pressure at the outer perimeter of the impeller. Water moves outward from the impeller at a high velocity and pressure into an expanding volute and is discharged.

A single-stage centrifugal pump, that is, a single impeller, usually operate against low to moderate heads. For heads greater than approximately 250 ft (75 m), multistage pumps are generally used. A multistage centrifugal pump consists of two or more stages and is essentially a high-head pump. The single-stage pump is normally used for high volume and relatively low head.

12.1.9.2 Calculating Dynamic Head

The essential information needed to properly select a pump is the required flow rate in gpm (L/s) and the total dynamic head in ft (m). Flow rate is dependent primarily on operational factors such as the anticipated rate of flow into a pit or underground mine. Determination of the total dynamic head requires consideration of suction lift, elevation difference between the pump and discharge point, pressure requirements, if any, at the discharge outlet, friction along pipes and fittings, and velocity head.

Dynamic lift of water at the suction side is calculated as the required pressure needed to raise water from the water surface to the height of the centerline of the pump and to overcome frictional resistance in the intake pipe and fittings. Twenty-three ft (6.7 m) is considered the practical limit of suction lift. This is further reduced by long or undersized intake pipes, a large number of fittings, higher mine site elevation, and warmer waters. Table 12.1.7 contains the practical static suction lift as a function of site elevation and temperature.

Friction loss in pipes is a function of pipe diameter and length, type of pipe material, and flow rate. The Hazen-Williams equation is often used to calculate friction loss:

$$H_{f100} = \frac{K(Q/C)^{1.852}}{D^{4.87}} \tag{12.1.9}$$

where H_{f100} is friction loss per 100 ft (100 m) of pipe; K is the conversion constant, 1045 with English units and 1.22×10^{12} with SI units; Q is flow rate in gpm (L/s); C is retardation coefficient = 120 for coated steel and = 150 for *PVC*; and D is inside pipe diameter in in. (mm).

Friction loss in fittings is usually approximated by the equivalent pipe length (Table 12.1.8).

The velocity head h_v, in ft (m) is usually small and may often be neglected. It can be calculated using the following relation:

$$h_v = \frac{V^2}{2g} \tag{12.1.10}$$

where V is velocity of liquid in fps = $0.408 \times \text{gpm}/D^2$ (English units) and = $1273 \times L/s/D^2$ (SI units), D is pipe diameter in in. (mm), and g is acceleration due to gravity = 32.2 fps^2 (9.81 m/s^2).

Example 12.1.2. Consider a pump that is to be located 4 ft (1.2 m) above the water level of a sump. The mine is at 6000 ft (1830 m) and the water temperature is not expected to exceed 70°F (21°C). A flow rate of 900 gpm (56.8 *L/s)* is required. A 6-in. (152-mm), 40-ft (12.2-m) long suction line was specified with two 45°, 6-in. (152-mm) ells, a gate valve, a vacuum gage installed on a tee, and a check valve. Will the total practical lift of the pump be exceeded?

Solution. Total Dynamic Suction Lift = Lift Height + Friction Head + Velocity Head. Lift height is given as 4 ft (1.2 m). The equivalent pipe length of fittings totals 153.5 ft (46.8 m). Pipe friction head is calculated for the 40 ft (12.2 m) section from Eq. 12.1.9 as 7.1 ft/100 ft of pipe. For the total equivalent pipe length of 193.5 ft (59 m), the friction head loss is 13.7 ft (4.2 m).

Flow velocity is approximately 10.2 fps (3.1 m/s), and the velocity head is 1.6 ft (0.5 m) (Eq. 12.1.10). Thus the total dynamic suction lift is 4 + 13.7 + 1.6 = 19.3 ft (5.8 m). The practical lift at 6000 ft (1830 m) for water at 70°F (21°C) from Table 12.1.7 is 18.3 ft (5.6 m). Thus the practical lift of the pump approximated in Table 12.1.7, will be slightly exceeded, causing pump cavitation and a drop in pump performance.

Pump manufacturers provide either static suction lift or net positive suction head (NPSH) curves for each pump model over the entire operating range. The NPSH subtracted from the values listed in Table 12.1.7 provides an estimate of the maximum allowable dynamic suction lift for a given model at a specified operating point. Selection of a more efficient check valve, reduction of intake pipe length, lowering the pump closer to the water, eliminating fittings, or increasing the suction pipe size will reduce the total dynamic suction head. It should be noted that improper design and installation of the suction line are primary causes of poor pump performance.

In a similar manner to suction head calculations, the total dynamic pumping head must be calculated prior to pump selection. The total dynamic head is the sum of (1) suction head, (2) the elevation difference between the center line of the pump and the discharge point, (2) friction loss in pipes and fittings, (3) discharge pressure (zero if atmospheric discharge), and (4) velocity head.

Example 12.1.3. Assume that a 900-gpm (56.8-L/s) discharge is required to dewater a pit. The elevation difference between the pump and discharge point is 70 ft (21.3 m) and a 400-ft (122-m), 6-in. (152-mm) PVC pipe will be used to convey the pumped water. No fittings are needed.

Table 12.1.7. Practical Suction Lift[1]

Elevation ft	(m)	50°F ft	(10°C) (m)	70°F ft	(21°C) (m)	90°F ft	(32°C) (m)
0	0	23.8	7.2	23.2	7.1	22.6	6.9
1000	305	22.9	7.0	22.4	6.8	21.8	6.6
2000	610	22.0	6.7	21.5	6.6	20.9	6.4
4000	1220	20.4	6.2	19.9	6.1	19.3	5.9
6000	1830	18.9	5.8	18.3	5.6	17.8	5.4
8000	2440	17.5	5.3	16.9	5.2	16.4	5.0

[1]70% of theoretical siphon lift.

Table 12.1.8. Equivalent Length of Pipe, ft

	Nominal pipe size, in. (mm)				
	1 (25)	2 (50)	3 (75)	4 (100)	6 (150)
90° ell	2.7	5.5	8.0	11.0	16.0
45° ell	1.3	2.5	4.0	5.0	8.0
Tee	6.0	12.0	17.0	22.0	33.0
Globe valve, open	13.0	29.0	45.0	60.0	110.0
Gate valve, open	0.6	1.3	2.0	2.5	4.5
Check valve	8.0	19.0	32.0	43.0	100.0

Conversion factor: 1 ft = 0.3048 m.
Source: Adopted from Bise, 1986.

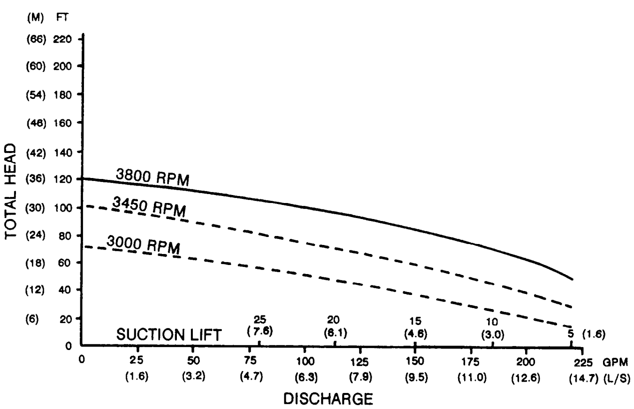

Fig. 12.1.11. Pump characteristic curves for engine-driven pump. (Modified from Anon., 1966.)

Solution. Applying Eq. 12.1.9 yields a friction loss H_f on the discharge side of 4.7 ft (1.4 m). The total dynamic head is the sum of the dynamic suction head 19.3 ft (5.8 m), elevation difference 70 ft (21.3 m), and discharge friction loss 4.7 ft (1.4 m), which yields 94 ft (28.6 m). Thus the selected pump must have the capacity to pump 900 gpm (56.8 L/s) at a total dynamic head of 94 ft (28.6 m), and a dynamic suction lift at this operating point of 19.3 ft (5.8 m).

12.1.9.3 Pump Selection

A pump characteristic curve shows the relationship among discharge in gpm (L/s), total dynamic head in ft (m), and either suction lift or NPSH in ft (m). A representative pump characteristic curve is illustrated in Fig. 12.1.11. Along the vertical axis, the amount of head that will be developed, expressed in ft (m), is shown. The x axis contains discharge in gpm (L/s). The lines marked 5 (1.5), 10 (3.0), 15 (4.6), 20 (6.1), and 25 ft (7.6 m) indicate the maximum flow in gpm (L/s) the pump is capable of delivering at designated suction lifts. To read the curve, start at either the x or y axis.

Example 12.1.4. Assume 200 gpm (12.6 *L/s*) is needed.

Solution. Follow across the bottom scale until 200 gpm (12.6 *L/s*) is reached; then proceed up this line until the 3800-rpm line is intersected. Reading across, it is found that the pump is capable of discharging 200 gpm (12.6 *L/s*) against a total head of 65 ft (19.8 m), provided the suction lift is no more than 7 ft (2.1 m).

Example 12.1.5. Similarly, if a total head of 80 ft (24.4 m) is required, proceed horizontally across to the 3800-rpm line and then vertically to the gpm (L/s) axis to read 160 gpm (10.1 *L/s*). If the suction lift is 15 ft (4.6 m), the maximum discharge is 150 gpm (9.5 *L/s*).

Pump characteristic curves for an electric-motor-driven pump contain additional information on pump speed, efficiency, horsepower, and suction head. Motors operate at a constant speed. Their rpm cannot be varied like a gasoline or diesel engine. A V-belt pulley arrangement is used to adjust a motor to the desired operating speed.

Example 12.1.6. (a) For a specified operating rpm, (e.g., 1750) the brake horsepower (brake watts) can be directly determined from Fig. 12.1.12. A ½-hp (0.4-kW) motor is needed. At 3450 rpm, a 3-hp (2.3-kW) motor is required since the 3450-rpm line is between the 2 and 3 hp (1.5 2.3 kW) scale. Pump efficiency is indicated by the U-shape curves, e.g., 56, 50, 45%. Brake horsepower can be calculated from Eq. 12.1.11:

$$BHP = \frac{Q \times H}{3960 \times \text{Eff}} \quad (12.1.11)$$

$$\text{brake watts} = \frac{Q \times H}{6.2 \times \text{Eff}} \quad (12.1.11a)$$

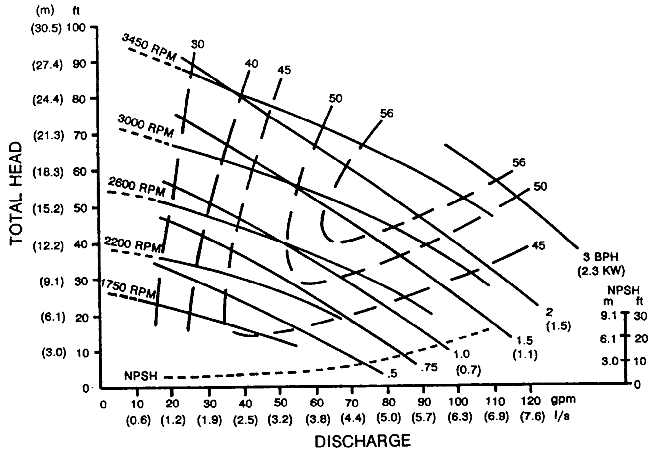

Fig. 12.1.12. Pump characteristic curves for electric-motor-driven pump. (Modified from Anon., 1966.)

where Q is flow rate in gpm $(\mathrm{L/min})$, H is total dynamic head in ft (m), and Eff is pump efficiency expressed as a decimal.

(b) The required net positive suction head (NPSH) is the minimum net energy required by the pump at the eye of the impeller to avoid cavitation and reduce pump performance. NPSH is a function of pump design. If the total dynamic suction lift (i.e., static suction lift plus friction loss and velocity head) exceeds the NPSH required by the pump, then cavitation will occur (Anon., 1983).

At a flow rate of 60 gpm (3.8 L/s), the NPSH, read from the lower dashed line and the NPSH axis, is 6 ft (1.8 m). The total dynamic suction lift is determined by subtracting the NPSH from the appropriate value listed in Table 12.1.7. For example, at 1600 ft (305 m) and 70°F (21°C), a 22.4-ft (6.8-m) practical suction lift is needed. Thus, for the above values, the total dynamic suction lift must be less than 16.4 ft (5.0 m), i.e., 22.4 to –6 ft (6.8 to –1.8 m).

The total head and pump discharge can be changed by placing pumps in series or parallel or by changing the operating speed. To plot characteristic curves for parallel and series pumping installations, it is required to secure each pump's characteristic curve. For parallel pump characteristic curves, the flow rates are added at a given head; for series pump characteristic curves, the heads are added at a given flow rate. As the pump speed is increased, (1) the discharge is proportionally increased, (2) head varies as the square of the RPM ratio, and (3) BHP (brake watts) varies as the cube of the RPM ratio. Refer to Bise (1986) for detailed examples.

12.1.9.4 Pump Troubleshooting

A properly designed and installed pump will reduce potential operational problems. A vacuum gage, installed a minimum of one pipe diameter from the pump inlet, can solve the majority of problems. A high gage reading indicates a partially blocked suction line, whereas a low reading often indicates air leakage through fittings on the suction side. A vacuum gage can easily detect common problems such as a non-primed pump; too high a dynamic lift; excessive air in the water due to the intake being near the water surface; air leakage in the inlet pipe, fittings, or stuffing box; or the strainer, foot valve, or suction pipe is too small or restricted by debris. If a discharge pressure gage reads too low, the pump may not be primed, rpms too low, total dynamic head is too high, impeller rotating in the wrong direction, excessive air in water, mechanical defects, etc. Excess pump vibration may indicate misalignment, worn bearings, bent shaft, or an obstruction has lodged in one side of the impeller.

Chapter 12.2
WASTE DISPOSAL AND CONTAMINANT CONTROL

ERIC G. ZAHL, F. BIGGS, C.M.K. BOLDT, RANDALL E. CONNOLLY, LESLIE GERTSCH, ROBERT H. LAMBETH, BILL M. STEWART, AND JIM D. VICKERY

12.2.1 INTRODUCTION

Waste disposal is the handling, transporting, and placing of mine wastes to meet stability and environmental goals by the most economical means. Mine waste includes overburden, waste rock, refuse, mill tailings, slag, process sludge and residues, acid mine drainage, and seepage water. Although technically not waste, low-grade and ore-grade stockpiles and leach heaps and dumps are included here because they must be given the same considerations as waste materials. Some of these materials may reside only temporarily in any one of the above categories, but it is still necessary to design the structures to meet stability and environmental goals.

Over the last few decades, construction methods have been developed for building structurally stable impoundments, waste storage structures, and effluent handling facilities (Vick, 1983; Williams, 1975; Argall, 1978), but few publications address both environmental and structural aspects of waste management comprehensively (Legge et al., 1982; Anon., 1989a; Hood et al., 1988). Design goals are quickly changing to meet the demands of increasingly stringent environmental regulations (Anon., 1985a), a topic that is covered in detail in Chapters 3.4 and 7.3 of this *Handbook.* The requirements to meet these environmental regulations are so extensive that substantial changes are often necessary in previously acceptable designs or, in some cases, entirely new disposal configurations are needed.

The intent of this chapter is to identify the basic design considerations to meet both traditional structural goals and emerging environmental goals. Low-volume special wastes, such as those classified as hazardous by the Environmental Protection Agency (EPA), and stack effluent are not discussed; neither are detailed methods for addressing many reclamation and environmental issues, even though these issues are integral to waste disposal.

Adverse environmental effects have primarily been the result of contamination of water resources by acids and metals and reclamation practices that were aesthetically unpleasing and that left few options open for future land use. Other less obvious impacts include contamination by process reagents, sediment loading of surface waters, and waste dispersal by wind. Methods to prevent or control these effects are usually the most costly and complex aspect of waste disposal and should be treated accordingly. Opening new operations, permitting ongoing operations, and minimizing future liability for environmental cleanup depend directly on preventing contamination or treating wastes to bring contamination to acceptable levels through appropriate disposal practices.

The enormous potential for liability, the quick evolution of technology and regulations, and the complexity of both site-specific and general factors make it imperative for a design engineer to develop the specific components of a design based on current information from many disciplines. It may be necessary to look to other industries, such as the coal-fired power plants industry, to find information relevant to environmental concerns (Anon., 1986a; Summers et al., 1983). References have been selected to provide the most current sources of information from which a design engineer may begin a search for appropriate information to address specific design constraints.

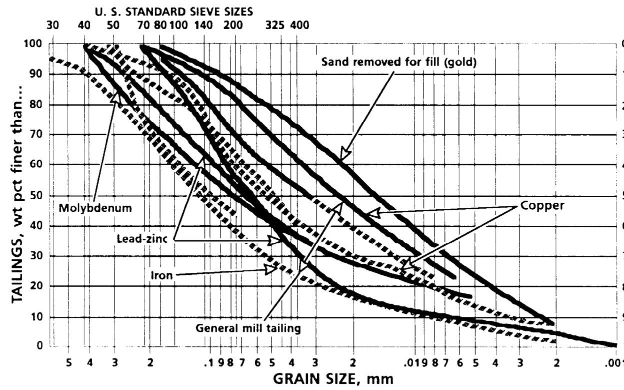

Fig. 12.2.1. Typical grain-size distributions for different types of mine tailings.

12.2.2 COMPOSITION OF WASTES

Solid mine waste usually consists of (1) waste rock from mine development or overburden, (2) stockpiles of low-grade ore or ore with unfavorable milling mineralogy, (3) leach dumps or heaps, and (4) milling waste. It is classified as coarse, fine, or slime. Fig. 12.2.1 illustrates common grain-size gradations for different mine waste types.

12.2.2.1 Waste Rock

Waste rock is usually coarse and is classified as cobbles, rocks, or boulders with associated fines. Disposal options for waste rock include valleyfill, crossvalley, sidehill, ridge, heaped, or diked dumps; embankments; and backfill (Fig. 12.2.2). In a dump, the most frequent concerns are the structural stability of the dump and wind and/or water erosion (Anon., 1972). When waste rock is used as backfill, it may be crushed, ground, blended, and/or chemically modified to give it characteristics that will meet structural and environmental constraints.

12.2.2.2 Fine Waste

Fine mine wastes usually result from milling or processing operations. Typical grain sizes range from 100% > 5 mm for iron ore tailings to 100% < 0.006 mm for phosphate slimes (Fig. 12.2.1). Water is often used to transport these fine materials to the deposition area. The water will usually be released slowly, which requires that special attention to be paid to controlling the level of the phreatic surface, which directly affects structural stability (Center and Zlaten, 1982; Coates and Yu, 1977; Soder-

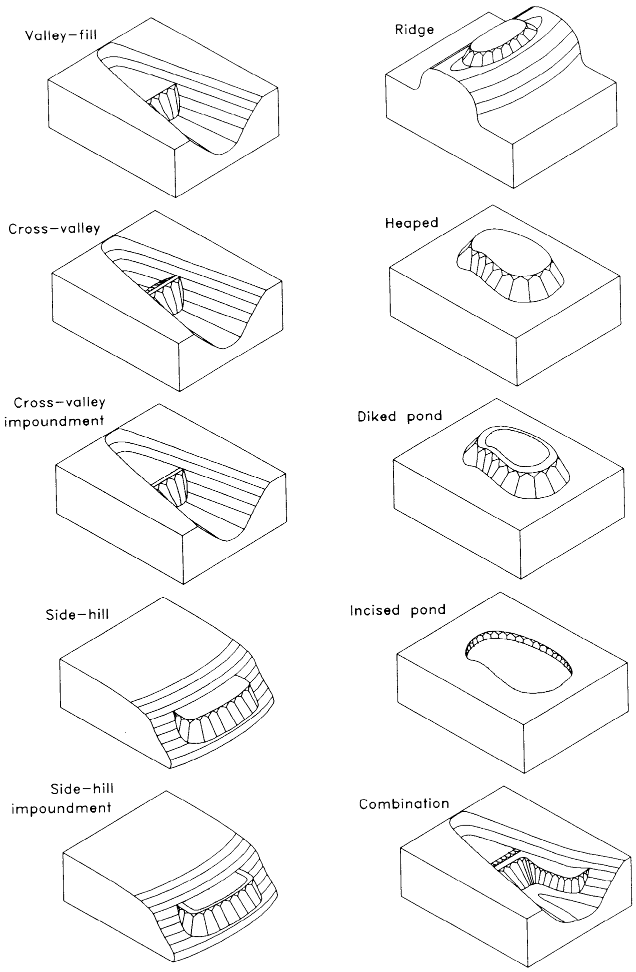

Fig. 12.2.2. Configurations of waste depending on topography.

berg and Busch, 1977). Embankments for fine waste impoundments are constructed of coarse waste or borrow materials or from the coarser fraction of fine materials.

Slimes are the smallest particles that make up fine waste. They are derived from both ore and waste rock and include clay, alumina, hydrated iron, near-colloidal common earths, and weathered feldspars. Slimes are characterized by low permeabilities that must be considered when designing for water control.

Sludges and slimes settle so slowly and incompletely that they typically remain in a liquid or easily reliquefied state. Tailings pond dike failure thereby constitutes a significant environmental threat, and the costs in human life and property damage of such disasters can be enormous.

Dewatering options are many, and choosing the appropriate method for a given site can be an important economic decision for the mine operator. For example, the Florida phosphate industry searched for many years for a viable solution to their ultrafine slimes disposal problem, and finally determined that the most effective method was simple compaction with a specially designed heavy-tired vehicle. Electrokinetic techniques have been shown to work well with responsive coal and metal-mine wastes (Kelsh, 1990). Flocculation, filtration, and use of mechanical settlers are the more traditional dewatering techniques. Cost and effectiveness will vary widely, and preliminary laboratory and pilot-scale tests are strongly recommended before choosing the dewatering method for a specific slurry.

12.2.3 WASTE STRUCTURES AND DISPOSAL METHODS

Planning waste disposal facilities requires determining regulatory constraints, locating an appropriate site, designing the structural and environmental integrity of the facility, developing an operating and maintenance plan, and developing a reclamation plan for future land use (Center and Zlaten, 1982; Ritcey, 1989). Specific factors to be considered are the engineering properties and contamination potential of the waste, effects of seismic loading, and ways to control water to maintain stability and limit contaminant release (Vick, 1983). These factors will not be treated separately here, but a designer should be aware that they need to be addressed in detail. The geomechanics of stability in relation to waste disposal is covered in more detail in Section 10 of this *Handbook.*

The layout of waste structures can be in one or more of the following forms, depending on the type of waste, the purpose of the waste structure, and the physical constraints at the site (Fig. 12.2.2).

As the name indicates, a *valleyfill dump* fills a valley. The top surface is usually sloped to eliminate water ponding. Construction begins at the upstream end of the valley and dumping proceeds along the downstream face. This type of embankment can also be started as a crossvalley structure where the area is subsequently filled upstream.

A *crossvalley* structure crosses the valley bottom, but the valley is not completely filled upstream. The structure is usually designed to control the storage and/or discharge of flood flows. If the structure is not designed to retain water, then a water diversion system must be installed to provide drainage around it. This type of structure is typically used as a retention dam for fine coal or waste slurries.

A *sidehill* structure lies along the side of a hill or valley but does not cross the valley bottom. It can be built to impound either water or mine waste slurries. As with a crossvalley structure, a sidehill embankment must control the storage and/or discharge of flood flows if it is to retain water or slurries.

A *ridge embankment* straddles the crest of a ridge, and waste material is placed along both sides of the area. This type of structure is not typically used to contain material or water.

A *diked embankment* is constructed on nearly level terrain and can either impound fine-grained or coarse-grained mine waste. If fine wastes are impounded by coarser waste, the structure is considered a dike. If the embankment is homogeneous and coarse, the embankment is termed a heap.

12.2.3.1 Leach Dumps or Heaps

Leach dumps or heaps consist of low-grade ores that are dumped loosely in piles so that fluids may be sprinkled on the piles to leach recoverable metals (Chapter 15.2). Heaps are placed on impermeable liners, while dumps are placed on soil surfaces. Care must be taken to ensure structural stability of the piles and control metals-laden seepage during and after leaching operations. Upon completion of the leaching process, reclamation of the piles must include environmental and structural stability. Cyanide is of particular concern with gold leach heap operations (Ingles and Scott, 1987; Scott, 1987).

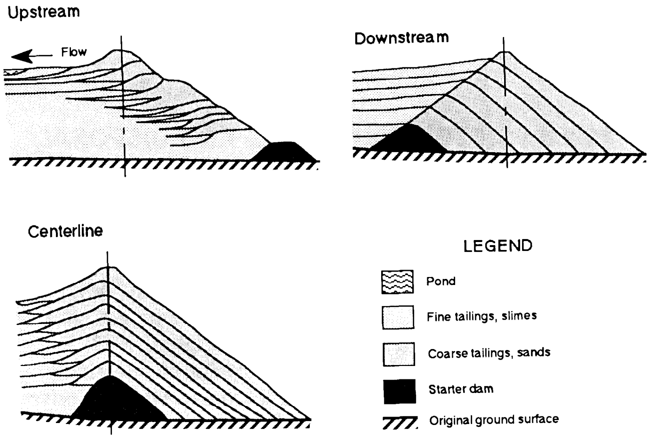

Fig. 12.2.3. Methods of dike construction for tailings impoundments.

12.2.3.2 Stockpiles

Stockpiles are ore that is stored much the same as waste rock except that they must be isolated from waste so that the ore may be recovered at some later time. This material may be chemically unstable, and so specific efforts must be taken to keep water from infiltrating the ore and becoming a contamination concern. Stockpiles must also be structurally stable and must be prevented from eroding.

12.2.3.3 Surface Impoundments

Impoundment structures are those designed to contain solid waste and effluents generated during the processing of coal and metal/nonmetal ores (see Chapter 7.4). Impoundment structures are typically water retention dams or embankments raised during waste disposal. Water retention dams are used where large amounts of water must be stored during specific periods (i.e., during spring runoff) or where the impounded water is not reusable for processing. Since design of a water retention dam does not need to incorporate rapid drawdown of water, the inside slope of an embankment can be steepened to reduce embankment volume and costs.

Raised embankments are favored over water retention dams because costs are significantly lower and mine waste materials can be used as part of the embankment, reducing volume requirements correspondingly. In addition, an embankment does not require that suitable embankment material be located and transported or that the entire structure be built before disposal begins. Three methods of constructing raised embankments have been developed to address various design requirements (Fig. 12.2.3). These are the upstream method, the centerline method, and the downstream method. Advantages and disadvantages of these methods may be seen in Table 12.2.1.

The upstream method is the least costly and the most widely used, but it is subject to a number of crucial constraints. Special consideration must be given to stability, particularly the stability of the phreatic surface within the embankment. Stability is controlled indirectly by (1) grain-size segregation near the embankment, which controls permeability and internal water flow, (2) location of the impounded water relative to the embankment crest, and (3) permeability of the foundation of the impoundment relative to the embankment. Successive levels of dikes rest on the beach of a previous dike. The weight-bearing capacity and settlement characteristics of these beaches must be considered. Waste is spigoted from single or multiple discharge points off a transport pipeline. The coarser portion of the waste settles out near the crest, and the finer material is carried toward the interior of the impoundment. Hydrocyclones can be used to improve the separation of the coarse materials; drained coarse material is used to raise the impoundment perimeter. Advantages of this technique include low construction costs, a minimum amount of dike fill to obtain storage capacity, and the capability of raising the embankment rapidly. The major disadvantages are that the embankment perimeter is built on previously deposited slimes, and the meandering flow of slurries from a spigot results in pockets of weak slime and sand along the periphery.

The downstream method of depositing waste requires a starter dike and, usually, an impervious layer of some sort on the upstream face of the dike. This layer acts as a seepage barrier to control the level of the phreatic surface in the dike and can allow water to pond near the inner face of the embankment. Hydrocyclones are used to separate the slurry. The coarse underflow is used to build the embankment downstream of the point of deposition, and the overflow is discharged into the interior of the impoundment. Blanket or finger drains should be provided downstream from the starter dam to collect and discharge seepage water deposited with the slurried waste. This technique avoids building the perimeter on previously deposited slimes; however, each successive downstream extension requires greater volumes of coarse material.

The centerline method begins with a starter dam and subsequent deposition of hydrocycloned underflow materials on both the upstream and downstream sides of the embankment. Blanket or finger drains are installed downstream of the centerline, much like in the downstream method of deposition.

Very fine waste, such as phosphate or coal slimes, are impounded by an embankment of coarse waste or borrow material. Internal drainage and reduction of pore water pressures within the waste may take many years; therefore, the impoundment structure must be designed and constructed as a water-retention-type dam.

Other deposition techniques include thickened discharge and subaerial. In some settings, these techniques may provide greater engineering strengths and more rapid dewatering, which may be critical for environmental or structural requirements. The thickened discharge technique consists of thickening the slurry and pumping the mix to a central deposition point or points to form a conical hill (Lighthall, 1987). A small embankment around the perimeter is used for collecting waste and runoff water. Chemical flocculants and/or mechanical dewatering devices can be used to accelerate thickening of the waste slurry.

The subaerial technique requires that the slurry be discharged through spray bars on a gently sloping beach of previously deposited waste. The laminar flow settles the solids in layers and the excess water flows over the beach to the collection pond. The method allows for continuous draining of the deposited material, thereby consolidating the mass through negative pore water pressures (Haile and Brouwer, 1988; Lighthall, 1987; Knight and Haile, 1983).

Many fine-waste disposal methods may need to be altered during freezing weather conditions, because freezing will alter deposition characteristics and may create ice lenses, areas of weakness, and other problems. Often during freezing conditions, spigoting or cycloning may be deferred in lieu of point discharge further into the pond interior to avoid creating embankment conditions that could weaken the structure.

12.2.3.4 Backfill

When possible, coarse waste rock from underground development operations is transported to previously mined-out open-

Table 12.2.1. Surface Impoundment Embankment Types

Embankment type	Mill tailings requirements	Discharge requirements	Water storage suitability	Seismic resistance	Raising rate restrictions	Embankment fill requirements	Relative embankment cost
Water-retention borrow	Suitable for any type of tailings	Any discharge procedure suitable	Good	Good	Entire embankment constructed initially	Natural soil	High
Upstream	At least 40–60% sand in whole tailings. Low pulp density desirable to promote grain-size segregation	Peripheral discharge and well-controlled beach necessary	Not suitable for significant water storage	Poor in areas of active seismicity	Less than 15–30 ft (5–10 m)/yr most desirable. Greater than 50 ft (15m)/yr can be hazardous	Natural soil, sand tailings, or mine waste	Low
Downstream tailings	Suitable for any type of details	Varies according to design	Good	Good	None	Sand tailings or mine waste if production rates are sufficient, or natural soil	High
Centerline	Sands or low plasticity slimes	Peripheral discharge on nominal beach size necessary	Not recommended for permanent storage. Temporary flood storage acceptable with proper design details	Acceptable	Height restrictions for individual raises may apply	Sand tailings or mine waste if production rates are sufficient, or natural soil	Moderate

ings to avoid hoisting time and cost, as well as surface waste disposal. Waste created during milling operations can also be transported underground or back to a pit and used as backfill (Boldt et al., 1989; Biggs et al., 1989). This backfill material can be "classified" waste (the coarse fraction of the total amount). Waste material is ordinarily pumped as a slurry by pipeline to the specific area to be backfilled, placed behind constructed bulkheads, and allowed to dewater or solidify. Classified waste material may be placed with or without the addition of cement, depending on the requirements of the mining technique being used. Total waste material is placed with lower water contents than classified materials, and any added cement tends to use the excess water in the hydration process. The excess water must be discharged (or consumed) from the waste backfill materials to eliminate the potential for liquefaction failures of the fill (Aref et al., 1989).

Backfill disposal in a surface mine requires enough room to place the waste material without interfering with the active mining (resource recovery) operation. In coal area mining (a variation of strip or open cast mining), the overburden is backfilled into the mined-out section, leveled, and the topsoil replaced.

12.2.3.5 Placer Waste

During placer mining, the practice of washing sand and gravel to recover minerals produces tailings with particle sizes ranging from coarse to fine and waste water streams loaded with fine sand, silts, and/or clays (slimes) (see Chapter 15.1). Proper placement of tailings and clarification of the waste water to meet effluent discharge requirements are primary design goals. Unneeded water should be diverted around the mining operation, and the amount of water directed to the operation should be kept as low as possible; lower water volumes and flow rates will result in more efficient settling pond systems. Water bypass systems will also reduce flood risk, reduce the amount of water going through settling ponds, allow fish to pass more freely, and provide a drier working area for equipment.

Settling ponds should have a length-to-width ratio of at least 2:l and should be large enough to retain the volume of expected sediments (Hanneman et al., 1987). Settling efficiency can be increased if more than one pond is used. Presettling ponds in series or in parallel can be used to remove up to 50% of the heavier sediment before the waste water reaches the main settling or recycling pond (Ault, 1986).

In general, a properly designed system of multiple settling ponds will allow requirements for suspended solids to be met. However, to meet turbidity and dissolved metals requirements at some placer mining operations, special techniques are necessary, such as flocculation (Phillips and Pollen, 1987), mechanical dewatering, liquid fluidized beds (Fuerstenau and Han, 1988) and/or a combination of these treatments. Environmental costs for waste stabilization and effluent treatment also need to be considered in feasibility studies of economic placer mining (Stebbins, 1987).

12.2.3.6 Uranium Waste

Because nuclear power plants are an important source of electrical power in the United States, and because of the threat and mobility of radionuclides, disposal of uranium mill tailings is one of the most regulated of mining activities and requires design goals at the onset of planning that will include cost-effective containment considerations for long-term stabilization, public health and safety, and environmental protection. After the best site has been selected, design and construction of tailings piles are critical to ensure meeting design goals. A final environmental impact statement on uranium milling (Anon., 1980a) lists alternative disposal systems for uranium mill tailings. The Nuclear Regulatory Commission has published several "how to" documents regarding disposal of uranium mill tailings. Particular topics of concern are treatment techniques (Sherwood and Serna, 1983), assessment methods (Serna and Peterson, 1983; Denham et al., 1985), long-term stability (Nelson et al., 1986), leachates (Opitz et al., 1985), erosion (Walters et al., 1986), and reclamation (Beedlow et al., 1985).

12.2.4 WASTE TRANSPORT SYSTEMS

Transport options for various disposal schemes should be considered when planning a waste disposal system. The selection and design of waste transport systems depend primarily on the type of waste produced by the mining or milling facility and the disposal method used. Transport methods can be categorized according to their suitability for handling coarse or fine mining wastes. Other considerations include how fast (rate) and for how long (duration) the waste is to be transported; moisture, specific gravity, cohesion, and abrasiveness of the waste; distance and terrain over which the waste is to be transported; and environmental constraints. Many disposal systems can be optimized by the use of more than one transport technique. In general, it is most desirable to select a transport system that can deal with large variations in particle size. Some of the available waste transport options are described briefly in the following, along with an explanation of the fundamental mechanics of the systems.

12.2.4.1 Coarse Waste Transport Systems

The size distribution of particles classified as coarse may cover a broad spectrum, from boulders to sands. The following methods are suitable for coarse waste transport. An in-depth treatment of haulage logistics may be found in Chapters 9.3 and 13.3.

GRAVITY FLOW. From an operations standpoint, the final disposal site should be at a lower elevation than the waste storage or production area so that transport costs can be minimized through the use of gravity. However, most waste transport systems cannot rely entirely on gravity flow but will require additional transport methods.

Coarse wastes can be dumped on an open slope or through rock passes to allow gravity flow, but this method is usually limited to the construction of waste dumps. Waste materials can also be transferred from individual systems through chutes. Poorly designed transfer chutes can limit the efficiency of the entire waste handling system.

The probability of blocking rock passes or conduits is a function of size of the waste particles being handled, ratio of conduit diameter to maximum particle size, shape of the particles, velocity profile across the flowing material, amount of moisture in the waste, and cohesion and frictional properties of the waste. Specific design criteria have been developed to evaluate the flow of materials through various components of a gravity flow system (Hambley, 1987; Hambley et al., 1983).

TRUCK HAULAGE. Trucks are the most efficient form of transport when great flexibility is needed to accommodate changes in disposal destination. However, this method would usually be considered only for operations using truck haulage for ore removal. Trucks are available in a wide variety of sizes and configurations to meet most needs. Compatible equipment should be selected for loading trucks at the desired production rate. Road maintenance should also be considered.

RAIL HAULAGE. If there are long distances between the storage or production area and the disposal site or if rail haulage is already being used to remove waste from the mine, rail haulage may be most applicable. While rail haulage affords little flexibility in changing disposal destinations, it may be suitable for waste-dump construction.

CONVEYORS. In common with rail haulage, conveyors have limited flexibility when disposal areas must be changed. However, several movable and/or modular conveyor systems have been constructed that greatly increase flexibility. In general, conveyor systems are suitable where large volumes of waste product need to be transported over a long period of time (Rajaram, 1982). Conveyors may be the most desirable method for transporting waste rock as backfill in underground mines (Watkins, 1978). Conveyors can operate in small entries, yet they provide a large hauling capacity. Additional equipment, such as reclaimers and spreaders, can increase the efficiency of conveyors in waste disposal. Sticky wastes can become a problem with belt conveyors, especially at transfer points.

PNEUMATIC TRANSPORT. Low-pressure, high-volume pneumatic transport of coarse wastes has been used primarily for backfilling (Reynolds, 1972). These systems are usually limited to handling rock with a maximum particle size of 3 to 4 in. (75 to 100 mm) (Tweedy, 1984). Pneumatic systems are only suitable for dry, noncohesive wastes; in some extreme cases, they may require that the moisture in compressed air be removed to prevent plugging. Pneumatic systems typically consist of three basic components: the compressor, which provides airflow; the feeder, which meters the flow of waste into a pipeline and prevents air leakage; and the pipeline. The main distinction among the systems offered by various manufacturers lies in the feeder device used to introduce solids into a stream of air. The output capacity of pneumatic systems is determined by the size and specific gravity of the material, flow rate of air, and pipeline dimensions, as well as layout (Sands et al., 1990).

12.2.4.2 Fine Waste Transport Systems

Fine wastes are typically the product of beneficiation processes, and the physical properties are highly dependent upon the nature of the specific process. For instance, milled wastes originate as a slurry of finely ground waste rock and water. These slurries may be placed in impoundments or used as backfill, both of which require dewatering at the disposal site. Given proper conditions, many fine wastes may be transported by the same methods described for coarse wastes. However, the following transport methods are usually considered more suitable for fine wastes.

HYDRAULIC TRANSPORT. As previously noted, many mine wastes originate as slurries and are transported most suitably in this form (see Chapter 25.2). The flow of slurries can be characterized as either heterogeneous, homogeneous, or compound. These flow regimes are determined by the grain-size distribution, specific gravity of the solid, and the flow velocity.

Several empirical tests to determine friction loss and critical velocity of deposition for heterogeneous slurries have been developed, but these tests are only applicable for laminar flow conditions (Verkerk, 1985). Homogeneous slurries, especially those of high solids concentrations, must be investigated with full-scale tests or theoretical models that require knowledge of the rheological properties of the slurry (Hanks, 1986). Most slurry operations have used gravity or centrifugal pumps for the heterogeneous flow regime. However, transport of waste backfill may not be limited to hydraulic transport techniques. Test results indicate that thickened, unclassified waste slurries, which would require no underground dewatering, could be pumped by equipment developed by the concrete industry (Vickery and Boldt, 1989).

PNEUMATIC TRANSPORT. Pneumatic systems for transporting fine wastes consist of the same basic components as those used for coarse wastes. The main application of pneumatic transport for fine wastes has been in European coal fields to stow mine wastes (Wood, 1983). Pneumatic systems may be characterized as dense phase or dilute phase, depending upon the concentration of the solids conveyed in the pipeline.

Dilute-phase conveyances use high-velocity air to suspend and transport discrete particles. In dense-phase conveyance, the transport material is forced through a pipeline in "slugs" separated by pulses of compressed air. Since the material is delivered relatively slowly, system wear and energy consumption are reduced as compared to pneumatic suspensions (Roberts et al., 1985). Theoretical solutions to determine a system's operating parameters have been developed for each phase of the conveying process, and preliminary designs have been simplified by the use of computers (Latincsics, 1982).

12.2.5 CONTAMINANT CONTROL

Designing waste disposal facilities that meet environmental goals is a complex task because of the large number of factors that influence waste, the many disciplines involved, a general lack of experience in meeting environmental goals, and the number of inherent uncertainties about geologic and geochemical parameters that must be managed. Spatial and temporal changes in any of these factors can vary by orders of magnitude even at one site.

The processes that control the rate of contaminant mobilization and transport also vary significantly from site to site, and many are very slow. For example, acid water and metals from wastes have been released years after sites have been reclaimed and revegetated, destroying the work of reclamation efforts and requiring resolution of the much greater problems involved with acid-generating wastes. Other problems arise in that some of the methods used to control one set of contaminants may cause another set to be released.

The purpose of contaminant control, as discussed here, is to prevent or limit the release of designated contaminants associated with waste disposal. Contaminant controls can be implemented anywhere along the contamination pathway from source to receptor. Usually, the most economical and environmentally effective approach is to implement controls as close to the source as possible.

The mechanisms underlying the chemical release of contaminants are not yet well understood. Oxidation is considered to be the primary cause of contaminant release; however, other mechanisms have been observed. Water contamination is most often a result of pyrite oxidation, which lowers the pH of interstitial water and mobilizes metals. Once pH is about 4.5, acid formation can be dramatically accelerated by action of bacteria such as *Thiobacillus ferrooxidans*. Some studies suggest this bacteria may speed the process by more than a factor of 1000. Contaminants can also be carried as solids in water or air in both surface and groundwater via surface runoff, failure of containment structures, seepage, and wind. The technology to address contamination associated with mining has been developed primarily for eastern US coalfields (Anon., 1979; Skousen et al., 1990) and Canadian hard-rock mines (Filion and Ferguson, 1990; Anon., 1988a, 1989b, 1990a). This technology is now being applied to noncoal mining in the United States (Anon., 1988b).

Environmental control measures, which are in various stages of development at the present time, involve the use of liners, hydrologic barriers, pH-control materials (Cravotta et al., 1990), chemical treatment, wetlands, and bactericides; drainage collection and treatment; and underwater disposal.

12.2.5.1 Investigations and Tests

Testing the properties of waste materials at a given site is a primary means by which mine operators manage waste and meet environmental regulations. Generally, an operator's main concerns are predicting (Anon., 1989c) and verifying effects on local surface water and groundwater systems (see Chapter 12.1). Understanding the chemistry of the water is a major factor in determining dissolution and contamination potential. Many good sources of information are available when considering these aspects of water chemistry (Hem, 1985; Anon., 1985b).

The physical groundwater system is delineated by taking depth-to-water measurements with piezometers and in wells drilled for other purposes (exploration wells, water wells). Care must be taken when a well intersects more than one aquifer because water levels will reflect the interaction. Bentonite seals should be placed between aquifiers if water quality is significantly different among them to prevent one aquifer from contaminating another. The hydrologic budget is determined from precipitation records, evapotranspiration estimates, and groundwater inflow/outflow measurements. The controlling equation is outflow = inflow + storage. Groundwater flow paths and residence times are determined through the use of isotopes such as tritium and carbon 14. A source of periodic information can be found in the *Groundwater Monitor Review*, a bulletin published monthly by the National Water Well Association, Dublin, OH. Different aspects of investigation and testing are listed below.

MODELING. Advances have been made recently in the use of hydrologic models as predictive tools to simulate the complex flow and fate of water and/or dissolved or suspended constituents (Anon., 1987, 1990b; Kincaid et al., 1984). A model can be used as a design aid to approximate the hydrologic and hydrochemical consequences of a planned mine waste disposal system quantitatively. There are three basic types of hydrologic model: (1) physical (a scaled-down version of the designed system), (2) analog (a model of the behavior of an analogous, but different, medium), and (3) mathematical. Physical and analog models tend to be impractical, so only mathematical computer models are commonly used.

Many different hydrologic and geochemical computer models are available, ranging from simple drawdown determinations to complex programs with three-dimensional graphics capabilities (Melchoir and Basset, 1988; Wang and Anderson, 1982; McDonald and Harbaugh, 1984; Nordstrom and Ball, 1984). A common assumption of most geochemical models is that equilibrium is reached; however, equilibrium is a function of temperature and kinetics and will not be valid for many components. Some codes suffer from inconsistency among the thermodynamic databases they utilize, making them inadequate for certain applications. Most geochemical programs were developed for specific applications, and consequently, no single program or program family has emerged that can be applied universally to mine waste management.

The user should select a program or group of programs that best meets project needs and incorporates as many of the following parameters as possible: constituents (including ion speciation), temperature, pH, redox potential, pressure, and alkalinity. The thermodynamic data base and the mineralogic data base should correspond as closely as possible to the field situation. One feasible approach is to use a program such as the US Geological Survey's WATEQ4F (Ball, 1987), which has excellent dissolved species and mineralogic data bases, to predict equilibrium conditions, and then use a mass balance code such as BALANCE (Parkhurst et al., 1982) to test the results. Others have published brief synopses of various geochemical codes (Nordstrom and Ball, 1984; Nordstrom et al., 1979), and the International Groundwater Modeling Center distributes other references as well as many of the programs. Other computer models are available from the USGS, EPA, and CANMET (Ottawa, Canada). Another newer code (not currently verified for mining applications) that simulates the transport and fate of inorganic chemicals in the subsurface environment is FASTCHEM (Hostetler et al., 1989). A wide variety of other codes and references is available at the International Groundwater Modeling Center, Holcomb Research Institute, Indianapolis, IN.

WATER SAMPLING AND TESTING. Monitoring surface and groundwater for possible contamination has been required for a number of years. Because only low levels of contaminants are now allowed, and because instruments now have the ability to detect levels as low as 1 ppb, sampling has become much more sophisticated (Driscoll, 1986; Skougstad et al., 1979) and regulated (Anon., 1986b). Great care must be taken to ensure that the sampling procedure, sampling devices, and preservatives do not contaminate the sample, react with the sample, or interfere with the analytical method, thereby leading to expensive and possibly unnecessary legal action. Information concerning well design criteria, sampling protocol, and preservation procedures is available from the EPA, National Well Water Association (NWWA), and state agencies.

Surface water samples are taken directly from the source, but groundwater samples require a device that can sample at depth. Usually this is a bailer or pump in combination with a piezometer. Where depths are very shallow, a bailer may be functional, but because of the EPA recommendation to purge two casing volumes prior to sampling, this is impractical for deeper wells, and a pump should be used. Lysimeters, which use a vacuum to "pull" a sample through a porous filter, may be installed in certain situations, such as beneath an impoundment during its construction or through the center of a hollow-stem auger. Unlike a piezometer, which must be installed below the phreatic surface, a lysimeter will attract a sample from the unsaturated zone by differential pressure. Proper selection of the filter pore size allows differential sampling of pore gas or pore water. Other more sophisticated devices are available, but they are expensive and are most applicable to special situations.

The selection of the construction materials and installation method for a monitoring system is governed by the anticipated chemistry of the water to be sampled (Anon., 1980b) because the installation method can contaminate the sampled area. Bentonite and additives in drilling mud have a profound chemical effect, and compressed air can act as an oxidant. Contamination by drillbit and stem shavings must also be considered. During installation, samples of the native material should also be obtained, preferably using a method that yields minimal disturbance, such as coring or by Shelby tube. Identification of precipitates can provide information relative to attenuation mechanisms and water chemistry, and a mineralogic analysis can be used to determine adsorption and ion exchange capacities of the soil or aquifer. Grain-size distribution can also be used to estimate the hydraulic parameters of an aquifer.

SOLID WASTE SAMPLING AND TESTING. Many standard procedures have been developed for collecting solid wastes and testing them to predict their contamination potential. Field sampling techniques are particularly difficult because of inherent radical changes within mine wastes. These variations are both temporal and spatial, and the fact that relatively few samples must represent large volumes of waste must be taken into account. However, there are a number of sources that provide direction on sample collection (Anon., 1989d).

Traditionally, slurry leach tests such as the EP Toxicity, TCLP, and Method 1312 (Anon., 1988c, 1989e) have been applied to mining wastes. However, these tests are being replaced by more accurate ones that better simulate the complex, long-term geochemistry that results as contaminants are being transported (Lawrence et al., 1989; Anon., 1989e; Doepker, 1988, 1990), and these tests are increasingly being used to make critical and costly regulatory and management decisions.

Care should be taken to ensure that the specific factors prevalent at a site are accounted for whatever testing procedure is chosen, because these factors will influence the reactivity and contamination potential of a waste. These include grain size, mineralogy, sulfate and metal content, water flow characteristics within and surrounding a waste, availability of oxygen and water to initiate geochemical reactions, pH, temperature, presence and degree of activity of sulfide-oxidizing bacteria, and presence or absence of neutralizing material such as carbonates. The mechanism that influences most contamination associated with mine waste is pyrite oxidation; however, the processes that control oxidation vary significantly and are not well understood (Lowson, 1982; Crundwell, 1988). The Acid Base Accounting test has been used extensively in the past with coal waste and is still used to distinguish whether sites have great or little potential for contamination from pyrite oxidation (Anon., 1983; Ferguson and Ericson, 1987; di Pretoro and Rauch, 1988; Smith and Brady, 1990; Sobek et al., 1978).

HYDROLOGIC FIELD MEASUREMENTS. Determination of hydrologic factors and their interactions at a mine is one of the tasks necessary to determine the best alternatives to prevent or remediate water contamination. Contamination as a result of acid drainage in underground mines requires an in-depth assessment of mine hydrology (Williams et al., 1986). Typically the problem in hydrologic field measurements is looking at the subsurface below waste disposal facilities. The aquifer properties from which transmissivity and storativity are derived are hydraulic conductivity, porosity, and compressibility (Freeze and Cherry, 1979; Ferris et al., 1962; Bentall, 1963). These are best determined with field tests, generally using one or more boreholes. Attempts to collect aquifer material for laboratory permeameter tests invariably alter the measurements of the properties.

The following field tests are used to understand groundwater flow.

Steady-state Pumping Injection—In these tests, water is pumped out of or into a borehole at a steady rate while the water levels in surrounding wells and piezometers are recorded (Doe and Remer, 1981). Water level drawdown is a function of distance from the pumped well and indicates the flow properties of the aquifer. Analysis requires several simplifying assumptions regarding the physical nature of the aquifer system. Once these assumptions are chosen, curve-matching and iterative numerical techniques are available to determine aquifer parameters. The results contain large inherent uncertainties.

Slug or Impulse Test—These tests are similar to the steady-state test, but measure instantaneous injection and withdrawal of a significant amount of fluid rather than steady flow over a period of time. Slug tests are also referred to as transient state tests. The results are used to calculate slightly different aquifer parameters, such as storativity.

Tracer Test—Tracers are introduced into surface or groundwater flowfields to determine speed and direction of flow. Tracer materials include colored dyes, fluorescent dyes (fluoroscein and rhodamine compounds), conducting materials (calcium chloride), and mildly radioactive elements (tritium, iodine, bromine, and others). Freon is gaining popularity because it is nonreactive and is detectable in very small concentrations.

12.2.5.2 Containment

LINERS. Liners may be made of synthetic membranes or of natural materials such as clays. For natural liners, recent research indicates that diffusion models may provide better estimates of the performance of low-permeability lining materials than the commonly used Darcy equations (Shackelford, 1988). Natural materials have fallen into disfavor with regulatory agencies because these materials may occasionally develop leaks and because agencies have typically used Darcy models, which may grossly overstate flow for materials of very low permeability, such as clay materials. Clay is often available locally, although each new source must be tested for its sealing capability. Slimes may reduce the permeability of waste impoundments fairly effectively. Slime layers often form naturally with time at the bottom of waste impoundments and provide an important barrier to water and contaminant movement. Bentonite is a type of clay widely used as a sealant because it expands and therefore closes off flow pathways when saturated.

Synthetic waste impoundment liner materials include elastomers, asphalt, and concretes (Koerner, 1989; Richardson and Koerner, 1990). These materials must be selected for their resistance to the liquids expected to form in the wastes and the length of time that a barrier is required. The effective life of such liners has not been clearly established. However, estimates have been made that are considerably shorter than the time that many wastes would still be releasing metal ions and acids. Elastomers must be sufficiently thick to resist punctures and tears, yet flexible enough to conform to the containment structure. Concerns include seaming sheets of elastomeric material together, damage caused by equipment operating on the impoundment, degradation by ultraviolet light, damage by animals, and settling of the structure. Asphalts and concretes are very expensive to place in large impoundments and are often more easily damaged by settling than are elastomeric liners. Drain systems are often constructed to detect and capture any leakage from lined impoundments. Natural and synthetic liners have been used in Sweden for capping and lining to control acid drainage from abandoned mine wastes (Lundgren, 1990).

GROUTS. Grouts are broadly categorized as cement or suspension grouts and chemical or liquid grouts (Nonveiller, 1989; Houlsby, 1990; Karol, 1983). The cements include cement/water suspensions, cement and activated mortars, and cement plus clay and sand. Cement grouts tend to be relative inexpensive compared to chemical grouts. If acidic groundwater conditions are expected, a sulfate-resistant portland Type V cement may be used. Chemical grouts include sodium silicate, sodium silicate plus reagent, bentonite, organic resins, and asphalts. Chemical grouts are usually from 2 to over 100 times more costly than cement grouts. Organic resins seem to have lost favor recently because of their toxicity, cost, and short life under field conditions. Boreholes are drilled to develop grout curtains and slurry trenches are dug to develop grout walls. In some cases, it is appropriate to pregrout before excavating a waste disposal pit, then test and grout from the pit bottom. In addition, Russian clay grouting technology is being adapted to limit groundwater contamination caused by mining (Kipko, 1988; Anon., 1990c).

12.2.5.3 Prevention and Treatment

CHEMICAL/BIOLOGICAL. There are a number of different approaches that are being tried to chemically bond contaminants, harness biological activity, or alter natural processes that lead to contamination. Success with any particular method is highly dependent on site conditions; what works well at one site may have disastrous consequences at another. Extensive investigation and assessment of techniques is normally warranted before a full-scale facility is constructed. Developing wetlands to treat acid mine drainage has been studied extensively for coal wastes (Hedin, 1989; Hedin and Nairn, 1990; McIntire et al., 1990), but very little for noncoal wastes (Dollhopf et al., 1988) because heavy-metal chemistry is typically more complex and difficult to control in wetlands. Biocides have been used successfully at some sites to dramatically reduce acid generation for the short term (Sobek et al., 1985; Erickson et al., 1985).

Many methods are being developed to prevent the production of contaminated waters by limiting the availability of oxygen, and therefore oxidation reactions, within the waste. For example, underwater disposal of tailings has been successful at some sites (Pederson and Drysdale, 1990; Pelletier and Birch, 1990). Control of acid generation from waste rock is also of concern (Anon., 1989b; Robertson and Barton-Bridges, 1990). Other processes are used to neutralize and/or inhibit releases. The most commonly used reagents are lime, cement, fly ash, sodium silicate, clay, polysilicates, or a combination of these (Anon., 1989b, 1990a; Cravotta et al., 1990). Research and field trials have also been completed on blending wastes to limit their acid-generating potential (Pelletier and Howe, 1990).

WIND. Movement of mining wastes by wind can be reduced by capping waste piles with coarser material, such as slag, that is not prone to being blown away by wind (Walters et al., 1986; Bohn and Johnson, 1983). Other approaches include periodic wetting, solidifying or agglomerating materials to increase particle density and material cohesion, or leaching contaminants of concern from near-surface to deeper levels. Some are temporary measures intended to prevent problems until final reclamation. The installation of windbreaks (trees and bushes) or planting vegetation on waste piles may also help reduce movement of contaminants by wind. However, revegetation can create problems as plants take up metals and bring them into the food chain.

WATER. Water control systems must be engineered to handle ponding and runoff from waste facilities and upgradient drainage basins. Such systems are normally ditches and/or stream diversions or barriers designed to prevent infiltration and recharge of groundwater (Johnson et al., 1985). Drains will reduce recharge head and the volume of water entering lakes and ponds, route water flow around waste, and draw off potential recharge water before it reaches the waste. Planting trees in low, flat areas may increase evapotranspiration, thereby reducing infiltration and recharge (Loofbourow, 1979). Waste piles and ponds may be capped to prevent infiltration of rainwater and snowmelt.

Control of groundwater becomes important when surface water controls have not been used or have failed. Control is accomplished by using interceptor wells to draw off recharge water before it reaches a waste. Water curtains create areas of artificially high head upgradient from a waste and these areas act as barriers to regional flow. Water curtains are often used in conjunction with interceptor wells. Groundwater may also be diverted by grouting with cement slurries or chemical grouts. Grout and waste in which the sand has been removed can be used to plug solution channels, and clay can be used to plug pores or fractures.

12.2.6 CONCLUSIONS

The trend in developing regulations is to specify disposal facility *performance* rather than disposal *techniques*. This places more responsibility on a design engineer to plan and defend creative disposal facilities, whether to obtain operating permits or to upgrade existing disposal systems. This chapter was written to delineate design consideration with numerous references so that the "how to" detail could be accessed. From this, the design engineer may plan waste disposal facilities as well as address new issues in waste disposal, including remediation of existing or abandoned waste disposal facilities, refinement of techniques to minimize contamination potential at a specific site, and exploration of alternative uses for a waste.

Chapter 12.3
RECLAMATION

RICHARD J. SWEIGARD

12.3.1 INTRODUCTION

12.3.1.1 Scope of Reclamation

At the outset, it is appropriate to establish the meaning of the word reclamation and set it in the proper context since the term has many connotations. Reclamation is sometimes used synonymously with restoration; however, this is not necessarily appropriate. One definition of reclamation is the process of gaining or recovering land, bringing it into a condition for cultivation or other use (Anon., 1946). In the broadest sense, land reclamation need not be in response to some disturbance caused by human activity (e.g., reclamation of desert land). As it relates to mining, however, *reclamation* is a response to any disturbances to the earth and its environment caused by mining activity.

Restoration implies that the exact conditions of the site existing before disturbance will be replicated afterwards (Anon., 1974). In contrast, *rehabilitation* involves returning the disturbed site "to a form and productivity in conformity with a prior use plan." Since complete restoration is a virtual impossibility, the term reclamation, as it is applied to the mining industry, has taken basically the connotation of rehabilitation. This fact is evidenced further by the Surface Mining Control and Reclamation Act of 1977 (SMCRA). SMCRA states that, among other provisions, reclamation must "restore the land affected to a condition capable of supporting the uses which it was capable of supporting prior to any mining, or higher or better uses." Reclamation of land disturbed by mining, therefore, has been linked closely to the issue of land-use capability. It is not necessary, nor is it possible in most cases, to return the land to its original condition as long as its capability is not diminished.

While it is most common to consider reclamation as an aspect of surface mining, underground mining and mineral processing activities also impact the land in such a way as to affect its use. Reclamation activities must address all the impacts of mining as it impacts land-use capability. Land disturbance by the mining industry can be classified in several ways. Two useful classifications involve mineral commodities and mining functions. From Fig. 12.3.1 (commodity distribution), it is apparent that coal mining is by far the largest land user in the mining industry. In Fig. 12.3.2 (functional distribution), the affected total land area is classified according to mining function. Surface mining is responsible for 85% of the total land utilized. Underground mining accounts for a relatively small percentage (5%). Mineral processing wastes occupy the remainder (10%) of lands (Johnson and Paone, 1982). Therefore, a large component of the efforts in reclamation planning, research, and regulatory controls is directed toward surface mining, particularly the surface mining of coal.

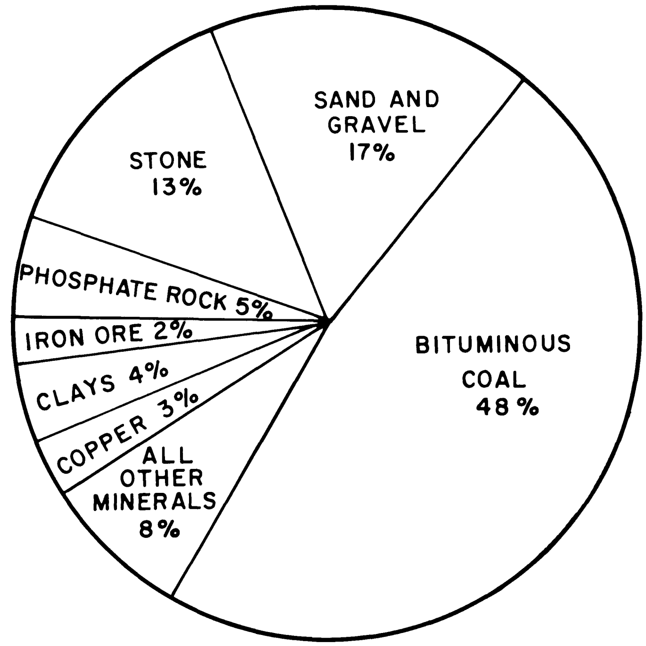

Fig. 12.3.1. Percentage of land disturbed to mine selected commodities, 1930–80 (Johnson and Paone, 1982).

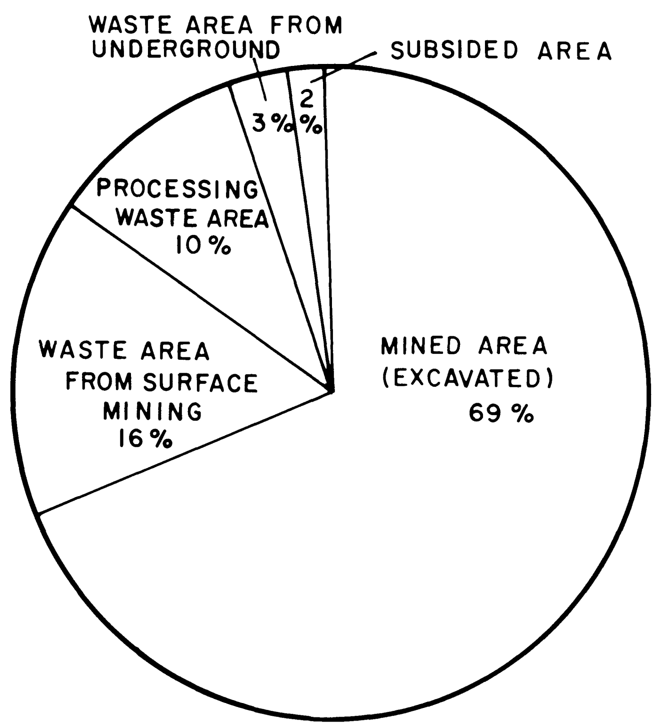

Fig. 12.3.2. Percentage of land disturbed by mining function, 1930–80 (Johnson and Paone, 1982).

12.3.1.2 Historical and Legal Framework

Historical developments in reclamation are linked closely to the regulatory systems that have been created to control environmental effects of mining. Since reclamation generally results in a cost incurred after the mineral has been extracted and does not add to the inherent value of the mineral, there was little incentive in the past for mine operators to reclaim the land. This was particularly true in a climate where the rights of the private landowner to use the land for whatever purpose he or she chose were unchallenged. This attitude had changed by the early- to mid-twentieth century to the point that the public viewed environmental pollution or any loss in land-use capability as a social cost that must be taken into account by the mineral industries.

The approaches taken to reclamation are as varied as the minerals in question and their methods of extraction. For example, the sand and gravel operators have had to address the issue of postmining land use due to the proximity of most operations to urban areas. This segment of the industry is recognized for its pioneering work in applying site-planning principles to mining and reclamation operations (Ahearn, 1964; Baxter, 1969).

The first recorded instance of reclamation by the US mining industry occurred in 1918 when some surface-mined land in Indiana was planted with fruit trees. Following this initial example, a group of mine operators comprising the Indiana Coal Association agreed in 1926 to plant five acres (two hectares) of trees for each shovel or dragline that they used (Bowling, 1978). These first voluntary reclamation efforts did not include any grading or topsoil replacement.

Concern by governments for effective reclamation of land disturbed by mining has been evidenced through the years in both the passage of regulations and increased research and development efforts (Chapter 3.4). The earliest state reclamation laws addressed only coal mining. Prior to 1965, only seven states had specific laws requiring postmining land reclamation. The first state surface mine reclamation act was adopted by West Virginia in 1939, followed by Indiana (1941), Illinois (1943), Pennsylvania (1945), and Ohio (1947). These state laws addressed limited grading and revegetation of spoil piles. Over the years, more comprehensive state laws evolved through modifications and amendments to existing legislation. In the 1950s and 1960s, the laws were modified to include stricter grading requirements, soil conservation measures and water quality control. Modifications in the late 1960s and 1970s went beyond simple reclamation standards to the control of all major activities before, during, and after mining. Not all state programs addressed each of the major areas of concern.

By 1977, legislation to regulate mine reclamation had been enacted in 38 states. Seven of the states regulated only coal mining activites, and several were concerned only with surface mining. However, 28 states had regulations that covered virtually all minerals and at least nine states regulated the surface effects of both surface and underground mining. The scope of performance standards found in the state reclamation regulations includes slope stabilization, grading, revegetation, neutralization of toxic materials, visual screening, waste disposal, control of drainage, and other sources of pollution and erosion (Anon., 1979).

After nearly ten years of legislative efforts and three presidential vetoes, the federal government attempted to standardize reclamation policy with the passage of SMCRA in 1977. Although the gradual evolution of various state laws and regulations had an impact on mining and reclamation operations, SMCRA had immediate and far-reaching effects. This law applies specifically to coal mining, but it does address the surface effects of both surface mining and underground mining. Although SMCRA is a comprehensive piece of legislation that deals with such matters as diverse as abandoned mine land, mining research, and enforcement of the federal government's policy, the most direct impacts upon reclamation were in the form of standardized reclamation planning requirements and extensive environmental protection performance standards.

In addition to SMCRA, there are several federal laws that, while not being directed specifically at the mining industry, require some reclamation activity or other form of environmental compliance on the part of mineral operations. These laws include, as a minimum, the Federal Water Pollution Control Act, the Clean Air Act, and the Resource Conservation and Recovery Act. There are also a number of laws that deal with special cases such as the Uranium Mill Tailings Act and those involving the use of federal land including the exploitation of minerals.

12.3.1.3 Reclamation Operations

For the purpose of discussion, the topic of reclamation can be subdivided into three general categories. The first area is reclamation planning. As the size of operations has grown and reclamation requirements have become more complex, the importance of reclamation planning has increased greatly. The next general category includes all of those reclamation activities that are either continuous or periodic but are related in some way to the ongoing cycle of mineral extraction. The final category encompasses all of the isolated or sporadic reclamation activities that are not related directly to the production cycle.

Although a document known as a reclamation plan is a legal requirement for many mining operations, the concept of reclamation planning extends beyond the simple preparation of a document for regulatory purposes. It is a valid consideration for any operation that results in land disturbance even if it is not required by a particular regulatory authority. Since one of the primary goals of reclamation is to restore the land-use capability of disturbed land, reclamation planning must be related, in some degree, to land-use planning. It should encompass the consideration of natural and cultural factors that impact land use as well as economic and technical feasibility of the mining and reclamation methods; it should also employ the most current planning processes available.

Those reclamation activities that are continuous or periodic are sometimes associated with the concept of contemporaneous reclamation. This is particularly important in the surface mining of coal where strip (open cast) mining methods are in common use. These mines are characterized by the disturbance of large surface areas within a fairly short time frame compared to the length of time that an open pit mine or quarry may be in operation. Although backfilling, grading, topsoil replacement, and revegetation are the major components of contemporaneous reclamation, a detailed list of all reclamation activities associated with surface mining of coal is given in Table 12.3.1.

The isolated or sporadic reclamation activities do not lend themselves to simple characterization. They may include such diverse operations as final mine closure, reclamation of box-cut spoil, or mitigation of mine subsidence damage. Therefore, it is necessary to describe these activities on an individualized basis.

12.3.2 RECLAMATION PLANNING

12.3.2.1 Planning Objectives

Since one of the primary goals of reclamation is to restore land-use capability to disturbed land, reclamation planning is necessarily related to land-use planning. The scope of this chapter, therefore, goes beyond the strict sense of reclamation plan preparation as mandated by federal and state regulations. The term *reclamation planning*, as used here, encompasses the consideration of natural and cultural factors that impact land use, economic and technical feasibility of reclamation plans, mining methods, and current planning processes employed by the mining industry and the public sector.

The planning problem with regard to mining is one of maximizing production and maintaining environmental quality, con-

Table 12.3.1. Time Sequence of Reclamation Activities for Surface Coal Mining

I. During site preparation:
1. Install control measures (diversion, sediment traps and basins, etc.).
2. Clear and grub—market lumber if possible; stockpile brush for use as filters; run brush through woodchipper and use chips for mulch.
3. Stabilize areas around temporary facilities such as maintenance yard, power station, and supply area.

II. During overburden removal:
1. Divert water away from and around active mining areas.
2. Remove topsoil and store it if possible and/or necessary.
3. Selectively mine and place overburden strata if possible and/or necessary.

III. During coal removal:
1. Remove all coal insofar as possible.
2. For the purpose of controlling postmining groundwater flows, break, or conversely prevent damage to, the strata immediately below the coal seam as desired.

IV. Immediately after coal removal:
1. Seal the highwall if necessary.
2. Seal the lowwall if necessary.
3. Backfill—bury toxic materials and boulders, dispose of waste, ensure compaction.

V. Shortly after coal removal:
1. Rough grade and contour, taking these factors into consideration—
   a. Time of grading—specific time limit; tied to advance of mining; seasonal considerations.
   b. Slope steepness.
   c. Length of uninterrupted slope.
   d. Compaction.
   e. Reconstruction of underground and surface drainage patterns.
2. If necessary, make mine spoil amendments (root zone), taking these factors into consideration—
   a. Type of amendment—fertilizers, limestone, flyash, sewage sludge, or others.
   b. Depth of application.
   c. Top layer considerations—temperature (color), water retention (size consist, organics), mulching and tacking.

VI. Immediately prior to first planting season:
1. Fine-grade and spread topsoil, taking seasonal fluctuations into consideration.
2. If necessary, manipulate the soil mechanically—ripping, furrowing, deep-chiseling or harrowing, or constructing dozer basins.
3. Mulch and tack.

VII. During the first planting season:
Seed and revegetate, considering—time and methods of seeding, choice of grasses and legumes.

VIII. At regular, frequent intervals:
Monitor and control—slope stability; water quality, both chemical (pH, etc.) and physical (sediment); vegetation growth.

sistent with the constraints imposed by the regulatory agencies and the need to satisfy the profit objectives of the companies. In the 1970s, several research projects were initiated to aid in the premining planning of surface coal mining (Grim and Hill, 1974; Anon., 1976; Imhoff et al., 1978; Ramani and Clar, 1978; Pugilese et al., 1979). The necessary planning steps are (1) make an inventory of the premining conditions; (2) evaluate and decide on the postmining requirements of the region, consistent with the needs and desires of the affected groups; (3) analyze alternative mining and reclamation schemes to achieve best the objectives; and (4) develop an acceptable mining, reclamation, and land-use scheme that is the most suitable under the technical, social, and economic conditions (Ramani et al., 1977; Riddle and Saperstein, 1978).

12.3.2.2 Reclamation Plan

SMCRA established very specific requirements for obtaining a mining permit. Section 508 of SMCRA states that a reclamation plan of sufficient detail must be submitted to demonstrate that reclamation can be achieved as required by federal or state programs. The various components that are required by law in the reclamation and operations plan are listed in Table 12.3.2. Such a plan must cover, among other aspects, the following important points with regard to the uses of land:

1. Uses existing at the time of the application, and if the land has a history of previous mining, the uses which preceded any mining.

2. The capability of the land prior to any mining to support a variety of uses, giving consideration to soil and foundation characteristics, topography, and vegetative cover.

3. The use that is proposed to be made of the land following reclamation, including a discussion of the utility and capacity of the reclaimed land to support a variety of alternative uses and the relationship of such use to existing land-use policies and plans, and the comments of any owner of the surface, state and local governments or agencies thereof which would have to initiate, implement, approve, or authorize the proposed use of the land following reclamation.

4. A detailed description of how the proposed postmining land use is to be achieved and the necessary support activities that may be needed to achieve the proposed land use.

5. The consideration that has been given to making the surface mining and reclamation operations consistent with surface owner plans, and applicable state and local land-use plans and programs.

6. The consideration that has been given to developing the reclamation plan in a manner consistent with local physical, environmental, and climatological conditions.

The requirement that companies must submit a reclamation plan is not new. However, that surface mine planners must investigate "the utility and capacity of the reclaimed land to support a variety of alternative uses" [SMCRA, Section 502(a)(8)] was not a requirement in most state laws. It is beyond the scope of traditional reclamation planning and enters into the area of environmental site planning or land-use planning. This provision of the law requires additional expertise in and involves the inclusion of many disciplines in the mine-planning process.

12.3.2.3 Information Requirements

Since the ultimate goal of the reclamation plan is to ensure that the surface-mined land is returned to a productive use, it is appropriate to consider information needs for postmining land use planning. Land-use factors can either be classified as natural or cultural. Natural land use factors include, at least, the geomorphic, climatic, hydrologic, and soil characteristics of a site. Although these characteristics can be altered by man, they were initially the result of nature. Cultural factors include all geographic, demographic, and economic characteristics that are the result of man's activities. Important factors that must be considered are listed in Table 12.3.3. Detailed discussion of these factors can be found in Clar (1982), Clar and Ramani (1986), and Ramani and Sweigard (1983).

12.3.2.4 Land-Use Analysis

Current land-use patterns may provide the best guidelines for use after reclamation. For example, forested hillside land adjoining a pasture may be more desirable as a pasture after mining if the need is for pasture lands. Similarly, orphaned mine land in a wilderness area may be more useful if restored as a forest. Future land-use plans contrary to premining use are unusual and not the common practice. Acceptance of mountaintop removal and valley-fill mining methods that create new flat areas in regions where such areas are in short supply reflect the permanent positive potential of the temporary drastic disturbance of lands due to mining.

Identification of probable future land uses can be summarized into the following categories that are defined in Section 701.5 of Title 30 of the *Code of Federal Regulations (CFR):*

1. Cropland.
2. Pastureland or land occasionally cut for hay.
3. Grazingland.
4. Forestry.
5. Residential.
6. Industrial/commercial.
7. Recreation.
8. Fish and wildlife habitat.
9. Developed water resources.
10. Undeveloped land.

Analysis of alternative long-term uses requires compliance with socioeconomic and public constraints as well as the economic goals of the mining company. Regardless of the choice of short-term and long-term land use, the plans must be linked to the mining plan in space, time, and method. Definition of the long-range plans do achieve a purpose by minimizing disturbance unnecessary for the determined future use and limiting those reclamation activities that are not a part of the normal mining or land-use plans.

The site-planning process has been applied to reclamation planning by Sweigard and Ramani (1986). Using this process, several alternatives can be evaluated through an iterative procedure applying social, economic, and environmental impact assessment techniques. For any mining area, there may be a number of feasible postmining land-use alternatives. Also since surface mining, in particular, affords an opportunity to completely reshape land forms, the potential for reclaiming the land parcel for different end uses is great.

Since each alternative plan will represent different amounts of earthmoving, grading, topsoiling, and planting, postmining topography is one of the most important factors to be considered. Postmining topography is approximated by applying mine-plan data, appropriate swell factors, and box-cut and end-cut locations to the premining topography. Other key factors are the location and thickness of high-capability soils. These factors are particularly important in determining the location of agricultural lands. Location of property boundaries and public right-of-ways and limitations on certain equipment are also taken into consideration. For example, the grade limitation on mechanical tree planters may influence the location of forest land or the type of planting pattern that is employed. Premining land use, however, may play the most important role in determining postmining land-use plans. Surface mine planners often endeavor to balance, as nearly as possible, premining and postmining areas devoted to various land uses. Although the distribution of land among various uses may not change significantly, planning skills are required in designing a site plan that spatially orients the land uses in an efficient and aesthetically pleasing manner.

In short, the planning of mining operations in general, and the planning of reclamation and postmining uses of land in particular, have become very complex. The premining definition of long-range land-use plans for minable lands makes it possible, in theory, to minimize any disturbance of the land that is not part of the normal mining or land-use plans and to limit reclamation activities to those required by the future-use plans. Thus the planning of mining operations must be very thorough, with preserving or enhancing the long-term use of the land as a major objective. The application of an integrated mining, reclamation, and land-use planning concept is required to achieve this end (Ramani, 1978).

12.3.3 SURFACE MINE RECLAMATION OPERATIONS

12.3.3.1 Backfilling and Grading of Spoil

General Requirements. Detailed backfilling and grading requirements are given in Section 816.102 of *CFR* Title 30. With few exceptions, backfilling and grading must achieve the approximate original contour that existed before mining. This includes the elimination of all highwalls, spoil piles, and depressions. Stable postmining slopes must also be achieved. Slopes may not exceed either the angle of repose or a lesser slope necessary to maintain a minimum long-term static safety factor of 1.3.

Minimization of erosion and water pollution, both onsite and offsite, is another objective. Exposed coal seams, acid- and toxic-forming materials, and combustible materials exposed, used, or produced during mining must be covered adequately. This burial process is performed to control the impact on surface and groundwater among other effects. The overriding objective of the backfilling and grading requirements is to prepare the land to support approved postmining land use.

IMPORTANT CONSIDERATIONS. In backfilling, three major areas of long-term concern are slope stability, groundwater control, and water-quality maintenance (Phelps et al., 1981). The primary source of slope failure is the prolonged action of water through erosion and mass wasting. The primary result of water action on slopes is erosion and sediment production. Long uninterrupted slopes are undesirable as compared to ones with terraces and diversions that decrease slope lengths and direct runoff water to safe outlets. Additionally, while backfilling, the permeability of the fill for water percolation can be modified. Such modifications are achieved by sealing or leaving the coal seam open, and by selective placement of the spoil.

Technical requirements of reclamation vary depending upon the degree of restoration. In today's standard surface mining approaches, selective replacement of material is relatively simple. Contour mining approaches such as block-cut, box-cut, haulback, mountaintop removal, and modified area mining are generally sufficiently flexible to allow segregation and selective replacement (Stefanko et al., 1973; Saperstein and Secor, 1973; Grim and Hill, 1974; Ramani et al., 1977). Larger-scale area methods employing traditional overcasting are less flexible. However, selective placement of spoils in these cases can also be achieved by a combination of equipment and methods. For example, selection of shovel-truck systems, as opposed to conventional overcasting, provides the needed flexibility in spoil placement (Ramani et al., 1990).

METHODS AND EQUIPMENT. The backfilling method to be employed is related closely to the method of overburden removal. In area stripping operations where direct casting methods of overburden removal are used, the primary stripping equipment backfills the spoil in the pit. Following are the most common methods of direct casting:

1. Dragline direct casting.
2. Stripping shovel direct casting.
3. Bucket wheel excavator (BWE) direct casting via cross-pit conveyor.
4. BWE in combination with a dragline or stripping shovel where the BWE strips a portion of the overburden and spoils it on top of direct-cast shovel or dragline spoil.
5. Dragline rehandle; can be done with the primary dragline or a second dragline (usually with smaller bucket capacity) working in tandem with the primary dragline.

Haulage backfilling methods are common in contour and open pit type operations. Due to pit configuration and limited reach of the overburden removal equipment, the material must be transported some distance before it can be disposed properly. These methods can be categorized into the following two types:

1. Separate loading and haulage units; this includes, primarily, loading shovel-truck operations and front-end loader (FEL)-truck operations.
2. Single units such as a scraper, dozer, and FEL used in a load-and-carry operation.

Regardless of the backfilling method, some grading is required. The amount of grading, however, is dependent upon the method of backfilling. Direct casting methods produce, in general, very large spoil ridges that require extensive grading. BWE backfilling may produce narrower ridges than stripping shovels or draglines, but leveling is still required. This grading is performed using large- capacity track dozers. Haulage methods of backfilling generally produce a more even surface than direct casting methods. Some leveling of the surface is still required prior to soil reconstruction. This is also accomplished primarily with dozers. However, graders may also be used in some specialized situations such as the construction of drainage structures.

The applicability of various types of equipment to regrading and backfilling was evaluated by Skelly and Loy (Anon., 1975) with respect to spoil configuration, rehandle percentage, transportation distance, and final surface contour. This evaluation is summarized in Table 12.3.4. General algorithms for calculating the production capacity of fixed-base stripping equipment, loading and haulage equipment, and single-unit load-and-carry equipment are given in Chapter 9.4 of this text.

Various refinements of the above methods are being practiced. For example, low-ground-pressure dozers have been employed in reclamation operations to minimize compaction. However, their primary application is in the grading of soil which is addressed in the following segment. Another refinement is the variety of dozer-blade configurations available (Fig. 12.3.3). Blades are selected upon such considerations as required maneuverability, distance the material must be transported, type of material, and special applications. Specific characterisitics of the various type blades are summarized in Fig. 12.3.3 (Anon., 1982).

12.3.3.2 Soil Reconstruction

General Requirements. Topsoil and subsoil requirements for surface mine reclamation are found mainly in Section 816.22 of *CFR* Title 30. They require all topsoil to be removed as a separate layer and segregated. If the topsoil is less than 6 in. (150 mm) thick, the topsoil and unconsolidated material immediately below must be removed and treated as topsoil. Proper methods of stockpiling are specified when it is not practical to redistribute immediately. Redistribution, when it occurs, must achieve a stable uniform thickness, prevent excess compaction of the materials, and protect materials from wind and water erosion. Provisions exist for the use of substitute or supplemental material. However, the responsibility lies with the operator to demonstrate that the resulting medium is equally or more suitable for sustaining vegetation than the existing topsoil and that it is the best available material in the permit area for that purpose.

The operator may be required to remove and redistribute the B horizon, C horizon, or other underlying strata if the regulatory authority finds that this is necessary to comply with the revegetation requirements. Such measures are required for all prime farmland reclamation (Sections 821.12 and 821.14) and will be addressed under a separate subheading.

Important Considerations. Jansen and Melsted (1988) have summarized some of the theoretical and practical considerations of soil reconstruction. As with reclamation in general, the proposed land-use objective should be identified to insure that the reconstructed soil is capable of supporting that use. Various land uses are more suited to soils exhibiting different characteristics. However, the ability of the mine operator to reconstruct soil with any particular set of characteristics is limited by the nature of the available material. For surface mine reclamation, it can be assumed that, as a minimum, the soil must be capable of supporting vegetation similar to that which existed before mining. While the chemical properties of the soil are important for successful revegetation, they are easier to manage through soil amendments than physical properties such as texture. Therefore, when adquate topsoil is not available, or when substitute material is otherwise needed, special attention should be given to the texture, coarse-fragment content, and mineralogy of the material. When crop production is the intended use, the soil should consist of medium-textured materials (silt loams, loams, or silty clay loams), be free of coarse fragments, and have a clay content within the general range of 20 to 35% (Jansen and Melsted, 1988).

Bulk density and soil strength are two additional physical properties that are very important. Unlike texture, which is of principal concern in the selection of suitable material, bulk density and soil strength are concerns while the soil is being handled. Compaction caused by the equipment used for soil reconstruction causes bulk density and soil strength to increase. This inhibits root penetration and movement of air and water through the soil. The result may be unsuccessful revegetation. Therefore, it is important to minimize compaction of the soil while it is being reconstructed.

Equipment and Methods. Scrapers are used almost exclusively to remove the topsoil. Scrapers are also used frequently for subsoil removal; however, alternatives do exist. The use of shovels for subsoil removal has been increasing for two reasons: (1) it has been suggested that subsoil haulage and replacement by trucks results in less compaction than by scrapers, and (2) some companies have realized a cost advantage with trucks and shovels in comparison to scrapers. Another alternative to scraper removal of subsoil is to use BWEs. This is practical only when there is a rather thick mantle of unconsolidated overburden and will result generally in mixing of the B and C soil horizons. In at least one case, a BWE was used without topsoil removal as an approved experimental practice when there was evidence that the resultant soil mixture would be more suitable for the vegetation requirements.

Haulage and replacement of soil are related to the method of soil removal. Topsoil or subsoil removed by scrapers is typically hauled and replaced by the same machine. The soil is spread evenly over the site in lifts until the desired depth is achieved. A minimal amount of grading is required in the operation; however, the number of scraper passes necessary to satisfy soil reconstruction standards is blamed most frequently for the compaction problem. Roll (1987) has described a unique use of scrapers in combination with a BWE where the topsoil is removed by scrapers and stockpiled on the highwall side of the pit. Dozers then

The "A" blade is designed for sidecasting. The "C" blade is used for on-the-go push-loading. "Balderson U-Blades" provide high-volume movement of light non-cohesive materials (Anon., 1982, by permission: Caterpillar, Inc.).

push the topsoil into slots in the highwall where the BWE loads the topsoil onto a cross-pit conveyor for replacement on previously graded wheel spoil. The BWE has also been used in conjunction with an around-pit conveyor transportation system and a spreader for soil replacement. More variability can be observed in the use of trucks for subsoil haulage and replacement than is seen in scraper operations. Both rear-dump and bottom-dump trucks are in use. Bottom-dump trucks traverse the graded spoil and previously replaced subsoil in a manner similar to scrapers. However, they are capable of replacing the subsoil in thicker lifts than scrapers, necessitating fewer passes. Also bottom-dumps can be used to windrow the subsoil, allowing dozers to spread it to the required thickness and thus minimize the extent of rubber-tired traffic on the soil. Rear-dump trucks can travel either on the graded spoil or on previously replaced subsoil. Operating conditions in the field determine to a great extent where the trucks must travel, but from a reclamation perspective, traveling only on graded spoil is preferred over traversing previously replaced subsoil. When direct placement of topsoil or subsoil is not possible, the material must be stockpiled, resulting in an additional loading and haulage component of the process (Sweigard and Siemsglusz, 1989).

An evaluation of various equipment types for topsoil removal and replacement, as conducted by Skelly and Loy (Anon., 1975), is summarized in Table 12.3.5.

12.3.3.3 Revegetation

General Requirements. Section 816.111 of *CFR.* Title 30 specifies that the vegetative cover required following mining must be diverse, effective, and permanent. It must consist of species that are native to the area. (Introduced species require special approval.) The vegetative cover must be at least equal in extent to the natural vegetation of the area. It must also be capable of stabilizing the soil surface from erosion. Section 816.114 requires that planting must be done during the first normal season for favorable planting conditions after replacement of the plant-growth medium. The standards for revegetative success are given in Section 816.116. Although the specific standards depend upon the approved postmining land use, the criteria used must be representative of vegetation on unmined lands in the area. In general, achieving 90% of the established

standard is considered successful revegetation. Revegetative success cannot be achieved in one successful growing season, however. In areas that receive more than 26 in. (660 mm) average annual precipitation, the responsibility period is five years. Where the average annual precipitation is 26 in. (660 mm) or less, the responsibility period is 10 years.

IMPORTANT CONSIDERATIONS. Revegetation operations must be planned and executed in light of the approved postmining land use. Many considerations such as species selection, soil amendments, and methods of planting are related specifically to the land use. Other considerations such as soil stabilization, water infiltration, and compaction are more independent of the end use. Powell (1988) has addressed many of the major considerations involved in reclaiming surface-mined land to a variety of uses. Some of these considerations are summarized in the following discussion.

In the case of reforestation, one of the primary concerns is competition from herbaceous vegetation. This requires control either by scalping or proper uses of herbicides. In reclaiming land for pasture and hayland, one must be concerned with water control, selection of best species for the climate, and time of seeding, fertilizer, final seedbed preparation, seeding method, and proper use of surface mulches. The exact method of final seedbed preparation should depend upon the species selected. However, for reclaimed land, a rougher surface seems better because it results in greater infiltration and a less dense rooting zone. Smoother and firmer seedbeds necessitate the use of surface mulches.

The primary considerations for establishing cropland are similar to those for pasture/hayland such as seedbed preparation. An additional concern in cropland reclamation is the addition of organic matter required for good crop production. This is often accomplished by establishing a quick-growing cover crop of grasses and legumes, then using this as “green manure” when the cropland species are planted at a later time. Rangeland, which is an important postmining land use in the western United States, presents the major concern of less than adequate water availability. Tillage tools can be used that leave a rough surface allowing the available water to be trapped and to infiltrate the ground. Seed drills developed especially for rough terrain can be used to provide good contact between the seed and soil particles. For reclaiming rangeland, mulching is important and supplemental irrigation is desirable in establishing the initial stand.

METHODS AND EQUIPMENT. The selection of appropriate species is a key concern once the land-use objectives have been established. Various extensive lists of recommended species are available in the literature. The reader is directed to a recent USDA Forest Service publication by Vogel (1987) for a detailed listing of species recommended for surface mine reclamation in both the eastern and western United States.

Seedbed preparation can consist of two phases: (1) primary tillage and (2) secondary tillage (Lyle, 1987). Primary tillage penetrates rather deeply, breaking the soil into large clods through the use of some type of plow (moldboard, chisel, disc, etc.), a subsoiler, or a rotary tiller. This produces an uneven surface with large clods. Therefore, secondary tillage is performed, usually with some type of harrow (disc, spike-tooth, spring-tooth, tine, roller, etc.), to produce a suitable seedbed.

Drilling and broadcasting are the two basic methods of seed planting. Seed drills create a furrow with an implement, drop a seed into the furrow, and cover the seed immediately with soil. In the broadcast method, seeds are scattered over the surface of the ground by mechanical means or by hand for very small areas. Large areas can be seeded by hydroseeders or even airplanes. Direct seeding of most tree and shrub species has not been very successful on reclaimed land. Therefore, hand planting or the use of a mechanized seedling planter is usually required (Vogel, 1987).

Common approaches to soil amendments involve the addition of lime, fertilizer, and mulch as needed. Many mulches have been used to assist in establishing vegetative cover. Straw or hay can be manually applied, but they as well as wood chips are often spread mechanically or hydropneumatically. Mulches should be held in place with tar or chemical emulsion (Ramani et al., 1990).

Fly ash and stabilized sewage sludge are other amendments that can add needed nutrients to reclaimed mined land. However, use of these recycled amendments requires considerable testing and characterization of the material. For example, the composition of different fly ashes varies, and some may prove toxic to plant growth. Also care must be taken to avoid poisoning the soil with too high a level of heavy metals and salt from sewage sludge (Grim and Hill, 1974).

A summary of the revegetation equipment evaluation performed by Skelly and Loy (Anon., 1975) is given in Table 12.3.6.

12.3.4 RECLAMATION OF MINE WASTE DISPOSAL SITES[1]

12.3.4.1 Waste Disposal Problem

Solid wastes consist mostly of overburden and waste rock from mining, together with tailings, slurries, and slimes from processing (Andrews, 1975), but include some waste from the treatment of air and water, ordinary garbage, and debris from construction and discarded equipment. About twice as much waste results from mining as from processing, most of the mining waste being overburden.

The physical and chemical properties of this waste influence its stability and handling, as well as the potential for further beneficiation and for recovery of byproducts. These properties further influence the procedures that are needed to protect public health and to control environmental effects. The physical properties also affect the appearance of the solid waste and may strongly influence its ultimate form on the land surface, as in the case of disposal of tailings as a slurry (Brawner and Campbell, 1972). The chemical properties of this waste, besides being primarily responsible for any possible hazards to public health, are the factors that mainly determine its suitability for further processing and its effect on the physical and biological environment.

12.3.4.2 General Reclamation Practices

Certain areas of agreement are found in the technical literature on what approaches and goals are appropriate for reclamation in mining, including the economic desire for maximum results from a given outlay of money (O’Neil, 1977). These goals clearly influence current practices in that most mining companies now reclaim or rehabilitate land and disposal areas to some degree.

Effective reclamation, of course, serves many purposes. For most sites, reclamation is understood as rehabilitating the disturbed area by grading in a manner compatible with the surrounding landscape, or with the intended postmining use, and establishing a self-sustaining vegetative cover. Reclamation is intended to control erosion, to restore the hydrologic balance, and to limit the offsite impacts, during and after mining. The ultimate purpose is to restore the mining site to productive use, for example, for agriculture, forestry, industry, housing, recreation, or fish and wildlife habitat. Desirably, this use should be at least as beneficial as the capability of the site before mining, although not necessarily for the same purposes.

In assessing the rehabilitation potential of a particular mining area, a number of factors are relevant. Some of these, according to O’Neil (1977), are (1) magnitude and topography of the disturbed land, (2) chemical properties of the mining wastes, (3) physical properties of the waste, (4) an economic analysis of the mining and reclamation plan, and (5) climatic factors. In arid regions, the quantity and availability of water for irrigation is an especially important consideration, although for most commodities the predominant water use is for processing and waste disposal. The possibility of reclaiming a mining area for social needs may also be pertinent.

A long-term ecological approach to land reclamation deemphasizes the agricultural aspects and places greater weight on successional processes so as to develop self-perpetuating plant and animal communities (Curry, 1975; Ludeke, 1977; Wahlquist, 1976). This ecological approach stresses the concept of minimal impact and recommends that a “mining ecology” be developed,

integrating mining and nonmining uses of the land under a system that reflects an understanding of the ecology of the area (Bonham, 1976; Wali and Kollman, 1977). That is, the ecological approach attempts to limit long-term impacts that would reduce the plants and animals of an area or limit biological productivity.

Rebuilding the soil is thought to be the key to lasting reclamation success (Cryderman and Shetron, 1976; Dean et al., 1969). Soil development is greatly influenced by the available moisture, a factor that may severely inhibit reclamation success in arid regions (Berg, 1972; Brown, 1976; Hodder, 1977). Large-scale contouring and grading, when used with small-scale surface treatment, is often beneficial in conserving moisture and reducing erosion (Brown, 1976; Draskovic, 1973; Anon., 1973; Ludeke, 1977; Stephan, 1977). Machines have been developed to meet these needs (Hodder, 1976, 1977).

To plan for an ecological approach to reclamation, specific baseline data are needed, beginning with exploration and continuing through mine development (Clark, 1974; Anon., 1973; O'Neil, 1977; Wahlquist, 1976). Such an inventory includes information on all the physical and biological features—for example, the groundwater hydrology and characteristics of the overburden (Schuman et al., 1976; Dean et al., 1973; Packer, 1974).

Although aesthetic appeal is seldom a primary reclamation objective, it deserves some consideration in most mining and reclamation plans (Beverly, 1968; Anon., 1974; Arthur et al., 1977). Surfaces can be shaped and waste material from mining and processing can be placed such that a desired landscape design is achieved, thus helping to control erosion by wind and water and leaching of unwanted constituents, as well as creating areas having new and productive uses. Recreational lakes are an example, particularly in old quarries. For this purpose, the services of landscape architects can be helpful (Chironis, 1977; Down and Stocks, 1977; Greenwalk, 1976; Matter et al., 1974).

Revegetation is currently the preferred method of stabilizing disturbed sites (Dean et al., 1973, 1974). Some of the recommended practices are as follows:

1. Burying materials poisonous to plants (Farmer et al., 1976).
2. Leaching of tailings and other chemical methods of treatment to ensure success of plant growth (Anon., 1973; James, 1966; Kenahan and Flint, 1972; Nielson and Peterson, 1973; Watkin and Winch, 1974); e.g., allowing the land to lie fallow after its initial grading can increase leaching (Gemmell, 1975; Ludeke, 1977).
3. Combining chemical stabilizers with vegetation to enhance control of erosion (Brown, 1974; Kay, 1977).
4. Adding fertilizer in beneficial amounts, but avoiding continuous use that can hinder the development of self-perpetuating vegetation (R.W. Brown, 1976; Gemmell, 1975; Gordon, 1969; Shetron and Duffek, 1970).
5. Using sewage sludge as a soil amendment in order to control erosion and to stimulate plant growth (Dean and Shirts, 1977; Dean et al., 1973; Anon., 1973; Gordon, 1969; Hodgson and Townsend, 1973; Ludeke, 1977; Peters, 1974; Watkin and Winch, 1974). Other organic soil additives such as mulches can hold seed in place and improve the water balance of the soil (Hodder, 1977; Ludeke, 1977).
6. Encouraging nutrient recycling (Peters, 1974) and nitrogen-fixing plant growth as a means of increasing soil productivity (Berg, 1976).
7. Using microbial soil inoculants from neighboring undisturbed soils to provide beneficial microorganisms that enhance vegetation growth (Aldon, 1976; Reid and Grossnickle, 1978).
8. Adding topsoil, where feasible, to improve revegetation success (Brown, 1976; Anon., 1973; Schuman et al., 1976).
9. Increasing plant diversity and the number of native plants to improve the potential for plant survival (Aldon, 1976; Brown, 1976; Chosa and Shetron, 1976; Curry, 1975; Ludeke, 1977; Usai and Suzuki, 1973).
10. Planting more easily grown, non-native plants as a nurse crop for native plants (Berg, 1976; Dean et al., 1969; Hodgson and Townsend, 1973). Species capable of withstanding harsh site conditions, particularly high concentrations of metallic ions, may be advantageous for initial planting (Goodman et al., 1973; Kenahan and Flint, 1972; May, 1967; Stephan, 1977).
11. Collecting native seeds or plants in an area and then planting them on disturbed areas (Ludeke, 1977).

Although revegetation is the most commonly accepted approach to reclamation, alternatives do exist. One procedure would be to use the mine waste as building or construction material (Kenahan and Flint, 1972; Spendlove, 1977).

RECLAMATION OF WASTE ROCK. Control of air and water pollution from piles of waste rock may be enhanced by suitable placement, construction of diversion ditches, and the like, but a stable cover on the waste pile can further reduce fugitive dust and impede the loss of surface moisture. The cover could consist of rocks, gunite, asphalt, concrete, smelter slag, bark, or replaced topsoil. Among these materials, topsoil is the only cover that blends with the natural surroundings and that serves biological needs.

Chemical stabilizers, although not intended to be permanent, can effectively hold down dust in extreme situations and inhibit erosion by water. These chemicals are particularly useful in areas of harsh climates or where topsoil is not available.

RECLAMATION OF OPEN PITS. It is axiomatic that a mineral can be mined only where it is found. Thus, if an ore deposit is mined by open pit methods, the resulting pit may be more or less conspicuous, depending on geological circumstances. Active open pits, as compared with surface (open cast) coal mines, provide little opportunity, if any, for simultaneous mining and reclamation because the pit continues to expand and deepen as long as the mine is producing. Also the ultimate depth and shape of the pit, although roughly predictable, are dictated by the economics of mining and the geometry of the ore deposit rather than by particular reclamation goals. Indeed, the very size of a large open pit would make restoration by backfilling, or even by reshaping, an enormous economic burden of uncertain benefit, and inactive open pits could be reactivated if economic conditions became favorable. Thus, in practical terms, reclamation of open pits is limited to planning for the placement of rock dumps and tailings ponds that will remain when the mining operation is closed. Principles of landscape design can be applied at little additional cost in placing these materials in a manner that achieves beneficial postmining land use (Matter et al., 1974). The landscaping could be done by the mining company itself, or redevelopment rights could be leased or sold. The potential forms of redevelopment vary significantly from one mine setting to another, as do considerations of economic, social, and physical feasibility.

In summary, where large volumes of material are handled in open-pit operations, redevelopment could be a legitimate post-mining land use, in lieu of reclamation aimed only at establishing the original conditions. Such use can yield an economic return to offset the costs of reclamation and maintenance.

RECLAMATION OF TAILINGS. Of all the mining wastes, mill tailings are the most intractable to reclamation, in part because their amounts can be very large, from 30,000 to 100,000 tons (27,000 to 90,000 t)/day (Soderberg and Busch, 1977). A complicating factor is that reclamation of waste rock and tailings could be premature if future technology or economic conditions make them attractive as deposits of lean ore (Mantell, 1975). However, the need to limit airborne dust may require that tailings be reclaimed in a timely manner.

Revegetation of tailings is inherently difficult, regardless of the ore mined, because tailings seem to be physically incapable of supporting higher plants (Dean et al., 1969). Their fine-grained particles, which are easily picked up by wind when dry, and which are physically unstable when saturated, are also a major problem for reclamation. In addition, tailing ponds may have steep outer slopes, deficient water for plant growth, and severe surface temperatures (Down and Stocks, 1976). Finally, the tailings may be cemented or compacted, and old tailings can develop a hard oxidized layer about 8 in. (200 mm) below the surface (Peters, 1974).

Water is an extremely limiting factor in revegetating tailings (Cook, 1976; Ludeke, 1977; Hodder, 1977). Where the precipitation exceeds 20 in. (500 mm), revegetation problems are considerably simplified, but reclamation in the arid West and at high altitude or high latitude requires special techniques and comparatively greater effort.

Reclamation of tailings must start by building physically stable gradients and by then developing a medium for plant growth on the tailings. This cover should resemble undisturbed soils near the mine in order to minimize long-term maintenance and to promote the growth of native plants (Curry, 1975). Adverse characteristics of the tailings must be mitigated, namely deficient nutrients, extreme alkalinity or acidity, excessive salts and heavy metals, deficient microbial populations, and frequent blowing dust (Dean et al., 1974). Soil stability can be achieved through the use of mechanical surface manipulation, mulches, planting of annual species, and finally, by establishing permanent vegetation (Hodder, 1976). Soil moisture can be increased by impeding runoff, increasing infiltration, and reducing evaporation.

Soil neutralization, which enhances plant growth and reduces the mobility of heavy metals (Nielson and Peterson, 1973), can be accomplished through either natural or induced leaching. Spraying an area with a fine mist until leaching progresses below the root zone has been successful in some cases (James, 1966). Drip irrigation also has been used to leach the root zone, but its practicality in large revegetation projects is limited (Shoji, 1977; DeReemer and Buch, 1977). In humid areas, letting a site lie fallow for one or two years will allow natural leaching of salts (Gemmell, 1975). Other neutralization procedures include adding sulfuric acid to saline and alkaline soils, and treating acidic soils with limestone or fly ash (Dean and Shirts, 1977). If fly ash is used, the toxic elements that are commonly found in fly ash can be bound up as organic complexes by use of compost, manure, or barley straw. Placing the fine and coarse fractions of tailings in layers also helps to reduce the salinity (Dean et al., 1973).

Tailings are poor in nutrients, and use of commercial fertilizer is often recommended, even though the resulting plant cover may then require continued applications. Cook (1976) says that commercial fertilizers should not be applied until the second year, if used at all. Inoculation of tailings waste with native soil or commercial mycorrhiza (a microorganism found in soils) has been shown to be particularly helpful in establishing vegetation (Aldon, 1976; Reid and Grossnickle, 1978).

Applying sewage sludge to tailings appears to enhance revegetation (Peters, 1974). Furthermore, Hodgson and Townsend (1973), from revegetation experiments on pulverized fuel ash, found that any bulky ameliorant such as sewage sludge, shale, or peat improved the growth medium. Spreading the sludge can alleviate blowing dust on tailings ponds (Peters, 1974) and is more effective than topsoil in creating a growth medium where soils are poorly developed (Ludeke, 1977). Sludge increases the water-holding capacity of the soil, moderates the pH, helps to dilute any phytotoxic materials that may be present, and is a good source of nutrients (Dean and Shirts, 1977).

Legumes and other nitrogen-fixing plants should be encouraged to enrich the soil in nutrients (Hodgson and Townsend, 1973), and early growth on tailings should be plowed back in to conserve nutrients and reduce the need for fertilizer (Peters, 1974). For this reason, harvesting during the initial years is not recommended, and grazing by livestock and wildlife should be prevented.

Native species are often recommended (Aldon, 1976; Curry, 1975; Ludeke, 1977), and transplanting them to disturbed areas has been found to be effective (Ludeke, 1977). Whether or not native species are used initially, they may become established on the tailings after non-native plants have been growing for a few years.

Both broadcast seeding (Hodder, 1976) and drilling (Cook, 1976) have been recommended as methods of planting. Also most authors agree on the importance of some type of mulch to protect seeds, keeping them in place and providing some additional soil moisture (Hodder, 1977; Kay, 1977). Hydroseeding with a combination of mulch, seeds, and chemical stabilizers can provide a stable medium for germination (Day and Ludeke, 1979); the most successful chemicals are elastomeric polymers (Kay, 1977; Berg, 1972).

12.3.5 SPECIALIZED RECLAMATION PROBLEMS

12.3.5.1 Prime Farmland

The reclamation of prime farmland that has been disturbed by surface mining presents a special challenge to reclamation personnel. Land designated as prime farmland by the Soil Conservation Service must be reclaimed according to standards given in Part 823 of *CFR* Title 30. There are two general classes of regulations that must be satisfied: (1) soil reconstruction standards and (2) revegetation success standards. Soil reconstruction standards require that all topsoil must be removed and replaced as a separate layer. The B or C horizons or other suitable soil material must be removed also and replaced as a separate layer so that a minimum reconstructed soil thickness of 48 in. (1.2 m) is achieved. Revegetation success standards specify that the average yield must equal or exceed the average yield of a reference crop grown on similar nonmined soils in the surrounding area. This yield must be reached for a minimum of three years, and the reference crops must be selected from the crops produced most commonly on the surrounding prime farmland. The row crop requiring the greatest rooting depth must be one of the reference crops. In many cases, this crop will be corn.

Surface mine operators have attempted, in general, to satisfy the prime farmland soil reconstruction requirements using conventional construction equipment. The method used most often has been scraper haulage. Ground pressure from reclamation equipment (especially rubber-tired equipment) causes the bulk density and strength of the soil to increase, resulting in restricted root growth (Albrecht and Thompson, 1982). Soil structure is also affected by soil handling, resulting in less water and air being available to plant roots. The resultant soil condition is referred to generally as compaction.

Excessive soil compaction is cited as the major obstacle to returning agricultural land to high levels of productivity (Anon., 1985). At present, two general solutions to the problem are being considered. The first is to employ alternative methods of soil reconstruction that limit the amount of soil compaction (Albrecht and Thompson, 1982; Jansen and Dancer, 1981; Blakely, 1980; Roll, 1987; Sweigard and Escobar, 1989).

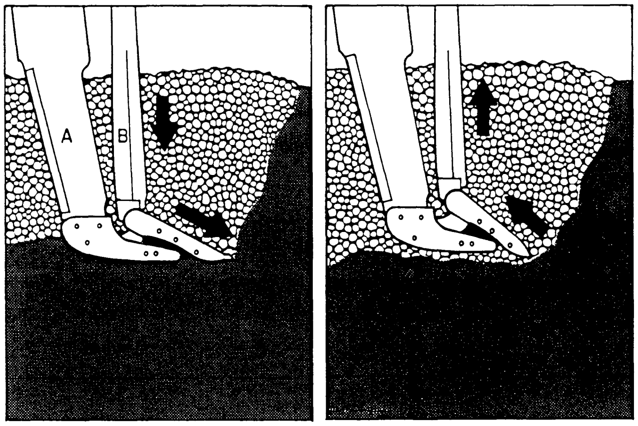

Fig. 12.3.4. Cut-lift system of the Kaelble-Gmeinder TLG-12 shanks: a) cutting—preloosening phase that causes coarse fracturing; b) lifting—fine-loosening phase that results in soil shattering (Chugh and Prasad, 1983).

Table 12.3.7. One-Year Corn Yield Data from Illinois Test Plots

Treatment	Area #2	Area #3	Mean
	yield, bu/a		
Scraper/TLG	136	108	119 a*
Scraper	117	56	91 b
Undisturbed	94	94	94 b

*Yields within a column with a similar letter are not significantly different at the 0.05 level. Conversion factor: 1 acre = 0.404 hectare.

Source: Hooks, Jansen, and Holloway, 1987.

Several of these methods involving truck-shovel combinations and BWEs are addressed in 12.3.3.2. In many cases, the alternative method is used only for subsoil replacement, requiring the use of scrapers to replace the topsoil.

The second general solution is to augment the soil after it has been reconstructed. Deep tillage has been the primary means of augmentation (Albrecht and Thompson, 1982; Hooks, Jansen, and Holloway, 1987). Soil-loosening techniques include but are not limited to ripping, plowing, discing, and rotary tillage (Chugh and Prasad, 1983). Most devices have been developed specifically for agricultural applications and are effective, under favorable conditions, in the upper 12 to 30 in. (300 to 760 mm) of replaced soil. A few deep-tillage machines have been designed to loosen soil below 30 in. (760 mm). One such device is illustrated in Fig. 12.3.4. This machine has three moving shanks that break the soil by a “cut-lift system.” The “cutting” portion of the system consists of the downward and forward motion of the shanks (Fig. 12.3.4a), which fractures the soil coarsely. The fine loosening is accomplished by the “lifting” portion of the system through the upward and backward motion of the shanks (Fig. 12.3.4b). Actual yield data given in Table 12.3.7 indicate a positive response to this method of deep tillage at one site studied. It is important to note that the effectiveness of deep tillage is greatly dependent upon soil moisture. Soils with moisture contents near the plastic limit will resist fracturing. Therefore, deep tillage will be most effective when it is performed under dry field conditions.

Another problem encountered in returning reclaimed land to full agricultural productivity is differential settlement of the ground surface. Differential settlement results in the formation of depressions where the soil remains saturated for extended periods of time. Impeded aeration resulting from poor drainage can inhibit revegetation. This presents a problem not only in terms of increased reclamation costs but also in potential delays in obtaining final bond release.

The mechanism by which differential settlement occurs has not been identified definitively. However, its occurrence seems to be related to such factors as the method of spoil placement, amount of unconsolidated material in the overburden, the moisture content of the spoil when it was placed, and reestablishment of the water table within the spoil. The methods of dealing with the problem are fairly straightforward. The effects of differential settlement can be reduced greatly by eliminating perfectly flat surfaces. In recontouring the surface, a slope of at least 1” will prevent most closed depressions from forming. When closed depressions do occur, remedial work can involve land leveling, construction of grassed waterways to drain low areas, and additional earthmoving in the most extreme cases (Sweigard, 1987).

12.3.5.2 Adverse Soil Conditions

ACIDIC SOILS. In addition to an acidic environment for plant roots, high acidity in the reconstructed soil contributes to higher concentrations of such toxic elements as iron, aluminum, manganese, selenium, chromium, nickel, and cadmium. It also contributes to a reduction in the availability of phosphorus (Vogel, 1987).

Application of lime is the most common method of treating acidic soil. Lime is available in various forms with different neutralizing capabilities. Liming materials are classified according to their calcium carbonate equivalent (CCE), that is, the relative neutralizing ability of the material expressed as a percentage of the neutralizing capacity of pure calcium carbonate ($CaCO_3$). Agricultural lime, which is finely ground limestone, is used most frequently. This material varies in quality and may have a CCE as low as 80%. The particle size of agricultural lime is important. If it is not ground finely enough, additional quantities may be needed. Hydrated lime (calcium hydroxide) has a CCE of 135%; however, it is more expensive than agricultural lime. Dolomitic limestone (calcium-magnesium carbonate) usually has a higher neutralizing potential than agricultural lime but may be toxic to plants in soils that already have high magnesium concentrations. Burnt lime (calcium oxide) is used infrequently. Some wastes such as calcium silicate slag and alkaline fly ash or bottom ash can be used, but care must be exercised to prevent toxicity problems caused by other elements in the waste (Vogel, 1987).

The rate of lime application is based upon soil pH. It is desired generally to achieve a soil pH of 5.5 to 6.5, depending upon the type of vegetation to be supported. The higher values in this range are desirable for most agricultural uses. A crude estimate of the lime application rate based upon soil pH is given in Table 12.3.8. It is recommended that lime be incorporated at least 6 in. (150 mm) into the soil using a disc or chisel plow. For extremely acidic material, deeper incorporation is suggested, and the application rate should be adjusted accordingly. When topsoil is being replaced on top of acidic spoil material, it is advisable to apply the lime and incorporate it into the spoil before the topsoil is replaced (Vogel, 1987).

SALINE AND SODIC SOILS. High concentrations of soluble salts in mine soil result in an increase in osmotic pressure of the soil solution with impedance of water uptake by plants. Therefore, plants growing in this environment are extremely suscepti-

Table 12.3.8. General Guide for Lime Application to Mine Soil

ble to moisture stress. The effects of excessive sodium are somewhat different. Sodium has a dispersive effect on clay particles and dissolves organic matter. This results in a soil that has poor structure, low infiltration capacity, and is highly erodible. Any soil with an exchangeable sodium percentage (ESP) greater than 15 is considered sodic. Very fine-textured sodic surface mine spoils are common in the western US (Sandoval and Gould, 1978; Jansen and Melsted, 1988).

Several management and improvement principles have been reported by Sandoval and Gould (1978). These include (1) establishment of drainage to lower water tables, (2) leaching of excess soluble salts, (3) replacement of exchangeable sodium, and (4) rearrangement and aggregation of soil particles to improve structure. In areas of low precipitation, irrigation is suggested as a means of leaching. Application of gypsum (calcium sulfate) is a common method of facilitating sodium ion replacement. Calcium chloride, ammonium nitrate, and ammonium sulfate can also be used (Vogel, 1987).

Wherever possible, undesirable material should be buried deep in the spoil and covered with better quality overburden. In particular, the graded spoil should be covered with nonsaline and nonsodic soil material (Jansen and Melsted, 1988). The upward migration of soluble sodium may have an adverse effect on vegetation over time, even on topsoiled sites. However, incorporation of gypsum does seem to deter this migration. As a final precaution, it is recommended that sodium-tolerant species be selected for revegetation (Vogel, 1987; Sandoval and Gould, 1978).

12.3.5.3 Excess Spoil Disposal in Mountainous Terrain

Disposal of excess spoil is a problem for surface coal mining operations employing both steep-slope mining and mountaintop removal methods. Steep-slope mining includes those methods employing lateral movement of overburden that result generally in a return to the approximate original contour (AOC), while mountaintop removal results in a flat or gently rolling surface that is exempted from AOC requirements due to an approved alternative land use. Various safety and environmental problems can be associated with these disposal sites that are situated generally in valleys and head-of-hollows. A typical head-of-hollow fill is illustrated in Fig. 12.3.5. Specific standards for their construction are given in federal and state surface mining regulations. This problem was studied in detail by the Committee on Disposal of Excess Spoil (CODES) of the National Research Council (Anon., 1981). Following is a summary of the committee's findings, including an overview of the engineering concerns. However, the reader is referred to the full report by CODES for a more in-depth handling of the subject.

The general requirements for disposal of excess spoil are given in Sec. 816.71 of *CFR* Title 30. To ensure mass stability, the design must provide a minimum long-term static safety factor of 1.5. The fill must be constructed on the most moderately sloping and naturally suitable area available. When spoil is disposed on a downslope greater than 2.8:1, either a keyway cut to bedrock or a rock-toe buttress must be provided. Before any material can be placed, all vegetation and organic material must be removed. The excess spoil must be placed in horizontal lifts no greater than 4 ft (1.2 m) thick and must be compacted concurrently as necessary to provide stability. Adverse effects on surface water and groundwater must also be minimized. Surface diversions are necessary to prevent spoil erosion and infiltration into the fill. Also the fill is to be underlain by drains constructed of durable, nonacid-, nontoxic-forming rock. Minimum sizes of main underdrains for different types of valley fills are given in Table 12.3.9. Lateral drains are to be constructed from seeps and springs to the main drains. Rock-core chimney drains may be used in head-of-hollow fills instead of underdrains and surface diversions. The fills must have no permanent impoundments. They must be revegetated and suitable for the approved postmining land use.

A site investigation should precede the design of any fill for excess spoil disposal. This includes geologic and geotechnical investigations of the foundation conditions. The primary function of these investigations is to identify any materials or conditions that could lead to failure (e.g., a layer of weak shale with a particularly unfavorable orientation). Information that is required before a design can be attempted includes (1) engineering properties (density, cohesion, and internal angle of friction) of the spoil and underlying material; (2) pore-water pressure anticipated within and beneath the spoil; and (3) the nature of external forces (e.g., blasting or earthquake). After this information is obtained, various embankment configurations can be considered and their stability analyzed. Various methods of analysis are available. However, the method used most commonly is the limiting equilibrium analysis. Using this method, driving forces and resisting forces can be estimated considering different failure surfaces (both curved and planar), and a factor of safety determined for each case. The design process leads to the selection of an embankment configuration that satisfies the factor of safety requirement (1.5 in most cases) for the critical failure surface. After the fill has been completed, it is advisable to monitor its performance through the measurement of such parameters as surface settlement and pore-water pressure.

12.3.5.4 Highwall Elimination

Another specific reclamation problem encountered, particularly in surface coal mining, is highwall elimination. The AOC provisions of SMCRA require that, with very few exceptions, all highwalls must be removed. Exceptions may be granted for remining in steep-slope regions where adequate spoil is not available to satisfy the requirements. In those cases, the requirements must be satisfied to the extent that is feasible. Exceptions also may be granted in some western states where portions of highwall can replace cliff-type habitats disturbed by mining. The provisions for a variance relating to AOC based upon an alternative approved land use do not generally include leaving highwalls, however. The problem of highwall elimination differs between contour mining and area mining operations. The Committee on Highwalls and Approximate Original Contour (COHAOC) of the National Research Council has investigated this problem on a national level (Anon., 1984). A portion of the findings are summarized in the following discussion.

In the steep-slope regions where contour methods are employed, there seem to be some differences among state regulatory authorities on the interpretation of highwall elimination. Some states allow no exposed rock face while others permit a few feet (meters) of exposed rock when it forms one side of a drainageway. The major engineering problem related to this requirement seems to be whether it is possible to eliminate the highwall completely and still achieve the required factor of safety (in the range of 1.3 to 1.5). This is a valid concern since many natural slopes in the region are known to be unstable. The theoretical relationship between slope angle, internal angle of friction, and factor of safety is illustrated in Fig. 12.3.6. This relationship is based upon an assumption of zero pore water pressure within the spoil. Water within the spoil, however, can both increase the driving force due to gravity and decrease the shearing resistance. Pore water pressure can be related to several factors including (1) infiltration into settlement cracks at the contact between spoil and highwall, (2) undisturbed barrier at the outcrop that restricts drainage, and (3) auger holes that may drain into the spoil. The required safety factors may be difficult to achieve in slopes greater than approximately 25°, but several measures will enhance the stability of these slopes. Compaction of the fill material increases the effective friction angle and should be done carefully. The build-up of pore pressure at the toe of the fill can be minimized by providing drains at acceptable intervals in the outcrop barrier. Also diversion ditches or terraces can be constructed to prevent water from flowing over the face of the slope. These diversions must have adequate slope to minimize infiltration.

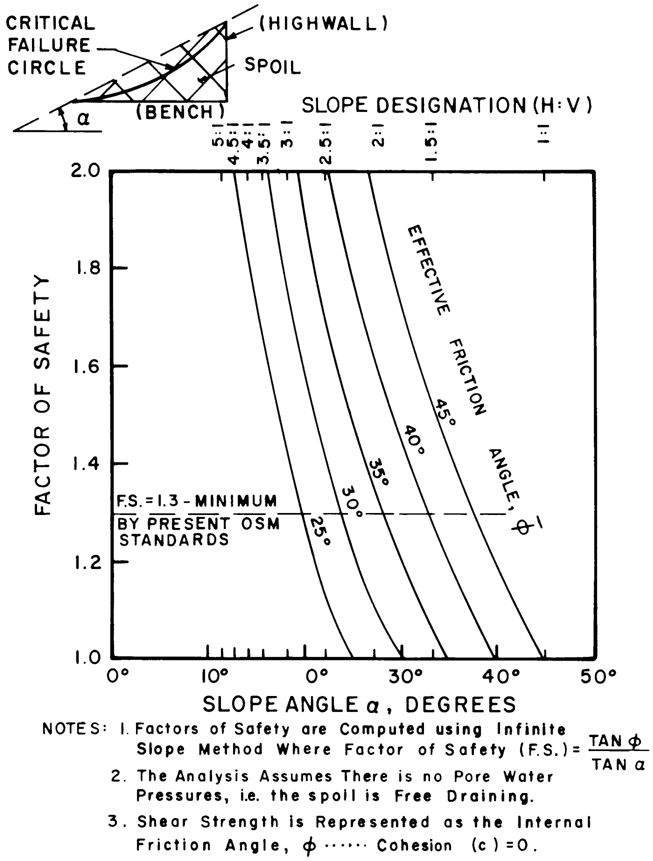

Fig. 12.3.6. Graphic representation of relation of slope stability to slope inclination for varying spoil shear strengths (Anon., 1984).

Finally, a layer of coarse-textured durable rock on the pit floor helps to improve internal drainage.

Highwall elimination is less of a problem in area mining situations. One reason is that the relative length of highwall to be reclaimed is smaller, since it is only the final cut in area mining that is affected. Secondly, stability is not a serious problem, since steep slopes are eliminated more easily in flatter terrain. Two general methods are being practiced depending upon the site conditions and specific state regulations. One method is to backfill the pit and grade the side slopes to a gradient that is less than or equal to a value specified by the regulatory authority. In this case, drainage is provided so that no water is impounded. Another method practiced in some states allows water to fill the final cut with grading of the highwall and spoil to acceptable slope angles down to an elevation slightly below the estimated minimum water level. Both methods may require some additional blasting of consolidated material in the highwall to satisfy the maximum slope requirements. Final cut impoundments present some interesting land-use potentials including recreational use and wetlands. However, impoundments may not diminish the quality or quantity of water used by nearby landowners, and the quality of the impounded water must be permanently suitable for its intended use. Potential water quality problems can be minimized by covering the exposed coal and segregating toxic spoil.

12.3.5.5 Subsidence Mitigation

Surface subsidence can result from underground mining of any laterally extensive stratified deposit. Most often, it is associated with underground coal mining. Surface subsidence damage caused by underground coal mining is addressed in Sec. 817.121 of *CFR* Title 30. The regulations recognize two distinct types of damage: (1) damage to the land surface and (2) damage to structures or facilities on the surface. Operators are required to correct any material damage to the surface. This implies maintenance of the presubsided land-use capability. To the extent required under state law, operators must also correct material damage done to structures or compensate the owner for the damages. Repair of subsidence damage may include rehabilitation, restoration, or replacement of the structure. In addition to the types of damage, two types of subsidence can be characterized as well. The first type is the result of longwall and high-extraction retreat mining. It occurs fairly rapidly and predictably, producing a regularly shaped subsidence trough. This is referred to as planned subsidence. A second type of subsidence is associated with failing pillars in room and pillar mining. Considerable time may pass before pillars begin to fail, making this type of subsidence much less predictable with respect to location and severity. It is frequently associated with abandoned underground mines. Mitigation measures are influenced by both the type of damage and the subsidence characteristics.
