Subsidence damage to the land surface results from changes in topography and overall drainage. This type of damage is usually associated with the extensive troughs produced by planned subsidence. Its greatest impact is upon the use of the land for agricultural purposes. Darmody et al. (1988) reported that farmability can be impaired by alteration of subsurface soil drainage, soil chemistry and structure, and surface drainage caused by subsidence. Corrective measures include improvements to drainage such as installing subsurface drain tiles or constructing surface drainageways. Regrading of the surface may also be necessary to remove depressions. When this is done, topsoil should be removed before grading and replaced afterwards to avoid loss or contamination during the grading process.

Most structural damage caused by subsidence is due to strain. This can result in distortion, cracking, and failure of foundations and structural members. Unplanned subsidence under existing structures requires structural repairs as damages occur. Repairs may include repointing of masonry walls, shoring and bracing of the superstructure, and possible replacement of foundations and floor slabs (Bruhn et al., 1983). New construction in areas prone to subside can employ some protective measures to minimize damage. Peng (1986) describes both a flexible design approach, which allows structural elements to deflect according to the subsidence profile, and a rigid design approach using heavily reinforced structural elements that are intended to cantilever or span across subsided areas. When subsidence due to longwall or high-extraction retreat mining is planned under existing structures, it is possible to lift the superstructure from its foundation using jacks, maintain it in a level position until the surface is stable, and then return the superstructure to a rebuilt foundation.

Chapter 12.4
ELECTRIC POWER AND UTILIZATION

LLOYD A. MORLEY AND THOMAS NOVAK

12.4.1 INTRODUCTION

Mine electrical power systems have traditionally held little interest for the mining engineer, who has tended to avoid them, or for the electrical engineer, who has given them scant attention. However, today's mine power systems are complex and subject to numerous legal constraints, and it is no longer possible to treat the subject with the indifference shown in the past. Mining equipment is usually mobile and self-propelled; most is powered electrically through portable cables and, for safety, must be part of an elaborate grounding system. The machines and power distribution equipment are seldom stationary and must resist extreme levels of dust, moisture, and vibration. The electrical loads created by mining machinery are cyclic and can be extremely variable. In the ever-moving mining scene, where distribution of power must be constantly relocated and subjected to abuse by machine and worker alike, the potential for safety hazards is always present. Designing and maintaining such an electrical system is demanding and challenging. It requires a specialist with knowledge of both mining and electrical engineering. Also effective management of a mine requires that anyone responsible for production and safety also be familiar with the mine electrical system.

This chapter is intended to provide the engineer with an introduction to electrical power use in mining. Many guidelines are included but, because the subject is so extensive, comprehensive examples cannot be presented. For more in-depth coverage, the references should be consulted, in particular, other works by the authors.

12.4.1.1 History of Mine Electrical Use

Electricity was first introduced into mines shortly before the beginning of the twentieth century in the form of direct current (dc) for rail haulage. *Direct current* was used because, at that time, most systems were powered by dc generators. Direct current has a number of advantages for haulage, the most outstanding being the fact that the dc series-wound motor has excellent traction capabilities. Batteries served as the first power source; hence battery-powered vehicles were extremely mobile even though constrained by rails. However, it was not long before trolley wires were introduced in several mines. Allowing the trolley wire to act as one conductor and the rail as the other provided the simplest form of power distribution yet known to the mining industry. Thus the dc system at a voltage of 250 or 550 V became firmly entrenched in mines.

Underground, the first electrically driven mining machine, the coal cutter, was introduced in the early 1920s. Although dc offered no special advantage, it was readily available, and the machine was equipped with a dc motor and added to the system. The cutter was followed almost immediately by the loader, and it was driven by dc motors as well. In mines with rail haulage, trailing cables supplied power from the trolley wire and the rail to the machines.

The next significant increase in power consumption came with the introduction of the shuttle car, almost 20 years after the first use of the coal cutter. Actually, when the shuttle car was first invented in 1937, it was battery-powered. The addition of an automatic reeling device to handle a trailing cable came later in an attempt to overcome the deficiencies of batteries. These trailing cables were also connected to the haulage power system, and this equipment, when combined with the cutters and loaders, placed additional demands on the dc distribution system.

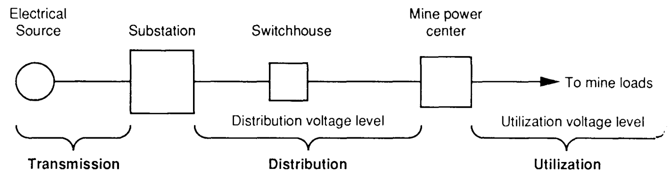

Fig. 12.4.1. Basic power system.

In the late 1940s, when continuous mining machines first began to be used extensively in coal mines, dc was again expected to provide the power. The continuous miners normally needed more energy input than the sum of the various conventional mining machines they replaced, and because this required horsepower caused high current demands, dc was found to be entirely unsatisfactory in most cases. The attendant current demand created enormous voltage drops in the distribution system. As a result, the dc supply system was separated from the haulage system; however, even this proved to be inadequate. During peak operating periods, voltages at the machines were so far below rated values that even moderate efficiency was impossible. Additional problems were caused by the increasingly large cable sizes required to supply the needed power, and cable handling was difficult. The use of *alternating current* (three-phase ac) distribution and motors was an obvious answer. However, some mining companies were reluctant to make the change for another decade. In many instances, this was because the laws in some states limited the maximum voltage in underground mines.

When higher voltages were finally permitted, the desirable economics of ac employment could be realized, and there was a swift transformation from dc to ac for both distribution and high horsepower loads in underground mines. As a result of conversions, mine power systems generally have two voltage levels, *distribution* and *utilization,* which are illustrated in Fig. 12.4.1. Here the substation transforms the utility voltage down to distribution levels, most often at voltages greater than 1000 V. Power at this voltage is distributed through conductors from the substation to the power center; hence it is termed the *distribution system.* The power center or load center, in actuality a portable substation, transforms the voltage to utilization levels, typically at low voltage (in US mining practice, defined as 660 V or less), or medium voltage (661 to 1000 V). It is at this level, or face voltage, that power is normally delivered to the equipment. Despite this reference to voltage levels, it should be noted that distribution and utilization describe functions of a power-system segment, not a specific voltage range.

Originally, primary ac distribution was made at 2300 or 4160 V. In most mines, these levels were later increased to 7200 V, and some operations even increased the voltage to 12,470 or 13,200 V. The principal reason for increasing the voltage was that, for the same load, current would be correspondingly smaller, and lower distribution losses would result. From the beginning, 440-V ac was the most popular for utilization, despite the fact that, when the continuous miner proved so successful, its horsepower was progressively increased. The additional horsepower resulted in an increase in trailing-cable sizes, until their weight was almost more than personnel could handle. To compensate, the most common move was to raise the rated motor voltages to 550 V. More recently, manufacturers have produced machines with 950-V, 2400-V and 4160-V motors to further overcome trailing-cable problems. The two higher voltages have recently gained increased popularity for high-capacity longwall mining systems (Morley, Kohler, and Smolnikar, 1988; Morley, Novak, and Davidson, 1989).

Whereas dc series motors were universally employed in underground rail haulage, the first large motors used in surface mining were dc shunt wound because of their constant speed characteristics. The initial distribution for electric shovels was also dc because of the nature of the power generation. Technological advances soon made ac power systems superior, and ac motors were tried with some success. However, by 1927, ac/dc motor-generator (m-g) sets and the invention of the Ward-Leonard control concept caused these efforts to be abandoned. The new control system enabled motor speed to be varied and controlled by varying the armature voltage while maintaining a constant voltage across the shunt field. The m-g sets functioned as on-board power-conversion units, thereby establishing the use of ac distribution in surface mines. Motor-generator sets driven by synchronous or induction ac motors, Ward-Leonard control, and dc motors established the standard, and even now the combination is still used on many mining excavators.

Distribution and utilization voltages in surface mines increased to keep pace with rapid increases in mine machinery horsepowers. Until the mid- 1950s, 4160 and 2300 V were the usual mine levels. Then, with the advent of larger concentrated loads, it was found that 7200 V was advisable (Rein, 1968). However, this level proved inadequate when machines larger than 100 yd^3 (76 m^3) were introduced, and 13,800-V mine and excavator voltage became a standard. With machines greater than 200 yd^3 (153 m^3) in capacity, 23,000-V utilization was established, but even with these substantial increases in distribution, some loads up to 1000 hp (746 kW) continued to be driven at 480 V. Production shovels up to 18 yd^3 (14 m^3) commonly stayed at 4160 and 7200 V, while in general 4160 V became standardized for machinery with 1500 hp or less, and as a result more than one voltage level could be required at a mine when excavators of different sizes were employed.

12.4.1.2 Power Terminology

Several power terms are used to describe the electrical operation of a power system. These terms are applicable not only in system design, operation, and maintenance, but also in utility company billing practices. If the sum of the electrical ratings is made for all equipment in an electrical operation, the result will provide a total connected load. The measure could be expressed in horsepower, but electrical units of kilowatts (kW), kilovolt-amperes (kVA), or amperes (A) are more suitable. (The connected horsepower can be easily converted to connected kilowatts simply by multiplying by 0.746.) Many loads operate intermittently, especially mining production equipment, with varying load conditions. Accordingly, the demand upon the power source is frequently less than the connected load. This fact is important in the design of any mine power system, as the system should be designed for what the connected load actually uses, rather than the total connected load. Obviously, these considerations have great impact on power-system investment or the capital required to build the system.

Because of the importance of assessing equipment power demands, the Institute of Electrical and Electronics Engineers, Inc. (IEEE) has standard definitions for load combinations and their ratios. Several of the important definitions follow (Anon., 1986):

1. *Demand* is the electrical load for an entire complex or a single piece of equipment averaged over a specified time interval. The time or demand interval is generally 15 min, 30 min, or 1.0 hr, and demand is generally expressed in kilowatts, kilovolt-amperes, or amperes.
2. *Peak load* is the maximum load consumed or produced by one piece or a group of equipment in a stated time period. It can be the maximum instantaneous load, the maximum average load, or (loosely) the maximum connected load over the time period.
3. *Maximum demand* is largest demand that has occurred during a specified time period.
4. *Demand factor* is the ratio of the maximum demand to the total connected load.
5. *Diversity factor* is the ratio of the sum of the individual maximum demands for each system part or subdivision to the complete-system maximum demand.
6. *Load factor* is the ratio of the average load to the peak load, both occurring in the same designated time period. This can be implied also to be equal to the ratio of actual power consumed to total connected load in the same time period.
7. *Coincident demand* is any demand that occurs simultaneously with any other demand. All these definitions may be applied to the units of average power, apparent power, or current. Thus they are invaluable in power-system design, and some examples will illustrate their versatility.

Consider a power cable supplying several mining sections in an underground mine. The sum of the connected loads on the cable, multiplied by the demand factor of these loads, yields the maximum demand which the cable must carry. When applied to current, this would be the maximum amperage. Good demand factors for mine power systems range from 0.7 to 0.8, depending upon the number of operating sections. The lower value is used when there are fewer producing units (e.g., from two to four). The demand factor can be extended to include estimates of average load. For instance, the sum of the average loads on the cable multiplied by the demand factor provides the average load on the cable. A prime applications here is for approximating the current that a conductor is expected to carry. If, for example, 10 identical mining sections would each draw 53 A, the conductors feeding all these sections would be expected to carry

$$\begin{aligned}&(\text{total average load})\ (\text{demand factor})\\&\quad = (\text{average load})\end{aligned} \tag{12.4.1}$$

or

$$(10)(53\ \text{A})(0.8) = 424\ \text{A}.$$

The demand factor and the diversity factor can be applied to many other mine electrical areas, such as estimating transformer capacities, protective-circuitry continuous ratings, and the load that a utility company must supply.

The load factor can be used to estimate the actual loads required by equipment. Here the total connected load multiplied by the load factor is an approximation of the actual power consumed. It should be noted that the average load factor in underground mining tends to be rather low, mainly due to the cyclic nature of machine operation but also to the employment of high-horsepower motors needed to perform specific functions and sometimes operating only for a small fraction of possible running time. For instance, when cutting and loading, a continuous miner may have all motors operating, thus have a total connected load of 385 hp or (0.746) (385) = 287 kW. The average load factor might be 0.6; therefore, the actual power consumed is (0.6) (287) or 172 kW. The load factor can also be applied to equipment combinations.

The maximum power demand normally forms one basis that utility companies use to determine power bills; most often, one month is the specified time period. Demand meters are often installed at the utility-company metering point.

12.4.2 DESIGN CRITERIA

The goal of the engineer is to provide an efficient, reliable electrical system at maximum safety and for the lowest possible cost. The types of information made available to the engineer include the expected size of the mine, the anticipated potential expansion, the types of equipment to be used, the haulage methods to be employed, and whether or not power is available from a utility company. The amount of capital assigned for the electrical system is also designated.

The designed system must meet certain minimum criteria. IEEE (Anon., 1986) has defined the basic criteria for industrial electrical systems that must be applied to mines:

1. Safety to personnel and property.
2. Reliability of operation.
3. Simplicity.
4. Maintainability.
5. Adequate interrupting ability.
6. Current-limiting capacity.
7. Selective-system operation.
8. Voltage regulation.
9. Potential for expansion.
10. First cost.

Of these, safety, reliability, and simplicity are closely related, and most are dependent upon good preventive maintenance. In the cramped and inhospitable environment of an underground mine, these are of vital concern. Most routine maintenance should be capable of being performed by nontechnical personnel, since it will most often be done by the miners themselves. Training for these tasks must be provided.

Adequate interrupting capacity, current-limiting capability, and selective-system operation are projected at safety through reliability. The first two areas ensure protection during a disturbance. Current limiting, when applied to grounding, is perhaps the most significant personnel safety feature of mine electrical systems. Selective-system operation is a design concept that minimizes the effect of system disturbances. *Voltage regulation*—the fluctuation of voltage resulting from change in electrical load—is a limiting factor in system design, particularly underground, and is often the main constraint to mine expansion. It should be anticipated that when the size of the mine is increased, this might involve augmenting the power-system supply through additional power sources.

While first cost is important, it should never be the determining factor, since high-cost equipment, projected at maximizing safety and reliability, can easily offset the increased first cost through the reduction in operating costs. At times, this fact appears to elude some company purchasing agents.

Using the data available, the task of the mine electrical engineer is to select one combination of power equipment over another; provide power or circuit diagrams; estimate equipment, operating, and maintenance costs; set the specifications for the system; and receive and assess the proposals from suppliers. For success, the engineer requires a firm knowledge of mine power systems, but this understanding cannot be based on a standard mine electrical system because such a standard does not exist: no two mines are exactly alike. The engineer must resort to the fundamental concepts, an awareness of what has worked in the past, and a clear understanding of the legal constraints.

12.4.3 POWER DISTRIBUTION EQUIPMENT

A few pieces of power equipment have already been mentioned but only to the extent necessary to describe the concepts of distribution and utilization. The evolution of mine systems has resulted in major items of power apparatus, each serving a specific function. In general, they can be listed as (Anon., 1964; Lordi, 1961)

1. Mine power centers.
2. Switchhouses.
3. Main substations.
4. Portable and unit substations.
5. Distribution (conductors and connectors).
6. Generation.

12.4.3.1 Power Equipment Types

MINE POWER CENTERS. The power or load center is one of the more essential power system units for underground mines and, in a simpler form, for surface mines. Its primary function is to convert the distribution voltage to utilization voltage for operating equipment throughout the mine. It must also incorporate protective circuitry to ensure safe, efficient, and reliable operation.

The electrical components of the power center are usually metal clad, that is, housed in a heavy-duty steel enclosure that may be tire-mounted, skid-mounted, or track-mounted. Towing lugs or pin-and-link couplers are commonly provided on each end of the enclosure to permit towing as mining advances or retreats. Bumpers or check plates are often installed to protect externally mounted components, such as couplers, from damage by mobile equipment. Similar enclosures can be used in surface mines, but here the simplest power center can consist of outdoor components assembled on a flat-bed trailer with a fence or gates to discourage unauthorized entry.

Fig. 12.4.2 shows typical internal components of a mine power center, and a discussion of the various devices follows. It should be noted that a "standard" power center does not exist because of the variety of mining practices and the numerous types of mining equipment used. The power center may supply only one motor or as many as 20 pieces of machinery; it may be totally ac, dc, or a combination of ac and dc. The distribution voltage received by the power center can be 4.16, 7.2, 12.47, 13.2, or 13.8 kV. The outgoing ac utilization voltage may be 480, 600, 995, 1040, 2300, or 4160 V or a combination of one of the higher voltages with one of the lower voltages. Direct current can be at 300 or 600 V, but is almost always 300 V for face applications. As a result of this variety, manufacturers custom build units to meet the individual needs and specifications of the customer.

High-voltage Compartment—The *disconnect* or *load-break switch* is a mechanically operated, air-type switch. Its primary

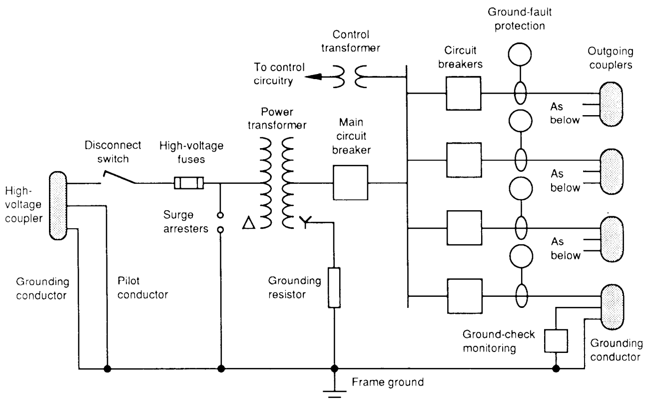

Fig. 12.4.2. Simplified diagram of a mine power center.

function is to allow a quick means of disconnecting the primary of the power-center transformer. A spring-loaded or torsion-bar mechanism provides quick-make and quick-break operation, independent of the speed of the manually activated handle. With observation windows in the power-center enclosure, the switch can serve as a visible disconnect.

Current-limiting fuses are typically used in mine power centers to protect the primary of the transformer. With high fault currents, they operate very quickly, and only a portion of the available destructive short-circuit energy is passed through.

Surge arresters are used to protect the transformer from transient overvoltages, which can be caused by lightning, switching surges, and some types of faults. The functions of a surge arrester are to discharge the energy associated with a transient overvoltage, to limit and interrupt the current that follows the transient current through the arrester, and to return to an insulating state without interrupting the supply of power to the load. The rating of the surge arrester should be coordinated with the insulation level (basic impulse level) of the transformer.

Power-center Transformers—The main transformer can be considered the heart of the power center since its primary function is to convert the distribution voltage to utilization. Proper selection is imperative from the standpoints of safety, efficiency, and reliability. IEEE (Anon., 1979) has established classifications and specifications for determining transformer characteristics as an aid in design and application, and these standards are in general use in the mining industry. A transformer may be classified by the insulation system as liquid or dry. Liquid insulation includes mineral oil or synthetic fluids, and dry transformers are ventilated or sealed gas-filled types. Ventilated dry units are used almost exclusively in mine power centers. Dry transformers used in mine power centers should have Class-220°C insulation (a rating always given in degrees Celsius). The classification places an absolute allowable maximum temperature on the transformer when it is operating continuously under full capacity at rated voltage and current.

There is no set formula for determining the capacity rating for a power-center transformer. For constant loads, it is a common rule-of-thumb to allow 1 kVA/horsepower of connected load. However, the mining process does not produce a constant load (i.e., all connected motors are not operating at the same time on a continuous basis); hence using this rule-of-thumb will normally result in oversizing the transformer. Past experience and demand factors established by manufacturers and operators, along with the horsepower of the connected load, are essential for determining the transformer capacity. For typical underground mining sections, the kVA rating may lie within the range of 50 to 80% of the connected horsepower. Over the years, power-center manufacturers have arrived at certain standard or typical transformer capacities, created mainly by repeat demand of the industry. Many manufacturers supply capacities at any increment of 50 kVA.

As an example of transformer sizing, consider the following continuous-mining section:

1. 370-hp continuous miner (gathering head, pump, tram, and cutter motors)
2. two 125-hp shuttle cars (traction, conveyors, and pump motors)
3. 80-hp roof bolter (traction and pump motors)
4. 50 hp of auxiliary equipment (section fan, sump pump, hand tools, etc.).

The total connected horsepower is the sum of the individual loads or 750 hp. If the demand factor has been determined to be 75%, the effective load (maximum demand) would be (0.75)(750) = 562 hp. Thus a 600-kVA capacity would be indicated. However, flexibility must always be considered in mining applications and, as a result, it may be necessary to select the next higher kVA rating, or 650 kVA, to accommodate anticipated additional loads.

All mine power-center transformers are three-phase, being either three single-phase units where each transformer is rated at one-third of the total required capacity, or integral three-phase types with construction allowing field replacement of failed windings. The integral three-phase transformers are preferred because they have equal reliability, lower cost, higher efficiency, take less space, and have fewer exposed interconnections than three single-phase units.

Delta primary and wye secondary are the preferred connections for standard two-winding power transformers and are the connections commonly used in mine power centers. The wye secondary provides an easy means for resistance grounding, and the delta-connected primary provides isolation of the distribution circuit from the utilization circuit with respect to ground currents. The delta-wye connection also stabilizes the secondary neutral point and minimizes the production of harmonic voltages. In certain situations, a delta-connected secondary may be specified or required, and the primary may be delta or wye in this case. If neutral grounding is desired or required, a grounding transformer is needed to derive a neutral.

Mine power centers are usually cooled by natural convection, and the side panels of the transformer compartment normally have louvers to allow air circulation. The transformer windings are designed so the heat generated is exposed to an adequate amount of cooling to handle the expected loads. The effective cooling areas are the inside of the winding, the outside of the winding, and the cooling ducts within the winding. The movement of air by convection carries away the heat generated by the winding.

Low- or Medium-Voltage Compartment—Molded-case circuit breakers are normally used to protect ac utilization equipment and their associated cables for applications up to 1000 V. High voltage (greater than 1000 V) requires vacuum or oil circuit breakers, which are discussed in the segment on switchhouses. Molded-case breakers are also used for 300-V dc applications.

Molded-case circuit breakers can provide both short-circuit and overload protection. Each circuit breaker usually has an undervoltage release, which is an auxiliary solenoid that trips the operating mechanism of the breaker whenever its coil voltage drops below 40 to 60% of its rated value. Other protective relaying external to the breaker, such as ground-fault relaying or ground-check monitoring, can use the undervoltage release to initiate circuit-breaker tripping. The selection of molded-case

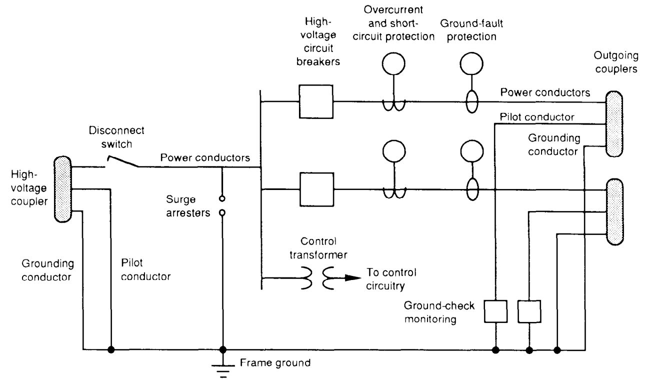

Fig. 12.4.3. Simplified diagram of a switchhouse.

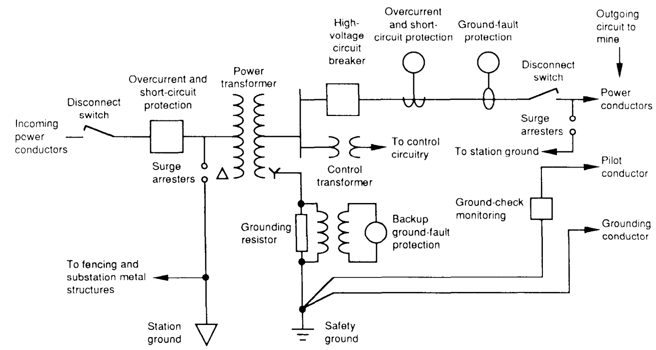

Fig. 12.4.4. Simplified diagram of a substation.

circuit breakers is based on voltage, frequency, interrupting capacity, continuous-current rating, and trip settings.

Fig. 12.4.2 shows *ground-fault protection* on each outgoing machine circuit. *Zero-sequence relaying* is the most common method of ground-fault relaying. With this method, the three-line conductors are passed through a window-type current transformer, and the secondary of the current transformer is connected to a ground-trip relay. The normally open contacts of the ground-trip relay are connected in series with the undervoltage release of the associated molded-case circuit breaker. If a ground fault occurs, the current transformer senses an imbalance in the three-line conductors, and current is induced in its secondary winding which activates the ground-trip relay. The contacts of the ground-trip relay then open and de-energize the undervoltage release which results in tripping the circuit breaker.

Fig. 12.4.2 also shows *ground-check monitoring* on each outgoing circuit. Its purpose is to continuously monitor the continuity of the grounding conductor. Monitors in common use in mining are impedance types and continuity types. *Impedance-type monitors* require the trailing cable to have a pilot conductor. The monitor is calibrated to the impedance of the loop formed by the pilot and grounding conductors. The device then monitors the change in impedance from the initial calibration. If the impedance of the loop increases beyond a preset value, the monitor trips its associated circuit breaker by opening a set of contacts in series with the undervoltage release. *Continuity monitors,* also termed wireless or pilotless monitors, do not require a pilot conductor. The monitor generates an audio frequency that is coupled to the grounding conductor by means of a transmitting coil. The pilot wire is eliminated by using the line conductors as a return path. Filters within the monitoring location and within the monitored machine are necessary for coupling and uncoupling the audio signal from the line conductors. If the grounding conductor is open, the receiver coil will not pick up a signal, and the monitor will cause a set of contacts to open in the undervoltage circuit of its associated circuit breaker.

SWITCHHOUSES. Switchhouses are portable equipment that protect and provide a means for branching of the distribution circuit. Switchhouse components (Fig. 12.4.3) are contained in metal-clad enclosures, similar in construction to those of mine power centers. The internal components consist of visible disconnects and sectionalizing units. As with power centers, the principal function of the disconnect switch is to remove power manually from downstream mine power equipment that is connected to the distribution system. The sectionalizing aspect is to provide protective relaying in the distribution system and to allow branching. The principal component is the high-voltage circuit breaker. Both *vacuum* and *oil circuit breakers* have been used in switchhouses, but vacuum breakers are more popular.

Induction-disk and, more recently, *solid-state relays* are used for protective-relaying applications in switchhouses. These relays have a range of adjustment for both the pickup current and time delay so they can be applied to a variety of situations. The protective relays in a switchhouse must be coordinated with other upstream and downstream protective equipment. Unlike molded-case circuit breakers, the overcurrent and short-circuit sensing devices are not an integral part of the high-voltage breaker. Instead, current transformers are used in conjunction with the induction-disk or solid-state relays to provide overcurrent and short-circuit protection.

The equipment name is modified depending upon the number of circuit breakers and associated protected outgoing circuits: for example, a double switchhouse contains two breakers and circuits. Because of size limitations, the units in underground mine power systems are rarely larger than double switchhouses, but surface mines often incorporate four-breaker switchhouses, or switching skids as they are commonly called. The schematic diagram for surface or underground applications is practically the same: the only basic difference is the repetition of internal components to correspond to the number of circuit breakers used.

SUBSTATIONS. It is common mining practice to purchase all or most power from utility companies, if it is available. As utility voltages usually range from 24 to 230 kV, a main (primary) substation is required to transform incoming levels down to a primary distribution voltage for the mine. Typical components are shown in Fig. 12.4.4. Main substations may range from 500-kVA capacity supplying 480 V for only pumps and conveyors, to 50,000 kVA servicing a large surface mining operation and processing plant (Rein, 1968). In addition to the transformer, substations contain a complex of switches, protection apparatus, and grounding devices, all serving a safety function. The nature of the mining operation and its power requirements dictate how many main substations are required and where they should be placed. These may be owned by the utility or the mining company; the decision on ownership is commonly dependent upon economics. However, if the total connected load is greater than 1000 hp (746 kW), mine ownership is often more favorable.

Main substations are usually permanent installations with components mounted on concrete pads. Power-conductor terminal structures, commonly made of galvanized steel but also of wood, support the conductors and cables that provide connections for transformers and circuit breakers. Insulators, usually made of glazed porcelain or glass, insulate the overhead conductors from the supports.

Portable or unit substations are popular for small load requirements and, in larger installations, they may serve to transform the primary distribution voltage to a lower distribution level. The term unit means that the substation and power equipment is designed and built as a package. In a surface mining deployment, a large dragline may require 24 kV while the production shovels and other mining equipment need 4160 V.

Substation Transformers—Transformers for permanent surface substations are almost always liquid (oil) immersed and built to IEEE standards (Anon., 1987). Capacities commonly range from 5000 to 30,000 kVA (sometimes less but rarely more). In addition to the mine, the loads may include a preparation plant and general surface loads, such as pumps, ventilation fans, maintenance shops, and office and bathhouse facilities. When an underground mine is involved, it is recommended that a separate transformer be used for the underground power system.

The selection of transformer capacity must be based on an estimation of the electrical load. Up to 2000 or 3000 kVA, a general rule of 1 kVA/hp of connected load is perhaps satisfactory. This provides more than adequate capacity for the load and will allow minimal load growth. Note that a worst-case demand factor of 0.75 to 0.85 is built into the selection. Such oversizing will also allow for an adverse power factor. When the requirements are greater than this, a more precise load estimate is required if optimal equipment costs are to be achieved. Considering the common capacity needs for the majority of mining operations, a load-flow analysis must be performed. In some cases, capacity might be determined on a per-connected kVA basis (about 0.75 per connected hp) to allow for the growth in demand factor that always exists.

Past practice in the industry was to use three single-phase transformers for easy replacement of failed units, and a spare was often included to facilitate the changeover. However, improved manufacturing techniques have now resulted in transformers being among the most reliable components; thus the common practice today is to install three-phase integral units (Wade and Kunsman, 1978). The same advantages of three-phase transformers given for power centers hold for substations.

Protective Equipment—To provide a visual disconnect for maintenance, *knife-blade load-break switches* or *fused cutouts* are located on the primary and secondary of the substation transformer. The switches are usually housed in metal-clad enclosures, while the cutouts are pole-mounted. High-voltage fuses or circuit breakers may be used for transformer protection. A general rule is to use a primary circuit breaker with protective relaying when the transformer capacity is 5000 kVA or greater. The short-circuit, overcurrent, and ground-fault protection is essentially the same as employed in switchhouses. Fig. 12.4.4 shows potential relaying across the grounding resistor; this is used as backup ground-fault protection. If a ground fault occurs, a voltage will develop across the grounding resistor. A potential transformer is used to step down this voltage to within the rating of the ground-trip relay. When the ground-trip relay is energized, it trips the circuit breaker.

Two physically separated ground beds are required at the substation. Surge-arrester grounding conductors, static conductors, metallic frames, and fencing are connected to the station bed, while only the distribution grounding conductors are tied to the safety ground bed. The purpose for the separation is to prevent voltages produced across the station bed from being transferred to the safety bed. The segment on mine grounding systems will further discuss this subject.

DISTRIBUTION. This category of major power equipment is often referred to as the weakest link in mine power systems. It encompasses all the overhead power lines, cables, cable couplers, and trolley lines used to carry power and grounding between the power equipment and eventually to the loads.

Cables—Cables carry the electricity from the substation, where the power is taken from utility company lines, to the point of utilization by a mining machine, pump, conveyor belt, or other pieces of equipment. There are many possible variations in mine distribution, and several types of cables can be put to a similar use.

The type of cable is dependent upon the application; some cables remain in stationary locations for several years, while others are moved frequently. The cables that are connected to mining machines are termed portable (Anon., 1978; Anon., 1980). Federal regulations use the term *trailing cables* for the specific variety of portable cables used in a mine (Anon., 1981). Trailing cables are flame-resistant flexible cables or conduits through which electrical energy is transmitted to a machine or accessory.

In underground mines, trailing cables are generally attached to the low-voltage side of the power center or distribution box. The portable cables that feed the power center, or are attached to the high-voltage side, have to be moved when the power center is moved, but they are not moved as often as the trailing cables. The most stationary cables are those that bring power into the mine, for instance, down the borehole and from the borehole to the portable switchhouses. These are the *feeder cables*, and a special type, designated *mine power feeder*, can be used for installations that may not be moved for several years. However, the use of the word “feeder” here is to denote a cable type rather than the application in distribution. Both feeder and portable cables can be used for feeder applications; here the cable supplies two or more major loads.

Similarly, in surface mines, the cables that feed from the switchhouses or unit substations to mobile equipment are trailing cables. Those moved only occasionally that are not connected directly to a machine are portable cables. Stationary cables can be feeder or portable types.

Moving the cable is a recurring task both underground and aboveground. Some trailing cables are placed on reels or spools to facilitate moving. Prime instances of reeled cables are those associated with the reeling devices on-board shuttle cars and mobile cable reels used with surface excavators.

An identifying code related to standard specifications designated by the Insulated Cable Engineers Association (ICEA) is embossed on the cable throughout its entire length. The code includes any federal approval number for flame resistance and approval by the Commonwealth of Pennsylvania (indicated by the letter P preceding the federal approval number). The code also includes identification of the number of power conductors in the cable (e.g., 3/c for three conductors), the approved voltage designation, and the cable type. Fig. 12.4.5 shows the cross sections and components of several popular mine cable types. The three basic cable components are the *conductors, insulation,* and *jacket,* although there may also be fillers, binding, shielding, and armor. Conductors are surrounded by insulation, and the jacket covers the insulation. Cable selection is based on a number of parameters, including, current-carrying ability, voltage rating, and configuration (see Chapter 8 of Morley, 1990, for full details). Components and selection parameters are discussed in the following paragraphs.

In order to obtain the required flexibility, cable conductors are composed of many wires combined into strands, and a number of strands form the conductor. The conductors are either copper or aluminum; the latter is cheaper and lighter but has lower conductivity. Aluminum is sometimes used in feeder cables, but poor flexibility eliminates its use in trailing cables. The cross-sectional area of conductors is important for mechanical

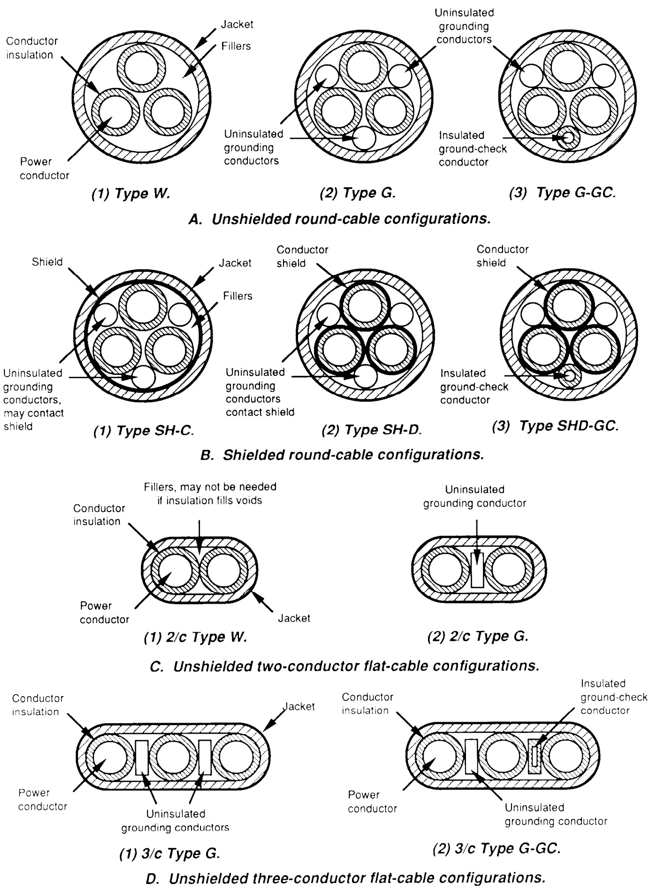

Fig. 12.4.5. Cross-sectional sketches of popular mining cables.

strength and is closely related to the current-carrying capacity. In the United States, both the American Wire Gauge (AWG) and circular-mi1 designations are used.

Insulation is required to withstand stress from heat, voltage, and physical abuse. It must be specially designed not only to protect mine personnel from electric shock but also to separate power and grounding circuits effectively. Excessive heat is particularly destructive to insulating compounds, and the main sources of heat are the ambient temperature and power loss in cable conductor resistance. The maximum, normal, continuous current the conductors can carry safely is directly connected to cable heating, and the term ampacity is often used to describe this current level. The ampacity rating is usually based on the maximum conductor temperature rise, with the temperature limit chosen on the basis of the specified life expectancy of the cable insulation. The *temperature class* (always given in degrees Celsius) describes the maximum allowable sustained conductor temperature in an ambient temperature of 40°C (104°F).

A cable used in a confined space can become overheated with continuous current at the ampacity rating. Perhaps the best example is a cable wound on a reel, either for storage purposes or to increase mining machine mobility. The ampacity of the cable must be derated in these cases; ampacity and derating factor tables are available in federal regulations (Anon., 1981) and other standards (e.g., Anon., 1978; Anon., 1980; and Anon., 1990).

The most common insulating compounds are neoprene, styrene butadiene (SBR), ethylene propylene (EPR), and cross-linked polyethylene (XLP). SBR is used in 600-V trailing-cable insulation. It has good elasticity and flexibility, a 75°C temperature rating, and resists damage by crushing from runovers and rock falls. EPR has replace SBR in many trailing cables because it allows the cable rated voltage to be increased to 2000 V and the temperature rating to 90°C, while maintaining the same insulation thickness as SBR and neoprene. XLP is also rated at 90°C and is used in high-voltage mine-feeder and portable strip mining cables. XLP is rather stiff and is not recommended for reeling applications.

The thickness of a specific insulating material yields the *voltage rating* of the cable, and the most common ratings are 600 V, 2 kV, 5 kV, 8 kV, 15 kV, and 25 kV. The 5-kV, 8-kV, 15-kV, and 25-kV ratings are primarily used for stationary feeder cables and are generally not connected to mining machines, except in surface mines. Usually 4.16-kV distribution requires 5-kV rated cables, 7.2 kV requires 8 kV, and 12.47 kV and 13.2 kV require 15-kV ratings. Utilization voltages of 250 V dc, 440 V ac, and 550 V ac usually call for 600-V or 2-kV cables, and medium-voltage applications need 2-kV insulation.

The main purpose of the cable jacket is to provide protection for the inner components and hold the assembly in the designed configuration. Common jacket materials are neoprene, nitrile-butadiene/polyvinylchloride (NBR/PVC), and chlorosulforated polyethylene (CSP, also called Hypalon). Armored cables are used in some borehole applications; the jacket is a heavy metallic covering that affords extra protection to the conductors and insulation.

Flat cable configurations are commonly used on mining machinery that incorporate cable-reeling devices (e.g., shuttle cars), whereas round cables are typical on all other mining equipment. The flat shape allows an increased length on cable reels and is less susceptible to run-over damage than round cables. Direct-current machines employ either Type W or Type G, where the Type G has a separate grounding conductor. Low-voltage ac mining machines commonly use the unshielded Type G or Type G-GC configuration. Grounding conductors are placed in the interstices between the power conductors in Type G, and a pilot (or ground-check) conductor replaces one of the grounding conductors in the Type G-GC.

There are two basic configurations for shielded cables: SH-D and SH-C. The shields of the SH-D cable surround each insulated conductor; in the SH-C cable, one shield encloses all power conductors and grounding conductors. The SH-D shielding is preferred because the grounding conductors are in intimate contact with the shields. The round shielded-cable configuration, SHD-GC, is also used extensively for medium-voltage and high-voltage trailing cables. Stationary power cables are often mine power feeders of the MP-GC type. Though similar in cross section to SHD-GC, MP-GC cables are less flexible, have higher tensile strength, and use different shield materials. Mine-power feeder cables are also designed for use in boreholes, aerial installations, ducts, and direct burial.

Current and voltage regulation are the major concerns in sizing cable power conductors for an intended application. The effective continuous current through the cable power conductors must be less than the the cable ampacity, with correct derating factors applied. The voltage drop across the distribution and utilization systems must be such that the voltages at the loads are within allowable tolerances. Current is often the determining factor for machine trailing cables, since these cables are almost always short in comparison with the balance of the system. Feeder cables serving many loads, however, are often so long that voltage drop becomes a principal concern. Even though the cable size may be found adequate in terms of ampacity and voltage drop, other factors may enter into the conductor sizing, such as tensile load, weight, and available short-circuit current. An important trailing-cable limitation is weight, as the cable cannot be too heavy for miners to physically handle. This maximum conductor size is usually considered to be 4/0 AWG for three-conductor cables.

There are several methods which can be used to find cable current, including full-load current, effective current demand, and applying a load factor. Regardless of the method employed, it should be realized that typical current requirements of mining machinery change continuously over time and may be described as unsteady in nature. The extremely wide variability of mining conditions makes it difficult to define current levels for any part of a given duty cycle with precision. Thus, unless current measurements are taken, current values can only be estimates, and a worst-case situation, such as assuming full-load current, is recommended to insure actual currents will be less than cable ampacities.

The primary concern for voltage conditions is that satisfactory voltage must be at the machine terminals for proper starting and operation. The allowable voltage tolerance on machine motors is usually ± 10% of rated voltage. Maintaining adequate voltage is one of the more difficult problems in mining, and is often the main constraint on mine expansion from a point of power delivery to the operation. Good practice calls for limiting the maximum voltage drop under normal load conditions to not more than 10% of the nominal system voltage across each voltage level, that is the distribution system, the utilization system, etc.

For a thorough voltage study of a mine, all impedances and all loads in the power system must be known. A circuit diagram must then be prepared and calculations performed to see if there are satisfactory voltage levels at the machines. Analyses are performed not only for normal load conditions but also for the starting of critical motors. If calculated voltages are below those tolerated, system impedance must be reduced, and the most convenient way is to increase cable conductor sizes. The process is continued by trial and error until desired results are obtained. Even with a small system, the computations can become so involved that load-flow computer programs are the only practical solution medium (Trutt and Morley, 1988).

Cable Couplers—Couplers are complex plugs and sockets used throughout the mine distribution system to connect mobile machinery to trailing cables, to connect cables with one another, and to connect cables to power centers, switchhouses, and substations. Their complexity is a direct result of the mine environment in which they are used; they must resist damage, be sturdy enough to withstand repeated use, prevent electrical hazards, be watertight and dustproof, and withstand heat and cold. Some models are rated explosion-proof. The coupling mechanism must be easy to accomplish yet secure. Couplers in the 15-kV, 500-A range are used as connections to switchhouses and mine power centers, to join high-voltage cables, and for high-voltage machines. These high-voltage couplers accommodate three power conductors, one or more grounding conductors, and one or more ground-check conductors. The standard sizes for low-voltage and medium-voltage couplers are 225 A, 400 A, 600 A, 800 A, and 1200 A. Their primary use is to connect mobile equipment to power centers and junction boxes, and to connect cables in the 600 V to 1000 V range. Their construction is sturdy but less complex than high-voltage couplers.

TROLLEY SYSTEMS. The conductors that provide power for electric track-haulage systems form a major part of the power distribution system in many underground mines. Several conductors are used in the trolley circuit: trolley wire, feeder cable, rail-bond cable, and steel track rails. The trolley wire supplies power directly to a rail-mounted vehicle, such as a mine locomotive, through a collector called a shoe or harp. The trolley-wire and collector connection can cause frequent severe arcing that may damage either part and cause an obvious ignition hazard. Proper positioning of the trolley wire, particularly at curves and switches, correct holding force on the collector, and the required amount of lubrication are necessary to minimize arcing.

A feeder cable supplies power to the trolley wire; both must be sized properly to provide enough current-carrying capacity yet minimize heating and voltage drop. In addition, rectifiers must be positioned at adequate intervals to supply the proper voltage to the feeder. The current return path utilizes the steel rails, which much have adequate conductivity to minimize the total system resistance. Rails are laid in segments, and the connections between them can loosen or the rails could break; hence, rail-bond cable is installed to maintain continuity. Rail-bond cable is attached at each rail joint and, as a further precaution, between the two rails at specified intervals (cross bonds).

SURFACE OVERHEAD LINES. The most common method used for surface electric power transmission and distribution is overhead conductors. Although their size and detailed construction can vary widely, overhead power lines normally consist of bare metallic conductors supported by insulators from some elevated structure. The conductors use air space for insulation over most of their length, while their elevation protects them from contact with personnel and equipment.

Overhead line installations use numerous types of conductor arrangements and support structures in various combinations. Utility systems range from single wooden poles carrying conductors at low voltages to self-supporting steel towers bearing major transmission lines. Wooden-pole lines with or without crossarms, for example, may be part of a single-phase or three-phase distribution system with voltages of 2.3 to 35 kV. By contrast, steel towers often carry lines transmitting large amounts of power at 115 kV and up, connecting major load centers of a utility company grid (Anon., 1964b). Utility-owned lines are commonly classified by function, which is related to voltage. There is no utility-wide standard for voltage classification, but the system typically used differs from the classification employed in the mining industry.

Overhead conductors are arranged in various configurations to reduce line-to-line contacts due to wind, ice loading, or sudden loss of ice load, and may include different combinations of power, neutral, and static conductors. Aluminum conductors with steel reinforcement (ACSR) are commonly used because of their strength and relatively low price, but special applications may call for such other materials as copper.

The types of overhead line installations used for mining applications are similar to those in utility distribution systems. Typical are pole lines to supply equipment in surface mining and lines feeding surface facilities related to mining. These lines are normally installed on single wooden poles and may carry only two conductors, as in single-phase supplies, or have up to six conductors, including three power, one grounding conductor, one ground check (pilot), and one static. The pole lines may be relatively permanent installations such as those feeding plants, shops, and other surface facilities, and long-term pit baselines or ring mains. Sometimes, temporary poles are mounted in portable bases (such as concrete-filled tires) for ease of relocation, and these are commonly used in surface mining operations to carry power into the pit. Conductors are again usually ACSR, but hard-drawn copper is used where blast damage is a problem (Anon., 1978).

12.4.4 POWER SUPPLY

12.4.4.1 Utilities

As utility companies are the principal power supplier for mines, an understanding of utility system power transmission and distribution is important. Often this system greatly affects the power available to the mine, including voltage regulation, system capacity during power failures in the mine, and overvoltage occurrences. In a nearby substation, power from a generating station is transformed up to a transmission voltage, commonly 69,000 V or more (Anon., 1986). This power is carried on transmission lines to major load areas, either supplying large industrial users directly or powering the utility's own distribution substations. Distribution substations step the voltage down, this time to a primary distribution level ranging from 4160 to 34,500 V, but most often at 12,470 or 13,200 V. The utility service, therefore, can be any of the following standard values: 138, 115, 69, 46, 34.5, 23, 13.8, 12.47, 6.9, 4.16, and 1.4 kV. Generally, the delivered voltage ranges from 23 to 138 kV, but others such as 480, 2300, and 7200 V are also found. What is available to the mine depends on whether the possible connection is to the power company transmission system, a primary distribution system, or a distribution transformer.

It is the responsibility of the mining company to select that voltage best suited to its needs. Primarily, the choice depends on the amount of power purchased. It is not safe to assume that the power company has the capability to serve a large mine complex from existing primary distribution lines or even from the transmission system. The problem stems from the fluctuating nature of mine loads. For example, large excavators in surface mines can require high peak power for a short time followed by regenerative peak power, cycling within the span of 45 sec. The fluctuating load may create voltage and frequency variations beyond the limit set for other utility customers. Accordingly, most large draglines and shovels require power from 69-kV to 138-kV transmission systems to get adequate operational capacity, and the construction of several miles of transmission equipment can result in a sizable cost for the mine budget.

Regardless of where the mine substation is tied into the utility complex and who owns that equipment, its outgoing circuits will here be termed the *mine primary distribution system,* or simply distribution. The incoming power will most often be referred to as the *transmission system.*

12.4.4.2 Generation

The purchase of electric power from a utility company is generally less expensive and more reliable than operating a small generating plant. However, a mine may be located in a remote area, a long distance from a utility transmission or distribution system. Thus self-generated electric power may be the only feasible alternative. Generating plants for mines are typically powered by diesel engines or by coal-, oil-, or gas-fired boilers. In some instances, even water-powered plants have been used. It should also be noted that some mines that purchase electric power also use diesel-powered generators for emergency electric power. If the primary source of power is lost, a diesel-powered generator can be quickly started and used to supply emergency power to critical equipment, such as ventilation fans and personnel or elevator hoists.

12.4.5 POWER DISTRIBUTION ARRANGEMENTS

12.4.5.1 Basic Arrangements

The basic distribution arrangements available for industrial applications are radial, secondary-selective, primary-selective, primary-loop, and secondary-spot networks (Anon., 1986). Radial systems are the most popular arrangements in mining, though other configurations can be found where special circumstances call for greater system reliability (Anon., 1976). Surface mines have, of course, greater flexibility than underground mines and employ a wider range of distribution arrangements. Secondary-spot networks, which are the most popular system for large facilities in other industries, are uncommon but could be applied to preparation and milling plants. The following descriptions of the main distribution patterns are based on IEEE definitions.

RADIAL SYSTEM. *Radial distribution* in its simplest form consists of a single power source and substation supplying all equipment. Radial systems are the least expensive to install as there is no duplication of equipment, and they can be expanded easily by extending the primary feeders. A prime disadvantage is tied to their simplicity; should a primary component fail or need service, the entire system is down.

An *expanded radial system,* or load-center radial, is commonly used in the mining industry. As in Fig. 12.4.1, two or more voltages levels are established, but the feeders form a tree-like structure spreading out from the source. This system has the advantages of the simple system and others too. If the load centers or distribution transformers are placed as close as practical to the actual loads, most distribution will be at the higher voltage. This allows decreased conductor investment, lower electrical losses, and better voltage regulation.

SECONDARY-SELECTIVE SYSTEM. In a *secondary-selective system,* a pair of substation secondaries are connected through a normally open tie circuit breaker. The arrangement allows greater reliability and flexibility than a radial system. Generally, the distribution is radial from either substation. If a primary feeder or substation fails, the bad circuit can be removed from service, and the tie breaker is closed either manually or automatically. Maintenance and repair of either primary circuit is possible without creating a power outage by shedding nonessential loads for the period of reduced capacity operation. Economics often justify this double-ended arrangement if substation requirements are above 5000 kVA.

OTHER DISTRIBUTION SYSTEMS. In the *primary-selective system,* each substation can receive power by switching from either of two separate primary feeders. During normal service, each feeder should handle one-half the load. The system is simple and reliable, but costs are somewhat higher than radial or secondary-selective because of the duplication of primary equipment.

Though found in some mines, the *primary-loop system* is not considered good practice. The cost can be slightly less than primary selective, but this configuration can result in dangerous conditions when a primary-feeder failure occurs. A failed portion can be energized at either side creating a hazard to maintenance personnel.

In the *secondary-spot network,* two or more distribution transformers are supplied by separate primary distribution feeders. The secondaries are tied together through special circuit breakers, called network protectors, to a secondary bus. Radial secondary feeders are tapped to the bus and feed the loads. This system creates the most reliable distribution system available for industrial plants. However, the arrangement is expensive, and the reliability gain is not warranted for the majority of mining applications.

12.4.5.2 Surface Mine Distribution

Mine power systems can be divided into three categories depending upon the purpose of a specific portion: (1) transmission or subtransmission, (2) distribution, and (3) utilization. Power system installations can vary greatly at distribution and

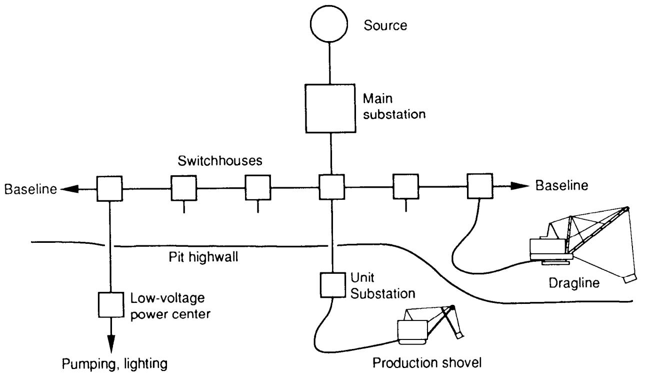

Fig. 12.4.6. Simple all-cable radial distribution system applied to strip mining.

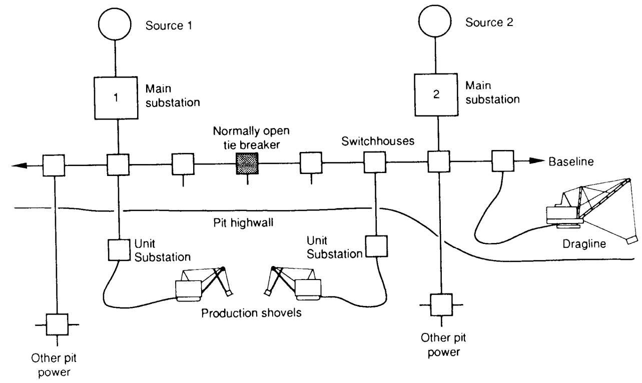

Fig. 12.4.7. Secondary-selective all-cable distribution system applied to strip mining.

utilization levels, but in some mines, distribution and utilization can be the same system.

The location of the mine substation is usually an economic compromise between the cost of running transmission lines and power losses in primary distribution. From the main substation, power is distributed to the various centers of load in the operation. However, individual loads or complexes, such as preparation plants and other surface facilities, may have large power requirements or be so isolated that primary distribution operation is not practical. In these cases, or for safety reasons, incoming utility transmission should be extended close to the load. The extension is designated a subtransmission system, and the conductors are usually suspended as overhead lines. Subtransmission commonly requires a switchyard of high-voltage switching apparatus for power tapping.

Subtransmission circuits, primary switchyards, and main substations are almost always located in areas unaffected by the mining operation. The main substation is where the grounding system for the mine is established. This ground is carried along the power lines through overhead conductors or in cables and is connected to the frames of all mobile mining equipment.

Mine power distribution, in its simplest radial form, has already been shown in Fig. 12.4.1 to consist of a substation, distribution, and a power center feeding the mining equipment. The arrangement is very common in small surface operations where the distribution voltage is commonly 4160 V but can be 2300 V in older equipment. In the smallest mines, power is purchased at low-voltage utilization (often 480 V) and fed to a distribution box to which motors and equipment are connected. At times, simple radial systems are employed in large surface mines where only one machine must be served or an extensive primary distribution network cannot be established, as in some contour operations.

The great majority of strip mines employ radial distribution, but secondary-selective can also be found. Simplified examples of these systems are provided in Figs. 12.4.6 through 12.4.9. In all configurations, a portion of the primary distribution is established as a baseline or bus. The baseline is usually located on the highwall, paralleling the pit for the entire length of the cut. Its location is typically maintained 1500 ft (457 m) ahead of the pit, and it is moved as the pit advances (Anon., 1976). Distribution continues from the baseline to the mining equipment, with the connections maintained at regular intervals. As the machines move along the pit, the baseline connections are changed to other convenient locations.

The baseline can consist of overhead polelines as shown in Fig. 12.4.9. The overhead poleline plus cable arrangement is

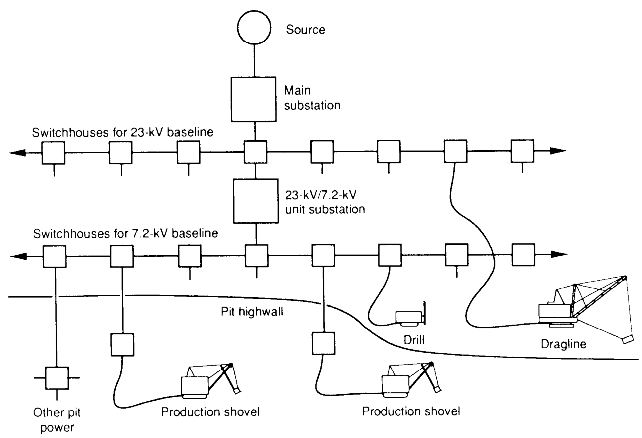

Fig. 12.4.8. Dual-baseline all-cable radial distribution system applied to strip mining.

common in older mining operations, especially when utilization is at 7200 V or less (Anon., 1976). Typical spacing between poles, or line span, is 200 ft (60 m), and drop points are noted in the figure by triangles. These are terminations between the overhead conductors and the cables, mounted about 8 ft (2.4 m) above the ground on poles. The drop points are spaced at regular intervals of around 1000 to 1500 ft (305 to 457 m). Cables connected to the drop points deliver power to skid-mounted switchhouses located on the highwall or in the pit. The skids can be either boat design with flat bottoms or have fabricated runners, depending upon the allowable bearing pressure of the mine terrain. Cable couplers are commonly used for both feeder and trailing-cable connections. Disconnect and circuit-protection functions are required for each distribution load, and double switchhouses (two-breaker skids) are frequently employed for two loads. Unit substations often contain internal circuit protection on the incoming side and thus do not require a breaker skid.

Trailing cables are usually 1000 ft (305 m) in length, although lengths to 2000 ft (610 m) can be found. When longer cables are necessary to reach a breaker skid, in-line coupling systems can be used, and these are commonly mounted on small skids for easy movement. Trailing-cable handling for stripping equipment is often assisted by cable reels mounted on skids or self-propelled carriers. Large excavators can require the self-propelled variety.

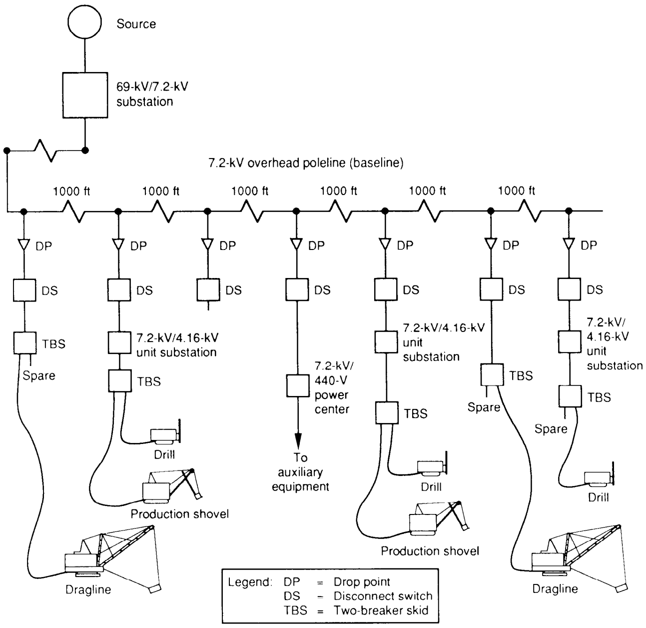

Fig. 12.4.9. Radial distribution system in strip mining using overhead polelines.

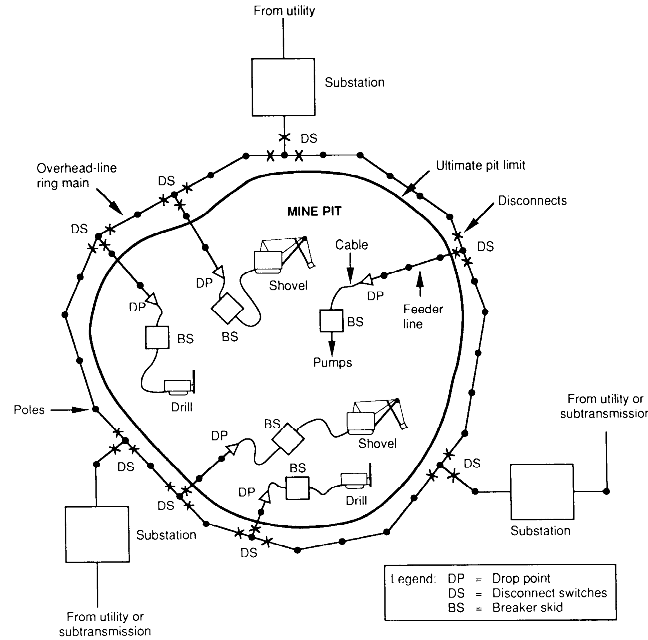

Fig. 12.4.10. Distribution system for an open pit mine illustrating a ring main.

The layout for all-cable mine distribution (Figs. 12.4.6 through 12.4.8) is very similar to that just described. In this case, however, the baseline is assembled using cable-interconnected switchhouses. The common approach is to use disconnect skids with three internal switches in the baseline and have separate breaker skids in line with the cables feeding the machinery. Another approach is to combine the single breaker skids into the baseline switchhouses.

When a secondary-selective configuration is used, as shown in Fig. 12.4.7, a normally open-tie circuit breaker is placed in the baseline in a location approximately equidistant from the main substations. In some operations, the two substations and the tie circuit breaker may be in the same location with two feeders running from the substation area to the baseline. More than two main substations may be established in very large operations.

Distribution voltage for the surface mine may be 7.2, 13, 23, and to a lesser extent 4.16 kV. Regardless of the level, drills and production shovels usually operate at 7200 or 4160 V. Therefore, when higher distribution levels are needed, portable unit substations are commonly used in the pit. One instance would be when the load created by a large machine is several times that for auxiliary machines. Another method is to establish two baselines on the highwall for two distribution voltages, as shown in Fig. 12.4.8. Here, a large unit substation interconnects the two baselines. Even in this situation, as can be seen in the preceding drawings, low-voltage unit substations or power centers are often required for 480-V auxiliary equipment.

The primary purpose of any distribution scheme in a surface mine is to provide a flexible, easily moved or modified power source for the highly mobile mining equipment. System designs must also be considered as an integral part of the total mine operation. Those described have these objectives in mind. The distribution system in any surface or underground mine that serves portable equipment is subject to damage from the mining machinery itself, and as a result, the system must be designed with optimum flexibility and consideration for personnel safety.

Open pit power systems are quite similar to those of strip mines with one main exception: distribution typically establishes a ring bus or main that partially or completely encloses the pit. Radial ties to the bus complete the circuit to switchhouses located in the pit, and portable equipment again uses shielded trailing cables. An example is shown in Fig. 12.4.10. Distribution voltage is normally 4.16 kV, but 7.2 (or 6.9) and 13.8 kV are sometimes used. Unit substations are employed if equipment voltages are lower. The distribution portion of the system is almost always constructed with overhead lines.

12.4.5.3 Underground Mine Distribution

As shown in Fig. 12.4.11, underground mine power systems are somewhat more complicated than those for surface applications. A coal-mine power system is depicted as an example. By the nature of the mine and its service requirements, distribution must almost always be radial; the freedom in routing distribution enjoyed by surface mines is not available underground. For increased reliability, secondary-selective main substations are employed (Fig. 12.4.12). Distribution voltage is most commonly 7200 V; however, older 4160 V systems can still be found, and 12,470 V has increased in popularity in recent years.

Power and mine grounding are fed underground in insulated cables, either through a shaft or borehole or an intake entry. In coal mines, these cables are required to terminate in disconnect switches within 500 ft (152 m) of the point of power entry into the coal seam. These switches allow total removal of underground power in an emergency. From the disconnects, which may be part of a switchhouse, the power is distributed through cables to power centers or rectifiers that are located as close to the machinery as practical. All the cables on high-voltage circuits, usually involving only distribution, have shielding around each power conductor.

The prime load concentrations in underground mining are created by the mining sections. Distribution terminates at the section power center that is a transformer combined with a

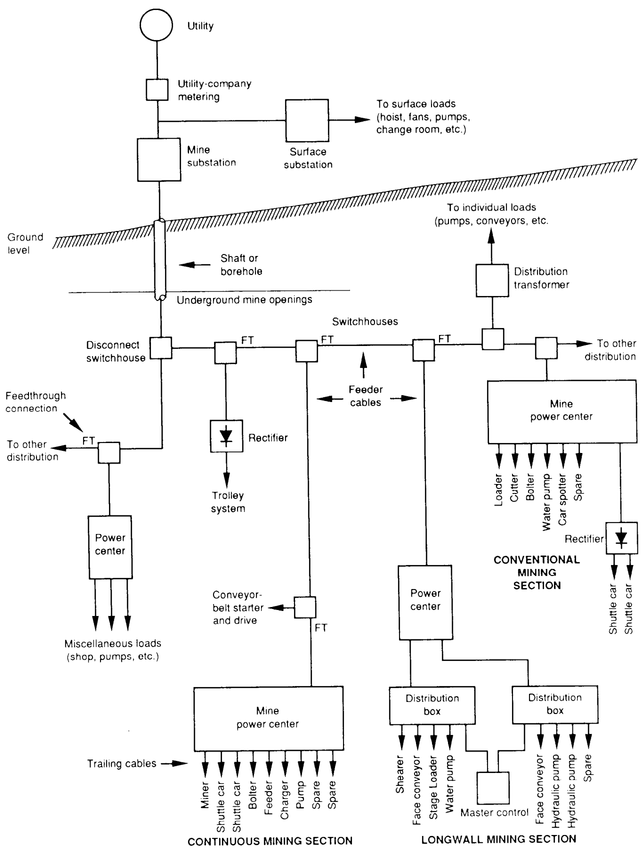

Fig. 12.4.11. Simplified radial distribution system for an underground coal mine.

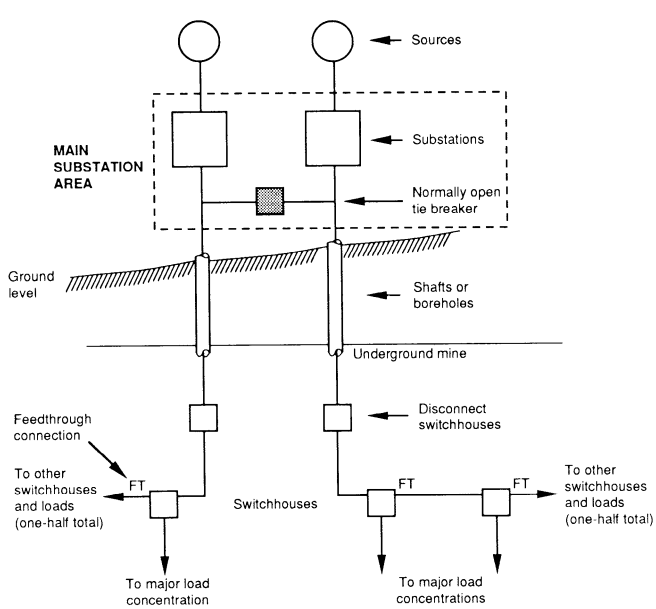

Fig. 12.4.12. Secondary-selective distribution applied to an underground mine.

utilization bus and protective circuitry. From this, several face machines are powered through couplers and trailing cables.

If belt haulage is used, distribution transformers are located close to all major conveyor belt drives and are referred to as belt transformers. After transformation, power is supplied through starter circuitry to the drive motors. With rail haulage, distribution terminates at rectifiers that contain a transformer and rectifier combination. The rectifiers are located in an entry or crosscut just off the railway. Direct-current power is then supplied through circuit breakers to an overhead conductor or trolley wire and the rail, with additional rectifiers located at regular intervals along the rail system. For further protection, the trolley wire is divided into electrically isolated segments. The typical rectifier supplies the ends of two segments of trolley wire, and each feeder has its own protective circuitry to detect malfunctions. In some mines, dc face equipment and small dc motors are powered from the trolley system through a fused connection (or nip) to the trolley conductor and rail. The dc distribution can also serve large motors directly through switchgear; however, this practice is rare.

All power equipment used underground must be rugged, portable, self-contained, and specifically designed for installation and operation in limited spaces. In addition, all equipment and the cables connecting them must be protected against any failures that could cause electrical hazards to personnel. This is provided primarily by protective relaying built into each system part, with redundancy to maximize safety.

12.4.5.4 Mine Grounding Systems

The concept of protecting mine electrical equipment and personnel against the consequences of electrical failures by suitable grounding has existed since electricity was first introduced into mines. As early as 1916, the US Bureau of Mines recommended equipment frame grounding as a means of preventing electrical shock to miners working on or around electrical equipment (Clark and Means, 1916). For the mining industry, a suitable grounding system has always been a difficult problem, more complex and difficult than in other industries.

GROUND BEDS. For mine usage, the electrical distribution cables and overhead transmission circuits carry into the mine one or more grounding *conductors* in addition to the line conductors. Each piece of ac equipment has its frame solidly connected via these grounding conductors to a safety ground bed commonly located near the main substation and consisting of buried horizontal conductors, driven rods, or a combination of both. The neutral of the substation-transformer secondary is also connected to the safety ground bed through the neutral grounding resistor (Trasky, 1965).

The substation actually requires two ground beds, seen in Fig. 12.4.4, maintained some distance apart. Lightning discharges and other transformer primary surging conditions are directed to the system or station ground. The system and safety grounds must be kept separate so current flow intended for one will not enter the other. It is essential for the safe operation of the mine power system that the resistance of the beds be maintained at 5.0 Ω or less (Anon., 1964a; King et al., 1978; Lordi, 1963). A ground bed with this resistance range is often termed a low-resistance ground bed.

GROUNDING IN UNDERGROUND MINING. Early practice in underground mining was to drive a metal rod into the mine floor and use that as a ground. In almost every case, this arrangement proved to be totally unacceptable. With the exception of pumps, the contact resistance of mining machinery with the mine floor also proved to be too high for adequate grounding. Rail-haulage track systems, even though often poorly bonded, showed much lower resistance to ground than most metallic rods driven specifically for that purpose. As a solution, Griffith and Gleim (1943) stated that consideration should be given to a grounding circuit carried to the outside of the mine. Present mine practice adheres to this concept.

A simple form of grounding systems in use in underground mines today is described as follows. After transformation, three-phase ac power enters the mine to supply the various three-phase ac loads. Some of the ac power is converted to dc at rectifier stations to power the trolley system and occasionally dc face equipment. More often, any dc face machinery is powered from rectifiers located in the mine section. Except for the trolley system, all dc as well as the ac equipment frames are connected to a common junction that is tied to the surface safety ground bed. In order for the system to be effective, grounding conductors must be continuous, and this continuity must be verified.

Trolley locomotives generally utilize the overhead trolley wires as the positive conductor and the tracks as the negative. Neither of these is tied to the rectifier-station frame ground. However, because the track is in contact with the mine floor, the negative conductor for the trolley system is grounded. The dc system that supplies power to face equipment normally employs trailing cables that have neither the negative nor positive conductor grounded.

At each transformation step within the power system, such as in a power center, an additional neutral point must be established on the transformer secondary. The neutral is tied through a grounding resistor to the equipment frame, and from there through the grounding conductors to the safety ground bed.

GROUNDING IN SURFACE MINES. The typical grounding system for a surface mine is similar to that for underground mining. One or more substations with resistance-grounded secondaries are employed to transform the incoming utility voltage to the lower potential used by the mining machines. At this level, pit distribution is carried on overhead lines or cables to supply switchhouses located near the particular piece of equipment. A trailing cable completes the power circuit from the switchhouse to the machine. A switchhouse is sometimes connected by cable to a portable substation which supplies lower voltage power to production, auxiliary, or lighting equipment. Substation grounding includes both a system and a safety ground bed, each physically removed and electrically isolated from the other.

12.4.5.5 Protective Relaying In Mining

There are two groups of protective relaying equipment within a typical power system: primary and backup. Primary relaying has the goal of clearing all faults and overloads and aims to isolate offending power-system segments with minimum interruption to the system balance. Backup relaying operates only in the event of a primary relaying failure; its action is only for uncleared faults. For overload, short-circuit, or ground-fault relaying in mining, both groups are used extensively to the point of redundance.

ZONES OF PROTECTION. Protection to the entire system is principally related to primary relaying and is accomplished by establishing zones of protection. Each zone has an associated circuit breaker and fusible disconnect, or fuses with the required sensing devices, and adjacent zones overlap (Mason, 1956). If a failure occurs within an individual zone, only the switching apparatus within that zone should open. If there was no overlap, there could be an unprotected region in the system in some situations; a failure within this area would produce no safety tripping. The coordination of protective relaying between the zones is extremely important. The aim is to isolate faults downstream from the power source without disturbing upstream zones. Unfortunately, obtaining this coordination is perhaps the most serious problem of relaying.

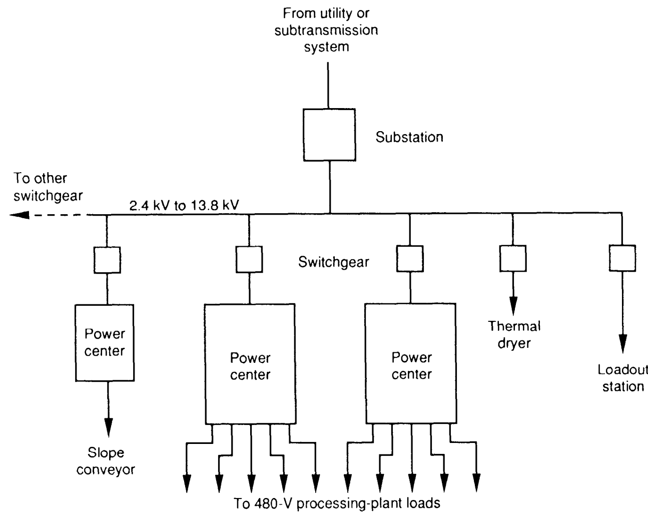

Fig. 12.4.13. Simple radial distribution applied to a mineral processing plant.

The objective of coordination is to determine the optimum characteristics, ratings, and settings for the protective relaying devices (Anon., 1986); consequently, fault analysis of the system must be involved. The two common coordination schemes that are utilized are pickup setting and time. One technique or the other may be applied to provide coordination between zones in the mine power system; at times, a combination might be needed. The design of this protective relaying system can be a substantial problem, as exemplified by the fact that many engineers consider protective relaying more of an art than science.

12.4.5.6 Mineral Processing Plants

The surface activities of any mine, which may include shops, change rooms, offices, ventilation fans, hoisting equipment, processing plants, and so forth, can have large power requirements. For safety, these facilities should at least have an isolated power source and, at times, a separate substation.

In mineral processing plants, the distribution arrangements are almost always expanded radial or secondary-selective (Lordi, 1956). Representative system layouts are shown in Figs. 12.4.13 and 12.4.14. In both, distribution is at 2.4 to 13.8 kV, with 4160 V the most common. Power is distributed at one of these levels to centers of electric load. This power may be used directly for high-voltage motors, but usually the voltage is stepped down to supply groups of motors or single high-horsepower motors. The power centers must be in an elevated location or totally enclosed. The rooms used for these and other electrical components may also be pressurized to exclude coal dust.

The most popular voltage for processing plant utilization is 480 V. This voltage is used to drive all motors throughout the plant except those with high horsepower demands, such as centrifugal driers and large fan drives where 2300 or 4160 V is commonly employed. These higher voltages may also be preferred for any motor that requires continuous service or independence from the power-center loads. Most modern mineral processing plants use group motor control instead of individually housed control units, since this method facilitates maintenance and enables the interlocking of the various motor functions re-

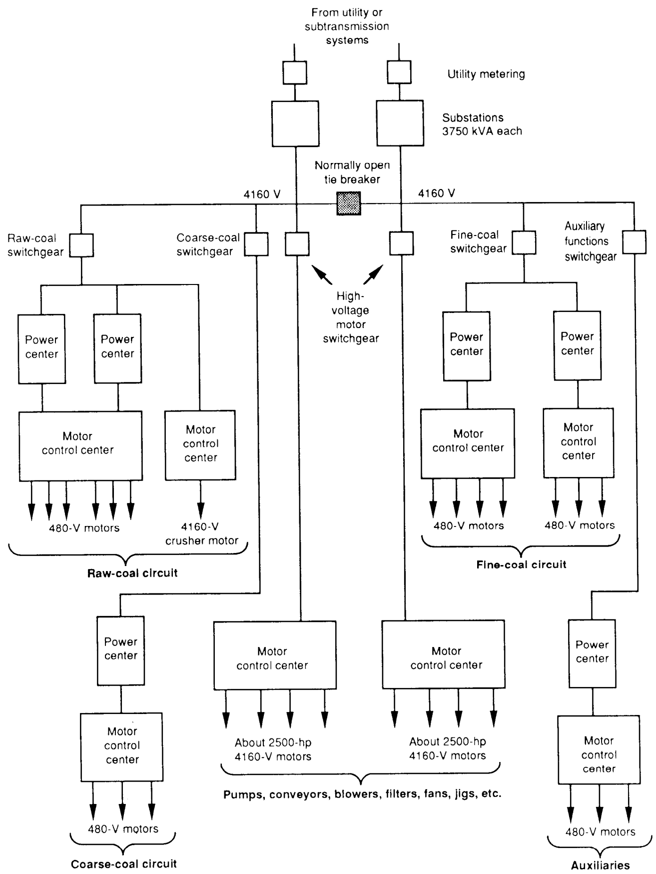

Fig. 12.4.14. Secondary-selective distribution applied to a coal processing plant.

quired for semi-automatic facilities. All manual controls, indicating lights, and so on are grouped in one central operating panel to allow easy access and visual indication of plant operation. The panel is often called a motor control center, as noted in Figs. 12.4.13 and 12.4.14.

12.4.6 SPECIAL CONCERNS

12.4.6.1 Mine Motors

Mine motor functions can usually be divided into two groups: auxiliary and face (Tsivitse, 1969). Auxiliary motors are employed for fans, pumps, conveyors, hoists, compressors, and other vital functions in mines aside from the actual process of mineral extraction. These operations commonly call for direct use of general purpose industrial motors. Face motors are associated with mining equipment, such as continuous miners, shuttle cars, loaders, roof bolters, and locomotives, where they are mounted in the machine. Their duty usually involves cyclic or random loading as well as the possibility of shock loading. The result is higher electrical and mechanical demands than those placed on equipment in other industrial applications. Because mining equipment operates at the tail end of the distribution system, voltage drop becomes an important factor in the selection and utilization of motors. This is more critical for ac equipment than it is for dc.

The horsepower rating for a motor is based on the maximum winding temperature for a continuous duty or intermittent duty. Continuous duty is quite obvious and refers to a substantially constant load (torque) over an indefinitely long period. Intermittent duty, however, means that loading is at alternate intervals of load and no load (motor running idle); load and off; or load, no load, then off (Lloyd, 1969). Each portion of the cycle is equal, and the time interval is specified. In some cases, face-motor intermittent duty is given a definite time interval of 15, 30, or 60 min, but it is often just listed as mine duty (Hugus, Buss, and Parker, 1955; Tsivitse, 1969).

Alternating-current motors in mining machines normally have four or six poles with synchronous speeds of 1800 and 1200 rpm, whereas dc motors often have comparable base speeds of 1750 and 1175 rpm. These are high enough to provide adequate horsepower, but low enough to have reasonable reliability. Series-wound motors for traction are built to withstand rotation up to 6000 rpm, such as might occur during maintenance.

Mine motors are presently standardized at a 90°C (194°F) allowable temperature rise based on a 25°C (77°F) ambient temperature. Older motors may have a 75°C (167°F) temperature-rise limit but are still based on the 25°C (77°F) ambient. The base temperature closely fits the typical conditions found in underground operations. The allowable temperature rise is effective to elevations of 3300 ft (1000 m); above this, the allowed temperature rise is reduced 1% for every 330 ft (100 m). In addition, for maximum ambient temperatures exceeding 25°C (77°F), the allowable rise must also be reduced by the difference above the base temperature. For example, a motor with 75°C (167°F) temperature-rise insulation, operating at 6600-ft (2000-m) elevation in 30°C (86°F) ambient temperature, has only a 62.5°C (144.5°F) allowable temperature rise.

Although the vast majority of mine motors are three-phase and dc, single-phase motors do find some use for auxiliary functions aside from the mining process. As a general rule, single-phase induction motors have one running speed and require a separate means for starting rotation, usually a separate stator or starting winding. Motors are classified by their starting method. The most common techniques are split-phase and capacitor-start.

12.4.6.2 Permissibility and Hazard Reduction

Any industrial area in which flammable or explosive gases, vapors, and dust can be encountered is designated as a hazardous location. Since the occurrence of this hazard depends upon the presence of an ignitable mixture, an ignition source, and contact between them, the chance of ignition is always present when electrical apparatus is used in hazardous atmospheres. The possibility of ignition cannot be totally eliminated in any portion of an underground mine, nor in selected parts of surface mines and surface facilities such as preparation plants. Hence electrical hazard-reduction techniques must be applied in these areas to protect both personnel and equipment.

TERMINOLOGY. Important measures used to reduce incendive hazards in underground mines include provision of adequate ventilation, control of flammable coal dust through mandatory rock dusting and watering, and the regulation of equipment. There are specific terms used by federal regulatory agencies in the United States for electrical equipment intended for use in underground gassy mines (Anon., 1981).

Accessories mean associated electrical equipment such as a distribution or splice box that is not an integral part of the machine. *Approval* applies to completely assembled electrical machines and accessories; it means that a formal document has been issued by the regulatory agency which states that the machine or accessory has met the applicable requirements of the regulation. An *approval plate* is then attached to the approved machine or accessory identifying it as suitable for use in hazardous locations. Such equipment is subsequently referred to as *permissible equipment*. This process is mandatory for all electrical equipment used in the face area and in return air of gassy mines. The term *certification* applies to an electrical component, that is, an integral part of an electrical machine or accessory that is essential to the functioning of the machine. Certification means that a formal written notification has been issued by the regulatory agency, stating that the component complies with federal requirements and is suitable for incorporation in a permissible machine. *Acceptance* is connected to flame-resistance requirements and is applied to auxiliary equipment such as a cable, hose, or belt. Acceptance means that written notification has been received from the regulatory agency, designating the equipment as meeting requirements for flame resistance. *Acceptance marking* is the identification that appears on the equipment. *Intrinsically safe* identifies equipment that is incapable of releasing enough electrical or thermal energy under normal or abnormal circumstances to cause ignition of a flammable mixture.

Hazardous locations in US surface mines and surface portions of underground mines are often classified by guidelines specified in the National Electrical Code, Article 500 (Anon., 1990). In this classification system, the nature of the hazard and the degree of hazard are the main considerations, and a location is specified by a class, group, and division designation. The class refers to the generic nature of the hazardous material, and the following are of specific importance in mining:

Class I: locations containing flammable gases or vapors that may be present in the air in sufficient quantity to produce an explosive or ignitable mixture.

Class II: locations having combustible dust in quantities that can cause a hazard. The group designation is a subclassification and refers to the nature of the hazard. Each group contains a listing of materials that present the same general hazard. The groups of interest in coal mining include:

Group B: atmospheres containing hydrogen or gases or vapors of equivalent hazard such as manufactured gas.

Group D: atmospheres containing gasoline, hexane, naptha, benzine, butane, propane, alcohol, acetone, benzol, lacquer-solvent vapors, or natural gas (methane).

Group F: atmospheres containing carbon black, coal, or coke dust. When more than one hazard is involved, the class and group describing the most serious situation usually applies. The division defines the probability of a hazardous material being present in an ignitable concentration:

Division 1: locations where the hazards exist continuously, intermittently, periodically, or where they may exist during maintenance or equipment failures.

Division 2: locations where hazards are presumed to exist only under abnormal conditions.

HAZARD REDUCTION METHODS. Hazard reduction is a practice in low probabilities, specifically low incremental probabilities, and relies on the fact that a safe electrical installation in a hazardous location does not significantly raise the probability of fire or explosion above that existing without the equipment (Magison, 1978). The methods adopted to reduce hazards are based on the principle that the occurrence of a hazard depends upon the presence of an ignitable substance, an ignition source, and contact between them. The methods focus on one or another of these interrelated factors. Among hazard-reduction methods used in or around mines, explosion-proof and dust-ignition-proof containers are the most important. Here internal ignition is possible, but the resulting combustion is so well controlled and contained that hazard is prevented.

Explosion-proof Enclosures—The explosion-proof enclosures used in US mines comply with applicable federal design requirements (Anon., 1981). They are able to contain internal explosions of methane-air mixtures without undergoing damage or excessive distortion of its walls or covers, without causing an ignition of a surrounding methane-air mixture, and without discharging flame from the inside to the outside of the enclosure. Outside the United States, the same definition often refers to flameproof enclosures, but the words "discharge of flame" are omitted (Anon., 1971). Although the terms flameproof and explosion-proof commonly have the same connotation, flameproof enclosures are not presently allowed in US underground gassy mines unless they also meet the federal requirements.

Explosion-proof enclosures are found on all electrically powered face mining machines in US gassy mines and all motor applications in Class I, Division 1 locations in all US industries. These enclosures have heavy-walled cast or welded construction and bolted or threaded close-fitting flanges; however, they are not necessarily vapor tight. Ignitable gas may enter a properly secured explosion-proof enclosure in several ways (Jones, Altimus, and Myers, 1971). Enclosures on machines allowed to stand for several hours in a gas-filled place can become completely filled with that gas from diffusion through openings, even though those openings are very small. Another process, "breathing," results from the expansion of the enclosure atmosphere during operation and contraction as it cools at rest. Air is forced out during expansion, and the atmosphere outside including any gas present around the machine is drawn in when cooling. Gas may also enter the enclosure when covers are removed for inspection and repair.

Ignition of the explosive gas by electrical means can be triggered in several ways. Arcs of sufficient energy, termed incendive, can result from normal or abnormal operation of electrical devices. Another source of ignition is contact with hot surfaces, but this depends on the surface heating sufficiently above the auto-ignition temperature (Magison, 1978). One reason for a hot surface would be excessive current through fine conductors, such as in a damaged cable.

Although explosion-proof enclosures have been researched since the turn of the century, little concrete information has been gained about the phenomena that make them effective, but it is accepted that cooling and inhibition are two of the more probable mechanisms (Phillips, 1971). The hypothesis can be explained considering that an explosive methane-air mixture can exist both inside and outside the chamber. After an explosion is initiated inside the enclosure, a flame front propagates toward the chamber walls, burning the available combustible material. This raises the temperature and pressure inside the chamber, and unburned gas, then heated burned gas, are forced through the flange gap. The jet of heated gas is cooled first by heat transfer within the flange gap. As it exits from the enclosure, it may be further cooled by adiabatic expansion into the surrounding atmosphere; during this process, combustible gas from the outside methane-air mixture is also entrained in the jet. If the jet entrains an excessive amount of combustible gas in this last phase, the heat supplied by the jet will be less than that lost through cooling, and no ignition of the outside gas will occur.

The action within the flange gap is believed to go beyond cooling. Combustion of a gas-air mixture does not proceed with a single chemical reaction but rather a chain of reactions. If the chain carriers or active molecules from a preceding step are inhibited, for instance by contact with the flange wall, then combustion stops. This theory is also used to explain the protection properties of flame safety lamps.

Reducing Dust Hazards—In Class II hazardous locations, the types of enclosures in common use are dust-ignition-proof and dust-tight. Pressurized and intrinsically safe systems are used less frequently (Magison, 1978). The objective of these enclosures is to keep dust away from ignition sources and to prevent ignition of layered dust. Dust-ignition-proof enclosures meeting Underwriters Laboratories, Inc. requirements conform to both objectives (Anon., 1974). The requirements are similar to those for explosion-proof containers but less severe. The goal is to provide an enclosure that will prevent hot particles from escaping and dust from entering. The maximum allowable temperature for the surface of such equipment is 150°C (302°F) for equipment that can experience overload and 200°C (392°F) for equipment that will not usually overload. Dust-ignition-proof motors are suitable for both Division-l and Division-2 locations.

Dust-tight enclosures are intended only for Division 2 locations. The standards for their dust-tight construction are less restrictive than for equipment in Division 1 locations, but they undergo the same tests by the Underwriters Laboratories, Inc. (Anon., 1973).

OTHER HAZARD REDUCTION METHODS. *Increased safety* is an approach in hazard reduction in which special design considerations are given to ensure an extremely low probability of electrical or mechanical breakdown that could produce a spark or temperature rise. Like intrinsic safety, the principle is to remove the ignition source. The technique is widely used in West Germany and is frequently applied in mine lighting fixtures. Increased safety designs include such features as large spacings and creepage distances between live parts, protection against hot spots, large rotor-stator clearances for motors, superior amounts and quality of insulation, and special enclosures and fastenings to prevent unauthorized entry.

Immersion systems rely on controlled environments to reduce or remove hazardous atmospheres from ignition sources. In sealing or potting methods, granular material such as sand is used to encapsulate the potential hazard. This does not actually isolate the source but quenches any incipient flame, thus preventing any effective contact between the source and the hazardous atmosphere. Purging or pressurized systems use liquid (oil) or inert gas to provide protection. The pressurized approach is rarely used in mining applications.

The basic problem with most of these hazard-reduction methods is their complexity. The overriding considerations for electrical hazard reduction in mining are robustness, interchangeability, and mobility; hence there is no indication that bolted explosion-proof enclosures will lose their popularity in the near future.

INTRINSIC SAFETY. As previously defined, intrinsically safe equipment is incapable, under normal or abnormal conditions, of releasing sufficient energy to cause an ignition of the most ignitable methane-air atmosphere (Widginton, 1968). The principle applies to complete electrical circuits and not to individual components. The advantage is that safety is inherent in the design and is difficult to defeat. Normal conditions are taken to include the effect of extreme power-supply and environmental variations (within the equipment specifications) as well as the opening, faulting, or grounding of all conductors leading to the apparatus (Magison, 1978). Abnormal conditions involve all failures of internal components and wiring.

12.4.6.2 Batteries

Batteries have a variety of uses in mines, including powering cap lamps, instruments, and equipment such as locomotives, articulated ram-dump haulers, tractor-trailer units, and scoops (front-end loader tractor units). The battery-powered off-track units eliminate problems involved with shuttle car trailing cables. There are inherent hazards in battery use: batteries emit hydrogen, an explosive gas, while charging; batteries and battery chargers are capable of delivering a fatal electric shock; and batteries can be a potential fire hazard. A number of less catastrophic hazards may also be encountered, ranging from acid burns from spilled electrolyte to pinched fingers from careless handling.

A *storage battery* can be defined as a battery in which the electrochemical action is reversible; that is, after an output of electrical current (discharge), the battery can be returned to the original state (recharged) by passing current through it in the opposite direction. Two types of storage batteries have been employed in underground traction, alkaline and acid. The nickel-iron or Edison cell is an alkaline cell because of the type of electrolyte used. Edison batteries were once popular in the mining industry because of their high-reliability and low-maintenance characteristics, but lead-acid batteries have now entirely replaced the Edison type as a result of their high energy per unit volume and high power capability.

About 110% of the ampere-hours discharged must be returned to fully charge a lead-acid battery. The rate at which charge is restored is an important consideration in attaining the maximum number of charge cycles and maximum life for the battery. Manufacturers may publish a normal or finish rate; this is also the current level at which the battery can be safely charged any time charging is required. The charge cycle usually takes eight hours. Most of the electricity supplied to a cell being charged is used to transform water and lead sulfate into sulfuric acid, lead, and lead peroxide, but some of the current causes electrolysis, breaking the water down into its constituents, which is called gassing. A certain amount of gassing is a necessary consequence of a good charge, which explains why water must periodically be added to batteries, but excessive gassing or overcharging causes damage to the plates, excessive water consumption, and excessive hydrogen emission. For this reason, the charging current must be controlled as the battery charges.

Proper battery maintenance has a very significant influence on battery life. Battery manufacturers normally include a recommended maintenance program with their batteries based on specific gravity levels and equalizing schedules. Equalizing is the process by which all the cells in a battery are brought to the same voltage. In lead-acid batteries, the electrolyte specific gravity is a function of the state of battery charge. Consequently, a plot of electrolyte specific gravity vs. discharge depth for a particular battery is important. All lead-acid batteries require periodic equalization, but excessive equalization can cause unnecessary battery deterioration.

Daily battery maintenance activities should include the monitoring of one battery cell, which is called the pilot cell. Any battery cell can be used as the pilot. The following cell characteristics should be recorded during each charge: (1) specific gravity before and after charging and (2) water level in the cell. If any of the pilot parameters falls outside those specified as acceptable by the manufacturer, all cells should be checked and corrective action should be taken. Other daily maintenance activities should include checking the battery for physical defects such as cracked cell plugs and ensuring that the charger output voltage is correct. The weekly maintenance program includes checking all battery cells for proper water level (the water consumption of a good battery is generally equally distributed among the individual cells) and routine cleaning of the battery tops. Every three months, it is good practice to take a complete set of cell voltage and specific gravity readings at the end of an equalizing charge to ensure that these parameters meet manufacturer specifications.

CHARGERS. Most mine batteries are charged from the ac distribution system, using a transformer-rectifier combination. Several methods can be used to control the rate of charge. Most are designed to initiate the charge at a fairly high current or starting rate. The level is then tapered off to the finish rate as the battery charge is restored. Some chargers reduce the starting rate to the finish rate in one step when the charge is about 80% complete, but control devices that taper the charge rate are more common in mining. Regardless of the type, the charge is usually stopped automatically when full charge is reached.

CHARGING STATIONS. Special charging stations are required in underground mines to charge vehicle batteries. These stations must be designed and constructed to meet specific ventilation requirements, but because mining methods and plans vary widely, it is extremely difficult to define a rigorous set of guidelines.

BATTERY-BOX VENTILATION. The ventilation of the traction battery enclosure is not only important while charging but also during operation. Following the charge cycle, the covers are closed and the vehicle is placed in service. From chemical reactions and entrapped gas within the cells, lead-acid batteries continue to emit gas for several hours after receiving a charge, no matter whether they are open-circuited or on discharge. Considering the ignitability of hydrogen, it is possible that a dangerous hydrogen-air mixture will accumulate. Hence it is necessary to provide adequate ventilation for the evolved hydrogen in the closed box while the battery is in operation.

Chapter 12.5
COMPRESSED AIR POWER

J.L. GENT AND R.H. KING

12.5.1 INTRODUCTION

12.5.1.1 Scope and Objective

Compressed-air-powered equipment is widely used in many underground metal and nonmetal mines and even in some coal mines. Compressed air power is expensive due to the high costs of energy, equipment, and supplies. Furthermore, if air quantity and pressure are not available when needed, resulting delays and decreased operating efficiency can severely reduce productivity. In fact, lost production is probably the highest cost of an inadequate compressed air system.

Therefore, optimal system design is necessary to obtain the required air power at the lowest cost. This chapter demonstrates a correct design procedure using manual calculations and explains how computer-aided design is useful for alternative analysis in large systems.

12.5.1.2 Design Method Summary

The procedure described herein addresses determination of the following compressed air requirements:

1. Air quantity, pressure, and compressor horsepower.
2. Valve and fitting selection and their proper placement.
3. Optimal pipe diameter(s).
4. Hose diameter(s).
5. Receiver size.
6. Overall system capital and operating costs..

To determine these requirements, a sizable amount of information must be gathered or estimated for either manual calculations or the computer program. Initial resources should include:

1. A scaled mine map or schematic showing possible routes so that preliminary pipe lengths and fitting locations can be determined. The drawing should also include probable locations of all air consuming equipment.
2. An overall production schedule for the longest planning horizon possible is needed if compressed air quantity and maximum pressure requirements are to be determined for various critical times in the future. This schedule may be mapped, graphed, or otherwise presented so it can be analyzed by stages. For example, mine management may wish to defer capital expenditures by purchasing a smaller compressor initially and adding additional units later in the mine life.
3. All available or planned compressed-air-powered equipment and the corresponding manufacturer's specifications in psia and scfm or lbm/sec (kPa and m^3/s).
4. Diversity factor estimation, equipment scheduling, and operational priority.
5. The types and sizes of hoses, pipes, valves, compressors, and receivers that are currently available or are preferred by the engineer.
6. Leakage location and magnitude, when known.

After this information is gathered, the following design steps are undertaken:

1. Determine machine requirements.
2. Estimate leakage locations and quantities and apply them to the system.
3. Calculate equivalent lengths for valves and fittings and add to the downstream branch.
4. Decide equipment placement.
5. Balance flow rates at nodes (where possible).
6. Calculate pressure losses.
7. Calculate inlet pressures and quantities for the network.
8. Calculate compressor horsepower and receiver capacity.
9. Calculate optimal pipe diameters. Repeat steps 6 thru 9 until optimal diameters become fixed.
10. Analyze the system to further minimize costs, if possible.
11. Calculate capital and operating costs.

The required calculations are computationally intensive, but available computer programs remove the repetitive calculations, allowing the engineer to concentrate on design improvements.

A simple mine layout is used as an example throughout this chapter to illustrate the design procedure. The procedure developed can be used to obtain a quick approximate solution or a precise result, depending on the availability of good input data and the user's requirements.

For additional information on these methods, the reader is referred to CAGH, *Compressed Air and Gas Handbook* (Rollins, 1973), or *Flow of Fluids Through Valves, Fittings, and Pipe,* Technical Paper 410 of the Crane Co. (Anon., 1978). Both references focus on volumetric analyses. Mass flow analysis is more accurate but requires longer solution times. The design procedure covers steady-state analysis only. A computer program designated COMPAIR (Gent, 1986) was used to develop the numerical examples in this chapter.

12.5.2 DESIGN CONDITIONS

The example mine encompasses radial and combined (loop and radial) compressed air systems (Fig. 12.5.1). Equations are presented for the optimum pipe diameter, air quantity and pressure, compressor horsepower, and receiver size for both types of distribution networks.

Figs. 12.5.2 and 12.5.3 are schematics of the example mine radial and combination networks, respectively, which include the section numbers, and valves and fittings. Pipe intersections are defined as *nodes,* and a *branch* is defined as the pipe and fittings between nodes.

Eight air hammers requiring 175 scfm (0.08259 m^3/s), two air hammers requiring 123 scfm (0.05805 m^3/s), and three overshot muckers that require 210 scfm (0.09911 m^3/s) per motor are used in the example. All equipment requires 90 psig (620.5 kPa) minimum. The example mine surface facilities are at 7800 ft (2377 m).

Table 12.5.1 lists the abbreviations for drift headings, raises, and stopes used in Figs. 12.5.1 through 12.5.3. Tables 12.5.2 and 12.5.3 show pipe lengths and diameters for radial branch pipe and the combination network respectively. Symbols used in the figures are American National Standards Institute (ANSI) standards.

Although the example mine is small, the iterative design requires the same series of steps as a larger operating mine: (1) determine machine requirements; (2) calculate the quantity in each branch and in total; (3) adjust quantities for altitude and leakage; (4) select line sizes; (5) place the appropriate valves and

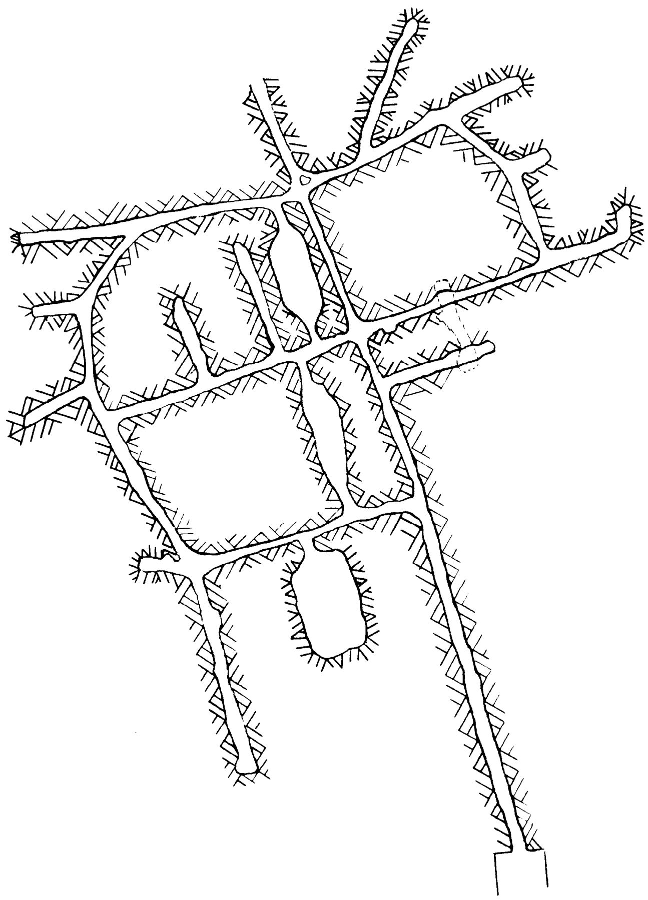

Fig. 12.5.1. Example mine layout.

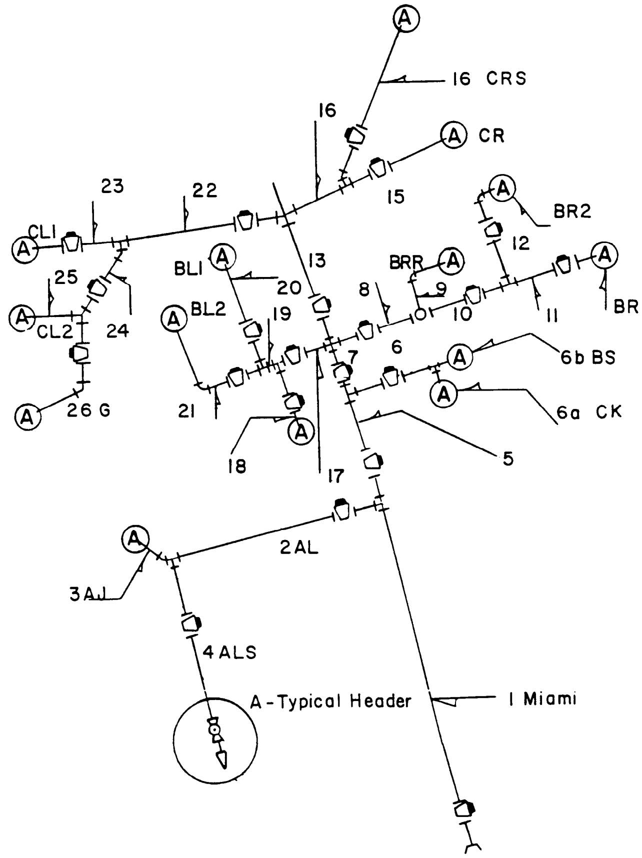

Fig. 12.5.2. Radial network layout.

fittings; (6) calculate the equivalent length for each branch; (7) calculate the corresponding pressure drop; (8) determine compressor air quantity, discharge pressure, and horsepower; (9) determine optimal diameters; (10) calculate the required receiver volume; (11) estimate the overall cost; and (12) reiterate parts of the solution to analyze effects on the assumed data.

12.5.3 MACHINE REQUIREMENTS

Compressed air requirements for most equipment can be obtained from the manufacturer. For the equipment to perform optimally, its air horsepower requirements must be met.

Quantity is normally expressed as the volumetric free air flow rate at a specific pressure. Most manufacturers define *standard free air* volume as 1 ft^3 of air at 60°F, 14.7 psia, and 0% relative humidity (0.002832 m^3, 15.6°C, 101.4 kPa)

Manufacturers always include the operating pressure with their stated quantities because operating pressure affects rotation rates and blow frequencies. The operating pressure is usually expressed as gage pressure (psig or kPa), which is the pressure differential between the compressed air and free atmospheric pressures. The corresponding quantity is normally denoted scfm or cfm (m^3/s).

Mass is also used to designate flow rates throughout the chapter (lbm/sec). When a *mass flow* is stated, temperature and pressure accompany the rate. If temperature is not designated, standard conditions are assumed.

An acfm is 1 ft^3 (0.002832 m^3) of air at any condition. As an illustration, consider the internal volume flowing in a pipe. It is equal to scfm divided by the compression ratio *r*, using the assumption of isothermality. The compression ratio is defined as the absolute pressure of the compressed air divided by the atmospheric pressure:

$$r = \frac{\text{psia of compressed air}}{\text{psia of free air}} \qquad (12.5.1)$$

If drill quantity requirements are unknown and manufacturers' data are unavailable, they can be estimated using data from Staley (1949) or calculated if additional information is known.

To calculate the air requirements for a drill or other machinery, additional information (the bore, stroke, frequency of blows, or total horsepower) must be known. For a piston-type machine such as a drill, the calculation procedure is as follows:

1. Calculate the per stroke displaced air volume.
2. Multiply the stroke volume by the frequency to obtain acfm at operating conditions.
3. Convert acfm to scfm by multiplying by the compression ratio.

This calculation should always be based on standard air to insure compatibility with altitude correction factors. If so, results will closely parallel published data. However, manufacturers base some data on bench tests that differ from calculated values.

Example 12.5.1. Calculate the required scfm if a drill has a 3.0-in. (76.2-mm) bore and a 2.5-in. (63.5-mm) stroke. The drill delivers 2400 bpm at 90 psig (620.5 kPa).

Solution. Determine the actual flow rate through the drill by Eqs. 12.5.1 through 12.5.3:

$$V_c = \pi D^2/4\ S_c \tag{12.5.2}$$

$$acfm = V_c\,(Hz) \tag{12.5.2a}$$

Definitions for mathematical symbols are provided at the end of the chapter.

Cylinder volume by Eq. 12.5.2 is

$$V_c = [\pi\ (3.0\text{ in.}/12\text{ in./ft})^2/4]\ (2.5\text{ in.}/12\text{ in./ft})$$
$$= 0.0102\text{ ft}^3\text{/blow } (0.0002899\text{ m}^3\text{/blow})$$

Actual flow rate by Eq. 12.5.2a is

Table 12.5.2. Radial Branch Pipe Lengths and Initial Diameters

24	CLeft	3	150
25	CL2	2	130
26	G	2	250

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm.

$$acfm = (0.0102\text{ ft}^3\text{/blow})\ (2400\text{ bpm})$$
$$= 24.48\ acfm\ (0.01156\text{ m}^3\text{/s})\text{ at }104.7\text{ psia }(721.9\text{ kPa})$$

From Eq. 12.5.1,

$$r = (90\text{ psig} + 14.7\text{ psia})/14.7\text{ psia} = 7.12$$

The required scfm by Eq. 12.5.3 is

$$scfm = acfm\ (r) \tag{12.5.3}$$

$$scfm = (24.48)(7.12) = 175\text{ scfm }(0.08259\text{ m}^3\text{/s})\text{ at }2400\text{ bpm}$$

The preceding example used a jackleg rated at 175 scfm (0.08259 m^3/s) and 100 psig (690 kPa), which varies less than 2% from the calculation. Ex. 12.5.1 ignores volumetric efficiency, which may become important for old equipment where the volumetric efficiency is reduced.

An overshot mucker has two motors that rarely operate simultaneously at their peak demand, so manufacturers recommend derating one motor by 50%. Therefore, a quantity of 305 scfm (0.1439 m^3/s) is appropriate for each mucker in this example.

Exact quantity requirements are difficult to determine because mining machines are operated dynamically, and actual consumption may vary considerably from manufacturers' data. For example, Gent (1986) tested four S83F drills and found that the average flow was 205 scfm (0.09675 m^3/s) at 88 psig (606.7 kPa) with a 59.9-scfm (0.02826-m^3/s) standard deviation. Peak values varied from 237 to 284 scfm (0.1119 to 0.1340 m^3/s). Measurements on 12B muckers resulted in an average 286 scfm (0.1350 m^3/s), with a 55 scfm (0.02596 m^3/s) standard deviation,

and peaks of 347 scfm (0.16377 m^3/s) when tramming and lifting and 180 scfm (0.08495 m^3/s) when lifting.

Quantity varies with time because the air consumed by equipment depends on the task being performed at a specific time. Dynamic simulation of duty cycles is one way to approach the problem. The other, used here, is to rely on manufacturers' data that represents an average during machine run time. However, if actual operating data is available, it is preferable to manufacturers' data. For example, King's and Gent's (1989) measurements on the S83F varied from the manufacturers' data because the equipment studied was old and worn.

Manufacturers generally specify pressure and quantity because minimum pressure must be provided if the advertised capabilities are to be achieved. Higher pressures are acceptable and will improve machine performance (especially in drill penetration rates) as long as the maximum pressure ratings are not exceeded.

12.5.4 QUANTITY ADJUSTMENT

Free air quantities are published at standard conditions; however, equipment rarely operates at standard conditions, and consumption rates must be adjusted.

Altitude adjustment can be accomplished in three ways: (1) Use the correction factors in Table 12.55, (2) calculate mass requirements and correct for changes in density, or (3) use the following volumetric formula:

$$F_v = P_s (P_o + P_e)/P_e (P_o + P_s) \qquad (12.5.4)$$

Note that acfm at the new atmospheric pressure = F_v (scfm).

The volumetric approach accounts for the metering effects of air tools. Air tools operating at steady state are essentially a meter passing a constant volume of compressed air acfm, regardless of the inlet pressure provided. Thus the same volume of compressed air must be provided by the compressor at any altitude.

When calculating pressure drop in pipes using CAGH tables, the altitude adjustment factor should not be used because the tables are based on scfm rather than acfm. Consequently, only the compressor is corrected for altitude. The pressure-loss segment of this chapter will demonstrate the procedure.

Adjustment, based on the mass of air, can be calculated in two ways. The inlet approach is based on a ratio of free air densities while the outlet approach uses compressed air density ratios. Both approaches assume that a constant mass of air must be supplied to the drill irrespective of altitude. Each technique has advantages. However, it is believed that the inlet approach is the easiest to understand and apply. For the inlet approach,

$$F_i = P_s/P_e \qquad (12.5.5)$$

and for the outlet approach,

$$F_o = (P_o + P_s)/(P_o + P_e) \qquad (12.5.6)$$

The most conservative answer results when using the ratio of inlet densities. Less conservative answers result when using volumetric adjustments and the least conservative using the ratio of outlet densities.

Example 12.5.2. Determine the altitude correction factor and the free air quantities required by the machines for the example mine.

Solution. The mine portal is at 7800 ft (2377 m) elevation, and the atmospheric pressure is 10.40 psia (71.7 kPa). If a drill requires 90 psig (620.5 kPa) at the header, the correction factor is

1. by volumetric approach,

$$F_v = 14.70(90 + 10.40)/10.40(90 + 14.70) = 1.35$$

2. by mass flow at the inlet,

$$F_i = 14.70/10.40 = 1.41$$

3. by mass flow at the outlet,

$$F_o = (90 + 14.7)/(90 + 10.40) = 1.04$$

The average of the results is 1.27, compared with a value of 1.29 in Table 12.5.4, an altitude correction listing.

For the example problem, the inlet density correction factor will be used. The free air quantity that must be supplied by the compressor for drills and muckers (refer to the problem statement) is given in Table 12.5.6.

In addition to the quantity used by the machine, it is necessary to account for leakage in the system. In mines, it is estimated that leakage ranges between 5 to 20% of total consumption. Leakage is very costly in terms of fuel and power costs. Estimated costs run as high as \$0.20/1000 acfm (\$0.42/m^3/s) (Loomis, 1980). There are many ways to account for leakage; two methods are presented here.

Table 12.5.6. Free Air Equivalent Quantities at 7800-Ft Elevation

Drill quantity (83)	= 1.41 × 175	= 247 acfm at 10.40 psia
Drill quantity (53)	= 1.41 × 123	= 173 acfm at 10.40 psia
Mucker quantity	= 1.41 × (1.5 × 210)	= 444 acfm at 10.40 psia

Conversion factors: 1 ft = 0.3048 m, 1 acfm = 0.0004719 m^3/s, 1 psi = 6.895 kPa.

In a simplified approach, leakage factors can be applied at a small number of discrete locations, for example, at the operating machines only. This is justified because the majority of leaks occur closest to the working areas where frequent damage, improper installation, and little preventative maintenance exist. This method is conservative but adequately models the real environment.

A more comprehensive method is to decide where all probable and possible leakage points exist in the system and assign leakage quantities. This is a more accurate and time-consuming method. The computer program reduces the computation time for this technique.

Very few measurements have been made to quantify leakage in mines. A simple test to determine overall leakage is to start a compressor and record the operating time to maintain minimum pressure. This type of test has some disadvantages. It is not possible to determine the quantities at each leakage point or determine where compressed air is being used for ventilation. Compressed air used for ventilation and cooling should be considered a load. Example 12.5.3 adjusts the quantities at the example mine for leakage.

Example 12.5.3. Determine leakage quantities at the example mine.

Solution. The design at the mine under consideration assumes poor installation and maintenance. For these conditions, 10% leakage (L_f = 1.1) will be assumed for two different points at each heading: (1) the connection between the pipe and hose and (2) the connection between the machine and hose.

Table 12.5.7. Design Quantities (scfm) at Sea Level

Drills:		
(83) Quantity at hose outlet	= (175) (1.1)	= 193 scfm at 90 psig
(83) Quantity at hose inlet	= (193) (1.1)	= 212 scfm at 90 psig
(53) Quantity at hose outlet	= (123) (1.1)	= 135 scfm at 90 psig
(53) Quantity at hose inlet	= (135) (1.1)	= 149 scfm at 90 psig
Mucker:		
Quantity at hose outlet	= (1.5) (210) (1.1)	= 347 scfm at 90 psig
Quantity at hose inlet	= 347 × 1.1	= 381 scfm at 90 psig

Table 12.5.8. Design Quantities at 7800-Ft Elevation

Drills:		
(83) Quantity at hose outlet	= (247) (1.1)	= 271 acfm at 10.4 psia
(83) Quantity at hose inlet	= (271) (1.1)	= 299 acfm at 10.4 psia
(53) Quantity at hose outlet	= (173) (1.1)	= 191 acfm at 10.4 psia
(53) Quantity at hose inlet	= (191) (1.1)	= 210 acfm at 10.4 psia
Mucker:		
Quantity at hose outlet	= (444) (1.1)	= 489 acfm at 10.40 psia
Quantity at hose inlet	= (489) (1.1)	= 537 acfm at 10.40 psia

Conversion factors: 1 psi = 6.895 kPa, 1 acfm = 0.0004719 m^3/s.

Tables 12.5.6 and 12.5.7 display design quantities at the hose inlet and outlet for the drill and mucker, respectively. Table 12.5.7 shows design quantities for use with the CAGH tables. Table 12.5.8 shows quantities that were corrected for altitude and used for the volumetric pressure loss calculations.

Leakage assumed at any location requires certain decisions that are best left to experience or actual field measurements. The guidelines that are presented here should be replaced by other methods where appropriate.

12.5.5 EQUIVALENT LENGTHS

Before analyzing radial or combination networks, valves and fittings must be placed appropriately. Fittings placement is relatively obvious, but valve placement and selection is not and requires careful consideration for maintenance and safety. For mining applications, quick shut-off valves such as butterfly or plug valves are necessary. Globe valves are usually avoided due to high frictional loss and purchase cost. Gate valves should be avoided because they require many revolutions to stop airflow.

Valve and fitting placement is a trade-off between (1) potential maintenance and lost production and (2) initial cost. At a minimum, valves must be placed at the compressor outlet and at each working face. However, if this minimum cost scheme were followed, every broken line or an extension to the existing network would shut down the entire mine. Lost production easily justifies the cost of more valves; therefore, valves should be placed at the start of each heading, at the face, and at major feeder intersections, similar to those shown in Fig. 12.5.2. Other shut-off valves may be required at particular sites.

Replacing the valve or fitting with an equivalent pipe length is an accepted and convenient method for calculating the additional resistance. This method determines the length of straight pipe that will produce the equivalent pressure loss through the specified valve or fitting. Fig. 12.5.4 shows victaulic piping symbols.

Before equivalent length can be determined, pipe diameters must be known or estimated. Therefore, some iteration occurs within the design process. At this point, pipe-size estimates must be made, and the designer must later calculate optimal diameters. Consequently, the designer may not wish to determine equivalent lengths until approximate pipe diameter are analyzed throughout the system. Diameters assumed for the example mine are given in Tables 12.5.2 and 12.5.3.

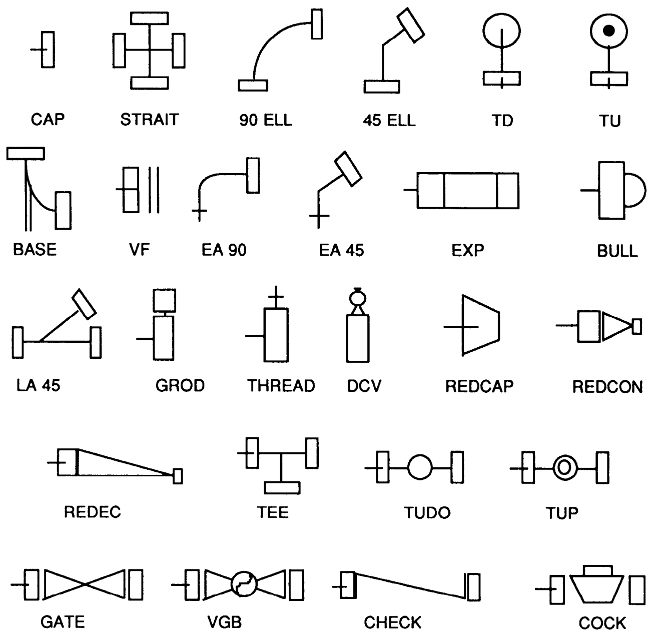

Fig. 12.5.4. Victaulic piping symbols

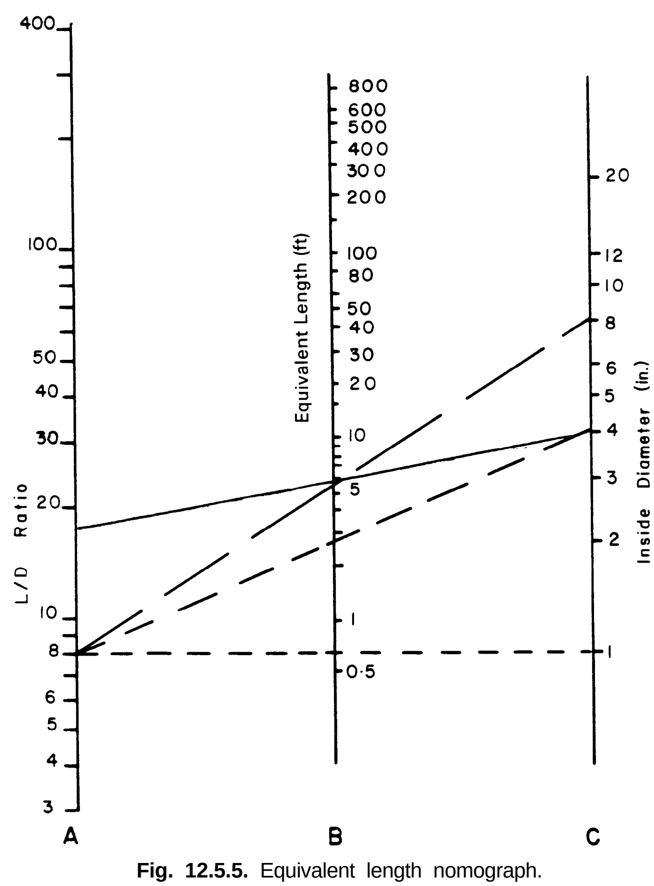

Fig. 12.5.5. Equivalent length nomograph.

There are many tables and charts available on equivalent length. However, most of these are taken from Crane's Technical Paper 410 (Anon., 1978). Figs. 12.5.5 and 12.5.6 are based on

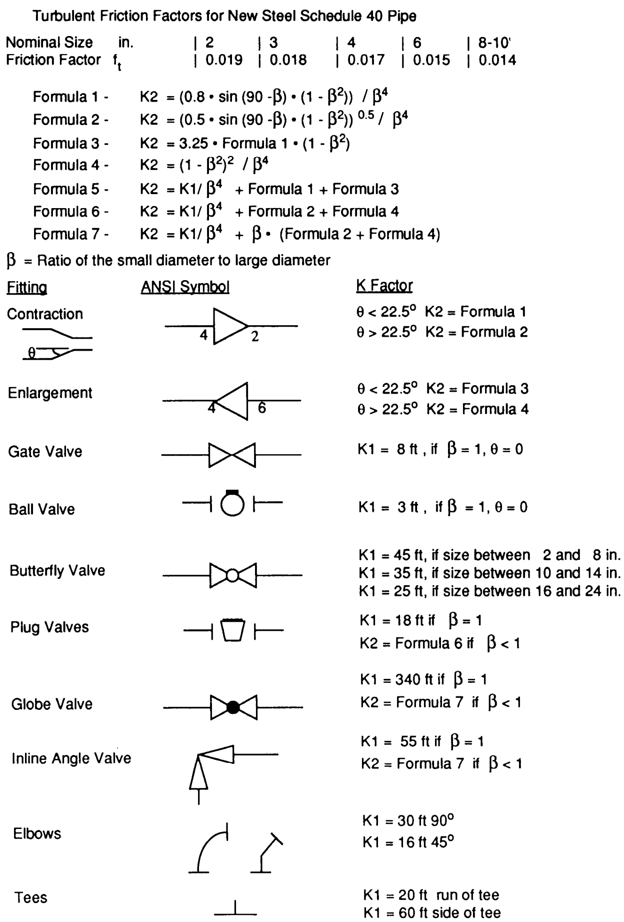

Fig. 12.5.6. Equivalent length formulas (Anon., 1978).

this document and are used in equivalent length calculations in Ex. 12.5.4.

Example 12.5.4. Determine the equivalent length of a 4-in. (101.6-mm) plug-cock valve.

Solution. Determining equivalent lengths using the charts from Technical Paper 410 is a relatively simple and very versatile procedure. The first step is to determine the L/D ratio from Fig. 12.5.6. The L/D ratio is the K_e number in ft that appears before the turbulent friction factor b. For instance, the L/D ratio for a straightway plug-cock valve is 18. For some β values, K_e must be calculated from the Fig. 12.5.6 formulas:

$$L_e = D\,(L/D) = (4.026/12)\,(18) = 6 \text{ ft } (1.829 \text{ m}) \qquad (12.5.7)$$

Equivalent length can be determined from Fig. 12.5.5 if L/D is known. Locate the L/D ratio on the ordinate labeled A. Next locate the internal pipe diameter on ordinate C, and draw a line between these two points. The point where the line intersects ordinate B determines the equivalent length. For the 4-in. (101.6-mm) plug-cock valve, the equivalent length is 6 ft (1.829 m).

Figs. 12.5.2 and 12.5.3 show valves and fittings for the example mine problem. Equivalent length was added to the pipe lengths from Figs. 12.5.2 and 12.5.3 to obtain total lengths shown in Table 12.5.9.

Table 12.5.9 tabularizes the fittings for each branch, the physical branch length, and the total calculation length. Equivalent length for valves and fitting should be added to the downstream branch, as shown in Table 12.5.9, because this is where the additional loss will occur.

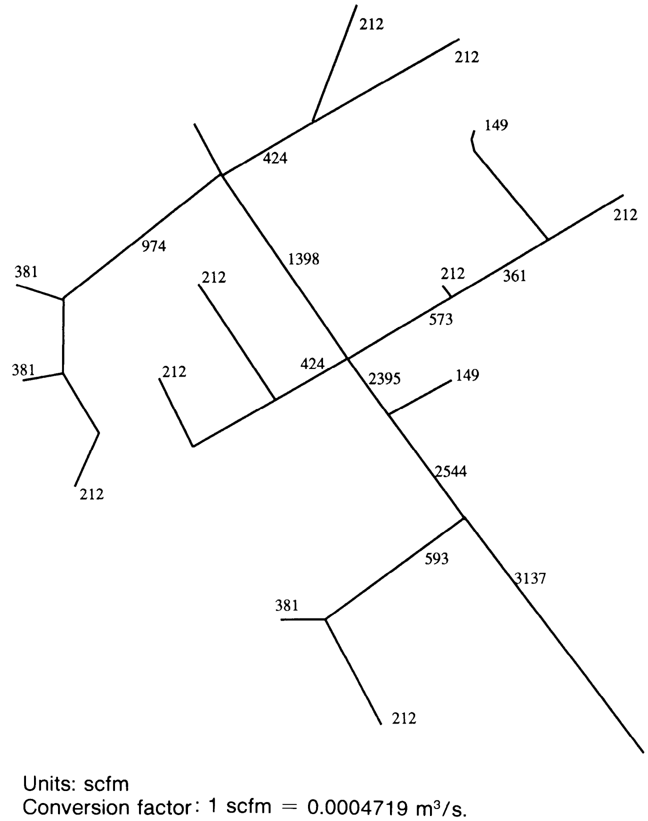

Fig. 12.5.7. Flow rates for the radial network (CAGH method).

12.5.6 MACHINE ALLOCATION

Deciding equipment configuration (machine placement in working headings) is one of the most difficult design steps because limitations are being imposed. One procedure is to design for the worst condition; another is to design for the most likely conditions. Both have advantages and disadvantages.

The worst condition may only occur for a limited time or during certain shifts. Since short-duration low-pressure periods may be tolerable, worst-condition design is not cost effective, or the most efficient utilization of resources. Designing a system for average load, with no consideration for peak demand, may limit productivity.

As with any design, a balance must be maintained between the two and this balance is a site-specific decision. The best method is to calculate the requirements for several cases using the computer program and compare costs and limitations.

When placing equipment at specific headings, it is difficult to predict the worst-case condition. However, equipment arrangements that increase pressure drop and simulate worst-case conditions can be achieved by placing equipment with the highest consumption rates at headings on the largest resistance paths.

A method of equipment placement for worst-case simulation is to divide the branch length by its proposed diameter and sum the diameter-weighted lengths to each working face, as shown in Table 12.5.10. Next, place equipment with the highest pressure

Table 12.5.9. Actual, Equivalent, and Total Lengths for Each Branch

requirements on the longest weighted paths, and concentrate the highest consumption equipment on the largest diameter-weighted path.

Example 12.5.5. Allocate equipment at the example mine using the diameter-weighted-distance (dwd) technique.

Solution. Table 12.5.10 lists the path from each heading to the portal using the branch numbers from Fig. 12.5.2. Pipe diameter and branch lengths from Table 12.5.9 were used to calculate the dwd.

Table 12.5.10 can be interpreted by using heading CK as an example; path 1-5-6A was divided into two segments because two different pipe sizes were assumed in the path. Branches 1 and 5 are 759 and 224 ft (231.3 and 68.28 m), respectively, and are 6 in. (152.4 mm) in diameter. The third branch, 6, has 184 ft (56.08 m) of 2-in. (50.8-mm) diameter pipe.

12.5.7 BALANCING FLOWS AT RADIAL NODES

When balancing mass or volumetric flow rates at nodes, radial networks must be treated differently from combination networks. However, regardless of the system being designed, mass flowing into a node must equal mass flowing out of the node.

With a compressible medium such as air, the only correct way to balance at nodes is to use mass rather than volume as the

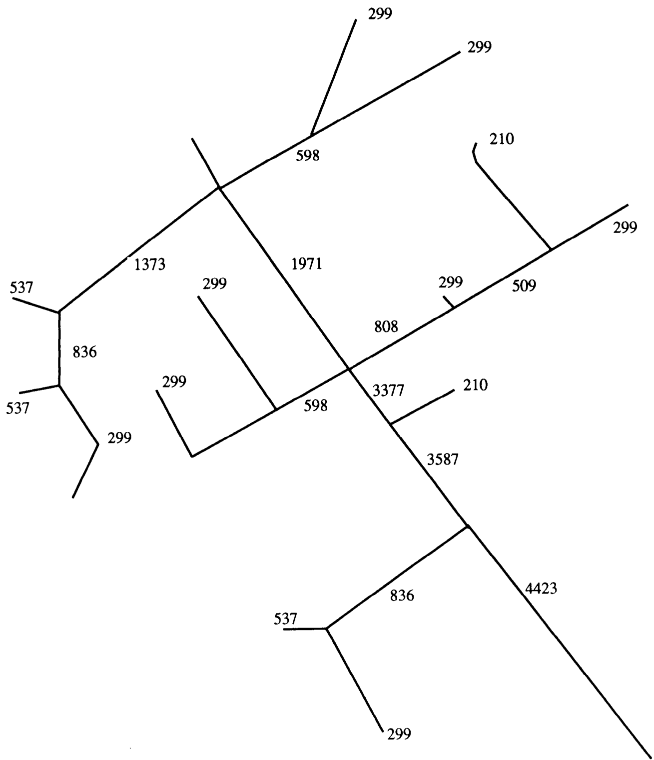

Fig. 12.5.8. Flow rates for the radial network (volumetric and mass flow).

basic flow unit. Only if the fluid is assumed incompressible will the quantities flowing into and out of nodes sum exactly to zero. However, quantities change in mine compressed air systems because decreased pressure caused by friction and shock loss allows air expansion within the system. For many situations, the loss of accuracy caused by the incompressible assumption is negligible, and inlet volume approximately equals the outlet volume.

Balancing a radial network is relatively simple since flow directions are defined by the physical layout, and splitting is determined by equipment placement. Air volumes by branch are determined by balancing nodes from the machines to the compressor.

Flow rate determination in loop networks is considerably more difficult. The Hardy Cross method or nodal iterative techniques must be used to determine splitting at nodes. Hardy Cross assumes continuity of mass and iterates until continuity of energy is obtained. Nodal techniques assume continuity of energy and iterates until continuity of mass is obtained.

Fig. 12.5.7 shows the flow rates for the example problem in a radial configuration.

12.5.8 PRESSURE LOSSES

Many methods can be used to calculate pressure drop, but only three are discussed here: (1) CAGH table formula, (2) the Darcy-Wiesbach equation, and (3) the mass flow equation.

Tables are generally used for manual calculations. The Darcy-Weisbach equation is most commonly used in existing fluid flow computer programs. The computer program, COMPAIR (Gent, 1986), referenced herein employs either the mass flow or the traditional volume approach.

12.5.8.1 CAGH Table Equation

The CAGH tables were generated from the following equation:

$$\Delta p = 0.1025\ LQ^2/3600\ r\ D^{5.31} \tag{12.5.8}$$

Example 12.5.6. A quantity of 560 scfm (0.2643 m^3/s) is flowing in a 375-ft (114.3-m), 4-in. (101.6-mm), Schedule 40 pipe with a 97-psig (668.8-kPa) inlet pressure. The pipe is located at sea level. Using the CAGH table formula, determine the pressure loss.

Solution. Use Eq. 12.5.8. The compression ratio is calculated using Eq. 12.5.1 as shown here:

$$r = (97 + 14.7)/14.7 = 7.6$$

and the resulting pressure loss is

$$\begin{aligned}\Delta p &= 0.1025(375)(560)^2/3600(7.6)(4.026)^{5.31}\\ &= 0.27 \text{ psig } (1.862 \text{ kPa})\end{aligned}$$

A table of standard pipe weights appears in Table 12.5.11 for reference.

12.5.8.2 Darcy-Weisbach Equation

Calculating pressure loss with the Darcy-Weisbach equation allows selection of absolute roughness and viscosity, thus allowing friction factors to be calculated for any flow regime.

The Darcy-Weisbach equation for pressure loss is

$$\Delta p = f\ p\ L\ V^2/(288\ D\ g_c) \tag{12.5.9}$$

Example 12.5.7. A quantity of 560 scfm (0.2643 m^3/s) is flowing in a 375-ft (114.3-m), 4-in. (101.6-mm), Schedule 40 pipe at 97 psig (668.8 kPa). The pipe is at sea level, and the internal temperature is 60°F (15.6°C). Determine the pressure drop using Eq. 12.5.9.

Solution. Determining the Moody friction factor is the most complicated part. The first step is to calculate the fluid velocity:

$$\begin{aligned}acfm \text{ at 97 psig} &= scfm/r = 560/7.60\\ &= 73.70\ acfm\ (0.03478 \text{ m}^3/\text{s})\\ &\quad \text{at 111.7 psia (770.1 kPa)}\end{aligned}$$

The cross-sectional area A of a 4-in. Schedule 40 pipe is 12.73 in.^{2} (8213 mm^2). The air velocity is:

$$\begin{aligned}V = Q/A &= (73.70)(144 \text{ in.}^2/\text{ft}^2/(60)(12.73 \text{ in.}^2)\\ &= 13.89 \text{ fps } (4.234 \text{ m/s})\end{aligned} \tag{12.5.10}$$

Reynolds number can be calculated from the following relation:

$$R = 10.325\ D\ (V/\nu) \tag{12.5.11}$$

The internal pipe diameter is 4.026 in. (102.3 mm), the veloc-

Source: ASTM Standard Specifications A53.33.
Conversion factors: 1 in. = 25.4 mm, 1 in.^{2} = 645.16 mm^2, 1 ft = 0.3048 m, 1 ft^3 = 0.02831685 m^3.

ity is 13.89 fps (4.234 m/s), the absolute viscosity is 0.018, and the fluid density r can be calculated as follows:

$$\rho = (144\ P_f)/(R_c\ T_o) \qquad (12.5.12)$$

For this example,

$$\rho = 144(97 + 14.70)/(53.34)(459.69 + 60)$$
$$= 0.58025 \text{ lbm/ft}^3 \ (9.295 \text{ kg/m}^3)$$

Relative viscosity is

$$\nu = 0.018/0.58025 = .031021 \text{ cp ft}^3/\text{lbm}$$

Reynolds number is

$$R = (10.325)(12 \text{ in./ft})(4.026 \text{ in.})(13.89 \text{ fps})/$$
$$0.031021 \text{ cp ft}^3/\text{lbm} = 223{,}400$$

A Reynolds number of 223,400 indicates a flow regime in the transitional region, the most common region for mine compressed air applications. If the absolute roughness is 0.00015, the relative roughness is

$$\epsilon/D = 0.00015 \text{ ft}/(4.026 \text{ in.}/12 \text{ in./ft}) = 0.0004471$$

Based on this relative roughness, the Moody friction factor is 0.019. The calculated pressure loss is

$$\Delta p = 0.019(0.58025)(375)(13.89)^2/288(4.026/12.0)(32.174)$$
$$= 0.26 \text{ psig } (1.79 \text{ kPa})$$

12.5.8.3 Mass Flow

Mass flow assumptions are similar to the other methods. An isothermal process is usually assumed, but this can be changed to isentropic or adiabatic. Steady state is assumed for the pressure loss calculation. The pressure loss can be calculated using the following expression (Anon., 1980):

$$\Delta p = \frac{P_1 + \text{m}^2}{\left[\dfrac{\rho\ 144\ g_c\ A^2}{fL/D + 2\log(P_1/P_2)}\right](P_1 + P_2)} \qquad (12.5.13)$$

Mass flow calculations are more complex and time consuming because the physics is more complicated. The mass flow approach readily lends itself to a nodal analysis because pressures at both nodes can be estimated; then the corresponding flow rates can be calculated. A full mass-flow nodal analysis discussion is given by Gent (1986).

Example 12.5.8. A quantity of 560 scfm (0.2643 m^3/s) is flowing in a 375-ft (114.3-m), 4-in. (101.6-mm), Schedule 40 pipe. The inlet pressure is 97 psig (668.8 kPa). Determine the pressure drop if the pipe is at sea level and the internal temperature is 60°F (15.6°C).

Solution. As with the Darcy-Weisbach equation, the most difficult part of this calculation is determining the friction factor. Since Exs. 12.5.7 and 12.5.8 have identical stated conditions, the friction factor and internal densities determined in Ex. 12.5.7 are used. The next step is to determine the mass flow rate.

From Ex. 12.5.7, the internal flow rate is 73.70 acfm at 97 psig, and the internal density is 0.58025 lbm/ft^3. Mass flow rate is

$$m = (73.70 \text{ acfm}/60 \text{ sec/min})\ (0.58025 \text{ lbm/ft}^3)$$
$$= 0.71274 \text{ lbm/sec } (0.3233 \text{ kg/sec}) \qquad (12.5.14)$$

The mass flow equation as presented is an iterative equation. If fluid acceleration is ignored or the inlet to outlet pressure ratio is close to one, then 2 log(P_1/P_2) can be neglected without an appreciable loss of accuracy. Substituting ΔP for $P_1 - P_2$, and combining similar terms (negligible acceleration), a closed-form equation results:

$$P_2^2 = P_1^2 + \left(\frac{m^2 P_1 f L}{144\, g_c\, D\, \rho\, A^2}\right) \qquad (12.5.15)$$

The area of a 4-in. (101.6-mm) Schedule 40 pipe is 0.088405 ft^2 (0.007815 m^2), and the internal diameter is 0.3355 ft (0.1023 m), the solution for P_2 is

$$P_2^2 = (111.7)^2 + [(0.7125)^2(111.7)(0.019)(375)/(144)(32.17)$$
$$(0.3355)(0.5803)(0.0884)^2] = 12{,}419.54$$

$$P_2 = 111.44 \text{ psia } (768.4 \text{ kPa})$$

$$\Delta p = P_1 - P_2 = 111.7 - 111.44 = 0.26 \text{ psig } (1.793 \text{ kPa})$$

Notice there is no difference between answers by the mass flow and volumetric methods; this, however, is not always the case. When the flow rates increase and the distances become longer, the solutions of the two methods will diverge.

All analyses presented are for new clean pipe. Pipe will not remain in this condition forever. The pipe will rust, become coated with oil, collect dirt and scale, and become bent and ovaloidal in cross section. To account for this, corrections must be made to the friction factor.

A 1% decrease in diameter will increase the pressure loss by 5%. For a 2-in. (50.8-mm) Schedule 40 pipe, this equals less than 1/64th in. (0.3969 mm) of buildup on the interior walls. A 5% decrease in diameter increases the pressure drop by 29%. Crane's Technical Paper 410 (Anon., 1980, p. 17) reports that aging effects increase the roughness factor 20% in as little as three years with only moderate use. It is recommended that the pressure drops be increased by 20 to 50% for fouling.

12.5.8.3 Altitude Pressure Differential

Compressed air distribution systems can be three-dimensional. None of the calculations presented thus far have accounted for changes in altitude. Ex. 12.5.9 illustrates corrections for altitude.

Example 12.5.9. Calculate the altitude pressure differential in a 500-ft (152.4-m) raise with a base elevation of 2500 feet (762 m).

Solution. A vertical air column (vertical pipe) will create a static pressure differential that is proportional to the change in elevation. This can be calculated through the use of the following formula:

$$\Delta P_h = \rho\, H/144 \qquad (12.5.16)$$

At l00-psig (690-kPa) average pressure, the altitude pressure differential is:

$$\Delta P_h = (0.5891)(500)/144 = 2.05 \text{ psia } (14.13 \text{ kPa})$$

As an alternative, altitude correction can be approximated as 4.1 psig/1000 ft (9.3 kPa/1000 m) of elevation change.

12.5.8.5 Pressure Loss in Hoses

Hose pressure loss can be found in the tables provided in CAGH. The tables assume smooth hose and use standard fluid flow theory or a two-phase flow regime.

Utilizing the Darcy-Weisbach method, pressure drop calculations for a hose supplying a jackleg drill are given in Ex. 12.5.10.

Example 12.5.10. Calculate the pressure drop for a l-in. (25.4-mm) diameter hose supplying 272 acfm (0.1284 m^3/s) at 10.4 psia (71.70 kPa) to a jackleg drill. The drill operates at 115.7 psig (797.7 kPa). The hose does not have an in-line oiler.

Solution. The compression ratio is

$$r = (115.7 + 10.4)/10.4 = 12.13$$

The inside area of a l-in. (25.4-mm) hose is

$$A = \pi\, (1.00/24)^2 = 0.005454 \text{ ft}^2\ (0.0005067 \text{ m}^2)$$

Internal velocity is

$$V = 272/(12.130)(0.005454)(60) = 68.55 \text{ fps } (20.89 \text{ m/s})$$

Internal density is

$$\rho = 144\, (115.7 + 10.4)/(53.34)(519.69)$$
$$= 0.6551 \text{ lbm/ft}^3\ (10.49 \text{ kg/m}^3)$$

Reynolds number is

$$R = 123.9\, (68.55)(1.00)/(0.018/0.6551) = 309{,}100$$

Relative roughness is

$$\epsilon/D = 0.000001 \text{ (smooth hose)}$$

The friction factor f is 0.0145.

Coupling equivalent length should be accounted for when calculating hose pressure drop. Assuming the couplings can be modeled as a sharp entrance or exit, the equivalent length is 6 ft (1.829 m). The pressure drop for 40 ft (12.19 m) of l-in. (25.4-mm) hose is:

$$\Delta p = (0.0145)\, (0.6551)(46)(68.55)^2/(288)(32.174)(1.0/24)$$
$$= 2.67 \text{ psig } (18.41 \text{ kPa})$$

Hose linings deteriorate with age and abuse. Used-hose friction may be 1.2 to 1.5 times greater than new hose. Assuming an average 35% deterioration,

$$\Delta p = (1.35)(2.67) = 3.59 \text{ psig } (24.75 \text{ kPa})$$

The pressure-drop calculation for hose containing an in-line oiler is most accurately calculated by the use of homogenous two-phase flow theory (Gent, 1986). The pressure loss of a two-phase fluid is calculated by mass weighting the viscosities and applying mass flow equations.

Publications such as Rollins (1973), Loomis (1986), and Anon. (1983) have reference tables for pipe and hose pressure losses. Many of these tables must be interpolated or extrapolated unless gross estimates are desired. The two-phase flow technique or careful interpolation provides more accurate results and can be obtained in a comparable amount of time using calculators or computers.

12.5.9 COMBINING NETWORK FLOWS AND LOSSES

To begin the network solution, pressures must be assumed at both inlet and outlet ends of the system. One way to determine

Table 12.5.12. Pressure and Pressure Losses (COMPAIR & CAGH Method)

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 psi = 6.895 kPa, 1 scfm = 0.0004719 m^3/s.

starting pressures is to use the rated pressure of the compressor. Even if a compressor has not been selected, it is quite reasonable to use 125 psig (861.8 kPa) as an upper bound. Another way is to guess where the largest resistance path will be (see design step 4) and work from the machines to the compressor.

Fixing the compressor outlet pressure is the easiest way to determine starting pressures and, subsequently, pressure drops. It simplifies starting the network solution and relieves the engineer of the tedious calculations needed to determine the largest resistance path. It can, however, produce a network that has poor pressure regulation or has wasted capital. Excess pressure is rarely a problem in mining, but lack of pressure plagues many mines.

Improper equipment placement and fixed inlet pressure can produce a design that provides inadequate pressure to headings during certain operating conditions. A computer program, such as COMPAIR, allows multiple scenarios to be evaluated, eliminating many of the problems described by reducing calculation time.

Pressure regulation is a valuable tool for determining problem areas in the design. It is analogous to voltage regulation in electrical networks and calculated in a similar fashion. Notice from Eq. 12.5.17 that as pressure loss increases, P_r degrades, but a higher P_c improves P_r:

$$P_r = (P_c - P_h/P_c)\ 100 \qquad (12.5.17)$$

Loomis (1986) recommends pressure regulation for the main and primary feeders be limited to 3% each. This guarantees a maximum of 6.1% pressure regulation to any heading or stope.

The example mine design meets this specification in all but one instance, the primary feeder for C Left. Switching to a 4-in. (101.6-mm) pipe for branch 22 would correct the deficiency. To illustrate the difference between the design using the CAGH equation, Darcy-Weisbach analysis, and mass flow analysis, an arbitrary compressor outlet pressure of 123 psig (848.1 kPa) was selected. This value provides enough difference to illustrate the effects of pressure on pressure loss.

The next step in analyzing the network is to calculate the quantities and pressure drop for each branch. The assumptions used are

1. $\epsilon = 0.00015$.
2. constant temperature of 60°F (15.6°C).
3. deterioration factor = 1.35.

12.5.9.1 Radial Networks

Branch flow rates are determined by summing at each node with Kirchhoff's node equations, that is, quantity flowing in must equal quantity flowing out. The quantity at each machine location (shown in Fig. 12.5.2) was adjusted for leakage, then combined at nodes balancing from the machine to the compressor (Ex. 12.5.11).

Example 12.5.11. The mucker at heading CL1 (refer to Fig. 12.5.2) requires 315 scfm (0.149 m^3/s). Leakage adjustment (Ex. 12.5.3) brings the quantity to 381 scfm (0.180 m^3/s). This quantity is listed for branch 23 in Table 12.5.12. It is added to the machine quantities from branch 24 (593 scfm or 0.280 m^3/s) to obtain 974 scfm (0.460 m^3/s) in branch 22. See Fig. 12.5.7.

These quantities were used to determine pressure losses using the CAGH equation. The pressure loss for each branch and cumulative pressure loss along the paths (from Table 12.5.10) are shown in Table 12.5.12. The results from COMPAIR are also included for comparison.

Table 12.5.13 presents the pressure drops and inlet pressures calculated using the Darcy-Weisbach equation. Inlet pressures are used to calculate pressure losses. A better method is to calculate pressure drop based on the average pressure in the pipe.

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 psi = 6.895 kPa, 1 scfm = 0.0004719 m^3/s.

In fact, the computer program iterates for the average pressure. However, with small line losses (less than 10% of inlet pressure), failure to average the pressure will not introduce significant error.

The mass flow technique results are presented in Table 12.5.14. Table 12.5.15 summarizes the nodal pressures, pressure loss, and pressure regulation for each of the methods described.

12.5.9.2 Combination Networks

There are advantages and disadvantages to utilizing loops in compressed air networks. Some of the advantages are:

1. Improved pressure regulation.
2. Decreased downtime for network maintenance.
3. Reduced wasted energy costs.

The disadvantages are

1. Increased initial capital cost.
2. Increased safety problems.
3. Higher maintenance costs.

Valve Placement. Valve placement in a combination network is not the same as placement in a radial network. Safety and serviceability are still the paramount placement criteria; however, more thought must be given to the zones of protection for each working place. A zone of protection is defined as the independent paths providing air to a heading. The minimum is one, and it may be desirable to have two or more.

With loop networks, valves placement can insure all headings will operate during repairs, if the zones of protection are established properly. This may be excessive if some headings are not worked on a regular basis or if several headings are assigned to the same crew.

Safety requires that, as a minimum, each heading or working place have two quick (quarter-turn) shut-off valves, one at the face and one where the heading intersects a loop. Three valves at an intersection are rarely necessary except when a four-way intersection is encountered—otherwise, two valves provide adequate protection with less confusion and reduced maintenance. The general rule for the number of valves required at an intersection is the number of branches minus 1.

12.5.9.3 Hardy Cross Technique

Combination network analysis is more difficult than radial network analysis because flow direction and quantity are unknown in loops. The Kirchhoff node equation is not adequate to determine flow direction; therefore, an iterative approach must be undertaken.

Two solution techniques, the Hardy Cross and nodal methods, were tested extensively (Gent, 1986). The Hardy Cross technique, probably the most widely used in simple fluid analysis (e.g., water lines, mine ventilation), assumes conservation of mass will govern the iteration process, and that conservation of energy will be obtained through successive iterations. The following discussion will explain the technique. The pressure loss for any pipe branch in the network can be written in simplified form as

$$\Delta p = KQ^2 \qquad (12.5.19)$$

K varies with flow rate because the friction factor is dependent on Reynolds number, which varies with fluid velocity. It is often assumed constant or changed every four or five iterations to reduce computation time. K equals the given pressure loss divided by the corresponding quantity squared.

Conservation of energy for a loop can be written:

$$\Sigma\ \Delta p_i = 0 = \Sigma\ (\pm)\ K_i Q_i^2 \qquad (12.5.20)$$

This equation will sum to zero when all quantities are cor-

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 psi = 6.895 kPa, 1 scfm = 0.0004719 m^3/s.

rect. If initial guesses are made, then each quantity will differ from the correct value by some delta quantity as expressed in Eq. 12.5.20:

$$Q_i = Q_i' + \Delta Q \tag{12.5.21}$$

Substituting Eq. 12.5.21 into Eq. 12.5.20,

$$\Sigma\, \Delta p_i = 0 = \Sigma\,(\pm)\, K_i(Q_i' + \Delta Q)^2 \tag{12.5.22}$$

Using the binomial theorem and expanding Eq. 12.5.22, discarding the second- and higher-order terms (the quantity ΔQ is assumed small), and solving for ΔQ yields Eq. 12.5.23:

$$\Delta Q = \frac{\Sigma\,(\pm)\, K_i Q_i^2}{-\Sigma\,|2K_i Q_i|} \tag{12.5.23}$$

The mesh equation (Eq. 12.5.23) can be interpreted as follows. The numerator is the algebraic sum of pressure losses around a given loop (conservation of energy). The denominator is the summed K-weighted quantities representing the conservation of mass. Thus the ratio of conservation of energy to conservation of mass defines the correction. The negative sign makes the adjustment in the proper flow direction, and the n in the denominator (n = 2 in Eq. 12.5.23) reduces the adjustment size to control divergence. Adjusting quantities by ΔQ in successive iterations results in a ΔQ which is close to 0. Branches that are in multiple loops are adjusted by each loop's differential quantity.

There are two drawbacks to the Hardy Cross analysis. As with all numerical techniques, the solution does not always converge or is slow to converge, and can be time-consuming if poor first estimates are made. It is also tedious to define the mesh equation.

The first step in solving a combination network after all of the physical parameters are determined is flow rate estimation in loop branches. It is strongly recommended that zero flow rates be avoided because they increase convergence time. If a computer program is unavailable, the K values for each branch will have to be estimated as demonstrated in Ex. 12.5.12.

Example 12.5.12. Calculate the K factor for a 4-in. (101.6-mm) diameter Schedule 40 pipe that is 450 ft (137.2 m) long and has two plug valves along its length. The flow rate is 3000 scfm (1.4158 m^3/s) at 125 psig (861.8 kPa).

Solution. The equivalent length of two 4-in. (101.6-mm) plug-cock valves is 15.2 ft (4.632 m), and the total length is 465.2 ft (141.8 m). The pressure loss is 6.3 psig (43.44 kPa).

The K value for this branch is

$$K = \Delta p/Q^2 = 6.3/(3000)^2 = 7.00 \times 10^{-7}$$

Sign convention is clockwise positive; therefore, flow in branches that are in two independent loops will have opposite signs as the sign convention applies to all loops. If one loop has positive flow defined in a clockwise direction, all loops must be similarly defined.

Fig. 12.5.9 shows initial combination network assumptions for flow rates at the example mine.

Example 12.5.13. Explicitly write the mesh equations for the example mine.

Solution. The mesh equations are, for loop I,

$$\Delta Q = \frac{-K_7Q^2 - K_5Q^2 - K_2Q^2 + K_{29}Q^2 - K_{30}Q^2 - K_{33}Q^2 - K_{17}Q^2}{K_7Q + K_5Q + K_2Q + K_{29}Q + K_{30}Q + K_{33}Q + K_{17}Q} \tag{12.5.24}$$

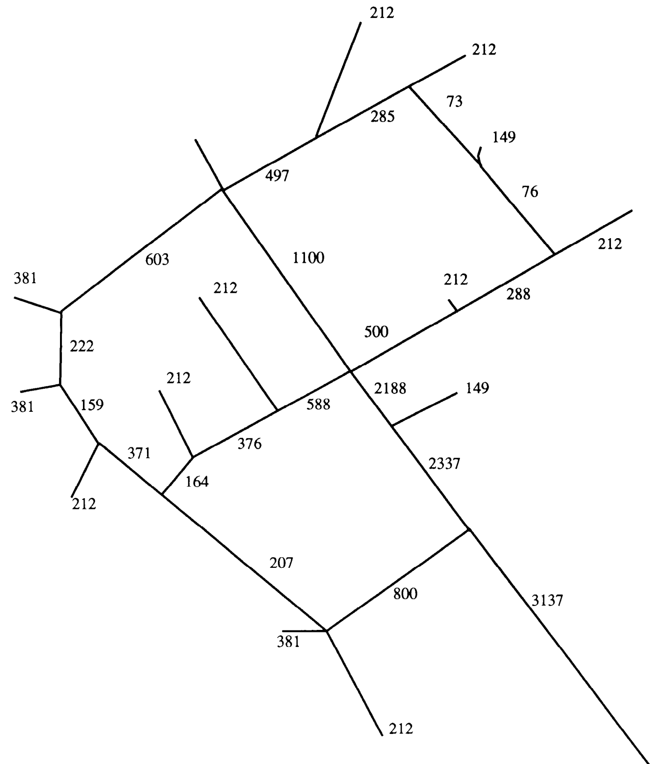

Fig. 12.5.9. Initial flow rates (combination network).

Table 12.5.16. *K* Factors for Hardy Cross Calculations

2 = 2.8890 E-06	5 = 4.5230 E-08
7 = 2.3735 E-08	8 = 2.8890 E-06
10 = 1.0192 E-05	12 = 1.2285 E-05
13 = 5.6537 E-08	14 = 6.8722 E-06
15 = 2.0240 E-05	17–19 = 6.0613 E-06
22 = 2.2389 E-06	24 = 1.3151 E-06
28 = 1.3493 E-05	29 = 1.9103 E-05
30 = 1.2486 E-05	31 = 5.5637 E-06
32 = 1.4453 E-06	33 = 6.0612 E-06

For loop II,

$$\Delta Q = \frac{K_{30}Q^2 + K_{33}Q^2 + K_{17}Q^2 + K_{31}Q^2 - K_{32}Q^2 - K_{24}Q^2 - K_{22}Q^2 - K_{13}Q^2}{K_{30}Q + K_{33}Q + K_{17}Q - K_{31}Q + K_{32}Q + K_{24}Q + K_{22}Q + K_{13}Q} \tag{12.5.25}$$

For loop III,

$$\Delta Q = \frac{K_{13}Q^2 + K_{14}Q^2 + K_{15}Q^2 + K_{28}Q^2 - K_{12}Q^2 - K_{10}Q^2 - K_8Q^2}{K_{13}Q + K_{14}Q + K_{15}Q + K_{28}Q\, K_{12}Q + K_{10}Q + K_8Q} \tag{12.5.26}$$

There are two ways to account for flow reversals. The first is to maintain the mesh equations in their present form and allow negative flow rates. The other is to maintain positive flow rates and adjust the equations. The second is the most popular, especially in computer programs, since they generally update the K factors during every iteration, and negative velocities create problems when determining friction factors.

The K factors for the example mine, given in Table 12.5.16, were calculated in the same manner as presented in Ex. 12.5.12.

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 psi = 6.895 kPa, 1 scfm = 0.0004719 m^3/s.

Table 12.5.17 summarizes the flow rates, pressures, pressure losses, and cumulative pressure regulation for each branch in the combination network. Both the upstream and downstream pressures are given.

Table 12.5.18 lists the gage pressures, pressure drops, and pressure regulations for the volumetric, radial, and Hardy Cross analyses. Improved pressure regulation was obtained with the combination network. Example 12.5.13 shows pressure losses around closed loops sum to zero.

Example 12.5.14. Sum pressure losses around the example loops to insure conservation of energy has been maintained.

Solution. Loop I

$$PL_I = 1.58 + 0.40 - 0.01 - 0.35 - 0.99 - 0.24 - 0.12 - 0.26 = 0.01 \text{ psig } (0.07 \text{ kPa})$$

Loop II

$$PL_{II} = 0.01 + 0.35 + 0.99 + 0.24 + 0.17 - 0.01 - 0.23 - 1.43 - 0.09 = 0.00 \text{ psig } (0.00 \text{ kPa})$$

Loop III

$$PL_{III} = 0.09 + 1.22 + 0.78 - 0.00 - 0.27 - 1.34 - 0.47 = 0.01 \text{ psig } (0.07 \text{ kPa})$$

When the pressure losses around all loops sum to zero (or within a specified tolerance), conservation of energy has been achieved, representing convergence of the Hardy Cross algorithm.

12.5.9.4 Nodal Technique

Nodal analysis assumes conservation of energy will govern all iterations until conservation of mass is achieved. The derivation of the adjustment scheme for nodal analysis is almost identical to the Hardy Cross method, except pressure is the independent variable and flow rate is the dependent variable that is calculated from the nodal pressures.

Manually analyzing combination networks with the nodal technique requires much computation, even more than the Hardy Cross method. It does, however, produce a small computer algorithm that removes the burden of user-specified meshes.

The nodal form of the mesh equations is

$$\Delta P_{ij} = \frac{n \, \Sigma \, m_{ij}}{\Sigma \, m_{ij} \, P_{ij}} \qquad (12.5.27)$$

Table 12.5.19 presents the initial flow rates and fittings for the combination analysis utilizing the nodal method. Table 12.5.20, generated by COMPAIR, shows the results. Solution was achieved after 30 iterations (approximately 5 minutes on a

microcomputer) with the largest deviation from exact conservation of mass equivalent to 10 scfm (0.004719 m^3/s) at the intersection of B Left and C Left. Pressure differences were less than 0.0001 psig (0.0007 kPa).

There is no significant difference between the flow rates calculated with the Hardy Cross and nodal techniques.

12.5.10 COMPRESSOR HORSEPOWER

Compressor horsepower calculation is simple if the compression cycle is assumed to be an adiabatic process. In actuality, the cycle is neither adiabatic nor isothermal but somewhere between the two. If the horsepower for a single-stage compressor is desired, and the process is assumed adiabatic, the following relation applies:

$$ihp/100 \text{ acfm} = 1.542\ P_s(r^{0.283} - 1) \qquad (12.5.28)$$

To calculate the horsepower for a two-stage compressor, a slightly different formula is used:

$$ihp/100 \text{ acfm} = 3.084\ P_s(r^{0.1415} - 1) \qquad (12.5.29)$$

Eqs. 12.5.28 and 12.5.29 determine indicated horsepower not brake horsepower. To obtain brake horsepower from indicated, divide the indicated horsepower by the appropriate efficiency, which is commonly around 85%.

Example 12.5.14. For the example mine, a two-stage piston compressor with a mechanical efficiency of 87% is assumed available. Determine the indicated and brake horsepowers for this compressor.

Solution. 1. For CAGH analysis, the compressor indicated and brake horsepowers are as follows:

$$r = (105.6 + 10.40)/10.40 = 11.154$$

$$ihp = [(3137)(1.41)/100](3.084)(10.40)(11.154^{0.1415} - 1) = 577.0$$

$$bhp = 577.0/0.87 = 663.2, \text{ or approximately } 675 \text{ (503.3 kW)}$$

2. For volumetric analysis:

$$r = (123.0 + 10.40)/10.40 = 12.827$$

$$ihp = (4423/100)(3.084)(10.40)(12.827^{0.1415} - 1) = 616.9$$

$$bhp = 616.9/0.87 = 709.0, \text{ or approximately } 725 \text{ (540.6 kW)}$$

3. For mass flow analysis:

$$r = (125.0 + 10.40)/10.40 = 13.019$$

$$ihp = (4423/100)(3.084)(10.40)(13.019^{0.1415} - 1) = 621.1$$

$$bhp = 621.1/0.87 = 713.9, \text{ or approximately } 725 \text{ (540.6 kW)}$$

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 psi = 6.895 kPa, 1 scfm = 0.0004719 m^3/s.

The mass flow rate of 3.98 lbm/sec was converted to scfm to perform the above calculation.

The reader should notice that the required horsepower increases as pressure increases. When calculating horsepower using the CAGH method results, the flow was corrected for altitude since compression ratio affects horsepower, and therefore all calculations must be done at actual conditions. The other methods already accounted for altitude.

When selecting compressor(s), consideration must be given to the number of compressors to be purchased. One large compressor or multiple smaller compressors can be selected as long as capacity requirements are satisfied. Multiple compressor arrangements are more expensive in both initial capital costs and ongoing maintenance costs; however, they are insurance against complete shutdown, and their purchase can be spread over time as the mine expands.

Determining receiver volume is the next step in the design. Typical recommendations for receiver size are 10 to 20% of the acfm compressor capacity, or alternatively one can use manufacturers tables. For the example mine, the above rule of thumb requires a receiver capacity between 400 and 800 ft^3 (11.3 and 22.7 m^3). A 400-ft^3 (11.3-m^3) receiver will be selected as additional capacity is provided by the network. In fact, with large networks where flow rates are very high, surface receiver capacity requirements are generally negligible.

Receivers can be useful to supply short duration demands in excess of compressor capacity., for example, if numerous air starters are activated at the beginning of a shift. In this instance, another method for estimating receiver capacity should be used (Rollins, 1973):

$$V_r = T\ C\ P_e/(P_{ri} - P_{rf}) \tag{12.5.30}$$

12.5.11 OPTIMAL PIPE DIAMETERS AND SYSTEM COSTS

Capital and operating cost estimates vary by location and the method presented is by no means a complete treatment of the subject. Valves and fittings costs vary widely throughout the world, and the values presented in Table 12.5.21 are estimates.

Steel pipe cost can be estimated by weight. A complete treatment of this method is given in the optimization section. Table 12.5.22 provides a sampling of pipe costs.

Initial compressor cost (Table 12.5.23) and installation also vary widely due to local differentials in labor rates, options installed, and size. Options include dewatering, oil removal, pre- and post-cooling, and monitoring. The provision of a receiver can be another major cost.

Determining optimal diameters can be extremely beneficial in reducing the overall cost of mine compressed air networks. The following equation can be used to determine the optimal inside diameters required. The equation developed by Gent

(1986) balances energy costs with initial installation costs to determine the optimal diameter

$$D_o = 1.465 \left[\frac{m^3 f y C_e P/A}{[(1 + P/A) b + F + z] P_1^2 X E}\right] \qquad (12.5.31)$$

Optimal diameters in the range of 1 to 16 in. can be determined with this model. Caution should be exercised with diameters outside this range.

Table 12.5.22. Pipe Cost and Weight Information, Schedule 40

Diameter (in.) Nominal	Actual	Cost $/ft	Weight lb/ft	Cost $/lb
2	2.067	1.44	3.65	0.395
3	3.068	2.46	7.58	0.325
4	4.026	3.44	10.79	0.319
6	6.065	5.75	18.97	0.303
8	7.981	8.45	28.55	0.296
10	10.020	11.90	40.48	0.294
12	11.938	15.05	49.56	0.304

Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 lb = 0.4536 kg.

Example 12.5.15. The following assumptions will be used to determine the optimal pipe sizes for the radial and combination networks:

1. Internal rate of return is 15%.
2. Installation is 20% of pipe cost.
3. Cost of electricity is 0.07 $/kWh.
4. Mine operates 3000 hr/yr at full capacity.
5. Life of the design is 10 years.
6. Minimum size pipe is 2 in. (50.8 mm).
7. Maximum size pipe is 12 in. (304.8 mm).

Table 12.5.23. Compressor Costs

Conversion factor: 1 in. = 25.4 mm.

8. 95.2 psig (656 kPa) required at C Left 2nd.
9. Maintenance is 7% of initial pipe cost per year.
10. List prices given in Tables 12.5.11 and 12.5.12 apply.
11. Overall energy conversion is 85% efficient.

Solution (Radial Network). Table 12.5.24 gives the radial network initial and optimized pipe and fitting costs, respectively.

To provide 95.2 psig (656 kPa) to C Left 2nd requires 104.5 psig (721 kPa) in the unoptimized case and 95.9 psig (661 kPa) in the optimized case. The required horsepower to produce the required quantity and pressure is as follows:

$$bhp = (3.084)(44.23)(10.40)\,[(104.5 + 10.40/10.40)^{0.1415} - 1]/0.85 = 676 \text{ (504.1 kW)}$$

$$bhp = (3.084)(44.23)(10.40)\,[(95.9+10.40/10.40)^{0.1415} - 1)]/0.85 = 650 \text{ (484.7 kW)}$$

$$\text{Energy saved} = (676 - 650)(3000)(0.7457) = 58{,}164.6 \text{ kWh/yr}$$

$$\text{Cost} = (58{,}164.6)(0.07) = \$4071.52/\text{yr}$$

$$\text{Present value at } 15\% = 5.019(4071.52) = \$20{,}435$$

The cost of using the larger-diameter pipe is $20,501 including the additional 20% for installation. The yield on the investment is 15%.

12.5.11.1 Combination Network

Solution. Initial and optimized costs are presented in Table 12.5.25 and Table 12.5.26, respectively. It is evident from the total costs that the optimized design is more capital intensive.

* Accounted for in the previous branch
Conversion factor: 1 in. = 25.4 mm.

However, energy cost savings provide a 17% rate of return on the investment.

To provide 95.2 psig (656 kPa) to C Left 2nd requires 103.1 psig (711 kPa) from the compressor in the unoptimized case and 95.9 psig (661 kPa) in the optimized case. The horsepower required is as follows:

$$bhp = (3.084)(44.23)(10.40)\,[(103.1 + 10.40/10.40)^{0.1415} - 1.0]/0.85 = 672\ (501.1\ \text{kW})$$

$$bhp = (3.084)(44.23)(10.40)\,[(94.9 + 10.40/10.40)^{0.1415} - 1.0)]/0.85 = 650\ (484.7\ \text{kW})$$

$$\text{Energy saved} = (672 - 650)(3000)\ 0.7457 = 49{,}216.4\ \text{kWh/yr}$$

$$\text{Cost} = 49{,}216.4\ \text{kWh}\ 0.07\$/\text{kWh} = \$3445$$

$$\text{Time zero value at } 15\% = 5.019(3445) = \$17{,}291$$

The cost of using the larger diameter pipe is $18,554. The yield on the additional investment is 14%.

Chapter 12.6
MONITORING, CONTROL, AND COMMUNICATIONS

JEFFERY KOHLER

12.6.1 INTRODUCTION

The application of technology to improve all aspects of mining is especially evident in the areas of communications and monitoring systems as well as in automation and robotics. It is important to recognize that decisions to apply these technologies are based on certain expectations that tangible benefits, such as improved safety or reduced costs, will be realized. Mine monitoring systems can provide quality information in a timely fashion; timely information can be used to improve the decision-making process, and in so doing allow realization of the desired benefits. Similarly, mine communications systems that have been carefully planned and correctly designed facilitate information flow throughout all levels of the organization. However, the achievement of expected benefits will only occur when the technical characteristics of the selected systems are capable of satisfying the mine's needs for information. All too often, the mine's information requirements are not carefully considered prior to the purchase and installation of a system, and once a system is installed, it is very difficult to correct mistakes. Thus it is important to thoroughly address these issues.

Regulations establish minimum requirements for communications systems in general and for mine monitoring systems in specific instances. Beyond these required minimums, every aspect of the system synthesis must be driven by information requirements. One means of defining these requirements is to provide answers to the following (Kohler et al., 1987):

1. *Who* needs what information?
2. *How often* is this information needed?
3. What *level of detail* is needed?
4. What *presentation format* will satisfy the need?

System synthesis must be based on justifiable needs rather than desires and fads; this list is useful for identifying these needs. The tradeoff between information and cost must also be considered. Almost any piece of information can be obtained if economic constraints are removed. Accordingly, steps should be taken to identify the added incremental cost to obtain various information elements from the monitoring system. The following specific comments apply more to monitoring rather than communication systems, though there are some common aspects, especially in the case of systems that combine both monitoring and voice communication capabilities.

The determination of *what* information is needed will define the type of sensors and, ultimately many parameters relating to system communications and architecture. The who aspect affects the architecture, generally reflecting a requirement for a distributed architecture, when certain information is required in different locations with different levels of processing. After this question is answered, the locations for terminals, display screens, or annunciator panels will be evident. It is important to allow easy access to the monitored information in locations where it can be utilized.

The responses to the first question will have a significant impact on the system hardware; the other three questions/answers will tend to dictate the software structure of the system, although there are obvious hardware ramifications as well. All three questions focus on the difference between data and information. Computer-based data collection systems in general—and monitoring systems in particular—are good at collecting large amounts of data within short time periods, and overwhelming amounts of data over longer time frames. In fact, the sheer volume of data collected has often discouraged its use. All data, however, are not information.

Information, by definition, reduces uncertainty. Thus, for example, if the concentration of gas is known, an additional piece of data pictorially representing the gas concentration does not reduce any uncertainty, and as such is not information. Anyone who has ever sorted through a stack of printer paper from a monitoring system output can attest to the fact that there were few data elements that reduced uncertainty in a decision-making framework. Accordingly, the challenge is to process the large volume of raw data and extract and display useful information. The 1970s was a period in which the utility of mine monitoring was restricted by hardware inadequacies and shortcomings; the 1980s was a decade when the utility of monitoring systems was limited by their inability to handle information. Just as research and development efforts overcame the hardware limitations of the 1970s, similar efforts successfully addressed the information issues of the 1980s. Actually, information management became a key concern in many aspects of engineering operations. Despite the advances that have contributed to improved information management within monitoring systems, the burden is still on the user to match the local information needs with the technical capabilities of the system.

The second question of *how often* has an operational side in addition to the information management aspect. In general, there should be two modes for accessing information: alarm and interrogation. In alarm mode, information elements such as sensor values are not displayed unless the value is outside a predefined region; in the interrogation mode, information is available on demand, whereby the user can "interrogate" the system for sensor values and other information. Sometimes a third mode is available, wherein the user can configure one or more standard reports that will be automatically generated on a periodic basis. The reports may include graphs as well as tables.

It is not the purpose of this chapter to examine information management issues, other than to point out that the aforementioned questions must be answered before the monitoring system software for a management information system (MIS) can be selected. Careful attention to the questions of information need and usage will result in an accurate and comprehensive understanding of the mine's information needs. These can be fully documented; such a document will be most useful in developing the specifications for the proposed monitoring system.

The design and fabrication of mine monitoring systems is essentially the activity of manufacturing companies, not mining companies. Although a few mining companies have become involved in these systems at the circuit-board level, it is not necessary nor desirable for mining personnel to become involved in these details. However, if the monitoring system is to be well matched to the mining application, it is essential for mining personnel to clearly and accurately state the systems-level requirements to manufacturers and vendors. Toward this goal, it is helpful to understand the composition and function of the building blocks that constitute a monitoring system, and how the specification of these will directly affect the performance of the system.

12.6.2 GENERALIZED MONITORING SYSTEM

Fig. 12.6.1 illustrates the building blocks of a monitoring system insofar as a user is concerned. Each of these aspects will be discussed as they relate to the specification of a mine monitoring system, and those aspects that are appropriately addressed by the mining engineer are emphasized in the following discussion. It is also assumed that the specified components will be *mine-worthy,* a term suggesting that the component can withstand the harsh mine environment, including moisture, dust, temperature extremes, vibration, and shock.

12.6.2.1 Sensors

The choice of the right sensor is dependent upon an understanding of the property that is to be measured (the *measurand)* and the performance parameters of the sensor. Sensor selection is an aspect of the overall system specification in which the mining engineer should actively participate. In fact, many situations could be improved through monitoring if it were recognized that a wide variety of sensor types can be used with a mine monitoring system, even though they are not necessarily sold by the manufacturer of the mine monitoring system.

Characteristics of the measurand include the expected range of values, significant and insignificant variations that must be detected or ignored, respectively, and the presence of factors or compounds that might introduce error into the measurement or cause other problems. It is always best if the interaction between the sensor and the measurand and its environment are understood. Otherwise, in the case of a gas sensor for example, the presence of one gas in the environment may result in an erroneous indication of the gas that is of interest, or in some cases, it may even "poison" or ruin the sensing element. Taking the time to understand all aspects of the measurand can pay unexpected dividends. It may turn out that the property of interest can be sensed indirectly, and that the sensor for this secondary indicator of the measurand is more reliable or perhaps less expensive than a sensor for directly measuring the measurand.

The key performance parameters for sensors are accuracy, resolution, dynamic range, and stability. Cost is an important factor, especially if large numbers of a particular sensor must be purchased for many locations. For the purpose of this discussion, *accuracy* is defined as the deviation of the measured value from the true value; *resolution* is the smallest part of the whole that can be detected; *dynamic range* is the range of values over which the sensor can be used with the stated accuracy and without causing permanent damage to the sensor and is sometimes called *full-scale range* (FSR); *stability* is a measure of the sensor's tendency to drift, that is, for the output to change due to unrelated factors such as elapsed time or temperature.

It is noteworthy that these parameters are somewhat interrelated. For example as the sensor's accuracy is increased, the dynamic range will decrease, stability will tend to worsen, the cost will increase, and the resolution will probably increase. Oftentimes, accuracy is even given as a percentage of the full-scale range (dynamic range). Accordingly, it is important to match the performance parameters as closely to the application as possible, as illustrated in the following example.

Example 12.6.1. A current with an expected range of 90 to 120 A is to be measured. Information on available sensors is obtained, and the choice is narrowed to one of two models. The first has a rated range of 0 to 100 A with an accuracy of +2% of FSR; the second has a range of 0 to 500 A, also with an accuracy of 2% of FSR. Since the expected value of 120 A exceeds the FSR of the first model, the second model would normally be selected. The error associated with this model could be 10 A (2% of FSR), making the actual error as a percentage of the measured value around 10%. This might be satisfactory for some situations, but regardless, the actual measurement accuracy in this application will be five times worse than the mistakenly expected value of 2%.

Upon discussion with the manufacturer, it is learned that the FSR of either sensor can be doubled without harming the sensor, although the accuracy deteriorates to 3% at 100% overload. Given this, the first model could be used, and assuming a worst-case accuracy of 3%, the actual measurement accuracy would also be on the order of 5%, which is significantly better than that of the second model.

A published accuracy often reflects a fixed error or bias in the sensor in addition to a variable and sometimes random component. In marginal cases, this should be investigated; it is often possible to perform onsite calibration, resulting in significant improvement in the actual measurement accuracy as compared to the published accuracy.

Resolution is often given little consideration or is unneccessarily sacrificed for dynamic range.

Example 12.6.2. Suppose that a pressure sensor is to be selected to measure air pressure in automated pressure/quantity mine ventilation surveys. It is determined that a resolution of 0.2 in. water (49.8 Pa) is necessary. A piezoresistive pressure sensor is selected with a dynamic range of 0 to 15 psia (103.4 kPa), and an accuracy of 0.1% FSR with an output of 0 to 1 V. The transfer function is assumed to be linear and is 0.0024 V/in. (0.094 mV/mm); given an accuracy of 0.1 %, it is clear that the resulting error of 0.42 in. water (104.5 Pa) is larger than the desired resolution of 0.2 in. (44.8 Pa), although a workable resolution on the order of 0.4 in. water (99.5 Pa) would be possible, and for many applications satisfactory. However, a more serious problem may exist.

The monitoring system uses a 10-bit *analog-to-digital convertor* (ADC) with a FSR of 10 V. The resolution, *R,* of an n-bit ADC is given as

$$R = \mathrm{FSR}/2^n \tag{12.6.1}$$

which in this case is calculated to be 9.8 mV. Given the foregoing transducer specification, it becomes clear that the smallest detectable change, that is, 1 bit, is going to be 4.07 in. water (1013 Pa). If the accuracy of the ADC is a typical value of 0.1% FSR (for a 10-bit ADC), a worst-case error would be in excess of 4.5 in. water (1120 Pa). This is absurd, and yet installed systems can be found with such gross mismatches as attempting to resolve an air pressure to within 0.5 in. water (124.4 Pa) with an overall system limitation that is almost 10 times larger than that of the measured quantity.

There are, of course, a variety of options available to rectify this problem if it is recognized before components are purchased. A 12- or 16-bit ADC would be appropriate, as would a reduced FSR. However, in particularly demanding applications such as this one, additional steps would be required. By recognizing that the pressure sensor will be used only over a small part of its dynamic range, it is possible to amplify only that portion, resulting in a significantly larger swing in sensor output for a small change in pressure. A second stage of amplification prior to the input of the ADC may also be desirable. By fully utilizing the ADC's FSR, acceptable levels of both resolution and accuracy can be achieved. Generally, monitoring system manufacturers

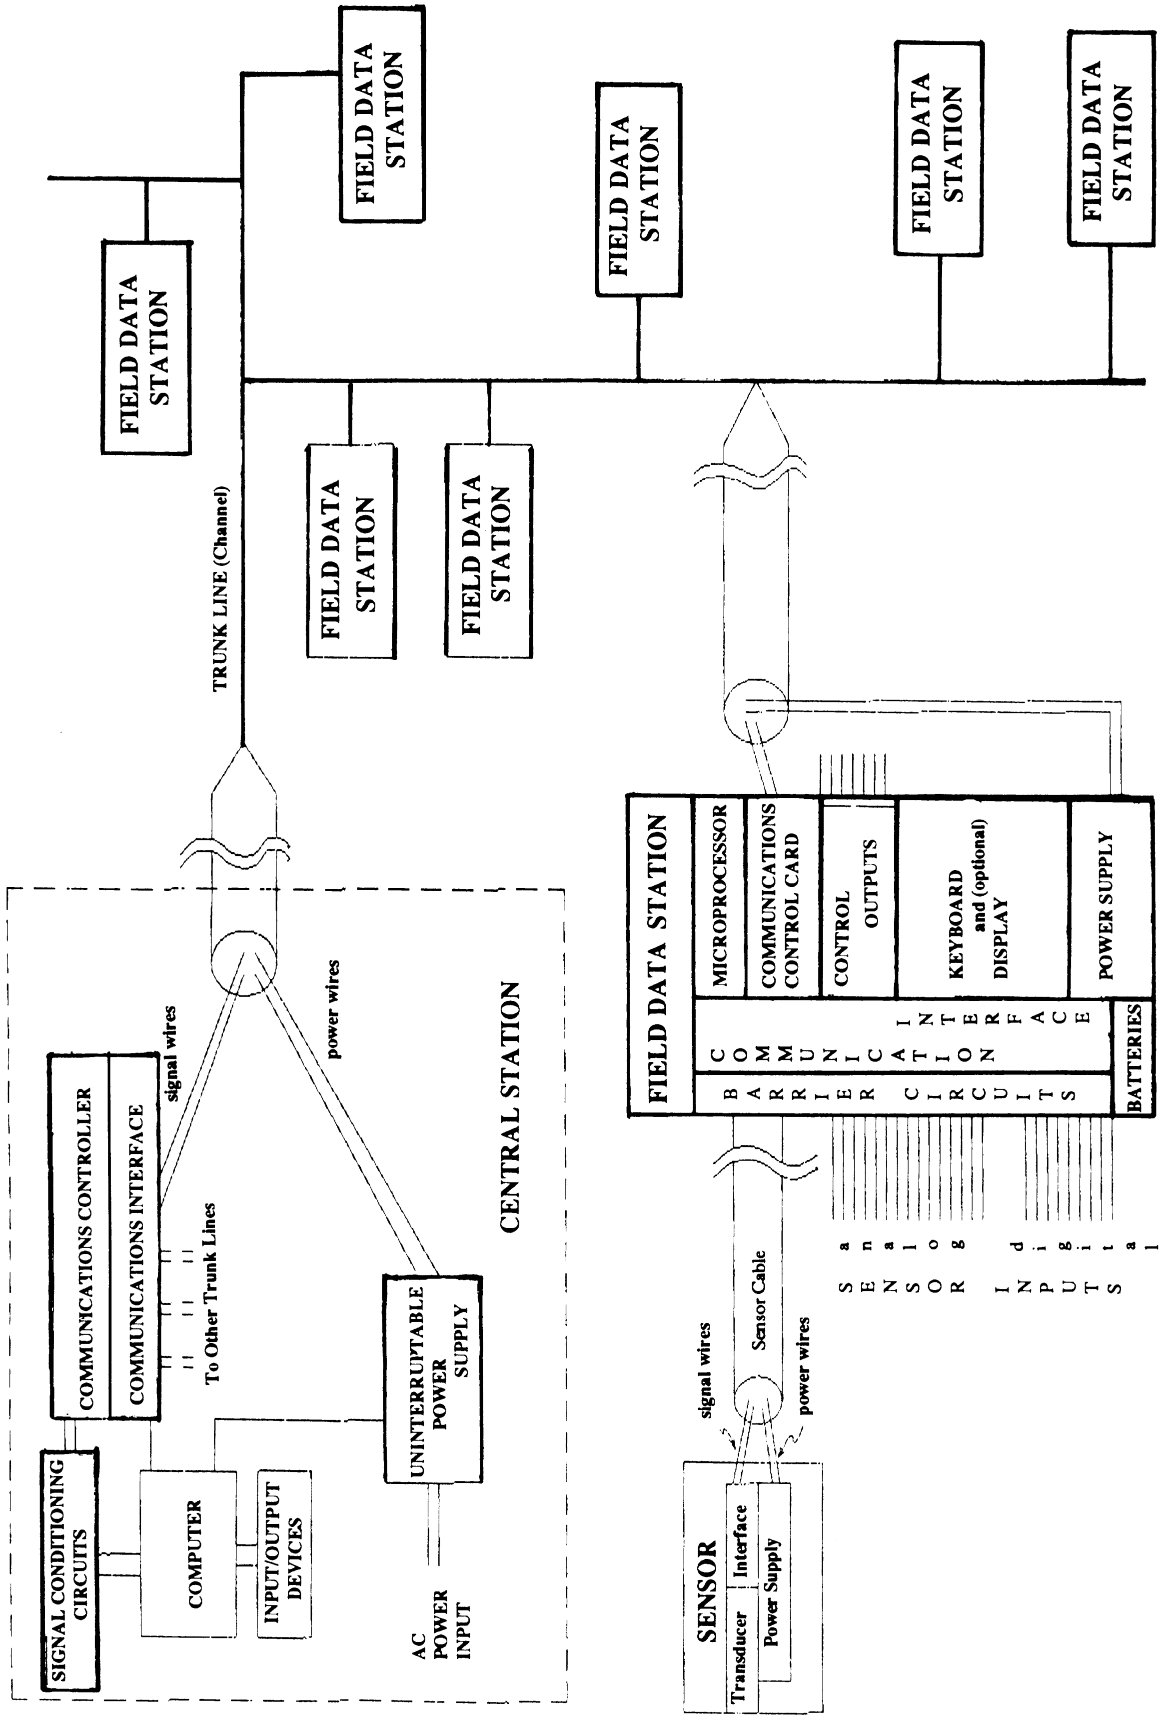

Fig. 12.6.1. Block diagram of a mine monitoring system.

can provide the type of custom interfaces and circuitry that would be needed here.

The latter problem illustrates the importance of matching performance specifications throughout the system, and calculating resolution and accuracy at all points in the system. Additional information on sensors, in general and for mining applications, can be found in the literature (e.g., Anon., 1986; Anon., 1988; Chilton and Cohen, 1983).

12.6.2.2 Interfaces

The function of an *interface* is to match the output of one device with the input requirements of the next device in the system to which it is connected. Just as a three-pronged electrical plug will not fit into a two-pronged socket without an adapter plug (interface), the electrical characteristics must be compatible at all points where two different components are connected. In addition, the sensor interface may be employed to provide general signal conditioning to improve overall performance. Interfaces maybe an integral part of a component, such as a sensor, or maybe installed as a separate device. Some common signal conditioning techniques are described here.

Attenuation or *amplification* of a signal to improve the signal-to-noise ratio, or to utilize the FSR of an ADC to improve resolution, as illustrated previously, is a common practice. The transducer output within a sensor may not be in the form desired for transmission of the signal. Voltage outputs are sometimes converted to frequency where the transmitted frequency is proportional to the magnitude of the original voltage. Such a scheme allows for a signal to be transmitted over long distances without suffering deleterious effects from attenuation. Another scheme more commonly employed to avoid problems from line loss is to convert the voltage to a current; this also allows the use of a non-zero baseline.

The 4- to 20-mA current loop interface transmits a signal of 4 mA when the sensor output is zero, and up to 20 mA for the sensor's maximum value. This non-zero baseline is particularly attractive in an application like mining when there is a risk that the transmission line between the sensor and the central station can be damaged. Consider, for example, a gas sensor that has an output of 0 V when the gas concentration is 0%. The monitoring system will register 0 V and report a gas concentration of 0%. Now assume a rockfall cuts the transmission line between the sensor and the central station; the monitoring system will still register 0 V. However, if a 4- to 20-mA current-loop interface had been used, the system would have registered 4 mA (or the equivalent voltage drop across a known impedance) when the sensor detected 0% gas, and 0 mA after the transmission line was damaged.

Isolation is another important function performed by an interface. Isolation is desirable when an event (normal or abnormal) on one side of the circuit could cause an undesirable event (ignition, shock hazard, failure, etc.) on the other side. Typically, isolation will be performed to isolate voltage levels and to achieve intrinsic safety; this is usually achieved by using contacts and, transformer or optical isolator circuits.

Contacts, either from a relay, as auxiliary contacts on a contactor, or as an inherent part of a sensor, can be checked for closure by the monitoring system. For example by detecting a set of auxiliary contacts on a motor contactor, such as for a belt drive, the status of the device in the power circuit is determined without connecting the monitoring circuit to the high-power circuit. In other situations it may be possible to insert a relay into a circuit: the relay coil, when energized, will open or close contacts that can be sensed by the monitoring system. As with the auxiliary contacts, information is obtained without directly sensing high voltages, and to the data-acquisition equipment anything over about 15 V may be considered high and potentially damaging.

Isolation circuits utilizing either transformers or optical couplers are also readily available and often used. However, optical couplers usually provide a higher degree of isolation and better frequency characteristics and would be used if high-frequency information were of interest. Transformer-based isolation circuits are satisfactory if only increased reliability is desired. For example, if a control circuit for a machine is being monitored, a failure in the monitoring circuit might affect the machine's control circuit, thereby idling the machine; in these cases, transformer isolators can be used to insure that this will not be a problem.

If a sensor is going to be located in an area of the mine where there is concern that an ignition may occur, or in an area where permissible equipment is required, then a different kind of isolation may be needed. Circuits, known as barriers, are often used to prevent potentially dangerous levels of energy from moving from the monitoring-system circuitry to a connected sensor.

Outstations contain sufficient energy to cause an ignition and, accordingly, are normally not located in areas that require permissible circuits. The sensors connected into the outstation, however, may be located in hazardous areas and, even though the sensor may be permissible, a failure inside of the outstation could allow sufficient energy to reach the sensor to cause an ignition. To prevent this, the wires going to the sensor have to pass through an intrinsic-safety barrier strip. These barriers contain circuitry that limits the energy to non-incendive levels, by clamping the voltage and limiting the current. The class of the barrier strip must be matched to the operating characteristics of the sensor to achieve satisfactory performance.

A separate but related issue is the permissibility of the sensor, if it is going to be located in a hazardous area. If the sensor is intrinsically safe (i.e., under any normal or abnormal mode of operation, it cannot produce an incendive arc or spark in a methane-air mixture), and if it has been certified by the Mine Safety and Health Administration (MSHA) as permissible (legal for use in gassy mines), then the sensor may be located in the restricted area of the mine. Nonetheless, barriers will still be required, in virtually all cases, because a failure in the monitoring system's circuits could allow incendive levels of energy to pass to the intrinsically-safe sensor. Some sensors cannot be made intrinsically safe, because, to operate, they require more than 0.3 mJ of energy, which under certain conditions could cause an ignition. For these, part of the sensor must be placed inside of an approved explosion-proof (XP) enclosure.

Filtering is another signal conditioning technique available to improve the quality of the signal. The most common application is to remove unwanted signals that are interfering with the legitimate signal. Commercially available filters include lowpass, highpass, bandpass, and notch filters. Lowpass filters pass frequencies below a specified value and attenuate frequencies above it; highpass filters attenuate frequencies below a specified value; bandpass filters pass only frequencies between two specified values; and notch filters pass everything except for the frequencies between two specified values. Lowpass filters should be used when a Fourier transform will be performed on the signal, for example, in a predictive maintenance application, to prevent aliasing; another application is to use a 60-Hz notch filter to eliminate this component from sensor signals.

Other signal conditioning techniques are employed, but the ones described are the most likely to be encountered in a mining operation. Some techniques that could be grouped here, such as analog-to-digital conversion, encoding, and modulation, are discussed in the next segment.

12.6.2.3 Communications

The communication blocks in Fig. 12.6.1 facilitate the interchange of data between different parts of the monitoring system. The choice of communications parameters in the system will directly affect both the quality and quantity of information that passes through the communications channel. *Channel* is a general term for the medium through which the signal is sent; channels may be either wired or wireless. Data communication are emphasized in this section, although voice communication is merely a special case of data communication.

The central issue in communications is preserving information in a signal. During a telephone conversation when there is a "bad connection," one experiences some difficulty in trying to hear and understand the other person. When the connection deteriorates to the point where information is lost or misinterpreted, a real problem exists. The same is true in data communications. To prevent these problems, it is necessary to understand the nature of the noise (unwanted interference signals), the source of the noise, and the technology that can be employed to overcome the problems. Fortunately, this is an area that has been investigated for in-mine applications and is well understood (Bredeson, Kohler, and Singh, 1981).

Many of the potential problems with noise are circumvented by using a *digital communications scheme.* In such a scheme, the analog signal, which is a continuous function of time, is digitized using an analog-to-digital convertor. As a result, the original signal is represented by a string of "zeros" and "ones," which is then transmitted. To illustrate the simplified task of accurately receiving the transmitted state, assume that a "zero" can be considered as any pulse less than 1.5 V, and a "one" as any pulse greater than 3.5 V. Then a 5-V pulse will be transmitted for a "one" and no pulse for the digital "zero." Obviously, these pulses would have to undergo extensive noise corruption before it would be impossible to differentiate between the two allowable states. An analog signal, however, loses information with the least amount of noise. The quality of digital communications is further enhanced by utilizing a transmission scheme known as *frequency-shift keying* (FSK) in which the amplitude is constant but the frequency is changed to correspond to a binary 1 or 0; this is particularly useful if the distances involved are large. Regardless of distance, however, this scheme is used almost exclusively in mine monitoring systems for communication between the outstation and the central computer; communication between the sensor and the outstation is usually accomplished with an analog scheme.

The digitization of the analog signal by the ADC can be accomplished by a number of means. The successive-approximation technique is quite common and is well-suited for mining applications; integrating convertors are less expensive, but the longer conversion time is often unacceptable. The ADC's specifications will impact significantly the information-collection capability of the monitoring system. While many of its characteristics are of more concern to the manufacturer than to the user, there are some factors with which the user should be familiar. The number of bits, as indicated previously, is important because it determines the system resolution; the settling time and conversion time of the ADC may limit the sampling rate, which will limit the number of channels that can be scanned in a certain time period. Finally, the accuracy of the ADC must be considered in determining the overall accuracy of the system.

Wired channels are commonly used as the transmission medium, although wireless channels are particularly suited to receive signals from mobile equipment or from non-mobile equipment over short distances where it would be cumbersome to run a signal cable. Frequency-modulated (FM) transmitters are often used for this purpose. The selection of a wired-channel transmission medium is based on a number of factors, but for mining applications, twisted pair is satisfactory for most applications, except when a larger bandwidth requires the use of coaxial cable. Large and sophisticated applications in the future will probably utilize optical fiber data links. Although these are even finding some application in the mineral industries today, extensive use will come only after further reductions in the cost of the technology.

A number of decisions must be made in the selection of a cable for the mine monitoring system, but it first should be recognized that it is not just "a cable." Many problems have occurred in too many mine monitoring installations where the company settled for low-cost or surplus telephone cable. If funds for the proper cable are not available, then the monitoring system should not be purchased.

The physical configuration of the cable used for the monitoring system varies depending on the type of monitoring system, as well as the mine's requirements. A simpler cable can be used when it is unnecessary to provide power to the monitoring system through the cable. A more sophisticated, and relatively unpopular, configuration consists of insulated signal conductors, insulated power conductors, a bare ground wire, metallic shields, and possibly a messenger wire. Filler materials are added and these components are cabled and covered with a jacket or sheath.

The signal conductors almost always consist of twisted pairs of wire. Each twisted pair will carry the signal to or from one actuator or sensor. Each pair may be enclosed by a metallic shield, and cables with varying numbers of twisted pairs can be purchased. The power conductors, if needed, provide power to sensors. The signal and power conductors are stranded to increase their flexibility. The purpose of the steel messenger, when used, is to carry the weight of the cable; when it is suspended, very little stress is imparted to the signal or power conductors. Further, it provides a convenient place to attach the hardware that is used to hang the cable. The whole assembly is enclosed in a jacket which provides moisture resistance and reduces the chance of abrasion damage to the conductors.

The following parameters should be considered in the selection of a cable: losses, number of conductors, and shielding. The signal-conductor size must be large enough to minimize the resistive voltage drops that will occur over the length of the longest-expected trunkline. Usually, a 14- or 16-gage wire is preferred for its mechanical strength; these sizes are more than adequate for the signal lines. A second component of signal loss is due to the distributed capacitance of the signal wires. Over several thousand feet (meters), this component can become a limiting factor. Therefore, dielectric materials with relatively low capacitance (e.g., 25 pF/ft or 82 pF/m) are preferred. If power conductors are used, the voltage drop can become a limiting factor that should be checked. The monitoring-system manufacturer can provide the appropriate information to correctly size the conductors.

Shielding is used to reduce the reception of electromagnetic noise on the signal conductors by surrounding them with a grounded metallic covering. However, for mine monitoring applications, this practice is no longer recommended, except under very special circumstances, due to problems that develop through ground loops. Ground loops occur whenever a shield or ground wire becomes externally grounded at points that are physically separated. This can occur at a sensor, if it has a single-ended output or if one side of the differential output has been tied to a chassis or ground; it may occur within outstations and at the central station. As a result of ground loops, noise pickup can be increased dramatically, and chassis grounds can become elevated, causing a myriad of problems with ADCs and microprocessors. Since these ground loops can be difficult or impossible to prevent in an extensive system, recent experience in mining suggests that it is better to use unshielded twisted pairs, especially with the higher common-mode rejection available at the system inputs.

The purchase of a cable with surplus twisted pairs is often a good investment. Additional pairs are, on an incremental basis, inexpensive and offer considerable flexibility for future expansion—further, they make it easier to maintain the link over time. From a reliability point of view, the use of the embedded messenger is thought also to be desirable, as mentioned before. Unfortunately, there are no data available to support this position, and the incremental cost of including a messenger with an external sheath is significant. Few mines utilize a messenger.

The use of a twisted pair of wires to connect each sensor to the central-station computer is impractical except in small or local applications. The cost of installing the communication channel (the wires) throughout the mine is a major expense in implementing mine monitoring and, in fact, is an impediment to instituting monitoring in large existing mines. Thus various multiplexing schemes are used to allow information from multiple sensors to travel over the same twisted pair.

A *space-division multiplexing* (SDM) scheme is one in which separate wires are run for each sensor. This approach is appropriate when the distance is on the order of a several hundred feet (few hundred meters) or less, and when the sensors are not located along a straight line. It is a simple and straightforward scheme but too expensive to use over long distances. *Time-division multiplexing* (TDM) is a scheme where the sensors or other sources of information take turns utilizing a twisted pair. This is an economical system with few disadvantages other than speed. As the number of information sources becomes larger, it will take increasingly longer to query the sources. This time is quantified as the polling rate, and in larger systems this rate would become unacceptably long (on the order of minutes) if TDM were used exclusively.

Frequency-division multiplexing (FDM) offers the continuity of information flow and speed of SDM, with the use of only one twisted pair as in TDM. This is accomplished by partitioning the available frequency band and then giving each information source its own frequency band. It is necessary, of course, to utilize slightly more complex electronics to accomplish this. However, the cost of the signal-controlled oscillators and related circuits is more than offset by the reduced cost of cable and the improved performance.

An extensive monitoring system will typically employ all three forms of multiplexing. SDM is often used to connect sensors at outstations. FDM is usually used to communicate with an outstation; sometimes each outstation is interrogated by the central computer using a TDM scheme. If the monitoring system uses multiple trunklines, it would not be unusual to find that TDM was being used to access each individual trunk.

While many of the parameters that define data communications within the monitoring system are transparent to the user, such as those related to improving the signal-to-noise ratio or data security schemes, there are others that are of concern to the user. The minimum amount of time required to sample each sensor is of concern since this will determine the total time required to scan all of the sensors. In some schemes all sensors are effectively off-line when the system is scanning, except for the one that is currently being polled. In other systems, if a sensor goes into an alarm condition, it will interrupt the normal polling sequence so that this condition will be immediately known at the central computer. The *polling rate* or number of sensors sampled per unit time and the interrupt scheme must be commensurate with the needs of the user.

The *sampling rate* per sensor (the number of samples taken to define one reading) and the use of these samples (e.g., arithmetic averaging, etc.) should be defined. The system may take a sample in a few milliseconds. Thus, if there are time-dependent variations in the sensor signal, as is often the case with atmospheric parameters as well as others, then misleading readings will result. The ability to take multiple samples at the time of polling is useful because time-averaged values can then be calculated and displayed.

The sampling rate is also of concern if frequency information must be extracted from the measurement. In this case, the sampling frequency must be theoretically twice the highest frequency to be resolved, but practically it must be greater than the theoretical minimum. Mine monitoring systems, by their nature, are not well suited to sampling individual channels at high rates, particularly if there are a number of channels with this requirement. A better alternative is to use a dedicated microprocessor to sample at the high rate, perform the desired computations, and then output the result to the mine monitoring system data bus. Essentially, the microprocessor behaves like a *"smart sensor,"* and is treated simply as a sensor by the monitoring system.

Another consequence of the communications structure used by the manufacturer is system performance if the communications trunk line is severed. With some schemes, only those stations inby the cut will be lost. In other schemes, all stations on the trunk will be lost. A discussion of the technical alternatives is beyond the scope of this chapter, but the practical ramifications of the communications architecture is not. In addition to the aforementioned consideration of system performance when the trunk line is cut, the user should also understand, before purchasing a system, any limitations on the number of devices that can be connected to a trunk line and the maximum distance permissible between any two outstations or an outstation and the central station.

12.6.2.4 Outstations

Outstations or *field data stations* represent a point of aggregation in a hierarchical structure of data flow. They serve as an economical compromise by allowing access to the communications trunk by a number of sensors. Finally, they are convenient locations to provide local monitoring and control. The latter can be particularly crucial if there is a failure of the mine-wide system. The major function, however, is to provide a communications interface between a sensor and the trunk connected to the central station computer. Outstations cannot be located in areas that require permissible equipment, unless they have an MSHA approval number, which would be quite unusual. However, *blue outstations* can be used with sensors that are located in areas that require permissible equipment, whereas *red outstations* cannot. Intrinsically safe and permissible systems can be obtained, but they normally do not use the outstation-type architecture. An intrinsically safe system would have some advantages in gassy mines (Watson, 1982). Fig. 12.6.2a illustrates a typical outstation used with a mine monitoring system. The barrier strips, required in a "blue" outstation, can be observed in the figure. An outstation installed in an underground coal mine is shown in Fig. 12.6.2b.

It is possible to add a communications interface right into a sensor, thereby eliminating the need for an outstation. Such a sensor with a built in accessor card is shown in Fig. 12.6.3. If there are several sensors in close proximity, such an approach is not cost-effective; if there are many instances of isolated locations with only a few sensors, then elimination of the field data station would be cost-effective. However, it is usually not possible to mix and match within a given system: either the system is designed to

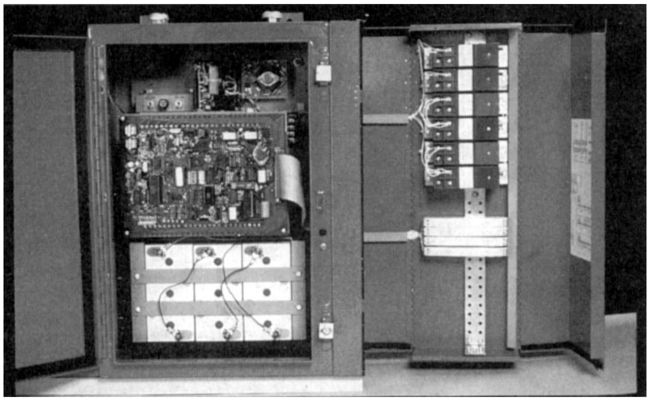

Fig. 12.6.2a. A field data station with the cover open to show the circuitry and barrier devices (*courtesy:* National Mine Service).

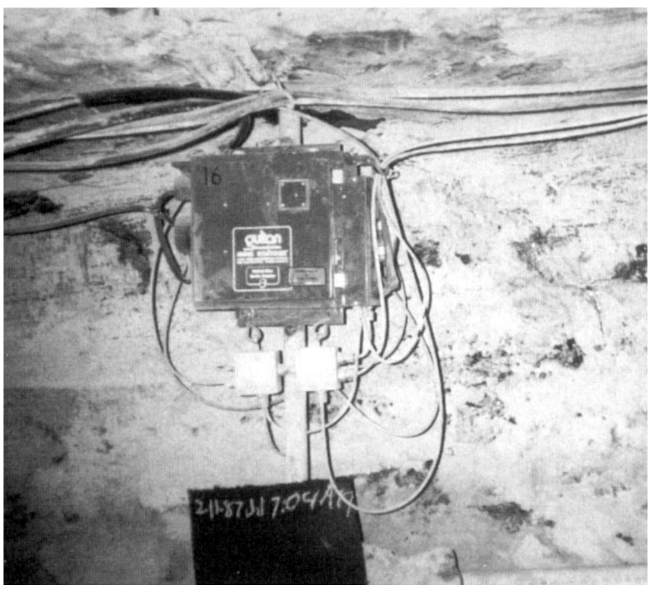

Fig. 12.6.2b. A field data station installed in a mine.

use outstations or it is not. In general, more sensors can be used on a trunk if outstations are employed than if they are not. This limitation, due to the number of unique addresses that can be defined in an n-bit communications signal, is rarely a problem, but should always be checked, especially in the larger and more comprehensive systems. Sometimes it is necessary to run multiple trunk lines in extensive installations. Intrinsically safe systems have been manufactured using the accessor-card type architecture, rather than the outstation type.

12.6.2.5 Central Station

This station, regardless of what it is called, contains the main monitoring system computer(s), terminals, data storage devices, and sometimes other components such as uninterruptable power supplies (UPS) and so forth. Often this area is staffed around the clock and may also serve as a communications center for the mine. A basic workstation in the central station will consist of one computer that is usually the equivalent of a personal computer, a keyboard, a monitor, a printer, and a UPS. Typically, the basic workstation is upgraded to include additional computers and monitors. Industrial-grade components should be used whenever available. Rather than review all of the components of a central station and the various options, all of which can be obtained from system vendors, the emphasis here will continue to be on specific aspects that should be given special consideration but are sometimes overlooked.

The availability of service and spare parts is always considered in the purchase of mining equipment but not always in the purchase of monitoring equipment. Yet, over time, these systems become just as indispensible to the operation. Some monitoring systems heavily utilize “off-the-shelf” hardware and software. Generally, this translates into better than average availability of parts and support if needed. On the other hand, systems utilizing “custom” processors may offer better performance; in some cases, this may offset any inherent disadvantages of the custom processor. Of course, the requirements document, discussed earlier, can again be consulted to determine if the additional performance is significant in the proposed installation. A backup computer was often included in early monitoring installations. However, with the higher reliability units available today, combined with the availability of replacement boards, it is seldom necessary to purchase a backup system. An inventory of spare boards is sometimes recommended.

The number of terminals available at the central station should be at least two and preferably three. One terminal is always needed to track alarm conditions; a second can be used to display specific graphics related to areas of interest, such as the belt system and the status of all sensors. A third terminal can be useful for displaying additional information or in performing off-line development and maintenance of system software, assuming this is supported by the monitoring system software. Naturally, if the utility of the system is to be realized, then the system should be able to support multiple terminals in remote locations. This would allow a terminal in the engineering office, the superintendent’s office, and so on. These locations would be determined through the information definition stage outlined previously. Most systems allow for the establishment of various access levels and security codes so that the information accessible by any user is easily controlled.

The usefulness of a monitoring system is determined, in part, by the usefulness of its displays. The display should contain as much relevant information as is practical, and this information must be displayed in a format that is clear and easy to understand. Achievement of this is quite a challenge, though advances in graphic displays (e.g., resolution, size, speed, software support) have permitted display formats that were impossible only a few years ago.

Color graphics allow an order of magnitude increase in the information that can be presented on a single display, and they are easier to interpret as well. Systems that easily allow the user to create custom maps and displays are desirable. In too many instances, however, complex graphics are used to display trivial or simple pieces of information, thereby unnecessarily tying up system resources. In other cases, systems are selected based more on the attractiveness of the graphics than the performance of the system.

The individual displays, including maps, flow charts, diagrams, and tables, will have to be created at the mine site, usually by engineers with little specialized training in computer software. Therefore, it is important that the graphics software provided with the system be suitable for the intended application. The suitability of a graphics package can be evaluated by determining the ease of creating a new display, the ease of modifying an existing display, the total number of display screens allowed, and the number of active elements that are allowed per screen (an active element will display the value of one sensor). The maximum requirement for active elements generally occurs on either the display for a diagram of the ventilation network or the belt system, where it is important to simultaneously show several sensor values.

It is not essential that an environmentally isolated and conditioned space be provided for the system in all cases, but a relatively dust-free and air-conditioned room will reduce failures and heat-related shutdowns. It is essential that the system be supplied with a quality power source; in most cases, an uninterruptable power supply (UPS) that is often required anyway, will satisfy this need.

Finally, it is desirable for the user to be able to set up data files and easily access these from another computer in order to facilitate analysis and use of the collected information. This cannot be accomplished unless the monitoring system stores files in a manner that allows retrieval by another computer system, such as a DOS-based personal computer. A personal computer, interfaced to the monitoring system computer and used as a file server, would certainly facilitate use of the collected information. A central station computer system, representative of the minimum required, is shown in Fig. 12.6.4. The next acquisition for the illustrated station would be an additional monitor and possibly another processor.

12.6.2.6 Control

Mining applications involving control are relatively rare (remote control of mining machines, automation, and robotics is excluded here and is covered in Chapter 22.2; process control is also excluded and discussed in Chapter 25.3). This is in part because of the resistance of regulatory bodies to recognize new technology and allow its application, and is also due to the absence of a strong need for such control. Currently, control in an integrated monitoring and control system consists solely of straightforward on/off control of equipment. Notable applications include drive motors for materials handling equipment, switchgear, and pump motors. An application offering promise is energy management, and it is believed that more mines will adopt this technology as it becomes better known (Toni, 1988).

Mine ventilation offers several notable opportunities for control. In a general sense, the control objective would be to exactly match the mine's need for air with the output of the mine ventilation system. Technologically, this can be accomplished by controlling regulators and the mine fan (Aldridge, 1976; Kohler, 1986); however, a change in the statutory requirements will be necessary before it will be possible to alter the ventilation network while workers are in the mine. Under less restrictive legislative environments, the development and implementation of ventilation control has been reported (Ching, 1987).

Most commercially available mine monitoring systems offer a control option. Typically, there are options for digital and analog output. A digital output might be used to control a device, such as a pump that has a built-in digital speed controller or any other similarly equipped device. The analog output might be used with a proportional controller or other device that responds to the amplitude of the control signal. For most applications in mining, however, it is only necessary to control a relay or contactor. Manufacturers provide relay boards that have a number of low-power contacts, each controllable by the software, that can be used in many control applications. If large amounts of power must be controlled, these contacts would be used to energize larger relays better suited to this requirement.

Programmable controllers (PC) have served, over the years, as a crucial evolutionary step between hard-wired relay logic and computer control of industrial circuits. PCs have undergone quite an evolution in which powerful microcomputers and sophisticated software have been incorporated into them. Today, it is possible for a user with a modest knowledge of the technology to custom configure a mine-wide monitoring and control system using PCs and associated devices. In certain situations, doing so may offer distinct advantages over purchasing an off-the-shelf system. Of course, such an approach could also be fraught with problems. Most commercially available systems can be interfaced to a PC. Thus local and specialized control loops are possible and straightforward to achieve. Typically, such control applications would be characterized by a need to monitor multiple variables, process the information in a timely fashion, and assert control on one or more actuators.

12.6.2.7 Standards

There are few standards to govern the construction of mine monitoring systems. MSHA controls aspects of the system design and construction that are related to permissibility. Some state mining agencies require an approval code for use of the systems within their states, but none have any specific criteria for approval. Some European countries have specific standards for monitoring systems, but again these apply more to permissibility issues than performance. The Institute of Electrical and Electronic Engineers (IEEE) has adopted and published a Recommended Practice for Atmospheric Mine Monitoring Systems, Std. No. P1203-1990. This document provides a wealth of information on features which should be a part of any monitoring system and even includes some information on recommended installation, maintenance, and operation practices.

12.6.3 REPRESENTATIVE APPLICATIONS

An overview of some applications in mine monitoring will serve to illustrate the potential of this technology as well as current practice; many others can be found in the literature (e.g., King and Eros, 1988). The most prevalent application is fire monitoring, typically using carbon monoxide sensors, in belt entries. Interest in this application is a result of the MSHA's

Fig. 12.6.4. A typical workstation for a mine monitoring system. (*courtesy:* Mine Safety Appliances Company).

requirement that a fire monitoring system be installed if the belt entries are to be used for intake air. This requirement resulted in the installation of many mine monitoring systems that otherwise would never have been purchased. As the technology developed and more systems were installed, companies looked for ways to more fully utilize the capabilities of monitoring systems. As a result of this effort, the second most frequent application is now conveyor-belt monitoring. Other less common applications include monitoring of production, pumping station parameters (both degasification and water), rock parameters, and equipment for predictive maintenance purposes. The results of a survey to determine the types of monitoring that are perceived to be important by managers of underground coal mines is shown in Table 12.6.1. The survey results shown in this table have been augmented to show the approximate percentage of installed monitoring systems that is being used for that purpose.

It is clear from Table 12.6.1 that companies are installing monitoring systems to satisfy perceived needs for information. (The only exception in the table is for production monitoring; this is because the technology to monitor machine state and related information has only recently been demonstrated.) Justifying these perceived needs is not often an easy task. Certainly if the installation of an atmospheric monitoring system is prerequisite to the use of belt air to ventilate a coal mine working place, then a cost-benefit analysis can be done, and the benefit of the monitoring technology can be demonstrated. In the case of a monitoring system to detect problems in the materials handling system, the monitoring system's economic benefits can be related to delay costs. For many other applications, the benefits may be difficult to quantify in a rigorous analysis. It is in these cases that the engineer must apply judgment and intuition to evaluate the worth of an investment in the technology.

Table 12.6.1. Mine Monitoring Applications Ranked by Decreasing Management Interest, Showing the Relative Number of Systems with that Capability

Application	Percentage of Installed Systems[a] that Perform this Application[b]
Production Monitoring	0 %
Materials Handling	45 %
Ventilation and Environmental	85 %
Maintenance	< 2 %
Power	10 %
Geomechanics	5 %

a. Based on 110 monitoring systems installed and operating in US mines in 1988. (Some data for this table provided by the US Bureau of Mines and MSHA.)
b. A mine-wide monitoring system is often used for multiple applications.

The examples of monitoring applications that have been included in the next part of this chapter are not meant to be exhaustive in coverage but rather to illustrate relatively common and successful applications of the technology, and in a few instances, to suggest extensions to current practice. It is always helpful to bear in mind a few often overlooked aspects of monitoring systems: (1) the monitoring system should be kept as simple as the application will allow; (2) once a system is installed, it will cost little extra money to add additional sensors, up to the systems capability; and (3) the types of things that can be monitored are limited more by one's own ingenuity and creativity than by technology.

Suppose that rail cars are to be counted at an automatic underground tipple. After reviewing the vendor catalogs, it is found that no one sells a "rail car counter." Thus it will be the engineer's responsibility to devise a sensor. The first step is to identify all of the unique aspects that characterize the event that is to be detected, in this case the number of cars that have been loaded. Next the fundamental parameters (e.g., pressure, displacement, event, current, concentration, etc.) that are associated with the event and for which transducers can be purchased must be noted. Then one of these parameters would be selected based on transducer cost, reliability, and implementation considerations. Finally the appropriate interface card would be purchased from the monitoring system vendor to allow connection of the sensor to the system.

For this example, a number of sensing options are available to determine the number of cars that have been loaded. These include weighing the coal, assuming a relatively constant capacity per car, or detecting an interrupted light beam when a car moves into position. A choice between these two alternatives is simple. The optical sensor employing the light beam will be far cheaper and probably more accurate than a weight sensor implementation. An infrared beam would provide better service than one in the visible spectrum due to the expected interference from airborne dust in the vicinity of the tipple. Still the sensor will require frequent attention. Another alternative is to sense a pressure change in the hydraulic system of the car spotter; assuming constant displacement each time the spotter is activated, this will be an inexpensive and accurate means of determining the number of cars. Further, it would require no routine cleaning or adjustment. In addition to a pressure transducer, a threshold detector with a binary output would be required at a comparable cost to the optical sensor. The key point is that a parameter or event can often be detected through many different means.

12.6.3.1 Atmospheric Monitoring

Monitoring of environmental and ventilation parameters is practiced in mines throughout the world. Carbon monoxide is a good early indicator of a fire, carbon dioxide of spontaneous combustion, and methane of an ignition hazard. A variety of other gases, including hydrogen, oxides of nitrogen, hydrogen sulfide, and oxygen, may be of interest in a particular instance. In addition to the use of this information in setting an alarm condition, it can be used for planning purposes and to mark the occurrence of events such as gas outbursts.

Ventilation parameters, including airway pressure and airflow velocity (which may be multiplied by cross-sectional area to obtain quantity) and fan parameters can be monitored and used for a variety of purposes. Real-time pressure/quantity surveys are technically and economically feasible but rarely incorporated in present day monitoring systems. Taken individually, velocity (quantity) and pressure can be used for both alarm and planning purposes. Ventilation control devices such as doors and regulators could be monitored if the position or status of these were of interest.

A wealth of useful information can be obtained by either adding sensors to the fan and connecting them into the mine monitoring system or by using a separate fan monitoring system and interfacing it with the existing mine monitoring system. Information on pressure and quantity is useful, as is information on power consumption. Fan speed can be sensed as well as blade pitch. A stall condition, or the conditions leading to fan stall, can be detected. Finally, predictive-maintenance monitoring should be performed at the fan. Present technology supports detection of bearing problems and mechanical unbalance as well as a number of incipient mechanical and electrical problems in the drive assembly.

A significant aspect in the implementation of atmospheric monitoring is sensor location. There are two issues: (1) strategic placement of sensors at locations in the ventilation network to satisfy information objectives, and (2) local placement at a desired network location to satisfy technical constraints. A methodology for the strategic location of sensors is necessary to minimize the number of sensors necessary to achieve a certain level of information; such a methodology is discussed by Cohen et al. (1987). Technical placement at a specific location is necessary to insure that the sensor reading is representative of the actual quantity. Since the sensors are of the single fixed-point variety, this is a concern. Furthermore, some sensors may give erroneous readings depending on their placement in the air course. A complete discussion of these, along with recommendations for placement, can be found in the literature (Kohler, 1987; Kohler and Thimons, 1987).

Atmospheric monitoring systems have been in use for three or more decades. Simple and early forms consisted of little more than remote telemetry systems to monitor an isolated mine fan. Despite the simplicity of these early systems, they performed an important function. Today mine-wide systems are becoming routine in new mines, and systems are being installed in many existing mines. The monitoring of CO and CH_4 accounts for the majority of system usage, although there is increasing interest in adding other parameters to the system. As incentives for monitoring are incorporated into mining regulations, this trend will be hastened.

For more detailed treatment of computer applications for monitoring in mine ventilation, see Chapter 11.10.

12.6.3.2 Materials Handling Monitoring

The most readily observed benefits of mine monitoring have occurred in this area, and the greatest benefit has been the immediate identification of a belt conveyor delay. By knowing the location and cause of a belt shutdown, it is possible to dispatch the appropriate personnel to the problem drive or location without losing time to determine the location and cause. An unexpected benefit that also occurs in some cases is that the record of delays tends to highlight problem areas, such as certain transfer points, that should be corrected. Munz (1988) discusses specific considerations for belt monitoring.

An analysis of materials handling problems that occur during peak-load periods should include a study of the material flows over time. Often it will be found that additional system capacity can be obtained by introducing small delays into the system. This can be accomplished by utilizing variable-speed drives in which the speed is controlled by a feedforward monitoring and control system. Such an alternative can be particularly attractive in a large system compared to increasing capacity by increasing the belt size. Other materials handling applications include skip and rail monitoring and automated tipples used in both surface and underground mines. Truck dispatching in surface mining operations has sometimes included an automated monitoring component, such as keeping track of the number of loads of ores of various grades, and automatically directing the transportation of these depending on the needs of the concentrating plant.

12.6.3.3 Maintenance Monitoring

Many predictive maintenance measurement techniques are well suited for continuous monitoring applications (on-board machine diagnostic monitoring is not considered here). Further, the use of such techniques on a continuous, rather than periodic, basis allows for more accurate detection of incipient problems and eliminates the chance that the periodic measurement will be overlooked. In particular, vibration, temperature, and current sensors can be used effectively to detect problems in time to schedule corrective actions, thereby eliminating the costs and hazards associated with an unexpected failure and the associated emergency maintenance actions. Typical candidates for vibration and temperature measurements are large drives and fans; in some cases, large pumps might also qualify. Large or crucial motors would qualify for current sensing.

The use of vibration data to detect bearing deterioration, coupler or shaft misalignment, and balance problems is well known. This type of monitoring is easily accomplished with a mine monitoring system, provided that a satisfactory sampling rate (typically, a minimum of 5 kHz) can be achieved and that an FFT algorithm can be obtained for the system. Temperature sensing is useful for detecting bearing deterioration and lubrication problems. Current sensing is somewhat useful if magnitudes are trended over time, but other more useful techniques have been developed that detect incipient motor failures (Kohler, Sottile, and Trutt, 1989).

12.6.3.4 Production Monitoring

A method of economically monitoring production-related information (machine state and raw tonnage) has been developed for use with existing mine monitoring systems and is described by Kohler and Gentzler (1989). The production monitoring system consists of a microcomputer and voltage and current sensors that are located in the load center. The machine states are determined for each machine; the machine identification number, machine state, and time are then transmitted over the existing mine monitoring system channel to the central station computer. The collected information is useful for checking the status of equipment on any section and identifying related problems, and is particularly useful for tracking and scheduling preventive-maintenance operations based on actual hours of operation. The accumulated information can also be used for planning purposes because of its similarity to time study information.

12.6.3.5 Electrical Power System Monitoring

The monitoring systems at some mines have included some power system parameters. Most commonly, the status of crucial circuit breakers in the distribution system were monitored. This yields much the same benefit as monitoring belt conveyor drives. Today mine power equipment such as sectionalizing switchhouses and load centers is being manufactured with built-in monitoring and control interfaces so that a number of parameters can be monitored in addition to the breaker's status. One such equipped load center is shown in Fig. 12.65. In many cases, the circuit breakers can be controlled remotely as well. Voltage, current, and power factor can be monitored at key locations; such monitoring provides important information for planning and diagnostic purposes.

Energy management systems have been commonplace in commercial installations for many years; manufacturing and other industries have also embraced this technology. Even some mining companies in other countries have installed such systems, and yet these are virtually unheard of in the US mining community. These systems have the potential to reduce power costs per ton in excess of 10 to 25% (Toni, 1988). An energy management system consists of sensors that measure a parameter that can be related to power consumption, a processor that can interpret the measurements and implement a control strategy to shed loads, and control devices that can automatically take loads off-line according to the predetermined strategy. It is even possible, and sometimes feasible, to utilize manual intervention, such as a call from a dispatcher, to shut down certain loads.

The inherent justification for an energy management system in mining is the demand charge levied by the electric utility (for a discussion of demand, see Croyle et al., 1987). As a result of the mechanics for computing this charge, a power peak within a 15-minute interval can cost thousands of dollars in penalty fees for one month and may even establish a minimum penalty that will be assessed every month over the next year. Such peaks can be avoided by means that have little or no effect on production. Shutting off a large pump for a few minutes, delaying a load of cars on the slope, or turning off electric heaters in the plant for a few minutes are just a few examples of actions that can result in savings of several thousand dollars per month. A case study for an underground coal mine and preparation plant is presented by Toni (1988).

12.6.3.6 Other Applications

Other less common applications include microseismic monitoring to facilitate prediction of coal bumps or rockbursts, water level monitoring in sumps, and monitoring of methane drainage equipment. Once it is recognized that the mine monitoring system is really a powerful data-acquisition system that can accept many sensor types, then the possible use of monitoring to solve a host of problems will become clearer.

12.6.3.7 Smart Sensors

Certain monitoring applications have special requirements that may restrict their implementation with a mine-wide monitoring system. These special requirements could include the need for sensors that cannot be directly connected to the system, the need for high sampling rates, or the need for large computation resources. Examples of such applications have been mentioned earlier, and include production monitoring, microseismic monitoring, and condition monitoring. When this situation is encountered, it is best to treat it as a separate monitoring system that will interface to the mine-wide monitoring system. This separate system will be addressed by the mine-wide system as though it were simply a sensor, hence the designation *smart sensor*.

Usually the smart sensor consists of a few sensors, signal-conditioning electronics, a microcomputer, power supply, and a communications interface, mounted in an enclosure that is appropriate for the application. In certain cases, local input and output devices may be supported or even included. Regardless of the specific application and hardware used to satisfy the application requirements, smart sensors function in a similar manner. They sample data and execute computational routines, therein relieving the mine-wide system of the necessity to provide these system-intensive services. The smart sensor then makes available key results to the mine-wide system. These can be available on a periodic basis whenever the mine-wide system interrogates the smart sensor, or the user may choose to have the smart sensor report to the mine-wide system on an exception-only basis, that is, when an alarm or otherwise notable event is detected.

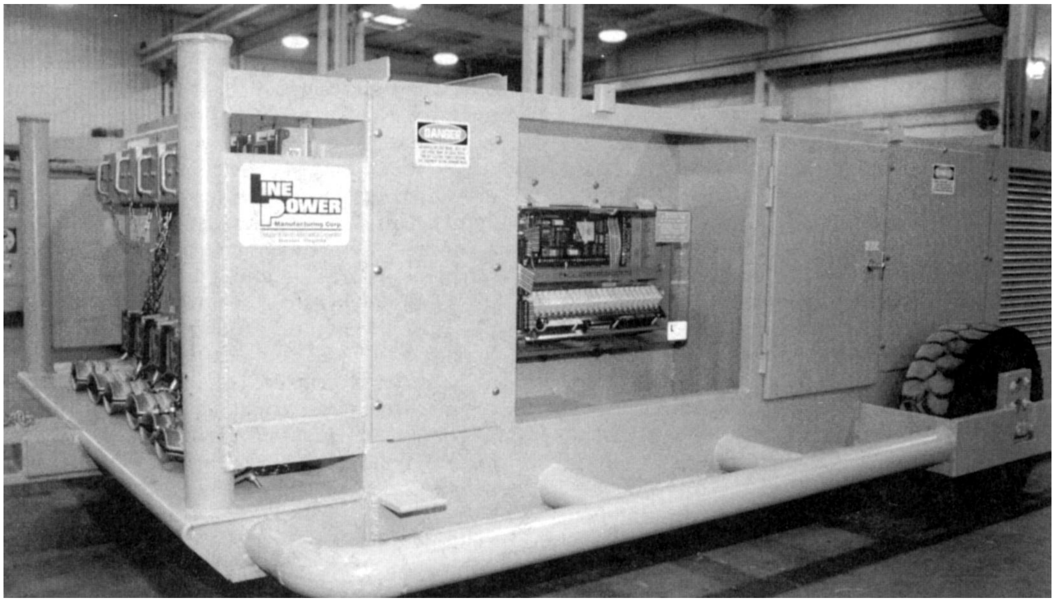

Fig. 12.6.5. Load center with built-in mine monitoring system interface (*courtesy:* Line Power Manufacturing).

12.6.3.7 Monitoring System Costs

The exact costs of a mine monitoring system are difficult to quantify given the almost infinite combination of features in a system as well as the differences in specific mine application sites; further, few people have kept records that would reflect their costs to install and maintain a system. Nonetheless, it is possible to estimate levels-of-effort and costs based on the industry's experience with the technology.

The purchase cost of a system, that is, sensors, outstations, and central station equipment, can range from $15,000 for a small system with a limited scope of application, such as only fire monitoring, to well over $250,000 for systems in larger mines that include a variety of monitoring functions, such as atmospheric, materials handling, and power, among others. Systems can be expanded— many times, a central station and a few outstations are installed, and then additional sensors and outstations are added as needed and as the budget permits. Quite useful systems that service the mine's needs now, but permit future expansion, can be purchased for $25,000 to $50,000.

Table 12.6.2 lists representative costs of system components. While this table is useful for estimating an order-of-magnitude cost, the reader is cautioned that many factors can change these costs. For example, the cost of certain sensors can increase by 50% depending on the enclosure; outstations fully loaded with digital and analog I/O cards, isolation, local display and control, and so on, can cost 100% more than shown in this table. The values in the table reflect the cost of components with typical options and of average quality, and as such are representative of equipment being sold today. Finally, it should be noted that more expensive components may actually cost less through reduced operating costs resulting from longer calibration intervals, automatic verification of operational status, and so forth.

Labor requirements will include hardware installation, programming, routine maintenance and calibration, and operation. The magnitude of the labor requirement is often underestimated or even neglected. Yet an average-sized installation will require one to two employee-years of effort. Often one or more permanent "monitoring-system" positions are created. The different components that comprise the labor requirement are discussed here.

Table 12.6.2. Representative Costs of Mine Monitoring System Components[1,2]

1. Central Station Computer & Software (basic)		$10,000
Additional graphics terminal & assoc. graphics Software (incl. license fees)		10,000
2. Outstation-Red, 8 channel	3500.	
Upgrade to Blue		500
Barrier, per channel		125
3. Sensors		
Belt Monitoring (1 drive, 8 voltages)		0
Methane Sensor		1000
Carbon Monoxide Sensor		550
Carbon Dioxide Sensor		550
Oxygen		550
Air Speed Sensor (vortex shedding)		1500
Air Pressure		750
Hydraulic Pressure		125
Electrical Current		100
Voltage		20
Temperature		40
Accelerometer		450
Event (proximity)		150
Speed (rpm)		250
4. Uninterruptable Power Supply		1000
5. Cable/1000 ft (4-16 Awg twisted pairs, shielded, Polypropylene insulation, PVC jacket)		500

1. In 1990 dollars.
2. These costs are representative of actual prices paid by the mine and are not list prices.

OPERATION. Daily operation of the monitoring system usually is assigned to the dispatcher or communications person at the mine and as such does not require that an additional person be employed. These people become quite adept with the systems with only a few hours of training and a few weeks of experience.

A few larger mines and preparation plants have created positions, such as monitoring system operator. However, these people generally assume additional system responsibilities such as software development, data analysis, and coordination of system maintenance.

PROGRAMMING. The amount of programming required at the mine site depends somewhat on the system that was purchased and on the level of customized graphic displays that are desired. The system programming is frequently done by an engineer at the mine after a week of training and study of the system manuals. As a minimum it is necessary to program system-level parameters, such as information on the connected sensors, threshold values, and display options. Modern systems provide user-friendly and interactive routines that allow this programming to occur with a minimum level of skill and time, often in less than a few days. The development of custom graphic displays can be much more involved, even with the best graphics software being sold with monitoring systems today. It is useful to remember that the objective of graphic displays is simply to facilitate information transfer, not to create graphic masterpieces for all to admire.

Engineers report spending as little as two weeks to as much as twelve weeks—with the median being close to four weeks—on the development of an average complement of display screens. This would include schematic diagrams with active elements of the ventilation and materials handling systems, and perhaps the power system. Other displays (e.g., for sumps, methane drainage stations, and fans) may be included if they are monitored. Various tabular displays, for both the video terminal and the printer, would be included as well. Once developed, these displays will require periodic updating to reflect changes in the mine. Such updating usually requires less than one day each month. Companies with several mines generally prefer to have a few people at the division or corporate level who handle all programming. Usually they will also be responsible for equipment selection and will be well-versed on the application of monitoring technology to mining problems.

MAINTENANCE. Routine maintenance includes battery replacement, sensor calibration, repair of damaged cable, and repair or replacement of failed components. This work is typically handled by the maintenance department, often by one or two electricians who have become familiar with the system. Sometimes the electrician responsible for the mine communications system will be assigned responsibilities for the mine monitoring system as well. A gas sensor in an atmospheric-monitoring system will take an average of 15 minutes to calibrate, excluding travel time. If the sensor must be calibrated monthly, and there are 30 such sensors, the monthly time committment to this task alone is significant. In many cases it is desirable to hire a full-time technician to calibrate and maintain the system. This person will often assist in the installation of the system.

INSTALLATION. The installation can be divided into three parts: the central station, the in-mine cabling, and outstation installation. Setting up the equipment in the central station, which is often in the dispatcher's room, requires as little as one day, although elaborate control rooms requiring weeks of effort can also be found. Hanging cable as the mine advances is easily accomplished as part of the same task as extending power and communications lines. Unfortunately, many new monitoring systems must be installed in large existing mines where it is necessary to install miles of new monitoring system lines. This can be a formidable task, requiring thousands of employee-hours of effort. Fortunately, it is usually possible to get a part of the system operational while in-mine wiring continues. Installation of an outstation, including the associated sensors, in which all of the sensors are in the immediate vicinity of the outstation requires from one shift to several shifts, depending on the amount of wiring required to connect the sensors. Installing voltage pickups in a belt center may take a shift whereas hanging and connecting a gas sensor can take less than an hour. If a sensor is located a few thousand feet (meters) from an outstation, additional time will be required to route and hang a twisted pair of wires.

Many mines using monitoring systems have found it best to create one or two positions, for example, for an engineer and a technician, specifically for the monitoring system. These people are responsible for all aspects of installation, maintenance, and often programming.

12.6.4 VOICE COMMUNICATIONS

The need for a quality mine communication system is evident in virtually every aspect of daily mine operation, and during an emergency, good communication is crucial. The importance of the communication system is reflected in statutory requirements that specify minimum system requirements. However, technological advances have made it possible for the communications system to serve a variety of functions beyond these minimums.

Voice communications is a specialized form of data communications, and much of the material presented previously is applicable here, especially the comments made in 12.6.1 on the information aspects of mine monitoring. The type of voice communication system and its degree of sophistication should be determined by well-defined needs to transmit and receive information in a clear and timely fashion. Fortunately a wide variety of systems, designed to meet virtually any need, are now commercially available. A comprehensive overview of mine communications is given by Anon. (1984) and examples by Anon. (1983).

12.6.4.1 Telephone

Telephone communication was first practiced in mines using crank-ringer phones. In the late 1940s and 1950s, pager phones were introduced, and pagers in some form are in use today in many mines. The pager phone, like the crank-ringer before it, is a party-line system. One line services all of the phones in the mine. A "call" is placed by paging, that is, saying the person's name while holding the page button; this message is then heard through the loudspeaker at each pager phone in the mine. If the page is answered, then the individuals can talk without having their conversation broadcast at each pager phone. However, it is not a private conversation because anyone who picks up another pager phone will be able to eavesdrop on any ongoing conversation.

The quality, that is, intelligibility, of pager phone conversations is good if the telephone line is maintained in reasonable condition. Although these phones continue to meet the needs of many mines, they have several disadvantages. First, as a party-line system, there is a lack of privacy to discuss sensitive issues. Second, in all but the smallest mines, there is often difficulty in finding the line free when a call must be placed, a problem that tends to be especially bad around shift change, and one that can be a real hazard when the phone is needed for emergency purposes. Third, as the volume of calls on the system increases, there will be a more or less constant series of pages. This results in two undesirable effects: people begin to "tune out" these background pages, and eventually they do not hear when they are being paged; all of this paging, at each pager phone in the mine, results in an accelerated draining of the batteries that power these units.

One improvement of the pager phone is the addition of selective paging, in which each pager is electronically assigned a unique identification number; then a phone will only broadcast those pages that have been prefaced by its identification number. In this way the needless paging at all pager phones is eliminated, thereby eliminating the background noise and battery problems mentioned previously. Nonetheless, all of the other problems still exist: to eliminate these, a dialer phone is needed.

Dialer systems, usually with a paging capability often involve a private branch exchange (PBX) at the mine. A pair of wires is needed to connect between each phone and the PBX. Since this can result in thick bundles of cables in large installations, it is desirable to utilize frequency-division multiplexing to allow multiple conversations to use the same wire. While the cost of a PBX system is higher than for a pager system, it offers significant advantages that can result in fewer delays in locating people and communicating a message. PBX systems are the system of choice for many newly opened mines, and a number of older mines have also been outfitted with this type of system.

Some of the features, in addition to the private line aspect, which make PBX systems both popular and useful are summarized here. First, the ability to call outside the mine—to an engineering office or parts supplier, for example—is a timesaver. The systems are often interfaced with pagers, both loudspeaker and personnel or pocket pagers that are carried by key personnel. This makes it easier to locate these people and lowers the average time needed to locate a person from 30 minutes, with a pager phone, to a few minutes. If the page is not answered, many systems can be set up to automatically retry the page every few minutes, and then when it is answered, an automatic callback is generated to the person who initiated the page.

12.6.4.2 Radio

Radio communication is attractive because it permits a degree of mobility by removing wiring constraints. The need and utility of wireless communication is evident in the widespread use of cap lamps and lamp signals to communicate simple messages among miners. Further, wireless systems eliminate the problem of not having access to a phone, and they make it easier to advance communication as the working area advances. The impediment to widespread use of radio communications in underground mines is the attenuation problem. Simply put, low-power transmissions, compatible with portable equipment, occur at wavelengths which tend to pass through obstructions, such as pillars, losing energy as they do so. As a result, good line-of-sight distances can be achieved, but the signals generally have only enough energy to travel around a few corners or bends (Lagace et al., 1975).

The transmission range is optimized, within the constraints, by transmitting within the medium frequency (MF) band (i.e., 300 kHz to 3 MHz). The characteristic of this band that makes it well suited for in-mine use is its tendency to couple onto water pipes, power cables, etc., for a "free ride" and then to re-radiate. Because of this, the effective transmission distance is much greater than would be expected. Most radio communications gear for the mine utilizes this frequency band.

One option to increase the transmission range is to utilize repeaters, devices that receive and retransmit signals to improve the range. The disadvantages are that they are typically required in some numbers, are not inexpensive, and must often be relocated as mining advances. As such the use of repeaters is limited in mining applications. Another option is to use a hybrid, combination wired and wireless system, in which a "leaky coaxial feeder" is hung in a main entry. This feeder radiates signals along its length to portable radios, and acting like an antenna, receives portable radio transmissions. Mines utilizing leaky feeder systems in conjunction with medium-frequency radios report unqualified success and complete satisfaction. Still, leaky feeder systems are used in relatively few mines, probably due more to a lack of understanding than anything else, although the purchase cost of the system can be slightly higher than a PBX system.

12.6.4.3 Trolley

Trolley communications are important to insure safety on the haulageway as well as for the efficient dispatching of traffic. Trolley phones utilize a carrier communications scheme in which the high-frequency signal is superimposed on the dc trolley wire. Filters are then used to isolate the communications signal at the trolley phone and to reject the dc component. In practice, the quality of the signal tends to be poor, for two reasons. First, there are a number of parallel loads that provide paths to ground for the signal; these paths include motors and rectifiers. As a result, the signal power is reduced at each parallel path. Second, high-frequency noise from arcing further degrades the quality of the signal.

A variety of technological improvements has resulted in greatly improved trolley phone systems. However, an attractive alternative is to use a hybrid system, in which a dedicated communications wire is installed adjacent to the trolley wire, and radio transmitters/receivers are installed in haulage vehicles. For a slight increase in capital cost, a superior communications system is available through this option. Of course, mines utilizing the leaky feeder system have no need for a separate trolley-phone system.

12.6.4.4 Shaft

Shaft or hoist communications are necessary to permit communication between persons in the cage and the surface or underground. In many cases, and particularly in underground coal mines, a phone line directly connects the cage to the mine communication system. In other cases, notably deep hard-rock mines, it would be difficult or costly to maintain such a cable. An alternative is to use a special system that employs the wire rope itself as a channel or low-impedance propagation path. An annular coupling antenna is placed around the rope at the top of the shaft and at the top of the cage; the transmitters/receivers are connected to these antennas, resulting in high-quality, relatively inexpensive, and reliable communication between the cage and the mine or surface.

12.6.4.5 Emergency

Communication systems play a crucial role during an emergency, and accordingly, the design of the system must reflect the different conditions that might exist. For example, it is likely that power will be interrupted, and it is also possible that some communication lines will be damaged. The traffic on the system is likely to increase as many people attempt simultaneous use of the system. Hardware to satisfy the mine's emergency communications needs, as well as the routine requirements is readily available from several manufacturers. There is a variety of other products available to meet emergency requirements (e.g., Hislop and Rundle, 1986). Over the past few years a number of high quality wireless and portable systems have been introduced into the marketplace. The durability and long-range characteristics of these units uniquely qualify them for use in rescue operations.

Through-the-earth communication systems, utilizing ultra-low frequencies (ULF), were developed to facilitate the location of trapped miners. Although the efficacy of such systems was successfully demonstrated, they never really gained acceptance.

Recently, however, this technology has been used to overcome an old problem common to metal mines: notifying personnel to evacuate when a fire has been detected. Historically, stench gas has been used by injecting it into the ventilation system and often the compressed air pipelines. The long time delays, often a half an hour or more, can prove fatal. The new ULF system will require a modified cap lamp which, when it detects the signal from the ULF transmitter on the surface, will begin to blink. A switch on the cap lamp must then be used to stop the blinking. This warning system, which has been successfully demonstrated to work over several miles, will provide virtually instantaneous warning to evacuate the mine, regardless of where the miner is located. The cost of the system is a few dollars per cap lamp and a few thousand dollars for the surface transmitter (Hjelmstad and Ackerson, 1990).

12.6.5 SUMMARY

Mine monitoring and communications systems allow mining personnel access to information in a timely fashion. Technologically, it is possible to achieve virtually any degree of sophistication desired in these systems. The constraint is the cost of obtaining the information; obviously, this must be commensurate with the information needs at the mine.

A variety of quality products are available to satisfy the mining industry's needs in monitoring and voice-communications systems. Several manufacturers even specialize in products for the mining industry. Given the types of sensors available, and a little imagination, it is possible to monitor virtually anything. However, given the many technical options and costs, it is essential that the mining engineer have some basic understanding of the technology, and have the ability to articulate the mine's needs to the manufacturer. By doing so, the many benefits of this technology can be realized.

Part IV
Surface Mining

Section 13 Surface Mine Development

DONALD W. GENTRY, ASSOCIATE EDITOR
WILLIAM HUSTRULID, SECTION COORDINATOR

Chapter 13.0
INTRODUCTION

W.A. HUSTRULID

The subject of surface mine development is large. This section covers the fundamental concepts involved in both the open pit mining of thick or steeply dipping deposits as well as the strip mining of thin, shallow, and relatively flat-lying seams or beds. Design involves the marrying of geometries, ore and waste characteristics, equipment, and economics so that the desired result is achieved. Generally, there are many possible combinations from which to choose. For example, extraction over a short time period requires one strategy while quite another is applied for longer times. Variations in supply and demand require some flexibility of operation. Customer requirements impose certain constraints regarding the set of possible designs.

Over recent years, planning and operating considerations for surface mining imposed by environmental requirements have increased markedly. There have, at the same time, been enormous advances made in the design aids available to the mine planner. Computer simulation of the various options, whether it be for mine design or equipment selection, provides detailed information for decision making in real time. A significant challenge to the engineer/planner is how to best use the aids available. Because of the widespread use of commercially available and in-house computer software by industry, this section does not deal with the details of planning (for basic coverage of mine development, see Section 7). Rather, some of the basic concepts are stressed. The principles involved in equipment sizing and selection are discussed. A highly important but sometimes overlooked aspect of planning, haul road design, is also covered. For surface mining operations of the future, in-pit crushing and conveying will become even more important. Some of the considerations for application evaluation are included. The section concludes with some future concepts for surface mining.

Chapter 13.1
OPEN PIT PLANNING AND DESIGN

G.A. FOURIE AND GERALD C. DOHM, JR.

13.1.1 BASIC CONCEPTS

G.A. FOURIE

13.1.1.1 Introduction

An *open pit mine* is an excavation or cut made at the surface of the ground for the purpose of extracting ore and which is open to the surface for the duration of the mine's life. To expose and mine the ore, it is generally necessary to excavate and relocate large quantities of waste rock. The main objective in any commercial mining operation is the exploitation of the mineral deposit at the lowest possible cost with a view of maximizing profits. The selection of physical design parameters and the scheduling of the ore and waste extraction program are complex engineering decisions of enormous economic significance. The planning of an open pit mine is, therefore, basically an exercise in economics, constrained by certain geologic and mining engineering aspects.

Several factors are significant indicators of economic and technological trends in surface mining. Among these are increasing production, a shift in emphasis from underground to surface mining, a decline in ore grade and quality of some crude materials, and, with few exceptions, an increase in productivity of labor. Increasing production is the result of a growing demand for more mineral commodities, induced by an increase in population and per capita consumption.

Paradoxically, productivity has increased even with declining grade and quality, which is indicative of the rapid technological improvement taking place in open pit mining techniques. This pattern of change has permitted production from many formerly uneconomic mineral resources occurring near the surface at a time when higher-grade ores are inadequate to meet increasing demand.

It is generally conceded that surface mining is more advantageous than underground mining in terms of recovery, grade control, economy, flexibility of operation, safety, and the working environment. There are, however, many deposits that are too small, irregular, and/or deeply buried to be extracted economically by surface mining methods. Furthermore, even where mineralization extends to a greater depth in open pit mines, the rapidly increasing amount of overburden to be handled imposes economic limits beyond which mining must either be abandoned or converted from surface to underground operations. The conclusions, although valid, are sometimes outweighed by a new set of factors that arise from differences in the physical character of mineral deposits available for future exploitation and from changes in technology, markets, and public policy.

Open pit design is conducted in several stages. They consist, technically, of devising a scheme or set of alternative schemes, followed by an evaluation and selection of the optimum scheme, as illustrated in Fig. 13.1.1.1.

The most economic final pit design often depends on factors that are largely outside the mining engineer's control, such as the geometric outline of the ore body, the distribution of ore within the ore body, topography, maximum allowable slope angles, etc. The economics of the mining program, however, depends upon the choice of mining ratio, production rates, and equipment, all of which are determined by the mining engineer.

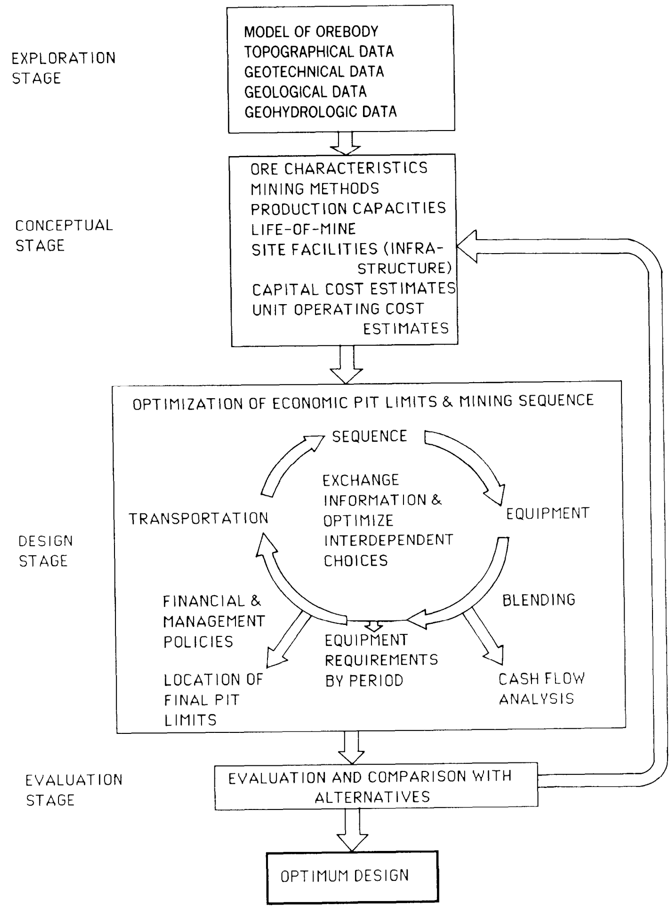

Fig. 13.1.1.1. Diagrammatic presentation of the design process.

13.1.1.2 Open Pit Terminology

Persons closely associated with open pit mines have coined terms or phrases for certain operations or for defining commonly occurring geometric parameters in open pit mining. The following are terms that commonly occur in open pit mine planning and are used throughout this chapter. These terms are illustrated in Fig. 13.1.1.2, which shows a pit section through an idealized tabular ore body.

A *bench* may be defined as a ledge that forms a single level of operation above which mineral or waste materials are mined back to a bench face. The mineral or waste is removed in successive layers, each of which is a bench. Several benches may be in operation simultaneously in different parts of, and at different elevations in the open pit mine.

The bench *height* is the vertical distance between the highest point of the bench, or the *bench crest,* and the *toe* of the bench.

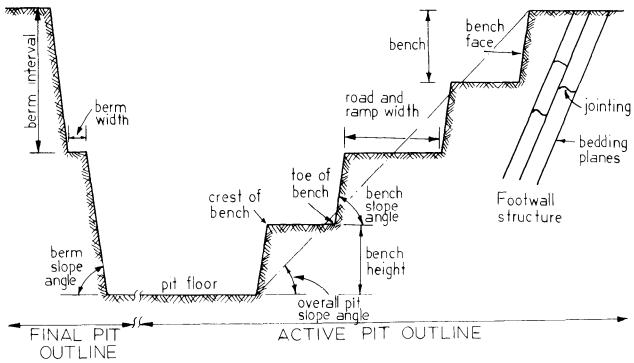

Fig. 13.1.1.2. Section through an open pit in an idealized tabular ore body.

The bench height is normally governed by the specifications of operating machines, such as drills and shovels, and by government mining regulations.

The *bench slope* is the angle, measured in degrees, between the horizontal and an imaginary line joining the bench toe and crest.

Pit limits are the vertical and lateral extent to which the open pit mining may be economically conducted. The cost of removing overburden or waste material vs. the minable value of the ore is usually the prime factor controlling the limits of the pit. Other factors that can influence pit limits are existing surface infrastructures, such as townships, rivers, etc.

In order to enhance the stability of a slope within the pit—and for safety reasons—*berms* may be left. A *berm* is a horizontal shelf or ledge within the ultimate pit wall slope. The *berm interval, berm slope angle,* and *berm width* are governed by the geotechnical configuration of the slope. The *overall pit slope angle* is the angle at which the wall of an open pit stands, as measured between the horizontal and an imaginary line joining the top bench crest with the bottom bench toe.

For the duration of open pit mining, a *haul road* must be maintained into the pit. A *spiral system* is an arrangement whereby the haul road is arranged spirally along the perimeter walls of the pit so that the gradient of the road is more or less uniform from the top to the bottom of the pit. A *zigzag* or *switchback* system is an arrangement in which the road surmounts the steep grade of a pit wall by zigzagging, generally on the footwall side of the pit. The choice of spiral or zigzag is dependent upon the shape and size of the ore body, truck economics, and pit slope stability.

Haul road width is governed by the required capacity of the road and type of haulage unit. The *grade* may be defined as the inclination of the road in terms of degrees from the horizontal or percentage of rise to the horizontal.

The *angle of repose* or *angle of rest* is the maximum slope at which a heap of loose material will stand without sliding.

The *suboutcrop depth* represents the depth of waste that has to be removed before any ore is exposed. This waste is often referred to as *preproduction stripping.*

13.1.1.3 Exploration Input for Open Pit Planning

In addition to defining the extent and value of a mineral deposit, exploration supplies data vital to mine development and exploration. Decisions regarding pit size and layout, production rate, and the mineral processing flowsheet are critically dependent on exploration data input. Procedures and particulars of mineral prospecting and exploration are provided in Section 4 and of project geology in Section 5.

A successful exploration program culminates in drilling and sampling information, useful in establishing mine operation parameters, geotechnical design, geohydrologic conditions, and mineral processing or metallurgical extraction. Two of three—geotechnical and geohydrologic investigations—warrant further discussion here. For detailed coverage of geomechanics, see Section 10.

Geotechnical Investigations. While soil masses are often homogeneous and relatively isotropic, this is rarely true of rock masses. The main reason for this is the presence of ubiquitous discontinuities in rock masses compared with soils. The behavior and stabilities of rock masses are controlled mainly by the nature and orientation of these discontinuities, while the stability of soil masses is controlled mainly by the strength of the intact material.

The importance of geotechnical and geohydrologic factors on open pit mining operations has been a very popular topic among researchers and cannot be overemphasized.

However, there is no definite system available prescribing geotechnical data-collection procedures; for this reason, mining companies seldom take into account geotechnical considerations during the initial exploration stage of the investigations, resulting in drill cores being disposed of shortly after completion of the drilling program. Geotechnical engineers are often consulted at an advanced stage of project evaluation, resulting in additional expenditures in order to obtain sufficient information.

Requirements for effective geotechnical drilling are briefly as follows:

1. Boreholes must be cored from as close as possible (or practicable) to surface through the overburden to at least 35 ft (10 m) into the footwall. If there is any suspicion of permeable zones at greater depth, the boreholes should be extended.
2. Cores should preferably be at least 2 3/8 in. (60 mm) in diameter and drilled with triple-tube core barrels to ensure minimal core disturbances.
3. In many cases, it may be desirable to drill inclined rather than vertical holes for the purposes of
   a. Orientating the core, either from the bedding traces or by the use of a core orientation.
   b. Intersecting steeply dipping joints, which are common in flat-lying sediments and which are poorly sampled by vertical holes.

The density of geotechnical drilling will be dependent primarily on the degree of variability of the material over the proposed mining area.

Drilling must be supervised by an experienced exploration geologist to record hole depths, core losses, and any other significant aspects (e.g., water losses) during drilling. Continuous liaison between the exploration geologist and the mine planning engineer is important to ensure that all mining-related data are collected.

As each core run is recovered, it should be carefully transferred to the core tray and allowed to dry before being

1. Photographed in color, ensuring that the core trays are adequately labeled and oriented.
2. Logged in detail for the following features:
   a. Rock type.
   b. Degree of weathering.
   c. Description of weak rocks or weak zones.
   d. Location, description, and orientation of any breaks in the core.

3. Sampled for materials testing.

Color photographs are an invaluable record of the original core condition. The core, even if available at a later date, may have deteriorated or be incomplete as a result of sampling.

Geologic data should be presented in graphical form to highlight the similarity or variations in properties across the proposed mining area. Rock hardness and bedding, or joint frequency, can be plotted in histogram form along the borehole paths. Such plots can be made with an exaggerated vertical scale to provide adequate detail, but it is also important to plot natural-scale sections in order to place the data into its actual physical content.

A basic program of materials testing is required to determine significant material properties and to confirm visual estimates during core logging. The relevant testing for open pit mines includes

1. Slaking and classification tests on weathered or suspected weak materials that could influence dump and pit stability.

2. Shear strength tests on soft or weak layers, particularly in the floor, and on overburden materials showing strong slaking behavior, for use in analysis of pit stability.

3. Compressive strength, point load strength, and drillability tests to provide information for estimation of overburden and ore excavation characteristics.

Geohydrologic Investigations. The presence of groundwater in the rock mass surrounding an open pit has a detrimental effect on mining operations for the following reasons:

1. Water pressure reduces the stability of pit slopes by reducing the shear strength of potential failure surfaces. Water pressure in tension cracks, or similar near-vertical fissures, reduces stability by increasing the forces tending to induce sliding.

2. High moisture content results in an increased unit weight of the rock and hence gives rise to increased transport costs. Changes in moisture content of some rocks, particularly shales, can cause accelerated weathering with a resultant decrease in stability.

3. Freezing of groundwater during winter can cause wedging in water-filled fissures due to temperature-dependent volume changes in the ice. Freezing of surface water on slopes can block drainage paths, resulting in a buildup of water pressure in the slope with a consequent decrease in stability.

4. Erosion of both surface soils and fissure infilling occurs as a result of the velocity of flow of groundwater. This erosion can give rise to a reduction in stability and also to silting up of drainage systems.

5. Discharge of groundwater into an open pit gives rise to increased operating costs because the water must be pumped out, and also because of the difficulties of operating heavy equipment on very wet ground. Blasting problems and blasting costs are increased by wet blastholes.

6. Liquefaction of overburden soils or waste dumps can prevail where water pressure within the material rises to the point where the uplift forces exceed the mass of the soil. This can occur if drainage channels are blocked or if the soil structure undergoes a sudden volume change, as can happen under earthquake conditions.

By far, the most important effect of the presence of groundwater is the reduction in stability resulting from water pressures within discontinuities in the rock mass.

There are two possible approaches to obtaining data on water pressure distribution within a rock mass:

1. Deduction of the overall groundwater flow pattern from consideration of the permeability of the rock mass and sources of groundwater.

2. Direct measurement of water levels in boreholes or wells or of water pressure by means of piezometers installed in boreholes.

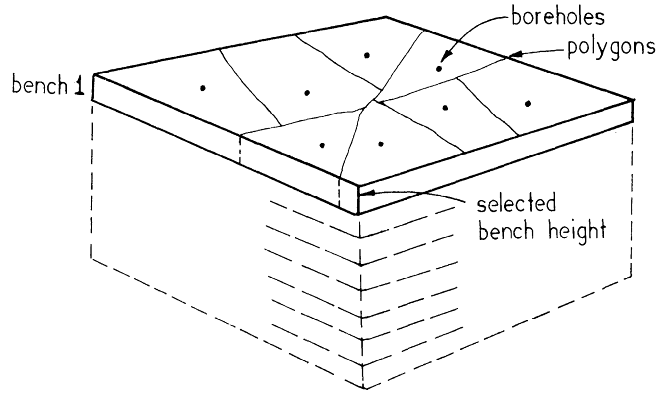

Fig. 13.1.1.3. Block model of an ore body.

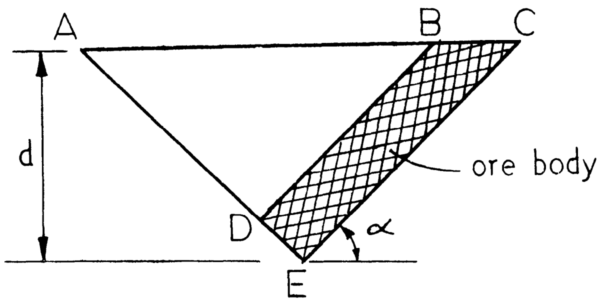

Fig. 13.1.1.4. Overall stripping ratio representation.

Both methods abound with practical difficulties; however, because of the very important influence of water pressure on slope stability, it is essential that the best possible estimates of these pressures be available before a detailed open pit stability analysis is attempted.

13.1.1.4 Bench Plan Preparation and Presentation

A key point in the design and operation of a modern mining operation is the construction of what is called an ore body model or *block model.* This model is a representation of reality constructed from predicted information. The blocks involved are merely subsets of the overall model that allows manipulation of the contained information on a local scale. In general, block models enable mine planners to effectively select the most promising means of extracting the ore both physically and economically. The uses of a block model can be quite diversified, but one must realize that a single model that satisfies all curiosities and forms of expertise is difficult to construct.

Because material removal or mining takes place along a particular bench, it is firstly important to prepare a series of bench plans that, when combined, forms the overall block plan of the modeled ore body. This is illustrated in Fig. 13.1.1.3.

With the assistance of modern computer facilities, sophisticated and complex bench plans can be prepared.

13.1.1.5 Stripping Ratio Considerations.

The parameter known as the *stripping ratio* is almost universally used and represents the amount of uneconomic material that must be removed to uncover one unit of ore. Fig. 13.1.1.4 represents an idealized open pit ore body, dipping at angle *a*.

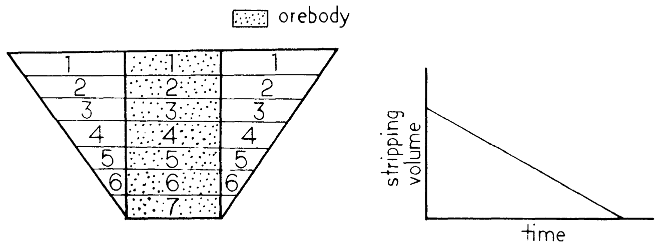

Fig. 13.1.1.5. Declining stripping ratio method.

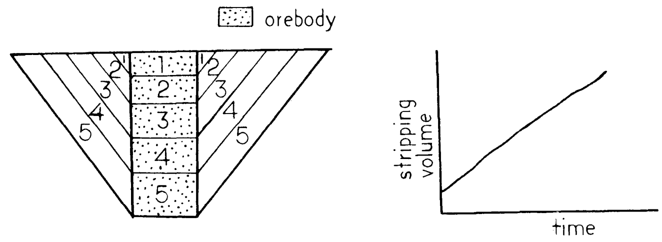

Fig. 13.1.1.6. Increasing stripping ratio method.

The ratio of the total volume of waste to the ore volume is defined as the *overall stripping ratio:*

$$R = \frac{\text{volume of waste removed to depth } d}{\text{volume of ore recovered to depth } d} = \frac{ABD}{BCED} \qquad (13.1.1.1)$$

While a volume relationship, calculated in cubic yards/cubic yards (cubic meters/cubic meter), it is more commonly expressed as tons/ tons (tonnes/tonne). Note that in mining certain mineral commodities, however, stripping ratio is expressed in units of cubic yards/ton (cubic meters/tonne).

A simple and widely used method of analysis to obtain pit limits is to utilize the cutoff stripping ratio. First, the pit slope is determined from geotechnical and other considerations and the stripping ratio then calculated. The *cutoff stripping ratio* is the one for which the costs of mining the ore and waste are matched by the revenue from that block of ore. Factors used to determine costs should include the added costs of mining as the pit deepens and the interest charges on the prestripping of waste.

In a more complete analysis, the entire ore body is mined on paper. The production from each time period is determined, the costs and revenues listed, and a cash flow generated. The profits from each year are discounted to reflect the time value of money in one of several ways, depending on management preference (investment analysis is discussed in Section 6). The result is considered to be the value of the mine or production. Mining is continued until it no longer increases the value, and so a pit limit is determined. The ratio of the total volume of waste to total volume of ore is then the overall stripping ratio.

With fluctuating commodity prices, increasing mining costs, and the introduction of more sophisticated mining techniques, the overall mining plan and overall stripping ratio can change over the total life of any mine.

For this reason, it is necessary to update the long-term plan of the mining project at regular intervals. Having determined the final pit limits and overall stripping ratio, the mining plan can be executed in a number of ways, as illustrated in the following.

Declining Stripping Ratio Method. This method (Fig. 13.1.15) requires that each bench of ore be mined in sequence, and all the waste on the particular bench is removed to the pit limit. The advantages of this method are the operating working space available, the accessibility of the ore on the subsequent bench, all equipment working on the same level, no contamination from waste blasting above the ore, and equipment requirements are a minimum towards the end of the mine's life.

The primary disadvantage of this method is that the overall operating costs are a maximum during the initial years of operation when maximum profits are required to handle interest and repayment of capital.

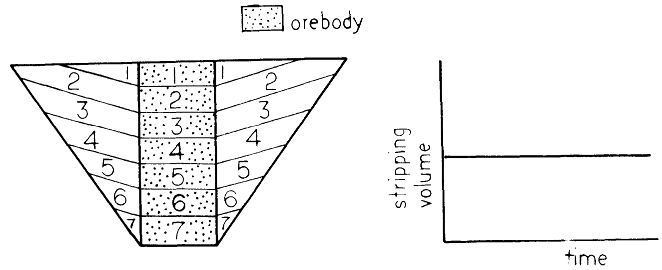

Fig. 13.1.1.7. Constant stripping ratio method.

Increasing Stripping Ratio Method. In this method, stripping is performed as needed to uncover the ore (Fig. 13.1.1.6). The working slopes of the waste faces are essentially maintained parallel to the overall pit slope angle. This method allows for maximum profit in the initial years of operation and greatly reduces the investment risk in waste removal for ore to be mined at a future date. This method is very popular where the mining economics or cutoff stripping ratio is likely to change on very short notice.

The disadvantage of this method is the impracticality of operating a large number of stacked, narrow benches simultaneously to meet production needs.

Constant Stripping Ratio Method. This method (Fig. 13.1.1.7) attempts to remove the waste at a rate approximated by the overall stripping ratio. The working slope of the waste faces starts very shallow, but increases as mining depth increases until the working slope equals the overall pit slope. This method, from an advantage and disadvantage point of view, is a compromise that removes the extreme conditions of the former two stripping methods outlined. Equipment fleet size and labor requirements throughout the project life are relatively constant.

In actual practice, the best stripping sequence for a large ore body is one in which the rate is low during the initial stages and towards the end of the project's life. The advantages can be summarized as follows:

1. A good profit can be generated initially to increase cash flow.
2. The labor and equipment fleet can be increased to maximum capacity over a period of time.
3. The labor and equipment requirements decrease gradually toward the end of the mine's life.
4. Distinct mining and stripping areas can be operated simultaneously, allowing for flexibility in planning.

13.1.1.6 Mine Plan Frequency

Mine plans vary in frequency from short- to long-range. The most common are (1) daily, (2) weekly, (3) monthly, (4) yearly, and (5) life-of-mine. The prime difference among these plans is the degree of detail. The shorter the time span covered by the plan, the greater the degree of accuracy and confidence that the actual performance will meet the forecast. For example, the daily mine plan details the production schedule on a shift basis for 24 hours, while long-range plans can be used to establish financial forecasts with regards to purchase of new equipment, changes in the work force, variations in operating costs due to increased haul distances, and dewatering requirements. Changes in the ore type may dictate the long-term blending criteria and possible changes in revenue from the sale of ore.

13.1.2 OPEN PIT FEASIBILITY STUDIES

GERALD C. DOHM, JR.

After a mineral deposit has been discovered and evaluated sufficiently to be considered an ore deposit, the problem then becomes how to mine and process that ore body in a way that *maximizes the net present value* (NPV) *within a practical operating format.*

The problem facing planners who must recommend mine plant size, equipment selection, and long-range scheduling is how to optimize a property not only in terms of mechanical efficiency but also in project life. Mine planning is dependent upon the interaction of contributing factors that lead to maximizing the NPV. Realistic mine planning is basic to the analysis. The process discussed here is best used when evaluating and planning undeveloped properties. This procedure is not intended to replace exacting mine analysis but rather to focus in on property evaluation for feasibility studies.

Derivation of the various input parameters is discussed only to the point where a meaningful correlation can be made to the overall analysis. The interrelationship of the parameters is the key as most company guidelines and financial analysts have their own standards when setting the various inputs.

Assume that the data are acceptable and provide at least the following categories of information and guidelines: (1) detailed drillhole data; (2) mineral and waste inventory; (3) geologic, hydrologic, and geotechnical criteria; (4) topographic layout, including property boundaries; (5) metallurgical flowsheet, recovery, and design criteria; (6) access, water and power information; (7) environmental baseline data; and (8) financial criteria (minimum rate of return, payback period, etc.).

Any evaluation of a property involves bringing all these parameters together. All, however, are interrelated and dependent upon one another. This means that without knowing the cutoff grade, the ultimate ore reserves cannot be calculated; without the ore reserves, the final pit limits cannot be established; without knowing the overall tonnages, the production schedule cannot be selected; and without the required capacity-generated capital and operating costs, the cutoff grade and total ore reserves cannot be derived. The optimization process is outlined in Fig. 13.1.2.1.

The iterative process closes in on the evaluation by going through the endless loop analysis cycle until no appreciable change is noted after continued refinement of the input.

Where does one start? After establishing the preliminary geologic and process data, one proceeds with a cursory treatment of equipment, facilities, and production scheduling. Historical operating parameters for a region or similar deposit provide a sound basis from which to start the evaluation. The data establish the basis for calculating preliminary ore reserves, mining techniques, and process design criteria.

Financial evaluations should utilize a discount rate that is equivalent to the cost of capital to a company plus associated risks. The resulting NPV is a functional yardstick by which to compare investment alternatives. Maximizing the NPV is primarily a function of production scheduling and ore cutoff grades. As a basic premise, the sooner the capital write-off occurs, the better the optimization level achieved. Therefore, some initial high-grading of an ore body or commencing operations in a low waste-to-ore ratio area would improve the cash flow.

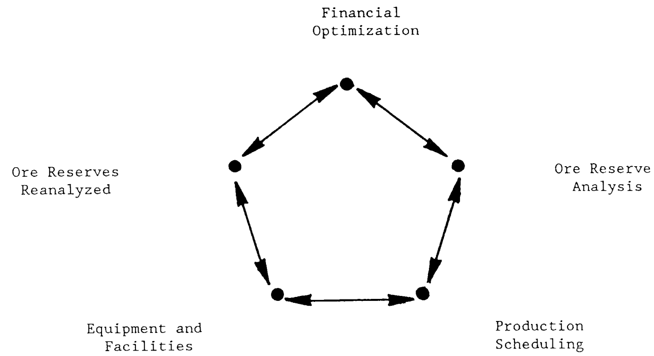

Fig. 13.1.2.1. Analysis components.

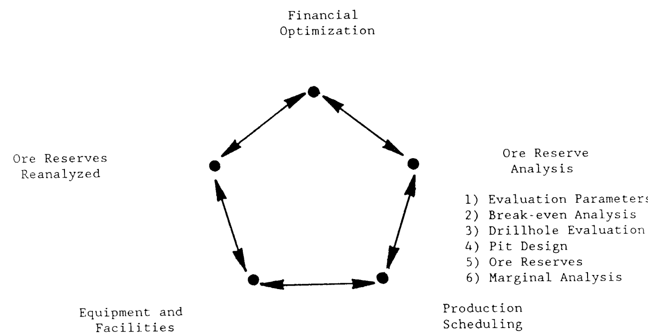

Fig. 13.1.2.2. Ore reserve analysis.

All capital and operating costs are expressed in current year dollars to forego having to project future cost and value trends. It will also be assumed that the ratio of income to production costs will remain constant throughout the life of the property. In reality, periodic reviews should be made during the operating life. Modifications to the ore reserves and operational plans may result if significant changes occur in the actual operating costs, commodity value, improved technologies, etc.

For the purpose of demonstrating the development of open pit evaluation, a simplified numerical case history is presented and evaluated step-by-step through one cycle.

For detailed discussion of ore reserve estimation procedures, see Chapter 5.6; for mine feasibility studies, see Chapter 6.2; and for equipment selection, see Chapters 9.3, 13.3, and 17.2.

13.1.2.1 Ore Reserve Analysis

A large, low-grade uranium deposit has been discovered and drilled to outline mineral at depths amenable to surface mining. The mineralization is in sandstone that lends itself to conventional mining techniques. The property is located in a rather remote region, and while there are unimproved roads into the area, all utilities have to be developed. The minimum acceptable rate of return will be set at 15%.

The first step is an analysis of ore reserves. The components of this analysis are indicated in Fig. 13.1.2.2, each of which will be briefly discussed.

Table 13.1.2.1. Overall Pit Slope (horizontal : vertical)

Vertical Height, ft	Overall Pit Slope
100	0.75:1
200	1.25:1
500	1.50:1

Conversion factor: 1 ft = 0.3048 m.

Table 13.1.2.2. Mineral and Waste Inventory

Grade % U_3O_8	Million* Tons	Avg. Grade % U_3O_8	Classification	Tonnage Ratios 1st	Tonnage Ratios 2nd
>0.080	8	0.129			
0.070	10	0.118			
0.060	14	0.103	Potential Ore	1	1
0.050	18	0.092	and Low-Grade		2
0.040	26	0.079			2
<0.040	16	N/A	Associated Waste**	0.6	
-0-	364		Primary Stripping	14	26

Conversion factor: 1 ton = 0.9072 t.
* Cumulative through 0.040 only
** Cutoff based on lower grades' inability to support mining, milling, and costs to do business [$14.80 cost vs. $13.50 value (0.030% × 20 × $25/lb × 0.9 recovery = $13.50 value)].

EVALUATION PARAMETERS. There are physical and financial evaluation parameters to be imposed.

Physical—A geotechnical evaluation was undertaken that indicated the overall pit slopes in Table 13.1.2.1 as acceptable for design purposes.

The specific gravity SG of representative rock samples was tested yielding an average value of 2.00. To convert the volume of rock to be mined and milled, a tonnage factor TF is calculated:

$$TF = \frac{2000 \text{ lb/ton}}{SG\ (2.00) \times 62.4 \text{ lb/ft}^3} = 16 \text{ ft}^3\text{/ton } (0.50 \text{ m}^3\text{/tonne}) \tag{13.1.2.1}$$

Initial metallurgical flowsheets and design criteria were also developed. The process is to be conventional acid leach-solvent extraction with an average recovery of 90%.

Financial— As a starting point for the calculations, regional operating and capital costs for operations having similar size, geology, and equipment are used. Amenability studies on which to base process specifications, reagent consumption, and product recovery are performed.

Regional operating economics (expressed in dollars/ton) include primary stripping (0.65); associated waste and ore mining (1.50); milling (7.00); direct costs such as salaries, utilities, maintenance, consumables, etc. (3.50); and indirect costs such as taxes, interest, depreciation, and corporate overhead (2.80).

For purposes of this example, the selling price of the recovered uranium oxide is set at $25/lb.

The drillhole grid is on 200-ft (60-m) centers, sufficient to outline the mineralized zone and associated overburden.

BREAKEVEN ANALYSIS. Establishing a cutoff grade for ore is necessary for drillhole evaluations. The process involves two steps and utilizes a tabulation of the mineral inventory in the area being considered for development (Table 13.1.2.2).

Table 13.1.2.3. Production Costs

Category	$/ton	1st Ratio	Total Cost, $	2nd Ratio	Total Cost, $
Stripping	0.65	14	$ 9.10	26	$16.90
Associated Waste	1.50	0.6	0.90	2	3.00
Ore Mining	1.50	1	1.50	1	1.50
Milling	7.00	1	7.00	1	7.00
Directs	3.50	1	3.50	1	3.50
Indirects	2.80	1	2.80	1	2.80
			$24.80		$34.70

Conversion factor: 1 ton = 0.9072 t.

The initial cutoff grade does not take into account primary stripping and associated waste. Using the ratios established in the first pass, the cutoff grade is recalculated.

Cutoff grade calculations are based on total operating costs, utilizing the overall ratio of tons of waste to tons of potential ore (Table 13.1.2.3).

$$\begin{aligned} \text{grade} &= \frac{\text{production cost}}{\text{value} \times \%\ \text{recovery}} \\ &= \frac{\$24.80\text{/ton}}{\$25\text{/lb} \times 0.90} \\ &= 1.10 \text{ lb/ton } (0.55 \text{ kg/t}) \\ &= \frac{1.10 \text{ lb/ton}}{20 \text{ (conversion factor)}} = 0.055\%, \text{ say, } 0.06\% \end{aligned} \tag{13.1.2.2}$$

The higher cutoff grade creates a new category of material, between 0.040% and 0.060%, which is classified as low grade. Under certain circumstances, it may be economically advantageous to process this material. This detail is reviewed later under marginal analysis.

DRILLHOLE EVALUATION. A simple approach for illustration is to use the polygon method to assign an area of influence for each drillhole. With the drilling grid on 200-ft (60-m) centers, the area of influence is 40,000 ft^2 (3720 m^2). Dividing the area by the tonnage factor, one finds:

$$\frac{40{,}000 \text{ ft}^2}{16 \text{ ft}^3\text{/ton}} = 2500 \text{ tons/vertical ft } (7440 \text{ t/m})$$

For simplicity, the deposit is assumed to be dry. The weight of water, when present, must be added to the weight of the rock. The total weight will then be used in the determination of operational costs, disposal considerations, and capital requirements.

All drillholes are evaluated from top to bottom. The economic bottom limit of mining is the depth at which the maximum net profit is realized. No credit is assigned to any values contained in material below the cutoff grade as they, in themselves, cannot justify any change in pit outline. This process is shown in Fig. 13.1.2.3.

The evaluation is repeated for all drillholes. This evaluation should also include those holes that obviously carry a negative value. In the expansion of the total reserves, many instances will be found where profitable holes will offset some negative values. The value of each must be known before a final determination can be made. The complete analysis is essential in establishing the ultimate pit limits, as discussed next.

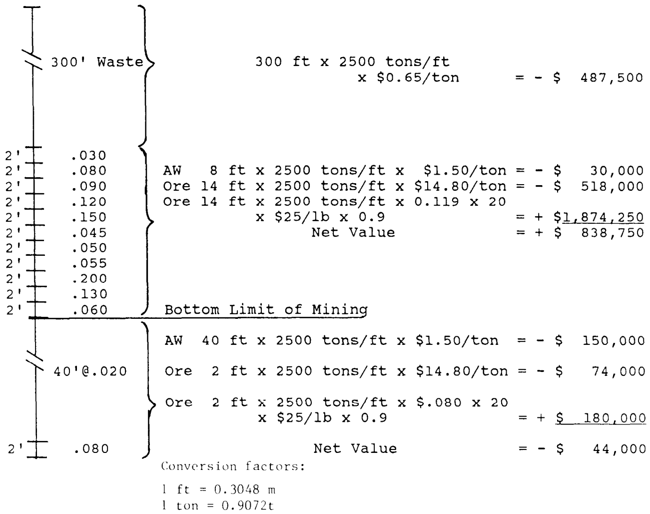

Fig. 13.1.2.3. Drillhole profit/loss calculation.

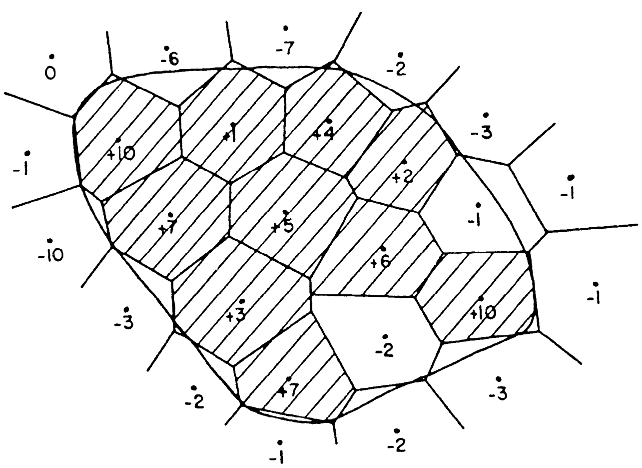

Fig. 13.1.2.4. Ore block smoothing.

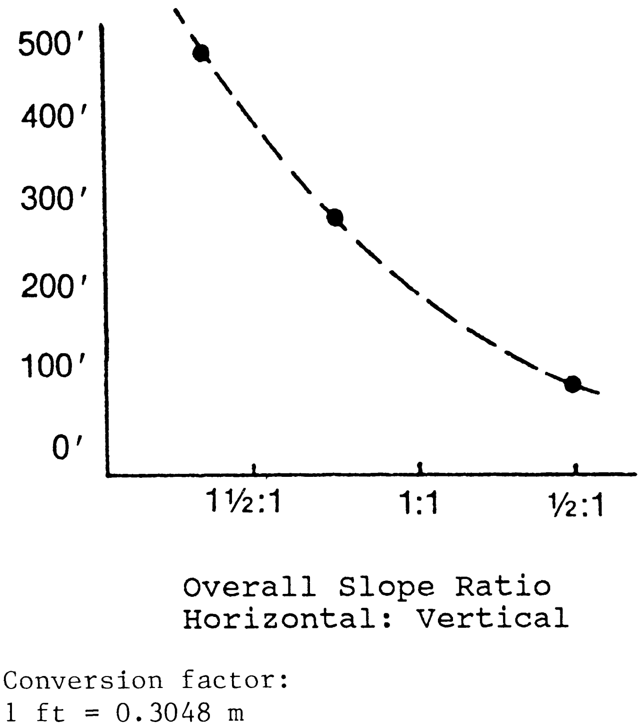

Fig. 13.1.2.5. Pit slope angle determination.

OPEN PIT DESIGN. The ultimate limits of the pit do not precisely follow the economic limits established in the drillhole evaluation. Refinements to the pit outline result from various working, financial and safety constraints. In practice, close-spaced development drilling will eventually be undertaken to better define pit boundaries and to develop information on where to commence mining activities. The bottom of mining may also be affected by the adjacent drillholes if bottom ore elevations vary to any appreciable extent.

Operation Efficiency—Operational efficiency increases advantageously as the horizontal section is smoothed by eliminating projections and generally irregular configurations. The drillhole evaluation helps with the smoothing of the pit walls and inclusion of waste by showing where positive values offset negative values. The objective is to maximize the total value and, at the same time, provide adequate access and working room (Fig. 13.1.2.4).

Overall Pit Slope—Use the steepest possible pit slope with regards to the safety factor deemed acceptable for the particular pit.

Overall pit slope angles are not only a function of the actual rock conditions encountered and the total vertical lift but also of the duration of exposure and the amount of water indigenous to or added to the formation. The effects of the latter two can be lessened by timely back filling and by either or both a mine dewatering program and a surface runoff diversion system. Where variable heights affect the ultimate design, a graph can be utilized relating height to slope angle at a safety factor where the slope is close to failure but does meet risk standards set within corporate guidelines.

In the example utilized herein, all slope angles are a direct function of height (Fig. 13.1.2.5). It must be remembered that in rough terrain, it is the difference in elevation from the surface to the economic bottom of the pit that ultimately establishes the final slope angle.

Design—One must provide adequate operating room for maneuverability and mining flexibility in ore/waste segregation requirements. A 0.5:1 pit slope between benches is used for design purposes. The desired overall slope angle is achieved by adjusting the widths of the benches:

$$\text{bench width} = \frac{\text{horizontal displacement}}{\text{no. benches required}} \tag{13.1.2.3}$$

$$= \frac{\text{vertical height} \times (\text{overall slope ratio} - \text{slope ratio between benches})}{(\text{vertical height} \div \text{bench height}) - 1}$$

In this example,

$$\text{width} = \frac{500 \text{ ft} \times (1.5 - 0.5)}{(500 \text{ ft} \div 50 \text{ ft}) - 1} = \frac{500 \text{ ft}}{9 \text{ benches}}$$

$$= 56 \text{ ft (17m)}$$

Table 13.1.2.4. Marginal Analysis Ore Reserves

Tons, million	Grade % U_3O_8	Material Classification	Ratio ton/ton
22	0.084	ore	1
20	N/A	associated waste	0.9
364		primary stripping	16.5

Conversion factor: 1 ton = 0.9072 t.

Table 13.1.2.5. Optimized Net Profit

300 ft stripping × 2500 tons/ft × $0.65/ton	−	$ 487,500
2 ft associated waste × 2500 tons/ft × $1.50/ton	−	7,500
22 ft ore × 2500 tons/ft × $14.80/ton	−	740,000
20 ft ore × 2500 tons/ft × $44.10/ton (0.098% × 20 × $25/lb × 0.9)	+	2,205,000
	+	$ 970,000

Conversion factors: 1 ft = 0.3048 m, 1 ton = 0.9072 t.

Individual bench widths may be adjusted to allow for ramps, lithology changes, etc., as long as the aggregate remains unchanged.

Having engineered a preliminary design, the ore reserves, associated waste, and stripping tonnages are now established.

ORE RESERVES. Total ore reserves are a direct result of the relationship between the drillhole evaluation and the open pit design. The calculation utilizes the concept of a break-even cutoff grade based on known or predicted operating costs. Another method, the break-even stripping ratio, that deals with the average relationships of the ore body is best suited to homogenous deposits. In this example, the grade is markedly different from one drillhole to the next, which requires separate ratios for adjoining areas of influence.

MARGINAL ANALYSIS. Once the pit limits are established and the resulting ore and waste inventories calculated, direct stripping and mining zone costs are estimated and are considered thereafter as sunk costs. Ore reserve optimization then involves the deletion of sunk costs from the analysis of the cutoff grade. The ensuing marginal analysis not only increases the ore reserves and tons to be milled but also lowers the waste-to-ore ratio:

marginal cutoff grade = operating cost – sunk cost + load and haul cost from stockpile to crusher ÷ (value × recovery cost) (13.1.2.4)

In this example,

$$\text{grade} = \frac{\$34.70/\text{ton} - \$24.00/\text{ton} + \$0.75/\text{ton}}{\$25/\text{lb} \times 0.9}$$

$$= \frac{\$11.48/\text{ton}}{\$22.50/\text{lb}} = 0.51 \text{ lb/ton} \ (0.25 \text{ kg/t})$$

$$= \frac{0.51 \text{ lb/ton}}{20} = 0.026\%, \text{ say, } 0.03\%$$

The calculation demonstrates that low-grade material can be milled profitably under the right circumstances. For planning purposes, however, it may not be prudent to consider all the low-grade material millable. A cushion should be established to cover profit margin, ore dilution, additional capital requirements, and uncertainties at this stage of the evaluation. Of the total low-grade from 0.03 to 0.06%, this example will consider only one-half the material, from 0.045 to 0.06%, as being economically justified to process (Table 13.1.2.4).

It can be seen that the ore tonnage increases from 14 million tons (12.7 million t) (Table 13.1.2.2) to a total of 22 million tons (20 million t) (a 57% increase), and the grade goes from an average of 0.103 to 0.084% (an 18% decrease). Recoverable pounds increase by 7.3 million, a gain of 28%.

While larger reserves appear to be the more efficient utilization of the mineral present, it is the cash flow and resulting NPV that dictate the cutoff grade. It should also be noted that marginal reserves cannot support capital expenditures for process capacity expansion. For the purpose of determining a cash flow, the marginal reserves are used in the total tonnage of ore to be milled, with the ends of the analysis spectrum being whether or not the marginal ore should be blended in with the ore or milled separately at the end of mine life.

A recalculation of the drillhole profit/loss calculation (Fig. 13.1.2.3) utilizing the marginal ore results in an improved net profit is shown in Table 13.1.2.5.

The net value increases by $131,250, an increase of 16% over the initial evaluation.

To recap, the break-even analysis is utilized to establish the ultimate pit limits within justifiable economic constraints. Once established, the marginal ore reserve calculation allows a greater utilization of lower-grade material, resulting in improved overall economics.

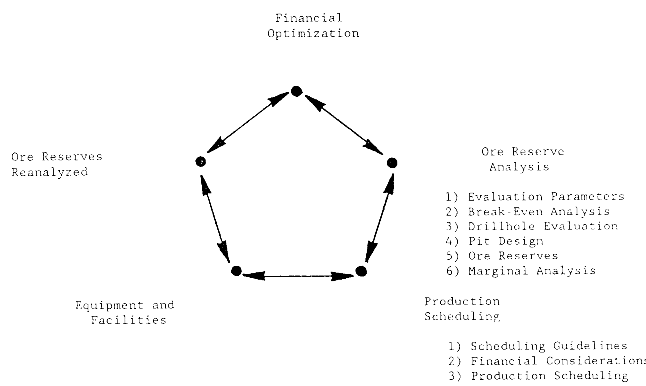

Fig. 13.1.2.6. Production scheduling.

13.1.2.2 Production Scheduling

Production scheduling (Fig. 13.1.2.6) is an important facet of mine planning. Once the mill feed grade has been established, maximizing the NPV of a property becomes highly dependent on scheduling. Scheduling determines mine life and, therefore, cash flows including capital requirements, operational costs, and revenues.

Initial production scheduling is based on marginal analysis ore reserves, a haulage study based on a conceptual pit design and overall facility layout.

SCHEDULING GUIDELINES. The following parameters provide guidelines for scheduling of the operation:

1. Minimizing preproduction costs.
2. Assuring adequate working room.
3. Smoothing of the stripping ratios.
4. Timely exposure of ore grade material.
5. Reclamation accountability.
6. Maximizing production.

Each point will be discussed in some detail.

Table 13.1.2.6. Cash Flow

Discount Factor @ 15% (end of period)		$ in thousands: Case I 2-yr preproduction ACF	DCF	Case II 1-yr preproduction ACF	DCF
Year 1	0.87	$ −500	$−435	$ −600	$−522
2	0.76	−500	−380	+500	+380
3	0.66	+600	+396	+500	+330
4	0.57	+600	+342	+500	+285
5	0.50	+600	+300	+500	+250
6	0.43	+600	+258	+1100	+473
7	0.38	+1100	+418		
Net Present Value			$+899		$+1196
Undiscounted Value		$ 2500		$ 2500	

Minimizing Preproduction Costs—Preproduction operational costs are treated as capital costs because they are incurred before production starts. These costs are not discounted and, in fact, should be assessed an interest charge for the time period used.

The following example only illustrates the time value of money, where two cases having the same total production costs ($5 million) and generated revenue ($7.5 million) are compared on slightly different production schedules.

The comparison involves a two-year preproduction period vs. a one-year preproduction period with a total five-year mill (revenue-generating) life for each case. Each example has a balanced production rate with stripping completed one year prior to the final production date in both cases.

Case I. Two-Year Preproduction
Total Cost:
Stripping $3 million ÷ 6 yrs = $ 500,000/yr
Mining and milling $2 million ÷ 5 years = $ 400,000/yr
Total revenue $7.5 million ÷ 5 yrs = $1,500,000/yr

Case II. One-Year Preproduction
Total Cost:
Stripping $3 million ÷ 5 yrs = $600,000/yr
Mining and milling $2 million ÷ 5 yrs = $400,000/yr
Total revenue $7.5 million ÷ 5 yrs = $1,500,000/yr

The *actual cash* flows (ACF) are the dollars spent each year, while the *discounted cash flows* (DCF) indicate the value today of future dollars.

The cash flow differences resulting from the different preproduction periods are shown in Table 13.1.2.6.

This example is oversimplified, but it stresses the importance of maximizing cash flow by lessening the preproduction commitment.

Contract stripping may also prove to be advantageous if used to the point where a positive cash flow is realized. Capital commitment for equipment and facilities can then be deferred. Here again, a cash flow analysis should be the determining factor.

Assuring Adequate Working Room—Especially in projects where the stripping ratio varies from one area to another, flattened working slopes should be used up to the point where the final pit configuration is intercepted. As mentioned under pit design, the flattening is accomplished by widening the benches. The resulting working areas are less congested, which provide for a smoother operational flow and minimizes traffic hazards.

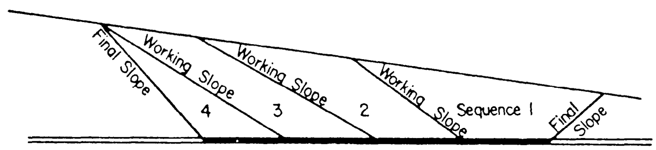

Fig. 13.1.2.7. Working slopes.

Also slope stability is improved as the back slope is flattened. Allowing the degree of slope flattening to fluctuate with the overburden ratio allows for a constant production rate and a predictable ore availability (Fig. 13.1.2.7).

Smoothing of the Stripping Ratios—For initial scheduling of operations, the average stripping ratio (tonnage basis) is used for determining working shifts and equipment required. It is important to avoid peaking the ratios as scheduling or capital requirements may become excessive.

Obvious exceptions exist, however. In preproduction stripping, it could be advantageous to commence operations in a low overburden-to-ore-ratio area that would only require utilization of a portion of the eventual fleet. Also, in instances where the stripping ratios change predictably over large areas such that equipment can be added or subtracted at a future date, it then becomes the average ratio of each area that becomes the scheduling basis.

Timely Exposure of Ore Grade Material—Proper sequencing is achieved through incremental pit design. Each increment is directly related to mill requirements within specific time constraints. Mining sequences are tentatively established and then analyzed to set the most logical development program. The mine sequencing then assures a predictable mill feed.

Reclamation Accountability—Environmental regulations require proper production planning and scheduling to minimize the costs associated with mine reclamation, The items most effectively handled by efficient planning are (1) returning ground contours to approximate premine conditions, (2) minimizing surface depressions to the greatest extent possible, and (3) revegetating disturbed areas.

Selected backfilling can create new slope angles within open pits and, in some instances, can completely fill portions of pits to achieve original contour. Generally, backfilling shortens waste haul cycles by reducing haul grades and distances. Waste dumps can be constructed on receding lifts, allowing the creation of flatter than "angle of repose" slopes with only a minimum of dozer work required. Whatever topsoil exists should be stripped and stockpiled for reemplacement at a future date.

With scheduling and design addressing reclamation requirements up front, operational efficiency is improved. The equipment and operating personnel required to do the work can then be added into the overall analysis.

Maximizing Production—The following points provide for more efficient scheduling and equipment utilization: (1) avoid excessive shovel moves, (2) minimize number of working areas, (3) work the lowest number of benches possible at any one time, and (4) reduce haul distances and ramp grades when practical. Increased productivity lowers operating costs. Additionally, rotating four crews through a seven-day week (20 shifts/week) gives the best utilization of equipment.

FINANCIAL CONSIDERATIONS. Property life directly influences the amount of capital expenditure required to produce a future income. While the evaluation of alternatives may identify an optimum-sized operation, it is wise to remember that mining plans are based on present-day parameters and, therefore, subject to changeover time.

Influencing factors are (1) capital and operating cost changes, (2) new mining and milling innovations, (3) increased knowledge of the deposit, and (4) changes in commodity value.

Ore and low-grade stockpiles allow the flexibility to supply a constant feed grade to the mill and also enable the producer to adjust to changing conditions. In addition, setting aside lower-grade ore for processing at the end of the operation could extend mill operations and financial profitability. Another form of optimization involves limited high-grading to cover spot sales, as outlined in the following example.

As applied to the example set forth in the text, the following considerations are offered. During mine life, a spot sale was contracted for over and above the commitments under existing contracts. The sale generates a $5/lb or $11/kg premium ($30/lb or $66/kg). The extra pounds are only available as above-average-grade ore, as the mill is operating at the designed capacity of 3000 tons/day (2720 t). The spot sale contract would be for an additional 500,000 lb (226,800 kg) during the third year of a 20-year production life.

The requirements for added production are:

$$\text{Tons/year @ } X\% = \text{original contract} + \text{spot sale}$$
$$1{,}095{,}000 \text{ @ } X\% = 1{,}655{,}640 \text{ lb/yr} + 500{,}000 \text{ lbs}$$

$$X\% = \frac{2{,}155{,}640}{1{,}095{,}000 \times 0.9} = 2.19 \text{ lb/ton} = 0.109\%$$

The high-grading would reduce the remaining grade of the ore body:

Ore Reserves	22 million tons	@ 0.084%
− 2 yrs production	− 2.2 million tons	@ 0.084%
− 3rd year production	− 1.1 million tons	@ 0.109%
Remaining Reserves	18.7 million tons	@ .082%
	(17.0 million t)	

Using the precalculated production costs of $34.70/ton (Table 13.1.2.3), a comparison of cash flows is calculated from the beginning of production through property life.

The value per ton (grade converted to recovered pounds × selling price) minus production cost equals the net value per ton. The results are summarized in Table 13.1.2.7.

Case I. Uniform Production

Discounted @ 15% on a 20-year life:

$3,394,500/year × 6.712 (cumulative PW factor) = $22,783,884

Table 13.1.2.7. Annual Cash Flow

Grade %	Net Value/ton	Annual Value @ 3000 tons/day
0.084	$ 3.10	$ 3,394,500
0.109	$14.35	$15,713,250
0.082	$ 2.20	$ 2,409,000

Conversion factor: 1 ton = 0.9072 t.

Table 13.1.2.8. Working Efficiencies

Classification	%	Working Time min/hr
Favorable	92	55
Average*	83	50
Unfavorable	75	45

*Used in Table 13.1.2.10

Case II. Inclusion of Spot Sale

Yrs 1 and 2	$ 3,394,500 × 1.74 (cumulative PW factor)	= $ 5,906,430
Yr 3	$15,713,250 × 0.71 (mid-period PW)	= $11,156,407
Yrs 4 thru 20	$ 2,409,000 × 4.26 (cumulative PW factor) 20th yr − 3rd yr)	= $10,262,340
	NPV	= $27,325,177

The illustration serves to point out that the time value of money is as important when optimizing production scheduling and resulting income as preproduction capital outlays and resulting income, as previously illustrated in Table 13.1.2.6.

Production scheduling guidelines provide the basis for alternative comparisons on which the highest NPV is determined. The basis for establishing alternatives is to vary the project duration (size).

The following discussion on production scheduling concentrates on the development of generalized operating costs for different production rates. These costs are applied to the current example.

PRODUCTION SCHEDULING. Scheduling is limited by constraints derived from historical data, regional information, and estimates based on industry-generated records.

Constraints by Equipment Type—

1. ELECTRIC SHOVEL APPLICATION.

(a) Diversity Factor: This refers to time lost due to moving, cleanup, and queuing of trucks. It is expressed as a factor of effective loading time. A common factor of 0.83 (based on industry time studies) is used here.

(b) Effective Loading Time: This means full shift minus time lost to lunch and waiting on trucks. Typical times are (minutes/shift)

480/full shift
− 30 lunch period
− 10 beginning of shift truck travel time
− 10 (5 lost on each side of lunch period)
− 10 end of shift truck travel time
420/net shift

2. TRUCK APPLICATION.

(a) Job Efficiency: This refers to the minutes of actual production during a 60-min hour. Manufacturers' data that apply to all equipment, except electric shovels, are listed in Table 13.1.2.8. The average efficiency may be used for evaluations until actual times are verified.

Table 13.1.2.9. Shovel Shifts (based on a 7-day working week)

No. Shovels	Shifts/ week	Working Shifts/ week	Availability %	Designation
1	21	10	48	unacceptable
	21	15	71	acceptable
	21	20	95	unrealistic
2	42	30	71	acceptable
	42	35	83	marginally achievable
3	63	45	71	acceptable
	63	50	79	acceptable
	63	55	87	unrealistic

(b) Production Time: This refers to operating time (full shift minus lunch period) times job efficiency (queuing, spotting, fueling, maintenance checks, etc.) minus travel time (to and from parking lot):

$$8 \text{ hr} - 0.5 \text{ hr} = 7.5 \text{ hr} \times 50 \text{ min/hr}$$
$$= 375 \text{ min} - 20 \text{ min} = 355 \text{ min/shift}.$$

Travel time (to and from parking lot) is optional. Many operations utilize 50 min/hr to account for both inefficiency and the extra travel time. Distance could be a factor when making this determination.

3. SUPPORT EQUIPMENT. Operating time is also estimated to be 7.5 hr/shift, but the actual production time will vary with property layout, scheduling procedures, etc.

4. FRONT-END LOADERS. Production time is calculated in the same manner as for trucks when the unit returns to the parking lot at the end of each shift, and as for a shovel when it remains in the work area between shifts.

Overall Constraints—

1. ANNUAL WORKING DAYS. This calculation includes the total days per year (365) minus holidays and unscheduled shutdowns (weather, labor disruptions, and major equipment breakdowns):

$$365 \text{ days/yr} - 10 \text{ holidays} - 5 \text{ unscheduled days} = 350 \text{ days/yr} \div 7 \text{ days/wk} = 50 \text{ wks/yr}$$

2. AVAILABLE SHIFTS. Selection of the number and duration of working shifts per week depends on required production and equipment utilized. Property life alternatives set annual production requirements. An 8-hr shift is the most efficient time allocation, based on overtime considerations and long-term productivity. It is also possible to operate on a 24-hr/day basis if required. Only 8-hr shifts are used in this example.

3. MECHANICAL AVAILABILITY. *Mechanical availability* is the availability after mechanical repair, preventive maintenance, and servicing have been accounted for.

A practical, long-range availability for shovel scheduling is in the range of 70 to 80% of total shifts available, depending upon working conditions and preventive maintenance procedures (Table 13.1.2.9).

Enough trucks should be purchased to provide 100% coverage of scheduled loader capacity. Using a 75% mechanical availability factor, full coverage is ensured by adding the appropriate number of extra trucks to the fleet.

Table 13.1.2.10. Scheduling Constraints

Shovels	Diversity Factor	0.83
	Effective loading time	420 min/shift
Trucks	Job efficiency	50 min/hr
	Production time	355 min/shift
Working weeks/year		50
Working shift duration		8 hours
Coverage: Shovels		70–80%
Trucks		100%
Manpower Availability Factor		1.10

$$\frac{\text{number of trucks required for loader coverage}}{\text{availability}} = \text{fleet required} \qquad (13.1.2.5)$$

$$\frac{8 \text{ trucks}}{0.75} = 10.7 \text{ or } 11 \text{ trucks}$$

4. MANPOWER. The manpower requirement multiplied by the availability factor yields the total number of individuals required. The availability factor is a variable based on local averages of vacations and absenteeism. For this example, absenteeism is set at 6% and a vacation average of 2.0 wk/yr as 4%, making the total time loss 10%. The manpower availability factor, then, is

$$100\% + 10\% \text{ loss} = 110\% \text{ or } 1.10$$

The total manpower required is

$$\frac{\text{No. working shifts} \times \text{hr/shift}}{\text{working hr/shift}} \times \text{availability factor} \qquad (13.1.2.6)$$

For example, assume there are 35 truck shifts/week:

$$\frac{35 \text{ shifts} \times 8 \text{ hr/shift}}{40 \text{ working hr/wk}} = 7 \text{ men} \times 1.10$$
$$= 7.7 \text{ or } 8 \text{ employees required}$$

In this case, the extra person is assigned to the labor pool and is used as required.

Table 13.1.2.10 recaps the constraints that are used later for example calculations.

5. PROPERTY LIFE. Maximum property life should be another limiting factor. Permanent installations (i.e., shops, mills, etc.) tend to become outmoded and wear beyond the point of reasonable repair. As a practical limiting factor, this example uses a maximum property life of 30 years as a basis for evaluation.

13.1.2.3 Equipment and Facilities

Open pit mining is becoming increasingly capital intensive as pits are enlarged and lower-grade ore is utilized. Contributing factors are (1) increased mechanization to handle the larger tonnages, (2) lower-grade ore resulting in higher plant investment per unit of refined product, (3) larger operations requiring greater preproduction cash outlays, and (4) environmental impact mitigation requirements.

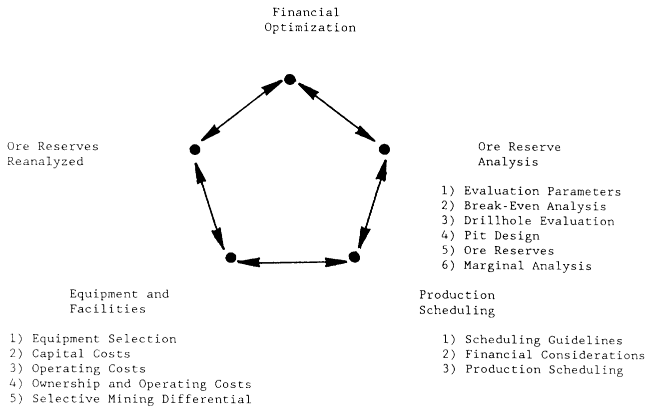

Fig. 13.1.2.8. Equipment and facilities.

Table 13.1.2.11. Overburden Swell

Lithology	% of total	% swell (decimal equiv.)	Weighted average % swell
Gravel	20	0.12	2.4
Clay	20	0.25	5.0
Sand-loose	30	0.10	3.0
Sandstone cemented	30	0.50	15.0
		Total	25.4

The major capital requirements that are a part of the final investment analysis are (1) plant, mobile units, and ancillary equipment, (2) preproduction stripping and mining, (3) spare parts inventory, (4) plant start-up, (5) working capital, (6) licensing and environmental assessments, and (7) cost of capital.

Both capital requirements and subsequent operational costs are developed at length to provide the basis for the selection of loading and haulage equipment. One should minimize and/or delay capital expenditures as long as feasible to improve the NPV. Capital expenses that do not lower production costs and increase earnings should not be considered. This segment is divided as shown in Fig. 13.1.2.8.

EQUIPMENT SELECTION. The selection of a fleet of equipment is accomplished by comparing production requirements against the capital and operating costs of appropriate alternatives. A pit haulage study is required to size and select types and number of haul trucks. Production requirements, rock characteristics, and desired flexibility are parameters guiding selection of the primary loaders. Equipment size should be standardized whenever possible.

Basic requirements for loader selection include rock breakage patterns, mine life, size of haulers utilized, tonnage factor, and swell factor. From drillhole log composites, lithologies are expressed as a percentage of the overburden. Using published tables, the weighted averages are made (Table 13.1.11).

$$\text{Swell factor} = \frac{1}{1 + 0.254} = 0.8$$

The tonnage factor for broken muck is

$$\text{TF} = \frac{\text{in-place TF}}{\text{swell factor}}$$

$$= \frac{16 \text{ ft}^3/\text{ton}}{0.8} = 20 \text{ ft}^3/\text{ton } (0.62 \text{ m}^3/\text{t}) \quad (13.1.2.7)$$

Table 13.1.2.12. Typical Electric Shovel Capacities

Shovel Size, kW	250	375	525	625	725
Nominal dipper, yd³	6	12	17	22	30
Nominal cycle time, sec	22	25	27	29	31
Tons/dipper	7.3	14.6	20.7	26.7	36.5
Nominal production Tons/shift	6,940	12,198	16,035	19,278	24,626

Conversion factors: 1 ton = 0.9072 t, 1 yd³ = 0.7646 m³, 1 hp = 0.7457 kW.

Table 13.1.2.13. Stripping Requirements

		Mill size, tons/day			
	Shifts/week	2,000	3,000	5,000	7,000
Property Life, yrs		30	20	12	8.6
Required Stripping, 10⁶ tons/yr		12.1	18.2	30.3	42.3
Required Stripping, tons/shift	15	16,178	24,267	40,400	56,400
	20	12,100	18,200	30,300	42,300
Required Stripping—multiple shovels, tons/shift/shovel	30	8,089	12,133	20,200	28,200
	40	—	9,100	15,150	21,500
	45	—	8,089	13,467	18,800
	60	—	—	10,100	14,100

Conversion factor: 1 ton = 0.9072 t.

$$\frac{27 \text{ ft}^3\text{yd}^3}{20 \text{ ft}^3/\text{ton}} = 1.35 \text{ tons/yd}^3 \ (1.60 \text{ t/m}^3)$$

Using an average bucket fill factor of 0.9, the dipper capacity is bucket capacity (yd^3) × tons/yd^3 × fill factor = tons/dipper:

$$6 \text{ yd}^3 \times 1.35 \text{ tons/yd}^3 \times 0.9 = 7.3 \text{ tons/dipper } (6.6 \text{ t})$$

Shovel production is

min/shift × diversity factor × cycles/min × bucket capacity = tons production/shift:

$$420 \text{ min} \times 0.83 \times \frac{60 \text{ sec}}{22 \text{ sec}} \times 7.3 \text{ tons} = 6940 \text{ tons (6296 t)/shift}$$

For the sake of simplification, only electric loading shovels are evaluated in this exercise. However, large front-end loaders and hydraulic face shovels offer advantages where increased mobility and lower capital investment may be required. Table 13.1.2.12 is based on typical manufacturers' recommendations.

The example in Table 13.1.2.13 utilizes the ratio between the stripping tonnage of 364 million tons (330 million t) and 22 million tons (20 million t) of ore as generated in the topic on marginal analysis (see Table 13.1.2.4). Stripping requirements are based on production levels and the number of shovel shifts scheduled.

Using the required stripping tons per shift, the shovels are selected by matching the nominal shovel production per shift to the production requirements for each case (compare Tables

Table 13.1.2.14. Dipper Selections

Shovel size kW	Dipper size yd^3	Tons/dipper	Tons/number passes 4	5	6
250	6	7.3	29.2	36.5	43.8
	7	8.5	34.0	42.5	51.0
	8	9.7	38.8	48.5	54.5

	32	38.9	155.6	194.5	233.4
	33	40.1	160.4	200.5	240.6
	34	41.3	165.2	206.6	247.8

Conversion factors: 1 ton = 0.9072 t, 1 yd^3 = 0.7646 m^3, 1 hp = 0.7457 kW.

13.1.2.12 and 13.1.2.13). A property should not be dependent on one prime earthmover because of downtime considerations and reduced flexibility in the operation, and to reiterate, equipment should be standardized whenever possible. Therefore, the following examples consider only two or more of the same shovels as viable options.

It should be noted that the production from a nominally sized bucket does not always meet requirements. However, by upsizing the bucket within the manufacturer's guidelines, the required capacity will be generated.

Once a shovel is selected, the dipper capacity is sized to accommodate various truck capacities. Manufacturers' guidelines suggest that with the overburden specific weight of this example, dipper capacities shown in Table 13.1.2.14 may be utilized. Four or five passes per truck is considered optimum, although six is acceptable under normal conditions.

Truck fleet options are generated by matching dipper sizes to number of passes to rated hauler capacities. Maximizing truck size to shovel capability is an effective objective, although adverse haulage grades, equipment availability, and cumulative bucket capacities also contribute to the final selection.

A modifier to be used when establishing shovel cycle times is to increase cycle times by 1 second for each 2 yd^3 (1.5 m^3) above nominal dipper capacity. It also should be noted that nominal truck capacity may be exceeded by up to 5%; however, increased maintenance and tire wear can be expected under these conditions.

Although not limited to the shifts or truck sizes in Table 13.1.2.15, the choices that follow have been made to simplify the comparison process.

After sizing the truck, it is important to select the engine horsepower, gear ratios, and tire size necessary to provide satisfactory performance under anticipated working conditions. Manufacturers provide performance charts that relate the power provided by the vehicle power train (rimpull) to the vehicles weight and total rolling resistance (RoRi).

Rolling resistance is the measure of force required to overcome the retarding effect between the tires and the ground. RoRi is primarily the cumulative effect of vehicle weight, tire penetration, and road grades.

Vehicle weight is the primary factor in the amount of force required to overcome RoRi. Using level, compacted roads as the base, the RoRi is 40 lb/ton (18 kg/t) vehicle weight, or expressed as a percentage:

$$\frac{40 \text{ lb}}{2000 \text{ lb/ton}} = 2\%$$

Tire penetration or road flex is an added resistance factor due to soft conditions. Use 30 lb RoRi/in. (0.54 kg/mm) tire penetration. When expressed as a percentage:

$$\frac{30 \text{ lb}}{2000 \text{ lb/ton}} = 1.5\%/\text{in.} \ (0.06\%/\text{mm}) \text{ penetration}$$

In the planning stage some basic assumptions must be made regarding penetration in various areas. This example utilizes the following:

- Loading areas and waste dumps — 2 in.
- Approaches — 1 in.
- Established haul roads — 0 in. (base)

For grades both positive and negative, use 20 lb RoRi/ton (10 kg/t) per % grade. Expressed as a percentage, this becomes

$$\frac{20 \text{ lb}}{2000 \text{ lbs/ton}} = 1\%/\% \text{ grade}$$

To bring all the factors together, consider a truck leaving the shovel approach area on a gentle 2% uphill grade:

Table 13.1.2.15. Truck-Shovel Combinations

Property Life, yr	Shovel No., kW	Shifts	Dipper size, yd^3	Tons/ dipper	Cycle time, sec	No. passes	Tons/ load	Truck Capacity tons	Tonnage/shovel shift calculated	Tonnage/shovel shift required	Capacity %
30	2-250	30	8	9.7	23	5	48.5	50	8,821	8,089	109
20	3-250	45	8	9.7	23	5	48.5	50	8,821	8,089	109
	2-375	30	13	15.8	25	5	79.0	85	13,219	12,133	109
12	3-375	45	14	17.0	26	5	85.0	85	13,676	13,467	102
	2-525	40	19	23.1	28	5	115.5	120	17,256	15,150	114
	2-625	30	24	29.2	30	5	146.0	150	20,358	20,200	101
8.6	4-525	60	17	20.7	27	4	82.5	85	15,977	14,100	113
	3-625	45	24	29.2	30	5	146.0	150	20,358	18,800	108
	2-725	40	30	36.5	31	4	146.0	150	21,548	21,150	102

Conversion factors: 1 ton = 0.9072 t, 1 yd^3 = 0.7646 m^3, 1 hp = 0.7457 kW.

$$\begin{aligned}\text{Total RoRi} &= \text{weight } (2\%) + \text{tire penetration } (1 \times 1.5\%) \\ &\quad + \text{grade } (2 \times 1\ \%) \\ &= 2\% + 1.5\% \text{ (say } 2\%) + 2\% = 6\% \text{ total RoRi}\end{aligned} \tag{13.1.2.8}$$

The RoRi reduces the rimpull available from the power train. A loaded 50-ton (45-t) truck has a gross weight of approximately 175,000 lb (80,000 kg). A 6% RoRi reduces available rimpull by 10,500 lb (175,000 × 6%)(4760 kg). The remaining rimpull is available for acceleration.

Vehicle speed under a given set of conditions results from the relationship of the truck's weight and RoRi to the vehicle's performance chart, published by the manufacturer. The maximum speed, as determined by this relationship, is then modified by speed factors that convert maximum speeds to average speeds over segments of the haul.

The first step in establishing speed factors is to determine the vehicle weight to flywheel horsepower (FWHP) ratio:

$$\frac{\text{vehicle weight (with or without load)}}{\text{FWHP}} \tag{13.1.2.9}$$

A loaded 50-ton (45-t) hauler (175,000 lb or 80,000 kg) with 600 FWHP (450 kW) has a ratio of 282 lb/hp (175,000 ÷ (600) (170 kg/kW). This ratio is used to select the proper table to determine the speed factor. The factors are then obtained by matching the haul road length to the point where the truck is starting from 0 mph (or stopping), or where the grade is level, downhill or uphill and the unit is in motion when entering this section.

The average speed for each haul segment is obtained by multiplying the maximum speed times the speed factor (Table 13.1.2.16).

Speed limits become the final modifier in the calculation. Speeds should be based on reasonable guidelines to ensure safe operation. This example utilizes the following:

• Loading and dump areas	5 miles/hr
• Long uphill and level roads	25 miles/hr
• Downhill grades	15 miles/hr

The number of trucks needed to move the required tonnage is a time function involving the sum of fixed and travel times. Travel time is

$$\frac{\text{haul road segment length (ft)}}{\text{average speed (mph)} \times 88 \text{ (conversion factor)}} \tag{13.1.2.10}$$

The example in Table 13.1.17 typifies a truck cycle time of a 50-ton (45-t) unit traversing a complete load, haul, dump, and return cycle.

Haulage studies should consider the following:

1. Overall layout indicating centroids of pit excavation sequences and incremental waste dump growth.
2. Haul road widths, passing lanes, intersections, and curves
3. Pit profiles detailing level hauls and grades and the length of each.
4. Waste dump geometry including height, width, and traffic patterns.

Truck fixed times are nonproductive periods that include truck spotting, loading, and the time required to turn and offload at the waste dump. The times are based on industry norms and can be used or modified as local situations warrant.

A typical example for a 333-hp (250-kW) loader and a 50-ton (45-t) hauler is as follows:

Shovel spotting	0.42 min
Shovel loading	1.92 min
Turn and dump	0.85 min
Total fixed time	3.19 min

The total truck cycle time for the 50-ton (45-t) unit is

10.04 min travel time + 3.19 min fixed time = 13.23 min

The number of trucks required for the 30-year property life shown in Table 13.1.2.15 is determined as follows:

No. shovels and size (kW)	2 @ 250
Hauler capacity, tons	50
Individual truck cycles/shift (355 min ÷ 13.23)	27
Payload tons	48.5
Tons/shift/truck (27 × 48.5)	1,310
Required tonnage/shift	16,178
Required trucks/shift (16,178 tons ÷ 1,310)	12.4
Trucks required at 75% availability (12.4 ÷ 0.75) = 16.5 − use	17

Production scheduling is set by limiting stripping tonnage by truck coverage and not shovel capacity. The latter is usually

Table 13.1.2.16. Speed Conversion Factors (under 300 lb/hp only)

slightly higher. When determining the total number of trucks required, round 0.00 to 0.29 to zero, and above 0.29 is rounded up. A recap of truck requirements is shown in Table 13.1.2.18.

CAPITAL COSTS. No attempt is made in this example to derive the costs of the mill and related administration and maintenance facilities nor of any offsite facilities. Offsites include access road, electric power, water, and natural gas. The assigned costs are listed in Table 13.1.2.19.

One should establish specifications for the major equipment. Work closely with vendors who not only have access to their technical data, but are also experienced with applications over diverse conditions. Once the major rolling stock has been speci-

fied, send out requests for quotations to the manufacturers being considered. A cost pattern should emerge on which to base the estimate.

Accurate capital cost estimating of production equipment, both shovels and trucks, is essential to the evaluation for two reasons:

1. Overall costs are usually the basis for fleet selection.
2. The cost of ancillary equipment can be estimated on the basis of the major rolling stock.

As a general rule, capital committed to shovels and trucks can be the basis for prorating ancillary equipment capital costs for estimating purposes. The combined ancillary capital costs represent approximately 30% of the total capital costs. When expressed in terms of the shovel-truck cost, this percentage becomes 43% (3/7).

The breakdown in Table 13.1.2.20 is based on averages generated from equipment lists sufficient to handle the total material generated from 10,000- to 200,000-ton (9000- to 180,000-t)/day operations. Individual situations may dictate different percentages, but they should be altered only if sufficient detail has been developed to warrant changes.

Drilling utilizes rotary production units with average rock condition suggesting the following relationship: one large diameter (9 to 12 in., or 229 to 305 mm) rotary drill per 30,000 to 40,000 tons (27,000 to 36,000 t)/day of stripping. Smaller drills (6 to 9 in., or 152 to 229 mm) will suffice for the lower tonnage operations at the rate of one per 10,000 to 15,000 tons (9000 to 13,600 t)/day.

Blasting covers the explosive-handling vehicles and the air-track drills that are required for secondary breakage in most operations.

Field and miscellaneous support equipment includes dozers, patrols, light duty and maintenance vehicles and cranes. The support equipment is very dependent upon local conditions, making detailed relationships an impractical matter. However, the overall relationship to the total capital remains fairly constant.

Utilities include transformers, power distribution, water, air, gas, firewater, and telephone lines.

Buildings cover administration, maintenance, welding, lube and tire shops, changerooms, and warehousing.

Table 13.1.2.21. Production Equipment Capital Costs

Shovels		Trucks	
Size, kW	Cost, $ millions	Capacity, tons	Cost, $1000
250	2.0	50	400
375	2.5	85	500
525	3.0	120	600
625	3.5	150	700
725	4.0		

Conversion factors: 1 ton = 0.9072 t, 1 hp = 0.7457 kW.

Tools and initial spare parts inventory include only those purchased prior to operations start-up. Preproduction mining is also a capital item, expensed for tax purposes. However, it will be addressed only as a function of production scheduling in this example.

Capital costs of the shovels and trucks are given in Table 13.1.2.21.

The overall capital costs for each case (Table 13.1.2.15) are assembled in Table 13.1.2.22.

It should be noted that with options utilizing more units of smaller-sized equipment, a higher initial capital cost is generally experienced.

OPERATING COSTS. Capital requirements alone cannot serve as the basis for selection of production and ancillary equipment. Combine operational and capital costs to arrive at a single-fleet choice for each property life alternative. The four fleets selected provide the framework for the financial analysis and ultimate pit optimization.

Again, as in capital costs, no attempt is made to derive mill operating costs. Assigned costs are listed in Table 13.1.2.23.

The first step is to determine the operating hours/year for the loaders and the haulers involved in each option (Table 13.1.2.24).

Hourly operating costs are generated based on field experience and manufacturer's guidelines.

A 525-kW shovel will be costed out in detail. The operating costs of other shovels are calculated in the same manner, but they are only summarized here. The primary costs include electric power, labor, maintenance, and repair.

Power costs are generated by multiplying kilowatt hours by the commercial rate. Consumption is rated at 525 kWh with the rate being $0.05/kWh:

$$525 \text{ kWh} \times \$0.05/\text{kWh} = \$26.25/\text{hr}$$

Labor costs are calculated by multiplying combined operator and oiler rates by payroll burden. Next multiply that figure by 8 hr/shift divided by 7 productive hr/shift. Hourly rates are $12 and $11/hr. The payroll burden is 35%. Payroll burden includes vacation, holidays, overtime, unexcused absenteeism, payroll benefits, FICA, health insurance, unemployment insurance and workmen's compensation. Labor costs become

$$(\$12 + \$11) \times 1.35 \times 8 \div 7 = \$35.50/\text{hr}$$

Repair and maintenance is expressed as a cost/ton multiplied by the tons/hr. Assume that the cost/ton is $0.02 ($0.018/t) (experience factor). Production is 17,314 tons (15,707 t)/shift divided by 7 hr/shift equals 2473 tons (2244 t)/hr, or,

$$\$0.02/\text{ton} \times 2473 \text{ ton/hr} = \$49.50/\text{hr}$$

The total cost of power, labor, and repair and maintenance is $111.75/hr (Table 13.1.2.25).

Table 13.1.2.22. Overall Capital Costs For Equipment and Facilities

Property life, yr	Production combinations: Shovels No., kW	Trucks No., tons	Costs, $ millions: Fleet	Ancillaries	Mill and Offsites	Total
30	2-250	17-50	$10.8	$ 4.6	$34	$ 49.4
	3-250	25-50	16.0	6.9	39	61.9
20	2-375	16-85	13.0	5.6	39	57.6

		85	7.5	26		146,250
	(2)	625	7	3	15	15,750
		150	7.5	16		90,000
	(3)	725	7	2	20	14,000
		150	7.5	12		90,000

Conversion factors: 1 ton = 0.9072 t, 1 hp = 0.7457 kW.

The operating costs of a 120-ton (109-t) hauler is detailed utilizing experience factors and local wage rates.

Operator costs are obtained in the same manner as the shovel labor is calculated:

$$\frac{\$11.00/\text{hr} \times 1.35 \times 8 \text{ hr/shift}}{7.5 \text{ productive hr/shift}} = \$15.85/\text{hr}$$

Tire cost is the cost/tire times the number of tires divided by the hours of expected life:

$$\frac{\$7500/\text{tire} \times 6 \text{ tires}}{4000 \text{ hrs}} = \$11.25/\text{hr}$$

Fuel cost is the gallons consumed/hour times cost/gallon:

$$30 \text{ gal/hr} \times \$0.80/\text{gal} = \$24.00/\text{hr}$$

Maintenance, service, and repair are covered by utilizing the relationships between:

1. Mechanics wages, including burden ($\$11/\text{hr} \times 1.35 = \$14.85/\text{hr}$).
2. Wearable items, historically related to truck horsepower.
3. Working conditions.

The first relationship, between mechanics' wages and truck size, generates a cost factor of wearable items and mechanical labor. Once derived, the factor is related back to truck size to generate the cost per hour of maintenance, service, and repair. The cost per hour is then modified by the working conditions, expected to be experienced-based on haulage analyses and overall site conditions.

Working conditions impact the costs as follows:

Average:	costs @ 100%
Favorable:	Includes light duty resulting from gentle grades, low RoRi, minimum traffic restrictions, etc. Cost × 80% (lower limit)
Adverse:	Includes long ramps, steeper grades, high RoRi, adverse weather, etc. Costs × 130% (upper limit)

Manufacturers' graphs are utilized to obtain costs suitable for estimating purposes. For this case, 120-ton (109-t) haulers and a cost of $25.90/hr under average conditions for maintenance, service, and repair will be utilized.

Total cost of operators, tires, fuel and maintenance, service and repair for the 120-ton (109-t) hauler is $77.00/hr. Table 13.1.2.26 lists operating costs for all trucks used in this comparison.

Table 13.1.2.25. Shovel Operating Costs

Shovel size, kW	Operating cost, $/hr
250	$ 71.45
375	87.65
525	111.75
625	121.80
725	134.65

Haul Truck, tons	Operating cost, $/hr
50	49.22
85	69.50
120	77.00
150	83.74

Conversion factor: 1 ton = 0.9072 t.

Table 13.1.2.27. Ancillary Operating Cost Breakdown

Classification	% of Total
Drilling	7
Blasting	3
Roads	6
Dumps	4
Total	20%

The fleet operating costs become the basis for estimating the ancillary operating costs. Allocation of operating costs is highly variable. Expected operating conditions are influenced heavily by weather conditions, rock characteristics, general terrain, etc., and should so be anticipated when assigning operating costs. This example utilizes the generalized percentages outlined in Table 13.1.2.27.

The total ancillary operating costs represent 20% of the total operating costs. When expressed in terms of shovel-truck cost, this percentage becomes 25% (2/8).

The production fleet overall operating cost/hour for mine lives and equipment combinations is given in Table 13.1.2.28 based on the same equipment options shown in Table 13.1.2.22.

Owning and Operating Costs. Capital costs are depreciated, using the straight-line approach for simplicity, over the expected useful life of the individual components. The results are expressed in dollars/operating hr and, when combined with operating costs, provide total *ownership and operating costs* (0 and 0) from which a single fleet will be selected for each mine life.

Ownership costs are obtained by dividing capital costs by the expected life of each type of equipment. Ancillary costs are split between mobile and stationary equipment because of the difference in their expected lives. Operating hours for mobile ancillary equipment should be the same as the truck fleet. The stationary equipment is utilized for 8 hr/shift (Table 13.1.2.29).

A compilation of the 0 and 0 costs for the 12-year life case, utilizing 525-kW shovels and 120-ton (109-t) trucks, is shown in Table 13.1.2.30. Total 0 and 0 costs for the equipment combination options are listed in Table 13.1.2.31.

Only the cases with the asterisk are used for further mine comparisons. The following points should be noted:

1. Utilizing 20 shifts/week results in the lowest initial capital investment but not necessarily the lowest 0 and 0 cost.
2. The largest equipment produces the lowest overall 0 and 0 cost.
3. In the 8.6-year example, case 2 was selected over case 3 because of the increased scheduling and operations flexibility resulting from more available equipment and shifts if required. This option should only be used where 0 and 0 costs are similar.

A summation of stripping costs based on total required operating hours is shown in Table 13.1.2.32. The costs are expressed in dollars/ton for ensuing financial analyses.

Selective Mining Differential. Under many circumstances, enough information now has been generated to recalculate the ore reserves based on appropriate 0 and 0 costs for the alternatives being considered. However, this example is somewhat more involved in that the selective mining requirements of the ore zone require a separate calculation of direct mining costs. As in any instance of highly selective ore mining, operating costs run higher than stripping costs because of slower rates, tighter supervisory control, and extra equipment requirements.

Refined mine operating costs are not calculated here in detail. However, by using parameters as previously generated, new operating costs are established.

The equipment shown in Table 13.1.2.33 is considered capable of producing 3500 tons (3175 t)/shift of combined ore and associated waste. Being a mid-range calculation, the operating costs/ton are appropriate for all four options.

In cases where mining has no bearing on stripping fleet selection, additional costs are not added to the total 0 and 0 costs. Mining costs shown in Table 13.1.2.33 will contribute to revised ore reserves and are included in the cash flow analysis.

The direct operating cost/ton is

$$\frac{\$6102.50/\text{shift}}{3500\ \text{tons/shift}} = \$1.74/\text{ton}\ \ (\$1.92/\text{t})$$

The mining fleet will be depreciated over an average life 50,000 hours. The ownership cost/ton milled is the same in all four cases as mining-fleet size is directly proportional to mining tonnage requirements.

$$\text{Ownership period: } \frac{50{,}000\ \text{hrs}}{5625\ \text{hrs/yr}} = 8.89\ \text{yr}$$

Tonnage: 8.89 yr × 2,100,000 tons of ore, low-grade and associated waste/yr. = 18,699,000 tons (16,964,000 t)

$$\text{Ownership cost: } \frac{\$3{,}975{,}000\ \text{capital cost}}{18{,}669{,}000\ \text{tons}} = \$0.21/\text{ton}$$

($0.23/t)

Table 13.1.2.28. Overall Fleet Operating Costs

Mine Life, yr	Fleets: Shovels No., kW	Fleets: Trucks No., ton	Production Costs, $/hr	Ancillary Costs, $/hr	Overall Cost, $/hr
30	1) 2-250	13-50	782.76	195.69	978.45
20	1) 3-250	19-50	1,149.53	287.38	1,436.91
	2) 2-375	12-85	1,009.30	252.33	1,261.63
12	1) 2-375	18-85	1,513.95	378.49	1,892.44
	2) 2-525	11-120	1,070.50	267.63	1,338.13
	3) 2-625	12-150	1,248.48	312.12	1,560.60
8.6	1) 4-525	26-85	2,254.00	563.50	2,817.50
	2) 3-625	16-150	1,705.24	426.31	2,131.55
	3) 2-725	12-150	1,274.18	318.55	1,592.73

Conversion factors: 1 ton = 0.9072 t, 1 hp = 0.7457 kW.

Total 0 and 0 costs for the mining fleet are $1.74 + $0.21 = $1.95/ton ($2.15/t).

13.1.2.4 Ore Reserves Reanalyzed

The original ore cutoff grade of 0.06% was based on preliminary data. New cutoff grades are now established reflecting respective operating costs of each case. Reanalysis utilizes projected operating costs to modify criterion illustrated in Fig. 13.1.2.9.

CUTOFF GRADE. The calculation utilizes the initial cutoff grade of 0.06% and original waste and low-grade-to-ore ratios to establish new cutoff grades. The second step uses the revised cutoff grades to establish new waste-to-ore ratios.

Direct operating costs are tabulated in Table 13.1.2.34 and extended to calculate total direct operating costs for each ton of ore processed. The resultant cutoff grades are then calculated.

Ore reserves generated for each case are different. Ore grades change as do the waste to ore ratios, as shown in Table 13.1.2.35.

DESIGN ALTERNATIVES. At this point it would be prudent to reanalyze drillhole data as some alteration in pit design may result. This example will not make that iteration, because all four cases bracket the original example without significant deviation (± 15% of grade).

MARGINAL ANALYSIS. The new stripping ratios have the potential to further alter cutoff grades. This process can be re-

Table 13.1.2.29. Anticipated Equipment Life

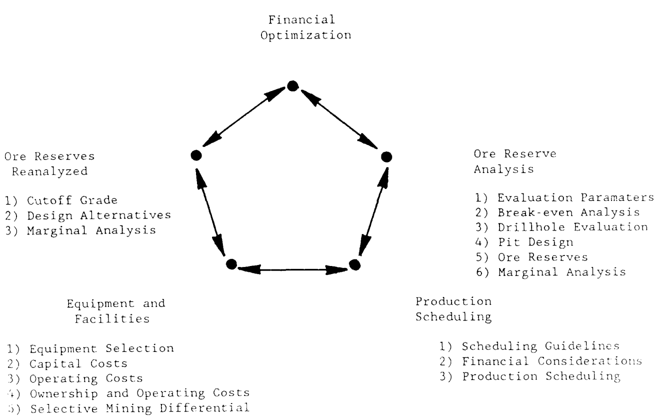

Fig. 13.1.2.9. Ore reserves reanalyzed.

peated, with diminishing returns, until no further change is noted. However, the accuracy at this stage is considered sufficient for a feasibility study.

The milling rate needs no adjustment as the upper half (0.045 → 0.06%) of the marginal ore reserves was used to set mill processing tonnage. Verification that marginal reserves (0.03 → .06%) still cover the four cases is analyzed in Table 13.1.2.36.

In each case there is sufficient marginal ore to satisfy milling requirements at the previously established milling rates. This example will then use the previously established milling grade of 0.084% for all four cases.

13.1.2.5 Financial Evaluation

The steps to be followed to obtain the financial evaluation are outlined in Fig. 13.1.2.10.

CASH FLOWS. Annualized cash flows need to be generated for use in the economic evaluation.

Annual revenue is determined by using the marginal analysis ore reserve grade of 22 million tons (20 million t) at 0.084%, a mill recovery of 90% and a selling price of $25/lb ($55/kg) (Table 13.1.2.37). Operating costs/ton of ore processed are summarized in Table 13.1.2.38.

Ownership costs thus far have included both *initial capital investment* (ICI) and replacement capital for direct comparative purposes. Setting up a cash flow statement requires that these costs be separated. Replacement capital applies to the stripping and mining fleets only. The mill and related facilities will be considered functional for the life of the property. Mill maintenance is a component of direct operating expenses.

Equipment replacement is based on scheduled hours of operation and expected useful life. Where equipment is spared or only selected shifts are worked, equipment operating hours should be adjusted accordingly (* in Table 13.1.2.39). For example, it can be demonstrated that mining capital costs already calculated are adequate for the 2000-ton/day (1800-t/day) at 2 shifts/day and 3000-ton/day (2700-t/day) cases, while the 5000- and 7000-ton/day (4500- and 6400-t/day) cases require capital increases of 50% and 100% respectively. The replacement factor is based on capital investment. Table 13.1.2.39 details the derivation of the replacement costs for case 1 at 2000 tons/day (1800 t/day) and 30- years life.

The annual replacement cost is then $37,240,000 ÷ 30 yr = $1,241,000.

Straight-line depreciation may be applied to total capital expenditures over the life of the mine for tax calculations. For simplicity, this evaluation does not consider salvage value at the end of mine life as the present value would be heavily discounted and would not influence the outcome substantially.

In Table 13.1.2.40, the initial capital investment and the total replacement capital are summed and then divided by mine life to obtain the average annual depreciation.

The next step is to establish a cash flow statement that provides the basis for calculating investment criteria such as net present value, *investment efficiency* (IE), and *return on investment* (ROI). The statement provides a common basis for evaluating project alternatives.

ROI is the interest rate earned on an investment. ROI standards are the minimum acceptable rates of return on a project. A higher rate than required by capital markets is used to provide a safety factor to cover risks inherit in any new project.

NPV is the value today of future net cash flows. The NPV of a project is calculated by discounting the cash flow at the ROI standard used for the project.

IE is the ratio of the NPV of the project to the amount of initial capital investment. The ratio provides a quick visualization of value added per initial dollar invested.

Depletion is a deduction from taxable income that approximates the value of the exhaustible mineral deposit. The percentage allowed is multiplied by the gross revenues, but the total amount cannot exceed 50% of a property's net income.

The present value factors used are for mid-period to average the flow of money over a year. Standard tables are available for this purpose. Table 13.1.2.41 compares the four selected cases.

In the cash flow statement, it is obvious that the NPV and ROI continue to grow with the increasing size of operation. Theoretically, it could be demonstrated that a duration of one year would yield the highest NPV. That is an absurd situation, but it does highlight the need to approach the evaluation from a practical operating standpoint and also to evaluate project gains incrementally.

With an extremely short duration project, an inordinate amount of capital equipment is required, most of which cannot be properly sized nor fully depreciated. The equipment becomes salvage and must be transferred or sold. Operating problems

Table 13.1.2.34. Revised Production Costs

Categories	Tonnage ratios	2000 $/ton	2000 total	3000 $/ton	3000 total	5000 $/ton	5000 total	7000 $/ton	7000 total

Conversion factor: 1 ton = 0.9072 t.

such as traffic congestion, skilled manpower availability, etc. become magnified. The optimum plant size is, in part, obtained only by increasing the size to the point where the most workable plant operation exists.

The 30-year, 2000-ton/day (1800-t/day) case fails to meet the 15% ROI standard and is eliminated from further consideration. The remaining three cases all satisfy the minimum acceptable rate and continue to increase in value as the plants become larger. However, by analyzing incremental growth a different picture emerges.

Using the data available from Table 13.1.2.41, the delta gains between the four cases are determined. Table 13.1.2.42 examines the incremental returns on investment.

Table 13.1.2.37. Annual Revenue

Mill Size tons/day	Ore 1000 tons/yr	Product 1000 lb	Revenue 1000 $

Total	53.4					37,240

Table 13.1.2.40. Replacement and Depreciation Costs

Case tons/day	Life yr	$1,000 ICI	Total Replacement	Annual Replacement	Total Capital	Annual Depreciation
2,000	30	53,400	37,240	1241	90,640	3,021
3,000	20	61,600	24,520	1226	86,120	4,306
5,000	12	80,000	11,440	953	91,490	7,620
7,000	8.6	103,000	6,768	787	109,768	12,764

Conversion factor: 1 ton = 0.9072 t.

It is apparent that the incremental gains do not warrant the expenditures necessary to increase the size of the project to 7000 tons (6400 t)/day. After 5000 tons (4500 t)/day, the IE drops substantially and the capital investment requirement, per percent gain, blossoms almost fourfold.

Based on the preceding analysis, the optimum plant size is in the range of 5000 tons (4500 t)/day. Adjustments may be possible by bracketing the case with 4000 and 6000 tons/day (3600 and 5400 t/day) options and repeating the analysis using data generated in the first iteration.

MARGINAL ORE UTILIZATION. As earlier mentioned, postponing the milling of the marginal ore to the last few years of the property enhances the NPV. The ore reserves and values for the 5000-ton (4500-t)/day case are listed in Table 13.1.2.43.

To illustrate the difference in values, cumulative NPV factors are applied to each scenario.

Option 1. Marginal ore milled after ore milled:

7.6 yr @ $43,034,000/yr × 4.672	= $201,054,840
4.4 yr @ $4,435,000/yr × 1.141	= $ 5,060,335
Total NPV	= $206,115,175

Option 2. Uniform milling of combined reserves:

12 yr @ $31,536,000/yr × 5.813	= $183,319,760

Postponing the milling of marginal ore to the last years of mine life results in a net NPV increase of $22,795,415 or 12%.

From a practical standpoint, unless the higher-grade ore is located in distinct areas of the pit and can be accessed in a normal operational flow, the preceding illustration is not possible. However, the engineer should always keep his eyes open to the potential of opening the pit in a higher-than-average grade area and sequencing the advances such that higher-grade material is exposed first. If that opportunity exists, an improved cash flow often is possible.

The time value of money is critical when planning property development. Deferment of the ICI is possible by the following steps:

1. Contract out the initial stripping until a positive cash flow is experienced.
2. Strip initially in areas with lower overburden to ore ratios to reduce equipment requirements.
3. Minimize the preproduction construction and mine development period to the greatest extent possible.

A final consideration is what to do with the low grade between 0.030 and 0.045%. This material will not contribute to the economics of the project, but it should not be treated as waste. Low-grade stockpile areas should be provided so that an

option exists to mill the material after the mine has closed or if market conditions improve substantially.

The first evaluation has now been completed. The degree of accuracy presented herein is adequate for many engineered feasibility studies. Further optimization is probable, first by re-analyzing the ore reserves using the recalculated ore cutoff grade. Reconfiguration of the pit boundaries may result. Secondly, the 5000-ton (4500-t)/day target can be bracketed and ancillary costing performed in addition to the loading and hauling costs. The analysis should then be repeated in the same manner until one is satisfied that more significant improvement is not likely.

SENSITIVITY ANALYSIS. The analysis is sensitive to the uncertainties inherent in any new project. The most critical parameters in terms of effect on the evaluation are

1. Ore reserves: Has the mineral been properly sampled?
2. Mill recoveries: Are the amenabilities studies based on representative samples?
3. Product selling price: What is the market volatility in this commodity? Are long-term sales contracts obtainable?

Each can have a profound effect on the ultimate outcome of the property as they all have a direct influence on the total value of the deposit. Capital and operating cost variations also can have an effect, but because these are generally more predictable and less volatile, their variations have less impact on the overall cash flow.

As the major sensitivities directly influence the anticipated revenue, it is a relatively simple exercise to generate a spectrum of annual revenues based on variations in ore reserves, mill recov-

Table 13.1.2.43. Ore Reserve Values

Case	Reserves	1,000 Tons and grade	Value, $/ton	Cost, $/ton	Net Value $/ton	Annual Value $1,000	Reserve, yr
1	Ore	15,600 @ 0.098	44.10	20.52	23.58	43,034	7.6
	Marginal Ore	6,400 @ 0.051	22.95	20.52	2.43	4,435	4.4
2	Combined Reserves	22,000 @ 0.084	37.80	20.52	17.28	31,536	12.0

Conversion factor: 1 ton = 0.9072 t.

eries and selling price. Recalculation of the cash flow statement for the 5000-ton (4500-t)/day option will indicate how much revenue loss can be experienced before the project drops below the 15% minimum ROI.

In any event, a decision must be reached on whether or not the potential project will become a reality. Decisions must be based on sound engineering and financial judgments to decide on the basic merits of the investment. It is the engineer's responsibility to provide as detailed a basis as possible upon which a particular project can be evaluated.

Chapter 13.2
STRIP MINE PLANNING AND DESIGN

MATTHEW J. HREBAR AND THOMAS ATKINSON

13.2.1 PLANNING PROCEDURE AND RESERVE ESTIMATION

MATTHEW J. HREBAR

13.2.1.1 Planning Procedure

Planning a surface mine using the strip (open cast) mining method requires consideration of many variables with complex interrelationships (Table 13.2.1.1). Following a collection of general deposit and project-related information, a development and extraction plan is conceived. Project economics is determined, and an economic analysis is performed to determine project viability. Note that steps III and IV are iterated until an "optimum" solution is found. These iterations may include consideration of various mining method/equipment combinations, mine size/equipment combination, mining method/pit layout combinations, etc.

As seen in reviewing the list of variables and information, the problem areas relate to geology, engineering, environmental sciences, and economics. As a result, the planning and development process is interdisciplinary in nature and requires inputs and guidance from numerous individuals with diverse backgrounds and training. The correct mine plan will result in a feasible operating plan, as well as one that optimizes the economic return subject to the numerous contractual, environmental, legal, and other constraints related to the specific property (see Section 7 for general details of mine development).

Jones (1977) has outlined the 10 major steps involved in planning and developing a surface coal mine. These steps are detailed in Table 13.2.1.2 and shown in a Gantt chart in Fig. 13.2.1.1. The planning and development process can take up to 10 years and require millions of dollars of expenditure exclusive of that for actual mine preparation and equipment purchase.

13.2.1.2 Reserve Estimation and Stripping Ratio Calculations

A major portion of the planning process centers on the reserve estimate and geologic "model" of the deposit. These estimates can be quite preliminary or can be made in great detail. The level of effort should correspond to the stage in the exploration/development program. Prospecting and exploration are covered in Section 4 and project geology in Section 5.

SAMPLING METHODS. In most cases, a combination of rotary and diamond core drilling methods is used to obtain sample data from the deposit. Rotary drilling is used to determine overburden depth and coal thickness. A rotary rig is used to drill through the coal seam(s). Then a geophysical probe is lowered into the hole and a log of the hole is produced. Combinations of parameters such as gamma logs and density logs are used to pick the coal/overburden interface. Quality data (e.g., Btu/lb, % ash, % S, etc.) are obtained by diamond core drilling. The solid cores of the coal seam are processed in a lab with the analysis returned for appropriate posting. Core data of the overburden are taken occasionally to determine if toxic overburden exists on the property.

Sample spacing will vary depending on the variability of thickness and quality parameters of the seam. An initial rotary grid spacing (e.g., 2000 ft or 600 m) might be followed by a closer-spaced grid (e.g., 1000 ft or 300 m) or a hole at the center of the original grid. This follow-up drilling is usually conducted to provide further resolution in a second phase of drilling that would be contingent upon success in the more widely spaced initial program. The coal core drilling usually is performed on a lesser spacing than rotary drilling. Closely spaced fences of holes normally are drilled perpendicular to the cropline to determine the extent of the burned or oxidized zone. This contact usually corresponds to some depth of overburden. However, in areas where the overburden is badly fractured, the burned or oxidized zone may not correlate with depth of overburden, and more extensive drilling is required. Overburden coring is usually performed with a hole density of approximately four to five holes/section.

CALCULATION METHODS. The method of calculation used should be a function of the seam variability and to some extent the mining history of the seam in the particular locale.

Tons/Acre Method—The tons-per-acre approach is commonly employed where there is little seam variability or where a rapid approximation of reserves, overburden, and stripping ratio is required. As seen in Table 13.2.1.3, the method involves calculating the tons of coal/acre-ft (tonnes/hectare-meter) and then multiplying this figure by the average thickness of the coal to determine the tons/acre (tonnes/hectare) of coal. The area of reserves in acres is then multiplied by the tons/acre (tonnes/hectare) of coal to arrive at the reserve. Two reserve figures are generally presented: (1) the in-place reserve and (2) the recoverable reserve, which includes allowances for mining and for preparation plant recoveries.

Similarly, overburden/acre is calculated using the average overburden height, and the reserve area is multiplied by this figure to arrive at total overburden.

The average stripping ratio (i.e., bank cubic yards of overburden/ton of coal, or cubic meters/tonne) is calculated by dividing total volume of overburden by total weight of coal, usually on a recoverable basis. In these approximate calculations, average coal and overburden thickness dimensions are usually based on simple means of the drillhole data. The area is usually found by planimetering the area bounded by the outcrop, subcrop, and/or property lines. If more precision is required, techniques such as the polygon or triangular approach can be used to more precisely assign areas of influence to the drillholes. However, the iso-line approach is most commonly used when a detailed reserve and overburden analysis is required.

Iso-Line Method—The iso-line method involves construction of lines of equal values for overburden thickness and coal thickness in an effort to present a model of these parameters representing the deposit.

The iso-overburden map is generated from the surface topography map and a topographic map of the top of the coal seam. The latter is constructed by using drillhole data (depth to top of

coal) and the surface drillhole collar elevations. The two maps are then overlaid, and by subtraction of the surface and top of coal elevations, the thickness of overburden can be established either at the topography intersections or on a regular grid basis. These values are then contoured to produce the iso-overburden thickness lines (Fig. 13.2.1.2).

The iso-coal thickness map is generated either by using the top and bottom coal contours or by interpolation of actual drillhole thickness intercepts. When coal structure contours are used, the top and bottom coal elevation maps are overlaid and the values calculated at either the line intersections or at regular grids. These thicknesses are contoured to produce the iso-coal

thickness lines. If coal intercepts are used directly, the values are interpolated to produce the thickness iso-lines. The most common approach is utilization of the coal structure topography, because these maps are utilized in pit haulage and drainage planning.

The coal thickness and overburden thickness iso-lines are then utilized to calculate the amount of overburden and coal, using procedures outlined in Table 13.2.1.4. The data are usually summarized by overburden range, as indicated in step 8 of the table.

Iso-stripping ratio lines can also be constructed by overlaying the overburden and coal thickness map, calculating the stripping ratio at the line intersection or on a regular grid, and then interpolating and contouring the stripping ratios. The iso-stripping ratio map is extremely useful in determining the economic limits, as discussed under stripping ratio.

Computer Models—Many operators utilize computer software to perform the previously described reserve calculations and to generate the associated graphics utilizing flat-bed plotters. A typical software system will have the following capabilities:

1. Drillhole data loading and editing with data including drillhole identification, location, lithology on a from-to basis, rock type, seam codes, coal seam analysis, etc.
2. Drillhole data listing and abstracts.
3. Drillhole data quality summaries by seam, list, and area with averages for specified parameters.
4. Polygonal reserves with reserves by hole and seam with maps generated showing polygonal shapes.
5. Topography loading by drillhole or by digitizing contour maps.
6. Vertical cross sections, to scale, showing overburden, coal, and other input data.
7. Plan maps showing drillhole locations, crop lines, property lines, etc.
8. Interpolation of data to produce a gridded model of overburden thickness, coal thickness, top and bottom coal elevations, etc.
9. Seam reserves based on gridded data for any area or series of areas with ability to limit reserves based on numerous parameters or combinations of parameters (e.g., minimum coal thickness, maximum overburden thickness, maximum percent sulfur, etc.)
10. Mining cut data generated on a cut-by-cut basis to allow simulation of alternative mine plans and comparison of coal and overburden amounts, coal quality, etc.

Such software is available from numerous companies. A fairly complete directory of programs available has been compiled by Gibbs (1987). Use of computer-assisted reserve calculation and mine planning must be considered state-of-the-art in the surface coal mining industry.

LIMITATIONS. In arriving at a minable reserve for a specific property, consideration must be given to various limitations and losses that will be encountered. These can be grouped into economic limits, equipment limits, and mining and barrier losses. All of these factors will result in coal left in place or lost in the process of extraction. The minable reserve is usually significantly less than the in-place or geologic reserve. For a discussion of economic considerations, see Section 6.

Economic Stripping Ratio—The economics of stripping increasing amounts of overburden is a factor controllable by mine management. The basic premise involves setting a minimum acceptable profit/ton of coal recovered and then adjusting the amount of stripping to satisfy that profit constraint. Such an approach results in a maximum allowable stripping ratio and places a boundary on the area that can be mined economically.

The concept is illustrated in Table 13.2.1.5. As seen in the example, the portion of the property with a limit greater than 32 yd^3/ton (27 m^3/t) would not be considered a surface minable

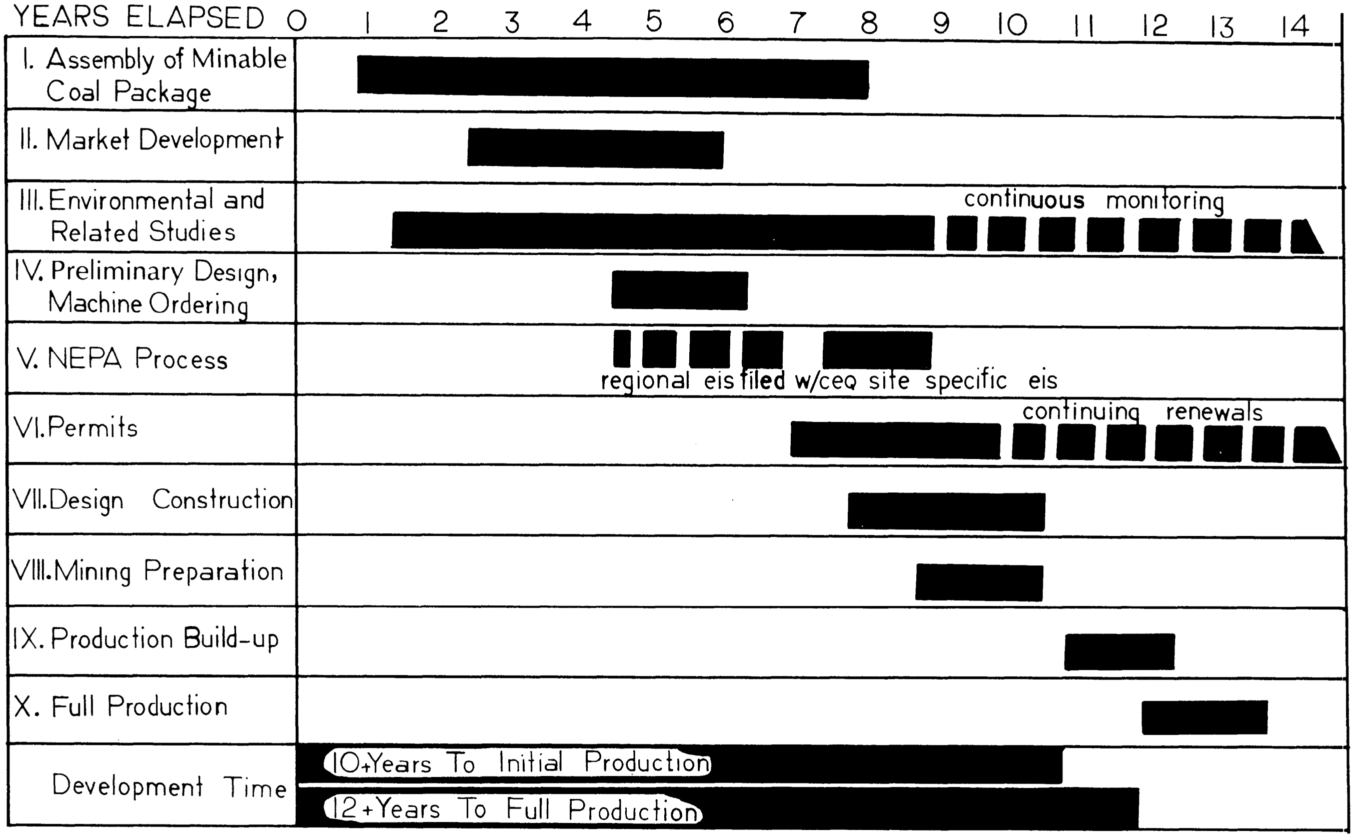

Fig. 13.2.1.1. Illustrative surface mine development schedule (Federal Coal-West) (after Jones, 1977).

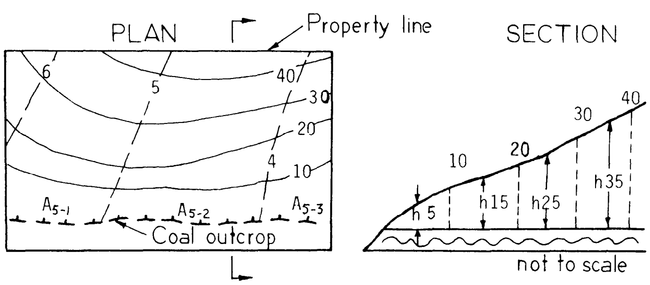

Fig. 13.2.1.2. Plan and section views for a reserve calculation using the iso-line method.

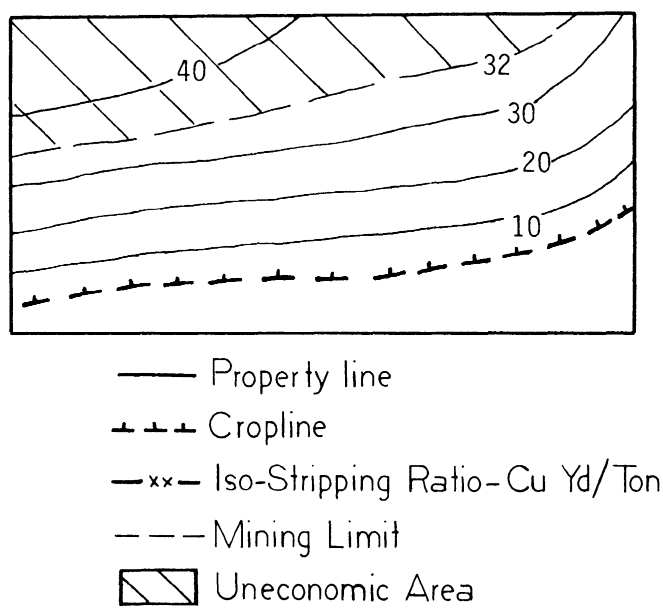

Fig. 13.2.1.3. Plan view used in economic or ultimate stripping ratio calculation.

reserve, and thus the reserve would exclude that area (Fig. 13.2.1.3).

It should be noted that costs of production exclusive of stripping and stripping costs should be "marginal" costs and not average costs. The marginal costs should represent the best estimate of actual costs at that specific area on the property. For example, consideration must be given to any additional costs of stripping caused by greater depths of overburden or any additional haulage costs resulting from increased haulage distances.

Equipment Limitations—In some cases, stripping equipment digging-depth limitations or coal-loading equipment height limitations may limit the minable area. In certain deposits, highwall or spoil instability may preclude use of deep-digging techniques and limit the minable area with a maximum digging depth. In this situation, extended bench or spoil-side pullback may not be possible, causing a depth limit on the reserve (deep-digging methods are described in a subsequent chapter).

A minimal coal thickness is required to economically recover thin seams using surface techniques. In very thin seams, dilution from top and bottom material will preclude recovery of a marketable product. As a result, depending on the coal loading tech-

Table 13.2.1.3. Reserve Calculations: Tons/Acre Method

1. $$\frac{tons}{ac\text{-}ft} = 43{,}560\,\frac{ft^2}{ac} \times \frac{coal\ density}{2000 lb}$$

e.g., density = 82 lb/ft³

$$\frac{tons}{ac\text{-}ft} = 43{,}560 \times \frac{82}{2000} = 1786\,\frac{tons}{ac\text{-}ft}$$

2. $$\frac{tons}{ac}\ (raw) = \frac{tons}{ac\text{-}ft} \times average\ thickness\ (ft)$$

e.g., average thickness = 4.5 ft

$$\frac{tons}{ac}\ (raw) = 1786 \times 4.5 = 8037\,\frac{tons}{ac}\ (raw)$$

3. $$\frac{tons}{ac}\ (recoverable) = \frac{tons}{ac}\ (raw) \times mining\ recovery \times preparation\ plant\ recovery$$

e.g., mining recovery = 90% prep. plant recovery = 85%

$$\frac{tons}{ac}\ (recoverable) = 8037 \times .90 \times .85 = 6148\,\frac{tons}{ac}$$

4. $$tons\ (raw) = \frac{tons}{ac}\ (raw) \times ac$$

e.g., 640 ac

tons (raw) = 8037 × 640 = 5,143,700 tons

5. $$tons\ (recoverable) = \frac{tons}{ac}\ (recoverable) \times ac$$

e.g., 640 ac

tons (recoverable) = 6148 × 640 = 3,934,700 tons

Stripping Ratio

6. $$\frac{overburden}{ac} = 43{,}560\,\frac{ft^2}{ac} \times \frac{avg.\ overburden}{27\ ft^3/yd^3}\ (ft)$$

e.g., overburden thickness = 60 ft

$$\frac{overburden}{ac} = 43{,}560 \times \frac{60}{27} = 96{,}800\,\frac{yd^3}{ac}$$

7. stripping ratio or overburden ratio

$$stripping\ ratio = \frac{overburden/ac}{tons/ac\ (recoverable)}$$

e.g., tons/ac = 6148

$$stripping\ ratio = 96{,}800/6148 = 15.7\,\frac{yd^3}{ton}$$

Conversion factors: 1 ft = 0.3048 m, 1 ton = 0.9072 t, 1 acre = 0.405 hectare, 1 yd³/ton = 0.8428 m³/t, 1 ton/acre-ft = 7.37 t/hectare-m, 1 lb/ft³ = 16.0185 kg/m³.

Table 13.2.1.4. Reserve Calculation: Iso-Line Method (see Fig. 13.2.1.2)

Step 1. Construct iso-overburden lines.

2. Measure areas bounded by iso-overburden lines with planimeter. (e.g., A_5 (outcrop-10), A_{15}(10-20), etc.)

3. Assign thickness to overburden, calculate volume for each "slice":

Area (A)	Height (h)	Yardage (A × h/27)
A_5	h_5	CY_5
.	.	.
.	.	.
A_n	h_n	CY_n
		Sum CY

4. Construct iso-coal thickness lines.

5. Measure sub-areas bounded by iso-overburden and iso-coal thickness lines for each A_n or "slice".

6. Assign coal thickness to each sub-area and calculate coal quantity. Summarize, calculate stripping ratios, etc.

Sub-area	Coal Thickness	Tonnage $A_{5-i} \times T_{5-i} \times$ Density/2000	Stripping Ratio CY_n/T_n
A_{5-1}	T_{5-1}	Ton_{5-1}	
.	.	.	
.	.	.	
A_{5-m}	T_{5-m}	Ton_{5-m}	
		T_5	SR_5

7. Repeat 5 and 6 as required.

8. Data usually summarized as follows:

Overburden Range	Overburden Quality	Coal Quality	Stripping Ratio
0–10			
10–20			
20–30			
30–40			
40+			

Conversion factor: 1 yd³ = 0.7646 m³.

Table 13.2.1.5. Economic or Ultimate Stripping Ratio Calculations (See Fig. 13.2.1.3)

$$\text{Economic Stripping Ratio} = \frac{\text{Recoverable Value/Ton} - \text{Production Cost/Ton*} - \text{Minimum Profit/Ton}}{\text{Stripping Cost/Yd}^3}$$

*Exclusive of Stripping

Example:

	Recoverable Value	=	\$17.00/Ton
	Minimum Profit	=	\$ 3.00/Ton
	Stripping Cost	=	\$ 0.25/Yd³
	Production Cost*	=	\$ 6.00/Ton

$$\text{Economic Stripping Ratio} = \frac{17.00 - 6.00 - 3.00}{0.25} = 32\,\frac{\text{Yd}^3}{\text{Ton}}$$

Conversion factors: 1 ton = 0.9072 t, 1 yd³ = 0.7646 m³, 1 yd³/ton = 0.8428 m³/t.

nique employed, areas with coal thicknesses below that minimum would be considered unminable.

Mining and Barrier Losses—Mining losses are those associated with the extraction process. These losses include the following:

1. Top of coal: losses at upper coal contact with overburden as a result of cleaning coal after stripping.
2. Bottom of coal: losses at lower coal contact with bottom as a result of loader losses; both top and bottom losses, as a percentage, are a function of seam thickness.
3. Rib: losses at side of seam adjacent to spoil as a result of spoil piled on coal rib during stripping or slides of spoil on coal; function of pit width.
4. Other: includes fly rock (blasting) and transportation losses (dust and spillage).

In eastern area operations, these losses account for some 10% of the reserve (Anon., 1977). In thicker-seam western operations, these losses are probably a lesser percentage because of the thicker seams and wider pits generally encountered.

Barrier losses are caused by coal left in place for various practical and regulatory reasons. Barrier losses include outcrop (coal left as a low-wall barrier or for quality reason), right-of-way, stream, underground mine, oil and gas wells, property line, building, and cemetery. In eastern area operations, these losses account for 5.2% of the reserve (Anon., 1977). These losses are quite site-specific and depend on the geologic and geographic setting of a property.

Mining and barrier losses are significant and are given thorough consideration in estimating minable reserves.

13.2.2 STRIPPING AND PIT DEVELOPMENT

MATTHEW J. HREBAR

The surface coal mining method selected for a specific property is generally keyed to the overburden removal system, since this unit operation usually involves the greatest capital and operating cost components. Once the stripping method and complementary equipment have been selected, compatible equipment systems are selected for the other unit operations (i.e., coal fragmentation, coal loading and hauling, etc.).

The following segment describes development for the major systems commonly encountered in surface mining of coal, especially at large western operations. In addition, major performance standards and Office of Surface Mining (OSM) regulations are integrated into the presentation of unit operations.

As previously mentioned, standard engineering practice dictates that various alternatives be investigated, not only for the stripping system, but also for the other unit operations. The goal is to provide maximum resource extraction at a minimum cost including both capital and operating cost considerations.

13.2.2.1 Alternative Stripping Methods

Three alternative stripping procedures are described.

AREA/DRAGLINE METHOD. The area/dragline method (Fig. 13.2.2.1) involves opening an initial box cut, removing the coal exposed in the box cut, and then placing the overburden from the next longitudinal cut into the mined-out, box-cut area. The procedure is then repeated on a cut-by-cut basis. The method is also referred to as “deep plowing.”

The method is generally employed in flat to moderately dipping coal seams with relatively constant overburden depths. Such a method can also be employed in areas where coal dip or overburden slope result in reaching the economic limit in relatively few cuts. In this mode, the method is referred to as a modified area or box-cut contour operation. The major difference is the rate at which the limit is reached.

The advantages and disadvantages of the area/dragline method combine the characteristics of the dragline excavator and the method. Generally, the alternative piece of equipment used to perform stripping is the stripping shovel. The industry has purchased few large stripping shovels in recent years, and there are only approximately 20 stripping shovels (i.e., direct casting machines mounted on eight crawlers) currently in operation. Draglines have been chosen in these applications primarily because of their flexibility in varying operating conditions. The dragline can handle varying overburden depths, varying overburden characteristics, and multiple seams by changing the operating mode. Although these changes often cause some loss in machine productivity, they allow mining through the specific set of conditions without major additions of auxiliary equipment that would be required with a stripping shovel. For a more detailed discussion of stripper selection, see Atkinson (1971) and Steidle (1977).

MODIFIED OPEN PIT/SHOVEL-TRUCK METHOD. Modified open pit or terrace mining is generally used in thick-seam properties with low stripping ratios. In these applications, seams are generally flat-lying, gently dipping, or rolling. The method shown in Fig. 13.2.2.2 involves opening an initial pit and placing the overburden in temporary off-site storage. Coal is then removed from the initial pit area. The next cut is taken in the direction of mine advance and the overburden is hauled around the existing pit and dumped in the mined-out area. Coal is removed and the haul-back process is repeated as the relatively small pit advances.

In new pitching or steeply dipping seam operations, the initial pit is opened and coal removed. The initial box cut is opened to the economic limit down dip. Subsequent cuts are advanced on-strike, and overburden hauled back into the mined-out initial pit.

BLOCK AREA/DOZER-SCRAPER METHOD. The block area method, which utilized construction-type equipment, was first conceived in the mid- 1970s as an alternative to the area/dragline method. At that time, draglines were not readily available because of the high demand and long lead times in procurement. Alternative methods were sought that would employ readily available construction-type equipment (i.e., dozers and scrapers). This method takes advantage of the dozer’s ability to move material over short distances at low costs and the scraper’s ability to elevate material over steep grades for short distances at reasonable costs.

In this method, it must be noted that there is a relatively narrow window of application from a material standpoint. As the degree of consolidation of material increases, wear and tear on the scrapers makes the method cost prohibitive because of high repair, maintenance and supply costs, and reduced machine

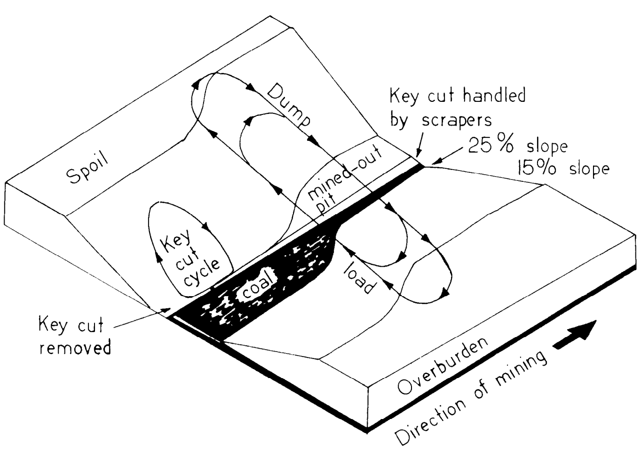

Fig. 13.2.2.3. Block area/dozer-scraper method (after Ryan, 1982).

productivity. One version of this method is shown in Fig. 13.2.2.3.

13.2.2.2 Dragline Pit Design

Pit parameters and configuration selected for a given site are a function of deposit geometry and prevailing regulations. The following points must be given consideration.

PIT LENGTH. The average length of pit in the central United States is approximately 5500 ft (1.67 km), and although specific data are not available for the western part of the country, lengths are similar. The following factors influence pit length.

1. Property dimensions: Can limit maximum length.

2. Dragline efficiency: Longer pits (Over 3000 ft or 900 m) preferred.

3. Coal inventory: In some cases, a pit inventory is kept to meet seasonal demand or compensate for low stripper availability; amount is a function of seam thickness, pit width, and length of block in place.

4. Spoil instability: If spoil stability is a function of time, shorter pits are preferred to limit spoil failures.

5. Pit flooding: In high-rainfall areas, short pits limit water quantities in pit.

6. Power system: In low mine-voltage systems, voltage drop becomes excessive with long pits.

PIT WIDTH. Pit width in large midwestern mines ranges from 95 to 105 ft (29 to 32 m) and averages 120 ft (37 m) in western mines. In deep cover, widths range to 180 ft (55 m). The following factors influence pit width:

1. Stripping machine reach: Strippers are limited by reach, and therefore a limit is placed on the pit width and overburden depth combination if rehandling is to be avoided.

2. Overburden depth and dragline productivity: Simulation studies indicate that narrow pits should be chosen in shallower overburden because of decreased swing angles, and that wide

pits should be selected in deep overburden where extended bench is utilized to minimize percent rehandle. (Anon., 1976b; Hrebar and Dagdelen, 1979) These selections improve dragline production.

3. Reclamation: Narrow pits minimize spoil peak strike-off in regrading, while wide pits increase spoil area and strike-off quantities.

4. Coal loading and hauling: Some minimum width is required for efficient equipment operation; width is a function of equipment size and type combinations.

5. Coal inventory: Width will influence tonnage/unit length of pit.

PIT ORIENTATION. Selection of pit orientation and sequencing is critical to the mine plan, because it will determine equipment selection, operating costs relative to production life, coal quality relative to production life, and so forth.

Straight vs. Curved Pits—Where a property contains a curved outcrop or subcrop where stripping will begin, the operator must decide if the subcrop will be followed or whether straight pits will be employed. Where curved pits are selected, a series of inside and outside curves are usually encountered. The inside curves, where the advancing highwall arc is greater than the spoil side arc, can cause significant spoil room problems, particularly when overburden depth increases in the direction of mine advance. In this case, each new cut contains more overburden volume than is available in the prior cut spoil volume. Excess spoil is soon generated and costly rehandling is required.

Outside curves, with the advancing highwall arc less than the spoil side arc, can be used to advantage in areas of increasing overburden depths. In this case, each new cut has less area than the adjacent spoil area, and this difference can be utilized to accommodate the added volume caused by the increase in overburden height. Outside curves can be used to advantage where an operation encounters ridges perpendicular to the cropline or subcrop.

In addition to the inside-curve problem, curved pits are difficult to lay out in the field and difficult to execute from an operating standpoint. They also require coal haulage on curves in the confined pit. As a result of these problems, many operators choose to develop straight pits, which alleviate these problems.

Straight pits are developed either by a series of short pits or by varying pit width. A series of short pits on the cords of an outside curve can be utilized to straighten the pits. In many cases, auxiliary equipment such as a scraper fleet is used to strip these pits so that the dragline is not utilized until long straight pits are available. This has the advantage of not applying the dragline in inefficient short pits and of postponing dragline investment while low capital cost equipment is used to begin the operation. The other alternative is to utilize the dragline and employ wide pits at the outside curves and narrow pits at the inside curves until a straight pit configuration is achieved. This alleviates the short pit inefficiency but is more difficult to engineer, lay out, and execute. Two papers (Anon., 1976b; Anon., 1977) provide an in-depth discussion of inside and outside curves.

Average vs. Minimizing Stripping Requirements—Orientation of pits and pit sequencing are crucial to the entire mine planning scheme. The common alternatives are averaging and minimizing the stripping ratio over time.

When the ratio is averaged, approximately the same stripping ratio and the same quantity of overburden are handled each year. Overburden depths range from low to high in a given year to balance and average the ratio. The advantages of this approach include fairly constant stripping capacity requirements, constant costs/ton (exclusive of inflationary effects), and constant manpower requirements.

When the ratio is minimized, areas with the low stripping ratio are mined in early years, mid-range ratio in midyears, and high ratio in later years. These plans must also consider such constraints as minimum pit length, avoidance of excessive dragline walking by selecting a logical progression throughout the property, and allowance for efficient haul-road access. The primary advantage of this approach is that the best economics is generally achieved because of postponement of capital expenditure and low direct operating costs in early years of production. However, the disadvantages include continually increasing equipment and manpower requirements in order to strip increasing amounts of overburden. Management of the constantly changing operation is more difficult. However, the economic benefits of minimizing stripping ratio are significant, as described in the case study in the final section.

HAUL ROAD LAYOUT. The average strip mine haul distance in the central United States is approximately 5 miles (8 km) one way. Strip mine roads are usually spaced on 1500- to 1800-ft (450- to 540-m) centers through the spoil to facilitate one-way hauls if possible. In deeper overburden, fewer haul roads through the spoil may be used as a result of significant spoil volume losses. Where contemporaneous haul-road reclamation is required, the trend appears to be fewer haul roads through the spoil. In addition, there seems to be a trend toward steeper ramps. Both of these trends cause decreases in truck productivity because of increases in turnaround areas in the pit and increases in time spent hauling up ramps. Generally, these roads are located to minimize haul distance and designed to facilitate high-speed haulage using width and construction guidelines similar to those presented by Kaufman and Ault (1977).

Two other haul-road arrangements are used in certain situations. Highwall side ramps are used where soil stability problems, spoil volume losses, or unusual property geometry are factors. The prime disadvantage of the highwall side ramps is the dragline inefficiency and auxiliary equipment time associated with continuous rebuilding as the mine advances. Pit-end haul roads are used where spoil volume losses or spoil instability are factors. This requires unique pit geometry, cropline on three sides, or deep box cutting to maintain the access. Long in-pit haul distances are generally associated with pit-end haul roads.

13.2.2.3 Pit Development

CLEARING AND GRUBBING. This involves clearing the property of trees and shrubs and then removing the stumps and roots to insure a homogeneous topsoil. Grubbing is often done with rake-like grubbing attachments on agricultural tractors or dozers.

TOPSOIL REMOVAL. Regulations dictate that the topsoil be removed and ultimately replaced upon graded spoils. Topsoil can either be stockpiled at the side of the pit area for later redistribution or hauled immediately to the graded area for redistribution. In the latter case, the topsoil can either be hauled around the pit or across the pit on spoil bridges. The decision is made on the basis of economics considering topsoil quantities and haul distances.

Self-elevating scrapers are the most common means of removing and redistributing topsoil, although loader/truck or wheel excavator/belt systems find application where topsoil quantities are large and/or haul distances are long.

Topsoil thicknesses are usually determined by auger drilling, and the regulations dictate that a minimum of 6 in. (150 mm) of material be removed. In cases where multiple soil horizons (i.e., A, B, and C) exist, these layers must be removed separately and stockpiled and redistributed to maintain the integrity of each horizon. Topsoil storage, if longer term, must be revegetated to prevent water and wind erosion.

MINE DRAINAGE AND EROSION AND SEDIMENT CONTROL. For many years, it has been good operating practice to divert surface water from active pit areas to eliminate in-pit water problems. Diversion ditch systems were utilized to deflect the water and direct it into natural drainages.

Under current regulations, this practice has been expanded to include the following:

1. Surface drainage from disturbed areas must pass through a sediment pond.

2. Effluent from the ponds must meet limitations of pH, iron, manganese, total suspended solids, etc.

3. Sedimentation ponds must be constructed to standards on capacity, detention time, dewatering, location, slopes, etc.; these standards, particularly the capacity standards, have been contested by industry.

4. Discharge compliance must meet 10-year, 24-hour precipitation events.

5. Treatment is required, if necessary to meet effluent standards.

General design measures taken to meet these standards economically include minimizing the disturbed area, stabilizing backfill, diverting overland flow around or through disturbed areas to reduce pond size, revegetating immediately to reduce sediment load, and separating pit water from other water to minimize treatment. Skelly and Loy (Anon., 1975) have provided an in-depth treatment of drainage and erosion control (see also Chapter 12.1 in this *Handbook*).

REGRADING. Regrading or striking-off the spoil is usually accomplished with large-horsepower dozers, and final grading is done with large graders. Regulations provide a number of general guidelines including:

1. Restoration to approximate original contour.
2. Elimination of highwalls.
3. Restoration of natural drainages to the extent possible.
4. Construction of final slopes not exceeding original slopes.
5. Productivity equal or greater than premining productivity. In addition, the regrading must be done within 180 days or with regrading kept within four spoil ridges of the active pit.

TOPSOIL REPLACEMENT OR REDISTRIBUTION. As previously discussed, scrapers, dozers, or loader/trucks are utilized in this operation with topsoil replaced continuously or from stockpile. Some preparation of the graded spoil, plowing, etc., is usually done to stabilize the topsoil bed. Traffic patterns are designed to prevent over-compaction of the bed.

REVEGETATION. Planting is accomplished either by hydroseeding or with conventional farm equipment and must be done as soon as practical with seed selection based on postmining land use. Success is usually judged by comparison with a reference area, with production rated as some percentage of that area. Erosion must be controlled so that gullies or rills more than 9 in. (276 mm) in depth do not develop. A period of extended responsibility is involved (e.g., 10 years where rainfall is less than 26 in. or 660 mm annually).

More coverage of reclamation is provided in Chapter 12.3.

13.2.3 CAST BLASTING OF DEEP OVERBURDEN

THOMAS ATKINSON

For strip (open cast) mining, overburden must often be blasted so that it can be economically excavated by a dragline, that is, the overburden must be well fragmented and loosened, with relatively small lateral displacement. For many years mining engineers have been attracted to *cast blasting* (explosives casting) of overburden to take advantage of the abundant chemical energy of explosives (Brealey and Atkinson, 1968; McDonald, Smith, and Crosby, 1982). The favorable heaving effect of ammonium nitrate-fuel oil (ANFO) and its low cost increased this interest. The advantages of cast blasting become even more desirable when considering deeper, stronger overburdens requiring high powder factors (pounds of explosive/cubic yards of overburden blasted, or kilograms/cubic meters), 1.1 lb/yd^3 (0.65 kg/m^3) being typical for some very strong sandstones, for example, in South Africa and Australia. Recent developments have shown that in certain circumstances, cast blasting in deep overburden can be more economic than conventional stripping.

Early trials were based on reducing the primary overburden cast by the dragline (Fig. 13.2.3.1). In addition to reducing the dragline duty, this method has the added advantage of casting very large rock fragments from the base of the highwall onto the floor of the pit to form the base of the spoil heap, thereby improving spoil heap drainage and stability.

Blasting theory is covered extensively in Chapter 9.2.1.

13.2.3.1 Presplit Blasting

Presplit blasting has been used for dewatering permeable overburden. Where clay-rich and similar materials are absent,

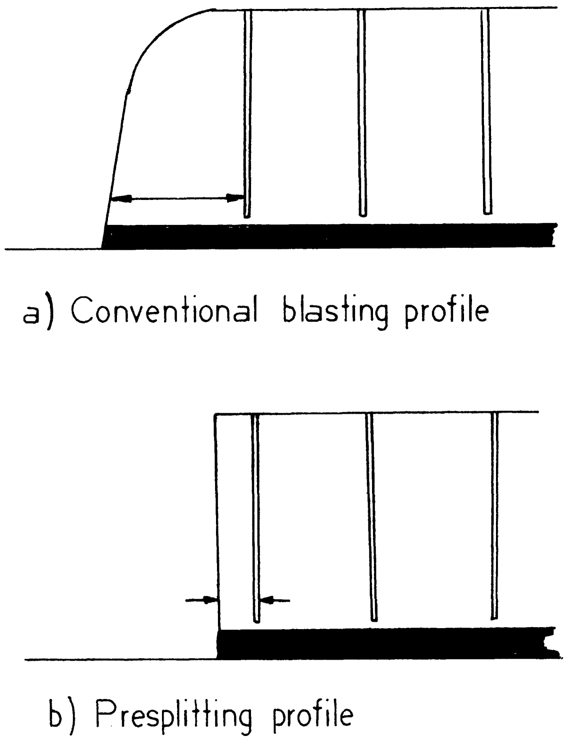

Fig. 13.2.3.2. Vertical presplit highwall.

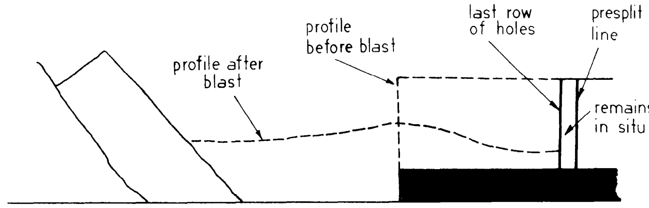

Fig. 13.2.3.3. Blasting with parallel tie up.

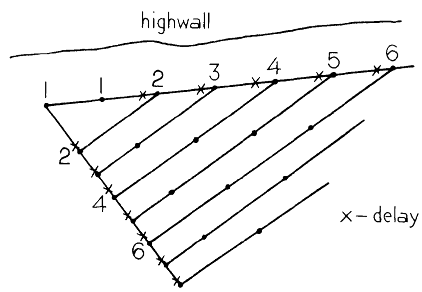

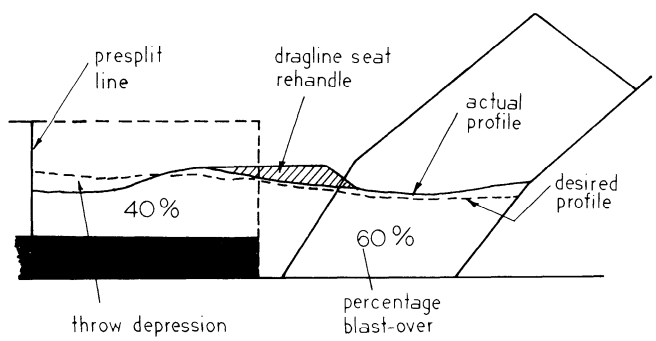

Fig. 13.2.3.4. Blasting method.

low-cost, bulk-placed ANFO has been used in place of more expensive water-resistant explosives, such as water-gels, heavy ANFO, etc. Additionally, in strong ground, a vertical face can be created after blasting the total burden as compared with the irregular sloping face produced by conventional blasting (Fig. 13.2.3.2). It is obvious from Fig. 13.2.3.2b that the vertical face, with greatly reduced distance from the front row of blastholes to the toe of the highwall, will result in far more efficient cast blasting. The combination of pre-splitting and inexpensive ANFO can result in economic cast blasting. It can also be economic with non-vertical highwalls, where an inclined presplit line is used and the blasthole pattern suitably modified.

13.2.3.2 Casting Characteristics

BLASTING PATTERNS. The geometry of the spoil after cast blasting must be controlled to provide a section suitable for dragline operation while moving as much spoil as possible across the pit. Conventional blasting patterns in strip mining are usually square or rectangular with a 90° tie up, that is, rows of holes at 90° to the highwall are detonated simultaneously, then sequentially, so that the spoil is thrown parallel to the highwall. It appears, therefore, that if rows of blastholes parallel to the highwall are detonated simultaneously, initiated from the highwall progressively from front to back, maximum spoil will be cast across the pit. Experience shows that marginally more spoil is cast by this tie up, but a section of overburden between the presplit line and the last row of blastholes remains in situ (Fig. 13.2.3.3).

The best results appear to occur with about a 30° tie up using a staggered "V1" pattern with relatively long, inter-row delays. Fig. 13.2.3.4 illustrates a typical section and the desired section. The "throw depression" can be greater than desirable, and some minor rehandling of the thrown spoil is necessary to form the "seat" for dragline operation.

The spacing:burden ratio of the blasting pattern is affected by site-specific factors and requires detailed consideration to obtain control of the trajectory of the thrown spoil.

Blasthole diameters of 10 to 12 1/4 in. (254 to 311 mm) are currently used. It is doubtful whether larger-diameter holes will provide additional advantages in strong ground, unless more energy can be packed into the blasthole, and closer spacing rather than larger blasthole diameters may be preferable.

DEPTH/WIDTH RATIO. A measure of the efficiency of cast blasting is the amount of spoil thrown beyond the edge of the mineral seam. This may be expressed as the percentage volume thrown by blasting across the edge of the mineral seam, that is, the *percentage blast-over*. Intuitively, for a constant strip width, the percentage blast-over will be expected to increase with increasing depth. There are few published data on this subject, but the results from two sources where strong sandstone overburden was cast blasted gave the following relationship:

$$\text{percentage blast-over} = 57.5\frac{d}{w} + 18 \qquad (13.2.3.1)$$

where d/w is depth/width ratio varying between 0.4 and 0.9, d is depth of the pit to base of the mineral seam, and w is width of the exposed strip.

The percentage blast-over obviously will vary considerably due to site conditions and blasting efficiency, but Eq. 13.2.3.1 is adequate for initial mine planning purposes.

13.2.3.3 Cast Blasting Methods

Major advantages accrue where the dragline can be located on the spoil side of the pit. These are

1. The access ramp roads can be located on the highwall side of the pit, eliminating the problems caused by lack of spoil space at the junctions of the strip with the access ramps (e.g., major rehandling of spoil), since generally, spoil must be piled higher at these junctions and often results in serious spoil-side failures (Walton and Atkinson, 1978).
2. The stripping rhythm is maintained since access ramp junctions do not have to be formed, and dragline productivity on prime overburden is increased greatly.
3. Equipment scheduling is simplified.
4. Access to mineral benches in multi-seam settings is greatly facilitated.
5. Surface reclamation is simplified and land is returned to its planned use at an earlier date due to the absence of access ramp roads through the spoil.

The main disadvantages are

1. The dragline may operate in the less efficient "chop-down" mode.
2. Separate electrical reticulation systems are required on both sides of the pit-on the spoil side for the dragline and on the highwall side for the blasthole drill rigs.

SINGLE-SEAM, CROSS-PIT, CHOP-DOWN OPERATION. A dragline used in the chop-down mode is about 60% efficient compared with the conventional drag mode. Bucket maintenance costs are also higher (although this is considerably alleviated by the better fragmentation achieved in cast blasting). The depth/width ratio of the pit should exceed 0.4 to achieve greater than 40% blast-over for chop-down to be considered; that is, the method is more suited to deeper pits.

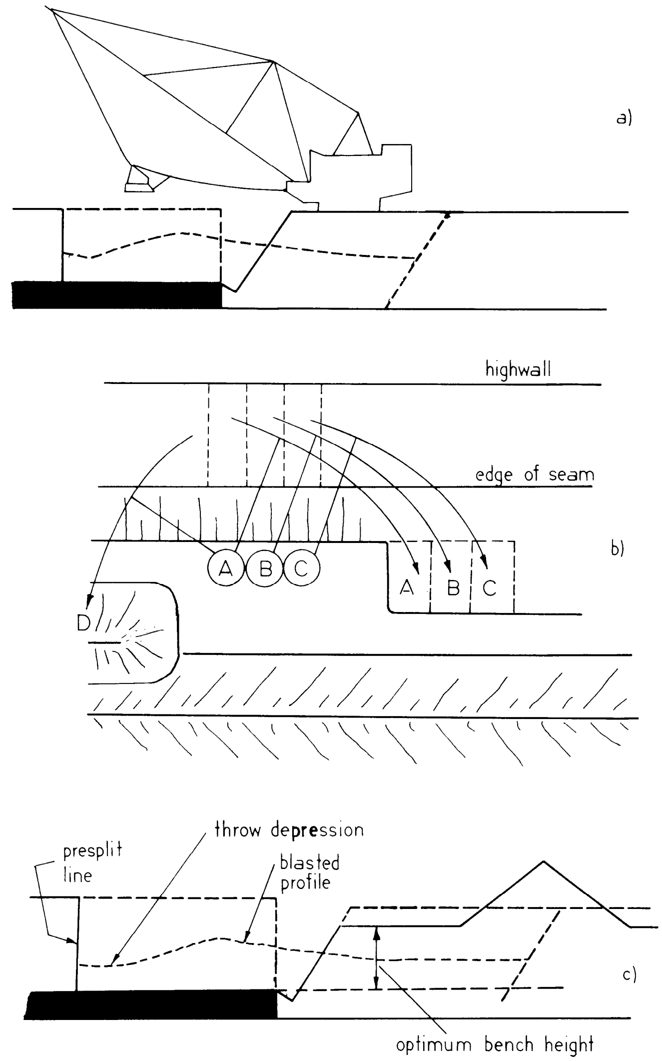

Fig. 13.2.3.5. Cross-pit, chop-down with single seam.

Fig. 13.2.3.5 shows the method of operation. The dragline seat bench height in (c) can be fixed so that all the spoil is required for leveling, that is, the need for leveling spoil peaks for land reclamation is eliminated. This advantage can only be fully realized, however, if the height of the dragline seat above the top of the mineral seam does not exceed the optimum digging depth. Where this height exceeds the optimum digging depth, the bucket must be dragged to a higher elevation so that it may be hoisted away for dumping, thereby increasing the cycle time. In these circumstances, it is usually more economic to level the spoil peaks with conventional mobile equipment. (Note that for a dragline to hoist a full bucket of spoil, the hoist and drag ropes must form an angle, 90°, i.e., be within a semicircle drawn through the fairleads and boom sheaves).

The single-seam, chop-down method may be used to strip seam partings where other seams exist beneath the seam being extracted. This operation results in a reduction of dragline productivity of up to 50%, but if the ratio of parting to lower seam thickness is low, it can be economic.

TWO-SEAM METHOD. Fig. 13.2.3.6 shows a sequence of operations for a typical two-seam setting.

(a) Pit section prior to blasting.

(b) Interburden blasted into the void left after extracting the mineral from the previous strip. Note that large rocks will form the base of the spoil heap and are not handled by the dragline.

(c) Blasted overburden. Note that the throw depression of the interburden blast is filled by overburden spoil.

(d) The dragline seat is prepared by bulldozer.

(e) A key cut is formed to the lower seam, and the upper seam is stripped; this spoil is dumped on the lowwall to provide material for the spoil bench.

(f) The spoil bench is dozed level, and the remaining spoil is "pulled back," being dumped on the spoil bench.

(g) The lower seam is stripped. The mineral extraction operation can now commence. After the mineral is removed, the cycle can be repeated.

The method results in an increase in dragline productivity above that of conventional dragline stripping, but insufficient experience is available in comparable conditions to quantify this increase. There are, however, other marked advantages:

1. Both seams are exposed together, allowing simultaneous mineral extraction. The upper seam can be dozed over the side of the bench (or by other suitable means) on to the lower seam, thereby concentrating and simplifying mineral loading opera-

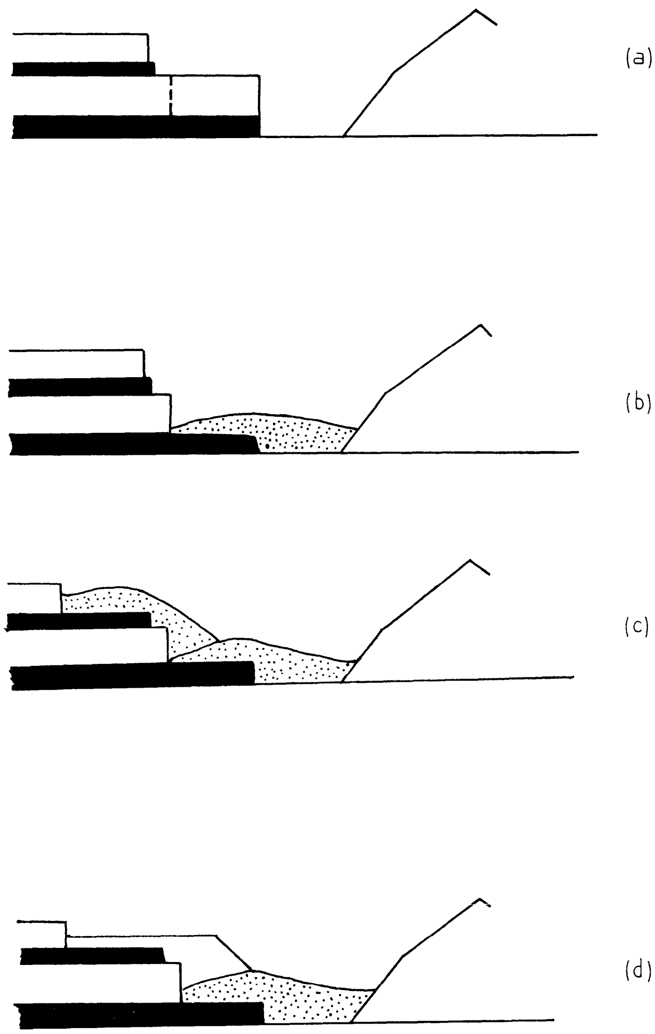

Fig. 13.2.3.6. Two-seam method (a), (b), (c) and (d).

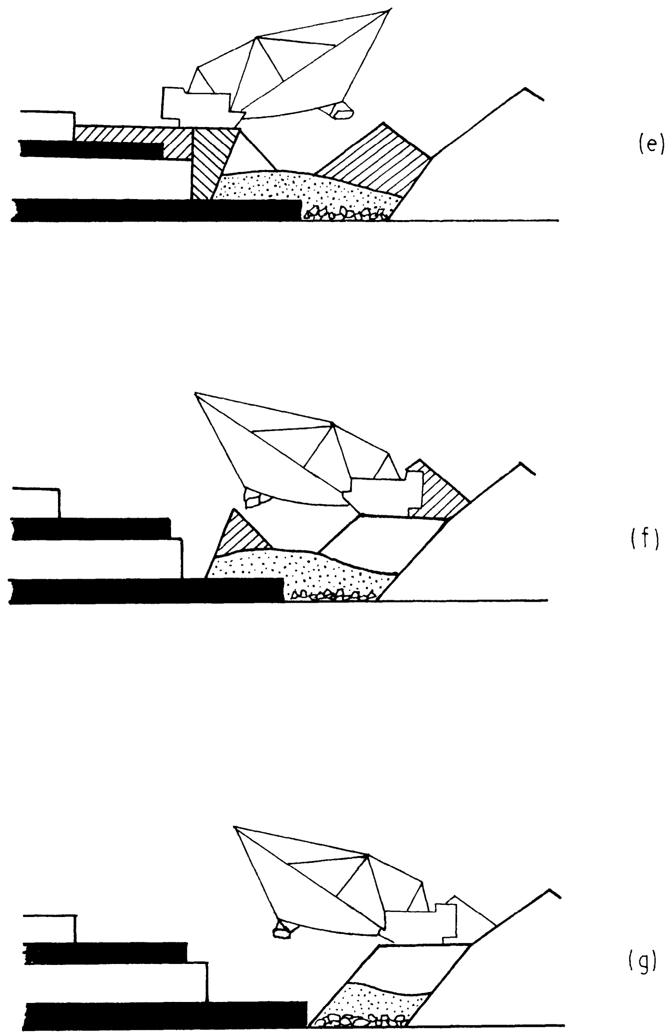

Fig. 13.2.3.6. (Continued) Two-seam method (e), (f) and (g).

tions and improving blending. The volume of in-pit exposed reserves is increased allowing greater flexibility in operation.

2. Spoil-heap stability is greatly improved as strong rocks from deep within the overburden form the base of the spoil heap. In conventional dragline stripping, weaker weathered material forms the toe of the spoil heap.

3. Both seams are exposed simultaneously. In conventional dragline stripping, two dragline passes are necessary. Dead heading is therefore halved.

4. The deeper, stronger interburden is cast by blasting into the void to form the base of the spoil heap, and is not handled by the dragline. Bucket maintenance costs are therefore greatly reduced.

The method can also be used for single-seam, thick-overburden settings to eliminate the chop-down operation of the upper overburden. Where weathered material exists near surface, the upper bench can be presplit with more closely spaced holes than for the lower, more competent overburden. Providing weathering is not too deep, the upper bench slope can often approach 90º (vertical) because the presplit face did not seriously deteriorate after blasting and due to the enhanced drainage effects.

STRIPPING PREVIOUSLY WORKED DEPOSITS. In many countries, thick coal seams that have been previously partially extracted by underground methods (e.g., room and pillar mining) can be economically recovered by strip mining. In some situations, the security of the dragline can be in question where conventional dragline stripping is proposed. Cast blasting provides an alternative stripping method where the dragline is not located over the pillared coal, thereby eliminating any dragline security hazard.

Chapter 13.3
SELECTION AND SIZING OF EXCAVATING EQUIPMENT

THOMAS ATKINSON

13.3.1 INTRODUCTION

The main operations in a surface mine—ground preparation, excavation and loading, transport, and mineral treatment—are interdependent, and the optimum cost per ton may not be obtained by attempting to minimize each of the individual operational costs. It is not good practice to focus on any one item in isolation. The increased use of explosives may result in reduced loading, transport, and crushing costs, which could amply recover the increased ground preparation costs. Adverse rock materials cause numerous equipment selection problems in surface mining. Abrasion and stickiness cause major problems that are accentuated where intensive continuous systems are employed.

The importance of not selecting items of equipment in isolation and of material properties testing, both prior to selection and during excavation, cannot be overstressed.

The selection of the excavator or loader is of prime importance because it largely determines the other equipment required and the mode of operation; it is the key to low-cost production but is not usually the starting point in planning.

The competence and "diggability" of ground is of major importance in the selection of excavating equipment. It depends on many factors, for example, (1) the intact strength of the ground, (2) the competence of the ground as a whole, (3) the abrasive properties of the mineral constituents, (4) the bulk density of the ground, both in situ (bank) and broken (loose), (5) the flow properties of the broken ground, possible stickiness, etc., and (6) the degree of ground preparation contemplated to achieve a desired fragmentation.

At present, there is no generally accepted quantitative measure of diggability, but a fairly reliable indication can be obtained from (1) similar excavations in the area; (2) the behavior of ground excavated in trial pits; (3) physical tests on core samples recovered by drilling (some caution must be exercised, because exposed beds may have very different characteristics from the cores; the most widely used tests are uniaxial and triaxial compressive strength, shear box, abrasion hardness tests, and a variety of simple field tests; and (4) refraction seismology tests (these are easily carried out, but their interpretation can be difficult in disturbed geologic conditions). Fig. 13.3.1 shows excavation possibilities without blasting and the seismic velocities of various rocks. Generally, several of the above methods are used in conjunction with one another.

Other factors that must be taken into account are the reach of the excavator, both horizontal and vertical, above grade and below grade, both digging and discharging; the bearing strength of the working bench; maneuverability; power supply; capacity; etc. Where the mineral grade varies considerably and stockpiling is uneconomic or not possible because of the nature of the mineral, a larger number of smaller-capacity excavators may be required to meet the mill feed requirements than if the grade is reasonably uniform or if stockpiling is possible.

Basic principles of materials handling are discussed in Chapter 9.3.

13.3.1.1 Cyclic vs. Continuous Excavators

Numerous operational systems and machines are available, and it is necessary to summarize the factors that influence their selection. Fig. 13.3.2, a classification diagram, is based on the method of working, that is, continuous or cyclic, and also shows the materials handling alternatives.

Where it can be applied, *continuous* operation is preferable, since it provides fuller plant utilization and reduces margins added to plant capacity, as well as peaks of all forms (e.g., material flow, mechanical stresses, electrical maximum demands). In open pit mining, the continuous system is typified by the multi-bucket excavator (bucket wheel and bucket chain).

The *cyclic* system is represented by shovels, draglines, front-end loaders, scrapers, rippers, bulldozers, etc.

There is a great deal of overlap between the excavating and loading capabilities of the many machines available, and in order to confine this discussion to a reasonable length, it is proposed to consider here only those that are most widely used in mining. For mechanical and electrical considerations, see Atkinson (1969).

13.3.2 LOADING SHOVELS

The crawler-mounted loading shovel is the machine most capable of handling hard, dense, abrasive, badly fragmented

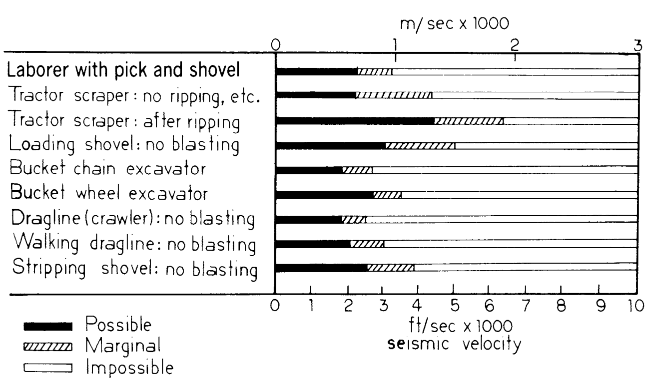

Fig. 13.3.1. Seismic velocity method for determination of excavation possibilities.

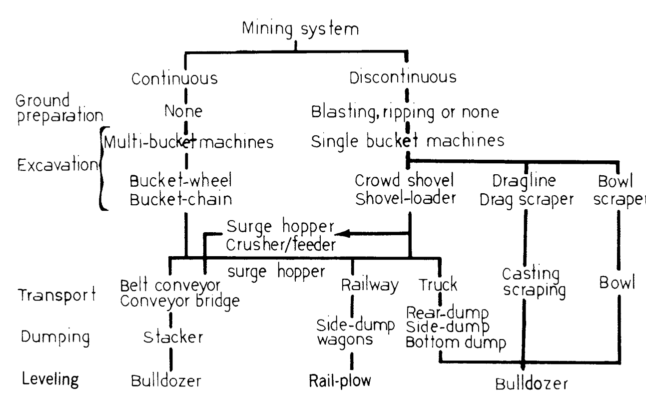

Fig. 13.3.2. Materials handling system classification diagram.

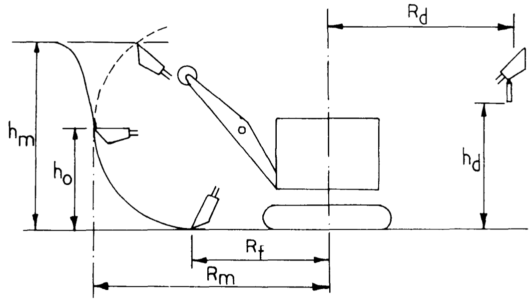
Table 13.3.1. Loading Shovel Cycle Times (sec)

B_c yd^3	m^3	E	Digging Conditions M	M–H	H
4	3	18	23	28	32
5	4	20	25	29	33
6	5	21	26	30	34
7	5.5	21	26	30	34
8	6	22	27	31	35
10	8	23	28	32	36
12	9	24	29	32	37
15	11.5	26	30	33	38
20	15	27	32	35	40
25	19	29	34	37	42
45	35	30	36	40	45

E:
Easy digging, loose, free-running material, e.g., sand, small gravel
M:
Medium digging, partially consolidated materials, e.g., clayey gravel, packed earth, clay, anthracite, etc.
M–H:
Medium–Hard digging, e.g., well blasted limestones, heavy wet clay, weaker ores, gravel with large boulders, etc.
H:
Hard digging–materials that require heavy blasting and tough plastic clays, e.g., granite, strong limestone, taconite, strong ores, etc.

Table 13.3.2. Correction Factor for Shovel Cycle Time Where Digging Depth is Less Than Optimum

Optimum digging depth, %	40	60	80	100
Cycle time correction factor	1.25	1.10	1.02	1.00



ground—by virtue of its positive crowd action and the possibility of applying a high breakout force. It can accurately spot for loading into dump trucks, rail cars, loading hoppers, etc. Because of its robust construction and simple action, it can have relatively high availability; but it is not very mobile and has a poor subgrade digging capability. A competent floor is essential unless oversize crawlers of low bearing pressure are used.

Loading shovels can be divided into three main categories: (1) heavy-duty, mine loading shovels (for dense, abrasive, badly fragmented ground, as is found in most metal mining operations); (2) general purpose loading shovels (for lighter, well-fragmented materials, e.g., sand and gravel, coal, bauxite, etc.); and (3) hydraulic shovels. Loading shovels with dippers as large as 45 yd^3 (35 m^3), are in service.

13.3.2.1 Size Selection

The first major step in shovel selection is the determination of dipper size. Since mine planners are mostly concerned with in situ volumes (bank volumes), these are generally used in calculations. Dipper size can be expressed as

$$B_c = \frac{Q}{C \times S \times A \times O \times B_f \times P} \tag{13.3.1}$$

where B_c is dipper capacity (volume), Q is production required (bank volume per hour), C is theoretical cycles per hour for a 90° swing = $60/t_c$, t_c is shovel cycle time for a 90° swing in minutes, A is mechanical availability during the scheduled hours of work, O is the job operational factor, B_f is the dipper factor, S is the swing factor, and P is the propel time factor.

C: Theoretical cycles per hour. Values of C may be obtained from manufacturers' literature or from time studies. Alternatively, the approximate times in Table 13.3.1 can be used in association with an approximate dipper size. The skill of the operator has some effect on the cycle time, and without the benefit of time

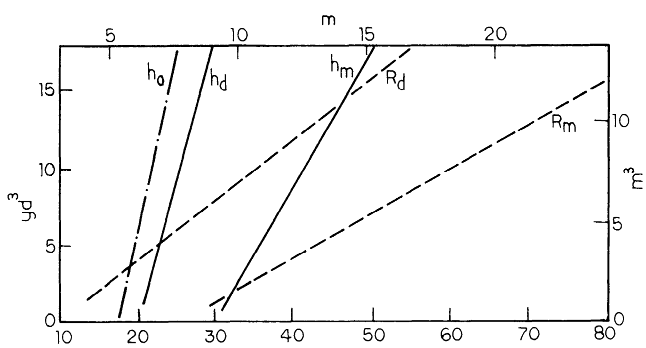


Fig. 13.3.3. Approximate dimensions of loading shovels for initial investigations.

studies or previous experience in similar conditions, precise figures cannot be justified initially.

For most open pit mining operations, shovels have no difficulty in loading up to their optimum digging depth. In strip (open cast) mines, however, the mineral bed may be relatively thin; hence the crowd-hoist time in the shovel cycle will be increased to obtain a full dipper. This may be corrected from Table 13.3.2. The optimum digging depth for a range of shovel sizes is shown in Fig. 13.3.3. In some strip mining operations, the bed underlying the mineral may be insufficiently competent (e.g., fireclays) for the passage of rubber-tired trucks. The haul roads are then located on top of the mineral bed, and the loading shovel may be fitted with a longer-than-standard boom and dipper handle to provide sufficient reach to load the trucks. In these circumstances, the loading shovel cycle times will be greater than those shown in Table 13.3.1, and manufacturers' literature should be consulted, if available. An approximate allowance of 7 to 12% may be added to the cycle times shown in Table 13.3.1.

Table 13.3.3. Shovel Swing Factor

Angle of swing, degrees	45	60	75	90	120	150	180
Swing factor	1.2	1.1	1.05	1.00	0.91	0.84	0.77

Table 13.3.4. Shovel Operating Efficiency

Job Conditions	Management Conditions			
	Excellent	Good	Fair	Poor
Excellent	0.83	0.80	0.77	0.70
Good	0.76	0.73	0.70	0.64
Fair	0.72	0.69	0.66	0.60
Poor	0.63	0.61	0.59	0.54

S: Swing factor. Loading shovel cycle times are normally based on a 90° swing. Variations in the angle of swing necessitate correction of the shovel cycle time; most manufacturers provide charts to determine this correction, but Table 13.3.3 may be used as a guide for preliminary calculations.

A: Availability. A is the availability of the shovel for work during the manned hours; it is generally defined as the mechanical availability during the scheduled hours.

O: Job operational factor. Loading shovels are part of a system and as such are subject to delays due to management, supervision and labor deficiencies, job conditions, climate, etc. The dipper capacity must be increased to compensate for these losses in production time. The job operation factor also can be determined by industrial engineering methods. Care must be taken to ensure that if the propel time *P* is included in *O,* it is eliminated from Eq. 13.3.1.

OA: Operating efficiency. Where no experience is available to enable *O* and *A* to be determined, their product *OA,* the *operating efficiency,* may be determined from Table 13.3.4.

Given a climate that is extreme, in a dusty environment where the ground is dense and abrasive, and if the quality of the labor is poor, performance will be affected adversely due to "poor" job conditions.

If management and supervision are excellent, with good workshops, planned maintenance programs, minimum transport delays, high availability, etc., the actual time spent in producing will be high. Conversely, poor management and supervision will reduce production, and the dipper capacity must be increased to meet production requirements (Drevdahl, 1960).

B_f*: Dipper factor.*

$$B_f = \frac{\text{Fillability}}{\text{Swell factor}} \qquad (13.3.2)$$

Fillability is the loose volume of material excavated in an average load as a ratio of the dipper capacity B_c; this is best determined by field measurements, but Table 13.3.5 provides an approximate guide. *Swell factor* is defined as

$$\text{Swell factor} = \frac{\text{Weight/unit volume (bank)}}{\text{Weight/unit volume (loose)}} \qquad (13.3.3)$$

This is felt to be the preferred method of defining swell factor as it indicates the degree of swell. Most American literature describes this figure as percentage swell, however, and its reciprocal as the swell factor.

Some caution is needed in placing a value on swell factor especially with less-consolidated materials that can decrease in volume with repeated handling. This must be taken into account when field measurements are being planned. Table 13.3.5 provides a guide for common materials.

P: Propel time factor. P depends upon the time required to propel the shovel during maneuvering. In strip mining, where a relatively thin narrow bed is exposed, the shovel must move more often than in the case where a high rock pile is being loaded. Again industrial engineering methods can be used to determine the propel time factor. Table 13.3.6 has been compiled from a large number of operations. The propel time factor is sometimes combined with *O* or *OA,* and care must be taken to avoid double compensation.

The approximate size having been fixed, a standard dipper size can be chosen and a range of shovels can be selected from manufacturers' information. The actual production capacity of each model must then be calculated, manufacturers' data being used to determine that production requirements will be met (e.g., see Table 13.1.2.11).

Detailed studies are required to determine space requirements for a loading shovel. Ample bench room is necessary for operational efficiency, but in general, the slope angle for a single bench, with double-spot loading, is too flat for most multi-bench, conical pits (Fig. 13.3.4) and several bench levels forming a machine loading group must be excavated in sequence. Space must also be available for drilling and blasting and to allow for the passage of trucks. For pits with rail haulage, clearance must be provided for rail track, trolley lines, and shovel; the whole sequence of drilling, blasting, and loading; and trolley and track shifting. The approximate leading dimensions of loading shovels are shown in Fig. 13.3.3 and the clearance heights of rear dump trucks in Fig. 13.3.5 These may be used for early planning, but the actual dimensions of the selected equipment must be used in subsequent mine plans.

13.3.2.2 Cost Estimation

Throughout this chapter, both *ownership* and *operating costs* are estimated. Where discounted cash flow rates of return are to be calculated, all cash outflows are negative cash flows and must be debited at the time of payment. Initial capital costs for equipment must be included in the cash flow at the date of purchase. Replacement capital costs must also be debited at the date of purchase. Ownership costs, other than capital charges (e.g., insurance, etc.) must be debited at the date of payment. Operating costs must be debited on an annual basis.

OWNERSHIP COSTS. Many shovels have a useful life in excess of 20 years, but it is unusual for this figure to be assumed in any assessment of depreciation. Individual company depreciation and replacement policies may determine the depreciation period, and advantage may be taken of tax regulations to write off a machine over a shorter period.

Table 13.3.5. Bulk Density, Swell Factor, and Diggability of Common Materials[1]

Rock	Bank Density (t/m^3)	lb/yd^3	Swell factor	Fillability[2]	Digability[3]
Asbestos ore	1.9	3200	1.4	0.85	M
Basalt	2.95	5000	1.6	0.80	H
Bauxite	1.9	3200	1.35	0.90	M
Chalk	1.85	3100	1.3	0.90	M
Clay (dry)	1.4	2400	1.25	0.85	M
Clay (light)	1.65	2800	1.3	0.85	M
Clay (heavy)	2.1	3600	1.35	0.80	M–H
Clay and gravel (dry)	1.5	2500	1.3	0.85	M
Clay and gravel (wet)	1.8	3000	1.35	0.80	M–H
Coal (anthracite)	1.6	2700	1.35	0.9	M
Coal (bituminous)	1.25	2100	1.35	0.9	M
Coal (lignite)	1.0	1700	1.3	0.9	M
Copper ores (low-grade)	2.55	4300	1.5	0.85	M–H
Copper ores (high-grade)	3.2	5400	1.6	0.80	H
Earth (dry)	1.65	2800	1.3	0.95	E
Earth (wet)	2.0	3400	1.3	0.9	M
Granite	2.41	4000	1.55	0.8	H
Gravel (dry)	1.8	3000	1.25	1.0	E
Gravel (wet)	2.1	3600	1.25	1.0	E
Gypsum	2.8	4700	1.5	0.85	M–H
Limonite	3.2	5400	1.4	0.85	M
Iron ore (40% Fe)	2.65	4500	1.4	0.8	M–H
Iron ore (+ 40% Fe)	2.95	5000	1.45	0.8	M–H
Iron ore (+ 60% Fe)	3.85	6500	1.55	0.75	H
Iron ore (taconite)	4.75	8000	1.65	0.75	H
Limestone (hard)	2.6	4400	1.6	0.80	M–H
Limestone (soft)	2.2	3700	1.5	0.85	M–H
Manganese ore	3.1	5200	1.45	0.85	M–H
Phosphate rock	2.0	3400	1.5	0.85	M–H
Sand (dry)	1.7	2900	1.15	1.00	E
Sand (wet)	2.0	3400	1.15	1.00	E
Sand and gravel (dry)	1.95	3300	1.15	1.00	E
Sand and gravel (wet)	2.25	3800	1.15	1.00	E
Sandstone (porous)	2.5	4200	1.6	0.8	M
Sandstone (cemented)	2.65	4500	1.6	0.8	M–H
Shales	2.35	4000	1.45	0.8	M–H

[1] These figures vary from location to location, and tests should be made where possible. Allowance should be made for operation in wet conditions as density varies with moisture content.
[2] Based on shovel dippers.
[3] For explanation, see footnote to Table 13.3.1.

Table 13.3.6. Propel Time Factor

Strip mines	0.75
Open pit mines	0.85
Sand and gravel pits	0.90
High-face quarries	0.95

In addition to the FOB price, freight and insurance costs, erection costs, insurance during erection, and interest charges up to the time of going into production must be included.

The following form is intended as a guide for the estimation of ownership costs for loading shovels and, with suitable modifications, for any production-cycle equipment. (Note: this is the format followed in Chapter 13.1.2 for the numerical example).

These figures include the cost of supervision of erection by the manufacturer, that is, time, subsistence, local transport, skilled and unskilled labor, erection equipment (e.g., cranes, tools, slings), workshop costs, etc., but not the travel expenses of the manufacturer's erectors. The costs should be adjusted to take account of (1) distance from port of entry, railhead, road, etc., from erection site (off-loading facilities, availability of heavy transport); (2) availability of skilled labor; (3) quality of mine supervisory staff; and (4) availability of cranes, tools, workshop services, etc.

OPERATING COSTS. Operating costs consist of maintenance and supply costs, electrical power, and labor. The list of steps initiated under the ownership cost is continued on the following form.

TOTAL OWNERSHIP AND OPERATING COSTS. The total cost is the sum of the ownership and operating costs, also appearing on the cost form.

It should be noted that no administrative, development, or other charges are included in these figures.

13.3.3 LOADING DRAGLINES

The crawler-mounted dragline finds limited application as an open pit loading machine because (1) it has a less positive digging action, particularly when chopping down, than the shovel, and the smaller sizes are not suitable for loading dense, badly fragmented rocks; (2) the cycle time is longer than that of an equivalent shovel; and (3) it has poor spotting ability when loading.

Guide for Estimation of Ownership and Operating Costs

1. FOB machine price, including optional extras, sales taxes, etc. ______
2. Freight and insurance (to site) ______
3. Import duty (if any) ______
4. Subtotal ______
5. Ballast, if locally manufactured ______
6. Erection costs (see Table 13.3.7) ______
7. Insurance during erection ______
8. Subtotal ______
9. Interest up to start production (allow interest on 30% of sub-total 8) ______
10. Subtotal ______
11. Shovel write-off period:
    (11 a) n = _____ years
    (11 b) _____ hours/year
    (11 c) _____ total hours
12. Machine depreciation and amortization

$$Cost/h = \frac{(Subtotal\ 10)}{(Item\ 11c)} = \underline{\qquad\qquad}$$

13. By use of average investment formula, assuming depreciation charges, replace original investment; average machine investment

$$= \frac{(Subtotal\ 10) \times (n + 1)}{2n} = \underline{\qquad\qquad}$$

14. Interest rate __________%
15. Insurance __________%
16. Taxes, etc. __________%
17. Total __________%
18. Interest, taxes, insurance, etc. (Costs/hour)

$$Machine = \frac{(Total\ \%) \times (Item\ 13)}{(Item\ 11\ b)} = \underline{\qquad\qquad}$$

19. Trailing cable costs (if electrically powered) Capital cost + import + insurance up to start of production (see Table 13.3.8)
20. Trailing cable life
    20 (a) _____ years
    20 (b) _____ hr/year
    20 (c) _____ total hr
21. Trailing cable depreciation

$$Cost/hr = \frac{(Item\ 19)}{(Item\ 20)} = \underline{\qquad\qquad}$$

22. Trailing cable, average investment

$$= \frac{(Item\ 19) \times (Item\ 20\ a + 1)}{2 \times (Item\ 20\ a)} = \underline{\qquad\qquad}$$

23. Trailing cable interest, taxes, insurance, etc.

$$Cost/hr = \frac{(Item\ 22) \times (Item\ 17)}{(Item\ 20b)} = \underline{\qquad\qquad}$$

24. Total ownership costs/hr: ______

$$(Item\ 12) + (Item\ 18) + (Item\ 21) + (Item\ 23)$$

25. Maintenance and supply costs/hr

$$= \frac{10\% \times (\text{Subtotal 4}) \times (\text{H (Table 13.3.9)}) \times (\text{M (Table 13.3.10)})}{(Item\ 11b)} = \underline{\qquad\qquad}$$

26. Electrical power consumption/hr × cost/kWh (see Table 13.3.11) ______
27. Labor rate/hr (to include social benefits, taxes insurance, etc.) ______
28. Total operating costs/hr
    (*Item* 25) + (*Item* 26) + (*Item* 27) ______
    * Where there are no figures available from other mining operations in the area, rates based on local wages rates are invariably too low. Opening a new mine usually stimulates the local economy and local wage rates often double within one year. The social benefits must be carefully investigated as these can be as high as 250% of the monetary wages.
29. Total ownership + operating costs
    = (*Item* 24) + (*Item* 28) ______
30. $\text{Cost/ton} = \frac{(Item\ 29)}{\text{tons/hr}}$ ______

Conversion factor: $1/yd = $1.09/m.

The excellent deep-digging characteristics of the dragline result in reduced gradients for truck and rail haulage operations where the bucket excavates below grade. It can operate from any horizon within the excavation and, unlike the shovel, can stand on a selected competent bed. Because of its deep-digging capability, the crawler-mounted dragline finds application in wet pit operation (e.g., sand and gravel, chalk, etc.) excavating box cuts, recovering remnants from pit floors, etc., and in general work (e.g., digging sumps, extending inclines, etc.) The basic formula for loading shovels can be adapted to determine the output of crawler-mounted draglines, but, because of their limited use in

open pit mining, a full treatment is not appropriate here. Table 13.3.12 provides a summary of the outputs of crawler-mounted draglines. Ownership and operating costs can be calculated by use of the method adopted for loading shovels.

13.3.4 CYCLIC STRIPPING MACHINES

Large single-bucket stripping machines mainly were developed in the United States to expose relatively near-surface coal deposits, whereas the major developments in multi-bucket machines took place in German brown coal mines. Application of these machines has now extended into all strip mining operations. The most important machines in this group are walking draglines, stripping shovels, and bucket wheel excavators.

Because of the huge capital investments involved, and because the investment decisions are usually irrevocable, the selection procedure for large stripping machines must be sufficiently comprehensive to cover all eventualities throughout the stripping of a deposit.

Table 13.3.12. Outputs of Crawler-mounted Draglines (bank volumes)[1]

[2] For explanation, see footnote to Table 13.3.1.
Conversion factor: 1 yd^3/hr = 0.7646 m^3/h

The first stage in the selection procedure is to fix the production requirement of the mineral loading machines; from this, the output of the stripping machine is determined. This is not usually a single calculation since some optimization procedure within the market constraints is often essential. The maximum volume to be stripped is the main factor in the determination of the output of the stripping machine, and the maximum depth decides the reach. The geometry of most strip mining operations allows fairly limited reserves only to be exposed; stripping and loading facilities must therefore be correctly matched and machine availabilities must be accurately forecast.

Where the demand for a product is seasonal (e.g., fuel minerals, building materials, agricultural fertilizers, etc.), and stockpiling is not possible or economic, the viability of the operation must be based on the use of machines that can meet the maximum production requirements. If significant lateral variations in grade occur, and again if stockpiling is impractical, a number of small stripping operations may be needed to exploit a deposit. This entails the use of a greater number of smaller-capacity machines, but since the reach of the stripping machines is determined by the depth of overburden, the reach will remain substantially the same as for a larger-capacity single machine, and this invariably results in increased overall capital cost.

Because they are used for similar duties, it is convenient to consider walking draglines and stripping shovels together as single-bucket excavators. Multi-bucket machines are considered in a separate segment.

13.3.4.1 Walking Draglines

Walking draglines are extensively used for direct casting operations since they have a better (capacity × reach)-to-service weight ratio than any other single-bucket machine. They can be designed to create relatively low bearing pressures by the use of a large tub, but this, of course, results in the center of rotation being farther back from the edge of the cut, thus reducing the reach of the machine. Walking mechanisms are usually cam-operated, but, because of weight distribution problems, hydraulic systems have been adopted for large machines in the United States and the USSR. Walking draglines have been extensively developed over the past 20 years, and a machine with a 220-yd^3 (170-m^3) bucket, a 400-ft (122-m) boom, a machine mass (service weight) of 14,000 tons (12,700 t), and a connected (ac) load of 48,500 hp (36,000 kW) is in service in the United States.

Table 13.3.13. Approximate Cycles/Hour for Stripping Shovels and Draglines*

Bucket or dipper size			
yd^3	m^3	Dragline	Shovel
8–35	6–27	58	69
36–59	28–45	56	68
60–200	46–150	53	64

* These figures are based on a 90° swing for a shovel and a 120° swing for a dragline, which approximates most field conditions.

Table 13.3.14. Stripping Machines—Swell Factor and Fillability*

Overburden conditions	Swell factor	Shovel dipper fillability	Dragline bucket fillability
Light blasting	1.23	0.90–0.95	0.85–0.90
Medium blasting	1.33	0.85–0.95	0.80–0.90
Heavy blasting	1.40	0.80–0.90	0.75–0.85
Bad fragmentation	1.45	0.75–0.85	0.70–0.75

* For fillability, the lower figures refer to small machines and the higher figures to large machines

Although smaller machines work most efficiently in less-consolidated, well-fragmented rocks, large draglines are extensively used in strong but well-blasted ground. To prepare a highwall for dragline working, blasting must result in sufficient fragmentation to ensure efficient bucket loading, and the blasted burden must remain sufficiently stable to allow the dragline to dig and travel without danger of collapse. This may entail buffer blasting and decking of charges where some strata are likely to yield large lumps.

The bottom plates of the dragline tub can become distorted or punctured by point loading, and it is usual for a track to be prepared on which the machine will "walk." The costing of the operation must take into account the price of the bulldozer or other units used for this purpose.

13.3.4.2 Stripping Shovels

The stripping shovel has found application because it is usually more productive than the walking dragline by virtue of its positive dipper loading action, shorter swing time, and ability to handle strong, dense rocks. The largest machine reported in service to date has a 180-yd^3 (138-m^3) dipper on a 215-ft (65-m) boom with an ac installed load of 30,000 hp (22,500 kW). Self-cleaning crawlers and hydraulic leveling jacks are universal.

A competent floor is essential, and for large machines, some preparation of the floor may be necessary to reduce excessive local bearing pressures and to obtain satisfactory crawler life. The cost of this operation must be accounted for.

SHOVEL vs. DRAGLINE. The fields of application of stripping shovels and draglines greatly overlap. However, with the advent of inexpensive ANFO explosives, the superior digging depth and reach of the dragline, and its lower capital and operating costs, the walking dragline has virtually superseded the stripping shovel.

13.3.4.3 Size Selection

The main steps in selecting a stripping machine are (1) determination of the approximate dipper or bucket capacity, (2) determination of the machine geometry, and (3) selection within a standard range, where applicable, and reassessment of the model selected.

The approximate dipper or bucket capacity can be readily calculated from Eq. 13.3.1, the overburden stripping rate having been determined from the mineral production requirements. Because of the huge capital investments involved, stripping machines are usually scheduled to work 22.5 hr/day and up to 350 days/yr. Detailed investigation and planning are essential to ensure that adequate exposed reserves are available during periods allocated for deadheading, overhaul, etc.

C: Theoretical cycles per hour. C may be obtained from time studies or from Table 13.3.13.

S: Swing factor. No correction for swing factor need be made in the preliminary calculations unless, in the case of a dragline, a large proportion of chopping down is proposed. That portion of the operation where chopping down is used should have the number of cycles per hour reduced by 20%.

Example 13.3.1. A dragline performs 60 theoretical cycles/hour for a 120° swing; 30% of the overburden is cast by chopping down.

Solution. The cycles/hour when chopping down are

$$60 \times 0.8 = 48$$

The total approximate theoretical cycles/hour are

$$\begin{aligned} 0.3 \times 48 &= 14.4 \\ 0.7 \times 60 &= \underline{42.0} \\ & \underline{56.4} \end{aligned}$$

OA: Operating efficiency. Where no experience is available to determine *O* and *A*, their product *OA* may be determined from Table 13.3.4.

B: Dipper or bucket factor. If no data are available, the fillability and swell factor may be obtained from Table 13.3.14.

P: Propel time factor. In the absence of time studies, the following propel time factors can be used (Weis, 1969):

shovels	0.96
draglines	0.94

These figures are based on normal operations and include the deadheading associated with such operations. Should the mineral deposit be such that greater than normal deadheading is necessary, allowance must be made for this. Time studies often include the propel time in the operating efficiency and care must be taken to avoid overcompensation.

The approximate dipper size having been determined, the next step is to determine the machine geometry.

MACHINE GEOMETRY. The two main dimensions to be determined are the dumping radius and the dumping height. Fig. 13.3.6 illustrates an idealized dragline stripping operation.

Usually, to avoid an excessively long boom, no berm is used in dragline operations, the cut width being equal to the pit width and all exposed mineral being loaded out. If the dragline is located on the surface, as in Fig. 13.3.6, the minimum width of cut can be determined by the mineral loading and transport equipment requirements (see Figs. 13.3.3 through 13.3.5). For small loading shovels, pits can be as narrow as 50 to 60 ft (15 to 18 m); for large shovels, up to 15 yd^3 (11.5 m^3), pit widths of 80 to 100 ft (24 to 30 m) are required. Apart from a reduction of the boom length required, and, hence of the capital cost, a narrow

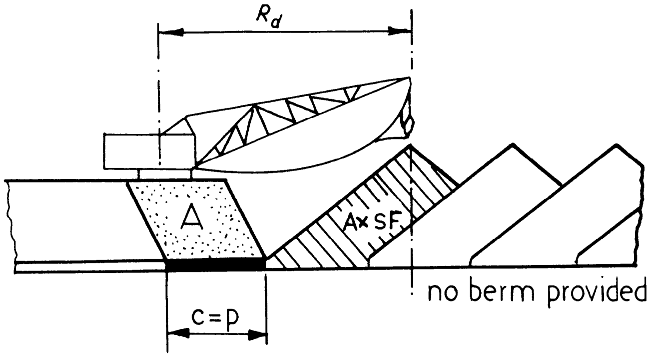

Fig. 13.3.6. Idealized dragline stripping operation.

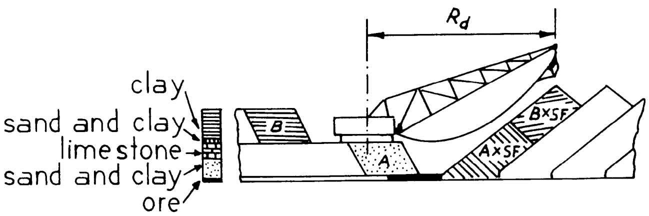

Fig. 13.3.7. Dragline on intermediate bench.

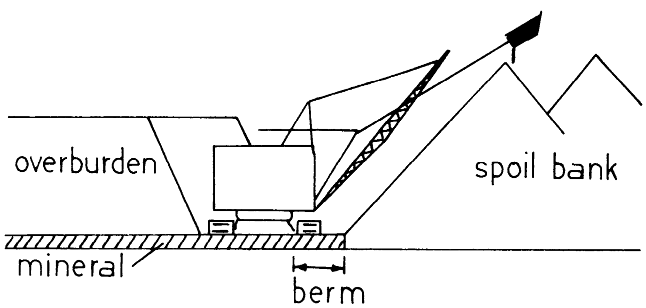

Fig. 13.3.8. Idealized stripping shovel operation.

cut (and in this case, pit) width provides more efficient use of the spoil space since it reduces the valleys between the spoil peaks. Short boom lengths reduce the dragline cycle time, some increase in stripping capacity being achieved.

Other factors affect pit width, for example, an increase may be desirable to allow greater flexibility of the loading operation, or safety of personnel and equipment may require a wider pit than the minimum. Fig. 13.3.7 illustrates the practice adopted where the ground bearing strength of the surface is too low to support the dragline. A competent bed is selected within the overburden as the horizon of the working bench. In this case, the minimum pit width must be sufficient to allow the dragline boom to swing through 90° when in the operating position nearest the edge of the highwall.

Fig. 13.3.8 illustrates an idealized shovel stripping operation. Obviously, the pit must be wide enough to allow the shovel to swing through 90° when it is in the operating position nearest the spoil bank. The stripping cut width may be less than the pit width, and a berm of mineral remains. The stripping cut width is dependent on the width required for the operation of the

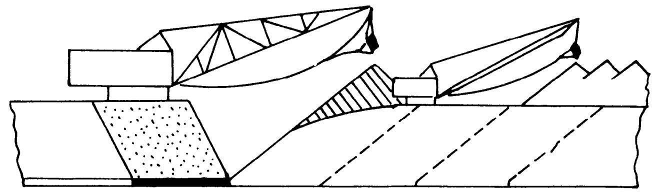

Fig. 13.3.9. "Hay-making" operation: double handling with two draglines.

mineral loading and transport equipment. It is, therefore, generally equal to the mineral cut width or a multiple of it.

The overburden thickness may vary considerably due to hillside outcrops, steeply inclined mineral beds, or areas of undulating surface topography. If, in these circumstances, the reach of the dragline is determined by the average overburden thickness, it will be inadequate for the thicker overburden. To avoid over investment where occasional areas of thick overburden occur, the following short-term measures can be adopted: (1) spoil the overburden on an outside curve to create additional spoil space; in contour mining operations with short irregular strips, this can often be achieved; (2) temporarily reduce the pit width to the minimum possible; (3) make a forecut, outside contractors possibly being employed; and (4) in the case of a shovel where the spoil is broken rock, operate with the spoil bank side crawler off the mineral bed.

If thick overburden is extensive, it may be necessary to extend the reach of the stripping machine to cater to the maximum overburden thickness, or to rehandle the spoil, usually by "hay-making" (Fig. 13.3.9) or by the spoil bridge methods.

The geometry of stripping machines is best determined by drawing or computing average and extreme pit sections and plans showing both stripping and loading operations. Some trial and error is involved. Pit sections for uniform conditions can be prepared quickly by use of the method shown in Fig. 13.3.10. The overburden and mineral thicknesses, the safe slope of the highwall, and the angle of repose of the spoil are known, and the cut width can be determined from the loading and transport requirements. The width of the berm (if any) required for transport, blasthole drilling, or other purposes can be decided and the pit width determined. The section can then be partially drawn, the slope of the pit side faces of the spoil heaps only being indicated. The broken line /–/ is then drawn at distance H × swell factor parallel to the floor of the mine. The /–/ line is then bisected as shown, and the peaks of the spoil heaps are determined by drawing in the other face of the spoil heaps at the angle of repose of the spoil. The dumping radii and the dumping heights of shovels or draglines can then be determined.

A method proposed by Rumfelt (1961) for the preliminary selection of stripping machines uses the "maximum usefulness concept." The *maximum usefulness factor* MUF = dipper or bucket capacity × reach of the machine. Rumfelt investigated a large number of stripping machines and produced MUF—machine mass (service weight) curves for shovels and draglines. To ensure valid comparison, the reach of each machine was modified to provide tubs or crawlers that gave the same ground bearing pressures, and flat, uniform, geological conditions were assumed. Rumfelt showed that the curves were straight lines with slopes (yd^3-ft/lb or m^3-m/kg) of $1/745$, for shovels and $1/575$, and $1/467$ for draglines.

The steeper curve for draglines represents newer and prospective designs, whereas the flatter curve relates to older designs. The method may be used for preliminary evaluation either

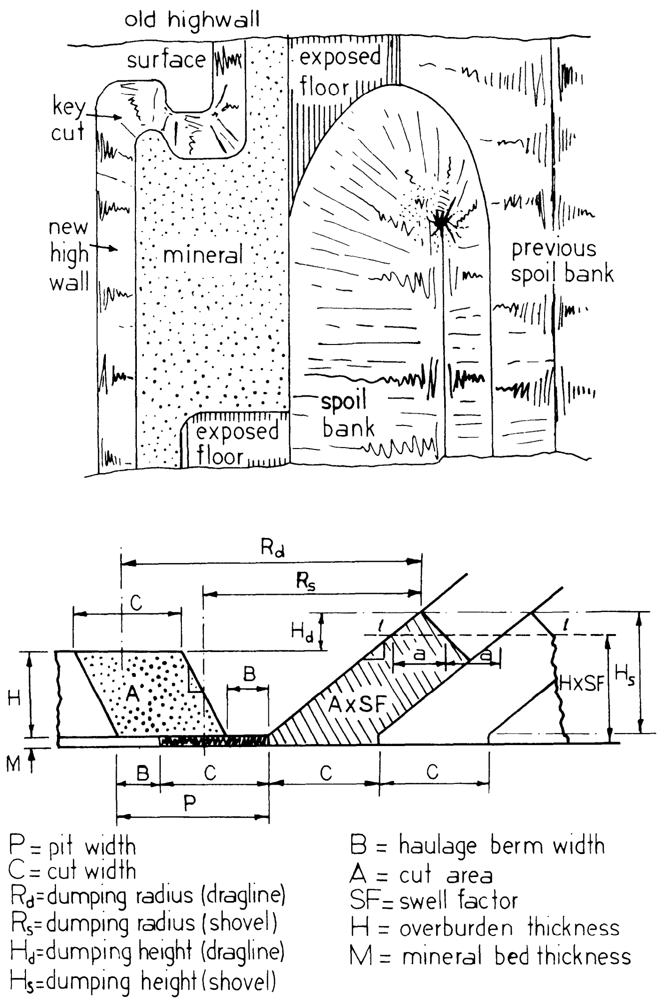

Fig. 13.3.10. Strip mining cut diagram for determination of stripping.

within or beyond the present range of designs. Final selection must, however, be based on more detailed analysis.

A further method (Weis, 1969) used computer-generated tables covering a range of pit geometry variables.

In thick mineral operations, it may be advantageous to load out ore with the stripping dragline. Pit plans and sections must be drawn in detail to determine the machine geometry, and account must be taken of the increased cycle time when loading, as the bucket must be accurately spotted.

FINAL SELECTION. The bucket or dipper size, the dumping radius, and the dumping height having been determined, it is not always possible to select a machine with perfect dimensions, and the nearest model may have to be adapted. Usually, an increase in dumping radius can be achieved by a reduction in dumping height, and vice versa. Careful investigation is essential to avoid selecting an oversized machine, and hence incurring over-investment (see Table 13.3.15). Often large stripping machines are not catered to by standard models, and investigations and discussions with manufacturers are essential before the final design is settled.

When the machine has been selected, it is necessary to recalculate its production by use of the manufacturer's cycle times and swing factors. If a single manufacturer has not been selected, Table 13.3.16 may be used for estimating cycle times. The figures given in the table are based on normal-geometry machines; (1) for stripping shovels, average overburden thickness = 0.4 × maximum dumping radius; and (2) for walking draglines, average overburden thickness = 0.3 × dumping radius. For extra-long-boom units, add 0.75 sec to the cycle time for each 1 yd (1 m) that the above-reduced radii dimensions exceed the overburden thickness.

13.3.4.4 Cost Estimation

OWNERSHIP COSTS. The format used to calculate ownership costs for loading shovels may also be used for single-bucket stripping machines. A stripping machine can have a useful life in excess of 30 years, but company policy, tax regulations, etc., influence the actual depreciation period. It is usual to schedule large stripping machines to operate up to 350 days/yr on a three-shift basis of 22.5 scheduled hours.

It is not possible to define erection costs as simply as for loading shovels, for both the dumping radius and dumping height, as well as the dipper or bucket size, influence the erection cost of stripping machines. The mass (service weight) may be obtained from manufacturers' literature or from Rumfelt's MUF—service weight curves (Rumfelt, 1961). It should be remembered that these curves use the reach of the machine, however, and not the dumping radius. The erection costs based on 1989 projections are

$$\text{Erection costs (\$US)} = cW \qquad (13.3.4)$$

where, in English units, W is machine mass (service weight) in lb, and c is a constant = 0.28 for stripping shovels and = 0.38 for walking draglines. In SI units, W is machine mass in t, and c = 128 for stripping shovels and = 176 for walking draglines. The figures obtained are on the same basis as those given in Table 13.3.7; they should be adjusted as necessary where conditions warrant.

Some care is necessary with very large machines as erection costs may include onsite fabrication and machining of large components. In these circumstances, detailed consultation with the manufacturer is essential.

The trailing cable should form part of an integrally engineered electrical system, but, for preliminary purposes only, the cost figures in Table 13.3.17 may be used.

OPERATING COSTS. Again the format used for loading shovels may be used for the calculation of operating costs for stripping machines. Maintenance and supply costs are calculated in the same way, except that the following figures should be used in item 25 (Weis, 1969):

Walking draglines	7%
Stripping shovels	8%

The correction factor H for hours of operation does not generally apply as it is usual to operate for the maximum possible number of hours, and the above figures are based on an annual operation of at least 7000 hr.

The correction factor M for different types of overburden is shown in Table 13.3.18. Some account should also be taken of the abrasiveness of the overburden; for example, if the overburden is highly abrasive and badly fragmented, then M would be taken as 1.25.

TOTAL OWNERSHIP AND OPERATING COSTS. Total ownership and operating costs, the cost per unit volume (bank), and the stripping cost per ton (tonne) of mineral can be calculated in the same general way as for loading shovels. Again no administrative or amortization charges are included.

Overburden conditions	M
Light blasting	0.9
Medium blasting	1.0
Heavy blasting	1.1
Bad fragmentation	1.2

13.3.4.5 Selection of Buckets and Dippers

Abrasion and wear of buckets and dippers cannot be eliminated, but liner plates, shrouds, etc., can be used to obtain longer life. The increased weight involved, however, means that longer life can only be provided by a reduction in capacity. By the correct location of liner plates, etc., and the careful selection of the materials used, wear can be economically counteracted.

For walking draglines, lightweight buckets can provide maximum capacity, but the actual drag pull per cubic yard (cubic meter) excavated is reduced; thus they can only be used for relatively light, easily loaded materials. Their selection should be restricted to conditions where wear life and maintenance costs are not critical factors. If a spare bucket is available, or if maintenance can be scheduled to avoid downtime, a lightweight bucket may be economic.

Medium-weight buckets are generally selected for heavier rocks and have the widest application.

For severe duties, or operations where it is uneconomic to hold a spare bucket (e.g., small mines or short-life operations

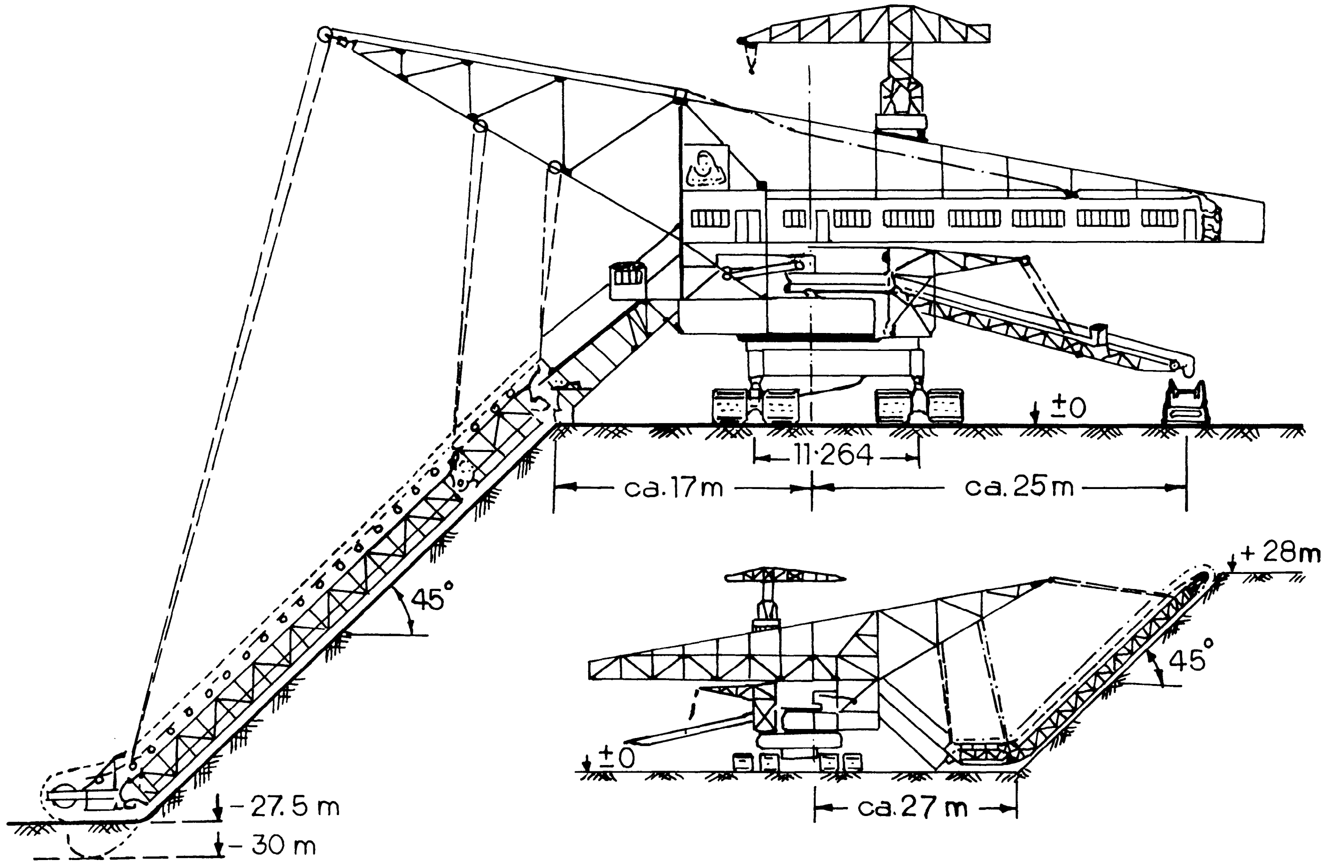

Fig. 13.3.11. Bucket chain excavator (*courtesy:* Friedrick Krupp GmbH Maschinen und Stahlbau Rheinhausen). Conversion factor: 1 ft = 0.3048 m.

which require at least 14,000 hr of operation before major repairs are carried out), heavy-duty buckets of lower capacity are needed.

Bucket capacity is primarily dependent on the difference between the maximum allowable suspended load of the dragline and the mass of the bucket plus rigging. Thus, for abrasive conditions, where an oversize drag chain is used to combat wear, the bucket capacity would have to be reduced.

13.3.5 CONTINUOUS EXCAVATORS

The two most important types of continuous excavator—the bucket chain excavator and the bucket wheel excavator—were developed mainly in the German brown coal fields. Some development has also taken place in Czechoslovakia, the United States, Australia, and the USSR.

13.3.5.1 Bucket Chain Excavator (BCE)

Earlier machines were track-mounted, but this involved frequent track shifting due to the inherently narrow width excavated at each pass of the excavator, and modern machines are invariably of the slewing type mounted on crawlers, performing block excavating operations. Fig. 13.3.11 shows a large BCE which is in service in an Italian mine; it has a theoretical output of 1920 yd^3 (1470 m^3) bank/hr, a machine mass (service weight) of 1640 tons (1495 t), and installed ac power of 3060 hp (2285 kW).

The BCE can mine high outputs in weak unconsolidated ground, but it cannot dig hard ground and is not selective in operation. Its most advantageous feature is its excellent downward-digging capability, combined with reasonable upward-digging capability.

13.3.5.2 Bucket Wheel Excavator (BWE)

The BWE is the most effective machine for mining large outputs in weak unconsolidated ground, although its application is extending into harder formations. It can selectively mine faulted or intercalated ground. It is possible to accurately cut bands as thin as 4 in. (100 mm), but with much reduced output. It has poor downward-digging capability, but this can be improved by a boom sandwich belt, or a special long-boom design which reduces the boom angle sufficiently to allow successful conveyor operation when digging below grade. The sandwich belt does not give satisfactory service when boulders or large frozen lumps are being handled.

The BWE is fitted with evenly spaced buckets on the periphery of the wheel. Excavated material is fed via a transfer point inside the wheel (e.g., a plow, rotating disc, etc.) to the belt conveyor system of the excavator for discharge. Machines are in service with theoretical outputs of up to 13,000 yd^3 (10,000 m^3)

Table 13.3.19. Approximate Power Consumption

Machine	Power consumption kWh/m^3	kWh/yd^3
Loading Shovel	0.45–0.71	0.35–0.55
Stripping Shovel	0.52–0.91	0.40–0.70
Walking Dragline	0.88–1.21	0.68–0.93
Bucket chain excavator	0.41–0.60	0.32–0.46
Bucket wheel excavator	0.30–0.50	0.23–0.38

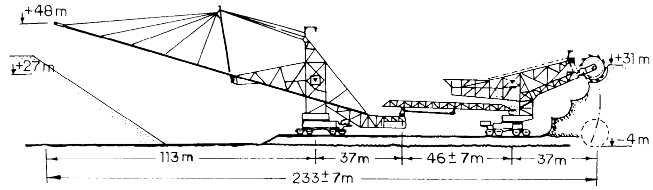

Fig. 13.3.12. Mobile boom stacker for BWE (*courtesy:* Friedrick Krupp GmbH Maschinen und Stahlbau Rheinhausen). Conversion factor: 1 ft = 0.3048 m.

bank/hour and with machine masses (service weights) exceeding 7700 tons (7000 t).

ADVANTAGE OF CONTINUOUS EXCAVATORS. Continuous excavators have lower impact loadings than comparable single-bucket machines. This tends to reduce dynamic stresses, machine mass (service weight), maintenance costs, and power consumption. The slower slewing (swing) speed and reduced digging impacts results in gradual load transfer across the crawlers, with a consequent reduction in ground bearing pressure; operation is therefore possible in conditions in which a single-bucket machine may work only with difficulty.

Land reclamation is generally easier with continuous excavators—many fine examples of reclamation can be seen in Germany and Czechoslovakia.

OUTPUT OF CONTINUOUS EXCAVATORS. Continuous excavators are usually rated in terms of theoretical output:

$$Q_{th} = \frac{60Fs}{\text{Swell factor}} \qquad (13.3.5)$$

where Q_{th} is theoretical output in yd^3/hr (m^3/h) bank, F is capacity of a single bucket, s is number of bucket discharges per minute, and the swell factor is that of the material being excavated. Table 13.3.19 lists approximate power consumption numbers.

Some caution is needed in comparing the theoretical outputs of similar BWEs because manufacturers of different nationality may define F, the bucket capacity, differently. In addition to the actual bucket capacity, some may add (for cell-less buckets) 50% of the associated ring volume or 100% of the associated ring volume, and (for bucket wheels with cells) the volume of the individual cell. It is suggested that the best basis for comparison is to use the bucket volume only. (Note that SI units are generally used as most BWEs and BCEs are of continental manufacture.)

BCE VS. BWE. Since World War II, the BWE has, to a large extent, superseded the BCE. The BCE has continued to be built in eastern Germany where ground conditions are comparatively easy and where designs and operational experience with the BWE were not available. The present trend in eastern Germany, however, is towards the BWE.

In selecting a continuous excavator, the following points favorable to the BWE must be considered.

1. The BWE is selective in operation because of its horizontal action in part-block operation. The BCE cannot selectively mine a deposit.

2. The BWE can, in certain conditions, excavate relatively hard ground (sandstone, shales, etc.) The BCE cannot dig hard ground or handle occasional boulders.

3. Because it has a much greater number of wear points, maintenance costs of the BCE are higher than those of the BWE. Consequently, the availability of the BCE is less than that of the BWE when working in the same conditions.

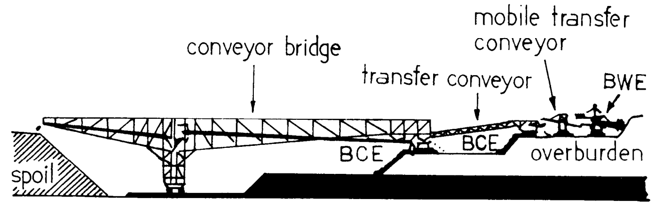

Fig. 13.3.13. Overburden bridge for BWE.

4. The BWE has excellent high-digging capability, whereas the BCE is not as efficient owing to bucket-filling difficulties in high digging. The BCE has excellent deep-digging capability, and the BWE has relatively poor deep-digging capability.

5. The bucket-clearing action of the BWE is superior to that of the BCE, and it has less difficulty in handling sticky materials.

The following conditions favor the BCE, provided boulders or hard bands are not present and selective mining is not necessary:

1. Soft, nonabrasive rocks where high and deep cuts must be performed by one machine.

2. Situations in which the initial box cut is opened in these conditions.

3. Wet pit operations.

4. Where it is necessary to reduce transport gradients.

5. Overburden bridge operations where cuts must be taken below grade level of the bridge crawlers (Strzodka and Piatkowiak, 1969).

6. Where exact slope profiles are required.

7. Where there are large undulations in the surface of the mineral bed.

Most of these advantages are due to the better downward-digging capability of the BCE. Most other applications, however, favor the BWE.

OPERATIONS. Continuous excavators are generally limited to the following gradients: excavating 1 in 20, traveling 1 in 10.

The BWE can be used in thin mineral/thin overburden strip mining casting and can strip deeper overburden or provide a greater pit width than single-bucket stripping machines. The BWEs of the River King and Northern Illinois mines of Peabody Coal Co. in the United States are typical examples of this form of machine.

To obtain the advantage of the shortest possible lift and transport distance and lowest stripping costs in thicker overburden and/or thicker mineral, the direct across-the-pit range of the BWE and the BCE can be extended by use of (1) the mobile stacker boom (Fig. 13.3.12) and (2) the overburden bridge (Fig. 13.3.13). Because of their limited operational flexibility, these units impose a strict discipline on planning, and the following conditions should exist: (1) sufficient proved reserves to jus-

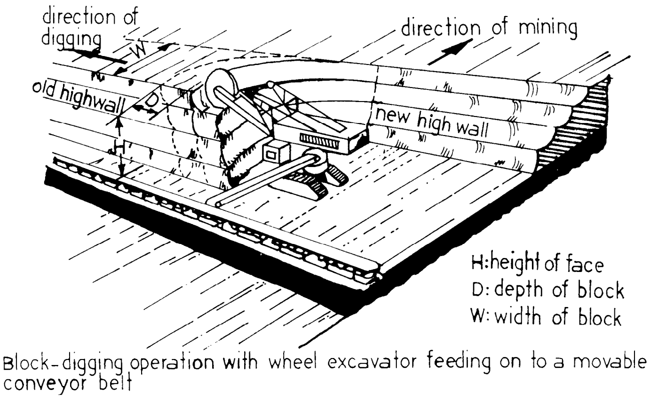

Fig. 13.3.14. Full-block operation, bucket wheel excavator.

tify the capital cost of the relatively expensive machine complex, (2) relatively horizontal stratification over a wide area of the deposit, and (3) uniform geologic conditions (i.e., absence of major faulting, severe undulations, large variations in overburden thickness, etc.).

The most important application of continuous excavators is in weak sedimentary deposits of relatively great thickness where direct transport of the overburden across the pit is impracticable because of excessive pit width. Most of these operations employ several benches, and overburden must be transported round the pit by a conveyor or rail transport system and dumped in the spoil space provided by the advancing pit.

The full-block method with BWEs (Fig. 13.3.14) is normally adopted where selective mining is not necessary. The part block method has lower volumetric efficiency since the thickness of the ground being mined is usually less than the optimum, it involves greater traveling time with increased crawler wear and reduced digging time, and is therefore restricted to selective mining operations. Short booms are not suitable for part block operations. If part-block operation is proposed at a horizon high up the bench face, an oversize bucket wheel is necessary to obtain clearance for the boom if a reasonable block width is to be maintained.

The mass (service weight) of BWEs fitted with booms having crowd action is greater than equivalent BWEs with rigid booms. For large BWEs cutting large bench heights, a crowd action boom requires a long crowd travel motion, which can introduce ground bearing pressure problems.

TRANSPORT SYSTEMS. Clearly, considerable planning is essential before the selection of a continuous excavator can be made. As with any continuous system, the excavators and their transport systems must be engineered initially as a complete system.

The two main systems used with continuous excavators for round-the-pit transport are (1) high-speed belt conveyors and (2) locomotive rail haulage.

The side-slewable, high-speed belt conveyor is gaining preference over rail transport because operation on steep slopes (1:3) is possible, large areas used for wide curves, inclines, sidings, etc., by rail track, especially in deep pits, being eliminated; and the time spent by the excavator in waiting for the transport system is greatly reduced, that is, the whole system becomes truly continuous.

The main disadvantages of high-speed conveyors are their high capital cost and high power consumption.

Rail transport can still prove economic where long distances on relatively horizontal grades have to be covered, for example, from the benches to treatment plant, pit to outside spoil bank, etc.

As each block width (Fig. 13.3.14) is mined, the transport system must be moved forward. To reduce the frequency of this operation and hence the production lost, a mobile, crawler-mounted, transfer conveyor can be used between the excavator and the transport system to increase the range of the excavator.

MECHANICAL DESIGN FEATURES. *Bucket Wheel Design*—Bucket wheels can be of the following construction: (1) with cells, that is, with individual chutes from the buckets to the transfer point supplying the boom conveyor; (2) with half cells; or (3) without cells.

Earlier bucket wheel designs were fitted with cells. They have low maintenance costs and power consumption, but are more suited to granular materials (sand, gravel, etc.), excavated material tending to compact within the cells if high wheel speeds are used or if the material tends to be sticky. Some difficulty is also experienced in clearing the cells when deep-digging with BWEs with reversed buckets. Wheel peripheral speeds between 200 and 400 fpm (1.0 and 2.0 m/s) are used.

The cell-less wheel was first developed in the United States in 1943 for the Kobe excavator. It has since been intensively developed elsewhere, particularly in Germany. It handles sticky materials better than the wheel with cells and provides better bucket clearance when down-digging. Wheel speeds up to 1000 ft/min (5 m/s) are used.

The half-cell wheel has found application in large machines without compaction occurring and with negligible spillage. Chain-backed buckets tend to flex in operation and are superior to solid buckets for handling sticky materials. At one bauxite operation with very sticky overburden material, flow has been improved in those parts of the buckets and wheel not subject to scouring action by the fitting of magnesium liner plates (Sluyeter and Bennett, 1970). Linatex rubber and similar lining have also proven successful in very sticky materials.

There are numerous bucket teeth configurations, and some trial and error may be necessary before a satisfactory arrangement is found.

In strong, highly abrasive material, tungsten-carbide inserts with welded, hardfacing of the parent metal may be necessary (Rasper and Rittner, 1961).

Bucket Wheel Drives—In variable ground it is necessary on occasions to adjust the wheel speed (and slewing speed) to meet the digging requirements and to avoid excessive vibration in hard ground. This may be achieved by the adaptions to the power transmission system.

Crawlers—As continuous excavators usually operate in less consolidated formations, it is often necessary to limit the ground bearing pressure to a low value, and rigid crawlers such as those used on shovels should only be used for very small machines up to about 55 tons (50 t) machine mass (Fig. 13.3.15 (a)). With this form of construction, it is economically possible to limit the average ground bearing pressure to 8.5 psi (60 kPa).

Up to 165 tons (150 t) machine mass, crawler tracks with two wheel bogies should be used so that the crawlers adapt at least partially to uneven terrain (Fig. 13.3.15 (b)). Larger machines generally require the type of crawler design shown in Fig. 13.3.15 (c).

The larger the excavator and the crawler bearing area, the greater may be the imposed ground bearing pressure since a large pressure cone is developed beneath the crawlers and average ground bearing pressures between 21 and 23 psi (150 and 160 kPa) can be used. Large spreaders with the crawler arrangement in Fig. 13.3.15 (c) working on unconsolidated spoil in the German Rhineland impose bearing pressures as high as 17 psi (120 kPa). With crawlers of this construction, tests show that the

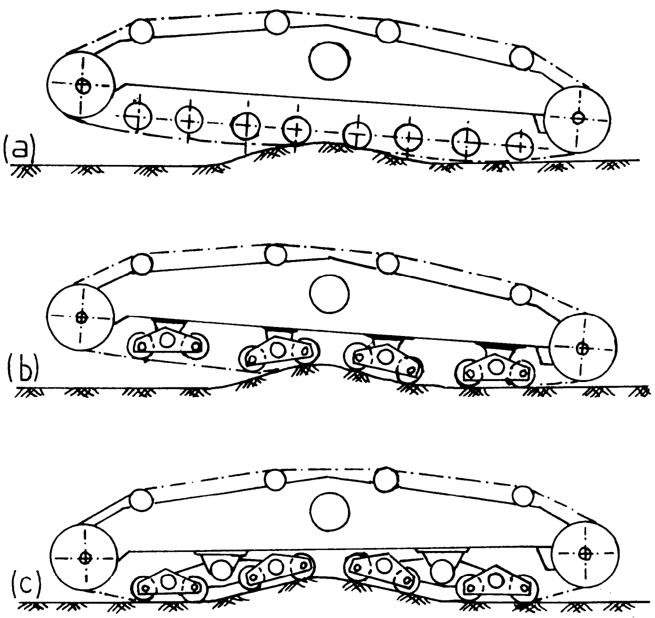

Fig. 13.3.15. Continuous excavator crawlers (courtesy: Friedrick Krupp GmbH Maschinen und Stahlbau Rheinhausen).

maximum ground bearing pressure is about 1.4 times the average figure. For the rigid construction shown in Fig. 13.3.15 (a), the maximum figure can be up to three times the average figure.

Steerable crawler track designs are available and should be selected for large machines to increase their maneuverability.

Specific Cutting Force—The bucket wheel drive power, the mechanical strength of the bucket, and machine mass (service weight) of the BWE depend on the digging resistance of the material being excavated. Investigations in Germany, Czechoslovakia, and the USSR have so far failed to produce a uniform quantitative approach to digging resistance. The relationships between digging resistance, intact rock strength, jointing, bedding, tooth shape and sharpness, angle of attack, and wedge angle of the bucket cutting lip have yet to be determined.

A specific cutting force *k* (expressed in kp/cm of bucket cutting lip edge) is widely adopted. For machine design, however, most engineers prefer to use the "specific digging force" (expressed in kp/cm^2 of bucket slice area). The values given in Table 13.3.20 have been suggested.

There is still much to be done in this field in relating conventional rock properties to specific digging force. Careful investigation is essential. If an insufficiently robust machine is designed, structural and drive failures will occur, but overdesign can, of course, be costly. The large capital investments required for continuous excavators warrant detailed study of similar operations and comprehensive discussions with manufacturers before the limits of specific digging force are specified.

Hard Ground Operation—Large, modern bucket wheel excavators with high wheel speeds and slower slewing speeds can mine materials that shovels cannot mine without blasting (e.g., hard clays, phosphates, sandstones, frozen oil sands). This is only possible with machines of sufficient mass to transfer the cutting forces through the crawlers to the ground. Provided that the rock does not contain large boulders that will not pass through the bucket wheel, ground with a uniaxial compressive strength of 2150 to 2550 psi (15 to 18 MPa) can be excavated without ground preparation. Fig. 13.3.16 shows a modern com-

Table 13.3.20. Specific Cutting and Digging Forces for BWEs

Material	kp/cm cutting lip	kp/cm^2 slice area	Reference
Compact sands	33–103		(Habermaas, 1969)

pact BWE working in difficult overburden. Fig. 13.3.17 shows a large BWE working in Australia excavating preblasted overburden.

The production rate of the BWE operating in hard ground is usually much less than the theoretical output because of loading difficulties and flow difficulties through the bucket wheel. Some attempts have been made to excavate stronger rocks subjected to blasting, but with mixed success. Unless exceptionally uniform fragmentation is achieved, considerable difficulty is experienced owing to the breaking out from the face and spilling of large lumps.

13.3.5.3 Size Selection

MACHINE OUTPUT. The theoretical output of a continuous excavator provides a convenient means of comparing similar machines, but the actual production rate may vary considerably from the theoretical. The bucket filling can vary from 0.4 for difficult conditions (e.g., hard or sticky ground, ground containing boulders, etc.) to 1.32 for free-flowing granular materials, such as sands and gravels, when down-digging with a BCE. Some care must be exercised to use these values correctly since methods of calculating theoretical outputs vary. Most mine planners usually prefer to use a "field factor" that allows for (1) bucket filling, (2) planned maintenance stoppages, (3) stoppages due to breakdowns, (4) conveyor or rail track shifting, and (5) nonworking days.

Because of the large capital investments involved, continuous excavators are usually operated on a three-shift basis. In Germany and elsewhere, statistics show that a daily scheduled operating time of 19.2 hr is normally attained if the excavator is correctly matched to operating conditions. If Sundays and holidays are available for maintenance (including annual overhaul), 5000 scheduled hr/yr is the average operating time. In difficult operating conditions (e.g., hard, abrasive or sticky ground, severe climate, etc.), this will be reduced.

The annual production is then

$$Q/\text{yr} = Q_{th} \times 5000 \times \text{service factor, yd}^3/\text{yr (m}^3/\text{yr)} \qquad (13.3.6)$$

The service factor covers periods when the excavator is not working to full capacity because of poor bucket-filling, maneuvering, transport stoppages, etc. This service factor can vary from 0.5 to 0.8, depending on ground conditions, management efficiency, climate, etc., and may be estimated from plant records.

For initial planning, however, it is usual to base calculations on a field factor since the scheduled hours, management efficiency, climate, ground conditions, etc., are not independent of one another.

The annual production is then

$$Q/\text{yr} = Q_{th} \times \text{days/yr} \times 24 \times \text{field factor} \qquad (13.3.7)$$

where Q_{th} is based on the volume of the bucket only, and the cell or ring volumes are not included.

If studies from similar operations are not available, the values in Tables 13.3.21 and 13.3.22 may be used, where

$$\text{Field factor} = OE \times JC \qquad (13.3.8)$$

Table 13.3.21. Operating Efficiency (*OE*) for Continuous Excavators

Ground conditions	Management conditions			
	Excellent	Good	Fair	Poor
Light	0.70	0.63	0.55	0.47
Medium—heavy	0.65	0.58	0.50	0.42
Heavy	0.57	0.50	0.43	0.36
Hard ground	0.42	0.37	0.32	0.27

Table 13.3.22. Job Conditions Factor (*JC*) for Continuous Excavators

Excellent	0.92
Good	0.83
Fair	0.73
Poor	0.62

MACHINE GEOMETRY. The machine geometry of continuous excavators is determined by the pit layout. The overall slope angles involved are usually not steep because (1) the rocks involved are relatively weak, and (2) the deposits mined may be relatively flat, advance being lateral rather than vertical, so that advance stripping is not quite so economically undesirable as for a deposit of mainly vertical aspect.

Because of this, the benches are usually wide, and space restrictions are not often a major problem. If an excavator must perform upward and downward digging, it requires adequate reach to work on both sides of the transport system. In a rotating pit operation the excavator must be able to work up to the pivot point, where space is restricted, however; whereas in a parallel advancing pit, where end-bench, lift conveyors may be used, the excavator must be capable of digging up to the corner of the pit. The machine geometry may impose some limitations on pit layout, and considerable planning is required before the final machine geometry can be decided. The solutions to these problems are best achieved by plotting pit plans and sections. In some cases, it may be necessary to use a mobile, crawler-mounted, transfer conveyor; for large machines, a telescopic discharge boom conveyor may have to be incorporated into the excavator design.

Table 13.3.23. Constant for Calculating Erection Costs of Continuous Excavators

Machine Mass, tons	Constant a[1]
Below 1000	880
1000–2000	720
2000–3000	600
3000–4000	520
Above 4000[2]	432

[1]Erection cost = aM ($)
[2]Some discretion is needed with very large machines as increased erection costs may be necessary because of increased site fabrication due to the size of component parts, but a reduction in works cost may be expected.
Conversion factor: 1 ton = 0.9072 t.

Table 13.3.24. Trailing Cable Prices ($/yd) for Continuous Excavators*

Theoretical output, m^3/h	Voltage, kV		
	4–7	13	25
0–1000	32	40	—
1000–2000	60	64	—
2000–3000	84	84	—
3000–5000	108	104	108
5000–7500	—	—	132

* Based on a copper price of $2900/t, 1989 projected prices.
Conversion factors: 1 yd^3/hr = 0.7646 m^3/h, $1/yd = $1.09/m.

Table 13.3.25. Maintenance and Supply Cost Factor

Material	Factor
Light ground (free-flowing)	0.01
Medium ground	0.02
Heavy ground	0.03
Hard or frozen ground	0.05
Ground containing boulders	0.04–0.05
Abrasive sandstones, shales, etc.	0.05

13.3.5.4 Cost Estimation

OWNERSHIP COSTS. Continuous excavators can have service lives in excess of 30 years, and machines commissioned in 1935 are still in daily operation in eastern Germany; but tax concessions, company depreciation policies, etc., can influence the write-off period. It is difficult to compare single-bucket excavators with continuous excavators because they usually perform different duties, but for the same (production rate × reach), continuous machines are usually more expensive in capital cost than single-bucket machines. Because of the large capital sums involved and the irrevocable nature of the investment decision, comprehensive investigations and detailed discussions with manufacturers are essential before the selection of a continuous excavator can be finalized. As they also form part of a continuous system, which in a multi-bench mine, must be synchronized with other excavator-transport systems, detailed planning of mine operations is imperative.

Again ownership and operating costs can be estimated using the method for loading shovels (see 13.3.2.2). Tables 13.3.23 through 13.3.25 supply additional information.

13.3.6 MOBILE EQUIPMENT

Mobile earthmoving equipment originally developed for the construction industry has found considerable application in modern mining operations. The major types of equipment are front-end loaders (FEL), tractor-scrapers, bulldozers, rippers, etc. In general, their use has been limited to soils and the weaker, less consolidated rocks, but the introduction of inexpensive explosives has greatly extended their range, and there is some overlap between their application and that of conventional loading equipment.

13.3.6.1 Crawler vs. Rubber-tired Mounting

Crawler-mounted units have the following features:

1. They possess strong digging capability as a front-end loader or as a tractor scraper.
2. Ground bearing pressure is relatively low, and they have excellent tractive effort in bad ground conditions.
3. Performance on steep inclines is good.
4. The degree of maneuverability is high.
5. Travel speeds are relatively slow, and hence they can only be economically used where the distances between digging and discharge points are short.
6. Maintenance costs in abrasive materials are relatively high.

Rubber-tired units have the following characteristics:

1. They are very mobile.
2. Maintenance costs in easy to medium conditions are relatively low.
3. Tire costs are high where sharp, broken, or abrasive rocks are encountered (e.g., basalt, taconite, angularly broken schists, etc.).
4. They are less maneuverable than crawler-mounted units, but center-articulated units are still highly maneuverable in comparison with conventional excavating and loading equipment. They are well suited for operation on narrow benches. Four-wheel-drive units have reasonable maneuverability whereas two-wheel drive units have poor maneuverability.
5. Travel speeds are relatively high; they can therefore, economically dig and transport excavated material over longer distances than crawler-mounted machines. This feature has been responsible for the development of rubber-tired units as load-haul-dump machines, e.g., FELs and tractor-scrapers.
6. Ground bearing pressures are relatively high. The machines are not efficient in bad conditions where rolling resistance is high.

TIRE SELECTION. Considerable research has been undertaken by tire manufacturers, particularly in the United States, and a very wide range of tire types is available. In view of the importance of tire maintenance and replacement costs, it is surprising that many mine operators fail to keep accurate records of or make detailed investigations into tire life. Undoubtedly, the best selection and costing procedures are based on past records. Factors to be considered are surface condition, loading, speeds, curves, grades, temperature, maintenance standards, etc.

Table 13.3.26 shows the average life of tires used in their correct applications. Recapped tires have about 80% of the life of new tires, and usually three recaps are possible during the life of one tire.

13.3.6.2 Front-end Loaders

In recent decades, rubber-tired front-end loader applications have greatly expanded in open pit mining. Units with rock buckets up to 35 yd^3 (27 m^3) are in service, but in metal mines, the

Table 13.3.26. Tire Life

	Job Conditions			
	A	B	C	D
Average life, operating hours	4000–5000	3000–3500	2000–2500	400–1500

A: Good haul roads with operation over soft, non-abrasive rocks.
B: Clays, marls, soft shales, wet gravels, etc., with average haul roads.
C: Medium hard rocks, e.g., hematite, abrasive shales, etc., with short transport distances in average bench conditions.
D: Severe conditions, taconite, angularly fragmented basalt, etc., with poor bench surfaces.

Table 13.3.27. Front-end Loaders

Bucket capacity		Fixed time, sec			
yd^3	m^3	E	M	M–H	H*

10	7.5	37	39	51	—
12	9.0	39	42	56	—
15	11.5	41	44	60	—

* The application of FELs in "hard" digging conditions is marginal and requires comprehensive investigation.

FEL has been mainly restricted to weak overburden stripping and auxiliary duties. Compared with loading shovels, they are short-life machines not greatly affected by obsolescence. Many observers forecast increased acceptance of FELS in face loading, and larger machines capable of handling rock will undoubtedly be developed to take advantage of the following features:

1. Mobility—the FEL can quickly travel from one part of a pit to another, move out of blasting zones, etc.
2. Comparatively low capital costs—the correct selection procedure is to compare different machines by using a discounting method, but the FEL becomes attractive in situations of uncertainty (e.g., political, economic) where capital expenditure must be restricted.
3. Operational flexibility—FEL can perform many auxiliary operations (e.g., haul road construction and maintenance, stockpile and blending operations, drainage and bunding operations, ripping, truck "boosting" on inclines, etc.).

PRODUCTION RATE. Because of its mobility, the most important factor in determining the production rate of a wheel loader is the operating load (bucket load) rather than bucket capacity, since if a FEL operates at maximum load when handling a light material, it will be underpowered and unstable if transferred to handling a dense material. Bucket capacity has been defined by the Society of Automotive Engineers (Anon., 1967). In determining bucket capacity, the bucket load being known, the struck volume of the bucket should be used as most materials do not heap during the loading process. For granular materials (e.g., sand, gravel), a fillability of unity is normal, but for other materials, the fillability factors in Table 13.3.5 should be employed.

The bucket capacity B_c is

$$B_c = \frac{\text{Operating load}}{\text{Loose density} \times \text{fillability}} \tag{13.3.9}$$

The operating cycle is made up of (1) loading, (2) hauling, (3) dumping, and (4) return.

The loading and dumping times are combined as the *fixed time* and hauling and return as the *variable time.*

The fixed time may be based on time studies or, in the absence of experience, values may be taken from Table 13.3.27 for varying digging conditions. The variable time may be determined from time studies or from Fig. 13.3.18.

The production rate in tons/hour of a FEL can be calculated from:

$$\text{Production rate} = \text{Operating load} \times C \times A \times O \tag{13.3.10}$$

Operating Load: This is taken from manufacturers' literature

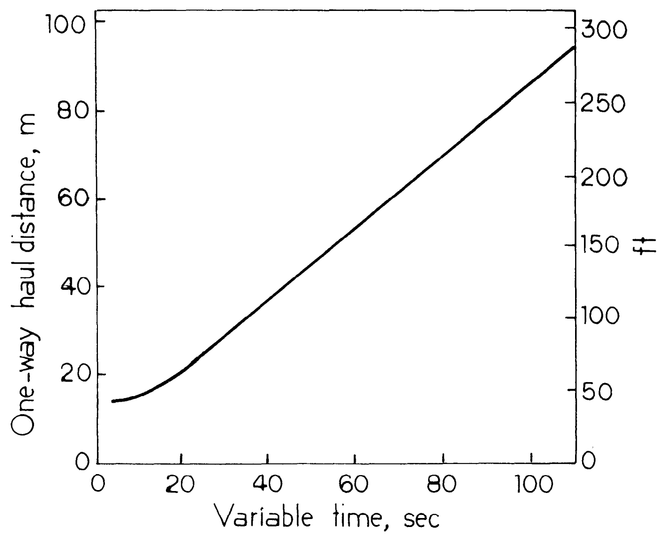

Fig. 13.3.18. Front-end loaders: variable time.

for the machines being considered, the bucket capacity being determined from the operating load.

C: Theoretical cycles per hour.

$$C = \frac{60}{\text{Fixed time (min)} + \text{variable time (min)}} \tag{13.3.11}$$

A: Availability. The mechanical availability during scheduled hours may be obtained by industrial engineering methods from plant records.

O: Job operational factor. This may also be obtained from plant records.

OA: Operating efficiency. Where no previous experience is available to determine *A* and *O,* their product *OA* may be obtained from Table 13.3.4. The job operational factor is very dependent on operator skill, and this factor must be suitably weighted.

COST ESTIMATION. The economic life of a FEL depends on the condition of service, the skill of the operator, and the standards of management supervision. Table 13.3.28 provides a guide to the life in operational hours where no previous experience is available.

If the duty involves long transport distances over good surfaces of nonabrasive materials on relatively flat grades and easy digging conditions, with highly skilled operators, the job condi-

Table 13.3.28. Economic Life of Front-end Loaders (Operating Hours)

Job Conditions	Management Conditions

Table 13.3.31. Filter Costs for Mobile Equipment Diesel Engines ($/hr)

Engine hp	Dusty Conditions	Normal Conditions
150	0.2	0.14
250	0.24	0.18
350	0.50	0.35
500	0.60	0.48
750	0.64	0.50

Conversion factor: 1 hp = 0.7457 kW.

tions are classed as *excellent.* For very short transport distances over abrasive rocks, where dense, badly fragmented material must be dug and the quality of the operating labor is poor, the job conditions are classed as *poor*.

If management and supervision are excellent and maintenance is good, management conditions are classed as *excellent;* conversely, poor management and supervision combined with bad maintenance require the management conditions to be classed as *poor*.

Because of the relatively short life of FEL tires, their cost is deducted from the machine cost and treated as an operating cost item. Otherwise, the format used to calculate ownership and operating costs follow that provided in 13.3.2.2 for shovels. See Tables 13.3.29 through 13.3.31 for additional necessary information.

FRONT-END LOADERS vs. LOADING SHOVELS. Since the introduction of the 10-yd^3 (8-m^3) FEL in 1967, controversy has abounded regarding the relative merits of FELs and loading shovels as primary loading equipment. Briefly restated, the features of both machines are as follows.

FEL Advantages—(1) Excellent mobility—can quickly travel to any part of the pit. (2) Good versatility—can be used for a wide variety of duties, including face loading, cleaning up stockpile operations, haul-road construction and maintenance, etc. This must not be over-emphasized, however, as in one mine in which a large FEL was used, the following applied: primary loading, not sufficiently robust; cleaning up, satisfactory with bucket teeth fitted; difficulties experienced with continuous bucket lip; stockpile duties, excessive degradation of iron pellets when bucket teeth fitted, but satisfactory with continuous bucket lip. Changing duties, therefore, may not simply mean traveling to a different location. (3) Can operate on moderate grades without difficulty. (4) Lower capital cost—has obvious advantages in situations of capital rationing, overseas investments where there is political and economic uncertainty, etc. (5) Not affected by obsolescence. (6) Only one operator needed per machine. (7) Large lumps are not trapped in the bucket, as can happen with a shovel dipper.

FEL Disadvantages—(1) Unsuitable for hard, dense rocks that fragment badly due to open fissures, joints, bedding planes, and other discontinuities. (2) Ground preparation must be extremely thorough. There are, of course, overall savings to be made by increased blasting with most forms of loading machines. (3) Tires require special attention to avoid excessive costs. (4) High operating costs. (5) Greater operator fatigue and proneness to operator abuse. (6) Relatively high ground bearing pressures, poor performance with bad floor conditions.

Shovel Advantages—(1) Well proven in the field of digging hard, dense, badly fragmented rocks. (2) Low operating costs. (3) Less sensitive to poor quality maintenance than wheel loaders. (4) Reduced operator fatigue and less prone to careless operation. (5) Lower ground bearing pressures and not so badly affected by poor floor conditions.

Shovel Disadvantages—(1) Lack of mobility—for multi-bench, sequence operations in open pits with a number of shovels, this need not be a particular disadvantage. (2) Single-purpose loading machine. (3) Higher capital cost. (4) Cannot travel on steep grades. (5) Affected by obsolescence, but many 30-year-old shovels are still performing economically in severe condition. (6) Support equipment may be needed for bench clean up, etc.

Operational Experience—Of about 20 mine operators having experience with both FEL and loading shovels, those handling hard, dense rocks, particularly metallic ores, considered that the FELs presently available are insufficiently robust for regular primary loading duties. Almost all agreed that FELs were indispensable for general duties and emergency primary loading. All were appreciative of their mobility and versatility.

Some operators engaged in mining weaker rocks felt that the FEL had some application, but the majority preferred the loading shovel because of its long-term reliability. Prejudice against the FEL possibly exists as some operators complained of excessive operating costs towards the end of its life when, probably, it should have been scrapped.

Those engaged in mining weaker materials or soft overburden were slightly in favor of FELs. Some who were producing materials for the construction industry felt that they could not plan realistically ahead beyond four years, and they therefore favored the FEL because of its lower capital costs.

CRAWLER-TYPE FRONT-END LOADERS. Recent developments of the front-end loader have resulted in an extension of its use into job applications previously considered suitable only

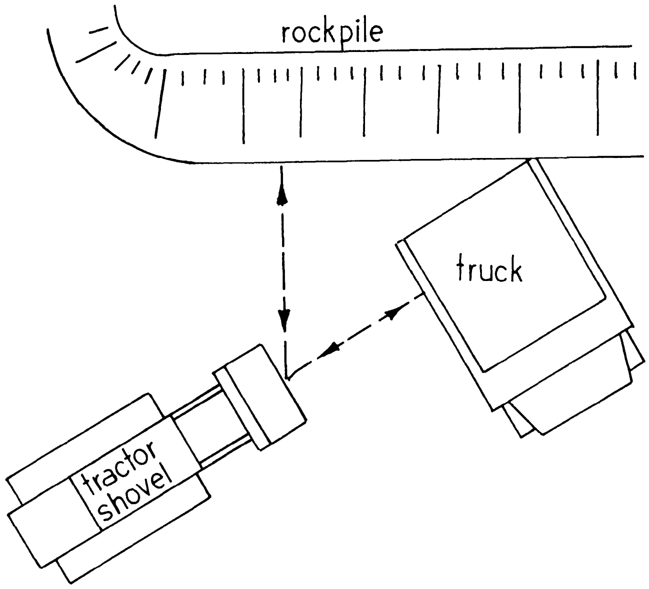

Fig. 13.3.19. V-shaped path: crawler-mounted, front-end loader operation.

for crawler-mounted machines. The main duty of the crawler-type FEL in open pit mining is as a support machine. Although it has not the mobility of the rubber-tired loader, it is much more mobile than the loading shovel, and is particularly useful for excavation of inclines, sumps, etc.

For face loading, the machine follows a V-shaped path with overall cycle times between 0.7 and 1.0 min (Fig. 13.3.19). For excavating inclines, etc., a fixed time of 0.65 min is normal, and an overall haul speed of 2.4 mph (4 km/h) can be used to calculate the variable time.

The cost estimation method used for rubber-tired FELs may be used for calculating ownership costs, except that no deduction is made for tire costs. Fuel and lubricant costs are about 1.2 times those shown in Table 13.3.29. Maintenance repair parts and labor are about 1.1 times greater than those for rubber-tired FELs. There are, of course, no tire costs.

13.3.6.3 Hydraulic Excavators

Initially introduced in the United States as a back-hoe ("hydraulic dragline"), the hydraulic excavator is largely a European development. Line production in the 200- to 240-ton (180- to 220-t) class is currently available from three manufacturers, and 500-ton (450-t) face shovel machines are operative in the United Kingdom. A large machine is currently successfully operating in difficult conditions in a large open pit in Nambia. Development of the 200-ton (180-t) plus machine with its effective working mass and flexible front-end geometry makes the hydraulic excavator a serious competitor to the rope-type shovel in metal mining.

The face shovel machine is usually fitted with an opening dipper bullclam. Because of its flexible geometry, the hydraulic excavator develops high-crowd, prying, and breakout force characteristics. It can mine selectively and follow the contours of irregular beds much better than a rope-type shovel.

In the back-hoe mode, the hydraulic excavator can stand on top of a bench and load a truck spotted on the bench below. Due to the small swing angle in this position, the cycle time is short, resulting in high production. Spotting the bullclam over the truck body is facilitated as the excavator operator looks directly into the truck body.

The back-hoe mode may also be used to load trucks on the same bench when it is difficult to operate trucks on the bench below.

Most hydraulic excavators are diesel powered, but electrical versions with cable reels for the trailing cable are available. The electric drive does not cause the wide fluctuations in system load characteristic of rope-type shovels with solid-state rectification systems, and generally has lower operating costs than diesel drives.

COST ESTIMATION. The usual cost estimating procedure is used with hydraulic excavators (see 13.3.2.2). In calculating ownership costs, the hydraulic excavator is considered a medium-life machine (8 to 10 years), the larger machines tending to have longer life. In areas where maintenance personnel have little previous experience with hydraulic systems, machines may have a shorter life (7 to 8 years) until experience is gained with their operation.

In estimating operating costs, availabilities of 90% or more are generally assured. The operating costs of the electric-drive hydraulic excavator are about 70% of the diesel drive, while the capital costs of the electric drive are about 20% higher than for the diesel drive.

13.3.6.4 Tractor Scrapers

Many medium to strong rocks tend toward blocky fracture after ground preparation and are unsuitable for excavation by tractor scrapers. Their open pit mining applications are mainly confined to overburden stripping, where their productive capacity and mobility are of considerable value, although they are also used to some extent in limestones and other medium rocks that fragment well after blasting or ripping.

Many models are available, some of 90-yd^3 (70-m^3) capacity with 120-yd^3 (92-m^3) designs proposed, but the most popular sizes in mining are in the 20- to 44-yd^3 (15- to 34-m^3) struck capacity range. Although here they are being considered as excavators, they are load-haul-dump machines, and their complete cycle is amenable to investigation by simulation techniques. Of the four main types available, the *single-engine conventional scraper* has the widest range of economic application. Except in very easy, downhill conditions, a pusher tractor is needed for loading. The tractor then boosts the scraper to haul speed. The conventional scraper does not perform well where the duty cycle includes steep adverse grades, high rolling resistances, poor floor conditions, or where the haul distances are short.

The *tandem-powered machine* has an all-wheel drive from front and rear engines, which provides a high power/weight ratio and tractive effort suitable for conditions with high rolling resistances and adverse grades. It can, therefore, work where other scrapers cannot, especially in mud or when dumping in wet conditions on uncompacted spoil heaps. Normally, the tandem-powered scraper operates with the assistance of a pusher tractor, but it can partially self-load or even fully load on downhill runs.

Elevating scrapers are self-loading and are ideally suited for short to medium haul distances where a queue can form while waiting for the pusher tractor. They do not perform well on adverse grades or with high rolling resistances.

The *elevating scraper* cannot efficiently handle sticky materials or material containing rock or boulders larger than 8 in. (200 mm). Because of its ability to work alone, the elevating scraper is ideally suited for selective mining or for small-fleet operations. The action of the elevating flights also breaks down and helps to blend the material being loaded. It is easier to spot over dumping hoppers than other scrapers.

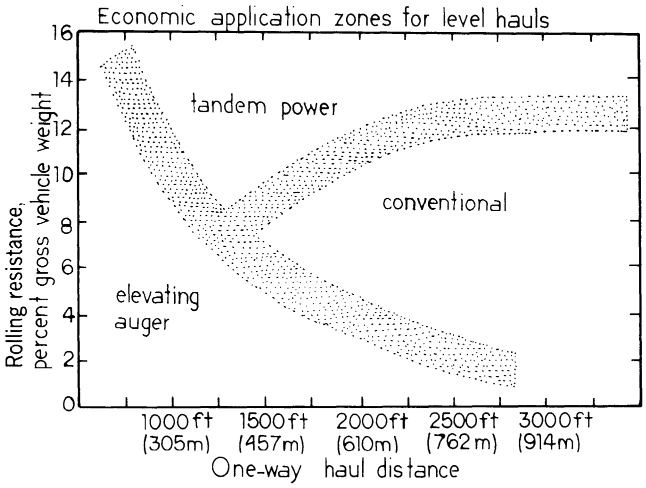

Fig. 13.3.20. Tractor scraper application zones: level haul (courtesy: Caterpillar Tractor Co., Ltd.).

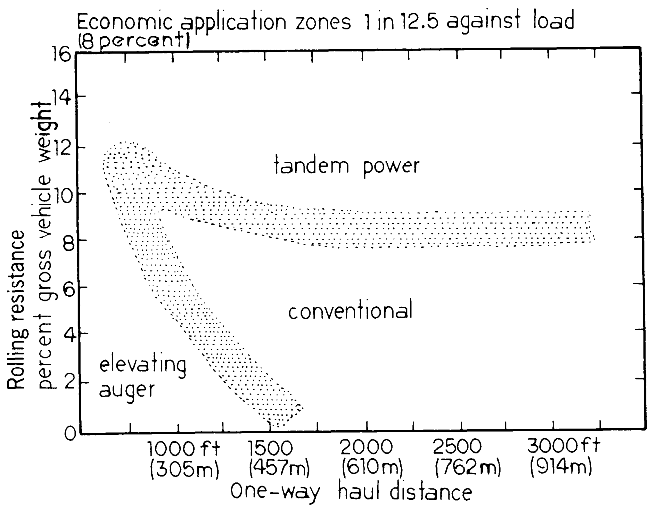

Fig. 13.3.21. Tractor scraper application zone: 1 in 12.5 against load (courtesy: Caterpillar Tractor Co., Ltd.).

The *auger scraper* is a self-loading machine and provides an alternative to conventional, push-pull elevating machines. The auger is placed at the center of the bowl, and as material flows over the scraper's cutting edge, it is fed to the rest of the bowl by the rotating motion of the auger.

The auger scraper requires a shorter cut distance, has excellent ejection characteristics, increased tire life, retains material well when hauling, and is suitable for a wide range of conditions. It cannot efficiently handle material containing large rock fragments or boulders larger than 12 in. (300 mm).

EQUIPMENT SELECTION. There is some overlap in the application of the different types of scraper, but Figs. 13.3.20 through 13.3.22 may be used to determine the economic application. These are based on the results of a computer simulation study by a leading manufacturer (Anon., 1972). Typical values of rolling resistance are shown in Table 13.3.32.

Scraper Cycle Times—The fixed time is made up of decelerating, spotting the scraper by the pusher vehicle, loading, accelerating ("boosting"), dumping, and spreading, plus the variable time,

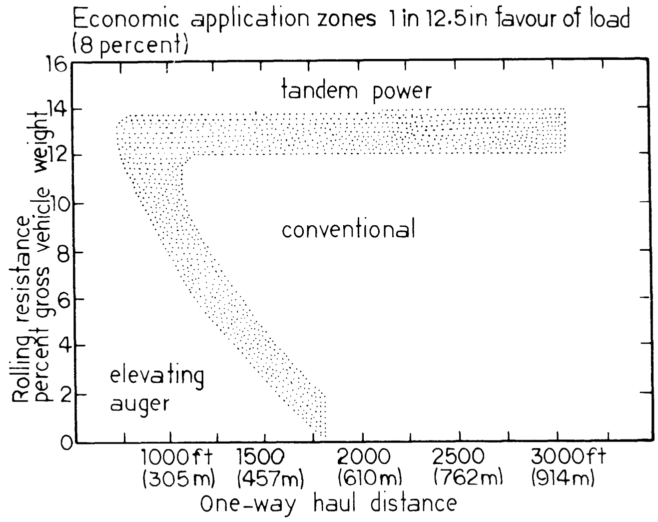

Fig. 13.3.22. Tractor scraper application zone: 1 in 12.5 in favor of load (courtesy: Caterpillar Tractor Co., Ltd.).

Table 13.3.32. Rolling Resistance for Rubber-tired Tractors (as a Percentage of Gross Vehicle Weight)

Description	% Gross vehicle weight
Hard pavement, no penetration (concrete or asphalt)	2
Flexible pavement (macadam or packed gravel construction)	3–3.5
Dirt road, flexing considerably (maintained)	5
Unmaintained dirt road (no compaction)	7.5
Loose sand or gravel	10
Soft muddy rutted road	15–20

Note: Ground preparation for and tractor scraper operations are described elsewhere (Caterpillar, 1970).

Table 13.3.33. Standard Fixed Cycle Time for Tractor Scrapers

Type	Time, min.	
Conventional	1.45	(push-loaded)
Tandem power	1.25	(push-loaded)
Elevating	1.55*	(self-loaded)

* No spotting time included

traveling between cut and dump. The fixed time is best determined by time studies, but in the absence of experience in similar conditions, the values given in Table 13.3.33 may be used.

The variable time is made up of the loaded and empty travel times:

$$\text{Variable time} = \frac{\text{Haul distance}}{\text{Haul speed (loaded)}} + \frac{\text{Haul distance}}{\text{Haul speed (empty)}} \tag{13.3.12}$$

Haul speeds, loaded and empty, are determined by time

Table 13.3.34. Fillability and Swell Factors: Tractor-Scrapers

Digging Conditions	Fillability	Swell Factor
Easy, dry	0.95–1.00	1.15–1.25
Medium, common earth	0.90–0.95	1.2–1.3
Medium-hard, clays,	0.85–0.9	1.35
weak rock	0.85–0.95	1.35–1.45
Hard, wet clay,	0.70–0.80	1.4
well broken rock	0.75–0.80	1.5
Extreme, broken basalt, etc.	0.50	1.5–1.6

studies or from manufacturers' performance charts, the gradient and rolling assistance of the haul road being taken into account. Therefore, the scraper cycle time t_c is

$$t_c = \text{fixed time} \div \text{variable time} \tag{13.3.13}$$

Scraper Production—The load hauled is usually expressed in bank volume and is based on scraper heaped capacity, fillability, and swell factor.

$$\text{Scraper production (bank volume/hr)} = \frac{\text{Scraper heaped capacity} \times \text{Fillability} \times 60 \times AO}{\text{Swell factor} \times t_c} \tag{13.3.14}$$

OA: Operational efficiency. Where no previous experience is available to determine *A* and *O,* their product *OA* can be obtained from Table 13.3.4. If the job conditions are bad owing to excessive rain, ice, and snow; dusty, bad haul roads; severe adverse grades; dense, abrasive, poorly fragmented rock; poor-quality operating labor; etc., then it should be given a *poor* rating. If management and supervision are poor, with bad maintenance, inefficient workshops, poor availability, bad job layout and organization, then it should also be given a *poor* rating. Conversely, with first-class management and very good job conditions *excellent* ratings are used.

Fillability: The fillability of scraper bowls is generally higher than that of other excavators because of the limited range of materials handled. Table 13.3.34 provides an approximate guide.

Swell factor: Because of its mode of loading, the swell factors of scraper-handled material can be different from those for other machines. Table 13.3.34 gives approximate figures.

When dense, broken rock is being loaded, it is essential to ensure that the maximum load of the scraper will not be exceeded.

Pusher Tractors: To avoid queuing of scrapers at the start of each cut, the number of scrapers must be correctly matched to the number of pushers. Because of variations in cycle time, a perfect match is never possible in an actual mining operation, and some waiting time is usually unavoidable.

The maximum number of scrapers served by each pusher tractor should not exceed the following:

$$\text{No. scrapers} = \frac{\text{Scraper cycle time}}{\text{Pusher cycle time}} \tag{13.3.15}$$

where pusher cycle time in min

$$= 1.4 \text{ (scraper load time)} + 0.25 \tag{13.3.16}$$

The pusher cycle time is usually in the range of 1.2 to 2.0 min.

Table 13.3.35. Economic Life: Tractor-Scrapers (Operating Hours)

Job Conditions	Management Conditions			
	Excellent	Good	Fair	Poor
Excellent	13,000	12,500	11,500	10,500
Good	12,500	11,500	10,500	9,500
Fair	11,000	10,500	9,500	8,500
Poor	10,000	9,000	8,500	8,000

Table 13.3.36. Maintenance Factor: Tractor-Scrapers

	Job Conditions			
Scraper Type	Excellent	Good	Fair	Poor
Conventional	0.65	0.80	1.00	1.2
Tandem Power	0.66	0.82	1.02	1.23
Elevating	0.68	0.84	1.05	1.28

In determining the number of pushers required, it is necessary to take the fleet size into account, especially with conventional scrapers, since the added costs of an extra pusher shared between a number of units may be justified by obtaining maximum production. Where haul distances are short, queuing also can become a serious problem, and an adequate number of pushers is essential. The problem with tandem-powered scrapers is not so acute as they can partially self-load.

Push-pull Operations: Pairs of tandem-powered scrapers are used in the push-pull method. The two machines link up through push blocks and a hook and bail assembly and enter the cut; the second scraper push-loads the first, the first then pull-loads the second; they disconnect and drive individually to the dump. Cycle times are slightly greater than for single push-loading, but, of course, pusher-tractor costs are not incurred.

COST ESTIMATION. The economic life of a tractor-scraper depends on job and management conditions. Where no previous records are available, values from Table 13.3.35 may be used as a guide. Table 13.3.36 lists maintenance factors.

Easy digging, long level hauls over good roads of non-abrasive materials with highly skilled operators would rate as *excellent* job conditions, whereas hard-digging, short hauls over steep adverse grades, with bad, rutted, muddy or abrasive road surfaces would rate as *poor* job conditions. Similarly, with good supervision and maintenance, the management conditions are *excellent;* whereas bad supervision, together with inadequate maintenance, would rate as *poor.* Tire costs are normally deducted from the machine cost and treated as an operating cost item.

Follow the procedure of 13.3.2.2 in estimating scraper ownership and operating costs.

13.3.6.5 Bulldozers

Although not usually employed as a primary excavator, the bulldozer has considerable application in surface mining. The crawler-mounted machine is more generally accepted, and 70-ton (63-t) units are at present in operation; but because of its mobility, the rubber-tired bulldozer is increasingly finding application. For short hauls in severe conditions where scraper operations would be difficult, bulldozing can usually be adopted.

Table 13.3.37. Swell Factor: Bulldozed Materials

Material	Swell Factor
Broken rock	1.65
Heavy clay (wet)	1.45
Earth with boulders	1.35
Earth	1.25
Sand and small gravel	1.1

Table 13.3.38. Maintenance Factor: Bulldozers

Type	Job Conditions			
	Excellent	Good	Fair	Poor
Crawler	0.8	0.95	1.1	1.3
Rubber Tired	0.7	0.85	1.0	1.2

EQUIPMENT SELECTION. The blade capacity (loose volume) can be obtained from manufacturers' literature. The swell factor for bulldozed material is not the same as for other forms of excavation, and the figures given in Table 13.3.37 may be used.

The cycle time of a bulldozing operation does not contain any fixed time element. The gears to be adopted for various materials, gradients, etc., and their speeds may be obtained from manufacturers' literature. First-gear dozing speeds of up to 3.6 fps (1.1 m/s) and third-gear reverse speeds up to 9.3 fps (2.8 m/s) are normal.

The cycle time t_c found as follows:

$$t_c = \frac{\text{Haul distance}}{\text{Dozing speed}} + \frac{\text{Haul distance}}{\text{Reverse speed}} \tag{13.3.17}$$

The production is then

$$\text{Bank volume/hr} = \frac{\text{Blade capacity} \times 60 \times AO}{t_c} \tag{13.3.18}$$

AO may be determined from Table 13.3.4 if previous experience is not available.

COST ESTIMATION. Ownership and operating costs for bulldozers may be obtained by use of the format for tractor-scrapers, with the following modifications. The economic life should be taken from Table 13.3.35. Tire costs do not apply to crawler-mounted machines. For maintenance, repair parts, and labor, see Table 13.3.38.

For pusher-tractor operations, multiply the maintenance factor by 0.8 to allow for absence of blade wear.

13.3.7 TRENDS IN EXCAVATION

There are considerable advantages to be derived from continuous excavation methods, but it is difficult to envisage any major breakthrough in the field of hard-rock excavation in the near future. A much better knowledge of rock properties, and particularly rock machining, must be gained before any revolutionary developments can be forecast. At present, no mechanical device can match the huge quantities of energy that can be so compactly stored in chemical form in an explosive charge, and the drill-blast-load cycle is likely to remain the major excavation method for some time in stronger rocks.

Chapter 13.4
DESIGN AND LAYOUT OF HAUL ROADS

THOMAS ATKINSON

13.4.1 INTRODUCTION

Over the past three decades, off-highway trucks have been developed for surface mines up to 400 tons (360 t) in capacity, although 200 tons (180 t) is generally the largest size in fleet operation. They represent a huge capital investment and a significant percentage of total costs (Table 13.4.1). If haul road design is inadequate, the trucks can be highly lethal in the confines of a surface mine.

Despite these facts, haul road design until recently has received little attention (Kaufman and Ault, 1977). The two major functions of haul roads are to promote (1) efficient transport and (2) safety. Haul road design factors must ensure:

1. Minimum costs on a net present value basis for the transport of mineral and waste throughout the life of the mine.
2. A minimum of traffic congestion and the maintenance of safe, ready access to the mining operations.
3. The avoidance of areas where slope stability problems could occur.
4. The use of long-life haul roads rather than short-life roads. This reduces haul road overall construction costs and operating costs as well as reducing the demand for haul road construction materials which may not be available in sufficient quantities from the overburden.

Other factors include the locations of mineral preparation plants, stock yards, external waste dumps, environmental constraints, etc. All these factors direct attention to:

1. Haul road layout.
2. Haul road geometry.
3. Haul road construction materials.

13.4.2 TYPICAL HAUL ROAD LAYOUT

13.4.2.1 Strip (Open Cast) Mines

As seen in Fig. 13.4.1, these operations are characterized by the T junctions formed by the intersection of the haul roads (access ramps) through the spoil with the pit. Because the presence of the access ramp eliminates some spoil space (and also involves rehandling of spoil), the spoil heaps at these junctions must be piled higher than elsewhere, often resulting in spoil heap failures due to incorrect dumping procedures. Generally, it is not practical to dump spoil directly to form these junctions; the side slopes are best cut from placed soil. This usually results in more stable slopes, since substructures may be formed within spoil heaps from consolidation due to self-weight; they can be excavated to stable angles steeper than the angle of repose of the spoil, thereby partially reducing the volume of rehandle required.

Table 13.4.1. Typical Truck Haulage Costs for Surface Mines

Operation	% of total costs
Strip	7–15
Bench	20–40*
Open pit	30–50

* These figures represent shovel/truck mines. Costs for bucket wheel excavator/conveyor mines are much less.

Because of the flat aspect of strip mines, the bottom-dump truck is the preferred haulage unit. For gradients greater than 6% (3.5°), however, rear-dump or alternatively unitized trucks may be essential. Careful attention to dips, pavement contours, etc., is therefore needed during layout.

Where sandstones and other competent materials are present in the overburden, there are usually few construction materials problems, but where mudstone, silts, clays, etc., predominate, it may be necessary to import materials for haul road construction. The pavement must be of suitable material for temporary haul roads within the strip. Where it is not, the haul road may be located on the top of the mineral bed and the boom length of the loading shovel (located on the floor) must be increased or a back-hoe excavator used from the top of the mineral bed.

The advent of cast blasting (explosives casting—see Chapter 13.2.3) provides the opportunity for locating the access ramps on the highwall side of the strip (Atkinson, 1983), eliminating the spoil stability problems at the junctions of the access ramps with the strip, as well as reducing interference to the rhythm of the prime stripping operation. To be successful, cast blasting usually requires relatively strong overburden that will stand almost vertically at the highwall. This also implies there will be an adequate supply of material suitable for haul road construction within and outside the overburden on the highwall side.

13.4.2.2 Terrace Mines

Haul roads are required in bucket wheel excavator/conveyor mines for access by service vehicles traveling at modest speeds. Apart from the need for bridges to cross conveyors at key points, haul road requirements are not a major consideration. Generally,

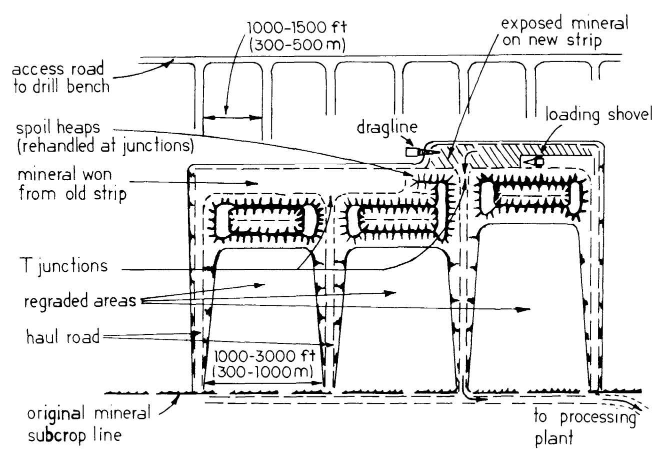

Fig. 13.4.1. Diagrammatic strip mine layout.

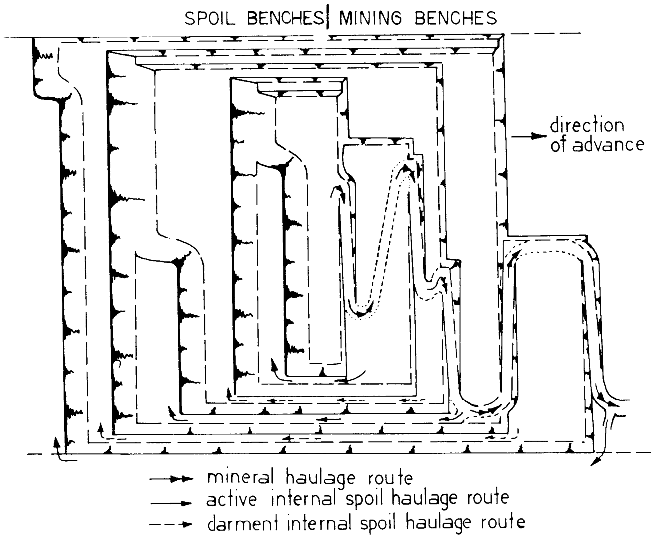

Fig. 13.4.2. Diagrammatic terrace mine layout.

such mines are excavated in relatively unconsolidated formations (e.g., lignite and bauxite mines) and materials suitable for haul road construction may not be available. Volumetric requirements are small, however, and in the case of lignite operations with a captive power station, can often be satisfied by the use of fly ash.

Shovel/truck terrace mines (Fig. 13.4.2) require major haul road construction, mostly of a temporary nature. Stratiform deposits with dips in excess of 14% (8°), where spoil stability problems could occur if down-dip strip mining is adopted, are increasingly being considered for terrace mining. In general, the strata dips are too steep for efficient truck haulage on the full dip, and it is necessary to form haul roads in the overlying strata.

Although haul roads in underlying strata may reduce haul distances for some spoil dumping, they can cause instability by undercutting the footwall bedding planes, as well as increasing stripping volumes (Walton and Atkinson, 1978).

Again, where suitable materials occur in the overburden, haul road construction need not be a problem, but in some geologic formations, a total lack of such materials, except for the mineral itself, may be experienced. This requires the import of large volumes of suitable materials and can have a significant impact on the visibility of such operations.

13.4.2.3 Open Pits

Massive ore bodies, steeply dipping stratiform deposits, and coal accumulations are generally mined by a benched, inverted, conically shaped open pit.

The facilities external to the pit (i.e., mineral preparation plant, waste dumps, etc.) are usually located by topographical, geotechnical, and environmental considerations. These locations may influence the alignment of the access roads to the crest of the pit.

The in-pit access haul road (Fig. 13.4.3) may be a clockwise or a counter-clockwise spiral, or a switchback or zig-zag (where the haul road turns back on itself). The main factors deciding the selection of layout are

1. It may be possible to locate permanent access haul roads on a "tight" side of a pit (e.g., the footwall of a stratiform deposit), in which case a switchback layout is adopted.

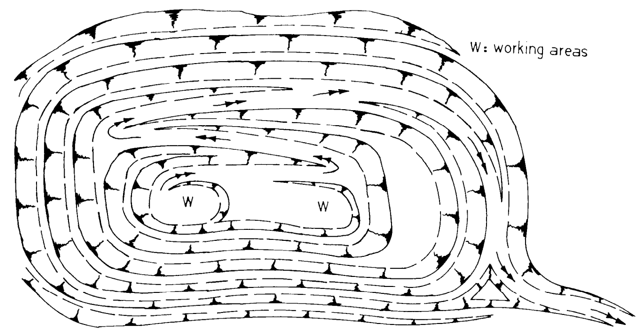

Fig. 13.4.3. Diagrammatic open pit layout with switchback haul road. W = working areas

2. In large pits, the haulage distance may be too great if a spiral layout is used.

3. Areas where potential slope stability hazards exist should be avoided, possibly eliminating a spiral layout.

4. The pit walls may be too steep to allow suitable bends to be formed for the switchback layout without greatly increasing the stripping ratio. In this case, the spiral layout would be adopted. Similarly, branching haul roads may exert an influence on the choice of layout.

Gradients of 8 to 10% (4.5 to 6°) are usually adopted, and rear-dump trucks are the preferred haulage unit, but a 12% grade may be adopted for trolley trucks.

Many metallic deposits are either igneous or metamorphosed, and haul road construction materials rarely present problems. Stratiform deposits, including accumulations, present the same materials problems as strip and terrace mines, but the bedding planes often dip into the pit, and the location of haul roads may cause difficulties.

Ideally, overall pit slopes are decided by geotechnical considerations. Bench heights are set by the operating requirements of the excavator, usually 30 to 50 ft (9 to 15 m). Loose material from minor falls must be contained on safety benches or berms from 30 to 40 ft (9 to 12 m) wide. These safety benches flatten the overall slope and are usually left after every 2 to 4 lifts.

Haul roads also flatten the overall slope (Fig. 13.4.4). In some cases, the geometry imposed by safety benches and haul roads result in overall slopes that are flatter than required by slope stability considerations alone, thereby increasing stripping costs.

The location of the haul road within or outside the ore body can also have a significant effect on mining costs. Fig. 13.4.4a shows diagrammatically the haul road located outside the ore body. The location increases the volume of minable ore but also the stripping ratio. Fig. 13.4.4b shows the haul road located within the ore body. The stripping ratio is reduced, but the volume of minable ore is also reduced in accommodating the haul road. The effects of the location of the haul roads must be fully considered. In general, the problem is site specific and must involve geotechnical as well as economic considerations.

13.4.3 HAUL ROAD GEOMETRY

There are a number of items that are best considered separately.

13.4.3.1 Number of Lanes

In-pit roads are usually constructed for single-lane, uni-directional traffic or two-lane, directional traffic (1) because traffic

density may not be high or (2) because of space problems. Haul roads from the pit to external waste dumps, preparation plants, etc., however, may require more than a single lane per direction. The number of lanes may be determined from the relation,

$$n = \frac{t\, d_b}{550\, v} \qquad (13.4.1)$$

where n is number of lanes for unidirectional travel, v is vehicle speed in mph, t is traffic density in vehicles/hr, and d_b is normal safe distance between trucks in ft. In SI units,

$$n = \frac{t\, d_b}{100\, v} \qquad (13.4.1a)$$

where v is vehicle speed in km/h, and d_b is normal safe distance between trucks in m.

13.4.3.2 Safe Distance Between Trucks

The safe distance between trucks depends upon driver reaction time (usually taken as 2.0s), the gradient, and the road surface plus an allowance (usually 16.5 ft or 5 m). The safe distance can be determined from

$$d_b = \frac{v}{1.08} + \frac{v^2}{91.5\,(C_t \pm i)} \qquad (13.4.2)$$

where C_t is coefficient of traction (less than unity), and i is steepest haul road gradient expressed as a fraction. In SI units, it becomes,

$$d_b = \frac{2.0\, v}{3.6} + \frac{v^2}{254\,(C_t \pm i)} + 5.0 \qquad (13.4.2a)$$

13.4.3.3 Road Width

The widest vehicles proposed determine the haul road width. For straight, regular grade roads, the rules of thumb given in Table 13.4.2 are adequate.

For sharp curves, additional width must be included, both on the curve and the tangent to the curve, to cover the front and rear overhangs of the vehicle and the difficulty of negotiating the curve. Minimum percentages of the figures for straight haul roads are given in Table 13.4.3.

Long tangents to curves assist drivers in negotiating curves.

13.4.3.4 Super Elevation

Trucks negotiating tight curves are subjected to an outward centrifugal force, which is opposed by the side friction between the tires and the road surface. Obviously, a good surfacing material is essential on sharp curves, and super elevation of the road surface is normally included in the haul road design. There are practical limitations to super elevation, since trucks driven at slow speeds on sharp curves could (1) overload the tires on the inside of the curve, and (2) in areas of ice, snow, and heavy rain,

Table 13.4.4a. Super Elevation Rates e Expressed in (in./yd)

Table 13.4.5b. Maximum Recommended Rates of Super Elevation Change on Tangents (mm/m)

Truck speed, km/h	5	25	35	40	50	<60
Super elevation change/100 m of tangent (mm/m)	260	260	250	230	200	160

tend to slide towards the inside of the curve. Table 13.4.4a (or 13.4.4b) shows the super elevation/safe truck speed relationships for practical road construction.

Where possible, all the super elevation should be uniformly introduced in the tangent to the curve, the minimum amount being 70% of the total super elevation. Where sharp curves occur at the end of long downhill grades, maximum truck speeds must be restricted to those given in Table 13.4.4 and the maximum permissible travel speed read from Table 13.4.4 to prevent trucks sliding in towards the center of the curve.

Tangent lengths vary with truck speeds and total super elevation. Maximum recommended rates of change of super elevation are shown in Table 13.4.5a or 13.4.5b.

13.4.3.5 Gradients

Maximum gradients may be statutorily limited to between 8 to 15% (5 to 8.5°) for sustained gradients, but in general when considering the economics of uphill haulage, as well as downhill safety, the optimum gradient for most situations is about 8%

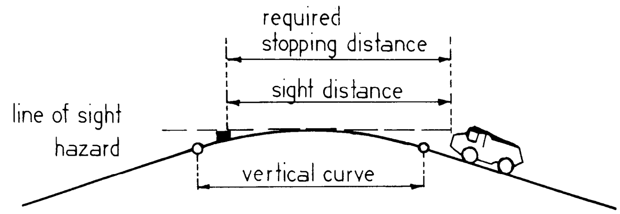

Fig. 13.4.5a. Vertical curve line of sight.

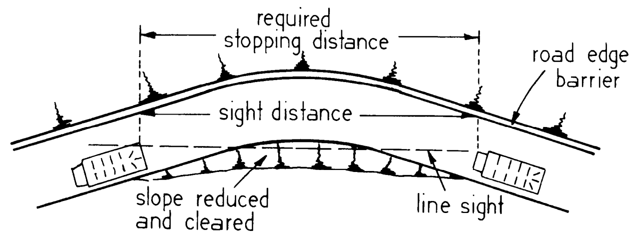

Fig. 13.4.5b. Horizontal curve line of sight.

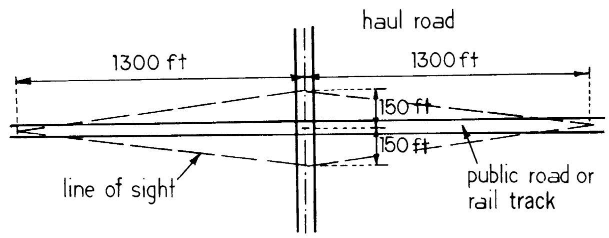

Conversion factor: 1 ft = 0.3048 m.

Fig. 13.4.5c. Line of sight at route crossing.

(4.5°) but up to 12% (6.8°) for trolley-assist trucks. For safety and drainage reasons, long steep gradients should include 150-ft (50-m) long sections with a maximum gradient of 2% (1°) for every 1500 to 1800 ft (500 to 600 m) of severe gradient.

13.4.3.6 Safe Sight Distances

Sufficient sight distance must be possible to ensure that a truck can stop when traveling at its operational speed before reaching a hazard. Methods of determining suitable geometries related to safe stopping distances have been advocated using the following criteria (Kaufmann and Ault, 1977).

1. Vertical curves should provide smooth transitions from one grade to another and provide ample sight distance for the required braking distance at the operational speed. The sight distance should be taken from the lowest driver's eye height for vehicles in the fleet to a hazardous object 6 in. (150 mm) high as in Fig. 13.4.5a.

2. Similarly, horizontal curves must be laid out to provide ample sight distance (Fig. 13.4.5b). This may involve slope reduction at the inside curve.

3. Where a haul road crosses a public road or a rail track, a safe crossing geometry is shown in Fig. 13.4.5c. Where vision is obstructed (e.g., by a road located in a trench, trees, vegetation, etc.) 150 ft (50 m) either side of the crossing, a distance to 1300

ft (400 m) back along the public road or rail track must be cleared. Approach gradients should be as flat as practicable.

In some situations, it may not be possible to apply these criteria, and approach speeds must therefore be restricted.

13.4.3.7 Haul Road Signs

In general, totally inadequate road signs are used in surface mines since it is often considered that truck drivers become familiar with the route, but the pattern of traffic may be continually changing throughout the life of a mine. Large professionally produced signs with durable surfaces should be installed as needed throughout a mine haul road system. These signs can quickly become obscured by dirt and require periodic cleaning with a high-pressure water jet.

13.4.3.8 Lighting

Lighting is usually provided at crushers, dump points, etc., to improve efficiency, but the level of illumination must be gradually reduced from an illuminated area to a non-illuminated area to help drivers' eyes to adjust safely to these changes in illumination.

13.4.3.9 Runaway Precautions

Runaway trucks can be a serious hazard on steep downhill gradients, and safety provisions to guard against these hazards must be provided as part of haul road design. One well-tried method, originating in Australia, is the location of triangular piles of nonconsolidated fines along the centerline of the haul road. In the event of brake or retarder failure, the truck driver maneuvers into line with the pile so the truck straddles the pile and the truck is brought to a halt (Fig. 13.4.6a), with only minor damage to the equipment on the underside of the truck. The geometry of these "median berms" is fully described in the literature (Anon., 1978).

Escape lanes (Fig. 13.4.6b) are a further method available for arresting runaway trucks, but lack of space may prevent their application in many situations. Where switchback haul roads are employed, escape lanes may often be conveniently located at the end of long, steep grades where the direction of the haul road is reversed. Particular attention must be paid to the radius of entrance curves, haul road width, super-elevation, wearing materials, arresting materials, etc. (Anon., 1978).

13.4.3.10 Cross Slope

Where possible (e.g., dry situations, short-life roads, etc.), a level surface between road edges is preferable, since this provides more even tire loading and less driver fatigue. Where heavy rain is experienced, a cross slope is desirable. Any degree of cross slope must be a compromise that provides adequate drainage without incurring adverse tire loading conditions and driver fatigue. The normally accepted rate of cross slope is 0.75 to 1.5 in./yd (20 to 40 mm/m) depending on conditions.

In conditions of ice, frost, and snow, or on smooth permeable surfaces (e.g., crushed rock) with rock base and sub-base, a 0.75-in./yd (20-mm/m) slope is advisable.

For rough surfaces where ice, frost, and snow are not a problem, a cross slope of 1.5 in./yd (40 mm/m) should be adopted.

Single- and two-lane haul roads may have all the cross slope in one direction, while on benches, the cross slope should be applied inwards, but three- and four-lane haul roads may have a center high point with the cross slope applied in both directions.

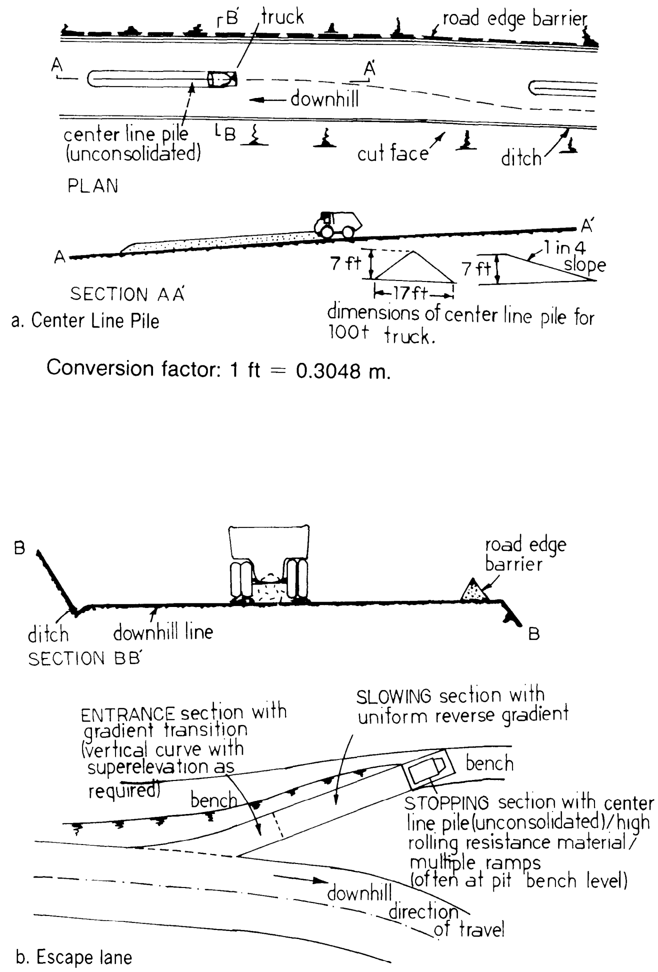

Fig. 13.4.6. Runaway precautions.

Road edge barriers (rock boulders, windrows of graded material, fines, etc.) should be located between roads and adjacent excavations (Kaufman and Ault, 1977).

13.4.3.11 Drains and Culverts

Run-off water can create major problems due to washouts, mud slides, and saturation, making provision of drains and culverts essential. The degree of drainage is dependent on rainfall, catchment area, ground conditions, depth of road base, storm water disposal requirements, etc.

V drains are generally more easily constructed and maintained, and the following features are desirable:

1. Drains should not be excavated in weak spoil (unless lined with flumes).

2. On benches, the cross slope should drain inward with drains excavated along the toe of the slope above. In cuts, drains should be excavated on both sides of the haul road.

3. Where the haul road is constructed on fill materials, drains should be excavated on each side of the embankment.

4. The ground between the edge of the haul road and the drain should be graded towards the drain and must not be obstructed by debris.

5. The sides of the V drains should have slopes of 4:1 where possible, with 2:1 as a minimum.

Table 13.4.6. Culvert Discharge Protection

Discharge Velocity		Slope Angle	Method
fps	m/s	%	
< 3.0	< 1.0	< 10	Divide outlet
< 3.0-10.0	1.0-3.0	> 10	Broken rock mat*
> 10.0	> 3.0	> 10	Divide discharge to broken rock fan

* Note that in some geologic settings, broken rock may not be available. In these circumstances, a velocity reducer may be economically constructed from oil drums spaced at 6-ft (2-m) intervals, manifolded to the culvert discharge. Small-diameter holes are drilled in the drums to provide a dissipated discharge.

6. Drain cross sections must be able to handle the predicted run-offs (Jackson and Walton, 1983). The materials in which the drains are excavated can affect the flow rates (e.g., low flow rates are necessary in weak erodable materials).

7. Where possible, the gradient of drains should be restricted to:

< 3% weak materials
3-5% strong clays, etc.
> 5% crushed rock lining required.

8. Long lengths of down-grade haul roads should be avoided. Sections of flat grade should be included. At these places, the drains should be diverted to the natural drainage system, or a pit sump, through drains or culverts.

Culverts are required to conduct run-off water beneath and away from haul roads. Culvert location, size, etc., is site specific but should include the following criteria:

1. Where possible, culverts should be governed by statutory requirements.
2. Culverts should be installed at all low points beneath haul roads where they intersect the natural drainage system.
3. All haul road intersections, construction changes, etc., require individual culvert design.
4. Drains should be diverted by culverts at regular intervals to the natural drainage system or a pit sump, to reduce flow in the haul road drains.
5. The culvert cross section must be sufficient to accept the maximum predicted run-off without causing excessive back-up at the entrance to the culvert. Several forms of culvert pipe are available, galvanized, corrugated steel, sectional pipe generally being most applicable due to its lightness, ease of handling, and recoverability. Manufacturers provide flow capacity vs. pipe diameter curves.
6. Culvert entries should be protected by a header wall of broken rock or concrete block masonry.
7. Culverts should not discharge on to spoil slopes and must be extended to a point beyond the toe of the spoil slope.

Table 13.4.6 should be used as a guide for avoidance of excessive erosion.

13.4.4 TROLLEY-ASSIST HAUL ROADS

The main advantages of trolley-assist haulage are cost savings through reduced fuel consumption; increased productivity due to increased speed and reduced cycle time; a reduction in electric wheel armature currents, allowing longer hauls out of deeper pits; and greatly increased engine life. At the Rossing Uranium operation, in Namibia, a 12% grade (6.8°) operation is highly successful with less than 2% initial (electrical) rejection on entry.

Driver skills, however, must be enhanced because of higher speeds and narrower steer paths, which demand greater skill and concentration. This can be facilitated, for example, by alignment lights and reflector targets fixed on support poles, etc. The most common accidents are line or pantograph/trolley pole damage caused by not steering on line. This fault is generally quickly corrected. The truck must be positioned under the trolley wire at the required entry speed while activating the pantograph/trolley pole, requiring a short driver training period.

Haul road geometry considerations are important, and the following points provide guidance:

1. A level section at the entry point to the trolley wire facilitates successful contact.
2. Curve radii of not less than 670 ft (200 m) assist the driver in maintaining contact.
3. Lanes should be wider than normal to accommodate higher speeds.
4. Three-lane ramps are necessary to allow trolley-assist trucks to overtake diesel trucks and service vehicles. Additional ramps for shovels are required between benches.
5. Reduced explosive charges and delay firing close to the trolley wire are essential to prevent trolley wire damage due to flyrock.
6. Because of higher speeds, haul roads must have well-graded surfaces, ± 18 in. (457 mm) control of pavement level being essential to ensure constant trolley wire contact; this is best achieved by laser beam indication of the bulldozer blade position during road surface formation.
7. Spillage must be constantly graded off the haul road to avoid trucks being steered off line.

13.4.5 HAUL ROAD CONSTRUCTION MATERIALS

Many mine operators, in the interests of capital cost, simply cut or fill haul roads with the materials existing at the location. This may present various problems since

1. In weak materials, the road surface will deteriorate and passage of trucks will be impeded.
2. Where competent rock is exposed, it is unlikely that an acceptable surface of suitable gradient and elevation will be exposed; irregular and jagged edges may form.

Both problems may result in reduced production and increased costs of fuel, maintenance, and tires.

The primary objective is to construct a roadbed or pavement that permits the transfer of wheel loads over the subgrade (i.e., foundation materials) so that the bearing capacity of the subgrade is not exceeded. It is necessary, therefore, to use guidelines for material selection that allow for the use of a wide range of construction materials including, ideally, those that arise onsite. Both subgrade and roadbed materials may be assessed using the empirical California Bearing Ratio (CBR) test (Anon., 1977a), which estimates the resistance to penetration of compacted materials.

13.4.5.1 Design Approach

Conventional design methods for flexible pavements (Anon., 1970), are generally inadequate for mine haul roads, since they are concerned with on-highway trucks having axle loadings typically less than 9 tons (8 t). Mine trucks may have axle loadings that exceed 60 tons (54 t). Airfield construction criteria have occasionally been adopted, but such methods remain difficult to interpret in the mining situation. A more recent approach recommended by Kaufman and Ault (1977) is preferred; this

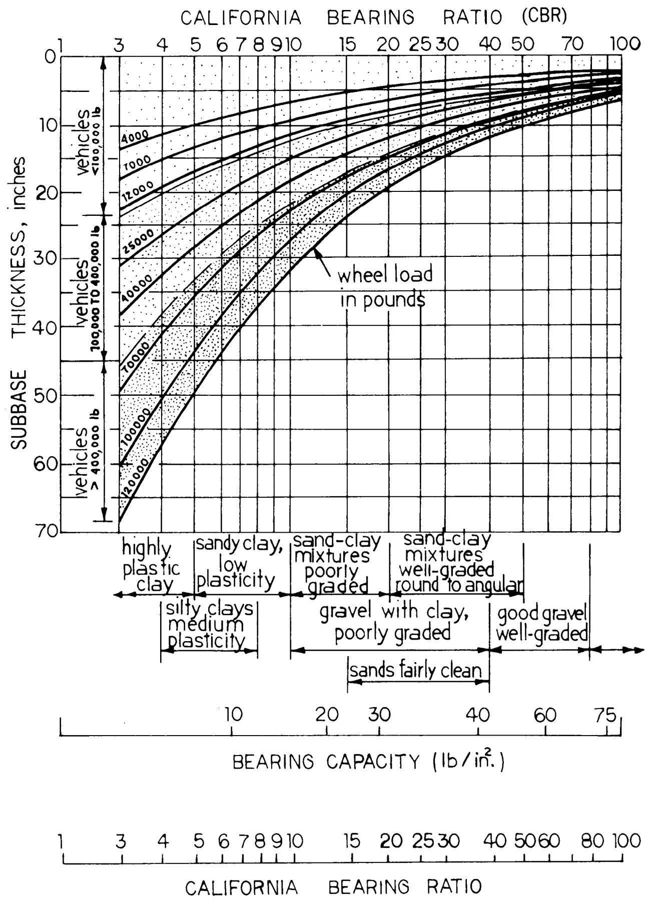

Fig. 13.4.7a. Classification and design curves for haul road construction materials, in English units (Kaufman and Ault, 1977).

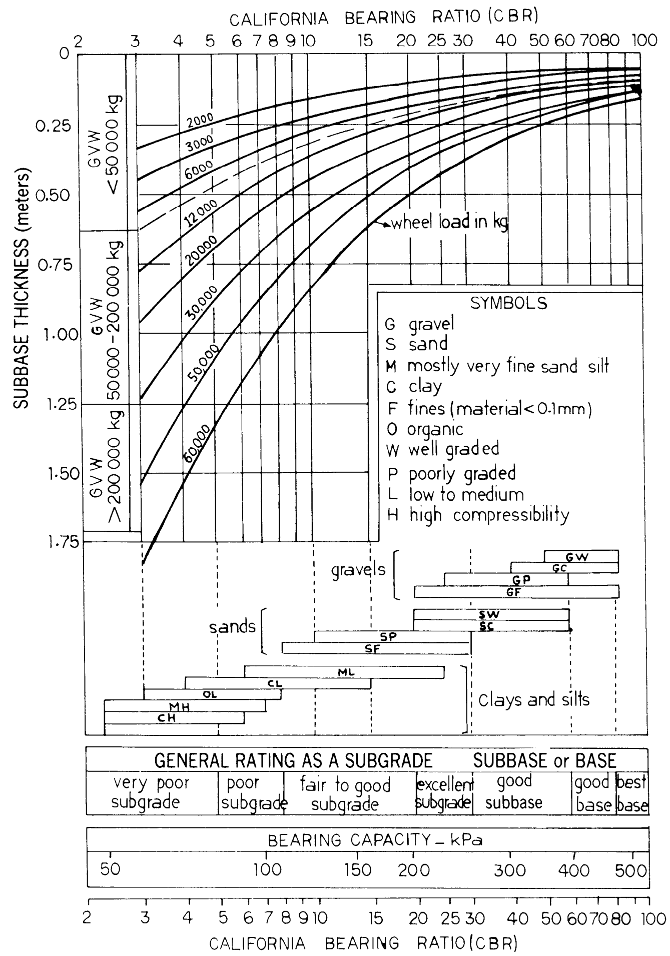

Fig. 13.4.7b. Classification and design curves for haul road construction materials, in SI units (Kaufman and Ault, 1977).

requires that CBR values and wheel loadings are first ascertained.

CBR values must be determined for likely subgrade and roadbed or pavement materials. The roadbed or pavement may comprise up to three distinct courses, a wearing or surface course, a base course, and a subbase; in certain circumstances, the subbase and even the base course may be omitted. Fig. 13.4.7 shows typical CBR values that should only be used as an initial guide. In subsequent design, CBR values must be determined from both soaked and unsoaked tests (Anon, 1977a); in areas with high rainfall or poor drainage, soaked results should be used.

Maximum wheel loadings may be calculated from manufacturers stated axle loadings divided by the number of tires per axle. Wheel loadings on tandem wheels are increased by 20%.

Fig. 13.4.8 illustrates the application of this approach with respect to a haul ramp in a proposed surface gypsum mine in which the constraints were as follows:

Maximum wheel loading 33,000 lb
Subgrade CBRs 5, 15, and 80%
Potential subbase CBR 15%
Required base course CBR 80%
Required running course CBR 80%

Considering the poorest CBR, the steps in calculating the roadbed thickness are as follows:

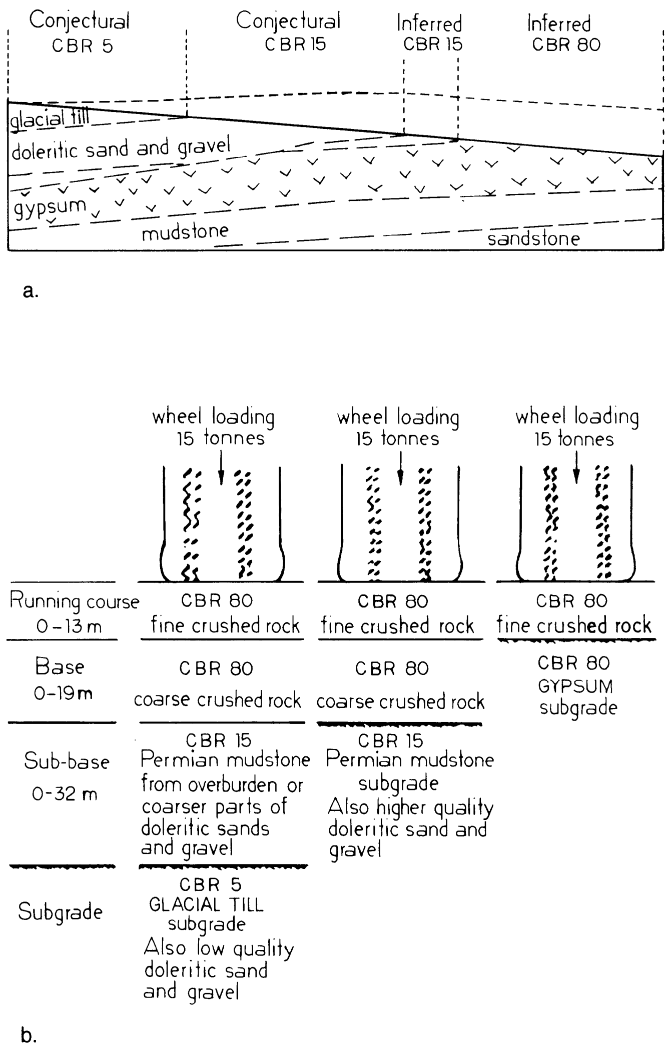
1. A subgrade CBR of 5% intersects as interpolated 33,000 lb (15,000 kg) a maximum wheel load line at 25 in. (635 mm). The top of the subgrade will be 25 in. (635 mm) below the road surface.

2. A subbase (or subgrade) CBR of 15% intersects the interpolated 33,000-lb (15,000-kg) maximum wheel load line at 12.5 in. (318 mm). The top of the subbase (or subgrade) will be 12.5 in. (318 mm) below the road surface. For conditions where the subgrade CBR has a value of 15%, only a base course need be found.

3. A running course CBR of 80% intersects the interpolated 33,000-lb (15,000-kg) maximum wheel load line at 5 in. (127 mm). The top of the base course will be 5 in. (127 mm) below the road surface, and the base course, therefore, will be 12.5 − 5 = 7.5 in. (190 mm) thick. A running course may be directly placed on naturally occurring base course material with a CBR of more than 80%; such materials must, however, be scarified, leveled, and graded.

13.4.5.2 Materials for Construction

It is apparent that both the materials over which haul roads must be routed and any onsite materials likely to be used during construction should be tested to give CBR values. Assessments should be made of the quantities required and the availability of materials within the scheduled mining operation; it is not uncommon to find the most suitable construction materials arise



Conversion factor: 1 ft = 0.3048 m, 1 ton = 0.9072 t.

Fig. 13.4.8. Use of construction material design chart. a. Section along haul road. b. Haul road pavement design.

in the later stages of working. Due regard must be given to roadbed thicknesses, widths, lengths, and future realignments in estimating quantities, particularly when materials may be imported onto the mine site. The various components of the roadbed may be considered separately.

SUBGRADE. As far as possible, this must be graded to an even surface; in many surface mines, this is the only step in road construction. While adequate for short-life haul roads in favorable materials and nonsevere climatic conditions given frequent regrading, such conditions are rarely adequate for longer-life haul roads. However, for very short-life lengths of haul road, the adequacy of naturally occurring materials with respect to trafficability may be assessed by reference to the recently developed moisture conditions test (Anon., 1982). A test value of greater than 13 indicates soils unlikely to give short-term problems with respect to rutting, etc., when the GVW does not greatly exceed 100 ton (90 t). Adverse subgrade materials appear to be increasingly encountered as more marginal mineral reserves are worked.

Excessive amounts of imported material are sometimes required. At one mine, the only economic solution was to construct the roadbed of coal; at another group of mines, peaty deposits had to be covered by soft-to-firm clay, which would rarely be considered as an ideal subbase. It is sometimes considered that synthetic membranes or fabrics reduce the quantity of subbase and base course materials in areas with poor subgrade. This is an over simplification. Membranes primarily restrict the loss of material punched down into subgrade materials (and may aid subsequent recovery for future road construction). The pumping or injection of weak subgrade into the roadbed is similarly inhibited.

The same approach to design thicknesses of the roadbed should, however, be used in all settings; membranes may allow the design to be achieved (Rankilor, 1981). Membranes also permit better compaction of the subbase and consolidation of the uppermost layers of the subgrade due to moisture loss occurring without mud pumping. It is often advisable to place sand and gravel-sized material over membranes if alternative subbase materials include large rock fragments that may excessively damage the membrane. Nonwoven fabrics are less prone to tearing. Whilst experience of the use of membranes is good, the economics of each case must be investigated and less expensive alternatives reviewed. These alternatives can include the use of brushwood and straw in extreme conditions such as peat bogs, and sand or fly ash over soft clays and silts, prior to forming the roadbed.

SUBBASE. The subbase width should exceed the surface and base course width by 24 in. (610 mm). Wherever possible, use should be made of on-site materials which should be compacted in layers of 6 to 8 in. (150 to 200 mm) in thickness. Compacted materials should be placed using rollers or with the controlled passage of mine trucks.

BASE COURSE. Most suitable materials for base courses are those having high CBR values such as crushed rock -4 in. (-100 mm) or high-quality gravels. Frequently, these are the least readily available materials, and offsite resource surveys are commonly required. It is essential that large lumps of rock are excluded, as well as organic material, clay, and silt. Materials should be compacted as for the subbase. The reuse of base course (or subbase) material is sometimes necessary, often justifying the use of synthetic permeable membranes.

Recent developments of high-water content (circa 90%) materials for underground mine packs (e.g., "Tekpack") show promise for use in base (or subbase) courses where the availability of other materials may present problems. Long-term stability is as yet undetermined, and a minimum temperature of 70°F (20°C) is required for the material to set.

Several chemical additives often known as binders or packers, including hydrated lime, calcium chloride, cement, and other stabilizers, are available for improving the characteristics of base course materials (and also subgrades). The effectiveness of these additives is heavily dependent on chemical compatibility. The economics for each site must be proven; materials other than cement, however, are often unsatisfactory and construction methods that rely on building a roadbed of adequate thickness in relation to the character of the subgrade materials may be preferred.

RUNNING OR SURFACE COURSE. The best surface courses are those that give hard, even surfaces and little dust with no penetration under load. High adhesion and low rolling resistance coefficients are preferred. The best surface materials that also have a low permeability are, therefore, concrete and asphalt (see Table 13.4.7), although construction costs are high. Where available, finer crushed rock –0.5 to +1.0 in. (–10 to +20 mm), coarse sand-size mill tailings, clean gravel, and clinker are

Table 13.4.7. Adhesion and Rolling Resistance Coefficients

Description	Coefficient of Adhesion	Rolling Resistance % GVW
Concrete of blacktop	0.9	2.0
Rock base, dry	0.7	3.0
Rock base, wet	0.65	3.5
Pit floor, rock	0.55	5.0
Partly compacted gravel	0.45	5.0
Gravel, unmaintained, wet	0.4	7.5
Weak materials, flexing considerably	0.35	8.0
Soft, muddy, rutted road	0.3	15.0–20.00
Ice	0.1	1.0

suitable low cost materials if compacted when moist. Fines (silt and clay) should essentially comprise between 5 and 10% of such running courses.

The coefficient of rolling resistance can be related to tire penetration by the equation (in SI units),

$$\text{Coefficient of rolling resistance} = 0.02 + 0.0007 \times \text{mm of tire penetration.} \tag{13.4.3}$$

Only carefully constructed haul roads will permit safe, high running speeds that will both improve production and reduce maintenance, tire, and fuel costs. Money spent on the investigation of materials and on haul road construction is usually a sound investment.

13.4.6 CONCLUSIONS

The construction of surface mine haul roads differs in many respects from regular highways in that the wheel loads in mining are far higher, yet the pavement life is often quite limited (Atkinson and Walton, 1983). The same general principles as those in highway engineering may apply, but the problems of economics, design life, continual change of layout, etc., in surface mine haul roads requires a different approach. The mine designer is required to use continuing ingenuity in layout by the use of cuts, spoil bridges, and ramps, etc., to provide the shortest, least steep and most easily negotiable haul roads.

The high investments tied up in truck fleets require high-quality haul roads to ensure:

1. Maximum production, by the use of high but safe truck speeds, less down time for maintenance, and increased efficiency because of reduced driver fatigue.
2. Reduced operating costs due to reduced fuel consumption, reduced repair costs, and longer tire life.
3. A safer working environment that will improve efficiency.

In the past there has perhaps been a failure to recognize that inadequate haul roads can be a major cause of reduced profitability. As the trend to larger pits, using large equipment, to achieve economies of scale continues, the need for improved haul road design and construction is readily apparent.

Chapter 13.5
IN-PIT CRUSHING AND CONVEYING

EARL M. FRIZZELL AND THOMAS W. MARTIN

In 1956, the first mobile crusher was installed in a limestone quarry in Hover, West Germany. The crusher enabled the quarry operator to take advantage of continuous belt conveyor haulage and eliminated a problem of high-cost road construction and maintenance in wet soft ground, with resultant cost savings. Since that time, the number of mobile in-pit crushing and conveying operations has increased to over 100 (Table 13.5.1). Most of these installations are limestone quarry operations of less than 1100 tph (1000 t/h) and are fed directly by a mine face excavator because of ground conditions in the quarry.

13.5.1 IN-PIT CRUSHER SYSTEMS

Crushing is done in-pit mainly to allow transport of the material out of the pit by a conveyor system. Therefore, the units used for primary crushing are jaw gyratory, gyratory, hammer, impact, roll, and jaw crushers. A summary of the capacity, type of crusher, and amount of material being processed world-wide is shown in Table 13.52.

In-pit crusher systems have mobility capabilities that range from fully mobile units in continuous use to permanently fixed units (Fig. 13.5.1). Once installed in the pit, fixed crushers normally require that haulage trucks travel a gradually increasing distance from the mining face.

The term "mobile" has been used to describe any type of crusher that can be moved. The term has become a generic one and should be used when referring to any crusher that is movable. The system (or sections of the system) is mounted on a frame base, allowing the complete unit to be moved by skids or a transporter, such as a crawler system or a walking mechanism, that may or may not be an integral part of the unit itself. An integral mobile crushing plant includes a hopper, feeder, crusher, and discharge conveyor, in addition to all the required auxiliary and electrical systems. The following terms are presented to help distinguish the range of mobility among mobile crusher systems now in use.

13.5.1.1 Mobile Crusher

This type of crusher works at the mine face, is directly fed by an excavator, and moves in unison with the excavator on its own transport mechanism as mining progresses. An example is the unit delivered in 1976 to Yamama Cement Co. in Reyadh, Saudi Arabia. Its capacity is 880 tph (800 t/h) in limestone using a double-shaft hammer crusher. Plant weight is 660 tons (600 t) (Fig. 13.5.2).

13.5.1.2 Semimobile Crusher

This unit works close to the mine face but is moved less frequently than a mobile crusher. The transport mechanism may be a permanent part of the crusher frame. Such a unit was delivered in 1971 to S.A. des Cements de Champagnole, Rochefort sur Nenon, France. A single-shaft hammer crusher provides the 496-ton (450-t) plant with a 660-tph (600-t/h) capacity in limestone (Fig. 13.5.3).

13.5.1.3 Movable Crusher

A movable crusher is centrally located in a mine near the same level as the mine's working face. It is relocated every 1 to 2 years, as required, to maintain the relationship between distance and elevation from the face. Fig. 13.5.4 shows the Dutex system at the Sierrita mine in Arizona. Copper ore is processed at rates up to 4000 tph (3628 t/h) by a gyratory crusher, which is part of a movable three-section system. The crusher can be completely relocated in 48 hours because no concrete structures or retaining walls are required.

13.5.1.4 Portable Crusher

This term is used in Europe for crushers with temporary support foundations. The crusher plant is moved in sections. In the United States, this term refers to units that can be moved on a highway with a minimum amount of dismantling. This term is ANSI-approved and is a national standard, with the number CAPPA-78.

13.5.1.5 Modular Crusher

In a modular crusher, the crusher station can be disassembled into modules and reassembled in a new location in about 30 days. Such moves normally would not be made more than every three to five years. An example is the 4- × 6-ft (1.2- × 1.8-m) primary gyratory crusher station designed for the Majdanpek copper mine in Yugoslavia, which can be dismantled into modules having a maximum weight of 58.7 tons (53.2 t) and a maximum size of 42 × 22 × 22 ft (12.8 × 6.7 × 6.7 m) (Fig. 13.5.5).

13.5.1.6 Semifixed Crusher

A semifixed crusher is mounted on a steel platform, which reduces the need for a concrete foundation. Any planned relocation would not be for less than 10 years. The two 4.5- × 6.6-ft (1.4- × 2-m) primary gyratory crushers at the Twin Buttes copper mine in Arizona were erected in part on heavy steel structures and can be moved. The original plan was to have the crushers remain in place for at least 10 years, after which they would be relocated down in the pit in a series of leap-frog moves to capitalize on the advantages of belt conveyors reaching to the bottom of the pit (Fig. 13.5.6).

13.5.2 TRANSPORTER TECHNOLOGY

Mobile crushers weighing up to 800 tons (725 t) have been moved by crawlers, tires, and walking mechanisms. Generally, the smaller and more mobile units are moved by skids, tires, or crawlers, and the larger semimobile units are relocated by crawlers or walking mechanisms. A transport system that should be considered is rail wheels, which carry extremely heavy loads with great efficiency because of their low rolling friction. Rail wheels create a severe braking problem on grades approaching 10%, however, which probably limits their use. Air flotation devices have moved more than 1500 tons (1360 t), but use of

Conversion factor: 1 ton = 0.9072 t.

these devices is restricted to extremely level surfaces. Climbing a 10% grade, as required in a mine, would be impractical with current air flotation technology.

13.5.2.1 Crawlers

Crawlers are widely used in moving heavy equipment, such as mine shovels and dozers. Single sets of crawlers have moved up to 1000 tons (900 t) and can be teamed to move even heavier loads (Fig. 13.5.7). Crawlers are also able to move at relatively high speeds (up to 40 fpm, or 12 m/min) loaded. Crawler transporters are almost always diesel-powered and have hydraulic lift mechanisms. The weight of a 1000-ton (900-t) lift crawler transporter is approximately 200 tons (180 t).

Crawlers provide a stable platform and, with the tracks properly suspended, can move on uneven ground. They can negotiate steep slopes, although they are limited to grades of 10% or less when transporting a crusher. This is because traction forces are limited and the center of gravity and resultant moments on the crawler frame shift. Crawlers are very durable, but they are likely

to suffer damage from shock and vibration if they are left loaded under a working crusher for long periods of time. They can almost complete a turn in one spot by running one set of treads while locking the other. Under a heavy load, this maneuver is

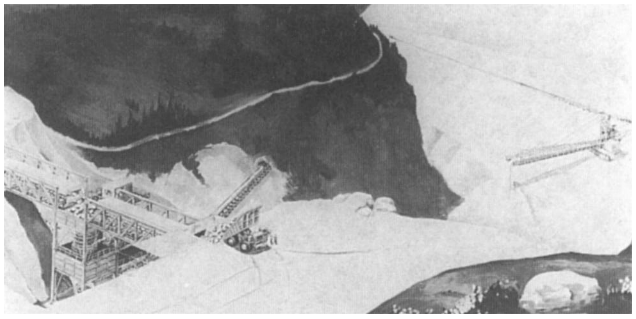

Fig. 13.5.5. Modular crusher (*courtesy:* Stephens-Adamson, Aurora, IL).

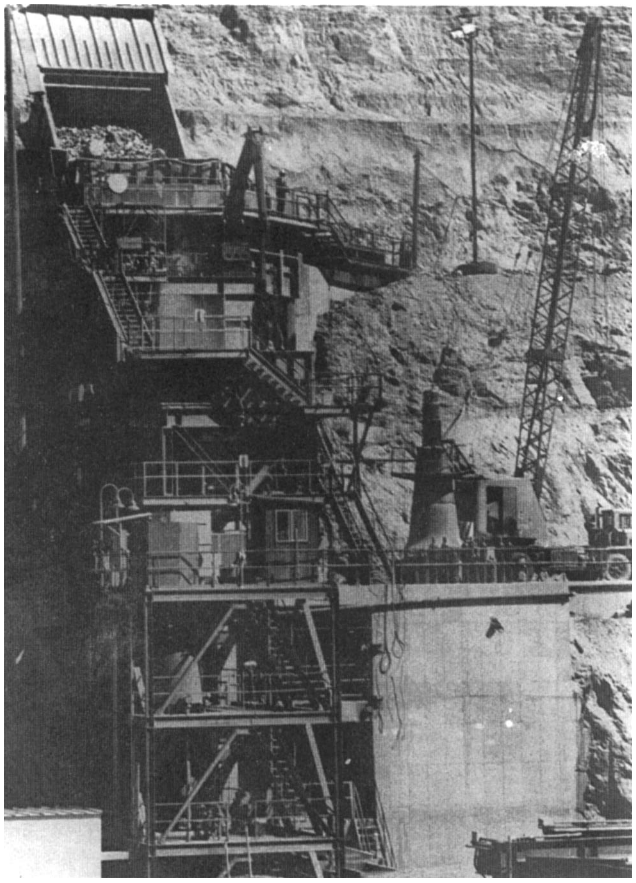

Fig. 13.5.6. Semifixed crusher (*courtesy:* Rexnard, Milwaukee, WI).

restricted for more than a few degrees of angular rotation because of ground damage or tread damage on the locked track.

13.5.2.2 Wheels

Wheels, either tired or rail, are the most widely used means for transporting heavy loads. Multiple wheels can carry very large loads, but speed is highly restricted. Drive mechanisms for tires includes electric motors like those used in haulage trucks and hydraulically operated wheels that can produce more torque.

Fig. 13.5.7. Movable crusher in transit on crawler transporter (*courtesy:* Krupp International, Houston, TX).

The cost of tires is relatively low, but the drive motors and controls can make tired transport cost more than a crawler or a walking mechanism.

Grades up to 10% are negotiable, and both electric and hydraulic motors will assist downhill braking. Rubber tires are quite durable and are relatively immune to shock and vibration. Wheels can be left under a crusher for long periods but tend to take a set if the carcass is made of nylon or steel cord. Cold temperatures also embrittle rubber tires, but the rubber can be compounded to reduce temperature-related problems and are, in fact, used in very cold climates. Ozone also attacks and embrittles rubber, but this can be reduced with chemical additives.

13.5.2.3 Walking Mechanisms

Walking mechanisms are the most widely used method of moving loads in excess of 1000 tons (900 t) (Fig. 13.5.3). Machines have been built that can lift up to 5000 tons (4500 t) and are capable of moving approximately 200 fph (60 m/h), a speed sufficient for modular or semifixed crushers. However, walking mechanisms are less desirable than crawlers where speed is necessary or constant hourly use is likely. These systems are generally less expensive than crawlers and have a good service record for reliability.

Walking mechanisms require careful ground preparation so they will not be impeded or the load redistributed by small bumps. Spillages around a crusher from dumping or from the conveyors have to be cleaned up before the units can be moved. The walking mechanism is very durable and can be left for long times under load (both static and dynamic) because when the hydraulic system is depressurized, the metal beam (foot) carries the load. In units up to 1000 tons (900 t), walking mechanisms have demonstrated the ability to turn 360°.

13.5.3. CONVEYOR SYSTEMS

A drawback of conventional conveyor haulage out of open pits is that the maximum vertical slope angle a conveyor can achieve is 17 or 18°, which does not coincide with the typical slope of an open pit wall, which ranges anywhere from 38 to 45°. This requires that either the conveyor must be run out of the pit

Fig. 13.5.8. Conveyor flights leaving a pit via switchbacks.

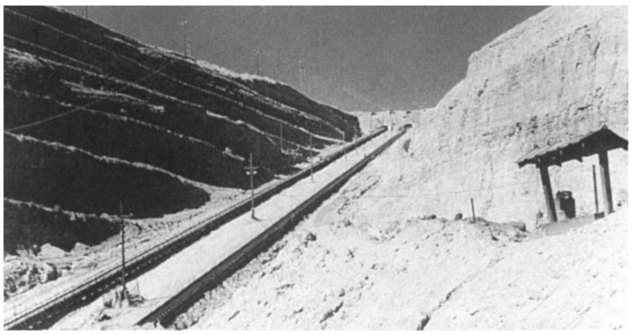

Fig. 13.5.9. Open pit conveyor trench.

in switchbacks similar to those used for truck haulage roads or that a trench must be cut through the side wall of the pit. Both of these approaches have disadvantages. Transfer systems must be installed to facilitate the change in direction of the conveyors at each switch point (Fig. 13.5.8) or a greater amount of waste material must be removed from the pit to create a lower slope angle (Fig. 13.5.9). These problems have led to the development of high-angle conveyors to remove material from a pit (see Chapters 9.3 and 13.3).

There are many types of belt systems that should be considered in developing a conveying system for a specific installation. These belt systems generally fall into the following categories:

1. Fabric belt systems.
2. Steel cable belt systems.
3. Cable belt systems.

13.5.3.1 Fabric Belt Systems

Conventional fabric (canvas) belt systems have been in operation for many years, but they have been greatly improved recently by the use of a synthetic carcass. The Rubber Manufacturer's Association has classes for belt carcasses from MP-35 through MP-240. Each classification number is an indication of the strength of the fabric used in manufacturing the belt carcass. Shorter belt conveyors that can use mechanical splices normally use belts up to a rating of MP-70, allowing for 55 lb/ply/in. of splice (0.98 kg/ply/mm) for maximum tension. The MP-240 rating, on the other hand, is for a vulcanized splice that will allow up to 240 lb/ply/in. of splice (4.3 kg/ply/mm) for maximum tension. Although conveyor belts can be made with more than 10 plies, it is a general rule that for a coordinated type installation, seven plies are a maximum. Therefore, a limitation is placed on the driver size and capabilities, or maximum belt tension that should be kept in mind with the use of fabric belts. For example, a 7-ply, MP-240, 60-in.- (1.5-m-) wide belt should carry only 100,889 lb (45,763 kg). The reason for the seven-ply limit is that pulley diameters are directly affected by the number of plys and the type of fabric construction in a belt. Other than limitations posed by pulley diameters and the capability of the belt to run smoothly in a trough, fabric belts can run on most conveyor systems.

13.5.3.2 Steel Cable Belts

A steel cable conveyor belt consists of multistrand steel cables embedded in a rubber or plastic compound. The steel cables are the load-carrying members of the conveying system. These units have the advantage of being able to take much greater tensions than fabric belts. The steel cable belts can be constructed to handle any desired tension ranging from 500 lb/in. (9 kg/mm) width of belt to 5000 lb/in. (89 kg/mm) width of belt. For example, a 60-in. (1.5-m) belt with a rating of 5000 lb/in. (89 kg/mm) width would allow a maximum tension of 300,000 lb (136,000 kg).

13.5.3.3 Cable-supported Belt Systems

A relatively new long conveyor system is the cable belt conveyor. These systems do not have cross roll idlers, and the belt is not the tension member. Rather, the belt is driven by friction on load-carrying steel cables running lengthwise in molded cleats or grooves near the outer sides of the belt on the upper run, and approximately a quarter of the belt width in from the sides on the return belt. The cables are in turn supported by cable sheaves and driven by specially designed drives and take-up systems. The driving cables for the cable belt system generally range in diameter from 1¼ to 2½ in. (32 to 64 mm). General alignment of this type of belt is simpler than the troughing belt idler system. Long-radius horizontal curves can even be accommodated with this system.

Capacities of the cable belt system have varied from 3000 to 5000 tph (2700 to 4500 t/h) with drives up to 10,000 hp (7450 kW). These cable belts are presently being manufactured and installed up to 60 in. (1.5 m) wide and have been included in installations for run of crusher materials. One such installation handles 1815 tph (1634 t/h) net of copper ore at 800 fpm (244 m/min), and uses a 2493-hp (1860-kW) drive. The conveyor is 42 in. (1.07 m) wide by 32,480 ft (9900 m) long with 50 ft (15.2 m) of lift. Another installation is a 3500-hp (2600-kW) cable system raising 800 tph (720 t/h) of iron ore 2432 ft (741 m) over a distance of 15,140 ft (4615 m).

13.5.4 AUXILIARY SYSTEMS

In addition to the crusher and main conveying system, other considerations when installing an in-pit system are the feeder to the main conveying system and rock transfer from one conveyor flight to the next.

13.5.4.1 Discharge Feeders from the Primary Crusher

There are three major types of feeders presently used under the primary crusher ore pocket.

OVERLAPPING FLIGHT APRON FEEDER. This feeder looks and functions much like a crawler tread where the crushed output falls directly on top of the tread. The ore is then carried out over the end of the feeder and dropped on to the conveyor. Depending upon the size and type of material handled, the flights are fabricated steel pans or heavy cast steel. This is an articulated type of feeder and normally runs less than 80 fpm (24 m/min). This is the most common output feed system used in large open pit mines because it is extremely rugged and can start up with a heavy load on it.

VIBRATING FEEDER. This type of feeder may have a flat pan up to 8 ft (2.4 m) wide and may be vibrated by more than one vibrating head. Up to 6000 tph (5400 t/h) of stone have been handled in stone quarries under primary crushers. The amplitude of this feeder is controlled by a DC controller and can be varied. Other types of eccentric weighted mechanical feeders are used. The variable speed arrangement on these latter units are not as easily controlled as one which has an electrical or mechanical impulse system.

BELT FEEDER. Because of the tendency of fabrics to rip when handling larger-sized material, the use of belts under primary crushers as feeders has only come about in recent years with the development of stronger materials. These materials are extremely heavy fabric or steel cable belts with nominal l-in. (25-mm) covers and breaker strips. The belts are usually thickened further with a layer of molded or vulcanized rubber (wear pads), so that the overall thickness of the belt cover could be 2 to 3 in. (50 to 75 mm). The rubber is added to improve abrasion, crushing, and tearing resistance of the belt. Belt feeders cost much less initially, can be made longer, and require less mechanical maintenance and cleanup than apron feeders. Because of these advantages, it can be assumed that belt feeders will be used more frequently in the future as belt technology improves.

13.5.4.2 Transfer Chutes

If the design and configuration of major conveyor systems calls for switchbacking conveyor flights to leave the pit, a major consideration will be the means of transferring material from one conveyor to another. The transfer height between one belt to another should be reduced as much as possible by almost laying the material on the receiving belt. This will not only minimize equipment wear, but will save energy by reducing the overall vertical height the material must be conveyed. While this is desirable, it may not readily be attainable where there are other than parallel transfers.

A transfer system stops the forward movement of the material moving in one direction, turns it, and starts it in a new direction. Transfer is usually accomplished by dumping the conveyed material into a rock box, dissipating much of the energy of the material. From the rock box, the material is transferred by chute or slide onto the next conveyor in the direction of movement of that conveyor. The back of the chute is sloped to impart velocity in the direction of the conveyor.

A major problem with transfer systems, especially when moving large, blocky types of stone or ore, is excessive wear on the belt surfaces and idlers directly below the loading area caused by the impact of the material. To alleviate wear, the back portion of the chute may also contain a grizzly, which allows the fine materials to fall through and provides a cushion on the belt for the large-sized materials that load at the end of the chute. Where grizzlies are not practical, a V-shaped chute can be constructed. A V-shaped chute restricts impingement of large pieces of ore or overburden directly on the center of the next conveyor belt and also tends to load finer materials onto the belt before larger materials.

13.5.4.3 Conveyor Hoods and Wind Guards

In moderate climates, conveyor hoods prevent the belt from blowing off the idlers when the belts are empty and prevent some dusting from the materials being handled. In more severe northern climates, the hoods greatly reduce the snow and ice problems. Hoods also retain dust at the approach and take-away areas of a transfer station.

As an alternative, wind loops of round steel bars can be arched over the top of the belt and attached to the idler support system. Spacing depends upon operational requirements. The supports for standard hoods can also be used, if hoods are a future consideration.

With deep trough idlers, the underside area of the belt exposed to wind is considerable. Permanent side shields have been used to prevent problems in these cases. These are adaptable also to tripper belts or trunk line stacker belts that cannot use hoods or loops.

13.5.5 SELECTION AND DESIGN GUIDELINES

Those material characteristics that affect the selection of an in-pit crushing and conveying system are the same as those affecting overland crushing and conveying equipment. The density, moisture content, maximum lump size, size consistency, abrasiveness, and degradation and dusting of the material are all factors to be considered.

13.5.5.1 Crushers

The size of the crusher is determined on the basis of the material to be crushed, the rate of production, feed size, and output size that is related to the selected belt width, which is a function also of the system capacity. Primary crushers reduce run-of-mine rock from the as-shot size to a size that can be carried on a conveyor or utilized in the rest of the processing plant. The requirements for a crusher include the following factors:

1. The crusher must be able to reduce the largest-sized feed normally received.
2. The maximum particle size for conveyed material should not exceed 30% of the belt width.
3. Ideally, the crusher should be able to break the rock to a size that reduces the amount of subsequent crushing required (for in-pit crushing and conveying, this is less important than sizing the rock to be carried on the conveyors without causing damage to the conveyor).
4. The crusher should use the minimum amount of power possible (however, the power consumed by the primary crusher is not really great compared to the power consumed in the following crushing and grinding stages).
5. The crusher should be labor efficient. It should not require a great deal of attention to remove oversized rock or to prevent clogging.
6. Its wearing components should last as long as feasibly possible (wear liner and mantle replacement ranges from 2 million tons (1.8 million t) of taconite before replacement to almost 10 million tons (9 million t) in copper ore).
7. The crusher should operate economically and dependably and should yield a long service life (current primary crusher installations in the mining industry are expected to operate from 20 to 30 years without needing replacement).
8. It must be backed by excellent maintenance services, as generally the entire throughput of a mine goes through one or two crushers, and the failure of these crushers can cause serious financial hardship to a mine.

Table 13.5.3. Advantages and Disadvantages of Specific Belt Fabrics and Construction

Advantages	Disadvantages
Synthetic Fabric	
1. Initial cost is generally lower than that of comparable belt systems. 2. The belt can be mechanically spliced when used at low tension. 3. Belts are stock units and are readily available. 4. Belts are adaptable to short conveyor systems.	1. Maximum strength is limited. 2. Large pulley diameters are required with more plies to handle the resulting stiffness of the belt. 3. Vulcanized splicing, which is required for heavier belts that cannot be spliced mechanically, cover large sections of the belt. 4. Thicker belts do not run easily in troughs. 5. Large amounts of take-up movement are required on long conveyors because fabrics tend to stretch. 6. Fabrics are susceptible to both crosswise and longitudinal ripping by foreign objects.
Steel Cable Belts	
1. Greater belt tensions are supported, permitting longer hauls with higher lifts. 2. Permanent steel cable splices that require no mechanical connection of cables and that can supplement a vulcanized rubber cover over the splice can be on site. 3. A very short take-up length is required as compared to fabric belts. 4. Belts are fabricated with steel cables under tension. 5. Cables are laid precisely in the same plane during fabrication and are controlled during curing, resulting in belt alignment superior to that of a fabric belt. 6. Steel cable belts have greater resistance to general impact and abuse.	1. Initial cost is generally much greater than that of a fabric belt where both have the same maximum tension rating. This generally applies only to the lower range of the steel cable belts. 2. Splicing a steel cable belt is more difficult and time consuming than splicing a fabric belt. 3. Smaller pulley diameters can be used with resulting savings in gear reductions and drives when compared to thick heavy fabric belts. 4. Belts are susceptible to lengthwise tearing.
Cable Belts	
1. Cables are easily inspected. 2. Because they are not connected to belts, off-center loading has little or no effect on the belt system. 3. The width of the belt is entirely determined by the capacity of the system. 4. End-drive cables are available in continuous lengths without separate splicing and so can be used in systems that are up to 10 miles (16 km) long. 5. Belts can go up and down over various landforms without major structural or conveying problems other than use of power. 6. There are few drive cable splices and a minimum of belt splices.	1. Cable belts are not readily movable and must be considered only for long fixed haulage distances.

13.5.5.2 Conveyors

The size, weight, and physical characteristics of the material, transport rate, and horizontal and vertical distances the material must be carried determine the type of conveying system to be used to handle the material. Table 13.5.3 lists the advantages and disadvantages of specific belt fabrics and construction.

13.5.6 ECONOMIC CONSIDERATIONS

In open pit metal and nonmetal mines, the cost of transporting materials out of the pit constitutes roughly 60% of the operating cost of mining. In many mines, this cost percentage is even greater. Consequently, haulage costs are the major factor influencing the economic viability of a mining operation and constitute a major opportunity to reduce costs and effect savings.

Because of their operating flexibility, relatively low capital cost, resale value, and mobility from operation to operation, trucks have historically been the favored method of moving both ore and waste from open pit mines. Technical developments, such as diesel engines and electric wheel drives, have led to larger and larger vehicles. Currently, several manufacturers produce 240-ton (216-t) trucks, and the largest truck in operation is a 350-ton (315-t) unit. Continuing this trend will probably result in standard units of 300 tons (270 t) within 15 or 20 years. The use of microprocessors to monitor, control, and dispatch vehicles has resulted in improved efficiency and increased productivity in recent years, a development that should continue as computer technology expands in the future.

Within the current state of the art, conveyors are the lowest-cost method of handling bulk materials. For truck haulage, 60% of the fuel energy goes to moving the truck weight and only 40% to moving the payload. For belt haulage, the corresponding relationship is 20% to belt weight and 80% to payload. Using diesel fuel costs of $1.14/gal ($0.30/L) and electricity costs of $0.05/kWh, energy costs favor conveyor haulage by a factor of 4 to 1.

In addition, conveyors provide automatic, instantaneous start-up and continuous operation. They are very reliable, achieving up to 90 to 95% availability. Their operation is not impaired by bad weather, which often halts truck haulage. Conveyors have lower manpower requirements; a 100-person crew operating and maintaining a truck fleet can be replaced by a 10-person crew handling the equivalent amount of materials via conveyor. Conveyors also have a significant potential to be automated in varying degrees.

Belt conveyors operate efficiently at grades up to 30%, while the maximum grades over which trucks and rail haulage can operate are 10 and 2%, respectively. The capability of using steeper grades lowers the need to remove overburden and establish haulage roads, thus improving the operating ore-to-overburden ratio and reducing costs.

Disadvantages of belt conveyors include the lack of operating flexibility at the loading area. Initial capital costs can be higher, but vary depending upon the size of the operation. A deeper, larger pit normally requires more capital for additional trucks relative to extending a conveyor system. For a 656-ft- (200-m-) deep pit, investment costs for trucks might be about the same as for conveyors. However, it has been reported in European surface mines and elsewhere that conveyor systems actually require lower initial costs than truck systems.

Within four or five years, however, higher operating costs cancel the initial cost advantage of truck haulage. The longer the life of the project, the more economical the conveyor system, especially in deep pits or pits that rapidly increase in depth. Thus, taking into account the necessity of purchasing additional haulage trucks to accommodate increasingly difficult haulage routes and to replace trucks as they wear out, conveyor systems will actually require lower capital costs over the life of a mine. Conveyor systems handling ore in numerous large crushing and port facilities, which have operated since the early 1950s, have clearly demonstrated a useful conveyor life of more than 25 years. In contrast, off-highway trucks have life spans of six to eight years.

Data generated from several large mines where in-pit crushing and conveying systems have been installed indicate lower operating, maintenance, and overall unit costs compared to the costs of conventional truck haulage. Productivity is increased with reduced truck fleet requirements and shorter truck cycle times. As pits deepen and hauls lengthen, in-pit crushing and conveying systems become even more economically attractive, since conventional truck haulage costs increase dramatically with pit enlargement. Consequently, the economics of belt conveying are particularly attractive in large-volume operations, in those where steep climbs are involved, and in those where haulage distances are longer than a few miles (kilometers).

Chapter 13.6
FUTURE CONCEPTS IN SURFACE MINING

THOMAS ATKINSON

13.6.1 INTRODUCTION

Many surface mines have depleted reserves of shallow, high-grade ores in simple geologic settings. This will inevitably require mining companies to consider deeper deposits of greater complexity, with more critical groundwater conditions, increased geotechnical problems, greater stripping ratios and waste volumes, which are further from markets. While underground mining has made considerable progress in improving productivity over the past 10 years, however, surface mining has not matched these improvements (Atkinson, Burdon, and Longworth, 1985). During this period, two major factors have mitigated against surface mining:

1. The depletion of economic reserves near the centers of population and the large, extremely expensive infrastructures required for remotely located mines may cost many times that of establishing the mine itself. This dictates the need to achieve economies of scale, which have been pushed to the limits over the past three decades.

2. The activities of the environmentalist/conservationist lobbies.

In the past, as economic conditions deteriorated, the problems were reduced by (1) increasing equipment size to achieve economies of scale and (2) productivity gains achieved through increased efficiency. Neither of these solutions may remain available today since equipment sizes appear to have reached a plateau in the early 1970s, and only very marginal improvements in efficiency are available when full capacity using conventional systems is possible.

For smaller, short-life operations, major reductions in infrastructure costs may be achieved by the "fly in/fly out" of personnel, a well-established technique in the oil industry. The economics of this operation has yet to be tested for large-volume production mines.

This chapter explores possible concepts and trends for the future in surface mining. For other views, applicable to various forms of mining, see Section 22.

13.6.2 TOWARD CONTINUOUS MATERIALS HANDLING SYSTEMS

The disproportionate increases in price of petroleum-based products compared with the general rate of inflation since the OPEC action of 1973 have forced mine operators to consider continuous systems (usually with belt conveyor transport) to take advantage of cheaper electrical energy generated from other fuels, for example, coal. Truck transport systems are generally favored by mining engineers because of their inherent flexibility in operation, but in terms of energy efficiency, trucks utilize only about 40% of the energy consumed for payload, the remaining 60% being required to haul the tare weight of the truck. Belt conveyors use up to 80% of the energy consumed for transporting the payload.

Although oil prices were slashed in 1986, the energy costs for trucks in many parts of the world still remain in the region of 50% greater than for conveyors on level grades and 300% greater on steep grades. Belt conveyor systems are less labor intensive, relatively simple in design and operation, reducing the need for highly skilled labor, the cost of which tends to inflate at a rate greater than the general rate of inflation. Major operating cost savings are possible with belt conveyor systems compared with truck haulage, and the recent considerable interest in continuous systems is a result of these potential savings (Atkinson, 1985; Brealey and Atkinson, 1968) and may be summarized as follows:

1. Low operating costs, low manpower requirements, and long-life equipment (i.e., relatively inflation proof).

2. The need for buffer storage, etc., between individual operations can be almost eliminated.

3. Peaks of electrical demand, mechanical stress, materials flow, etc., are considerably reduced.

4. Lower specific energy requirements (hp/ton-mile or kWh/t-km).

Major disadvantages are

1. High capital cost.

2. If one component of the system is defective, the total system must stop (although availabilities of about 80% can be achieved).

3. Best suited to large-volume, long-haul operations.

13.6.2.1 Continuous Excavators

For many years, large, full-face tunneling machines have excavated medium-to-strong rocks using disk cutters. The first Robbins Mobile miner, fitted with disk cutters and now in early operation, has successfully cut extremely strong quartzite [40,000-psi (275-MPa) uniaxial compressive strength (UCS), with up to 93% free silica]. For most full-face tunneling machines, it is essential to provide rigid constraint to contain the reaction to cutting. In the surface mining situation, the cutting forces are transferred through the machine to its base. The machine must have the right combination of geometry and mass to contain these forces. This probably requires a different machine configuration (and probably a bench layout) from that of existing machines, with shorter booms, squatter profiles, increased crawler area, and possibly a limit on digging height. Additionally, the machine must handle larger volumes than tunneling machines. The bucket wheel excavator (BWE), and possibly the placer mining dredge, is the only machine currently excavating at the necessary rate. The BWE is the most effective machine for mining large outputs in weak ground. Its application is extending into stronger formations (e.g., Neyveli, India, and Athabasca, Canada), but the BWE's marginal performance near the limit of its application zone indicates that far more in-depth investigation is required in this area.

Surface mines encounter a range of weak-to-strong materials. The rotating bucket arrangement of the BWE, which can efficiently clear large volumes of cuttings for loading onto a belt conveyor, unfortunately does not perform well in more competent ground. Roadheader-type machines perform well in weak to medium-strength rocks (up to 14,500 psi or 100 MPa UCS) and give reasonable service in "soapy" materials, because the pick peripheral speeds are sufficiently high to keep the cut-

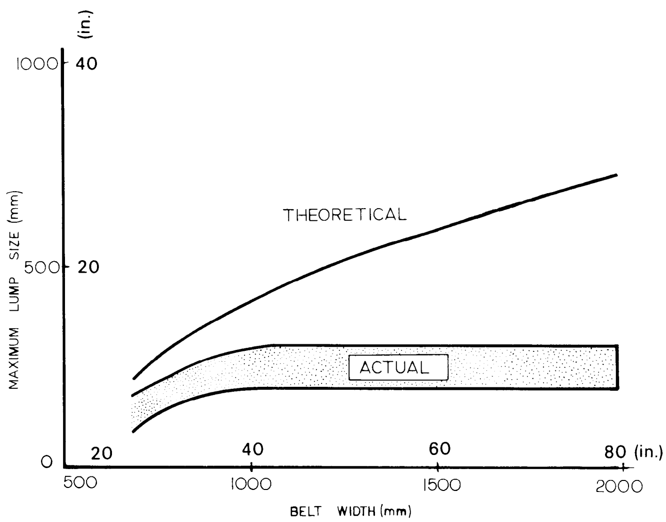

Fig. 13.6.1. Maximum lump size for belt conveyors.

terhead free. To meet the demands of surface mining duties, new designs are necessary to clear the large volume of cuttings from the cutterhead and load them onto a continuous transport system. Disk cutters may not excavate well in weak ground, such as engineering soils (particularly if clay-rich), but they give excellent performance in medium to strong rocks. Again new designs are needed to transfer the large volumes of cuttings to a continuous transport system.

These observations point towards a modified BWE configuration with driven precutters (e.g., disk cutters or roadheader-type cutters) in front of each bucket. Compensation for differing angles of attack due to changes in slew speed would probably be necessary but should not be an insurmountable problem. *It should be noted, however, that abrasion is of much greater importance for continuous excavations than for single-bucket excavators, and much more detailed study of the properties of rocks to be excavated is necessary* (Atkinson and Cassapi, 1984). The research and development of such a machine should be one of concerted effort over the next five to ten years.

13.6.2.2 In-Pit Crushing

Because of the absence of a suitable continuous excavator, in-pit crushing systems have attracted considerable attention in order to obtain the benefits of belt conveyor systems (Chapter 13.5) (Atkinson, 1985; Anon., 1982). A blasting/excavator/crusher/belt conveyor operation must work as a system, the excavator dipper (or bucket) being used so it can handle only lump sizes that will pass into the crusher. To avoid excessive secondary breaking, the blast design must ensure adequate fragmentation. Similarly, the crusher must reduce the feed to a lump size that can be handled by the conveyor belt widths. Fig. 13.6.1 shows theoretical and practical lump sizes for various conveyor belt widths.

The application range of various crusher types appears in Table 13.6.1.

Gyratory crushers can handle strong, abrasive rocks but are relatively heavy, incur high capital costs, and have a high feed height. At the other end of the range, roll crushers are relatively light, have a low feed height, a reduction ratio of 5:1 (usually adequate for feeding belt conveyors), can handle weak or sticky materials, and have low capital cost. They experience high wear rate for materials containing more than 4 to 5% free silica. In many situations, the ideal crusher must have a low feed height and low capital cost and, in general, be able to handle medium to strong, abrasive rocks; that is, it should combine the advantages of the gyratory and roll crushers but not have the disadvantages of either. The immediate thrust must be to reduce the size and cost of crushers (reduced size will also increase mobility). The MMD crusher has interesting possibilities (Potts, 1986).

The second approach must be directed towards improving the energy consumption of crushers, especially as large volumes of waste must be crushed, which represents an additional energy cost for which no additional revenue is generated. This requires a much better specification of the crushing requirements and an improved knowledge of rock material behavior during the crushing process. The use of ultrasonics in grinding provides spectacular reductions in energy requirements. A similar approach to crushing practice (including microwaves) may produce more economic operation. If this method is successful, it would have a major impact on the whole field of comminution. The long-term future may be in a new technique such as ultrasonics rather than in mechanical crushing.

13.6.2.3 Run-of-mine Rock Conveying

A recent US Bureau of Mines (USBM) study (Martin, Noble, and Derby, 1984) considered the use of belt conveyor systems for *blasted rock without crushing* (termed "mine-run rock"). It was proposed to use a crib and cable design very similar to early cable belt conveyor systems. The main factor that limits lump size on conventional belt conveyors is collision impact between the large lumps on the moving belt and the fixed idlers, the impacts damaging both idlers and belt. The rope-driven, crib supported design eliminates this problem (Fig. 13.6.2). A further major problem is due to impacts and blocked chutes at transfer points. The effect of impacts can be greatly reduced by the use of closely spaced, pneumatic-tired, impact idlers under the belt, a grizzly that allows fines to fall on the belt partially absorbing the impact of large lumps, and finally a chute that accelerates the large lumps to greater than belt speed, in the direction required. The life of the relatively short drive ropes that contain a "long splice" with a short profile is an unknown.

A disadvantage of the design is the belt speed limitation of 500 to 700 fpm (2.5 to 3.5 m/s), compared with up to 1000 fpm (5 m/s) of conventional high-speed belt conveyors.

Inclinations up to 20° are possible using the crib and cable design, compared with 16 to 18° with conventional belt conveyors for similar materials. The vibration of a material created by the moving belt over fixed idlers and the up-and-down motion of the belt as it passes over the idlers are eliminated. Initial tests carried out by the USBM appear promising.

The particle-size distribution of mine-run rock is not readily available; furthermore, it changes as rock properties and blasting effectiveness change. Generally, the maximum chord length of the largest lumps does not exceed 5 ft (1.5 m). In some mines, as little as 2% is this large, while generally it does not exceed 10%. By scalping off the large lumps prior to loading onto a mine run rock conveyor, the crushing operation can be eliminated. The oversize material can be dozed together and loaded into a truck, or broken by a pile hammer and loaded onto the conveyor.

The particle-size distribution of mine-run rock in varying conditions warrants further study. One possible method of estimating the maximum chord length of material in a rock pile is by miniature aerial photography carried out by model aircraft

Table 13.6.1. Application Ranges of Crusher Types

Rock/Soil Code[1]	Description	Compressive psi × 10³	Strength MPa	Crusher Type[2] G	J	H	RC
R7	Extremely strong rock	> 30	> 200.0	X[3]	M		
R6	Very strong rock	15.0–30.0	100.0–200.0	X	X	M	
R5	Strong rock	7.5–15.0	50.0–100.0	X	X	X	M
R4	Moderately strong rock	2.0– 7.5	12.5– 50.0	X	X	X	X
R3	Moderately weak rock	0.7– 2.0	5.0– 12.5		X	X	X
R2	Weak rock	0.2– 0.7	1.25– 5.0			X	X
R1	Very weak rock	0.09– 0.2	0.60– 1.25				X
C4(G4)	Stiff (weakly cemented)	0.02–0.09	0.15– 0.60				X

(Walton, 1985), the photographs being image analyzed so that blasting procedures can be modified as required.

13.6.2.4 High-Angle Conveyors

The elimination of truck haulage out of relatively deep pits, using conventional belt conveyor gradients, invariably requires conveyor ramps at much flatter angles than the pit slope angle. This results in additional excavations, often during the early life of the mine, which has an adverse effect on the discounted cash flow rate of return for the project (Atkinson, 1985). The conveyor ramp can also create sharp re-entrant angles, forming promontories into the pit and reducing pit wall stability in the conveyor ramp area. To overcome these problems, high-angle (HAC) (> 40°) and steep-angle conveyors (SAC) (18 to 40°) are in use and under development.

Several different belt systems have been proposed (Fig. 13.6.3), including (1) the "sandwich" belt, (2) corrugated "bellows" belt (e.g., "Flexowell"), and (3) the "pipe" belt. These may be installed on mobile or fixed installations. There are three basic mobile installations.

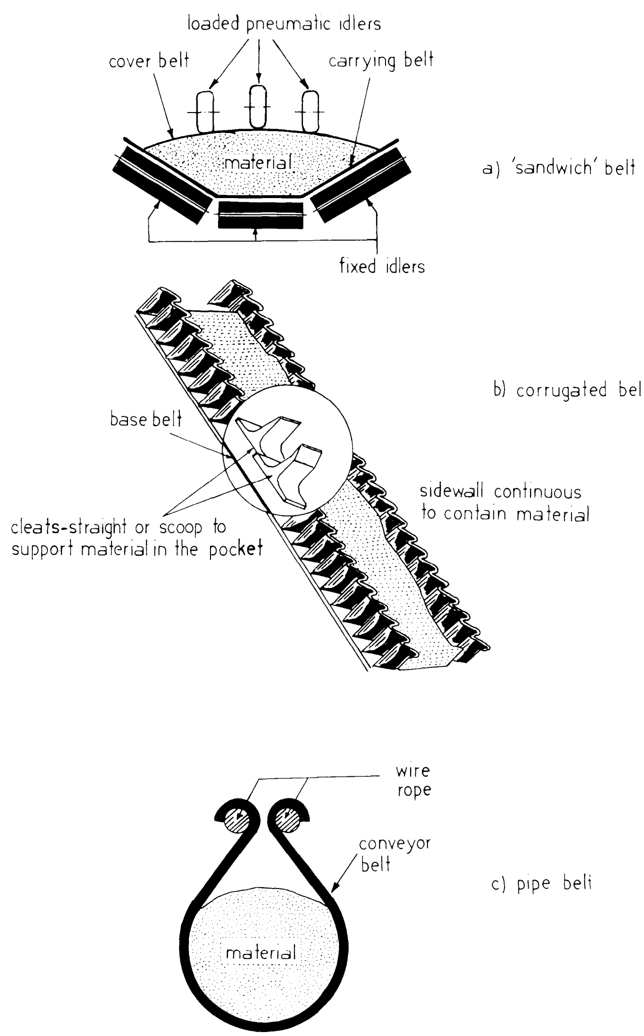

Fig. 13.6.3. Belt systems for high-angle conveying.

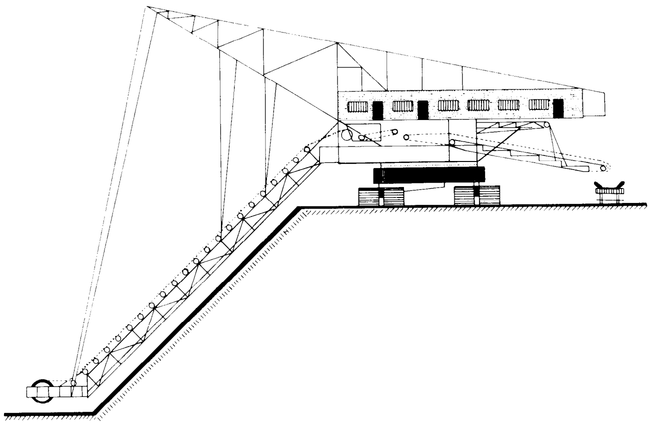

Fig. 13.6.4. High-angle conveyor: dredge type.

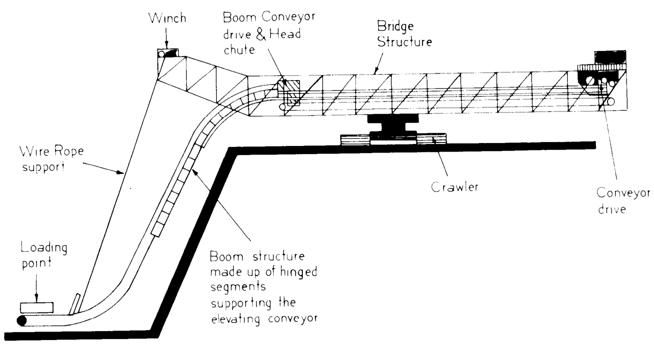

Fig. 13.6.5. High-angle conveyor: retractable boom type.

BENCH LIFT CONVEYORS. These conveyances are usually crawler-mounted bridges of triangular tubular section. Bench height adjustments are made by positioning the crawlers to change the inclination of the bridge. Special leveling devices are required to correct the inclination of the conveyor at the loading and discharge points. At least two manufacturers are developing this design probably for SAC, which is an extension of conventional bench lift conveyors (Brealey, 1963). The machine is relatively cheap to construct but is inflexible in operation.

DREDGE DESIGN. This is based on a bucket chain excavator configuration, that is, a crawler-mounted machine standing on top of the bench (Fig. 13.6.4), the boom being made of rigid linked sections. No slewing mechanism is being proposed to reduce cost. The boom can be raised to a horizontal position and the machine crawlers maneuvered to swing the boom over level ground for maintenance. It has the advantage of being more mobile than the bench lift conveyor; the boom angle can be altered to suit the bench slope, but it is of higher capital cost. This machine is being developed by a German manufacturer for vertical lifts up to 100 ft (30 m).

RETRACTABLE BOOM, MOBILE ELEVATOR. This is a recent Australian development using a segmented, hinged retractable boom (Fig. 13.6.5). It will be a crawler-mounted machine, standing on the top of the bench with the same advantages as the dredge design (James, 1985). It could be up to 50% lighter and of lower capital cost than other equivalent single-standing machines, with a much lower profile, reduced wind loads, greater stability, and faster relocation. The boom length is adjustable and is claimed to be capable of vertical lifts of 180 ft (55 m). Because the boom is retractable, maintenance work is greatly simplified. The boom length can be varied to suit the bench height and the boom angle varied to suit the bench angle.

The high capital costs of HAC and lack of experience in their use have been major deterrents to their adoption. HACs (up to 90°) are in use in other industries with vertical lifts of 300 ft (90 m). The newer developments should provide greater confidence in their use, for example, the "Hurise" conveyor.

13.6.2.5 Cross-pit Conveyors

Cross-pit conveyors can greatly reduce the haul distance of around-the-pit truck or belt conveyor routes in terrace mining operations. Depending on pit length, they can have lower capital cost than around-the-pit systems and invariably have lower operating costs. Bridge units (two sets of crawlers) are available from British and German manufacturers, while single-crawler, "spreader" types are available from German and US manufacturers. A spreader-type, cross-pit conveyor of 1000-ft (300-m) overall length and a 670-ft (200-m) discharge boom is scheduled to go into service in a Texas lignite mine.

Many mine operators are deterred by the presence of a conveyor structure crossing the benches of a mine since it requires more precise planning and scheduling, especially for bridge units that require a graded track on both sides of the pit. The advantages of the cross-pit conveyor are enumerated elsewhere (Collin and Waring, 1983).

13.6.3 DEVELOPMENTS AND TRENDS IN TRUCK HAULAGE

13.6.3.1 Conventional Trucks

From 1955 to 1975, substantial increases in mine truck size occurred due to the development of (1) economic, reliable, high-speed, lightweight diesel engines and (2) larger, long-life, high-load capacity tires. By the late 1970s, the haul-cost vs. truck-size curve had leveled out with an economic payload of 170 tons (150 t) or above (providing the mine could accommodate such truck sizes). The six major reasons inhibiting development of more economic, larger-capacity trucks are

1. Lack of suitable engines.
2. Cost of construction of haul roads (Atkinson and Walton, 1983), particularly on loading benches.
3. Truck maneuverability problems.
4. Maintenance problems due to access difficulties.
5. Poor potential cost savings, inhibiting development by manufacturers.
6. Problems in manufacturing, transporting, and handling larger tires.

The major routes for cost reduction are to achieve higher speeds with larger trucks fitted with higher power, GVW (gross vehicle weight) ratios (upgrade) and better braking, steering, and handling characteristics (downgrade), together with driverless (or semi-driverless operation), so that shift change, meal break, etc., delays are eliminated.

Developments beyond 170 tons (150 t) envisage the "power cube" engine, that is, a removable module engine of compact dimensions for easy removal and maintenance. Note that volume is far more important than mass as engine mass is only about 2% of GVW. Based on this concept (Atkinson, Burdon, and Longworth, 1985), Table 13.6.2 indicates future availability.

Mechanical transmissions will probably remain at 1600 hp (1190 kW) maximum, while two axle configurations with 2200-

Table 13.6.2. Future Availability of Truck Engines

Engine Power		Year	No. of
hp	kW	Available	Manufacturers
1343	1800	1985	4
1492	2000	1986	3
1615	2165	Available	1
1695	2272	1987	1
2014	2700	1987	1
2596	3480	?*	1

* Current turbo-charging technology applied to existing 16-cylinder engine.

hp (1640-kW) engines are available, and a three-axle, 3300-hp (2460-kW) system has been developed.

The largest tire in operation, 40.00 × 57, appears to be the upper size limit, and increased tire loadings are being sought. Radials are reported to be reducing fuel consumption, as well as increasing operating speeds, that is, conventional rather than off-highway development. Increased TMPH (ton-mile/hour) capacity is available from radials, but at increased first cost. One-piece, 15° rims, presently operating and now accepted in the United States are achieving cost reductions.

Disk brakes have virtually replaced drum brakes. Dry disks have the benefits of easy access, low cost, and cost-effective component life. Wet disks (oil-cooled) are fitted on one truck, using pump-circulated oil as the coolant, the rear brake pack operating as service brake and retarder. Long-term operating costs have yet to be established for comparison with the proven 20,000 to 50,000 hours achieved by dry disks.

Electric drives have the potential for adaption to monitoring and diagnostic assistance, minimizing down time and erroneous service calls. Electronic engine control is being developed to improve fuel efficiency, with reduced pollutants on starting and better emission control. For smaller trucks with mechanical transmissions, electronic control will produce a wider range of gear ratio combinations to maintain optimum engine outputs to suit haul road profile and conditions. Monitoring of payload and load distribution will possibly bring reduced operational problems.

13.6.3.2 Trolley-assist Truck Haulage

Although trolley-assist systems have been available for some years (Shevyakov, 1965; Atkinson, 1969), they have received most attention since the increase in oil prices in 1973. The main advantages of trolley-assist are

1. Reduced costs due to reduced fuel consumption. On adverse grades, electric power is used (except for the service loads on the truck).
2. Increased productivity due to increased speeds and reduced cycle time.
3. Reduced electric wheel armature currents allowing long hauls out of deeper pits.
4. Greatly increased engine life.

The South African operations—Sishen, Palabora, and Grootegeluk—employ trolley-assist systems. The full benefits of the system have probably yet to be achieved since full-capacity working has not been required, but other advantages, especially increased engine life, have been established.

Trolley-assisted haulage layout was discussed in Chapter 13.4.

13.6.3.3 Mammoth Trucks

A recent paper (Walker, 1985) advocated the development of even larger trucks. The paper analyzed the historical data of

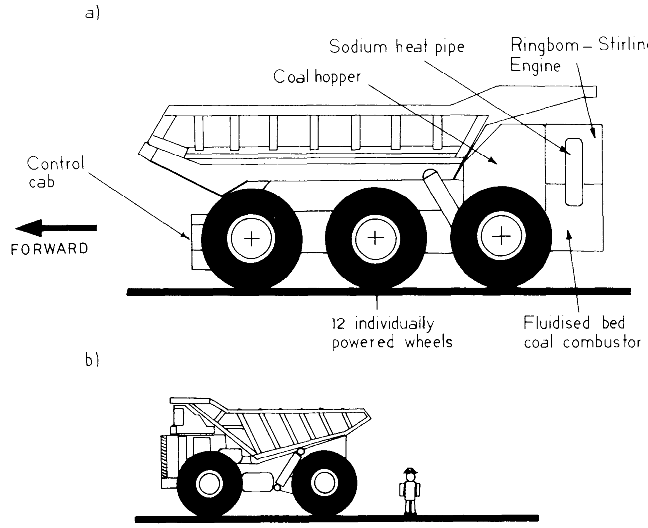

Fig. 13.6.6. Comparison between (a) projected 1000-ton (900-t) truck and (b) existing 200-ton (180-t) truck.

mine trucks to establish the power laws governing their past development, and using these laws, projected the geometry of 500-, 750-, and 1000-ton (450-, 670-, and 900-t) trucks (Fig. 13.6.6). The projections are not impractical. Diesel oil will again be expensive and in short supply in the future. The use of steam engines and coal-fired diesel engines has been advocated previously (Atkinson, 1982), but here the alternative of the external combustion engine (the Stirling engine) is suggested. Microprocessor control with driverless operation is considered feasible, the unmanned vehicles operating under the direction of a central computer. If the development from 30 to 300 tons (27 to 270 t) over 30 years is considered, the 1000-ton (900-t) truck could be a reality by the end of the century.

13.6.4 ROCK FRAGMENTATION

13.6.4.1 Blasthole Drilling

Rotary blasthole rigs have changed little since their introduction. Drillhole sizes up to 15 in. (381 mm) in diameter are most popular, and it is unlikely that hole diameters, say, up to 17½ in. (445 mm) will give adequate blast control or be cost effective. Deeper holes are attracting interest (200 to 250 ft, or 60 to 75 m) requiring longer masts, crawlers, and drill pipe. Angled drillholes can be profitable, and the ability to angle the crawlers to correctly orientate the rig to the bench face at each hole is essential. Greater inclination of the hole is desirable, but this creates problems due to cuttings packing at the lower side of the hole and some form of secondary flushing is indicated. Additionally, control of drill-pipe deviation is needed. Recovery of data from the drilling operation can be used to improve blasting effectiveness, reduce costs, and improve productivity. Tailored blasting, a more innovative approach to ground preparation, involving decked charges, emulsion explosive water stoppers, phased initiation, etc., is currently available but requires better information from borehole logging.

The rig of the future will have an automated drilling package (Waller, Ambrose, and Casappi, 1987) that will

1. Continuously perturb all the drilling parameters (i.e., thrust, peripheral speed, flushing rate) and select the best combi-

nation of parameters to maximize penetration rate, with minimum bit wear. The major obstacle is measurement of bit wear while in the hole.

2. These changes will be continuously monitored to provide blast design information.

3. Deviation of the drill from the desired direction will be monitored and the thrust altered to correct the deviation.

4. The crawlers will be programmed to locate and orientate the rig at each blasthole, using a gyro.

5. The hole locations, borehole inclinations, etc., will be logged so that each blast can be back analyzed.

13.6.4.2 Explosives

The effect of fragmentation and rock-pile profile on excavator performance and overall cost per ton have previously received inadequate attention (Winzer, Anderson, and Ritter, 1983). There are opportunities to use untapped, present-day technological advances. The present state of the art employs:

1. Bulk ANFO (plus water gels or emulsions in wet holes).
2. V1 sequencing with surface delays.
3. Equilateral triangle blasthole patterns, for optimal explosives distribution.

The following available techniques have the potential to significantly reduce costs:

1. Dense ANFO for increased energy and reduced drilling costs, particularly in stronger rock (Harries and Grieve, 1978).
2. Pre- and post-splitting for more economic blasting and improved slope stability.
3. In-hole delays for optimizing blasting, improving blast design, and tailoring blasts.
4. Cast blasting to exploit the cheap chemical energy of explosives compared with conventional excavation and transport (Chapter 13.2.3) (Atkinson, 1983).

The future indicates the need for further blasting research to incorporate the quality of the rock mass gained from better monitoring, blasting analysis [e.g., fragmentation and burden movement (Winzer, Anderson and Ritter, 1983)], and the use of computer modeling for the prediction of the effects of changes in blast parameters.

13.6.5 AUXILIARY AND SUPPORT DEVELOPMENTS

13.6.5.1 Electrical Power Systems

The economy of size and great flexibility of electrical drive systems has lead to their widespread use in the surface mine plant. They also have the advantages of reduced maintenance compared with other drives, and they are competitive in energy costs. Despite these apparent advantages, there is still room for improvement in their design and in their cost of operation.

Electricity costs have reached a level where they are a major component of the operating cost in electrically powered, mechanized mining, and it is therefore, well worth pursuing methods of reducing this cost. Whether electrical power is generated on site or obtained from a utility supply company, there are two cost components: a maximum demand cost and a unit cost. The unit cost is based on the quantity of electricity consumed, usually measured in kilowatt-hours (kWh). To minimize this cost, the consumer should be concerned with the efficiency of utilization of electrical energy and the potential advantages of using low-loss machines and controllers. The pay-back period of the difference in cost between normal and low-loss motors is often less than 1 year.

The maximum demand, measured in kilovolt-amperes (kVA), is used to determine the maximum capacity and, therefore, the cost of the supply system. Mine supplies experience large fluctuation in load, mainly as a consequence of cyclic operations that are typical of draglines and shovels. Devices are currently available to continuously monitor the maximum demand and, if necessary, limit it by shedding load by the switching off or the current limiting of plant. Automatic maximum demand control is not yet in widespread use, but there are many operations that could benefit from its application. In the future, individual large plant items should be fitted with maximum-demand monitors, data from which can be used to minimize peaks. Centralized control can de-synchronize operations avoiding simultaneous peak demands from a number of cyclic operations.

During design, it is important to adopt a systems approach to the whole of the drive, from the driven load right back to the point of supply. Dynamic models of induction motors have been designed, and complete computer-aided design (CAD) of electromechanical drives is used in other industries. It is also important to match the power ratings and speeds of multi-drive plants to ensure that the over- or under- capacity of one drive does not prevent the full utilization of the other drives.

For the overall design of the power distribution system, both the static and dynamic performance may be checked by using load flow models (Trutt and Thomas, 1981). Where static controlled variable speed drives or non-linear loads are used, then the effects of harmonic pollution and the desirability of filtering should be checked (Stratford, 1980). It is important that the operational data used to develop models are based as far as possible, on practical operating experience and not on idealized cycles that are only rarely achieved.

Variable speed drives are in common use in surface mines. In the future, most will be based on solid state or static control systems. The trend will be away from direct-current machines towards synchronous and induction machines driven via variable frequency and voltage invertors. For low speed or at very high power, the cycloconverter is preferred, but continued improvements in semiconductors—in particular high-speed, high-power switching transistors and gate turn-off thyristors—will extend the range of application of link converters. In addition to increasing power capacity, improvements in controller performance can also be anticipated with faster responses, improved reliability, extensive condition monitoring and self-diagnostics, reduced harmonic pollution, and maximum demand control. The greatest advances will come through the use of automatic control, most probably based on microprocessors and including closed loop, sequencing, and optimal and intelligent knowledge-based control systems.

As a consequence of the high cost of small-scale power generation, it has only been used for emergency power, peak lopping, supply stiffening, or in locations too remote for connection to utility supplies. The efficiency of the small-scale generation plant has improved, and this, together with waste heat unitization, is making local total energy programs attractive.

13.6.5.2 Electronics

Rapid advances in the capabilities and applications of electronic systems during the past three decades have already had a significant impact on the industry. As yet, there are no signs of any slowing in the rate of advance of electronic technology, and we can anticipate continuing improvements for some time to come. Despite its many successes, however, the rate of application of this technology in the mining industry has been retarded by some early failures.

The greatest advances made in the field of electronics are those resulting in simplification. Simplification reduces the burden of design work and improves reliability. Although systems may be complex, they are built up from a network of individual stages. Without simplicity of design at each stage, the feasibility of complex systems is destroyed. Greater emphasis can now be placed on the whole system performance and on its relationship with the application and the user.

One of the major fields of application for electronics in mining is in operational monitoring and control (Chapter 12.6). This involves the use of a measuring system to monitor critical operating parameters and relay this information to the user. The user may be an individual or an automatic control system. In either case, the measured parameter is compared with a desired value and the difference, or error, is used to modify the operation in order to minimize the error. This forms the basis of *control engineering,* another enabling technology, the full potential of which has not yet been realized. There are a number of reasons for this, some technical and some human.

The most severe technical limitation to our ability to control operations in mining is the availability of transducers to convert operating parameters into measurable signals. Often that transducer is required to operate at the "front end" of the process under severe environmental conditions and, as a consequence, suffers from poor reliability. These problems have long been recognized, and investment in research and development has yielded some suitable devices. The solution has often been to derive the parameter via an indirect measurement. This has enabled either the transducer to be moved to a more protected environment or for an unmeasurable parameter to be derived by its effect on some other measurable parameter(s). There is still plenty of scope for development in transducer technology, both in traditional techniques and in the utilization of optical, acoustic, chemical, and bacteriological techniques.

Since the majority of electronic systems into which these transducers will feed will be digital, then wherever possible, digital transducer techniques should be developed and utilized.

Much of current control engineering has evolved from the analysis and design of simple positional and speed control systems. In this situation, it is not difficult to formulate equations describing the precise response of the system and the control actions required to obtain the desired performance. In the real world of mining, the processes involved do not readily yield to rigorous analysis. Despite the opinion of some control engineers, it is not necessary to obtain a rigorous mathematical model of a process as a prerequisite to satisfactory control. There are many applications for which an approximation for the system is quite sufficient to get a control scheme started. Fine tuning and adaptation can then be used to optimize the response.

Often as a precursor to a full automatic control system, a scheme of data acquisition is used to gather operating data. The specification of the system must cover those parameters that are critical to the operation (Anon., 1983). There is a great temptation to collect data simply because the technology to do so is available. Data acquisition costs money and must be fully justified and followed up with an effective strategy for data utilization (Harrison, 1978).

Improvements in electronics technology have had impact in other areas, principally in digital electronics and computing, areas that are discussed separately in the following.

13.6.5.3 Image Analysis

Vision is one of the most advanced and complex of man's senses. Those of us who enjoy adequate vision are capable of a vast range of analytical observations. Some of the most basic functions of vision are to recognize shape, outline, color, and/or intensity and movement. Image analyzers are a rudimentary electronic equivalent to vision. They are developing rapidly and, in some situations, can replace human observers, frequently with dramatic improvement in performance.

Television images are familiar to most of us. The normal TV picture is made up of 625 horizontal lines with the picture refreshed at 25 times/sec. Image analysis systems further subdivide the horizontal lines so that the final picture is made up from a matrix of individual points called pixels. The intensity of each pixel is then measured and assigned a gray scale value. In color systems, the process is repeated for three separate primary color frames. Grouping of pixels with similar gray scale values, counting and determination of orientation enables the recognition of shapes and objects and the measurement of areas and a range of other tasks.

The technique has already been applied successfully to mineral identification tasks in both geologic and mineral processing applications. In the future, we can anticipate a wider spread of new applications for these systems in operations where vision and visual identification of features is important.

APPLICATIONS. Application of image analysis techniques to various aspects of surface mining operations will occur over the next few decades. The advent of this technology results in the need to define areas of possible application. A number of areas would appear to offer promise, all of which could broadly be defined as *automatic real-time surveying.*

This includes the use of multiple-scanning video cameras to provide images of the pit from a number of positions. These images could then be processed and the position of particular features identified from each of the video signals. Precise measurement of the camera orientation and magnification would provide data that would allow the calculation of three-dimensional coordinates of features of interest (using intersection techniques). "Targetless" surveying using similar principles but without image analysis and employing laser beams is already available (Anon., 1985).

Thus a single system would be capable of comparing current images with previously stored images to provide real-time information for the following:

1. Production volumetrics.
2. Slope stability monitoring.
3. Equipment positioning (possible links with automated dispatching).
4. Geologic data collection.
5. Blast performance monitoring.

Constraints on this type of system being developed in the near future are

1. Limitations of current recognition techniques to regular shapes.
2. Insufficient processing speed and capacity.
3. Recognition of the implication of image changes.

As images analysis techniques develop, however, and the benefits of parallel processing and artificial intelligence start to be applied, there would appear to be no reason why this type of system could not be introduced as a means of drastically reducing surveying costs while providing management with the most up-to-date operational information.

Some of the other potential operational applications of image analysis are the following.

Manless Operation—Positioning of the bucket of shovels, bucket wheel excavators, or draglines is controlled by the operator who relies entirely on visual identification of the desired digging position. Vision is also used to locate and maneuver the bucket to bring it to this position. Image analysis could be used to identify the broken material and blocks in the rock pile or to delineate the target material and waste and then guide the bucket to the optimum position.

A similar situation exists in truck haulage, with visual identification of the desired road position and visual feedback used to assist in maintaining the truck in that position. There are other potential truck guidance techniques that might prove easier to implement, but image analysis is one of the few techniques able to identify obstacles in the truck path.

Closed-circuit TV has already been used to provide blind-side vision for BWE operators and rear vision for truck drivers. Accidents during truck reversing are still too frequent, and in addition to TV, radar and ultrasonic image techniques have been used to give warning of obstacles.

Fly Rock Analysis—Conventional TV cameras do not respond well to fast-moving objects. Recently developed charge-coupled device (CCD) cameras have overcome this problem, and high-speed imaging is now possible. High-speed video used as input to an image analyzer could enable automatic fly-rock analysis.

The input to an image analyzer is not restricted to conventional or CCD cameras using visible light; ultraviolet and infra red imaging is also used. For precision work, scanning laser imaging could be used, this carries the additional benefit of distance measuring capability. The scope for real-time photogrammetry has yet to be explored.

13.6.5.4 Ultrasonics

Sonics or sound waves and vibrations can be used for detection and measurements in two main modes: in a passive or listening mode by detecting stress-induced noise, or in an active mode using an artificial source and detecting reflections and/or propagation velocities.

There are two main current applications for passive mode sonics. The first involves periodic monitoring of the vibrations induced in machinery: increasing levels are frequently a precursor to failure. By measurement of the frequency or spectral content, it is often possible to identify which component is failing. The technique has been known for more than two decades but is only now beginning to find acceptance in the industry. In the past, the time taken in measurement and data reduction has deterred from its general use. Modern microprocessor-based portable instruments will do much to alleviate this situation.

The second passive application is in the monitoring of microseismic activity (Chapter 10.3). Small acoustic or ultrasonic pulses (microseismic pulses) are emitted from materials during fracture propagation. Brittle materials such as rock are particularly good emitters of microseismic pulses. The production of microseismic events commences long before total failure, and by measurement of their rate of production, it is sometimes possible to predict failure. Much work has been done in South Africa and the United States on rockburst prediction from microseismic activity (Brink, 1985). The work involves not just the counting of event rates but also the location of each event, as well as measurement of its spectral content and the event's total energy. The technique has also been used with great success for monitoring the growth of hydraulic fractures in a dry-rock geothermal project (Baria, Hearn, and Batchelor, 1985). The technique could be adapted to monitor slope failure and might yet find application in surface mining.

In current applications, sonics have been used to investigate materials properties from the macroscopic, in global-scale seismology, down to the microscopic in detecting flaws and fractures of the order 10^{-5} ft (5×10^{-6} m) in engineering components. Its range of application is staggering, from measurements of rising magma chambers at Mount Washington to the measurement of blood flow in fetal arteries. With high-intensity sources, sonic energy can be used for agitation, homogenization, and cleaning, and at very high intensity, dislocation and material fracture can be induced. Ultrasonics are already in routine use for "stone" breaking—albeit gallstones, with logical progression to rock breaking. The energy consumed in rock breakers far exceeds the specific energy required to fracture the rock. For small particle sizes, in-slurry ultrasonic grinding might be used, while at larger sizes, ultrasonic aided mechanical crushing could be used to improve energy efficiency. In-pit crushing with continuous transport could benefit considerably.

High-energy ultrasonics could also be used as an aid in drilling operations by assisting in breaking out of chips, thereby increasing penetration rate. In conventional core drilling, one of the major problems, particularly when drilling heavily fractured material is core (barrel) blockage. This results in additional tripping and delay while blockages are cleared. By vibrating the barrel using an ultrasonic device, it should be possible to reduce blockages thereby reducing drilling cost.

Surface seismic survey are used routinely for the delineation of geologic structure. Surveys also may be made from borehole to surface or between boreholes. By measurement of the velocity of propagation, it is also possible to derive some of the mechanical properties of the target material, for example, the frequency and orientation of fractures and the elastic constants. More recently, in-seam seismics (Mason, Buchanan, and Booer, 1980) have been used to locate discontinuities in coal seams. The ability to predict changes in the structure of the target mineral is of great value in the planning of production. These techniques will find wider application in surface mining in the near future.

Ultrasonics are well established in the field of nondestructive testing (NDT) of engineering components. Routine testing gives an early indication of fatigue failure or of faulty manufacture. Adaptations of the acoustic camera, as used in medical scanning, can produce 3-D images of internal structure. Probing of the internal structure and microstructure of mineral deposits will be of great assistance in mine and processing plant design and in the assessment of abrasivity.

13.6.5.5 Laser

At this point, we enter the realm of speculation by exploring the potential of the laser. The laser is simply a device capable of producing narrow beams of short wave length, coherent radiation. Larger versions can be used to focus high power into small areas. For a long time, the laser has been dubbed as the solution looking for a problem, but it is now coming of age.

Low-power lasers have been used in surveying work for over a decade, in particular, for alignment and distance measuring (Chapter 8.2). Machine guidance systems have also been developed for underground and surface mining machines. Harrison and Thompson (Harrison and Thompson, 1982) have described a laser-based system for maintaining bench levels in open pit operations. A fixed laser rotating in the horizontal plane is set up to establish the required bench level. A vertical rod fixed to the BWE's boom is equipped with three arrays of sensors that detect whether the boom is above, below, or on the desired level. An indicator in the operators cab gives a clear indication of the position enabling the operator to take corrective action. The advantages claimed of the system include increased productivity, improved drainage, less operations wear and tear on the BWE and conveyors, and a payback period of only a few weeks. An underground system for laser-assisted alignment of roadheading machines has been developed, a system that includes automatic profile control (Anon., 1986).

In open pit operations, items of plant fitted with retro-reflectors could be located by a scanning laser. The ability to continuously locate plant is of great importance for effective scheduling and dispatching. The system could also be used to position drilling rigs and excavators. If sufficiently high resolution can be obtained, then the system could be used to monitor slope stability. Electronic total stations currently are capable of these functions but require manual operation; automation is the next step.

High-powered lasers have been used for two decades in cutting and welding operations, particularly with difficult materials. The feasibility of cutting rock has been demonstrated on numerous occasions. Debris removal remains a problem; fluid jets perhaps with the addition of ultrasonic energy might yet provide a solution. The very high temperatures reached during laser cutting glassifies the surrounding material, leaving a smooth and sealed profile, ideal in most mining applications. Laser-profiled holes, which do not even need to be round, would be of great help in maintaining dry holes open in water-bearing or weak strata.

13.6.5.6 Radiowave Techniques

Radiowaves can be used in two main modes: for the conveyance of information of the sensing of electrical characteristics of the surrounding media.

The first mode familiar to everyone is through television. In surface mining operations, the value of radio voice communications has long been appreciated (Chapter 12.6). The quality of voice communication equipment has improved considerably, mainly as a consequence of the development of military equipment. There is still room for improvement in its cost. Radiowave communication is not restricted to voice—digital data is ideal for transmission. Indeed, early radio communication was entirely digital and used Morse code. Data from shovels, trucks, and other mobile equipment can easily be sent over a radio network link and the data used for real-time adaptive scheduling, maintenance, and production monitoring.

Electromagnetic induction techniques may be used in both monitoring and communication. Voice communication using low-frequency induction transmitters and receivers has not yet realized its full potential in underground mining. Low frequency is used since the energy passes through the rock. Development in this field continues, and improvements in the performance and scope of new electronic devices will do much to accelerate the pace. Voice communication in underground, combined underground and surface, and surface mines with difficult high-frequency radio propagation characteristics could all benefit from the use of low-frequency radio communication.

Induction techniques are well established in geophysical exploration. Adaptations of the techniques can be used to detect moving objects or the proximity of metal objects. This has been utilized in the detection of the entry and exit of vehicles from zones within an open pit operation, and by fitting each vehicle with a coding device, individual vehicles can be identified. As an alternative, each vehicle could be fitted with a radio beam that could then be located using scanning direction finding. The same beacon could be used for voice and data transmission.

High-intensity radiowaves can also be used for rock breaking. There are two basic mechanisms involved. The conversion between electrical and mechanical energy can be made in a number of ways, one of which is through the piezoelectric effect. In materials exhibiting the piezoelectric effect, changes in mechanical stress result in an electrical stress or voltage, and vice versa. Many natural materials exhibit some piezoelectric effect, crystalline quartz being one of the best. Strange electromagnetic effects have been reported during the major stress relaxations from earthquakes. It may prove possible to monitor microseismic activity by monitoring the electrical pulses induced in the ground by the piezoelectric effect during microseismic events. The reverse process might be utilized; by the application of high energy electrical pulses, it may be possible to induce sufficient stress to cause failure. Rock failure may be also caused through thermal stress. Electrical impulse or induction heating causes both direct thermal stress and vaporization of interstitial moisture. The resulting weakening and failure could be of use in drilling and grinding operations.

13.6.5.7 Computer Technology

Many of the technologies described elsewhere in this chapter are dependent for their successful exploitation on the availability of cheap, rapid, and powerful computer processing. For discussion of computer methods in general, see Chapter 8.4.

The dramatic rate of growth in computing power per unit cost over the past 10 years seems certain to carry on and may even increase in the near future. The development of the so-called fifth generation of computers, linked to research in artificial intelligence (13.6.5.8), is well advanced.

The new generation computers will employ parallel-processing architecture instead of conventional serial-processing. Parallel-processing subdivides complex tasks into many simpler tasks, each of which is handled concurrently and independently, thus allowing the whole problem to be solved rapidly. Once this technology is developed, performance increases (in terms of processing speed and capacity) of the order of 10,000 times, are expected in the next decade. At the same time, computer hardware will become more compact and rugged. Hardware constraints are likely to be reduced to minimal levels in the next decade or so.

As hardware costs reduce, there is a tendency for computing power to decentralize. This will continue to occur as individual pieces of equipment are provided with the processing required to make intelligent decisions (e.g., each drill, excavator, truck, pump, etc. will have its own processor). Improvements in communications and networking and significant reductions in the real cost of data transfer have already contributed to this trend.

As the performance per unit cost increases dramatically, it seems probable that the limiting factor in the development of computer systems will continue to be software costs. As systems become more intelligent, they are able to program themselves; hence current shortages of applicable software may be a manifestation of “dumb” computing systems.

The computer will become easier to use as developments in the following areas occur:

1. Natural programming languages.
2. Voice recognition.
3. Graphical interaction (3-D holography).
4. Communications and networking.

The techniques that have improved our ability to measure the activities involved in a mining operation have already been discussed. The main feature of the increase in our capability to measure is that the volume and, hopefully, the quality, of the data at our disposal is greatly increased. However, in many instances, certain parameters have been monitored simply because we have the ability to do so and on the basis that the data might prove useful later.

Our current ability to collect, transmit, store, process, and display these volumes of data has been made possible by the digital computer. Current systems are based on a central computer to which all information is directed via outstations. The information is then available for display at a control console via visual displays and indicators. Control actions, which are generated manually at the control disk or automatically by software in the control computer, are then routed back to the appropriate plant again via the outstations. The trend now, and into the future, will be to make more of the control actions automatic and to distribute the computing power to the level of the outstation and the individual plant (Harrison, 1978). This will reduce the demands placed on the operator, central computer, and communication network and will distribute the software development burden.

Performance monitoring systems have already been applied to excavating and transport systems in surface mines. The Bucyrus-Erie BEPAL (Matuszak and Radomilovich, 1984), General Electric DIGMATE (Ivanco and Stobbelar, 1984), and the BHP Engineering DRAGLINE PERFORMANCE MONITOR (DPM) (Godfrey, 1984) are examples of on-board production and condition monitoring systems. These enable detailed analysis of digging cycles, plant, and operator performance, and can lead to reduced down-time, optimization of digging cycles, and maximization of power consumption. The DPM system also tracks the movement of a walking dragline, allowing automatic transfer of the path onto the mine plan, which enables rapid identification of inefficient digging positions.

Most of the effort to date appears to have been in the development of software and transducers. It is probable that these aspects of development will continue to dominate since many manufacturers of computer hardware produce off-the-shelf, ruggedized equipment quite suitable for mining use. It is unlikely that in-house development of computer hardware will be cost effective in the long term.

The level of microprocessor applications is now such that each individual stage of the operation can have its own dedicated controller. Each stage can then feature such facilities as

1. Signal conditioning and linearization.
2. Automatic closed-loop control.
3. Detection and action to alarm conditions.
4. Plant condition monitoring.
5. Self diagnostics.
6. Data collection and distribution.

It is difficult to identify any operation in surface mining that has not or will not in some way be influenced by the microcomputer. Any application must, however, be based on cost effectiveness. The evaluation of the potential benefit requires careful and detailed appraisal. Techniques of evaluation have been described by the British Coal Board (Anon., 1983), and a method based on the return on investment has been given by Harrison (1978).

Microprocessor-based survey instruments have increased both the speed and accuracy of field survey work. Many instruments allow data storage and direct transfer to automatic computer-aided mapping systems. The data can also be used for rapid volumetric calculations, of great value for stockpile or reserve estimation (Hodges and Alderson, 1985).

13.6.5.8 Artificial Intelligence

The objective of *artificial intelligence* (AI) is to extend the range of problems that can be solved with computers to include those that require decisions to be made (Chapters 8.3, 22.2).

The term AI is used to cover a broad range of relatively new computing techniques. The *"expert system"* or *"intelligent knowledge-based system"* falls in the category of AI.

Expert systems attempt to take information about a subject from a number of sources and to transform it into a knowledge base. This knowledge base can then be used to generate a set of rules concerning the subject. A major advantage of these types of systems is their ability to store vast amounts of expertise, to rapidly process this information, and to then make it available to non-specialists. The non-specialist can also feed in facts about a particular process, let the expert system interrogate the knowledge base, and provide recommendations about the process based on the experience loaded into the system (King, 1986).

Intelligent knowledge-based systems (IKBS) have enormous potential in the field of control engineering, particularly in the more difficult control situations typical of mining. They have the great advantage of being able to learn the rules for control of a process from a knowledge base. The knowledge base can be built up from a number of sources that include observation of manual operation or manual input of process rules, or the controller itself can explore the process by perturbation and observation, thereby deriving the process rules. In mining, both the processes and the raw materials suffer from enormous variability. The ability of an intelligent controller to continuously adapt to the changing conditions opens up new fields for automation. The principle has already been used for the control of feed to a grinding plant, and a system for automatic optimization of rotary drilling parameters is currently under development (Waller, Ambrose, and Casappi, 1987). IKBS control will, in the longer term, form the basis for automation of the excavating plant. The controller will learn typical digging cycles from manual operation; this combined with remote sensing of the optimum digging and loading position will lead to fully automatic operation. A similar scheme could be applied to manless trucks and a range of other manual operations.

The ability of IKBS to cope with large volumes of data makes it ideally suited to condition monitoring, maintenance, and diagnostic functions. As the size and cost of the work plant increases, rapid maintenance, fault diagnostics, and correction is vital.

Expert systems are already making an impact outside mining and appear to offer major benefits to the surface mining industry in a number of areas:

1. Geologic appraisal and reserve assessment.
2. Geotechnical hazard assessment.
3. Prediction of operational problems.
4. Enhancing computer-aided design (CAD) systems.

As improvements in data collection and processing occur, it would seem logical to further integrate real-time production data into the knowledge base. This would allow the IKBS to assess the efficiency of operations and to recommend ways of improving operations in the light of experience.

Constraints on widespread introduction of this type of technology are

1. Techniques not yet sufficiently advanced.
2. Processing power and capacity not yet cost effective.
3. Knowledge bases not wide enough (reluctance of experts to give up hard-earned information).

These systems are, however, currently available in relatively crude form and will undoubtedly find application in the surface mining industry in the very near future.

13.6.6 SURFACE MINE DESIGN AND OPERATIONAL PLANNING

The distinction between mine design and mine planning is often ill-defined (Chapters 13.1, 13.2). In the future, the two areas will tend to become even more fully integrated.

13.6.6.1 Mine Design

It is often stated that computers will never be able to fully cope with the complexities of mine design, or more commonly that they are unable to handle the constraints imposed by non-

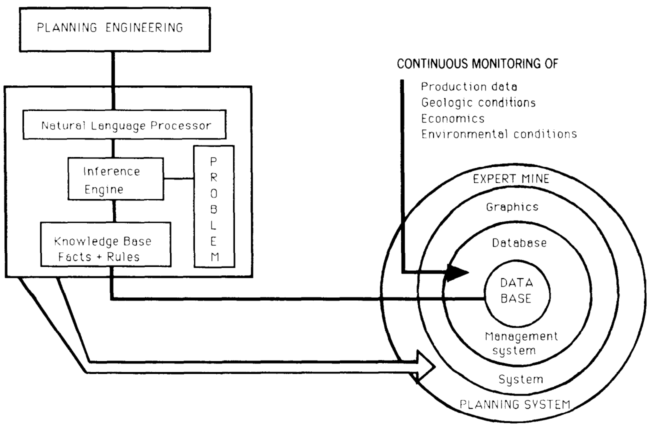

Fig. 13.6.7 Structure of expert mine planning system.

standard working methods (what is a "standard" working method?). Current CAD systems, for example, find it difficult to optimize haul-road positioning and usually rely on an engineer to modify an optimum pit limit design and an optimal mining schedule to produce a sub-optimal overall design.

More *integrated* mining CAD systems will become available that, when combined with increasing efficiency in operation, more powerful processing and greater machine intelligence will result in better design.

The mining CAD systems of today, while appearing to be sophisticated, are in fact no more than simple calculating tools, still relying on human experience and interaction to ensure that sensible mine designs are produced. This includes systems that attempt to optimize pit limit design or production scheduling, because these systems are currently incapable of handling or utilizing fully all the relevant information that is necessary for good design. Although this is likely to remain the case in the near future, in the long term, it seems likely that computers using AI will be capable of producing realistic mine designs, automatically and rapidly. Fig. 13.6.7 shows how this type of system may be implemented.

Computer applications have already resulted in surface mines being designed more rapidly, or resulted in better designs in the same time. As mine design rates increase and the design itself is more automated, it becomes easier and faster to redesign operations.

As the external constraints on optimal mining operations alter both in the short and long term (e.g., changes in market demand and mineral prices, exchange rate variation, etc.), and the data available from operations alter continuously, it becomes necessary to reexamine pit limits, production rates, areas, targets, grades, etc., more frequently to ensure that optimum mining strategies and tactics exist at all times (note the increasing importance of this as deposits become more marginal). Design systems will hence become much more dynamic and increasingly more sophisticated and powerful computing systems become available. The complete redesign of a surface mine in hours, minutes, or even seconds, while appearing ridiculous by today's standards, may not appear so in 10 years' time. Standards are also dynamic in nature.

13.6.6.2 Operational Planning

As increasingly marginal deposits are exploited, there is an obvious need to improve operational planning in order to remain competitive. Operational planning must therefore look to

1. Utilize the available information efficiently.
2. Employ the best analytical techniques.
3. Transfer the results of this analysis to the operations.

As operational planning now employs mathematical programming technology at a number of stages, it appears obvious that improvements in computing technology will benefit the planner. Operations research (OR) techniques will therefore, tend to be employed in production planning on a more intensive basis than is currently the case (Chapter 8.3).

As economies of scale reach their limits, the use of scientific management techniques is being seen as an area for increasing application (Atkinson, Burdon, and Longworth, 1985). The optimization of more complex production problems, using linear and dynamic programming, for example, will become possible as faster processing develops. This will allow larger scheduling problems with more complex constraints to be solved in real time. Once again, feedback of up-to-date production and exploration data will ensure that optimum extraction is taking place. This will become even more important if more flexible mining systems are employed to win minerals.

The boundaries between long- and short-term scheduling and daily production scheduling will become even more indistinct as more complex optimizations are carried out more rapidly.

It seems likely that more and more operational decisions will be made by computer. The introduction of automated truck dispatching systems, although meeting with varying degrees of success at the present time, is an example of the optimizing of operational processes. As teething problems are overcome, communications capabilities increase, and costs reduce sufficiently, it would appear that effective utilization of trucking capacity will become the norm rather than the exception.

Simulation techniques also will benefit significantly from increases in computer power and streamlining of the simulation process itself. More complex processes will be modeled and simulated, providing the planner with better information prior to the implementation of particular schemes. Simulation of parts of the surface mining system is already accepted practice.

The raw data for operational planning will be continuously collected as improvements in transducer and communications technology occur. Increases in the integration of planning and design systems with production data collection and processing will provide the opportunity to employ better input data. Hence, more realistic proposals will result from OR techniques as better input becomes available.

Section 14 Surface Mining: Mechanical Extraction Methods

DONALD W. GENTRY, ASSOCIATE EDITOR
M.K. MCCARTER, SECTION COORDINATOR

Chapter 14.0
INTRODUCTION

M.K. MCCARTER

Surface mining applies to extraction of mineral resources from water and sediments of rivers, lakes, seas, and oceans; from solutions circulating through broken rock and soil; and from rock and soil excavated from the earth. Surface mining is responsible for the majority of mineral production in the United States and a substantial portion of the world's total production. This section deals specifically with extraction methods which employ mechanical processes in a relatively dry environment to free minerals from the earth. The following section, Section 15, deals exclusively with aqueous methods.

With recognition of the importance of reclamation in all activities which temporarily disturb the earth's ecosystems, it is appropriate to classify mechanical extraction methods as either *deferred reclamation* or *concurrent reclamation.* Deferred reclamation is necessary when the shape and logistics of the excavation require that it remain open throughout the productive life of the project. Upon exhaustion of economic reserves, the opening is then reclaimed in a manner consistent with public safety, environmental acceptability, and land use policy. Methods employing deferred reclamation are commonly referred to as *open pit* or *quarry mining.* Metallic ores, industrial minerals, and coal are all extracted using open pit methods. Typical examples are provided in Chapter 14.1.

Dimension stone is also produced in surface mines which, for the most part, remain open throughout the economic life of the deposit. *Quarry mining of dimension stone,* however, employs substantially different elements in the mining cycle, and for this reason is dealt with as a separate chapter (Chapter 14.2).

In the United States and in many other nations, concurrent reclamation is required for most coal and industrial mineral deposits mined by surface methods. These methods may be classified as *area mining* (open cast, strip, or furrow mining), *modi-*

fied open pit mining, contour mining, and *auger mining*. In all four cases, extraction and reclamation are contemporaneous and interrelated. Area mining, as the name suggests, covers large tracts of land and is usually the method of choice for nearly horizontal bedded deposits. In modified open pit and contour mining, the excavations are usually longer in the direction of advance compared to the width. Reclamation is accomplished by back-filling the rearward portion of the pit as the forward portion advances. There are many variations in area and contour mining. These variations depend primarily on deposit geometry and equipment used for excavation and haulage. Typical examples are presented in Chapter 14.3.

Auger mining consists of boring nearly parallel, horizontal openings into thin coal seams. It is employed to recover reserves beyond the economic limits of area or contour mines and where conventional underground methods are not economically viable or technically feasible. The distinguishing feature of this technique is the specialized excavator used to bore the holes and convey the coal to the surface. Because of the more or less specialized application of this technique, it is dealt with separately in Chapter 14.4.

In order to provide a broad overview of current practice, several case studies are presented covering typical operations and principal mineral products. Each presentation follows essentially the same format. A description of the mine and geologic setting provides background necessary to understand the conditions addressed by the selected method. This introduction is followed by a description of mine planning and development. The mining cycle (e.g., drilling, blasting, excavation, haulage, etc.) is then described with an emphasis on operational detail. Quality control of the mine product follows the discussion of unit operations, and the study concludes with a description of ancillary facilities and special processes typical of specific mineral commodities.

Chapter 14.1
OPEN PIT MINING

M.K. McCarter, Jeffery D. Tygesen, Gerald C. Smith, J.W. Villar, A.W. Swanson, Donald K. Winsor, David W. Farnsworth, George B. Whitman, and Bernard L. Grove

14.1.0 SURFACE MINING—DEFERRED RECLAMATION

M.K. McCarter

Open pit mining is a term properly applied to surface methods in which reclamation is deferred until all or nearly all of the deposit is removed within economic limits. The reason for deferring reclamation is usually a matter of access. If mining progresses sequentially to greater depths, backfilling the upper levels will either obstruct haulage routes or endanger work areas at the base of the slope.

Surface mining legislation distinguishes between "open pit mines" (usually metal) and "strip mines" (usually coal). In the western United States, mining permits for some metallic deposits, some industrial minerals, oil sands, and other commodities exclusive of coal may not require backfilling the pit. In this case, complete backfilling may never occur, and reclamation is usually deferred until the operator is certain that the economic limit has been reached.

Typically, overburden removed from an open pit is transported to an adjacent waste embankment or to a previously mined-out pit. Seldom is waste redeposited at its place of origin. In some operations, waste is placed on engineered surfaces and treated to recover values which are not high enough in grade to justify processing through normal milling operations. This activity, referred to as "leaching," is common for copper, gold, and uranium wastes (Dorey, van Zyl, and Kiel, 1988; Duncan and Smolik, 1977; Muhtadi, 1988) (see also Chapters 15.2 and 15.3).

In some open pit operations, typically western US uranium and phosphate deposits, the pits may be large enough or configured in such a way as to allow some backfilling before the entire pit is completed. This may be done to minimize haulage costs, reclamation costs, or as a matter of convenience. This handling of waste, however, is not required as part of the mining process as in other methods to be discussed later (Chapter 14.3). Mining procedures in which backfilling is done as a matter of choice should be described as open pit rather than area mining, contour mining, or other techniques in which excavations are filled and reclaimed contemporaneously with ore extraction.

There is a tendency to refer to all surface mining of coal as strip (area) mining. In some cases, particularly steeply dipping coal seams, the method is actually open pit mining. In such deposits, mining progresses through one or more seams. All overburden must be removed in order to gain access to the deepest economic volume of coal. Since the reclamation is deferred and all or most of the overburden is removed, the method satisfies the requirements for classification as an open pit method.

Mountaintop removal, as practiced in the coal regions of Appalachia and less frequently in bedded deposits other than coal, satisfies some of the requirements for open pit mining in that overburden is transported to a waste embankment located outside the area of mining. Reclamation of the exposed surface may or may not proceed contemporaneously with mining. The term "open pit," however, connotes a depression below the natural ground surface, which is not the case for removing the top of a mountain. Mountaintop removal, therefore, does not conveniently fit either definition. It may be considered "area mining" without concurrent reclamation, or as "open pit mining" without a pit.

Classic open pits such as Bingham Canyon, UT, can be thought of as inverted, truncated, circular cones where the radius of each circular bench decreases with depth. This shape is characteristic of large disseminated deposits such as copper. Open pits in deposits that are stratiform, shallow, and of substantial aerial extent often appear as footprints with steep sides and more or less flat bottoms.

Removal of material proceeds in one of two patterns referred to as *sequential pushbacks* or *pushbacks.* One or more pushbacks constitutes a phase or intermediate plan. The sequential pushback pattern is illustrated in Fig. 14.1.1. In this example, three zones are identified as A, B, and C, and one excavator (typically an electric shovel) would be assigned to each zone. Assuming zone C is ore and zones A and B are waste, it is necessary for cuts to be made through the areas identified as B1 through B4 before ore can be mined in areas identified as C5 through C8. Similarly, areas identified as Al through A4 must be removed before mining can proceed to areas B5 through B8. This pattern requires close coordination so that shovel A finishes its final level and begins to move up to the initial cut in zone A before shovel B moves up to initiate a new series of cuts in zone B. Through proper scheduling, waste stripping can be accomplished so as to provide the "mining room" needed to sustain the required level of ore production lower in the pit.

Zones in a sequential pushback pattern are separated by haulage ramps as can be clearly seen in Fig. 14.1.2. The elevation of the ramp is not constant but cycles through a range of elevations with a more or less constant number of benches between ramps. (The number of levels between ramps may decrease in the upper reaches of a large mine to accommodate the greater circumferential distance compared to benches at lower elevations. Alternatively, larger shovels may be employed at higher elevations to increase the rate of face advance to keep up with

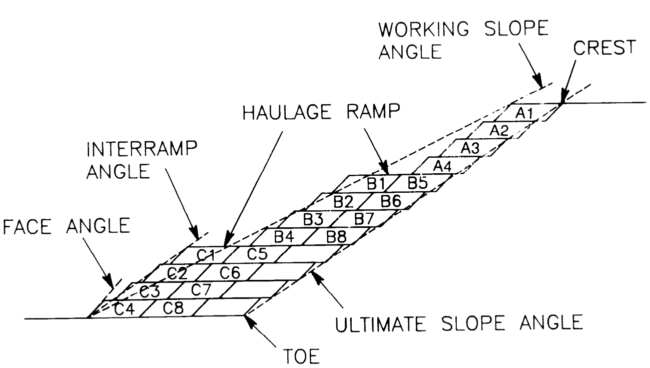

Fig. 14.1.1. Cut sequence for sequential pushbacks.

Fig. 14.1.2. Haulage ramp pattern in waste zone of a western US copper mine (1970).

the mining room requirements lower in the pit.) The ramps must be wide enough to accommodate the excavator and haulage equipment; therefore, the overall slope is less than the interramp slope which is less than the bench face angle (less by virtue of the catch bench between individual levels). This arrangement provides a "working slope" that is less than the design or ultimate slope.

Working slopes flatter than the ultimate have operational advantages. One advantage is additional production faces in both ore and waste. Additional faces provide greater flexibility and more uniform production. Dispersing production faces reduces the likelihood of incidental problems such as sector power outages or localized bench failures from having a major impact on production quotas. Additional production faces in ore also allow blending of ore types to optimize mill performance. Blending is often a difficult task in high-tonnage operations because of surge pile limitations. Finally, working slopes typically limit the size and consequences of major slope failure. At best, selection of an ultimate slope angle is based on geotechnical analysis of available information and engineering judgment. As new information is acquired, adjustments in the design angle may be needed. Approaching the pit limits using a shallower working slope provides an opportunity to obtain more geotechnical information and operating experience before committing to an ultimate slope angle. Selection of an inappropriate angle, either too large or too small, will have far greater consequences for pits approaching a depth of 1000 ft (300 m) than for pits with depths on the order of 100 to 300 ft (30 to 90 m). In the case of deep pits, massive instability caused by angles that are too steep may jeopardize the entire operation. If they are too shallow, the cost of stripping may be excessive resulting in lost revenue and low recovery of natural resources.

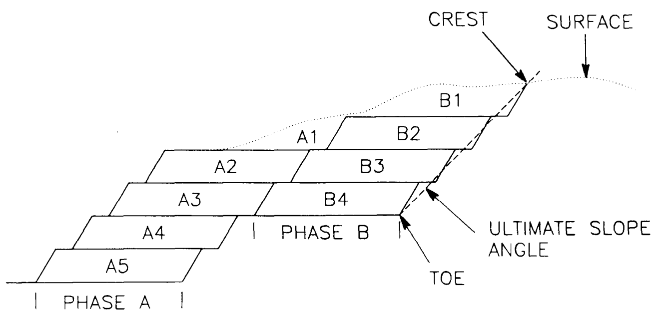

Fig. 14.1.3. Cut sequence for conventional pushbacks.

Conventional pushback, the more popular of the two mining patterns, is commonly employed in shallow pits and in some larger mines. As illustrated in Figs. 14.1.3 and 14.1.4, a pit sector of substantial plan area is mined in whole benches, one at a time, from the top down to perhaps the lowest ore level. One advantage of this method is less complicated scheduling compared to the sequential pushback method. The larger plan area also allows more working faces within a given sector of the mine, which reduces the number of supervisory personnel and requires less maintenance of mine utilities and haul roads. The disadvantages are less flexibility in scheduling operations, greater vulnerability to operational problems, and less opportunity to blend ores from other areas of the mine.

The backslope of a conventional pushback is often cut to the ultimate slope angle. This is an advantage in that the ultimate slope design is tested early in the mine life but at a scale that

Fig. 14.1.4. Pushback in progress at a western US copper mine (1979).

will not jeopardize the entire mine. The disadvantage is that if slope instability does occur, there may be a substantial but temporary loss in production.

The major steps in development of an open pit mine include (1) determining the three-dimensional distribution of mineralization and grade (Barnes, 1980; Barnes, 1989); (2) establishing the economic limits for the pit (Soderberg and Rausch, 1968; Koskiniemi, 1979; Robb, 1979); (3) selecting suitable sites for waste embankments and soil stockpiles (McCarter, 1985; McCarter 1990); (4) clearing vegetation from the land intended as sites for pit and waste embankments; (5) siting of processing, maintenance, office, and transport facilities close to the pit but outside potential pit limit expansion (Myntti, 1979); (6) selecting equipment; laying out haulage roads; and (7) initiating "pioneering" cuts. These initial cuts may be in the form of "box cuts" (Hartman, 1987) or access roads on steep hillsides that are enlarged to form mine benches.

Standard unit operations (drilling, blasting, excavating, and haulage) are generally employed in removing both waste and ore. The type of drills most commonly used include rotary and down-hole percussion rigs. If the material cannot be ripped, the explosive of choice is ANFO for dry blastholes and emulsion for wet blastholes. Some operations prefer to pump water from holes and install plastic liners to prevent degradation of the ANFO. After breakage, material is excavated using electric shovels, hydraulic shovels, backhoes, front-end loaders, scrapers, and, less commonly, draglines and bucket wheel excavators. The height of a bench is normally dictated by the reach of the prime excavators to be used. The height should be well within the maximum digging range so that the slope and the tendency toward caving of the face and highwall can be better controlled (Rumfelt, 1968). The width of individual benches is determined by the clearances required to conveniently load into the matched haul units, stability of the pit wall, and by the break-even stripping ratio. Haulage is accomplished with trucks, scrapers, conveyors (there is a current trend toward in-pit crushers and conveyors), and less frequently with rail, skip hoist, and hydraulic transport.

Open pit mining accounts for approximately 60% of the production from surface mines (Hartman, 1987). The principal metallic products and number of mines worldwide are shown on Fig. 14.1.5. The same information for nonmetallic products is shown on Fig. 14.1.6.

The following case studies provide examples of principal commodities and mining techniques for current open pit practice.

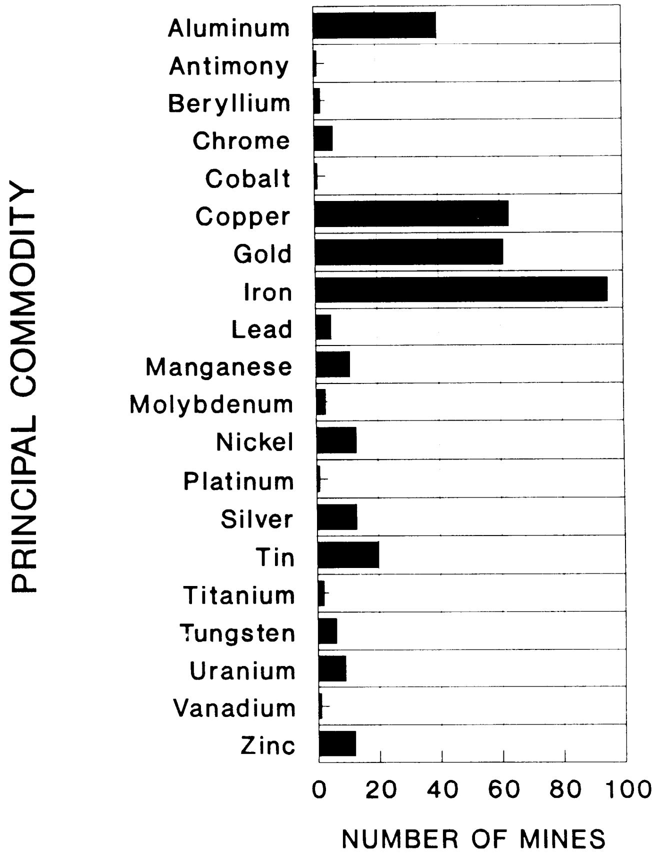

Fig. 14.1.5. Number of major metalliferous open pit mines in the Free World by commodity (Anon., 1988).

14.1.1 PORPHYRY COPPER: BINGHAM CANYON MINE

JEFFERY D. TYGESEN

14.1.1.1 Mine Description

The Bingham Canyon mine is the world's first low-grade, open pit copper mine and the largest man-made excavation. Since its inception in 1906, over 5 billion tons (4.5 billion t) of material have been removed and 13 million tons (11.8 million t) of copper have been produced. The mine's estimated life will extend until 2015, with an average stripping ratio of 0.4:1.

A new mill, completed in 1988, made Bingham Canyon one of the most cost-effective and productive mines in the copper industry. Following completion of this mill, mine production was at 107,000 tpd (97,000 t/d) of ore. In 1989, production increased to 111,000 tpd (101,000 t/d) of ore and 99,200 tpd (90,000 t/d) of waste[1]. The annual production of metals processed through smelting and refining was about 210,000 tons (191,000 t) of copper, 350,000 oz (11,000 kg) of gold, 2,500,000 oz (71,000 kg) of silver, and 14,000,000 lb (6350 t) of molybdenite. An additional grinding line will be added to boost concentrator throughput to 142,000 tpd (129,000 t/d).

The mine is located in the Oquirrh Mountains, 30 miles (42 km) southwest of Salt Lake City, UT (USA). The mine area including waste dumps encompasses approximately 9500 acres (38 km^2). The dimensions of the mine are roughly 2.5 miles (4.0 km) across at the rim and about 0.5 miles (0.8 km) from the rim at the 7740 level[2] to the bottom at the 5090 level (see Fig. 14.1.1.1).

Access to the mine is provided by truck-haulage ramps (width approximately 150 ft or 46 m) on the north and south sides of the mine. The north ramp exits the mine at the 6190 level and extends approximately 2.5 miles (4.0 km) to the Dry Fork dumps at an elevation of 6650 ft (2027 m). The south ramp exits the mine at the 6800 level, extending approximately 1 mile (1.6 km) to the East Side dumps at an elevation of 6800 ft (2073 m). A vehicular roadway through Bingham Canyon provides additional access to the northeast side of the pit at the 6190 level.

In addition to the roads, three tunnels enter the mine at the 6040, 5840, and 5490 levels in the northeast sector and exit into Bingham Canyon. These tunnels are 18 ft (5.5 m) wide and 24 ft (7.3 m) high. The lengths are 2500 ft (762 m), 5200 ft (1585 m), and 16,300 ft (4968 m) respectively. The two upper tunnels are equipped for rail haulage of ore from reload facilities within the pit; the lower tunnel is equipped with a 72-in (1.83-m) belt used to transport ore to the Copperton mill.

Operations are scheduled three 8-hour shifts/day, 365 days/year. The work force at the mine includes 70 supervisory and administrative personnel and 540 hourly personnel. The work force is generally divided into two categories, operations and maintenance. The operations group totals 336 people while the maintenance group accounts for 274 people.

14.1.1.2 Deposit Description and Geology

The Bingham Canyon ore body is a porphyry deposit centered in and around a complex monzonitic stock. This stock was intruded into older monzonite and surrounding Pennsylvanian sediments. Approximately 100 m.y. ago folding and faulting associated with mountain building processes resulted in a strong system of intersecting high-angle faults. This "structural crossroads" produced areas of weakness, which facilitated emplacement of magmatic material and, later, access to the host rock for hydrothermal solutions. Mineralization, dated at about 40 m.y., includes disseminated deposits, fracture or vein fillings, and replacement deposits in reactive limestone units.

Monzonite and monzonite porphyry are the most important host rocks for copper mineralization at Bingham Canyon. Quartz monzonite, a medium-grey, equigranular rock, makes up about 33% of the pit exposures. Porphyritic quartz monzonite, quartz monzonite porphyry, latite porphyry, and quartz latite porphyry are other intrusive materials accounting for about 12% of the pit exposures. Pennsylvanian quartzite occurs mostly in the east, north, and northwest sections of the mine making up about 40% of the pit exposures. The highly metamorphosed Jordan and Commercial limestones occur in beds 160 to 190 ft (49 to 58 m) thick in the south and southwestern sectors of the mine. These units account for 9% of pit exposures and are generally very blocky and difficult to mine. Moderately soft siltstone, intercalated with quartzite, makes up about 6% of pit exposures. Individual beds of siltstone average about 9 ft (3 m) in thickness and commonly are associated with low-angle thrust faults.

Overburden is divided into two categories. Iron-stained sediments occurring in the upper part of the mine have been oxidized

[1] The term "waste" is an economic classification referring to barren rock or rock with less contained copper than economically feasible to cover by conventional milling processes.

[2] Level designations are in terms of feet above mean sea level.

Fig. 14.1.1.1. Aerial View of the Bingham mine from the south.

and naturally leached of sulfide minerals. The remaining portion of the overburden consists of sediments and intrusives containing less copper than can be economically recovered through milling. This material is removed from the mine and deposited on dumps.

The primary copper-bearing minerals at Bingham Canyon are chalcopyrite, bornite, and chalcocite. Molybdenite, gold, and silver are the primary byproduct metals. Pyrite is the most common sulfide gangue mineral. Lead, silver, and zinc ores occur as a result of lode or replacement deposits in the peripheral areas outside the porphyry intrusion and the perimeter of the current pit. Copper oxides are negligible.

The metal distribution within the deposit is in the form of inverted shells or domes surrounding the Bingham stock (Fig. 14.1.1.2. The mineral zones are (from inside out) central barren core, molybdenite zone, bornite-chalcopyrite zone, chalcopyrite-pyrite zone, pyrite zone, and galena-sphalerite zone.

14.1.1.3 Mine Development

HISTORICAL PERSPECTIVE. The first ore was milled in nearby Copperton in August 1904. This 300-tpd (272-t/d) gravity pilot plant was constructed to demonstrate the feasibility and practicality of the milling and crushing equipment. In 1908, the Utah Copper Company built a 6000-tpd (5400-t/d) concentrator near Magna, some 15 miles (24 km) north of the mine. In 1909, Boston Consolidated completed a 3000-tpd (2700-t/d) mill in Garfield near the Magna concentrator. In 1910, the two companies merged as the Utah Copper Company, and within one year modified the mills and increased production to 13,500 tpd (12,200 t/d). Ore production had risen to 90,000 tpd (81,600 t/d) by 1940.

In 1966, the Bonneville facility was completed providing additional grinding capacity, and production increased to

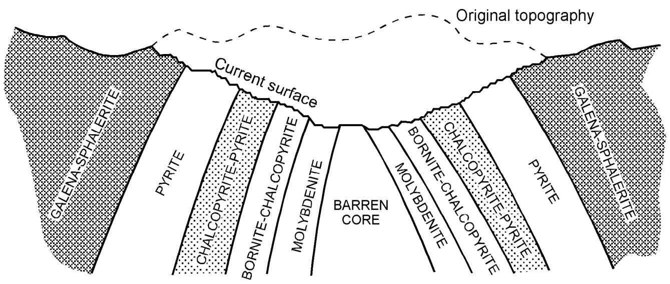

Fig. 14.1.1.2. Generalized shape of mineralized zone.

108,000 tpd (98,000 t/d). In part, the increased production was required to offset the declining ore grade (At the inception of open pit mining, ore grade averaged over 1.9% copper. In 1989, the average grade was about 0.6%). In the late 1970s, recognizing that the labor-intensive operation of the aging Magna and Garfield concentrators would not support future production requirements, plans were made to modernize milling and concentrating operations. In 1988, a new Copperton concentrator was completed. The plant was designed to process 77,000 tpd (70,000 t/d). Ore transport from mine to mill was accomplished through an in-pit crusher and 5-mile (8-km) conveyor.

By 1992, the new mill, with the addition of a fourth grinding line along with the Bonneville/Magna facility, will support a production of 142,000 tpd (129,000 t/d) for the next 25 years. The general layout of the mine, mills and smelter is shown in Fig. 14.1.1.3.

MINING PLAN. Mining progresses in the form of successive pushbacks. The pushbacks range from 100 ft (30 m) to 200 ft (61 m) in width and 50 ft (15 m) in height. The operating interramp pit slope, including bench face angles and catch benches, is 34° as shown on Fig. 14.1.1.4. Catch benches are 50 ft (15 m) wide and effectively collect spillage from blasting and loading.

In 1989, five ore shovel faces and five waste shovel faces were required to ensure planned production. Five ore shovels were required to meet grade and metallurgical blending requirements. The five waste shovels were required to meet long range stripping requirements ensuring future ore. The geometry of the deposit is such that the majority of the ore is located in the lower 900 ft (270 m) of the pit, roughly at the 5740 level and lower. The highest active waste cut is approximately 2000 ft (610 m) higher in elevation on the 7740 level. In the extreme case, mining room must be brought down nearly 40 benches before new ore is exposed; this process can take as long as seven years.

A recent reassessment of slope angles for ultimate pit designs resulted in subdividing the pit surface into 26 sectors based on rock type, structure, material characteristics, and strike and dip of geologic structure relative to pit slope orientation. The slope angles defined for each of these sectors range from 29 to 50°. Design slope angles in sediments, located in the upper benches, range from 30° on the east side and up to 50° on the northwest side of the pit. Design slope angles in intrusive materials range from 29 to 46°.

These slope angles will be achieved by double benching or single benching using a modified mining technique for cuts adjacent to the final slope. This technique includes controlled blasting, "digging to hard", and using dozers in soft material on final surfaces.

Slope dewatering also will be incorporated where necessary, using near-horizontal drains. Successful depressurization typically provides an average 3 to 5° steepening in ultimate slope angles for conditions at Bingham Canyon.

Long-term mine planning is implemented through the use of a model consisting of blocks measuring 100 by 100 ft (30 by 30 m) in plan by 50 ft (15 m) in height. Each block is assigned representative grades for copper, molybdenum, gold, and silver generated by Kriging techniques. In addition, the blocks are assigned values representing rock type and physical properties of the geologic formation encountered at the location of the block. Information for grade assignments, geologic data and physical properties is based on development drilling on 400- to 600-ft (122- to 183-m) centers. Material density varies only slightly with rock type; 2.18 tons/yd^3 (2.58 t/m^3) represents average conditions.

Mining plans are developed by defining the volume of ore and waste between a particular future pit surface and the existing topography. This material is then sequentially mined by a computerized mining simulator algorithm. This algorithm allows material with the highest relative profit margin to be mined first. The planning steps thus created are then modified to reflect haulage roads and operational constraints. The result is a series of annual plans for the first five years followed by five year plans to the end of mine life.

14.1.1.4 Unit Operations

DRILLING AND BLASTING. Rock breakage is accomplished by a crew of 13 working an average of 5 days/week, 2 shifts/day. Blastholes are drilled by eight Bucyrus-Erie 60R track-mounted drills. These drills are capable of exerting 120,000 lb (534,000 N) thrust and can drill 57 to 65 ft (17 to 20 m) in a single pass. Average production of 12.25-in. (311-mm) holes is about 12 per 8-hour shift. Rotary tricone bits with carbide inserts are used.

In addition to the 60R units, production blastholes also are drilled with two Driltech D75K track-mounted units and a secondary drill capable of drilling angled holes. The D75K drills employ carbide insert bits 9.875 in. (200 mm) in diameter and carry four 35-ft (10.7-m) drill rods. The mobility of these drills and the smaller-sized hole they produce make these drills useful in resilient formations where closer patterns are necessary for proper fragmentation. These drills also are used in pioneering shovel cuts where electric power and space are not available for the larger electric drills.

A secondary drill uses 2.5-in. (64-mm) bits and 12-ft (3.7-m) drill rods. The resulting holes are loaded with dynamite to break boulders and high spots in haul roads. Secondary breakage also is accomplished with a Drott, rubber-tired, backhoe chassis equipped with a Tramac rock breaker head. The rock breaker is used where blasting is not advisable because of proximity to equipment or facilities.

Drilling patterns vary with rock type but range from 30 × 30 ft (9 × 9 m) to 36 × 36 ft (11 × 11 m) for 12.25-in. (311-mm) holes and 25 × 25 ft (7.6 × 7.6 m) to 30 × 30 ft (9 × 9 m) for 9.875-in. (200-mm) holes. The hardest, least-fractured rock types are metamorphosed units of the Commercial and Jordan Limestones, locally known as metalimestone. This material produces blocky fragments and requires more closely spaced holes to improve fragmentation and material handling.

Explosives are loaded using two, front-discharge, one-man, bulk ANFO trucks. Blending of ammonium nitrate prills and fuel oil occurs when the bulk delivery trucks deliver these compo-

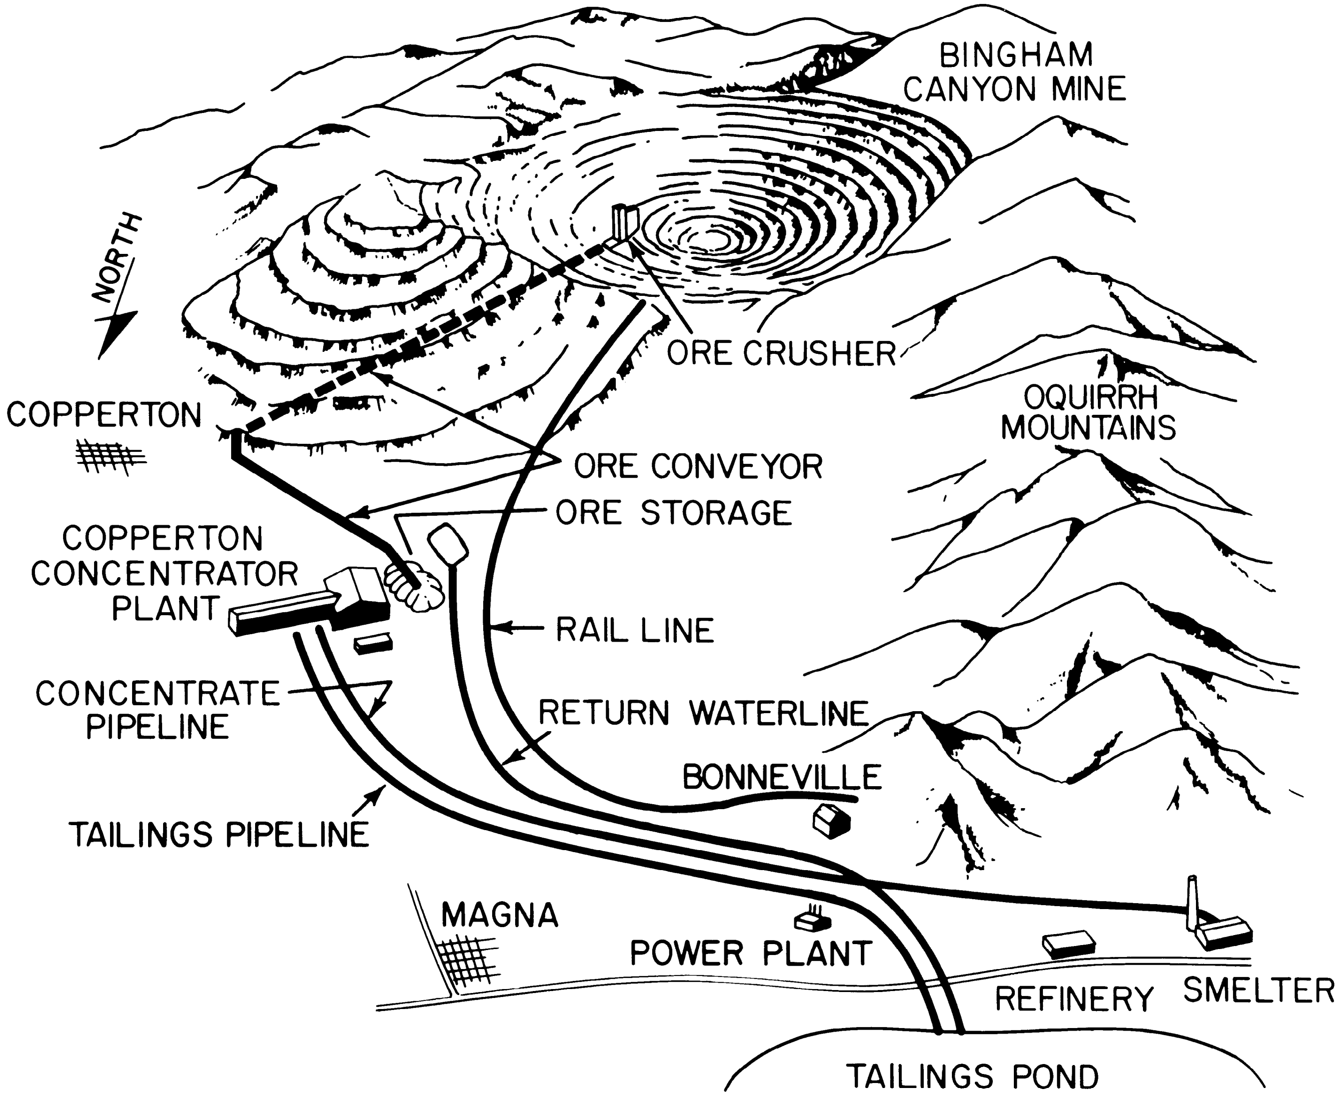

Fig. 14.1.1.3. General locations of mine, concentrators, smelter, and refinery.

nents to the mine-site storage tanks. ANFO is the preferred explosive, but commercial bulk emulsion-blend explosives are used in wet holes.

Typically, holes are primed with two 0.75-lb (0.34-kg) boosters. Both boosters are placed near the bottom of the explosive column. A 200-ms delay is inserted into each booster and connected to individual 7.5-grain Primaline down-lines. Twenty-five-grain detonating cord is used for trunk lines and cross ties. Surface delays of 17 ms are used between holes and 100 ms between rows. A single strand of detonating cord is extended from the pattern and initiated by a non-electric cap taped to the cord.

Drill cuttings are used for stemming. Each hole produces approximately 2.4 to 3.7 tons (2.2 to 3.4 t) of cuttings, depending on hole diameter. These cuttings are forced into loaded holes using two rubber-tired stemming machines developed at Bingham. The machine consists of a small front-end loader (FEL) chassis equipped with curved opposing arms that are closed by hydraulic cylinders.

Powder factors vary from 0.13 to 0.25 lb/ton (0.065 to 0.125 kg/t), depending on rock type and spacing of geologic discontinuities. The overall average is 0.16 lb/ton (0.08 kg/t). For purposes of blast design, geologic materials are classified as intrusive, quartzite, and limestone with the appropriate powder factors assigned.

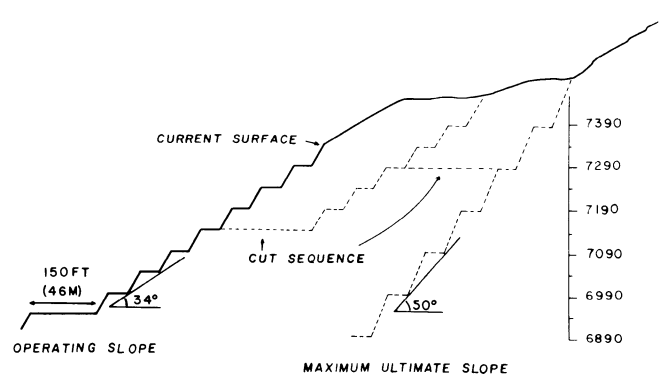

Fig. 14.1.1.4. Typical cut sequence (vertical section).

The objective in drilling and blasting is to loosen the material sufficiently to meet production goals without degrading the integrity of the final pit slopes. With this in mind, ground motion due to blasting is limited to 25 in./sec (640 mm/s) at planned final pit slopes.

LOADING. Primary production utilizes the following number and type of units:

2 15-yd^3 (11.5-m^3) P&H 2100 electric power shovels
4 27-yd^3 (20.6-m^3) P&H 2800 Mark II electric power shovels
3 30-yd^3 (22.9-m^3) P&H 2800 XP electric power shovels
2 34-yd^3 (26.0-m^3) P&H 2800 XPA electric power shovel

The 15-yd^3 (11.5-m^3) shovels are used primarily for ore reload into trains, narrow cuts, and construction cuts. The larger shovels are used exclusively for waste and ore production faces.

The availability for the 2100 shovels averages 78% while that of the larger shovels averages 88%. The smaller shovels are scheduled 2 to 3 shifts/day and shovels larger than 15-yd^3 (12.5-m^3) are scheduled 14 to 15 shifts/day. Average productivity for the 2100 is 10,000 tons (9100 t); for the Mark II and 2800 XP, 15,000 tons (13,600 t); and for the 2800 XPA, 20,000 tons (18,100 t) per shovel shift.

Power is provided by 44-kva distribution lines circling the pit. At appropriate points power is fed to 13.8-kva substations. Radial lines are then fed through smaller substations where the voltage is reduced to 5500 V ac to power shovels and drills. Electrical connections between the switch houses and shovels are made using trailing cables up to 2000 ft (607 m) long for shovels and 3000 ft (914 m) long for drills. However, cables have been run as long as 5000 to 6000 ft (1524 to 1828 m).

In addition to the main production fleet, two 8-yd^3 (6.1-m^3) International, one 12-yd^3 (9.2-m^3) Clark, and two 12-yd^3 (9.2-m^3) Caterpillar rubber-tired FELs are used for construction, clean-up, reload, and auxiliary production when needed.

HAULAGE. Originally, the mine was entirely rail haulage. Steam engines gradually were replaced by trolley locomotives, which, in turn, were replaced by diesel locomotives. Truck haulage was introduced in 1963, and by 1983, all primary production was accomplished by trucks. Rail reload operations are a vestige of the original haulage system and will continue to supplement ore production as long as they are profitable. In 1989, the rail haulage system accounted for approximately 30% of the ore production. The majority of the ore is hauled by truck to an in-pit crusher and transported to the mill by belt conveyor.

Rail reload utilizes 15-yd^3 (11.5-m^3) shovels and 12-yd^3 (9.2-m^3) loaders to fill 100-ton (91-t) rail cars. Each 25-car train is powered by two 135-ton (122-t) diesel locomotives. The total rail fleet consists of 11 locomotives and 500 ore cars. Ore is currently being transported approximately 12 miles (32 km) to the Bonneville facility for crushing and processing.

Truck haulage utilizes a fleet of 44 trucks. This fleet is composed of

28 190-ton (172-t) Caterpillar mechanical-drive trucks
8 170-ton (154-t) Unit Rig diesel-electric trucks
8 170-ton (154-t) Wabco diesel-electric trucks.

At the 1990 production level, approximately 34 truck-shifts/shift are scheduled, with an average availability of 94% for the new, larger trucks and 84% for the older, smaller trucks. All trucks are equipped with two-way mobile radios, which assist appropriate dispatching.

The in-pit, movable, 60- by 109-in. (1.5- by 2.7-m), 1000-hp (745-kW) Allis-Chalmers gyratory crusher can accommodate 120,000 tpd (109,000 t/d) on a continuous basis. The crusher can handle two trucks at a time and a dumping rate of one truck per minute. This rate is achievable only for short periods when the rock is highly fragmented. This facility is situated on the 5490 level, which is centrally located with respect to planned ore production over the next eight years. The entirely self-supporting crusher assembly is 100 ft (30 m) high (from the truck dump ramp on the 5590 level to conveyor discharge on the 5490 level). Currently, it is resting on a 4200-yd^3 (3200-m^3) concrete foundation. The crusher will be relocated using a 2000-ton (1814-t) crawler transporter. Three to four weeks will be required from the time a move begins until the crusher is brought back on-line at its new location.

Material processed through the facility is crushed to -10 in. (-250 mm) and fed directly to the first flight of a six-segment 72-in. (1.8-m) belt. The belt system is 5 miles (8 km) long and capable of 10,000 tph (9072 t/h) at 900 ft/min (4.5 m/s).

After the ore is processed at the Copperton concentrator, the copper concentrate is pumped through a 6-in. (152-mm) diameter pipeline 17 miles (27 km) to the smelter. The tails also are pumped through a 48-in. (1200-mm) diameter pipeline 12 miles (19 km) to the tailings pond near Magna.

14.1.1.5 Product Control

The Mine Planning Department defines cuts to meet production budgets for short-term and long-term schedules. Once a cut sequence is defined, a computer model of the deposit is used to project whether the material is ore or waste. When the actual cut begins, blasthole cuttings are sampled. If the area is within a projected ore zone, all samples are assayed using atomic absorption spectrometry. If the area is within a projected waste zone, only every fourth hole is assayed. Each hole defines the grade of the surrounding material equal to the drill pattern spacing.

Each mining block is identified by survey stakes and marked with flagging. This procedure allows the area supervisor and shovel operator to distinguish between ore and waste.

The mine also is mapped geologically for structure, rock type, and material characteristics. These properties are associated with individual ore blocks to allow projection of milling performance in terms of recovery, fines production, and Bond work index/SAG work index.

14.1.1.6 Ancillary Facilities

LEACHING OPERATIONS. Since 1923, leaching and precipitation processes have been used to treat rock containing very low copper values. The copper-bearing solutions resulting from this operation are collected in clay or concrete lined ditches or pipe routed to the precipitation plant. The current precipitation plant consists of one module housing 13 cone units. The 13 cones are designed to process copper-bearing solutions through shredded scrap iron on a continuous basis and discharge a copper precipitate slurry at preset intervals into a thickener. Precipitate slurry is pumped from a surge-mixing tank to a filter press for dewatering and drying. This material, containing 80% copper, is then shipped to the smelter for further processing.

Barren solution from the cones passes through a 140-ft (43-m) settling basin with the overflow going to the sump of the central pump station. The distribution system delivers leaching solution from the central pumping station 2.5 miles (4.0 km) to a height of 1270 ft (524 m) on the east-side waste embankments. The west-side water is pumped 3.0 miles (4.8 km) to heights over 1400 ft (430 m). The water is applied to the dump surfaces dissolving soluble copper as it percolates through the dumps. The copper-bearing solution flows from the bottom of the embankment to a collection system that carries it back to the precipitation plant.

The entire leaching complex, including solution distribution, collection, makeup and primary water systems, and various specialized auxiliary lines, requires more than 45 miles (72 km) of pipe. Water is stored in two reservoirs totaling 520 million gallons (2 million m^3) of storage capacity. The copper produced from these facilities is approximately 3 to 4% of the total copper production at Bingham Canyon.

OVERBURDEN EMBANKMENTS. Active embankments are located to the northwest and east of the pit. The most common construction is end-dump, side-hill fills; however, valley fills and heaps also are employed. The older, inactive embankments were built using 100- to 200-ft (30- to 60-m) lifts. Current embankments are constructed in lifts up to 900 ft (270 m).

MINE MAINTENANCE. Mine operations are supported by a maintenance group of about 274 people, approximately one-half of the total mine work force. Maintenance personnel include mechanics, electricians, welders, lubemen, warehousemen, field repairmen, boilermakers, water servicemen, carpenters, and millwrights. Facilities to maintain operations comprise an eight-bay haulage-truck shop and a three-bay haulage-truck tire shop, both located at the 6 190 level at the head of Bingham Canyon. In addition, the field repairmen and field electricians are headquartered adjacent to the mine to service shovel, drill, and crusher/conveyor equipment. Additional facilities are located approximately 2 miles (3.2 km) down-canyon. These facilities include two warehouses and shops for electrical motor repair, welding, machining, small equipment repair, railroad car repair, and diesel locomotive repair.

ROAD DEPARTMENT. At the mine site, 28 miles (45 km) of haulage roads and approximately 40 miles (64 km) of support roads are maintained. It is well known that high-quality roads result in higher productivity and lower maintenance costs. The road department is staffed with 37 people who operate the following equipment:

20 dozers (Caterpillar D-9H, D-9L, D-10L)
11 graders (Caterpillar 16G)
2 scrapers (Caterpillar 631)
4 salt trucks (6-ton or 5.4-t capacity)
6 water trucks (converted 65-ton or 59-t haulage trucks, 10,000- to 30,000-gallons or 38- to 114-m^3 capacity)

14.1.2 WESTERN US DISSEMINATED GOLD: GOLD QUARRY MINE

GERALD C. SMITH

14.1.2.1 Mine Description

The Gold Quarry mine (Fig. 14.1.2.1) is the largest of six deposits being mined by Newmont Gold Co. (90.1% owned by the Newmont Mining Corporation) along the Carlin Trend in Northeast Nevada (Fig. 14.1.2.2). The mine is located in the Maggie Creek Mining District approximately 7 miles (11 km) north of the town of Carlin in Eureka County, NV, at an elevation of 5400 ft (1646 m).

Of the 100.3 million tons (91 Mt) of ore and waste mined in 1988 by Newmont Gold Co. from the ore bodies along the Carlin Trend, the Gold Quarry mine accounted for 57% or 56.9 million tons (51.6 Mt) of ore and waste. Of this total, 4 million tons (3.6 Mt) were mill-grade ore, 18 million tons (16.3 Mt) were leach-grade ore, and 34.9 million tons (31.7 Mt) were waste. The overall waste-to-ore ratio was 1.59:1.

The Gold Quarry mine operates 3 shifts/day, 7 days/week and is scheduled to mine 205,000 tpd (186,000 t/d) of ore and waste for a total of 74.8 million tons (67.9 Mt) during 1989.

14.1.2.2 Deposit Description and Geology

The complex geologic history of Nevada has been described by Stewart (1980) and by Rota and Ekburg (1988). During early Paleozoic, the Carlin Trend area lay along the western margin of the North American continent. A westward thickening wedge of sedimentary rocks, varying from carbonate in the east to siliceous clastic and cherty units to the west, was deposited offshore on the slope and in a marine basin.

Tectonic activity related to the Antler erogenic event in late Devonian to possible earliest Triassic time resulted in the transport of thick sequences of Ordovician deep-water siliceous and volcanic rock eastward along the Roberts Mountains Thrust over Silurian and Devonian shallow-water carbonate rocks. Subsequent doming, faulting, and erosion have exposed the lower plate Devonian and Silurian carbonates through windows in the upper-plate Ordovician rocks. The various mines along the Carlin Trend are located within or adjacent to these windows.

According to Rota and Ekburg (1988), the Gold Quarry mine is located along the southern edge of the Carlin Window, a large structural feature similar to the Lynn Window that hosts the Carlin deposit 7 miles (11 km) to the north. The deposit is hosted by siltstone, shale, sandstone, silty limestone, and chert assigned to the Vinini Formation. These thin-bedded sediments have been locally argillized and highly silicified, particularly along high-angled structures.

Gold Quarry is divided into two ore bodies: the upper, structurally controlled Main ore zone and the lower, stratiform-replacement Deep West ore zone. Together, these ore bodies form a northwest-trending deposit 4000 ft (1219 m) long, 2500 ft (762 m) wide, and 1200 ft (397 m) deep.

The main ore body at Gold Quarry is a stockwork system along a series of north-northwest trending faults. Arsenic, antimony, copper, lead, nickel, and mercury all occur in elevated geochemical abundance throughout the deposit. Silver occurs in variable concentrations, with an overall gold/silver ratio of about 2:1.

Preexisting, high-angle, normal faults and associated fractures are the major controlling features of Gold Quarry mineralization. Mechanically induced fracture systems formed channels that directed the mineralizing hydrothermal fluids. This pro-

Fig 14.1.2.1. Newmont Gold Company. Gold Quarry mine.

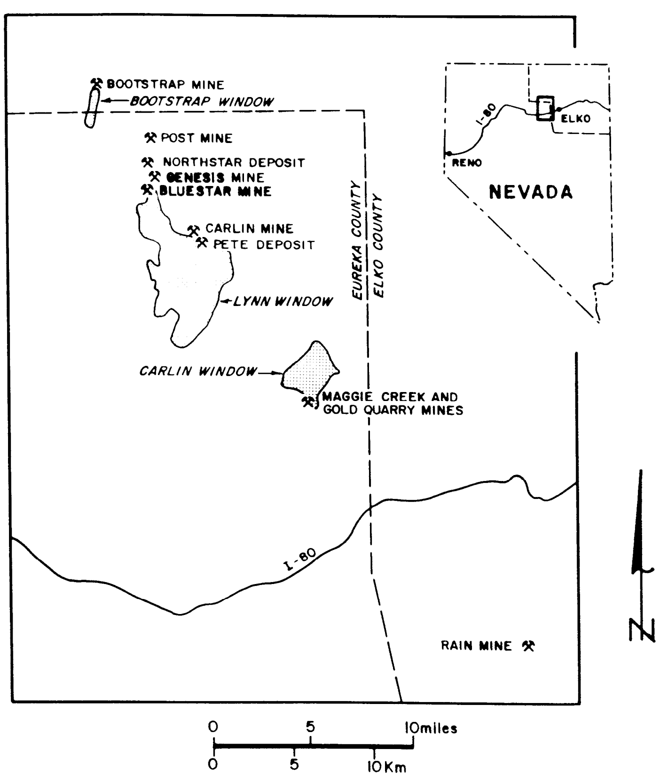

Fig. 14.1.2.2. Newmont Gold Company. Major gold deposits of the Carlin Trend.

duced the observed pattern of high-grade ore zones, concentrated along major structures, surrounded by overlapping lower-grade zones.

Submicroscopic-sized gold is disseminated throughout the shale, chert, and silty limestone of the Vinini Formation. The bulk of the near-surface waste material within the present pit is composed of lacustrine tuffs, siltstone, and sandstones of the Tertiary Carlin Formation. These sediments contain abundant montmorillonite and bentonite, which creates difficult mining conditions during inclement weather.

Hypogene alteration is so extreme that ore types are distinguished more by intensity of alteration than by primary lithology, which is often not recognizable. At Gold Quarry, silicification is the most pervasive type of alteration. Intense argillization followed and locally overprinted the earlier silicification.

Supergene oxidation followed formation of the deposit. Weathering removed most of the carbonaceous material from the upper ore body. Carbon occurring in the lower ore body is associated with calcareous lithologies.

The proven and probable ore reserves for the Gold Quarry mine, as of Dec. 31, 1988, were 246.1 million tons (223.3 Mt) at 0.042 oz/ton (1.4 g/t) and contain 10.3 million oz (320 t) of gold.

14.1.2.3 Mine Development

Several deposit models were developed by a joint effort of the Newmont Gold staff and the Technical Scientific Services group of Newmont Mining Corporation, using varying kriging techniques and parameters. The current kriged block model was developed then compared with 11 benches of production data to verify its accuracy. The model parameters used were 20-ft (6-m) assay composites compiled from atomic absorption (AA) and fire assays at 5-ft (1.5-m) intervals, 50- by 50- by 20-ft (15.2- by 15.2- by 6-m) blocks and the updated surface.

Several geologic zones were included in the model. The Main Zone contains disseminated stockwork mineralization controlled

Fig. 14.1.2.3. Gold Quarry ultimate pit based on cone Z130 and $400 gold.

by structure and the Deep West Zone contains disseminated replacement mineralization controlled by lithology and structure. The alluvium bedrock contact also is included in the model.

Fig. 14.1.2.3 is a plan of the Gold Quarry ultimate pit, which was produced using a computerized floating cone program. Parameters used to produce the ultimate pit outline include mining production unit costs, milling costs, leaching costs, and refining costs. Revenue factors included were the gold price, mill recovery, leach recovery, and royalty payments. Breakeven grades were included for cone definition on mill ore and leach ore. Pit physical design parameters included tonnage factors of 16.0 ft^3/ton (0.5 m^3/t) for alluvium and 13.2 ft^3 /ton (0.4 m^3/t) for rock. Slope angles are 45° (inter-ramp for bedrock), 35° for alluvium less than 300 ft (91.4 m) thick, and 30° where the alluvium is more than 300 ft (91.4 m) thick. Haul roads were designed 80 ft (24.4 m) wide with a maximum 8% grade.

A large portion of the prestripped waste at Gold Quarry was used to construct a tailings dam 3000 ft (914.4 m) long and 200 ft (61 m) high. The dam also serves as a connecting road from the mine to the mill, truck shop, and administration building.

Phased laybacks 300 ft (91 m) wide are planned to keep ore material exposed until the ultimate pit limit is reached. The larger shovels work a bench 30 ft (9 m) high in these phased layback areas of waste, while the ore benches are held to 20 ft (6 m) because of ore control concerns.

Around the ultimate pit perimeter, the alluvium waste varies from zero to more than 300 ft (91 m) thick. The pit slopes will be flattened as this unstable alluvium becomes thicker. An ongoing slope stability program monitors pit slopes, waste dumps, and dump leach pads for stability problems.

The number of working faces available for mining each shift varies from day-to-day, but on the average, six areas in the ore and leach grade material are kept ready for mining. Several areas in the waste material also are available. Each shift operates seven loading units.

14.1.2.4 Unit Operations.

DRILLING. There are eight rotary drills available for drilling blastholes at Gold Quarry. All of the drills are track-mounted, equipped with dust collectors that are a no-visible-emission type with pleated paper filter elements, pneumatic backflushing, and have heated water injection systems for positive dust control. The three oldest drills are Driltech D60KII, equipped with low-pressure Sullair 1200 screw compressors, 3408 Caterpillar engines, and have a maximum pulldown of 60,000 lb (267 kN). Four Ingersoll-Rand DM-M rotary drills are at Gold Quarry. Three of these drills are equipped with Ingersoll-Rand single-stage, oil-flooded, asymmetrical rotary-screw compressors of 1200 ft^3/min (40 m^3/min), and one drill has a 1400-cfm (47-m^3/min) capacity. Cummins KTA19C engines provide power for these units. These drills also have a pulldown capacity of 60,000 lb (267 kN). The eighth drill is a Reedrill SK-60II, equipped with a Sullair series 32 asymmetrical, screw-type, 1200 cfm (39.9 m^3/min) compressor, a Detroit Diesel 12v-71T engine for power, and has a pulldown capacity of 70,000 lb (3 11 kN).

The blastholes are drilled using a 7 7/8-in. (200-mm) tricone rotary carbide-button bit to a depth of 25 ft (7.6 m), which allows about 5 ft (1.5 m) of subgrade drilling. All of the drills utilize an integral drill steel, 30 ft (9.1 m) long, with either an API or Beco threaded box on each end. When the bit end becomes worn, the steel is turned end-for-end, which doubles the life of one piece of steel.

Each drill is operated by one operator drilling the 25 ft (7.6 m) without a steel change. A 14- by 14-ft (4.3- by 4.3-m) drill pattern is standard.

The drillhole spacing and the 20-ft (6-m) bench height is a function of ore grade control. A study is underway to determine the hole spacing and bench height that will optimize drilling, fragmentation, loading height, and ore control.

During 1988, the drills averaged 90 fph (27.4 m/hr).

BLASTING. Presently, two Amerind-McKissic 7-ton (6.4-t) pneumatic prill trucks are used for loading holes. Blasting-grade ammonium nitrate prills are loaded into the trucks from bulk storage bins. Diesel oil is sprayed onto the prills at the required 6% by weight as the prills are being pneumatically placed in the blastholes at a rate of 550 lb/min (204 kg/min) through a 35-ft by 3-in. (11-m by 76.5-mm) hose.

All holes are bottom primed with a 1.0-lb (0.453-kg) cast primer. Ensign-Bickford 25-grain E-cord is used as downlines to detonate the cast primers. Ensign-Bickford 18-grain Detacord is used for the trunk lines and cross ties. Displacement is minimized by using millisecond delays between the rows. The blast is initiated with two no. 6 caps and fuse that are attached just prior to blasting.

Wet holes are loaded with ANFO packaged in waterproof bags measuring 5.0 in. (127 mm) in diameter. Flat cast primers are used with 50-grain detonating cord. Bagged slurry also is used in some of the wet holes. A slurry loading truck will be required when mining reaches the water table.

Drill cuttings are used for stemming whenever possible. During the winter, stemming may be transported to the shot if the

cuttings are frozen. Blasting is performed every day shift at lunch time.

Good fragmentation is obtained, and very little secondary blasting is required. The overall powder factor averaged 0.30 lb/ton (0.15 kg/t) during 1988.

LOADING. The mine plan calls for loading 205,000 tpd (186,000 t/d) of material. This is accomplished by using seven or eight of the loading units shown in Table 14.1.2.1 per shift. The remaining loading units are used as backup. Three of the front-end loaders (FELs) are used to feed the three primary crushers, in order to smooth out the feed between trucks and to blend ore from the stockpile at the crushers.

Two Demag H-285 shovels are used to strip alluvium in 30-ft (9.1-m) benches. Hydraulic shovels have been very successful working in the extremely muddy conditions which prevail during inclement weather.

All loading equipment is diesel powered and mechanically driven except for the four Letourneau FELs, which have electric wheel motors in all wheels. The FELs are very advantageous at Gold Quarry because of their mobility.

HAULAGE. There are 36 trucks available for haulage: two 100-ton (91-t) Dresser-Wabco mechanical drive Haulpak, eighteen 120-ton (109-t) Dresser-Wabco electric drive Haulpak, five 140-ton (127-t) Dresser-Wabco electric drive Haulpak, and eleven 140-ton (127-t) Caterpillar mechanical drive 785 trucks.

A computerized dispatch system added in April 1989 should help optimize truck haulage.

Everyday, haulage is required to deliver 25,000 tons (22,700 t) to either of two primary crushers supplying mill feed, 50,000 tons (45,400 t) to one crusher for leach material, and 130,000 tons (118,000 t) of waste to the waste dumps.

The haulage and loading units are equipped with two-way radios to facilitate communication between the dispatcher and pit supervision.

Haul roads are maintained with three motor graders and two rubber-tired dozers. Track dozers maintain the dumps and stockpiles.

A complete mining equipment list is provided in Table 14.1.2.2.

14.1.2.5 Product Control

While drilling blastholes, a 20-ft (6-m) composite sample of the blasthole drill cuttings is taken by the driller. A cylinder containing an open sample bag is placed in a holder and lowered through a hole cut in the drill deck 18 in. (460 mm) from the drill steel. The cylinder is lowered to the ground into the cuttings stream, and a representative sample of the cuttings is collected from every blasthole. The driller removes the sample before drilling the subgrade.

The sample bags were developed to be compatible with a new automated and computerized assay lab, which utilizes robotics throughout the assaying process. The bags are provided with a bar-coded label for easier and faster identification, and they are able to withstand temperatures of more than 250°F (121°C) encountered in the automatic sample drying process.

The samples taken from the blasthole drilling are logged into the assay lab where they are analyzed by fire assay methods to indicate total gold values and by atomic absorption methods of cyanide agitated solutions. A ratio of the atomic absorption assay to the fire assay indicates the approximate recovery that can be expected from this ore through the oxide mill circuit. Low-recovery ores are considered refractory. Further assaying is performed on this material to determine if the refractory nature is caused by carbonaceous material that adsorbs gold from the pregnant solutions (“preg-robbing”) or from the fine gold particles being encapsulated or locked-up by coarse-grained quartz. A solution with a known gold value is added to the sample from which the original atomic absorption assay was derived. The sample is reassayed and the results compared to the first assay. If the second assay does not equal the first assay plus the amount of gold added for the second assay, within established criteria, the sample is considered to be preg-robbing and will be identified as such in the kriging program and flagged in the field. The results of the fire assay, the atomic absorption, the recovery ratio, and the preg-robbing assay are automatically entered into the computer blasthole datafile after verification.

Blasthole locations, which are supplied by the mine engineering surveyors using total station surveying instruments, together with the blasthole assays, that are supplied by the computerized assay lab, are automatically entered into the blasthole datafile within the company computer system. A kriging program was developed by Newmont’s Technical Scientific Service group with preset kriging parameters and the blasthole datafile to produce a computer-plotted map that defines the ore, leach, and waste zones. The blast patterns are numbered, as are the different zones within the pattern for identification during mining. Coordinates outlining the different zones within the pattern are provided to the surveyors, who stake the various boundaries with color-coded lath after blasting to identify the field location of ore, leach, and waste. Also, a sign identifying each zone is placed in the field so that a loading unit can identify the zone being mined to the computerized dispatch system. As a zone within the staked boundaries is being mined, the loading unit signals the haulage unit either by a horn signal or by two-way radio to identify the destination for each load. The computerized dispatch system stores the number of tons and grade loaded by each loading unit and will track the haulage unit to ensure that the material is taken to the correct destination.

A five-year mine plan is generated each year by the mine engineering department. The first year of the plan is detailed by months, and the subsequent years are annualized. This five-year plan is used by all departments to develop a detailed cost and production budget, which is compiled into a five-year business plan.

An engineer using a graphics work station develops a rolling two-month detailed mine plan. This plan is complete with tabulated forecasted production quantities and maps showing the mining cuts and haulage access for each month.

The graphics work station contains the block model, the geological surfaces, the ultimate pit outline, and the current mining surfaces, based on end-of-month surveys. The monthly plans are the subject of weekly meetings held to discuss production vs. the mining plan with representatives from the mine engineering, mine operations, geology, maintenance, milling, and leaching departments. Adjustments are made to the monthly plan to compensate for higher or lower mine production and for changes in milling requirements.

14.1.2.5 Ancillary Facilities

WASTE DISPOSAL. The waste dumping area is approximately 2 miles (3.2 km) east of the Gold Quarry pit. Most of the waste material in the present pit consists of water-deposited sediments containing abundant amounts of montmorillonite and bentonite. This material is very unstable, and major failures occur when a dump height of 80 ft (24 m) is exceeded. The material deposited near the edge of the dump will slump vertically and run at the toe like wet concrete. A dumping sequence was developed to minimize these failures. This sequence generates a stair-step configuration where the lower lifts are advanced first, to keep the dumping height less than 80 ft (24 m).

Topsoil is stripped from the dumping areas and stockpiled for reclamation purposes. The final dump plan allows for an overall 3:1 slope. The edges of the dump lifts will be rounded, and the dump area will be reseeded.

MAINTENANCE. Maintenance facilities are located approximately 2 miles (3.2 km) from the mine. These facilities include an eight-bay truck repair shop, a tire repair and change area with a heated jacking pad, an enclosed truck washing building (high enough to allow the trucks to raise their beds), a drive-through lubrication bay, and a separate light-vehicle wash, repair, and lubrication shop.

Roving field mechanics cover every shift in the mine and repair minor items on all production equipment. These roving mechanics troubleshoot problems, repair small failures, and refer larger failures to the shop, which dispatches crews to the disabled unit. Haulage trucks are sent to the shop for repair, if possible.

Engines, transmissions, wheel motors, and other larger components are exchanged with vendor rebuilt units.

Consultants were used to implement a preventive maintenance (PM) program called "assembly-line preventive maintenance." The maintenance planner issues a maintenance schedule for all equipment based on operating hours. Every two hours, mobile equipment is brought to the wash bay and cleaned with high pressure water. After washing and cab cleaning, the equipment is moved to the lube bay for two hours of lubrication, oil changes, and filter exchange. The equipment is then moved to a PM bay for a third two-hour period, and a group of mechanics inspect, repair, check pressures, and install backlog items. At the end of this two-hour period the equipment is released back to operations, or if a major problem is found, the equipment is sidelined for repair.

A maximum of three units is in the preventive maintenance line at any one time. Shovels and drills are covered by a field preventive maintenance crew. Utilizing this system of PM, the mechanical availability, which includes the PM time, of the mining equipment has remained at an average of 85%.

When the front tires of the haulage units are about 60% worn, they are replaced with new tires, and the worn tires are rotated to the dual position for wear out.

A lubrication crew works with a lube truck and a fuel truck to fuel and lube the shovels and loaders when they shut down for a staggered lunch period. Haulage trucks report to a fuel station near the pit for fuel and daily lube.

A computerized warehouse is attached to the truck shop to facilitate checkout of replacement items.

Maintenance records, component histories, tire records, and maintenance scheduling are all kept on the main computer system.

14.1.3 LOW-GRADE IRON ORE: EMPIRE MINE

J.W. VILLAR AND A.W. SWANSON

14.1.3.1 Mine Description

The Empire mine (Fig. 14.1.3.1), operated by the Cleveland-Cliffs Iron Co., has the capacity to produce 8 million long tons/year (8.1 million tpy) of high-grade iron ore pellets from a low-grade, magnetic ore. The pellets, which contain over 65% iron, are a desirable feed for blast furnaces located throughout the Great Lakes steel producing areas. The mine is located on the Marquette Iron Range, 2½ miles (4 km) south of Negaunee in the Michigan Upper Peninsula, not far from where iron mining first began in the US in 1847.

The Cleveland-Cliffs Iron Co. is a wholly owned subsidiary of Cleveland-Cliffs Inc., headquartered in Cleveland, OH. The Empire mine is owned by Inland Steel Co., Wheeling-Pittsburgh Steel Corp., and Cleveland-Cliffs. As manager of eight iron ore mines in North America and Australia for the ownership interests of Cliffs and various steel companies, Cleveland-Cliffs is the world's largest producer of iron-ore pellets.

The mine area (Fig. 14.1.3.2), including open pits, waste stockpiles, concentrator, tailing basins, water reservoirs, and pellet plant, covers 13,500 acres (55 km^2) and extends over 7 miles

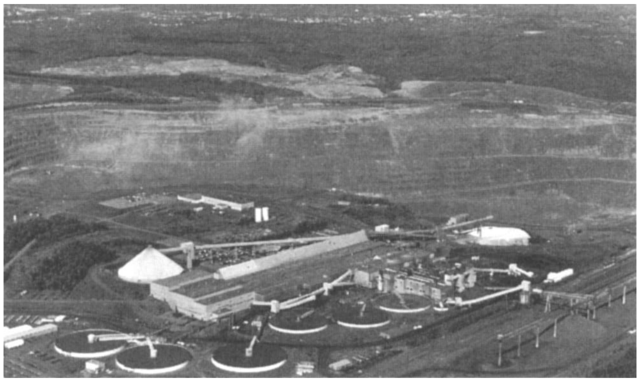

Fig. 14.1.3.1. Overview of plant and mine.

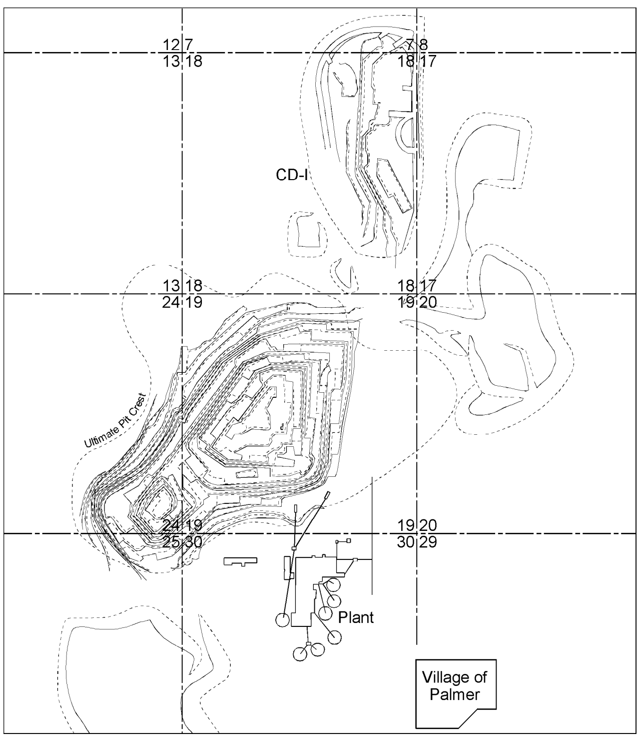

Fig. 14.1.3.2. General layout of Main pit, CD-I pit, and plant for the Empire mine (1990).

(11 km) north and south and 8 miles (13 km) east and west. The Main pit will ultimately have a surface area of 850 acres (3.4 km^2) and crest-to-crest dimensions of 5000 by 10,000 ft (1500 by 3000 m). The adjacent CD-I pit will cover 165 acres (0.7 km^2) with crest dimensions of 3000 by 5000 ft (1100 by 1500 m).

During 1989, over 61 million long tons (62 Mt) of total material was removed from the active mining areas. This consisted of 360,000 long tons (366,000 t) of unconsolidated surface overburden hauled to stockpiles, 35.2 million long tons (35.8 Mt) of rock stripping hauled to waste stockpiles, and 25.6 million long tons (26.0 Mt) of crude ore hauled to the crusher. A total of 8 million long tons (8.1 Mt) of pellets was produced from this ore. Of this production, 4.5 million long tons (4.6 Mt) were standard pellets assaying 65.0% iron, and 3.5 million long tons (3.6 Mt) were fluxed pellets containing 60.2% iron and 6.0% lime.

Operations at the mine and mill complex are scheduled to run continuously (365 d/yr). Total employment at the complex at year end in 1989 was 1214 persons, with 178 salaried and 1036 hourly. Of these, 28 salaried and 291 hourly were charged to the pit operating group. Pit maintenance included 21 salaried and 172 hourly, for a grand total of 512 persons.

14.1.3.2 Deposit Description and Geology

The Marquette Iron Range is located in Marquette and Baraga counties of Michigan. The topography is rugged, heavily forested, with numerous rock outcrops interspaced with lakes and swamps. The highest points are over 1200 ft (365 m) above nearby Lake Superior, which is at an elevation of 602 ft (183 m) above sea level. General elevations range between 1400 and 1600 ft (425 and 490 m).

The Empire ore deposit is in the lower portion of the Negaunee Iron Formation, which is part of the Menominee Group of Middle Precambrian Age. This member, which has a total stratigraphic thickness in excess of 3500 ft (1000 m), is and has been the major site of iron mining on the Marquette Iron Range. The ore body consists primarily of banded, magnetic, cherty carbonate with varying amounts of iron silicate and small amounts of hematite. The banding is due to alternating layers rich in iron oxide and silica.

Structurally, the major feature of the Marquette Range is a westward pitching synclinorium, open at the west end. The Empire mine is located in the southeastern part of the structure where locally the formation strike varies from northeasterly in the south end of the pit to northerly in the north. The beds dip to the northwest at about 30 to 40°. Local variations in strike and dip are common, with numerous drag folds plunging generally to the northwest. The ore zone is separated into a number of individual blocks by a series of dike-filled transverse faults. The ore body is overlain by glacial drift that in some areas reaches up to 150 ft (45 m) in thickness but generally averages 30 to 40 ft (9 to 12 m) thick. The lower portion of the minable zone grades into a predominantly silicate iron formation, which cannot be upgraded economically. The hanging wall is a lean subeconomic iron formation that contains occasional zones of ore-grade material. The footwall is composed of the Siamo slate, the member that lies conformably below the Negaunee and is exposed near the southeast crest of the Main pit. The iron minerals in the ore are magnetite, iron carbonates, iron silicates, martite, and earthy hematite with minor geothite and pyrite. In the Empire mine area, the basic iron formation has been altered by oxidation, enrichment, and low-grade metamorphism. This has increased the acid-soluble iron content to 33%, from an average of 26% in unaltered areas. The economic iron mineral is very fine-grained magnetite, requiring grinding to 90% minus 500 mesh (0.028 mm) for liberation. Enrichment continues to below economic mining depths, as indicated by diamond drilling showing good ore grades to depths of 1740 ft (530 m).

The ore grades within the minable zone vary from a low of 13% iron as magnetite (cutoff grade) to a high of 32%. The average mill head in 1989 was 23.36% iron as magnetite and a total soluble iron of 33.99%. It is necessary to carefully schedule the number and location of the shovels to be operated each shift so that a uniform grade of crude ore is presented to the mill. In addition to the magnetite content, grain size, and liberation characteristics of the crude ore, scheduling daily production also depends on analysis of the iron concentrate that will be produced and amenability of the crude ore to autogenous grinding.

A portion of the annual waste rock movement consists of the overlying, low-grade iron-formation hanging wall, although approximately two-thirds of the total waste rock is produced from interbedded waste zones within the ore horizons. The cutoff grade for ore is greater than 20% concentrate weight recovery, greater than 65% iron, and less than 7.5% silica in the concentrate, as determined by analysis of diamond drill core from exploration drilling and production blasthole rotary drill cuttings. Zones of waste or ore less than 20 ft (6 m) in thickness are not mined separately and are included with the adjacent material.

Exploration drilling, totaling in excess of 250,000 ft (76,000 m), has been done on a 300- by 300-ft (91- by 91-m) grid. The majority of these holes are vertical with about 20% drilled at an angle to better define the geology.

As of Jan. 1, 1990, the Empire mine had an estimated reserve of 775 million long tons (787 Mt) of crude ore remaining in the present design of the pits currently being mined. To mine this tonnage of crude ore, an estimated 448 million long tons (455 Mt) of waste rock and 34 million long tons (34.5 Mt) of surface overburden must be removed from the pit. A total of 226.5 million long tons (230.1 Mt) of standard pellets with an average analysis of 64.9% iron can be produced from this reserve for an estimated mine life of 28 years at the current production rate.

The specific gravity of the ore and waste rock varies with the soluble iron content. To estimate reserve tonnages, a regression equation based on extensive test work is used to calculate the conversion from volume to weight. It is $13.45 - (0.0792 \times \%\ \mathrm{Fe}) = \mathrm{ft}^3/\mathrm{long\ ton}$. For surface overburden, tonnages are based on a specific gravity of 2.0, or 1.5 long tons/yd^3 (2.7 or 2.0 t/m^3).

Ultimate overall pit slopes for the Main pit are designed to be 49° on the west hanging wall and 37° on the east footwall. Slopes for the north and south walls are to be 55°. Ultimate depth of this pit will be 1500 ft (460 m).

As of Jan. 1, 1990, the Empire mine had produced a total of 393.7 million long tons (400.0 Mt) of crude ore and 349.7 million long tons (355.3 Mt) of waste rock and overburden stripping. From this, a total of 122.8 million long tons (124.9 Mt) of pellets has been produced.

In addition to the ore reserves in the pits presently being mined, there are several other ore bodies in the immediate area that are held as long term reserves. In total, they contain in excess of 250 million long tons (254 Mt) of crude ore, from which over 72 million long tons (73.2 Mt) of additional pellets could be produced.

14.1.3.3 Mine Development

Initial pellet production at a rate of 1.2 million long tons/year (1.22 million tpy) began in late 1963 after an almost two-year construction period. Expansions to 3.2 million long tons (3.25 Mt) of annual capacity occurred in 1966, to 5.2 million long tons (5.28 Mt) in 1974, and to 8 million long tons (8.13 Mt) in 1980. Total capital investment for the mine and plant was $408 million.

Original production from the ore body occurred during the period 1907 to 1950 when a total of 6,364,133 long tons (6,466,258 t) of direct-shipping, low-grade siliceous ore was mined from several small pits by other operators. In the 1940s, the Cleveland-Cliffs Iron Co. began assembling the present property and, in the mid 1950s, started exploration and metallurgical testing of the ore. Bulk grinding tests using both conventional rod and ball mill grinding and autogenous milling were run at the Cleveland-Cliffs pilot plant. In 1961, a pilot plant using full-size autogenous grinding equipment was erected on the property. Over a five-month period, 148,000 long tons (150,000 t) of crude ore were treated, showing it was possible to liberate the fine-grained iron mineral by grinding to 90% minus 500 mesh (0.028 mm). With confirmation that the process was commercially viable, construction of the concentrator and pelletizing facilities began in early 1962. Preproduction stripping, conducted in 1962 and 1963, removed 2.5 million long tons (2.5 Mt) of overburden before mining of crude ore began. Initially, mining at the rate of about 11,500 long tons/day (11,700 tpd) on a single-shift, five days/week basis, provided the 3 million long tons/year (3 million tpy) of crude ore necessary for the first stage of plant capacity. Currently, all material movement is budgeted at 57,000 long tons/shift (57,900 t/shift), 21 shifts/week. This results from 24,000 long tons (24,400 t) of crude ore and 33,000 long tons (33,500 t) of waste rock. On an annual average, an additional 400 long tons/shift (410 t/shift) of surface overburden also are moved.

Bench heights are 45 ft (13.7 m) in both ore and waste, with 15 benches presently active. Ore is being produced from almost all benches, with major waste movement concentrated on the upper benches. The ultimate pit crest has been developed in portions of the southwest extension and on the footwall side of the Main pit, with further expansion of the pit crest planned to the north, northwest, and east. Working benches are generally maintained at a minimum width of 180 ft (55 m), but they are being expanded to a width of 300 ft (91 m) in stripping areas to accommodate a new 33-yd^3 (24-m^3) shovel that will soon be placed in operation.

14.1.3.4 Unit Operations

DRILLING AND BLASTING. Drilling is conducted 21 shifts/week on the same schedule as the balance of the mine. Drilling is performed with five large track-mounted rotary machines using 9-7/8- and 16-in. (251- and 406-mm) tricone bits with carbide inserts. The drills are electrically powered at 4160 V through trailing cables. A 1000-ft (300-m) reel is mounted on each machine; although up to 5000 ft (1500 m) of cable may be used.

The majority of holes are drilled 50 ft (15 m) deep, providing 5 ft (1.5 m) of subdrilling below the 45-ft (13.7-m) bench height. Machines are equipped with 60-ft (18-m) masts, allowing single-pass drilling of all holes. Average penetration rate with 16-in. (406-mm) bits is 50 fph (15 m/h), with an actual average production per shift of 210 ft (64 m). The 16-in. (406-mm) bits are used for production blastholes, and the 9-7/8-in. (251-mm) bits are used for drilling final pit walls. Average shift production with the smaller bits is 345 ft (105 m). A single operator per machine is employed. Bit life for 16-in. (406-mm) bits averages 5100 ft (1550 m) and 3200 ft (9800 m) for 9-7/8-in. (251-mm) bits.

Approximately 60% of the holes are loaded with bulk ANFO and the balance with aluminized emulsions. Emulsions are used primarily in wet holes. The average powder factor is 0.37 lb/ton (0.17 kg/t) broken. Loading of holes is performed by a contract explosive supplier with separate bulk trucks for ANFO and emulsion under the direct supervision of mine employees.

Two 16-oz (0.45-kg) boosters are used to prime each hole, with the bottom booster located at the bench grade and the upper booster midway between the grade line and top of the charge. Blasts are fired in echelon or staggered patterns with 17-ms delays between holes and 50 ms between echelons. In-hole delays of 400 ms also are used. Holes are fired using a noiseless nonelectric system.

Waste rock, crushed to –7/8 in. (22 mm) for use as haul-road surfacing, is used for stemming with 26 to 28 ft (8 to 9 m) used in each hole for production blasting. Presplit 9-7/8-in. (251-mm) holes, which are loaded with about 135 lb (61 kg) of powder, are blocked off with an expansion bladder 12 ft (4 m) below the collar of the hole, and then the balance of the hole is stemmed with crushed rock.

Drill patterns in ore and most waste rock are typically 40 ft (12.2 m) burden and 42 ft (12.8 m) spacing when using 16-in. bits (406-mm). In certain diabase-sill waste-rock areas, patterns are reduced to 38 by 40 ft (11.6 by 12.2 m). Individual blast sizes vary widely, depending on pit location and production requirements, with over 1 million long tons (1 million t) broken in the larger ones and 300,000 long tons (305,000 t) in an average size production shot. Blast patterns are generally composed of four or five rows parallel to the length of the bench containing a total of 80 to 100 holes.

At the final pit wall, a single row of presplit 9-7/8-in. (251-mm) holes are drilled on 15-ft (4.6-m) centers. These lines are shot, and then buffer patterns of 9-7/8-in. (251-mm) holes, three to four rows wide, are drilled. These patterns are generally 22 by 30 ft (6.7 by 9.1 m) with the final row 17 ft (5.2 m) behind the next row and 10 ft (3 m) in front of the presplit holes.

Blasting is normally scheduled for 12:10 pm each weekday to take advantage of the general shutdown for lunch break. An average of 3.9 blasts is fired each week.

Seismograph readings at one or two locations are taken for each blast to confirm that ground movement is held below levels that could cause damage beyond property boundaries. As a general rule, weather conditions have not been a concern with regard to air-blast damage and have not been a factor for blast scheduling.

The drilling and blasting program at the Empire mine is designed to minimize the total mining cost by balancing increased breakage costs against savings in loading and haulage. This practice results in well-broken ore, but care is taken not to overblast as it is necessary to ensure sufficient coarse material in the mill feed to provide grinding media for the autogenous mills. Secondary breakage is minimal, and no additional drilling or blasting is done. Secondary breakage is performed with a drop ball with one 50-ton (45-t) rubber-tired crane scheduled one shift on weekdays.

LOADING. The Empire mine shovel-loading fleet is made up of nine 11-yd^3 (8.4-m^3) machines and four 9-yd^3 (6.9-m^3) machines. The units are powered through trailing cables up to 5000 ft (1500 m) long at 4160 V. Essentially all production loading is performed by these machines, with only a minor amount of pit clean up being done with front-end loaders (FELs).

The productivity of 11-yd^3 (8.4-m^3) machines averages 7300 long tons (7400 t) per operating shift, while that for the 9-yd^3 (6.9-m^3) units is 4700 long tons/shift (4800 t/shift). Nine or ten of the machines are scheduled to operate 21 shifts/week for a utilization of almost 75%. The age of this fleet varies from 8 to 27 years and averages about 14.

A single operator is assigned to each shovel with all maintenance and lubrication done with mobile lube units. When bench width exceeds 120 ft (37 m), double-side loading is normally practiced.

A fleet of seven rubber-tired dozers is utilized to maintain the loading areas around the shovels by cleaning up spills and throw rock. Normally four units are scheduled on each shift, with each machine assigned to maintain loading around two or three active shovels.

HAULAGE. The production truck haulage fleet consists of thirty 120-ton (109-t) units and ten 170-ton (154-t) units. In addition, there are six 85-ton (77-t) trucks which are used as utility units to handle road dressing, flux stone, concentrates, and pellets. All are diesel-electric, single-drive-axle units.

The 120-ton (109-t) units move an average of 1600 long tons/shift (1630 t/shift), and the 170-ton (154-t) trucks move 2700 long tons (2740 t). About 75% of the trucks are scheduled for operation on each shift.

Haul distances average 1.5 miles (2.4 km) for ore and waste. Haul roads are 110 ft (34 m) wide with a maximum grade of 8%. Haulage roads are constructed by cutting to the desired elevation with the primary loading shovels. High spots or poorly broken areas are brought to grade by ripping with a dozer. Haulage roads are then surfaced with graded crushed rock. Approximately 500,000 long tons (510,000 t) of waste rock are used for this purpose annually. This material is produced by a contractor who crushes 100% through a 7/8-in. (22-mm) screen. Tire life averages 4.6 tires/million long tons of all material moved.

A fleet of four graders is utilized in maintaining the 41 miles (66 km) of haulage roads within the pit and serving the crushers and waste stockpiles. On average, three units are scheduled on day shift and two on the off shifts.

All truck movement is directed by a radio dispatch system using a computerized program to maximize truck utilization. Radios are installed in all haulage units, shovels, and dozers and at locations along the haulage roads to report actual unit movements. The dispatch system also is used to notify truck drivers when their units require fueling by keeping track of operating time. When 16 hours of operating time have been accumulated, the driver is instructed to refuel at either the fueling station near the crusher or one adjacent to a waste haul road.

Waste rock is hauled to one of three stockpile areas, dependent on material type and haul distances. Waste rock is dumped short of the stockpile crest and pushed over the edge with a dozer to maximize both safety and haulage output. The crude ore is hauled to one of two 60-in. by 89-in. (1.52-m by 2.26-m) gyratory crushers where it is reduced to –9 in. (229 mm). From the crusher, the broken ore is conveyed to ore storage facilities that have a total capacity of 610,000 long tons (620,000 t), or enough for about 8 days of operation.

14.1.3.5 Ancillary Facilities

MILLING. Crushed ore from the surge piles is withdrawn by under-pile-feeders and conveyed to 24 lines of two-stage, fully autogenous milling where the final concentrate is ground to 90% – 500 mesh (0.028 mm) (Fig. 14.1.3.3). The primary mills include

3 8500-hp (6300-kW), 32-ft (9.8-m) diam., 16.5-ft (5.0-m) long
5 3500-hp (2600-kW), 24-ft (7.3-m) diam., 12.5-ft (3.8-m) long
16 2200-hp (1600-kW), 24-ft (7.3-m) diam., 8.0-ft (2.4-m) long

The primary autogenous mills are closed circuited with double deck-vibrating screens. Undersize material is magnetically cobbed, with the magnetic portion going as feed for the pebble grinding circuit and 48% of nonmagnetic material discharged to tailing. The top deck provides pebble media for the secondary circuit and the intermediate product is recirculated.

The pebble mills include

16 1500-hp (1100-kW), 12.5-ft (3.8-m) diam., 24-ft (7.3-m) long
5 2200-hp (1600-kW), 15.5-ft (4.7-m) diam., 24-ft (7.3-m) long
6 2500-hp (1900-kw), 15.5-ft (4.7-m) diam., 32-ft (9.75-m) long

The pebble mill grind is controlled by cyclones with the underflow going to siphonsizers where another 13 to 15% is rejected to tailing. The siphonsizer underflow is further upgraded with magnetic finishers and flotation to 66.9% iron and 5.3% silicon.

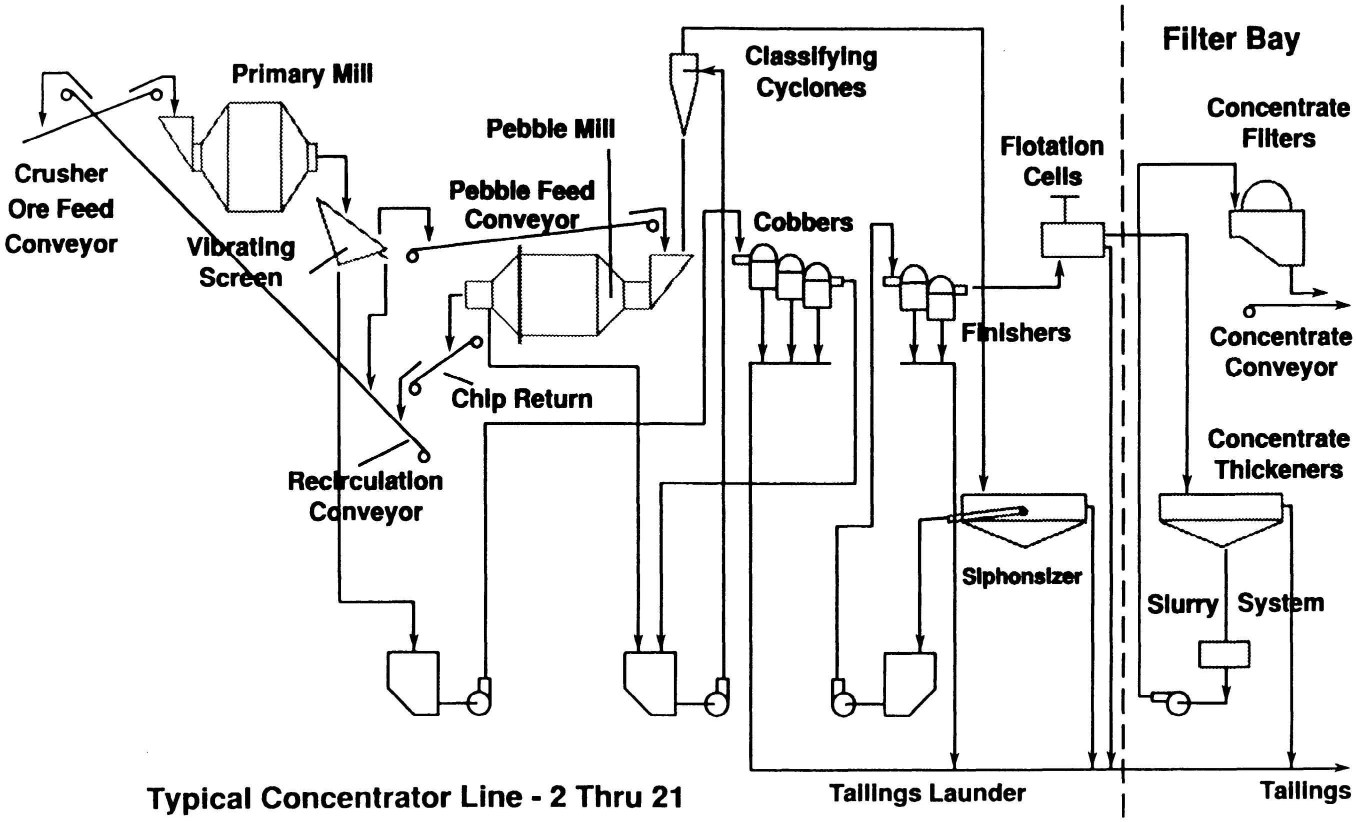

Fig. 14.1.3.3. Simplified flow diagram for concentrator and filter bay.

The concentrate is thickened, filtered, and conveyed to the pelletizing plant where it is balled and indurated in one of the four grate kiln pelletizing units. The fired pellets, which are heated to temperatures of 2330°F (1275°C), are cooled and conveyed to rail car loading bins or stockpiles for later shipping.

The plant is equipped to produce up to 3.2 million long tons/year (3.3 million tpy) of fluxed pellets with facilities to receive and grind 500,000 long tons/year (510,000 tpy) of limestone and dolomite as additives to the green balls.

TAILING DISPOSAL. The combined tailings discharged from the plant are thickened to about 45% solids and pumped at the rate of 12,000 gpm (0.76 m^3/s) through 18,000 ft (5500 m) of 26-in. (660-mm) pipe to a tailing basin located 4 miles (6 km) southwest of the plant site. This basin, which is adequate for the disposal of tailing until the year 2002, covers 3050 acres (12.3 km^2). At completion, the tailings will be almost 100 ft (30 m) in average thickness.

The initial basin site has little natural relief, requiring dikes to be constructed around essentially 100% of the perimeter by the time ultimate height is reached. These dikes were initially built using locally available glacial till borrow. In areas where a long tailing beach is developed and the pond is a long distance from the dike, dikes are raised by the upstream method, using tailings. In areas where the pond is adjacent to the dikes, dikes are raised downstream with borrow material.

Decant water from the tailing basin is further clarified in secondary and tertiary settling basins before return to the plant for reuse. Additional new water at the rate of approximately 10,000 gpm (0.63 m^3/s), to make up losses in the process, tailing disposal, and evaporation, is obtained from a separate reservoir that impounds spring runoff and freshet flows.

14.1.4 SOUTH TEXAS URANIUM: RHODE RANCH MINE

DONALD K. WINSOR

14.1.4.1 Mine Description

The Rhode Ranch mine is a joint-venture mining operation between Chevron Resources Co. and Total Minerals Corp., a subsidiary of Total Compagnie Francaise des Petroles, with Chevron being the operator. A total of 1,500,000 lb (680,000 kg) of uranium oxide will be recovered annually after a 1,000,000-lb (454,000-kg) first-year objective. To produce 1,500,000 lb (680,000 kg), 4.2 million bank yd^3 (3.2 million m^3) of overburden, 220,000 tons (200,000 t) of cap rock, 1.3 million tons (1.2 Mt) of internal waste, and 300,000 tons (272,000 t) of ore will be moved.

The mine is located in McMullen County, 50 miles (80 km) northwest of Corpus Christi, TX, some 30 miles (48 km) west of George West. Overburden removal began in late 1987 and ore production began in January 1988. The uranium-bearing sand is processed at the Chevron mill in Panna Maria, TX, 85 miles (137 km) northeast of the mine site.

The permitted area covers 4400 acres (17.8 km^2). There are 63 people employed at the mine. The overburden crews work four 10-hour shifts/week, two shifts/day. The two mining crews alternate working seven days on and seven days off. They work 80 hours during the seven-day period. Maintenance crews are set up to cover the overburden and mining shifts.

14.1.4.2 Deposit Description and Geology

The Rhode Ranch deposit is one of the approximately 100 known uranium occurrences that define the South Texas Uranium Region. This area consists of an arcuate belt measuring 250 miles (400 km) long and 40 miles (64 km) wide. Total production from both open pit and in situ leaching operations and remaining reserves amounts to approximately 100 million lb (45.4 million kg) of uranium oxide. Economic concentrations of uranium ore are hosted mainly in the Eocene Age Jackson Group. The Oligocene Age Catahoula Formation, the Miocene Age Oakville Formation, and the Goliad Formation of Pliocene Age form only a modest interval of the more than 50,000 ft (15,240 m) of interbedded Tertiary marine and non-marine sediments that compose one of the largest accumulations of clastic Cenozoic sediments in the world. The constant loading of sediments into the Gulf Coast Basin produced instabilities that led to the development of local growth faulting. In many cases, displacements on the growth faults arranged sands and shales in juxtaposition and formed ideal traps for hydrocarbon accumulations. The fault plane subsequently provided a pathway for the upward migration of hydrogen sulfide-bearing gases and solutions into overlying sediments. This invasion of sulfide-rich solutions into shallow aquifers is a critical aspect of the localization and concentration of uranium in the South Texas Uranium Region.

Uranium at Rhode Ranch is localized into ore rolls hosted within the Manuel and Rincon Members of the Miocene Age Oakville Formation. The mineralized sediments are fine- to medium-grained quartz arenites to arkosic arenites with interstitial digenetic calcium carbonate cement. The Oakville sediments are interpreted to have been deposited as bed-load and mixed-load channel fill and associated sheet flow splay sands that are bounded by flood plain muds and silts.

Hydrogen sulfide-bearing solutions emanating from a fault, located roughly parallel to the roll fronts and about 0.5 miles (0.8 km) to the southeast, are thought to be responsible for engendering the plume of pyritic sediments capable of reducing and precipitating the uranium and causing subsequent rereduction of all geochemical cell-related oxidation. Coffinite is identified as the dominate uranium phase with subordinate amounts of a brannerite-like mineral. Pyrite and/or marcasite are believed to encapsulate much of the uranium. The lack of recent oxidation of the ore body has allowed radiometric equilibrium conditions to be established. Structurally the sediments are flat-lying with a minor southeastward dip toward the Gulf of Mexico. Aside from the growth faults, the sediments are structurally undisturbed.

Ore reserves are estimated to be 7 million lb (3.2 million kg) of recoverable uranium oxide. At the projected rate of 1,000,000 lb (454,000 kg) in 1988 and 1,500,000 lb (680,000 kg) annually thereafter, the ore body has a mine life of five years. There are other uranium occurrences in the vicinity that may be mined, depending on the outcome of current grade evaluations and future uranium prices.

14.1.4.3 Mine Development

Initial mining operations began by removing the topsoil and placing it along the pit perimeter in a continuous berm for runoff control and reclamation. A box cut was made, starting at the extreme north end of the main ore body (see Figs. 14.1.4.1 and 14.1.4.2). The overburden was placed in a stockpile to be used for final reclamation. A topsoil berm was placed around the stockpile area to collect run-off water for dust control use. The waste embankments can be seen to the right of the pit in Fig. 14.1.4.1. The dark areas are shadows cast by the highwalls.

Fig. 14.1.4.1. Aerial photograph, Rhode Ranch mine.

Overburden was ripped, and scrapers were push-loaded to heaped capacity. Sloper blades on two dozers kept the highwall smooth for ground control as the overburden was removed.

The cap rock in the initial box cut was thin enough to be ripped and pushed off the ore sand by dozers. After mining was completed, the cap rock was pushed back into the mined-out area. The cap rock thickness normally varies between 4 and 20 ft (1.2 and 6.1 m) and averages between 8 and 12 ft (2.4 and 3.7 m). This material must be drilled and blasted.

When the cap rock was removed, the ore was mined by a backhoe that made cuts 2- to 3-ft (0.6- to 0.9-m) deep across the uncovered area until the bottom of the ore sand was reached. Ore control personnel probed the sand and backhoe buckets using hand-held scintillometers as mining took place. Trucks hauled either to the ore pad at the top of the pit or to mined-out areas, depending on the grade of material.

As stripping and mining progressed, it was possible to begin backfilling mined-out areas. This practice substantially limited the amount of material that needed to be handled more than once. After only one year of operation, 90% of the overburden was being replaced as permanent backfill.

14.1.4.4 Unit Operations

OVERBURDEN REMOVAL. Stripping operations (Fig. 14.1.4.3) utilize Caterpillar (Cat) 651 scrapers push-loaded by two Cat D-9 push dozers and one Cat D-10 dozer (see equipment

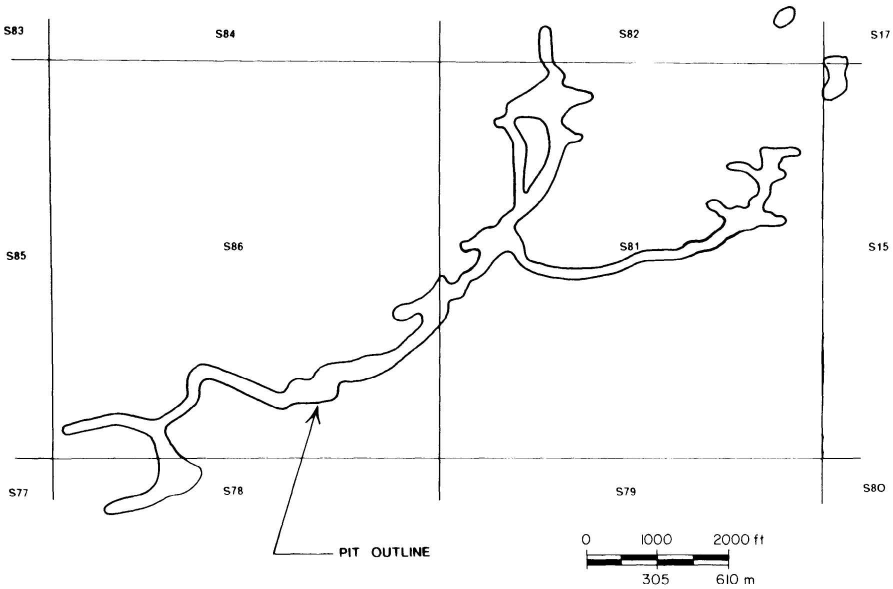

Fig. 14.1.4.2. Pit outline.

Fig. 14.1.4.3. Stripping operations—overburden removed and rock exposed for drilling.

list, Table 14.1.4.1). The scrapers haul to either the waste stockpile or to backfill. The overburden removal ramp serves as one of the accesses to the mine and is kept at a maximum 10% grade to facilitate ore hauling to the ore pad. The overburden is ripped by D-9 or D-10 dozer/rippers prior to removal. The highwall is groomed using sloper blades mounted on the D-9s. The stripping crew also operates a motor grader to keep roads and ramps in good driving condition and a water wagon as needed for dust control.

Table 14.1.4.1. Mine Equipment List (1989)

Make, Model and Type	Number	Usage
Cat 651 scrapers	11	Stripping, reclamation
Cat D-9 dozer	11	Stripping, mining
Cat D-10 dozer	1	Stripping, mining
Cat 16G grader	2	Stripping, mining, and reclamation
Water wagons, 8000 gal	2	All roads and pit
Cat 245 backhoe	2	Mining
Cat 769 truck	3	Mining
G-D 3100 track drill	1	Drilling caprock
I-R ECM 360 track drill	1	Drilling caprock

Each scraper moves an average of 2500 bank yd^3 (1900 m^3) for each 10-hour operating shift and operates for approximately 190 days/year. Rain-outs were projected at 15% but were less than 5% during the first year of operation. Day shift normally operates three scrapers with six on night shift. The highwall varies from 50 to 120 ft (15 to 37 m) to the top of the cap rock.

CAP ROCK REMOVAL. Drilling the cap rock is accomplished by utilizing one of two drills and occasionally both drills operating together. The drills include a Gardner-Denver Model 3100 track drill pulling a G-D Model 800 portable air compressor and an Ingersoll-Rand ECM 360 self-contained drill. The ECM 360 is preferred because of its faster penetration rate and because the air compressor is a part of the machine.

Hole size is 3.5 in. (90 mm), and the depth varies with the thickness of the cap rock. Hole burden is 7.5 ft (2.3 m), and hole spacing is 7.5 ft (2.3 m). The optimum blast is 300 holes (25 rows with 12 holes/row). Blasts have been made with as few as 80 holes and as many as 700 holes.

Cap rock removal is the responsibility of the mining crew, so the whole crew participates in loading each blast. The optimum size blast takes less than five hours to load and shoot.

Each hole is primed with a 1 1/8- by 6-in. (29- by 150-mm) stick of a non-nitroglycerin emulsion cartridge and detonated by a nonelectric delay cap. ANFO is used as a blasting agent, with 3 to 5 ft (0.9 to 1.5 m) of 3/4-in. (20-mm) gravel stemming, depending on the depth of the hole. The holes in each row are initiated by detonating cord placed along the row. The first row is detonated by an instantaneous electric cap. All subsequent rows are initiated by a nonelectric delay connecting the end of each row to each end of the next row. Approximately 24 lb (11 kg) of explosive is loaded in each hole, resulting in an average powder factor of 2 tons/lb (4 t/kg).

There are high-pressure natural gas pipelines, shallow oil wells and their pipelines, and a gas well either within the pit limits or in close proximity to the pit. In order to meet regulations limiting ground motion due to blasting, initiation was changed from whole row, using detonating cord, to nonelectric delays in each hole. Fragmentation also was improved by this change.

When two mining faces are available, D-9 dozers push the cap rock into the mined-out area adjacent to the blast while the second face is being mined. When only one mining face is available, the backhoe and trucks may have to help move the cap rock due to space limitations. Probers follow the cap rock removal down to the ore sand to determine when the ore is reached. Occasionally, there is ore in the bottom of the cap rock, which is mined if above cutoff grade.

ORE REMOVAL. Mining is accomplished using a Cat 245 backhoe loading two Cat 769 trucks. As the ore sand is very loosely consolidated, blasting is not required. Mining of ore and waste takes place approximately 300 days/year. This schedule includes days lost due to holidays, training, loading and blasting, and rain-outs. With the ratio of 4.5 tons of waste/ton of ore, the mining crew removes 4300 tons/day (3900 tpd) of waste and 1000 tons/day (907 tpd) of ore per day of mining operations.

A 2- to 3-ft (0.6- to 0.9-m) cut is taken by the backhoe for better grade control and more selective mining.

ORE HAULAGE. Ore is taken from the mine to the crest of the pit and dumped on an ore pad for transshipment to the mill at Panna Maria, some 85 miles (137 km) away. Transportation of the ore is accomplished using a contract hauler. The equipment used consists of single and tandem belly-dump trailers. The contractor furnishes and operates the loader to load the trucks.

RECLAMATION. Enough of the pit had been backfilled to the original contour by the end of 1988 to begin reclamation. The reclamation plan requires systematic sampling of the backfill for radiation. The topsoil is to be replaced to the original approximate thickness using the Cat 651 scrapers and the Cat 16G motor grader for final smoothing. Coastal Bermuda grass will be planted in the drainage areas to help control erosion. A mixture of Kleingrass, Buffel grass, and Bell Rhodes grass will be seeded on the rest of the area. Cattle grazing is the primary use of the land. A pond will be left at the extreme northeast end and near the southeast end of the ore body in existing drainages for run-off control and livestock watering.

14.1.4.5 Product Control

From drillhole data, the geology department makes l-ft (0.3-m) contour maps of the ore. These maps are called "slice maps" and are used by the shift foreman and prober to assist in grade control.

Fig. 14.1.4.4. Probing material in backhoe bucket for grade control.

Grade control is accomplished by a prober who follows the backhoe and monitors buckets and the sand being removed (Fig. 14.1.4.4). The cutoff grade for ore/waste separation was 0.08% U_2O_3 until late 1989, when it was changed to 0.10% U_2O_3 for economic reasons. Averaging the prober's results gives the daily grade of ore produced. Another prober drills 2-ft (0.6-m) holes with an auger ahead of the backhoe. These holes are probed for grade and marked by colored flags as to ore/waste grade. Samples are taken of the cuttings and checked in an X-ray analyzer as additional control.

14.1.4.6 Ancillary Facilities

Milling of the ore is performed at the Chevron mill in Panna Maria utilizing a two-stage acid leach and solvent extraction. Recoveries are in the 96 to 97% range. At a milling rate of 70 tph (64 t/h), the mill operates 14 to 15 days/month yielding a total of 24,000 tpm (21,800 t/m).

A 10-acre (40,500-m^2) site was established outside the mining area for all maintenance, personnel, and office facilities. A 120- by 190-ft (36.7- by 57.9-m) building was constructed to house the shop, warehouse, tool room, lunch room, men's and women's restrooms/change rooms, and offices for staff, engineering, geology, safety/first aid, and maintenance. Accounting and major purchasing are performed at the Panna Maria offices.

The shop has four drive-through bays and is equipped with two 2-ton (1.8-t) and two 10-ton (9.1-t) overhead cranes, air compressor, and a welding area. A field maintenance crew takes care of minor repairs and fueling of the mobile equipment. The shop crew performs major repairs in the shop. A night crew works with the night stripping crew for minor repairs in the pit and in the shop for major work as time permits. A fueling station for scrapers is located at the shop/office site. All other mobile equipment is fueled in the pit area.

14.1.5 WESTERN PHOSPHATE: HENRY MINE

DAVID W. FARNSWORTH

14.1.5.1 Mine Description

The Henry mine is located in the heart of the Western Phosphate Field, just east of the small town of Henry, ID (Figs. 14.1.5.1 and 14.1.5.2). The mine provides the necessary phosphate ore for Monsanto Company's elemental phosphorus furnace plant located 18.5 miles (29.8 km) south, near Soda Springs.

One challenging aspect of Monsanto's operations is the complicated surface and mineral ownership illustrated on Fig. 14.1.5.3. Two federal phosphate leases (ID-011451 and ID-

Fig. 14.1.5.1. North Henry mine area showing backfilled pit in the center (dark area). Aerial photo.

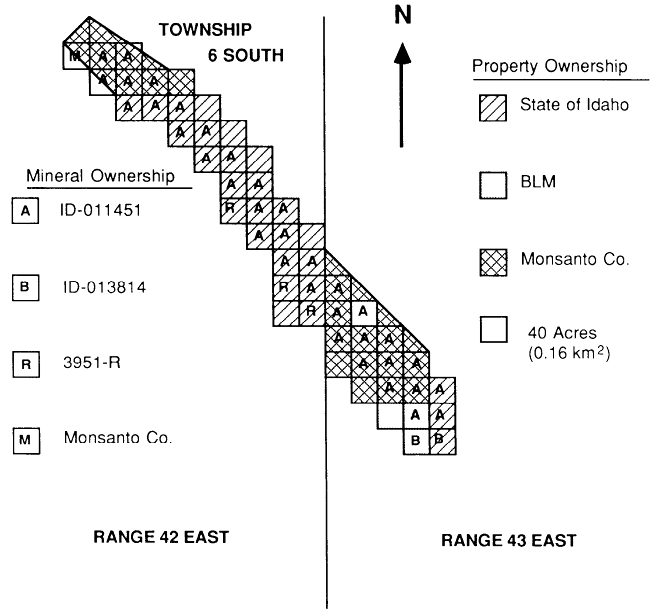

Fig. 14.1.5.3. Henry mine, mineral and property ownership.

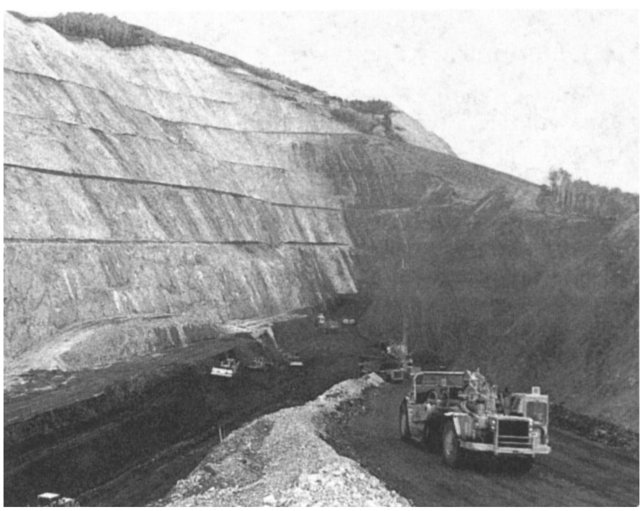

Fig. 14.1.5.2. General pit workings, 1989.

013814) and one State of Idaho phosphate lease (3951-R) comprise the mineral ownership of most of the deposit. In addition to the lease areas, a small unit of private mineral under lease to Monsanto, occupies the extreme northern end of the mine area. In total, some 1642 acres (6.6 km^2) are under lease or control.

Surface ownership is divided among the Bureau of Land Management (BLM), the State of Idaho, and the Monsanto Co. A surface easement from the State of Idaho Department of Lands covers 1080 acres (4.4 km^2). The federal phosphate lease allows for use of 120 acres (0.5 km^2) during mining, and a "phosphate use permit" allows for use of an additional 40 acres (0.2 km^2). Monsanto Co. owns the remainder of the surface estate.

Monsanto's mining operations in southeast Idaho began in 1951 at the Ballard mine. As that deposit was nearing depletion, operations were begun at the Henry mine in 1969. Operations have continued there at an approximate production rate of 1,000,000 tpy (907,000 t/a) of ore. Annual waste volumes vary greatly from year to year. Waste requirements vary, depending upon topography, dip of the ore structure, haul lengths, required ore volumes, and other factors. Total ore and waste volumes range from a low of only 2.5 million yd^3 (1.9 million m^3) to a high of about 5 million yd^3 (3.8 million m^3).

Monsanto's personnel are responsible for all aspects of leasing, exploration, environmental monitoring, permitting, mine design, contractor oversight, and reclamation. Actual mine operations and maintenance are under the direction of Monsanto's mining contractor, Dravo-Soda Springs. The contractor is responsible for overburden removal, ore mining, and delivery of ore to Monsanto's elemental phosphorus plant.

Waste removal is scheduled for two 10-hour shifts each day, four days each week. Ore is normally mined only during the day shift. Ore haulage to Monsanto's plant is limited to the warm-weather months, typically beginning early in May and ending by mid-October. To complete the haul within this period, two 10-hour shifts, five days/week are scheduled. In order to cover both mine operations and the ore haul, maintenance personnel are split into three crews. These crews also work 10-hour shifts, with the third crew overlapping portions of the other groups' hours.

14.1.5.2 Deposit Description and Geology

The Henry mine is located along a 5-mile (8-km) long outcrop of the Phosphoria Formation in Caribou County, ID. The Phosphoria outcrops near the base of a northwest-trending ridge formed of Wells Limestone. To the north and east, the ground slopes gently into Enoch Valley. The deposit is terminated by the Henry fault on the north and east sides. To the south, the deposit is terminated and offset to the east by another smaller fault system. The ore strikes approximately N35°W and dips to the northeast at 40 to 80°.

The Phosphoria Formation is composed of Permian marine sediments. In the mine area, the formation is composed of two members, a lower phosphatic shale member and an upper Rex Chert Member. The phosphatic shale member is composed of interbedded black mudstone, phosphatic mudstone, limestone,

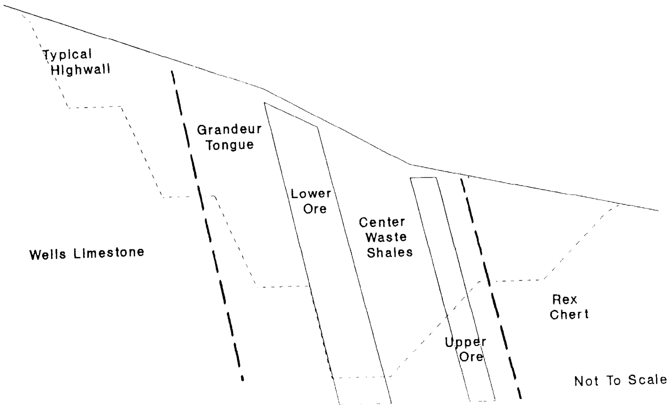

Fig. 14.1.5.4. Typical cross section for the Henry mine area.

and oolitic phosphate rock. Usually, the shale member is not exposed in outcrops but is eroded to form a characteristic swale between the underlying Wells and Grandeur Tongue Formations and the overlying Rex Chert Member. A typical cross section in the mine area is shown on Fig. 14.1.5.4.

At the Henry mine, two major ore horizons are recognized within the phosphatic shale member. The lower ore zone extends from about 5 ft (1.5 m) above the Grandeur Tongue/Phosphoria contact upward for about 40 to 50 ft (12.2 to 15.2 m). The other zone, termed the upper ore, is typically some 80 ft (24 m) above the top of the lower ore zone and is approximately 20 ft (6 m) thick. The strata between the ore zones consist of extremely low-grade phosphatic shale, mudstone, siltstone, and limestone beds. These units are collectively referred to as the center shales or center waste shales.

The other member of the Phosphoria Formation, the Rex Chert Member, consists of bedded dark gray and black chert and cherty mudstone. Much of the chert weathers to brown and reddish brown. Locally, the chert is highly weathered and fractured.

Underlying the Phosphoria Formation is the Permian Grandeur Tongue Limestone and Permian/Pennsylvanian Wells Formation. The Grandeur is composed of limestone, dolomite, and some chert beds. It ranges from 80 to 100 ft (24 to 30 m) thick. In some locations it is a very hard, consistent, and competent formation. The Upper Wells, which also is encountered in the footwall, is composed of a calcareous quartz sandstone with scattered limestone and chert beds.

14.1.5.3 Mine Development

The initial step in developing an area prior to mining is the removal of vegetation. Any timber is offered for sale to a private logging operator. In most areas, insufficient volumes of merchantable timber are present to make logging economical. Douglas fir and quaking aspen, along with most of the other smaller underbrush, are knocked down with dozers, piled, and burned.

Following removal of vegetation, the recoverable topsoil is removed. In most areas of the Western Phosphate Field, the true topsoil is only about 12 to 18 in. (0.3 to 0.5 m) thick. No differentiation of prime topsoil and subsoil is attempted as the thickness of individual units varies greatly over a mine area. When other nearby areas are at the stage in reclamation where they can be covered with planting medium, the topsoil from a new mining area is loaded in scrapers and direct-placed on the reshaped land. However, in most cases the topsoil is stockpiled for use following completion of mining in the area.

With the vegetation and topsoil removed, the area is ready for the start of normal mining operations. Waste removal begins at the high point of the limestone footwall. Lifts of 25 ft (7.5 m) are excavated in the waste until the mining floor encounters the lower ore section. At this time, operations shift from the limestone to the center waste shales and a 20-ft (6-m) lift of shale material is removed, leaving a lift of ore ready for mining. The ore is mined and the process of developing lifts of lower ore repeated until the upper ore zone is encountered. The upper ore zone is mined in a similar manner. The waste material between the upper ore and the toe of the hanging wall is removed first to expose a lift of ore.

During the period from May to October, removal of the limestone and some chert is minimized, and up to 75 vertical ft (23 m) of waste material is left in place for later removal. Operations during this period concentrate on ore mining to maximize ore quality and minimize rehandle on the stockpile. Removal of the limestone and chert backlog is then scheduled for the winter months when the blocky material can be moved more efficiently.

Individual ore beds, or in some cases, a series of similar grade ore beds, are mined separately. The lower ore zone, which ranges from 40 to 50 ft (12 to 15 m) in thickness, is mined in as many as nine different units. Individual splits are made upon such factors as chemistry, grade, and hardness. The minimum minable thickness is considered to be 0.75 ft (0.23 m); although some units of 0.5 ft (0.15 m) may be handled separately. This extreme level of selectivity is achieved by utilizing a slope board or side arm attached to the side of a dozer blade. The slope board is hydraulically controlled by the dozer operator who can manipulate the arm to match the dip of the bedding. Thin beds are knocked down in order to allow the scrapers to load the material. Thicker beds are pushed down sufficiently to yield the width necessary to operate the scraper fleet on top of the section.

Slope design is very critical in achieving design depths in the highly weathered materials encountered in the Western Phosphate Field. Just as the ore material is highly leached and altered, so too are the adjacent limestone and chert wall rocks. Monsanto Co. conducts an extensive drilling and mapping program to sample wall materials and ascertain bedding structures. Bedding in the limestone is inconsistent, and often weathering of the strata has eliminated the actual bedding structure. Leaching, coupled with the stresses induced during uplift, has produced a very broken chert mass. Since mining is limited primarily to the altered shales, the shale material is of very low strength.

Intact rock strengths of the limestone and dolomite are extremely high, as high as 24,000 psi (155 MPa). However, analysis of core recovered from the footwall indicates few if any areas with significant amounts of intact rock. Therefore, fracture strengths are used in slope designs. Measured fracture strengths in the limestone vary from a low of about 5 psi (34 kPa) to a high of 18 psi (124 kPa). Because of the highly fractured nature of the chert, recovery of suitable core samples for measurement has been limited. Analysis of the recovered core indicates a cohesive strength of only about 3 to 5 psi (21 to 34 kPa). The ore and center waste shales are very highly weathered, with little or no compressive strength.

The footwall is designed utilizing the measured fracture strength of the limestone and by mirroring the bedding structure of the lower ore zone. A trial design, based on past designs and actual construction, is proposed and tested utilizing various computer simulations. These programs yield probability of failure and factor of safety estimates for the proposed design. The wall design is tested for both overall integrity and bench-sized failures. A typical footwall design calls for a bench 40- to 45-ft

(12- to 14-m) wide spaced 60 to 80 ft (18 to 24 m) vertically. Slope angles between benches are a maximum of 60°. The slope is laid back to the angle of repose through the highly weathered, near-surface material. A typical highwall design is shown in Fig. 14.1.5.4.

The hanging wall design is typically based upon the measured joint angles in the chert section. In most areas of the Henry mine, the primary joint angle is at 70 to 90° to the bedding plane. The wall angle must provide for removal of most of the material along the joint plane while minimizing the total volume of waste required to be moved. In most of the Henry mine pits, the hanging wall angle is about 45°. The hanging wall is not benched because of its lower overall height and physical characteristics that make stable benches difficult to maintain. In some pits, an access roadway of 50 to 70 ft (15 to 21 m) in width has been included in the hanging wall design. Minor failures during mining may reduce the safe operating width of these roadways to 30 ft (9 m) and one-way traffic.

The foregoing is a general discussion of average wall design conditions. Specific conditions have allowed for areas of much steeper designs. In one area, a pit included a section of the Grandeur Formation where the detrimental effects of alteration were nearly absent. By increasing the slope of the footwall from an average of about 40° to an overall angle in excess of 50°, the entire design was incorporated into the material of the Grandeur Tongue Formation. On the other hand, in another area, the chert had been weathered away and replaced by alluvium to a depth of about 150 ft (46 m). Included in the alluvium were several basalt seams 2 to 10 ft (0.6 to 3 m) thick. The extent and depth of alluvium were missed by exploratory drilling. During mining, failure of some 50,000 yd^3 (38,000 m^3) of the alluvium occurred. Because mining had progressed to a sufficient depth, and the adjacent location of ore stockpile areas limited "recut" operations, an alternate solution had to be developed to allow mining to continue down-dip. The failure and adjacent intact areas were extensively modeled and analyzed to determine the cause of the original failure. Based upon the results of this analysis, a new design for the remaining hanging wall was developed that required no additional removal of waste material but still recovered the majority of the ore present. In addition, a rock fence was designed and implemented to capture pieces of basalt that were loosened by minor failures in the underlying alluvium.

14.1.5.4 Unit Operations

The Henry mine employs both scraper loading and haulage as well as truck and shovel operations.

DRILLING AND BLASTING. Drill and blast operations are conducted on an "as needed" basis. The limestone and chert material both require blasting. At depth and for shovel loading, portions of the center waste shale section are lightly blasted. Equipment consists of two Reich blasthole drills. One is mounted on a crawler chassis, and the other on a rubber-tired truck chassis. Drillholes are normally spaced on a 16 by 16 ft (4.9 by 4.9 m) pattern in both the limestone and chert. Holes are 7-7/8 in. (200 mm) in diameter. In the shales, the pattern is adjusted to conditions and material hardness. Both drills have steel measuring 30 ft (9.1 m) long and can drill holes 25 to 28 ft (7.0 to 8.5 m) deep.

Approximately 50 to 65% of all waste materials require blasting prior to loading. Most blasting is performed during the fall and winter months. Bagged ANFO is used almost exclusively, as few if any holes are wet. Powder factors range from about 0.3 lb/yd^3 (9.2 kg/m^3) in the altered shales to 1.0 lb/yd^3 (0.5 kg/m^3) in some areas of the Grandeur Limestone. The altered shales are "bumped" (lightly blasted) to increase shovel productivity. Patterns and powder factors are adjusted frequently based upon the degree of alteration in the rock. The ore is not blasted prior to loading.

Fig. 14.1.5.5. Slope board used to recover thin, steeply dipping layers of ore.

As a supplement to blasting in waste and at all times in the ore, four Cat D-9H, two D-9L, and one D-10N crawler tractors are used. Most of these units are equipped with double-shank rippers. Following blasting, all scraper material is ripped to further aid productivity. In most cases, ripping of the well-altered waste shales is sufficient. Individual ore beds are separated utilizing one of the D-9Ls or the D-10N. These dozers have hydraulically controlled side-arm blades or slope boards (Fig. 14.1.5.5) that are used to knock down the individual beds creating a zone of sufficient width to allow scraper operations. During mining of the ore, it is frequently ripped to aid scraper loading.

LOADING AND HAULAGE. Prior to 1987, all loading and hauling of both ore and waste was accomplished by a fleet of Cat tractor scrapers. In March 1987, a Hitachi 801 hydraulic shovel and a fleet of Cat 777B trucks were added. A used Cat 992 front-end loader (FEL) was added as backup to the shovel. Subsequently, blocky waste will be scheduled for the shovel; the scraper will be used in the shales and ore. During the summer months, some shale and minor amounts of ore are moved with the shovel to maximize its utilization and productivity. Shovel production averages about 600 yd^3/hr (460 m^3/h). For the first two years of operation, the shovel averaged over 96% availability and over 97% utilization of available time. An integrated shovel/scraper operation is illustrated in Fig. 14.1.5.6.

Loading of the scrapers is accomplished using either a Cat Quad D-9 unit or the Cat D-10N series tractor as a pusher. Three Quad D-9s are available for use. Typically, the scrapers are divided into two spreads with a quad for loading and a D-9L dozer for support. Nearly all loading is done with the push dozers. This action maximizes loading efficiency while minimizing tire damage. Since quad units are no longer available, a Cat D-10N tractor is being evaluated as a pusher for eventual replacement of the quad.

The scraper fleet consists of eight Cat 651B single-engine scrapers and four Cat 657B dual-engine units. The 651 units were originally put to work in 1976 and by 1989 averaged in excess of 31,000 operating hours. The current fleet of 657 units was purchased in 1981 and 1983 to replace four older 657s which had been in continuous service since 1970. These units average over 16,500 operating hours each. Because of the age and number of available scrapers, availability ranges from 60 to 90% and utilization from 35 to 70%.

Five Cat 777B trucks were selected for use with the hydraulic shovel. These are 85-ton (77-t) units and have 10-in. (0.3-m) side

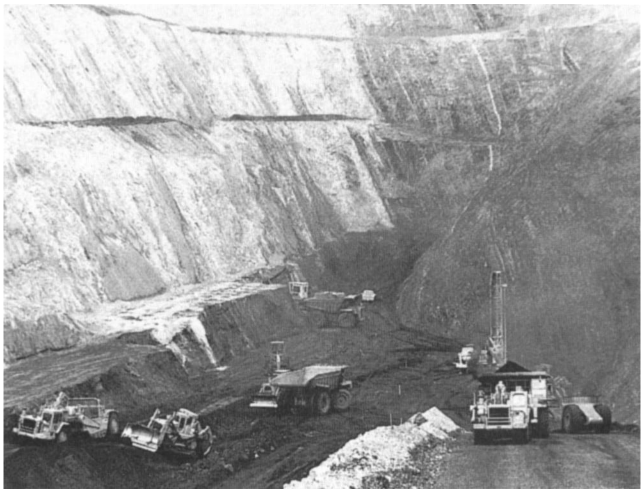

Fig. 14.1.5.6. Integrated shovel and scraper operations.

Fig. 14.1.5.7. Henry tipple and ore transport truck and trailers.

boards. Weight studies show a typical load to average about 80 tons (73 t). These units were put to work in 1987 and averaged about 4200 operating hours by 1989. Availability averages about 94% and 67% utilization of available time.

The equipment used on any particular day is dependent upon the available materials, haul distances, and weather conditions. The shovel is matched with sufficient trucks to maximize its output; typically this requires three trucks. Because of the extreme weather conditions encountered, truck operation in winter storms may be shut down and the operators transferred to scrapers. The scraper fleet also is adjusted to reflect operating conditions. During winter storms and pioneering operations, a larger number of all-wheel-drive 657s must be used. As grades flatten and hauls lengthen, more 651s are utilized. Two scraper spreads are worked on a typical day. Each consists of two 657s and five 651s.

The usual assortment of patrols, water trucks, dozers, portable light plants, and other equipment support pit operations. In addition to the dozers used in scraper support, one or two units/shift are scheduled to cover waste dumps, shovel cleanup, and scaling of the highwalls. During the warm weather months, an 8000-gallon (30-m^3) water truck is used for dust control on all pit roadways. A Cat 16G patrol is used for maintenance of haul roads.

Ore mining is conducted only during daylight hours to maximize ore recovery and quality control. As noted previously, the individual ore beds are knocked down utilizing the side-arm-equipped dozers. The ore is loaded into the scrapers and hauled to the adjacent tipple stockpile area. There it is put in three graded ore piles. During the period of May through October, the ore may be placed in stockpiles or placed directly over the loadout hoppers, depending upon the grade of material being shipped to the plant. The volume of ore mined during the off season is minimized because of quality problems encountered during winter mining and the need to minimize the volume of ore requiring double-handling.

The final operation at the Henry mine is screening and loading ore into the haul trucks for transportation to the plant (Fig. 14.1.5.7). Ore from the stockpile area is dozed into two hoppers buried in the stockpile pad fill. From there it is conveyed out and over two single-deck screens. Oversized material is directed to a rotating trommel with the undersized product falling directly into loadout hoppers. Some ore accompanies the oversized material in the form of high moisture balls or as a surface coating on limestone seams that are too thin to be economically separated during the mining process. The rotating action of the trommel is usually sufficient to break down the balls of ore and clean the ore from the waste material. The fine ore falls through the sides of the trommel and is conveyed back to the screens. Oversize material coming from the trommel is backfilled with the normal pit waste.

The haulage fleet for the haul to the plant consists of seven specifically designed tractors and 14 belly-dump trailers. Each trailer has a 70-ton (64-t) payload. Three of the tractors are newer units equipped with 750-hp (559-kW) Cat engines and specially designed Clark transmissions. These units were built by Kenworth and Pacific specifically for this operation. Each of these units pulls three trailers. The remainder of the tractors were built in 1970 to pull three trailers down the haul profile to the plant from the original tipple site. Each of these units, however, is capable of pulling only two trailers from the present tipple. In current practice, two older tractors pulling two trailers are used along with the newer units. The final trailer is coupled to one of the older tractors and maintained on standby for use when repairs to one of the main trucks extend beyond one shift.

14.1.5.5 Product Control

As with many sedimentary deposits where the ore zone is restricted to specific lithologic units, quality control is simplified greatly. However, production of a quality product is still of the highest priority. Most ore/waste designations are obvious. Analysis of the core obtained during exploratory drilling is used to predict each area's overall chemistry and general mining scheme. Ore unit designations are made based upon the chemistry and hardness characteristics of the core and verified during operation.

Pit sampling during mining is used to update and monitor the original chemistry forecast. Detailed trench sampling of both major ore units is conducted on about 300-ft (90-m) centers for each mining lift. The samples on the next lift will be offset by 100 ft (30 m). In this way, trends in chemistry can be monitored. Additionally, faulted zones are sampled to determine if normal lithological grade correlations can be maintained or if downgrading of one or more units is needed to maintain quality limits of each stockpile. Periodic grab samples are taken on the ore face and stockpile to ensure that proper cleanup of waste seams has taken place.

In order to track mining progress, a minimum of five complete field surveys of the active working area is conducted each year. Progress against final wall designs is surveyed each time the pit floor drops 10 to 15 ft (3 to 4.6 m) vertically. Each lift of ore is surveyed as to the location of the top and bottom of each major bed. At the end of one year, a detailed map is prepared and submitted to the BLM showing all disturbed and reclaimed areas.

The surveys are monitored by mine planning personnel for deviations in geology and progress. Problems noted are evaluated for possible adverse effects on wall stability and reconciliation of ore and waste volumes. Typically, during the third quarter of each year, an operating plan, which produces sufficient ore for the coming year's anticipated elemental phosphorus production, is developed. This plan is reviewed and updated at year-end based upon the actual surveys.

14.1.5.6 Ancillary Facilities

Placement of overburden materials is an important part of the planning and mining process. It is Monsanto's goal to provide for the return of disturbed lands to premining uses as soon and as efficiently as practical. In order to achieve this, the planning of material movement is critically important. Every effort is made to maximize backfilling of each pit area without the rehandling of waste materials.

Each area is designed to minimize the volume of waste rock placed in outside waste piles. These outside waste areas are prepared by removing vegetation and topsoil. This provides for the most stable base practical. Coarse limestone and chert are placed in the core of the waste pile. The altered center waste shales are layered on the sides and top. A minimum covering of 3 to 5 ft (0.9 to 1.5 m) of altered shale material is placed over all areas. Research efforts by Monsanto, the US Forest Service Intermountain Research Station, and other western phosphate producers have shown the altered waste shales to be an effective growing medium for reclamation plantings. In this way, the small amount of topsoil recovered from the pit and outside waste piles is saved for use after the cessation of operations on roads, stockpiles, service areas, and other disturbed lands. The waste piles are designed to be rounded in shape with a maximum side slope of 3 ft (0.9 m) horizontal to 1 ft (0.3 m) vertical. These areas blend well with the surrounding natural features and are easily reclaimed.

The adjacent mined-out areas are targeted for most of the waste material. Once again, the coarse limestone and chert material is dumped into the bottom of the pit and the altered shales placed over it. The available material is strategically placed to minimize the visual effects of mining. Material is placed higher along the highwall faces leaving a shallow swale in the middle of the now partially backfilled pit. Slopes are targeted at 18°, but some areas are allowed to go as steep as 24°.

All disturbed areas are reclaimed as soon as practical after mining. Placement of altered shales and final shaping is an integral part of the mining process. Reclamation crews complete only minor shaping and seedbed preparation. Although artificial fertilization is not a necessity, almost all areas are fertilized utilizing a tractor-drawn spreader. The addition of artificial fertilizer aids in rapid plant growth and the prompt control of runoff. The area is typically seeded with a Brillion seeder-packer. On flat or gently sloping terrain, the fertilizer spreader and seeder are pulled by a farm type tractor. On steeper slopes or where the seedbed may be rocky, a Cat D-5 tractor is used. Seeding is done along the contour on slopes of up to 18°, and up and down the slope on steeper terrain. The seed mix used consists of a mixture of grasses, legumes, and forbs.

Two maintenance work areas are utilized at the Henry mine. The mining contractor's office and major shop facilities are located at the Ballard mine. Since this site is now some 6 miles (9.7 km) from the active mining area, a separate yard and outdoor service area are located adjacent to the active pit. During the summer months, almost all maintenance is conducted at the mine, with the Ballard shop handling only the mine-to-plant ore trucks and major overhauls. During other periods, more maintenance work is shifted to Ballard. The Ballard shop has three drive-through bays (each of which is sufficient to handle an ore haul truck with two trailers), a small two-story warehouse, and an outside wash area. These facilities were originally constructed in the mid-1960s and are no longer adequate to service the current mining fleet. Height and width considerations preclude using the Ballard shop for servicing the Cat 777Bs, and distance constraints will not allow servicing of the hydraulic shovel at this facility. For these reasons a new shop will be constructed near the active mining areas in the near future.

14.1.6 STEEPLY DIPPING BITUMINOUS COAL: KEMMERER MINE

GEORGE B. WHITMAN

14.1.6.1 Mine Description

The Kemmerer mine (Fig. 14.1.6.1), owned and operated by The Pittsburg & Midway Coal Mining Co. (P&M), is located 3 miles (5 km) southwest of the town of Kemmerer, WY (Fig. 14.1.6.2). Coals produced are high-quality subbituminous B with the following characteristics: 9900 Btu/lb (23,027 kJ/kg), 0.6% sulfur, 5.0% ash, 39.0% fixed carbon, 36.0% volatile matter, and 20.0% moisture. Underground mining at this property commenced on a small scale as early as 1881 and continued intermittently until 1964. Underground production was replaced entirely by the current surface operations, which began in 1951.

Surface coal reserves are approximately 120 million tons (109 Mt), while the probable underground reserves are at least 500 million tons (454 Mt) (as of 1989).

The 10,000 acres (40 km^2) under permit consist of a series of active and proposed pits that extend in a north-south direction for approximately 7 miles (11 km), from the FMC mine on the south to US Highway 30 on the north. Annual production is in the range of 3 to 4 million tons (3 to 3.6 Mt). Approximately two-thirds of the production is shipped by conveyor to a mine-mouth power plant; the balance is shipped by train to smaller industrial customers. The mine uses shovels and trucks to move 15 to 20 million bank yd^3 (11.5 to 15.3 million bank m^3) of waste rock on an eight-hour shift, three-shift day, five-day week, and approximately 250 days/year.

There are three mining areas that include 1-UD started in 1971, 2-UD in 1983, and I-Area in 1988. Each of these areas is

Fig. 14.1.6.1. Aerial photograph of the Kemmerer mine (1-UD pit) looking south.

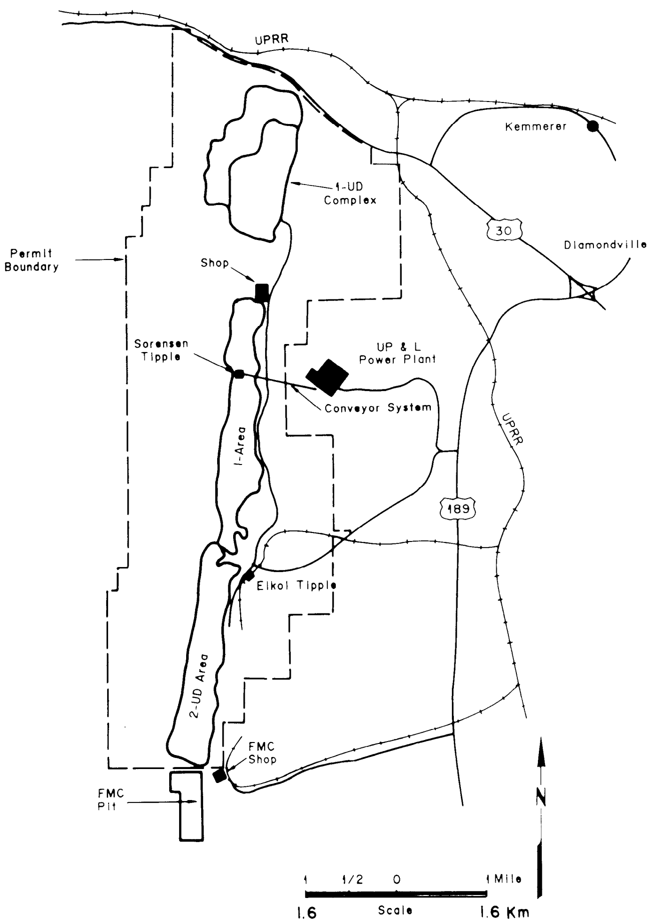

Fig. 14.1.6.2. Map of the Kemmerer mine and surrounding facilities.

separated from other areas by either geologic features or conditions left by earlier mining activities.

14.1.6.2 Deposit Description and Geology

Two coal-bearing formations exist in the immediate area (Fig. 14.1.6.3), the Frontier and the Adaville. The Frontier Formation has three major seams ranging from 5 to 15 ft (1.5 to 4.6 m) thick. The Adaville has up to 30 different seams ranging from 2 to over 100 ft (0.6 to over 30 m) thick. These two formations are separated by the Hilliard Formation, which is about 5000 ft (1500 m) thick.

The Kemmerer mine is situated within the Adaville Formation. The Adaville is approximately 2900 ft (880 m) thick and is Late Cretaceous in age. The youngest sediments in this formation are possibly of Tertiary Age. The Adaville consists of gray interbedded sandstone, siltstone, and clay with carbonaceous clay zones and coal seams. The sediments strike generally north-south and dip to the west from 18 to 28°.

During Late Cretaceous time, this portion of the North American Continent was located at 60° latitude. At this time, the area was a large delta-prodelta-swamp environment. A vast sea existed to the east, and volcanically active mountains existed to the west. The complex geology within the Adaville Formation was caused by the constant shifting of the delta and the transgression and regression of the sea.

In the Early Tertiary age, major structural changes occurred in this area, creating what is known today as the Overthrust Belt. Located approximately 1 mile (1.6 km) west of the mine, the Absaroka Thrust Fault displaced up to 15,000 ft (4600 m) of sediments and is one of several faults of this nature. At the same time, the faults were active, and considerable folding also occurred. As a result, the Adaville Formation was tilted into its present position.

14.1.6.3 Mine Development

The entire upper horizon of topsoil is removed prior to mining and overburden disposal. The topsoil is strategically stockpiled for later reapplication to reclaimed areas, or topsoil is replaced immediately if adjacent reclaimed sites are available.

Within each mining area are a series of pits, and within each pit are a number of horseshoe-shaped cuts open to the east. The cuts, as defined at Kemmerer, extend vertically from the surface to the lowermost seam. Since most of the coal is concentrated in the three lowest seams (i.e., No. 1 through No. 3), these seams must be available when developing less-productive portions of adjacent cuts.

Scheduling of adjacent cuts within the individual areas and combining area productions results in desired coal flow and uniform costs. Each cut must be scheduled carefully to achieve balanced coal production by combining high-ratio benches with low-ratio benches that intersect the bottom three seams. This combination of cut ratios for all mining areas is referred to as the overall phase ratio.

1-UD AREA. The 1-UD area (Fig. 14.1.6.1) is permitted as a special bituminous operation, allowing total out-of-pit spoil and minimum in-pit reclamation. As permitted, the entire pit was intended to be left open. However, an acquisition of the adjoining reserves to the north will result in a revised mine plan that will employ the original 1-UD pit for disposal.

Production benches are at 33-ft (10-m) intervals with 50-ft (15-m) safety benches at 100-ft (30-m) vertical intervals. The overall pit wall is designed at 45° (Fig. 14.1.6.4).

The 1-UD area encompasses nine distinct coal seams (Table 14.1.6.1), numbered in sequence from bottom to top. These thicknesses are taken at mid-pit on an east-west cross section.

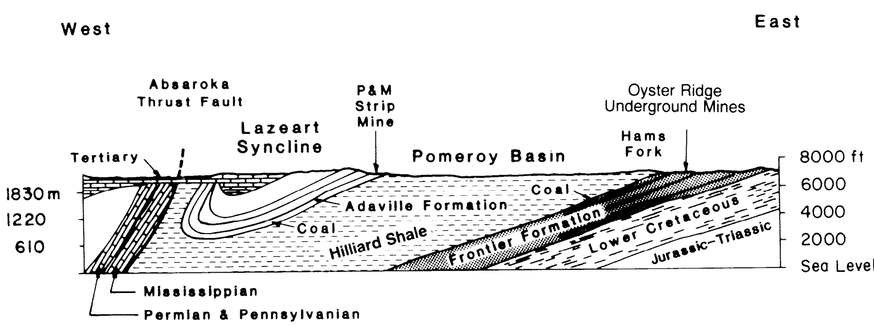

Fig. 14.1.6.3. Geologic cross section.

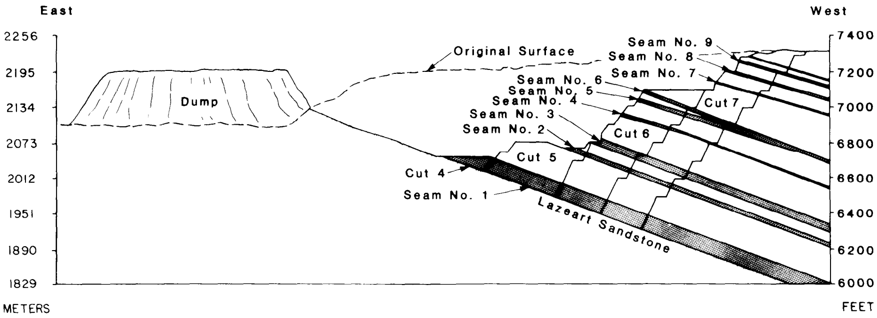

Fig. 14.1.6.4. Typical cross section through the 1-UD pit.

Table 14.1.6.1. Coal Seams in 1-UD Pit

Seam No.	True Thickness	
1	87 ft	26.5 m
2	28 ft	8.5 m
3	55 ft	16.8 m
4	12 ft	3.7 m
5	25 ft	7.6 m
6	15 ft	4.6 m
7	6 ft	1.8 m
8	9 ft	2.7 m
9	12 ft	3.7 m
Total	249 ft	75.9 m

There is wide variation in individual seam thickness along strike. Local faulting, particularly in the south wingwall of 1-UD, makes it difficult to forecast available coal. As a consequence, sequence changes involving other areas have been necessary to maintain the desired overall mining ratio. This condition is expected to persist in future mining areas.

Overburden waste is disposed of entirely out-of-pit in the 1-UD operation (Fig. 14.1.6.1). The dump development plan includes the initial construction of a three-terrace outer ring with 50-ft (15-m) benches, variable vertical intervals, and 17° slopes. These maximum slopes are stipulated in the approved reclamation plan and are necessary for stability and to enhance revegetation.

Fig. 14.1.6.5 illustrates a typical mining sequence in the south wingwall or end section. The north wingwall development is similar, except for variations in the number and location of seams. The bench width varies from 350 to 400 ft (107 to 122 m); in this case, a section line is drawn to split the bench in halves.

The inner half of the bench serves as the haulage road for coal and overburden exiting the area to the east. There are five seams of coal to be removed, with the No. 4 Seam missing in this illustration.

Because the seams dip to the west, all development must progress from west to east, which alternately removes overburden and coal. The sequence to uncover the seams varies, depending on the relative location of each seam.

Access ramps are limited to 8% Pit planning, therefore, requires sufficient horizontal distance between adjacent seams to drop 33 ft (10 m), the designed bench interval. Seams 6, 2, and 3 can be removed in this manner. Because of space limitations, seams 5 and 1 are accessed horizontally, as shown in Fig. 14.1.6.5.

After all seams have been removed, the ribs that remain are taken, progressing from east to west. During this process, the

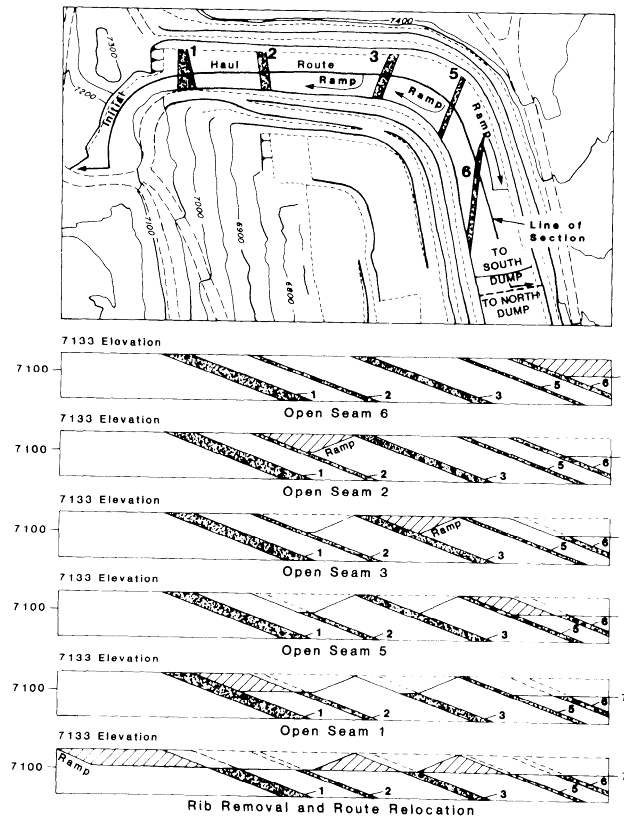

Fig. 14.1.6.5. Bench development for the south wingwall, 1-UD pit.

overburden haulage route is relocated to the outside of the bench and extended to the east pit limit. Finally, the inner portion of the bench is removed in a sequence similar to the process identified on Fig. 14.1.6.5. In this case, however, all development is horizontal, and work progresses from the outside inward.

2-UD AREA. The first pit in the 2-UD area was designed with three vertical cuts containing 40 million yd^3 (30.6 million m^3) of overburden and 8 million tons (7.3 Mt) of coal. There will be a series of seven additional pits developed, in succession, to the south—each one fully or partially fitting into the previous pit.

The lowest minable coal in 2-UD is the No. 2 Seam. The seam identified as No. 1 was mined earlier by underground methods and terminates just beyond the limits of the first pit development. The final pit must be backfilled to the extent that positive drainage is achieved. To accomplish this, some material from previous pits will be stockpiled at the perimeter for final haulback.

Table 14.1.6.2. Drilling Summary

Unit	Application	Pattern	Hole Diameter	Production Rate
45R	Overburden	37 × 39 ft (11.3 × 11.9 m)	10 5/8 in. (270 mm)	75 ft/hr (22.9 m/h)
DM50	Overburden	30 × 39 ft (9.1 × 11.9 m)	9 in. (229 mm)	68 ft/hr (20.7 m/h)
DM50	Coal	20 × 25 ft (6.1 × 7.6 m)	9 in. (229 mm)	83 ft/hr (25.3 m/h)

Table 14.1.6.3. Primary Loading Equipment

Unit	Size	Number	Util.	Production
201M Electric Shovel	25 yd^3 (19 m^3)	2	97%	1001 yd^3 OB[a] (765 m^3)
2100 P&H Electric Shovel	15 yd^3 (11 m^3)	1	93%	774 yd^3 OB (592 m^3)
UH-801 Backhoe	12 yd^3 (9 m^3)	1	79%	301 yd^3 OB (230 m^3)
600E Front-end Loader	12 yd^3 (9 m^3)	1	60%	OB and Coal
600E Front-end Loader	22 yd^3 (17 m^3)	2	87%	OB and Coal

[a]Overburden

The 2-UD production benches are at 50-ft (15-m) intervals, and safety benches are 100 ft (30 m) wide. An oversized bench is designed into the highwall for eventual haulback operations. The overall highwall angle is 45°.

I AREA. Development of I area started on the south end, with the eventual removal of 36 million yd^3 (27.5 million m^3) of out-of-pit spoil. A succession of pits follows with the north limit being just short of the shop/office complex. The final pit will not be backfilled, but the floor will be topsoiled and seeded.

Production benches will be 50 ft (15 m) high with safety benches 50 ft (15 m) wide at 100-ft (30-m) intervals. The highwall designed slope angle is uniformly 45°.

14.1.6.4 Unit Operations

DRILLING AND BLASTING. Four units are used for blasthole drilling. These include two Bucyrus Erie 45R electric, and two Ingersoll Rand DM-50 diesel-powered drills (Table 14.1.6.2). The highly flexible diesel drills are necessary in confined areas and on the steep slopes resulting from the 20° dip of the formation.

In dry overburden holes, heavy ANFO is used as the bottom load and standard ANFO as top load. Emulsions are used in wet holes. The density is adjusted depending on energy requirements.

LOADING. Two 25-yd^3 (19.1-m^3) and one 15-yd^3 (11.5-m^3) electric shovels comprise the principal overburden loading equipment (Table 14.1.6.3). Auxiliary equipment includes a 12-yd^3 (9.2-m^3) backhoe for use in confined areas adjacent to the highwalls, and a 12-yd^3 (9.2-m^3) front-end loader (FEL) employing an ejection-type bucket. Coal is loaded using two 22-yd^3 (16.8-m^3) FELs, also with ejection buckets.

HAULAGE. Fifteen 170-ton (154-t) Euclid rear-dump trucks are used for overburden haulage. These units also are used occasionally for coal haulage when demand increases or there is a temporary shortage of coal trucks. Coal is hauled in six 120-ton (109-t) Wabco rear dump trucks and one 150-ton (136-t) rear dump truck.

Coal is transported the entire distance to the tipples by truck from the three active pits. Typical coal haul distances are shown in Table 14.1.6.4. The pit/tipple combination is determined by the quality and availability of coal.

Table 14.1.6.4. Coal Haulage Distances—One Way

Origin	Destination	Distance
1-UD Pit	Sorensen (Power Plant) Tipple	2.8 miles (4.5 km)
1-UD Pit	Elkol (Rail/Industrial) Tipple	5.2 miles (8.4 km)
2-UD/I-Area	Sorensen Tipple	3.5 miles (5.6 km)
2-UD/I-Area	Elkol Tipple	1.2 miles (1.9 km)

14.1.6.5 Quality Control and Production Coordination

All area design limits are based on an exploration program consisting mainly of structure holes on wide centers and a sufficient number of core holes for long-range quality scheduling. An annual summer development drilling program is conducted to assure greater quality detail and to identify unusual localized structural conditions that might impact coal flow.

Fortunately, there is a high degree of quality uniformity within each of the nine minable seams. As the quality of each seam is established through grab samples or actual experience, future control is assured with only slight variations. With critical limits on ash, care must be exercised to thoroughly clean the top of coal (often a difficult operation on 20° slopes). During coal cleaning (using dozers), it is estimated that 0.5 ft (0.15 m) is lost on both the top and bottom of the seam. This 1-ft (0.3-m) loss also is one of the parameters used in the computer reserve model.

An ASTM sampler is located at both tipples. There also is an on-line ash analyzer on the conveyor system to the power plant. This device permits controlling "as received ash" to ± 0.5% on a shift-by-shift basis.

Broad, long-range mine plans are reviewed on an annual basis by top management and in greater detail at closer intervals as required.

An engineer is assigned to each mine area. This individual, in consultation with production personnel, develops a three-week plan based on the performance of all primary excavating units. This entire plan is provided on a detailed map.

14.1.6.6 Ancillary Facilities

The shop is located near the north end of the I area. It contains large equipment and light-fleet maintenance shops, as well as the warehouse. The large equipment shop includes 10 bays with an area of 16,000 ft^2 (1500 m^2). The steam-cleaning bay, electrical shop, and unheated storage are separate and detached.

14.1.7 AGGREGATE: FREDERICK QUARRY

BERNARD L. GROVE

14.1.7.1 Mine Description

The Frederick Maryland quarry of Genstar Stone Products is located on the eastern edge of Frederick, MD. Frederick city itself is located 40 miles (64 km) west of Baltimore and 40 miles (64 km) northwest of Washington, DC. The area is traversed by two interstate highways, I-70 to Baltimore and I-270 to Washington. Additionally, the CSX railroad serves Frederick, thereby providing an alternate means of transporting crushed stone. The proximity of two major cities and their attendant growth peripheries provide a strong and growing market for the limestone products produced at the Frederick location.

The mine site covers some 800 acres (3.2 km^2), an assemblage of smaller tracts aggregated over the course of 100 years. The current quarry (December 1988) occupies about 120 acres (0.5 km^2), while the disturbed area covers about 200 acres (0.8 km^2). The mine is approximately 2500 ft (760 m) long by 1500 ft (460 m) wide and 220 ft (67 m) deep at the lowest level.

A predecessor of Genstar Stone Products, the M.J. Grove Lime Co., began quarrying limestone at the site in the late 1880s. At the time, most of the stone production was converted to lime through shaft and pot kilns. The lime was used for agricultural purposes and in the masonry trades. Because the chemical content of the limestone deposit was not homogeneous, the trend over the life of the quarry has been away from lime and into crushed commercial aggregate. Lime burning was abandoned completely in 1956.

In 1988, the quarry produced and sold 4.6 million tons (4.2 Mt) of commercial aggregate over a wide range of products. Available products range from armor stone in sizes up to 10,000 lb (4500 kg) down to mineral filler with top size of 120 mesh (0.12 mm). Of the majority of products sold, approximately 95% lies between –2 in. (50.8 mm) and +200 mesh (0.07 mm) in size. Waste product generated at Frederick is minimal. The demand for fill dirt in the growing metropolitan area provides a market for most of the earth waste. In recent years, the overburden rock and soil has been processed, producing a substandard base material. This product is highly salable. Any waste generated is used to build boundary berms (Fig. 14.1.7.1). These berms create a buffer between the quarrying operation and the growing commercial area around the quarry.

Fig. 14.1.7.1. View of boundary berm construction.

Fig. 14.1.7.2. Preparation of top bench.

The quarry and crushing plant are operated 10 months/year. Generally the months of January and February are utilized for maintenance. The quarry and primary crushing plant are operated on two-shift, 18-hour days. The secondary crushing plants are run three shifts a day, five days a week, with some Saturday crushing for special high demand sizes.

14.1.7.2 Deposit Description and Geology

The Frederick quarry sits astride two massive limestone formations. These beds lie on a north-south-trending fold. The eastern deposit in the quarry is the Frederick Limestone. This is a blue, slabby, thin-bedded limestone with minor shale of Cambrian Age. The deposit is approximately 500 ft (150 m) thick. The western deposit is the Grove Limestone. This is a light-to-dark gray, thick-bedded limestone containing dolomite beds in the lower measures. The deposit is of Cambrian Age and is approximately 600 ft (180 m) thick.

Both the Grove and Frederick Limestones have good-to-excellent properties for commercial aggregate. Los Angeles abrasion test results are in the 25 to 30 range. There are occasional problems with the shape of the Frederick Limestone particles, but this problem is overcome through controlled reduction at the tertiary crushers and blending of the Frederick and Grove materials.

The ratio of waste to stone is very low at the present time, measuring about 14:1 stone to waste. The ratio will increase as the quarry is deepened, and local demand for waste, fill dirt, and substandard base should also increase. The proven permitted reserves at the Frederick quarry at the end of 1988 were 500 million tons (454 Mt), but development drilling indicates an additional 250 million tons (227 Mt) lower in the stratigraphic sections.

14.1.7.3 Mine Development

Due to the increasing demand for materials previously considered as waste products, site preparation at Frederick has changed substantially in the last 40 years. The quarry is presently on a five-year mining plan that is updated annually. The plan considers expansion of the quarry westerly, southwesterly, and vertically over the five-year period. One major objective of the plan is to optimize the blending of the two limestones and minimize the haul to the primary crusher.

Initial removal of soil and subsoil is performed by outside contractors seeking select fill. The properties of the overburden, a combination of soil and weathered limestone sand, make an ideal fill material. Once the overburden has been removed to a predetermined elevation (Fig. 14.1.7.2), a decision is made as to whether or not the uncovered area is to be crushed for its value as substandard base or treated as waste. This area also represents the top bench or level in the quarry. As the top level is pushed back, a series of faces, ranging from 40 to 100 ft (12 to 30 m) in

Fig. 14.1.7.3. Overview of mine benches.

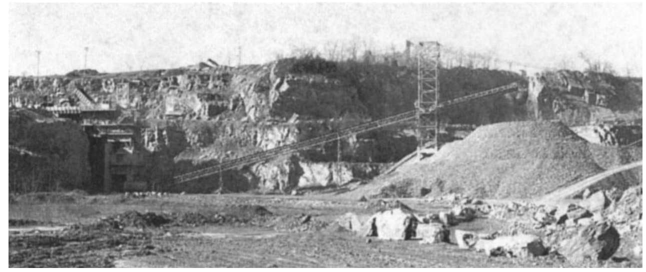

Fig. 14.1.7.4. In-pit crusher.

height, are developed (Fig. 14.1.7.3). Bench heights are based on rock quality, stability, and quarry development stage. At the present time, there are five benches on the deepest side of the operation.

14.1.7.4 Unit Operations

DRILLING. Contract drillers provide all holes for blasting using air track and well drills. Air tracks are utilized in the top or substandard levels because of their greater maneuverability and stability. Small holes also are more practical in the seamy upper levels where spacings must vary widely due to sand pockets. A typical drill pattern in the upper level would be 9 by 9 ft (2.7 by 2.7 m) drilled to a 40-ft (12-m) depth using bits 2.5-in. (64-mm) in diameter. Once the substandard or top level is removed, all drilling, other than toe holes or secondary blasting is accomplished with rotary drills. The contractor performing this work has 10 drills and can provide drilling equipment as required. The primary drills used for production are IRD-4s. The holes are 6 3/4 in. (171 mm) in diameter, drilled on an average pattern of 14 by 18 ft (4.3 by 5.5 m). The pattern, however, varies based on bench heights, site conditions, and production requirements. The hole depth varies from 40 to 100 ft (12 to 30 m). Primary production drilling averages 25 holes per 10-hour day, but the schedule varies widely based on demand. All drilling and blasting are performed under the direction of a Genstar quarry supervisor. Seismographs are utilized with every shot, and all records are analyzed by an independent consultant. Records also are maintained at the quarry site and are available to various state agencies and any concerned citizens.

BLASTING. The evolution of explosives technology industry-wide is mirrored at the Federick quarry. Dynamite and all stick material, along with fuse and electric caps, have been replaced with ANFO, slurries, and nonelectric detonating systems. Water is not generally a problem, but where water occurs, holes are dewatered and, whenever possible, bulk loaded with a combination of slurry in the bottom and ANFO higher in the column. If water is persistent and the ground highly permeable, sleeves may be used to protect the explosive. All shots are double primed. A booster is placed at the top and bottom as a precautionary safety measure. Each hole is stemmed with 12 to 14 ft (3.7 to 4.3 m) of granular material. Again, as with drilling, all explosives work is performed by contractors under the supervision of Genstar's quarry supervisor. Very little explosive is stored on site, as most of the bulk explosives are brought in daily from a bulk storage facility at another Genstar location.

Powder factors vary widely, depending on operating experience in the particular area of the quarry. A good average is 2.5 to 1 ton/lb (5.0 to 2.0 t/kg).

LOADING. Once a shot is fired, loading is performed by two 11-yd^3 (8.4-m^3) hydraulic shovels. The loading operation at the Frederick location mirrors the evolution of loading within the quarry industry. Until the late 1960s, all primary quarry loading was performed by 2.5- and 3.5-yd^3 (1.9- to 2.7-m^3), cable-hoist shovels. Beginning in the late 1960s and continuing through the early 1980s the primary loading machine was the rubber-tired loader. Loaders, while very versatile, are high-cost machines for large, well-developed quarries such as Frederick. In 1983, the first hydraulic shovel was acquired. This machine, with some 20,000 hours of operation as of December 1988, was the first large hydraulic shovel placed in a quarry operation in the eastern United States and has proved to be a highly reliable and efficient loading machine.

In 1988, to meet increased production demands, a second 11-yd^3 (8.4-m^3) shovel was added. The machines provide a combined loading capacity of 1500 tph (1360 t/h) and to date have an availability in excess of 90%. An 8-yd^3 (6.1-m^3) rubber-tired loader is available for backup, cleanup, and loading rip rap and other stone sizes.

HAULAGE. Hauling from quarry face to primary crusher is performed by off-highway trucks. As with the quarry loading equipment, the size of the haul units has increased over the years. Prior to 1973, haulage units were 30 to 35 tons (27 to 32 t) in capacity. In 1973, 50-ton (45-t) trucks were placed in service. In 1987, two 85-ton (77-t) trucks were purchased, and an additional truck was added in 1989. The present quarry fleet consists of three 85-ton (77-t) and three 50-ton (45-t) trucks with a 50-ton (45-t) truck in reserve. As a general mode of operation, one shovel loads two 85-ton (77-t) trucks, while the second shovel loads 50-ton (45-t) trucks. The average haul to the primary crusher is approximately 2000 ft (600 m) round trip.

CRUSHING. Primary crushing is accomplished in-pit, (Fig. 14.1.7.4). Rock is hauled from the face to the primary crushing station and is dumped into a 250-ton (225-t) rock box above a 7- by 24-ft (2.1- by 7.3-m) reciprocating plate feeder. The use of this feeder has proven invaluable, both in optimizing truck utilization and in reducing lost time at the primary by providing a controlled feed to the crusher.

The primary crusher is a 42- by 65-in. (1.1- by 1.65-m) gyratory. Crushed rock with nominal 15-in. (0.38 l-mm) top size is fed by 54-in. (1.4-m) belt to an 80,000-ton (72,575-t) surge pile located over a vault. The vault contains a 5- by 10-ft (1.53- by 3.05-m) feeder. At the feed point, the crushing system becomes automated and is under the control of a microprocessor. Feed from the surge pile is carried to the ground elevation. This requires a lift of approximately 100 ft (30 m) via an 850-ft (259-m), 48-in. (1.2-m) conveyor. The feed is split through a 200-ton (18l-t) splitter bin. The splitter bin feeds a new secondary crushing plant with a nominal capacity of 750 tph (680 t/h) (Fig. 14.1.7.5) and an old secondary crushing plant with a nominal

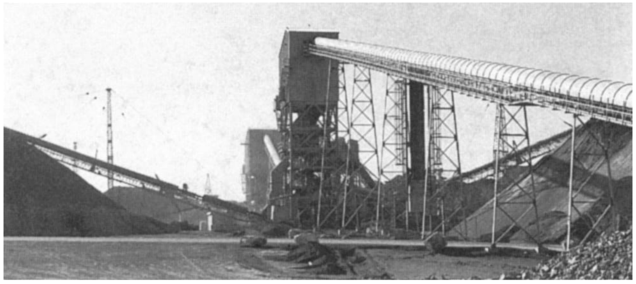

Fig. 14.1.7.5. Secondary crushing plant.

capacity of 500 tph (454 t/h). Through a variety of tertiary crushing stations, it is possible to produce as many as 20 different products simultaneously upon demand. This unique ability to produce a wide variety of sizes has played a key role in the growth of the Frederick operation.

PRODUCT TRANSPORTATION. Of more than passing interest is the fact that due to the quarry's strategic location, more than one-third of the commercial aggregate produced is converted or incorporated into other construction materials. Five bituminous concrete plants are located at or adjacent to the quarry. Included in these is the largest bituminous concrete plant in the state of Maryland. There are four ready-mixed concrete plants at or adjacent to the quarry. Finally, a large modern concrete block plant is in close proximity. The location of these end users provides significant economic advantages. Raw materials can be provided to the user plants by large mobile equipment not subject to highway weight restrictions. A second benefit is the elimination of double hauling; that is, raw material is delivered directly to the finishing plant and finished product is hauled out. With finishing plants at or adjacent to the quarry site, finished product goes directly to the point of use. This fact has a significant effect on reducing volumes of traffic over increasingly congested urban highways.

14.1.7.5 Product Control

Commercial aggregate sold from the Frederick quarry is under strict product control, both as to quality and quantity. Federal and state specifications are becoming more rigid each year. Product samples are taken from operating faces on a daily basis to assure conformity with specifications. By utilizing frequent sampling techniques, trouble spots can be isolated and corrected. Additionally, as there are size overlaps within products, frequent gradation checks assure the operations management that optimum production of critical sizes can be assured.

14.1.7.6 Ancillary Facilities

The sale and billing of all aggregate are fully automated. All vehicles, whether customer or contract hauler, transporting stone from the Frederick quarry must stop on the inspatch side of the Material Distribution Center (MDC). At the MDC, all information relative to the sale involving the individual vehicle is recorded. The truck is then directed to the proper loading point where material is loaded. The vehicle then returns to the MDC on the dispatch side. As the truck crosses the scale at the MDC, a ticket is created. Once the ticket is created via scale, the information from the ticket is handled electronically and is not seen again until the invoice is received and opened by the customer.

All phases of product and material handling and dispatch from mine planning to weighing of the finished product are under the direct control of the plant superintendent. This concentration of control minimizes jurisdictional disputes and makes problems easy to find and correct.

One area of paramount concern with both residential and nearby commercial neighbors is maintaining acceptable environmental conditions. Frederick's first step is to buffer the operation on all sides. Buffering is accomplished with berms created from waste. The berms are planted with grass and legumes and eventually with fast growing trees. As a result of the buffering, few people are aware of the large-scale operations at the site. In addition to buffers, dust and noise control are essential. The Frederick quarry has embarked on a long-range paving program that will, over a five-year period, provide a paved surface for all plant haul roads. A sweeper will be provided to remove dust from the paved surface. The new secondary crushing plant is a wet-process plant, thereby eliminating process dust. Plans are currently underway to incorporate wet process into the entire secondary crushing facility to reduce dust emissions. Noise emissions are monitored by regular boundary-level readings by dosimeter. Any violations can be pinpointed and corrected. Seismograph readings are taken with every shot, and historical data provide limiting loads for blastholes, the number and design of delays, and overall size for shots.

Maintenance is another major concern. All major equipment, mobile and stationary, is placed in a preventive maintenance program. The mobile equipment shop is capable of accommodating any piece of equipment presently used, including the hydraulic shovel and 85-ton (77-t) trucks. This facility ensures an environment for safe and clean maintenance of equipment free from weather hazards.

Well-trained and educated employees, sound environmental practices, good preventive maintenance, and adherence to maintaining these programs are the keys to survival in a modern aggregate operation. Being a good neighbor with responsible attitudes also is essential for acceptance in the community.

Chapter 14.2
QUARRYING

M.K. McCarter and L.P. Meade

14.2.0 QUARRY MINING

M.K. McCarter

Quarry mining is a term often applied to either mining of dimension stone or aggregate (Morrison and Russell, 1973). It is preferable, however, to restrict this term to production of dimension stone only (Hartman, 1987).

The products of quarries are prismatic blocks of rock such as marble, granite, limestone, sandstone, slate, etc., that are useful for primary construction of buildings and monuments or decorative facing materials for the exterior or interior of buildings. Quarries normally have benches with vertical faces ranging from a few feet (meters) to 200 ft (60 m) in height. The overall depth of a quarry may be as much as 1000 ft (300 m). Material is removed in a highly selective manner using time-consuming and expensive methods for freeing the blocks from the surrounding formation. Production from individual quarries is relatively small compared to other surface mining methods but has a high average product value of $114/ton ($126/t) (Hartman, 1987).

From the mid-1800s through the mid-1900s, the dimension stone industry was an essential resource for construction of North American cities, railroads, and major public buildings. It reached a zenith in the 1960s and then entered a slump which continued through 1985. The current high demand for natural stone is bringing about a resurgence in the industry. This demand is forcing higher product values along with sharply increasing US imports, principally from Italy. Production in the United States, however, is lagging the demand because of environmental restrictions along with the required investment and lead time necessary to develop deposits or restore existing quarries. In addition, the demand for cubic stone, a more abundant resource, is declining in favor of large panels of exterior and interior cladding which is more difficult to produce. As of the late 1980s the number of active quarries in North America was approximately 300 with only about six integrated quarries and mills of major importance to the local economy (Meade, 1986a).

The characteristics that make a deposit commercially viable for dimension stone include color, appearance, competence, uniformity, and freedom from defects. Location of suitable zones within a formation is accomplished normally through diamond core drilling. Planning the excavation is based primarily on geologic factors such as direction and attitude of bedding and on suitable disposal sites for overburden and unsuitable material from the quarry.

There are four major operations in quarrying: overburden removal and cutting, splitting, and handling stone. Overburden is loosened by ripping or blasting and then removed by dragline, scraper, or front-end loaders. Occasionally, the deposit is cleaned by hydraulic monitors (Chapter 15.1.6). Once the surface is cleared, an opening cut or slot is produced across the quarry width. This slot provides an additional free face which facilitates removal of subsequent blocks until the first lift, extending across the entire width and length of the quarry, has been removed or until sufficient room has been produced to remove another key block initiating the second lift (Morrison and Russell, 1973; Power, 1975).

Each stone quarry is unique and requires a customized cycle of unit operations. The upper surface and key slot provide two free faces (the top and front of a prismatic block). Three additional faces are produced, which define the ends and the back. These faces are normally produced by line drilling with pneumatic hammers mounted on a "quarry bar." Soft formations may be cut with wire saws, carbide tipped chain saws, or circular saw blades impregnated with diamond or other abrasive materials. Hard formations with minerals exhibiting contrasting thermal expansion characteristics can be cut with a flame jet known as the Browning torch. This method is particularly suitable for granite. Other formations are amenable to cutting by high-pressure water jet. Channel cutting for the torch ranges from 11 to 28 ft/hr (3.4 to 8.5 m/h). Slot drilling in granite ranges from 8 to 14 ft/hr (2.4 to 4.3 m/h) (Meade, 1986a).

Once the block is defined on five sides, the bottom is freed by wedging. A common practice in years past was to drill short holes at the base of the block and to insert "feathers and plugs." Hand hammering of these closely spaced wedges propagated a horizontal fracture (usually along a bedding plane) that detached the block at the base. Alternatively, the wedges can be used to produce a fracture along the back of the prism if the bottom is defined by a bedding plane or joint. Recent advancements include replacing the feathers and plugs with hydraulic wedges, air bags, or partially stemmed explosives for line splitting. Blocks are often tipped 90° and split along the bedding to form slabs close to the desired size before removal from the quarry.

Derricks are still widely used for hoisting of blocks. However, mobile equipment is being used more frequently because of greater flexibility and versatility. The use of mobile equipment has facilitated a substantial reduction in the number of employee hours expended per quarry block removed resulting in an increase of 30 to 50% in productivity over the past decade. Productivity ranges from about 5 to 18 ft^3 (0.1 to 0.5 m^3)/employee-hour in thinly bedded, easily cut deposits. Productivity in marble ranges from about 5 to 14 ft^3 (0.1 to 0.4m^3)/employee-hour (Meade, 1986a).

Large operations maintain mill and finishing shop facilities adjacent to the mine. In the United States and Italy, the trend is to upgrade the finishing facilities by installing automated equipment. Until the unit cost of domestically produced materials can compete with imports, European and South American products are likely to increase. North American producers are able to compete to some extent by selling a superior product. The American Society of Testing Materials has established world standards for dimension-stone test procedures, and close coordination needed between producers and customers to maintain quality control provides a slight edge for domestic producers. In addition, some producers have succeeded in developing markets for in-pit waste for use as construction aggregates, tennis court topping, whiting filler, and agricultural lime, thus reducing the overall mining cost. In some cases, however, it is now economically advantageous to produce the stone in the United States, ship it overseas for finishing, and then return the finished product to domestic customers (Meade, 1986b).

The following case study for the Friendsville quarry describes a typical operation involving both quarry and finishing plant in the eastern United States.

14.2.1 DIMENSION STONE: FRIENDSVILLE QUARRY

LANCE P. MEADE

14.2.1.1 Mine Description

Cost savings resulting from new quarrying methods are partly responsible for reactivating previously closed quarries in the Tennessee Marble District near Knoxville, TN. The Tennessee marble quarries are located in a limestone known as the Holston Formation. This material is a buff-to-pink fossiliferous limestone that, because it takes a good polish and can be cut into slabs, is classified as marble. Numerous buildings in Washington, DC (notably the National Gallery and Air and Space Museum), as well as older post offices and railroad stations in other parts of the country, have used this marble. The district was relatively active through the 1950s and into the 1960s. By the end of the 1970s, only one small quarry, saw plant, and finishing shop remained active.

In the early 1980s a small marble finishing shop (MSI) in Knoxville purchased a quarry property located off Vinegar Valley Road in the town of Friendsville, Blount County, TN. This

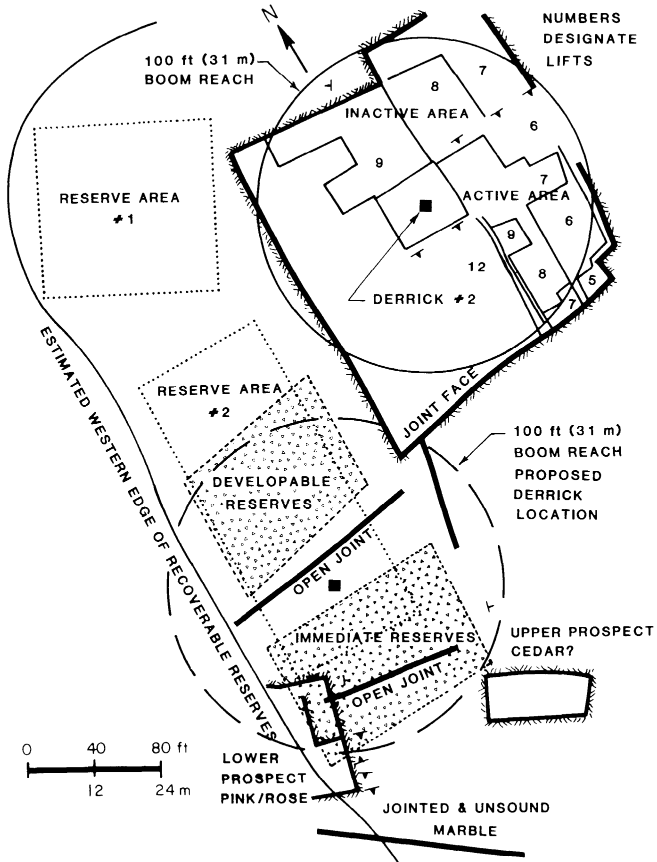

Fig. 14.2.1.1. Plan view of quarry operations.

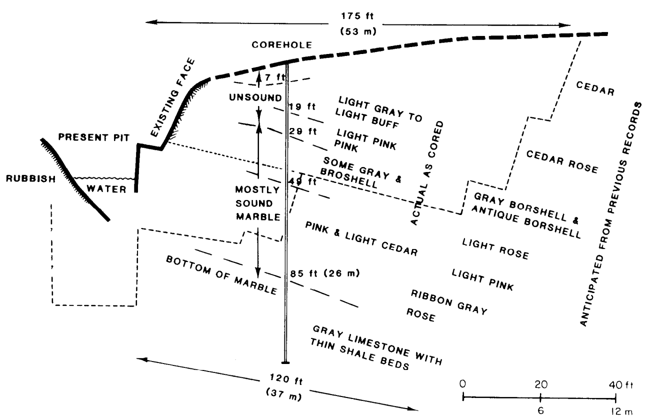
property was previously operated by the Vermont Marble Co. and the Grey Knox Marble Co. under the name of the Brown quarry. The marble was known for its pink color and uniform texture. It was a desirable marble, but the depth of the quarry, limited development work, and associated high production costs resulted in its abandonment in the 1950s.

The reopening of this quarry in 1985 and subsequent purchase of MSI by the Tennessee Marble Division of the Luck Stone Corp. reactivated the property. Since 1987, new equipment, overburden stripping, waste rock removal, and demand for the stone have contributed to the on going development of the quarry.

Approximately 39 acres (0.16 km^2) of the 52-acre (0.21-km^2) property cover acceptable marble beds and have the potential for development into quarry space (Fig. 14.2.1.1). Along with the existing 40,000-ft^2 (3700-m^2) Brown quarry opening, three smaller openings are being developed into a continuous working face of multiple benches accessible by rubber-tired loaders. The balance of the property is used for block and slab inventory, finished material, storage, and a diamond gang-saw plant with an adjacent finishing shop that cuts and polishes thin veneer marble panels, tile, and specialty items.

Current operations are emphasizing removal of overburden and waste rock in the new development area. When this phase is complete, approximately 150,000 yd^3 (115,000 m^3) of material will be removed. Since reopening of the quarry, annual production totals approximately 60,000 ft^3 (1700 m^3) of marble.



Conversion factor: 1 ft = 0.3048 m.

Fig. 14.2.1.2. Geologic cross section through quarry.

14.2.1.2 Deposit Description and Geology

The marble deposit occurs in easterly dipping (10 to 15°) layers of a homoclinal structure (Fig. 14.2.1.2). The Holston limestone is composed of partially recrystallized calcite that ranges from light buff or dark pink to dark mahogany in color. A minor amount of the deposit is a light-gray, Fleuri-type limestone of limited usage. Underlying the marble is a gray, shaley limestone.

High-angle, east-west-trending joints allow for easy extraction of blocks. In some portions of the property, diagonally intersecting joints minimize the recovery of usable blocks. Portions of the joint system exhibit deep weathering with subsequent solution cavities and mud seams. These areas are either avoided or removed and wasted in routine quarry development. Similarly, small areas of structurally and stratigraphically controlled cutters and pyrite zones also are avoided or removed as quarry waste. A marble recovery factor of 50 to 60% of quarry space has been the historical experience. Modular-sized panels and tile production should allow greater stock utilization and an improved recovery factor in the future.

The strike of the marble layers extends across the property in a north-south direction. Overburden is variable but averages 7 ft (2 m) in thickness. A 20-ft (6-m) underlying zone of unsound cap rock is wasted due to unacceptable mechanical properties and poor color. The commercial layer is 50 to 70 ft (15 to 21 m) in thickness, and within this horizon, six to eight varieties of marble normally occur that are classified by color. The present operating additional quarry (Quarry No. 4, Derrick No. 2) is approximately 80 ft (24 m) deep with working benches 30 to 40 ft (9 to 12 m) above the quarry floor.

A core drilling campaign verified by test block removal, has confirmed the existence and continuity of the marble layers, and subsequent proven reserves have been established. The reserves of a dimension stone deposit are usually not limited by the available stone but rather by the whims of architectural preference and profitable extraction. A 20-year supply (considered adequate by industry standards) is projected based on these reserves and current and projected demand.

14.2.1.3 Mine Development

The first three years of operation (1985–1988) consisted of predevelopment activity. During this time, the existing Brown quarry was dewatered and the derrick, hoist, and compressor recommissioned. Access to the working area was by a series of stairs and ladders for the men and a boom-fall derrick for the equipment and supplies. After cleaning up debris with a small front-end loader and removing it with the derrick, old working benches were evaluated for their potential yield of stone. Typical Tennessee-style, skid-mounted quarry bars with chain-feed air hammers were utilized for vertical drilling and broaching. Small pneumatic layer drills on horizontal quarry bars were used for breakline cuts.

Slabs from sawn blocks were graded, classified, inventoried, and marketed on small projects. Based on this experience, a contract was obtained for supplying marble to the Library Square project in Los Angeles, CA. This enabled scaling-up operations by purchasing additional quarry equipment, a second Bennetti wire saw, and lightweight drills that do not require a derrick for in-quarry moves.

Various alternatives for opening the existing quarry for direct access by mobile equipment were evaluated. The final decision was to develop the area adjacent and south of the Brown quarry for this innovative approach.

Cap rock is being removed by a combination of wire sawing, shooting, and wedging. The loosened rock is removed with the use of a dozer, excavator, and 988B loader. The waste is dumped in a grout pile or used for ramps and roadways. The careful preparation and maintenance of all road and haulageways has kept vehicle maintenance costs to a minimum.

With the old (pre-1970s) Tennessee quarry methods of working under a guyed boom-fall derrick and using large quarry bars and pneumatic hammers, 1.5 to 2.0 ft^3 (0.04 to 0.06 m^3) of stone could be removed per employee-hour of operation (with a 50% recovery factor). Currently, utilizing rubber-tired loaders, small wire saws, and lightweight pneumatic drills, this figure has been increased to 5 ft^3 (0.14 m^3)/employee-hour with a crew of eight. With present sales forecasts and production demands, the quarry crew size is expected to increase to 10 or 12.

14.2.1.4 Unit Operations

Currently, a crew of eight utilizes three Bennetti line drills for channel and line cutting, one penetrating drill for wire-saw pilot-hole development, and three Bennetti wire saws. Coupled with a layer hammer for horizontal drilling, a 988B loader, and a hydraulic jack system for raising and tipping blocks, the crew of eight produces what a crew of 18 would produce with the older system.

The confined space in the Friendsville quarry has necessitated retention of the horizontal floors and benches. Lifts of 4 to 6 ft (1.2 to 1.8 m) are made depending upon the soundness, color variations, or required block sizes. The initial key-way cut, made with the wire saw, is wide enough (8 ft or 2.4 m) to allow access for the layer hammer, if horizontal break lines are needed. Once the key blocks are removed, additional strips are cut. Depending on the height of the strip, they are tipped into the keyway for splitting. Splitting can also be performed in the vertical position (Figs. 14.2.1.3 and 14.2.1.4).

The newly developed quarry area will have benches of greater height (15 to 25 ft, or 4.6 to 7.6 m), which will allow tipping the strips of cut marble for splitting into required block sizes. Full use of the wire saws and mobile equipment allows for more efficient continuous cutting. The older Tennessee system resulted in more time moving and setting up equipment rather than actual cutting of stone. As the new area develops, a diamond chain saw is being considered for vertical cuts. These units can cut to depths of 13 ft (4 m) but are more efficient if the cuts are limited to 6 to 8 ft (1.8 to 2.4 m). The greater efficiency of the

Fig. 14.2.1.3. Line drilling in the Friendsville quarry.

chainsaw units will more than offset the need to revert back to lower working benches.

14.2.1.5 Product Control

One criterion that distinguishes dimension stone from ordinary rock is the consistency of color, texture, and soundness. In earlier times, very stringent requirements were placed on the particular variety names for various marbles. For instance, Tennessee cedar would be recognizable and consistent with all other Tennessee cedar. Job specifications and architectural requirements usually demand close product control and continuous coordination between the quarry, mill, finishing shop, and sales. The range of allowable variations usually is greater for nonpolished exterior applications than for highly polished and matched interior installations. The tightness or looseness of the job specifications has a very dramatic impact on the amount of quarry, mill, and shop waste that will result from each cubic foot (cubic meter) of quarry space excavated.

During the 1920s when the demand for dimension stone was at its peak, marble graders and stock specialists played a very significant role in the rating and classification of stone. This system generally was abandoned to some extent as interior usage of stone diminished in the 1970s. The current resurgence in demand for decorative interior marble has resulted in the need for closer stock selection and utilization.

14.2.1.6 Ancillary Facilities

One major difference between operating a dimension stone quarry in the 1990s vs. the 1920s is the type and amount of support services needed. In the 1920s the economy of major quarry localities, such as Knoxville, TN, Bedford, IN, and Rutland, VT, was centered around the quarries, mills, and shops. Local machine shops, foundries, and equipment manufacturing establishments supplied the quarries with the needed equipment, tools, and supplies.

In the 1990s, most of the quarry equipment is manufactured in Italy, Germany, and Finland. Inventory of replacement parts must be kept on hand or air-freighted to the job site in emergency situations. Repair of the newer hydraulic drills necessitates highly trained technicians rather than general maintenance personnel who repaired older pneumatic drills. In other words, factory repair personnel who speak a language other than English are a frequent part of a modern dimension stone operation.

Onsite blacksmith shops for hand-forging drill steel and bits are virtually obsolete. Likewise, the forge at the Brown quarry, used during the early stages of start-up, has now been abandoned. The use of slip-on and threaded bits has virtually eliminated the need for forged tools.

Chapter 14.3
OPEN CAST (STRIP) MINING

M.K. McCarter, Mark L. Bricker, G. Paul Anderson, Steven J. Kirk, David B. McDonald, Gary M. Stubblefield, Roger W. Fish, Ira J. Tussey, Gene Rand, Wayne N. McKee, and Steven I. Olson

14.3.0 SURFACE MINING—CONCURRENT RECLAMATION

M.K. McCarter

Surface mining in which reclamation is carried out contemporaneously with extraction may be classified as either area mining or contour mining. *Area mining* is often referred to as *open cast* or *strip* (furrow) *mining.* It is frequently practiced on a large scale, which results in low unit cost, high productivity, high recovery, and greater safety compared to underground mining. *Contour* (or collar) *mining* progresses in a narrow zone following the outcrop of a coal seam in mountainous terrain. The specific methods used in contour mining are referred to as haulback, box-cut, and block-cut mining (Anon., 1979). The unique aspect of both area and contour mining is that overburden, removed to gain access to the mineral commodity, is immediately placed in the previously mined area.

Coal of bituminous rank as well as lignite are the principal products of area mining. Phosphate and most oil sands are also mined in this manner. To a lesser extent anthracite, bauxite, and bentonite are also mined by area methods (Hartman, 1987). Contour mining is reserved almost exclusively for removing the thin coal beds of the Appalachian region.

In area mining, removal of overburden is accomplished with large draglines, stripping shovels, or bucket wheel excavators (BWEs). These machines excavate and deposit material in one continuous operation. The same function can be accomplished, in part, through the use of explosives (cast blasting). Often removal of soil and overburden is accomplished using a combination of casting machines to maximize the width of the mining area. Conventional excavation and haulage techniques (truck and shovels, scrapers, or dozers) are also used by themselves, or in conjunction with one or more casting machines. Conventional excavation and haulage may be dedicated to topsoil removal only, or it may be employed in removing both topsoil and overburden.

Area mining usually progresses in a series of parallel, deep trenches referred to as furrows or strips that may exceed several thousand feet (1 km or more) in length (Fig. 14.3.0.1). Material is removed from the undisturbed area on the highwall side forming a deep trench. It is then placed in the open pit at the angle of repose forming a spoil ridge. The width of the open pit is typically 75 to 150 ft (23 to 46 m), the height of the highwall may be up to 200 ft (61 m), and the height of the spoil ridge may be up to 250 ft (76 m). Typical highwall angles range from 50° to vertical. Typical spoilpile angles range from 30 to 45° measured from the horizontal. Angles steeper than 37°, which is the angle of repose for most materials, can be obtained by allowing the spoil to compact under its own weight then excavating the material a second time to an oversteepened condition. Experience has shown that oversteepened spoil, in some locations, is capable of standing long enough to extract the mineral and begin backfilling the pit before major instability occurs.

Haulback mining proceeds in a series of nearly square rectangular pits following the outcrop for as much as several miles (kilometers) (Fig. 14.3.0.2). The pit width is dictated by the economic stripping ratio and steepness of topography. Since mining roughly follows a contour, the path of mining is generally sinuous with both outside and inside curves. Mining progresses by first removing a box cut and hauling the overburden to a suitable disposal site. Thereafter, overburden is broken, excavated, and hauled by truck, scraper, or conveyor to fill previously mined-out pits with little or no waste deposited on the outslope. In this manner waste moves in a direction opposite to the direction of mining and hence the name "haulback."

Box-cut contour mining (Fig. 14.3.0.3) is practiced in moderately sloping terrain. It is essentially the same as area mining where the total number of strips is limited to two or three. The strips are oriented parallel to the outcrop line and progress uphill into the highwall. The first strip is a consecutive series of box cuts, which provides an open pit for spoil cast from the second strip.

A dozer is normally employed to clear vegetation over the box cuts and down-slope from the outcrop line. Overburden is then pushed from the box cuts to the outslope area. Once the coal is uncovered, it is removed, and the dozer establishes a level bench upslope from the box-cut line. From this bench, a dragline then excavates the overburden and deposits it into the adjacent box cut. In place of the dragline, a shovel can be used to remove overburden from the second cut thus eliminating the need to create an upslope bench. Upon reaching the economic limit of mining, dozers push the spoil uphill to cover the highwall before revegetation commences.

Block-cut mining can be applied to either area or contour mining. This method differs from conventional area and contour mining in that blocks of overburden in excess of 70 ft (20 m) wide are removed as a unit and deposited in mined-out areas either perpendicular to the direction of advance (area mining) or along the outcrop direction (contour mining). If the mineral commodity is relatively shallow with more or less uniform cover, the overburden can be removed by front-end loader (FEL) or pushed by dozer to the disposal site in one operation.

If a coal seam is close to flat lying and occurs near a mountain top, the deposit can be mined from outcrop to outcrop in series of strips as practiced in conventional area mining. In some cases, the spoil is leveled rather than contoured to approximate the original topography. This method is referred to as mountaintop removal (Anon., 1979). This modification, however, differs from mountaintop removal as described in Chapter 14.1. In the previous section, mountaintop removal was identified as a "deferred reclamation" technique because overburden was hauled to a disposal site away from the mining area. In the above case, overburden is deposited in the open pit adjacent to the seam being uncovered and reclaimed as mining progresses.

The cycle of operations includes clearing vegetation, soil removal, drilling and blasting overburden, stripping, removal of coal or other mineral commodity, and reclamation. In the case of area and contour mining, reclamation should be considered as a unit operation since it is repetitive and concurrent with mining.

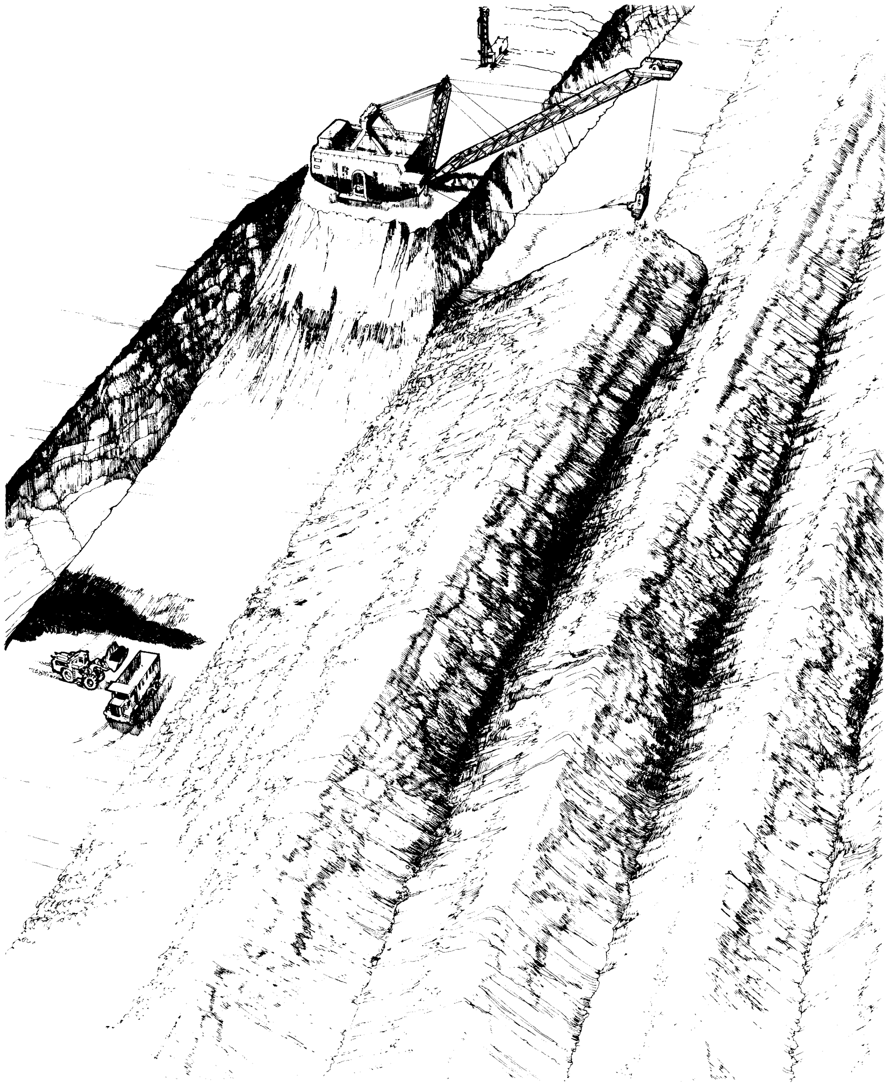

Fig. 14.3.0.1. Conventional area mining utilizing a dragline. (Anon.,1979; illustration by Frank Kulczak. By permission from Skelly and Loy, Harrisburg, PA.)

Clearing vegetation is nearly always accomplished with track-mounted dozers. Soil removal is often assisted by dozers but more commonly achieved with scrapers and dozers, or trucks and FELs. Overburden can be broken with dozers equipped with rippers if the rock is weak or drilled and shot if it is more competent. Drilling may be done with drag bits, rotary bits, or percussion. Holes are usually vertical, but occasionally inclined holes are used to achieve better highwall stability and more uniform fragmentation especially if the highwall is not vertical. The explosive of choice is ANFO unless water precludes its use.

Selection of an appropriate excavator is usually dictated by the properties of the overburden and mineral commodity as well as the deposit geometry. Stripping shovels are able to exert maximum digging effort and are the best choice for blocky material. They also have a shorter cycle time compared to draglines. The main disadvantage is that they must work on top of the seam to be mined. If this material is friable, fines are created by movement of the excavator, and the fines may contribute to poor recovery or poor product specifications. In addition, shovels must reach from the top of the seam to the top of the spoilpile rather than from the original ground surface to the top of the spoil pile as is the case for draglines.

Effective use of draglines requires well-broken and disaggregated material. The main advantage of the dragline over stripping shovels is flexibility. It usually has greater reach for a given set of circumstances and can operate on either the highwall side or on the spoil side. In addition, it can cope better with adverse pit conditions such as slides and flooding that would be difficult for a shovel. It can also dig a deeper box cut and can dig both above and below its position on the overburden. The cost per cubic yard (cubic meter) is slightly higher for bucket (dipper) sizes less than 70 yd^3 (54 m^3) compared to shovels but about the same for the larger sizes (Weimer, 1968).

Bucket wheel excavators perform best in material which is well fragmented and void of large boulders and buried vegetation. They are particularly well adapted to hard pottery clays, phosphates, tar sands, and bauxite. Often they are able to handle these materials without blasting. The advantage of BWEs is a more even power demand compared to either shovels or draglines. They also tend to provide more stable pit slopes, more uniform spoil piles, and greater control in selective mining of interbedded deposits. BWEs are able to excavate both above and below the elevation of the base of the machine. The major

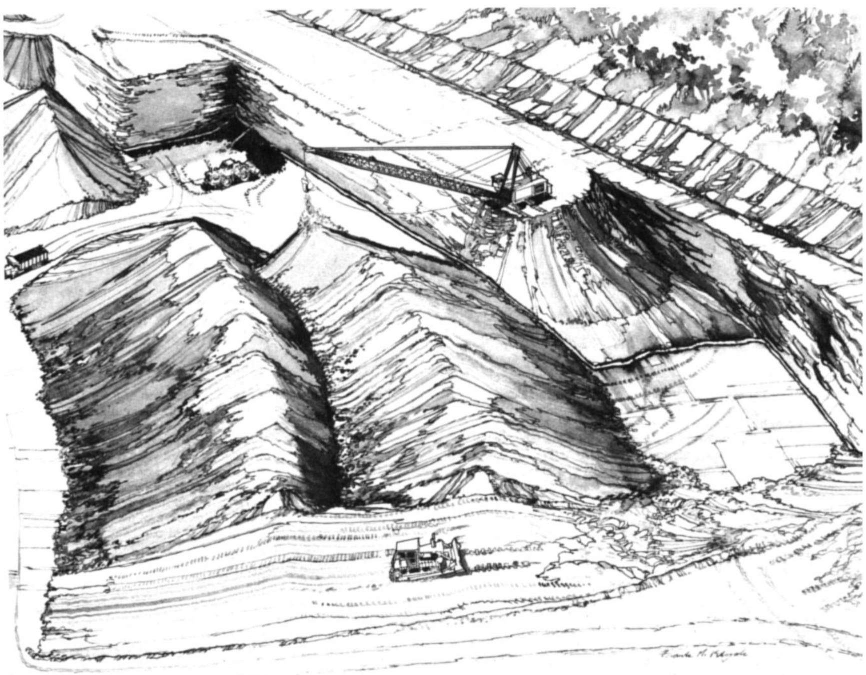

Fig. 14.3.0.3. Box-cut contour mining employing dozers and dragline. (Anon., 1979; illustration by Frank Kulczak. By permission from Skelly and Loy, Harrisburg, PA.)

disadvantages are the higher capital cost and lower maneuverability (Aiken and Wohlbier, 1968).

Proper selection of a casting machine (or combination of casting machines) is determined through use of a range diagram. This diagram represents the configuration of highwall and spoil pile in cross section. It allows graphical estimation of overburden "bank" volume and the equivalent volume of broken waste (swell is commonly 25 to 30%). This diagram allows planning of cuts and excavator moves. Careful planning is necessary to ensure that a spoil pile of given width, height, and slope angle can accommodate the volume produced by a highwall excavation of given width and depth of cover (Phelps, 1973).

Once the commodity is exposed by stripping, loading of coal or other materials may be done directly with BWEs, FELs, electric shovels, hydraulic shovels, or backhoes. Stronger material may require ripping or blasting for efficient loading. In the case of Florida-type phosphate deposits, high-pressure jets of water can be used to slurry the ore and transport it to a sump where it can be pumped to processing facilities.

Common applications for surface mining with concurrent reclamation can be subdivided on the basis of the deposit geometry and type. Area mining may be applied to deposits where (1) the overburden is thick and uniform down to a single, near-horizontal coal seam or down to several coal seams separated by thin parting; (2) the overburden is shallow and the coal seam is thick and near horizontal; (3) the layers of overburden are interspersed with numerous nearly horizontal coal seams; and (4) the overburden is of variable thickness covering coal seams which are dipping. Contour mining is applicable where nearly-horizontal, thin seams are exposed in mountainous terrain. Area mining can also be applied to lignite, tar sands, and phosphate. Case studies of each of these situations are presented in Chapters 14.3.1 through 14.3.8.

14.3.1 MONOLITHIC OVERBURDEN, HORIZONTAL COAL SEAMS: BRIDGER MINE

MARK L. BRICKER

14.3.1.1 Mine Description

The Jim Bridger mine is operated by Bridger Coal Co. and is located in Sweetwater County, 35 miles (56 km) northeast of Rock Springs, WY. The general location of the mine site is shown on Fig. 14.3.1.1 and an aerial overview on Fig. 14.3.1.2.

Bridger Coal is a joint venture of the operator, NERCO Coal Corp., and Idaho Energy Resources Co. The permit boundary encompasses in excess of 20,000 acres (81 km^2) and is nestled against the western side of the Continental Divide.

Production started on July 3, 1974, and by the end of 1989, the mine had produced 83 million tons (75 Mt). Annual production averages 5 to 7 million tons (4.5 to 6.4 Mt) of run-of-mine coal. Coal is consumed on site by the Jim Bridger Power Plant, a 2000-MW generating station, and the electricity is transmitted to the Pacific Northwest power grid (Oregon, Idaho, Northern California, etc.).

Dragline stripping operations are scheduled around the clock, two 12-hr shifts/day, seven days/week, 356 days/year (nine holidays are observed). A dragline crew works a 12-hr shift each day for four days and then has the next four days off. The remaining operations are scheduled for three 8-hr shifts/day, five days/week, 251 days/year. Some maintenance and warehouse personnel work the same schedule as the draglines.

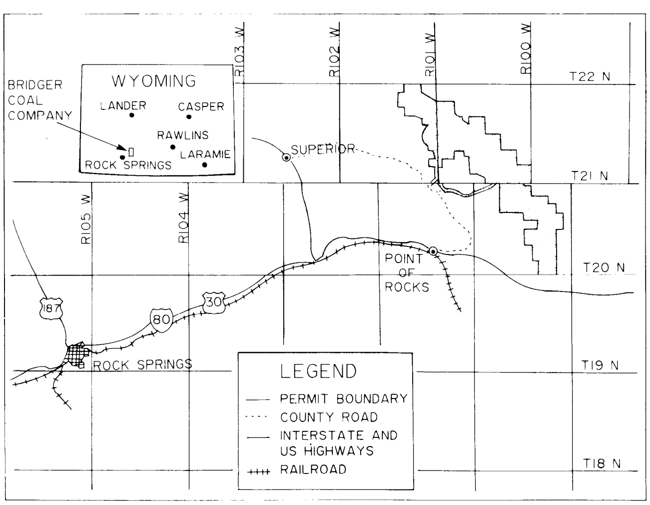

Fig. 14.3.1.1. General location map.

Fig. 14.3.1.2. Aerial overview of mine site and power plant.

The mine employs four draglines and one shovel for casting operations and two front-end loaders (FELs), one shovel, and one hydraulic backhoe for five to six active production faces. The total number of employees at the mine is 422. Of this number approximately 109 are in supervisory or administrative positions.

14.3.1.2 Deposit Description and Geology

The Jim Bridger mine is located on the northeastern flank of the Rock Springs uplift, a broad, asymmetrical anticlinal feature about 60 miles (97 km) long and 35 miles (56 km) wide with a north-trending axis. This uplift separates the Green River Basin to the west and the Great Divide and Washakie Basins to the east.

Precambrian rocks on the apex of the uplift are estimated to be 17,000 ft (5200 m) above the Precambrian rocks in the Green River and Washakie Basins. Normal faults with generally less than 100-ft (30-m) vertical displacement cut through the uplift. The dip of strata on the flanks is generally between 3 to 15°.

The coal seams occur in the Deadman Coal Zone of the Fort Union Formation, which is Paleocene in age. This zone is about 60 to 80 ft (18 to 24 m) above the contact with the underlying Lance Formation. The Fort Union Formation is about 1500 ft (460 m) thick, and the Lance Formation is about 900 ft (270 m) thick. There are five coal seams exposed in the mine; they are designated D5 through D1 from top to bottom. Various combinations of these seams exist throughout the field forming single-seam, two-seam, three-seam, and four-seam areas. The seams generally dip 2 to 5° to the northeast.

Sedimentary rocks of the Fort Union Formation represent depositional processes of a fine-grained, fluvial-flood-basin complex with extensive swampy conditions and minor lacustrine influence. Recognized depositional environments within the three-dimensional framework include poorly drained swamps, well-drained swamps, crevasse splays, and fine-grained channel sandstone deposits.

Overburden and interburden materials consist of interstratified sandstones, siltstones, claystones, and minor shale and thin, discontinuous limestone stringers. These stratigraphic units exhibit a high degree of rock variability, both laterally and vertically.

Table 14.3.1.1. Coal Reserves

Lease	Acres (km^2)	Tons $\times$ 10^6 (t $\times$ 10^6)
Federal Coal	8595.68 (34.79)	91.5 (83.0)
State Coal	1280.00 (5.18)	0.4 (0.36)
Union Pacific Coal	8579.46 (34.71)	103.8 (94.2)
Totals	18,455.14 (74.69)	195.7 (177.5)

Stripping ratio: 8 bank yd^3/ton (6.7 m^3/t)

Table 14.3.1.1 is a summary of reserves and stripping ratio for the mine. Coal leases are held by the federal government, the State of Wyoming, and the Union Pacific Railroad.

The coal resource is classified as subbituminous. The energy content averages 9400 Btu/lb (21,864 kJ/kg) with 18% moisture, 9.5% ash, and 0.59% sulfur.

14.3.1.3 Mine Development

Soil is removed from areas prior to stripping operations. In the early years of the mine, reclaimed areas were not available for direct application of soil. Therefore, soil was placed in stockpiles at various locations. This stockpile practice is not preferred because of the loss of soil fertility and the microbiological community. Use of stockpiled soil on reclaimed areas requires fertilization, while direct-applied soil has reduced fertilization costs over 50%. Direct-applied soil is hauled from the highwall side of the pit across or around the pit and distributed on reclaimed areas. Soil depths at Bridger range from 0 to 60 in. (0 to 1524 mm) with a field average of 15 in. (381 mm). A buffer of 600 ft (180 m) is maintained from the highwall for operational flexibility.

Once soil is removed, the overburden material is drilled and blasted. Outcrop development is generally accomplished by a scraper or truck and shovel fleet. The outcrop overburden material is placed to minimize out-of-pit spoil. After outcrop is developed, the draglines remove overburden by simple side casting or extended bench methods up to approximately 80 ft (24 m) in depth. Depths greater than 80 ft (24 m) require a multiple-pass, spoil-side, dragline stripping method.

Highwall angles generally range from 50 to 70°, with an average of 65°. The angle of repose for the spoil material is 36°.

General pit development is northwest to southeast along the strike of the coal beds. Each successive pit is farther down the dip of the coal seams. Pit widths vary greatly throughout the mine, but generally outcrop pits are 200 to 250 ft (61 to 76 m) in width. Where the overburden is less than 150 ft (46 m), the pit width varies from 150 to 200 ft (46 to 61 m). For overburden depths greater than 150 ft (46 m) in depth, pit width ranges from 120 to 150 ft (37 to 46 m) in width. An overall average pit width is 150 ft (46 m).

The active pit is approximately 9 miles (14.5 km) in length. Spread across this area are four draglines, a truck fleet and shovel operation, and a scraper fleet operation. Therefore, as many as six faces are operative at any time.

Pit access is available through a series of ramps or entries spaced at approximately 4000-ft (1220-m) intervals. Since the mine is located to the northeast of the power plant, the ramps start at the pit floor and advance through the spoil side of the pit up a 3 to 5% grade to a haul road network ending at the power plant truck dump.

Table 14.3.1.2. Drilling Equipment

Drill Name	No.	Bit Size in. (mm)	Purpose
Bucyrus-Erie 60R	1	12¼ (311)	Overburden
Drilltech D60K	1	10⅝ (270)	Overburden/ Parting
Schroeder Twin Mast	1	5¼ (133)	Coal
Drilltech D50K	1	9⅞ (251)	Overburden/ Parting
Marion M-3	1	12¼ (311)	Overburden
Drilltech D25K	1	6 (152)	Parting/ Coal

Future mine development will consist of opening the remaining southern portions within the permit boundary, which will extend the pit approximately 6 miles (9.7 km). As the southern expansion is started, final reclamation will begin in the currently active area. This development philosophy minimizes the total area disturbed and allows portions of the mine to return to its original livestock and wildlife land use as soon as possible.

14.3.1.4 Unit Operations

DRILLING AND BLASTING. Drilling is accomplished by six different makes and models of drills. Table 14.3.1.2 identifies the drill fleet at the mine.

Blast patterns are rectangular or square and vary with depth and type of material. An emulsion-product mix is used, which is a blend of 33% emulsion and 67% ANFO. In extremely wet areas, the product mix is raised to 50% emulsion and 50% ANFO. Powder factors average between 0.6 to 0.8 lb/yd^3 (0.36 to 0.47 kg/m^3) for overburden, 0.4 lb/yd^3 (0.24 kg/m^3) for coal, and 0.8 lb/yd^3 (0.47 kg/m^3) for parting.

OVERBURDEN REMOVAL. After outcrop development, draglines remove overburden by simple side casting or extended bench methods up to approximately 80 ft (24 m) in depth. These methods are illustrated in Fig. 14.3.1.3 for simple side casting and Fig. 14.3.1.4 for extended bench methods.

Depths greater than 80 ft (24 m) require a multiple-pass, spoil-side, stripping method. The overburden is split into two lifts of approximate equal depth and the first or upper lift is drilled and stripped by simply sidecasting the material into the empty pit (Figs. 14.3.1.5 and 14.3.1.6).

Next the dragline maneuvers from the highwall elevation down a ramp (cut out of the upper lift) to the lower lift elevation. Prior to cutting the ramp with the dragline, the lower lift material is drilled and blasted. The dragline strips a key cut that establishes the lower portion of the highwall and places that material behind the upper lift spoil.

Finally, the entire upper lift and lower lift key-cut spoils are leveled, and the dragline maneuvers onto the spoil-side pad. From this position, the dragline strips the remaining lower lift material and spoils the material in its final position.

Since mining operations occur in multiple-seam areas, supplemental stripping operations usually remove the interburden materials. In areas where the parting and overburden materials are approximately equal, the multiple-pass dragline operation described above is altered to allow the dragline to remove interburden materials. These interburden materials must be tested prior to mining to ensure they are not toxic. Only nontoxic materials can be deposited with dragline spoil.

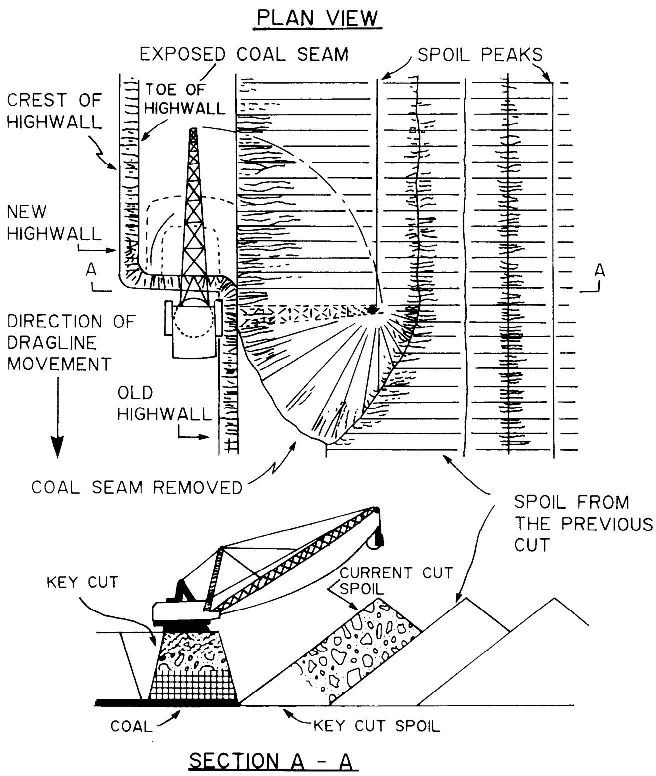

Fig. 14.3.1.3. Simple side casting.

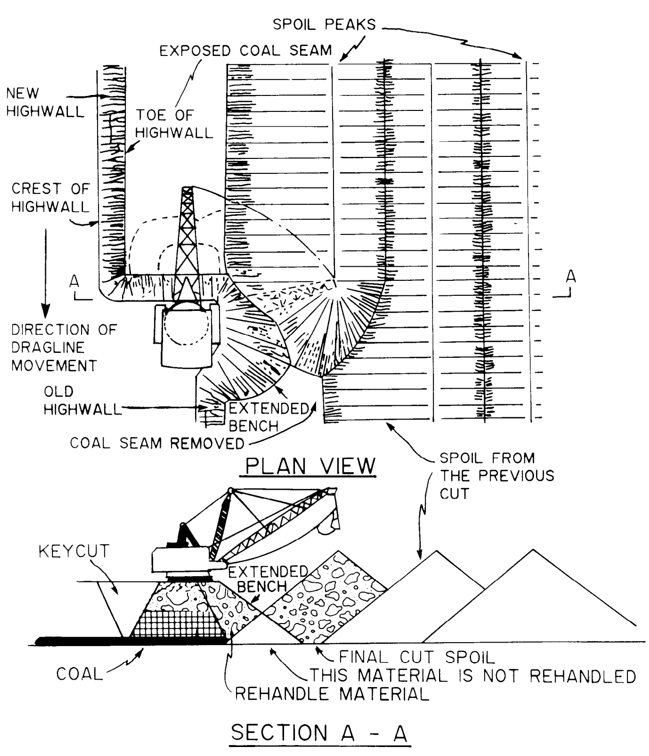

Fig. 14.3.1.4. Extended bench stripping.

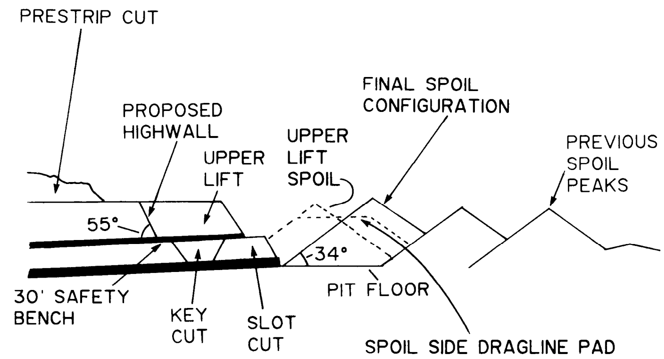

Fig. 14.3.1.5. Multiple-pass, spoil-side stripping. Conversion factor: 1 ft = 0.3048 m.

Fig. 14.3.1.6. Dragline on the spoil side.

Table 14.3.1.3. Stripping Equipment

Description	No.	Size yd^3 (m^3)	Rate yd^3/shift (m^3/shift)
Marion 8200 dragline	2	75 (57.3)	16,000 (12,234)
Page 757 dragline	1	60 (45.9)	13,000 (9940)
Page 732 dragline	1	20 (15.3)	5000 (3823)
Bucyrus-Erie 195B shovel	1	12 (9.2)	3000 (2294)
777B Caterpillar 90-ton truck	3	130 (99)	N/A
657 Caterpillar scraper	4	32 (24.5)	4500 (3441)

Note: All production rates are expressed in terms of 8-hr shifts.

Supplemental stripping operations consist of a truck-and-shovel fleet or a scraper fleet. These operations provide added flexibility to the mine by selectively handling toxic materials, performing advance benching of the highwall for the dragline, or removing interburden materials in multiple-seam areas.

Table 14.3.1.3 summarizes the stripping equipment as of 1989.

Fig. 14.3.1.7. Coal loading operations.

Table 14.3.1.4. Coal Loading and Support Equipment

Description	No.	Size yd^3 (m^3)	Rate yd^3/shift (m^3/shift)
Dart 600 C FEL	1	23 (17.6)	7100 (5429)
Caterpillar 992 FEL	1	13 (9.9)	4100 (3135)
Koehring 1266E hydraulic backhoe	1	15 (11.5)	6600 (5046)
Bucyrus-Erie 195B shovel	1	18 (13.8)	7800 (5964)
Michigan 380 RT dozer	3	N/A	N/A
Caterpillar 16G blade	3	N/A	N/A
Caterpillar 633 scraper	1	34 (26)	N/A
Caterpillar 777B truck	5	130 (99)	N/A

COAL PRODUCTION. Once the overburden and/or interburden has been removed and the top surface of the coal seam exposed, the coal surface is cleaned by rubber-tired dozers, blades, or scrapers. The coal is then drilled using twin-mast auger drills employing 5 1/4-in. (133-mm) bits. The material is lightly blasted to facilitate loading operations.

Coal loading is accomplished by FELs, electric shovels, or hydraulic backhoes (Fig. 14.3.1.7). Table 14.3.1.4 summarizes the coal loading equipment as well as the major pieces of support equipment.

HAULAGE. Prior to 1989, coal was hauled 11 miles (17.7 km) from the mine to the power plant by a fleet of thirteen 120-ton (109 t) bottom-dump trucks. Due to length of haul, a 42-in. (1067-mm) conveyor system was installed in 1989 to reduce the distance for truck haulage. Five 90-ton (82-t) end-dump trucks replaced the bottom-dump trucks. These new trucks shuttle coal a distance of approximately 4 miles (6.4 km) round trip from the pits to two truck dump sites feeding the conveyor system. Each truck dump site uses a feeder-breaker to size the coal to – 6 in. (– 147 mm) prior to loading the belt.

The conveyor system consists of a 13,000-ft (3962-m) main belt and an 8000-ft (2438-m) northern wing. The belt runs at 825 ft/min (244 m/s) and conveys coal at a rate of 1500 tph (1361 t/h). Coal is discharged at the power plant's newly constructed transfer building.

RECLAMATION. Reclamation consists of spoil pile leveling and grading, soil application, fertilization, and mulching. Spoilpile leveling is initiated by dozers and completed by the scraper fleet. The regraded area is deep-ripped with a dozer prior to soil application. Generally, in order to meet approximately original contour (AOC) criteria, as defined by the Wyoming Department of Environmental Quality (WDEQ), spoil material must be moved several hundred feet (meters), thereby requiring use of the scraper fleet.

Once an area has been regraded, soil is applied directly from the highwall or from soil stockpiles. Soil is applied to regraded areas at an average thickness of 15 in. (381 mm). A survey of elevations and results of chemical analyses of samples from the regraded area are submitted to the WDEQ for evaluation prior to soil application.

After soil is applied, the area is lightly ripped with a blade or a chisel plow along the contour, and native seed mixes are drill-seeded. Finally, most areas are mulched with hay to provide additional protection from erosion. Presently, there are over 1130 acres (4.6 km^2) of reclaimed land on the mine site, and the WDEQ has rated 90% of Bridger's reclamation as fair to good.

14.3.1.5 Product Control

Coal quality is monitored by an in-pit sampling program of cuttings from production drillholes in coal. Short proximate analyses and sodium oxide content in the ash analyses are performed at the mine utilizing the power plant's coal lab. These data are used for daily and weekly forecasts as well as actual daily quality delivery estimates. Minimal in-pit blending is required, as the coal generally exceeds the contractual quality restrictions. Long-term coal quality projections are based upon core drilling on 500- to 1000-ft (152- to 301-m) spacings. These coreholes are gridded and modeled on the computer, resulting in values for the life-of-mine plan.

14.3.1.6 Maintenance Facilities

Maintenance is performed onsite in a large diesel shop and small gas vehicle shop. These facilities are located adjacent to the power plant and main mine office. The diesel shop is 30,000 ft^2 (2787 m^2) and consists of four repair bays, one lube bay, one wash bay, a warehouse, three welding bays for dragline buckets, and offices for maintenance and warehouse personnel. Additional satellite facilities are located closer to the pit for large pieces of equipment, such as shovels and drills.

14.3.2 MONOLITHIC OVERBURDEN, THICK HORIZONTAL COAL SEAMS: JACOBS RANCH MINE

G. PAUL ANDERSON AND STEVEN J. KIRK

14.3.2.1 Mine Description

Kerr-McGee Coal Corporation's Jacobs Ranch mine is a two-pit operation located approximately 52 miles (84 km) southeast of Gillette, WY, and 11 miles (18 km) east of Wright, WY. It is one of 15 coal mines currently (1989) operating in the Powder River Basin of Wyoming (Fig. 14.3.2.1). The mines in the Powder River Basin are typified by thick coal seams and relatively thin overburden. This mine, along with the majority of surrounding mines, employs the truck-shovel method as the sole means of overburden stripping and coal mining. Two pits

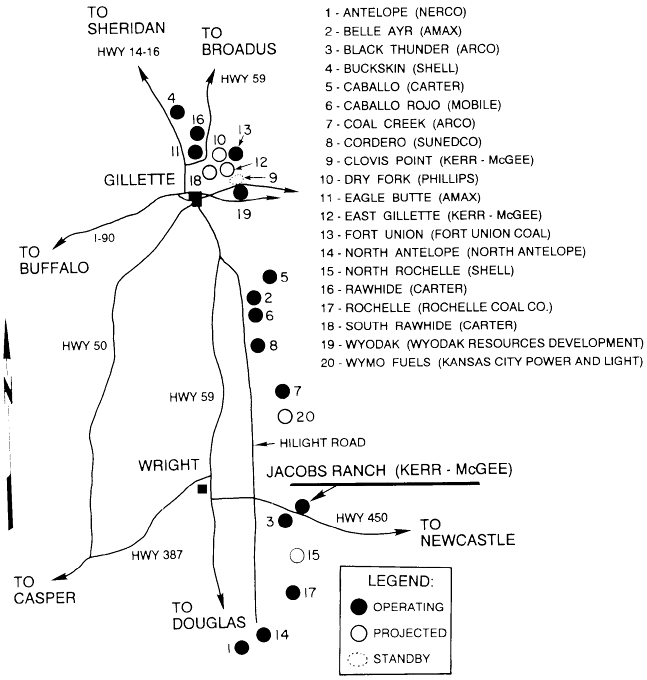

Fig. 14.3.2.1. Campbell County coal mine locations.

Fig. 14.3.2.2. Aerial photograph of Jacobs Ranch mine.

are mined so that coal can be blended to meet coal quality needs of customers (Fig. 14.3.2.2).

Construction began at Jacobs Ranch mine in 1975. Kerr-McGee erected the first shovel at Jacobs Ranch mine and began stripping overburden in August 1976. Coal shipments began in February, 1978 and are currently scheduled through the year 2009.

Annually, the mine produces 15 million tons (13 Mt) of subbituminous, low-sulfur coal that is used to generate electricity in Texas, Louisiana, Arkansas, and Oklahoma. Stripping and mining are currently conducted during three 8-hr shifts, 7 days/week, 355 days/year. Trains are loaded every day of the year, at any hour.

14.3.2.2 Deposit Description and Geology

The 12,000-mile^2 (31,000-km^2) Powder River Basin contains an estimated 22.8 billion tons (20.7 billion t) of subbituminous

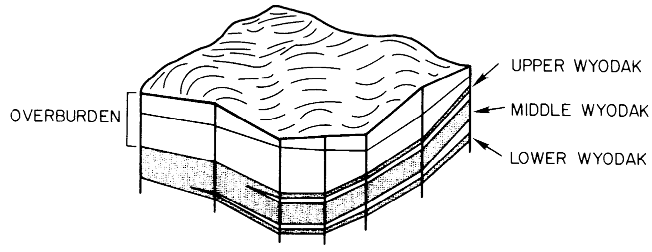

Fig. 14.3.2.3. Geologic cross section of Jacobs Ranch mine.

coal that can be economically recovered using surface mining methods. In general, the coal increases in heating value from north to south. The coal north of Gillette averages 7900 Btu/lb (18,375 kJ/kg). Coal in the southernmost portion of the Powder River Basin has an average heating value of 8900 Btu/lb (20,700 kJ/kg) (Glass, 1982).

Bounded by the Big Horn Mountains on the west, the Black Hills on the east, and the Laramie Range and accompanying highlands on the south, the Powder River Basin stretches across northeast Wyoming in the form of a syncline. The sediments that fill the basin were deposited over a 500-m.y. period, but the structure itself is a product of Laramide folding that began about 70 m.y. ago. At that time, the land folded to create a system of rivers, flood plains, and swamps (Ayers, 1986). Streams originating in the highlands to the south and the southwest carried sand and mud into the basin, where they were deposited in channels and on flood plains. The swampy areas between the channels supported a dense growth of grasses. The remains of these plants constitute some of the thickest coal deposits in the world (Ayers, 1986).

The deposit at Jacobs Ranch mine consists of 375 million tons (340 Mt) of recoverable subbituminous coal. The coal averages 8600 Btu/lb (20,000 kJ/kg), 0.46% sulfur, and 5.58% ash. Over 125 million tons (113.4 Mt) have been shipped since 1978. The 5000-acre (20.23-km^2) coal deposit is located on the 15,000-acre (60.70-km^2) Jacobs Ranch, an active cattle property.

The formation being mined at Jacobs Ranch mine is the Wyodak coalbed. This horizontal seam is continuous throughout the lease area except near the eastern and southern boundaries and in Burning Coal Draw, where it has naturally burned in the geologic past. The coalbed is comprised of up to three separate coal seams referred to as the Upper, Middle, and Lower Wyodak. Only in the southwestern part of the lease do the three seams merge to form a coal unit 50 to 60 ft (15 to 18 m) thick (Fig. 14.3.2.3). The bed is contained within the Fort Union Formation.

The Upper Wyodak coal is the uppermost coal being mined. It is present as a separate unit over all the lease, except where it merges with the Middle Wyodak Seam. The Upper Wyodak Seam ranges from 0 to 7.5 ft (0 to 2.2 m) in thickness and shows no discernible trends.

Separating the Middle Wyodak Seams from the Upper Wyodak Seam is Split A, a carbonaceous shale parting 0 to 38 ft (0 to 12 m) thick. Below Split A is the Middle Wyodak coal. The seam is approximately 40 to 55 ft (12 to 17 m) thick over much of the lease and shows no trends, except for a gradual decrease in thickness that begins about 1000 to 1500 ft (305 to 457 m) from the geologic burnline.

The Lower Wyodak coal ranges in thickness from 0 to 8.5 ft (0 to 2.6 m) over the lease. It merges with the other two coal seams in the southwest and is separated from the Middle Wyodak toward the northeast by a shaley parting. This parting, referred to as Split B, varies from 0 to 73 ft (0 to 22 m) in thickness,

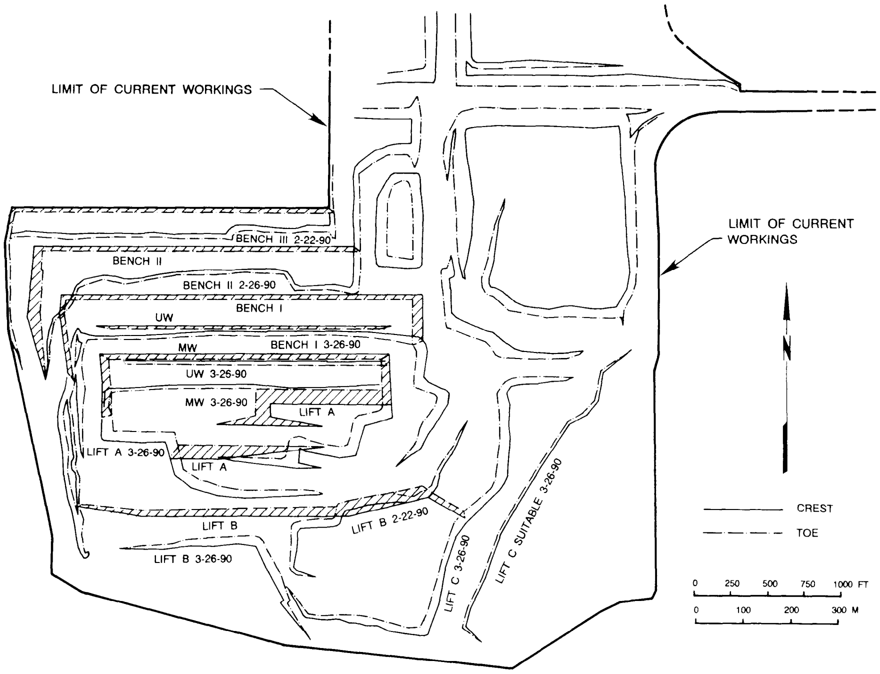

Fig. 14.3.2.4. Monthly mine plan.

averaging between 5 to 10 ft (1.5 to 3.0 m) thick over most of the lease.

About 70% of the Jacobs Ranch coal lease is rolling upland. This upland consists principally of shale and sandstone of the Wasatch Formation. Playas in scattered depressions occur on the plateau. These intermittent lakes, varying in size from less than a few yards (meters) to about 0.5 miles (0.8 km) in diameter, may be caused by local structure of the underlying strata. The remainder of the lease area is either shale slope or alluvial terrace.

The overburden-to-coal ratio varies throughout the Powder River Basin. Ratios range from 0.80:1 to almost 3.00:1. In general, overburden is thinner in the northern part of the Basin; however, stripping ratios vary from mine to mine and throughout individual deposits.

14.3.2.3 Mine Development

As is typical with surface coal mines in the United States, no surface disturbance can occur without the proper permits. Jacobs Ranch mine is regulated by several federal and state agencies. The Office of Surface Mining, the Bureau of Land Management, and the Forest Service all oversee activities at the mine. In addition, the Wyoming Department of Environmental Quality (WDEQ) requires that a mining permit be renewed every five years. An annual report also is required for WDEQ.

In order to reclaim the land successfully after mining, topsoil must be categorized, removed, stockpiled, and planted. The categorization of topsoil types and quantities is accomplished by augering on a grid with a maximum spacing of 200 ft (60 m). An environmental technician analyzes the topsoil and recommends the depth to which it should be removed. Scrapers then remove the topsoil and transport it to strategically located stockpiles or place the topsoil directly on recontoured overburden surfaces. If the topsoil is placed in a stockpile, it is seeded with a quick growing, perennial crop to hinder wind and water erosion.

The initial stripping at Jacobs Ranch mine was made in an area of low-overburden depth. The "box-cut" material was placed in permanent overburden piles adjacent to the initial openings. Due to marketing demands, the mine soon became a two-pit, blended-coal operation.

The pit and backfill design must be performed concurrently. Optimal pit design minimizes haul distance, while taking into account the after-mining contours. The overburden highwall stands at an angle of 1:1, horizontal to vertical. The backfill angle of repose is 1.5:1.

Because of the complex, three-seam coal deposit at Jacobs Ranch mine, the pit geometries are "stair-stepped" in both lateral directions from the pit floor. As mentioned previously, the coal thickness averages between 50 and 60 ft (15 to 18 m). The pit width averages approximately 2000 feet (610 m). The total disturbed length, at any time, varies between 2400 and 4000 ft (730 to 1200 m) along the axis of advance.

Haulage for overburden occurs on roads built into overburden benches (Fig. 14.3.2.4). Coal haulage to the preparation plant is on semi-permanent haul roads.

14.3.2.4 Unit Operations

DRILLING AND BLASTING. Virtually all the coal and overburden is drilled and blasted to maintain high truck and shovel productivities and low operating costs. Drillholes are spaced on approximate 50-ft (15-m) centers and are loaded with ANFO explosives if the holes are dry, and ANFO-based slurries if the holes are wet.

LOADING. The unit weight of overburden at Jacobs Ranch mine averages 111 lb/ft^3 (1778 kg/m^3) and is loaded with stripping shovels that have bucket capacities up to 36 yd^3 (27.5 m^3) (Fig. 14.3.2.5). In addition, front-end loaders (FELs) perform waste removal on an as-needed basis. The diesel/electric loaders can load 15 yd^3 (11.5 m^3) per pass.

The stripping equipment is used on an around-the-clock basis. (A shovel operates up to 6000 hr/yr after allowing for mechanical breakdowns and operating inefficiencies. FELs are used one-half that time.) The thick coal seams and homogeneous overburden contribute to high productivities and economies of scale.

Fig. 14.3.2.5. Stripping operations: 36-yd^3 (27.5m^3) shovel loading 170-ton (154-t) end-dump truck.

Fig. 14.3.2.7. Continuous-miner loading a 170-ton (154-t) bottom-dump truck.

Fig. 14.3.2.6. Production face: 40-yd^3 (30.6-m^3) shovel loading 170-ton (154-t) bottom-dump truck.

Fig. 14.3.2.8. Preparation of topsoil for reclamation.

Coal mining is normally conducted during 2 shifts/day, 5 days/week. One coal shovel is assigned to each of the two pits. Bucket capacities for the coal shovels range up to 40 yd^3 (31 m^3) (Fig. 14.3.2.6). The output from each of these shovels is regulated, on a shift-by-shift basis, in order to blend the coal properly.

In addition to the shovels and FELs, Jacobs Ranch mine recently purchased a continuous loader (Fig. 14.3.2.7). The loader employs a rotating drum that cuts coal in horizontal slices. The coal is discharged directly into trucks by a movable conveyor belt. A typical coal crew consists of a shovel operator, an oiler, and truck drivers. Support equipment includes rubber-tired dozers, crawler tractors, road graders, and water trucks. It is commonplace to have overburden and coal shovels operating simultaneously.

Productivity at Powder River Basin mines ranges between 100 and 300 tons of coal (76 and 272 t)/employee-shift. Productivity also is measured by total units produced. A unit is considered to be either a cubic yard (0.76 m^3) of overburden or a ton (0.91 t) of coal. The unit productivity in the basin ranges between 300 and 700 units/employee-shift.

HAULAGE. All material transported at Jacobs Ranch mine is moved by trucks. The overburden is hauled mainly by 170-ton (154-t) end-dump trucks that have a capacity of 104 yd^3 (80 m^3) of overburden per trip (Fig 14.3.2.5). The mine is also using four 240-ton (218-t) trucks in an attempt to further increase production efficiency. Coal is hauled primarily by 170-ton (154-t) bottom-dump trucks (Fig 14.3.2.6).

RECLAMATION. Kerr-McGee Coal's philosophy toward reclamation is straightforward: make the land more productive than it was when mining began. This simple goal translates into many hours spent planning, testing, and restoring the Wyoming range lands in an efficient and effective program, at the lowest possible cost. Recognition of these efforts includes the National Reclamation Award given by the Department of the Interior in 1988.

At Jacobs Ranch mine, reclamation is continuous. The mining process is similar to a "moving hole," as overburden removed ahead of mining is placed behind the advancing pit. Once the backfilled overburden has been contoured to match the surrounding terrain, topsoil is spread on the site. The ground is planted with blends of up to 14 types of grasses and shrubs (Fig. 14.3.2.8). The blend ensures vegetation hardy enough to withstand harsh Wyoming winters. Fences protect the lands until the grasses are healthy and established.

In addition, employees erect natural rock habitats that provide cover for small animals and vantage points for birds of prey.

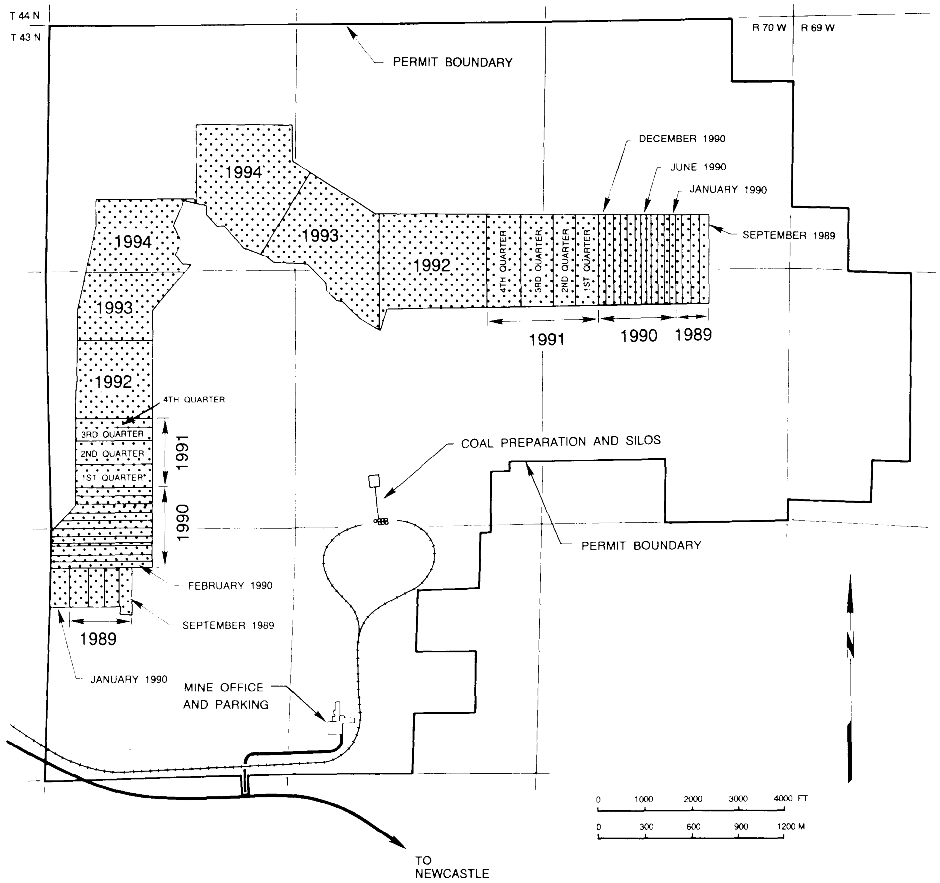

Fig. 14.3.2.9. Five-year mine plan.

Before completing reclamation, crews dig ditches and ponds to prevent run-off water from eroding topsoil.

The best testimonies to Kerr-McGee Coal's success in reclamation are the deer and antelope grazing on the protein-rich grasses growing on acreage that has yielded its coal. Studies carried out at Jacobs Ranch mine document that reclaimed areas are more productive than surrounding undisturbed range land.

14.3.2.5 Product Control

As mentioned previously, coal quality at Jacobs Ranch mine varies throughout the deposit. The challenge for the engineers at Kerr-McGee Coal Corporation was to determine an ultimate mine plan that would ensure quality coal over the life of the mine.

Every year an updated five-year mine plan is completed (Fig 14.3.2.9). Monthly mine plans shown in Fig. 14.3.2.4, are prepared in accordance with the five-year outline.

On a daily basis, a quality control engineer inspects the pit and ensures that proper grade control is maintained for the shovels and loaders. The quality control engineer is responsible for blending the coal into the silos and, eventually, into the coal trains. Onsite proximate analyses are performed for all coal shipments.

14.3.2.6 Ancillary Facilities

MAINTENANCE. Jacobs Ranch mine's ongoing maintenance program emphasizes inspections and repairs of mining equipment before a major failure hampers coal production. This effort requires two teams of diesel mechanics, welders, and maintenance electricians. The maintenance shop is large enough to accommodate 24-ft (7.3-m) tall haul trucks. Equipment too large and slow to be brought to the shop is serviced in the field. This equipment includes bulldozers, drills, and shovels.

COAL PREPARATION. The preparation plant at Jacobs Ranch mine has two parallel circuits that are each capable of producing coal at 2000 tph (1815 t/h). The coal delivered to the preparation plant hopper ranges up to 15 in. (381 mm) in diameter. A dual stage crusher in each circuit reduces the coal to its final 2-in. (51-mm) size.

Coal is sampled as it is placed in one of seven, 14,000-ton (12,700-t) silos. Coal is loaded into two unit trains using automatic train loading and top-off systems. The 115-car unit trains are loaded to within ±0.2% of the desired weight.

Individuals with supporting skills such as accounting, engineering, and computer science help ensure that Kerr-McGee Coal meets its goals. The company strives to provide the safest working environment, to deliver high-quality coal, and to continue operating as a responsible corporate citizen in the Powder River Basin.

14.3.3 VARIABLE INTERBURDEN, HORIZONTAL MULTIPLE COAL SEAMS: COLOWYO COAL COMPANY

DAVID B. MCDONALD

14.3.3.1 Mine Description

The Colowyo Coal Co., a 50-50 partnership of W.R. Grace & Co. and M.A. Hanna Co., started coal production on March 11, 1977. The mine (Fig. 14.3.3.1) is located at Axial, CO, which is 26 miles (42 km) southwest of Craig, in Moffat County, CO. The elevation of the mine site is 7000 ft (2100 m). Colowyo operates on federal and state coal leases with some private ownership of the surface. The logical mining unit (LMU) is 11,405 acres (46 km^2).

Colowyo's 1989 production rate is 4.1 million tpy (3.7 Mt/a) of coal that requires the removal of 27 million yd^3 (21.4 million m^3) of virgin overburden and 3.8 million yd^3 (2.9 million m^3) of rehandle. The mine is designed and permitted to operate at a maximum production rate of 4.4 million tpy (4 Mt/a). In order to produce at this rate, Colowyo operates 323$\frac{2}{3}$ days/year, 3 shifts/day. Twenty shifts/week are scheduled in operations, with the 21st shift being a maintenance shift. The remaining days not worked are 14 days for a vacation shutdown, 10 holidays, and 17$\frac{1}{3}$ days that comprise the 21st shift.

14.3.3.2 Deposit Description and Geology

GEOLOGIC SETTING.

Formation—The coal measures mined at Colowyo are contained in the Williams Fork Formation, part of the Late Cretaceous Mesa-Verde Group deposited approximately 70 m.y. ago. In the western United States, the Mesa-Verde Group contains several coal-bearing formations. The Williams Fork Formation consists of alternating beds of sandstone, siltstone, shale, and coal, typical of deposits along a linear clastic shoreline. The Williams Fork Formation is approximately 1600 ft (490 m) thick in the vicinity of the Colowyo mine.

Structure—The predominate regional structure is influenced by the White River/Sierra Madre uplift to the east, the Uinta Uplift to the west, and the Sand Wash Basin to the north. Within

1 - Primary coal crusher
2 - 37 yd^3 (28.5 m^3) dragline
3 - 27 yd^3 (20.5 m^3) dragline
4 - 25 yd^3 (19.2 m^3) electric shovel
5 - 28 yd^3 (21.6 m^3) electric shovel
6 - Overburden drill
7 - Equipment parking lot
8 - Explosive storage
9 - In-pit rock crusher
10 - Coal cleaning
11 - Overburden shot-rock inventory
12 - Topsoil removal
13 - Topsoil replacement - final reclamation
14 - Active waste dumps - truck and shovel

Fig. 14.3.3.1. Aerial view of the Colowyo mine looking eastward.

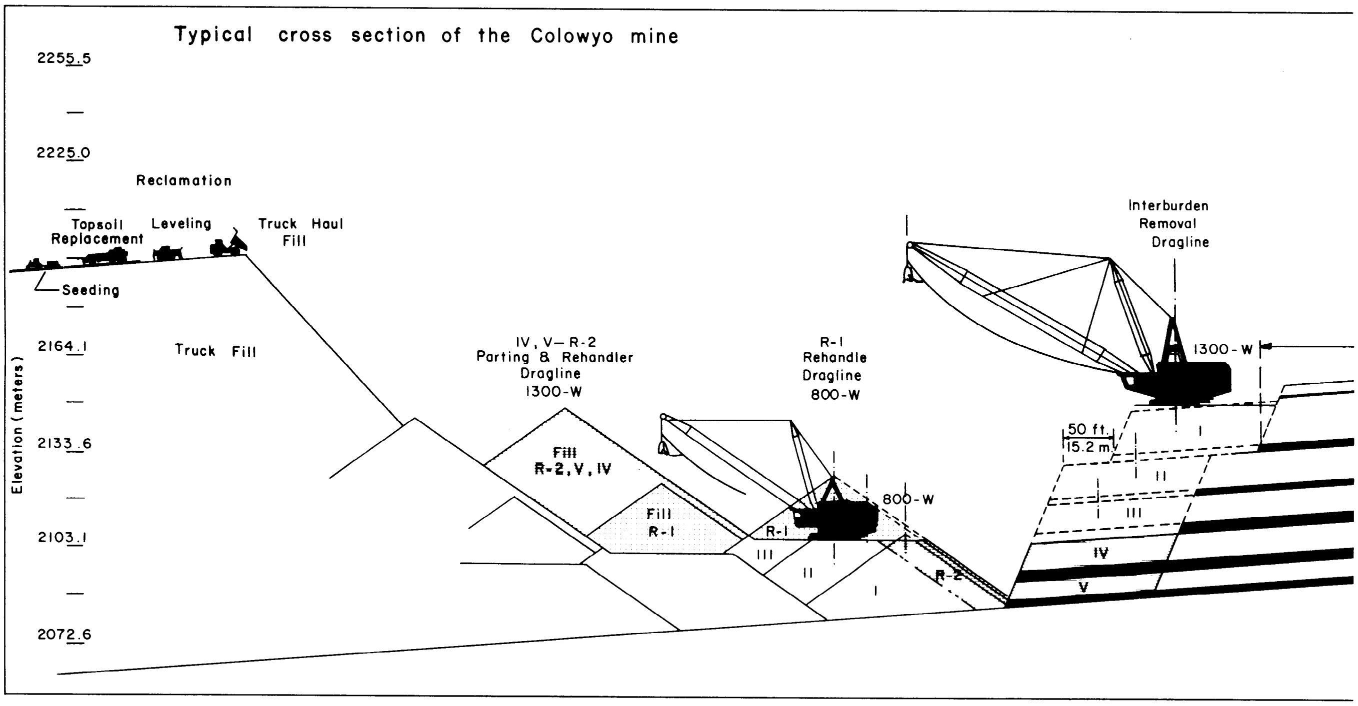

Fig. 14.3.3.2. Typical cross section of Colowyo mine.

the mine area, the geologic attitude of the overburden and coal seams strike at an orientation of N70°W and dip 4 to 6° north. Minor interruptions in the local attitude are seen through the effects of differential compaction linked to changes in interburden material and thickness. Local structural anomalies surrounding the Colowyo leases cause abrupt changes in attitude beyond the Colowyo lease boundaries.

Maximum overburden depth, including the thickness of the coal seams, is about 400 ft (120 m). Near outcrop locations, where the upper coal seams have eroded, the minimum depth of the pit will be about 275 ft (85 m). Interburden depths range from 12 ft (4 m) to 90 ft (30 m).

NUMBER AND THICKNESS OF SEAMS. Colowyo mines coal from eight major seams. In addition to the eight-seam operation, two of the major seams split within the area of the pit, bringing the total number of coal seams currently recovered to ten. Fig. 14.3.3.2 is a typical cross section showing the geometry and distribution of the coal seams mined at Colowyo.

PROPERTIES OF MATERIALS. The coal rank is subbituminous ‘A’ and ‘B’. The coal averages 10,700 Btu/lb (24,888 kJ/kg), 0.2 to 0.4% sulfur, 4 to 6% ash, and 14 to 16% moisture. The overburden and interburden consists of sandstone, siltstone, shale, and claystone.

STRIPPING RATIO. The in-place stripping ratio is 6.5 yd^3/ton (5.5 m^3/t) and will increase to 7.5 yd^3/ton (6.3 m^3/t) due to coal splits and subsequent loss in recovery.

ESTIMATED RESERVES. The recoverable reserves amenable to surface mining include 138 million tons (125 million t). The recoverable underground reserves are estimated at 74 million tons (67 Mt) as of 1989.

14.3.3.3 Mine Development

The eight major seams can be mined by either of two different scenarios: (1) all truck and shovel or (2) a combination of truck and shovel and draglines. The latter system was used in the mine design due to the inherent cost advantage of draglines. The mine is separated into two areas using different types of mining equipment but still integrally tied together. The interburden for the first three coal seams is mined by standard truck and shovel mining methods and has a stripping ratio of approximately 10 yd^3/ton (8.4 m^3/t). The remaining five coal seams are mined with draglines, with a stripping ratio of approximately 4:1. The mining cuts are 150 ft (46 m) wide in both mining areas, and the two mining areas are separated by at least two mining cuts (Fig. 14.3.3.2). This mining configuration of five dragline seams and three truck-and-shovel seams is designed for a nominal 4 million tpy (3.6 Mt/a) of coal production. Increasing or decreasing annual production requires lowering or increasing the vertical height of the dragline highwall and a corresponding addition or reduction in the truck and shovel area. In all production scenarios, the two mining systems must move through the deposit at the same rate. The constant rate keeps the truck haulage cycle distance approximately the same, which, in turn, stabilizes the required haulage truck fleet. In this scenario, the mine is a moving V, which removes approximately three mining cuts per year.

The mine design incorporates an in-pit or stockpile coal reserve of two-months production. The dragline area of the mine has no significant in-pit coal reserves, as sequencing of the mining process does not allow coal to be left behind the draglines without limiting dragline production. The coal must be removed and the next lower bench shot before the dragline can be moved to the next bench. The mining sequence of removing interburden—cleaning, drilling and blasting coal, mining and hauling coal, drilling and blasting overburden for the next bench, and then reconstructing the coal haul road without delaying the dragline—requires careful pit planning and engineering. Two draglines working within a pit less than 1 mile (1.6 km) in length also increases the critical nature of dragline scheduling.

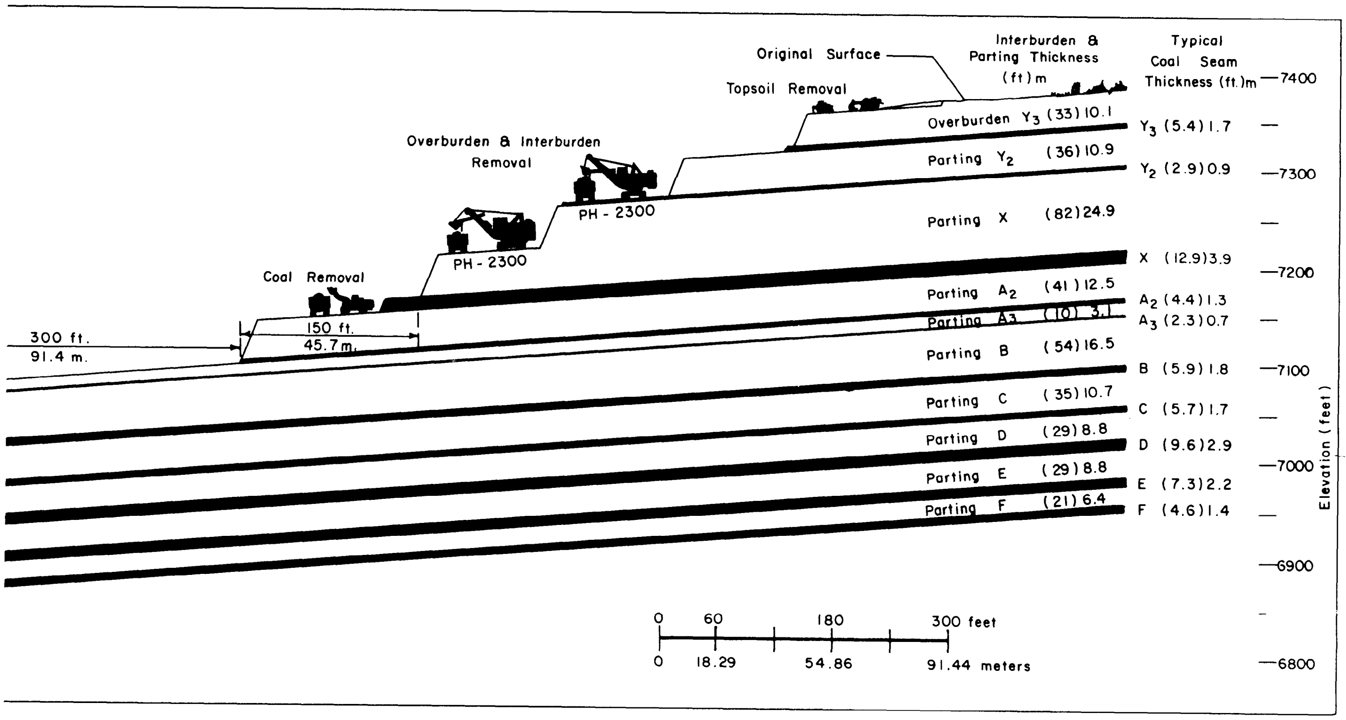

Fig. 14.3.3.2. (cont.)

In-pit reserves are maintained on the ‘X’ coal seam in the truck and shovel area.

The coal seams dip about 6%. The mature pit is 4600 ft (1400 m) long and 2000 ft (610 m) wide, with highwalls at an average angle of 63.5°. The swell factor for the dragline dump is approximately 25% and only 14 to 15% for the truck-and-shovel dump. The average truck haulage distance is 8400 ft (2560 m).

14.3.3.4 Unit Operations

DRILLING. All overburden is drilled and blasted. Overburden drilling is accomplished with three rotary drills. One electric drill is capable of drilling 10 5/8-in. (270-mm) holes and is used mainly in the truck and shovel area. The other two drills are used in the dragline area of the mine, where maneuvering room is limited and numerous holes are required due to the limited thickness of overburden. The two diesel machines drill 9 7/8-in. (250-mm) holes. All drills use 8 5/8-in. (219-mm) steel, medium formation tricone button bits and are capable of angle-drilling a 15° hole. Scheduling of drills in the dragline area of the mine requires advance planning due to the limited time available to keep the dragline supplied with broken material. Drill availability and utilization is critical for the cast blasting of ‘B’ level and requires maximum utilization of all drills. The hole size, drill pattern, and average depth of each level is shown on Table 14.3.3.1.

Coal drilling is accomplished with one Schroeder Brothers 4-in. (102-mm), twin-auger drill mounted on a John Deere tractor. The drill averages about 1500 ft (457 m) per shift and is used 5 shifts/week.

BLASTING. Blasting is accomplished daily using either ANFO or heavy ANFO. Heavy ANFO is a mixture of 25% emulsion to ANFO by weight in dry holes, while a 35% emulsion is used in dewatered wet holes. The 25% blended heavy ANFO has a specific gravity of 1.18, while the 35% blended heavy ANFO has a specific gravity of 1.28. Regular ANFO has a specific gravity of 0.85.

The ‘Y,’ ‘X,’ ‘A,’ and ‘B’ overburden benches have about 50% wet holes; therefore, these areas use the majority of the heavy ANFO. The lower overburden area, ‘C,’ ‘D,’ ‘E,’ and ‘F’ benches, rarely have wet holes and use the regular ANFO for blasting.

Table 14.3.3.1 lists the drill patterns, powder factors, tie-in and direction, and type of explosives used for each bench. Cast blasting is utilized only on ‘B’ level. Fig. 14.3.3.3 shows a typical cast blasting pattern.

LOADING. From the original surface to the ‘A_3’ seam (Fig. 14.3.3.2), overburden and interburden are removed by two 25-yd^3 (19.2-m^3) shovels and one 15-yd^3 (11.5-m^3) shovel. The two 25-yd^3 (19.2-m^3) shovels are scheduled 20 shifts/week. The 15-yd^3 (11.5-m^3) shovel is a spare. The mining cut is 150 ft (45 m) wide, which allows enough working area for double spotting of haulage trucks.

Interburden removal below the ‘A_3’ seam is accomplished with Bucyrus-Erie walking draglines (one 800W and one 1300W) with capacities of 27 yd^3 (20.8 m^3) and 37 yd^3 (28.5 m^3), respectively. Both units work from either the highwall or spoilpile locations. Beginning with the interburdens over the ‘B’ seam, the 800W dragline, located on the east end of the pit, mines toward the west; the 1300W (37-yd^3) (28.5-m^3) dragline, located on the west end of the pit, mines toward the east.

After ‘B’ interburden is removed, the 800W moves down the ramp to remove the ‘C’ interburden, mining to the east. The 1300W then mines the ‘B’ ramp and removes the remaining ‘C’ interburden from west to east.

In the ‘D’ seam interburden, the 800W moves down the ramp and mines a small portion of the ‘D’ interburden on the east end of the pit, while the 1300W completes removal of the ‘C’ interburden. The 1300W then replaces the 800W and com-

Table 14.3.3.1. Drilling and Blasting

Bench or Area	Hole Size in. (mm)	Drill Pattern ft (m)	Average Hole Depth ft (m)	Tie-in and Direction	Explosive	Powder Factor lb/yd^3 (kg/m^3)

pletes the removal of the 'D' interburden, moving once more from west to east. At this point, the 800W rehandles a portion of the 'B,' 'C,' and 'D' interburdens, preparing the spoilpile from west to east so the 1300W can remove 'E' and 'F' interburdens. The 1300W digs a coal ramp for 'E' and 'F' coal removal on the west end of the pit and then proceeds west to east again, removing 'E' interburden from the spoil side and casting spoil 180° against the previous cut spoil. Meanwhile, the 800W removes a necessary portion of the previous cut spoil, starting in the center of the pit and proceeds from west to east to make room for the 1300W to spoil 'E' interburden.

Once the 'E' interburden is removed, the 1300W begins on the west end, removing 'F' interburden from the spoil side, advancing from west to east. The dragline exits the pit via a 10% ramp on the east side through the spoilpile and walks to the west end of 'B' level to start its sequence over again. During this period, the 800W pulls 'F' rehandle and incurs some idle time waiting for the east 'B' bench to be blasted. Table 14.3.3.2 shows the major equipment and corresponding productivity.

A 22-yd^3 (16.9-m^3) front-end loader (FEL) is used to load coal and to remove the overburden when dressing a coal face. This overburden comes from blasting the material directly over coal. Smaller 4- to 7.5yd^3 (3.1- to 5.8-m^3) FELs are used to load topsoil and clean the top of the coal.

HAULAGE.

Overburden—Two 25-yd^3 (19.2-m^3) class electric shovels are scheduled to remove overburden. One shovel is assigned to each side of the pit and each works to a point that is equal distance between the working face and the centroid of the truck dump. Each shovel is scheduled with six haulage trucks. The haulage profile is balanced by working one shovel on the higher benches on a long haul and the other on the lower benches with a short haul. The haulage truck fleet consists of fourteen 170-ton (154.2-t) trucks, three 120-ton (109-t) rock trucks, and four 120-ton (109-t) end-dump coal trucks.

The haulage roads for overburden have a maximum 8% grade with a preferred grade of 6%. Coal hauls from the dragline area have a maximum grade of 10%, with a preferred grade of 8%. The coal haul ramp is located on the west end of the pit.

Coal—Coal is mined with a 22-yd^3 (16.9-m^3) FEL. From the pit, coal moves in 120-ton (108.8-t) end-dump trucks to a primary crusher on the pit rim. The primary crusher is a feeder breaker that reduces pit-run coal to a 6 × 0-in. (152 × 0-mm) product. The coal is then stored in a 150-ton (136-t) surge bin. Fifty-ton (45-t) bottom-dump coal haulers are loaded from the surge bin and haul the coal 3.7 miles (5.92 km) to the rail loadout facility. These coal haulers are heavy-duty, on-highway trucks that travel loaded down a 7.5% grade to the secondary crusher at the rail loadout. The trucks' primary braking system is an electric magnetic retarder that is located in two of the three rear axles on the trailer. The trucks also have a normal braking system, and the tractors are equipped with Allison transmissions for more retarding power.

Topsoil—An average of 18 in. (457 mm) of topsoil over 50 acres (0.2 km^2) is removed each year in front of the advancing mine faces. The topsoil is dozed into piles and loaded into three 50-ton (45-t) haulage trucks by a 7.5-yd^3 (5.8-m^3) loader. The topsoil is then placed on the dump surface that has been prepared for reclamation. During the time this fleet is not moving topsoil, it is used to build haulage roads and to haul mine-made crushed rock for road surfacing.

RECLAMATION. During the years of exploration, and prior to active surface mining, Colowyo conducted extensive baseline environmental studies. In addition, a 3-acre (12,141-m^2) area was disturbed to simulate mining, and many reclamation studies (including runoff plots, shrub establishment, mulching, and planned species trials) were conducted for use in developing the Colowyo reclamation plan.

When the Colowyo mine was permitted by the State of Colorado under the permanent program of the Surface Mining Control and Reclamation Act, Colowyo submitted a complete application through the year 2017 and thereby obtained a life-of-mine approval. By obtaining a life-of-mine approval, Colowyo has the

"right of successive renewal" for each five-year permit term through 2017.

Reclamation activities are conducted in accordance with the approved reclamation plan which includes a "reclamation topography map" representing the approximate original contour. By survey control, overburden is dumped by trucks into the final configuration of the reclamation topography map and graded to final configuration by dozers. Where practical, the uppermost weathered overburden is placed on the surface to provide the most acceptable rooting material to enhance revegetation.

After final grading of the overburden is completed, topsoil is end-dumped with 50-ton (46-t) and 120-ton (109-t) trucks. Since the mine is in a mature configuration, the regraded area is prepared prior to topsoil removal for the next year, thereby allowing the topsoil to be hauled directly from the mining advance. The replaced topsoil is spread to a depth of 12 to 18 in. (305 to 457 mm) by dozers. Since the initial 6 in. (152 mm) of

Table 14.3.3.3. Coal Quality History

Year	Btu/lb	kJ/kg	Heat contents Ash (%)

1988	10,704	24,898	4.96

topsoil are an important source of native plant materials, that material is segregated and spread on top when practical.

The regraded topsoil is then checked for the required depth and sampled for plant nutrients. If necessary, appropriate amounts of nitrate-phosphate fertilizer are applied to the surface. After fertilizer is applied, all areas are tilled with a chisel plow to a depth of approximately 8 to 12 in. (203 to 305 mm) to reduce compaction.

A substantial amount of the Colowyo reclaimed area consists of 3:1 slopes. Newly reclaimed slopes require special attention to control erosion. Colowyo's D7 dozer has been equipped to pull farm implements, which allows the 3:1 slopes to be worked on the contour to increase erosion control. After the area has been chisel plowed, it is seeded by a rangeland drill using the approved seed mixture with approximately 30 different species of plants.

While seeding, contour furrows approximately 8 in. (203 mm) deep and 14 in. (356 mm) wide are cut into the topsoil by plowshares attached to the two outside ripper shanks on the D7 dozer. The use of contour furrows and the chisel plow are the primary reasons that Colowyo has been able to successfully control erosion on 3:1 slopes.

In addition, for every 100 ft (30 m) in elevation, a 2% ditch approximately 8 ft (2.4 m) wide and 2 ft (0.6 m) deep is constructed to carry any runoff that accumulates in the permanent drainages. The remaining reclaimed areas on flatter slopes are prepared in a similar manner by utilizing a farm tractor to pull the chisel plow, a rear blade for contour furrows, and the rangeland drill.

Most of the 3:1 slopes are outslopes of a 54,000,000-yd^3 (41,300,000-m^3) excess-spoil valley fill. The fill is a critical element of the Colowyo mine, and was constructed as an experimental practice. Existing regulations required, among other things, 4-ft (1.2-m) lifts. Colowyo's fill has been constructed in lifts that vary from 75 to 200 ft (23 to 61 m). The primary regulatory concerns have been over stability, and after 10 years of monitoring, no significant movement has been detected.

To meet permit requirements, approximately 15% of the reclaimed area on 10% or flatter slopes is revegetated to forbs and shrubs only. Shrubs are established from seed, seedlings, and by transplanting mature shrub clumps taken from the pit advance areas prior to topsoil stripping.

Reclaimed areas are monitored the first year after seeding and every three years thereafter to determine the reclamation success during the ten-year reclamation liability period.

14.3.3.5 Product Control

Quality of the Colowyo coal has been optimized since the mine achieved a mature pit configuration. Table 14.3.3.3 illustrates this in terms of the "as shipped" Btu/lb (kJ/kg) and ash percentage. Sulfur has been maintained at a relatively constant 0.35% during this period.

Quality is evaluated through application of the principles of statistical process control. The Quality Control Department is responsible for inspection, sampling, testing, statistical evaluation, and customer feedback.

INSPECTION. Prior to drilling and blasting, the coal is cleaned by a FEL or rubber-tired dozer. This progress of cleaning is monitored and reported by the Quality Control Department. As the coal is mined, periodic inspection is conducted to observe the extent of product dilution. Also the coal is inspected at other stages of transport and stockpiling. Observations of any inferior product are reported to the coal foremen.

SAMPLING. Sampling is done before mining, during production, and upon loading of rail cars. Pre-production sampling involves the collection of drill cuttings or channel samples just prior to mining of the coal. Production samples are taken from truck tops after loading at the primary crusher for transport to the rail loadout. As rail cars are loaded, a three-stage mechanical system collects the shipment samples. A backup system is in place for car-top sampling in the event of mechanical system failure. These systems are continuously monitored for performance through statistical testing.

TESTING. The Quality Control Laboratory performs short proximate analyses, ash fusibility, Hardgrove grindability, ash elemental analysis, and other tests as needed. A mine-site lab is maintained in order to furnish timely results.

STATISTICAL EVALUATION. Production and preproduction sample data are used to define production goals. Data from each dragline and each shovel mining cut are used to predict the potential qualities for subsequent mining cuts. Causes for deviations are normally easy to track and correct; monthly production averages then are normally close to quality goals.

Control of shipment quality is based on past performance. The Quality Control Department constructs control charts to define the expected limits of variability for each customer. Two standard deviations are used for warning limits and three for rejection limits. When a shipment is in the warning region, a search for assignable cause is made. If a shipment is in the rejection area, corrective action is taken immediately by management, and the customer is informed.

CUSTOMER FEEDBACK. Customers are willing to share with Colowyo their changing needs, especially with respect to quality parameters. The most common request from the customer is for product consistency. Consistency is primarily achieved through blending.

BLENDING. A blended product with consistent qualities is achieved by tracking certain quality parameters and recommending mining, stockpiling, and coal removal in a sequence that is compatible with the mining and customer shipment schedules. The main variations in properties are a function of coal age (depth). In-pit coal reserves are not maintained in the dragline area of the mine; therefore, the five lower coal seams are always being mined. The upper three coal seams in the truck and shovel area of the mine are naturally blended into the coal flow on an "as needed" basis. Natural blending through mining meets most requirements. The use of one- or two-layered stockpiles allows this process to be fine tuned. Table 14.3.3.4 illustrates the impact of increased blending on reducing the standard deviation (sigma) in "as received" Btu/lb (kJ/kg) for one of Colowyo's customers.

14.3.3.6 Ancillary Facilities

MAINTENANCE FACILITIES. Maintenance facilities are located at the rim of the pit. The maintenance department is

divided into three areas: (1) mobile equipment, (2) field equipment, and (3) electrical. The truck shop has eight truck bays, a tire shop, and a machine shop. Near the shop is a wash building for haulage trucks and pickups. In addition, Colowyo has a welding shop, light vehicle repair bays, electrical shop, and a dozer repair bay. The warehouse, along with its outside storage area, is attached to the truck shop. The total enclosed maintenance area is approximately 67,800 ft^2 (6300 m^2).

The 21st shift is a maintenance shift and is scheduled normally on Friday during the day. One dragline is scheduled for a 16-hour preventive maintenance every other week. On the off-week, it receives electrical maintenance for eight hours. Shovels and drills are scheduled for 16 hours of preventive maintenance every two weeks. Haulage trucks receive an assembly-line, six-hour preventive maintenance check every 150 operating hours. Every 150 hours, the maintenance cycle is increased in depth and type of maintenance accomplished.

At the annual 4.1-million ton (3.7-Mt) coal production rate, the maintenance department is staffed with 116 employees. The operating department has 197 employees. Table 14.3.3.5 shows a breakdown of each department by classification, along with staff and administration.

RAIL LOADOUT. Colowyo ships its coal by rail on the Denver & Rio Grande Western Railroad. The primary product is 1.5 × 0-in. (38 × 0-mm) crushed coal for the thermal market. The 50-ton (45.4-t) bottom-dump coal trucks deliver 6 × 0-in. (152 × 0-mm) coal to the secondary crusher located at the rail loadout. The crusher is a ring hammer mill that reduces the coal to the primary product size.

The rail loadout utilizes an open storage concept. The facility consists of a 125-ft (38-m) high stacking tube capable of stockpiling 120,000 tons (108,840 t) of coal, of which 17,000 tons (15,419 t) is live storage for direct loading into unit trains. Unit trains move through a tunnel under the stockpile and are loaded at an average rate of 5000 tph (4535 t/h), using one or two 5-ft (1.5-m) square chutes. The facility is equipped with a unit train sampling and rail weighing "in-motion" system. Stoker coal is loaded into railroad cars by a FEL on a side track and shipped weekly.

14.3.4 MONOLITHIC OVERBURDEN, INCLINED COAL SEAMS: TRAPPER MINE

GARY M. STUBBLEFIELD AND ROGER W. FISH

14.3.4.1 Mine Description

The Trapper mine (Fig. 14.3.4.1), operated by Trapper Mining Inc., is located 6 miles (9.7 km) south of Craig in the northwest corner of Colorado. With an annual coal production of 2.1 million tons (1.9 Mt) delivered from a property encompassing 9600 acres (39 km^2), Trapper ranks as the third largest producing coal mine in the state (1991). Three electric draglines strip waste material from five dipping coal seams. These units work three 8-hour shifts/day, 5 days/week, except during periods when the strip ratio is greater than 10:1 yd^3/ton (8.4:1 m^3/t). In addition, stripping can occur 6 or 7 days/week when box-cutting is necessary. Coal extraction activities are performed 2 shifts/day, 5 days/week.

14.3.4.2 Deposit Description and Geology

Trapper is situated at the southern edge of the Green River Coal Field in a geologic setting of gently rolling, east-west-striking anticlines and synclines. The mine is on the southern flank of the Big Bottom Syncline where the coal dips at a fairly consist-

Fig. 14.3.4.1. Aerial view of Trapper mine looking southward.

1987 Avg	—	10,000 (23,260)	0.39	7.7	17.1

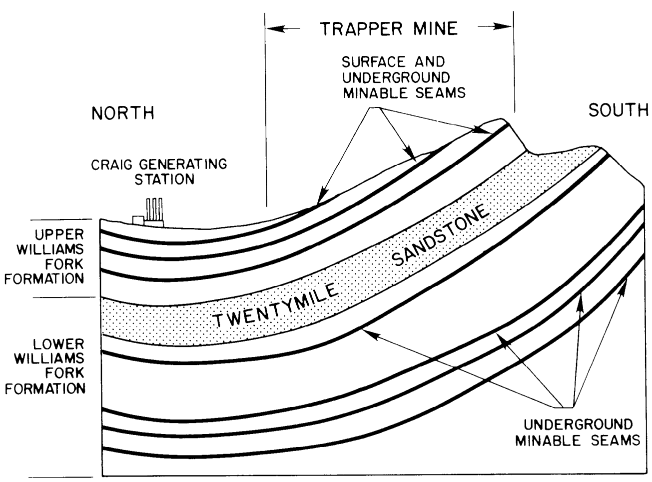

Fig. 14.3.4.2. Typical Trapper mine cross section.

ent 16% to the north, about 2% steeper than the surface of the land. There are few faults on the property. Overburden ranges from 0 to 140 ft (0 to 43 m) at the economic stripping limit. Fig. 14.3.4.2 presents a typical cross section of the mining area.

Seven major surface-minable coal seams exist within the permit boundary, with five of these seams mined from three active pits. Coal at Trapper is ranked as high-volatile subbituminous and is dedicated to steam coal application. Currently, delivered coal averages 9900 Btu/lb (23,028 kJ/kg), 0.4% sulfur, 7.5% ash, 44% fixed carbon, and 17% moisture, with a coal recovery of roughly 90%. Table 14.3.4.1 exhibits the average thickness and run-of-mine quality of the seams mined at Trapper.

Waste material (overburden and interburden) consists primarily of interbedded shale, siltstone, and sandstone layers. The waste is generally soft with an average in-place density of 3400 lb/yd^3 (2017 kg/m^3). Trapper's minable strip ratio (1991) averages 9:1 yd^3/ton (7.6:1 m^3/t).

An estimated total of 67 million tons (61 Mt) recoverable, strippable reserves remain within the permitted boundary at a minable strip ratio of 8.5:1 yd^3/ton or 7.2:1 (m^3/t). Coal recovery is expected to average 89% overall. Of the 9600 surface acres (39 km^3) of reserves controlled by Trapper, 51% is leased from the State of Colorado, 44% from the federal government, and the remaining 5% from Moffat County or private individuals. Underground reserves controlled by Trapper above the Twentymile Sandstone (Fig. 14.3.4.2) total an estimated 270 million minable tons (245 Mt) or 130 million recoverable tons (117 Mt) from five deep coal seams. An additional 300 million minable tons (272 Mt) exist below the Twentymile Sandstone.

14.3.4.3 Mine Development

TOPSOIL REMOVAL. Trapper's mining sequence begins with topsoil removal operations during the summer months of June through October. Caterpillar (Cat) D9 dozers first windrow surface vegetation onto an adjacent area where the topsoil has previously been removed. Six to eight Cat 627E scrapers are then used to remove an average of 17 in. (432 mm) of topsoil (range is 6 to 24 in., or 152 to 610 mm) from an area large enough to allow mining to continue until the following summer. After the topsoil is loaded, it is either hauled directly to previously mined and recontoured areas or stockpiled for later deposition. Topsoil is transported directly to regraded areas approximately 40% of the time by way of either across-pit ramps or haulage routes around the end of the pits.

Topsoiling productivities are 150 and 200 yd^3/hr (115 and 153 m^3/h) for direct respread and stockpiling, respectively. Over 600,000 yd^3 (459,000 m^3) are handled each year.

LAYOUT AND ACCESS TO PITS. Trapper presently has four active pits: Ashmore, Browning, Colt, and Derringer. Each extracts two major coal seams. As the Colt pit progresses to the west, it will be mined in conjunction with the Browning pit. A recently idled pit, Enfield, was a single-seam operation that employed cast blasting. Operations at Enfield were moved to Colt in order to recover coal before a neighboring underground longwall mined below the reserves. Three additional pits, Flintlock, Gatlin, and Hawkin, are projected to be activated in the future as reserves are exhausted in current pit areas.

The pits are accessed by 60-ft (18-m) wide main haul roads. Ramps into the pit are placed approximately 1000 ft (304 m) apart and may be situated through the spoil or highwall, depending largely on which side the main haul road accesses the pit.

OVERBURDEN REMOVAL. Given the dipping seams and sloping topography at Trapper, the three theoretical techniques available for a dragline to remove overburden are strikeline, dipline, and oblique stripping. Fig. 14.3.4.3 present the general layout of the strikeline and dipline methods. *Oblique stripping* is a combination of the first two methods where the pits are oriented between the strike and dip of a seam.

With the strikeline method, the dragline advances the cut along the strike of the coal. Strikeline pits can be laid out either beginning at the outcrop or at the point of maximum economic overburden depth. It is obvious that the latter option will incur the highest initial stripping costs, since stripping operations begin at the point of maximum cover. Other problems with beginning at the deepest overburden include highwall instability, possible coal reserve sterilization down-dip from the boxcut, and poor utilization of equipment in later years. Alternatively, starting at the outcrop eliminates high initial production costs. However, as the pits get deeper, smaller areas are available to spoil the increasing quantities of waste. This problem, referred to as being spoil-bound, requires substantial waste rehandling, a process that is both inefficient and costly.

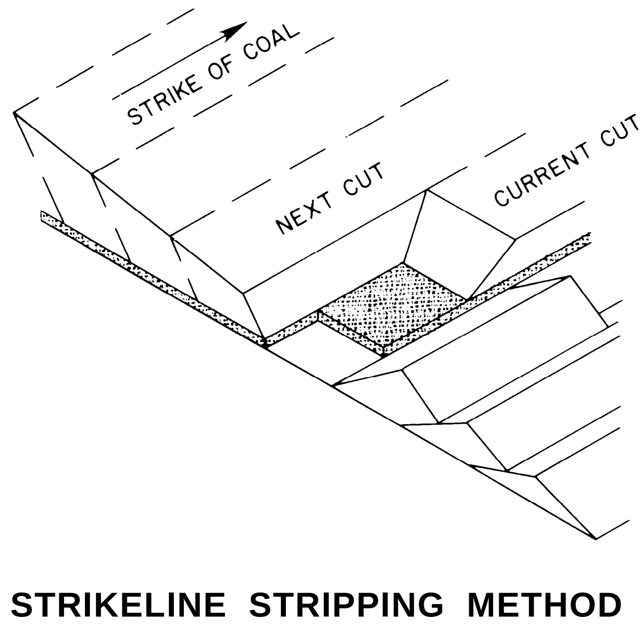
Oblique stripping is defined as aligning the pits at an angle to the strike of the coal. The technique assumes the same advantages and disadvantages as the dipline method as the orientation of the pit approaches the dip direction. Conversely, it assumes the same advantages and disadvantages as the strikeline method as the orientation approaches the strike direction.

Trapper selected the dipline method because of the greater highwall stability and lower rehandle quantities relative to the strikeline method. Another advantage of the dipline method is the uniform stripping costs and equipment requirements realized from similar amounts of overburden taken in each cut. To make this stripping plan work, Trapper had to develop an efficient method of moving the draglines up and down the dip slope.

Dragline Movement—The procedure for moving along the pit length has evolved from a switchback ramping system to a benching or "see-saw" method. In the switchback method shown in Fig. 14.3.4.4, the dragline digs a ramp to an intermediate bench approximately 45° away from the pit and then makes a switchback to the next bench above or below the original bench. Since this method requires considerable walk-road construction and rehandle, the see-saw method was developed to reduce the rehandle and provide the dragline a longer digging time on the same bench.

The sequence for the see-saw method moving uphill on the spoil begins with the dragline at position 1 on pad 1 as presented in Fig. 14.3.4.5. Using interburden material from the pit, the dragline builds a bench extension, area A, and moves onto the extension to position 2. While stripping from this position, the dragline spoils waste into area B and a dozer builds an 8% ramp and another bench 20 ft (6 m) higher than pad 1. When complete, the dragline walks up the ramp to pad 2 at position 3 and begins the sequence again. The reverse procedure is utilized for moving downhill if required.

Stripping Sequence—Several plans have been implemented in the process of developing a method that maximizes dragline productivity. It has been a learning process that has included input from many sources, especially the dragline crews themselves. Through the years, Trapper has developed a method that allows the draglines to remove overburden from the highwall as they move downhill and to extract interburden as they dig back uphill on the spoil side. Since the four active pits have fairly similar sequences, the following is a general discussion of the method employed at Trapper.



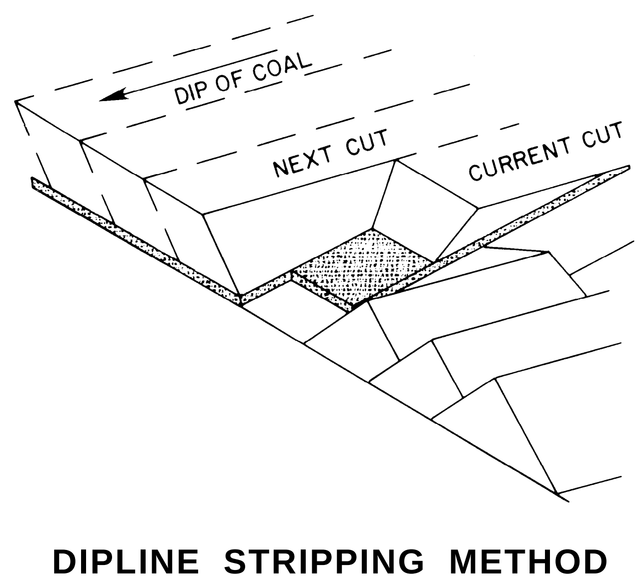


Fig. 14.3.4.3. Stripping methods for dipping seams.

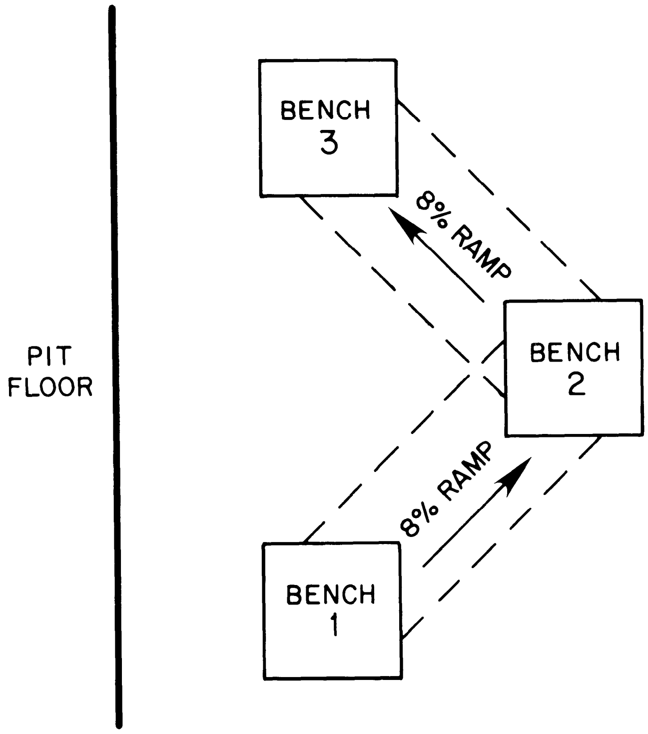

Fig. 14.3.4.4. Switchback method on the spoil side. Plan view showing dragline movement up the hill.

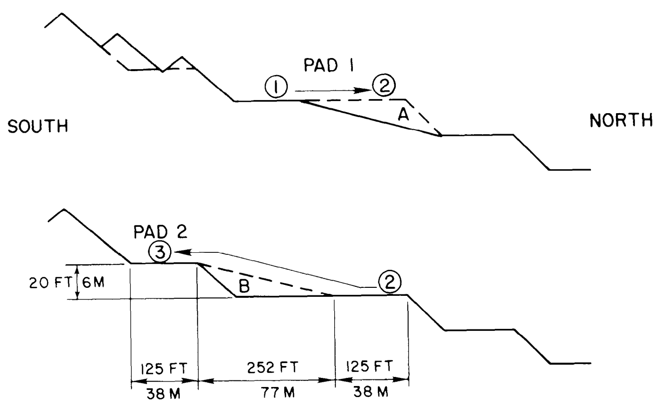

Fig. 14.3.4.5. See-saw method on the spoil side. Plan view showing dragline movement up the hill.

Typically, the dragline begins at the top of the hill near the outcrop and digs overburden to the bottom seam on the highwall side. As the dragline progresses down the hill, it encounters the upper seam outcrop and switches to removing overburden above the upper seam until it reaches maximum economic cover at the end of the pit. Using an in-pit spoil bridge, the dragline crosses over to the spoil side of the pit and waits until the upper seam is mined out and the interburden to the lower seam is drilled and blasted. Once blasted, the interburden is removed by the dragline, exposing the lower seam as it continues back up the hill using the see-saw method shown in Fig. 14.3.4.5. As the dragline reaches the point where the upper seam originally outcropped, it bridges back over to the highwall side to begin the sequence again. Thus the dragline strips down and then back up the hill to complete one cut.

Table 14.3.4.2. Major Equipment Productivities

Machine Type	Productivity
Draglines, 30 yd^3 ($22.9\ m^3$)	1400 yd^3/digging hr ($1070\ m^3$/digging h)
Overburden drills	120 ft/drilling hr (36.6 m/drilling h)
Coal drill	720 ft/drilling hr (219 m/drilling h)
Coal backhoes, 15 yd^3 ($11.5\ m^3$)	550 tons/operating hr (499 t/operating h)
Coal trucks, 50 tons (45.4 t)	130 tons/hauling hr (117.9 t/hauling h)

Ashmore pit uses this method to recover the H and I seams, as does Colt to mine the L and Q seams. However, a variation of the preceding general case is used in Derringer. Here three seams are recovered (L, Q, and R), and no across-pit ramping in the middle of the pit is necessary. In portions of the pit where all three seams are recovered, the interburden is generally thin (less than 10 ft or 3 m). This allows one of the parting intervals to be pushed by a Cat D9L dozer or loaded by other equipment.

PIT DIMENSIONS. Because the coal dips more steeply than the topography, the maximum strip limit of approximately 140 ft (43 m) is reached quickly at the bottom of the hill. This situation sometimes requires the pits to be short, from 800 to 6000 ft (240 to 1830 m). Scheduling becomes difficult in short pits; thus 175-ft (53-m) pit widths are purposely designed to keep the dragline on the same working bench as long as possible before moving up or down to the next digging level.

Highwall angles vary widely from 26 to 63°, depending upon overburden competency and existence of ancient stream channels situated in the highwall. An average slope of 37° for the spoils provides adequate stability for the broken material.

14.3.4.4 Unit Operations

Productivities for major production equipment are summarized in Table 14.3.4.2. Trapper has continued to improve equipment performance, partly due to the high level of experience and dedication of its union operators. Since the mine's inception in 1976, the average hourly labor employee has over 13 years of service at the mine.

DRILLING. Waste materials are prepared by three rotary drills using 10⅝-in. (270-mm) tricone bits. The drills are positioned on a series of level benches cut into the hill slope. Patterns for blastholes vary depending on the type of material but commonly average 20 by 30 ft (6.1 by 9.1 m) for overburden and 22 by 25 ft (6.7 to 7.6 m) for interburden. A twin-masted auger drill is used for drilling all 4½-in. (114-mm) blastholes in coal. Coal patterns are drilled on a 12- by 15-ft (3.7- by 4.6-m) grid.

BLASTING. A mixture of ammonium nitrate and 6% fuel oil (ANFO) is used almost exclusively for overburden and interburden blasts. The gas-generating characteristics of ANFO provides better digging conditions relative to the more expensive, high-velocity slurry explosives. Bagged emulsion and bulk slurries are used occasionally when blastholes are wet. However, when only small quantities of water are encountered in the blastholes or when the shot will proceed in a short period of time, a plastic hole liner is used to sleeve the bulk ANFO. Blasting operations utilize the Detaline system with down-hole and surface delays for blast initiation and sequencing.

In general, all waste materials are shot. Powder factors average 0.7 lb/yd^3 (0.42 kg/m^3) for overburden buffer blasting, 1.0 lb/yd^3 (0.59 kg/m^3) for overburden cast blasting, and 0.6 lb/yd^3 (0.36 kg/m^3) for interburden materials. All three figures are based on weight of explosive per volume of material blasted. These powder factors provide optimum fragmentation to allow efficient digging with the 30-yd^3 (23-m^3) buckets. When designing cast blast shots, a breakeven cast benefit of 15% must be attained. The single-seam Enfield pit extensively used cast blasting with a resulting average of 22% of blasted material in final position.

ANFO was initially used for blasting the coal seams, but due to occasional water problems and fairly high labor requirements, higher costs for thin seams resulted. A packaged slurry explosive and a powder factor of 0.16 lb/ton (0.08 kg/t) to loosen the already highly cleated coal has provided lower costs and acceptable loading characteristics. The low powder factor presents no problem for high break-out force of the hydraulic backhoes used to load the coal.

OVERBURDEN REMOVAL. Surface mining (open cast or strip mining) is the only mining method used at the Trapper mine. Three Page 752 long-range draglines remove overburden to expose the coal. Arched 30-yd^3 (23-m^3) buckets are utilized in areas, of dense and poorly fractured overburden and where chopping is required. This bucket is well suited for these purposes, due to its heavier construction. Archless buckets with a capacity of 32 yd^3 (24.5 m^3) have been used with good productivity in overburden which is lighter and well fractured. High-density plastic bucket liners minimize the quantity of overburden material carried back between swings. The Page 752LR has the ability to negotiate 8% uphill and 10% or greater downhill grades, which is essential for the steep slopes at the Trapper mine.

Dragline productivities and utilization have been high at Trapper due to aggressive training and safety programs. Another important reason for the high production and cost efficiency of Trapper's draglines is the use of computerized monitoring and control systems installed on each machine. These systems have allowed for automated lubrication pumping, tightline prevention, and instantaneous operation feedback on data related to motor and bearing temperatures, tightline warnings, and productivity parameters, such as load counts, digging rates, and cycle times. The goal of these systems is to assist the operator to improve performance and reduce costs through better preventive maintenance. Radio links are used to transmit data from each dragline to the engineering department to facilitate reporting daily statistics and tracking overburden volumes and delay times.

Scrapers and dozers remove thin horizons of separable waste material between seam splits. Dozers typically rip these parting layers and assist by push-loading the scrapers. Scrapers are desirable because they allow greater recovery of the top 1 to 2 in. (25 to 50 mm) of the coal seam instead of dozers that tend to break the coal surface. In addition, Trapper has recently begun its first small scraper pit in an area of low cover to supplement coal production from the three dragline pits.

COAL LOADING. Coal loading operations are performed by three Demag H-111 hydraulic backhoes with 15-yd^3 (11.5-m^3) buckets. One backhoe is generally stationed at each pit and loads from atop the coal seam. The crawler-mounted backhoes were selected over rubber-tired loaders because of the backhoe's excellent performance in a pitching environment and possible wet floor conditions. Loading is performed from 25-ft (7.6-m) wide slots directed down dip to provide coal trucks a path following the dip of the coal.

COAL HAULAGE. Coal from the mine is delivered under a long-term fuel supply contract to a steam generating utility located adjacent to the mine. Typically, six trucks from a fleet of nine 50-ton (45-t) Euclid end-dump coal haulers are employed to haul the coal an average of 2.5 miles (4 km) one way to a crusher that feeds the power plant. Since the crusher is located at the bottom of the hill, the haul profile is favorable for loaded trucks. Coal is dumped onto an adjacent stockpile if the crusher is down or surge capacity is reached. A Cat 988B front-end loader trams the stockpiled coal to the crusher when required.

As mining operations begin to advance away from the crusher, analysis of alternative coal haulage methods will ensue. Two options Trapper will investigate are (1) upgrading its 50-ton (45-t) haulage fleet to 85-ton (77-t) or greater capacity and (2) utilizing an overland conveyor to directly feed the plant crusher.

RECLAMATION. After all coal is mined, overburden from the next adjacent pit is spoiled by the dragline into the just completed cut. After the overburden is graded and contoured by Cat D9L and D9N dozers and Cat 16G graders, the scraper fleet redeposits the topsoil; the area is seeded in the fall of the year. A mixture of grasses, forbs, and shrubs is planted to assure proper forage for wildlife and domestic livestock. Wheat or an alfalfa grass mix is used on reclaimed croplands found on the lower slopes.

Where possible, surface water above the mining area is diverted around the mine pits and directed into settling basins to control suspended solids in water being discharged from the mine area. Groundwater encountered in the mine pits is pumped out and allowed to continue through the surface drainage system. Due to Trapper's pitching topography, drainage maintenance and reconstruction are important aspects of reclamation activities.

In 1981, 1987, and 1989, Trapper received state reclamation awards for outstanding achievement. These awards exhibit that a mine can be a profitable venture while maintaining the necessary balance between resource development and environmental integrity.

14.3.4.5 Product Control

Daily coal samples are taken from each seam being mined to determine in situ quality. An onsite coal laboratory runs a modified short proximate analysis for tracking current seam qualities and forecasting future seam quality trends.

Samples also are captured from the crusher stream for analysis by the customer to determine the "payable" quality of coal delivered to the power plant. Trapper is paid on the basis of total heat content delivered.

The seams present at Trapper usually need no blending to achieve the minimum daily requirement of 9500 Btu/lb (22,100 kJ/kg). However, when blending is required, it is performed by alternating loads of high- and low-Btu coal from different seams. No stockpile blending is required.

14.3.4.6 Ancillary Facilities

Trapper's mine maintenance system (MMS) has progressed significantly since its first formal program in 1978. Since that time, the dedication of mine management and maintenance personnel to improve maintenance performance has resulted in achieving significant improvements in equipment availabilities, minimum staffing levels, and machine component lives.

The priority of the MMS focuses keenly on maintenance planning and control systems. The program contains the following major elements:

1. Work Order System—captures repairs needed, repairs completed, employee-hours consumed, and parts used.

2. Repair and Cost History—kept on all major equipment units and components in order to reveal long-term repair problems requiring special attention.

3. Preventive Maintenance (PM)—strictly scheduled routine maintenance.

- Oil Analysis—done in conjunction with the PM program.
- Component Failure Analysis—identification of the causes for component failures so remedies can be implemented.
- Labor Utilization Reporting—tracks labor performance to spot inefficiencies in maintenance methods.
- Mechanic Training and Safety Incentives.
- Maintenance Planning—daily and weekly plans to coordinate maintenance objectives and parts inventories.

The maintenance facilities are located near the main haul road to the power plant and adjacent to the mine administration building. The maintenance complex includes eight large equipment bays, two bucket bays, wash and lube bay, welding shop, light duty shop, and electrical shop.

14.3.5 APPALACHIAN CONTOUR MINING, HORIZONTAL COAL SEAMS: MARTIN COUNTY COAL CORPORATION

IRA J. TUSSEY

14.3.5.1 Mine Description

Martin County Coal Corporation's mine is located in the Appalachian coalfields, Martin County, KY, near the West Virginia border. The leasehold extends from the southern portion of Martin County into northern Pike and Floyd Counties (Fig. 14.3.5.1). The property is bordered by Brushy Fork of John's Creek to the South and Middle Fork of Rockcastle Creek to the north. Wolf Creek, the other major watershed within the leasehold, bisects it. The total leasehold covers more than 33,000 acres (134 km^2).

Total annual production at Martin County Coal Corp. is currently 2.5 million tons (2.3 Mt) but has exceeded 3 million tons (2.7 Mt). Approximately 45% of the annual production comes from two surface mines, one of which is dedicated wholly to mountaintop removal mining. The remaining balance is produced from five underground mines. Martin County Coal Corporation's work schedule consists of 240 days/year, two 9-hour shifts/day.

The topography of the area is characterized by rugged hills and ridges and sharp V-shaped valleys demonstrating a cliff and slope topography. This topography consists of alternating benches of outcrop sandstone and slopes. The deep valleys have been carved by the actions of many small streams in the area. These streams are contained within the steep slopes of narrow, twisted mountain ridges. The ridges are underlain by massive sandstones, causing them to be sharp and rocky. The height of the hills above the valley floors ranges from 400 to 800 ft (120 to 240 m).

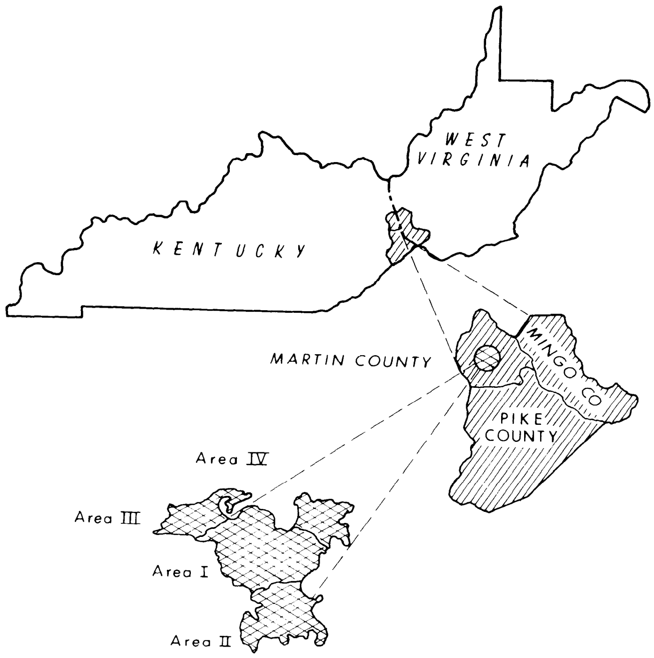

Fig. 14.3.5.1. Regional location map.

14.3.5.2 Deposit Description and Geology

GENERAL GEOLOGY AND STRATIGRAPHY. The stratigraphic sequence of the property consists principally of sandstones, siltstones, shales, coals, and underclays of the Upper Breathitt Formation of the Pennsylvanian Age and demonstrates a pattern of cyclic deposition. Approximately 60% of the strata overlying the coals is sandstone. The marine-fossil Magoffin Shale Bed is present throughout the leasehold at an elevation of 800 to 850 ft (240 to 260 m) and ranges in thickness from a few inches (tens of millimeters) to several feet (meters). Its unique lithologic characteristics and areal consistency have made it an excellent marker bed for coal-seam correlation. Structural dip across the property is generally to the northwest at a magnitude of 0.75 to 1.5%; however, local flexures have modified this somewhat in certain areas (Fig. 14.3.5.2)

COAL SEAMS OF IMPORTANCE. The major coal seams presently being mined by Martin County Coal Corp. are in the following descending stratigraphic order: No. 5-Block, Clarion, Lower Clarion, Stockton, Coalburg Rider, and Coalburg. All of these seams are high-quality bituminous steam coals. Other coal seams occurring below the Coalburg are of lesser economic consequence and are not being mined presently. These include the Little Coalburg, Winifrede/Haddix, and Taylor (Fig. 14.3.5.3).

No. 5-Block—The No. 5-Block seam is present only near the crests of the higher knobs on the property and ranges in thickness from 6 to 11 ft (1.8 to 3.4 m). This seam is mined exclusively by the mountaintop removal method. Because of its proximity to the crests of the mountains, its aerial distribution and recoverable reserves are restricted. The No. 5-Block consists of many benches of varying thickness and quality and contains numerous partings.

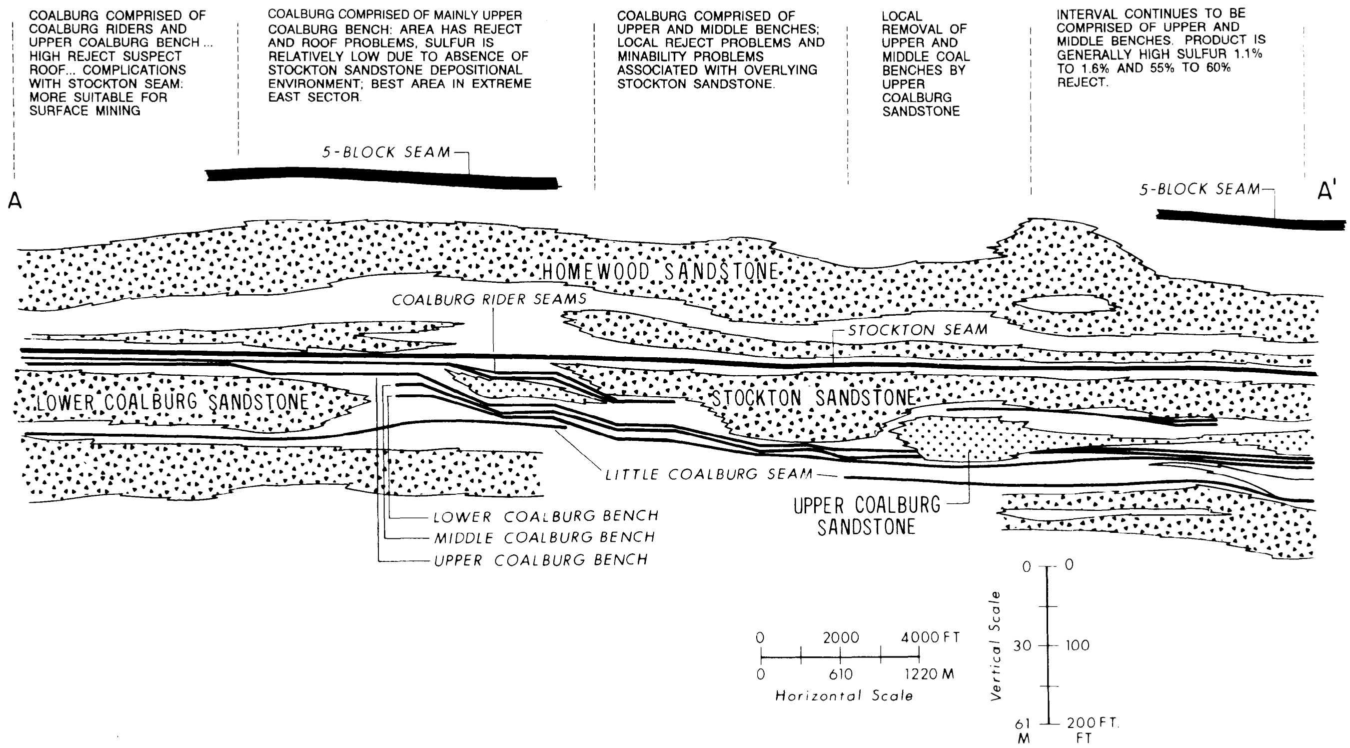

Fig. 14.3.5.2. Geologic cross section.

Clarion—The Clarion seam underlies the No. 5-Block by a depth of 10 to 40 ft (3 to 12 m) across the property and ranges in thickness from 6 to 60 in. (152 to 1524 mm). The seam is a relatively clean coal with few or no partings. Like the No. 5-Block, the Clarion seam lends itself exclusively to mountaintop removal.

Lower Clarion—The Lower Clarion occurs only locally in certain areas and is surface mined in conjunction with the No. 5-Block and Clarion. It is also a relatively clean coal with few impurities.

Stockton—The Stockton seam underlies the Clarion seam by a depth ranging from 180 to 210 ft (55 to 64 m). Its thickness ranges from 30 to 86 in. (762 to 2184 mm) across the property, but is typically 50 to 60 in. (1270 to 1524 mm). This coal is mined by a combination of mountaintop removal, contouring, and underground mining. The seam displays excellent consistency, uniformity, and quality with few associated geological complexities. It consists of a single bench with a small bone parting in the upper portion of the seam.

Coalburg Rider—The Coalburg Rider seam lies from 2 to 40 ft (0.6 to 12 m) above the Coalburg and is mined in conjunction with surface mining of the Coalburg seam. It is typically less than 24 in. (610 mm) in thickness and is a high-grade coal with few impurities.

Coalburg—The Coalburg seam underlies the Stockton by 20 to 130 ft (6 to 40 m) across the property and is stratigraphically the most complex seam of the leasehold. It consists of three individual, distinct benches or splits: the Upper Coalburg, the Middle Coalburg, and the Lower Coalburg. The Coalburg seam displays a high degree of lateral stratigraphic change across the property and has been completely replaced with sandstone in a number of areas. Total seam height ranges from 20 in. (508 mm) to several feet (meters). However, the seam contains numerous partings of fireclay and shale with abundant plant material. All three splits are mined in one or more forms by both surface and underground mining methods (Fig. 14.3.5.4).

Little Coalburg—Approximately 20 to 80 ft (6 to 24 m) below the Coalburg lies the Little Coalburg seam. The Little Coalburg is generally thin throughout the property and is not presently considered a potentially minable reserve.

Winifrede/Haddix— The Winifrede/Haddix lies approximately 90 ft (27 m) below the Little Coalburg. It is also a relatively thin seam. However, potential deep mining reserves exist for this seam in localized areas.

Taylor— The Taylor seam lies directly below the Magoffin Shale Bed. It, too, is a thin coal with only limited reserves.

Total Reserves—A recent reserve study revealed that Martin County Coal Corporation's total reserve base is approximately 100 million tons (90 Mt) of clean recoverable coal, extending the life of mining capabilities well into the next century based upon current production levels.

14.3.5.3 Mine Development

General Description of Contour Surface Mining. Contour surface mining is a technique of mining where the coal is extracted by removing the soil and rock (overburden or spoil) immediately overlying the coal with bulldozers, trucks, shovels, and other earthmoving equipment. The mined location is then reclaimed to its approximate original contour (AOC) by depositing overburden from the next successive cut in the area and then completing by grading and seeding. This procedure is followed along the outcrop of the coal seam as successive cuts are taken. Martin County Coal's Lee Construction Co. surface mine operation is presently engaged in contour surface mining (Fig. 14.3.5.5). Monthly production at this surface mine is in excess of 40,000 clean tons (36,000 t), and drilled yardage exceeds 400,000 yd^3 (306,000 m^3) per month. The employees of this mine

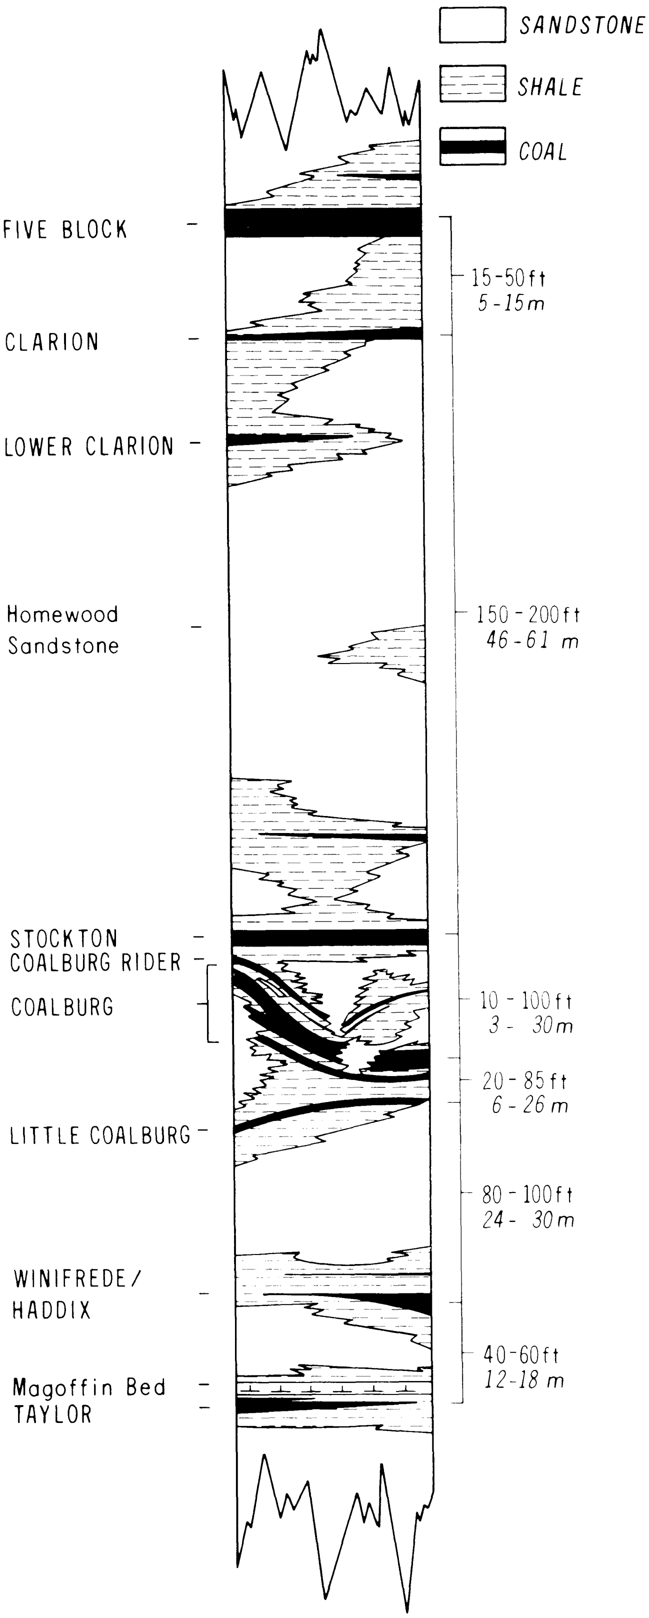

Fig. 14.3.5.3. Generalized stratigraphic column.

have won several safety awards from the National Safety Council and the Holmes Safety Association.

MINE PLANNING. Prior to mining activities, a mine plan is devised in which projections for surface and underground mines are developed with consideration to the safety and optimum efficiency of each operation, least interference with each other, and maximum resource recovery at the lowest possible cost. Topographic maps are prepared by Martin County Coal Corp. engineering personnel showing coal seam outcrops, proposed highwalls, coal pits, hollowfills, roads, sedimentation structures, and underground portal areas. These projections are then reviewed with production personnel and revisions and adjustments are made if indicated. After this mine plan is developed, a surface disturbance permit is obtained from Kentucky's Department for Surface Mining Reclamation and Enforcement (DSMRE). The permit application is prepared by an outside consulting firm. The designs contained within the application are reviewed and approved by Martin County Coal Corporation's Engineering Department prior to submission of the application.

STRIPPING RATIO. Martin County Coal's contour operations attempt to maintain a surface mining ratio of 10:1 yd^3/clean ton (8.4:1 m^3/t). Variances may occur in some local areas. The height of the highwall is dictated by the thickness of the coal seam, topography, and equipment size.

POND CONSTRUCTION. Mine development is initiated with the construction of sedimentation ponds in accordance with designs approved by DSMRE. The purpose of these structures is to trap any runoff from the area disturbed by mining activities and to maintain water quality. Since the structures remain intact during mining and reclamation activities, proper construction is crucial. These sedimentation ponds are constructed in smaller streams near their confluence with the major streams. After all trees and other organic material are cut, grubbed, and removed from the site, bulldozers push earth from the valley slopes into the streams and compact the material in lifts to the elevation of the principal spillway. The principal spillway, a corrugated metal pipe 36 to 60 in. (914 to 1524 mm) in diameter, is placed at the proper elevation. Additional earth is then placed on the dam and compacted to the proper elevation. The width at the top of the dam is a minimum of 12 ft (3.7 m), and side slopes are 2.5:1.0 horizontal to vertical configuration. The emergency spillway is then constructed by cutting into solid rock on one side of the pond with a bulldozer and drilling the rock with a pneumatic drill. This rock is blasted, with the shot rock used to rip-rap the slope below the principal spillway.

ACCESS ROAD CONSTRUCTION. After the sedimentation pond is completed, road construction to the area begins. These roads are constructed with the intention of retaining them as permanent facilities after release of the reclamation bond. With this concept in mind, the roads are constructed on as moderate a gradient as possible and are composed of high-grade, shot-rock that does not weather easily. The design and construction of these roads also are approved by DSMRE. The roads intersect an existing haulage road and are constructed to a head-of-hollow fill where mining begins. Road width averages 100 ft (30 m).

14.3.5.4 Mining Operations

Mining commences by cutting the timber overlying the proposed cut on the Coalburg coal seam. This timber is dragged by bulldozers to the outcrop of the coal seam. A "catch basin" or ditch is simultaneously constructed to prevent any rock or spoil from falling or rolling below the outcrop line. Timber in the head-of-hollow fill is also cut, piled, and burned, or dragged to the perimeter of the planned head of hollow fill. Because of the steep slopes and timbering activities at the turn of the century, little or no topsoil is present on the property. Consequently,

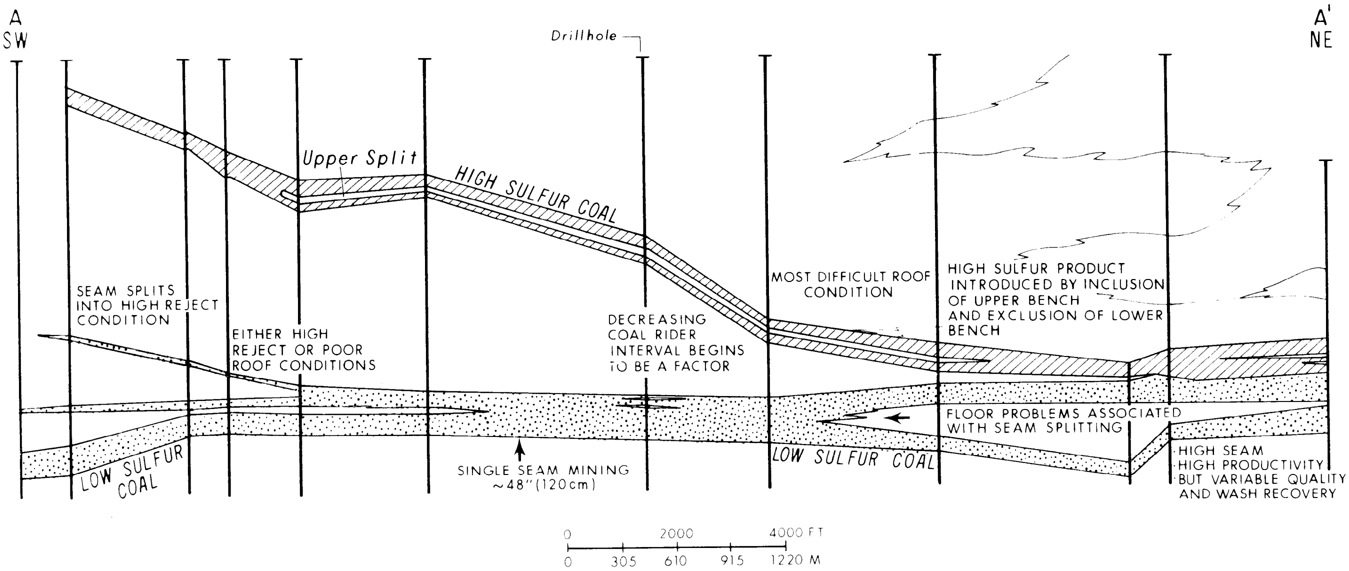

Fig. 14.3.5.4. Coalburg seam showing lateral physical and quality changes.

Fig. 14.3.5.5. Typical mining area.

removal and subsequent redistribution of topsoil is not required. Alternate topsoil material exists in abundance and is located in close proximity to the coal seam, generally 1 to 5 ft (0.3 to 1.5 m) in depth. This material consists of sandstones and shales and is usually the last stratum to be encountered and removed. As a result, it is the last material to be used in backfilling operations and is distributed in quantities necessary to promote plant growth. Fertilizers and other soil nutrients are applied as needed to the alternate topsoil material to enhance the chemical and physical properties and to promote growth of grasses, legumes, and trees specified by DSMRE.

OVERBURDEN REMOVAL. The Stockton outcrop is utilized as a marker for constructing the drill bench for the Coalburg highwall. A bulldozer prepares the drill bench by following this outcrop. After the drill bench is established, a crawler-mounted rotary drill begins drilling presplit holes. These holes are 40 to 44 ft (12.2 to 13.4 m) deep, 9 in. (229 mm) in diameter, and are drilled on 18- to 20-ft (5.5- to 6.0-m) centers. Presplitting is accomplished by utilizing approximately 5 ft (1.5 m) of ANFO (ammonium nitrate and fuel oil, S.G. of 0.85), 2-lb (0.9-kg) cast primers, and non-electric caps and lead line. Hill seams and other geological discontinuities are localized and have been found to follow no definite trend or pattern. Consequently, presplitting the highwall is necessary to minimize potential adverse effects on safety and productivity. All presplitting is accomplished vertically. This results in a vertical or near vertical highwall angle. Attempts made to bench the highwall at underground "face-up" areas have resulted in fracturing, backbreak, and large rocks being disjointed above the coal seam. As a result, benching the wall is not attempted, and a cleaner, smoother, and safer wall is obtained. Highwall height and subsequent pit widths vary and are dictated by seam thickness, existing topography, equipment size, and other factors. Highwall height ranges between 80 to 100 ft (24 to 30.5 m) and pit width between 160 to 180 ft (49 to 61 m).

After the presplit shot is detonated, the overburden is drilled with a crawler-mounted rotary drill. These drillholes are 9 in. (229 mm) in diameter and 21 ft (6.4 m) in depth. Burden and spacing range from 15 to 18 ft (4.6 to 5.5 m). The drillholes are loaded with approximately 12 ft (3.7 m) of ANFO and are detonated using 2-lb (0.9-kg) cast primers and non-electric blasting caps. ANFO is delivered in bulk to the mine site where it is stored in 40-ton (36.3-t) storage bins.

After the overburden shot is detonated, bulldozers push the spoil into the head-of-hollow fill and simultaneously construct another drill pad. The crawler-mounted drill is again moved back to the site and drilling is resumed, this time to a depth of 20 ft (6.4 m). This shot is drilled on an 18- by 18-ft (5.5- by 5.5-m) pattern. Bulldozers move a large portion of this shot into the head of hollow fill. They are assisted by rubber-tired loaders with a bucket capacity of 13.5-yd^3 (10.3-m^3) and 85-ton (0.91-t) trucks that haul the remaining spoil into the head-of-hollow fill.

Fig. 14.3.5.6. Beginning of final highwall grading operations.

Fig. 14.3.5.7. Final highwall slope configuration.

The highwall is "scaled" or cleaned of any small rocks by the loader at this time.

After this spoil is removed, the crawler-mounted drill again prepares another presplit shot to the coal. Following detonation of this shot, drilling the remaining overburden resumes with drillholes going down to the coal seam. A powder factor of 1.10 lb/yd^3 (0.59 kg/m^3) of overburden is maintained on production blasts. This powder factor is economical and produces excellent fragmentation of the overburden. After detonating this shot, the loader and trucks move the blasted material to the head-of-hollow fill. Because most of the sandstones and shales do not readily degrade, durable rock fills are constructed by dumping the spoil over the edge of the hollow-fill in a single lift. This results in an excellent underdrain system composed of large boulders that is constructed simultaneously with excess spoil placement.

COAL REMOVAL. After the spoil is completely removed, the coal is cleaned and piled with small rubber-tired loaders 7.0 yd^3 (5.4 m^3). Because the coal is friable, blasting is not required. Dozers rip or break the coal, when needed, to facilitate loading. Any "binders" (in-seam impurities) greater than 4 in. (100 mm) are wasted and not loaded.

BACKFILLING. After the coal is removed, backfilling operations begin. The pit is immediately backfilled with overburden from the next adjacent pit to be mined. This spoil material is moved into the pit by a combination of bulldozers, loaders, and trucks. As the equipment removes the overburden from the coal, it is placed into the previous pit, thereby restoring the mined land to AOC. Once a sufficient quantity of spoil is placed in the pit to eliminate the highwall, bulldozers begin final grading operations (Fig. 14.3.5.6). The spoil is pushed to the top of the wall and "walked in" to the toe of the backfill. A road is retained at the bottom of the backfill to provide access to the mine. This activity is repeated as the operation moves along the periphery of the coal seam. The final slope configuration is approximately 30° (Fig. 14.3.5.7).

Because overburden removal and backfilling operations follow a sequential order, it is difficult to maintain more than one pit in either coal seam. At times, it is possible to access the coal from two directions. When this situation exists, two or more pits may be open at one time.

A calculated spoil balance is prepared to determine the volumetric requirements of the head-of-hollow fills. Hollow-fills are sized as small as possible to minimize disturbed acreage and contain only the volume of rock originated by the swell of the blasted rock and the volume contained in retention of "face-up" areas for underground mines. The "face-ups" are constructed whenever possible near the head-of-hollow fills so as to take advantage of the additional area for coal stockpiles, mine management areas, etc.

Because current regulations require elimination of the highwall, contour mining must end on a point of a ridge to avoid rehandle of spoil. A higher cut on the point is taken, and the excess spoil is used to eliminate the wall from the previous cut. By ending mining operations on a point, rehandle of spoil material is eliminated, and the last remaining highwall is reclaimed as it is mined. After the Coalburg seam is mined, the overlying Stockton seam is mined in the same manner. Mining is initiated in a head-of-hollow fill and progresses along the coal seam outcrop. Underground "face ups" are retained where projections indicate. Contouring the Stockton also ends on a point.

Exceptions to this sequence occur when the No. 5-Block and Clarion coals are present in sufficient quantities to "spoil over" on the Stockton bench. The Coalburg overburden is placed into the head-of-hollow fill. The Coalburg highwall is eliminated by covering it with Stockton overburden. The Stockton highwall is then eliminated by covering it with overburden from the No, 5-Block and Clarion coals, as they are mined by mountaintop removal. On other occasions the topography will lend the Coalburg and Stockton coals to point removal. When this situation exists, the spoil overlying these seams is placed in head-of-hollow fills, and highwall elimination is not required. This method leaves a long, narrow, flat area on a ridge that previously was rocky and steep (Fig. 14.3.5.8).

These two methods are safer and more economical. They have the added advantage of leaving large flat areas on what previously was mountainous terrain. However, they are not practiced a great deal due to the No. 5-Block and Clarion seams having been eroded or the topography not lending itself to point removal.

AUGER MINING. Auger mining (Chapter 14.4) follows contouring in a few isolated cases but, in general, is not an integral part of the mining operations. Augering is performed only when mountaintop removal cannot be performed or where underground mining cannot be accomplished because of inaccessibility. This inaccessibility may be caused by narrowness of the ridges, property lines, gas well barriers, or previous mining operations.

RECLAMATION. Reclamation is an ongoing operation and begins in the strictest sense when the pit is backfilled with spoil

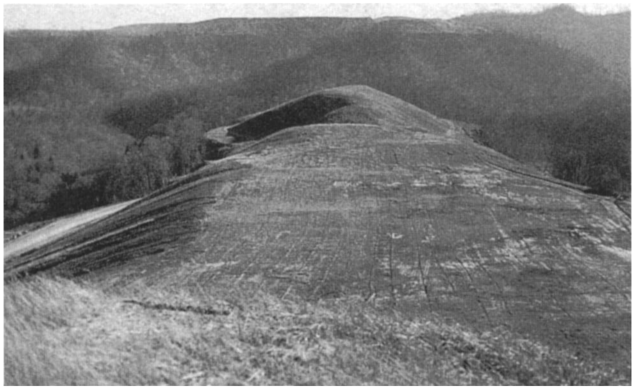

Fig. 14.3.5.8. Reclaimed mountaintop removal area.

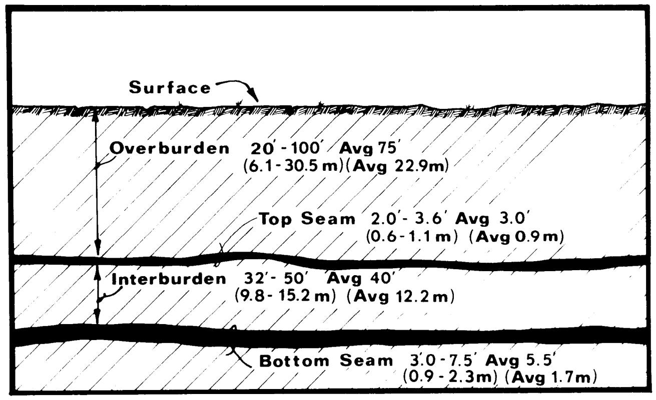

Fig. 14.3.6.1. Typical cross section B area.

from the next adjacent pit. This procedure is continued until the area is reclaimed to its approximate original contour. Bulldozers then begin to prepare slopes to final grade. Following final grade work, the slopes are sprayed by a hydroseeder with a mixture of grasses, legumes, fertilizers, and mulch. Seedlings of approved tree species are then planted. Reseeding or spot seeding is accomplished on an "as needed" basis.

The head-of-hollow fills are reclaimed as soon as practicable after they have reached their designed capacity. The outslope of the hollow-fill is graded to 2:1 (horizontal to vertical). Benches or terraces. are then cut by bulldozers after the face of the fill is graded. These terraces are graded to a 3% slope toward the fill and do not exceed 50 ft (15 m) vertically. Surface runoff is carried across these terraces to designed drainage channels in natural ground along the periphery of the fill. The top of the fill is graded to 5% toward these drainage channels.

14.3.5.5 Product Control

Martin County Coal Corp. maintains close supervision over the quality of coal in the pit. Previous core drilling (usually on 1/4-mile or 400-m spacing) provides a good indication of the coal quality. These holes, however, are usually drilled in the center of the ridges and are sometimes far removed from the surface mine pits. Regional trends relating to coal quality can be accurately predicted. Additionally, in order to maintain close supervision of the coal quality, a number of samples are taken from each pit prior to loading. If indicated, blending is accomplished by combining coal from the underground mines and from the other surface mine.

14.3.5.6 Ancillary Facilities

A four-bay shop area is maintained adjacent to the mine. It is equipped for major repair of trucks and other mobile equipment. Field crews service drills and other large equipment that cannot be easily moved to the shop area.

14.3.6 LIGNITE: BIG BROWN MINE

GENE RAND

14.3.6.1 Mine Description

The Big Brown mine is a mine-mouth operation owned and operated by Texas Utilities Mining Co. The mine produces 6 million tons (5.4 Mt) of lignite annually as fuel for the two nearby 575-MW units of the Big Brown Steam Electric Station owned by TU Electric. The mine is located 90 miles (144 km) south of Dallas, TX, in Freestone County near the town of Fairfield. Initial lignite production began in 1971. The permitted mining area covers some 15,000 acres (60.7 km^2). The mine employs 410 and operates 24 hours/day, 7 days/week, 365 days/year.

14.3.6.2 Deposit Description and Geology

The lignite at the Big Brown mine is recovered from two minable seams within the Calvert Bluff Formation, which is the uppermost member of the Wilcox Group, Early Eocene. The reserves trend southwest to northeast and dip to the southeast at approximately 1°. The overburden and interburden material consists of unconsolidated fine-grained sand and laminated silts and clays that do not require drilling or blasting prior to removal. The sand in the overburden locally contains groundwater that must be dewatered in advance of stripping operations.

Lignite is recovered from two mining areas located about 1 mile (1.6 km) apart. The southernmost area, the B area, generally contains two minable seams, as shown in Fig. 14.3.6.1.

Stripping ratios of 9.5 to 14.3 yd^3/ton (8.0 to 12.1 m^3/t) exist over the remaining 15 years of life in this area. Approximately 28 million tons (25.5 Mt) of lignite will be recovered during this period.

The northernmost mining area, the C area, is underlain by two lignite seams in the southern two-thirds of the deposit and a single seam in the northern third of the area. The general profile of this area is shown in Fig. 14.3.6.2.

The C area contains approximately 90 million tons (82 Mt) of recoverable lignite that will be removed over the next 15 years at ratios of 6.9 to 12.1 yd^3/ton (2.7 to 4.0 m^3/t).

The average lignite quality for the total deposit on an as-received basis is as follows:

Heating Value	6800 BTU/lb (15,817 kJ/kg)
Moisture	31.5%
Ash	15.3%
Sulfur	0.76%

14.3.6.3 Mine Development

Initial mining operations began with a box cut along the sub-crop at the extreme southwestern edge of the deposit and

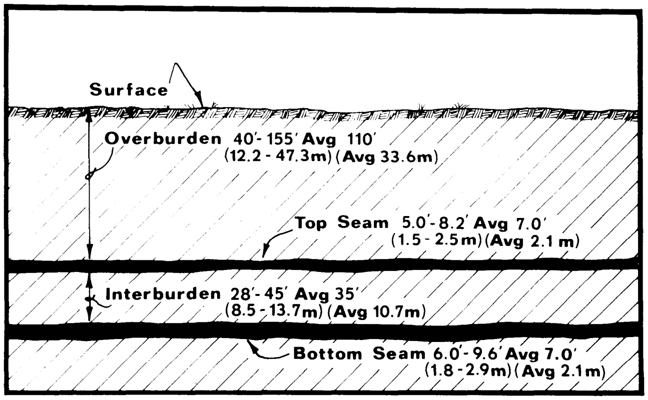

Fig. 14.3.6.2. Typical cross section C area.

progressed down-dip. As the overburden became deeper, sand channels containing groundwater were encountered, causing highwall and spoil instability. Since 1981, dewatering wells have been installed to remove most of the groundwater in advance of stripping operations. Most of the wells required are in the C area.

Surface water run-off from haul roads and other disturbed areas is contained and processed by a specially designed network of sedimentation ponds prior to discharge into the natural drainage.

In the B area, all overburden and interburden materials are removed with a dragline working in a pit 10,500 ft (3200 m) in length. Haulage ramps enter the pit at each end and in the middle from the highwall side.

The C area contains one pit 27,000 ft (8235 m) long in which two draglines and a cross-pit spreader are used to remove overburden and interburden. Haulage ramps in this pit are maintained at each end and at approximately 4000-ft (1220-m) intervals along the highwall.

In both mining areas, highwall angles are cut at 70° while spoil angles average 32°. Pit widths are maintained at 120 ft (36.6 m). Slopes on haulage ramps are held to a maximum of 8°. From time-to-time, 637D scrapers are used to remove overburden and interburden material when additional capacity is required.

14.3.6.4 Unit Operations

OVERBURDEN REMOVAL. Stripping operations in the B area utilize a Bucyrus-Erie 1500-W dragline with a 70-yd^3 (54-m^3) bucket. The dragline uncovers the upper lignite seam by conventional side-casting from the highwall.

The interburden is removed by the dragline working from the spoil side of the pit. A range diagram of this operation is shown in Fig. 14.3.6.3.

This dragline moves 18 million bank yd^3 (13.8 million bank m^3) of material per year. Rehandle averages 30% while availability averages 80%. A Caterpillar (Cat) D9N dozer is used around the dragline to prepare the walkway, move the power cable, and clean the top of the lignite seam prior to loading.

The C area pit utilizes a cross-pit spreader (XPS) system designed by Mannesmann DeMag of what was formerly West Germany to remove up to 100 ft (30 m) of overburden. The remaining overburden and interburden is removed by a Bucyrus-Erie 1500W dragline with 70-yd^3 (54-m^3) bucket and a Bucyrus-Erie 1350W dragline with a 60-yd^3 (45-m^3) bucket.

The XPS is a unique pre-stripping system that is designed to assist in the recovery of deeper lignite seams. The XPS system is designed to remove 24.5 million bank yd^3 (18.7 million bank m^3) per year of generally unstable unconsolidated overburden. The 656-ft (200-m) discharge boom transports the material across the pit and deposits it behind the second dragline spoil pile. This system creates a bench for a dragline to remove the remainder of the overburden above the top lignite seam from the highwall side of the pit. After the upper lignite seam has been loaded, the interburden is then removed by a dragline sitting on the lower bench. An overview of the XPS system and dragline combination is shown on Fig. 14.3.6.4.

The XPS system, commissioned in December 1985, consists of two bucket wheel excavators (BWEs), each rated at 2000 bank yd^3/hr (1530 bank m^3/hr), discharging onto a mobile across-the-pit conveyor (Fig. 14.3.6.5). Overburden material travels nearly 1000 ft (305 m) from the digging face to the spoilpile. The design availability of the XPS is 80%. The 1500-W dragline moves 18 million bank yd^3/yr (13.8 million bank m^3/yr), while the 1350-W dragline moves 16 million bank yd^3/yr (12.2 million bank m^3/yr). Both draglines operate at 80% availability. Overall productivity for the stripping operations at the Big Brown mine is 560 yd^3 (428 m^3)/employee-shift.

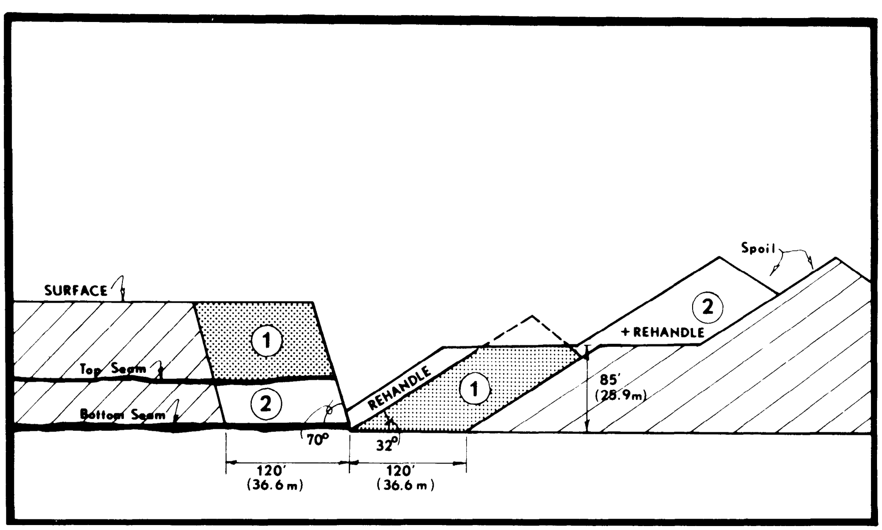

Fig. 14.3.6.3. Range diagram B area.

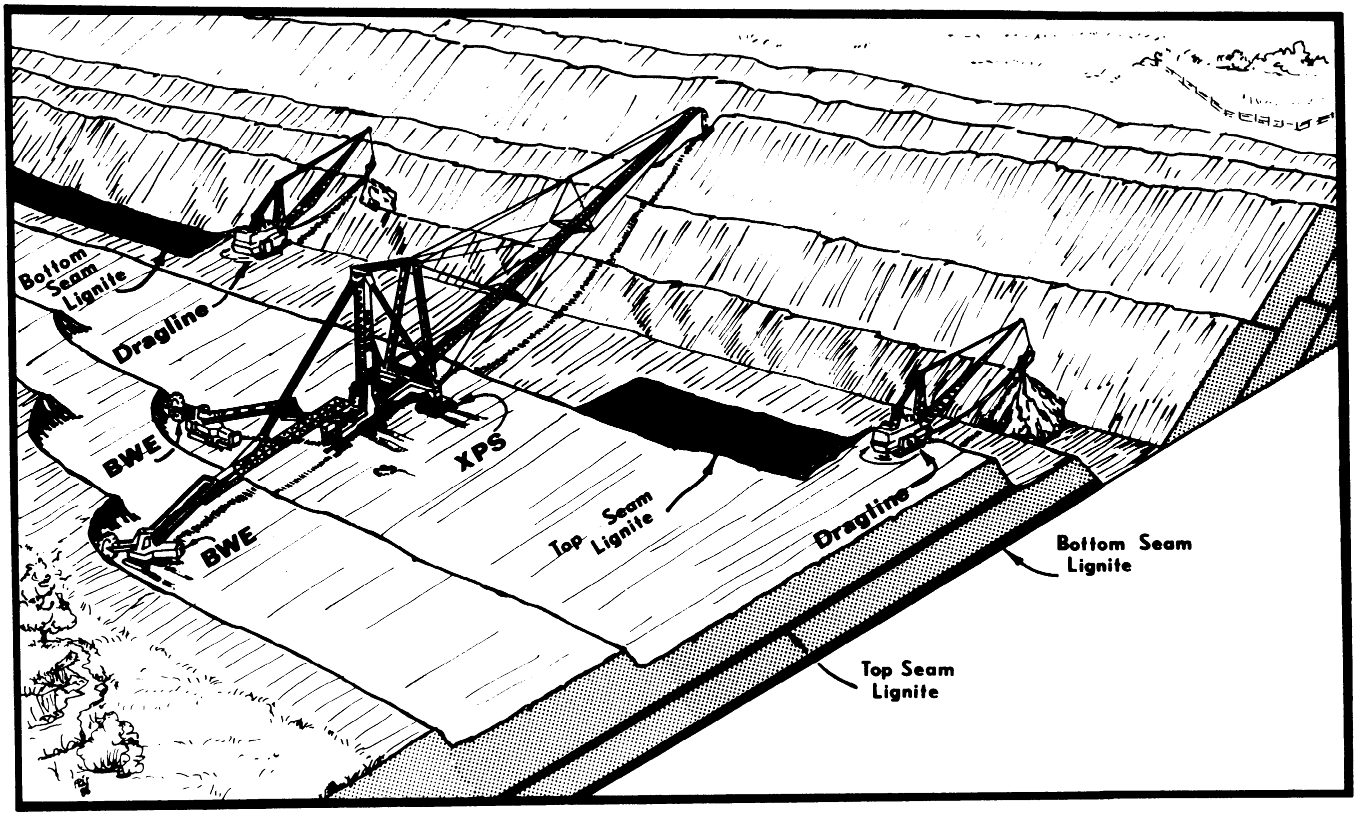

Fig. 14.3.6.4. Cross-pit spreader and dragline combination C area.

Fig. 14.3.6.5. Cross-pit spreader and BWE combination.

LIGNITE LOADING. Lignite loading in the B area is accomplished by a Cat 992-C front-end loader (FEL) with a 16-yd^3 (12.2-m^3) bucket.

In the C area, lignite is loaded with a Hitachi EX 1800 backhoe with a 13.5 yd^3 (10.3 m^3) bucket. A Cat 992 is also used.

The backhoe and FELs operate at 92% availability. Overall productivity at the Big Brown mine is 46 tons (41.8 t)/employee-shift.

LIGNITE HAULAGE. Lignite is hauled from the pits using 11 Dart 100-ton (91-t) bottom-dump coal haulers. These trucks were originally purchased when the mine began operations in 1971 and have been rebuilt as necessary. Approximately 17.5 miles (28.2 km) of haul road are maintained with five Cat 14G motor-graders and four 8000-gal (30.3-m^3) water trucks. Haul road width is 50 ft (15.3 m) to allow safe passage of haulage trucks and service equipment. Water used for dust suppression on haul roads is taken from holding ponds used for surface water control.

LIGNITE PROCESSING. Lignite is dumped from the haulage trucks into a 600-ton (545-t) double-compartment hopper. The lignite flows from the hopper through two reciprocating feeders into two McNally-Pittsburg 30- by 60-in. (762- by 1524-mm) double-roll crushers rated at 550 tph (500 t/h). The lignite is crushed to –6 in. (152 mm) and dropped onto a 60-in. (1524-mm) wide belt conveyor traveling at 520 ft/min (2.6 m/s) for transfer to the power plant stockpile.

RECLAMATION. Since the beginning of mining and reclamation activities in 1971, in excess of 8400 acres (34 km^2) have been reclaimed to a permanent cover of grasses, trees, and ponds. The mined area is leveled to the approximate original contour, as required by law, soon after the stripping process is completed. Three Cat D10N dozers are used to level the spoil areas. Planting of the various cover crops takes place according to a previously-approved reclamation plan.

Perennial grasses comprise approximately 75% of the reclaimed area. This is consistent with premine vegetation since the majority of the land-use is for livestock grazing. Coastal Bermuda grass is the principal grass species utilized for livestock forage and to maximize erosion control.

Ponds extend over 2% of the reclaimed area, which is consistent with premine conditions. The ponds facilitate pasture management and provide the required environment for certain shrub and tree species.

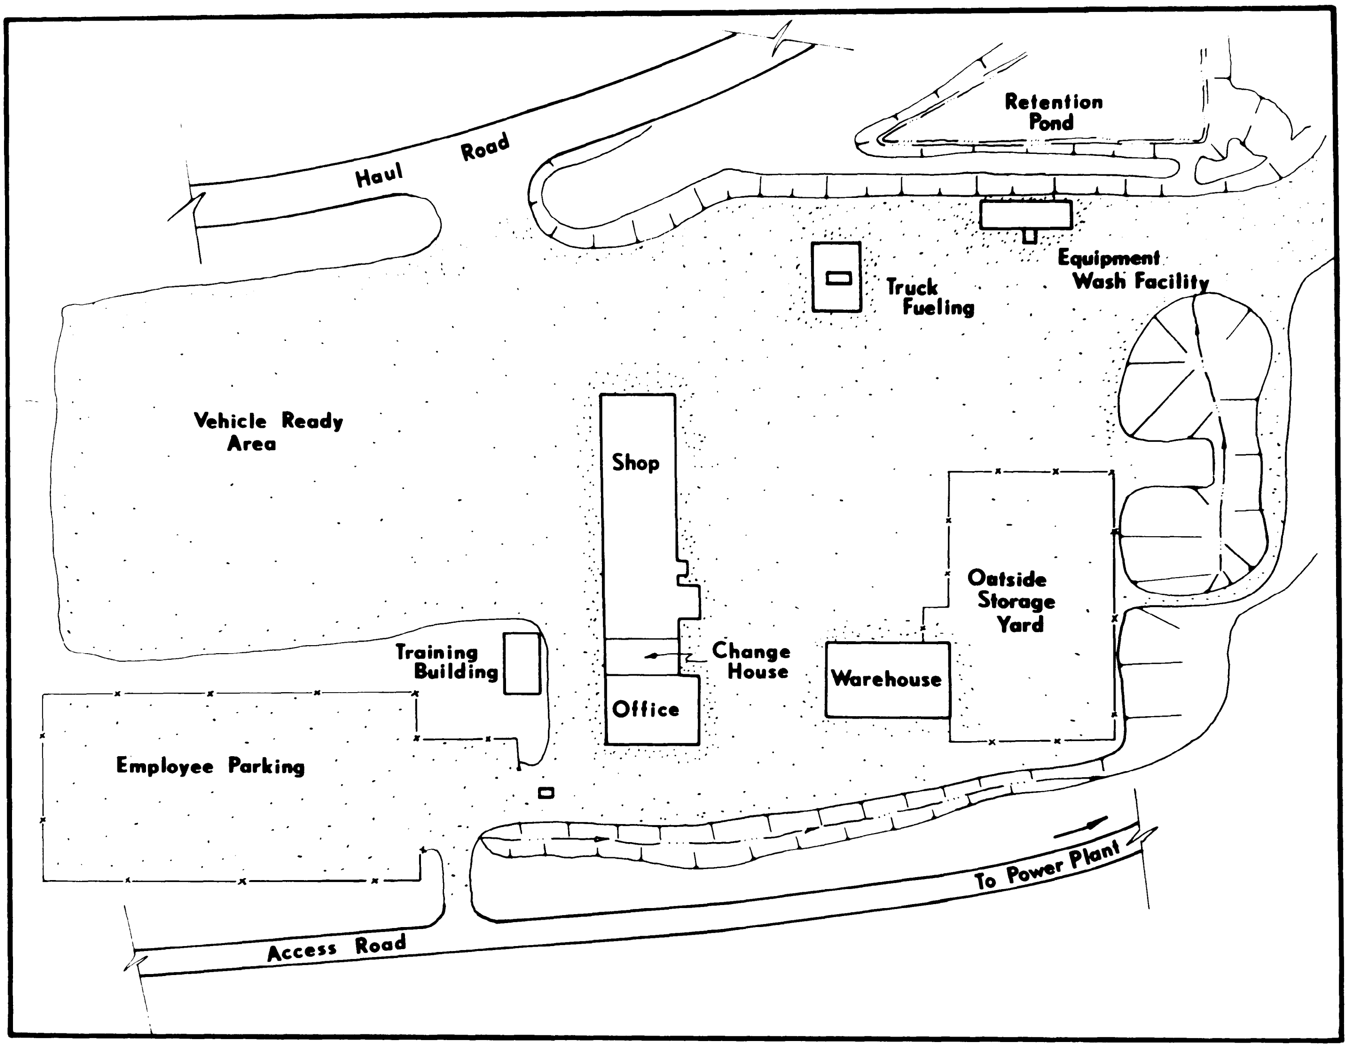

Fig. 14.3.6.6. Plan view of ancillary facilities.

The establishment of approximately 23% of the postmine acreage with hardwood and conifer tree species, shrub, and native grass species also is part of Big Brown's program. This is done to provide proper pasture-land management in order to enhance wildlife habitat, to increase species diversity, and to provide for distribution and cover for livestock. Tree stocking rates range from 200 to 700 trees/acre (50,000 to 173,000/km^2). To date, over 500,000 trees and shrubs have been planted at the Big Brown mine.

14.3.6.5 Product Control

Lignite samples are taken daily from the conveyor belt that delivers to the plant stockpile. These samples are analyzed in the quality control laboratory at the power plant. Results of the lignite analysis are returned to mine management for future use in mine planning.

14.3.6.6 Ancillary Facilities

A plot plan of the ancillary facilities at the Big Brown mine is shown in Fig. 14.3.6.6. The shop contains 21,440 ft^2 (1,994 m^2) and is equipped with a tool room, four welding machines, two air compressors, a bulk lubrication tank, six drive-through bays, and two 15-ton (13.6-t) overhead cranes. Repair and maintenance of mine vehicles are performed in the shop. Routine maintenance and small repairs on mobile equipment working in and around the pit area are performed in the field. When vehicle repairs have been completed in the shop, vehicles are moved to the ready area. Other usable equipment and vehicles are parked in the ready area when not being operated. Lignite haulage trucks, water trucks, and motor-graders are refueled and serviced at various intervals throughout the day. This eliminates much congestion around the shop area when trying to service many vehicles in the short period of time at shift change.

The changehouse area contains 3840 ft^2 (357 m^2). It features separate shower and locker space for male and female employees. This area is conveniently located next to the parking lot and shop area. Employees working in the pit area are picked-up near the changehouse for transportation to their workplace.

The office area, 6420 ft^2 (597 m^2), contains space for management offices, a conference room, engineering offices, accounting and personnel offices, and storage space for file cabinets. The training building located near the office and changehouse provides 1100 ft^2 (102 m^2) of space for employee training in safety, first-aid, and technical skills.

The warehouse, 10,880 ft^2 (1012 m^2) in area, is located in a separate building to reduce congestion around the shop and office area. The outside storage area provides space for tires, bucket parts, wire rope, large shafts and gears, and other items that need no protection from the weather.

Over the years, the Big Brown mine has been a consistent reliable producer of lignite fuel for the Texas Utilities System. In the future, Texas Utilities Mining Co. will continue to rely on this mine to provide a low-cost supply of lignite for use in electric power generation.

14.3.7 ATHABASCA OILSANDS: SYNCRUDE MINE

WAYNE N. MCKEE

14.3.7.1 Mine Description

The Syncrude mine, located 26 miles (42 km) north of the city of Fort McMurray, Alberta (Canada), is an integrated operation that has produced synthetic crude oil from the Athabasca oilsand deposit since 1978. The operation owned by Syncrude Canada Ltd., consists of a surface mine, a bitumen extraction plant, a bitumen upgrader, and a utilities plant, produced 60.3 million bbl (9.6 million m^3) of synthetic crude oil in 1991. Production from the Syncrude operation has increased steadily since start-up and is expected to peak over 70 million bbl (11.1 million m^3) per year within the next few years.

The Syncrude surface mine covers a total area of 8545 acres (34.6 km^2), shown as the Base mine in Fig. 14.3.7.1, with the mined-out portion at the end of 1991 amounting to 3885 acres (15.7 km^2) of this total. Significant additional mining areas exist in the remaining portions of the Syncrude oilsand leases. The strip mining operation involves two production highwalls 3 miles (5 km) long advancing to the east and west from a common box cut. A total of 420 acres (1.7 km^2) of ore body is mined out each year.

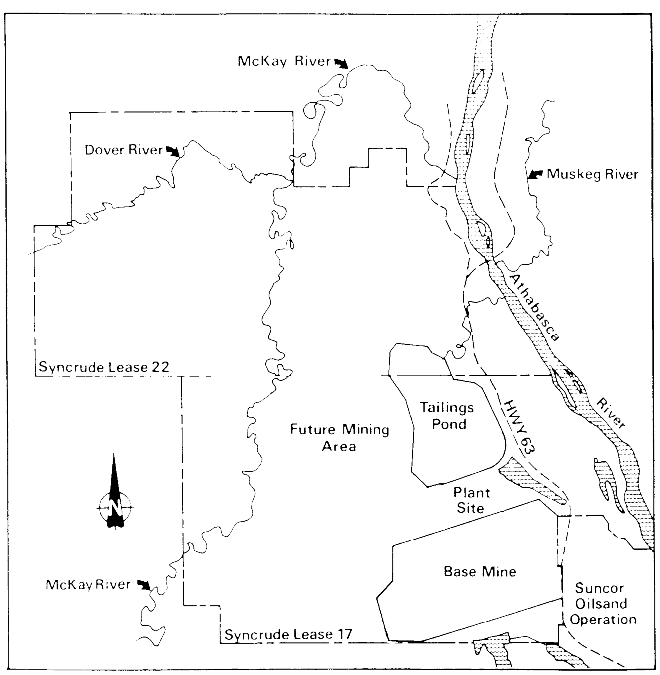

Fig. 14.3.7.1. Syncrude oilsand lease plan.

Ore production was in the 120 to 137 million tpy (109,000,000 to 124,300,000 t/a) range for the 1988 to 1991 period, with 140 million tons (127.5 Mt), or 79 million bank yd^3 (61 million bank m^3), projected for 1992. Production normally averages 400,000 tpd (364,000 t/d) but can peak at 500,000 tpd (455,000 t/d). Production is limited to 50% of normal during the annual maintenance shutdowns of the upgrader, lasting 30 days.

Waste handling by the shovel-and-truck fleet has increased steadily since 1985, with the volume rising from 28.9 million to 67.1 million bank yd^3 (22.1 million to 51.3 million bank m^3) in 1991. The 1992 waste handling volume is projected to be 72.2 million bank yd^3 (55.2 million bank m^3), of which 62.1 million bank yd^3 (47.5 million m^3) is in situ overburden and muskeg, 5.5 million bank yd^3 (4.2 million bank m^3) is oversized rehandle from the extraction plant, with the remaining 4.6 million bank yd^3 (3.5 million bank m^3) covering miscellaneous activities.

The Syncrude mine is operated on a continuous basis with two 12-hour shifts/day, 365 days/year. Four complete operating crews are required to maintain the 12-hour shift cycle. Maintenance crews operate on a modified cycle, with most workers permanently assigned to day shift. All technical, planning, and clerical staff work normal 8-hour/day shifts. The total mining workforce of 1400 consists of 975 occupationals and 425 staff. In functional terms, the total workforce is divided into 485 assigned to ore production and waste removal, 600 to maintenance, 140 supervision and management, and 175 technical and administrative.

14.3.7.2 Deposit Description and Geology

GEOLOGICAL SEQUENCE. The geology of the Syncrude mine is illustrated on the east-west cross section shown in Fig. 14.3.7.2. The oil-bearing McMurray Formation is of sedimentary origin, deposited unconformably in an extensive drainage basin eroded into the Devonian Limestone. The lower layer of the McMurray Formation, consisting of saturated silts and muds from a marsh environment, created a highly pressurized basal aquifer when overlain by the remainder of the deposit. The upper sedimentary layers are complicated by depositional and erosional patterns on a local and regional scale that create a structure of irregularly dipping bands within the ore body. The overburden deposit lying above the McMurray Formation consists of marine silts and clays, glacial tills, and muskeg. The lowest-lying and thickest unit of overburden is the Clearwater Formation, consisting of highly plastic and saturated silts and clays. The Clearwater Formation is overlain by a variety of material types including sand, gravel, clay, glacial till, and muskeg.

ORE ZONE. The upper layers of the McMurray Formation constitute the main ore zone, containing oilsand with a bitumen content varying in both horizontal and vertical directions from near zero to 15% by weight. Oilsand is an average composition of 86.8% quartzose sand, 11.0% bitumen, and 2.2% water. The extraction and upgrading processes produce an average of 0.74 bbl (0.12 m^3) of synthetic crude oil from each barrel (0.16 m^3) of bitumen in the mine feed.

The main ore zone varies from 115 to 164 ft (35 to 50 m) in depth, with approximately 15% of the zone grading as waste below the cutoff grade of 6% bitumen. Waste occurs in bands throughout the ore zone with variable thickness and irregular lateral extent (Fig. 14.3.7.2). Closely spaced core drilling (approximate 300-ft or 100-m square grid) and continuous highwall mapping are required to accurately locate waste bands for accurate separation. Thin clay bands up to 2 ft (0.6 m) in thickness are often found in the ore zone, usually associated with waste and ore contacts. These clay bands can create failure surfaces

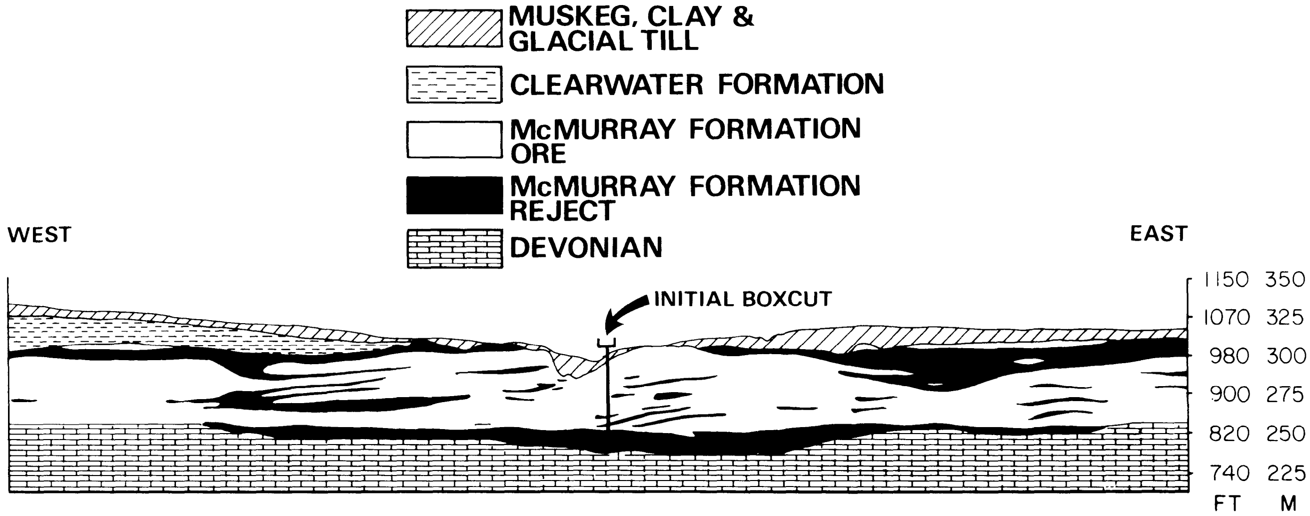

Fig. 14.3.7.2. Typical geologic cross section of Syncrude mine.

when dipping 10° or more out of the highwall. Siltstone lenses also occur in the main ore zone, predominantly within or along the waste bands. The lenses, normally less than 2 ft (0.6 m) thick, are horizontally discontinuous and fracture into large rectangular slabs when excavated.

The sand, bitumen, and water composition of oilsand cause the material characteristics to vary greatly with temperature. Oilsand is soft and sticky in summer and stiff or frozen during winter. Oilsand is very abrasive at all temperatures, due to the composition of angular sand grains suspended in the bitumen.

OVERBURDEN. Overburden material varies in thickness (Fig. 14.3.7.2) and generally becomes thicker as the mine progresses east and west from the box cut. Overburden thickness has increased from near zero in 1977 to 61 ft (18.3 m) in 1992, with a maximum of 98 ft (30 m) to be encountered in the future. Overburden is composed of loosely packed granular materials and uncemented clays with numerous lenses of siltstone. Overburden siltstone is generally thicker and more continuous than that found in the ore zone, with some lenses as thick as 3 ft (0.9 m). Gravel deposits occur within the overburden in quantities much lower than required for the ongoing needs of the plant.

The base elevation of the overburden removal operation is normally designed within the upper layers of the McMurray Formation. Low-grade oilsand and occasional bands of ore are encountered in conjunction with the overburden materials.

RESERVES. The in situ minable reserves remaining within the Syncrude mine after 1991 include a total of 739 million bank yd^3 (565 million bank m^3) of waste and 790 million bank yd^3 (604 million bank m^3) of ore (1.4 billion tons or 1.27 billion t) grading 11.1% bitumen in situ. The waste to ore ratio of the remaining mine reserves is 0.94:1.

The total potential reserves contained within the Syncrude oilsand leases, excluding the existing mine, are 10.2 billion bank yd^3 (7.8 billion bank m^3) of waste and 7.2 billion bank yd^3 (5.5 billion bank m^3) of ore grading 10.7% bitumen in situ. The waste-to-ore ratio rises significantly in these areas, averaging 1.43:1 due to greater overburden thickness.

14.3.7.3 Mining Methods

ORE PRODUCTION METHOD. In principle, the ore mining method shown in Fig. 14.3.7.3 is relatively simple. Draglines excavate the entire ore zone and deposit the ore in windrows on the operating bench. Waste is separated from the ore by the draglines and it is cast in to the mined-out pit. Bucket wheel reclaimers are paired with the draglines to reclaim ore windrows onto a conveyor system for transport to the extraction plant. Positioning of the major equipment is such that four independent production areas or quadrants are created, each with a dragline, bucket wheel reclaimer, and conveyor system (Fig. 14.3.7.4).

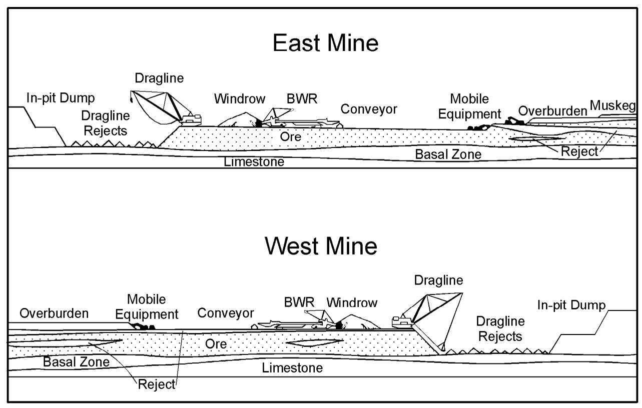

Fig. 14.3.7.3. Typical mining bench arrangement.

The mining method, employing both excavating and reclaiming equipment, was selected after extensive technical and economic evaluation of specific mine geology, production requirements, and capital cost. The use of a conveyor system was considered essential to handle long-distance transport of high ore tonnages at low operating cost. The mining method has proven successful in the first 14 years of operation, with numerous advantages apparent. These include

1. Blasting of ore is minimized because of dragline excavating capabilities.

2. Waste material is efficiently rejected from ore zone to mined-out pit.

3. Conveyor system complexities, necessary for the handling of ore and waste, are avoided because of the ability of draglines to separate ore and waste.

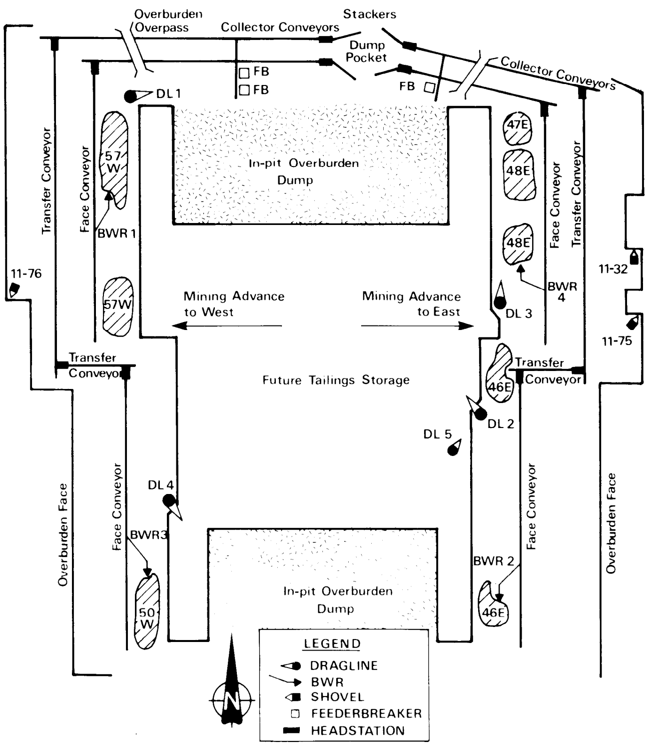

Fig. 14.3.7.4. Schematic mine layout.

4. Bench preparation is minimized by the draglines excavating the entire ore zone from one bench.

5. Trafficability is improved by avoiding operations on weak saturated basal sediments.

6. Lifting of ore by conveyor is minimized because draglines hoist all ore above the in situ ore zone.

7. Preproduction development costs are minimized by establishing one ore bench only.

The major disadvantages of the method are

1. Highwall stability must be continuously monitored to ensure dragline safety.

2. Inter-equipment delays are encountered due to the close proximity of equipment and the required mining sequence.

3. Power supply must be designed to handle high peak demands of draglines.

While simple in principle, the mining method actually requires significant technical support to ensure efficient, continuous production at the high rates required. The most notable areas of complexity are geologic interpretation, equipment positioning, material placement, highwall stability, and production scheduling.

OVERBURDEN REMOVAL METHOD. The overburden removal operation utilizes a shovel and truck fleet in a conventional benching method, with the waste material hauled to the mined-out pit for storage. The fleet excavates north-south strips of overburden in advance of the conveyor systems (Figs. 14.3.7.3 and 14.3.7.4), creating an operating surface for the production equipment. Timing of overburden strip removal is a critical balance between adequate preparation for the advancing ore production equipment and minimal preinvestment in overburden removal.

Preparation of the original ground surface is carried out well in advance of the overburden removal operation, due to the saturated condition of most upper overburden layers. Trees are cleared approximately five years in advance, allowing adequate time for subsequent muskeg drainage, muskeg removal, and overburden drainage. Muskeg is a loosely-compacted, saturated, organic material located in isolated surface channels. Muskeg is hauled directly to land reclamation sites or to separate storage areas for future use.

The overburden removal method has proven successful under Syncrude conditions, providing a high-degree of flexibility in acquisition of additional capacity, flexibility of operation, and relatively low capital cost. The Syncrude-owned fleet is supplemented by contractor equipment to handle long-term peak demands. Disadvantages of the shovel-and-truck method include relatively high operating cost, large operating and maintenance work force, and road building with less than ideal materials.

Numerous other overburden removal methods have been considered. The most notable was a bucket wheel excavator-conveyor-stacker method. High capital cost and questionable ability to handle high-strength siltstone lenses were the major reasons for rejecting this alternative.

14.3.7.4 Unit Operations

OVERBURDEN REMOVAL. The overburden removal operation is conducted by a mobile equipment fleet consisting of electric and hydraulic shovels, front-end loaders, and haul trucks, as described in Table 14.3.7.1. The utilization and productivity levels listed are sustainable averages, inclusive of seasonal variations in performance. In addition to the major equipment listed, the overburden removal operation also utilizes support equipment, including 9 Cat D10/D11 dozers, 3 Komatsu 475 dozers, 3 Cat 824/834 rubber-tired dozers, 6 Cat 16G graders, plus packers and service vehicles. Mobile equipment numbers have increased steadily to match increasing volume requirements. The initial fleet in January 1981 was composed of two Demag shovels and 10 Titan trucks. Options for handling further increases in overburden volume over the next few years include contracting, equipment rental, and Syncrude fleet expansion, with the final choice based on comparative costs, work force levels, and the availability of maintenance shop space.

Overburden removal is carried out in each mine quadrant, in north-south strips to accommodate the 490 to 660 ft (150 to 200 m) yearly advance of the draglines. Fig. 14.3.7.5 shows an active overburden strip located well in advance of the highwall and separated by the prepared bench. Bench space available for conveyor movement varies throughout the year, depending on completion of the overburden strip and rate of advance of the conveyor. The maximum bench space or "lead time" established in the south quadrants allows for nine months of conveyor shifting, while the maximum in the north quadrants allows for 12 months. The lead time criteria were established after considering capabilities of the removal equipment, conveyor move cycles, and seasonal limitations on bench surface preparation. The difference in lead time criteria between north and south quadrants is related to the different conveyor arrangement of each.

The overburden removal operation takes place in one or two lifts, depending on material thickness and type, and on the type of loading equipment being used. Other factors involved in bench design decisions include:

1. Trafficability of middle geologic units.

2. Recovery of construction-quality materials in the overburden face.

3. Recovery of ore bands in the overburden face.

4. Required strip completion date.

Overburden is hauled an average of 2 miles (3 km) one way to waste dump sites situated at the north and south ends of the mined-out pit (Fig. 14.3.7.4). Haulage routes are necessarily located around the ends of the ore conveyors. Bridges are used

Table 14.3.7.1. Major Equipment for Overburden Removal and Ore Production

Area	Equipment Type	Make and Model	Size	Fleet Size	Historical Utilization	Historical Productivity
Overburden Removal	Electric Shovel	Bucyrus-Erie 395B	34–36 yd^3 (26–27.5 m^3)	3	50%	2680 yd^3/hr[a] (2050 m^3/h)[b]
Overburden Removal	Hydraulic Shovel	Demag H241	19 yd^3 (14.5 m^3)	2	50%	1014 yd^3/hr[a] (775 m^3/h)
Overburden Removal	Front-end Loader	Hough 580	22 yd^3 (16.8 m^3)	1	50%	536 yd^3/hr[a] (410 m^3/h)
Overburden Removal	Hydraulic Shovel	O&K 200	21 yd^3 (16 m^3)	1	60%	1960 yd^3/hr (1500 m^3/h)
Overburden Removal	Haul Truck	Cat 789	200 ton (181 t)	6	68%	327 yd^3/hr (250 m^3/h)
Overburden Removal	Haul Truck	Titan T2000	200 ton (181 t)	4	68%	327 yd^3/hr 250 m^3/h)
Overburden Removal	Haul Truck	Titan T2200	240 ton (218 t)	2	NA	NA
Overburden Removal	Haul Truck	Titan 33-15B	170 ton (154 t)	16	68%	267 yd^3/hr[a] (204 m^3/h)
Ore Production	Dragline[b]	Bucyrus-Erie 2570W	80 yd^3 (61 m^3)	2	63%	4186 yd^3/hr[a] (3200 m^3/h)
Ore Production	Dragline[b]	Marion 8750	90 yd^3 (69 m^3)	2	63%	4186 yd^3/hr[a] (3200 m^3/h)
Ore Production	Bucket wheel Reclaimer[c]	O & K/Krupp	Schrs 2375 × 21 1.5	4	53%	6724 tph (6100 t/h)
Ore Production	Conveyors[c]	Krupp	6-ft belt (1.8-m) belt	18	53%	6724 tph (6100 t/h)
Ore Production	Feeder-breakers	Stamler/Syncrude	353-ton bin (320-t) bin	3	20%	3660 tph (2800 t/h)

[a] Volume is in bank units
[b] Indicated productivity is for all draglines combined
[c] Indicated productivity is for combined output of bucket wheels and conveyors
NA = Not available yet.

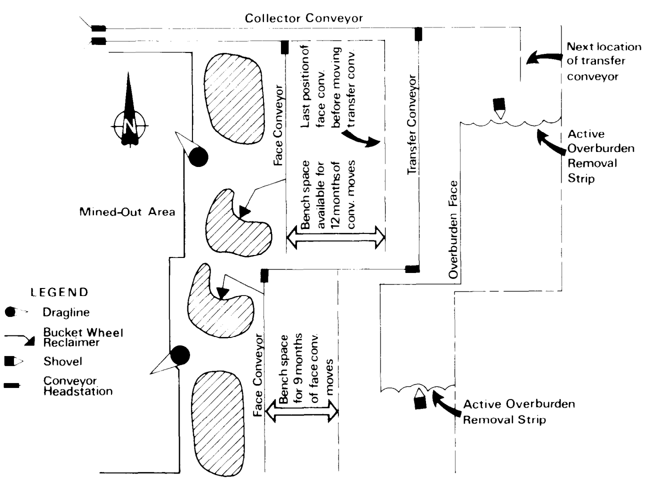

Fig. 14.3.7.5. Overburden strip removal and conveyor move sequence.

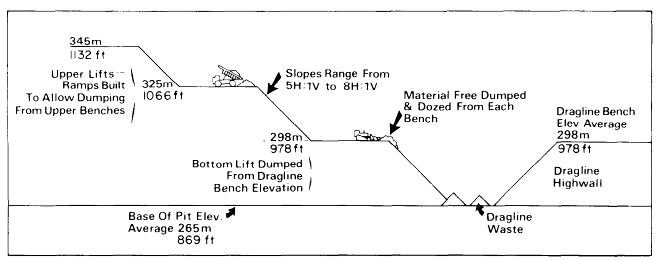

Fig. 14.3.7.6. Typical in-pit overburden dump cross section.

to cross collector conveyors situated along the north end of the mine.

Dump construction to a maximum height of 260 ft (80 m) is carried out in three free-dumping lifts (Fig. 14.3.7.6), with very little controlled placement of material required. Controlled placement is necessary only when hauling construction-quality material for capping of dump operating areas. Capping is necessary to ensure haul trucks can travel on dumps in the frost-free season.

The dump space available between ore highwall and dump toe is adequate to allow overburden to flow to an angle of repose as it is pushed over the edge of the dump. The types of overburden material and variable pit bottom contours lead to dump slopes as low as 8:1 (horizontal to vertical). The concept of building the dump at the angle of repose of the material avoids most stability concerns, except for localized slumping on the edge of each lift. Slumping does not threaten equipment safety because of the slow rate of movement.

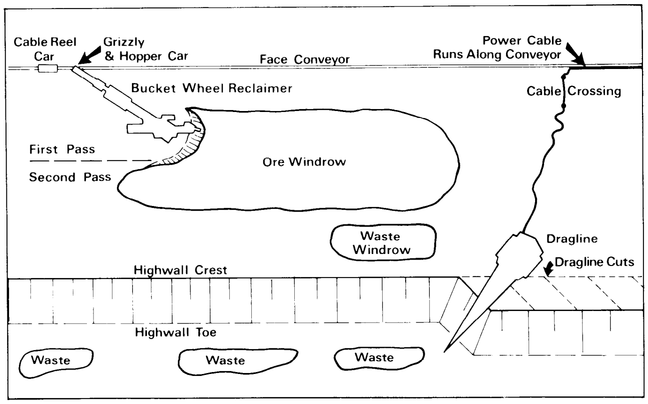

Fig. 14.3.7.7. Typical dragline and bucket wheel reclaimer configuration.

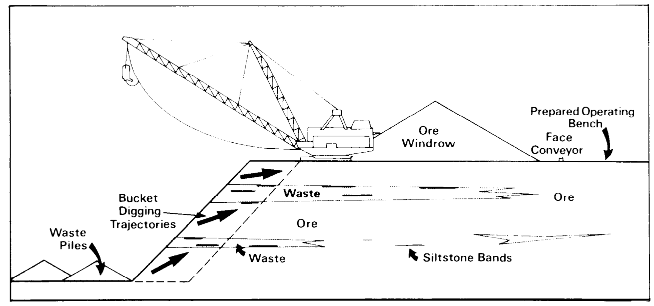

Fig. 14.3.7.8. Typical dragline highwall cross section.

Final bench preparation after overburden strip completion is a time-consuming and costly process, due to the tight specifications necessary to ensure efficient operation of ore production equipment. The preparation process involves subcutting and backfilling soft areas and leveling the entire bench surface within an acceptable tolerance of the original design. Bench preparation is complicated by a chronic shortage of quality backfill material, wet weather, and the low productivity of the work. The completed bench is quality tested by running a loaded haul truck over the surface and comparing actual rutting depth to a standard developed by trial and error.

Seasonal variation in overburden removal productivity is small. The winter operation is slightly more productive, due to a significant reduction in rolling resistance in the excavation and dump areas. Main haul roads are constructed to a high standard, with little variation in rolling resistance between seasons. An offsetting factor in winter is the 10 to 15% reduction in loading rate for shovels due to frost penetration. Blasting of overburden has proved to be economically unattractive.

OILSAND REMOVAL. Mining of in situ oilsand is carried out by four draglines (Table 14.3.7.1). The 360-ft (110-m) boom length of the four draglines is less than optimum for Syncrude highwall conditions, and this has a significant impact on material handling capabilities. With highwall depths averaging 148 ft (45 m) and highwall angles varying from 40 to 50°, situations frequently arise where dragline reach is insufficient.

Support equipment utilized in the dragline operation includes four Cat D10 dozers, one D9 dozer, one Komatsu 375 dozer, one 350 dozer, and one Cat 980 loader. In addition, two Cat 988 loaders have been modified to handle electrical cable spools, and two John Deere 300B loaders modified for electrical cable handling on the bench near the draglines.

The draglines mine the oilsand in 66- to 82-ft (20- to 25-m) wide panels over the 7550-ft (2300-m) length of each quadrant. The panel mining sequence is variable. Three main patterns are used, depending on highwall stability, production demands, and windrow inventory. Each panel is divided into 82-ft (25-m) long cuts (Fig. 14.3.7.7) providing a convenient increment of advance. Each dragline averages two cuts/day. Ore from each cut is placed in a windrow parallel to the receiving conveyor and at a predetermined distance from it. Careful windrow placement is necessary to minimize the dragline swing angle while ensuring the bucket wheel reclaimer can reach the entire windrow.

Dragline mining involves separation of oilsand into ore and waste as defined by the 6% bitumen cutoff grade. Grade bands are carefully delineated by core drilling and highwall mapping and communicated to the dragline operator by mine planners. Visual differentiation of grade bands is not always possible, and the operator must be assisted by a continuous indication of bucket depth by an on-board computer. The capability of the draglines to separate the relatively flat-lying bands in the McMurray Formation is restricted by the normal trajectory of the bucket (Fig. 14.3.7.8). Separation near the top of the highwall is good, and bands as thin as 10 ft (3 m) can be separated. Progressing down the highwall, the trajectory becomes closer to vertical, and efficient separation of bands can only occur if greater than 33 ft (10 m) thick.

Waste volumes vary considerably from cut to cut, and in some cases are high enough to allow large ore body blocks to be by-passed as uneconomical. Where waste volumes are high but the block still economic, rehandle is frequently necessary. Waste handling is carried out in various ways:

1. Placed direct to pit as it is excavated.

2. Placed on the bench beside the ore windrow until cut completion, and then rehandled into the resulting void.

3. Placed on the bench and left for later rehandle by mobile equipment .

Rehandle is minimized for economic reasons, and is normally carried out by the dragline. Mobile-equipment rehandle has a significantly higher cost, as well as logistical problems in getting the equipment in and out efficiently. Dragline waste is frequently required as construction or backfill material for the overburden operation, in which case, the waste is deliberately left in appropriate locations along the panel for later recovery by mobile equipment.

The amount of siltstone in each dragline cut is variable but predictable based on geologic interpretation and historical trends. Individual siltstone layers are usually impossible to reject unless associated with a thick waste band. The siltstone does not create a digging problem for the draglines, but once placed in the windrow, it does create a potential for damage to subsequent production equipment.

Stability of the highwall and operating pad is an important factor in efficient operation of the draglines. Considerable effort is put into preparing the pad by ripping and leveling prior to walking a dragline to a new cut. Tub deterioration has been reduced significantly by careful pad preparation work. Highwall stability is a major consideration due to the high risk of failure existing over approximately 15% of the highwall length. Numerous failure modes have been experienced to date, but very few situations have occurred where a dragline has been in jeopardy. An extensive geotechnical program, utilizing continuous instrumentation and visual monitoring, has been developed to virtually guarantee dragline safety.

In situations where bedding planes in the top 50 ft (15 m) of the highwall dip steeply toward the face, the geotechnical monitoring program alone is not adequate to ensure safe dragline mining of the affected area. Remedial work must be carried out to disrupt the bedding planes by either subcutting and backfilling, or blasting. Subcutting and backfilling are conducted by either dragline or mobile equipment.

The winter season affects the dragline operation by reducing the production rate by some 10%. Frost penetration up to 13 ft (4 m) can cause difficult digging conditions in faces that have been left unmined for extended periods. Blasting is used for all stable areas of the highwall, amounting to approximately 90% of the total length.

Bucket Wheel Reclaimer Operation. The windrows placed by the draglines, averaging 72 ft (22 m) high and 328 ft (100 m) wide, are reclaimed by the bucket wheel reclaimers (BWR) (see Fig. 14.3.7.7). The four reclaimers described in Table 14.3.7.1 are each capable of producing 30.8 million tpy (28 Mt/a), with production expected to peak at 31.4 million tpy (28.5 Mt/a) as downstream constraints are removed. Hour-by-hour production targets are met by utilizing three of the four reclaimers, allowing the fourth to be scheduled for preventive maintenance, component change-out, or conveyor shifting. In situations where only two reclaimers are available, production can be supplemented by mobile equipment.

Support equipment utilized in the reclaimer and conveyor operations includes two Cat 988 loaders, four Komatsu WA400/WA600 loaders, six Cat D10/D11 dozers, four Komatsu D355/D375 dozers, two Komatsu D355 sideboom dozers, two Cat 641 scrapers, three Cat 16G graders, and two 50 ton HaulPac trucks.

Reclaiming a window is accomplished in either a single pass or two approximately equal passes depending on the width of the window. The reclaimers are capable of reclaiming over a total range of 50 to 425 ft (15 to 130 m) from the conveyor centerline. Reclaimer reach is adjusted by changing the discharge angle between bridge and conveyor and by changing the length of the bridge discharge boom. The windrow is placed carefully to ensure that ore is kept within reclaiming range.

The sequence for reclaiming a windrow over a complete panel length is dependent on the relative position of the dragline and reclaimer and the amount of windrow existing in the quadrant. A complete panel over one quadrant contains approximately 3.3 million tons (3.0 Mt) of in situ ore, with the windrow inventory maintained between 550,000 and 1,650,000 tons (500,000 and 1,500,000 t). An ideal inventory of 1.1 to 1.6 million tons (1.0 to 1.5 Mt) in each quadrant allows flexibility in scheduling reclaimer production while providing a buffer in case of a dragline outage, either planned or unplanned. The reclaiming sequence is carefully planned to free the dragline when it becomes windrow-bound at the end of each panel. By ensuring the reclaimer is correctly positioned as the dragline completes a panel, the dragline can be freed in three days to start mining the next panel in the opposite direction. With the dragline starting a new panel, the reclaimer repositions to handle windrow in other parts of the quadrant, completing reclamation of the previous panel.

Operation of reclaimers in the winter season has been modified to solve the problems associated with frozen ore. Frost can penetrate a windrow pile to a depth of 6.5 ft (2 m), depending on the severity of the weather and the water content of the ore. Frost penetration is less in a windrow than in situ due to the "fluffed" state of the windrow. Small windrows, such as a second pass that is left unmined for an extended period, can freeze completely. Reclaiming during winter is accomplished at a 10% slower rate than in summer. The first and second passes are scheduled carefully to minimize frost penetration and to reduce the risk of damage to reclaimers and downstream production equipment. In addition, close coupling of dragline and reclaimer operations is carried out to reduce the exposure time of the windrow and to allow less frost penetration. Windrow inventory is maintained at lower levels. This lower level, however, increases the risk of windrow shortage during unplanned dragline outages.

Efforts to reduce the amount of frozen lumps and siltstone pieces being picked up by reclaimers have been partially successful, and damage to ring chute, slope sheet, conveyor belt, and baffle walls occurs on a much reduced frequency. Each bucket on the reclaiming wheel has a modified opening to restrict the size of lumps picked up. This modification was carried out by trial and error to find a suitable balance between production rate and lump rejection.

Conveyor Operation. Ore flow from each reclaimer is discharged through an A-frame grizzly, with one-directional bars, into a hopper located over a conveyor. Large frozen lumps and siltstone pieces are deflected to the ground and trammed by front-end loader to the highwall or into piles for later rehandle by dragline. The grizzlies are successful at removing most of the oversize material. Some tabular pieces, however, pass between the bars and onto the conveyor. Development of grizzlies has been by trial and error to find a balance between high throughput and maximum lump rejection.

The layout of conveyors from reclaimer to dump pocket appears in Fig. 14.3.7.4. The north quadrants each have a receiving conveyor, a collector conveyor, and a stacker conveyor. The south quadrants have a more complex system, each with an additional transfer conveyor to route the ore flow around the north quadrant. Ore is discharged from each stacker conveyor onto a surge pile at the north end of the mine. Total surge capacity is 303,000 tons (275,000 t), of which 27,600 to 33,100 tons (25,000 to 30,000 t) can be fed directly to the extraction plant through 16 conical drawpoints and four feeder conveyors. The remaining surge capacity is situated close to the drawpoints and can be dozed in when the feed rate from reclaimers is restricted.

Each conveyor has a headstation to provide belt drive power and tension, and to transfer ore to the next conveyor. Power is supplied by four 1250-hp (932-kW) electric motors in each headstation and supplemented by an additional motor on the tailstation, if required. Tailstation anchoring is accomplished with large concrete deadweights that can be added or subtracted to attain the necessary belt tension.

The conveyor system is expanded to the east and west to maintain correct positioning with respect to the highwall as the mine expands. The receiving and transfer conveyors are shifted over the bench surface by specially equipped dozers that traverse the length of the conveyor, pulling the conveyor sections over 1.5 ft (0.5 m) in each pass. Movable headstations are walked to a new location by three hydraulic "walking legs" that are detachable for common use. Collector conveyors remain in a fixed position and are extended east and west to match the headstation position of the receiving and transfer conveyors.

The sticky nature of oilsand causes conveyor operating problems, such as buildup on components and spillage within and under the structure. Build-up on conveyor idlers, causing premature shell and bearing failure, was resolved by changing from steel-shelled to rubber-lagged idlers. Build-up on the belt and pulleys has been resolved to some extent by belt wetting and mechanical cleaners. Research is continuing in this problem area. Spillage, occurring mainly from oilsand falling from the return belt, creates an ongoing need for cleanup. Specially equipped front-end loaders are used to clean under conveyor sections and around headstations.

AUXILIARY PRODUCTION SYSTEM. The main production system of reclaimers and conveyors is at times incapable of meeting production demands and must be supplemented by the auxiliary production system. The system, consisting of the overburden haulage fleet and three feeder-breaker units, is utilized in situations where the production shortfall is expected to last two hours or longer. Shorter periods of production shortfall can be supplemented by dozing on the surge pile. Various sources of ore exist for the auxiliary system, with the choice dependent on the necessary production rate and the inventory level of sources at the time.

Design of the Syncrude feeder-breaker units is a size-up from similar units operating at other materials handling operations. Consisting of a 350-ton (320-t) hopper, a single breaker drum, and a pan feeder, the units can break and transfer ore from haul truck to collector conveyor. The feeder-breakers have achieved average rates of 2755 tph (2500 t/h) each while handling ore containing frost lumps. The units have not been as successful at breaking siltstone, necessitating either a lower production rate or careful selection of feed sources to avoid high siltstone content. The units are installed against a Reinforced Earth retaining wall and ramp system, providing an efficient facility for haul trucks dumping into the hoppers.

RECLAMATION. Reclamation of disturbed land surfaces has been underway since 1985, with work carried out on both temporary and permanent surfaces. Final land surfaces have been available for reclamation since 1991.

Research is underway to find the optimum soil-building technique that will allow efficient reforestation of disturbed land areas. Current reclamation work is carried out by selectively stripping surface materials in advance of the overburden removal operation and creating a 2.3- to 3.3-ft (0.7- to 1.0-m) thick soil layer on disturbed surfaces. Fertilizer is incorporated into the new soil prior to planting indigenous grass or trees.

14.3.7.5 Ancillary Operations

DRILLING AND BLASTING. Blasting is utilized in the Syncrude mine for winter dragline digging. Blasting of the highwall prior to dragline digging is carried out with a cratering technique during the December to March period. Holes are drilled 4 in. (100 mm) in diameter to the depth of the frost, using auger and percussion drills. The grid pattern is approximately 10 by 13 ft (3 by 4 m). Amex explosives are used at a rate of 18 lb (8.3 kg) in the bottom of each hole with a Forcite primer, Primacord, and electrical detonation.

Blasting of auxiliary production sources for winter use utilizes the same technology as described for highwall frost blasting. Auxiliary production blasting is performed to loosen the oilsand to reduce frost penetration, and, therefore, a smaller explosive charge is necessary.

Blasting also is carried out to improve highwall stability by disrupting undesirable bedding planes. Approximately 2.2 million tons (2 Mt) of oilsand are blasted each year with a cratering technique that utilizes 31.5-in. (800-mm) diameter holes on a 66-ft (20-m) diagonal pattern. The holes are drilled by an auger drill to a maximum depth of 92 ft (28 m). Heavy ANFO (HANFO) explosives are loaded in the bottom of each hole to a maximum charge of 5070 lb (2300 kg), with l-lb (0.45-kg) primers electrically detonated at one hole per delay.

MAINTENANCE. Mine maintenance activity is divided between shop and field, with most mobile equipment maintenance carried out in the permanent shop facilities and most production equipment maintenance carried out in the field. A total of 187,300 ft^2 (17,400 m^2) of shop space is available at the north end of the mine for mobile equipment bays, fabrication work, dragline bucket rebuilding, conveyor belt splicing, electrical equipment rebuilding, and major component construction. In addition, a 60,300-ft^2 (5600-m^2) machine shop is available in the upgrader complex for use by all operating areas of Syncrude.

Field maintenance is carried out on the larger equipment utilizing trailer facilities to increase efficiency through reduced travel time and improved working conditions. Individual trailers containing worker facilities, tool cribs, parts stores, fabrication shops, and lubrication materials are set up adjacent to the maintenance work.

The total maintenance work-force of 600 is organized with 350 workers assigned to permanent day shift and 250 covering the night shift. Maintenance work during major equipment outages can be scheduled on a continuous basis depending on production need. A total of 40 inspectors is utilized to monitor equipment condition through visual and non-destructive testing techniques.

14.3.8 FLORIDA PHOSPHATE: FT. GREEN MINE

STEVEN I. OLSON

14.3.8.1 Mine Description

The Florida phosphate industry produces approximately 75% of the domestic output and nearly 25% of the world's supply of phosphate rock (Anon., 1988a). Agrico Chemical Co., which is a division of Freeport-McMoRan Resource Partners, a vertically-integrated entity which mines phosphate and sulfur and produces chemicals and fertilizer. Its roots can be traced back to the very beginnings of the phosphate mining industry (1880) and the sulfur mining industry (1912). Agrico currently has two operating mines: Ft. Green and Payne Creek located, respectively, in Imperial Polk County and Hardee County, FL.

Agrico's Ft. Green mine (Fig. 14.3.8.1), commissioned in 1975, produces about 4 million tpy (3.6 Mt/a) of phosphate rock. The Payne Creek mine, started in 1966, produces about 2.5 million tpy (2.3 Mt/a). The Ft. Green mine is typical of the newer and larger operations in Florida.

About 700 acres (2.8 km^2) per year are mined at the Ft. Green mine, which involves moving about 28 million yd^3/yr (23 million m^3/yr) of overburden and about 12 million yd^3/yr (10 million m^3/yr) of matrix.

Operating schedules in the mining and beneficiation of phosphate vary substantially from one operation to another, depending on the specifics of the operation (current supply/demand situation, mine/plant limitations, etc.). Production schedules range in the industry from a full seven-day schedule (24 hr/day and 7 days/week) to variations of five-day schedules that may run from 1 to 3 shifts/day. Some schedules take advantage of lower electric rates during off-peak demand periods.

The Ft. Green operation is on a full 7-day schedule with 1 shift/week scheduled for repairs to the beneficiation operation. Each dragline is scheduled for a one-shift repair period every third week.

14.3.8.2 Deposit Description and Geology

GEOLOGIC SECTION. The phosphate ore (matrix) of Central Florida is a sedimentary deposit located in the west-central part of the Florida peninsula in west-central Imperial Polk County, east-central Hillsborough County, and northern Manatee and Hardee Counties. This area is known as the "Bone Valley" and is the source of phosphate ore for present mining activities. A southern extension exists in southeastern Manatee, southwestern Hardee, and northern DeSoto Counties. As the land pebble district deposits become depleted, mining will continue into the southern extension. The industry in Florida has proven reserves for several decades, and resources are known (at current production rates) that would satisfy needs forward for over 100 years.

Fig. 14.3.8.1. Overview of the mine site.

Agrico's reserves lie in southwestern Imperial Polk and northwestern Hardee County. Recently acquired lands extend farther south into Hardee and into Manatee County. Currently about 98,000 acres (324 km^2) are controlled by Agrico.

The phosphatic, clayey sands, known as phosphorites, occur in the Hawthorn and Bone Valley Formations. The phosphate occurs as carbonate-fluorapatite (francolite). Varying degrees of weathering produce alteration minerals, such as wavellite or crandallite. The matrix consists of the phosphorites, silica sand, and montmorillonite and palygorskite clays.

The Hawthorn Formation is the source of primary phosphate, while the Bone Valley Formation phosphate is the result of reworking the underlying Hawthorn material. The primary phosphate is thought to be the product of biological and/or chemical precipitation that took place in a shallow marine environment during the middle Miocene Epoch (12 to 18 m.y. ago). Upwelling along the southeastern United States continental shelf provided cold nutrient- and phosphorus-rich waters to proliferate plant and animal life. Precipitated phosphate and marine skeletal remains were deposited, along with sands and clays, to form the youngest portion of the Hawthorn Formation. Dropping of the sea level exposed the Hawthorn to erosion and weathering during the Plio-Pleistocene Epochs (1 to 7 m.y. ago). The reworking of the top portion of the phosphate-bearing Hawthorn and redeposition produced the Bone Valley Formation, a sandy phosphate bearing material with various stages of weathering and cycles of reprecipitation of phosphate grains.

DEPOSIT GEOMETRY. At the Ft. Green mine, the overburden can vary from 5 to 45 ft (1.5 to 13.7 m) thick and averages 25 ft (7.6 m). It typically varies gradually over a local region. The matrix section consists of up to several horizontal strata that can vary considerably in components. Total matrix thickness varies from 0 to 25 ft (0 to 7.6 m) and averages about 10 ft (3 m). The phosphate can vary in product grade, diluent levels, and size distributions. The sand may vary in amount and occasionally the size distribution. The clay will vary in mineralogical composition and proportion. The top strata are frequently a "leach zone" that will tend to be higher in uranium values. These strata are usually mined for their phosphate values, but will occasionally be spoiled because of unacceptable product grades. The matrix will typically bottom out in a yellow, clayey, dolomitic horizon.

PROPERTIES OF ORE AND WASTE. The overburden in the Bone Valley is primarily a loosely-aggregated, clayey sand. The underlying ore, or matrix, is a composite of sand, clay, and phosphate. Historically, the industry has encountered matrix that averaged 1/3 sand, 1/3 clay, and 1/3 phosphate. Southern deposits tend to have more sand, less clay, and less phosphate. Agrico's is a southern deposit.

The sand is normal silica sand that ranges from about 14 to 150 mesh (Tyler) (1.2 to about 0.01 mm). The clay is a complex mixture of montmorillonite and palygorskite. The clay fraction (defined as – 150 mesh or –0.01 mm) has an average particle size of 1 μm and presents a challenge for disposal.

The phosphate grain sizes range from pebble-sized gravel to very fine sands. The color of the grains varies from an opaque black, brown, and tan to cream or a translucent amber.

GRADE AND SIZE DISTRIBUTION. During mining and beneficiation, purity is measured in BPL (bone phosphate of lime). In the chemical processing area, P_2O_5 is the standard unit. Ft. Green produces three phosphate products: pebble, intermediate pebble (I.P.), and concentrate. The pebble is the coarsest product and is –3/4 in. to +14 mesh (–19 mm to +1.2 mm). The I.P. is –14 to +20 mesh (–1.2 mm to +0.75 mm), and the concentrate is the product from a flotation process and is –20 to +150 mesh (–0.75 mm to +0.01 mm). Typical product grades are: 65 BPL for pebble, 60 BPL for I.P., and 72 BPL for the concentrate. Diluents include calcium, silica, magnesium, iron, and alumina. Each impacts the chemical processing requirements differently.

Over the years, Florida phosphate mining has produced primarily pebble. Before the use of the flotation process, the pebble-sized phosphate was mined and the sand-sized phosphate discarded with the silica sand and clay as tailings. Some operations still have pebble:concentrate ratios of 3:1. Pebble is a cheaper product that requires less processing to produce. Agrico's operations are not so fortunate. Typical ratios are 1:1 or occasionally less.

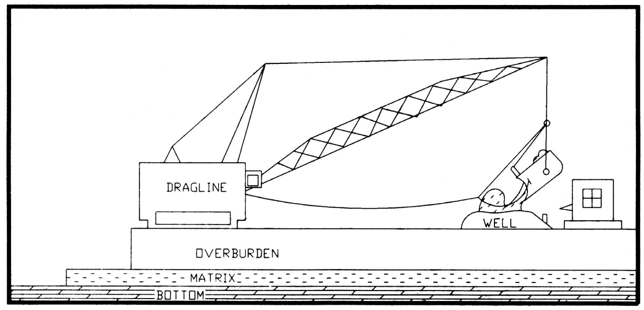

Fig. 14.3.8.2. Typical mining cross section.

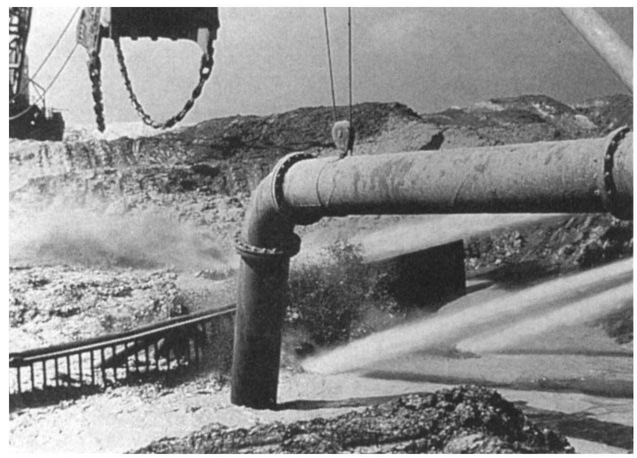

Fig. 14.3.8.3. Well and ore pumping station.

14.3.8.3 Mine Development

DEPOSIT DELINEATION. Prospect drilling is completed to initially delineate the deposit. This type of drilling is performed on a broad spacing of one 4-in. (100-mm) drill core to bedrock every 40 acres (0.16 km^2). The prospect cores are logged and cut by a staff geologist. Each stratum is then processed through a laboratory simulation of the actual process. Each core is measured and processed to produce metallurgical, analytical, and processing data.

Followup drilling is completed on 330-ft (100-m) centers (one hole every 2.4 acres or 9712 m^2). These prospect samples are handled identically to the preliminary drilling samples and are used to expand the resource database.

This drilling density enables more definitive planning and forecasting. From this level of detail, annual budgets and monthly forecasts are made. Some short-term "surprises" (richer or leaner areas encountered in a given period) still occur, but the drilling density provides a good representation in the long run for monthly and annual forecasts.

LONG-RANGE MINE PLANNING. A long-range mine plan is developed for the mine that is intended to optimize the reserves. This long-range plan includes not only mining specifics but also waste product disposal plans, reclamation plans, primary power distribution networks, and permit requirements. This plan is updated frequently to reflect recent reserve acquisitions, current demand situations, and anticipated time periods to secure the required permits. The long-range mine plan is refined prior to the beginning of each year. Pipeline and pump locations, hydraulic stations, dewatering schemes, permits, and local area power service needs are included in the plans.

PERMITTING. Permitting for phosphate mining has become more involved in recent years. The uncertainty of successfully receiving all required permits is a substantial disincentive for new mines. The permitting process for a new mine may take as long as 10 years and cost over $10 million (Anon., 1984). New mines (or major expansions) are required to prepare a State Development of Regional Impact Study. They may also be required to complete a Federal Environmental Impact Study.

Current mining operations must have permits from federal, state, regional, and county governments. Some of the agencies involved include the Environmental Protection Agency, the Florida Department of Natural Resources, the Florida Department of Environmental Regulation, the Army Corps of Engineers, the Southwest Florida Water Management District, State Department of Community Affairs, the regional planning councils, and various county agencies. Duplication and overlap exist in several areas. The FDNR requires mining and reclamation permits (reclamation plans must be approved prior to commencement of any mining activities). Several of the others are involved in wetland permitting. It is estimated that 20% of the Florida phosphate reserves are under wetlands (Anon., 1984). Wetlands are a scarce and unique part of the environment. They serve a role in water purification, recharging of aquifers, and wild life habitat.

14.3.8.4 Unit Operations

Stripping is accomplished with electric walking draglines, most typically in the 35- to 45-yd^3 (28- to 34-m^3) category. The draglines strip the overburden and spoil it into the voids left from the previous mining activity. After the overburden is removed, the ore or matrix is exposed. It is excavated and placed in a shallow well (Figs. 14.3.8.2 and 14.3.8.3). It is slurried with high-pressure water, washed through a grizzly, and pumped away for beneficiation.

Ft. Green has three walking draglines: two model 1260-W Bucyrus-Erie machines, each with 42-yd^3 (32.1-m^3) buckets, and a model 1250-W with a 36-yd^3 (27.5-m^3) bucket. Each has a boom 225 ft (68.6 m) long. Power at 4160 Vac is fed to the machine through a trailing cable and motor/generator sets that

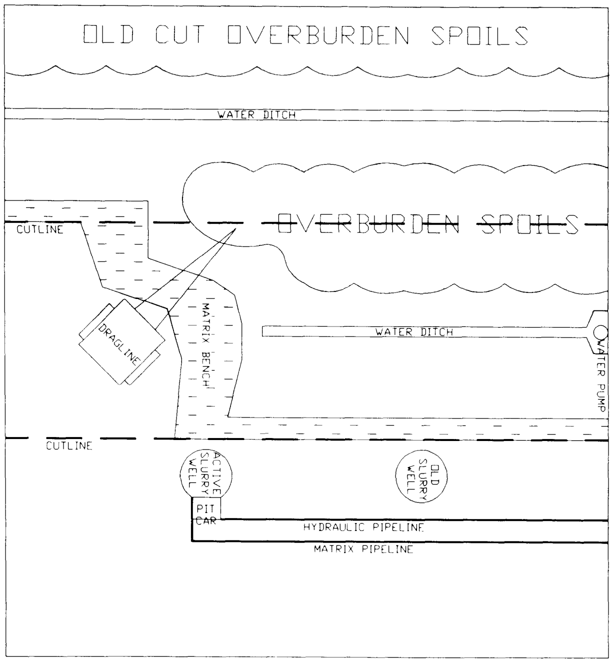

Fig. 14.3.8.4. Typical mining plan view.

produce direct-current power. Typical digging rates are 2400 yd^3/hr (1840 m^3/h) per dragline.

CLEARING. Area preparation for central Florida phosphate mining is relatively simple. The land is generally flat and is typically scrub brush with palmetto bushes and pine trees. These areas are prepared for mining by removing all the vegetation. Wetlands (swamps, bayheads, isolated ponds, etc.) also are common. Preparation of these areas following receipt of all permits can become quite involved.

MINING. The strip mining that occurs in central Florida is not complex. Mine planners lay out long cuts (3000 to 4000 ft, or 914 to 1218 m, if possible) that are 225 to 330 ft (68 to 100 m) wide (depending upon deposit geometry). The draglines remove the sandy overburden. The overburden from the first activity in the area must be spoiled on unmined ground. Subsequent overburden is placed in the void left from the previous cut. The phosphate ore, or matrix, is then exposed. In this mining geometry, the pumping system is moved parallel to the advancing dragline and is placed on the edge of the next cut to be mined by the dragline. A ditch is maintained by the dragline in the bottom of the cut to collect all seepage (Fig. 14.3.8.4). A submersible pump or "waterjack" is placed in the ditch and pumps the water to a drainage system on the surface that routes the water to the area hydraulic system for re-use. The ditch may be up to 15 ft (4.6 m) deep. The spoil from the ditch (Hawthorn Formation material) is placed at the bottom of the cut. This material, like the "leach zone," is slightly elevated in uranium values. Uranium progeny includes radon, which is a subject of concern for health in dozens of areas in the United States. Both are bottom spoiled when encountered to facilitate better-quality reclaimed land.

As the dragline advances (typically, 100 to 150 ft/day (30 to 46 m/day), the pumping systems must remain within the reach of the machine. They generally are moved 300 to 400 ft (91 to 122 m) at a time. A few rare situations, such as mining a corridor, call for "windshield wiper" cuts that are about double the normal width. In these cases, the pumping systems are centered behind the dragline. The dragline mines in a horseshoe pattern around the well (see Fig. 14.3.8.3) starting at the open cut. To facilitate dewatering, the dragline maintains a waterjack ditch that is tied to the one in the old cut. As the dragline mines and retreats down the cut, the pumping system is cut back directly behind the dragline.

ORE HANDLING. The initial or "pit" pump is a 20-in. (508-mm) centrifugal slurry pump fitted with a long suction pipe that extends into a depression behind a grizzly. It is slurried with water from three high-pressure (up to 275 lb/in.^{2} or 1900 kPa) water cannons, similar to those used in placer mining (Chapter 15.1). The material passes through a grizzly with 6-in. (152-mm) openings. The pumping systems from the mining area to the processing plant can be several miles (km) long in older mines. They average 4 miles (6440 m) at Ft. Green. Each system employs a 20-in. (508-mm) seamless, abrasion-resistant steel pipeline, with several booster pumps spaced from 3500 to 5000 ft (1070 to 1520 m) apart, depending upon ore characteristics, terrain, and system design. The systems are designed to handle 13,000 to 15,000 gal/min (0.8 to 0.96 m^3/s) of the matrix slurry at a density of 30 to 45% solids. One or more of the boosters in a given system has a variable speed control to allow for pipeline extensions or reductions coincident with pit moves. The pumps are powered by 1250-hp (932-kW) motors and are controlled remotely. All systems are radio-controlled. Mass flow systems are used extensively to optimize matrix pumping performance.

RECLAMATION. Mining is a temporary land use that disrupts the landscape (Anon., 1986). The Florida phosphate industry has been acknowledged as producing a reclamation result unequaled by mining industries in other states (Anon., 1988b). Various land forms have been created and are being used for agriculture, housing, industrial tracts, recreational areas, and wildlife preserves (Anon., 1986).

Deposition of tailings from the beneficiation plant is the beginning of reclamation. Tailings are pumped back into the mined area between the overburden spoil piles. An elevation is achieved that permits covering the surface with the overburden and sculpturing the landscape as articulated in the reclamation plans.

Examples of successful reclamation projects include a 366-acre (1.48-km^2) upland section that recharges a 150-acre (0.61-km^2) wetland area known as Morrow Swamp. The area has diverse vegetation and wildlife and is representative of a naturally occurring swamp. Agrico also has established pasture lands, orange groves, and several lakes. These efforts have received national awards.

Waste-clay disposal presents a challenge for reclamation. Historically, the clay ponds have been abandoned, and after two decades or so, the surface has adequately dewatered to permit limited grazing by cattle. The disposal of these poorly consolidating clays has been the subject of millions of dollars in research by operating companies, universities, private research groups, and various arms of the federal and state governments.

The clay disposal problem is a volume problem and is influenced by the composition of clay types. The clay in the matrix (after millions of years of consolidation) is typically in the range of 60 to 65% solids (by weight). The components, montmorillonite and palygorskite, have very poor settling characteristics, depending upon the specific mineralogy. A sample of clay could require from a few weeks to several years to consolidate from 3 to 5% solids initially to 15% solids during the desliming process. Generally speaking, the clay fraction must achieve about 30 to 35% solids to fit into the void left from mining (excluding the volume of the sand tailings).

Dozens of disposal schemes, settling enhancement methods, and consolidation improvement techniques have been investigated. It was discovered that the clays proceed through two phases: a settling phase (typically from 3 to 15% solids range), and then a consolidation phase (from 15% solids upwards). Flocculation studies by the dozens were completed. However, they generally only addressed the settling phase of the problem.

Disposal methods evaluated included freezing and thawing the clay slurry to produce enhanced consolidation. Potential uses for the clay were investigated. Sand was admixed to increase the unit weight to improve consolidation. Elaborate techniques were attempted to allow placement of a "cap" of sand upon partially consolidated clays to enhance consolidation. Some methods were proven to be technically successful, but none were proven to be commercially viable.

Currently, Agrico is employing one method that does show promise for rapid reclamation of these large clay disposal areas. Unique low-ground-pressure vehicles (tires are 6 ft or 1.8 m wide, and 5 ft or 1.5 m tall) are being used to facilitate surface drainage. They have a hydraulically driven attachment that cuts ditches in the surface of the pond. This surface is continuously reworked to enhance drying of the surface. With this method, clay ponds have been converted to functional land forms within a matter of five to seven years. They are being used as pastures and for farming research. The Institute of Food and Agricultural Sciences of the University of Florida, in conjunction with the Florida Institute of Phosphate Research, is conducting agricultural studies of these areas. The goal is to produce a landform that will be functional and useful for the local economy. (Agrico received a national award in 1987 for this innovative technique.)

14.3.8.5 Ancillary Operations

PRODUCT PROCESSING. The initial separation step in phosphate beneficiation is washing (Fig. 14.3.8.5). There the phosphate slurry is received from the transportation system and passed through several stages of disaggregation (log washers) and screening, with the purpose of separating the +14 mesh (+1.2 mm) pebble from the balance of the matrix.

At Ft. Green, the slurry from any two pumping systems is received in a tank where it is transferred to parallel trommels that reject the +¾ in. (+19 mm) material. The reject is termed "debris" and is primarily dolomite. The –0.75 in. (–19 mm) material then passes flume or "flat" screens, primary vibrating screens, primary log washers, secondary vibrating screens, secondary log washers, and tertiary or finish vibrating screens. All are fitted with plastic screen media and sized at 14 mesh (1.2 mm). The +14 mesh (+1.2 mm) or pebble is taken, via conveyor belt, to temporary storage, awaiting shipment by Agrico's own railroad to Agrico's South Pierce Chemical plant in Imperial Polk County, or to Agrico's Big Bend Terminal, which is a deep-water port in Tampa. From there, rock may be shipped to Agrico's Faustina or Uncle Sam chemical facilities in Louisiana.

As in other regions of this country, water consumption is a sensitive topic. The phosphate industry is obviously a large water user, but, in fact, it is not a large water consumer. The industry ranks third in the Southwest Florida Water Management District in water consumption, behind agriculture and municipalities. The industry has made major strides in water conservation. In 1970, 238 million gal/day (10.427 m^3/s) were used to produce 24 million tons (22.7 Mt) of phosphate rock. In 1980, 153 million gal/day (6.703 m^3/s) were needed to produce 43 million tons (39 Mt) (Anon., 1983).

Ft. Green uses about 100,000 gpm (6.39 m^3/s) of water. Between 90 to 95% is recovered and reused. The small amount of fresh water consumed is used in the second portion of the flotation process and for potable purposes.

Feed sizing follows the washing stage and includes desliming and classifying the feed into appropriate sizes for separation by flotation. The –14 mesh (–1.2 mm) material (sand, sand-sized phosphate, and clay) is processed through two stages of hydrocyclones to deslime the material. The size of separation is a nominal 150 mesh (0.1 mm). The waste clay (3 to 5% solids) is collected and pumped to large above-ground disposal areas called "ponds." The clays in the Florida phosphate matrix are montmorillonite and palygorskite, which have an average particle diameter of 1 µm and poor dewatering characteristics.

The –14 to +150 mesh (–1.2 to +0.01 mm) material is sized into three fractions: –14 to +20 mesh (–1.2 to +0.75 mm), –20 to +35 mesh (–0.75 to +0.45 mm), and –35 to +150 mesh (–0.45 to +0.01 mm). This sizing is achieved with a combination of hydraulic classification and screens. At Ft. Green, the twice-deslimed material is called "unsized" feed. It is processed through parallel hydrosizers that make a split at 35 mesh (0.45 mm). The hydrosizers achieve that separation with a combination of elutriation and hindered settling. The –35 mesh (–0.45 mm) portion is put through yet another stage of desliming and becomes the "fine feed." The +35 mesh (+0.45 mm) fraction is fed to vibrating screens that size at 20 mesh (0.75 mm). The oversize from these screens is called "I.P. feed." The fine fraction (–20 to +35 mesh or –0.75 mm to +0.45 mm) is "coarse feed". The processing of the coarsest of these fractions (I.P.) is an area of difference in most Florida phosphate beneficiation operations. Some will upgrade it using a fatty acid flotation step and spiral classifiers or belts. Others will basically ignore it and back-blend it with the pebble product. Agrico passes it through a single flotation stage using a strong amine in small flotation cells that have been supercharged. Fine sand is removed, and the product is used in the company's own chemical plants.

Separation of the sand-sized phosphate from the silica sand is achieved with a double-float "Crago" process that was developed about four decades ago (Anon., 1986). The process uses a fatty acid rougher flotation step to float the phosphate from the sand. The rougher concentrate is then de-reagentized, and a reverse, or cleaner, step follows that uses amine to float the remaining sand from the phosphate. In this manner, the minor constituents are reagentized and removed. The coarse and fine feeds are treated similarly. Prior to rougher conditioning, the pulp is deslimed again to remove residual –150 mesh (–0.1 mm) clays, and dewatered to 70 to 75% solids (by weight). The pH is adjusted to about 9.0 with ammonia. A mixture of fatty acid and fuel oil is added in the conditioners to facilitate separation. Fine flotation is completed in 500-ft^3 (14.2-m^3) Wemco flotation cells, retrofitted with operating mechanism from 1000-ft^3 (28.3-m^3) cells. Coarse flotation occurs in 300-ft^3 (8.5-m^3) Wemco units fitted with 500-ft^3 (14.2-m^3) mechanisms. The rougher concentrate from both fine and coarse feeds is combined, dewatered to +70% solids, and scrubbed with a small amount of sulfuric acid to de-reagentize the pulp. It is then rinsed to wash away the spent reagents and any clays that may have been generated. The pulp is conditioned with an amine, and most of the remaining silica is removed in a cleaner stage, conducted in 300-ft^3 (8.5-m^3) Wemco cells. Final concentrate acid insoluble levels (primarily silica) typically are 4.0 to 5.0%.

WASTE DISPOSAL. Flotation tailings are pumped to a mined-out area according to reclamation plans. Tailings pipelines are high-density plastic. Deposition of the sand tailings in the voids between the overburden spoil piles is the initial phase of reclamation. The water is recovered and added to the recycle system.

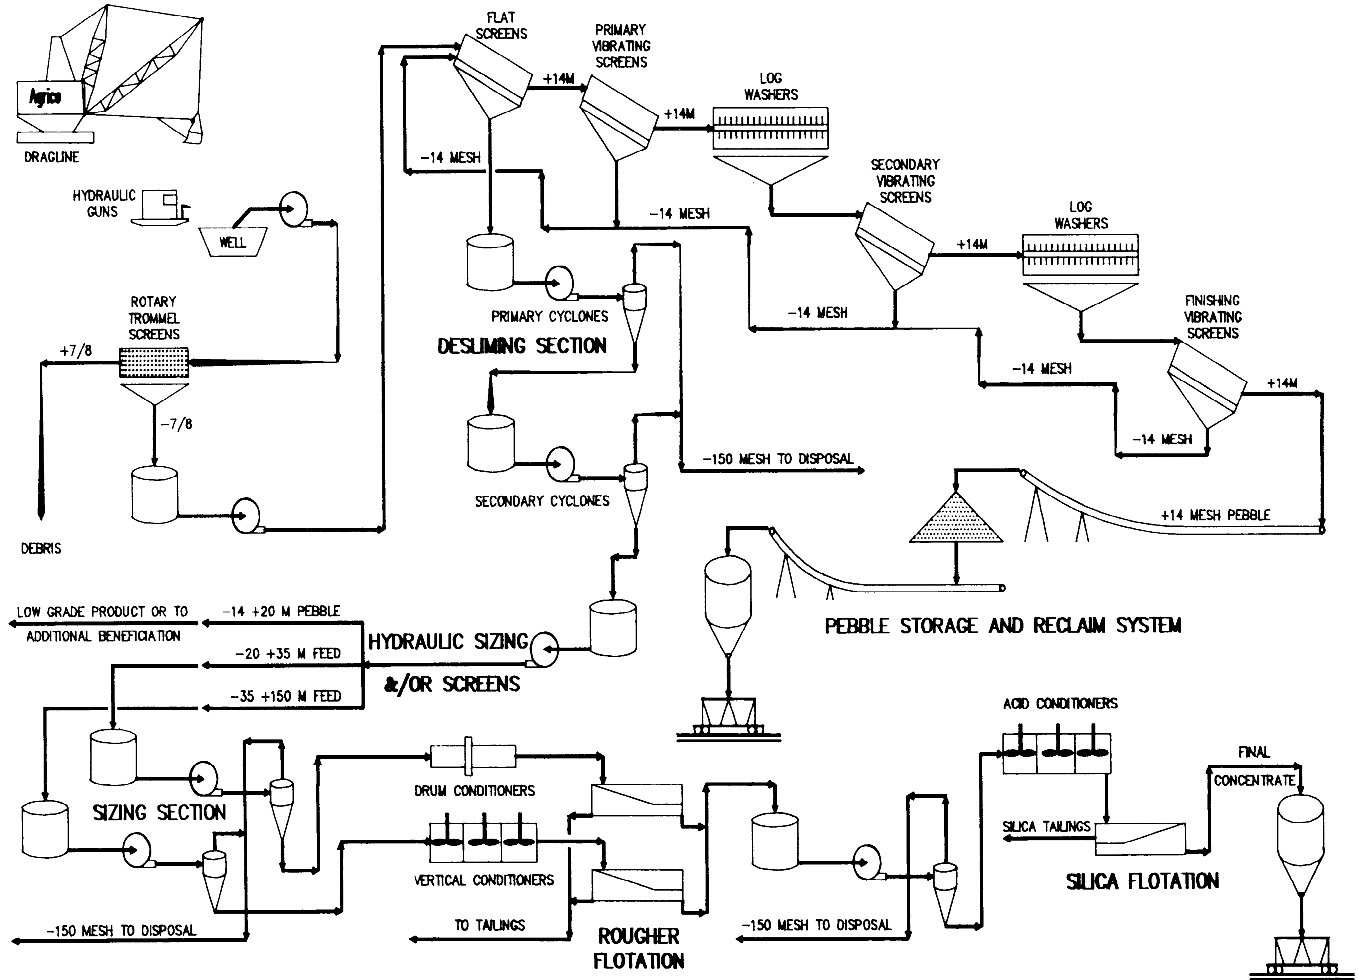

Fig. 14.3.8.5. Mining and beneficiation flowsheet.

The clay fraction is pumped to aboveground disposal areas that have been constructed on mined lands. The clay "ponds" are often 1 mile^2 (2.6 km^2) in size and can be 25 ft (7.6 m) to the crest. These impoundment areas are designed by specially trained soils engineers and are inspected by professionals on a regular basis. They are typically constructed adjacent to one another to permit "flow-through" from one to the next. This construction maximizes clay deposition, minimizes cost, and simplifies water recovery. These clay ponds act not only as clay disposal areas but are used in the management of the recycle water.

Chapter 14.4
AUGER MINING

M.K. MCCARTER AND HAROLD M. SMOLNIKAR

14.4.0 CONTINUOUS SURFACE MINING WITH AUGERS

M.K. MCCARTER

Auger mining refers to a method for recovering coal from thin seams, 2 to 8 ft (0.6 to 2.4 m) thick, beyond a highwall produced by conventional open cast or strip mining (area mining or contour mining), or from seams accessed by deep trenches. Coal is produced by boring openings into the seam beneath the overburden. It is used primarily where conventional surface or underground methods are not economically or technically feasible. Often this is the only means available for recovering coal that would otherwise be lost (Treuhaft, 1984).

The first augers were placed in service in 1945 in the bituminous coal fields of West Virginia. The earliest augers were adaptations of horizontal rock drills, which were used to produce holes measuring 6 to 9 in. (150 to 220 mm) in diameter (Anon., 1975).

An auger typically consists of three components: (1) cutterhead, (2) auger flight(s), and (3) prime mover. They are mechanically connected and function as an integral power train. The cutterhead is a barrel-shaped device that cuts and fractures the coal. The auger flight is a spiral wound about a drill stem, forming a screw conveyor that serves to transport the coal to the surface. In the case of a single auger, the coal fragments, confined by the sides of the hole, are forced towards the open end of the hole by the turning action of the drill stem.

The cutterhead often consists of more than one bit assembly. Single heads range in diameter from 1.5 to 8 ft (0.5 to 2.5 m), double heads from 1.5 to 3 ft (0.5 to 0.9 m), and triple heads from 1.5 to 3 ft (0.5 to 0.6 m) (Hartman, 1987). The multiple heads cut overlapping patterns, producing an elongated cross section with less coal left at the web. If two cutterheads are employed, each turns in opposite directions forcing the coal towards the center of the flight. This counterrotation stabilizes the assembly and assists boring of straighter holes with less out-of-seam deviation.

The prime mover is usually skid mounted or pad mounted. It is able to traverse uneven train and employs jack-legs to level the carriage. The carriage provides a mounting for the engine, drive head, and controls. The carriage is able to move towards the face in the driving mode and can retreat far enough to insert another flight to extend the hole to greater depth. Individual flights are stored in racks and are handled by hoists attached to the frame. As coal arrives at the surface, it is elevated by conveyor or front-end loader and deposited in waiting trucks.

Recent evolution of the auger has resulted in the thin seam miner (TSM), a form of surface continuous miner. This equipment incorporates a cutterdrum that cuts a rectangular hole 8 ft (2.4 m) wide and up to 5 ft (1.5 m) high. Power to drive the cutterdrum is supplied by hydraulic hoses rather than auger flights. The entire assembly is forced into the coal seam by push beams and rigid box sections which contain a screw conveyor to bring the coal to the surface. The cutterdrum is also equipped with sensors which allow detection of the bottom and the top of the seam.

The mining cycle for the TSM is automated and consists of a sump cut at the base of the seam. The cutterdrum then pivots upward, shearing the coal until it approaches the top of the seam. The cutterdrum is then advanced forward for another cycle. Ten cycles are completed before another 20-ft (6-m) push beam is added. Ten push beams can be used, providing a total depth of 240 ft (73 m). The length of the mining cycle is about three hours (2.5 hr mining, 0.5 hr retracting). Production can be as high as 300 tph (272 t/h) (Chironis, 1984).

At present, auger mining is most commonly practiced in the hilly coal country of Appalachia, primarily Kentucky and West Virginia. This area typically has steep slopes where the overburden increases rapidly and thin seams are common. This method, however, is now being considered for recovering additional reserves at the final highwall of large western mines employing conventional area mining. Future application may also include seam outcrops in rugged terrain where high stripping ratios or environmental concerns would make conventional surface mining unacceptable (Hartman, 1987).

Reserves amenable to augering in the United States have been estimated at about 24 billion tons (22 billion t) for augering depths up to 200 ft (60 m) and about 100 billion tons (90 billion t) for extended depth techniques to 600 ft (180 m) (Hartman, 1987). Optimum recovery will require reducing the amount of top or bottom coal left in place by matching cutterheads to the seam thickness. Techniques will also be needed to reduce or eliminate web (pillar) thickness between holes and to extend augering depth beyond conventional practice.

Web thickness is commonly about 1 ft (0.3 m) for a 2-ft (0.6-m) diameter hole. This spacing results in a 64% loss in coal recovery compared to leaving no web. The loss can be reduced by using corner reamers or expandable backreamers to produce a more nearly square hole (Chironis, 1985). When these devices are used, the web is weakened and provides less support for the highwall. It is a common practice to retract backreamers as the cutting action approaches the surface to provide more support at the immediate highwall. This results in greater stability of the highwall and less likelihood of sloughing or “raveling,” which would endanger personnel and equipment working at the base of the slope.

Development of an augering operation is relatively straightforward. Initial development drilling and experience derived through conventional mining is usually sufficient for establishing the continuity of the seam. Continuity, uniform seam thickness, and near-horizontal orientation (less than 10°) are essential for this technique. Once the continuity is established, the face is prepared by grooming the highwall to remove loose rocks and other hazards which would compromise the safety of operations. The pit floor is then leveled and cleaned to facilitate alignment of the prime mover and auger flights. A roadway parallel to the highwall is also needed for access, beltways, and/or truck transportation of the product. Generally, a clear area 50 to 75 ft (15 to 25 m) wide is all that is needed for efficient operation (Hartman, 1987).

Ohio and Kentucky mining regulations require specific procedures for reclaiming land mined by augers. In Ohio, holes are to be sealed with clay or other impervious material and covered

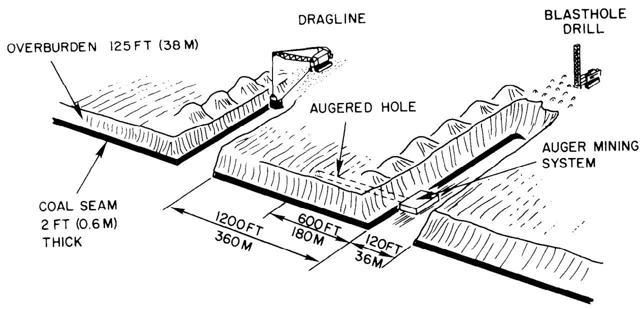

Fig. 14.4.0.1. Auger hole patterns and effect of highwall curvature (Treuhaft, 1984).

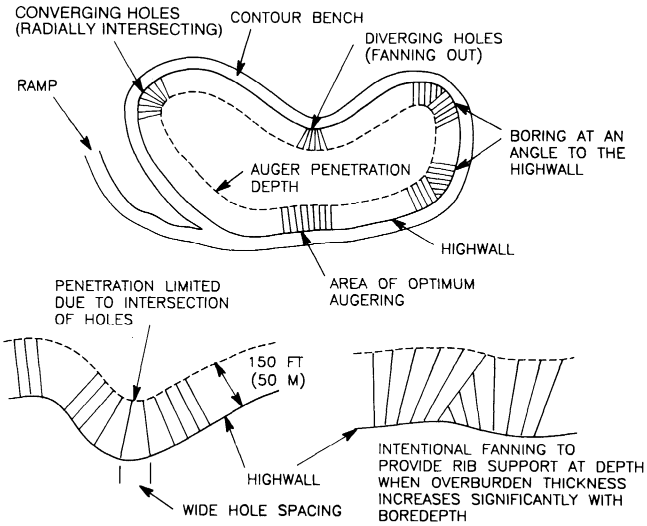

Fig. 14.4.0.2. Trench-strip mining with the extended depth highwall mining system (Treuhaft, 1984).

within 48 hours after removing the auger. In Kentucky, the highwall must be reduced to no more than 45°, and backfilling and grading must be completed within 15 days of augering (Anon., 1975). In addition, Kentucky requires that bench width on steep mountain slopes be no wider than 35 ft (11 m) (Anon., 1974).

Operations are usually low cost and highly productive, averaging 25 to 500 tons (22 to 450 t)/employee-shift. The size of the crew can be as few as three or four individuals producing 100 to 2500 tons (90 to 2200 t)/shift. Coal recovery, however, may be as low as 40 to 60% (Reilly, 1968).

Recovery can be further compromised by the shape of the highwall. If the holes are spaced far apart, coal will be lost between the holes. If they are close together, the ribs may be too thin to support the overburden. Maximum recovery is achieved with straight highwalls while inside and outside curves require fanning of the holes resulting in sterilization of reserves between holes. Clearly, careful mine planning is needed to optimize the shape of the final highwall before augering begins, and appropriate patterns for the auger holes are required to provide maximum resource recovery. Fig. 14.4.0.1 illustrates the effect of highwall curvature on the spacing of holes and strategy for various hole patterns.

A method which may be applicable in relatively flat topography and deep seams is referred to as trench-strip auger mining (Treuhaft, 1984). This concept requires excavation of a series of parallel trenches as shown in Fig. 14.4.0.2. The coal between the trenches can then be removed with augers working at right angles to the trench. The straight configuration of the highwall should maximize recovery and minimize the surface area requiring reclamation. It is estimated that less than 10% of the mined land will be disturbed if this method is employed, but the amount of waste to be handled will be reduced only by about 50% compared to conventional area mining. At this time, the method has not been proven but may become attractive as extended depth augering is perfected and demand requires exploitation of deeper reserves in more environmentally sensitive areas.

Auger mining can be implemented with relatively low capital investments, it is safer than underground mining, and more tons per employee-day can be produced than for either surface or underground methods. Productivity decreases as the depth of auger hole increases. Augered coal often contains less ash than surface-mined coal from the same seam. However, once the cutterhead enters the seam, the operator is not able to observe the cutting action and must rely on the "feel" of the machine to sense problems at depth. Because of this, augering is a highly specialized skill, and experience is essential for successful operation.

Reclamation laws are having an impact on the application of auger mining. The requirement to immediately cover exposed highwalls encourages abandonment of reserves beyond the current economic limit of conventional mining if auger or TSMs are not immediately available. The requirement to restore highwalls to the approximate original topography has also made contour mining less attractive; consequently, fewer sites are available for augering. In addition, it is easier to obtain a variance from the approximate contour requirement if the entire mountain top is removed. In the mountainous areas of Appalachia, this method is preferred, especially if the resulting flat area can be used for agricultural, industrial, commercial, residential, or recreational purposes. As a result, few new augers have been built recently, and the trend is to lease older units as the need arises (Chironis, 1985).

The description of auger mining presented in Chapter 14.4.1, describes current operations at the Winifrede mine.

14.4.1 SURFACE CONTINUOUS MINING, HORIZONTAL COAL SEAMS: WINIFREDE MINE

HAROLD M. SMOLNIKAR

14.4.1.1 Mine Description

Arch of Kentucky's Winifrede mine is located in Harlan and Letcher Counties, approximately one mile (1.6 km) north of the city of Lynch, KY. The mine lies within a 40,000-acre (162-km^2) tract, formerly owned by US Steel Corp. The bed being auger mined is named the Winifrede Seam. Extensive underground mining has taken place in the seam, and considerable surface contour mining was performed prior to enactment of the Surface Mining and Reclamation Control Act of 1978. Approximately 70,000 ft (21,340 m) of old highwall were available for augering, with an estimated in-place reserve of over 1,200,000 tons (1,090,000 t).

The annual production is 110,000 tons/year (99,790 tpy) of coal. The mine is scheduled to run 1 shift/day, 220 days/year at a production rate of 5090 tons/shift (4618 t/shift).

14.4.1.2 Deposit Description and Geology

The Benham and Appalachia USGS Geologic Quadrangle Map identifies the Winifrede Seam as being in the Hignite Formation of the Pennsylvanian Breathitt Group. The overall dip of the bed is about 1° to the southeast, but locally there are small rolls and folds that make local dips highly variable. The seam

Fig. 14.4.1.1. Typical sediment control structure on an auger bench.

elevation ranges from 2640 to 2907 ft (805 to 886 m) AMSL. The maximum topographic elevation in the area being mined is approximately 3600 ft (1097 m) AMSL. The area is typical of the Appalachian Mountain Region with steep, high, densely timbered ridges and narrow meandering valleys.

The seam thickness ranges from 43 to 70 in. (1092 to 1778 mm). The coal is classified as high-volatile A bituminous. The quality attributes of the coal are as follows: 13,000 BTU/lb (30,238 kJ/kg), 7.0% ash, 0.9% sulfur, and 6.0% moisture. The Hargrove Grindability Index is 53. There are 500,000 tons (453,590 t) of coal recoverable from the seam by auger mining.

The predominant highwall material is a hard, massive, gray sandstone. In some areas, the overburden immediately over the coal is a gray calcareous shale about 2 ft (0.6 m) thick. Where this is absent, the immediate roof material is sandstone. The floor material of the Winifrede Seam is a dark gray, fissile shale that grades into a siltstone and, finally, a fine-grained sandstone.

14.4.1.3 Mine Development

The initial preparation work for augering the Winifrede Seam consists of cleaning a few hundred feet (meters) of the old bench at a time, grading the haul road to an acceptable condition, and constructing sediment control structures. The cleanup of spoil material on the old bench is required to obtain sufficient bench width for operating room, and to remove any loose overburden that had previously been pushed over the seam. The preferred minimum bench width is 50 ft (15 m), with 42 ft (13 m) being an absolute minimum. Sediment control ponds, berms on the outside of the old bench, and ditches must be constructed prior to mining to catch any surface run-off from the auger area.

The sediment control ponds are built on the outside edge of the bench so that any clarified water overflow can be diverted down the slope of the mountain. Shallow ditches are constructed on the inside of the haul road as required to convey any surface water to the ponds. Culverts measuring 12 in. (305 mm) in diameter are placed wherever necessary to carry water under the haul road to the ponds. Fig. 14.4.1.1 shows a typical sediment control structure on the auger bench.

The loose spoil material cleaned up during the development work is either stockpiled along the outer edge of the bench, if there is room, or it is hauled to a wider bench area for storage. A D-7 bulldozer is used to clean the coal face, and a Caterpillar 988 front-end loader (FEL) hauls the material to the edge of the bench or loads it into a 35-ton Cat 769 haul truck.

Fig. 14.4.1.2. Coal auger.

After a few hundred feet (meters) of bench have been cleaned and properly developed, the auger is hauled to the site, assembled, and initially maneuvered into location by the bulldozer. When positioned approximately 5 ft (1.5 m) from and perpendicular to the highwall, the auger is ready to begin operating. Fig. 14.4.1.2 shows the auger set up and ready for operation.

Table 14.4.1.1. Specifications for Coal Auger

Front highwall guards	None	
Carriage overhang	29.5 ft	(9.0 m)
Operating length—Minimum	31.0 ft	(9.4 m)
Maximum	16.3 ft	(5.0 m)
Width (less auger racks, pan, conveyor, and skids)	18.0 ft	(5.5 m)
Width (overall)	31.5 ft	(9.6 m)
Height (with stiff-leg lowered)	16.3 ft	(5.0 m)
Height (with hoist removed)	11.3 ft	(3.4 m)
Auger length	12.0 ft	(3.7 m)
Auger diameters (dual MCD)	18-30 in.	(457–762 mm)
Primary power (maximum hp @2000 rpm)	510 hp	(380 kW)
Auxiliary power (maximum brake hp 2200 rpm)	200 hp	(149 kW)
Carriage thrust—push	32,500 lb	(144,560 N)
pull	15,900 lb	(70,723 N)
Distance between bottom of auger and bottom of skid	5 in.	(127 mm)
Leveling jacks—attached to skids	4-ft lift	(1.2-m lift)
Auger guide extension	30 in	(762 mm)
Skid cylinder stroke (maximum lateral movement/stroke)	7 ft	(2.1 m)
Estimate weight of machine (less augers and cutterheads)	112,000 lb	(498,176 N)

Notes: Gear train—combination 3-speed transmission (2 forward, 1 reverse) divider box driving adjustable swing type drop boxes for all auger sizes (single, dual, or tri-head) 18 in. (457 mm) and larger. Stiff-legged Mul-T-Action hoist handles one, two or three augers at once. Pendant control. Pan conveyor attached. Easily adaptable to discharge from either side.

14.4.1.4 Operations

AUGERING. Two Salem augers with different sized cutterheads and auger flights are used intermittently, depending on seam height and quality problems. One machine has a dual 22-in. (559-mm) cutterhead; the other has a dual 27-in. (686-mm) cutterhead. Each machine is equipped identically, except for the size of cutting equipment. Table 14.4.1.1 contains a list of the basic machine specifications.

A three-man crew operates the auger. One man controls the auger position along the highwall and the auger advance or retrieval in the seam. The second man is responsible for handling of the auger flights. A third man, a mechanic, is available as needed to provide fuel, lubrication, and maintenance.

Vertical control of the auger is accomplished through the use of four hydraulic jacks, one located at each corner of the machine on the main frame. The machine is raised to position, with the cutterhead approximately 6 in. (152 mm) below the top of the zone to be mined. Usually, this is 6 in. (152 mm) below the top of the seam. Care is taken to differentially level the machine to try to parallel the plane of the coal seam in order to avoid out-of-seam dilution. The dual cutterhead consists of the cutting unit, which is equipped with tungsten carbide-tipped bits, and the auger scroll to convey the coal away. The auger scroll is banded to minimize deflection of the steel. Raker bits between cutterheads cut the interior rib left between the rotating heads. Counter rotation of the individual auger tool strings assists in minimizing hole deflection. Rotation of the auger flights drags the coal out of the hole to an elevated chain stacking conveyor.

The auger is advanced into the coal by a combination of cutting action by the cutterhead and forward thrust by the hydraulically-powered thrust ram. When the 12-ft (3.7-m) flight section is completely advanced, the hydraulic push ram is disengaged and pulled back. Then another pair of auger flights is inserted, locking pins are hydraulically activated, and augering resumes again. Insertion of auger flights is completely mechanized, with one man using an overhead-mounted hoist to grip, lift, and spot two 12-ft (3.7-m) auger flights simultaneously. The rigid hoist mechanism has tongs that clamp each auger flight at each end, allowing exact positioning of the flights. This cycle of auger boring, advance, and insertion of auger flights continues until the auger reaches its maximum depth, encounters old mine workings, or cuts into the roof or floor resulting in excessive out-of-seam dilution. At this point, retrieval of the string of auger flights commences.

On retrieval of the stem of auger flights, the auger operator pulls the auger sections back and actuates a hydraulic uncoupler to unlock a set of flights from the tool string still in the hole. The pair of 12-ft (3.7-m) long flights are then picked up by the overhead hoist and stacked on a rack located on each side of the machine.

Upon retrieval of all auger flights from the hole, the operator engages the hydraulic jacks located on the corners of the machine to lower the machine into proper position for augering a second pair of holes. After proper leveling is completed, the augering cycle is repeated. After the upper and lower pair of auger holes are finished and all the steel withdrawn from the holes, the operator lowers the machine and prepares to move the auger parallel to the highwall to the next augering location.

Movement to the next location is achieved by activation of the hydraulically powered moving skid. Under each pair of leveling jacks, there is a moving skid operated by a double-acting hydraulic cylinder. When the leveling jacks are extended, the moving skid is advanced in the intended direction of travel. The leveling jacks are then retracted with the machine coming to rest on the moving skid; it is then hydraulically advanced on the skid. The maximum lateral machine movement per cylinder stroke is 7 ft (2.1 m). The machine is thus repositioned on the highwall so that a pillar or “web” of coal 6 to 12 in. (152 to 304 mm) wide is left between sets of holes. Fig. 14.4.1.3 shows the hole configuration and remnant web or coal pillar.

Fig. 14.4.1.3. Hole configuration and remnant web.

The maximum penetration the machine is capable of achieving is 150 ft (46 m). The average penetration experienced is 120 ft (37 m). The most common problem causing a set of auger holes to fall short of the maximum depth is augering into the roof or floor. This is generally caused by improper machine leveling, the coal rolling, or drifting of the auger flights. The average production rate achieved is 490 tons/shift (445 t/shift).

GROUND CONTROL. The pillar size or web between the auger holes varies throughout the operation and is largely determined by the judgment of the auger operator. The factors taken into consideration by the operator when determining the width of pillar are the following.

Change in Seam Thickness—As the seam thickens, the pillar height increases and subsequent life decreases unless pillar width is increased.

Increase in Overburden—The higher the highwall, the thicker the pillar must be.

Fractures or Jointing in the Highwall—If these features are noticeable in the highwall, the operator may try to change the angle of augering to allow the auger to penetrate in a perpendicular direction to the features, or if conditions are hazardous, he may choose to skip the area entirely. If the highwall is not fractured but the coal is, the operator may increase the width of pillars.

Soft Floor—The problem of a weak floor can result in pillars "punching" into the floor. This causes a redistribution of pressure along the highwall and into the augering area. Failure of the highwall or trapping of the auger flights can result from this pressure redistribution. By increasing pillar width, the time until failure occurs can be increased to allow for the safe recovery of coal.

Intersecting Underground Works—The intersecting of old works results in loss of support or abutment pillars to support the highwall or old mine entries. The result can be highwall failure or a trapped auger. It should be noted that whenever the auger removes coal in areas that are less than 50 ft (15 m) from old underground mine works, there is an increased incidence of highwall failure. This mandates an increase in web thickness.

Intersection of Auger Holes—This results in a reduction in size of the supporting pillar and may cause failure of the highwall. This most frequently occurs when working on a point at the end of a ridge.

HAULAGE. The coal discharged from the auger holes is dropped onto a short chain conveyor on the auger machine. This chain conveyor discharges the coal onto an elevating chain stacking conveyor that drops the coal onto a stockpile next to the auger machine. The coal is loaded from the stockpile with a Cat 988 FEL into dual-axle coal haul trucks with modified beds that accommodate 38 tons (34.4 t). Two trucks are normally required to haul the coal to the stockpile. Occasionally, the haul distance requires the addition of a third truck.

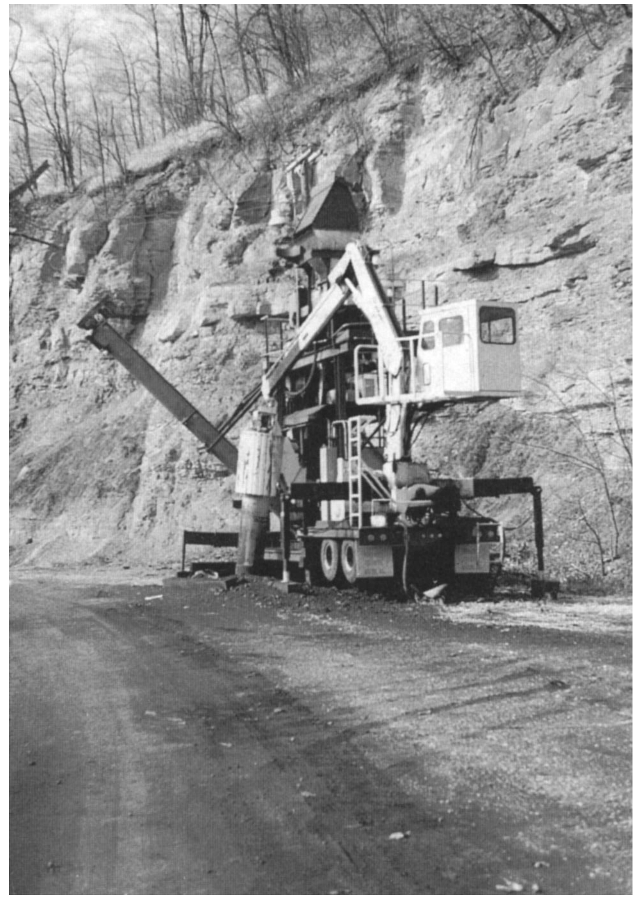

Fig. 14.4.1.4. Truck sampler.

The auger coal is pushed onto a stockpile that has a capacity of 12,000 tons (10,900 t). When coal is withdrawn from the stockpile, it is pushed by a dozer to a chute that discharges onto a belt measuring 42 in. (1067 mm) wide. This belt transports the coal approximately 120 ft (37 m) to a hammer crusher, which crushes the coal to a maximum size of 2 in. (50 mm). The crushed coal is discharged onto another 42-in. (1067-mm) belt that carries it to a 1000-ton (907-t) surge bin. The coal is then conveyed to a 500-ton (454-t) surge bin on top of a 5-ft (1.5-m) diameter, 740-ft (226-m) vertical borehole. The coal drops through the borehole to an old mine entry where a vibratory feeder meters the coal onto a 36-in. (914-mm) conveyor. The coal is then transported to a 2000-ton (1814-t) silo. From there, the coal is transported by a 60-in. (1524-mm) conveyor to the Lynch No. 1 loadout, where it is loaded into rail cars.

PRODUCT CONTROL. When haulage trucks arrive at the stockpile area on the Winifrede bench, each load is sampled by a truck sampler. The coal samples are analyzed daily by a commercial laboratory. If any problems are encountered, the augering method can be changed immediately. Fig. 14.4.1.4 is a photograph of the truck sampler.

14.4.1.5 Reclamation

Initial reclamation during auger mining has to be kept within 1500 ft (457 m) of the auger's location. The initial reclamation consists of covering the coal outcrop with a minimum of 4 ft (1.2 m) of spoil material, which must be non-combustible, non-acid forming, and non-toxic. Any permanent roads, ditches, or ponds also are graded to final configuration. The backfill material is graded to a 2:1 slope, and soil samples are taken to determine what amounts, if any, of fertilizer are required to support plant growth.

Seeding can be conducted in either the fall or the spring. Spring, however, is the preferred planting time. A fertilizer and grass seed mixture are hydroseeded with a wood-cellulose mulch material. The seed mixture used is 25 lb/acre (2800 kg/ km^2) Kentucky 31 Fescue, 20 lb/acre (2200 kg/km^2) of Perennial Rye, and 10 lb/acre (1100 kg/km^2) of Bermuda Grass. Fig. 14.4.1.5 illustrates a typical "pre-law" reclaimed auger bench.

After initial regrading and revegetation are completed, the areas are monitored for erosion and vegetation growth. In the event that erosion results in rills and gullies deeper than 9 in. (229 mm), the areas must be filled, regraded, and replanted.

After an area has been regraded and revegetated according to the mining permit, the area is inspected by the regulatory agency. If the area is approved, a partial bond release on the regrading can be requested. Bond money for revegetation is held for five years to ensure that good vegetative growth has been achieved.

Fig. 14.4.1.5. Typical reclaimed auger bench.

Chapter 15.2
SOLUTION MINING: SURFACE TECHNIQUES

W.J. SCHLITT

15.2.1 INTRODUCTION

Although commonly referred to as a type of solution mining, *surface leaching* techniques are really hydrometallurgical recovery operations practiced at the mine. The basis for this statement is the fact that these leaching systems must be used in conjunction with conventional open pit or underground mining operations. Mining provides the ore feed. This broken material is then leached in either run-of-mine or crushed form to extract the values. Surface solution mining practices thus represent alternatives to conventional ore beneficiation.

This is in sharp contrast to in situ operations that represent a true mining technique. Note that *in situ leaching* removes values from in-place deposits that are essentially undisturbed by conventional mining technology. Thus in situ leaching is an alternative to mechanical mining operations, while surface leaching is an adjunct to them. As a result of this distinction, in situ leaching is applicable to a wider variety of resources, including soluble salt and sulfur deposits, as well as hard-rock ores, such as those of copper and uranium. On the other hand, surface leaching systems have only been applied to hard-rock ores, mainly copper and gold/silver, and to a lesser extent, uranium.

Another distinction between the in situ and surface techniques lies in the relative importance that each has to the overall operation. In virtually all cases, in situ leaching is the *primary method of production.* However, surface leaching may be either the primary production option or only a *secondary,* or supplemental, *form of production.* A good example of the primary option is the mine-heap leach type of operation that has become so popular in the gold industry.

Adjunct or secondary leaching operations are most prevalent in the copper industry. Here total exploitation of the resource requires that leaching be applied to low-grade materials that must be mined in order to expose the mill-grade ore. In these cases, leaching will provide some additional production that would not be achieved otherwise. Such supplemental production often has a low incremental cost so that it lowers the overall average cost of production.

The wide variations in ore deposits make leaching a rather site-specific endeavor. To be successful, a *heap* or *dump leach* operation must satisfy two general sets of criteria. One relates to the characteristics of the ore or waste to be leached. The other involves the establishment of effective operating practices.

Clearly, first consideration must be given to the characteristics of the deposit and the leach material itself. These parameters include the location of the ore body, the extent of the mineral inventory, the mineralogy and mode of occurrence of the metal values, and the chemical and physical nature of the host rock. Obviously, nature must provide a sufficient tonnage of material with adequate recoverable values per ton. Otherwise, the leach project will never reach the point where operating practices are of any consequence. For a proposed operation, the same type of exploration and development program will be required as for any other mining project. These programs are covered elsewhere in this *Handbook.* The difference is that the metallurgical testing will be directed toward leaching instead of ore comminution and beneficiation.

The remaining portions of this chapter deal with the establishment of effective surface leaching operations. The first is a rather fundamental segment that covers ore–lixiviant systems. This is followed by two more practical parts dealing with materials handling and solution management. Next are two short segments that address commodity recovery systems and ancillary and infrastructure requirements. The final segment includes two case studies, one for copper and one for gold.

15.2.2 ORE LIXIVIANT SYSTEMS

The first consideration in any proposed leaching operation is the selection of the *lixiviant.* If a suitable lixiviant cannot be identified, then the project is not viable and no further effort need be expended on it. Ideally, the lixiviant should be highly selective and should attack the value(s) rapidly and completely. The chemical kinetics should be so fast that diffusion to or from the mineral surface is always the rate-controlling step in the process. Various actions can then be taken to enhance diffusion. Other characteristics of the ideal lixiviant include a low price, low toxicity, ease of handling, and a capacity for regeneration or recycling. The lixiviant should allow for ready recovery of the value(s) in concentrated form or even in the refined state.

Unfortunately, ideal lixiviants do not exist; practical considerations then dictate that the lixiviant be fast and selective in solubilizing the values. In addition, the cost should be low, net of any credits for recycling or regeneration of the reagents. Then the necessary environmental controls and handling and recovery systems can be designed to suit the operation.

There are a surprisingly small number of practical lixiviants for the metal values recovered in heap and dump leach operations These are reviewed in the following.

15.2.2.1 Gold/Silver

An alkaline sodium cyanide solution is virtually the only commercial lixiviant presently used in gold/silver heap leach operations. Studies on the mechanism of dissolution indicate that there are two reactions involved in gold dissolution (Dorey et al., 1988). Most of the gold dissolves according to the reaction,

$$2\ Au + 4\ CN^- + O_2 + 2\ H_2O \rightarrow 2\ Au(CN)_2^- + H_2O_2 + 2\ OH^- \qquad (15.2.1)$$

However, a small but still significant portion of the gold dissolves according to the Elsner's reaction:

$$4\ Au + 8\ CN^- + O_2 + H_2O \rightarrow 4\ Au(CN)_2^- + 4\ OH^- \qquad (15.2.2)$$

In both cases, the balancing cation is sodium, and oxygen is required. For any given ore, the gold dissolution rate is dependent on the cyanide concentration, the oxygen content, and the alkalinity of the solution. The optimum pH is about 10.3 (Dorey et al., 1988), but many operators tend to run at a somewhat higher value as a margin of safety. Since most ores are not so basic, an alkaline reagent must also be added to the system to raise the pH. This is generally done by blending lime (CaO) with the ore, or adding milk of lime [(Ca $(OH)_2$] or caustic (NaOH) to the solution.

In theory, there is nothing to prevent dissolution of virtually all of the gold in a heap or dump. In actual operations, extraction seldom exceeds 85%, and recoveries as low as 40 to 50% are not unheard of. The problem is accessibility of the gold values to the lixiviant. This can be caused by poor heap construction, which leaves portions of the ore blinded off. As a result, solutions do not wet the entire rock mass. Another cause is gold encapsulated in silica or locked in another refractory mineral such as pyrite or arsenopyrite. The processing of these so-called refractory ores is an area of technology that is undergoing significant development at the time of this writing. This is due to gradual exhaustion of accessible oxidized ores that are easily processed.

Although commonly extracted along with the gold, silver is not recovered as effectively. The dissolution reactions with cyanide are analogous, but there is not as great a chemical driving force involved. In addition, silver is much less noble than gold and tends to associate with various refractory minerals, in addition to pyrite and arsenopyrite.

Particularly troublesome are the manganiferrous silver ores that are virtually insoluble in cyanide. These ores can be processed in two stages. The first involves an aqueous sulfur dioxide leach to break down the manganese structure by converting it to soluble manganese sulfate. This liberates the silver so that it can be extracted in a cyanide leach. Unfortunately, the first step is actually a sulfurous acid leach that would necessitate a thorough neutralizing wash step prior to cyanidation. Hence, little silver has even been recovered from such ores.

A number of other precious metal lixiviants have been investigated as alternatives to sodium cyanide. The impetus is to find a lixiviant that overcomes some of the problems inherent with cyanide. These include the following:

1. High potential toxicity.
2. Environmental concerns such as aquifer contamination.
3. Relatively slow kinetics for dissolution of both gold and silver.
4. Generally poor extraction of silver.
5. Requirement for alkaline reagents when leaching acidic ores.
6. High reagent consumption due to poor selectivity when leaching complex ores containing various base metals. Particularly troublesome is copper, which often leaches well as it forms a highly soluble cyanide complex. In addition, the copper usually reports with average gold and silver as they are stripped from the leach solution. The presence of copper then complicates the final parting and refining of the precious metals.

Some progress has been made on alternatives to a straightforward cyanide leach. However, success has been largely confined to the treatment of high-grade ores and concentrates, rather than the low-grade materials likely to be leached in heap or dumps. One of these routes involves the extraction of silver using a brine leach on the concentrates. Another reagent with more promise is thiourea [$(CS(NH_2)_2$]. Hiskey (1981, 1984) among others has provided comprehensive reviews of this subject, and Charley (1984) has described development of a thiourea process for treating high-grade materials. The chemistry involved in thiourea leaching requires that the gold be oxidized from the free-metal zero state to the +1 oxidation state. In an acid solution, this can be done with an external oxidant like ferric iron or by oxidation of thiourea to produce formamidine disulfide (RSSR) by the reaction,

$$2\ CS(NH_2)_2 \rightarrow RSSR + 2\ H^+ + 2\ e^- \qquad (15.2.3)$$

Thus the overall reaction for gold becomes

$$2\ Au + 2\ CS(NH_2)_2 + RSSR + 2H^+ \rightarrow 2\ Au\ [CS(NH_2)_2]^+_2 \qquad (15.2.4)$$

Silver undergoes analogous reactions, except the final species involves three thiourea molecules: $Ag[CS(NH_2)_2]_3+$.

Care must be taken to avoid too high an oxidation potential in the leach circuit as this will cause irreversible oxidation of RSSR to elemental sulfur. This not only causes loss of reagent but generates sulfur that can coat the mineral surfaces and slow further dissolution.

The continued interest in thiourea leaching is generated by the following factors:

1. Thiourea leaches gold and silver 10 to 12 times faster than cyanide, implying a leach cycle of hours rather than days or months.
2. Thiourea is functional in an acidic rather than an alkaline medium.
3. Thiourea has a better selectivity for gold and silver than cyanide.
4. Thiourea has a lower toxicity than cyanide.

Ferric-sulfate-stabilized thiourea represents a potential improvement over use of thiourea alone for gold leaching. Huyhua et al. (1989) showed that leach times for gold and silver with ferric sulfate as an oxidant were up to four times faster than thiourea alone in air. Thiourea consumption increased only slightly due to the presence of the ferric oxidant; the increased rates and ultimate extractions obtained offset this cost. McInnes et al. (1989) reported the use of thiourea with ferric ion in conjunction with an acid ferric preleach to remove copper from a gold-bearing copper oxide/sulfide ore. This is a compatible system for gold recovery in an acidic, sulfide environment (pH = 1.5) and showed faster leach times than other types of oxidants (H_2O_2,O_2, or air). There is the promise that this approach could provide an acidic gold leaching system to be used with bio-oxidation or other chemical pretreatments in heap leaching ores with sulfides or cyanide consumers.

In spite of these advantages, thiourea has only been used commercially on concentrates and has not yet been applied to low-grade ores in heap or dump leaching. The main problems are high unit costs and consumption of thiourea.

15.2.2.2 Copper

The choice of a lixiviant for copper is dictated by the mineralization to be leached. The oxidized ores, including oxides, silicates, carbonates, hydroxides, and chlorides, can be dissolved effectively with nonoxidizing acids or a base like ammonia that forms soluble copper complexes. However, the unoxidized ores, mainly the various sulfide minerals and native copper, do require an oxidant. The oxidant may be either dissolved oxygen or an ionic species such as ferric iron in a sulfate-based system or ferric or cupric ions in a chloride system. Regardless of the lixiviant, the leach solution must be either acid enough or basic enough to carry copper in solution as copper salts tend to precipitate from near neutral solutions.

Sulfuric acid is the overwhelming choice as the lixiviant for oxide ores. The chemistry involves a straightforward dissolution reaction, such as,

$$CuCO_3Cu(OH)_2 + 2\ H_2SO_4 \rightarrow 2\ CuSO_4 + 3\ H_2O + CO_2 \qquad (15.2.5)$$

for malachite. The advantages of using sulfuric acid include the following:

1. Relatively benign with regard to materials of construction.
2. Compatible with recovery of copper by conventional electrowinning from concentrated sulfuric acid-copper sulfate (electrolyte) solutions.
3. Inexpensive and commonly available as a byproduct from copper smelters that are often nearby.

The only problem with sulfuric acid is that it must be applied in dilute form (pH 1 or higher). This means that heaps must be relatively shallow in order to prevent complete consumption (neutralization) of acid and reprecipitation of copper within the rock mass. Use of high acid strengths in short-term vat or agitation leaches is not a problem and does promote rapid and complete copper dissolution. However, in heaps and dumps, a high acid content would exacerbate acid attack on the gangue constituents. This will raise acid consumption per unit of copper recovered. In addition, the dissolved gangue species such as silica and calcium can lead to serious problems like gypsum precipitation in the copper recovery process. Acid decrepitation of the rock may also generate clays and fines that cause permeability or copper absorption problems during long-term dump or heap leaching operations.

Other mineral acids such as hydrochloric and nitric are more aggressive in terms of copper dissolution and have been proposed for hydrometallurgical treatment of concentrates. However, such acids are not likely to be used on heaps or dumps due to their higher costs and corrosiveness, and to their poorer compatibility with common methods of copper recovery.

The heap or dump leaching of sulfide or mixed oxide-sulfide ores is much more complex than the leaching of oxide ores due to the need for an oxidant. Virtually all operations rely on natural oxidation processes to accomplish the leaching. In such a system, ferric iron is the actual lixiviant for copper. It will attack all the common copper sulfide minerals, including chalcopyrite. However, in a sulfate-based leach solution, chalcopyrite is much more refractory than the secondary minerals such as chalcocite, covelite, or bornite. A typical ferric leach is represented by the reaction with chalcopyrite:

$$4\ Fe^{3+} + CuFeS_2 \rightarrow Cu^{+2} + 5\ Fe^{+2} + 2\ S^{\circ} \qquad (15.2.6)$$

Here the balancing anion is sulfate. Although small amounts of elemental sulfur are detected on partially leached mineral surfaces, there is certainly no elemental sulfur accumulation observed in actual operations. This shows that any elemental sulfur is transitory and is progressively oxidized all the way to sulfate in the presence of bacterial catalysts and oxygen in the air within the rock pile. The overall reaction is

$$S^{\circ} + H_2O + 3/2\ O_2 \rightarrow H_2SO_4 \qquad (15.2.7)$$

The iron that acts as the oxidant is itself derived from the oxidation of pyrite, which is typically three to ten times more abundant than the copper minerals. Pyrite oxidation (Hiskey and Schlitt, 1982) is analogous to chalcopyrite oxidation. However, pyrite oxidation serves to do more than provide iron in solution. It is also the net in situ source of the sulfuric acid needed to maintain a low enough pH to keep the copper and iron in solution. Finally, pyrite oxidation is strongly exothermic and causes the temperature of the rock mass to rise. This enhances the intrinsic copper leach rates. But more importantly, the heat provides the driving force for the convective flow of air through the heap or dump. Thus pyrite oxidation stimulates air convection and provides the oxygen that is ultimate oxidant in the system.

The leaching of sulfide copper is clearly complex and cannot be described in detail here. For this, the interested reader is referred to the papers of Cathles and Apps (1975) and Cathles and Schlitt (1980).

Native copper can be leached in a ferric sulfate solution like the sulfides. However, ammonia leaching also has been used commercially on native copper ores and tailings. According to Chase (1980), the preferred reagent is cupric ammonium carbonate. The reaction requires the presence of excess ammonia; the cupric complex is then regenerated in the presence of oxygen. These reactions are

$$Cu^{\circ} + Cu(NH_3)_4CO_3 \rightarrow Cu_2(NH_3)_4CO_3 \qquad (15.2.8)$$

$$Cu_2(NH_3)_4CO_3 + 1/2\ O_2 + (NH_4)_2CO_3 \rightarrow 2\ Cu(NH_3)_4CO_3 + 3\ H_2O \qquad (15.2.9)$$

Copper can then be recovered by steaming the pregnant leach solution to precipitate the copper as a basic salt while recovering the ammonia. Due to the scarcity of native copper ores, further information is not presented here (but see Chase, 1980, for details).

15.2.2.3 Uranium

Commercial heap or dump leach operations treating primary uranium ores are not common. One example is the Los Gigantes sulfuric acid heap leach operation in Cordoba, Argentina. Byproduct uranium has also been recovered from the copper sulfide dump leaching operation at Bingham Canyon, UT, and the Anamax copper oxide leaching plant in Arizona. However, substantial amounts of uranium are recovered by in situ leaching of sandstone deposits (see 15.3.3 in the following chapter, Solution Mining: In Situ Techniques).

Regardless of the method of leaching, the same lixiviant chemistry is applicable to the uraninite (UO_2) and coffinite [U(SiO$_4$)l-X(OH)$_4$X] ores that are commonly treated. As discussed by Grunig (1981), there is a choice of lixiviants on both the acidic and basic side. In order to minimize reagent losses in solution mining, these lixiviants have been tailored to avoid excessive gangue reactions. Thus a sulfuric acid-ferric sulfate system was developed for sandstone ore and a sodium bicarbonate or ammonium carbonate leach for uraninite in calcerous sandstone. The oxidant in the latter system is either hydrogen peroxide or oxygen dissolved in the leach solution.

In both cases, dissolution requires the oxidation of quadrivalent uranium to the hexavalent state. In dilute sulfuric acid (pH 1.6 to 2.0), uranium is oxidized by ferric ion and goes into solution as the very stable uranyl sulfate complex. Similarly, sodium or ammonium bicarbonate lixiviants form uranyl carbonate. Based on information presented by Merritt (1971), the overall reactions in an acid circuit are

$$UO_2 + Fe_2(SO_4)_3 \rightarrow UO_2SO_4 + 2\ FeSO_4 \qquad (15.2.10)$$

$$UO_2SO_4 + 2H_2SO_4 \rightarrow [UO_2(SO_4)_3]^{4-} + 4H^+ \qquad (15.2.11)$$

and in an alkaline circuit the reactions are

$$2UO_2 + 2H_2O_2 \rightarrow 2UO_3 + 2H_2O \quad (15.2.12)$$

$$UO_3 + Na_2CO_3 + 2NaHCO_3 \rightarrow Na_4UO_2(CO_3)_3 + H_2O \quad (15.2.13)$$

The acid and alkaline circuits are both well-established processes. They have seen extensive commercial applications in both solution mining and conventional mills employing agitation leaching.

15.2.2.4 Other Metal Systems

Potter et a1.(1982) have reviewed the potential for applying solution mining techniques to hard-rock ores containing values other than copper and uranium. In addition to gold and silver, the most likely candidates are aluminum and manganese. Neither has been recovered in commercial leach operations, but the potential is clearly evident.

For example, sulfuric acid leach liquors produced in copper leach operations often contain a higher aluminum content than copper. In fact, some of these solutions may be nearly saturated with soluble aluminum salts. Thus recovery of byproduct aluminum may be possible. In addition, sulfuric acid leaching of rock containing weathered alunite or various aluminum-bearing clays will generate aluminum sulfate solutions. The US Bureau of Mines solvent extraction process could then be used to recover alumina.

As suggested above, low-grade manganese ores would also be susceptible to solution mining. The lixiviant would be aqueous SO_2, which would react with MnO_2 according to the reaction

$$MnO_2 + SO_2\,(aq.) \rightarrow MnSO_4\,(aq.) \quad (15.2.14)$$

Less oxidized forms of manganese would require an oxidant such as dissolved oxygen, hydrogen peroxide, or perhaps ferric sulfate. Tests reported by Potter et al. (1982) suggest pregnant leach solution grades ranging upward of 10 to 12% $MnSO_4$, implying that manganese can be recovered as the sulfate by evaporation or as the carbonate or hydroxide by neutralization and precipitation.

15.2.2.5 Bio-leaching*

As suggested above, there is a microbial or bacterial aspect to sulfide leaching. The natural bacterial oxidation of sulfide minerals and its role in the leaching of copper heaps and dumps has been well-known for years. The chemoautotrophic bacterial strains *thiobacillus ferrooxidans* and *thiobacillus thiooxidans* play the predominant roles. The exact mechanisms for the bacterial action are still in dispute, but the accepted theory is that the bacteria obtain energy for growth from the enzymatic oxidation of ferrous to ferric iron and elemental sulfur to sulfate. With the addition of nitrogen, carbon, oxygen, phosphorous, potassium, and other elements as nutrients, the bacterial metabolism can be maintained to sustain a stable population.

The action of the bacteria is that of a catalytic agent in accelerating the chemical oxidation reactions. As presented by Brierly (1978) and LeRoux et al. (1973), the *t. ferrooxidans* bacteria catalyze the oxidation of ferrous to ferric iron:

*Segment 15.2.2.5 was contributed by Wayne C. Henderson, Brown & Root Braun, Houston, TX.

$$2\,Fe^{2+} + \tfrac{1}{2}\,O_2 + 2\,H^+ \rightarrow 2\,Fe^{3+} + H_2O \quad (15.2.15)$$

and the *t. thiooxidans* bacteria act to oxidize sulfur to sulfate:

$$S^\circ + 3/2\,O_2 + H_2O \rightarrow 2\,H^+ + SO_4^{2-} \quad (15.2.16)$$

The bacteria increase the rates of reaction by a factor of as much as 10^6 times those of the chemical, non-biological reactions alone.

There is little evidence for direct bacterial attack on the sulfide minerals (e.g., chalcopyrite or pyrite). The bacteria do, however, regenerate the chemical leachates (ferric iron and acid) and augment the oxygen transfer into the leach system. They also help keep the mineral surfaces free of solid reaction products that could retard the chemical leaching.

Surface leaching operations using bacterial catalysis have been confined predominately to copper and uranium systems in which these metal values are directly leached in the acidic environment favored by the bacteria (pH = 1.0 to 2.0). However, the use of a bacterially assisted pretreatment to oxidize refractory sulfide minerals containing gold or silver is just beginning to be developed. The gold and silver, once liberated by sulfide oxidation, would be extracted into solution by a separate leaching step.

A preleach washing and neutralization step would be required to convert the acidic bio-heap system (pH < 2.0) to that favored for conventional cyanide leaching (pH > 10.0). The other option would be to use an acidic lixiviant system to extract gold and silver after the bio-pretreatment (e.g., thiourea or halides).

The bio-pretreatment process actually serves a dual role. The acidic leach removes various base metals and other components that have a negative impact on the subsequent cyanide leach. Their removal prior to cyanidation substantially reduces cyanide consumption and preg-robbing potential. The pretreatment also liberates the gold or silver values from the sulfide mineral matrix. The liberation occurs not only by the oxidation and destruction of the sulfide matrix, but also by creation of additional porosity and permeability in the sulfide grains. The latter improves lixiviant access to the values, boosting extraction rates.

An attribute of the *bio-leaching process* is that the bio-oxidation reactions seem to favor the sulfide phases that contain high levels of dissolved or associated metals. These include arsenic, antimony, bismuth, and copper, among others. These phases are also commonly enriched in gold and silver. This virtue often allows bio-oxidation to achieve high levels of gold extraction in the subsequent cyanidation step with low levels of total sulfide oxidation. This selectivity reduces the time and oxygen transfer requirements for the pretreatment process to be effective.

Process testing and development for possible commercial implementation of bio-oxidation pretreatment for heap and dump leaching of gold ores are underway. Emphasis is being placed on overcoming a number of the major problem areas:

1. Establishing and sustaining an active, viable bacterial culture in the heaps.
2. Supplying sufficient oxygen to maintain bacterial growth and sulfide oxidation.
3. Developing washing and neutralization schemes.
4. Evaluating the feasibility of non-cyanide, acidic leaching systems.
5. Isolating and evolving sulfide oxidizing bacterial strains that are effective at higher pH levels (> 2.0).
6. Developing techniques and appropriate binders for agglomeration that can be used under acidic conditions.

In addition to the ferric sulfate/thiourea leaching system for gold or silver, there are other possible lixiviants that can be used effectively without neutralization following the acidic bio-oxidation pretreatment. The K-Process using a bromine-based reagent is reported by Soper (1988), and the use of brominated hydantoins (Sergent, 1988; Dadger, 1989) show some promise. Iodine-based and mixed halides (chloride, bromide and iodine) also are technically feasible lixiviants for gold under heap leaching conditions.

Environmental considerations and potential toxicity effects on the bio-oxidation pretreatment system would play an important role in selection of either cyanidation or an alternative lixiviant. The significantly faster leaching rates, higher possible extractions, and cost savings due to elimination of neutralization could offset the generally higher costs of the non-cyanide reagents. Economics would have to be defined for each specific system.

15.2.2.6 Metallurgical Testing

Regardless of the values to be recovered, a proper metallurgical test program will be needed for any new leach project. The results will establish expected operating parameters and set the design criteria needed to engineer and construct the leaching and recovery facilities. The most important single factor in any test program is the selection of the samples to be tested. Great care must be taken to assure that the samples are representative of the material to be leached. In fact, if the deposit contains more than one type of ore, either in terms of mineralogy or host rock characteristics, then each type must be thoroughly evaluated.

As discussed by McClelland (1988), there are at least two and generally three levels of testing to be undertaken:

1. Preliminary —small column percolation or bottle roll tests.
2. Detailed—larger column tests to optimize feed size.
3. Pilot scale—large column or field tests.

The preliminary tests provide good insight into the amenability of the material for leaching and permit selection of the preferred lixiviant, should the choice not be obvious. The test results also provide information on the chemical aspects of the proposed ore lixiviant system. These chemical parameters include reagent consumption and the rate and ultimate level of extraction of the value(s). Finally, the small-scale tests would indicate whether or not agglomeration is needed in order to avoid permeability problems with clays or fines.

Care must be exercised in trying to extrapolate the preliminary test results to predict parameters in the eventual operating system. Unless a factor is applied to the preliminary results, they will always indicate higher leach rates and reagent consumption than will occur in the commercial operation. The reason for this is that the material is crushed much finer in the small-scale tests than in the full-sized system. This will maximize liberation of the values and minimize diffusion distances to any mineralization that is not exposed. Thus the values will be solubilized rapidly and completely, assuming that the results are not impacted by complete reagent consumption in the typical batch-type tests.

Reagent consumption will also be maximized. In part, this reflects the high extraction of values but also the high host-rock surface area. In particular, the fine rock size will maximize reagent consumption in cases where the lixiviant is not highly selective for the values and attacks the host-rock (gangue) minerals as well. Such behavior is particularly common with acidic lixiviants since these tend to be less selective than the alkaline reagents. For example, in the acid leaching of copper, there is generally much more reaction with gangue constituents than copper minerals on a mass basis.

The detailed tests are run in larger columns and are generally intended to determine whether or not the ore should be leached in run-of-mine condition, crushed to some smaller size, or crushed and then agglomerated. In such a program, the extraction rate curves and reagent consumption figures are determined as a function of the particle size and degree of agglomeration. These tests can be run in one of two ways—single or multiple feed sizing. In the former, a medium-sized material is selected and column leached until the extraction rate levels off to near zero. Then the contents of the column are screened and assayed to determine recovery as a function of particle size. Generally, a second confirmatory test is then run on material crushed to the selected size. This approach is less costly but more time consuming than running parallel tests on multiple samples crushed to cover a range of sizes.

With either approach, the last step is to balance projected recoveries and projected revenues against the cost of progressively finer crushing and/or agglomeration. Then the most economic operating scenario can be selected.

The pilot scale tests are not always run due to the time and costs required to get meaningful results. However, if run, they greatly reduce the risk of a metallurgical failure when advancing to a commercial operation. Typical large-scale column tests are run with 20 to 40 tons (18 to 36 t) of gold/silver ore (McClelland, 1988) and as much as 200 tons (180 t) of copper ore (Murr, 1980). In many cases the large column tests will be more meaningful than small field heaps due to edge effects caused by the large percentage of material contained under the sloping heap faces. On the other hand, percolation characteristics in the columns probably will not duplicate those in heaps and dumps since material emplacement is different in each system.

Large-scale field tests are generally required only when the material will be leached at a coarse size in large piles for extended periods. The test heaps should be full height when compared to the planned commercial operation, or at least as high as the first lift. Costs can be controlled by making the pilot heaps the first commercial heaps so that the revenue from mineral production offsets the costs of the tests. If the tests suggest that modifications are required, these can be made on succeeding heaps or dumps.

McClelland (1988) compares the advantages and disadvantages of the large-scale field tests as follows:

The advantages for conducting large pilot heap tests include

1. A more representative bulk sample of the ore deposit can be obtained.
2. Commercial operation is simulated.
3. Accurate design data is obtained.
4. Actual recovery, recovery rate, and reagent usage requirements and data are determined.
5. Information concerning heap stability, heap blinding, solution channeling, and fines migration is obtained.

The principal disadvantages of large pilot heap tests include

1. Costs are higher than those for pilot column tests.
2. Environmental and/or operating permits may be required.
3. Obtaining large tonnage bulk samples may be difficult.
4. Preparation of leach pads and solution ponds is involved.
5. A solution application system must be designed and assembled.
6. A small solution recovery system must be constructed, but will probably not be used in the commercial operation.
7. Monitoring is difficult and the test is labor intensive.
8. Shutdown and removal (reclamation) of the test heap may be necessary.

In addition to the general test criteria outlined above, there are many commodity-specific aspects to metallurgical testing. These cannot be addressed in detail here but do require that a well-planned research program be conducted by knowledgable metallurgists and engineers in order to get meaningful results. To cite just one commodity specific example, bottle roll tests on cyanide extraction of gold should be done in open bottles. If the bottles are sealed, poor results may be due to oxygen deficiency rather than the presence of refractory mineralization.

15.2.3 MATERIALS HANDLING

15.2.3.1 Mining

Surface heap and dump leaching operations are almost invariably associated with open pit mining operations. These require essentially the same planning functions and employ the same unit operations as those described in Sections 13 and 14 of this *Handbook.* There are, however, two areas that may be impacted somewhat by leaching operations—mine planning, and drilling and blasting.

For operations where heap or dump leaching supplements production from conventional milling, the mine planning function can become more complex. One of these complexities lies in the need for more segregation of mined materials. Instead of dividing material into just two categories, mill ore and waste, three will be required: mill ore, leach material, and waste. Both leach and waste dumps will need to be planned, and the movement of all three types of material will have to be scheduled. In addition, water distribution and collection systems will have to be designed and installed for the leach system.

Supplemental production of leach copper also impacts on the calculation of the ore cutoff grade and the ultimate pit limits. Since leaching permits partial recovery of copper from material that would otherwise be wasted, the effect of a leaching operation is always to raise the cutoff grade on ore going to the mill. This, in turn, lowers the unit costs on the mill output. Also, since leaching boosts total recovery of values from the mineral resource, it has the effect of increasing the tons of material that can be profitably mined. Stated another way, a supplemental leach operation causes the ultimate pit limits to expand. The exact impact of leaching will be site-specific and will depend on the relative costs and output of leach production vs. mill production.

Drilling and blasting is another area that may be impacted by leaching—particularly when a mine-to-leach operation utilizes run-of-mine ore. Under this scenario, the drilling and blasting operation will be designed to give a well-fragmented product with minimal quantities of oversized rock, say, plus 8 to 10 in. (200 to 250 mm) across (see Chapter 9.2). The well-fragmented product should stack and leach well, while providing the good mineral exposure needed for effective leaching. As rock characteristics are very site specific, costs for the drilling and blasting program that gives an optimum as-mined leach product may need to be compared with costs for a low-cost drilling and blasting approach, plus primary crushing to produce material for leaching.

15.2.3.2 Ore Preparation

Material scheduled to go to heaps or dumps may be handled in run-of-mine condition or prepared for leaching in one of two ways: crushing or agglomeration. Crushing will be undertaken when the increase in production achieved with the finer product generates sufficient incremental revenue to cover the capital and operating costs for crushing. In general, low-grade wastes that must be mined to expose mill-grade ore will not support much material handling or preparation. Such material is often dumped in run-of-mine condition using dump locations that minimize haulage costs rather than maximizing leach output. Then the dump will be leached to recover some of the values that would otherwise be lost.

Agglomeration is undertaken to provide the opposite effect of a crushing step, that is, to provide a strong, porous and coarsely sized material that otherwise would be unleachable due to poor percolation characteristics when placed in heaps and dumps. This is particularly true when material finer than 50 mesh is present. Such conditions usually lead to low metal extraction because of slow and uneven percolation (channeling) of solution and the development of impermeable (dead) zones within the heap or dump. Clays are probably the leading source of fines, although fines produced by poor crushing practices are undesirable as well. Agglomeration is also required when heap leaching is selected as the route for reprocessing tailings or other very fine materials.

At present, agglomeration is widely applied only in precious metal operations. However, uranium-vanadium tailings have been agglomerated and heap leached in Colorado and chrysocolla is being agglomerated with a polymer binder and heap leached at the Ray mine in Arizona. For gold and silver, important parameters include the quantity of binder (typically, 10 lb/ton or 5 kg/t), the moisture content (10 to 20% total), and the curing period for the agglomerates (at least 8 hr). Since the subsequent cyanide leach requires alkaline conditions, binders are typically lime or Portland cement. These binders generally have two important properties. First, clay permeability is improved by the exchange of sodium ions in the clay with calcium ions in the binder. Second, the binders have a cementing or pozzolanic effect that strengthens the agglomerates. Leach extraction rates can also be accelerated by using a barren cyanide solution as the source of moisture.

Agglomeration follows one of two pathways. One causes the adherence of fines onto the coarser particles. The other involves agglomeration of fines into stable balls. As discussed in detail by Milligan (1983) and reported by McClelland and van Zyl (1988), design factors in agglomeration include feed characteristics (particle size and presence of fractures), process control, and equipment selection. For gold and silver materials, belt, drum, and pan agglomerators are the most popular types of equipment. Graphical design data on both agglomerator sizing and costs are reported by McClelland and van Zyl (1988).

Fine tailings are agglomerated much like ore, but optimum conditions and equipment are different. More binder is often required (10 to 15 lb/ton, or 5 to 7.5 kg/t), considerably more water is needed (16 to 22%), and curing times are longer (typically 72 hr). In addition, the agglomerator should roll, rather than bounce the particles. Generally, drums, disks, and pug mills provide good action, while belt agglomerators tend to bounce the particles.

Crushing is not covered in detail here, and the reader is referred to Chapter 25.3 and standard works such as the *SME Mineral Processing Handbook* (Weiss, 1985) for details. For dump leaching, there is generally no size reduction unless primary (in-pit) crushing is practiced in order to transport and stack the material by conveyors. For heap leaching, primary, secondary, and tertiary crushing are often used to produce a final product that is nominally –1.0 in. (–25 mm) to –0.5 in. (–10 mm). Occasionally, some grinding may also be needed to liberate encapsulated values. This material will then require agglomeration prior to heap leaching.

15.2.3.3 Ore Emplacement

The stacking of the material for leaching is a major factor in the success of a surface leaching operation. The approach to emplacement represents one of the principal differences between waste dump leaching and heap leaching. The former is characterized by dumping practices that reflect topographic constraints and minimization of haulage costs. Any consideration of leach recovery is usually limited to such practices as waste segregation and dump surface preparation. Segregation usually involves efforts to avoid mixing barren or mineralogically unleachable materials into the leach dumps. Surface preparation typically is limited to leveling and deep ripping to breakup the compacted zone associated with the truck traffic pattern.

Such waste dumps are often high; elevation differences of 300 to 750 ft (90 to 230 m) between toe and crest are not uncommon. This profile exacerbates the size segregation that occurs when run-of-mine material is dumped over the crest. This allows the coarsest material to slide to the bottom while the fines tend to remain at or near the crest. As a result, the least permeable and most easily compacted zone of material is found at the top. Application of leach solution then causes slow and uneven percolation at the top of the dump, with a great tendency for solutions to channel and short circuit through this layer. These poor percolation patterns normally persist at depth so that a significant volume of material in the dump is leached poorly, if at all.

There is also another form of segregation that inevitably occurs in waste dumps. This is the development of alternate coarse and fine layers of material that lie parallel to the angle of repose. The coarse zones act as conduits and carry the bulk of the lixiviant flow. Hence they are usually well leached in spite of their large particle size. By contrast, the fine material has a low permeability so it undergoes little solution penetration or leaching.

These factors in waste emplacement are responsible for the generally poor extractions observed in such dumps. For run-of-mine material, recovery of metal values seldom exceeds 50% after many years of leaching. Only 10 to 15% extraction during the first one or two years is not uncommon, at least for copper sulfide dumps.

As opposed to dump leaching, heap leaching involves careful emplacement of rock in order to maximize extraction of the values. In general, this will involve construction of much shallower lifts, typically 10 to 35 ft (3 to 10 m) high. This tends to minimize size segregation, as does the use of crushed or agglomerated ore. In turn, solution percolation is more uniform and solution-rock contact is improved, resulting in faster and more complete metal recovery.

As described by Muhtadi (1988), there are several approaches to heap construction that warrant consideration due to their widespread use.

TRUCK DUMPING AND DOZING. This method of construction is essentially the same as that described above for waste dumps. However, more care is given to emplacement of material. Typically, a ramp of waste is constructed to the height of the first lift. Then ore is dumped from the end of the ramp down onto the pad or foundation of the heap. As the ore builds up, the heap extends away from the ramp. To minimize compaction, an elevated roadway is often extended as the heap expands, with haulage trucks restricted to this path. Once the heap is completed, the roadway is dozed off and the surface of the heap is graded and ripped in an effort to assure good permeability and uniform percolation of solution.

In general, this method of heap construction is restricted to ores that do not undergo compaction or generate fines. This requires a strong, competent material handled either in run-of-mine or crushed condition. Agglomerated materials cannot generally be handled by truck dumping as they are too soft and friable. In addition, truck dumping can still cause the coarse-fine segregation noted above.

PLUG DUMPING. This method of emplacement also uses trucks, but is not characterized by the rough handling noted above. Hence it is suitable for softer ores and agglomerates. In plug dumping, the first step is to bed the liner or foundation with as much as 1.5 ft (0.5 m) of crushed rock as a protective measure to insure liner integrity. Then each haul truck dumps its load as closely as possible to the previously dumped pile until the entire pad is covered with overlapping mounds. This gives a maximum heap height of about 7 ft (2 m), slightly less if a dozer is used to level the tops of the mounds.

Another adaptation is to replace the trucks with large rubber-tired front-end loaders. These are very efficient and stack material to heights approaching 16 ft (5 m) without the need for bedding the liner first. Good operators can even produce a nearly level surface that is suitable for installation of the leach solution distribution system without the need for dozing.

CONVEYOR SYSTEMS. Conveyor stacking is gaining widespread acceptance in gold heap leaching. This concept is not new, however. It started at least as early as the beginning of the 20th century when high-grade copper ores were bedded and removed from leach vats using a clamshell bucket on a traveling gantry crane or another mechanical system. Indeed, one of the first stacking systems in gold heap leaching (Gold Fields Mining Company's Ortiz, NM, operation) utilized a traveling bridge that spanned a reusable pad and used a moving tripper to continuously add ore to the face of the heap. In this operation, spent ore was removed from the asphalt pad by front-end loaders.

Now conveyor hauling and stacking of ore on heaps has evolved into a highly mobile operation. The front end of the system usually consists of a short fixed conveyor that receives prepared ore from a crusher, agglomerator, or a stockpile via a feed hopper. This conveyor transfers material to a mobile, radial arm conveyor/stacker using a system of movable intermediate conveyor sections. The stacker has great flexibility and can bed the heap uniformly and without compaction to almost any height desired. Thus conveyor systems can handle anything from primary crushed ore to agglomerated tailings.

15.2.3.4 In-place Systems

In-place systems represent a special case of material handling that is intermediate between surface heap and dump leaching and in situ mining. This case involves broken or rubblized material that is leached more or less in-place. In-place leaching, clearly involves no loading or hauling of broken ore to heaps or dumps. However, unlike in situ mining, in-place leaching still relies on the downward percolation of solution through unsaturated leach material. (By contrast, in situ mining is characterized by pressure-driven solution flow in a saturated medium).

In-place systems are so site specific that discussion is limited to brief descriptions of a few commercial operations. Although broken uranium ore has been leached in underground settings, copper appears to have been the main target to date. Probably the largest-scale operation was undertaken by Ranchers Exploration and Development Co. when they drilled and blasted the entire upper portion of the Old Reliable ore body and then acid leached the rubblized zone in-place. Technically, Ranchers was able to fracture and rubblize the ore, but leaching yielded less copper and lower solution tenors than expected. Thus the project was not the commercial success that was hoped for.

Greater success has been achieved in programs that involve progressive rubblization and leaching of abandoned pit walls. Since most porphyry ore bodies contain a halo of low-grade mineralization around the economically minable zone, pit-wall leaching often recovers a portion of the copper that is otherwise left behind. Current examples include pit-wall leaching at Mineral Park and the Lavender pit near Bisbee, both in Arizona. Another good example is leaching of broken, remnant ore left behind in block caving operations. Current examples of this system include El Teniente in Chile and San Manuel in Arizona.

The pit-wall system uses a conventional solution distribution system (see the following segment) to apply lixiviant to the upper surface of the broken ore. Pregnant solution is then collected in the pit bottom or where solution breaks out at the bottom of rubblized material. However, leaching of underground material may pose problems in getting uniform distribution of leach solution throughout broken rock mass. In extreme cases, injection wells may have to be drilled from the surface, much like in situ mining. Solution is then recovered in one or more sumps at the bottom of the ore body.

15.2.4 SOLUTION MANAGEMENT

Materials handling and solution management are interactive, with rock preparation and stacking having a substantial effect on solution flow. For example, maximum recovery of metal values can only be achieved if the heap/dump design permits good distribution and collection of leach solution. The design must also provide for movement of air into the piled rock since oxygen is needed as a reactant in solubilizing many values. Likewise, the rock must be broken and stacked so that the entire rock mass is accessible to solution percolating down from the surface of the heap or dump. Nevertheless, once the rock has been prepared and put in place, there is little an operator can do except to optimize the way the leach solution is handled. This will accomplish two things. One is to transport the lixiviant to the mineralized values throughout the piled rock. The other is to wash the solubilized values from the heap or dump to the recovery plant.

15.2.4.1 Fluid Flow Phenomena

STATIC CONSIDERATIONS. From a theoretical point of view, solution flow in heaps and dumps involves the gravity-driven, downward percolation of water in an unsaturated, semiconsolidated (porous) medium. However, as reviewed by Schlitt (1984), this is a regime that remains too complex to address on completely theoretical grounds.

The first step in understanding solution flow through the rock mass is to categorize the space within the dump or heap. As shown in Fig. 15.2.1, there are at least four distinct regions. By far the largest is the solid rock (including isolated pores), indicated by v_s. This represents completely stagnant space and typically involves about 60% of the total volume. Blasting and handling the rock expose pores and create fractures or cracks on the faces of the rock fragments. The space associated with these openings ϵ is generally only 2 to 4% of the total volume. Nevertheless, this space is quite important because it greatly increases the exposed surface area and makes the contained mineral values more accessible to the lixiviant. The remaining volume within the rock pile is the void space. This results from the swelling that is a consequence of fracturing and stacking the rock during mining and handling. For newly prepared heaps, the void space associated with swelling normally constitutes about 40% of the volume of the rock pile. This will decrease as weathering and leaching consolidate the material. The void space will probably drop to less than 30% if a mine dump is leached over a period of years.

Obviously, the void space can either be filled with solution or with air. However, because the water/rock interface has a

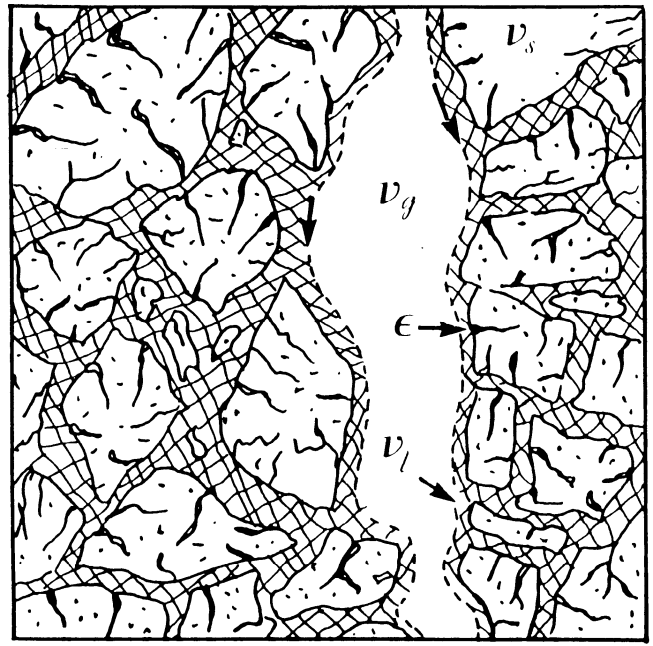

Fig. 15.2.1. The categories of space found within a heap or dump: solid rock (v_s), open space within rock fragments (ϵ) water-filled void space (v_l), air-filled void space (v_g), (after Schlitt, 1984).

lower surface energy than the air/rock interface, all the openings in the rock fragments will be filled with solution, and the rocks themselves will be covered with water under conditions of percolation. The water-filled void space v_1 represents the area for active water flow. On the other hand, mass transport within the ϵ-type space will occur only by diffusion. One other consequence of the difference in the interfacial energies is the location of the air-filled void space v_g. Under conditions of percolation, only the larger voids and channels will contain air, as the smaller openings are flooded.

Except under conditions of flooding, the competition between air and water for the available void space will be almost independent of the rate at which leach solution is applied. Instead, the controlling factor will be the effective particle size of the rocks in the pile. This is a consequence of the limitations imposed by capillary forces.

As shown in Fig. 15.2.2, capillary rise or drain-down height is related to effective rock size. The same figure shows the correlation between rock size and the percentage of the total void space that remains water-filled after leaching ceases and drain-down is complete. At this point, capillary rise is balanced by the force of gravity, and only evaporation will further reduce the water-filled void volume.

The experimental results shown in Fig. 15.2.2 are significant when ingress of air is needed to aid in solubilizing the metal values. The data demonstrate that if the material is finer than about 48 mesh, it will not drain down at all, and little or no air will be able to penetrate into the pile. On the other hand, if the material is coarser than about 10 mesh, the pile will drain down almost completely.

DYNAMIC CONSIDERATIONS. When leaching begins at a low application rate on a thoroughly drained dump, some additional air-filled void space becomes water-filled. This occurs at air-water interfaces, and flow begins. As the application rate increases, the only change will be to thicken the film of flowing water in the larger voids and channels where there is a solution-

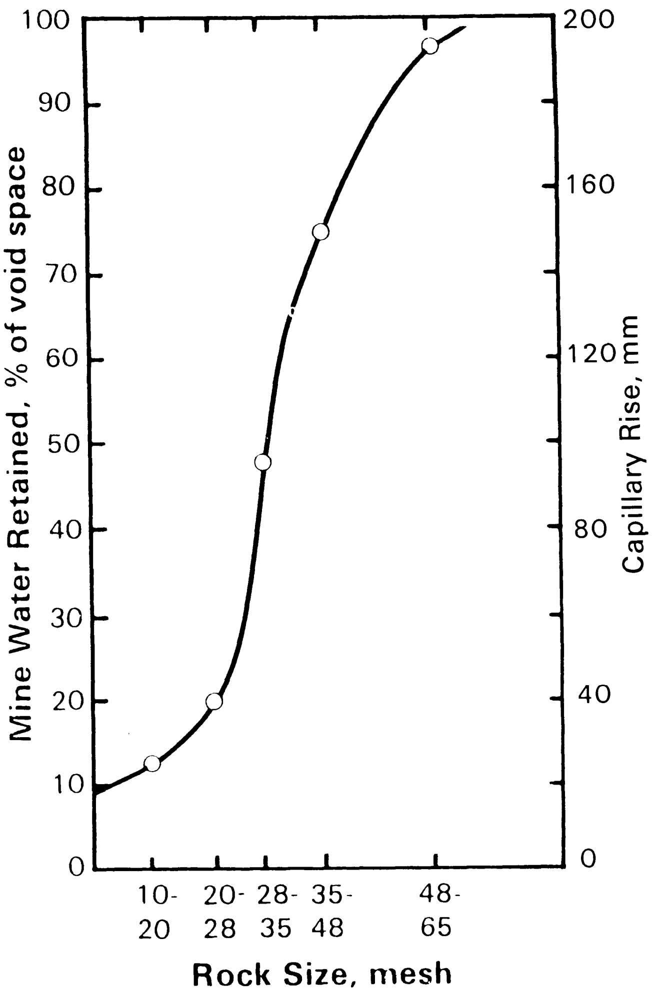

Fig. 15.2.2. Solution retention and the corresponding capillary rise as a function of rock size (after Schlitt, 1984).

air interface. No substantial change in the volumes occupied by air and liquid will occur until the application rate increases to the point where the air-filled voids begin pinching off. When such bottlenecks occur, the open voids will flood upward from the pinch points and the air-filled void spaces will begin disappearing. Experimental column data demonstrating this phenomenon are shown in Table 15.2.1. Note that at typical application rates (0.1 to 1.0 gal/ft^2/hr, or 4 to 40 mm/h), there is considerable air-filled void space. Thus adequate aeration should not be a problem unless the material being leached is very fine, for example, flotation mill tailings.

Regardless of the application rate, the velocity of solution flowing through a water-filled void is controlled by the pressure gradient associated with the hydrostatic head and the permeability at that location. This relationship is expressed by Darcy's law as given by Eq. 15.2.17:

$$V_l^\circ = \frac{k}{\mu}(dp/dx) \qquad (15.2.17)$$

where V_l° is superficial velocity of the leach solution, k is permeability, μ is fluid viscosity, and dp/dx is pressure gradient or hydrostatic head of the leach solution.

Table 15.2.1. Effect of Solution Application Rate on Water-filled Void Space

Application Rate		Water-filled	
mm/h	gal/ft²/hr	Void Space, %*	Comments
0	0	8.0	Drained
1.2	0.03	9.6	Capillaries filled
6.0	0.15	9.7	Typical range
24.0	0.60	10.1	of application
120.0	3.0	10.3	rates
3050.0	75.0	10.5	
4070.0	110.0	27.6	Flooded

*Expressed as a percentage of the total space within the rockpile.

Optimum Application Rate. Substituting appropriate values into Eq. 15.2.18 defines an equivalent maximum application rate q_{max}. This is the rate which can be used without experiencing shortcircuiting through the larger voids and channels that are partially air-filled. Using operator-oriented units, this expression is

$$q_{max}\ (\text{gal/ft}^2/\text{hr}) = 0.9k\ (\text{Darcy}) \qquad (15.2.18)$$

Although heaps and dumps typically contain a broad rock size distribution, the permeability and thus q_{max} will be dominated by the smaller particles that fill the interstices between the larger rocks. Since capillarity also confines the leach solution to the smaller voids, flow is limited almost entirely to these capillaries when the application rate is less than q_{max}. Once the water application rate exceeds this value, the excess floods laterally and substantial flow occurs in the films along the walls of the larger air-filled voids. Further increases in the application rate simply shunt an increasing volume of water to the large channels. This leads to significant short-circuiting of the leach solution and dilution of values in the pregnant solution.

Clearly, the average permeability of the heap or dump matrix will limit the application rate that can be used to flush the solubilized values to the recovery plant. When the rate of metal extraction is controlled by washing the soluble values from the water-filled void space, use of application rates in excess of q_{max} is detrimental. Such high flows mean that higher than necessary pumping costs are incurred. The recovery plant must also handle the excessive solution flow. In addition to higher operating costs, this means that capital costs must be increased to provide the oversized facilities.

The actual flow rates involved are high even when there is no short circuiting. For a matrix permeability of 5 darcies (equivalent to a particle size of 35 mesh), V_l° will be 4.5 m/day. However, the actual water velocity will be five times as high, or about 75 ft/day (22.5 m/day) assuming that the water-filled voids occupy 20% of total volume of the heap or dump.

Such a high flow rate within the interior of the rock pile does more than efficiently wash dissolved values out of the heap or dump. The flow will also rapidly distribute the lixiviant throughout the liquid-filled void space. However, this will not carry the lixiviant to the undissolved mineral values unless these are exposed on the outer surfaces of the rock particles.

As discussed above, when the values are contained within the rocks, the required lixiviant transport can only occur by diffusion. This will be orders of magnitude slower than solution flow. The penetration distance of the lixiviant will depend on the rate lixiviant consumption as well as on the diffusion rate.

Effective diffusional penetration will typically be about 4 in. (100 mm) before the lixiviant is consumed.

From the standpoint of the leach operator, the main point of the foregoing discussion is that the maximum effective application rate will be limited by the zone of minimum permeability in the system under leach. This may be the bulk permeability of the rock pile. However, care should be taken so that the solution application rate does not exceed the surface acceptance rate of the heap or dump. This is an important consideration because there are several factors which can combine to make the surface permeability lower than the bulk value. These factors include the following:

1. Accelerated decrepitation or weathering of the surface layer.
2. Breakup and compaction of the surface rock due to equipment movement, particularly haulage truck traffic.
3. Segregation of fine material at or near the top of the heap where dumping occurs.
4. Formation or accumulation of chemical precipitates such as gypsum or hydrated iron oxides.

Where surface permeability is lower than the bulk value, the application rate should be reduced to avoid ponding. Such surface flooding will prevent air circulation into or through the rock. Ponding will also provide ideal conditions for continued chemical precipitation that seals the surface of the rock pile.

To select the maximum effective application rate, the leach operator will need some knowledge of the range permeabilities found in his system. This information is probably best obtained by using one of the standard water permeability tests. Unfortunately, there is little published data on heap and dump permeability to serve as a guide. Limited field measurements on copper leach dumps suggest a value of q_{max} between 0.5 and 1.0 gal/ft^2/hr (20 and 40 mm/h). Higher flows simply cause increasing amounts of water to short-circuit through the rock without recovering additional values.

The importance of controlling the application rates is further demonstrated in Kennecott data published by Jackson and Ream (1980) for copper dump leaching. These results compare sprinkler leaching at 0.5 gal/ft^2/hr (20 mm/h) with trickle leaching at 2 gal/ft^2/hr (80 mm/h). Sprinkler leaching produced 11% more copper and a 15% higher copper content in the pregnant solution. Overall, 13% less water was pumped per pound of copper produced when using the lower application rate. This provided a significant reduction in power costs per unit of copper produced.

LEACH/REST CYCLES. Leach/rest cycles are a factor in solution management. Once a volume of rock has been thoroughly wetted with solution, the lixiviant will be distributed throughout the rock mass. From that point on, dissolution of the values will continue without further solution application unless the lixiviant is consumed. Thus rest cycles should not affect overall extraction of the metal values.

However, rest cycles can extend the economic life of older heaps and dumps, and this permits maximum recovery of values from the material that was mined. Use of rest cycles will also permit an operator to reduce costs by maintaining a limited flow of high-grade pregnant liquor to his plant. In both cases, the key factor is switching the application of water from one leach area to another. While standing fallow, chemical and diffusional processes dissolve the values and cause their concentration to build up in the water-filled void space. Then a relatively short period of active solution application will wash the solubilized values from the heap or dump. On older material a longer rest cycle may be required to build up an economic concentration prior to washing. In a similar vein, recycling barren solution to the oldest material first, then advancing the outflow to fresher material will reduce the volume and increase the grade of the pregnant solution being treated in the plant. For these reasons, leach/rest cycles should not be overlooked as a way of optimizing a leach operation and minimizing facility costs.

15.2.4.2 Production Aspects

PUMPING SYSTEMS. Selection of a pumping system depends on several factors: the hydrostatic head on the system, the line pressure needed to drive the solution distribution equipment on the heap or dump surface, the flow volume, and the corrosion potential of the lixiviant. Because there are so many site-specific factors involved, only general guidelines are provided here.

In many operations, the recovery plant is located at a lower elevation than the heaps or dumps. Thus pregnant leach solution generally flows to the plant by gravity in lined ditches or low-pressure pipelines. Any pumping from a heap or dump outflow or from a plant feed pond would generally require only a low-pressure horizontal pump. Such a pump may be mounted beside the pond with the pump intake suspended from a float in the pond. This readily accommodates a rising or falling water level.

With the situation noted above, the recycling of barren solution back to the heaps or dumps requires a high-head pumping system. Typically, this involves multistage vertical pumps. These may be mounted on a fixed structure, as in a pump house where pumping is from a sump. Alternatively, the pump may be barge-mounted and float in the barren solution pond. If the system pressure is not too great, flexible pipe or couplings can be used to tie the pump into the shore-based pipeline system. This allows the pump to rise and fall with the pond level.

The type of pipe will be dictated by the elevation difference between the plant and leach surface, plus the line pressure needed to drive the solution distribution equipment on the heap or dump surface. The elevation difference may be only 100 ft (30 m) or so, or may be as much as 2000 ft (600 m). The latter will require sophisticated design starting with heavy-walled metal pipe, shifting gradually to lighter schedules. The entire pipe system must be well anchored, yet allow for expansion and contraction due to temperature changes. In addition, the entire header system will almost certainly be above the 10- to 50-psi (70- to 345-kPa) pressure needed on the leach areas. This will require the installation of outlet stations on the main header line that will serve as pressure reduction points as well. Once the pipeline profile and other flow parameters are defined, sophisticated computer programs can be used to aid in the pipeline design.

Pipe materials must be selected with the chemical nature of the lixiviant in mind. When line pressure dictates metal pipe, 316L stainless is a frequent choice for acidic copper leach liquors that also contain ferric and cupric ions. Polyvinal chloride (PVC) or other liners have been tried on black iron or steel pipe, but the linings tend to deteriorate with time, particularly at joints. For alkaline solutions, black iron may be satisfactory.

For lower pressures, high-density polyethylene (HDPE) pipe is becoming the standard of choice. This is rugged, easy to cut and fuse in the field, resists scaling, and is essentially corrosion-proof. PVC and other rigid plastic pipe may be less expensive but are not as rugged and tend to shatter. One of the few problems with HPDE pipe is its lack of rigidity so that it twists and turns; it may require staking or anchor blocks to keep it in place. However, this flexibility can also be an asset when routing the pipe during initial installation.

SOLUTION APPLICATION SYSTEMS. As pointed out in 15.2.4.1, careful distribution of solution on the heap or dump surface is required to optimize the leach operation. Development of such a solution management system requires a clear understanding of three concepts:

1. *Application rate* is calculated by dividing the leach solution volumetric flow rate by the surface area to which the solution is actually being applied.

2. *Surface acceptance rate* is the maximum application rate that can be employed without encountering noticeable ponding.

3. *Irrigation rate* is a measure of the intensity of leaching. It is calculated by dividing the total volumetric flow rate by the total area planned for leaching. This area includes both areas under active leach and areas that are being allowed to rest. For sulfidic copper materials, typical irrigation rates are only 20 or 25% of the application rate, and may be only 10% on old areas needing a long rest cycle. Irrigation rates would be much higher when leaching gold, silver, and oxide copper since the extraction rates are higher.

The desired application rate should be based on q_{max} as defined in Eq. 15.2.18. However, not all leach systems are capable of delivering this flowrate. The most rudimentary system is pond leaching where a berm is dozed around an area that is then flooded with leach solution. Here the application rate may be as high as 5 gal/ft^2/hr (200 mm/h), assuming good surface acceptance. Such a high rate will almost certainly exceed q_{max}, leading to extensive short circuiting and dilution of the values being leached.

Trickle systems using drilled or perforated pipe are fed off main header lines. Typical trickle lines are spaced 20 to 25 ft (6 to 8 m) apart. Holes about 0.5 in. (12 mm) in diameter are drilled every 8 to 12 ft (2.4 to 3.6 m) at an angle of 15 to 20° from vertical in order to get wide coverage. The hole spacing decreases from the header line to the opposite end of the feeder line. This is done to compensate for the pressure drop along the line. Trickle systems typically provide an application rate of 2 gal/ft^2/hr (80 mm/h). As shown by Jackson and Ream (1980), this rate still exceeds q_{max}, at least for copper leaching.

Sprinkler leaching utilizes several types of equipment including rotating impulse sprinklers, Bagdad wigglers, and Senninger Wobblers. The first is much like the typical “Rain Bird” agricultural sprinklers except for materials of construction. These include acid resistant plastic or stainless steel for all wetted parts. The wiggler utilizes short pieces of surgical tubing attached to nipples on a feeder line. The tubing then flops randomly, giving fairly uniform solution coverage. Wobblers are off-center rotary action sprinklers that provide a coarse spray pattern which minimizes evaporation. However, the off-center design creates thrust problems, and Wobblers must be staked down.

All three designs are capable of providing a pattern of reasonably uniform solution coverage at an application rate of 0.5 gal/ft^2/hr (20 mm/h). This is safely below q_{max}. With their own pressure regulators, the Wobblers are sophisticated enough to provide even lower rates (e.g., 0.3 gal/ft^2/hr, or 12 mm/h), the level typically cited as the optimum for gold. Ranges of operating parameters for several types of sprinklers are shown graphically by Schlitt (1984) and are available in vendor literature.

Another type of leaching device, the pressure emitter, is seeing growing acceptance. This is equivalent to the drip irrigation devices used in agricultural applications. The emitters operate at low gage pressure, 15 to 20 psi (100 to 140 kPa), and produce a steady seepage of water that gives about the same application rate as sprinklers.

Muhtadi (1988) provides details on the design and installation of emitter systems. These have the following advantages over sprinklers:

1. The continuous drip minimizes droplet impact, reducing rock decrepitation, fines migration, and solution channeling.

2. The system works well either on the surface or when buried. The latter permits leaching to continue even under freezing conditions.

3. Evaporation losses are minimized, especially when the system is buried.

The major drawback to emitters is the likelihood of blocking the small flow channels with precipitated salts. Therefore, conditioning of the recycle solutions to prevent scale formation or remove suspended solids must receive careful attention if emitter plugging is to be avoided. Conditioning may involve use of settling ponds, filtration systems, or chemical additives.

15.2.4.3 Environmental Aspects

At least in the United States, obtaining the necessary environmental permits is probably the single most time-consuming activity in the development of a heap or dump leaching project. Permitting requirements will vary from state to state and may differ depending on whether the project is to be sited on private, state, or federally owned land. Because of these differences and constantly changing regulatory requirements, a detailed guide to the appropriate permitting process cannot be presented here. (For a general discussion of environmental law and practice, the reader is referred to Chapters 3.4 and 7.3.) The best approach is usually to hire knowledgeable environmental consultants who practice in the area where the project will be located. These people should be quite familiar with applicable regulations and procedures and will often know the local and state regulatory personnel.

Although specifics may differ from one site to another, the regulatory agencies generally have two major concerns regarding surface leaching projects. One is assuring the safe handling of toxic chemicals and reagents. The other is the prevention of contaminated run-off or seepage to ground water. Detoxification of the heaps or dumps may also be a concern in all future operations and is already having an impact on the gold heap-leaching segment of the industry. However, groundwater restoration, a major factor in in situ operations, will have little impact on surface operations unless contaminating leaks have been a problem.

The other environmental concerns are those common to most mining operations. These include control of particulate emissions (dust) from the mining and any crushing or processing operations. Another concern is topographic restoration to preexisting profiles and revegetation of the mine and leach areas. The restoration activities usually carry with them some sort of bonding requirements. In terms of cost, solution containment and heap or dump stability are the major considerations. Each is discussed below.

GEOTECHNICAL DESIGN. The design of piled rock structures that are stable under conditions of water flow, especially in seismically active areas, is a complex undertaking. Entire books have been written that address the necessary design features for both heaps (van Zyl, 1987) and dumps (McCarter, 1985). Because of this complexity, a detailed analysis of the problem cannot be presented here.

The first consideration is the method of heap or dump construction. The alternatives are reusable pads, expanding pads, and valley dumping. The major requirements and considerations in each case are provided by Dorey et al. (1988). In terms of both containment and stability, the reusable pad is the best. This system utilizes a sloping asphalt or concrete base that is highly impermeable and will easily support the single shallow lift of ore. This is bedded on the base with front-end loaders or an automated stacking system. Material is loaded with little or no compaction. The leach solution will usually percolate readily through the pile with the pregnant leach solution draining from the heap at controlled points. Solution is conveyed to the recovery plant in lined ditches or pipelines with little likelihood of loss. From an environmental point of view, the biggest concern is the integrity of the final impoundment area for the leached tailings. This will require a properly designed retaining dam and will also require a liner(s) to prevent seepage losses of residual reagents. A monitoring system will also be required to detect any leakage.

The other two types of heaps, the expanding system and the valley system, do not entail the rehandling required with the reusable pad. The expanding pad system involves continued extension of the prepared heap foundation, which is then loaded with a single lift of ore. This system is characterized by a gently sloping base, often with intermediate drains. Eventually, topography and property constraints may require that the original lift be overdumped with one or more lifts. Overdumping must be done with care as the upper lifts often leach less effectively than the original one.

The valley system utilizes a natural or constructed retaining structure such as a ridge or dam located at the bottom of a canyon or valley. Ore is then stacked behind the structure in progressive lifts to fill the canyon or valley. Total land area required is usually less than that required for an expanding system, but lining the underlying surface may be difficult due to slope and terrain features.

Solution containment in such one-time structures is addressed in the following segment, while stability is covered here. Stability depends on a number of factors including the strength and slope of the foundation, the load imposed by the stacked ore, and the build-up of a solution saturated zone at the foundation or elsewhere in the rock mass. The latter is critical as more heap and dump failures have been caused by the build-up of excessive pore pressure than any other cause (Caldwell and Moss, 1985). Without going into the mathematical details, the reason for this is that the pore pressure within a saturated zone will reduce the shear strength and frictional resistance of stacked material. As pore pressure builds, especially near a free face, it can cause the shear strength to drop below the loading imposed by the rock mass. At this point, the structure fails, often catastrophically.

The build-up of a saturated zone depends on several factors such as the permeability of the rock mass, the slope of the foundation, the length of the drain path along the foundation, and the application rate on the heap or dump surface. The latter illustrates another reason for avoiding excessive application rates, particularly those above q_{max}.

Obviously, the foundation design can be changed to mitigate against the development of a large saturated zone. This could be something as simple as the installation of drain lines along the foundation. These would serve as draw-down points for the saturated zone. In rare cases, a hole could be drilled into the saturated zone and then cased, with the water pumped out. This has actually been done on large waste dumps where water was building up behind an internal barrier and could not drain normally.

SOLUTION CONTAINMENT. An effective liner is the principal barrier to seepage losses. This applies not only to heap or dump foundations but also to catchment basins, flow channels (including ditches and trenches), and holding ponds. In addition, the point should be made that no containment system is perfect. Some seepage will occur and can be measured by Darcy's Law. As indicated in Eq. 15.2.17, the permeability of the liner and the hydrostatic head are the factors that control seepage. Thus the engineer must design the system so that the expected seepage level is within environmentally acceptable limits.

Strachan and van Zyl (1988) cover liners in detail, including liner selection, system design, and installation. Selection is based on the type of application, nature of the solution to be contained, physical loading, and exposure to the elements. Liner materials include clays, clay or chemically amended soils, and geomembranes (PVC, Hypalon, HDPE, asphalt, etc.). These may be used alone as single liners or in combination. When used in combination, the upper liner is usually a geomembrane while the lower one is a soil material. On double or triple liners, a leak-detection system is often installed in a porous zone between the layers.

A final point should be made about the use of systems that minimize seepage losses. These not only meet regulatory requirements, but they also make good sense from an operational perspective. Even a small leak, if undetected, can cause a major loss in metal values and reagents. Such losses are equivalent to lowering the ore grade or getting poorer metallurgical recovery. In many cases, the dollar value of the lost production equals or exceed the cost of a good solution-containment system.

15.2.5 COMMODITY RECOVERY SYSTEMS

The systems used in connection with recovery of values from heap and dump leaching operations are the province of the hydrometallurgist. The recovery systems themselves do depend on the lixiviant but are essentially independent of ore emplacement or solution management practices. Thus the unit operations are commodity specific and are covered in standard metallurgical texts and reference volumes. (See, for example, Ross and Mackiw, 1985). For completeness, current recovery systems are briefly described as follows.

COPPER. Historically, copper has been recovered as an impure metallic mud or "cement" by cementation (precipitation) on scrap iron. The product typically grades 70 to 85% copper (dry basis) and requires smelting and refining prior to sale. Now scrap iron cementation is rapidly being replaced by solvent extraction-electrowinning, a process that produces directly salable cathode copper at the mine site (see Chapter 25.4).

GOLD/SILVER. Pregnant solutions from heaps and dumps are currently treated in one of two ways. One is absorption on activated carbon granules packed in columns. The gold and silver cyanide complexes load on carbon that is periodically stripped into a concentrated cyanide solution. The gold and silver are then recovered by electrolytic deposition from the strip liquor. As an alternative, the gold and silver may be stripped from solution as a sludge using zinc precipitation (the Merrill-Crowe process; see Chapter 25.4). The precipitate is then dried and smelted to produce doré metal for refining. Since carbon is less effective for silver recovery than gold, high silver solutions are usually treated by the Merrill-Crowe process.

URANIUM. The relatively low-grade leach liquors from heaps and dumps are usually concentrated by ion exchange, then purified and concentrated further by solvent extraction. Finally, yellow cake (U_3O_8) is precipitated from the solvent extraction strip liquor.

The only potentially unusual feature of the various recovery systems is conditioning of the barren solution prior to recycling it to the heaps or dumps. Since most of these facilities must operate under conditions of zero discharge, use of a bleed stream to control the build-up of undesirable impurities may not be possible. Thus the conditioning may be done to control scale-forming constituents, remove potentially harmful impurities, replenish reagents that have been consumed, adjust solution Eh or pH, or simply make up the water lost to evaporation. Conditioning will be highly site specific and will depend on the ore-lixiviant system, gangue reactivity, and even the chemical makeup of the available process water. Overall conditioning requirements for heap and dump leaching are less than those needed for in situ mining. This comes about because of the sensitivity of the in situ formation to loss of permeability caused by suspended or precipitated solids building up and blocking the flow paths between the injection and recovery wells.

15.2.6 ANCILLARY AND INFRASTRUCTURE REQUIREMENTS

Ancillary and infrastructure requirements are much the same as those for any open pit mining operation. This is because heap and dump leaching are merely the ore processing operation associated with mining. The main considerations are electric power, water, a transportation system, and access to a sufficient labor force. Fuel (e.g., natural gas) is not a concern since there are generally no large furnacing or other heating operations. Building heat, small precious metal furnaces, and driers can easily be fired electrically or with bottled gas if there is no natural gas line available.

In general, ancillary and infrastructure requirements are lower for primary heap and dump leaching operations than they are for mine-mill operations. Thus leaching plants are well suited to small operations and those in remote locations. A good example is in site access. A mine and mill complex requires a rail line or a heavy-duty road, or both in order to move ore from the mine to the mill and concentrate from the mill to a smelter. However, the leach operation merely requires an all-weather access road since shipping is limited to receipt of reagents and other supplies and shipment of small tonnages of crude or refined product. Acid trucks or similar vehicles are likely to be the largest units entering or leaving the plant on a regular basis.

Labor requirements are also low in leaching operations, with most of the people actually needed for the mining activities. Exclusive of mining, labor may represent no more than 5 to 15% of the direct operating costs. The low labor requirements also mean that much of the work force can be recruited locally, even in rural areas. However, a camp arrangement may still be required at very remote sites. Specialized services such as instrument and computer system maintenance may also have to be done on a contract basis.

Power requirements will vary widely, depending on the type of operation. Gold plants generally have low requirements that go mainly for pumping relatively small solution flows and running small heaters and furnaces. As a result, many remote gold plants use diesel generator sets or other types of onsite generation as the power is cheaper and more dependable. On the other hand, a large copper leach operation is power intensive. With flows as high as 40,000 to 50,000 gpm (2.5 to 3.2 m^3/s), water distribution systems may include multistage pumps with 500- to 1500-hp (37.5- to 110-kW) motors. Copper electrowinning is also power intensive, requiring at least 1 kWh/lb Cu. Thus power is usually purchased from a utility company. This power will be a big factor in the operating costs and may incur a high capital cost if an extensive pole line with transformers, rectifiers, and substations is required.

Water is another requirement that must be considered. There are two separate aspects: startup requirements and steady state needs. Startup requirements will be the higher of the two. The main reason is that the various catchment basins and recovery plant feed and tail water reservoirs must be filled. The heaps and dumps must also be saturated with water before outflow will occur. This represents a significant solution inventory since the rock mass will retain 8 to 12% moisture by weight. This is about 0.1 gal/ft^3 (13L/m^3) of heap or dump material.

Steady state requirements will be less because these cover only evaporation and other miscellaneous losses. Since most plants will have to operate under zero discharge permits, no net makeup will be required to compensate for bleed off. The exact make-up requirement will generally vary seasonally with the local evaporation rate. For copper in the southwestern United States, a typical annual average figure is 10 to 15 gal/min/ton (35 to 50 L/min/t) of daily production.

15.2.7 CASE HISTORIES

Two case histories are presented, one for copper and one for gold. Any individual facility will embody many site-specific design criteria. The histories presented here are developed by combining information from several actual or proposed operations. The resulting composites are representative of the medium-sized leach plants that are being developed today.

As with any mining and ore processing operation, the operating costs for surface leaching plants are driven by the mining strip ratio, ore grade, and the percentage metal extraction. This is because the mining cost per total ton of material moved is not particularly site specific; that is, the cost probably does not vary by more than 10 or 15%. However, the strip ratio, ore grade, and metallurgical recovery will vary widely, depending on the site and nature of the ore. Thus the cost per pound or ounce of product recovered varies by a much greater percentage than the mining cost per ton of material.

15.2.7.1 Copper Leach Project

PROJECT DESCRIPTION. The copper leach project involves exploitation of a modestly sized copper oxide deposit in the southwestern United States. The terrain is fairly rugged, with elevations ranging from 5800 to 6300 ft (1900 to 2065 m). The climate is dry and mild with about 10 in. (250 mm) of precipitation a year. This comes in the form of short but intense summer thunderstorms, plus occasional winter storms (rain or snow). Freezing conditions are generally limited to winter nights.

A thorough exploration drilling program has shown that the ore body can be mined as an open pit and contains 13 million tons (11.8 Mt) of minable ore with an average grade of 0.6% acid soluble copper. The cutoff grade is taken as 0.3% Cu. The mine plan calls for a strip ratio of 2.0:1, waste to ore. However, this includes 7 million tons (6.4 Mt) of low-grade leach material, averaging 0.25% acid soluble copper at a cutoff grade of 0.1% Cu. The balance of the waste is considered barren.

Metallurgical test work shows that the high-grade ore warrants crushing from ROM to –2 in. (–50 mm) as this increases copper extraction from 60 to 80%. The extraction rate also increases so that 60% of the copper is recovered in a 45-day leach cycle. Then 50% of the remaining copper is extracted in a long-term leach. Only 60% of the copper in the low-grade fraction is extracted from the ROM material when leached in permanent leach dumps. Overall acid consumption is 7.65 lb acid/lb Cu.

In order to balance capital requirements against revenues and to fully amortize the process equipment, a 10-year mine life was selected. This provides a steady state cathode output of 7300 tpy (6600 t/a).

PROCESS DESCRIPTION. The contract mining operation segregates the mined material into three categories: high grade, low grade, and barren. The respective mining rates for each are 1.3, 0.7, and 1.9 million tpy (1.2, 0.6, and 1.7 million t/a). Mining is done in two 10-hr shifts/day, 4 days/week, year round.

Crushing and heap stacking operate on the same schedule as the mine. High grade is hauled to a 30- by 40-in. (760- by 1000-mm) single toggle, skid-mounted jaw crusher set. The crusher has a 380 tph (345 t/a) capacity. This is comfortably oversized and provides the flexibility to match variations in mine output and make up production lost during downtime.

With a closed side setting of 8 in. (200 mm), the crusher produces a nominal 312 tph (284 t/h) of ore with 80% passing 7.5 in. (190 mm). This material is moved by overland conveyor 1800 ft (550 m) to the permanent pad area. Here the crushed ore is screened at 1.5 in. (38 mm) using a 6- by 10-ft (1800- by 3000-mm) double-deck vibrating screen. Screen oversize (approximately 250 tph or 225 t/h) is fed to a 5.5-ft (1700-mm) diameter standard cone crusher with a l-in. (32-mm) closed side setting. Screen undersize and crusher discharge are combined, conveyed to the leach pad, tripped onto a traveling stacker with a 10 ft (3 m) stacking arm, and loaded onto the pad.

The permanent pad area is 365 by 840 ft (110 by 255 m). It is constructed with a layered composite of asphalt and geotextile fabric laid over a prepared base. The latter contains a network of perforated pipe to serve as a leak detection system. The asphalt is overlaid with 2 ft (600 mm) of crushed and screened rock (2 by 8 in. or 50 by 200 mm). This layer serves as a permanent protective liner and also provides good solution drainage from the heap.

Ore is stacked 20 ft (6.1 m) high and leached in a single lift. This provides more effective solution-rock contact than the multiple-lift approach (see following case study). Ore is leached for 45 days. The pad is operated in a continuous cycle, with some material under leach, while other zones are being loaded with fresh ore or unloaded. The partially leached ore is drained and then reclaimed and sent by conveyor 1800 ft (550 m) to the leach dump area where it is co-mingled with the ROM low grade.

The dump leach area is in an isolated canyon. This requires about 500,000 ft^2 (46,450 m^2) of area that was cleared and compacted. Where necessary, a chemical soil amender or a spray-on asphalt coating was used to reduce dump foundation permeability. As an additional precaution against solution loss, a grout curtain from the surface to bedrock was installed across the mouth of the canyon. A solution recovery well was installed on the canyon side to recover any subsurface seepage, and monitor wells were installed down gradient from the grout curtain. These can be pumped back into the PLS pond if a leak occurs in the grout curtain.

Both the high- and low-grade material are leached with a network of drip emitters installed 30 in. (760 mm) apart and fed from HDPE headers. Emitter operating pressure is maintained at 20 psi (140 kPa). Both the tops and sides of the leach areas are irrigated at a flow rate of 0.007 gal/min/ft^2 (17 mm/hr). The lixiviant is SX plant raffinate acidified to 10 g/L with sulfuric acid.

Both leach areas have separate PLS ponds, each with 330,000-gal (1250-m^3) capacity. These are constructed by a cut-and-fill technique, then compacted and lined with 40-mi1 (l-mm) HDPE sheeting. Each pond has a vertical barge-mounted pump equipped with a 100-hp (75-kW) motor and can deliver 1100 gpm (70 L/s) against a head of 200 ft (60 m). The dump leach pond has the capacity to recirculate solution to build up the copper tenor.

The pad leach delivers 840 gpm (53 L/s) of PLS at a heading of 2.36 gpl copper. The dump leach area contributes 966 gpm (60 L/s) of PLS at a heading of 1.68 g/L copper. These flows are combined in the 650,000 gal (2460 m^3) SX plant feed pond constructed like the other ponds. This provides a 4-hr operating capacity and delivers 1800 gpm (110 L/s) of PLS at an average copper tenor of 2.0 g/L. Flow from the feed pond to the SX units is by gravity.

Both the SX and EW facilities are over-designed by 10% to accommodate the normal variations in leach extraction. The SX plant consists of two stages of extraction and one stage of stripping (2 x 1 circuit), all operated in series. In the first two stages, copper is extracted from the PLS and loaded onto an organic extractant (12% by volume) carried in a kerosene-type diluent (88% by volume). Each extraction unit has a 3-stage mixer with a total retention time of 3 min. The organic to aqueous (O/A) ratios are 1.0/1.0, and the settlers are designed for a settling rate of 2.0 gal/min/ft^2 (4.9 $m^3/m^2/h$). Settlers are 48 ft (15 m) wide, 56 ft (17 m) long, and 40 in. (1000 mm) deep. Copper recovery from the PLS is 95% with a 95% plant availability.

In the stripping unit, the loaded organic (4.3 g/L Cu) is contacted with 345 gal/min (22 L/s) of lean electrolyte (35 g/L Cu and 160 g/L sulfuric acid). This strips copper from the organic, generating a rich electrolyte containing 55 g/L Cu and 146 g/L acid. This unit is similar to the extraction units, except that mixing is only 2-stage, and the overall O/A ratio is much higher (5.3:1).

From solvent extraction, the rich electrolyte is returned to the EW tankhouse via the electrolyte filter and recirculation tank. Barren leach solution returns to the 500,000-gal (1900-m^3) raffinate pond. There the leach solution is reacidified, and about 300 gpm (19 L/s) of make-up water is added to offset losses in leaching that are due to evaporation and entrainment in the ore. The raffinate pond has two operating vertical pumps, each with 150-hp (110-kW) motors. These can deliver 1100 gpm (70 L/s) against a 300 ft (90 m) head. One pump normally feeds each leach area.

The rich electrolyte is processed in the tankhouse to produce high-quality cathode. The ISA process system of permanent stainless steel cathode blanks is used instead of having a separate electrolyte circuit for production of copper starter sheets. The corresponding anodes are lead, alloyed with tin and calcium for corrosion control.

The tankhouse contains 36 cells, each holding 39 cathodes and 40 anodes connected by copper buss work. Cells are constructed of concrete with wooden floors and PVC para-liners and buffer sheets. Electrolyte is heated to 115°F (46°C) and flows through the cells at a rate of 0.75 gpm/cathode (0.003 L/s/cathode). A rectifier supplies 22,500 amps at 80 v dc. Primary voltage is 4160 v. The operating current density is 23.2-amps/ft^2 (250-amps/m^2). Current efficiency is 95%.

Operationally, one-third of the cathodes in a cell is pulled at a time. These are washed free of electrolyte, then manually stripped from the stainless steel blanks. The normal pulling cycle per cathode is 7 days, giving 190 to 200 lb (85 to 90 kg) cathodes for bundling and shipment. Slightly over 200 cathodes are normally stripped one shift per day to meet the 20-tpd (18-t/d) output.

The tankhouse itself has only a roof and partial siding to improve the ventilation needed to control the sulfuric acid mist arising from the cells. An overhead crane is provided to move cathodes (and anodes) as appropriate.

In addition to normal utilities and ancillaries, the copper leach project includes a tank farm. This contains the storage and circulating tanks for the SX and EW operations. The tank farm area is located below the SX and EW operations. This permits gravity flow to the tank farm and low head pumping back to the other areas. The SX area of the tank farm includes the barren organic surge tank, diluent storage tanks, a holding tank, a gunk tank, and the backwash bleed tank. The EW area contains the electrolyte filter and feed tank, the electrolyte heat exchanger and package boiler, the electrolyte recirculation tank, and the lean electrolyte tanks. The filter is a combined media (anthracite and garnet) automatic backwash unit. This unit is essential for maintaining electrolyte purity and ensuring production of high-grade cathodes.

CAPITAL COSTS. The capital cost (total installed basis) for the facility described above is developed in March 1990 dollars. No capital costs for mining equipment or mine support facilities

Table 15.2.2. 1990 Capital Cost Breakdown for the Copper Leach Project

Code of Accounts	Cost, $1000s

are included as the contract miner has responsibility for these. There is no allowance for housing or a construction camp. Any of the owner's costs incurred before the start of engineering are also excluded. This exclusion applies to permitting, although the facility was designed and constructed in accordance with regulations in effect at the time.

The total capital cost is $16,361,000. The cost breakdown is given in Table 15.2.2. This is based on a typical construction code of accounts. (Compare with the next case study where a process-area breakdown is used.) These costs exclude any sale or ad valorem taxes, the environmental monitoring system, and the power line upgrade. The latter is provided by the local utility with cost recovery through a rate adjustment.

OPERATING COSTS. The direct operating costs for the copper leach project are developed in March 1990 dollars. These include supervision, labor, supplies, and utilities. Staffing requirements are shown in Table 15.2.3.

Table 15.2.4. 1990 Operating Costs for the Copper Leach Project

Area	Annual Costs, $1000s	Cost $/lb Copper
General and Administrative	$ 454	$0.031

SX-EW	2796	.191
Maintenance	780	.050
Total Direct Operating Costs	$9867	$0.675

a. Includes transfer of ore from the pad to the leach dump.
b. Includes purchase of 55,845 tpy (50,770 t/a) acid @ $25/ton($28/t).
Conversion factor: 1 lb = 0.4536 kg.

Operating costs are presented in Table 15.2.4. Labor costs include a payroll burden of 32%. General and administrative costs include local taxes and insurance, but federal taxes are excluded. Also excluded are depletion, depreciation, capital financing charges, and any corporate allocations.

Mining is the single most expensive component of the operation. Contractor rates include $0.65/ton ($0.72/t) to mine and haul ore to the crusher, $0.85/ton ($0.94/t) to mine and haul barren and low grade, and $0.30/ton ($0.33/t) to move leached ore from the pad to the leach dump. These are substantially less than the unit costs in the following case study. The differences reflect shorter truck hauls, use of conveyors for ore movement, a longer-lived operation, and continuous (year-round) operation. Costs in the following case reflect the three-month idle period and the need to mobilize and demobilize annually.

Originally, the copper leach project was planned as a conventional heap leach operation. This called for the ROM ore (+0.3% Cu) to be leached on a single-use pad. Ultimately, this pad would have been covered with three 30-ft (9-m) lifts. Overall copper recovery would have been only 70%; no low-grade leaching was planned. This approach saved about $1 million in capital costs over the scenario described above. However, less copper was produced per ton mined, so more ore would have to be mined per year to reach the desired production level. This reduced mine life to seven years and increased operating costs by $0.11/lb ($.24/kg) of copper. Thus it was a less attractive option and was not pursued.

15.2.7.2 Gold Leach Project*

PROJECT DESCRIPTION. The gold leach project is located in northern Nevada. The setting is typical basin and range, with rolling hills and an average elevation of 6500 ft (2000 m). Subfreezing temperatures are prevalent during the winter so that mining and ore processing are conducted in a 9-mo/yr schedule (March through November). However, use of drip emitters allows for a year-round leach operation. Water is available from wells on the property, and power is available from the local utility.

The ore body is mined by open pit techniques and contains 7 million tons (6.4 Mt) of minable ore at an average grade of 0.05 oz/ton (opt) (1.7 g/t) gold and 0.12 opt (4.1 g/t) silver. For

*Case study contributed by J.H. (Jack) Templeton, Brown & Root Braun, Houston, TX.

purposes of illustration, two different waste-to-ore strip ratios are used: 0.75:1 and 2.0:1.

Column leach tests on agglomerated ore samples from throughout the deposit show average gold and silver extractions of 85 and 40% respectively. Similar recoveries are achieved in the operation, but leach times are extended to 60 days.

PROCESS DESCRIPTION. Contract mining is employed and uses conventional drilling, blasting, loading, and hauling operations described elsewhere (see Section 9). ROM ore is delivered to the crushing plant or the adjacent 10,000-ton (9100-t) stockpile. Both mining and primary crushing operate 40 wk/yr, 4 days/wk, two 10-hr shifts/day, giving 160 operating days/yr. Production is 8750 tpd (7950 t/d), equivalent to 1.4 million tpy (1.3 Mt/a) of ore.

The ore is normally dumped directly into a 100-ton (90-t) live-capacity hopper equipped with a fixed grizzly with 16-in. (400-mm) bar spacing. Any oversized rock is broken with an air-driven rock breaker mounted on a hydraulic boom. Ore is withdrawn from the hopper with an apron feeder. This feeds a single toggle jaw crusher (36 by 48 in., or 910 by 1200 mm) with a 9-in. (230-mm) closed-side setting. The primary crusher discharge feeds a 20,000-ton (18,200-t) live-capacity coarse ore stockpile.

This stockpile, nominally –8 in. (–200 mm), feeds the fine crushing plant. A single conveyor belt is fed by two under-pile vibrating feeders. The ore is delivered to two stages of fine crushing that are operated 6 days/wk, two 10-hr shifts/day, on the 40-wk/yr schedule. Production through this circuit is 5830 tpd (5300 t/d). Fine crushing is done in open circuit with an 8- by 20-ft (2400- by 6100-mm) double-deck vibrating screen equipped with 0.5-in. (13-mm) slots. The first crusher is a 7-ft (2130-mm) diameter standard cone crusher with a l-in. (25-mm) closed-side setting. This unit discharges to the screen. The screen oversize feeds a 7-ft (2130-mm) diameter short-head cone crusher. This uses a closed side setting of 3/8 in. (9.5 mm). Short-head crusher product is 80% –0.5 in. (–13 mm). When combined with the screen undersize, the agglomeration feed is 86% minus 0.5 in. (13 mm).

Water sprays at crusher and conveyor discharge points control dust emissions and provide an agglomeration feed moisture of 8%. The agglomeration immobilizes fines (–65 mesh or –0.2 mm) and improves heap permeability during leaching. The ore contains less than 5% clay and can be agglomerated by adding 10 lb/ton (5 kg/t) Portland cement and 3 lb/ton (1.5 kg/t) hydrated lime to the fine ore. The constituents are intimately mixed on three conveyor belts operating in series. Strong cyanide solution (1%) is sprayed onto the mixture at each free-fall point. This increases the moisture to 13% and provides about 50% of the sodium cyanide needed for leaching. This practice also starts gold dissolution before the agglomerates ever reach the heaps. To maximize the agglomerate strength, a minimum 72-hr curing period is used. This minimizes decrepitation of the agglomerates during leaching.

The agglomerated ore is transferred to overland conveyors and moved 1800 ft (550 m) to the leach area. This consists of three single-use leach pads or cells, each 600 by 100 ft (180 by 30 m). Ultimately, each cell will contain four 18-ft (5.5-m) lifts of agglomerated ore. The pads are sloped at a grade of 3% to facilitate drainage of PLS from the heaps. To meet environmental restrictions, the pads consist of a graded, compacted clay liner 6 in. (150 mm) thick. This is overlaid with a 40-mil (l-mm) HDPE liner. Liner protection is provided by a geotextile overlay bedded with 8 in. (200 mm) of –0.5 in. (–13 mm) crushed low-grade ore. Collection of PLS is enhanced by bedding 3-in. (76-mm) perforated plastic pipe in the crushed material.

For purposes of control, each cell is divided into four equal subcells. As soon as a subcell is available, it is leached with solution from the barren solution pond. This contains 1.0 lb NaCN/ton solution (0.5 g/L) at pH 10.5. Both the top and sides of the subcell are irrigated with a drip emitter system at a flow rate of 0.005 gal/min/ft^2 (12 mm/h). Leaching is continued for 60 days, with the PLS draining to the PLS pond. Average gold and silver contents in the PLS are 0.018 and 0.022 opt of solution (0.62 and 0.75 g/L), respectively. Following the 60 days of leaching, the subcell is allowed to drain and dry out for another 60 days. Then another lift of ore is added, and the leach cycle is repeated.

To avoid needless dilution of values, no rinsing will be done until the final lift has been leached. Following rinsing, the rinse water will be neutralized with an excess of dilute hypochlorite solution to destroy the residual cyanide. The neutralized solution will then be used to detoxify the heap.

Both the PLS and barren solution ponds have 2.4 million gal (9100 m^3) capacities and are lined with 40-mil (1-mm) HDPE. There is a third pond of the same capacity that holds the fresh water supply and contains any overflows or runoff. A fourth much smaller pond (35,000 gal or 130 m^3) is located at the process plant. This is designed to contain waste water and slurry streams from the carbon handling circuits. All ponds are fenced to exclude livestock and wildlife.

PLS is advanced continuously from the PLS pond to the carbon adsorption section at a flow rate of 1580 gpm (100 L/s). This section contains five 10-ft (3000-mm) high by 10-ft (3000-mm) diameter columns that are operated in series. Each column contains 2.6 dry tons (2.4 t) of 6- by 16-mesh (3.36- by 1.00-mm) activated carbon.

Solution advances from column to column by gravity due to the 3.5-ft (1100-mm) elevation difference between columns. Nominal solution retention time is 2 min/column. Carbon is advanced counter-currently using recessed impeller centrifugal pumps. Final carbon loading is 135 opt (4620 g/t) gold and 155 opt (5300 g/t) silver, with 95% gold adsorption and 90% silver adsorption from the PLS. The stripped solution is discharged back to the barren solution pond. The gold and silver contents of the barren solution are 0.0009 and 0.0022 opt (0.031 and 0.075 g/t) of solution, respectively.

Carbon is advanced from column to column at a rate of 1.3 tpd (1.2 t/d). Loaded carbon exiting the last column is dewatered and rinsed on a 3- by 6-ft (900- by 1800-mm) vibrating screen and is discharged into a conical bottom storage tank (3.5-ton or 3.2-t capacity). This allows for one 3.5-ton (3.2-t) batch to be processed 3 days/wk.

Processing utilizes a modified Zadra stripping technique. It is performed in a pressure stripping vessel operated at 35 psi gage (240 kPa) and 280°F (138°C). After being pumped into the vessel, the carbon batch is contacted with caustic cyanide solution (1% NaOH, 0.1% NaCN), which solubilizes the precious metals adsorbed on the carbon. Ten bed volumes (18,000 gal or 68 m^3) of strip solution are passed through the vessel to dissolve the gold and silver, a process requiring about 20 hr. The pregnant strip solution (PSS) is held in an insulated storage tank before being advanced to electrowinning.

The PSS exiting the stripping column passes through a plate and frame heat exchanger and warms the barren strip solution to 165°F (74°C). The warmed solution then passes through a second heat exchanger where live steam heats the strip liquor to 290°F (143°C).

Gold tenors in the PSS are increased and lower residual gold concentration on the stripped carbon are achieved by splitting the PSS. The first two-thirds of the PSS is sent directly to the electrowinning storage tank. However, the remainder is stored and used as the initial strip solution for the next batch of carbon. This also reduces the flow to electrowinning by one-third. Recovery of precious metals from the carbon averages 93% for gold and 90% for silver. The stripped carbon contains about 9.5 opt (325 g/t) gold and 15.5 opt (530 g/t) silver. This carbon is advanced to the reactivation circuit.

When a batch of carbon has been stripped, the PSS storage tank will contain 12,000 gal (45 m^3) of solution containing 428 opt (14,640 g/t) gold and 484 opt (16,600 g/t) silver. This solution is first pumped to the primary electrolytic cell at 10 gal/min (0.6 L/s). About 80% of the gold and silver are recovered here. The partially stripped PSS is then recirculated through a secondary cell at twice the flow rate until the gold content is reduced to a minimum of 10 ppm. This raises overall recovery to 89% for both gold and silver. At this point, barren strip solution is drained to the barren strip solution tank.

The primary and secondary cells are identical. Each has a volume of 20 ft^3 (0.6 m^3), with nine stainless steel wool cathodes and stainless steel plate anodes. Cell buss work is copper. Direct current is supplied to the cells at 168 amps and 6 v. Current density is 14 amps/ft^3 (490 amps/m^3) of cathode, and current efficiency is 30%. Solution residence time in the primary cell is 15 min. Total time to process a batch of PSS through the primary cell is 20 hr.

About 80% of the recovered precious metals deposit on the steel wool. The remaining 20% collects as a sludge on the cell bottoms. After each electrowinning cycle, half the loaded cathodes are removed from the primary cell and the other half are advanced. Sludge is collected once a week. The same operations are performed once every two weeks in the secondary cell.

The cathodes and dewatered cell sludge are dried and mixed with appropriate fluxes (sodium nitrate, sodium borate, borate, silica, and sodium carbonate). Then the mixture is charged to a l-ft^3 (0.03-m^3) induction furnace. When the charge is fully molten, the slag is poured off, and then the remaining doré metal is cast into a button. This doré is remelted in a smaller furnace (0.2 ft^3 or 0.006 m^3) and cast into bullion bars containing 47% gold and 53% silver. (This assumes a lack of contaminants, such as copper.) Total physical metal production is 59,500 oz/yr (1850 kg/yr) gold and 67,200 oz/yr (2090 kg/yr) silver.

The stripped carbon is either regenerated or returned directly to the carbon adsorption circuit, depending on its reactivity. However, every batch of carbon is washed with 5% nitric acid before regeneration. The acid wash dissolves the calcium carbonate that has deposited in the pores of the carbon. Washing with deionized water and then a 10% caustic solution removes any residual acidity. This is always a concern when sodium cyanide is one of the principal reagents used in the operation.

The washed carbon is dewatered and then reactivated. This requires heating the carbon to 1200°F (650°C) in a horizontal rotary kiln in an atmosphere devoid of oxygen. Carbon is treated at a rate of 200 lb/hr (90 kg/h). Retention time at temperature is 20 to 30 min. Great care must be exercised to avoid overheating or infiltration of air. These can greatly reduce carbon reactivity.

As an alternate to carbon adsorption, stripping and electrowinning, the gold and silver in the leach solution could be recovered by the Merril-Crowe zinc precipitation process. Here the addition of zinc precipitates both gold and silver from the clarified and deaerated PLS. The precipitate is then smelted to produce doré metal. Zinc precipitation is generally favored when silver contents are high. Since silver loadings on carbon are much lower than gold loadings, high silver contents mean that a very large amount of carbon must be handled. Also the cost for carbon stripping per ounce of gold recovered is increased. This creates materials handling problems and increases precious metals in inventory.

Table 15.2.5. 1990 Capital Cost Breakdown for the Gold Heap Leach Project

Area	Cost, $1000s
Crushing Plant	$ 2,019

a. Exclusive of contractor

In addition to the process facilities themselves, the normal types of infrastructure will be required. These include reagent receiving, storage, and mixing. The principal reagents are fresh carbon (delivered in drums), sodium cyanide (delivered as prills or briquets), cement and lime (delivered in bulk), caustic soda (delivered as flake or pellet, or as a 50% solution), nitric acid (64.2% solution), and an anti-sealant to keep the emitters and leach lines clear.

CAPITAL COSTS. The capital cost (total installed basis) for the facility described above is developed in June 1990 dollars. No capital costs for mining equipment or mine support facilities are included as the contract miner has responsibility for these. There is also no allowance for housing or camp costs. Owner's predevelopment costs are excluded from the estimate. These include land acquisition, exploration and in-fill drilling, assaying and test work, geotechnical and hydrologic studies, environmental baseline studies, and permitting. However, the capital costs do reflect a facility that is designed and constructed to meet all environmental regulations in effect in Nevada at the time of construction (early 1990). The leach pads required for the first year of operation are capitalized. Pads for subsequent years are expensed in the year incurred.

The total capital cost is $15,560,000 for the case where the strip ratio is 0.75. The cost breakdown is presented in Table 15.2.5. The higher strip ratio will increase needed working capital.

OPERATING COSTS. The direct operating costs for the gold heap leach facility are developed in June 1990 dollars. These include supervision, labor, supplies, and utilities. Staffing requirements are shown in Table 15.2.6. Labor costs include a

Table 15.2.7. 1990 Operating Costs for the Gold Heap Leach Project at a Strip Ratio of 0.75:1

Area	Annual Costs, $1000s	Costs, $/oz Gold
General and Administration	$ 1,198	$ 19.83
Mining	4,386	72.61
General Plant Operation	912	15.09
Crushing, Agglomeration, and Pad Loading	1,840	30.46
Leaching	1,792	29.66
Carbon Loading and Regeneration	455	7.54
Stripping, Electrowinning, and Refining	420	6.95
Maintenance	626	10.36
Total Direct Operating Costs	$11,629	$192.50

Conversion cost: 1 oz = 28.35 g.

Table 15.2.8. 1990 Operating Costs for the Gold Heap Leach Project at a Strip Ratio of 2.0:1

Area	Annual Costs, $1000s	Costs, $/oz Gold
General and Administration	$ 1,198	$ 19.83
Mining	6,486	107.38
General Plant Operation	912	15.09
Crushing, Agglomeration, and Pad Loading	1,840	30.46
Leaching	1,792	29.66
Carbon Loading and Regeneration	455	7.54
Stripping, Electrowinning, and Refining	420	6.95
Maintenance	626	10.36
Total Direct Operating Costs	$13,729	$227.27

Conversion factor: 1 oz = 28.35 g.

35% payroll burden, a 10% overtime allowance for hourly employees, and a 5% production bonus for supervisory positions. Local taxes and insurance are included, but federal income taxes are excluded. Depletion, depreciation, capital financing charges, and corporate (offsite) overhead allocations are also excluded. However, a 10% contingency is included.

Operating costs for the two strip ratios (0.75 and 2.0) are shown in Tables 15.2.7 and 15.2.8. These costs are based on a contract mining price of $1.20/ton ($1.32/t) of ore and waste mined. This figure includes the contractor's direct costs, general overhead, depreciation, and profit. The impact of mining is obvious from the tables. Even at the low strip ratio, mining accounts for over one-third of the operating costs or $73/oz ($2/g) of gold. Increasing the strip ratio to 2.0 adds about $35/oz ($1/g) to this cost.

Chapter 15.3
SOLUTION MINING: IN SITU TECHNIQUES

DONALD R. RICHNER, D'ARCY SHOCK, JON K. AHLNESS, DARYL R. TWEETON, WILLIAM C. LARSON, DANIEL J. MILLENACKER, AND ROBERT D. SCHMIDT

In situ solution mining is a true mining technique. It represents an alternative to mechanical excavation and is applicable to a wide range of commodities that are soluble in water or an aqueous lixiviant. Since most waste components are not soluble, the gangue constituents tend to be left in place as the values are solubilized and removed to a surface processing facility. As a result, in situ operations are characterized by a singular absence of mine waste piles and tailings impoundments. However, in situ mining does carry a significant potential for contamination of subsurface water. As a result, flow control is a major factor in the design of in situ well fields.

Chapter 15.3 is divided into three subchapters on the basis of the characteristics of the minerals being recovered by in situ techniques. Water soluble salts are addressed in Chapter 15.3.1. These include such minerals as potash, trona, nahcolite and, particularly, common salt (NaCl). In addition to a high degree of water solubility, these salts are typically found in extensive beds where the salt itself is the matrix.

Particularly for common salt, the cavern produced by solution mining may have greater value than the sodium chloride that was extracted. When such caverns are created in salt domes or beds, they have an invariant temperature and a very high degree of inherent stability. Thus the caverns are widely used to store hydrocarbon products and a variety of materials including hazardous wastes. Due to the removal of large contiguous quantities of material, surface subsidence can be a problem in such operations.

The second segment of the chapter, 15.3.2, focuses on Frasch sulfur mining. Frasch minable deposits do not occur in as massive a form as the soluble salts, even though the sulfur is often associated with salt domes. However, the sulfur occurrences are continuous even if they do not form the matrix of the deposit.

Unlike other forms of in situ mining, the water used in Frasch mining is not a true lixiviant. Instead, the water is merely the medium for transferring heat into the deposit. The heat then melts the sulfur so that it will drain to subterranean pools for pumping to the surface.

Hard-rock in situ mining is the final subject, 15.3.3, covered in Chapter 15.3. In this type of operation, the values are often disseminated and discontinuous when compared to soluble salts and sulfur. Another characteristic of hard-rock in situ mining is its similarity to surface leaching (Chapter 15.2), particularly in terms of ore-lixiviant systems.

A final point is that the soluble salts and sulfur can be mined from undisturbed in-place deposits. While hard-rock in situ operations also treat in-place deposits, some disturbance is often required. This takes the form of formation stimulation using such techniques as hydrofracturing which are borrowed from the oil industry. These are used to enhance the permeability of the formation so that the lixiviant can penetrate to the disseminated mineral values more easily.

15.3.1 IN SITU MINING OF SOLUBLE SALTS

DONALD R. RICHNER

15.3.1.1 Introduction

Extraction projects involving the solution mining of water-soluble evaporites have continued to expand rapidly during the past decade.

The selective dissolution, recovery, and processing of different kinds and/or admixtures of evaporite mineral deposits are being studied and field tested in many areas of the world. Commercial operations involving the dissolution of trona (sodium carbonate/sodium bicarbonate), potash (potassium chloride, potassium carbonate), and magnesium chloride have been established in North America and Europe, and are anticipated within South America, Asia, and Africa before 1992.

Problems relating to the selective dissolution and recovery of evaporite minerals (ores) are being approached from many fronts. Well drilling and completion technology now embraces a variety of nonvertical drilling techniques, low-density cements, special drilling fluid compositions, and diagnostic well-testing procedures. A variety of versatile geophysical well-logging tools has been developed and the identification and quantification of many different evaporite minerals and mineral assemblages are now possible. Core laboratory studies now frequently include a combined mineral identification/dissolution rate/rock mechanics investigation that can be directly integrated with a sophisticated geophysical well-logging program. After proper calibration of the two investigative systems, considerable detailed exploration can then be conducted using the more rapid, less-expensive well logging approach.

The dissolution process for mineral wells embraces a number of single-well concepts involving multiple concentric or independent tubing strings, various fluid injection/production depth combinations, as well as several different cavern roof-protection schemes involving "blankets" of liquid hydrocarbons (crude oil, LPG), gases (nitrogen, carbon dioxide), and solids (floatable "cements", hollow spheres, etc.).

Multiple-well interconnections can also be accomplished (when geologic conditions are appropriate) through roof padding, hole deviation, and hydraulic fracturing. Hole deviation technology, particularly horizontal drilling, is being driven by new opportunities for the development of thin petroleum reservoirs. Hydraulic fracturing concepts, fueled by recent rock mechanics investigations related to hydrocarbon production, now envision well interconnection through vertical or inclined fractures, as well as improved success in "horizontal" fracturing.

Underground storage technology (Chapter 24.2) has developed rapidly as a result of large-scale storage operations and

Table 15.3.1.1. Commodities Stored in Solution-Mined Salt Caverns (PB-KBB Inc.)

Solids	Liquids	Gases
Grains	Crude Oil	Natural Gas
Wastes	LPG[a]	Helium
	Ethylene Dichloride (FDC)	Chlorine
	Special Brines	Compressed Air
		Nitrogen
		Carbon Dioxide

[a] LPG (liquified petroleum gas) such as (1) propane, (2) butane, (3) LP mix, (4) ethylene.

research and development programs conducted by various governmental agencies, research institutions, and large petroleum operators. Within the United States, these include the Strategic Petroleum Reserve (690 million bbl or 110 million m^3 of crude oil), the Louisiana Offshore Oil Port (LOOP) (32 million bbl or 5 million m^3 of crude oil), and more than 1200 caverns in salt containing more than 450 million bbl (70 million m^3) equivalents of liquid and gaseous hydrocarbons. These storage facilities have created opportunities for the development of new materials of construction and new techniques for testing and evaluating materials, equipment, and procedures. There are also increasingly more stringent requirements for safety and the protection of the environment from hazards related to the development of such subsurface facilities. Table 15.3.1.1 contains a partial listing of commodities storable within solution-mined caverns.

The strong trend against disposal of industrial and hazardous wastes within landfills has generated considerable pressure toward incineration and burial underground within impermeable strata (Chapter 24.3). Under tightly controlled conditions, certain salt deposits appear to hold promise for the development of waste repositories. Preliminary designs for salt cavern repositories located within Texas have been completed, and permitting (licensing) efforts are presently underway for disposal within several salt domes.

The development and expansion of governmental regulation and control are two of the most rapidly growing forces leading to innovation and change in the subsurface technologies of solution mining, underground storage, and underground disposal.

The business slowdown of the mid-1980s also had a profound effect upon many down-hole technologies. Income and profits were severely squeezed, leading to the liquidation of numerous small, high-cost, and inefficient companies, and to the consolidation of many former competitors. Most services and some materials were heavily discounted. Several organizations used the general malaise in down-hole activity to press forward in research and development, an effort that has now yielded an explosion of new and/or improved equipment, materials, and services.

Still on the horizon: the potential advent of "superconductivity" could lead to a rapid increase in the development of cryogenic underground storage in salt caverns.

15.3.1.2 Types of Evaporite Deposits

The evaporite professional characterizes evaporite deposits as to their *chemical nature* and their *physical form.* Chemistry provides information concerning the products that can be manufactured and the processes that will be involved. Form—the physical attributes of the deposit and enclosing strata—indicate criteria concerning the solution mining system(s) and its geotechnical and economic limitations for producing ore.

Evaporite deposits being explored or developed by solution mining techniques include salt (halite), potash (sylvite, sylvinite, carnallite), magnesia (tachydrite, bischofite), trona (sodium carbonate and sodium bicarbonate), nahcolite (sodium bicarbonate), borates (borax, ulexite, colemanite), and sodium sulfate (mirabilite or glaubers salt, thenardite, etc.).

The form (shape, attitude, extent) of these deposits varies widely—from flat lying to vertical, in thin-to-thick extensive sheets to small discontinuous lenses, and at shallow to ultra-deep depths. Deposits such as the salt domes of the US Gulf Coast and the Middle East, or the highly contorted strata within the US interior, or the Zechstein of Europe require special solution mining techniques.

For discussion of the basic rock mechanics properties of evaporites, see Chapter 10.7.

15.3.1.3 Mineral Exploration/Evaluation

The exploration and evaluation of evaporite mineral deposits have been significantly improved through modified geophysical surveying equipment, procedures, and diagnostic capabilities.

Ground surface and down-hole seismic surveys may be combined to yield more useful stratigraphic information:

1. Both within and *below* an exploration borehole.
2. Lateral correlations beyond a borehole or between boreholes.
3. Vertical and horizontal boreholes within evaporite beds.

Down-hole geophysical well-logging equipment and procedures have improved the definition of thin (0.5 ft or 0.2 m) evaporite beds. In particular, gamma ray spectrometry has increased the potential for the identification and quantification of potash mineralization within vertical and inclined boreholes.

Geophysical well-log combinations readily provide geomechanical information relating to the in situ stress field: direction and magnitude of principal stress, improved hydraulic fracture diagnostics, probable direction of maximum cavern enlargement, etc.

Cavern sonar surveys, now offered by several companies, include both horizontal and inclined distance measurements from the borehole to cavern roof, walls, and floors. Digital recording and processing of all signals is now commonplace. At least one company (Prakla-Seismos AG) has developed the ability to survey within multi-fluid cavern environments (water, oil, and gas), and through one string of casing (Fig. 15.3.1.1).

Newly developed cavern radar surveys are also offered by Prakla Seismos. In 1988, this technique was introduced into the United States during the monitoring of the CAES (compressed air energy storage) cavern being developed by the Fenix & Scisson division of PB-KBB Inc. within the McIntosh Salt Dome near Mobile, AL.

15.3.1.4. Drilling Technologies

New drilling technologies have continued to evolve at a rapid pace. Their main goal is to improve the economics of drilling—to decrease costs per foot or meter—or to permit drilling under conditions that were formally prohibitive. Much of the industry's success is due to down-hole innovations such as measurement-while-drilling systems, steerable down-hole motors, and improved drillbits. Top-drive drilling systems are playing an important role in reducing hole problems and improving safety. Slanthole drilling is useful in the exploration of steeply dipping evaporite beds; horizontal and sub-horizontal directional drilling techniques are beginning to offer practical solutions to multi-cavern interconnection and operation.

DIRECTIONAL DRILLING TECHNOLOGY. Directional drilling technology presently provides controls to reach thousands of feet (meters) horizontally, and to build angles ranging

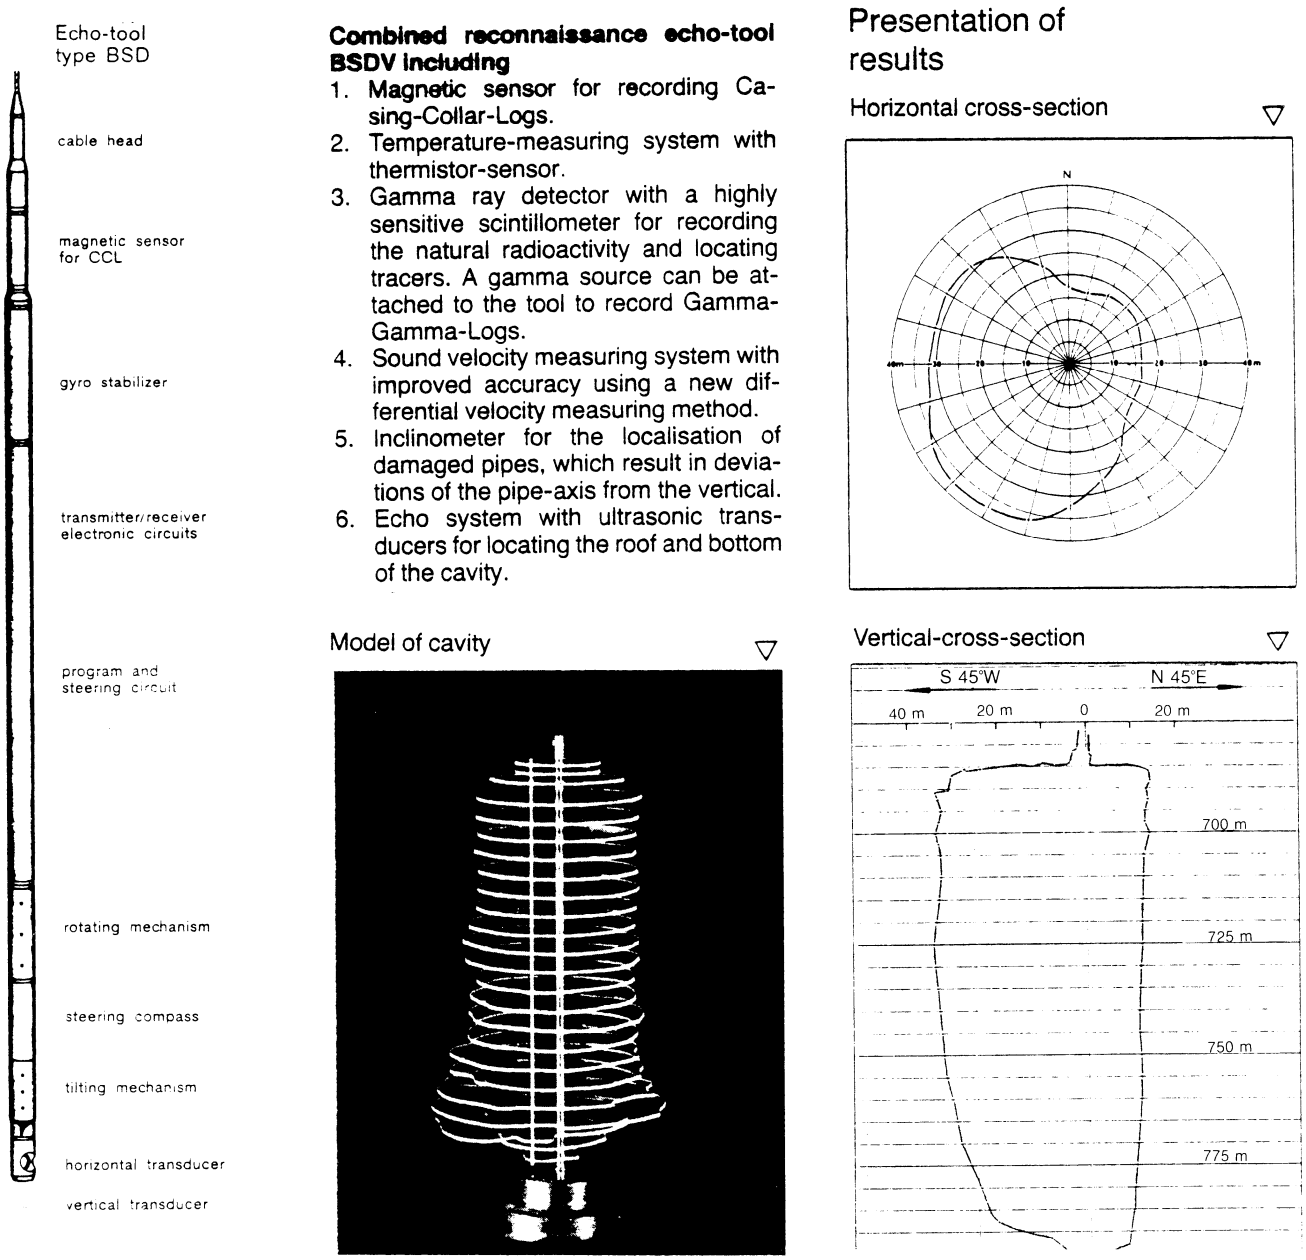

Fig. 15.3.1.1. Prakla-Seismos type BSD sonar surveying presentation (*courtesy:* PB-KBB/Prakla Seismos Joint Venture). Conversion factor: 1 ft = 0.3048 m.

from 3 to 35°/100 ft (30 m). Most drilling systems include a slow-speed, high-torque variable-bend, positive-displacement, down-hole motor, with special stabilizing features. Bottom-hole assemblies may contain a tri-cone or polycrystalline bit; a high-torque, slow-speed motor; a measurement-while-drilling (MWD) tool; and key positioning stabilizers of various designs and gages. Examples of directional drilling profiles are shown in Fig. 15.3.1.2.

Special problems related to high-angle drilling programs include (1) cuttings removal from the downside of the drillhole, (2) annulus in the cement sheath on the top side of the casing, (3) specialized equipment and procedures needed for geophysical well logging, and (4) difficulty in maintaining directional control within evaporite mudstones. Despite these problems, both the International Salt Co. (Akron, OH) and the Morton Salt Co. (Rittman, OH) have undertaken horizontal drilling in order to achieve an early connection between salt wells where hydraulic fracturing was unsuccessful and roof-pad interconnections by leaching were time-consuming. Additional installations are being designed for salt wells in Ontario, Canada, and nahcolite wells in Colorado.

Extended-reach horizontal wells are drilled as directional wells before becoming horizontal.

Drainhole drilling techniques usually involve entering an existing vertical well, cutting a section through the casing, and drilling a horizontal hole. The radius of the "drainhole" is typically only 30 to 40 ft (9 to 12 m), and the horizontal section of the borehole frequently extends only 300 to 400 ft (90 to 120 m).

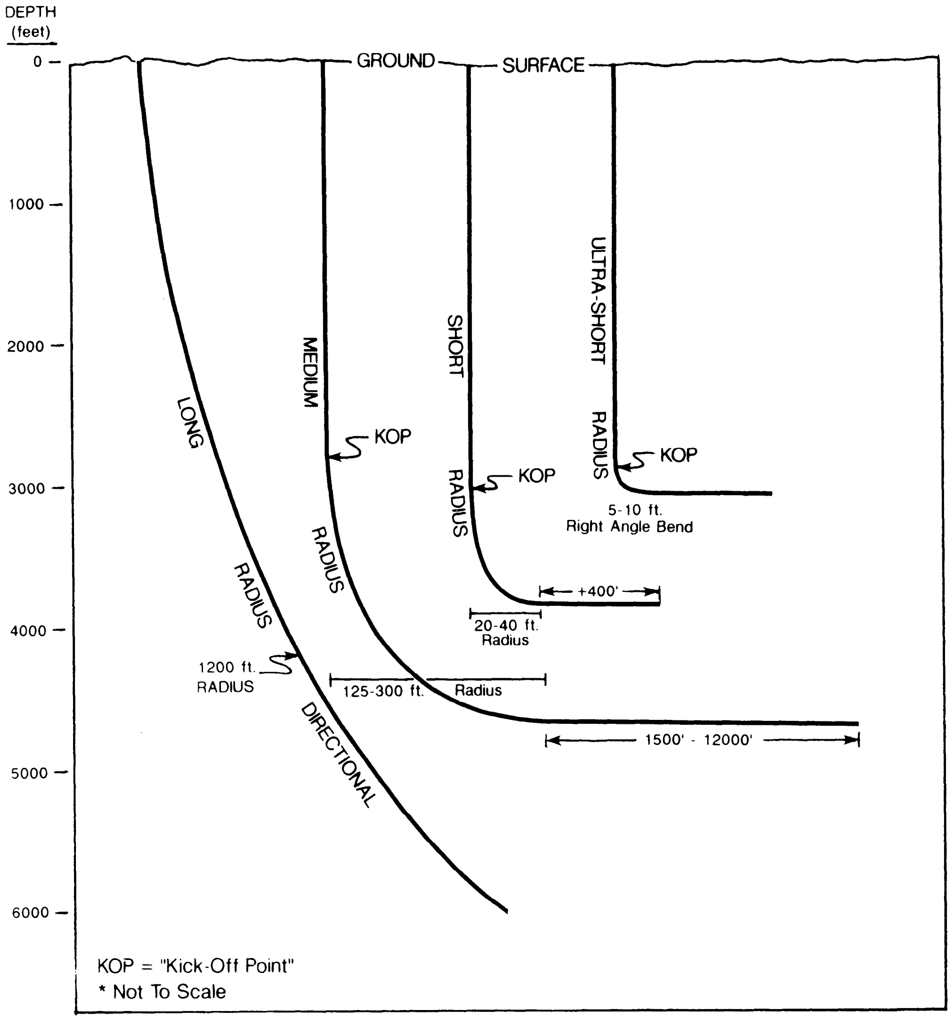

Fig. 15.3.1.2. Examples of directional drilling well profiles (*courtesy:* PB-KBB, Inc.). Conversion factor: 1 ft = 0.3048 m.

There is presently no good technique for logging or casing the horizontal section, and future applications to solution mining of evaporites may be limited to interconnections with existing brine caverns. The drainhole drilling technique is illustrated in Fig. 15.3.1.2.

Slanthole drilling requires a drilling rig with a mast that can be slanted up to 45°. Pipe drag during lifting and lowering operations is considerable. Lifting capacities required to pull off-bottom with the drill string or liner and push-down capacity to obtain force on the drill bit or push a liner to bottom can be significant. Such "push-down" capability is required because only 70% of the weight of the drill collars and heavyweight drill pipe is applied down the drill string at 45°. This effective weight rapidly declines as the wellbore angle from vertical increases.

Slanthole drilling techniques can be particularly useful during exploratory drilling of steeply dipping evaporite strata, such as potash or magnesium chloride beds within a salt diapir (Fig. 15.3.1.3).

Slanthole drilling has terminated in a horizontal drilling program within the shallow Athabasca oil sands. Modifications of this technique may someday be applied to selective solution mining or underground storage problems.

MEASUREMENT-WHILE-DRILLING (MWD). Measurement-while-drilling is another rapidly developing technology that provides additional geologic control and better directional control during the drilling process. Anadrill, a division of Schlumberger, provides equipment that can send down-hole measurements to the surface at rates exceeding 3 bits/sec. The service provides gamma ray and resistivity measurements every foot (0.3 meter) of the hole, as well as gravity tool face updates every 6 sec and a magnetic tool update every 4 sec. Down-hole information also includes down-hole weight on bit (DWOB) and down-hole torque (DTOR) updates. These data, used with a steerable drilling system, can allow continued drilling mechanics and formation logging without interruption of the directional drilling program.

15.3.1.5 Drilling Fluids

Drilling fluid technology within evaporites has advanced rapidly along two fronts, composition and density.

Water-based, salt (NaCl)-saturated drilling muds are still commonly used, but water-soluble calcium, potassium, and magnesium compounds find increasing use. Their appropriate addition reduces hole enlargement through soluble mineral beds (halite, trona, nahcolite, potash, etc.) and increases the stability of the borehole through intervening shale, mudstone, and marlstone layers. Such hole conditioning provides improved drilling conditions and a much better down-hole environment for geo-

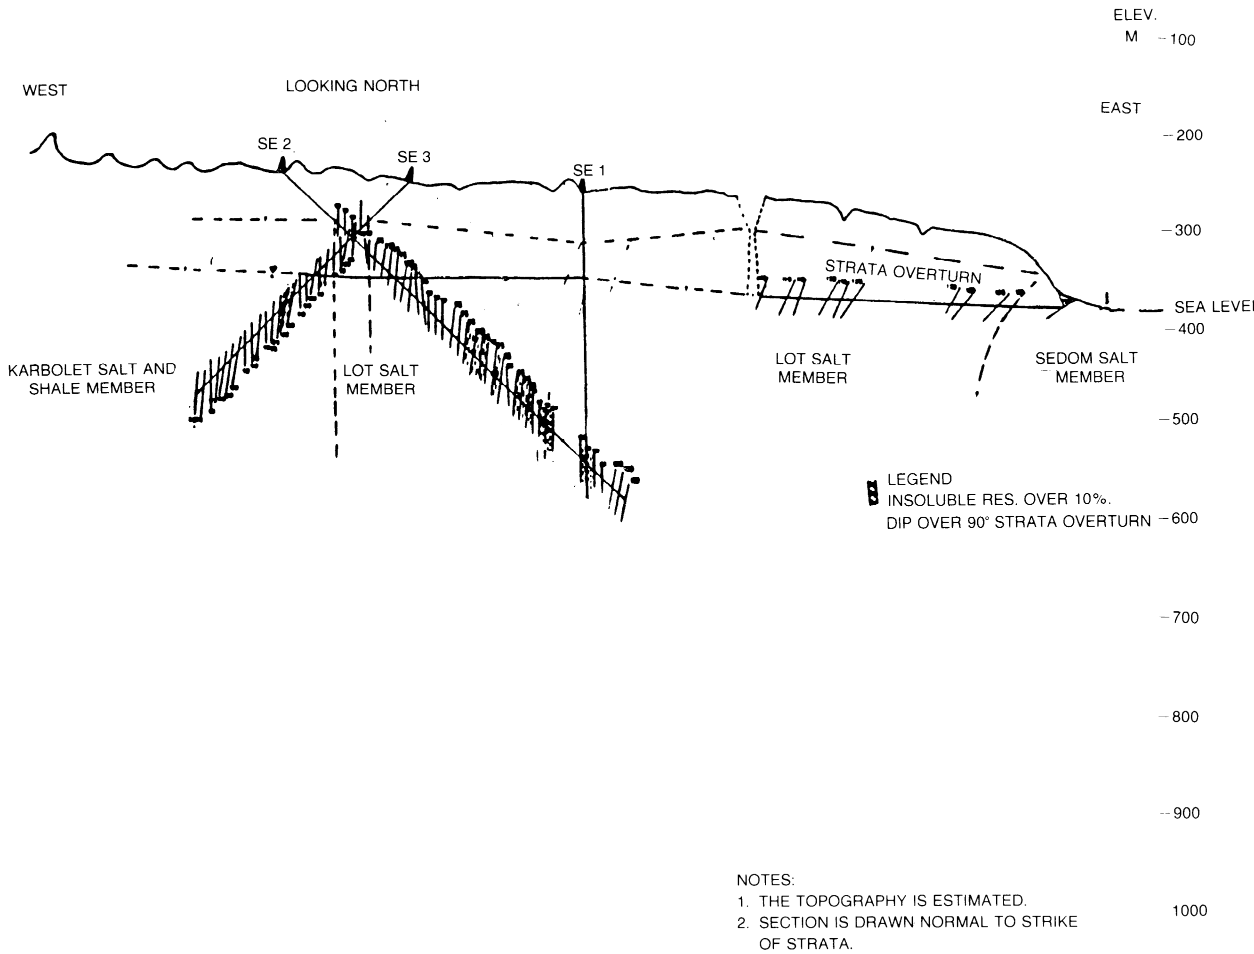

Fig. 15.3.1.3. Slanthole drilling at Mt. Sedom, Israel, during 1978 exploration program (*courtesy:* Petroleum Services Ltd.). Conversion factor: 1 ft = 0.3048 m.

physical well logging, running and cementing casing, and subsequent well/cavern development.

It is now well established that evaporite strata within certain regions of the United States (and within other countries) presently exist under conditions of high in situ lateral stress. In such instances, the use of high-density drilling fluids may be essential to prevent or minimize hole closure prior to running casing. Local and regional examples of high lateral stress areas can be found within the Appalachian and Michigan evaporites, and within the Williston, Denver, and Green River Basins.

15.3.1.6 Tubulars

Tubulars (casing, tubing, and liners) are readily available in an increased range of sizes (diameter) and strengths (tensile, compressive, and burst), with a variety of threads and from numerous foreign sources.

Small-diameter casings (B-Q, N-Q, and H-Q) are available for the continuous casing of slanted wireline coreholes. Medium-diameter articulated casings (4 to 8 in., or 100 to 200 mm) are now available for highly deviated and horizontal walls. Large-diameter casings (24 to 60 in., or 610 to 1524 mm, and larger) are available for special well completions, such as for CAES caverns or crude oil storage requiring high delivery schedules. Increased grades of seamless casing are now available with higher minimum internal yield, collapse, and joint strength properties. Such grades include US95, P-110, Q-125, and V-150. The minimum yield strength factors for casing, in psi (MPa), are:

Grade	Yield Strength, in psi (MPa)
H-40	40,000 (276)
J-55 and K-55	55,000 (380)
C-75 and E	75,000 (518)
L-80 and N-80	80,000 (552)
C-90	90,000 (621)
C-95	95,000 (656)
P-105	105,000 (725)
P-110	110,000 (759)
Q-125	125,000 (863)
S-135	135,000 (932)
V-150	150,000 (1035)

The round thread and buttress thread casings popular within the United States now include a variety of other casing threads developed for special purposes or produced by foreign manufacturers. Asian and European suppliers are rapidly expanding their share of the US and worldwide market for tubulars, in part because of the high cost of producing steel within the United States.

15.3.1.7 Cements and Cementing

The limits in physical and chemical composition and properties of cementitious materials, as well as their range of potential applications, have expanded rapidly during the past decade.

Considerable research effort has been focused upon increasing the long-term stability of portland cements. Reduction of porosity and permeability and delay of natural decomposition of cement materials have been achieved through fine grinding (to 1000 mesh) and through more extensive use of API Class G and H (high-temperature, sulfate-resistant) cement slurries. Special control of cement slurry properties emplaced within an evaporite environment is commonly achieved through the use of additives—particularly salt (to reduce dissolution of halite wallrock), bentonite (to induce expansion/reduce shrinkage of slurry during setting), and calcium chloride (to decrease slurry setting time and increase early cement strength).

A variety of unconventional cements and/or cementitious materials designed to solve special down-hole problems is now readily available. Such materials include:

1. *Epoxies.* Epoxy resins are most frequently used where very high bonding strength is required through short intervals, or when portland cement slurries might react rapidly with certain magnesium or calcium-containing evaporite wallrocks or strong brines. Usage is restricted to very special problems because of very high material and installation costs.

2. *Lightweight Cements.* Special lightweight cement slurries have frequently been used to reduce induced fracturing within incompetent formations having low parting pressures, or flow into such formations that are naturally highly fractured. Low-density additives such as gilsonite, expanded perlite, and pozzolans have long been favored.

New low-density cement slurries are now available through the addition of hollow organic and inorganic spheres and microspheres. High-strength cements can be developed with densities under 11 and 24-hr compressive strength of more than 1700 psi (11.7 MPa), cured at 300°F (149°C).

3. *Foamed Cements.* Ultra-light water cement slurries can be formed through the foaming action of gaseous additives. Air, carbon dioxide, and nitrogen have been most commonly used, depending largely upon cost and availability.

Foamed cements may be useful where formation fracture gradients are abnormally low. The material is also a good insulator and has potential for both arctic and geothermal operations.

Foamed cement slurries can be made with densities as low as 4 lb/gal (500 g/L). Although having little strength, the slurry will float on brine within a salt cavern, and can thus be used as a “bridging material” behind a cemented casing shoe that has been “washed out.”

4. *Asphalt Resin Cements.* Solid asphaltic resins occur naturally within various locations and types of mineral deposits within North America. The Athabasca tar sands (Canada) and the Brea tar pits (California) are well known examples.

Black asphaltic resins also occur as veins within country rock in Utah. One material, called gilsonite, is mined and processed by the American Gilsonite Co. Much of this finely powdered material is used as an additive to cement slurries used behind well casings, providing a plastic pore-space filler to an otherwise brittle cemented annulus. This usage has potential application within easily deformable evaporite formations. Under special conditions, where plasticity of the cement sheath is more important than its strength, the use of asphalt as the primary cementing ingredient may be economically justified within evaporite wells.

15.3.1.8 Geophysical Well Logging

Geophysical well-logging measurements are functions of the chemico-physical properties of the rock matrix, the fluid(s) within the formation, conditions within the borehole, the volume of rock investigated by the logging tool, the tool’s vertical resolution, and the design characteristics of each individual tool. Measurements are also affected by idiosyncrasies related to the logging cable, logging truck equipment and instrumentation, and operating personnel. Thus the response *measured* with a logging tool must always be considered an *apparent* rather than a *real* geotechnical property value.

The conversion of apparent-to-real properties frequently requires the expertise of a professional well-logging analyst. Inasmuch as fewer than 1/2% of all wells drilled are for the purpose of the evaluation or exploitation of evaporite deposits, the geotechnology of such log analysis is highly dependent upon adaptation from petroleum and water-well-logging technologies, and experienced evaporite well-logging analysts are a small select group.

Logging constants for various evaporite minerals and rocks are shown in Table 15.3.1.2. Log responses within a potash-bearing sequence are provided in Figs. 15.3.1.4 and 15.3.1.5. Trona beds within the Green River Formation in Wyoming can be identified by a gamma ray/sonic/neutron log suite while nahcolite beds within the Piceance Creek Formation of Colorado have similar log responses.

Geophysical well log “cross plots” are frequently used by log analysts to assist in the identification and evaluation of evaporite mineral deposits. Examples of sonic/neutron, density/neutron, and sonic/density crossplots (charts) are illustrated in Fig. 15.3.1.6.

The proliferation of small, local, independent logging companies was sharply curtailed during the recession of the mid-1980s. Strong competition for the dwindling down-hole dollar led to a consolidation of service companies, abandonment of antiquated equipment, and significant reduction in work force.

Several of the major well service companies used this period of temporary retrenchment to expand their research and development effort, mainly along four lines:

1. Improvements of existing logging tools, particularly their reliability, sensitivity, selectivity, and quantitative usefulness.

2. Synergistic integration of different types of well-log data, together with information derived from other down-hole services such as coring and core analysis, and down-hole seismic surveying.

3. Consolidation of service companies to provide a broad range of integrated down-hole services.

4. Improved global communication systems and computer networks to permit rapid evaluation and dissemination of down-hole data.

Three rapidly developing geotechnologies are of special interest to the evaporite professional:

1. Natural gamma ray spectral logging devices measure natural gamma rays through “energy windows” that permit determination of K (potassium) concentrations. The logs can be run in both open and cased wellbores and in useful combinations with various neutron devices. Following calibration against chemical analyses of cores, the log combinations can provide a rapid, less costly method of potash exploration.

2. Knowledge of the elastic properties and in situ stresses of the strata enveloping an existing or planned salt cavern is becoming increasingly important for both economic and environmental reasons. The elastic constants—Young’s modulus, bulk modulus, shear modulus, and Poisson’s ratio—are related to the density and elastic wave velocities of the rocks. The advent of special-

ized digital data handling permits the determination of both the compressional wave and shear wave velocities needed to define all four elastic constants.

3. Vertical seismic profiling (VSP) has attracted considerable attention within the geophysical community during the past decade. Its major potential uses by evaporite professionals include (1) providing geologic structural imaging near the borehole, (2) providing time-to-depth conversions for use with conventional surface seismics, and (3) predicting formation tops ahead of (below) the drillbit, or below hole TD. Examples of VSP are presented in Fig. 15.3.1.7.

15.3.1.9 Solution Mining Systems

Most single-well and multiple-well solution mining systems have been described in considerable detail by Jacoby (1973). Only a few modifications or innovations need be reported at this time.

General characteristics now common to most well systems are

1. Solution mining is initiated near the bottom of a selected water-soluble evaporite sequence. Subsequent vertical and lateral cavern development then proceeds in stages, governed by local geologic conditions, engineering requirements, and safety/environmental considerations.

2. Cavern dimensions are time-dependent, strongly influenced by the physicochemical properties of the host strata and the characteristics of cavern fluids and solids. Cavern heights have ranged between 20 and 2000 ft (6 and 600 m), but generally are 50 to 300 ft (15 to 90 m). Cavern diameters have ranged between 100 and 1000 ft (30 to 300 m), but generally are 150 to 300 ft (45 to 90 m). Caverns have been constructed with floors as shallow as 300 ft (90 m), or as deep as 9000 ft (2700 m), but their general depth range is 1000 to 4000 ft (300 to 1200 m).

3. A gaseous diesel (air, nitrogen, carbon dioxide, natural gas) or liquid (crude oil, LPG) roof pad, or "blanket" is usually employed to assist in controlling the shape and dimensions of each cavern.

4. Well/cavern underground storage systems are usually subjected to higher design, construction, and operational criteria than their counterparts used solely for brine production. Storage systems pose greater risks to the subsurface and surface environment and to the safety of living beings. For both environmental and economic reasons, however, there is a rapidly growing trend toward strengthening the criteria governing brine wells, not only to protect the environment but also so that they can be more readily converted to storage/disposal facilities, if desired.

SINGLE-WELL OPERATIONS. Historically, top-injection (Tully method) techniques have resulted in low investment costs

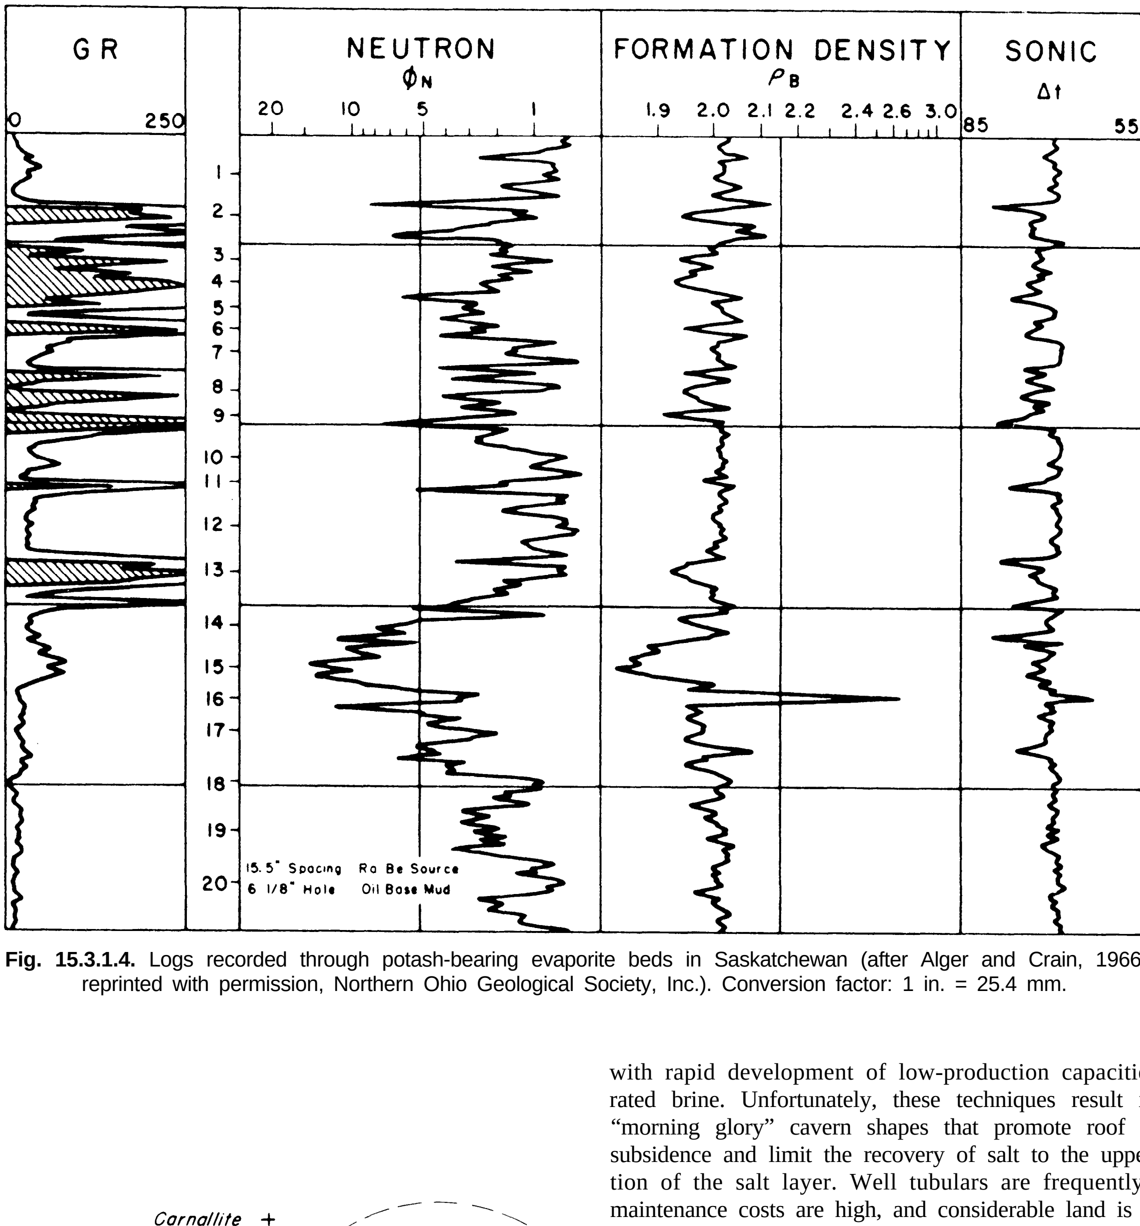

Fig. 15.3.1.4. Logs recorded through potash-bearing evaporite beds in Saskatchewan (after Alger and Crain, 1966, reprinted with permission, Northern Ohio Geological Society, Inc.). Conversion factor: 1 in. = 25.4 mm.

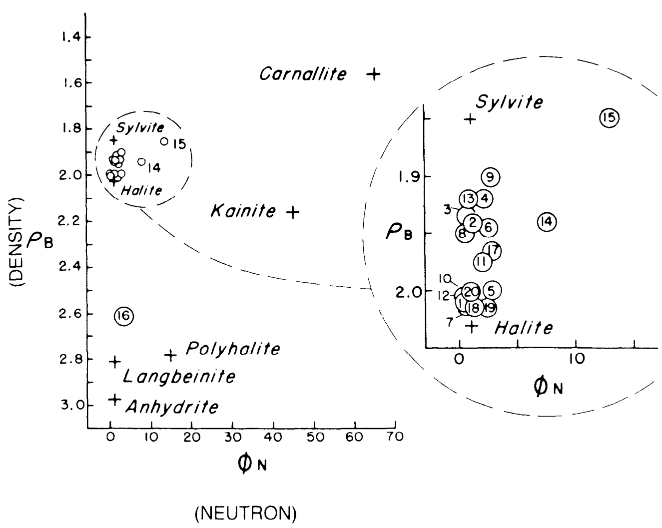

Fig. 15.3.1.5. Cross plot of density vs. neutron (derived from Fig. 15.3.1.4) identifies evaporite minerals (after Alger and Crain, 1966, reprinted with permission, Northern Ohio Geological Society, Inc.).

with rapid development of low-production capacities of saturated brine. Unfortunately, these techniques result in unstable "morning glory" cavern shapes that promote roof caving and subsidence and limit the recovery of salt to the uppermost portion of the salt layer. Well tubulars are frequently damaged, maintenance costs are high, and considerable land is required to support a long-term solution mining operations. This method, named for the earliest Allied Chemical operations at Tully, NY, is in general disfavor today.

The Allied Chemical Co. introduced the Trump method in the early 1930s whereby an undercut was achieved near the base of a selected salt layer. The original intent of this method was to develop a large-diameter undercut, a few feet (meters) in thickness, using a gaseous or liquid "blanket" to inhibit upward dissolution of the salt roof. More recent efforts have included coalescence of adjoining single caverns near the base of the salt, followed by two-well or multiple-well operation. This method frequently entails a 12 to 24-month cavern development period during which arrangements must be made for the disposal or usage of unsaturated brine. The method is most applicable to bedded salt deposits having low geologic dips.

The Detroit method, a bottom-tubing injection system, was developed to overcome many of the disadvantages of the Tully method. Cavern roof stability was improved, but salt brine (obtained from the top of the cavity) was usually below saturation, even at extremely low (50 gpm or 3 L/s) production rates.

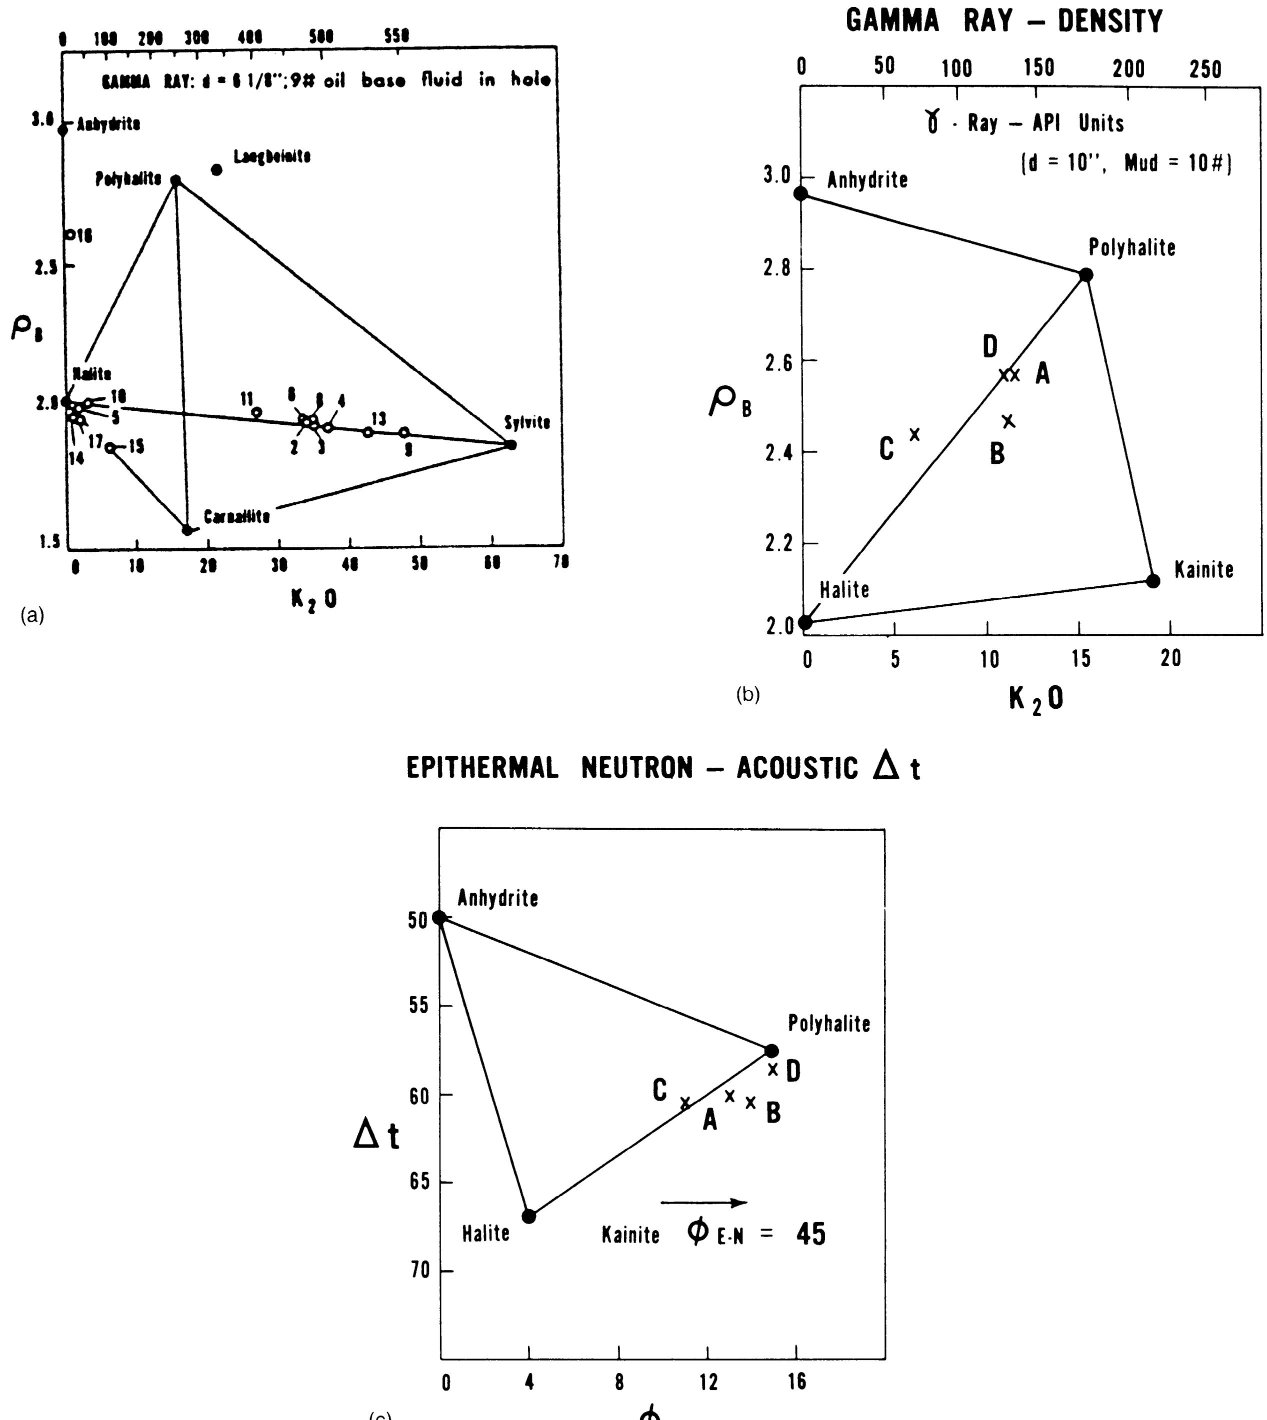

Fig. 15.3.1.6. Examples of various well-log cross plots derived from logs of one well through an evaporite section. (a) Plot of gamma ray vs. bulk density defines potash minerals; (b) plot of gamma ray vs. bulk density data from logs in (a); (c) plot of sonic neutron data from logs in (a). (Reprinted with permission, Northern Ohio Geological Society, Inc.).

Many single-well solution mining operations today are based upon a modified annular injection method wherein both the tubing string and the hanging casing string are positioned near the base of the lowermost salt layer to be dissolved. An undercut of 150 to 400 ft (45 to 122 m) diameter is achieved using an insoluble rock layer or a gaseous or liquid blanket to inhibit upward dissolution of the undercut. Saturated brine production rates in excess of 200 gpm (13 L/s) have been achieved from such wells after the protective roof pad has been removed. However, the effectiveness of the method is frequently dependent upon geologic factors such as formation dip, frequency and attitudes of discontinuities, and the in situ stress field. A schematic of this variable-point injection system is presented in Fig. 15.3.1.8.

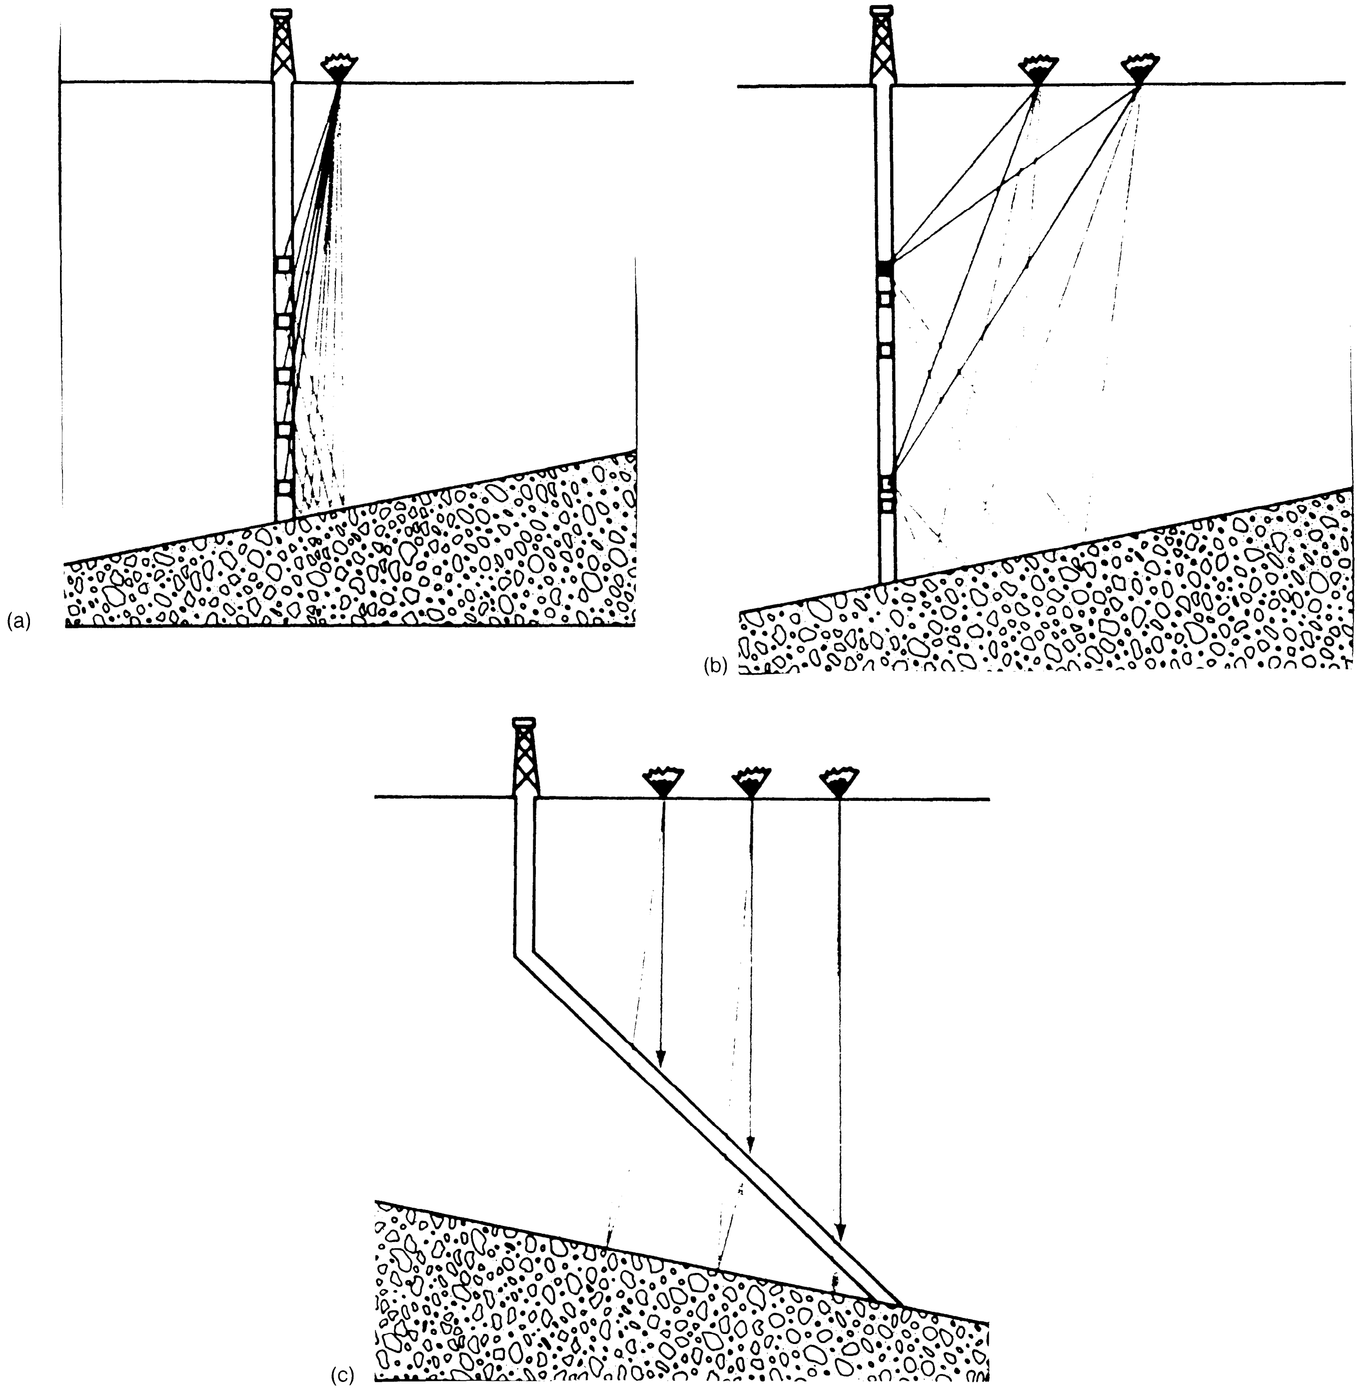

Fig. 15.3.1.7. Examples of vertical seismic profiles (*courtesy:* Schlumberger Well Services).

Deviated drilling techniques have been successfully used (Fig. 15.3.1.9) to avoid "rigging-up" within restricted or inaccessible land or water areas. Horizontal drilling is a technique used for thin-bedded evaporite strata such as nahcolite, trona, potash, and halite. The NATEC group (Houston, TX) expects to initiate a horizontal drilling program within their Piceance Basin (Colorado) nahcolite deposits in the early 1990s. In general, however, there are numerous technical and economic problems to resolve before horizontal drilling within evaporite strata can be regarded as other than experimental.

Many salt caverns have been developed through the use of multiple wells within a single cavern. This approach was taken during the construction of many of the SPR (Strategic Petroleum Reserve) caverns in the Gulf Coast of the United States in order to decrease the time required for full cavern construction and to provide for more rapid cavern fill/empty cycles.

At the Veedam brine field in the Netherlands, Billiton Refractories B.V. has constructed individual brine wells containing *separate* tubing strings, rather than the *concentric* tubing construction usually in practice. These wells are primarily for the

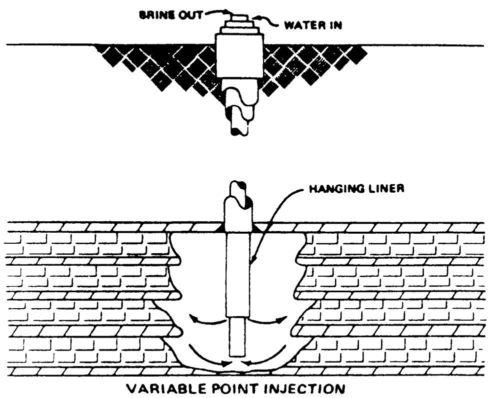

Fig. 15.3.1.8. Schematic of variable-point injection system (after Querio, *courtesy:* Salgema Mineracao, LTDA).

production of highly plastic magnesium salts. An illustration of one of their well designs is presented in Fig. 15.1.3.10.

MULTIPLE WELLS. There have been few recent innovations in the technology of single-well interconnection to provide multiple-well operation.

The updip coalescence of single wells, particularly when assisted by some undercut technique near the base of a salt bed, is commonly used. Well interconnection by hydraulic fracturing is widely regarded as a high-risk technique, requiring considerable geotechnical acumen to be successful. However, rock mechanics studies in nonevaporite strata, promulgated by the petroleum industry, are beginning to be translated into new considerations and techniques for the "controlled" development of both "bedding-plane" and "vertical" fractures within evaporite beds.

Single-well interconnection by horizontal drilling to provide a rapid technique for multiple-well operation is still in its infancy. Vertical and horizontal drilling control within thin-bedded, undulating evaporite strata poses presently unresolved problems.

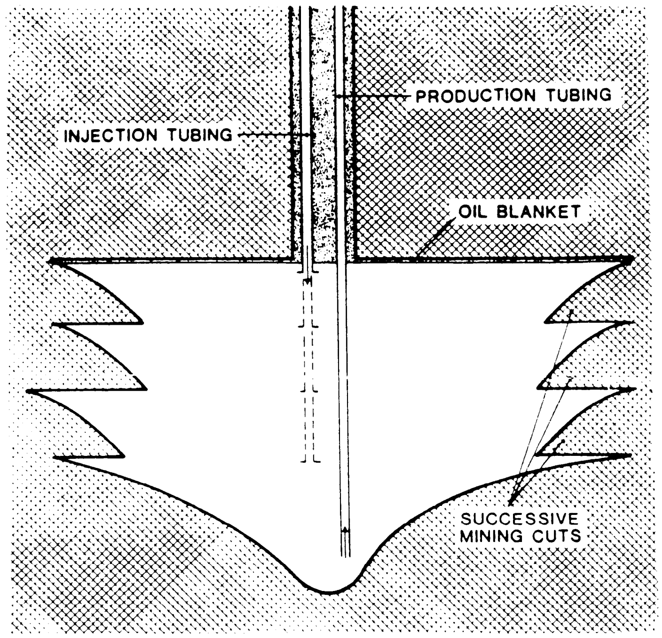

Fig. 15.3.1.10. Nozo strip mining concept (*courtesy:* Billiton Refractories B.V.).

Advances are also needed to resolve drilling fluid, cuttings transport, and cementing problems, as well as improvement in the use of well screens and articulated tubulars.

15.3.1.10 Underground Storage

Evaporite strata existing at depths below 1000 ft (300 m) frequently have very low porosities and permeabilities. These characteristics often permits their successful use for the storage of a variety of solids, liquids, and gases, as indicated in Table 15.3.1.3.

Where locations are favorable, most such storage has been developed by solution-mining techniques because of

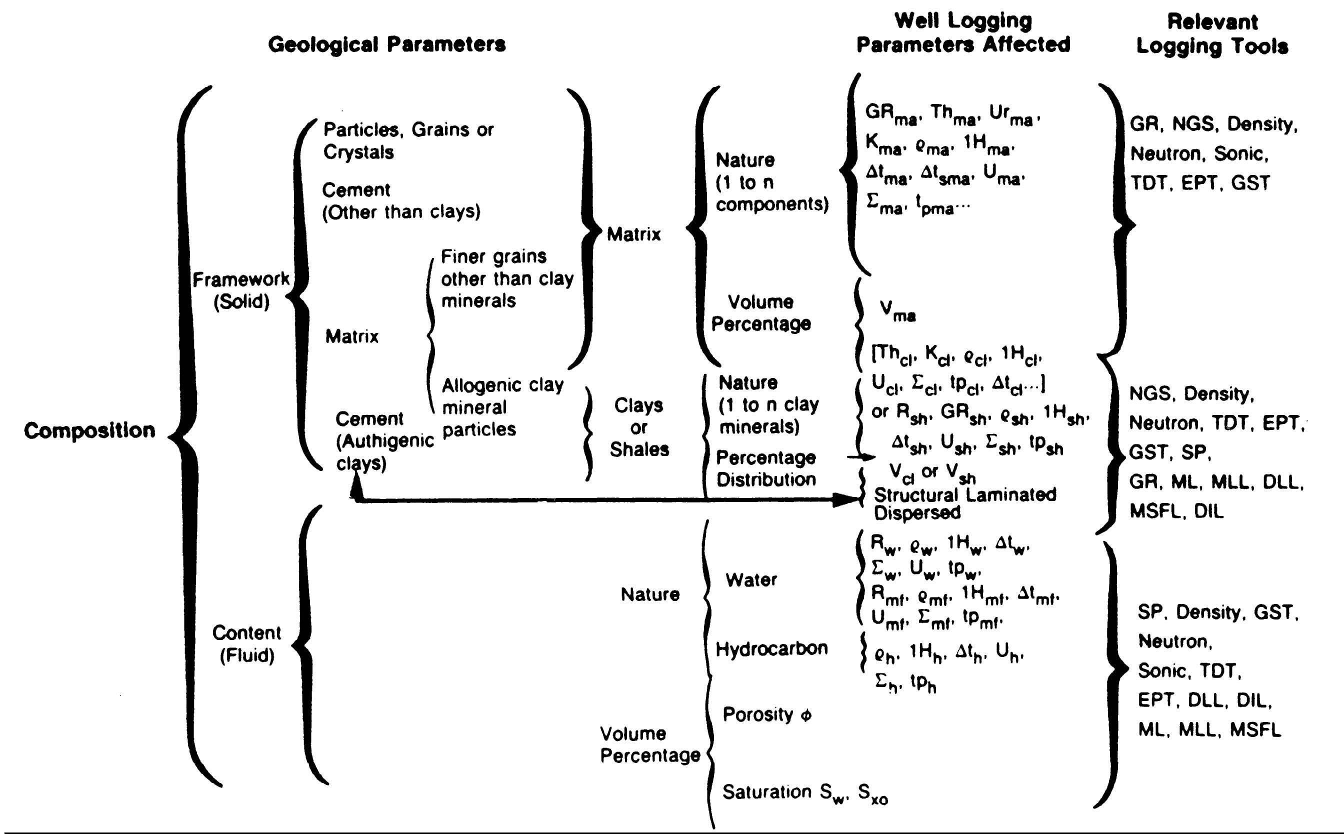
1. Simplicity of well/cavern design.
2. Flexibility in storage volume design.
3. Lower cost of construction.
4. Rapid installation.
5. Decreased operating and maintenance costs,
6. Increased safety to personnel, ground surface installations, and the environment.

COMMODITIES. National Petroleum Reserves: The largest underground storage system for crude oil was developed by the US Department of Energy (DOE) through its Strategic Petroleum Reserve (SPR). At the end of 1989, approximately 690 million bbl (109 Mm^3) of crude oil were being stored in one salt dome mine (Weeks Island, LA) and in salt dome cavern installations (Bayou Choctaw, LA; Big Hill, TX; Bryan Mound, TX; and West Hackberry, LA). Most of the SPR storage caverns were constructed within depths of 2000 to 4000 ft (600 to 1200 m), and have a storage capacity of about 10 million bbl (1.6 Mm^3) each of crude oil. A typical storage cavern is illustrated within Fig. 15.3.1.11.

National crude oil underground storage repositories within solution-mined caverns are also located in West Germany, East Germany, France, the USSR, Norway, Sweden, and Mexico.

LOOP/LOCAP Crude Oil Facilities: The LOOP (Louisiana Offshore Oil Port) is the only offshore deep-water port in the

Table 15.3.1.3. Relationship Between Risk Composition and Geophysical Well Logging Parameters



Courtesy: Schlumberger Well Services.

United States (descriptions of the LOOP/LOCAP systems have been summarized from in-house reports issued by PB-KBB, Inc.). It can handle tankers up to 700,000 DWT (635 kt). Crude oil is offloaded at the offshore marine terminal and is piped through an onshore booster station (Fourchon Booster Station) into salt dome storage caverns at the Clovelly terminal. The caverns serve as surge storage until the oil can be taken by pipeline. From Clovelly, crude flows through the LOCAP pipeline (jointly owned by several major oil companies) or to various refineries.

LOOP facilities include all equipment and piping necessary to receive crude and store it in the salt caverns. The LOCAP facilities include all equipment and piping necessary to transport crude from Clovelly to the LOCAP terminal and to the Capline terminal, both at St. James. A pipeline connection between the LOCAP facilities and the DOE facilities at St. James terminal provides capability for crude transfer between the two.

Fig. 15.3.1.12 depicts the location of the Louisiana Offshore Oil Port and connecting carriers. A preliminary design of a Clovelly terminal “surge” storage cavern is shown in Fig. 15.3.1.13.

Conceptual designs have been prepared by PB-KBB Inc. for the future enhancement of the SPR distribution system through flow reversal of existing LOCAP and LOOP oil terminalling transportation systems. Additional descriptions of these existing and proposed facilities are available through application to the appropriate DOE office.

LIQUEFIED PETROLEUM GAS (LPG)—There were more than 1200 solution-mined underground storage caverns in use within the United States in 1989. The liquid products stored include ethane, propane, E-P mix, normal butane, isobutane, natural gasoline, raw mix, ethylene, propylene, etc.

The Gas Processors Association, Tulsa, OK, conducts a biennial survey of such facilities. Cavern locations within the United States and Canada are shown in Fig. 15.3.1.14, and a tabulation of stored LPG substances is presented in Table 15.2.1.4. The rapid development of LPG storage within the United States from 1950 through 1987, ranging from 10 million to more than 433 million bbl (1.6 to 72 Mm^3), is illustrated in Fig. 15.3.1.15.

LIQUEFIED NATURAL GAS (LNG)—Much of the natural gas that is produced in association with crude oil has, in the past, been disposed of by flaring it in the field. However, the world’s ever-increasing energy demands have caused the prudent production, storage, transportation, and use of natural gas to become economically feasible. Since the density of natural gas increases almost 600 times by liquification to LNG (at –310°F or –190°C), overseas transportation within specialized tankers has become common. This gas is normally about 90% methane.

The benefits of underground storage in salt caverns are threefold:

1. The high density of the gas allows the use of considerably smaller storage caverns.

2. Underground storage is a safer process than aboveground terminals because, if LNG spills from its storage containers, it rapidly vaporizes (flashes) and becomes a highly flammable and explosive mixture in air.

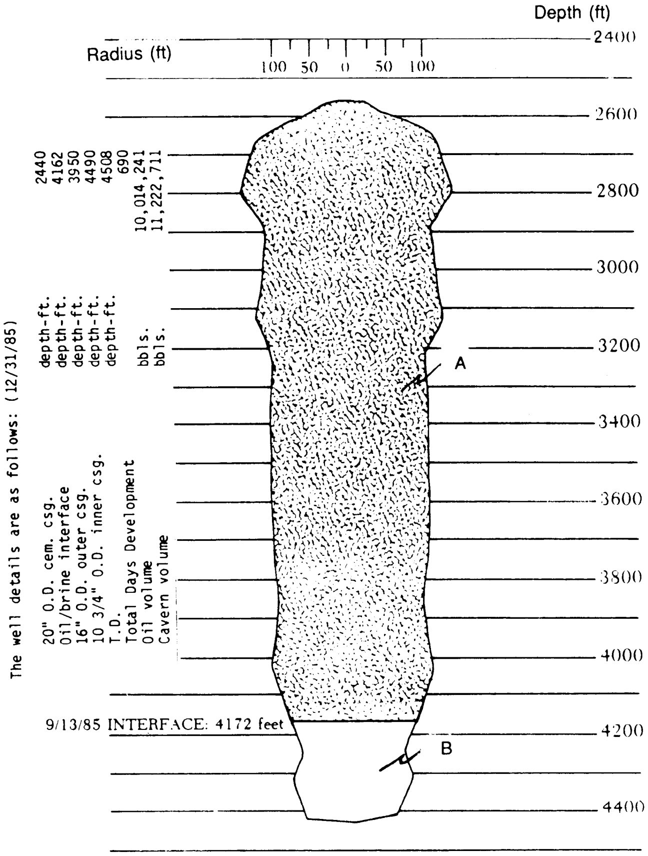


Fig. 15.3.11. Typical SPR crude oil storage cavern profile, West Hackberry Cavern No. 101, Louisiana. A=crude oil; B=rock sump (*courtesy:* PB-KBB Inc.). Conversion factor: 1 ft = 0.3048 m.

3. LNG stored in a salt cavern would cause heat flow from the surrounding salt mass into the cavern. This heat would increase the liquid gas temperature and pressure accordingly. Thus the total heat required for evaporation of gas prior to pipeline distribution is reduced by the energy from the natural source.

Library research and limited laboratory experiments were sponsored by KBB and Ruhrgas during the late 1970s. A field experiment was conducted in a small salt cavern under in situ conditions within a salt mine in Germany. This experiment is described in detail in various in-house reports at PB-KBB, Inc.

KBB has proposed the construction of a series of salt caverns to serve as interim storage for LNG arriving by tankers. These caverns would develop needed information for the analysis of thermodynamics (heat and mass transfer) and rock mechanics (cavern wall crack propagation) considerations.

The potential advent of superconduction technology during the next decade may completely change previous concepts concerning the economic feasibility of LNG storage in salt caverns.

NATURAL GAS (Methane)—Natural gas is normally stored within depleted or partially depleted gas fields or gas pools where the pertinent geologic parameters are usually well known and the infrastructure for the production, processing, and transportation of gas already exists.

Special geotechnical and economic conditions must exist in order that storage within salt caverns becomes a viable alternative.

The primary advantage of such storage involves the ability to withdraw gas very rapidly from a single-well/cavern system, independently from other well/cavern systems. The cost and time required for the development of a gas storage cavern system, of course, can be markedly decreased if existing LPG or brine storage caverns (and infrastructure) can be used with only minor modification.

The use of existing LPG or brine caverns, however, must be carefully investigated. Many of the readily available well/cavern systems cannot easily be adapted to storage of a highly mobile gas under considerably higher pressure. Moreover, well/cavern systems more than 10 years old may no longer meet the ever-increasing stringencies of environmental and safety requirements, or may not even be acceptable for repermitting for LPG storage.

The construction of new well/cavern gas storage systems is much more capital-intensive and requires associated water supply and brine disposal facilities. However, design, construction, and cavern development can be tailored to meet present day and/or anticipated future environmental and safety regulations.

Numerous candidates for conversion of existing LPG caverns for conversion to natural gas storage exist within bedded salt deposits (Kansas, Michigan, Ohio, etc.) and Gulf Coast salt domes (Texas, Louisiana). Local and regional natural gas utilities throughout North America are presently evaluating opportunities that will result from a resurgence of industrial and commercial activities.

COMPRESSED AIR ENERGY STORAGE (CAES)—Economical generation of electric power is difficult to achieve because power demands fluctuate widely both on a daily and seasonal basis. One of the "load-leveling" technologies presently being developed is compressed air energy storage within a salt cavern.

The basic elements of a CAES installation are shown in Fig. 15.3.1.16. Conceptually, air is compressed during periods of low electrical energy demand and temporarily stored within a salt cavern. This compressed air is later released, during a period of peak power demand, and allowed to energize a turbine generator.

The first large-scale CAES plant for electric utility load leveling was constructed at Huntorf, Germany, by the Nordwestdeutsche Kraftwerke AG (NWK). This plant stores off-peak energy from the NWK grid by compressing and storing air in caverns constructed within the Huntorf salt dome. The Huntorf dome was extruded from the Zechstein evaporite strata, is elliptical in shape, and has a layered and folded character. Salt was encountered at a depth of 1700 ft (500 m). Total as-constructed cavern volume was about 392,400 yd^3 (300,000 m^3). Minimum cavern air pressure is about 43 bars (4.3 MPa); maximum is 72 bars (7.2 MPa). Caverns were constructed about 700 ft (210 m) apart to minimize risks of salt cavern wall collapse. Minimum salt cavern roof thickness was established through rock mechanics studies at 2.6 times the diameter of the 170-ft (57-m) wide caverns. Cavern wall closure is expected to result in a 3% reduction in volume during the cavern's projected 30-year life.

The success of the Huntorf CAES project has generated considerable interest in the potential development of larger installations in other countries. Within the United States, preliminary studies have been conducted within northeastern Ohio (for the Cleveland Electric Illuminating Co.) and at the McIntosh salt dome in southwestern Alabama (for the Alabama Electric Cooperative, Inc.). The Alabama CAES installation has been constructed and was put into operation in mid-1991. Present construction includes a CAES plant having a nominal rating of 110 MW—supported by one CAES salt cavern having a volume of about $20 \times 10^6 ft^3$ (566×10^3 m^3).

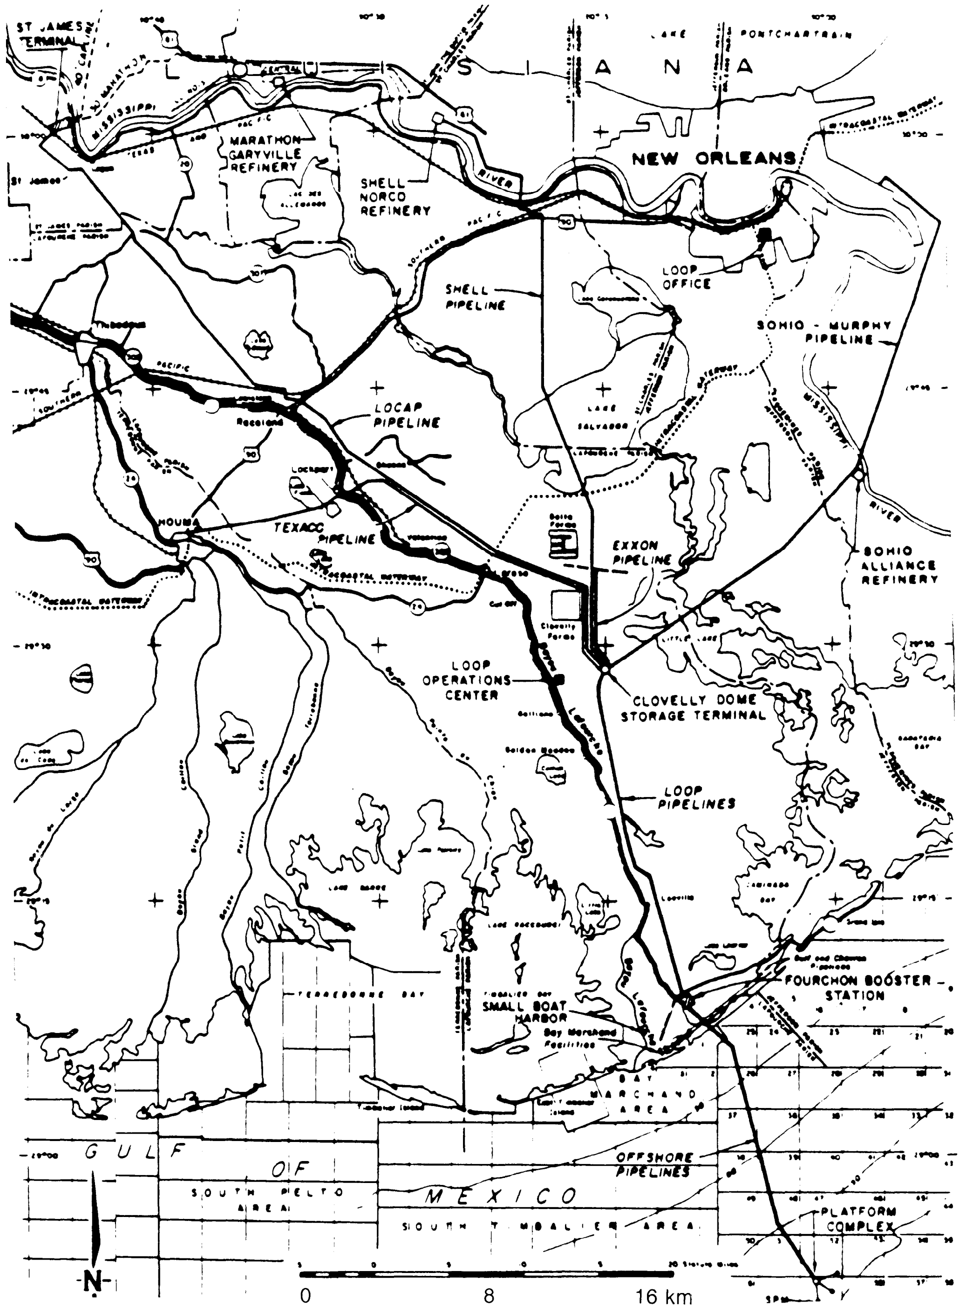

Fig. 15.3.1.12. Locations of the Louisiana Offshore Oil Port and connecting carriers (by permission: LOOP, Inc.). Conversion factor: 1 mi = 1.6093 km.

In designing the underground storage system, material properties of the McIntosh salt deposit, cavern geometry, and operational requirements were considered. Initial site exploration indicated a dissolution zone at the top of the salt, and scattered potash mineralization within the salt. Inasmuch as the solubility rate of KCl can be as much as 20 times that of NaCl, there appeared to be considerable risk that control of salt cavern shape and dimension might be difficult. A new site was selected and test drilled, with satisfactory results.

A preliminary design of the proposed CAES well and cavern construction is presented in Fig. 15.3.1.17. The Alabama CAES well and cavern was constructed at a 1991 cost of about US$/500 million.

MISCELLANEOUS GASES—During the past decade, the geotechnical and economic feasibilities of salt cavern storage of a variety of specialty gases have been evaluated. These gases have included hydrogen, helium, and chlorine.

Most of the time, the problems associated with these "specialty" gases, such as corrosion or embrittlement of tubulars, wellhead, instrumentation, and compressors are too severe to warrant more than feasibility studies and a few laboratory tests. However, the constant development of new materials of con-

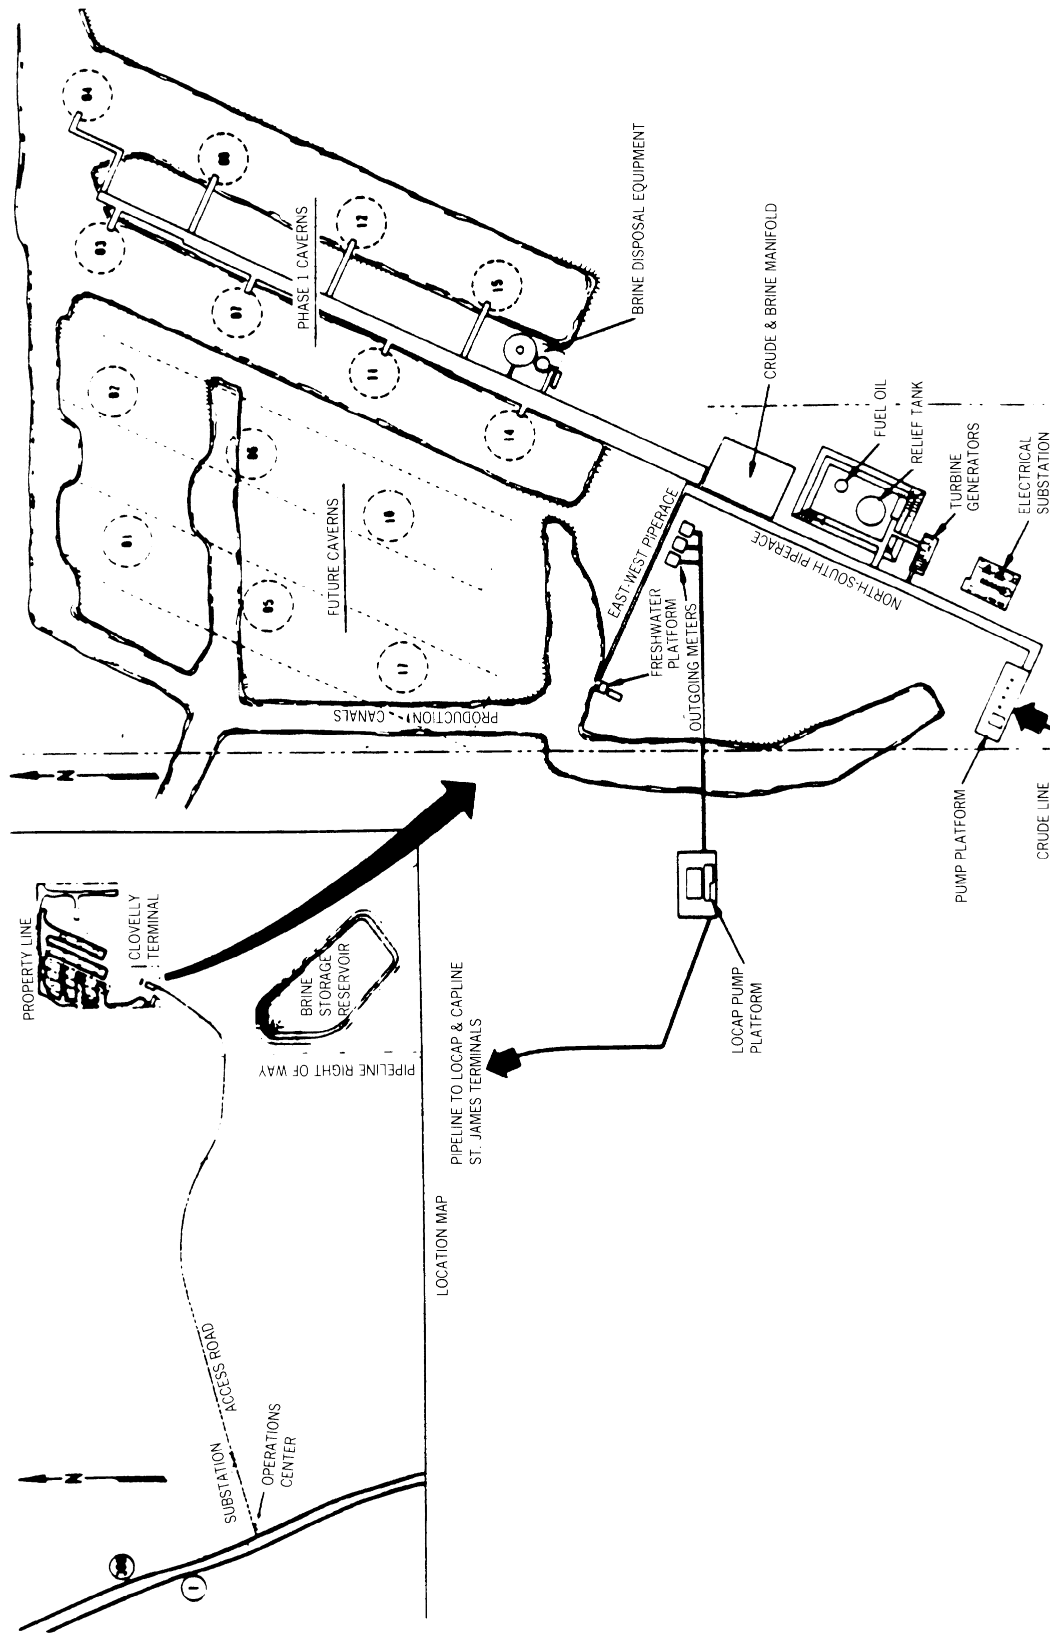

Fig. 15.3.1.13. Plan view of Clovelly terminal, Louisiana (by permission: Walk, Hydell & Associates, Inc.).

Fig. 15.3.1.14. Locations of LPG storage caverns in salt in the United States and Canada (1987 data from AGA). Conversion factor: 1 mi = 1.6093 km.

struction as well as changes in economic incentives generated by new safety and/or environmental requirements require a feasibility reevaluation every three to five years.

One example, the underground storage of hydrogen within aquifers or within conventionally mined or solution-mined facilities in the United States and Europe, has been proposed on numerous occasions. The primary driving force behind these proposals concerns safety. The hazardous nature of hydrogen arises chiefly due to its ability to combine with oxygen over a wide range of partial pressures, with very little energy requirement for activation.

Actual underground hydrogen storage experience has been very limited. Much of the relevant experience and operating data has been developed from an underground hydrogen-methane storage facility located at Reitbrook, West Germany. Here, more than 424 million ft^3 (12 Mm^3) of refinery gas, more than 60% hydrogen, was stored within an aquifer at a depth of 850 to 1300 ft (260 to 400 m).

Preliminary studies have indicated that solution-mined caverns will become the most attractive nonporous storage strata type, for all the reasons listed at the beginning of this underground storage segment.

15.3.1.11 Underground Disposal

Past and present regulations forbid the disposal or storage of radioactive wastes within solution-mined caverns. Industrial wastes from salt companies and chlor-alkali producers have been frequently disposed of in caverns with or without regulatory controls. The disposal of hazardous wastes, however, is a developing technology that is presently surrounded by political and geotechnical controversy. The topic of radioactive waste disposal is dealt with in Chapter 24.3.

INDUSTRIAL WASTES. Raw brine from a solution mine contains a small percentage of both water-soluble and insoluble substances that must be removed prior to introducing the brine into the chemical process plant system. Procedures used mainly involve clarification, settling, and/or filtration. Primary waste products contain calcium, magnesium, and iron, which can be treated and removed as solid precipitates (calcium carbonate, calcium sulfate, iron oxide, or sulfide, etc.) A portion of these sludges can be refined and marketed (e.g., calcium chloride, calcium carbonate); most have simply been contained within waste ponds, a form of landfill. Inasmuch as nearly 85% of these sludges consist of strong brine solutions, the potential for leakage

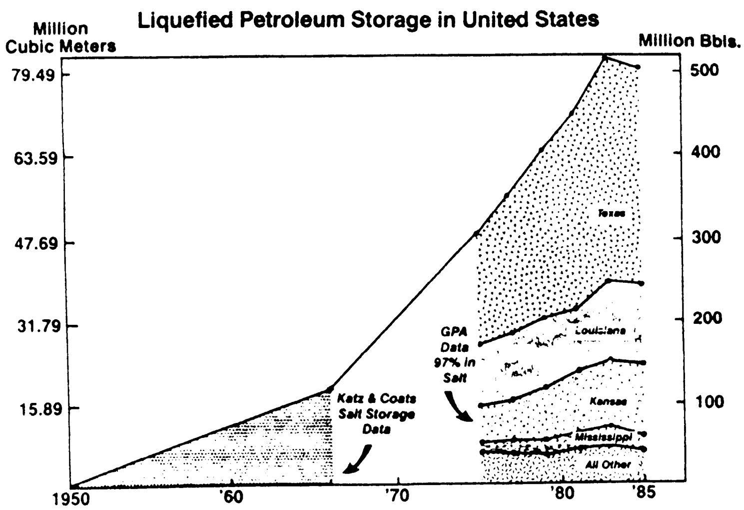

Fig. 15.3.1.15. Growth of LPG storage in the United States, 1950–1985 (*courtesy:* Gas Processors Association).

into the surface and subsurface drainage system has elicited considerable environmental concern.

Several companies have attempted to solve this problem by decreasing the liquid content of the sludge and pumping the solids into brine cavities that are being retired from active brine production. Many of these old well/cavern systems cannot meet modern environmental requirements, or are hydraulically connected to nearby production/storage caverns.

Under present federal standards, well/cavern systems must be permitted as Class II wells before disposal of industrial wastes is allowed.

HAZARDOUS WASTES. Many substances have been included within federal and state listings of hazardous and/or toxic wastes, subject to regulatory control.

During the 1970s, elemental mercury and many of its compounds were severely restricted because of their widespread usage and highly poisonous nature within the food chain. Mercury regulation has had considerable impact upon both the mining and the chemical processing (chlor-alkali) industries. Several companies using mercury cells for chlorine production had experimented with temporary disposal of mercury-bearing sludges within a solution-mined cavity, but these efforts had to be abandoned.

Landfill operations are rapidly being restricted as to location, operation, and usage. Subsurface disposal on a large scale in solution-mined cavities is now being investigated—amid strong controversy—in the state of Texas. As described in 15.3.1.12, federal, state, and local agencies all have a role in the permitting process.

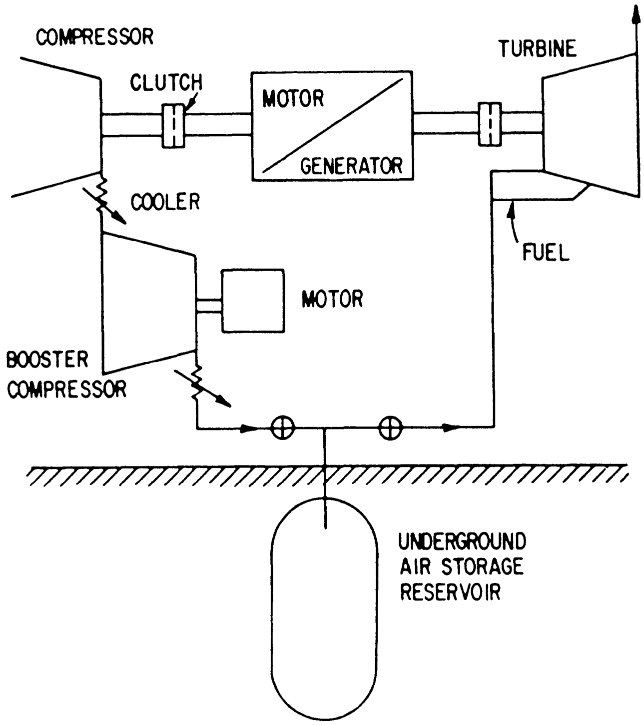

Fig. 15.3.1.16. Elements of a compressed air energy storage installation (*courtesy:* Electric Power Research Institute).

Five attempts to initiate hazardous waste disposal systems in evaporites in the United States are summarized in the following.

1. *Calcasieu Parish, LA.* The first proposed disposal installation was to be located in the Vinton salt dome, Calcasieu Parish, LA, where the top of a salt deposit was found at 700-ft (210-m) depth. The proposed installation was advanced by IMPACH, a Dutch-owned firm. This proposal was stopped by the Louisiana legislature, which voted for a two-year moratorium on disposal projects in salt domes. This moratorium has never been rescinded.

2. *Wharton County, TX.* United Resource Recovery Inc. prepared a study for the disposal of liquid toxic wastes in caverns to be constructed within the Boling salt dome in Wharton County, TX. The top of the salt deposit was at 975 ft (297 m), and proposed cavern diameters were about 100 ft (30 m). A permit application was submitted to the Texas Water Commission, which, after public hearings, rejected the permit application. This decision is being appealed.

3. *Anderson* County, *TX.* PB-KBB/ESE jointly prepared an extensive study of solid-waste disposal within the Keechi salt dome in Anderson County, TX. The project, named TEXTOR, found salt at a depth of 400 ft (122 m) in a corehole drilled in 1988. A multi-volume application for a permit was submitted to state authorities, but was withdrawn prior to required public hearings, again because of the loud outcry from local opposition forces.

4. *Liberty County, TX.* Hunter Environmental Inc., through it subsidiary Hunter Industrial Facilities Inc. (HIFI), has prepared a thorough study of solid-waste disposal within caverns to be constructed within the North Dayton dome in Liberty County, TX. Top of salt is at 800 ft (240 m) depth. HIFI proposes a system of 10 caverns, 120 ft (37 m) in diameter, constructed through the depth interval 1500 to 4000 ft (457 to 1219 m). Each cavern would have a fill capacity of about 4 million bbl (22.5 million ft^3, or 637 km^3).

The proposed surface plant would receive liquid toxic waste, which would be mixed with cementitious material and formed into solid waste pellets before injection into a cavern.

HIFI has submitted a multi-volume draft permit application to the Texas Water Commission and public hearings are expected soon. Again, there is considerable vocal opposition from regional and national environmental groups who dislike the concept of underground disposal of wastes.

5. *Detroit, MI.* A fifth waste disposal study and permitting attempt is underway at Detroit, MI, where a portion of the large, abandoned International Salt mine is available for storage/disposal activities.

There currently is controversy concerning "owners" and "users" rights within the mine and a formal application for a permit to dispose of hazardous wastes has not yet been submitted to Michigan authorities for consideration.

15.3.1.12 Government Regulations

All aspects of subsurface investigation, permitting, construction, operation, and abandonment of solution-mined well/cavern systems increasingly fall within the purview of government regulation (Chapter 3.4). Most of these regulations have evolved through environmental concerns about the long-term stability of underground openings, the potential for environmental damage to the enveloping strata, groundwater, ground surface, and atmosphere, and to the safety of personnel and other life forms at risk from an existing or proposed activity.

The primary federal regulating agencies are the EPA (Environmental Protection Agency) and OSHA (Occupational Safety and Health Administration). EPA now designates solution-mining and underground storage well/cavern systems as Class II wells and solid waste disposal well/cavern systems as Class I. Although headquartered in Washington, DC, EPA exercises control through regional offices and through publication of the *Code of Federal Regulations,* Title 40, entitled Protection of Environment and updated annually. Additional information and/or commentary is readily available through subscription to the *Environmental Reporter* (Bureau of National Affairs, Inc. [BNA], Washington) and the Underground Injection Practices Council, Inc. (UIPC) located in Oklahoma City, OK.

Regional, state, and local regulatory agencies occasionally promulgate modifications of federal law to meet specific geotechnical, environmental, economic, or political concerns. The potential contamination of groundwater supplies or of surface crops by brine leakage out of well/cavern systems has some historical basis in fact and can be readily conjured as a threat to local or regional populations.

The "permitting" process, the procedure necessary to obtain permits from *all* regulatory agencies for the drilling and testing of wells within a given area or region, may require several months to a year or more, largely depending upon the amount of controversy developed during the "public hearing" that follows submission of a permit application (Chapter 7.3). As of June 1990, no permit application for the storage of hazardous waste within a salt deposit has been approved.

Regional, state, and local regulatory agencies have frequently issued even more restrictive rules. Within the state of Texas, for example, an applicant should be familiar with the Texas Railroad Commission's *Forms and Procedures Manual,* Oil and Gas Statewide Rules, and the Texas Oil and Gas Conser-

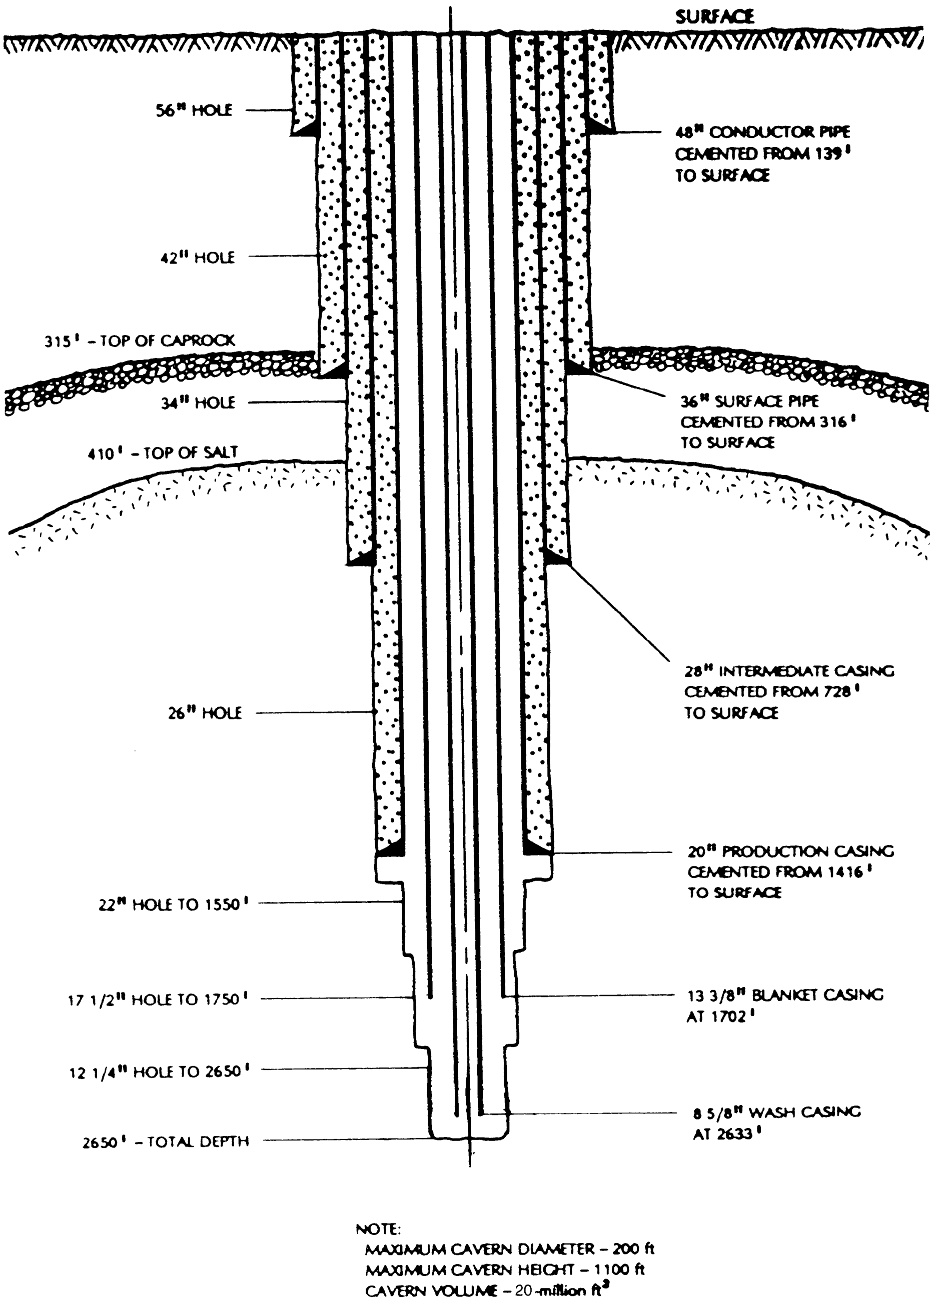

Fig. 15.3.1.17. Casing schematic of AEC CAES production well (not to scale) (*courtesy:* Electric Power Research Institute). Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 ft^3 = 0.02832 m^3.

vation Laws. The Texas Water Commission also exercises authority through the federal Safe Drinking Water Act.

The list of regulatory agencies that may influence a desire to construct an underground disposal well/cavern system is beyond the scope of this discussion.

15.3.1.13 Testing Solution-mined Well/Cavern Systems for Mechanical Integrity

Many well/cavern systems have developed avenues of fluid leakage into their subsurface and ground surface environments. This situation is particularly common with respect to wells drilled prior to 1980 when environmental regulations had neither the scope nor the impact that they have now.

During the past decade, the primary federal environmental agency, the US EPA, has promulgated increasingly more restrictive regulations concerning the design, construction, and operation of *all* wells, as briefly outlined in 15.3.1.12.

A major physical test, required by EPA before operational start-up of a well/cavern system, is commonly referred to as an MIT (mechanical integrity test). The EPA requires this test of the last cemented casing string at five-year intervals, at a minimum. Under special conditions, the MIT may be required by EPA, regional, state, or local agencies more frequently.

Several MIT procedures have been accepted by federal and state agencies, depending upon the region the test is to be employed. Nitrogen is a preferred testing medium although liquids or other gases may be used under special conditions.

An outline of a procedure commonly used in the Gulf Coast region is presented as follows:

1. *Cavern Preparation* .

a. Inspect wellhead for leaks or excessive corrosion. Correct as necessary.

b. Isolate cavern from other parts of the surface and subsurface system.

c. Provide access opening on each wellhead (a lubricator) to allow a logging tool unrestricted access to the center of the cemented casing or brine tubing.

d. Provide for pressure taps to connect continuous pressure recorders.

e. Provide source of saturated brine and pumping equipment to pressure the well.

f. Stop all stored product movement activity within the well/cavity system for at least 24 hr prior to test.

g. Prepare suitable access to the wellhead for logging and nitrogen trucks.

2. *Pretest Procedure* (minimum 24 hr before test).

a. Connect *calibrated* pressure gages to taps.

b. Pressurize well/cavern system to predetermined pressure, using saturated brine if possible.

c. Note and record pressures on the cemented casing annulus, casing/tubing annulus, and tubing string for at least a 24-hr period.

(Leakage discovered while using a liquid medium for pressurization will be greatly magnified under gaseous testing conditions.)

3. *MIT Procedure Using Nitrogen.*

a. Rig up wireline lubricator on the valve flange provided. Place interface/density logging tool into lubricator. Run tool into well casing (or tubing).

b. Make and record temperature survey of entire well to establish a baseline log.

c. Set interface/density tool at a predetermined depth. Inject nitrogen at predetermined rate (and volume) until gas/liquid interface reaches logging tool. Shut in for short test period; calculate measured nitrogen injection against casing (or casing/tubing) capacity at selected down-hole pressures. Compute amount and rate of leakage, if any.

d. Lower logging tool in depth stages, repeating nitrogen pressure test and subsequent calculations for each stage.

e. When the gaseous liquid interface reaches the casing shoe, shut in the well for at least a 24-hr period to test the entire cemented casing string for leaks.

4. *Cavern MIT Procedures.*

Principles and procedures involved in testing caverns are very similar to those previously described for testing the well. However, much larger volumes of the test fluid medium, higher wellhead and down-hole pressures, and greater testing-time intervals will be involved.

In general, most cavern leakage will occur behind the cemented casing shoe and/or within caved portions of the cavern roof. Specialized remedial techniques are frequently available for decreasing or eliminating such leakage.

15.3.2 FRASCH SULFUR MINING

D'ARCY SHOCK

15.3.2.1 History

The process by which elemental sulfur is produced from a geological formation is singularly credited to Herman Frasch. His concept of the mechanism of melting sulfur and then airlifting the molten liquid to the surface required a persistent effort in technical development and an expenditure of time and capital for a span of over 10 years before realizing significant success. The process is rightly named the *Frasch process* in his honor.

The initial production of sulfur by the airlift Frasch process began in 1896 with the operation of three wells which produced 2100 long tons (2134 t) of sulfur (Hynes, 1942). Difficulties in keeping the wells in production and high operating costs delayed a rapid growth of the system. With the discovery of the Spindletop oil field in 1902 and subsequent availability of inexpensive fuel, as well as improved petroleum well technology, more salt dome sulfur deposits were located, and the Frasch sulfur mining system became well established. Frasch sulfur produced at the Gulf Coast salt domes constituted the major source of US sulfur production and dominated the world market until approximately 1970. At this point, sulfur recovered as a byproduct of oil operations became a significant factor (Morse, 1986).

Decreased oil exploration in and around the Gulf of Mexico reduced the discovery of sulfur-bearing salt domes. As a result, sulfur prices strengthened and provided the incentive for development of Frasch-process mines in West Texas where the sulfur occurs in structural traps not associated with salt domes (Ellison, 1971; Anon., 1970). At the same time, the incentive to remove the sulfur from petroleum products continued; so that in 1982, petroleum byproduct sulfur production exceeded Frasch production, and this gap has continued to grow. Frasch sulfur mining has been applied to Mexican deposits that are similar to those along the Texas and Louisiana Gulf Coast. The prospects for growth in the United States seem doubtful, unless significant offshore salt dome sulfur deposits are discovered during oil drilling in the Gulf of Mexico. From a worldwide standpoint, however, the Frasch process undoubtedly will be applicable to situations where fuel and water are available and the geological circumstances are favorable, for example, the Mid-East petroleum production areas, Poland, and Russia.

15.3.2.2 Basic Requirements for a Frasch Sulfur Mine

Three basic resources are needed to develop a profitable Frasch sulfur mine. They are (1) a large deposit of ore of good grade (5% sulfur is suggested as a lower limit); (2) an adequate, reliable, and inexpensive source of water, preferably containing little dissolved solids; and (3) a low-cost source of fuel. Other factors such as market price, royalty payments, tax liabilities, and transportation costs also influence the economic feasibility of the project.

Utilities required to mine sulfur have been quoted as (1) an average water requirement of 5000 gal/long ton of sulfur (19.2 m^3/t) mined, (2) a fuel requirement of 2700 to 3000 Mcf of natural gas/million gal of mine water (20,000 to 22,300 Mm^3 of gas/m^3 of water), and (3) power requirements 600 to 700 hp/million gal/day of mine water (118 to 138 W/m^3 of water) (Anon., 1967). Reliable and economic transportation systems

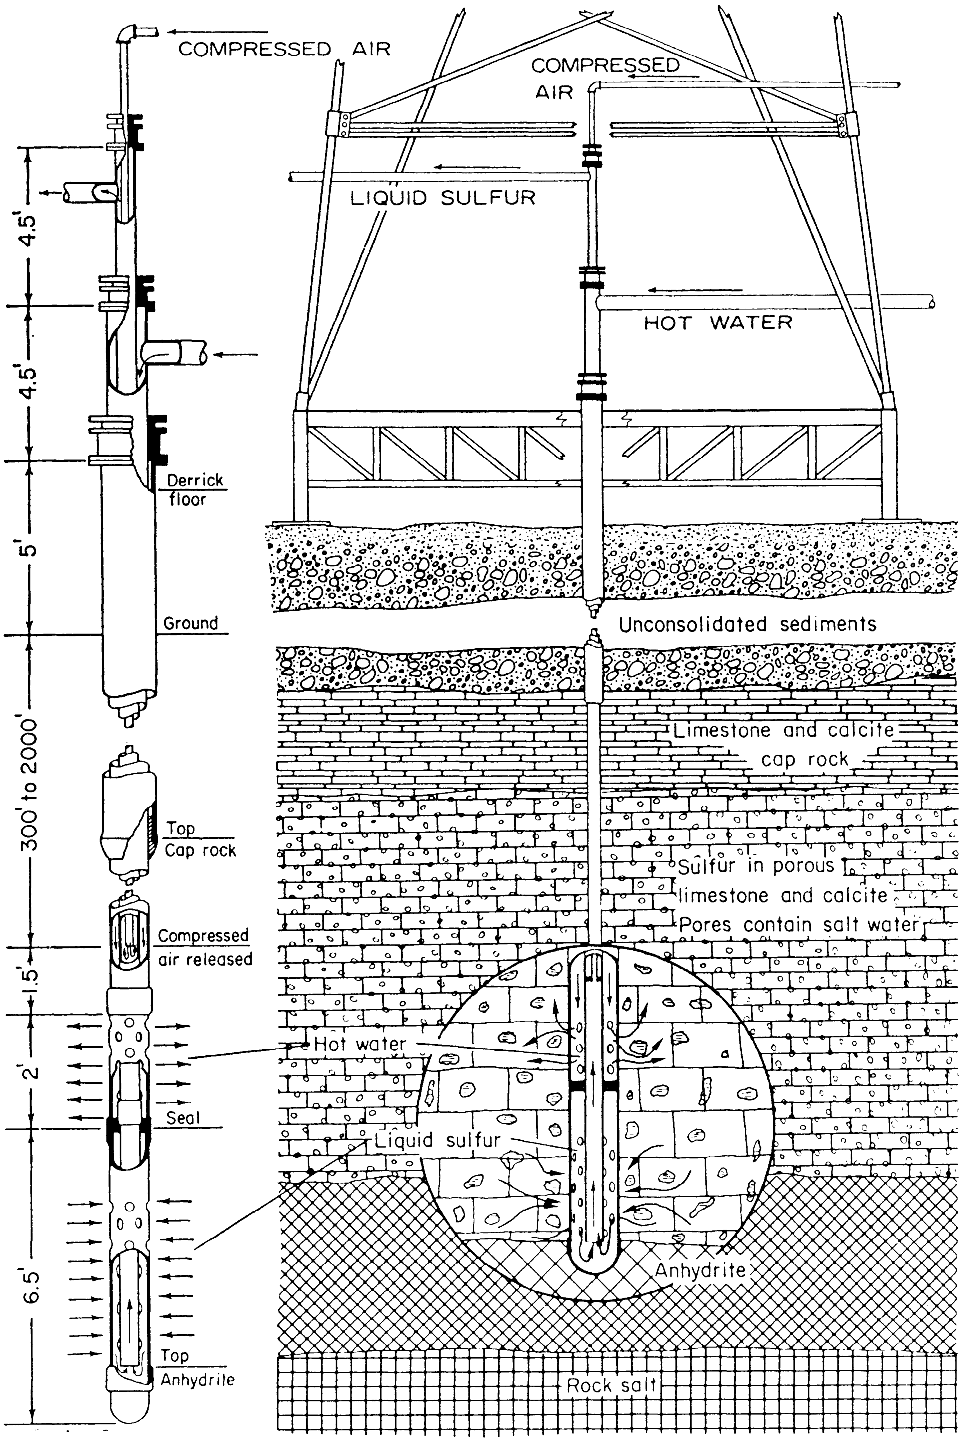

Fig. 15.3.2.1. Operation of a sulfur well (after Ellison, 1971). Conversion factor: 1 ft = 0.3048 m.

are also essential for distribution of the bulk sulfur. In this regard, transportation and storage of molten sulfur has been growing, particularly where low-cost water transport can supply shore-based distribution terminals. Sophisticated production personnel are important to operate and maintain the production and delivery systems.

15.3.2.3 Ore Deposit

The Frasch process was originally applied to removing sulfur from deposits located in association with salt domes. These domes have been formed by the intrusive flow of deep-bedded salt that penetrates the upper layers of sediments. Typically, the sedimentary layers are mud, shales, limestone, gypsum, and anhydrite. The salt plug normally is covered by an insoluble mineral cap. The sulfur is found below the cap in the vuggy porosity of the limestone. The sulfur location in the cap rock of the domes is highly variable, and not all salt domes contain sulfur-bearing rock.

Sulfate-reducing bacteria in conjunction with hydrocarbons and water are clearly capable of producing elemental sulfur. Thus sulfur can be formed from the gypsum and anhydrite and be precipitated in the porous limestone with the progression of water circulation.

The West Texas deposits of sulfur are associated with layers of gypsum, anhydrite, limestone, and dolomite. These deposits are not associated with salt plugs, and the porosity and permeability of sulfur-bearing beds follow the natural layered porosity of the strata and fracture system (Zimmerman and Thomas, 1969; Hentz et al., 1987).

15.3.2.4 Field Development

Efficient extraction of sulfur from the deposit depends on several interrelated factors. The hot water has to be introduced in such a way and at such a rate as to melt the sulfur so it will form a pool below the hot water. This pool of sulfur is then airlifted to the surface. The piping system consists of concentric pipes which extend into the minable formation (Fig. 15.3.2.1). The operating strings are a series of these concentric pipes. The outer casing is set into the caprock above the sulfur-bearing strata. The next string conducts the hot water and is set through the sulfur-bearing strata and is perforated at the bottom and also at some distance up the pipe. Another pipe is set concentrically within this pipe, and an internal seal is placed between the upper and lower perforations so that the flow of hot water is above the lower level. At a higher level, another pipe is run concentrically. The piping diagram is illustrated in Fig. 15.3.2.1, showing how hot water is introduced first, melting the sulfur. The sulfur, which is heavier, sinks to the bottom, runs into the lower pipe, and fills the second string. The molten sulfur is then airlifted with the compressed air and emerges as shown in the figure.

The molten sulfur is sent to storage, which can be handled in a number of ways. Since it may contain solid materials, or even small amounts of acid hydrocarbons, further processing may be required. Steam-heated leaf filters are commonly used for sulfur filtration. Precoating, usually with diatomaceous earth, is almost universal. The precoat should do the actual filtration to minimize blinding. The precoat will also neutralize some acid and reduce corrosion. However, small amounts of hydrated lime or ammonium bicarbonate may be added to the filter feed to neutralize acid. Such a system will produce sulfur that is free of ash and acid. If hydrocarbons must also be removed, activated clay may be added to bleach the dark sulfur. Other filter aids are also available to remove hydrocarbons. Filtration rates and precoat requirements will depend on the quality of the sulfur coming from the wells.

The sequence of the development of the well is shown in Fig. 15.3.2.2. The initial injection melts a pool of sulfur and seals the

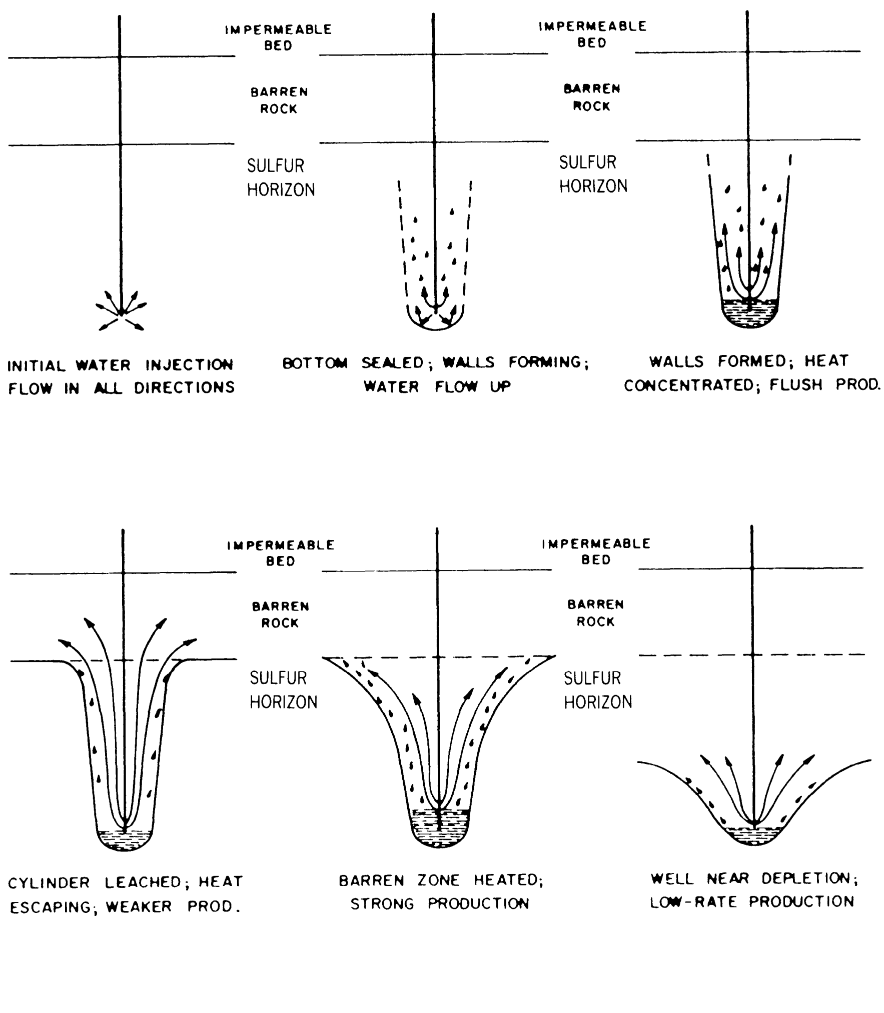

Fig. 15.3.2.2. Sequence of operations during the operation of a sulfur well (after Donner and Wornat, 1973).

bottom as shown in the figure. Hot water is forced further up the string, and a larger cylinder of rock is heated, melting more sulfur which is airlifted to the surface. This yields a concentrated flush production. This scenario is simple in concept; but in practice, where variability of permeability, sulfur content, heat flow problems, and the influence of other wells exist, the actual operation is very complex. It is necessary to reinject water produced in bleed wells to control flow, save heat, and dispose of waste water. The mining process is highly variable due to the nature of the deposits; and the uncontrollable nature of the reservoir system makes the process something of an art, that is gained by years of experience. Attempts have been made to apply reservoir engineering by substituting paradichlorbenzene as a meltable material for sulfur with some interesting insights (Rayne et al., 1956).

As mining proceeds, subsidence and collapse of overburden become a problem that can sometimes help, but may also shear tubing and cause many difficulties. Wells are often separated into groups to help control these problems and avoid total loss of field control. Corrosion due to molten sulfur contact is quite negligible. When the sulfur pool is drawn down to where the hot water and air come up together, the water flashes as steam, and a "blow" takes place. Hot water rising up the sulfur production string produces a corrosive environment; and with a blow, it becomes appreciable. The salinity of the water influences the rate markedly. If sea water is used and a blow occurs, the corrosion rate is disastrous (Hackerman and Shock, 1947; Shock and Hackerman, 1949). One of the practical solutions to controlling corrosion has been to use specially produced cement-lined pipes as well as limiting the salinity of the water. Treatment of the water to minimize corrosion and scale problems is essential.

Bleed wells are required to balance the water pumped into the formation at the production wells. Location of the bleed wells will depend on such site-specific factors as the depth, permeability, and hydrology of the sulfur-bearing structure. Due to environmental concerns, bleed water should be recycled to the maximum extent possible. When required, disposal of bleed water needs to be carefully planned due to the high concentration of dissolved hydrogen sulfide and other sulfur-bearing compounds. Aeration in ponds, chemical treatment, and use of deep disposal wells are all methods of handling these waters.

15.3.2.5 Facilities Needed at a Frasch Sulfur Mine

When a sulfur deposit has been located and defined by exploration drilling, a water supply located, and a fuel supply established, the design and construction of the needed facilities can proceed. Typical layouts showing both the well field and surface facilities are provided in the literature (Anon., 1970). Most mines will require some or all of the following:

1. Pumps, pipelines, and reservoir for the water supply.
2. Power plant for heating and treating the water, compressing the air, and generating the electricity and steam.
3. Equipment for drilling and servicing wells.
4. Pipeline system for carrying the mine water and air to the wells and the sulfur to collecting stations.
5. Control stations for the producing wells.
6. Sulfur collecting, loading, and storage facilities.
7. Purification equipment needed to meet customer specifications.
8. Shipping facilities for solid and/or liquid sulfur.
9. Bleed water disposal system.
10. Equipment needed for the maintenance of these facilities.
11. Employee transporting, dining, and housing facilities if the mine is remotely located.
12. Offices and buildings for material storage, laboratory, engineering, personnel, administration, and supervisory staff.

15.3.3 IN SITU MINING OF HARD-ROCK ORES

JON K. AHLNESS, DARYL R. TWEETON,
WILLIAM C. LARSON, DANIEL J. MILLENACKER, AND
ROBERT D. SCHMIDT

15.3.3.1 Overview of Methods

Today hard-rock in situ leaching techniques are being utilized to extract uranium and, on a small scale, oxide copper from undisturbed deposits. *In situ leach mining* involves the recovery of metal values from an ore body by circulating solutions through the ore in its native, essentially undisturbed geologic state and recovering those solutions for processing. In situ leach mining has been conducted from the surface (Fig. 15.3.3.1) as well as

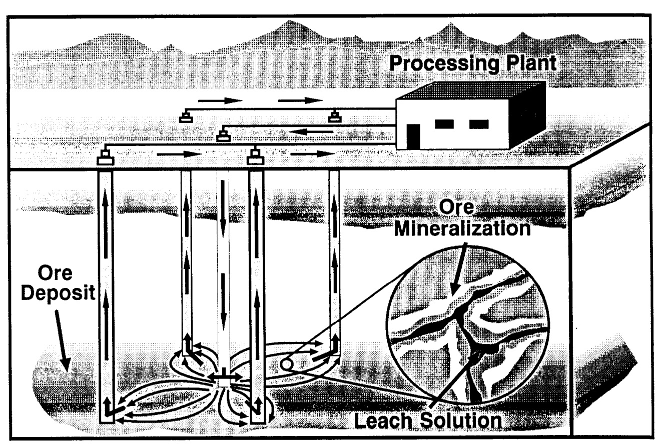

Fig. 15.3.3.1. In situ leach mining from the surface.

from underground workings (Fig. 15.3.3.2). By contrast, in conventional surface and underground mining, the ore is primarily recovered by large-scale, bulk handling techniques, through rock breakage and transport. In situ leach mining combines the operation of both surface processing facilities and subsurface remote mining in a way completely different from conventional technology.

A brief description of the in situ leach mining process is given here. A lixiviant appropriate to the target commodity or commodities (see Chapter 15.2) is used to dissolve the target metal and maintain production from the ore body, with solution processing occurring at a surface facility. A series of injection wells are used to inject or force the lixiviant into the pores and microfractures of the rock (ore). This solution travels through openings in the ore body and reacts with the minerals, mobilizing and transporting the metal species in solution. These openings may be the result of natural permeability or may be enhanced by using such oil field techniques as hydrofracturing (hydrofracing). A series of recovery wells are used to create a low-pressure hydrologic gradient where the metal-bearing solution can be collected and pumped to the surface. The metal-bearing solutions are processed for metal recovery and for regeneration of leach solution for subsequent reinjection through the flow paths and pores of the rock. Eventually, the metal values are depleted from the ore body, and a new series of wells are established to continue the mining operation.

In situ leach mining offers several advantages that may make metal mines more productive while reducing overall costs. Past in situ leach mining operations have shown that capital investment is reduced compared with conventional mining techniques. The advancement of this technology will ultimately mean that selected lower-grade deposits can be mined economically, thereby deriving maximum utilization from available resources. Because only fluid is being pumped, and ore is not being fragmented and transported to the surface, the energy requirements to produce the final product are significantly less. Other benefits of this technology include improvement of the health and safety environment of the miners, as they will not be directly exposed to the hazards of mining in and around the traditional rock handling and production areas.

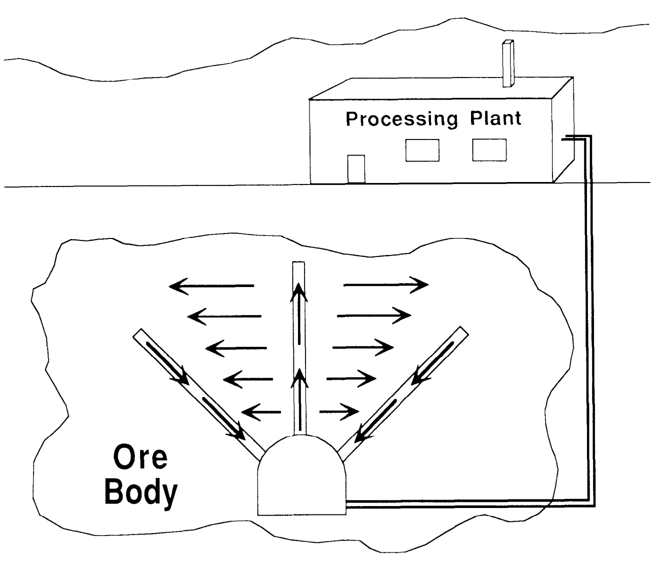

Fig. 15.3.3.2. In situ leach mining from underground.

The environmental impacts of this technology are much less than those of conventional mining from a waste-generation or air-quality standpoint. In situ leach mining removes the metal values from the host rock in place, and therefore will leave no waste piles or excavations to plague future generations. The primary environmental concern regarding this technology is the need to control and contain the leach solutions within the confines of the ore body. Restoration of the in situ leach mining zone may be required in order to prevent lixiviant excursions which could contaminate adjacent aquifers.

General advantages of hard rock in situ leach mining are summarized as follows:

1. No major surface disturbances, including open pits, waste dumps, or tailings.
2. No surface subsidence for most applications.
3. Minimal surface environmental impacts, including elimination of heavy mining equipment and processing plants such as mills and smelters.
4. Reduced labor requirements.
5. Reduced health and safety risks to workers.
6. Reduced energy requirements.
7. Quicker and more flexible startup and shut-down.
8. Lower capital investment.

However, in situ leach mining is not a universal panacea that is applicable to all types of deposits. Difficulties may include the following:

1. Difficulty in controlling or containing leach solutions due to faulting or lack of confining strata above and below the ore body.
2. Lack of suitable lixiviant for the contained metal value.
3. Inability to recover more than one or two values from polymetallic deposits.
4. Inability to accurately assess the level of recovery of values from the deposit.
5. Generally lower recovery of values than would be achieved in a heap leach on the same material.
6. Slower rate of recovery and lower overall level of recovery than that achieved in a surface milling and flotation or leaching operation.

15.3.3.2 Historical Perspective

URANIUM. Uranium is the only commodity that is successfully recovered in widespread, commercial, in situ leach mining operations. Commercial in situ uranium mining began in Wyoming in 1963 at the Shirley Basin site of Utah Construction and Mining Co., later Utah International (Anderson and Rithchie, 1968; Gardner and Rithchie, 1967). The company had started production in 1960 by underground mining, but poor ground conditions led to attempts at in situ leach mining. The company experimented with the system from 1961 to 1963. Commercial production with a sulfuric acid lixiviant continued from 1963 to 1969, when the company decided to extract the remaining uranium with open pit mining.

In Texas, experimentation with in situ uranium mining began in 1966 when the Dalco Co. (a subsidiary of Sabine Royalty) was organized to undertake uranium research and development (Knape, 1984). The first Texas permit for commercial leaching of uranium was issued in 1975 to Atlantic Richfield Company (ARCO) and its partners, US Steel and Dalco, for operation at their Clay West site in Live Oak County.

In situ uranium mining then expanded rapidly in the 1970s. In 1978, 12 in situ mines contributed 2,000,000 lb (900 t) of uranium out of total US production of 41,600,000 lb (19,000 t), or about 5% of the total (Shuck, 1979). US Bureau of Mines (USBM) personnel estimated the contribution, mostly from south Texas and Wyoming, grew to about 10% during the next two years. However, in the 1980s, the price of uranium decreased from over $40/lb ($88/kg) to less than $11/lb ($24/kg). Interest in opening new mines decreased along with the decrease in uranium prices. However, mines that had relatively low production costs and longer term contracts at higher prices continued to operate.

As of February 1989, there were three operating in situ uranium mines in Wyoming. One produced 923,000 lb (420 t) of U_3O_8 in 1988. The production of the other two was not reported. Only one of the other two was commercial. Informed sources in the industry unofficially estimate Wyoming in situ uranium production to be close to 2,000,000 lb/yr (900 t/yr). There was one mine in Nebraska. It was a pilot operation in 1988, so production was small. In Texas, there were four companies with six active commercial mines and at least one nearing the permitting stage. Although companies have not reported their production, informed sources estimated Texas in situ uranium mining produced somewhat more than 2,000,000 lb (900 t).

Total uranium production in the United States was 13,000,000 lb (5900 t) in 1987 (Anon., 1987), and was estimated to be about the same in 1988. Thus in situ uranium mining contributed about one-third of the total production. That fraction is expected to increase, as conventional mining declines. Byproduct uranium recovered from phosphate operations made Florida the largest producer of uranium in 1988, with an unofficial estimate of close to 4,000,000 lb (1800 t) produced. Conventional mining contributed the remaining one-third of production.

COPPER. There has never been a commercial in situ copper mining operation in undisturbed (unbroken) ore. However, a few in situ leach mining tests have been conducted and are described by Ahlness and Pojar (1983). These tests have been conducted in both oxide and sulfide ores at depths ranging from 100 to 2000 ft (30 to 600 m) below the surface. Lixiviant application and recovery have been conducted through wells and underground mine workings.

Perhaps the earliest in situ leach mining test took place at the Medler mine near Clifton, AZ, between 1906 and 1909. Mine water was pumped into underground mine workings on one level and allowed to seep through 60 ft (18 m) of rock to the next level where the pregnant solution was collected and processed. The copper mineralization was in sulfide form, and pregnant solution grade ranged from 0.2 to 0.6 g/L.

A major in situ mining research effort was conducted in the mid-1970s by Kennecott Minerals Co. at the Safford deposit near Safford, AZ. Testing was conducted in sulfide ore to a depth of about 2000 ft (600 m). A five-spot well pattern was constructed and leached, but the specific results are proprietary and have not been released. Commercialization of the site did not occur because of disappointing test results and the low price of copper at the time.

Another significant test was conducted at the Van Dyke deposit near Miami, AZ, in the late 1970s by Occidental Minerals Corp. A five-spot well pattern was constructed with corner-to-corner well spacing at 100 ft (30 m). Each of the wells was hydrofraced, and the leach interval ranged from 1000 to 1200 ft (300 to 600 m) below the surface. Dilute sulfuric acid lixiviant was injected in the center well, and pregnant solution was produced from the four corner wells. The test ran for several months and was considered successful. A commercial operation was not developed at the site because of difficulties in obtaining operating permits. The reason for the difficulty was that the ore zone partially underlay the town of Miami and was viewed as a possible threat to local water supplies.

There are currently two active in situ copper mining test sites (in undisturbed ore) in the United States, with one additional site in the development stage. The active sites are the Casa Grande mine near Casa Grande, AZ, and the Nacimiento mine near Cuba, NM. An in situ mining test facility is under construction at the Santa Cruz site near Casa Grande, AZ.

The Casa Grande mine is located about 30 miles (48 km) southwest of Casa Grande, AZ, and is operated by Cyprus Casa Grande Corp. The mine was originally developed as an underground block caving operation. At the conclusion of the caving operation, in situ leach mining of the remaining rubblized ore was conducted and is continuing to the present time. In addition to the block-cave leach, an in situ leach mining test is being conducted in an undisturbed zone of copper oxide ore. Injection and recovery wells are drilled in a fan pattern from the underground mine workings. Dilute sulfuric acid lixiviant is injected into the initially unsaturated ore zone. Pregnant leach solution is recovered from the recovery wells and is processed in a solvent extraction/electrowinning (SX/EW) plant on the surface. Details of this test are proprietary and have not been released.

The Nacimiento mine is located about 4 miles (6 km) southeast of Cuba, NM, and is operated by Leaching Technology Inc. The mine was originally developed as an open pit operation. The host rock is sandstone, and the primary copper mineral is chalcocite (sulfide mineral). A well field consisting of 9 contiguous five-spots (for a total of 16 injection wells and 9 recovery wells) has been constructed within the open pit. The ore zone is dipping and ranges from 150 to 400 ft (45 to 120 m) in depth to the bottom. The ore to be leached is saturated. The lixiviant used is a ferric sulfate solution. Operation of this in situ site has been sporadic. Decreasing communication between injection and recovery wells has apparently been a problem.

An in situ leach mining field test in a copper oxide deposit is being developed at the Santa Cruz site, which is located 7 miles (11 km) west of Casa Grande, AZ. This field test is a cooperative effort between the USBM and Santa Cruz Joint Venture formed between ASARCO Santa Cruz, Inc. and Freeport Copper Co. The goals of this test are to demonstrate the attainment of projected operating costs, copper production, equipment operability, and environmental compatibility. This will provide the mining industry with the data necessary to design and operate successful commercial in situ leach mining operations. The test may involve two contiguous five-spot patterns (Fig. 15.3.3.3) and is scheduled to run through 1996 (Ahlness, Millenacker, and Swan, 1989).

The Santa Cruz site has an estimated 97 million tons (87 Mt) of ore with an average grade of 0.7% oxide copper. The primary copper oxide minerals are atacamite and chrysocolla. The average depth to the bottom of the mineralization is 2200 ft (660 m), and the average ore thickness is 345 ft (105 m). The host rock is granite and quartz monzonite porphyry, with an in-place permeability of 5 to 20 millidarcies, a low value typical of such deposits.

An SX/EW plant will be built onsite. It will be designed to handle 10 to 50 gpm (0.6 to 3.2 L/s) of pregnant leach solution (PLS) with a maximum production capacity of 1000 tpy (900 t/a) of cathode copper. The dilute sulfuric acid lixiviant will be recycled. In other words, once copper is stripped from the pregnant leach solution, the solution will be reacidified and reinjected into the ore.

As part of its in situ copper mining research program, the USBM has developed a "Draft Generic In Situ Copper Mine Design Manual" (Davidson et al., 1988). This is a detailed source document for in situ leach mine design and economic modeling information and provides a systematic method for assessing the commercial feasibility of in situ leaching at any specific, undisturbed copper oxide deposit. The draft manual will be revised

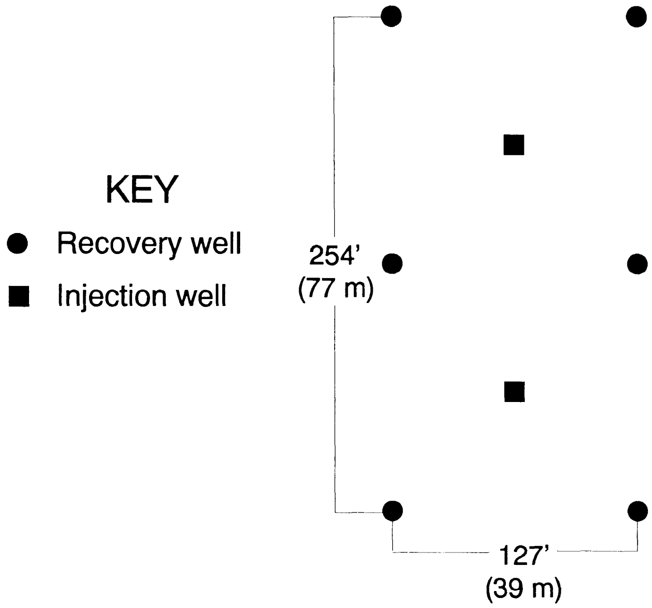

Fig. 15.3.3.3. Two contiguous five-spot well patterns.

by the USBM based upon data collected from the the Santa Cruz test.

15.3.3.3 In Situ Leach Mine Development

The following information is intended to help in determining the conditions under which in situ uranium and copper mining may be feasible and to provide suggestions for conducting initial tests. This information is not a substitute for the experienced, professional guidance required for planning an in situ leach mine. The discussion covers preliminary site evaluation, laboratory and field testing, economic analysis, well field development, product recovery, and environmental factors. Environmental issues are considered together as the last topic because initial permitting and final restoration are closely related.

This section will concentrate on in situ leach mine development for uranium because this technology is well developed and commercialized. In situ copper mining remains in the developmental stage. In general, the same basic steps as those discussed here for uranium will need to be conducted for any commodity to determine if a mineral deposit can be developed as a commercial in situ leach mining operation.

PRELIMINARY SITE EVALUATION. Many of the following suggestions for site evaluation were selected from an unpublished report prepared for the USBM (Buma, 1977). The general principles regarding site evaluation discussed in the report remain valid.

The following two questions require consideration:

1. Are the physical conditions of the deposit, including depth, hydrostatic pressure, and permeability, amenable to in situ leach mining?

2. Is the mineralogy of the deposit amenable chemically to a practical leaching system?

Physical Conditions—In general, uranium deposits amenable to in situ leach mining are associated with relatively shallow sandstone aquifers (less than 830 ft or 250 m subsurface) confined by low-permeability strata. Close proximity to faults could make control of leaching solutions difficult. From an environmental standpoint it is helpful if the deposit is in a well-confined aquifer and not in the same aquifer as municipal water supplies. Locating and plugging all old drillholes can be difficult. These drillholes must be plugged to prevent leach solution from flowing to overlying or underlying aquifers.

Upper and lower limits of acceptable permeability depend upon the depth of the aquifer. The flow depends upon the permeability and the pressure differential between the water in the wellbore and the water in the formation. The maximum allowable injection pressure is just less than the fracture pressure of the formation, which depends upon the depth as well as rock type.

The minimum permeability at most successful in situ uranium mines is 300 millidarcies. However, more important than absolute permeabilities are relative permeabilities of the mineralized and nonmineralized sandstone hosts. The relative permeabilities of different zones can be inferred from grain-size analysis. Zones having larger grain sizes generally have higher permeabilities. Sorting of the sands is also important. Better sorted sands have higher permeability than more poorly sorted sands of comparable size. The permeability of cores from different zones can also be measured. If higher grade correlates with higher permeability, then generally solutions can be controlled successfully. If the inverse is true, contacting the mineralization adequately with leaching solution may be difficult.

Reliable values of permeability or transmissivity are difficult to obtain. The best figures are obtained from draw-down tests performed in the field. These tests, however, yield an average result for the entire perforated interval. Spinner surveys can provide a flow profile for a well, but these are subject to error with low flow rates.

Mineralogy—Most uranium deposits suitable for in situ leach mining are of the sandstone roll-type. Roll-type denotes deposits in which uranium has precipitated from solution in ground water along an oxidation-reduction front (Larson, 1978; Langen and Kidwell, 1974), as shown in Fig. 15.3.3.4. Uranium was transported to its final location by the natural movement of oxygenated groundwater. Deposition occurred when ground water containing oxidized uranium as $[UO_2(CO_3)_3]^{-4}$ encountered a reducing environment where U^{+6} was reduced to U^{+4}. This caused precipitation from solution to form UO_2 as uraninite or pitchblende at the redox interface. The uranium mineral coffinite is also common, containing uranium in both the +4 and +6 valence states. Uraninite, pitchblende, and coffinite leach readily. If the reducing environment is disturbed, the uranium may be remobilized and form other uranium minerals, some of which may not be leachable. These include uranyl phosphate $[Ca(UO_2)_2P_2O_8] \cdot 8H_2O]$ and vanadates.

While the type of mineralization is certainly important, it is the distribution of the ore minerals within the host rock that is crucial. This will determine if the mineralization is sufficiently accessible to the lixiviant to permit economic in situ leach mining. The majority of ore mineralization needs to be located in or near the natural flow channels. Mineralization that is disseminated throughout the host rock matrix will not be accessible to the lixiviant within an economic time frame.

LABORATORY AND FIELD TESTING. Both laboratory and field testing must be conducted in order to determine the amenability of a deposit to in situ leach mining. Key questions that need to be answered are:

1. Is the ore mineralization amenable to selective dissolution within an economic time frame?

2. Can sufficient quantities of mineralization be contacted by the lixiviant to ensure the economic viability of the operation?

3. Can sufficient lixiviant flow be achieved in a well pattern with large enough well spacing to be economic?

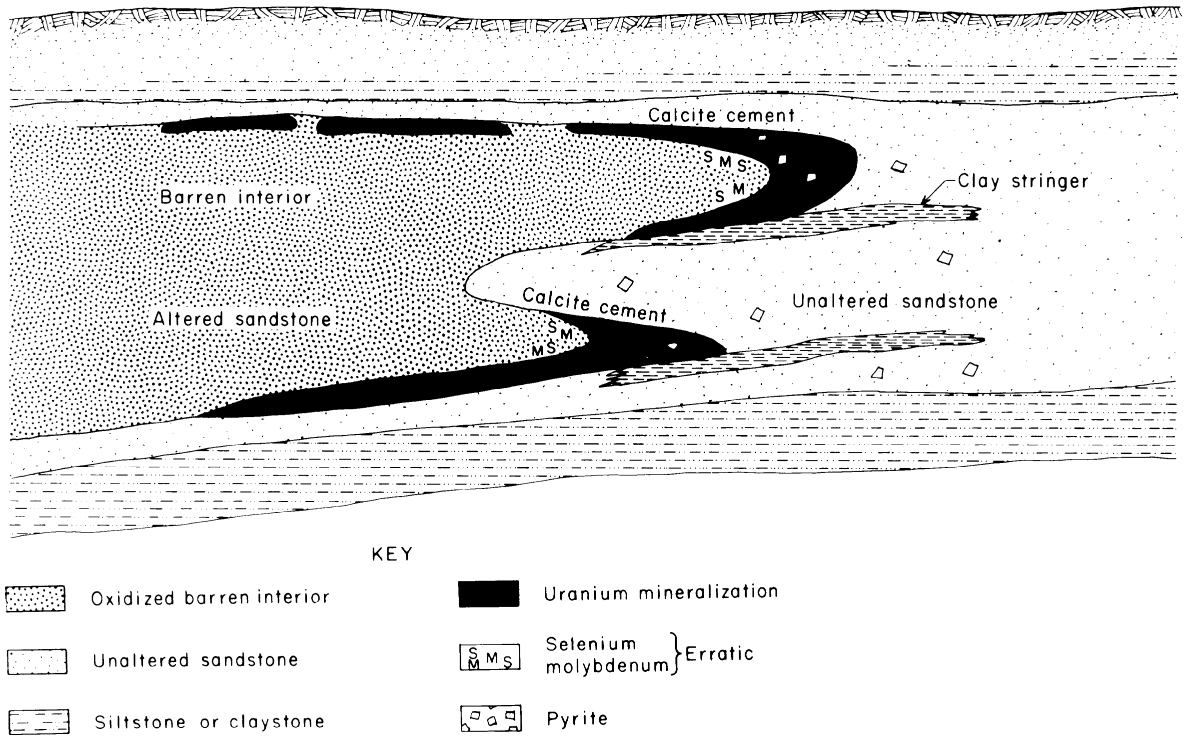

Fig. 15.3.3.4. Uranium roll-front deposit.

4. What is the preferred direction of fluid flow in the ore zone, and how will it affect sweep efficiency?

5. Can lixiviant be contained and recovered?

Laboratory testing can provide answers to the first two questions, and field testing can answer the others.

Solution Chemistry—Leach solution mobilizes uranium by reversing the chemically reducing conditions that originally led to deposition. It consists of ground water, an oxidant, and an anionic complexing agent that is usually carbonate. Using ground water from the formation minimizes swelling, precipitation, and other formation damage. The oxidant converts uranium from the +4 (reduced) to the +6 (oxidized) valence state, permitting its selective mobilization as an anionic complex. The ore-lixiviant systems for uranium are detailed in 15.2.2.3.

Many side reactions can occur between the leach solution and gangue minerals, such as calcite, clays, feldspars, zeolites, pyrites, and carbonaceous materials. These reactions can alter leach solution composition and/or mobilize contaminants, thereby impeding both uranium recovery and aquifer restoration. For example, oxidation of pyrite can produce sulfuric acid. Vanadium can also be mobilized and is recovered as a byproduct in some uranium operations.

Laboratory Testing of Leach Solutions—The two common types of laboratory tests are batch leach (sometimes called agitation leach) and column leach. Batch leach tests consist of agitating the ore and leach solution in a sealed container. Column leach tests consist of passing leach solution through a column packed with ore.

Much of the following information is from a USBM report (Tweeton and Peterson, 1981) describing methods for selecting leach solutions. Another reference, useful because of the similarities between milling and in situ leach mining, is Merrit's comprehensive book (1971) on chemical reactions in conventional uranium milling.

Sample Collection, Preservation, and Preparation—Obtaining meaningful results from batch or column tests requires care in obtaining, storing, and handling ore samples. When collecting the core sample, all drilling mud must be removed. The drilling mud can change the composition, Eh, and pH of the solution in contact with the core material. If the ore is inadvertently oxidized before being leached, then the measured oxidizer consumption will be too low. The degree of preoxidation can be estimated by conducting a leaching test under nitrogen. To avoid preoxidation, the ore can be sealed in airtight containers or frozen in dry ice soon after coring. If the ore is not preoxidized, the results will provide an upper limit to the oxidizer consumption because the oxidizing reactions will be more complete in the laboratory than in the field. Ore samples for permeability testing should not be allowed to dry. They should be preserved in sealed containers with water from the same hole or the moist samples may be frozen for shipping. Quick-freezing on site will retard chemical reactions that alter the sample, but may damage the clays.

Laboratory leaching solutions should be made from formation water, not from distilled water. A sample of formation water for use in the leaching tests must be collected and analyzed. Before collecting formation water, the well should be pumped until pH, conductivity, and Eh have stabilized and the water runs clear. One sample should be acidified immediately after collection and used for cation analysis. An unacidified sample should be kept for anion analysis. If precipitate forms before the sample can be analyzed, the sample should be shaken to mix the precipitate thoroughly and the precipitate analyzed along with the water.

To obtain the most reliable measurements of formation geochemical conditions, down-hole measurements of Eh, pH, conductivity, dissolved oxygen, and temperature should be made at the horizon from which the core sample was collected. Ideally, the water should be collected with a pressure sampler and the dissolved gas composition measured.

Laboratory studies should be conducted on homogenized ore samples. Meaningful comparisons of leach solutions require similar ore samples, but cores vary considerably in permeability and uranium content. Clay and calcite lenses in cores could have an overwhelming influence on core permeability while having very little effect on in situ horizontal permeability. The ore should be disaggregated gently to avoid breaking grains and thoroughly blended. Most sandstone uranium ore can be disaggregated easily. Some consultants advise removing clay lenses from the core prior to testing to reduce their effect on permeability. Their removal can also help avoid misleading results regarding the leachability of uranium adsorbed on clay or organic substrates.

Batch Leaching—Although batch leaching tests do not simulate down-hole conditions, they can indicate the relative rate and amount of uranium extraction and the relative consumption of oxidant as a function of leach solution composition. Variables include pH (e.g., 7, 8, and 9), carbonate or bicarbonate concentration (e.g., 1, 3, and 5 g/L), and oxidizer concentration (e.g., equivalent to 0.1, 0.3, and 0.5 g/L oxygen). The ore sample must be large enough to allow solution samples to be withdrawn without unduly disturbing the geochemistry and to provide sufficient dissolved uranium for analysis. Typical ore sample sizes are 100 to 500 g, with a liquid-solid volume ratio of three.

The measured parameters are usually pH, Eh, and concentrations of uranium, carbonate-bicarbonate, oxidizer, and site-specific elements such as vanadium. The Eh measurements do not necessarily represent in situ values, but changes in the Eh can indicate changes in the oxidation state of the uranium. Typical sampling times are 0, 1, 4, 8, 12, and 24 hours after the start of the test and once per day until equilibrium is reached, usually in 3 days or less. The uranium in the ore should be measured before and after leaching and a material balance made to check the validity of the measurements. Material balances must be calculated for proper control. Accounting for carbonate may be difficult because of losses in the production of CO,, but all cations should balance within reasonable limits.

Fresh solution should be added to the slurry after extracting the sample to maintain the liquid to solid ratio. Before extracting the sample, pH, Eh, and conductivity should be checked and recorded. The solution replacement for the sample should contain an adequate amount of fresh reagent to allow the leaching process to continue. Solution increments should not be so large as to overpower the system and mask other important effects.

Measuring the consumption of oxygen requires sealed experimental equipment and a method for withdrawing samples without losing oxygen. Some experimenters favor a chlorate oxidizer to avoid the need for pressurization. However, the consumption of chlorate and oxygen are not necessarily equal because their oxidizing powers are not identical.

Column Leaching—Column leaching tests simulate field conditions more closely than batch tests, but caution is still necessary when extrapolating from laboratory to field. The contact between ore and leach solution is more complete than in actual in situ leach mining, so the laboratory extraction of uranium is an upper limit for field results.

Permeability losses can be measured with column leach tests. Permeability is affected by ion-exchange reactions in clays, especially montmorillonites. Montmorillonite has exchangeable cations and a variable number of water molecules between the layers. Swelling can occur if the predominant cation in the leach solution has a larger ionic radius or lower valence state than those within the clay. A common example is the exchange of Na^+ for Ca^{++} in the montmorillonite. The Na^+ cation has a larger ionic radius than the Ca^{++} cation. Also two Na^+ cations are needed to exchange for one Ca^{++} cation to maintain electrical neutrality. This exchange increases the volume of the clay, causing swelling and decreasing permeability. Thus column tests are especially important in determining whether sodium carbonate leach solution will cause excessive clay swelling and loss of permeability.

Swelling can also occur if a solution having a lower ionic strength is introduced, as the clay admits more water molecules between layers. This problem can occur during laboratory leaching tests if the leach solution is made with distilled water instead of formation water.

A vertical column with leach solution entering at the bottom maximizes the rate at which air is swept out of the core. Horizontal tubes present the risk that ore will slump slightly, thereby creating a high permeability channel between the top of the ore and the inside of the column. Ideally, the column would be pressurized to simulate down-hole conditions and allow oxygen to be used. Using sodium chlorate in column leaching tests could reduce permeability.

In principle, the most reliable results will be obtained with the widest and longest columns. In practice, the amount of core is usually limited and the number of tests is large, so columns must be rather small. A column 2 in. (50 mm) in diameter and 3 ft (1 m) long appears to be a good compromise unless chromatographic effects are of special interest. Then a 1-in. (25-mm) diameter sectional tube with a total length of 10 to 17 ft (3 to 5 m) would provide more information. A series of vertical columns connected by flexible tubes is convenient for studying chromatographic effects. With small cells, the ore must press tightly against the sides of the cell to avoid large wall effects. For testing oxidizer consumption and response to oxygen under down-hole conditions, a small pressure cell can be used. Hassler pressurized cells 12 in. (300 mm) long gave good results at the University of Texas (Schechter, Lake, and Guilinger, 1984). Hassler cells can also be used for measuring the effect of various leach solutions on permeability, allowing careful control of experimental conditions.

Typical variables, measured parameters, and sampling times are similar to those for batch tests. Measuring permeability by measuring the pressure difference across the packed column at a constant flow rate is generally preferred over using a constant pressure. The velocity of the leach solution should be similar to that in the field, often about 10 ft/day (3 m/day). Excess flow rate or pulsing can lead to channeling, especially with horizontal columns.

Well Field Patterns—A pilot-scale field test is performed before starting commercial operation to evaluate leach solution behavior, to test well construction and completion techniques, and to demonstrate restoration procedures. These tests can be flow-through, where injection and production wells are separate, or push-pull (“huff-and-puff ”), where a well serves first for injection and then for production. Most commercial operations are flow-through. Push-pull may be used if hydrologic communication between wells is poor.

Experts disagree as to the value of push-pull tests. Some believe that these tests provide a reliable and relatively economical method of evaluating the leach solution under field conditions. For example, one push-pull well and two observation wells provided sufficient data for field evaluation of an experimental leaching process (Tweeton and Lake, 1986). The well pattern was an L, with the injection-production well at the corner. However, the results of flow-through tests can be quite different from those of push-pull tests. In unpublished flow-through tests at one site, increases in uranium concentration and Eh lagged behind the changes in the other components. Over three pore

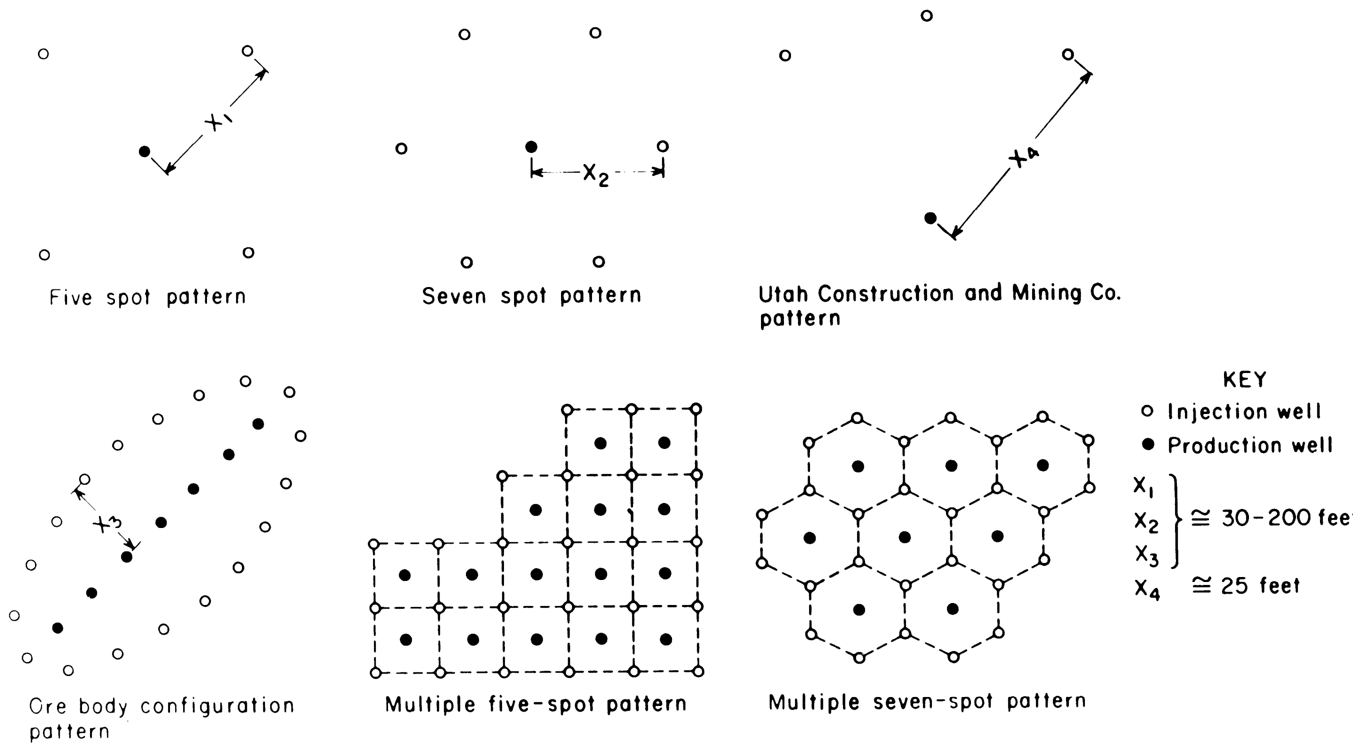

Fig. 15.3.3.5. Well field patterns. Conversion factor: 1 ft = 0.3048 m.

volumes of leach solution were injected before the uranium concentration and Eh rose, but that lag was not observed in a previous push-pull test at the same site. Therefore, the push-pull test resulted in an overly optimistic prediction about the ease of leaching. Conducting a flow-through pilot test before beginning a flow-through commercial operation is prudent if a push-pull test has been used for a preliminary evaluation.

Various well field patterns are shown in Fig. 15.3.3.5 (Larson, 1978). The most common configuration is a five-spot, either single pattern for tests or multiple pattern for commercial operation. A five-spot test provides directional permeability information, a reasonable sampling of the ore body, and closure for controlling solution flow. Capability for reversing the flow is sometimes helpful in restoring permeability. The usual flow pattern is to inject at the corners and produce at the center because there is generally more fluid resistance to injection than to production. This pattern also minimizes dilution. A disadvantage is that it is not possible to distinguish the arrival of solution via different paths. The distances between the injectors and producers can be adjusted to the permeability conditions. A 40- to 70-ft (12- to 22-m) span is typical. Experimentation with well spacing can be considered as part of development for production.

Advantages of a small field are that a test can be completed in less time, and the response time to operational changes is short. The smallest practical well spacing is about 20 ft (6 m) from injection to recovery well. This spacing is wide enough to allow drilling of post-test core holes between injection and recovery wells without danger of intersecting the wells.

Formation Clogging Causes and Cures—Clogging of the formation tends to be most severe near injection or production wells. Clogging of the formation near an injection well can occur due to poor well completion practices. Clogging will also occur if the lixiviant is incompatible with the formation. An example is clay swelling that occurs with a sodium carbonate-bicarbonate lixiviant used in a formation that is high in clay when the pre-leach groundwater is low in sodium. Usually, the incompatibility can be identified in laboratory column leaching tests. To prevent blockage of the formation by oxygen bubbles, the down-hole solubility of oxygen must not be exceeded.

Clogging of the formation near a production well can be caused by gas phase blockage or precipitation. The pressure near a production well is lower than in the rest of the formation, so some of the carbon dioxide undergoes exsolution. This can raise the pH and precipitate calcite. If the ground water is saturated with respect to calcium, the pH should be maintained at about the natural pH to avoid precipitation of calcite in flow channels. The solution pH should not be allowed to rise above 9.2, as this is the point at which silica is mobilized. Silica can form gels which block the formation and can poison the ion exchange resin in the extraction plant.

Reprecipitation of uranium is undesirable even if it does not cause serious clogging. It can occur if the strength of the leach solution (pH, Eh, or concentration) changes excessively from injection to production well. This problem can be minimized by increasing the strength of the leach solution gradually as leaching begins and by selecting a leach solution compatible with the formation. Reducing the well spacing is an expensive cure.

Hydrology—Darcy's Law and the equation for continuity of flow in an elementary volume of rock are the fundamental equations used to derive the partial differential equation that governs the unsteady-state flow of leach solution between injection and recovery wells. The analysis assumes a homogeneous isotropic aquifer setting. Darcy's Law states that the flow rate through a porous medium is proportional to the head loss and inversely proportional to the length of the flow path. The constant of proportionality in Darcy's Law (assuming a unit cross-sectional area of flow) is the *permeability*. *Storativity* is the volume of fluid that the rock mass releases from or takes into storage with a change in head (Walton, 1970).

Values for permeability and storativity in a saturated ore deposit may be obtained in situ from well tests or laboratory core leaching experiments. Field measurements of saturated permeability obtained from short-term well tests in fractured hard-rock deposits typically range from 0.1 to 10 millidarcys. For the most part these represent measures of effective fracture permeability rather than intergranular permeability. Intergranular permeability is commonly 1 to 4 orders of magnitude lower (Erskine, 1987). Typical values of storage coefficients for unfractured hard rock are 10^{-9} to 10^{-11}.

Insuring adequate flow rates between wells, and controlling the distribution of injected leach solution within the ore deposit are part of the in situ hydrologic design process. A number of important in situ design decisions must be made by site operators in order to meet these objectives.

In low permeability settings the design alternatives that are available to insure adequate well flow rates include imposing higher and lower head conditions on injection and recovery wells, choosing injection and recovery well locations closer together, and/or increasing the diameter of wells.

In saturated deposits, control of the flow and distribution of injected leach solution is accomplished by choosing wellhead conditions that ensure a net withdrawal of leach solution and ground water in the vicinity of the wells. Ground water injection wells, however, are sometimes used to create artificial hydraulic barriers at the boundaries of the site.

Leaching a low-permeability or poorly confined mineralized zone is difficult. An example is the mineralization tied up in the trailing edges on the oxidized side of a roll front. The unmineralized core of the oxidized side of a roll front is more permeable than the mineralized limbs. Leaching under such circumstances is possible, but the mode of operation must allow solutions to diffuse into the less permeable horizons and contact the mineralization rather than simply flowing through channels. Pressurizing the more permeable zones above and below the mineralized zone by injecting ground water can help to confine the leach solution to the mineralized zone (Schmidt and Ahlness, 1989).

Design decisions such as these must be made in the context of a complex hydrologic setting involving heterogeneities in permeability, flow in fractures, free saturated surfaces, partially saturated conditions, and mine void spaces. Application of an engineering hydrology model can greatly enhance understanding of this complex setting and make the decision process far easier (Schmidt, Salovich, and Jagusch, 1987).

Analytical or numerical hydrology models that are powerful enough to incorporate many of the complexities of an in situ field setting and at the same time permit easy trial-and-error manipulation of site conditions and design parameters are especially useful as engineering models. Most sites are too complex, and too little field data are generally available to permit precise prediction of field outcomes based on computer modeling. However, hydrologic modeling is extremely useful for exploring the effect of various parameters and testing their influence on desired outcomes (Strack, 1989).

At present, commercial copper in situ leach mining operations are being conducted in disturbed (broken) deposits that have been previously developed and exploited by prior conventional block caving or other underground mining methods. These settings offer a number of advantages over mining in undeveloped settings. Ore permeability is often greater as a result of mining-induced fracturing or rubblization of the deposit. Underground workings offer preferential access to a deposit and save on drilling costs. Underground mine void spaces are available as solution collection areas, and a developed deposit is generally better characterized geologically and mineralogically than an undeveloped deposit. However, prior mine development also contributes significantly to the hydrologic complexity of a leach site (Swineford, 1987).

While an ore body located in an undisturbed setting may be saturated and have a significant positive pore pressure, unsaturated conditions resulting from prior mine dewatering activity may exist initially in a partially developed deposit. Mining induced fracturing or rubblization of an ore deposit, and the presence of surface or underground mine void spaces results in a complex flow setting, making it difficult to isolate and assess the influence of individual hydrologic parameters.

The existence of unsaturated (negative pore pressure) conditions in a deposit prior to leaching can be a significant factor in controlling the distribution of injected leach solution, since practically speaking, the minimum head condition that can be imposed on a recovery well bore is zero. For leaching operations conducted under conditions of partial saturation, existing underground mine drifts rather than recovery wells may be the most effective collection mechanism (Schmidt, 1988).

Fracture heterogeneities can significantly affect the flow rates between individual wells, and the distribution of leach solution in the ore body. However, some of the most useful hydrologic information regarding fracture heterogeneities is acquired only as leaching operations are being conducted. In order to use this information fully, it is desirable to incorporate into a leach site design, as much flexibility as possible. The number of wells available for injection and recovery, their locations in the well pattern, and the head condition prescribed for each should be factors that can be independently manipulated in response to flow conditions that develop during leaching.

Injecting leach solution at pressures high enough to dilate existing rock fractures in the vicinity of the injection wells is a permeability enhancement technique that is currently being tested at a leach site. Preliminary results indicate that this technique can be an effective means of increasing solution injection and recovery rates. Questions remain, however, about the difficulty of maintaining fracture permeability at lower injection pressures, the influence of ambient pore pressure conditions on the pattern of dilated fractures, and most importantly the tendency of leach solution to flow preferentially between injection and recovery wells via a small number of highly conductive fracture flow paths (i.e., short circuits) as opposed to a more uniform distribution of flow in less-permeable, less-fractured rock.

A possible solution to this problem, which takes advantage of built-in flexibility in well specifications, involves converting injection/recovery well pairs that exhibit short-circuiting behavior to either paired injection or paired recovery wells. Such a well specification takes advantage of the highly conductive fracture flow path linking the two wells in order to distribute solution into lower permeability rock surrounding the fracture short circuit.

Data Collection—A five-spot field test will provide the most useful information for an economic evaluation, so care should be taken to collect an adequate number of samples during the test. As a minimum, four samples per day should be collected and analyzed for uranium, vanadium, molybdenum, selenium, arsenic, calcium, and CO_3. A spectrographic analysis of the pregnant solution should be obtained at the peak grade of uranium. The leaching conditions can be monitored by taking periodic in situ measurements of Eh, pH, conductivity, dissolved oxygen, and temperature.

To determine uranium recovery, a number of core holes should be placed within the test well field prior to initiating the test in order to obtain assay data. Because of the extreme variability of uranium deposits, the more pre-test and post-test core holes, the more reliable and consistent will be the results. As a minimum, post-test core holes should be placed midway between injection and recovery wells. Some post-test core holes should be placed outside the five-spot pattern to ascertain the extent of solution migration outside the well field. Statistical methods must be applied to data from field tests to get meaningful results.

ECONOMIC ANALYSIS. In situ uranium mining companies have lowered their costs of production since 1980. Informed sources in the industry estimate that direct production costs are as low as \$10 to \$12/lb (\$22 to \$26/kg) of uranium in some favorable deposits. These costs do not include royalties, taxes, or exploration. The cost reductions have been achieved through reducing the number of workers per unit of production, and by careful attention to technical procedures such as well field planning. At many sites, such cost reductions were not possible, and profitable production could continue only as long as higher-priced contracts with uranium buyers remained in effect. An example of the low labor costs possible with in situ leach mining was provided by Everest Minerals Corp. (Stover, 1989). During 1988, their Highland Uranium Project in Wyoming produced 2500 lb (1100 kg) of uranium/day while employing 55 people on site.

Economic evaluation models are available through private consulting companies in areas where in situ uranium mining is conducted. These models are mature, having been compared with actual costs. The models are proprietary, as are the costs for specific mines.

A nonproprietary cost model was released by the USBM (Toth and Annett, 1981; Toth and Larson, 1981, 1982) and can serve as a useful introduction to modeling of costs. The report presented the results of an assessment of uranium in situ mining costs through the application of process engineering and discounted cash flow analysis procedures. The model will generate mine life capital and operating costs as well as solve for economic production costs per pound (kilogram) of uranium. Conversely, the rate of return may be determined subject to a known selling price.

The databases of the cost model were designed to reflect variations in Texas and Wyoming site applications. Base case calculations gave the cost for producing uranium as over \$20/lb (\$44/kg) in both Texas and Wyoming. The biggest single item of expense was annual well field replacement costs, which were about \$5 to \$8/lb (\$11 to \$18/kg) of uranium for the base cases. Other direct costs were \$6 to \$8/lb (\$13 to \$18/kg). The results were most sensitive to pattern spacing and solution grade.

Perhaps the most important single factor in evaluating the economic viability of a potential in situ uranium mine is the grade-thickness product of the uranium reserve. The cutoff grade for in situ leach mining is lower than for conventional mining. Companies have used 0.03% as a cutoff, though the cutoff will vary with site conditions such as depth. Typical grade-thickness cutoffs range from 0.3 to 0.6%-ft (0.09 to 0.18%-m). In determining grade-thickness from logs, the nonleachable uranium associated with clays, shales, and coal must be eliminated. The cutoff depends not only on site-specific conditions but also on the price of uranium.

The advantages of the economic flexibility of in situ leach mining were discussed by Pool (1989). The flexibility occurs because fixed costs for in situ mining are a lower percentage of total costs than they are for underground or open pit mining, so production can more easily be changed to respond to price changes. Simulations with the USBM model indicated fixed costs are in the range of 35% of the total cost for a typical in situ leach mining operation. In contrast, fixed costs for underground mines are in the range of 50 to 65% of the total cost of full-scale production. For open pit mines, a 10:1 stripping ratio might easily put the fixed cost of an open pit at 90% of the total cost. Pool concluded that this higher degree of economic flexibility will stimulate the growth of in situ leach mining and provide additional insulation from fast-changing prices.

There are no economic in situ copper mining data available since there have been no commercial operations in undisturbed ore. However, a USBM publication contains a computerized cost model that can be used to estimate the economics of in situ leach mining for any specific oxide copper deposit (Davidson et al., 1988). The cost model develops detailed capital and operating costs and utilizes a discounted cash flow/rate of return (DCF/ROR) analysis to calculate either a pretax rate of return for a specified selling price of copper, or a pretax selling price of copper for a specified rate of return.

WELL FIELD DEVELOPMENT.—Many of the following recommendations are adapted from a USBM contract report (Shuck and Brooke, 1982) that describes in detail designing, drilling, grouting, and developing wells for in situ uranium mining. Where necessary, the recommendations are updated to reflect changes in practices.

Pump and Casing Selection—Pump specification and selection will depend on the characteristics of a particular site and the leach chemistry adopted. Because of the large number of pumps used, the total pumping cost should be used as the basis for their selection. The total pumping cost includes power costs, maintenance costs, and replacement costs. Excessive throttling or switching of oversized pumps should be avoided. The submersible pump must be hung on a pipe or tubing string of adequate strength to resist numerous starting-torque cycles. A separate safety line provides extra protection. The ability to withstand the corrosiveness of the leach solution is vital. Many operators have chosen stainless steel pumps, despite their higher price, to obtain higher reliability.

Casing must also withstand the corrosive effects of leach solution. PVC casing is used much more than fiberglass. Fiberglass is used only where it is needed because of unusually great depth. At normal depths (800 ft or 240 m), PVC is preferred because it costs less than fiberglass. If solvent welded PVC is used, proper procedures for joint make-up, casing emplacement, and grouting should be implemented and monitored to insure adequate casing integrity. Many operators use screws to hold the solvent welded joint while the solvent is drying. A yellow PVC casing which is marketed for mining use is available. It uses spline joints, so the problems associated with solvent welding are eliminated. However, it is more expensive than standard PVC.

Wherever practical, the use of PVC or fiberglass casing accessories is recommended over the use of steel accessories because of the reduced potential for casing damage during any subsequent work-over operations. Casing accessory specification will depend on the type of well completion.

Drilling—Because of cost and availability, hydraulic-rotary equipment with conventional circulation is recommended for in situ leach mining applications. The drill rig should have a rotating table which allows setting and grouting of the casing while still set up on the hole. The mud pump should be of sufficient size to maintain turbulent flow in the ascending fluid (i.e., a fluid velocity of 60 to 100 fpm or 0.3 to 0.5 m/s). Mud pits should be sized to permit maintenance of optimum drilling fluid properties for the particular site. This generally requires a pit volume at least 2 1/2 times the anticipated drillhole volume.

To obtain straight holes, it is important that sufficient weight and stiffness be incorporated into the drill string immediately above the bit. This is accomplished by means of drill collars to

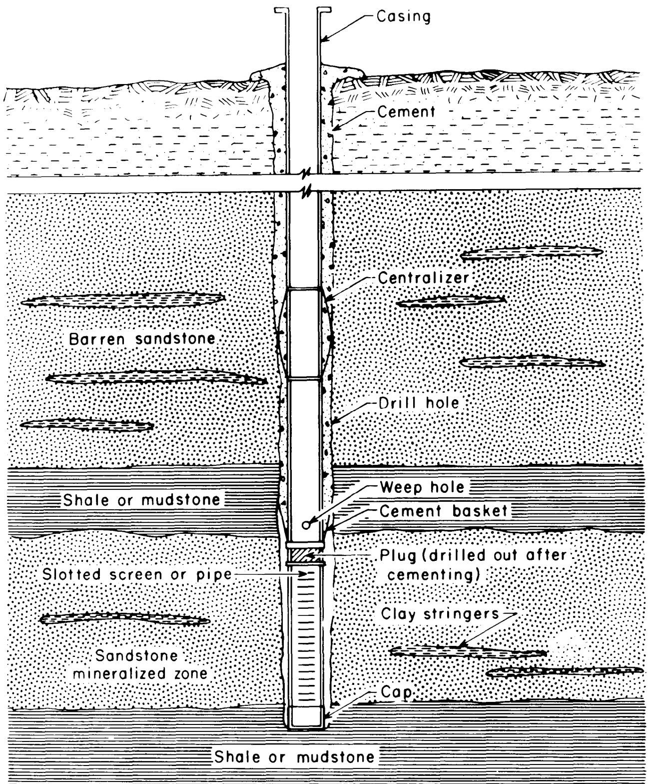

Fig. 15.3.3.6. Well completion using screen and cement basket.

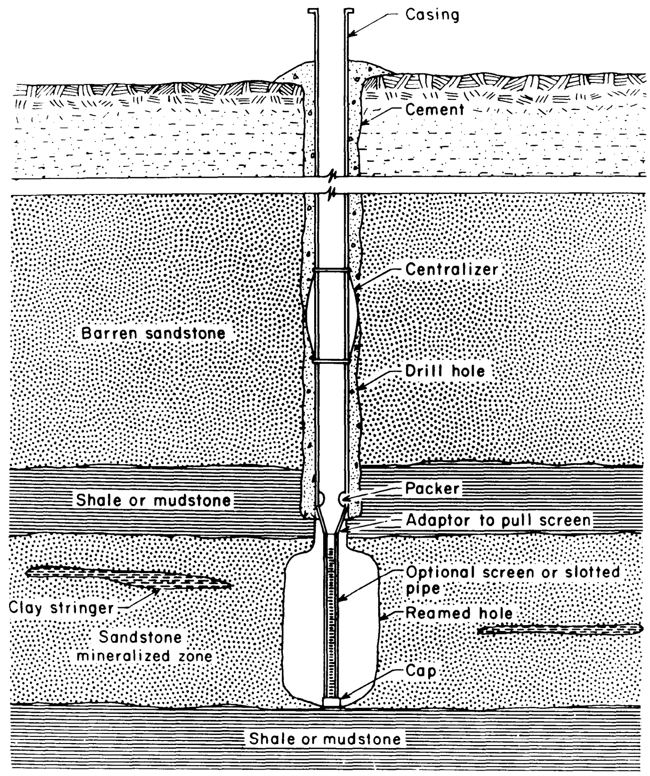

Fig. 15.3.3.7. Well completion using underreaming.

maintain the drill string in tension and obtain optimum drilling rates without pull down on the drill string. The type of bit(s) used to drill the hole will depend on the particular formation characteristics, but the bit should have a diameter at least 2 in. (50 mm) greater than the maximum external diameter of a casing joint. Drilling fluid selection should be matched to the well drilling and completing sequence to permit tight control of its characteristics when drilling the completion interval. To minimize the potential for damaging the formation while drilling, bottom hole pressures should be maintained well below the formation fracture pressure.

It is vital to avoid formation damage by drilling fluids. Wherever practical air-drilling of the completion interval is recommended to minimize damage to the exposed formation face. A chemically degradable polymer-based fluid is recommended where air drilling proves impractical. The four following principal fluid characteristics should be maintained while drilling the completion interval: recovered fluid density of 8.5 to 8.7 lb/gal (1.02 to 1.04 kg/L), Marsh funnel viscosity about 35 sec/qt (37 sec/L), filtration rate of 5 to 10 mL/half hour at 100 psi (690 kPa) pressure difference, and the minimum possible gel strength.

Well Completion—Two well completion methods are shown in Figs. 15.3.3.6 and 15.3.3.7. The method of Fig. 15.3.3.6 employs a screen or a slotted or perforated casing in the mineralized zone. Restricting the well completion interval to the mineralized zone is recommended but does not insure confinement of the leach solution to this zone. Most operators use screens attached to the casing rather than perforating or slotting casing. The screens provide better sand control without hampering well efficiency.

The method of Fig. 15.3.3.7 employs underreaming to enlarge the well bore in the mineralized zone to facilitate injection. A screen may be used, or, in competent ore, the underreamed portion of the hole may be left open.

The cement used to make the grout must be compatible with both the local groundwater and the leach solution composition throughout the course of the project. The grout should also be formulated to yield the required strength vs. time characteristics at the lowest practical slurry density. When the well design involves running casing through the target ore zone and either an under-reamed or perforated completion interval, the grout formulation should also have the lowest practical filtration loss. The need for other additives will depend on specific formation characteristics and ambient conditions. A minimum initial clearance of 1% of its calculated length should be allowed between the casing and bottom of hole to prevent contact during grout emplacement.

To assure the quality of grout seal required for in situ leach mining wells, through-casing emplacement with wiper plugs is recommended. Through-casing grouting involves injecting grout into the casing and allowing it to flow into the annulus between the casing and formation through holes (weep holes) near the bottom of the casing, as shown in Fig 15.3.3.7. A plug, generally plywood, below the weepholes prevents grout from falling into the inside of the well screen. This plug is drilled out along with the grout "heel" that remains above the plug. The cement basket prevents the grout from falling into the annulus outside the screen. The annulus is thus filled from near the bottom to the top.

A pregrout flush consisting of grout thinned to a density somewhat greater than the drilling fluid is recommended over water. It should be circulated at a flow rate sufficient to obtain turbulent flow in the annulus and continued for 5 to 10 minutes before grout emplacement is begun. The grout slurry volume used should be sufficient to obtain a return to the surface with the desired set characteristics. Once begun, grout emplacement should continue smoothly and continuously at a bottomhole pressure kept well below the formation fracture pressure. The volume of displacement fluid used should insure that a grout heel of at least 10 ft (3 m) is left within the casing when wiper plugs are not employed. To maintain grout displacement, it is essential that the grouting wellhead be leak-tight at the required shut-in pressure. Use of a weighted fluid which renders the casing neutrally buoyant is recommended where possible. As is true for casing accessories, PVC or fiberglass grouting accessories should be used down-hole wherever practical to minimize subsequent work-over damage.

Well Development and Stimulation—Current regulations require that injection-well integrity be verified prior to use. Pressure testing was once required in Wyoming, but resistivity logging is now accepted for verifying mechanical integrity in both Wyoming and Texas. If variable pumping arrangements are anticipated during operations, it may be preferable to test all wells rather than only injection wells.

Large leaks can be caused by well completion tools gouging holes in PVC casing. For example, leaks have been caused by underreamers when the tool has been pushed down or pulled up with the blade not fully retracted. Sand can interfere with retracting the blade. Damage can also be caused when any tool that fits tightly is forced past casing that is somewhat curved because of hole deviation.

Well development should begin as soon as practical after grouting is completed. The least vigorous method which proves effective should be used. The combination of chemical treatment to break down drilling fluid and grout residues followed by air lifting to remove the associated residues appears to be the most generally applicable and cost-effective development method. Chemical reagents used for this purpose should be limited to those with minimal impact on groundwater composition and related water processing for mineral recovery and groundwater restoration. During both chemical treatment and airlifting, caution should be exercised to prevent thermal damage to the casing as a result of either the heat of reaction or heat of compression. Only after such preliminary development should any of the more vigorous methods be used to complete well development.

Maintaining well performance requires the timely identification and correction of the causes for declining performance. When well stimulation is required, a combination of chemical treatment and pumping for reagent circulation and recovery is recommended. The type of pumping (cyclic followed by recovery vs. flow-through) employed in a given situation should be based on complete evaluation of the material to be removed, the reagents to be used, and the reaction products to be recovered. As in the case of well development, the chemical reagents should be carefully selected and sparingly used. Clogging of production well screens or the nearby formation can result from fines migration. Periodic vigorous well development such as airlifting may be required.

PRODUCT RECOVERY. Once the mineral values are in solution, they must be recovered. However, recovery is independent of the source of the pregnant leach solution (PLS) for in situ leaching, heap and dump leaching, or a hydrometallurgical plant. The recovery methods for uranium are covered in Chapter 15.2, and methods for copper are addressed in both Chapter 15.2 and Chapter 25.4.

ENVIRONMENTAL FACTORS.

Uranium—In situ uranium mining offers significant environmental advantages over conventional uranium mining. Much less radioactive material is left aboveground at the end of mining. In situ leach mine workers are exposed to less radon gas than underground miners are. Radium is less soluble than uranium, so most of the radium is left underground during in situ leach mining. In situ leach mining consumes less groundwater than dewatering for conventional mining. However, in situ leach mining, like conventional mining, has the potential to pollute aquifers. Therefore, regulatory agencies require companies to submit plans for monitoring of leach solution excursions and restoration of groundwater quality as part of a permit application.

The states in which in situ uranium mining is being performed include Texas, Wyoming, and Nebraska. There is some stope leaching in New Mexico, and interest in testing in situ leach mining, but there are no active in situ leach mines in undisturbed ore. Texas is an agreement state with the US Nuclear Regulatory Commission, so permit applications need to be filed only with the state. Permit applications should be submitted to the Texas Water Commission in Austin, TX. Also a Radioactive Materials Handling License is required from the Texas Department of Health. Wyoming, Nebraska, and New Mexico are non-agreement states, so permit applications must be filed with the NRC and state agencies. Applications to the NRC should be filed with the Nuclear Regulatory Commission Uranium Recovery Field Office in Denver, CO. The Wyoming Department of Environmental Quality, Land Quality Division, in Cheyenne, WY, receives the Wyoming permit applications (Anon., 1986a). In Nebraska, applications should be filed with the Department of Environmental Control in Lincoln. If the proposed mining zone is a fresh water aquifer, then an aquifer exemption from the US Environmental Protection Agency (EPA) will be required.

In Wyoming, Texas, and Nebraska, monitoring requirements are not given in detail, but rather are stated in terms of assuring that excursions (escape of leach solution from the well field) will be detected before leaving the operator's property or contaminating an aquifer. The pattern of monitor wells required will depend on local conditions such as velocity of groundwater flow and the proximity to aquifers from which water is being drawn for other purposes. In general, monitor wells will be required to surround the mine for sampling the mine aquifer and other monitor wells will be required for sampling overlying and underlying aquifers.

As shown in Fig. 15.3.3.8 (Stover, 1989) the overlying and underlying monitor wells sample aquifers that could become contaminated if leach solution were to migrate through the horizontal confining layers. Such migration could occur through natural discontinuities, through unplugged abandoned wells, or along poorly grouted injection or production wells.

In the past, restoration of groundwater quality after in situ leach mining was a long and costly process at sites that had been leached with ammonium carbonate. Restoring the ammonium levels to the required low levels was difficult because of the affinity of clays for ammonium ions and because the limits were set very low. Recent restorations have been more successful and less costly because sodium carbonate or carbon dioxide leach solutions have been used. The usual procedure now is to flush the field with water that is recycled and cleaned with reverse osmosis. Some companies inject a reductant, but most do not. The restoration is still a significant part of the operation, and its cost should not be neglected. However, it is less difficult than it was in the past. Typical requirements for restoration are to restore to drinking water standards or to the average concentration in the field before injection. In some cases, detection limits are the limiting factor.

The following information concerning restorations in Texas was supplied through the courtesy of the Texas Water Commission in Austin. A permittee is required to restore the aquifer after completion of mining in accordance with 31 Texas Administrative code 331.107 (Knape, 1989). Included in each production area authorization is a restoration table that provides resto-

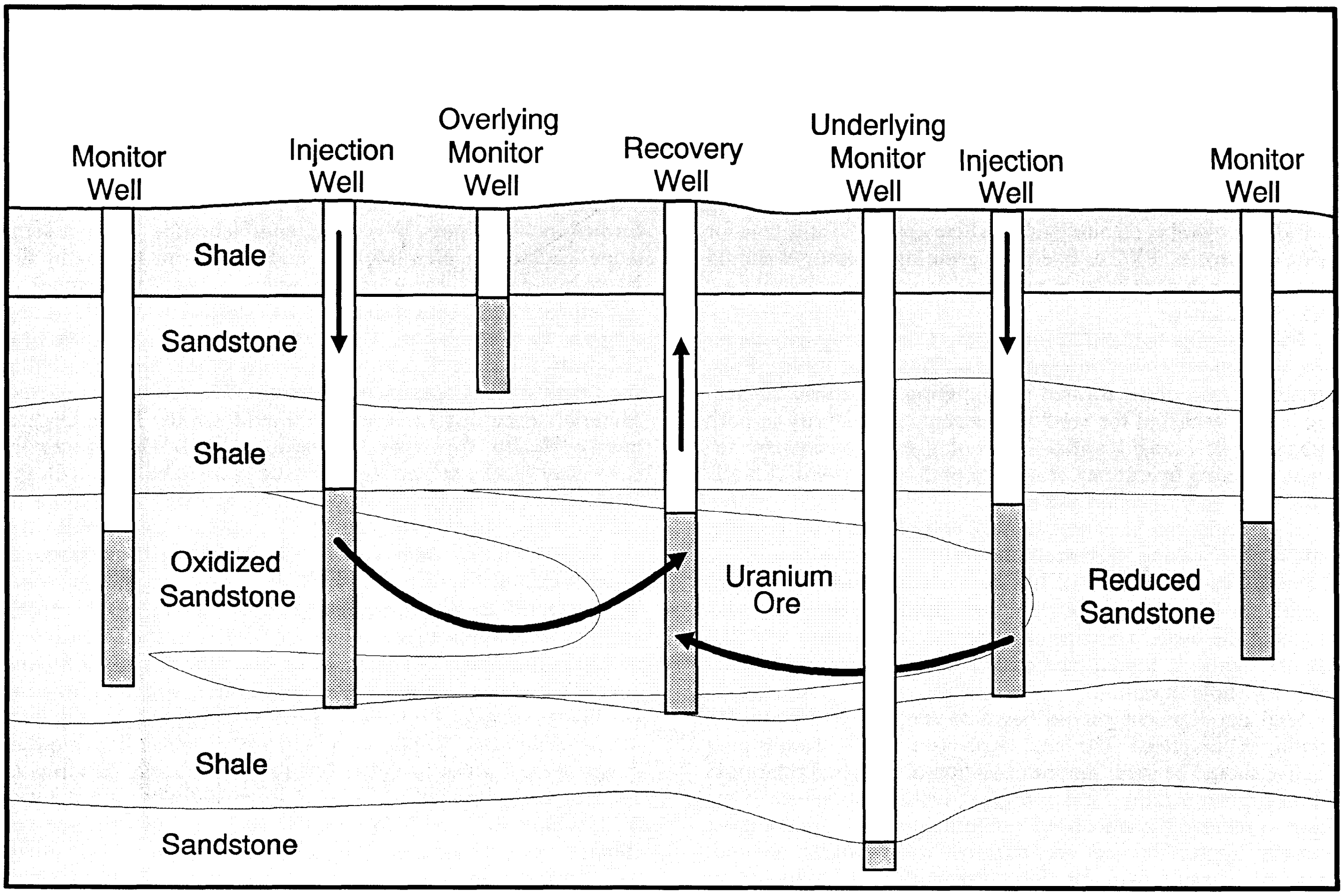

Fig. 15.3.3.8. Well field with overlying and underlying monitor wells.

ration values for 26 parameters. The 26 restoration parameters are calcium, magnesium, sodium, potassium, carbonate, bicarbonate, sulfate, chloride, fluoride, nitrate-N, silica, pH, total dissolved solids (TDS), conductivity, alkalinity, arsenic, cadmium, iron, lead, manganese, mercury, selenium, ammonia, uranium, molybdenum, and radium-226. The restoration values are based on analysis of water samples taken prior to mining. The radiometric parameters are set by the Texas Department of Health-Bureau of Radiation Control.

Required surface restoration basically consists of removing all pipelines, plugging and capping all well casings below grade, transporting contents of evaporation ponds to a licensed disposal site, filling in pits, and establishing appropriate revegetation. Financial security is also required for restoration and surface reclamation of the site. This financial assurance must be posted with the Texas Department of Health in accordance with a Memorandum of Understanding between the Texas Department of Water Resources and the Texas Department of Health.

Other environmental concerns, besides monitoring and achieving restoration, include the disposal of wastes generated during the mining and restoration. The following discussion is from Shuck (1979). Liquid wastes are generated from three principal sources: (1) well field over-production for the purpose of leach solution confinement, (2) process bleeds for the purpose of contaminant control, and (3) water treatment for the purpose of waste concentration and/or aquifer restoration. Liquid wastes are typically impounded for waste concentration and water reclamation via methods such as reverse osmosis. This approach minimizes consumptive water use during both production and aquifer restoration. Concentrated waste streams of approximately 15,000 ppm TDS are typically impounded and further concentrated by means of either natural or induced evaporation.

The principal sources of air emissions are the open surface of tanks and waste ponds and the product drying/packaging unit of the uranium recovery process. Generally, low TDS waste streams are utilized to scrub both particulate and gaseous emissions from the stack gases of the product drying/packaging unit. The spent scrub solution is impounded with other process wastes for further concentration via evaporation. Thus the principal source of untreated air emissions is the exposed surface of waste storage and concentration ponds.

Solid wastes result from the calcium control unit, waste concentration processes, filtered solids, laboratory wastes, and contaminated materials. These are typically impounded and maintained under a liquid seal to minimize atmospheric dispersion, pending permanent disposal.

Copper—Environmental issues specific to in situ copper mining are addressed through a permitting process administered by federal, state, and local governmental regulatory agencies. Each agency maintains jurisdiction over certain elements of the mining operation. Permitting involves preparation of comprehensive application documents by the mining company and subsequent document submittal to the appropriate agency. Authorization to proceed with the mining activity may be either granted or denied by the regulatory agency depending upon anticipated facility compliance with environmental protection requirements. Once permits are approved and the facility is constructed, facility operation requires strict adherence to environmental protection performance standards.

Environmental resources afforded special protection through permitting include groundwater, air, biological, and cultural resources. By the very nature of the in situ leach mining process, the greatest potential for environmental effect rests with the fluid injection-recovery system. Accordingly, the principal element of environmental permitting is protection of groundwater resources. Protection of air, cultural, and biologic resources is subordinate to this. Air emissions expected to result from an in situ leach mining operation include fugitive dust from access road traffic and volatile organics and sulfuric acid mist from operation of the SX/EW facility. Biological and cultural resources may be afforded special protection if there is public ownership of the property. Given its overriding significance, the emphasis of this discussion will be on groundwater permitting and protection.

Federal requirements that address the protection of groundwater from fluid injection activities are administered by the EPA under the Underground Injection Control (UIC) program. The UIC program was implemented under part C of the Safe Drinking Water Act, Public Law 93-523. Technical requirements of this program are identified under 40 CFR 144 and 146 (Code of Federal Regulations, Anon., 1986b). Requirements specified under part 144 address permitting and program specifications. Part 146 addresses technical criteria and standards for operation. Individual states may elect to develop their own UIC program and obtain primacy from EPA for program administration and enforcement. In developing its own UIC program, a state is not precluded from developing regulations more stringent than those established by EPA. States, by their own authority, may enforce additional requirements related to groundwater conservation and well construction.

EPA criteria under the UIC program specify that no fluid injection shall be authorized if it results in the movement of fluid containing a contaminant into an underground source of drinking water (USDW), if the presence of that contaminant may cause a violation of federal primary drinking water standards, or if it may adversely affect public health. If an aquifer within a prospective leach interval meets the definition of an USDW, it must be determined to be an “exempted aquifer” before lixiviant injection may commence. An exempted aquifer is one that would otherwise qualify as an USDW, but which has been determined to have no real potential as a drinking water source.

It is incumbent upon a mine operator to evaluate all environmental permitting and protection requirements as well as site conditions early in the mine planning process. This step is necessary to establish the feasibility, costs, and schedule for developing an environmentally acceptable mine design. The regulatory process remains in a state of flux, but permit applications must address ground water protection, a monitoring program, a groundwater restoration plan, and other site reclamation activities.

15.3.3.4 Future Trends

As the combination of more stringent environmental controls and lower-grade deposits continues to stretch conventional technology to its economic and environmental limits, in situ leach mining and other forms of advanced mining systems will emerge as viable options for mineral extraction. Depending upon the commodity and other hydrologic, geologic, and hydrometallurgical factors, in situ leach mining looks promising for small high-grade deposits, as well as large low-grade fracture-hosted deposits. If the development of in situ uranium mining technology is a precursor of what we might expect, then the future development of in situ leach mining technology looks very promising.

The next major demonstrated advance in this technology will be the in situ leach mining of copper oxides, due to the ease with which copper can go into solution using a dilute acid lixiviant. The primary candidates for this technology will be those deposits that are primarily fracture-hosted, which means that the copper mineral values occur predominately within the microfractures and joint system within the deposit. The state of Arizona has numerous oxide deposits that may be suitable for in situ mining technology. It is very likely that by 1993, in situ leach mining of copper oxides will be demonstrated and proved technically feasible. This will be a great advance for the mining industry in general because of the overall environmental advantages and significantly reduced surface disturbance.

Looking ahead, with the recent advances in biotechnology, down-hole directional drilling, and the ability to inject oxidants into the ore body, a fresh look will be given to in situ leach mining of copper sulfides. A focused, joint research effort by government, industry, and the universities will be required in order to solve the major technological barriers that are currently holding back such mining. Although several recent pilot tests have been tried on an industrial basis in the United States and Canada, a large-scale commercial operation has never been demonstrated. However, the extent of reserves in the United States almost assures that over the long term, in situ leach mining technology will be developed for copper sulfides.

In the longer term, some of the so-called critical and strategic minerals are candidates for in situ leach mining technology. These elements are so denoted because they are essential in the steel, aerospace, electronic, and defense orientated industries. The United States, for example, does not have high-grade deposits of manganese, cobalt, nickel, or platinum group metals and therefore must import most of its supply from foreign sources. In the United States, occurrences of small, deep and/or low-grade deposits of several critical and strategic minerals do exist. Included in these are the Co-Ni-bearing laterites of Oregon and California; the manganiferous ores of Artillery Peak in Arizona, the Cuyuna Range and Emily District in Minnesota, and the polymetallic deposits of the Blackbird District in Idaho and the Stillwater District in Montana. The problem, however, is that many of these deposits cannot be mined economically using conventional approaches. Possible leach systems for some of these are addressed in Chapter 15.2.

Ultimately, the advancement of in situ leach mining technology to the commercial scale will require the integration of numerous technical disciplines with advanced innovative mining techniques, and represents a significant challenge for the minerals industry. However, the challenge is worth the risk for several reasons. First and foremost, the successful development of this technology will keep United States producers competitive in the world minerals market. Secondly, from a domestic stewardship perspective, resource utilization will be maximized by making feasible the recovery of metals that would or could not be mined by conventional methods.

Section 16 Surface Mining: Comparison of Methods

DONALD W. GENTRY, ASSOCIATE EDITOR
ERNEST BOHNET, SECTION COORDINATOR

Chapter 16.0
INTRODUCTION

ERNEST BOHNET

Each mining operation is unique in some aspect—ownership; ore body location, size, geometry, grade, mineralogy, hydrology, or geotechnical parameters; or constraints such as environmental regulations. However, all mining operations are alike in one aspect; the prime objective of any mining project is to maximize the return on the investment. This is the golden rule, or in the language of mining, the investor's law of conservation.

A mineral resource, by definition, does not become a minable reserve unless the mineral or minerals can be extracted economically (and legally). The three preceding sections have covered the various types of surface mining options. The choice of the most economic method is dictated primarily by the type of deposit to be mined, the mining rate, and the physical characteristics of the deposit.

A comparison of surface methods must take into consideration the prime objective of mine planning: (1) develop the most economic plan for the overall project that will maximize the return on the monies invested, and (2) maximize the recovery of the resource.

Surface mines can be subdivided into various classes and subclasses and which can be illustrated as follows:

Class	Subclass	Method
Mechanical		Open Pit Mining
		Quarrying
		Strip Mining
		Auger Mining
Aqueous	Placer	Dredging
		Hydraulic Mining
	Solution	Surface Techniques
		In Situ Leaching

The purpose of this section is to discuss the relative advantages and applications of one method vs. another, as well as some of the more important evaluation parameters that must be considered in any method comparison.

Chapter 16.1
FACTORS AND CONDITIONS

ERNEST BOHNET

Open pit mining and strip mining are the two most dominant types of surface mining methods in the world, accounting for approximately 90% of the surface mineral tonnage. Strip (open cast) mining is used for large, tabular, flat-lying ore bodies or mineral seams, such as coal, that are relatively close to the surface. Backfilling of these mines is usually economically feasible and desirable as part of the advancing mine operations.

Open pit mining is typically applied to disseminated ore bodies or steeply dipping veins or seams where the mining advance is toward increasing depths. Backfilling usually cannot take place until the pit is completed; even then, the prohibitive cost of filling these pits with all of the waste rock removed at the end of the mine life, would seriously jeopardize the project's economics. Very few large open pits in the world could support such a costly handicap.

Seam deposit mining, like coal, uses different planning methods and terminology as compared to open pit mining for base and precious metals (Section 13). However, all surface mining methods have one common element: mining proceeds until the economic limit is reached. The method of determining the economic limit is different for the two types of deposits. Coal, for example, in most instances, is readily distinguished from waste rock and is of a near uniform quality and value per ton mined in each seam. Therefore, mine design limits are determined by the break-even strip ratio, commonly defined as cubic yards (cubic meters) of waste to tons (tonnes) of coal that can be mined. Since one ton of coal is approximately equal to one cubic yard (1 tonne ~ 0.84 m^3), the ratio is similar to a volume ratio.

The pit limits for a disseminated deposit, such as base or precious metals, is determined by a break-even economic analysis of the value of the ore in each finite incremental pit expansion. This economic analysis is a two-step process where first the net operating value is determined for each ton of material in a block model. Second, the pit limits are determined by expanding the pit shape to a break-even point where the net operating margin equals the cost of waste stripping. Since each ton of ore has a different grade and net value, a break-even stripping ratio cannot be utilized. Complicating this matter further is the potential for dual ore processes, such as milling and leaching of the same ore type. Milling is a higher cost process method used to increase metal recoveries, whereas leaching is a slower process with correspondingly lesser recoveries and lower costs.

Therefore, the mining engineer must have sufficient knowledge of the overall project: from ore geometries to the process extraction methods. This includes an awareness of all cost and recovery parameters, as well as the factors that affect the value of the salable product. For example, where process capital and operating costs are high, ore selectivity plays an important role in mine design and selecting the most appropriate mining method. Mining cost increases can be more than offset by reduced process capital and operating costs per unit of salable product.

The total amount and type of material to be moved per time period, coupled with ore body geometries, are the prime criteria in selecting the most economic and applicable mining method.

Other factors that affect the type of mining method as well as type and size of equipment include:

1. Topography.
2. Remoteness of operation.
3. Support infrastructure.
4. Availability and cost of skilled labor.
5. Climate and altitude.
6. Environmental restrictions.
7. Groundwater quantities.
8. Slope stability and ground conditions.
9. Investment risk.
10. Blasting restrictions.
11. Life of operation.
12. Waste rock disposal.

Topography, as discussed in the preceding chapters, can play a major role in selecting the most appropriate mining method. Generally, the more rugged the topography, the more limited are the choices of mining method and level of overall production.

Remote operations require substantial infrastructure to maintain the standard of living needed to attract a well-qualified work force. Therefore, the mining and processing methods selected must result in high productivities per employee-shift. Better ore selectivity in the mine will reduce process plant requirements and could, therefore, reduce overall staffing requirements. If the ore grade can be raised sufficiently, the ore may be transported offsite for processing at a less remote location. Large equipment can be utilized for the bulk of the waste stripping and small equipment employed to selectively mine the ore.

Where labor costs are high, the same philosophy can be applied. Lower labor costs and the level of labor skills available can also affect the choice of the mining method. For example, front-end loaders and mechanical drive trucks will require less diverse maintenance skills as compared to the labor force needed to maintain electric/hydraulic shovels and electric haul trucks.

With adverse climatic conditions, mining operations may be seasonal. Seasonal and short-life operations may use contractors for all mining operations or for only the bulk of the waste stripping. The use of contract miners is discussed in detail in Section 6.0.

Environmental considerations play an increasingly important role in the type of mining operation permissible. Open pits in populous areas may require backfilling, while the same type of operation in a remote location may have minimal environmental constraints. For example, hydraulic mining, outlawed in California in 1884, was used to remove the unconsolidated overburden at the Bougainville Copper mine in 1969–1971. Environmental and aesthetic conditions may be so restrictive in some areas as to eliminate surface mining options altogether. In some cases, this forces the use of underground mining, which will result in reduced mineral resource recovery.

Groundwater conditions and slope stability can play an important role in mining method options, mine design, production scheduling, and equipment selection. A large dragline may not operate safely where ground conditions are wet and unstable and the risk of slope failure high. If large water inflows are anticipated, mining may have to be accelerated to avoid high pumping costs from a lengthy operation. Ore can be stockpiled at the processing plant and treated months to years after the mine is completed.

The risk of foreign investment varies from country to country; however, if risks are high, then capital expenditures are usually minimized. Front-end loaders, with shorter useful lives and lesser capital costs, are preferred over large shovels and draglines. The larger the project and the longer the development period, the greater the investment risk.

Blasting restrictions due to the operation's proximity to populous areas or in foreign countries with explosive use constraints also can affect mining method selection. Continuous mining machinery similar to pavement cutters or ripping can be utilized in some circumstances as an alternative to drilling and blasting.

Available waste disposal areas may be a significant distance from the surface mining operation. A viable alternative in this situation is crushing and conveying of the waste, and this in turn can affect the mining methods. Where the ore has a high value per ton, in excess of one hundred times the cost of mining, very high strip ratios can be economically justified. The mining method in these circumstances is designed to be primarily a waste removal operation. Ore mining is a small cost component of the overall operation and great emphasis must placed on efficient waste production and mining methods. Since most open pit and strip mines have waste to ore ratios higher than 1:1, the majority of surface mines are waste rock operations. It is, therefore, important to ensure that any effort to reduce ore mining costs does not increase waste mining costs. For example, in a coal stripping operation using shovels and trucks, often a slot is left on one side of the backfilled pit for coal haulage to minimize coal mining costs. This slot prevents efficient waste haulage around both sides of the pit, thereby increasing waste haulage distances and costs significantly. As strip ratios increase, the mining method and haul road system will require modification to allow more effective waste transportation and reduced overall mining costs.

Quarrying is a special type of open pit mining used to produce dimension-stone products. Rock joint fractures are infrequent, and, therefore, the bench faces are vertical. The lack of fractures often permits near vertical highwalls that can approach up to 1000 ft (300 m). Quarrying is a high-cost selective method that is only used to produce dimension stone such as marble, granite, limestone, sandstone, flagstone, and slate.

Auger mining is primarily used to remove coal from under a final highwall. The final highwall position is determined by economic stripping limits, property boundaries, or physical constraints such as a body of water.

In the case of physical constraints, auger mining may be the only alternative to increase the amount of coal recovered. However, if the highwall position was determined using a break-even stripping ratio analysis, the cost of stripping the final 100 to 300 ft (30 to 100 m) break-even increment should be compared to auger mining costs and profitability.

Aqueous surface mining methods, uniquely involving the use of water for extraction, can be used in special circumstances. The mining of placer-type deposits that contain concentrations of heavy metals in unconsolidated overburden are particularly suitable to dredging and hydraulic mining if:

1. An adequate water supply is available.
2. The mining operation can comply with the applicable environmental regulations.

Hydraulicking, now often termed hydraulic mining, also requires the presence of a natural gradient away from the deposit to facilitate hydraulic transport of the resultant ore or waste slurry to the process or disposal area.

Dredging can be used if a natural or man-made body of water overlies the placer deposit. Dredging machines can be classified as mechanical, bucket-line, bucket-wheel suction, and dipper; or hydraulic, suction, and cutterhead. The type of dredging equipment selected depends on the type of material to be excavated.

Solution mining using surface or in situ techniques is applicable to deposits of minerals that can be recovered usually by dissolution, but also by melting, leaching, or slurrying. The two methods, are similar and are differentiated primarily through locale and the type of minerals recovered. Surface leaching generally employs heap or dump leaching of mineral values; copper, gold, and uranium are common examples.

In situ mining uses water to dissolve, melt, or slurry the minerals. Barren solution is introduced down one set of wells and the loaded solution returns to the surface through concentric or another set of wells. This mining method is primarily used with sulfur, evaporite, or water-soluble minerals. In situ leaching uses chemical or bacteriological reagents, usually mixed with water to selectively dissolve the valuable minerals. Drillholes are typically used to inject and recover the solution. Extraction may also be enhanced by rubblization of the ore zone prior to solution application. Solution mining will increase in the future as more effective reagents are developed and application methods are improved.

The preceding discussion has focused primarily on factors and conditions that can affect surface mining options. New technologies will result in a greater range of alternatives in the future. Therefore, the mining engineer needs to continually review these developments as applicable to each old and new situation encountered. Basic assumptions must be revisited to ensure that past premises are still valid in light of new developments. Mining is dynamic in nature, and therefore, mining methods will continue to change to meet new economic and environmental conditions.

16.1.1 DEVELOPMENT AND PRODUCTION SEQUENCES IN OPEN PIT AND STRIP MINING

The mining method and the selection of the appropriate size and type of equipment are closely associated. The following primarily addresses loading and hauling fleets, as applied to both strip mines and open pit operations.

The size of the operation over time has a direct bearing on the type of equipment selected. Loading and hauling fleets are dependent fleets, and, therefore, the effectiveness and availability of each affects the fleet requirements of the other. For example, if a mining operation had only one large shovel, the truck production will only be effective when the shovel is operable and broken rock is available at the shovel face for loading. Therefore, to have an effective operation, more than one unit per equipment type is desirable. A mining operation should have one drill per shovel and at least one back-up shovel/loader to load trucks when a scheduled shovel breaks down.

Large mining operations require time to develop sufficient working area for effective use of the equipment. Therefore, the equipment selected for full production may not always be suitable for the development period. It must also be noted that the development or preproduction period may require different mining methods due to lesser material movements and different types of material to mine. During the development stage, access haul roads need to be constructed, and in rugged terrain, bench widths may be much narrower than those available during production. Smaller equipment may be needed during this stage of mine development.

Sufficient time must be allowed in the production schedule to drill, blast, and remove the material from the mine. Narrow benches do not allow continuous mining unless access for drilling and blasting is provided in the plan.

During preproduction and during the stripping phase of each mining sequence, higher benches may be used. For example, stripping may be accomplished on 40-ft (12-m) benches and ore production on 20-ft (6-m) benches to minimize ore dilution. The advantages of higher benches include the use of larger equipment, minimal access construction, and overall cost reductions.

Large open pit and strip mines are subdivided into smaller phases to improve project economics. The objectives of dividing a surface mine into phases or mining sequences are to

1. Reduce preproduction stripping requirements.
2. Shorten the time between stripping and ore production.
3. Develop the highest net value ore first and mine the lowest net value ore last.
4. Avoid high stripping peaks that result in excessive equipment purchases and manpower requirements.
5. Blend the ore or coal to produce a less variable product.

The development and production sequencing requirements must be considered in selecting the most appropriate mining equipment types and mining method.

Chapter 16.2
METHOD ADVANTAGES AND DISADVANTAGES

ERNEST BOHNET

The advantages and disadvantages of one type of surface mining vs. another is related to the types of equipment utilized and the associated costs and benefits derived from the use of that equipment. In the following discussion, emphasis is placed on the mechanical extraction methods, generally open pits and strip mining.

Strip mining has the greatest choice of equipment, particularly for the mining of relatively flat-lying coal seams in gentle topography.

Open pit mining conversely is usually limited to shovel/truck or front-end-loader/truck-type operations. Shovel/rail-type operations of the past have been almost phased out in favor of the greater flexibility of mining with truck haulage.

Sections 13 and 14 cover the various types of mining methods and equipment applications for strip mining using draglines, shovels, bucket wheel excavators, conveying systems, and combinations of these types of systems.

In these same sections open pit mining is usually conducted using cable shovels, hydraulic shovels, or front-end loaders. The loading equipment is usually matched with haul trucks that can be loaded in four to six passes.

The choice of loading unit is dependent on total production requirements vs. the minimum number of active work areas, as well as ore selectivity and blending requirements. Additional factors to be considered are the type of material to be loaded and the ground conditions. In hard digging or with sharp rock in wet climates, tracked shovels are preferable over rubber-tired loaders. However, if the mine production requirements are relatively small or the mine life is short, the lower capital cost of the front-end-loaders must be taken into consideration.

The rubber-tired loader is commonly used to load material that is easy-to-medium digging and for operations requiring less than 100,000 tons (90,000 t) of daily material movement. Loaders are highly mobile and, therefore, are ideally suited for situations requiring frequent movement from one mucking face to another for ore blending requirements. Loaders also can be used to load-haul-dump material into a crusher from blending stockpiles dumped near the crusher. Some operations have a mismatch of large shovels and a small crusher. A mismatch occurs when the crusher rating of tons per hour is much less than what the shovel can produce through the truck fleet. If this situation occurs, there are advantages to stockpiling the material at the crusher to avoid truck dumping delays and thereby maximize shovel and truck productivities. The extra cost of a stockpile-rehandling loader is more than offset by the increase in shovel and truck productivities and their respective reduced fleet requirements.

Loader cycle times are approximately 25 to 50% greater than a shovel's cycle time. Therefore, a loader has to be 25 to 50% larger (bucket capacity) than a shovel to attain the same productivity. The loader bucket fill factor is usually less than a shovel's in medium to hard digging. Hydraulic shovels have similar limitations and advantages as a cable shovel. The hydraulic shovel is typically not used in very hard digging. Hydraulic shovels are available in a range of sizes comparable to front-end loaders. However, since the larger sizes over 30 yd^3 (23 m^3) are not common, large cable shovels are used as the prime loader at mines where production requirements are in excess of 200,000 tons (180,000 t)/day.

Hydraulic shovels can effectively load from smaller bank heights than cable shovels and, therefore, if ore selectivity is very important, these shovels can improve ore selectivity and minimize dilution. A hydraulic shovel has additional advantages over a cable shovel in the sense that the bucket can be vertically positioned anywhere in the mucking face and selectively load from either the top half or bottom half of the face. This advantage is particularly useful in mining seam deposits where waste separation from the seam is necessary, or in some precious metal (gold) deposits that have highly variable grades and/or oxide-sulfide mineralization contacts.

Hydraulic shovels can also be equipped with a backhoe-type loading bucket. This permits the shovel to sit on top of the bench and load trucks that are positioned on the same bench or on the bench below. Backhoe loading is particularly useful for loading a dipping seam or wedge of material where loading with a cable shovel would be impossible. Backhoe loading is also very useful in wet conditions, permitting the trucks to travel on a drier bench above the water, with correspondingly increased tire life.

The useful life of loaders, hydraulic shovels, and cable shovels varies according to the application, maintenance standards, and the company's general replacement policy. However, life for a front-end-loader is typically in the three- to four-year range, hydraulic shovels in the eight- to twelve-year range, and cable shovels are usually replaced on 20-year intervals. The longer the useful life, the more obsolete the equipment becomes in comparison to new technological advances. In order to combat this technological aging factor, many equipment manufacturers are progressing toward complete modular part replacement designs. These designs allow the mine operator to discard older components in exchange for new, more reliable modules that may have more advanced features.

Other factors that influence the choice of loading equipment is the trade-off between lower and higher capital costs vs. higher and lower operating costs. Complicating this analysis is the difference in useful life. Since the prime objective in mining is to maximize return on the investment, time value of money must be taken into consideration in any trade-off analysis. Discount rates of 10 to 15% commonly are used to convert future costs into a net present value. The higher the discount rate, the greater the emphasis on reducing current costs. Expenditures after 10 years have little significance on the total net present value. This method of ranking alternative fleets can be applied to all choices: dragline vs. a shovel and truck fleet in a coal stripping operation, or cable shovels with 170-ton (150-t) trucks vs. front-end loaders with 85-ton (76-t) trucks. However, it is important to note that other tangible and intangible factors may be present that often are overlooked in this capital vs. operating costs analysis. An example of this would be greater ore selectivity, which means less ore dilution and less ore discarded as waste, thereby resulting in higher-grade ore to the processing plant. A small grade change can significantly affect overall project economics.

As an example of this, project economics are very sensitive to changes in commodity price. However, grade changes and recovery changes have the same effect as a commodity price change. Therefore, if ore selectivity can improve the ore grade by 10%, this is far more significant than a 10% increase in both mine capital and operating costs. This factor must be taken into consideration in any equipment trade-off economic analysis.

Other factors that influence the choice of equipment and mining method are less tangible. As previously discussed, these include mobility requirements, ore blending, hard or easy digging, maintenance skills of the available work force, size of the operation, working area, and advance rate required.

In respect to this last point, open pit mines are subdivided into phases. Each phase is somewhat independent of the following phases; however, the object is to remove waste rock in a timely manner that exposes ore before ore reserves are exhausted in the prior phase. There are circumstances where the advance rate or number of benches to be mined each year in a phase requires more than one loading unit. If the working width of a bench is too narrow to permit more than one unit, then larger equipment may be required.

An example of this situation is a mine that was using 15-yd^3 (11-m^3) hydraulic shovels as the prime loading fleet. The mine plan indicated that after the tenth year of operation, the fourth mining phase required the movement of 15 million tons (13.5 Mt) of material per year for five years to expose ore. Since one shovel could not move this material, and since two shovels could not effectively work on the bench, the alternatives were to purchase a large 40-yd^3 (30-m^3) cable shovel or start mining the phase earlier. A discounted cash flow analysis indicated the better choice was to purchase one 40-yd^3 (30-m^3) shovel for the bulk of the waste stripping and to use the smaller shovels for ore production.

The purpose of subdividing an open pit into phases is to improve the project economics. This also can mean that material movement requirements through time will change significantly. It does not mean that mining quantities will change dramatically each year. An effective mine production schedule must be developed to take into consideration equipment and personnel requirements. A smooth schedule will give the mine operations and maintenance departments sufficient time to build up their organizations without significant annual variances. If total material movements are increased during the life of the mine, these increases should be smoothed to form a new production level that remains constant at a higher level for a number of years.

During preproduction, or at some point in the life of the mine, this may not always be feasible, and an alternative to this is contract stripping. Contract stripping can be justified if the mine life is short or the stripping peak is of fairly short duration, for example, less than three to four years. The trade-off again is lower capital costs vs. higher operating costs. The intangible benefits include the avoidance of hiring and training a large work force for a relatively short time period, greater assurance that the stripping will be carried out on time and per the contract terms, and less management skills required. The intangible disadvantages are less control over the operation, and it must be recognized that a contractor's goal is to move a volume of rock, not necessarily to separate ore and waste in the mine owner's best interest. Adequate ore control procedures must be conducted as part of the mine owner's responsibility to minimize ore dilution and loss. It is also the mine owner's responsibility to ensure that the mine plan is accurate, otherwise extra costs will be charged by the contractor for scope deviations.

The life of a mining project plays an important role in selecting the most appropriate mining method, equipment fleets, and whether to use a contract miner. Particularly with precious metal mines, capital costs may have to be minimized due to a lack of available funding for whatever reason.

The lack of available capital also may force the mine operator to look for used equipment for initial mining. This equipment may be replaced within a few years with new equipment if mine life is sufficient and positive cash flow has been demonstrated to the lending agency's satisfaction. Any economic analysis of used vs. new equipment is extremely subjective. Equipment maintenance costs are composed of maintenance labor and repair parts. The amount of maintenance required is related to the condition of the equipment purchased and commonly related to the operating hours on the equipment. If the equipment has been overhauled adequately, maintenance costs will be similar to that of a piece of equipment that has been in operation one year. The maintenance requirements of rebuilt used equipment will increase at an aging rate that is approximately double that of a new piece of equipment.

In order to adequately explain this factor for economic analysis, consider the following example of haul trucks that normally have a useful life of a maximum of 40,000 hours. If the average maintenance cost during the life of a truck is 1.0, then the relationship of maintenance costs to life can be stated as follows:

Operating Hours	Maintenance Factor	Mechanical Ability
0– 5,000 hr.	0.30	85%
5,000–10,000 hrs.	0.70	80%
10,000–20,000 hrs.	1.00	75%
20,000–30,000 hrs.	1.20	70%
30,000–40,000 hrs.	1.35	65%

If a truck with 30,000 to 35,000 hours is overhauled, maintenance costs should drop to the equivalent of a new truck with 5000 operating hours. However, after operating only 15,000 hours, the overhauled used truck would have the same maintenance requirements as a truck with 35,000 hours.

It also must be noted that used equipment availabilities are much less than that of new equipment. New equipment usually will have manufacturers' warranties and close field support.

The effect of purchasing used equipment with lower availabilities is that more units are needed to obtain the same production level, and the maintenance work force has to be significantly larger initially. Nonetheless, if capital funding is limited, used equipment or a contract miner may be the only viable solution.

The comparison of one type of mining method vs. another should not neglect to compare the various types of equipment that are dependent on another type, such as loading and hauling equipment, loading productivity vs. crusher capacity, and drilling unit capacity vs. scheduled shovel production.

For any analysis, it is better to have the first unit in the chain of production with greater capacity than the downstream unit. Therefore, drill capacity should exceed shovel/loader capacity, shovel capacity should be slightly higher than crusher capacity, or the capacity of two shovels should be matched with the capabilities of one crusher.

A mismatch occurs when there are only a few units in production and the capacity of one unit dependent on the production of another is significantly different, For any comparison of different mining methods or equipment types, it is very important to conduct the economic analysis using the most accurate and correct assumptions.

Two of the major expense areas in any open pit or stripping operation are the functions of loading and hauling. Typically, 30 to 50% of the total mining cost is related to hauling all material types out of the pit or to the waste backfill area. A cost comparison of equipment sizes and alternatives must be based on an optimum selection of loading and haulage fleet sizes, otherwise the comparison may be unfairly skewed one way or the other.

Table 16.2.1. Fraction of Time That (x) Units are Available Out of a Fleet of (n) Units That Have a Probable Availability of 70%

Fleet Size (n)	Number of Units Available (x) 0	1	2	3	4	5	6
1	0.30	0.70					
2	0.09	0.42	0.49				
3	0.03	0.19	0.44	0.34			
4	0.01	0.08	0.26	0.41	0.24		
5	0.00	0.08	0.13	0.31	0.36	0.17	
6	0.00	0.01	0.06	0.19	0.32	0.30	0.12

As outlined in the previous chapters, the first step in any comparison is the determination of unit productivities per operating shift or per hour. Loader productivities can be estimated by using the anticipated load time per specified truck size and dividing this into the estimated effective minutes per shift. Productive minutes per eight-hour shift (with no downtime) will vary from 330 to 420 minutes, depending on the efficiency of the assignment systems used and the balance between loading and haulage units. Industry standards typically use 350 minutes as a base for comparison.

Truck productivities can be determined from haul profiles for each specific time period. For initial studies comparing one system to another, average productivities per time period can be used to determine fleet requirements.

One method that can be utilized to more accurately analyze the loading and haulage fleet requirements is the binomial method. The best way to explain this method is by using a simple case to demonstrate its use in determining dependent fleet production.

Example 16.2.1. Consider the following fleet consisting of

1. One loader, 80% mechanical availability and an estimated productivity of 9000 tons (8200 t)/operating shift.
2. Three haul trucks, 70% mechanical availability and an estimated productivity of 4000 tons (3600 t)/operating shift.

Determine the fleet capacity.

Solution. Assume that the fleet is scheduled 100% of the time and will only be inoperable if either the loader or all the trucks are down for repairs.

One could incorrectly assume that the average loader production would be 80% of 9000 tons (8200 t)/shift, or 7200 tons (6500 t)/shift. However, since the loader production is dependent on available haul trucks, the truck downtime distribution must be considered.

Table 16.2.1, developed using the binomial formula, shows the fraction of time that x units are available out of a fleet of n units with a given availability of p where this fraction equals:

$$\frac{n\,!}{x!(n - x)!} \times p^x \times (1 - p)^{(n-x)} \tag{16.2.1}$$

This table indicates that 34% of the time, all three trucks are available; 44% of the time, two are available; 19% of the time, only one is available; and 3% of the time, the whole truck fleet is down. When less than three trucks are operating, the loader production will drop to the amount that the trucks can haul, in this case 8000 tons (7300 t) 44% of the time, and 4000 tons (3600 t) 19% of the time.

In summary, the fleet capacity can be stated as follows: The loader operates 80% of the time, and during this time, 34% will be at 9000 tons (8200 t)/shift, 44% will be at 8000 tons (7300 t)/shift, and 19% will be at only 4000 tons (3600 t)/shift. Total fleet capacity would average:

0.80 × 0.34 × 9000	=	2448 tons/shift
0.80 × 0.44 × 8000	=	2816 tons/shift
0.80 × 0.19 × 4000	=	608 tons/shift
TOTAL	=	5872 tons/shift (5340 t)

From this simple example, one can see that production from the loader would be 18% short of the initial estimate of 7200 tons (6500 t)/shift that was determined without consideration of the haul fleet. The same analysis holds true for haul truck requirements determinations. For example, if only the number of haul trucks needed was examined, the following could result:

Annual target objective	1,800,000 tons (1,636,000 t)
Shifts scheduled	250 shifts
Tonnage requirements/shift	7200 tons (6550 t)
Average truck productivity	4000 tons (3600 t)/shift
Need 1.80 operating trucks/shift	
3 trucks @ 70% availability will average 2.1 shifts	

Therefore, it could be incorrectly assumed that three trucks would be sufficient. However, we know from the previous discussion that if the loading fleet contained only one loader, then 20% of the time the haul fleet would be idle waiting for the loader to be repaired. We also know that the loader could not keep up with three trucks, and production would be limited to 9000 tons (8200 t)/shift, not the 12,000 tons (10,900 t)/shift indicated by the haulage capacity. Therefore, haulage capacity would be

250 shifts × 0.80 × 0.34 × 9000 tons =	612,000 tons
250 shifts × 0.80 × 0.44 × 8000 tons =	704,000 tons
250 shifts × 0.80 × 0.19 × 4000 tons =	152,000 tons
	1,468,000 tpy (1,335,000 t/a)

The solution in this case would be to purchase another loader or work more shifts. With larger fleets, the shortfalls caused by calculating fleets independently are not so easy to quantify without utilizing a computer program that takes into consideration the availability interaction of the two fleets. Haulage truck productivities can be averaged for these calculations; however, in reality, haul distances will vary, and this can be used to counter some of the production shortfalls that would otherwise occur when short of trucks or loading units. For example, if the mine were short of trucks, then the shortest haul distances would be used; and conversely, if the mine were short of loading units, longer hauls would be used to counterbalance the shortfalls that would otherwise occur. This may not always be possible, but haulage distance flexibility should be one objective of a good mine plan.

The lack of a loading unit more severely impacts haulage capacity than the lack of one truck. For this reason, it is better to have slightly more loading standby capacity and use an undertrucking philosophy to minimize both capital and operating costs. Haulage costs per ton of material mined will typically be a several times the loading cost.

It is not always in the miner's best interest to have operators for each piece of loading or haulage equipment. In fact, as the fleet sizes increase or availabilities decrease, the extra operators are more of an operating cost liability.

The binomial distribution can be utilized to determine the most likely number of operating shifts that will be obtained for a given fleet size, number of operators or equipment scheduled,

Table 16.2.2. Equipment Operating Shifts Attainable/Shift With a Probable Availability of 70%

Fleet Size	Number of Operators					
	1	2	3	4	5	6
1	0.70					
2	0.91	1.40				
3	0.97	1.76	2.10			
4	0.99	1.91	2.56	2.80		
5	1.00	1.97	2.80	3.33	3.50	
6	1.00	1.99	2.92	3.66	4.08	4.20

and the equipment availability. Table 16.2.2 is derived from the following formula

Operating shifts/shift =

$$x \frac{\overset{n}{\Sigma}\, bj}{j = x} + x - 1\,(b_{(x-1)}) + x - 2\,(b_{(x-2)}) + \ldots 1\,(b_1) \tag{16.2.2}$$

where x is number of assigned operators, n is number of units in the fleet, and b is binomial probability of n things taken one at a time

For example, the anticipated operating shifts for five pieces of equipment with a 70% availability and four operators is 3.33. Adding one more operator to the payroll would only increase loader operating time by 0.17 shifts. From another viewpoint, if a truck fleet were purchased to cover five operating loading units, then the trucks purchased for the fifth loading unit would only operate 17% of the time. During the remaining 83%, the trucks and their drivers would be wasted capacity unless the remaining loading units could handle the extra trucks effectively.

In order for the remaining loading units to handle the extra trucks, the operation must be initially designed to be undertrucked when all the scheduled loading units are operating.

The following example is taken from an actual case in China for which the initial fleet specified for review was severely overtrucked.

Example 16.2.2. Initial production plans indicated an overburden stripping requirement of 160,000 tons (145,500 t)/shift. Production rates for the shovels and trucks were estimated to be 20,000 tons (18,200 t) and 2500 tons (2300 t)/operating shift, respectively. It was proposed to purchase and schedule 10 shovels to operate at 80% availability to give a loading capacity of 10 × 80% × 20,000 tons (18,200 t) = 160,000 tons (145,500 t). In order to cover each shovel, it was proposed to purchase 10 trucks and schedule eight to operate at 80% availability giving an average capacity of 10 × 80% × 2500 tons (2300 t) = 20,000 tons (18,200 t)/shift, thereby matching each shovel's productive capacity.

Solution. The production plan devised assumed that trucks and their drivers, due to physical constraints, were not transferable between the various loading units, and the haul distances were always the same length. Therefore, the total equipment requirements were estimated to be 10 shovels and 100 trucks, of which 10 shovels and 80 trucks would always be scheduled to operate.

By applying the binomial function to a group of one shovel and 10 trucks, the anticipated output would be approximately 15,000 tons (13,640 t)/shift, or 150,000 tons (136,400 t) for 10 shovels. This is 10,000 tons (9100 t) short of the objective and is caused by the fact that there will be times when less than eight trucks are available resulting in lost shovel production. There also will be times when more than eight trucks are available, but since the shovel can use only eight, no increase in production can be gained to counterbalance the shortfall.

Table 16.2.3. Optional Fleets vs. Cost (Ex. 16.2.2)

	Case				
	1	2	3	4	5
Shovels in Fleet	10	11	10	11	11
Shovels Scheduled	10	11	10	9	9
Truck Fleet	100	107	100	85	81
Trucks Scheduled	80	85	80	70	70
Truck Productivity, tons					
Minimum	2,500	2,500	2,500	2,500	2,100
Maximum	2,500	2,500	2,500	2,500	2,600
Fleet Production, tons	150,340	160,049	159,544	160,498	160,240
Shovel Operating Shifts	8.00	8.80	8.00	8.39	8.39
Production/Shovel Operating Shift, tons	18,792	18,187	19,943	19,125	19,094
Truck Operating Shifts	75.20	80.05	78.41	67.34	64.71
Effective Truck Shifts	60.10	63.98	63.82	64.20	64.13
Production/Truck Effective Shift	2,500	2,500	2,500	2,500	2,499
Operating Cost/Ton*	$0.4438	$0.4447	$0.4364	$0.4118	$0.4085
Fleet Purchase Cost ($ × 10^6)	$140	$151	$140	$129	$125

*Loading and haulage cost only.
Conversion factor: 1 ton = 0.9092 t.

If the trucks could be transferred from shovel to shovel to balance out truck shortfalls, then production will be increased by approximately 10,000 tons (9100 t) and the target attained. However, this is avoiding the real problem, over-trucking. The 160,000 tons (145,500 t)/shift target can be obtained with different shovel/truck fleet combinations with a lower capital expenditure and at a reduced operating cost. Table 16.2.3 illustrates various fleet sizes that would produce 160,000 tons (145,500 t)/shift. For comparison, operating and capital costs of each fleet are listed, and the basis of these estimates are provided in Table 16.2.3. Case 1 is the base as originally specified; Case 2 is the base case but with the equipment increases that would actually be needed to reach 160,000 tons (145,500 t)/shift with the same constraints as Case 1. Case 3 is the production obtained if trucks can be transferred from one shovel to another, Case 4 is an optimum fleet balanced to minimize costs with fixed hauls, and Case 5 is an ideal case where haul distances can be flexed to accommodate truck or loading equipment shortages and maintain peak production efficiencies. In this last case, production efficiency is increased by changing the mine plan to allow flexible haul distances. Instead of a fixed 2500 tons (2300 t)/truck shift, dump points can be varied to shorten or increase haul distances to give a truck productivity range of 2100 tons (1900 t) to 2600 tons (2400 t)/shift, but still average 2500 tons (2300 t)/effective truck shift.

This example shows the magnitude of the savings that can be achieved by selecting the optimal fleet size and removing some of the high-cost constraints.

Table 16.2.4 gives basic assumptions for all cases.

A computer program that models the dependent fleet interactions can generate and investigate a large number of loader/truck combinations, select those that meet the production goal, and finally determine which combination will give the lowest overall combined cost/ton of material mined.

This type of evaluation is also a very useful tool for sensitivity analyses to investigate how changes in parameters such as avail-

Table 16.2.4. Basic Assumption for All Cases (Ex. 16.2.2).

	Shovels	Trucks
Mechanical Availability	80%	80%
Maximum Productivity/Operating Shift	20,000 Tons	As Noted
Operating Cost/Effective Shift	\$1,500	\$665
Operating Cost for Non-Productive Shift (Waiting Time)	\$300	\$220
Operating Labor Cost/Shift	\$240	\$120
Capital Cost/Unit (\$ $\times$ 10^6)	\$4.0	\$1.0

Conversion factor: 1 ton = 0.9092 t.

abilities, depreciation, and equipment and labor operating costs change the optimum fleet size.

The methods described using the binomial distributions were developed to quickly and easily analyze various loading/haulage fleet combinations with respect to costs, capacities, and the optimal fleets for comparing ore mining method and equipment choices to another alternative.

There are obvious limitations to the accuracy of this method in its application to a true mining situation. This evaluation, for instance, cannot recognize the difference between the expected output from an operation that has a well-functioning dispatch system as compared to one that is run with batch assignments. This simple method also does not consider the total picture in the sense that there are multiple haul profiles and that the loading equipment may have varying productivities and/or targets according to the material being mined. Only a fully developed mine simulation program can analyze an operation accurately to reflect all of the numerous variables.

The desired accuracy level and the complexity of the operation to be studied dictates the depth of study and method that should be used. The numerical examples illustrate the importance of correctly selecting the best loading and truck fleet sizes.

This case study of equipment proposed in a large strip mine has been given as a good example of comparing non-optimal equipment fleets with other types of mining. If the comparison was made of a dragline vs. a shovel/truck combination and that comparison indicated \$10 million in capital cost savings, the mine owners would have made the wrong choice of mining method and equipment. Therefore, it is of significance to correctly analyze the proposed equipment fleet to ensure that any comparison is valid and the proposed savings of one system over another are real.

Chapter 16.3
IMPORTANCE AND SUMMARY

ERNEST BOHNET

The preceding chapters in this section have outlined various aspects that should be considered in choosing one mining method over another, or one type of equipment over alternative types. In all surface mining operations, where there is a choice of mining method and equipment, the optimal alternative is often difficult to chose because the differences may be within the degree of accuracy of the trade-off study.

The five most important criteria in selecting the best mining method and equipment are

1. Type of deposit, seam or disseminated.
2. Geometry of the deposit and terrain.
3. Total material movement per time period.
4. Projected project life.
5. Geographic location.

Other factors of lesser importance include

1. Climatic conditions and altitude.
2. Availability and cost of a skilled labor force.
3. Environmental restrictions.
4. Slope stability and groundwater.
5. Investment risk and available capital funding.
6. Blasting restrictions.
7. Method of waste rock disposal, external or backfilling.
8. Availability of support services and infrastructure.
9. Availability of electric power vs. the local cost of diesel fuel.

Table 16.3.1 presents a comparison of ore body conditions favorable to the different surface mining methods.

A summary of the advantages and disadvantages of each surface mining method is presented in Table 16.3.2.

In conclusion, many factors need to be taken into consideration in selecting the best method coupled with the most economic fleet of equipment. When there is more than one option, it is best to select the alternative that gives the mining operation the greatest degree of flexibility. Mining is dynamic, and the operation that can adjust the easiest to changing conditions is the operation that will survive future crises.

Successful analysis of the options available ensures that the proposed project will operate at its competitive peak. The ideas presented in this section will hopefully help the mine operator meet the prime objective, that is, the investor's law of conservation.

Part V
Underground Mining

Section 17 Underground Mine Development

SCOTT G. BRITTON, ASSOCIATE EDITOR
G.T. LINEBERRY, SECTION COORDINATOR

Chapter 17.0
INTRODUCTION

G.T. LINEBERRY

Underground mine development begins with the positive investment decision to mine and ends with the inception of full-scale exploitation. It incorporates all activities, personnel, and equipment required for creation of underground access to a mineral deposit.

Because of the depletion of near-surface mineral resources, the reduced mobility of large surface mining equipment, increasingly stringent environmental constraints, and the introduction of promising innovations to rock penetration and rock excavating equipment (e.g., continuous miners, rock borers), underground mining is projected to account for an increased share of worldwide mineral production in the foreseeable future. Without proper engineering during the mine development phase, failure of the underground mining project is axiomatic.

A frustration attendant to coverage of the complex area of underground mine development lies not only with the need for treatment of the many disparate specialties within the area but even with the lack of systematization of these specialties in what is recognized as a vital precursor to successful mining. Section 17 offers insights into (1) the basic principles of the planning and design process, including baseline assessment, reserve determination, premine planning, and subsystem design (Chapter 17.1); (2) equipment selection and sizing, with emphasis on excavating and bulk materials handling (Chapter 17.2); (3) mine plant layout, divided into three major subcategories of surface, shaft, and underground plant (Chapter 17.3); (4) construction of development openings, including location and selection of shafts, methods of shaft sinking, and principles of slope construction (Chapter 17.4); and (5) hoisting systems, detailing the design and technical considerations to be examined when selecting components of a shaft hoisting system (hoist, conveyance, rope, shaft, and headframe) (Chapter 17.5).

The broad coverage of this section is intentional. It targets the engineer without a career emphasis in underground mine development, presumptive that involvement in one or two major mine development projects in a career is considered a probable maximum. The underground mine development specialist, however, should find utility in the comprehensive treatment of such an array of multifarious topics as well, some of which undoubtedly lie outside one's own area of technical expertise. For example, although details of shaft location and selection would be familiar to shaft contractors, principles of the analysis of underground excavating equipment might not be, despite the fact that both are mine development concerns. Throughout the section, the inquisitive reader, interested in adding depth to knowledge in any subtopic, is directed to related references.

Chapter 17.1
MINE PLANNING AND DESIGN

GEORGE W. LUXBACHER AND RICHARD J. KLINE

17.1.1 INTRODUCTION

An underground mine planning and design project is unique within the sphere of design engineering in that the primary infrastructure (mine workings) advance into conditions that vary over both space and time. Although generally a mine design moves through the three basic phases—conceptual, preliminary, and final design—the initial design remains the key. Any interpretive error in geology or design error in layout or facilities siting may result in technological, organizational, or operational difficulties, leading to excessive mineral loss or uneconomic operation that could continue through the life of the mine (Pazdziora, 1988). *Underground mine planning and design* has as its goal an integrated mine systems design, whereby a mineral is extracted and prepared at a desired market specification and at a minimum unit cost within acceptable social, legal, and regulatory constraints.

A large number of individual engineering disciplines contribute to the mine planning and design process, such that it is a multidisciplinary activity. Given the complexity of the mining system, *planning* assures the correct selection and coordinated operation of all subsystems, while *design* applies to the traditionally held engineering design of subsystems. A mining operation should be more correctly viewed as a system, because of the diversity of technological processes, facilities, and personal skills required, the large capital invested, the mutual relations that exist between subsystems, etc. The planning process necessitates a systems engineering approach suitable for complex design problems (see Section 6 and Chapter 8.3 of this *Handbook*).

Mine planning can be compared with organizational strategic planning; although the scale may differ, corporate strategy management (Thompson and Strickland, 1989; Steiner, 1979) is very similar to plan development and implementation. A planning process that considers both external (e.g., inflation, technological, industry, and market changes, environmental and political effects, competitor practices) as well as internal forces at work during the mine life will have an improved chance of success and a competitive advantage in the market place. Planning in this context could be considered an entrepreneurial activity while design is more administrative in context.

Although many of the basic principles of mine planning and design have not changed over many years, advancements made in individual systems such as rock mechanics or equipment design have either made or have the potential for making a significant impact on mining. Design guidelines developed as empirical rules based on experience or derived from regulatory requirements are no longer adequate for mine design. A proactive posture regarding mine planning and design is mandated for successful mining in today's complex and competitive minerals market.

Two of the major driving forces in this trend are the application of technical computing and the introduction of a systems engineering approach (see Chapters 8.3 and 8.4). The widespread acceptance of technical computing in the context of computerized mine design has expanded the scope of many older design techniques, yet has permitted the introduction of new techniques. This trend has been driven by the increasing sophistication of readily available software and hardware, augmented by the decreasing cost of hardware (personal computers, workstations, micro and mini systems), the range of software developed (spreadsheets through comprehensive mine planning systems utilizing interactive graphics), and the increasing applications of databases.

The planning process will, in general, move through four steps, irrespective of the design phase: (1) baseline assessment, (2) reserve determination, (3) premine planning, and (4) subsystem design. For a comparison with surface mine planning, see Chapters 13.1 and 13.2.

17.1.2 BASELINE ASSESSMENT

In any mining project, a baseline assessment of all available data precedes any planning efforts. The *baseline assessment* is a comprehensive initial review of all available information on the potential reserve or mine from geographic, geologic, environmental, technical, and economic standpoints. For example, the geographic location of a resource will have a great influence on economics and may dictate the mining method due to equipment and power availability, labor availability and skills level, supplies transport, etc. As the size of the resource is defined, it may be large enough to overcome the negative aspects of its location, but other problems may preclude its development. The major factors to consider in a baseline assessment can be classified as geologic, environmental, geographic, and economic.

17.1.2.1 Geologic Factors

A mine plan must build on the fundamentals of a sound mineral inventory base. It must be remembered, however, that a geologic model is only an interpretation of actual conditions based on data that are, of economic necessity, limited, and subject to the skill of the geologic professional making the interpretation. Exploration efforts are rarely fully achieved because of core recovery, alteration by drilling fluids, water inflow modified by drilling fluid migration, etc., and are often directed toward a specific purpose or goal other than that to which the data are finally applied (Pazdziora, 1988). New tests or additional drilling may be made as a project moves through the design phases that could dictate changes in interpretation, and consequently change the geologic model, the interpretation, or both. Techniques such as geophysical logging, core photography, and petrographic identification, that replace qualitative data of a general and subjective nature with quantitative data where parameters are measured in a systematic and verifiable manner, are often invaluable (Merritt, 1986). Geologic considerations are dealt with more fully in Sections 4 and 5.

Two approaches can be used to handle the uncertainty in the geologic model in mine planning efforts based on a quantification or qualification of risk: 1) accept the geology and develop the plan accordingly, or 2) acknowledge the uncertainty in the geologic model and direct the planning effort to assure sufficient subsystem flexibility to accommodate any potential impact.

17.1.2.2 Environmental Factors

Planning must account for both environmental protection, beginning as early as the initial exploration, and for reclamation.

It is critical that planning alleviate or mitigate potential impacts of mining for two key reasons: (1) the cost of environmental protection is minimized by incorporating it into the initial design, rather than performing remedial measures to compensate for design deficiencies, and (2) negative publicity or poor public relations may have severe economic consequences. If baseline data collection in the field is required, adequate time must be allowed for a comprehensive effort; an average of one to three years of baseline data may be required, although in an environmentally sensitive area, this may increase to as much as five years (assuming an environmental impact statement is required) (Anon., 1987).

Minimum necessary baseline environmental data required for the planning process include (1) overburden analysis, (2) soil surveys identifying topsoil and subsoil, (3) hydrologic studies, (4) a determination of characteristics of surface and ground water, (5) vegetation and existing land use surveys, (6) air quality analyses, (7) wildlife surveys and (8) archeological surveys.

For further discussion of environmental protective measures, see Chapters 7.3, 12.1, 12.2, and 12.3.

17.1.2.3 Geographic and Economic Factors

In the baseline assessment, there are a number of additional factors that must be considered; these can generally be grouped as either geographic or economic. The obvious, as previously used as an example, are geographic: the location of a reserve with respect to existing transportation infrastructure (for movement of equipment to the mine as well as shipment of the product); the type, size, and skill level of work force available to draw upon; the private and public facilities available to support additions to the local work force; climate; power availability; etc. These factors may strongly influence the choice of a mining method (e.g., labor intensive methods such as cut-and-fill or shrinkage stoping if equipment is not readily available, highly mechanized methods if the labor availability or skill level is insufficient or if labor costs are high). Other factors that strongly influence economics must be considered: the political and tax environment, the stability of the existing government, and the availability and replacement of equipment and supplies (Barnes, 1980; Anon., 1987).

17.1.3 RESERVE DETERMINATION

From a mine planning and design perspective, the characteristics of a reserve are as crucial as the reserve magnitude or grade; the depth, inclination, geometry (delineating shape and extent), type and properties of host and deposit rocks, quality, etc. may play a key design role. For example, concerns such as wall rock characteristics or structural features of a deposit strongly influence the choice of mining method and the mine operating costs (Barnes, 1980; Anon., 1987).

17.1.3.1 Criteria

A mineral deposit/resource can be classified as an ore deposit or reserve only when it can be successfully mined at a profit. Although the planning and design process attempts to identify the method of exploitation that allows this to occur, all or part of a deposit may not meet the reserve criteria. The impact of the geographic and geologic environments have been previously discussed. Criteria are also a function of market (demand) and mining technology. Categorization changes occur as the level of inventory and knowledge of a particular deposit increase. Reclassification will also occur corresponding to geographic and economic factors, technological advances in either mining, preparation, transportation, or utilization (impacting market or demand), and depletion. Classification methodology is often mineral- or country-specific. For example, several books have been written on the assessment and classification of coal reserves (Todd, 1982; Wood et al., 1983). From the planning and design perspective, reserve determination can best be expressed as a qualitative assessment of overall potential, expanded to include engineering and economic aspects. For details of mineral resource estimation, see Chapter 5.6.

17.1.3.2 Data Presentation

Reserve/resource data typically are presented in a matrix form, with one side of the matrix indicating the degree of certainty and accuracy of the existence of the ore or mineral, based on the distance from a point of measurement, and the other side indicating the comparative economic recovery viability. Although this format is adequate for data summary, it is of necessity a compromise presentation. Distance categories chosen to represent the degree of certainty may be derived from published sources or government agencies (e.g., Wood et al., 1983); however, categorizations specifically derived for a given deposit using techniques such as geostatistics or depositional modeling may yield more valuable information.

The widespread use of computers often leads to a comprehensive reserve summary of tabulation that is too voluminous for practical utilization. Effective graphics can often maximize communications.

17.1.3.3 Mathematical Methods

Reserve estimation involves taking point data (samples from drilling or prospecting) and extrapolating those data to blocks or grids for calculation purposes. Intermediate steps, such as mapping (determination of the sample point coordinates), compositing of sample data into a common unit or horizon, or determining categorization boundaries (reserve classification, leasehold boundaries, etc.), are often required. The point data are then extended using a wide range of mathematical techniques, of which the most common are (1) polygonal, (2) inverse distance weighing, and (3) kriging. Block size in terms of length and width may be defined on the basis of geologic structure, deposit variability, and data spacing (determining grid size in computer modeling) or may be dictated by mining methodology or quality forecasting requirements. Mapping of the block data and comparison with in-mine sampling is critical to confirm the extension methodology.

17.1.4 PREMINE PLANNING

A mine plan relates a detailed view of a complex process in action at only one specific point in time. The plan constantly evolves as physical changes occur to the existing infrastructure and as new conditions are encountered. Engineering science and mining technology are constantly advancing, while the mine, once constructed, is essentially locked in its initial physical framework. Although fixed assets such as equipment change with time, the basic design remains the same. This fact causes an ever-widening gap between existing and new mines.

When possible, a plan is chosen that will minimize the construction or development time required to get an operation into production. The shorter schedule will allow a more rapid cash flow and consequently better return on the capital investment. Although it may be preferable to drive to the property or deposit extremes and mine back to the plant for ground control or logistics reasons, this may not be economical. Plans are made to access the ore/resource soon after development is started, and to sequence development and production until the deposit is completely mined.

The mining method selection may be a tradeoff between capital investment, time from development to full production, and production costs (Chapter 8.1). As an example, in metal/nonmetal mining, a mining method such as block caving may require extensive capital and development time, yet yield lower production costs. Similarly, in coal mining, a selection of longwall mining may require extensive, high-cost development before lower operating costs, as compared with continuous mining, are realized. Conversely, in either coal or metal/nonmetal mining, a room and pillar mining method might be chosen to yield immediate production, although at a higher mining cost than other methods.

Most plans start with a feasibility study to provide an engineering assessment of the potential viability and minability of the project (Chapter 6.2). This study generally is an overview of the project, making reasonable assumptions about the physical and other key operating factors, to see if the project justifies further effort. Variations in the critical assumptions should also be evaluated to determine the sensitivity of the results to the corresponding input data.

The only way to obtain accurate cost forecasts (Chapter 23.3) for the complete project is to develop a life-of-mine plan for the reserve block, including costs associated with postmining reclamation and final land use. Postmining reclamation costs can be of such a magnitude that the project feasibly may be questionable. Potential damage to the land, water system, or community can preclude mining and can relegate a promising reserve to a resource classification.

Despite the fact that an almost limitless list of factors goes into a mine plan, the following is recommended as a checklist of concerns. Lineberry and Adler (1989) offer another organization of the complex array of concerns for underground coal mine design, as an atypical mine design model.

17.1.4.1 Regulatory and Legal Factors

From the start of the planning process, adequate consideration must be given to regulatory affairs (Chapter 7.3). The cost of compliance may be significantly reduced when taken into account in the design or planning process, in a proactive manner, rather than being addressed on an ad hoc basis as problems develop or enforcement actions occur.

For activities ranging from exploration drilling, taking grab samples, sampling streams for background water data, surveying property and well locations, etc., through mine construction, operation, and eventual closure, various regulatory agencies require the proper permits and approvals. Since the permits and approvals required may be at the level of a federal, state, county, local, regional, or multi-agency, depending on the location, the potential project impact, the regulatory and social climate, and other factors, a comprehensive examination for approvals must be made. These laws and regulations are further subject to continual revision or reinterpretation, necessitating an ongoing review throughout the planning process.

A review of the leases is required to determine mineral and surface rights for any mining venture. In some instances, lease requirements or compliance provisions may place a substantial burden on an operations plan.

As the plan develops, initial designs of the mine infrastructure or compliance plans for key subsystems will need to be submitted to the various agencies for approval. These items, needed before mining can be initiated, may include at least the following: (1) mine layout with projections, (2) strata/roof control plan, (3) ventilation plan, (4) fan stoppage plan, (5) dust control plan, (6) medical/emergency evacuation plan, (7) fire control/mine evacuation plan, and (8) escapeway map/plan. Most of these regulatory requirements must be considered in the plan from the onset. Special care must be taken to insure that the latest regulations, policy releases, court rulings, and proposed rule-making have been reviewed and are being incorporated.

17.1.4.2 Geologic/Geotechnical Factors

From the time an area is determined to have potential value for mining, data collection starts with a determination of the need for additional exploration (Chapters 5.2 and 5.5). Few properties have been so adequately explored that no more information is required. There is never enough information on a deposit to fulfill all design requirements. Ore-body variability can be mathematically defined, and depending on the detail needed, the number of data points and required spacing can be estimated for a required degree of confidence. From the start of the planning process, however, exploration permits are invariably needed to collect additional information to formulate the plan.

An understanding of the regional geology and depositional features forms the basis for every mine plan, although this is often acknowledged only for those mines operating in difficult geologic conditions. Structure and quality variations are mapped and an overall layout scheme meeting the extraction criteria is developed.

As was previously mentioned, economics usually favor the extraction of best-grade material or lowest mining cost areas at the onset of mining to maximize the return on investment and shorten the payback period. While immediate extraction in this manner enhances the economics, it usually creates a compromise in design.

Many geologic and geotechnical factors must be considered for a deposit, depending on the mining techniques under consideration. Among these factors include the identification of ore horizons within a potential minable zone, the quality of individual benches, horizons or plies, and the material type forming the mining horizon roof and floor. The location of oil and gas wells or exploration drillholes that have not been sealed must be determined. Areas of potentially adverse geologic conditions, such as faults, wants, rolls, low cover, or water inflow must be located or defined. Seam or horizon conditions are important also. Of practical interest is knowledge regarding seam/ore hardness and presence of partings/impurities. All of these factors are utilized in the planning process.

17.1.4.3 Environmental Factors

From the start of data gathering and permitting, environmental considerations are important, although benefits from a strictly economic sense may be intangible (Chapter 7.3). From exploration, where core holes must be sealed and the site reclaimed, through plan development, the impacts on the environment must be considered. These impacts include aesthetics, noise, air quality (dust and pollutants), vibration, water discharge and runoff, subsidence, and process wastes; sources include the underground and surface mine infrastructure, mineral processing plant, access or haul roads, remote facilities, etc. If mining will cause quality deterioration of either surface water or groundwater, remedial and treatment measures must be developed to meet discharge standards. The mine plan must include all the technical measures necessary to handle all the environmental problems from initial data gathering to the mine closure and reclamation of the disturbed surface area.

Reclamation plans include many of the following concerns: drainage control, preservation of top soil, segregation of waste material, erosion and sediment control, solid waste disposal, control of fugitive dust, regrading, and restoration of waste and mine areas. The plan must also consider the effects of mine subsidence, vibration (induced by mining, processing, transport, or subsidence), and impact on surface water and groundwater. These environmental items often dictate the economics of a planned mining operation and determine its viability.

17.1.4.4 Technical Factors

From an engineering perspective, the technical area is the most extensive in the overall plan (see other chapters in Section 17). Plan detail is defined using the data from regulatory, geologic, and environmental considerations. All information is used to develop each part of the plan, utilizing an iterative process to account for the many interrelationships that exist. The layout of the mine is determined by the size and shape of the ore deposit. The depositional features and conditions are used to calculate the mine reserves. After the mine area is delineated, access development to the deposit is considered. Access can be by vertical shafts, inclined slopes and drifts, or horizontal entries and adits. The relative size and production levels of the mine area will dictate the number and size of the access openings made. The larger and more extensive the area, the more complicated the plan will be. The optimum mine size or production level can be determined from a combination of mining area, workable reserves, and daily production. A small mine may not generate sufficient income to justify the cost, while a large mine may be penalized by high fixed costs incurred in the later years, primarily due to the cost of maintaining the infrastructure.

The size and technical parameters will form the conceptual basis for the plan; from this, the detailed plan takes shape. Each item is defined: key assumptions, physical factors, equipment, facilities, infrastructure, and transportation are detailed and modified as each item falls into place, dependent on the base data and "best-fit" technical determinations.

SURFACE FACILITIES. The productive capacity of the proposed operation and the reserve size determine the size and site placement of the facilities; extensive, large-capacity facilities need a correspondingly larger surface area than similar type smaller facilities (Chapter 7.2). Consideration must be made for access, extraction, removal, and storage of the ore, the physical needs of the workforce, and the operational needs of the facility (Anon., 1987). Transportation of the product may be by rail, truck, water, or a combination of modes. The ore may have a high reject or waste percentage and is consequently too costly to transport for processing; partial processing at the mine site with final processing at another location may be preferential. The processing facilities could be designed as a closed circuit system, recycling water internally, or could use a slurry system, settling out fine refuse. If slurry disposal is required, the facility design must insure adequate life. Land acquisition for disposal areas must be addressed. Water (potable and plant makeup) and power requirements must be considered. Dust, noise, safety, and layout efficiency are other design considerations. Future access as the mine is extended further beyond the initial development area will require life-of-mine planning to identify the location and function of the ancillary facilities in later years.

PHYSICAL FACTORS. Where the dimensions of the deposit determine working height (e.g., coal, trona), physical factors relate primarily to deposit height. Isopach mapping is used in these cases to develop the best mine layout, often giving consideration to the number of benches to be mined or the portion of the seam best matched to market requirements. The reserve can be constituted by a single vein deposit or by multiple veins, splitting and joining at different places throughout the mine area. Several levels may be operating simultaneously to produce the required product quality. The sequence of extraction can be important for quality and for maximizing the reserve recovery. The proper sequencing of mining in a multilevel deposit or multiple seam situation can greatly increase the recovery and can avoid mineral losses from mining sterilization. Quality parameters for each mining area must be considered, so that areas not meeting market criteria can be blended or avoided. Poor mining conditions must be factored into the analysis to account for changes in productivity rates and mine costs.

EQUIPMENT. The dimensions of the deposit and the hardness of the mineral are the primary determinants of the types of equipment needed (Section 9). Additional factors include seam or working height, mining dilution limits, production rates, and property extent. Ventilation, size constraints, regulations, and floor pressures may impact the choice of diesel- or electric-powered equipment. A large flat-lying deposit may allow the use of longwall mining equipment. The floor condition plays a big part in the equipment type.

Desired product size may also influence equipment selection. For example, the washability analysis for a particular coal seam at various size fractions may suggest the choice between continuous mining (fine-particle generation) and conventional mining systems (coarser product) for room and pillar mining, using preparation (washing) as a criteria. Consideration of other factors, such as equipment productivity, however may negate this particular criteria.

Equipment overhaul schedules should be developed to assure sustained productivity rates. Equipment replacement schedules should consider the incorporation of new technology as it becomes available.

SUPPORT SYSTEMS/INFRASTRUCTURE. Subsystems critical to, but not a part of, production at the face form the support systems, installed in the mine entries/drifts/levels as mining proceeds. This network forms the mine infrastructure.

All parts of the system must be evaluated for capacity and availability, and must be matched. Most systems are developed in series; if one part of the system fails, the whole system must be halted until the failed part is corrected. Although series systems are generally used out of necessity (due to the costs of redundant components or parallel systems), low availability cannot be accepted because of its potential negative profitability impact. The support systems are designed to be as maintenance free as practical, while minimizing capital and labor intensity requirements (although these two items are, in turn, classical trade-offs). They must have designed into them (albeit at a potential increased capital cost) the flexibility needed to serve the expected production levels. Given the number of support systems and the potential for delays outby the face area, the support systems may impact productivity more than the face systems.

Transportation—Transportation encompasses provisions for the movement of materials, personnel, and equipment into and out of a mine. Workers must reach their designated work area in a prompt and expeditious manner. Supplies must get to the proper area for use in the system before the need becomes critical. The equipment itself must be transported through the mine to get to the working area. And, of course, the ore or mined material must get from the face to the processing facility. A smooth flow of the transport systems must be ensured in a successful mine design.

The greatest design work is expended on the transport of ore. Usually other transport systems are dictated from that system. The haulage system must be compatibly sized, from the face extraction cycle to the facilities outside. Productivity rates must be matched, so that a highly productive face is not hindered by the capacity and availability of outby transportation. Many mines have failed or not achieved their profit potential because proper consideration had not been given to system capacity compatibility.

Regardless of how well capacities are matched in any materials handling system, a “bottleneck” will likely occur. The key is to keep the most expensive links in the system working at or near 100% capacity to maximize the return on net assets. The need to decouple the haulage system must be considered. Surge systems are weighed against large-capacity haulage units. Surge storage units (e.g., bins, bunkers) can serve both as a decoupler and as a ratio feeder for improved materials handling.

Future technology must be considered also. Is there new technology being evaluated now which will be available soon? It may be prudent to design haulage systems to meet capacity requirements from an improved production basis or from planning basis where large capacity longwalls will be installed later. The equipment from the face, through the intermediate haulage system, to the outside must be given due consideration.

The workers may get paid for portal to portal work, for 8- or 10-hour shifts, possibly changing at the face. Allowances must be made for overtime work. The various classification grades and possible contracts with labor groups must be considered. The fastest, most efficient system must be used, so that the non-face time will be minimized. Not only does this give more production time, but it also maximizes the utilization of costly labor. Clearance must be provided, both to the sides and overhead, for safe movement of personnel and equipment.

Manpower—Staffing of the system is a function of the required production level, selection of equipment, and technical objective selected to accomplish the objectives. Typically the manpower level is inversely related to the relative level of capital spending (in turn, usually a function of reserve size). Adequate personnel must be provided to allow the system to function properly, at the design utilization levels; personnel includes the supervisory workforce as well.

Consideration must be made for support staff levels (e.g., administration, engineering, financial). Centralization or a mine-based staff each may be more effective depending on the particular circumstances. The physical location of the mine must be considered. Are the environmental, engineering, personnel, and other support staffs a part of this staffing level? These considerations all become part of the staffing effort.

Mine Power—The mine productive capacity and mineral processing requirements govern the electrical power needs of the operation (Chapter 12.4). The regional distribution systems should be evaluated to determine if the power is available or whether a new distribution system must be designed and built. These systems must be of adequate size for the life of the mine. They must also be easily maintained and must provide adequate reliability. The distribution of power is designed from the power supplier to the location in the mine where it is being used. Adequate capacities and safeguards are considered so that the total system will be available when needed. In some areas, both on the surface and underground, backup systems may be needed, Also, in many mine areas, backup systems are being designed where different forms of power are being utilized, including solar radio transmitters, methane power generation, and hydroelectric power.

Mine communications systems are a part of this also (Chapter 12.6). Several types may be utilized for wired or wireless. Backup systems are often used. Many systems are now a part of the telephone system so that communications are complete to remote offices all over the world, from the mine face. Couple this with the mine monitoring systems and computers, and the design variables are almost unlimited. The proper communication of voice and data is vitally important. Timely and accurate documentation of the mining systems status can lead to very efficient operation and utilization of the mine resources.

Water—The supply of water is very important to the operation of the mine and preparation facility and is a subsystem in itself with its own distribution system from source to face (Chapter 12.1). Both process water and potable water must be supplied. There may not even be a source nearby, requiring that one be designed for in the premining phase. Public sources may be available, but they must be adequate for the amounts needed. Wells might have to be drilled, or impoundments made, to get the needed supply. Various mine systems need the water for cooling, dust suppression, fire fighting, processing, and personnel needs.

Services—The mine plan support systems also include distribution of dust suppression material, hydraulic oil, and other supplies (Chapter 12.7). Most mine equipment requires good, clean hydraulic oil for proper operation and continuous service. This system must be well thought out so that it is properly implemented. The use of diesels will require even more oil distribution systems, properly installed and maintained. The dust suppression materials, usually rock dust, in bag or bulk form, must be distributed properly. Bulk packaging of supplies for work areas will minimize handling, leading to less labor intensive supply systems.

Ventilation—After most of the other factors are laid out, the ventilation is designed to provide the mine’s life support system (Section 11). First consideration is for providing clean respirable air to the workers. The dilution of contaminants is next. In other cases, air can be used for cooling also. The mine life must be considered when doing the design. Changes in the mine extent or size will determine what areas need to be serviced. Contaminants (e.g., dust, radiation, and methane) must be diluted to safe levels and/or carried out of the mine. Areas may need to be sealed or isolated from the system to make the system efficient.

Mine layout is dramatically impacted by the ventilation system. Proper airflow requires proper sizing, location, and numbers of airways keeping in perspective ground stability requirements. Design considerations often require large-sized and high-horsepower fans for the proper utilization of the support systems. Combinations of holes, shafts, and adits are often utilized. Minimum and maximum velocities and quantities are often specified by the regulations and mine conditions. Petitions for variance are often needed because the regulations do not cover all circumstances found in the mines.

Development sections are sometimes harder to ventilate than production sections because they are usually driven into virgin territory, where conditions are not as well known. In many cases, the development unit is extended a long distance from the primary aircourses and adits, necessitating high pressures to provide the proper air quantity and quality. Production units can also be troublesome where high production causes high liberation of contaminants. In these cases, high quantities are required for proper ventilation.

17.1.4.5 Mine Closing and Reclamation

After the deposit has been completely mined, the mine area must be cleaned up and returned to approximately its original condition. Permits require bonds to be set for protection against not completing this reclamation. Sinking funds are usually made a part of the mine costs to cover these reclamation costs. Openings are filled and sealed, waste piles are covered and revegetated, and structures are removed. For details of mine closures and sealing, see Chapter 8.7.

17.1.5 CONCLUSION

The mine planning and design process is detailed and complicated, requiring comprehensive knowledge of geology, laws and regulations, equipment specifications, mechanical, electrical, and civil engineering technology, and general mining engineering. Throughout the process of planning, all the factors discussed above are used in a methodical way to arrive at a baseline assessment, to develop an initial plan, and then to evaluate various scenarios.

A plan is developed in a window of time that is stopped for the moment, and finalized, based on the then available data. When the plan is reviewed tomorrow, it is quite likely that new data will be found, or that different emphasis will be put on existing data, such that changes will be required to the plan.

Chapter 17.2
EQUIPMENT SELECTION AND SIZING

G.T. LINEBERRY AND A.P. PAOLINI

Equipment selection and sizing is a major mining engineering activity. It follows the positive investment decision to mine (Section 6) and begins with selection of a mining method (Sections 8, 21, and 23). Although equipment selection begins during the formulation of a "milestone diagram," in which the minable reserve is parceled out into zones distinguished by method of mining, suitability and production analyses for mining equipment are not conducted until after layout and sequencing are accomplished and before scheduling is undertaken (Lineberry and Adler, 1989). It is therefore apparent that equipment selection and sizing is a vital activity for a comprehensive, balanced underground mine design.

At the heart of mining is the excavation and handling of bulk materials. In fact, the primary objective of mining is to win ground, convert it into a fragmented solid, and then move this material to a suitable location for processing (Adler, 1984). In accomplishing this, the excavating and bulk handling system sets the pace for all other systems (ground control, life support including ventilation, and support services including power distribution and maintenance). It further determines suitable equipment type, equipment size and horsepower, and productive capabilities, and therefore to a large extent influences layout, sequencing, and scheduling. For these reasons, the selection and sizing of equipment, whose purpose is for the accomplishment of excavating and bulk materials handling, is emphasized here. Details for the selection and sizing of materials handling devices are subordinated, since these are treated in Section 9, Production Operations. Offered here are guidelines for the selection and evaluation of underground equipment, both mobile and fixed, as well as a standardized procedure for their analysis.

This chapter combines qualitative descriptions of many common underground excavators and handlers with an attempt to classify each as an aid to their proper selection and evaluation. Included in the classification system for completeness, however, are many common pieces of surface mining and construction equipment. Limits and ranges are offered, recognizing that these are valid only as frames of reference in a market area that is undergoing rampant innovation as operators and manufacturers seek higher productivity and enhanced safety. These goals are sought through technological improvements (e.g., coal interface detection, on- and off-board navigation, robotics, autonomous vehicle technologies) and improved management strategies (e.g., artificial intelligence, decision support systems, management information systems).

Major topics to be included here are (1) the development of the viewpoint of the primacy of excavating and bulk handling in mining, (2) a description of a recommended equipment classification system, (3) a review of the characteristics of the most common underground excavating and handling equipment, with major recent and impending innovations noted, and (4) an overview of a procedure for determining the performance of excavating and bulk handling equipment. Recommendations are also given for improving the selection and evaluation procedure.

Because there is little agreement as to what specific points should be considered, and even less on what procedure to follow, much of the material presented here combines established and time-honored principles with a new structure and framework. Specific goals are (1) the development of excavating and bulk materials handling as an area that is distinctively mining's, (2) introduction of a classification system that provides an organizational structure upon which to build, and (3) standardization of a procedure for analyzing excavating and bulk materials handling equipment.

Table 17.2.1. Dimensions and Symbols

Dimension	Notation	Query	Symbol (Suggested)	Description
Matter (material)	M	What?		Substance or agent in question
Space	L	Where?		Locate, delineate, measure, represent, classify
Time	T	When?		Specific time frames (past, present, future), or increments (Δt)
People	—	Who?		Skill, ability, experience, safety training, motivation
Money	—	How much?	$	Monetary value, cost, profitability
Purpose (major)	—	Why?	?	Reason for doing job or element of it (safety, economy)

17.2.1 BASIS FOR EQUIPMENT DIFFERENTIATION

17.2.1.1. Organizing Principles

Essential to proper selection of mining equipment is an appreciation for and an understanding of the unique conditions under which excavating and handling equipment is employed. In an integrated and intensive effort to define these mining conditions (termed encumbered space), the introduction of a standard set of engineering dimensions is appropriate. The complete range of engineering dimensions, which efficiently encompasses a mass of diverse properties, is shown in Table 17.2.1 and provides an essential checklist (Lineberry and Adler, 1988). These six key engineering dimensions not only aid in the characterization of the highly adverse and distinctive working conditions associated with underground mining but also assist in formulating a consis-

Table 17.2.2. Total Systems Context

Systems	Description
Ground Control (esp. underground)	Support, caving, closure, bursts, subsidence
Excavating and Handling	Rock penetration, fragmentation, bulk solid movement, storage, transfer
Life Support (esp. underground)	Ventilation, drainage, illumination, personnel safety and health
Normal Support (logistics & environment)	Power, supplies, repair, maintenance, surveying, construction, management, personnel, environment

tent methodology for equipment selection and sizing in encumbered space.

17.2.1.2. Mining's Uniqueness

To develop a consistent and replicable procedure for selecting and sizing underground mining equipment, the basic and unique attributes of mining engineering must be determined, described, and then appreciated. When systematically compared to other engineering fields, mining engineering is distinctive in (1) having a total systems concern, (2) dealing with encumbered space, and (3) requiring *full-spectrum practice.* Each of these, respectively, corresponds to the requirement of specifying tools and activities, conditions, and management. By considering an extreme case situation, underground mining variables which are often too subtle or ubiquitous to notice can be more readily identified.

Thoughout this development, the *mine face* will be emphasized because it is the focal point of all activities. Here, tools are marshalled, concentrated, and applied under the worst conditions. The remainder of the mine extending back to the surface, including worked-out areas, is termed the *mine plant.* The mine plant more closely resembles a normal, structured, manufacturing plant and is easier to operate and maintain. It is often the shared professional jurisdiction of mining, mechanical, civil, and electrical engineers. Only the mining engineer is willing and able to deal with the unstructured mine face with its difficulties, inherent hazards, and potential for disaster. The underground mine face has been termed "hostile" (Zegeer, 1986) and characterized as being "dirt-infested" (Sitek, 1980; Lineberry and Adler, 1988).

TOTAL SYSTEMS CONTEXT. The total systems concern ensures that vital excavating and bulk handling activities will occur and be assisted by the necessary synchronized supporting sytems: ground control, life support, and normal support, as shown in Table 17.2.2. In the aggregate, all of these systems are so complex that mining can be compared to a busy city, with concern for water, light, power, communications, transportation, supplies, sewerage, and construction. Because mining also requires rapid advance and retreat, an unprecedented demand for mobility exists, particularly at the face.

Excavating and Handling System—In accomplishing mining's mission, the excavating and bulk handling system sets the pace for all other systems. A fundamental choice must be made, especially at the face, between using mobile equipment or fixed machinery (Adler and Lineberry, 1986). Face mobility is exemplified by the trackless equipment characteristic of room and pillar mining, coupled with a possible switch to fixed machinery, such as a belt, further back in the plant. By way of contrast, longwall mining, with continuous haulage, is considerably more rigid. When using mobile equipment, the mining engineer is indispensable; with fixed machinery, the mechanical engineer assumes a more important role. Even with fixed machinery, mobile equipment is still necessary to prepare, trim, support, grade, and clean up.

It is important to note that in addition to milling and digging, excavating also employs the mechanisms of blasting, boring, ripping, scooping, caving, and impacting. All are carried out in the geologic mass, which, in combination with the tool, forms the *job-end.* Engineering dimensions of matter, space, and time are emphasized.

The bulk solids produced must be handled by the appropriate job-end tool (e.g., box, blade, belt). When the bulk solid lies in a muckpile or stockpile, loading is first necessary. The bulk solid material, which is also best described in terms of matter, space, and time, is also termed "loose," "fragmented," or "non-cohesive." It can be further processed by crushing, screening, sizing, and blending.

Ground Control System—Ground control is vital in all underground mining, especially of coal. It provides control of roof falls, closure, bursts, and subsidence and significantly assists excavating and handling. Because it depends upon poorly defined and highly variable geologic conditions, the ground control analysis is often questionable. Underground mining methods have been traditionally classified on the basis of ground control as open (self-supported), supported, or caving. When recovering pillars, a rapid in-out approach is favored, facilitated by highly mobile equipment.

Life Support Systems—Life support systems are essential in underground mining. They consist of (1) ventilation, (2) drainage, (3) illumination, and (4) personnel safety and health subsystems. In coal mining, ventilation demands major attention because it radically impinges on the face operation and influences the overall mine layout. As with ground control, the engineering of these systems depends on poorly defined geologic data (e.g., rock permeability) and uncertain engineering data (e.g., friction factor), requiring the practiced judgment of mining engineers.

Normal Support Systems—Normal support systems are required for surface as well as for underground mining. They provide (1) power, fuel, and supplies; (2) maintenance and repair; (3) management, communications, and personnel transport; (4) surveying, construction, moving, and cleanup; and (5) environmental protection. Hazards associated with some of these systems include exposure to high-voltage electricity and handling of explosives, volatiles, solvents, and cutting gases.

ENCUMBERED SPACE. To mine safely and efficiently, working conditions must be systematically defined. Their uniqueness distinguishes mining from other engineering professions. The worst case in underground mining is termed *encumbered space.* Working space is often inherently hazardous, transitory, and expensive. It is also tight, distorted, congested, isolated and inaccessible, of poor quality, and deteriorating. These adverse conditions endanger personnel, damage mobile equipment, and affect all activities, even on the surface. An integrated and intensive effort has been made to define mining conditions (Lineberry and Adler, 1988). Only a brief summary can be presented here.

General—Encumbered conditions are those which "impede motion or activity, as with a burden." They are singular to mining and convert normal difficulties into hazards, and hazards into potential disasters. Their distinctiveness and significance is sufficiently great to justify an engineering career emphasis.

Table 17.2.3. Causes of Encumbered Space

Causes	Description
Primary (Inherent)	Geology; geography; underground, ground control
Operational (Induced)	Total systems activities, overlapping (esp. excavating and handling), people
Worse-case Situation	Superposition of above at mine face (esp. disaster potential)

Source: Adler and Lineberry, 1988.

Encumbrances primarily impact on the excavating and bulk handling system, but all systems are involved.

The mining situation contrasts sharply with that in heavy construction, even with tunneling. In mining, the value of the excavated material is often just marginally higher than the cost of mining. In construction, the value resides in the resulting access structure and is several times greater than the cost of excavating. In mining, the life of the opening is brief and intense compared to that in construction. Consequently, initial costs in mining must be kept unusually low, especially those for ground control. Full mineral recovery is sought, and dilution and deadwork must be minimized. All of these factors intensify hazards and mandate that mobile equipment be flexible, versatile, and highly maneuverable.

The full impact of encumbered space does not really exist in a manufacturing plant nor in construction with its alternative sites and routes; it exists only in mining. At the mine face, conditions are sufficiently unprecedented so that traditional engineering no longer suffices. As conditions worsen, the operation slows down. This allows even further worsening, a downward spiral to failure. The underground structure can be dramatically likened to a large collapsing edifice, still occupied and undergoing demolition from within. Potential causes of accidents and even of disasters abound. Only the mining engineer can hope to compete with these severe constraints in time and space.

Inherent Causes—The causes of encumbered space, as shown in Table 17.2.3, are the result of natural conditions and of an underground workplace. A geologic mass is often practically impenetrable and highly variable, making its properties extremely difficult to predict. Natural conditions constitute the primary set of independent variables and are virtually unalterable. A material description of any geologic mass must include the rock type, geologic structures, contained fluids, and rock temperature and pressure. Fluids, gases, and water are often hazardous, and rock temperature discomforting. Subregions composed of uniform material properties must be located, measured, and described. However, because of impenetrability, both material and spatial descriptions are frequently inadequate.

Underground mining can pose severe ground control problems. In coal, the normal quasi-stable roof span is only about 15 ft (5 m) and, therefore, very restrictive. Pillars are often large, possibly 120 ft (35 m) for coal, and cause major detours in equipment routes. Deterioration often results in a progressive decrease of structural integrity, reinforcing the rapid in-out requirement, especially during secondary recovery of pillars.

Severe ventilation and drainage problems can result from contained fluids. Pillars serving as seals can deteriorate with time, compromising their effectiveness. The human environment is usually poor. Vision is limited due to darkness, fog, and obstructions. It can be damp, hot or cold, noisy, gassy, slippery, grimy, and dirty.

In closely following the deposit, especially when employing blasting, poor quality access space results. Cross sections are often misshapen, tight, and rough, while the centerlines are lengthy, circuitous, and abrupt. Underground mine surveying reflects these distinctive problems. Mine faces are dead-end and are often remote and inaccessible. Haulway surfaces typically are littered, dirt-infested, slick, rough, weak, or heaving. Since the bulk solid is raw, it often contains oversized fragments, resulting in spillage and interference. It can also be leaky, sticky, abrasive, and dusty. Water exacerbates many of these conditions and accelerates deterioration. The disposal of any waste or unwanted water is a major problem.

A more detailed approach to organizing the inherent components of encumbered space (Lineberry and Adler, 1988) describes the geologic mass, bulk solid, ground structure, running surface, man and machine environment, and centerline profile in terms of the five basic engineering dimensions. These components are then matched to major equipment components, including (1) job-end (to excavate and handle), (2) running gear (to provide mobility and/or reactions), (3) chassis and cab (the base for all components, the operator, and attachments), and (4) power and drive train (energy source and controls).

Operationally Induced Conditions—In order to cope with the many intrinsic adversities of the inherent state previously noted, the total systems are stuffed into already tight space to yield induced conditions. Each individual system to some extent bears a deliberate one-to-one relationship with an inherent component. Ground control heavily influences the ground structure; life support relates to the human environment; and, clearly, excavating and bulk handling incorporates the geologic mass, the bulk solid, and the running and reaction surface. The normal support system and the centerline profile remain ubiquitous, but in all cases, interactions occur. The addition of any remedial system is partially self-defeating, since in itself, it occupies valuable space, causes wear to running surfaces, deteriorates, and, in turn, must be serviced.

Four induced components of encumbered space are recognized as problematic: (1) interference, caused by adding moving equipment (e.g., bolters); (2) congestion, due to introducing stationary facilities, installations, and stores; (3) traffic, resulting from the keen competition for space by multiple haul units (e.g., ramcars); and, worst of all, (4) high labor intensiveness, exposing personnel to serious jeopardy in tight, short-lived, but very active areas. Special safety categories such as “struck by” and “caught between” emphasize the potential effects of these induced components of encumbered space.

Congestion in ground control can be caused by props, cribs, sets, and trusses. Bolts and grouting, being internal or superficial, are excluded. Short spans and large pillars have already been considered as inherent conditions. Roof bolters can prolong interference, especially when roof conditions are poor. Excavating and handling equipment for other parallel systems and for serial elements add to interference, while loading and transfer points promote congestion.

Ventilation near the face causes extreme congestion, with curtains, stoppings, ducts, and fans. Drainage requires pipes, ditches, sumps, and pumps. Water and firelines must be included, along with suitable escapeways. Rock dusting can offer interference also. For normal support, congestion is created by distribution systems for power (cables), water and compressed air (pipes), as well as for supplies and dumps. Explosives, volatiles, and cutting gases require special handling and storage (magazines).

Numerous personnel in constrained geometries and in nonideal conditions further complicate underground mining operations. Low spatial volume per worker ratios—with the lowest in the Appalachian Coal Basin of the United States—contribute to an increased hazard potential. Because activities are concen-

Table 17.2.4. Full-spectrum Practice

Phases	Description
Plan	Conceive, study, investigate
Design	Analyze, organize, synthesize
Implement	Install, construct, staff
Operate	Run, function, supply, maintain
Control	Manage, monitor, vary, alter

trated at the point of deepest penetration, it is not surprising that most underground mining accidents occur within 25 ft (8 m) of the face.

FULL-SPECTRUM PRACTICE. Engineering spans a spectrum from conception, through planning, to operating, as shown in Table 17.2.4. Different engineering disciplines stress different phases: civil engineering concentrates on plan and design. Electrical, mechanical, and chemical engineering shift towards design and control, with the latter done virtually automatically. Mining and industrial engineering, both of which are labor intensive, must shift even further to operate and control. For mining, this shift is intensified by geologic variability, geometric constraints, and severe market fluctuations. The mining engineer is one of the few practitioners who often "flies" his own design. Full-spectrum practice also requires applying administrative techniques, which already receive priority in many smaller mines. The transition from engineering to management remains awkward, although their close ties are well recognized.

In this discussion of equipment selection and sizing, engineering is emphasized over administration, with the analyses being conducted in the early phases of full spectrum practice. Operation and control will not be addressed, except as it applies to the safe and efficient use of underground excavating and handling equipment. Most coverage will focus on the use of performance analyses to properly select and size common pieces of underground equipment.

17.2.2 EQUIPMENT CLASSIFICATION SYSTEM

All types of mining and reclamation equipment can be systematically classified in order to reduce a vast quantity of information to manageable proportions. This classification serves to control the development of a market area undergoing rapid, even rampant, changes and assists in the safe and economical use of equipment. It also fosters an integrated view of what are often considered fragmented, disparate specialties.

An efficient and standardized classification system is the starting point for most analyses. However, an examination of the current classification systems for underground equipment indicates serious limitations. While the proposed classification is primarily intended for mining engineers, other engineers will also benefit. Many factors are considered in the classification. A cursory knowledge of the equipment is essential for its use.

17.2.2.1. Background

ALPHABETICAL INVENTORY. To fully appreciate the range and complexity of equipment types, an alphabetically-arranged inventory is presented in Table 17.2.5. Over 50 types are included, with their commonly accepted abbreviations noted. The term *equipment* often refers to mobile units (e.g., dozers, shuttle cars), while *machinery* refers to fixed assemblages (e.g., conveyors, borers), a distinction that is often blurred. Although this section is devoted to selection and sizing of common underground equipment, presentation of a complete inventory is preferred because performance analyses of all mining and reclamation equipment follow common basic principles.

NECESSARY REQUIREMENTS. In order to properly analyze excavating and bulk handling problems, the objectives, conditions, activities, and tools must be clearly stated (Adler, 1984). The objectives are either to excavate, to handle, or to do both. *Conditions* are the natural setting or environment in which mining objectives are being pursued. The *activities* are how the tool is used, maneuvered, or manipulated. The tool itself must be designated as to *type* (e.g., the continuous miner is a *type* of integrated excavator; a tunnel boring machine (TBM) is a *type* of rapid excavator).

CURRENT CLASSIFICATIONS. Existing systems are highly simplistic and usually consider only one condition: surface vs. underground, hard vs. soft rock, hoisting vs. transporting, gravity vs. mechanical flow, mining vs. construction use, and so forth (Apple, 1963; Carson, 1961; Nunnally, 1982; Anon., 1958; Anon., 1987). An industrial engineering classification for materials handling equipment distinguishes three types of equipment: (1) fixed-path types (e.g., conveyors), (2) limited-area types (e.g., cranes), and (3) wide-area types (e.g., trucks) (Peurifoy, 1979). This system, together with another developed for loader selection (Anon., 1958), are precedents for the proposed classification.

PROPOSED CLASSIFICATION. The most apparent and striking visual distinction between equipment types is their *degree of activity:* mobile equipment (e.g., scoops) vs. fixed-base equipment (e.g., TBMs). The differences are clearly self evident. An intermediate distinction covers equipment that remains fixed and in

Table 17.2.6. Major Equipment Groups Related to Types[a]

Group	Types
Mobile loaders and excavators	Dozer (and ripper), tractor scraper, FEL
Rotating excavators	Power & hydraulic shovels, backhoe, dragline, grade-all, clamshell (crane)
Integrated excavators	CM, BWEs, (and side-BWE), BCE trencher, auger dredge, cutting machine
Rapid excavators	Borers (raise, shaft, tunnel), reamer auger
Ground preparation	Drill/blast (hole loader), impactor (hydraulic or ball), ripper, cutter, hydraulicking
Loaders and muckers	Tunnel (ramp), shaft
Mobile conveyors	Modular (extensible), shiftable (in-pit), bridge (continuous handling)
Conveyors	Belt, bucket, flight, spiral, high-angle conveyors; hydraulic and pneumatic pipelines

[a] See Table 17.2.5 for meaning of abbreviations.
Source: Adler and Lineberry, 1986.

place while excavating but is mobile when tramming between sites (e.g., shovels). A second dimension is added to the classification by the *objective of activity:* whether it is for excavating (e.g., continuous miners) or for bulk handling (e.g., trucks). Again an intermediate distinction includes equipment doing both (e.g., LHDs loading from muckpiles or from stockpiles) or equipment used only for short-distance handling (e.g., shuttle cars). This matrix of degree of activity vs. objective of activity enables all equipment to be located systematically.

17.2.2.2. Classification and Value

An initial consolidation of over 50 equipment types is shown in Table 17.2.6, combining many types into well-accepted groups. Integrated and rapid excavators are distinct because they simultaneously excavate, load, transfer, and dump. On the basis of these groups and the remaining individual types, a comprehensive equipment classification is offered in Table 17.2.7, with abbreviations used whenever possible. Additional refinements concerning the relative location between types could be made within each block. In fact, an attempt has been made to supplement the classification system with greater detail, based on conspicuous visual distinctions within each equipment type (Adler, 1989a). By adopting classes, groups, types, and kinds, at successive degrees of refinement, a taxonomy has been developed based on clear visual differentiation, or on a morphology. Although promising, this refined classification has not been critiqued and standardized. Furthermore, uncertainties remain in the proposed taxonomy, especially below the level of type, and graphical deficiencies are still present in the morphology.

Production analyses of equipment with long cycle times (> 2 minutes) are notable since they use a *tabular duty cycle* approach. Short cycle times (< 2 minutes) are usually found in tables (with appropriate correction factors) or are time-studied on the job. Hoists have simple, uniform, precise, and repeated short cycles and employ a *graphical duty cycle* approach. Slushers and some tramways can be handled either way. In general, analysis of equipment with minimum operational variability and short cycles (e.g., hoists and rail haulage) favors a graphical technique.

17.2.2.3. Exceptions and Future Trends

Clear classification of equipment is difficult. The front-end loader acts sometimes as a tractor shovel (excavating), at other times as a load-haul-dump (LHD) (both excavating and handling). Some apparently fixed assemblages, such as the slusher or hoist, have considerable internal relative motion of the job-end and of the overall center of gravity. It is this motion that is deemed cyclical, locating these types in the intermediate rather than fixed classes. Judgments as to relative mobility are made in locating the rotating excavators alongside integrated ones. The bucket wheel excavator and boom-type continuous miner can be considered either rotating or integrated. Also fixed-base continuous excavators must periodically be advanced (borers) or the job-end direction reversed (longwall). Therefore, these excavators have broad secondary cycles.

It is often difficult to distinguish between equipment types that are intended exclusively for surface or for underground use, because variants have appeared of both. The continuous miner has been used infrequently on the surface, where there is a recent variant, the surface drum miner (e.g., Easiminer). The longwall shearer has been proposed for the secondary mining of coal

Table 17.2.7. Classifying Excavating and Bulk Handling Equipment[a]

	Activity		
Objective	Mobile (Cyclic)	Intermediate (Cyclic-Continuous)	Fixed-base (Continuous)
Excavating	*Mobile Loaders* (Grader, Compactor)	*Rotating Excavators* *Integrated Excavators* *Ground Preparation* FEL as Tractor Shovel	*Rapid Excavators* LW (SW)
Load (muck or stockpile)	FEL as LHD or Scoop	*Loaders and Muckers* Cable Scraper	Stacker, Reclaimer
Intermediate Haul (short)	Ramcar S/C	*Mobile Conveyors and Crushers*	Crusher, Bin Chute, Ore-pass, Dump (Feeder)
Bulk Handling	Truck RR Barge Air	Hoist Tramway	*Conveyors* Pipelines

[a] See Table 17.2.6 for makeup of equipment groups and Table 17.2.5 for meaning of abbreviations.
Source: Adler and Lineberry, 1986.

under highwalls (Moomau, Zachar, and Leonard, 1974). Tagline cable scrapers, a surface type, are obsolete, having been replaced by tractor scrapers, but slushers are still widely used underground due to their minimum cost and headroom requirement. Underground conditions are unique in having (1) tighter clearances (i.e., low profiles and restricted opening width) and (2) unusually tough excavating (e.g., hard rock). For surface work, not only are top clearances almost unlimited, making large chassis and long booms possible, but excavating is often easier, occurring in a soil or in a loosely consolidated, blocky, or bedded geologic mass (either naturally occurring or induced by light blasting or ripping). On this basis, equipment types exclusively for surface use consist of only draglines, bucket wheel excavators, and tractor scrapers (secondarily, also dredges, trenchers, stackers, and reclaimers). Equipment intended exclusively for underground use is self-evident: tunnel, raise, and shaft borers.

In excavating, there have been evolutionary trends from fixed-base to mobile and consequently to highly flexible equipment. Continuous processes are also being stressed, while miniaturization has frequently closed the gap between equipment types (e.g., between backhoe and front-end loader). Another trend that affects the classification is hybridization, resulting in many variants, which provides increased versatility but with major compromises. At worst, an equipment type will appear in the classification immediately next to other possible locations. The need for alertness in applying this classification does not diminish its usefulness, and exceptions frequently establish a general rule.

The major advantages of the proposed classification lie in its dense informational content, far exceeding previous ones, and in the many practical insights it gives on the functioning of equipment. Because "form ever follows function" (Sullivan, 1896), numerous clear relationships emerge, yielding considerably more information than all previous classifications. A wide variety of factors, conditions, and trends, ranging from output through diggability to costs, has been offered (Adler and Lineberry, 1986) for each degree of activity (mobile, intermediate, and fixed-base).

17.2.3 EQUIPMENT DESCRIPTION

17.2.3.1. Mine Plant vs. Mine Face Equipment

Before a standard procedure for analyzing and selecting underground mining equipment can be offered, a distinction should be drawn between what is termed mine plant equipment and mine face equipment. From this distinction, it will become clear why mine plant equipment selection and evaluation is more routine than that for mine face equipment. As the understanding of mine face analysis increases, these analyses will become more deterministic. Currently, the best computerized tools for underground production analysis are simulators (e.g., CONSIM, LONGSIM, UGMHS, FLEXMOD), which rely upon the user to vary equipment models and their capabilities when evaluating alternatives. No standard methodology exists for evaluating many pieces of mine face equipment and for selecting from alternative types and models. This is in sharp contrast to the well-developed and standardized procedures for analyzing and selecting mine plant machinery (e.g., conveyor belt, hoists, rail haulage, aerial tramways).

The classification system for mining equipment offered in 17.2.2 forms the basis for this discussion. This system organized equipment on the basis of its objective (excavating vs. handling) and its activity (mobile vs. fixed). A simpler classification system distinguishes underground mining equipment as being either a part of the mine face or of the mine plant. Any equipment used at the physical mine face for removal of material or for near-face transport of mined material can be termed *face equipment.* Equipment used to handle all products of the mine face to its final destination can be classified *as plant equipment.* In addition, plant equipment must provide all the needs of the activities, equipment, and personnel associated with the mine face from a source outside the face. Continuous miners, cutting machines, and loading machines are clear examples of face equipment. Belt conveyors, hoists, and rail haulage equipment are examples of mine plant equipment. Shuttle cars and other mobile bulk handlers can be classified as either mine face or mine plant equipment, although it is accepted that most activity of these devices is concentrated during loading near the face and, therefore, can perhaps best be classified as face equipment.

Generally, face equipment is transitory, that is, it is often switched about from place to place (trammed) and is mobile and impermanent. Another characteristic of face equipment is its high operating cost yet relatively low capital cost. Shuttle cars, scoops, and ramcars are examples of mobile haulage equipment, characterized by good maneuverability, flexibility, relatively low speeds 50 to 100 fps (15 to 30 m/s), and low capacities and production rates. Mobile equipment used in the face area is usually either rubber-tired or crawler-mounted. Rubber-tired vehicles, such as shuttle cars and scoops, are typically used when high speeds are desired and when road conditions are fair to good. Crawler-mounted equipment, such as continuous miners, is used when the terrain is rough or when the bearing capacity of the floor is problematic.

Plant equipment is typically static, fixed, and permanent to semi-permanent. Characterized by low operating cost but high capital cost, it can remain in place for a few months to 20 years or more, often for the life of the mine. Hoist, belt, and rail installations are examples of fixed haulage devices and are characterized by poor maneuverability, inflexibility, relatively high speeds, and high capacity and production rates. Examples of fixed plant equipment include conveyor belts, track haulage systems, and pipelines.

17.2.3.2 Common Components of All Mine Face Equipment and Mine Plant Machinery

MINE FACE EQUIPMENT. Because space is at a premium in underground mining, and because a rapid in-out approach is favored in selecting equipment, mobile equipment is emphasized here.

Mobile Face Excavating Units—Major components of all excavators are (1) a cutting mechanism (drum, borer, shearer); (2) loader or elevator (gathering arms and pan, auger, bucket); (3) conveyor for material transport through the mechanism (chain, flight, push blade); (4) running gear (wheels, crawlers, skids); (5) power supply (usually electric cable); and (6) cab (unless remotely operated). Continuous miners and boring machines are covered here. Selection and evaluation of other rock penetration devices (e.g., drills, shearers, plows) are covered in other sections.

Mobile Face Haulage Units—Major components of mobile face haulage equipment are common to all devices, with differences only in configuration, mechanism, and dimension. These components include (1) box (load-carrying component); (2) running gear (typically, rubber tires); (3) power supply (electric cable, battery, diesel); (4) conveyor (for material discharge); and (5) cab. Differences in construction, application, and limitations are evident in the routine review of the descriptions of shuttle cars, ramcars, and scoops, the three most common underground haulage devices (Lineberry, 1985; Stefanko and Bise, 1983). Front-end loaders and diesel trucks, although common in underground hard-rock applications, are not discussed here but are covered in Chapters 9.4 and 13.3.

MINE PLANT MACHINERY. Major components of mine plant machinery appear to be largely dependent on whether the equipment is mobile or fixed-base (stationary) and whether it is cyclic or continuous. In general, mobile, cyclic plant equipment (e.g., front-end loaders, trucks, rail haulage devices) compares favorably to mobile face haulage devices in regard to both major components and analysis. Mine plant machinery in the intermediate category (see Table 17.2.7) is both cyclic and continuous, yet is more closely akin to cyclic equipment in regard both to major components and to performance analysis. Common to rail haulage and hoisting, both used strictly for bulk handling, is that motive power is provided by an external source (locomotive and hoisting engine, respectively) and that more control is placed on the path of the load-carrying component (rails and shaft guides) than for mobile excavators and intermediate handlers. Fixed-base, continuous excavators, such as the rapid type (borers and reamer augers) and the longwall type, are comparable to mobile excavators in description and analysis, except that these devices have sacrificed mobility and flexibility for continuity of face operation. Fixed-base, continuous base handlers (e.g., conveyors, slurry pipelines) have two common major components: a load carrier (belt, pipeline) and power supplier (drive pulley, booster pump). Performance analysis for these two devices is also quite similar.

17.2.3.3 Common Underground Equipment: Excavators

CONTINUOUS MINING MACHINES. The decade of the 1980s has seen the continuous miner evolve as the most effective excavating tool for underground mining of coal and other friable materials. Because of regulations on underground blasting in coal mines and for reasons of safety and labor intensiveness, mineral extraction with conventional equipment (e.g., drills and cutting machines) is no longer cost effective in many instances.

Longwall mining is the most productive mining method, considered on a tons per employee basis. Longwall mining, however, requires a sizable investment in capital. Furthermore, longwalling must be complemented by continuous miners for entry development. Continuous miners are flexible and economical, being especially suitable for small two to three unit mines. Room and pillar mining, with application in undulating seams, is highly productive in low to high seams.

The three basic types of continuous miners are (1) rotating drum machines and auger miners, (2) boring machines, and (3) roadheaders. Rotating drum machines have evolved as the most productive and universal. Boring and roadheader types are limited to specialized applications. In this section, selection principles for drum-type continuous miners will be emphasized. Analyses of other underground excavators and handlers follow a similar line or reasoning.

Rotating Drum Machines—All manufacturers have concentrated on designs with increased horsepower and weight in order to maximize productivity to meet the economic needs of the underground mining industry. Simultaneously, machine design and development have addressed reliability to maximize availability and subsequent utilization, as well as ease of maintenance to minimize repair time and cost. Figs. 17.2.1 through 17.2.3 show three common drum-type continuous miners in use today.

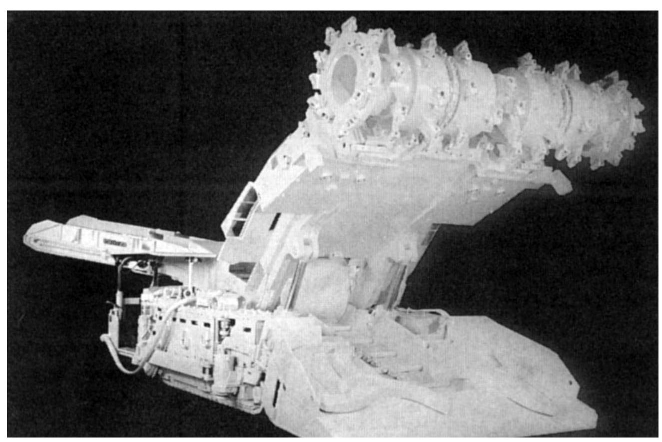

Fig. 17.2.3. Joy Model 12CM12, drum-type continuous miner. (*Courtesy:* Joy Technologies, Inc.)

GEOMETRY OF DESIGN. An aspect of the selection process that must be considered by users is the static design geometry of the miner. A simple static analysis of the physical characteristics of the machine is primary to an understanding of its effect on machine performance. A static diagram (Fig. 17.2.4) can be easily used to determine the sump and shear stability of a given machine, as well as its ability to utilize the full cutting power of the cutter head in applying bit force to break out the material

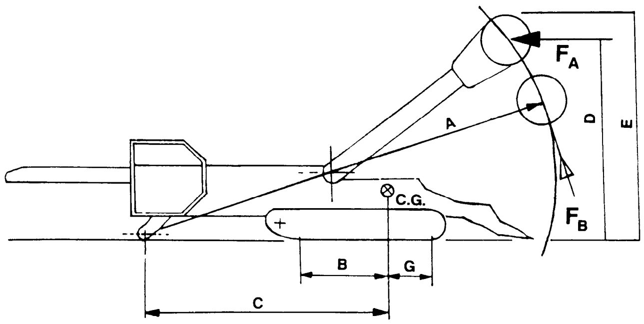

Fig. 17.2.4. Static diagram for typical rotating drum-type continuous miner.

from the solid face. The static elements of the machine must produce a force component F_A that is equal to or greater than the similar component produced by the sump force of the miner, with the sump force being determined by the machine weight and the coefficient of friction of crawler chains on the mine bottom. (The design of the crawler drive system must, of course, provide sufficient tractive effort to exceed this force.)

Concurrently, the static component F_B must be reasonably close to a similar component produced by the cutter head torque. Design expertise is required in this calculation in applying modification factors, such as the efficiency of the cutter head design and the bit force required to break out the material being mined.

SEAM HEIGHT PARAMETER. The flexibility of a continuous miner has a major constraint: the physical height of the machine. Manufacturers, while not having any published standards, generally classify continuous miners into four basic categories, on the basis of coal seam height:

Classification	Seam Height	
Very Low	26 to 30 in.	(0.66–0.76m)
Low	Over 30 to 42 in.	(0.76–1.07m)
Medium	Over 42 to 72 in.	(1.07–1.83m)
High	Over 72 in.	(+ 1.83m)

The only basic criterion for selection by seam height is operating clearance. Two basic factors influence machine selection for a particular seam height: the minimum practical mining height of the miner and its chassis height. In low and very low seams, without undulations, a minimum of 6-in. (150-mm) operating clearance is considered adequate. While more clearance is desirable, machine designs are not available to achieve this. Thus, in medium seams 12 to 15 in. (300 to 380 mm) is the desired operating clearance and 18 to 24 in. (460 to 610 mm) in high seams. This selection by operating clearance is clearly dictated by the economic need to utilize the most productive machine in each application. Tables 17.2.8 through 17.2.10 illustrate the physical specifications of commercially available continuous miners.

PRODUCTIVITY/AVAILABILITY. The economics of operation in parts cost per ton of material produced is an essential factor in the selection of any continuous miner. However, a low operating cost without good productivity will result in low-margin returns on investment. Thus availability and productivity must be carefully considered in the evaluation. The following example illustrates the importance of this comparison.

Example 17.2.1. Machine "A" mines at a rate of productivity of 10 tpm (9 t/m):

a. 1 minute cutting
b. 0.5 minute loading
c. 1 minute wait time
TOTAL: 2.5 minutes

Therefore, productivity is: 10 ÷ 2.5 = 4 tpm

Shift production is 180 minutes × 4 = 720 tons at 100% availability

Annualized productivity is 2 shifts × 5 days × 50 weeks × 720 tons = 360,000 tons.

Today, 93 to 96% availability is the accepted norm. Thus, at 96% availability in this example, the miner would produce 345,600 tons/year.

However, if replaced with miner B with 20% more productivity, utilized 3% less, or 93% availability, the results would be an annual production rate of 401,760 tons, an increase of 56,160 tpy, or additional annualized gross income of approximately $1,291,700 (based on a coal price of $23/ton). Lower availability would reflect higher parts cost per ton:

Parts cost, machine A: 345,600 × 0.30/ton = $103,680

Parts cost, machine B: 401,760 × 0.35/ton = $140,616

Thus the annualized gross income increase from Machine B is reduced to $1,254,700. If a profit margin of $4.00/ton is used, machine B produces $187,700 more profit dollars per year. The principle of miner selection by considering productivity and availability is graphically shown in Fig. 17.2.5.

MINER UTILIZATION. On-board machine operators have the effect of limiting the depth of a continuous miner's advance to 20 ft (6 m) or less, depending on roof conditions. Operation by remote (radio) control extends the potential depth of cut to 40 ft 12 m). Place-changing time is thereby reduced by approximately 50%, allowing increased utilization of the miner in cutting and therefore increasing productivity.

Two methods of on-board ventilation are available to dilute methane and reduce respirable dust concentrations in the working place with the deep-cut application.

On-board Dust Collectors—An electrically driven fan connected to a machine-mounted ducting system picks up the dust at the cutter head. It is then exhausted and collected on a filter screen. Downstream, a de-mister, mounted in the ductwork, separates the water from the air, allowing clean dry air to be exhausted at the rear of the miner. The criterion for efficient operation of dust collectors is that they must be used with blowing face ventilation. A typical dust collector arrangement is shown in Fig. 17.2.6. Fig. 17.2.7 shows its actual position on a continuous miner.

Fan Sprays—A second system is the Foster-Miller type of fan spray. This system increases the flow of incoming air, in combination with an increased number of water sprays that effectively control dust and increase the airflow sweeping across the face, thus permitting the use of deep cuts.

LONGWALL DEVELOPMENT. Contrary to room and pillar production openings, longwall development headings are normally driven as narrow as possible, consistent with accommodating face end equipment, ventilation requirements, etc. This introduces several disadvantages for continuous mining, such as inefficient two-pass operation, difficulty of place changing in more restricted space, and limitations on haulage equipment. The haulage system is also affected by the tendency to locate crosscuts on longer centers. This extends haulage times.

As a result, a different approach to these productivity contraints is occurring. Modern higher-powered continuous miners have no difficulty in cutting the full width of the heading (15 to 16 ft, or 4.6 to 4.9 m) in one pass. In addition to the obvious advantage of increased efficiency, single-pass mining ensures a consistent width of entry and makes it easier to maintain straighter roadways.

On the other hand, place changing with a full-width auger, even with pull-ins, can be difficult and, therefore, interest in roof bolting off the miner has increased. Early development in 1976

placed the bolters immediately in front of the operator's pit. Today the bolts can be placed within 11 ft (3.4 m) of the face.

By bolting off the machine, place changing can be virtually eliminated. However, production must stop while bolting takes place. This is obviously not achieving the aim of making "contin-

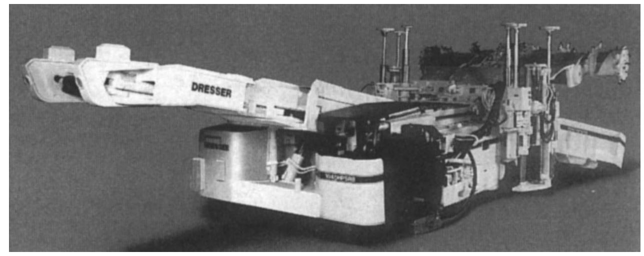

Fig. 17.2.8. Shuttle bolter. (*Courtesy:* Dresser Industries, Inc.)

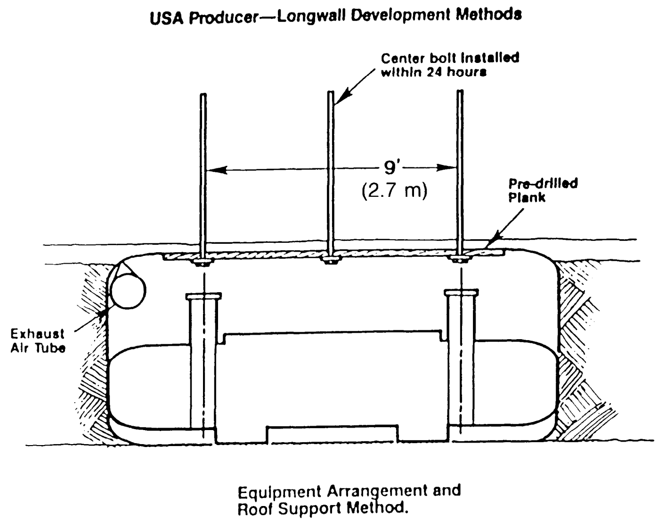

Fig. 17.2.9. Bolting plan for shuttle bolter.

uous" miners more continuous, so a new development became necessary. This is the shuttle bolter (Fig. 17.2.8).

Basically, the mining and bolting functions are separated, although the latter is powered from the miner. The bolters are mounted on a bridge structure that straddles the miner. This frees the machine to mine continuously while bolting takes place.

The shuttle bolter eliminates the dead time generated when the fixed bolting machine stops mining to complete the bolting cycle. This should allow approximately a 33% increase in productivity.

Where possible, the distance between crosscuts in longwall entries should be maximized. This, of course, introduces haulage constraints, and thus there has been a keen interest in continuous haulage systems that can operate in narrow entries. This equipment eliminates the change-over time in the entry. However, these systems do require excessive time to establish and to negotiate a place change. This system, integrating the mining and roof bolting operations and utilizing continuous haulage, shows potential as a highly productive system for longwall development. It greatly reduces lost time by moving the machine out of the place to allow the roof to be bolted. The bolters set two bolts, approximately 9 ft (2.7 m) apart, and utilize roof planks to support the roof. While not universally applicable due to variations in roof conditions, they have proved very effective in increasing the rate of entry development (Fig. 17.2.9). Further increases in the rate of development can be achieved with the use of continuous haulage to support the system. Fig. 17.2.10 illustrates a typical development plan.

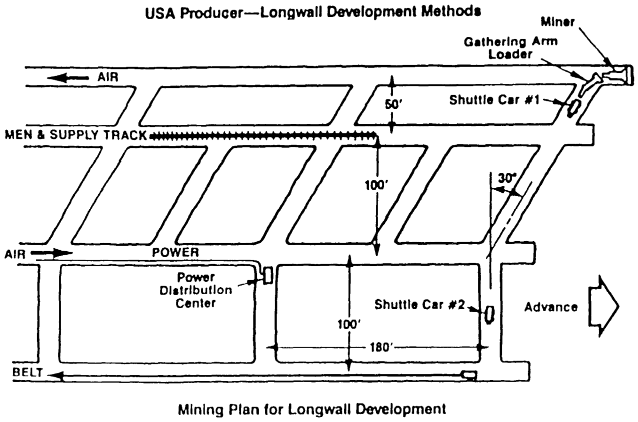

Fig. 17.2.10. Typical development plan for rapid longwall development, with use of continuous face haulage. Conversion factor: 1 ft = 0.3048 m.

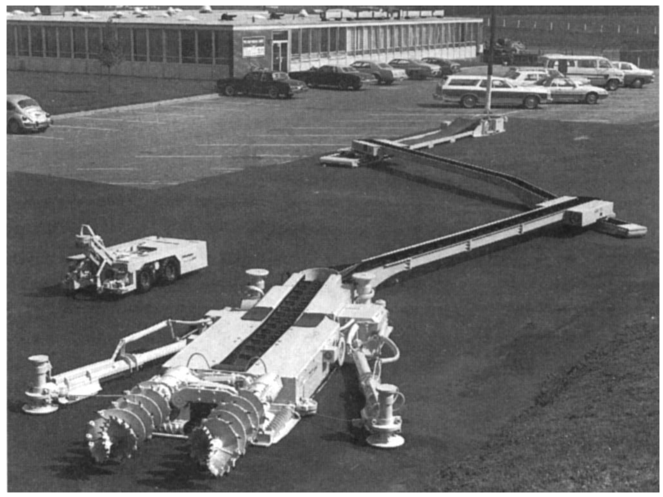

Fig. 17.2.12. Auger miner with hydraulic jack extensions. (*Courtesy:* Fairchild International.)

Continuous miners have now been developed into extremely productive machines. Place change time and haulage support systems are the limitations to further increases in productivity.

AUGER MINERS. One of the major mechanical design problems in the past has been packaging auger-type continuous mining machines into low-seam models. The result has been that, for a particular model, the high-pedestal mounting for thicker seams has resulted in a very good machine, but the low-seam models have been far less satisfactory. Originally, this model was developed by removing the cutter bar from a shortwall cutter, a type of cutter now obsolete, and by adding two cutter augers and a conveyor. The twin-cutting augers have an effective cutting depth of 5 ft (1.5 m) and are available with diameters of 20, 24, and 28 in. (508, 610, and 711 mm), to provide maximum mining heights of 30, 34, and 41 in. (762, 864, and 1041 mm) respectively, and can be lowered and raised at will.

In operation, the auger miner is positioned at the side of the heading with both augers at floor level. The rib-side auger is raised, and the machine is sumped into the face. The rib-side auger is then lowered and the other auger raised, and the machine is hauled across the face by ropes in the same manner as the shortwall cutter. A gathering conveyor, consisting of a single-strand chain with cast-steel flights, gathers the loose coal from between the augers and delivers it to the rear of the machine, where it is discharged into a bridge conveyor. A modern auger miner is shown in Fig. 17.2.11.

One of the undesirable features of an auger miner is that the jacks around which the ropes pull the machine across the face must be moved by the helper to maintain a cutting capability. This has resulted in a high incidence of accidents. To reduce the exposure of the helper to such accidents, a recent modification has been made to the machine. Two heavy-duty pivot jacks are frequently are mounted at its rear corners. The miner is moved with these jacks in conjunction with the anchor jacks and the ropes normally used. The difference is that the two anchor jacks are installed on each rib before the machine begins cutting. They remain stationary, the necessary maneuvering of the machine into and across the face being assisted by the pivot jacks. Among the advantages claimed for this mode of operation is that time-consuming sumping is eliminated; face workers to set jacks are not required, cutting down on exposure to hazards; and permanent roof supports can be set closer to the face, leading to greater safety and a need for fewer temporary supports and less labor. Finally, it is claimed that the semicircular coal face created by the auger miner offers better roof support and ventilation, although this is subject to question. The most recent modification uses hydraulic jack extensions for the pull ropes (Fig. 17.2.12).

TUNNEL BORING MACHINES. Full-face tunnel borers (Fig. 17.2.13) for a range of rock hardnesses are made by relatively few companies; the experience and expertise required to design and build such machines is considerable. Almost all those made are designed to match ground characteristics at specific projects, although machines have been reconditioned and sometimes modified after completing a task and used again. Boring machines are also available for shaft and raise driving.

The success of a TBM is highly dependent on the extent and accuracy of the ground investigations prior to design. The advances made in recent years in geotechnical sciences have contributed greatly to the increasing applicability of tunnel borers in mining and civil engineering works (Chapter 22.1). Considerable delays and increased costs can occur if there are, for example, unexpected fault zones, especially when filled with clay or water; wide variations in rock strength, toughness, abrasive-

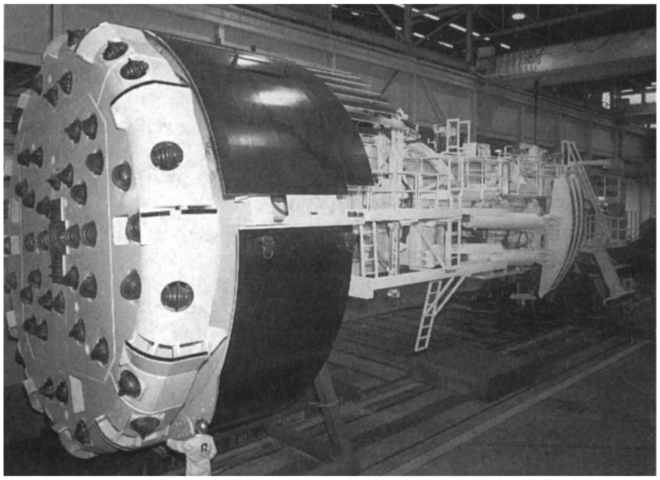

Fig. 17.2.13. A 27.9-ft (8.5-m) diameter hard-rock tunnel boring machine. (*Courtesy:* Robbins Co.)

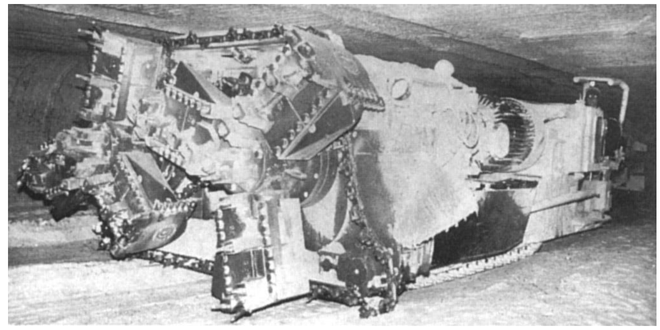

Fig. 17.2.14. Two-rotor boring miner. (*Courtesy:* EIMCO Coal Machinery Inc.)

ness, hardness, jointing, or lamination; or rapidly squeezing ground that may close onto the machine. Jointed and fractured formations may allow considerable improvement in boring rates compared with unfractured rock, but samples selected for testing purposes are often unfractured. Evaluation of this effect is, therefore, difficult and the many formulas proposed often provide widely differing results and thus are not presented here.

In brittle rocks, fractures may propagate rapidly from a high stress point if there are no inhibiting cracks or transverse platey minerals; in softer rocks that fail elastically after deformation, the pressure from a cutter may be released before a chip can form. Thus, for brittle rocks, high speeds would be preferred, but for softer rocks, low speeds and high torques are used. For minimum cutter costs, the cutter diameter, the cutter-ring cross section, and the cutter edge thickness should all be substantial. The hardness of the cutter edge is a compromise between abrasion resistance and toughness. Rotation speed must allow a balance between penetration rate and shock loading, especially in blocky ground. Increased cutter spacing results in reduced cutter costs and increased penetration, but too great a spacing will not allow a chip to be liberated by the cutter's shearing action, and grooving will occur.

Greater understanding of these complex variables over the last decade has led to considerable improvements in penetration rates and cutter costs, although the rate of improvement has shown some decrease. During boring operations, the front housing supporting the rotating head mechanism of the TBM must be held rigidly against the tunnel walls. After each complete stroke, the housing must be released to move it forward. The methods used to clamp the machine take several differing forms.

Mechanically positioned supports are fitted to stabilize the cutting head. These are adjustable to take account of gage cutter wear. On all these machines, steering is aided, normally with a laser target.

The choice between a roadheader or a TBM for development works is influenced by a number of factors. Favoring roadheaders are tasks involving roadways with changing cross sections, directions, or gradients, and where the lengths to be driven are relatively short (< 6600 ft or 2000 m). When access to the face is required for exploratory drilling, grouting, or drilling and when blasting through very hard strata, roadheaders present no problem. Rock compressive strength should not exceed 22,000 psi (152 MPa), although manufacturers stress that other important factors are tensile strength, abrasivity, cementation, lamination, jointing, and water content (which can increase the abrasive effect in siliceous rocks). The wear rate on the cutters may be a crucial cost factor, and pick manufacturers can usually conduct laboratory tests and advise accordingly. Tunnel boring machines are best employed for drivages in excess of about 10,000 ft (3000 m), when the required diameter is between 5 ft to 40 ft (1.5 to 12 m), and when the rock compressive strength is below about 40,000 psi (276 MPa). The best ground for TBMs is sedimentary, with bedding planes and jointing, and with good fracturing capability. Water inflow should be low and ground treatment unnecessary. Grades should be below ± 10° and curves less than radius, although there are special designs capable of tackling steeper gradients and tighter curves. (45° inclines and 100-ft [300-m] curves have been achieved.)

Tunnel boring machines will normally achieve increased advance rates than roadheaders in comparable conditions. Achievements reported from a variety of sources indicate speeds of advance for roadheaders between 50 to 275 ft (15 to 84 m) per week and with TBMs between 165 to 650 ft (50 to 200 m) per week. Thus, for about eight times the capital cost, depending on sizes and ancillaries, a doubling of advance rate is achievable. Because time costs money, as in many main mine development projects, this increased cost will often be well justified. The results achieved with either type of machine, however, will be influenced very strongly by the adequacy of the waste handling system, whether conveyor or rail car, by the efficiency of the supporting method, and by the competency of the project management team. These are always essential ingredients for project success.

BORING MINERS. As an alternative to ripper machines in coal and soft rock, boring-type machines were introduced almost at the same time. These machines have rotating arms equipped with bits that "bore" out the mineral product, hence the name.

The boring miner, as shown in Fig. 17.2.14, has a cutting chain on the bottom that creates a flat working bottom and an upper trimming chain, which, together with the boring arms, produce a roof configuration that is an arched or ovaloidal opening. The arms, which revolve relatively slowly, produce a much coarser product than does the rotating drum miner, minimizing gas and dust problems. Since cutting is accomplished by advancing the machine on its cats, it is very difficult to roof bolt and cut simultaneously with it, although drills have been mounted on telescopic devices and slide carriages on the machine with varying degrees of success. The greatest disadvantage of the machine is its great bulk; it occupies almost the entire entry. Although the extreme tips of the arms usually can be extended

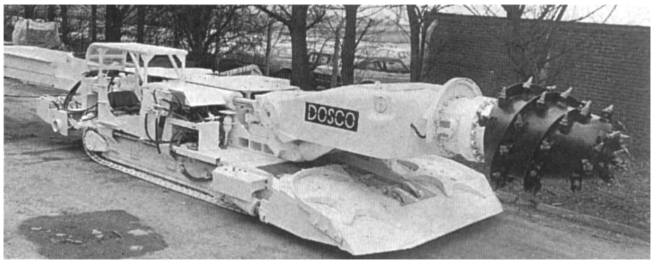

Fig. 17.2.15. Typical roadheader for use in coal or soft rock. (*Courtesy:* Dosco Corp.)

or contracted hydraulically over certain limits to provide some machine clearance during tramming, this generally is insufficient to allow very fast movements. Where the top and bottom have a tendency to converge, the machine can easily become wedged and, therefore, cannot be employed. Also the machine's bulk makes it difficult to keep the face ventilated. Because of these severe disadvantages, borers are rarely employed in mines today, except for occasional development work.

ROADHEADERS. Primarily intended for hard-rock mining and arched-roof profiles, roadheaders (Fig. 17.2.15) can mine materials that are harder to cut than continuous miners, although at a reduced productivity rate.

Roadheaders, originally built for coal and for relatively soft rocks, incorporate the cutter drive motor in the boom structure, which can be slewed by a rack and pinion. Machines that are built now, for high outputs in strata with compressive strengths up to 20,000 psi (138 MPa), have very strong, box-type booms that are hydraulically raised and swung. The power and the weight of the largest machines have increased dramatically over the past few years. The production obtainable has created a growing interest in the use of these machines for stoping operations (e.g., in borate and copper ores in the United States).

The slewing force on a transverse head is at right angles to the circumferential force, and the reaction is countered directly by the mass of the machine. When sumping, the direction of cut is the same as the circumferential force, and a large forward thrust is necessary. Several repeated cutting procedures may be required in all but the softest ground, pushing forward on crawler tracks to obtain sump depth that at most is about two-thirds of the head diameter. To obtain a clean final profile, irregularities on the roof and sides may need to be removed after moving back on the tracks. Sometimes the required profile is best obtained by the use of a telescopic and/or articulated boom. Movement of the head when excavating is, as far as possible, vertical.

With in-line heads, circumferential forces and slewing forces act in the same plane across the face. The reacting force will result in a sideways thrust, which with light machines, may need counteracting by bracing jacks. This is not a serious problem with heavyweight models, particularly those with wide gathering aprons and tracks, unless the floor is wet and slippery. Sumping requires less forward thrust compared with transverse heads, and any area of the face can be selected for the first cut, enabling weaker beds or lenses to be selected. The sump depth can equal the length of the head, although lesser depths may be selected when the ground is strong.

The sumping thrust available varies according to the machine weight, the gradient, and the floor conditions. Sumping thrust may be expressed as some fraction of the tractive effort available at the tracks, perhaps between 25% to 75%. Very few machines have telescopic booms, but these can exert an alternative means of applying sumping thrust, up to 20 tons (18 t), with the machine stationary, without respect to floor conditions, and, if necessary, spragged to the sides of the floor.

The design of in-line cutterheads shows considerable variation. Some are relatively short with closely spaced picks; others have long, conical, spiral vane heads, which are designed to ensure that a high number of picks are in contact with the rock and that vibration is minimized. The spiral vanes transfer the debris towards the gathering apron.

Pick speeds may vary between 200 and 680 fpm (1.0 and 3.5 m/s), the higher values tending to be employed for transverse cutters and for softer rocks. In harder ground, excessive pick speed usually results in high pick wear rates, increased dust generation, and, important in gassy mines, more risk of sparking. The most effective parameters are high forces and low speeds, provided the machine maintains stability. Some manufacturers offer alternative speeds, either by variable-speed motors or by gear changing.

Picks are generally point-attack conical types, especially in harder rocks, although chisel- or pentaprismic-shaped picks can be used. Angles and spacings for the picks are assessed by manufacturers to suit particular rock conditions, but modifications often have to be made after trials to achieve optimum speeds and pick life, especially on new projects. Contact pressure and torque increase with rock hardness.

Selection for any particular task is influenced by the power and weight, as determined by the type of ground and the output required. The robustness (ruggedness) of the machines and the engineering skills employed are also important factors, as are the availability of service and spares. Some general items stressed are the need for crawler tracks built for low ground pressure and high tramming speeds (similar to those on heavy-duty bulldozers) and hydraulics with a reasonably low pressure, preferably with gear-type pumps, especially if nonflammable fluid must be used. Easy changes of pick types and speeds are often important in variable ground or new projects. Debris handling might be by gathering arms onto a chain conveyor or by rakes or flight chains collecting from each side of a wide apron. The latter types are intended for advancing along the centerline of the tunnel, enabling the apron to extend the full road width and to hold debris during cutting operations. This makes possible accurate directional alignment and facilitates the provision of ancillaries such as a bridge conveyor, mechanized support, and dust extraction systems. However, widths must be above about 13 ft (4 m) and cannot vary during the job without machine modification.

17.2.3.4 Common Underground Equipment: Haulage Systems

Because face haulage systems for usual mining situations are relatively straightforward, both in equipment description and in terms of equipment selection and analysis (refer to Chapters 8.3 and 9.3), discussion here is limited to issues related to thin-seam mining of coal, which will assuredly receive increased attention in the future.

While the major changes have been made in underground excavation systems, face haulage has not been ignored, especially for underground coal mines. It is recognized that the capacity of the face-haulage vehicle is the major factor. Increased capacity reduces the number of change-outs and thus reduces lost production time. Commensurately, the higher-capacity vehicle takes longer to fill, allowing more time for the second or third vehicle to return from the dump point and be available for change-out.

As a result, there has been increased interest in battery- and diesel-powered vehicles. In certain conditions, they have been shown to have significant advantages over cable-powered shuttle cars:

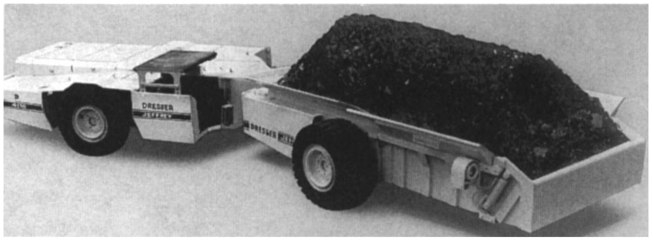

Fig. 17.2.16. Diesel-powered mobile handler. (*Courtesy:* Dresser Industries, Inc.)

1. Articulated design allows higher capacity within specific roadway dimensions.

2. Elimination of trailing cable allows use of three vehicles to reduce delays in change-out and provides more flexibility.

3. Better visibility is achieved for higher tram speeds. A diesel-powered ramcar is shown in Fig. 17.2.16.

Articulated vehicles do have the potential disadvantage of a three-point turn at the dump point, but this is offset by the much higher rate of material discharge. In addition, battery recharging or diesel maintenance are more onerous than cable-reel shuttle car maintenance. However, these requirements can be met off-shift and need not limit productivity. In addition, the shuttle car does have downtime from cable damage.

Example 17.2.2. In order to compare haulage vehicles, assume operation in a 6-ft (1.8-m) seam with 18-ft (5.5-m) wide entries in panels with 100- by 40-ft (30- by 12-m) centers. With 83-lb/ft^3 (1330-kg/m^3) material, an advance of 4.48 tons/ft (14.7 t/m) is obtained. It is also assumed that the continuous miner loads at 13 tpm (12 t/min), and the average load in a shuttle car and articulated vehicle is 6.5 tons (5.9 t) and 8.5 tons (7.7 t), respectively.

With respect to vehicle delays, it is assumed that all vehicles average 0.33 minutes to change-out behind the miner. Where shuttle cars are used, experience shows that, on average, there are "other delays" of 1 minute/car/load due to slowness in the trip to and from the dump point. Time studies show "other delays" of 0.6 minutes for two articulated vehicles and zero in the case of three vehicles, which shows the advantage of multiple haulage unit usage. A summation of time elements in a typical face haulage cycle is as follows:

Type of Vehicle	Two Shuttle Cars (min)	Two Articulated Vehicles (min)	Three Articulated Vehicles (min)
Loading Time Per Car	0.5	0.65	0.65
Change-Over in Entry	0.4	0.4	0.4
Other Vehicle Delays	1.0	0.6	0.0
Cycle Time	1.9	1.65	1.05
Vehicle Capacity (tons)	6.5	8.5	8.5
(t)	5.9	7.7	7.7
Mining Rate (tpm)	3.42	5.15	8.10
(t/min)	3.10	4.67	7.35

The above analysis is intended to be a relative one. Obviously, local conditions will modify performance, but the potential improvement in production with three vehicles is too large to ignore.

CONTINUOUS CONVEYOR HAULAGE. Continuous conveyor haulage has been widely used behind continuous miners for many years, although, until recently, its use has been largely confined to thinner seams. Below 36 in. (900 mm), the shuttle car becomes very inefficient because ground clearance requirements, particularly in rolling seams, limit capacity.

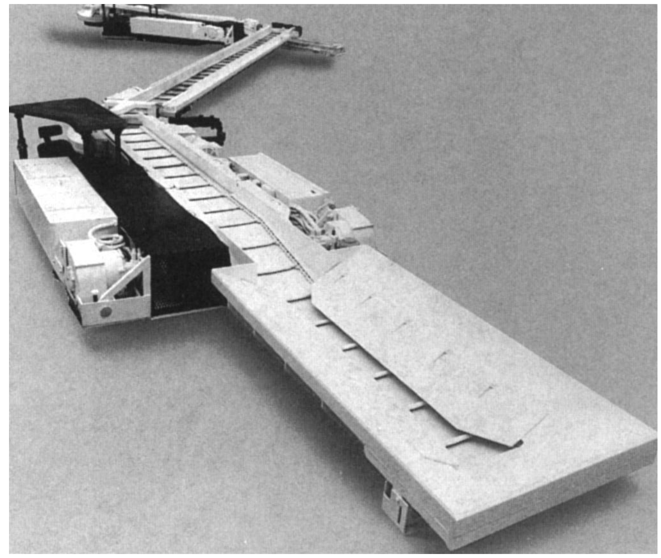

Fig. 17.2.17. Disconnected haulage system with surge hopper.

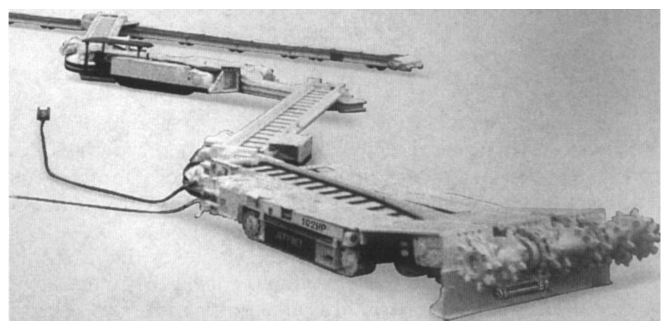

Fig. 17.2.18. Low-seam continuous haulage system. (*Courtesy:* Dresser Industries, Inc.)

Additionally, mining in these low seams is largely uneconomic unless entries of 18 ft (5.5 m) or more are maintained. This is the point at which cascading-type chain conveyor systems become practical, with component lengths of up to 30 ft (9.1 m). These systems comprise caterpillar-tracked mobile bridge carrier (MBC) units connected by simple bridge conveyors, which provide a degree of flexibility by riding along the receiving end of the MBC.

In the lowest seams, a swan-neck bridge conveyor is attached to the end of the continuous miner conveyor because there is not normally sufficient clearance for the miner conveyor to feed directly into the MBC. As seam height increases, a disconnected system is adopted. The miner conveyor feeds into an MBC with a limited capacity receiving hopper. This accommodates the surges that start to become more significant as the tonnage mined in the shear-down part of the cycle increases. The disconnected system provides increased length and flexibility (Fig. 17.2.17).

Low-seam systems, such as the one shown in Fig. 17.2.18, have capacities of 6 to 8 tpm (5.4 to 7.2 t/min), while seam installations can handle up to 13 tpm (11.7 t/min), with increased conveyor widths and sideboards (Fig. 17.2.19).

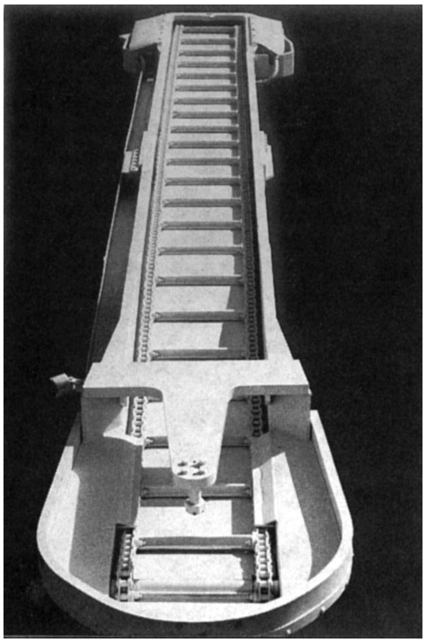

Fig. 17.2.19. High-capacity bridge carrier (*Courtesy:* Long Airdox Company)

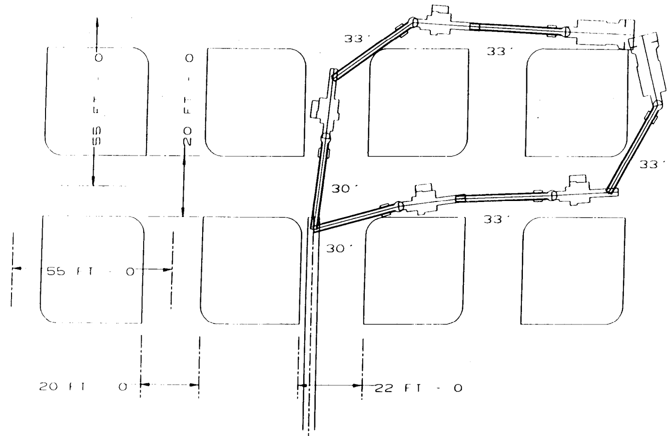

Fig. 17.2.20. Continuous haulage development plan. Conversion factor: 1 ft = 0.3048 m.

In higher seams, wider conveyors become a problem, as roadways tend to decrease in width. In addition, the mining rates on shear-down again overcome conveyor capacity, resulting in spillage or a need for operator restraint that is seldom maintained.

Despite doubts about reliability and efficiency that can only be obviated by industrial use, continuous conveyor haulage obviously offers a productivity improvement over rubber-tired haulage vehicles with their intermittent operation. However, there are significant trade-offs that must be evaluated:

1. Continuous haulage systems contain many more components than haulage vehicles and can be more prone to breakdown.
2. Conveyor breakdowns completely stop production, while rubber-tired haulage can still produce 60% of normal production with one of two cars available.
3. Entries have to be established and conveyor installed equivalent to the length of the continuous haulage system before operation. This is to accommodate retraction of the system during place changing.
4. Place changing of the continuous miner requires movement of the haulage system, which adds to the time taken and provides opportunities for further delays.

A typical continuous haulage development plan is shown in Fig. 17.2.20. Tables 17.2.11 and 17.2.12 give specifications for mobile bridge carriers and bridge conveyors, respectively. Table 17.2.13 illustrates a typical selection procedure for a recent continuous conveyor haulage system installation.

17.2.3.5 Common Underground Equipment: Face Preparation

To avoid repetition, face preparation by cutting machine is the only pre-extraction activity treated here. Face drilling for relief (e.g., presplitting) is covered in Chapter 9.2. Also omitted are the mechanics of rock penetration and treatment of drilling machines (Chapter 9.1), since drilling is more appropriately termed a production operation than true underground mine development.

CUTTING MACHINE. Drilling and blasting—the drilling of holes at the face in a certain pattern, the placement of explosives in them, and the subsequent blasting to fragment rock, coal, and ore—is conventionally practiced as an alternative to continuous mining. However, this method of fragmentation, called shooting from the solid, although practiced in nearly all hard-rock mining, tunneling, and similar construction operations, is frequently restricted by law in coal mining. It is both potentially dangerous and very inefficient. It requires the drilling of a large number of holes and the use of a sizable amount of explosives. Also there is a chance that the explosive may blow out of the hole during blasting, even if it is properly stemmed, igniting the coal dust and gas usually present and creating a serious explosion and fire hazard. Finally, the large amount of explosives required may result in roof damage from blasting vibration and shock.

Therefore, all coal seams using conventional mining processes should first be cut, a term unique to the mining of coal and other sedimentary mineral deposits such as salt and potash and the quarrying of dimension stone. This is accomplished by a coal cutter (Fig. 17.2.21), which is basically a giant chain saw. The cutter bar is generally 9 to 11 ft (2.7 to 3.4 m) long and equipped with bits to cut a 6-in. (150-mm) kerf. Most cutting machines are rubber-tired for mobility and are "universal," in that the cutter bar can be positioned to cut vertically or horizontally at an infinite number of planes. For low coal with a seam thickness no greater than about 5 ft (1.5 m), a horizontal slot is cut at the bottom. This provides a free face toward which the explosives in the single top row of holes can break the coal. A thicker seam requires two rows of holes for a bottom cut, but will be better fragmented if a shear (vertical) cut is also employed. While placing a horizontal cut at the roof line (top cutting) reduces vibrations in the roof from blasting and perhaps improves roof control, it is not often done because the ragged bottom that results hinders loading.

17.2.4 BASIC ANALYSIS FOR EXCAVATING AND BULK HANDLING

A fairly complex analysis has been offered (Adler, 1984) for selecting or evaluating a piece of excavating and bulk handling

Table 17.2.11. Range of Specifications for Mobile Bridge Carriers

equipment and for predicting its performance. At present, there is little agreement as to what specific points should be considered, and even less on what procedure to follow. Both of these are covered here in a consistent and direct form. The analysis applies to all types and sizes of equipment, from continuous miners to front-end loaders to shuttle cars. Because so many equipment types can be identified, and because of the complexity of providing detailed examples of all variants of the many analyses that constitute selection and evaluation of underground mining equipment, this basic procedure is preferred. If followed, this standard procedure serves well for the analysis of all mining equipment, both now and in the future.

The importance of equipment characteristics, job activities, and work conditions are stressed, and separate analytical stems are established in a flow chart for these factors. They are combined, using suitability tests, in the following steps: (1) problem statement, (2) natural conditions, (3) suitability guidelines, (4) appropriate equipment types, (5) operational activities, (6) encumbered space, (7) geometric design, (8) equipment sizing, (9) failure and limits, (10) performance and consumption, (11) public policy checks, and (12) costs and profitability. Public policy and economics, while considered throughout, receive emphasis toward the end. The procedure is iterative, containing distinct feedback loops. Of value is the lack of the need for hundreds of rules, formulas, variants, and exceptions for analysis in what is recognized as both a complicated yet essential area of mining engineering.

The purpose of this discussion is to describe a procedure for determining the *performance* of excavating and bulk handling equipment that is comprehensive, concise, and systematic. The procedure itself can be adopted as a standard and at least will provide a checklist of concerns. In doing so, the safe and efficient use of equipment is promoted.

The importance of excavating and bulk handling equipment in mining has already been established. This activity accounts for at least 50% of total direct costs, and perhaps for as many as 30% of all accidents. Of the several systems employed in mining, excavating and handling is the most important and sets the pace for all others. Recently, there has been an increased introduction of innovative types of equipment from manufacturers, some having a large and immediate impact. The number of types of excavating and bulk handling equipment is already prodigious, and their sizes vary vastly. This proposed analysis will be applicable to all types and sizes, and the approach developed should be of value to all professionals concerned with equipment application. The analysis relies heavily on the engineering sciences, and the procedure, while focusing on the excavating and bulk handling system, does consider the surrounding total systems context (see 17.2.1.).

Table 17.2.13. Selection Procedure for Conveyor System, Model 5010-HP-L System

Seam Height:	52 in.
Sump Speed:	8 fpm
Sump Depth:	26 in. = 2.16 ft
Miner Head Width:	10 ft 6 in.
Miner Head Diameter:	33 in.
Shear Rate:	12 fpm
Sump Volume:	62.56 ft^3
Shear Height:	52 in. − 33 in. = 19 in. = 1.58 ft.
Shear Volume:	36.02 ft^3
Coal (Solid):	80 lb/ft^3
Coal (Broken):	50 lb/ft^3
Run of Mine (Solid):	90 lb/ft^3
Run of Mine (Broken):	60 lb/ft^3
Percent Reject:	32%

Cycle Times (for 52-in. coal seam)

Sump	= 2.16 ft @ 8 fpm = 0.27 min
Shear	= 1.58 ft @ 12 fpm = 0.13 min
Rev. Cut Cusp	= 1 ft @ 30 fpm = 0.03 min
Tram to Face, Raise	= 3 ft @ 30 fpm = 0.10 min
TOTAL CYCLE TIME	= 0.53 min

Material Removed Per Cycle

$$\text{Sump} = \frac{62.56\ \text{ft}^3 \times 90\ \text{lb/ft}^3}{2{,}000\ \text{lb/ton}} = 2.81\ \text{tons}$$

$$\text{Shear} = \frac{36.02\ \text{ft}^3 \times 90\ \text{lb/ft}^3}{2{,}000\ \text{lb/ton}} = 1.62\ \text{tons}$$

Rate of Coal Removal Per Cycle

Sump = 2.81 tons/0.27 min = 10.4 tpm
Shear = 1.62 tons/0.13 min = 12.4 tpm

Capacity of "Wide-5010" at 439 ft^3/min

$$= \frac{439\ \text{ft}^3/\text{min} \times 60\ \text{lb/ft}^3}{2{,}000\ \text{lb/ton}}$$
$$= 13.1\ \text{tpm}$$

$$\text{Continuous Duty Cycle} = \frac{2.81\ \text{tons} + 1.62\ \text{tons}}{0.53\ \text{min}} = 8.58\ \text{tpm}$$

Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 lb = 0.4536 kg, 1 ton = 0.9072 t.

All disciplines require a standardized, well-established approach to solve their particular problems. Structural analysis, for example, requires specification of the loads, material properties, and structural geometries to determine stresses. Although arguably more complex, a comparable approach is proposed for excavating and bulk handling.

17.2.4.1 Requisites for Basic Analysis

MAIN STEMS. To determine the performance of a given piece of equipment, three necessary and sufficient requirements must be described: (1) *work conditions,* (2) *activities,* and (3) *equipment characteristics. Work conditions* are the broad encompassing factors associated with a work site, including, among others, diggability, available space, the haulway surface, and human factors. *Activities* are the movements or motions prescribed by the operation and cover such aspects as loading, hauling, and dumping. *Equipment characteristics* describe the tool or instrument required to do the job. Mining equipment is routinely described in manufacturers' specifications by capacities, weights, dimensions, and power. Merging all of these aspects together through *suitability tests* enables the performance rate—the heart of the analysis—to be determined. This yields the time it takes to accomplish the specific job. For excavating and bulk handling, the job is usually production, the rate of mining or moving material, termed *loose mean output* (LMO), in units of tons (tonnes) per hour.

PROBLEM STATEMENT. Problem formulation must be as definite and concise as possible. A statement that lacks clarity leads to vague, muddled, and even inconclusive analysis. Two basic types of problems can be distinguished: (1) an evaluation when the equipment has already been given and (2) a selection of the equipment when the conditions are provided. Combinations are also possible, and in all cases, performance assessment is the most critical analysis. When the performance rate is specified, along with the conditions, an indirect approach is necessary, with a trial selection of equipment in order. Successive approximations using additional trial selections are executed until adequate agreement is reached between the desired and calculated performance rates. If the equipment is already available, and if the site conditions can be altered, performance rates at each of their altered states are found until agreement is reached.

Usually, there are a number of alternative choices, exemplified by the choice of several small mobile haulers or one large stationary conveyor. Public policy concerns must then be added to the straight engineering approach, and when the results are adjusted for these, a feasible solution is achieved. The final selection will depend upon company capabilities and expectations. Economically, this is formalized in profitability and cost-benefit analyses.

In any engineering study, it is always useful to avoid serious omissions by checking the *basic engineering dimensions.* These are matter, space, time, people, and money—which correspond loosely to "what?," "where?," "when?," "who?," and "how?" (Anon., 1966). The "why?" is the objective of estimating the performance rate, and the "how?" is the proposed analysis itself (Table 17.2.1).

17.2.4.2 Analyses

The analysis yields the performance rate for a single piece of equipment of a specified type and usually of the largest feasible size. Alternatives would therefore include several units of decreased size as well as other suitable types. The final choice will depend mainly on economics, but also on availability, familiarity, and other intangibles.

TRADITIONAL ANALYSIS. The procedure presently used is exemplified in the duty cycle calculations performed for mobile equipment where the input data are highly selective and limited (Bishop, 1968). Conditions mainly cover the bulk solid density, distances, grades, and rolling resistance factors. Equipment characteristics are only capacity, vehicle weight, and horsepower. Activities are usually lumped into fixed times for loading, dump-

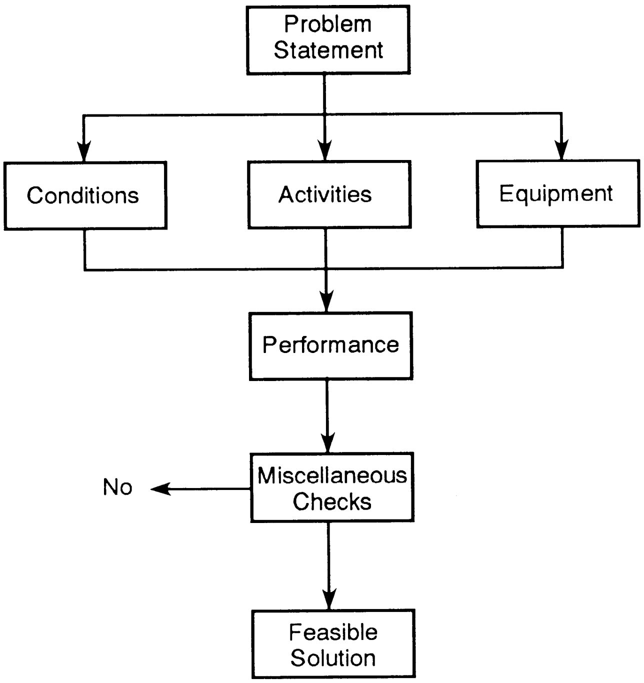

Fig. 17.2.22. Present flow chart for traditional analysis (Adler, 1984).

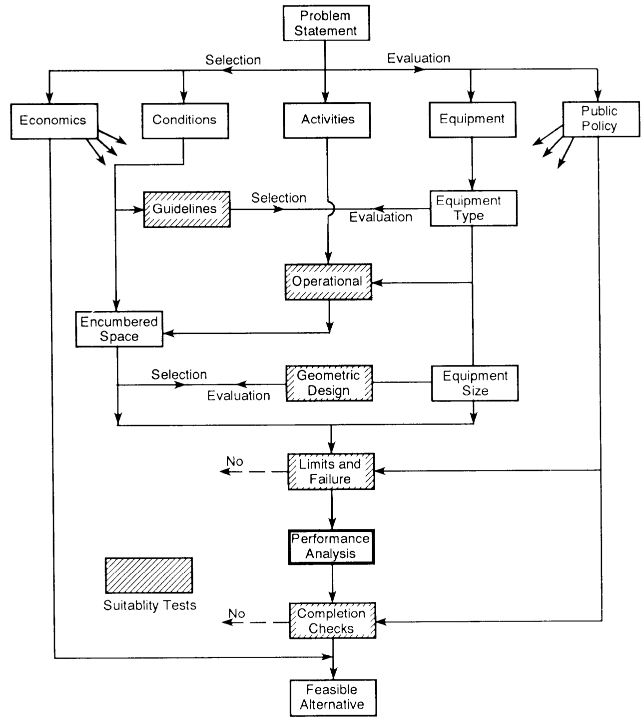

Fig. 17.2.23. Recommended flow chart for basic analysis (Adler, 1984).

ing, manuevering, and waiting. On this basis, the production rate is calculated and various constraints are subsequently invoked on speed limits, traction, and clearances. If any of these are exceeded, the input is varied and the solution reworked. Fig. 17.2.22 illustrates this procedure. It is important to add that this procedure is often valid for a first-order estimate of performance but is insufficient when selecting and operating underground mining equipment, particularly when the value of a single piece of equipment is in the hundreds of thousands of dollars.

The primary deficiency of the traditional, implicit method is its failure to discriminate between the various types of constraints. By lumping these constraints together and considering them only at the end, an inordinate number of iterations may become necessary. This number can be drastically reduced by examining and sorting out the constraints as early as possible, with the use of suitability criteria to yield a systematic flow from the general to the particular. The dependency between the working conditions and suitable equipment types is well established in various *"guidelines."* The spatial dependency between conditions and equipment *size,* which is of most concern in first-order selection and evaluation of mobile excavators and handlers (see 17.2.3.3), can be deliberately attacked in "geometric design." A part of any equipment's activities includes normal operating patterns and motions, which are dependent on the specific equipment *type.* By judiciously employing these suitability criteria at an early stage, the number of iterations is minimized. In addition, specific failure modes and regulations must be carefully evaluated, and, finally, the stage will have been set for a human factors analysis.

PROPOSED ANALYSIS. By establishing the three main stems—conditions, activities, and equipment—the necessary dependent links can be made early in the analysis and the stems systematically grafted and pruned. Fig. 17.2.23 shows the proposed analytical flow chart. It also indicates whether a selection or an evaluation procedure is being performed. For selection, the flow proceeds through conditions to guidelines to determine suitable equipment *types.* From equipment types, the analysis goes unidirectionally to operational activities, which are then added to other activities. The activity stem is then merged with the conditions stem in encumbered space. After this, the analysis proceeds through geometric design to establish the equipment *size.*

Knowing the equipment's type and size, its specifications can then be obtained. Merging encumbered space with the equipment stem is followed by examining limits and failure. The next step is the performance analysis, the focus of the procedure. Performance rate estimation (e.g., LMO), move and setup time, advance rate, clearing rate, bolting time is mainly considered here, but consumption rates are included also. When possible, all adjustments should be made prior to this step.

Additional checks and rechecks are then made, particularly for public policy (especially health and safety regulations), followed by the "completion" phase and human factors analyses. Throughout the procedure, public policy and economic concerns are regularly, but implicitly, dealt with. The final result, including necessary iterations, represents one of several feasible solutions.

17.2.4.3 Data Processing

CONDITIONS. The conditions under which underground equipment is operated can be divided into *natural conditions* and *site conditions* and can be differentiated by material descriptions. The natural and site conditions refer to the virgin state initially encountered in excavating, and then to the site developed for bulk solid handling by excavating, clearing, grading, and ripping. The natural conditions are immutable and therefore constitute independent variables. Of all the major inputs, these are the most complex, and their organization by engineering dimensions (matter, space, and time) is recommended (see 17.2.1.1). Spatially, subregions of uniform properties are established and described by location, size, and shape. Geography, predominately a surface mining concern, covers such material aspects as topography, climate (temperature, atmospheric pressure, precipitation), drainage, cultural features, and legal boundaries. A geologic description (ignoring resource values) concentrates on engineering capabilities, which entail costs. Material properties, predominately an underground mining concern, cover the rock type, geologic structure, fluids, and only peripherally rock pressure and temperature.

For excavating purposes, *properties* include rock density, strength, seismicity, jointing, abrasiveness, and water. These are recast into the extremely valuable job properties category, covering the ability to blast, drill, bore, dig, and rip (Adler and Krishnan, 1983). The bulk solids produced by excavating have unique properties, as will be noted later.

Handling involves moving any bulk solid, usually over a haulway. The haulway can be described in terms of rolling resistance, traction, bearing capacity, and roughness. Water again is significant and can dramatically influence the selection. Spatially, the haulway has various transverse cross sections strategically located along a longitudinal centerline. The centerline profile itself can be described by grades, curves, and distances, which may limit equipment selection. Uniform subregions or sections along the centerline can also be delineated. The properties of bulk solids, which can influence the equipment design, include density, fragment size distribution, fragment shape, friction angles, water content, stickiness, dustiness, leakiness, and friability. Chemical properties affect pollution, cementing, and oxidation and should be considered, although these do not influence the design or selection of handling equipment that contain the bulk solids for relatively short periods.

ACTIVITIES. Information on equipment activities is essential and comes initially from manufacturers. It covers normal vehicle motions and the total systems. (The latter has been extensively treated in 17.2.1.1, the former in 17.2.4.4.) These systems interact, and their impacts on the excavating and bulk handling system are of immediate concern. The ground-control system, for example, constrains with small spans, large support structures, and mobile bolting machines. Life support impedes through its demands for ventilating, water handling, and escape facilities. Normal support introduces impediments of power distribution cables, supply equipment, maintenance, and cleanup, as well as the personnel required to provide these services. Within the excavating and handling system itself, interferences also occur. All systems must be accounted for spatially, and contingencies must be anticipated. An excessive number of impediments represent a hazard.

EQUIPMENT. The numerous types of equipment available have already been inventoried, classified, and broadly described in 17.2.2. The major distinctions are between excavating and handling equipment and also between mobile (cyclic) and fixed (continuous) types. Intermediate equipment types exist, such as load-haul-dump units and rotating excavators. Manufacturers' specifications range from being highly detailed to severely condensed and rarely provide cost data. Each component of the equipment must be systematically addressed and understood. These include the job-end, running gear, power train, chassis, and operator's compartment. For fixed equipment, structural supports, accessories, and monitors require attention. Vital statistics, which relate horsepower to capacities (or to LMO), to dimensions, or to weights are very useful (Adler, 1986; Basu and Lineberry, 1988). It is important to note that it is common practice to customize excavating and handling equipment to meet operators' specifications, particularly for equipment with a value over about US$100,000 and especially in times of intense competitiveness in the minerals industry.

17.2.4.4 Suitability Analyses

GUIDELINES. Guidelines match conditions to equipment types. This information comes from texts, handbooks, periodicals, company files, and personal experience. While sometimes denigrated as "handbook engineering," its role is extremely important for quick and rough solutions, yielding orders of magnitudes and trends. Guidelines do have serious deficiencies, being often vague, incomplete, disorganized, unsubstantiated, and even contradictory. The basis for preference is often implicitly economic and only for normal circumstances. For excavating, tables are available comparing equipment to rock classes and mining methods to broad classes. For handling, there are tables relating equipment type to running surfaces, grades, distances, velocities, and acceleration. Mixed tables exist, covering flexibility, production rates, engineering intensity, site preparation, and costs. While assembling appropriate guidelines, the database can also be strengthened. This base includes values for limits and failure analysis (safety factors, strengths, and speed limits), performance analysis (fill and derating factors, fixed times, and availability), consumption rates, and estimates for equipment life. While it is deemed inappropriate to provide an exhaustive reference list here for such an area requiring broad treatment, the reader is directed to vendors' pocket guidebooks and performance handbooks, texts, and handbooks in the field of civil engineering construction and excavation, underground mining methods handbooks, and earlier editions of this *Handbook.*

EQUIPMENT TYPE. In following the selection procedure through the guidelines or in performing the evaluation procedure, with the equipment itself as the given information, the equipment type has now been established in both cases. A concentrated effort now is necessary to describe functional aspects and especially possible variants. Additional background can be acquired for such items as (1) history of the equipment type's use, (2) applications, (3) comparisons, and especially (4) potential failure modes. Size determination is deferred to geometric design.

OPERATIONAL ACTIVITIES. For each type of equipment, both surface and underground, there are characteristic motions associated with their normal operation. These operational motions, the study of which has been referred to as *operational kinematics,* is another essential ingredient of a successful suitability analysis.

Normal vehicular motions for mobile equipment, largely in the horizontal plane, can be categorized as (1) the I or shuttle pattern (shuttle car), (2) the O or loop pattern (ramcar), (3) the Z or parallel shuttle pattern (bulldozer), and (4) the Y or backup and turn pattern (scoop). Combinations also exist. The job-end motion can also be described as the boom and bucket digs, loads, or dumps. Horizontally, the boom often can swing through a specified arc, and vertically it describes slices or cuts. Vertical cuts can be classed as (1) at-grade (continuous miner), (2) below-grade (dragline), and (3) above-grade (shovel). Combinations again exist. Whether full- or partial-face extraction occurs must also be noted.

For fixed equipment, mostly mine plant machinery, the operational equivalent involves setting up, taking apart, and moving, as the working face advances or retreats (e.g., conveyor belts). This also applies to many support facilities and accessories. Since determination of the operational activities closely describes the equipment operator's job, the operator should be consulted in order to define intangibles such as contingencies, general problem areas, and to provide tips for safety and efficiency. This material, often subjective in nature, can be supported by appropriate field measurements and then converted into engineering terms.

ENCUMBERED SPACE. The cumulative effects that result from merging the conditions and activities is termed encumbered space (see 17.2.1.2). For underground coal mining, the worst-case situation, there is the potential for disaster from a safety viewpoint and the need for a clearer understanding of derating factors for production estimation.

GEOMETRIC DESIGN. The term geometric design derives from highway engineering. Using templates, sections, and layouts on graph paper or, alternatively, computer-aided design packages, equipment can be spatially matched to the encumbered space in which it must operate. If this is not done, equipment can get wedged, suffer glancing blows, and possibly collide. In the selection procedure, this establishes the equipment size; in evaluation, it determines the workplace dimensions.

For velocities of less than about 2 mph (3 km/h), static relationships apply and two concerns exist: to provide *clearances* and *reaches.* Clearances require that special attention be given to turning radii, dumping heights, and boom interference. When shifting or moving equipment between workplaces, clearances again must be considered. Reaches or ranges provide maximum digging and dumping heights (or depths), radii, and swing angles.

When velocities exceed 2 mph (3 km/h), dynamic effects are added to the static ones. Velocity-clearance curves must be considered, along with lines-of-sight for emergency stopping (Lineberry and Adler, 1984).

This analysis will yield a maximum acceptable size of equipment, with a minimum reach. In the selection procedure, the next step is to use the vital statistics (Adler, 1986) to approximately determine the horsepower, capacity, and weight and to pick a particular model. A complete set of individualized manufacturer's specifications then becomes useful. In evaluation, conditions and activities can now be modified to fit the equipment.

LIMITS AND FAILURE. Limits and failure will be treated here in simple terms, ignoring their complex and often progressive nature. Ideally, modes of failure are enumerated, their severity described, and their probability estimated. Although an attempt has been made to accomplish this (Adler, 1989b), limits and failure remain perplexing difficulties within the area of equipment selection and evaluation. Whenever possible, limits and failure should be considered prior to the performance analysis to reduce iterations. Failure falls in three broad categories, consistent with the earlier treatment of the basic engineering dimensions: (1) geometric failure, (2) material failure, and (3) time-related failure. Geometric failure has already been considered in terms of geometric design (see earlier in this section).

Material failure is of varying severity. Modes include (1) rupture and separation (belts, cables), (2) penetration (bearing surface, tires), (3) buckling (booms), and (4) cuts and bruises (belts, tires). In addition, skidding and overturning can be dangerous, and spillage should be avoided. The effects of water are obvious and particularly troublesome in mining.

Time-related failure is more subtle. It includes decreased life, capacity, availability, and performance, as well as increased wear (abrasion), maintenance, and consumption. Most weak spots tend to concentrate wear and then accelerate deterioration, especially for haulways, tires, and belts.

17.2.4.5 Performance Analysis

The performance analysis represents the end-product, providing the rate of doing a specific job. All analytical stems are involved, having first been sorted out and screened for suitability and failure.

TYPES OF PERFORMANCE. Several types of performance exist, the foremost being production rate or *LMO*, in units of tons (tonnes) per hour. Next in importance is the advance rate, in units of feet (or meters) per shift, which also corresponds to the penetration rate for boring. The advance rate is convertible to production by:

$$LMO = AR \times \rho \times SF \times A \times F \qquad (17.2.1)$$

where *LMO* is loose mean output in tons per hour, *AR* is advance rate in feet (or meters) per shift, *r* is in-place rock density in lb/yd^3 (kg/m^3), *SF* is swell factor in %, *A* is cross-sectional area in ft^2 (m^2), and *F* is a conversion factor.

Clearing, grading, and ripping rates, in acres per hour (square meters per hour), apply to site preparation. Other performance rates include those for bolting, timbering, moving, construction, and clean up. Equipment-specific measures of performance include mechanical availability, utilization, and overall efficiency.

PRODUCTION ANALYSIS. For cyclic equipment, the production rate is given by

$$LMO = (CAP/TIME) \times GF \qquad (17.2.2)$$

where *CAP* is capacity in yd^3 or tons (m^3 or kg), *TIME* is cycle time in minutes or seconds, and *GF* is a general factor to account for nonstandard conditions and conversion factors.

For short cycles of less than about 2 minutes (e.g., shovels, hoists), the cycle time and even the production rate can often be obtained directly from existing tables. Load-growth calculations can be very useful (Adler and Naumann, 1970). For long cycles, greater than about 10 min (e.g., front-end loaders, trucks), the cycle time becomes

$$TIME = FXD + VAR \qquad (17.2.3)$$

where *FXD* is fixed time in minutes and *VAR* is variable time in minutes.

Fixed times include delays, loading, dumping, and maneuvering, and are often obtained empirically or measured in the field. Variable times (travel times) are determined from duty cycle calculations, which include velocities, accelerations, and distances. For continuous operations (e.g., belt conveyors), the production rate is determined by:

$$LMO = A \times \rho \times VEL \times GF \qquad (17.2.4)$$

where *VEL* is velocity in fpm (m/s). In this case, *GF* is the product of load efficiency and fill factor.

CONSUMPTION RATES. Consumption rates are often estimated from the production rates, as with electric power in hoisting and battery selection for locomotives and scoops. For fuels, lubricants, explosives, and replacements, consumption rates are usually obtained from empirical data or manufacturers' specifications and their empirically derived information and guidelines.

17.2.4.6 Completion Analyses

PUBLIC POLICY. Checks on public policy should be done early. These are legally mandated regulations, codes, and contracts, covering safety and health, environmental protection, and labor, among others. Public policy checks are intrinsically controlled, monitored, and regulated, with much of the activity relating to equipment selection and evaluation going unrecognized.

HUMAN FACTORS. Human factors analyses serve to limit the mental and physical stress on an operator to make the job safer and more efficient. This is done by converting the operator's experience into simple engineering terms. Human factors is a significant specialty in industrial engineering and psychology, and, since modest beginnings in the 1960s, human factors (ergonomics) is now attracting wide attention in underground mining (Sanders and Peay, 1988).

The primary application of human factors in equipment selection and design is through the workload intensity concept (Adler and Lotfi, 1983). The mental stressors on an equipment operator due to conditions and the physical tasks due to activities are summed to obtain a plot of total stimuli vs. time. These data come largely from the operational activities and the performance analysis (see 17.2.4.4 and 17.2.4.5), where velocity was determined. When peaks in the workload curve violate a specified limit, corrective action is required. This can include altering conditions by (1) improving the human environment (illumination, noise, temperature, humidity), (2) improving the haulway (clean up bottom, broaden curves, widen cross sections), and (3) reducing congestion and interference (increase percentage of usable space, reduce traffic). Alternatively, activities can be staggered, simplified, and even slowed down to alleviate task peaks. The equipment itself can be redesigned to decrease both stressors and tasks, with enclosed cabs, automation and robotization, more precise and responsive controls (including computer controls), and by providing greater stability and agility. Training to improve operator performance has made strides by the use of physical simulators, such as for continuous miners, shuttle cars, front-end loaders, draglines, and shovels.

Other important areas of human factors, following more traditional organizational trends, are (1) systems design, (2) human capabilities and limitations, (3) human error and accidents, (4) design of displays, controls, equipment, and tools, (5) work physiology, (6) effect of environmental factors on safety and productivity, (7) training and retraining, and (8) motivation and organizational development (Sanders and Peay, 1988).

FINAL CHECKS. All limits, failure modes, and suitability criteria, especially those previously deferred, must now be examined or reexamined. Further iterations may still be necessary. When everything is satisfactory, a single feasible solution has been produced, one among several alternatives.

17.2.4.7 Economic Analysis

The profitability of each feasible alternative must be addressed before a final decision is made. All costs are estimated in dollars per unit time, and then converted into dollars per ton by using the production rate. Knowing the market value yields the unit profit, and multiplying this by gross tonnage gives the gross profit. Profitability measures for a specified time period can then be employed, such as (1) payback period, (2) discounted cash flow, and (3) rate of return. When evaluating the site conditions for possible upgrading, a cost-benefit analysis is appropriate. In any final decision, familiarity with the equipment, along with other intangibles (e.g., training requirements, level of confidence, after-sale service, and technical support), all play an important role.

17.2.4.8 Summary and Conclusions

A basic procedure has been developed to determine the performance rate of excavating and bulk handling equipment. By systematically involving the conditions, activities, and equipment characteristics, along with periodic suitability tests, the performance rate can be determined most efficiently. The analysis applies to all types and sizes of equipment—underground or surface, mobile or fixed, large or small—and can be used either to select or to evaluate. A flow chart guides the procedure through specific phases until one of several feasible alternatives has been found. The procedure is then repeated for other possibilities, with the final choice being largely determined by economic factors.

Numerical examples demonstrating equipment selection procedures appear elsewhere in this *Handbook* (Chapters 9.4 and 13.3).

Chapter 17.3
MINE PLANT LAYOUT

SCOTT G. BRITTON

Mine plant layout is a general term for describing the process of configuring a complex and often expensive portion of an underground mine. It encompasses the placement of all development facilities such as buildings and structures, machinery, pipelines, power lines, equipment, cables, ponds, roads, rails, and other auxiliary works needed to support any underground mine activities.

This chapter provides the reader with (1) an historical look at mine plant layout, (2) a general understanding of surface, shaft, and underground plant structures and systems, and (3) guidelines for basic mine plant layout.

Mine plant layout is defined as the design for integrating all structures, systems, or activities required to support the mining and processing of ores, minerals, or fuels for economic gain. Throughout man's history of mining endeavors, mine plant layout has required considerable attention, and in today's complex mining world, detailed planning for the mine plant layout is even more important and necessary.

As an example of this, consider the decision for choosing site locations for the original openings and plant buildings of a new mining complex. These decisions are influenced by a number of major factors, namely, (1) depth of cover, (2) location with respect to the reserve perimeter or ore body, (3) surface topography, (4) proximity to contract services (e.g., power, water, etc.), (5) location of railroads and market destinations, (6) geological structure, (7) proximity to population centers, (8) regulatory and environmental constraints, and (9) ease of access by personnel. Additional minor factors are numerous and relate specifically to each mining site, company objectives and strategy, and economics of the project.

Mine plant layout is broadly divided into three major subcategories: surface, shaft, and underground plant. As Fig. 17.3.1 depicts, each category describes the general location of the layout but does little to identify what each category encompasses.

The *surface plant* commences at the entrance to the property and mine opening site. This is generally seen in the form of roads, fencing, drainage and runoff ditches, lighting/power lines, and other items needed to provide the site with materials and services. The surface plant extends throughout the area to a point at the shaft collar or slope/drift portal and encompasses all the buildings, yards, controls, surface control structures, and equipment needed to service the underground mine. The surface plant also includes the hoisting headframe(s), hoist house, motors, cable, skips, hoists, and all other items included with the aboveground structure of the shaft.

The *shaft plant* subcategory begins at the shaft collar and consists of the airways, pumps, piping, water collection structures, communication and power lines, transportation systems, and other interconnecting components between the surface and underground mine operations. The shaft plant continues to a point where the underground development workings originate. At this point—and for anything inby this point—these systems are part of the *underground mine plant.* These systems would include, but not be limited to, ventilation (including heating and cooling), drainage, transportation, supply and materials handling, mine power, and communications.

The reader should distinguish between designing the mine plant for large and small mines. There is a cutoff that roughly parallels the expectation of management on three basic parameters of the mine complex: (1) the duration of the underground facility, (2) the profit expected from the mine, and (3) the needs of the mine for auxiliary services. As a rule of thumb, large or long-lived mines (i.e., with a life greater than 10 years) almost certainly need detailed and thorough mine plant engineering and a large layout area. Smaller mines with low production volumes and with an operational life of three to five years may have a portable surface plant, little or no shaft plant (especially with drift or adit type coal and metal mines), and a very basic underground plant layout.

Such a difference in size will ultimately influence the detail required for each plant component design. It will not, however, reduce the need for considering the component during the layout effort. For example, a large mine using a shaft entry system will in all probability have some type of surge bin storage system located underground at a point near the shaft skip pocket or hoisting shaft. This bin is used to lower the potential disruption and to maintain a high continuity of mining operations should a problem develop in the shaft hoisting system itself. For large coal mining operations, horizontal bunkering systems are becoming popular as an answer to this storage/continuity problem. In contrast to this is a small mine that is accessed via a series of adits or drifts. Although some thought is given to storage, it is probably limited to the stockpile area located on the surface and connected directly with a beltline or rail system.

17.3.1 HISTORICAL ACCOUNTS OF MINE PLANT LAYOUT

As an overall introduction of the subject, the first serious treatment of plant functions within a mining context for reference works was *De Re Metallica,* published in the Middle Ages by Georgius Agricola (1556). In this landmark work, Agricola wrote on the machines and techniques used to support the mining of ores and their preparation. Pumping, ventilation, and processing functions were the main interests at that time, and Agricola devoted much space faithfully describing these techniques and operations. The text provided word and picture descriptions, something rare in books at that time. The pictures were carved from drawings into woodcut blocks and used in a new invention of the time, the printing press. Figs. 17.3.2 and 17.3.3 are copies of woodcut diagrams included in the book and demonstrate the extensive treatment of such discussions. This text retained its currency and enjoyed wide usage until the 19th century.

Since the publishing of *De Re Metallica,* there have been fragmentary accounts of mine plant design in other texts. Every modern mining engineering text since that time (e.g., Peele, 1941; Lewis and Clark, 1964; Cummins and Given, 1973; and Hartman, 1987) has at least one discussion concerning the design and construction of various mine plant structures such as shafts, drainage and pumping stations, processing plants, haulage systems, and their layout. Specific to underground coal mining, several discussions appear in Crickmer and Zegeer (1981), Brit-

ton (1983) (Figs. 17.3.4 and 17.3.5); and Stefanko and Bise (1983). However, the chief drawback to these accounts has been and still remains the problem of fully discussing the variety of solutions needed to solve mine plant problems when confronted by unique sets of design circumstances. It is almost an impossible task.

However, one source stands out in its approach to covering the variety of solutions found within the mine plant. It is a definitive reference called *Mine Plant,* authored by Tillson (1938) and published by SME-AIME. In this unique text, Tillson did away with the usual word descriptions for plant functions and provided complete engineering drawings of specific mine-related structures used at that time. The text covers nearly all major plant functions and equipment design, including ore processing, shaft design and construction, headframes, pumps, fans, conveying, transportation, and so forth. The author attempted to

address layout planning by showing specific solutions to actual problems. Unfortunately, the material is dated and is primarily useful as a historical look at recent bygone mining practices rather than as a guide to modern mine plants. Figs. 17.3.6 and 17.3.7 are representative of the level of detail and complexity found throughout the text. *Mine Plant* currently suffers from not having any updated material. The text does not consider surface mining support or layout. Finally, it is out of print and difficult to find.

The preceding discussion is intended to leave the reader with the impression that it has been difficult trying to cover a complex subject within the changing mining field when no specific set of design parameters exist. However, behind any design layout there exists a general analysis approach required to successfully design a plant layout. It is this approach which will be emphasized in the following discussion.

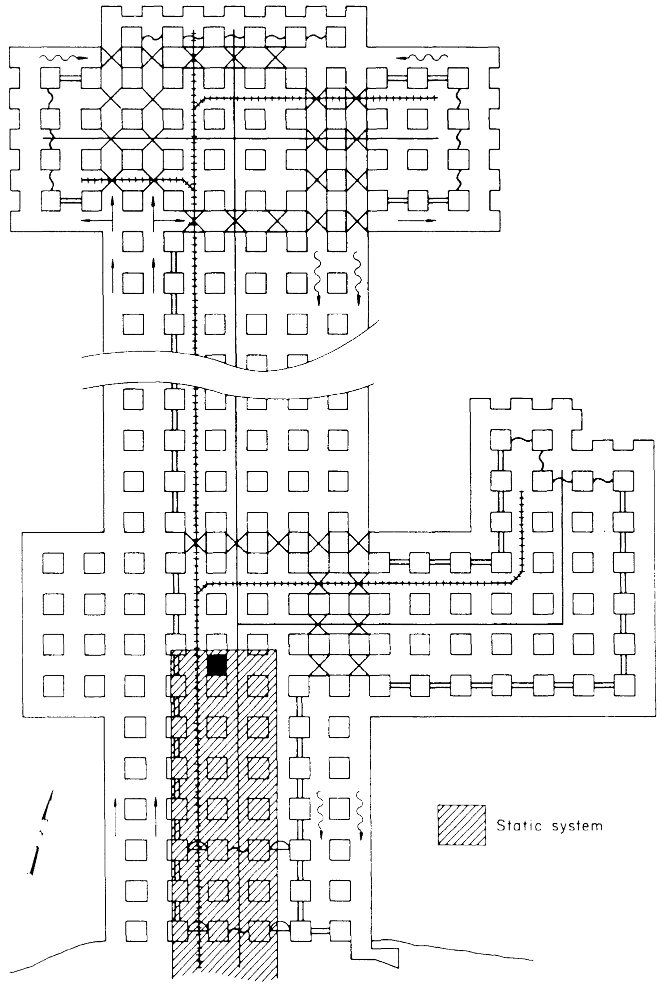

Fig. 17.3.4. Underground mine plant layout.

17.3.2 GUIDELINES FOR BASIC MINE PLANT LAYOUT

The mine plant layout is the backbone of efficient mine and plant operation. Whether in a remote mountain valley in Alaska, or on the outskirts of a major metropolitan area, mine plant design and layout does not vary in terms of the guidelines needed to successfully approach its design. These guidelines are considered both strict (because they are required for any design) and yet flexible (because they must meet each individual or site specific problem presented).

Guidelines for plant layout can be thought of as tiers of a pyramid. These guidelines have changed over time and will continue to change as new technological developments and government regulations impact their design. There are primary guidelines that govern the development of the mine plant design, secondary guidelines to aid in the interplay of subsystem designs, and tertiary guidelines to govern the overall fine tuning of the plant design to conform with regulatory approvals and unforeseen circumstances.

Primary guidelines are those guidelines that allow the engineer to (1) conform to effective, tried-and-true design practices, and (2) take advantage of current industry standards for the type of design being laid out. They are simple, straightforward, and based primarily on common sense and experience. There are five guidelines:

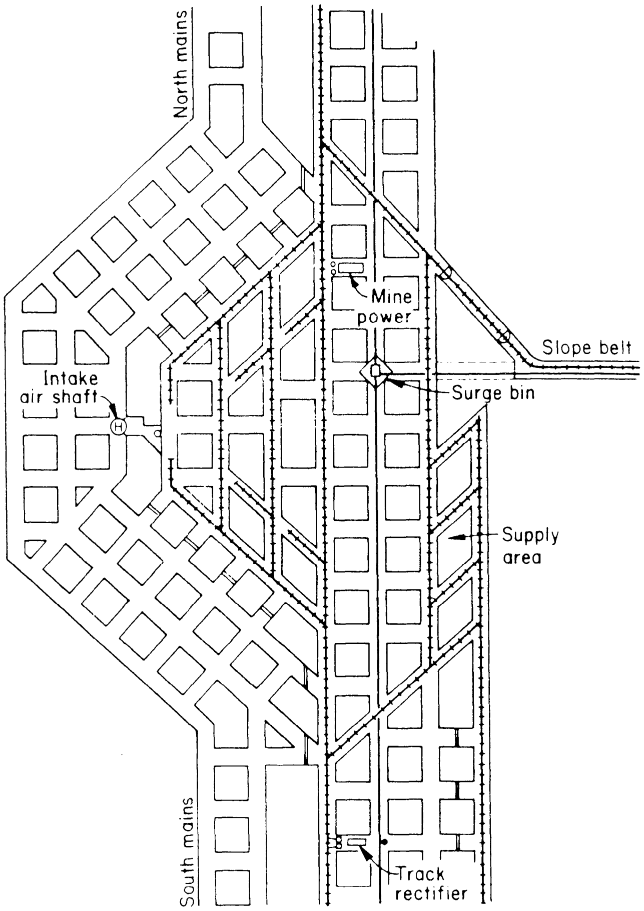

Fig. 17.3.5. Underground shaft/slope bottom layout.

1. Primary mine and preparation facilities should be designed to last the the life of the mine unless other circumstances (economics, safety, regulations, etc.) dictate a change.

2. Size of the stockpile areas, mine supply yard capacity, bathhouse space, and throughput of the preparation facilities should reflect the expected maximum design output of the mining operations. Limitations to this guideline include space, climate, and topography considerations, such as steep hillsides in West Virginia, deep cold temperatures of the arctic, or locations near urban areas.

3. Primary design components such as power, water, and access routes should reflect the most current available technology. For example, in underground coal mining, mine power voltages of 20 years ago reflected the general thinking that 440 V was adequate for primary production machinery. Today, a new trend towards 950 V is being heralded as the best available. Or, for example, heap leaching recovery of gold ores from waste tailings was unheard of 20 years ago, but today it is the preferred technology for most secondary recovery operations.

4. The shaft plant design should reflect sufficient flexibility in the placement of piping, cables, machinery, and wires to allow individual repair or replacement without significantly impacting any other component.

5. Shaft plant systems should be designed for the life of the mine unless circumstances dictate otherwise.

Secondary guidelines are concerned with the interdependence of the various mine plant systems. This can be best illustrated by examples, such as process water and mine dewatering, or underground machinery repair shops with surface repair facilities, or even power for the mine fan as it relates to other underground and surface uses. Secondary guidelines are used during the second stages of mine plant layout after the initial design considerations are determined, hence the term secondary. There area three secondary design guidelines:

1. Competing uses for primary resources such as power and water should be designed to complement one another and be able to service all needs during peak demand periods. For example, when a thermal dryer fan motor is turned on, the portal building lights should not dim or production machinery underground slow down. However, the rated voltages of the motors should be similar and circuits providing the power need to be isolated and properly protected.

2. The layout of any system should consider available built-in safety considerations so that it can function without problems (given reasonable maintenance), and that rupture, breakage, or failure of one system cannot directly affect another system (i.e., the "domino" effect). For example, power boreholes have become popular for several reasons, but mainly because they keep the cable out of the hoisting shaft and separated in view of the danger and potential damage if the electrical cable were to blow up or the skip cage were to derail and cut the cable.

3. The layout should, to the greatest extent possible, minimize any waste or inefficiency in repetitive operations between systems. For example, the mine material supply yard should be located next to—or as close as possible to—the point of entry underground (either a slope, drift, or shaft). It should not be located across the valley or behind the portal building. Likewise, the hauling of ore or waste should be so directed to provide the shortest route that is free of nuisance traffic and environmentally sound.

The final set, *tertiary guidelines,* is directed toward the layout of systems when competing regulatory agencies, outside organizations, and other unforeseen circumstances compel a change in the design. These instances generally occur when competing uses for natural resources are regulated by governmental actions based on law. They are set apart from the other guidelines because they do not impact the design process until the design itself is under review by external authorities such as state and federal environmental or safety agencies, labor unions, and the general public. These guidelines can be summarized as follows:

1. To the greatest extent possible, input from such agencies or outside organizations should be gathered early in the design process. Although, for example, an environmental permit may not be submitted until the end of the design process, it is prudent to obtain as much common understanding while changes can be made relatively easily. Public comment sessions are a necessary ingredient to good public relations and acceptance of the desired design layout.

2. In public debates or public meetings over technical design issues, "facts speak louder than words". For the mining engineer, this means being prepared with correct and complete data, and that facts should be stressed against emotional arguments. This is especially true for design issues surrounding environmental and safety issues. Both issues are extremely sensitive for the mining industry as a whole, and it generally falls to the mining engineer to correctly plan to mitigate any adverse impacts due to mining or milling activities.

In being effective with the use of "facts", the engineer should be able to reduce the numbers to easily understood graphs, charts, and tables. Audiences without technical training must be able to make decisions in favor of the mining project, its design, and its impact on sensitive issues by using this data. The use of impartial or outside expertise in communications may be required.

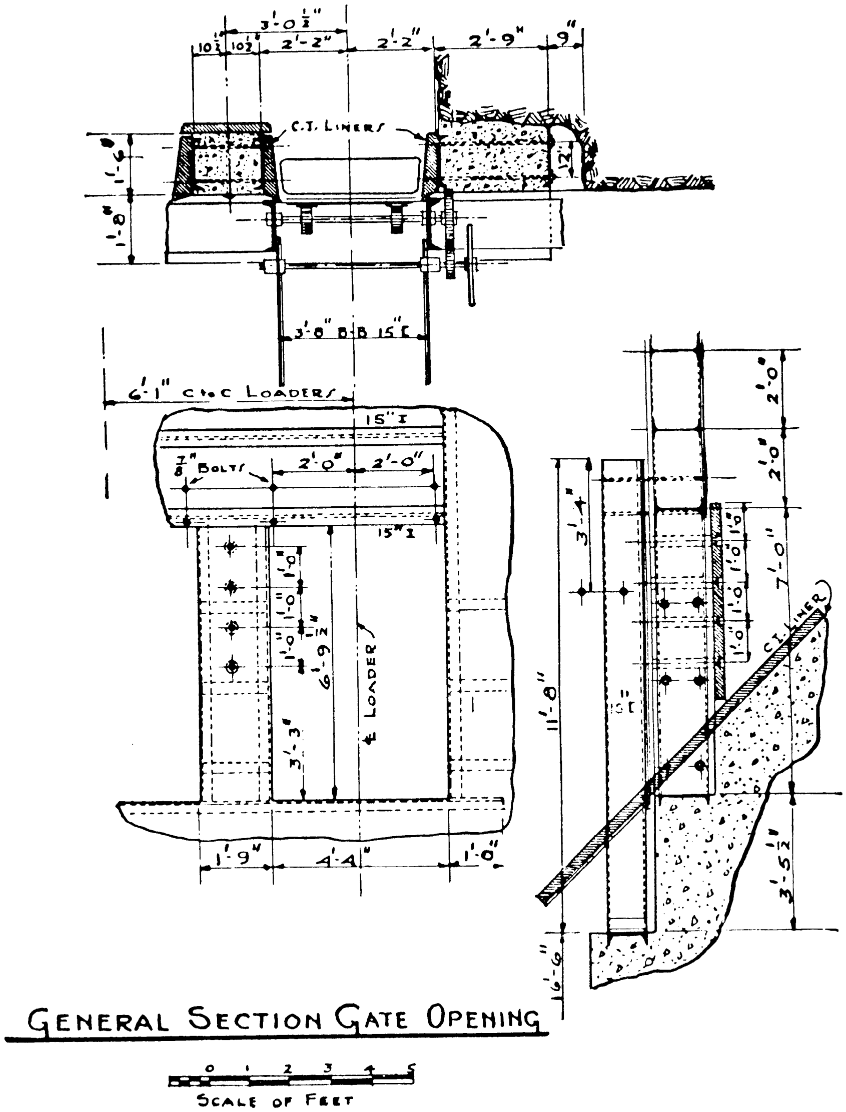

Fig. 17.3.6. Typical drawing from *Mine Plant* (used by permission of SME-AIME). Detail of gate opening for skip loader, Homestake Mining Co., Lead, SD.

3. Acceptable alternative solutions should be developed for those items within the design layout that may represent points of contention between various groups. These alternatives may serve to avoid costly delays or redesign problems later in the project design or construction phases. Refuse piles, air shafts, roads, plant effluent discharge, and other noticeable aspects related to mining operations should have their designs with acceptable alternatives or changes already considered by the mining engineer.

4. Keep design parameters conforming to known standards to aid in maintaining effective project design. For example, in the US, electrical installations should reflect current National Electrical Code Standards as well as local utility construction standards, if necessary. Mine materials should conform to US Bureau of Mines published standards or ASTM standards when cited by other government agencies such as the Mine Safety and Health Administration. Attention to health standards from the National Institute for Occupational Safety and Health or Occupational Safety and Health Administration increasingly are demanded during the design phase by third-party groups and corporate risk managers.

If these standards are not observed during this time, and there is a challenge over the particular design element, the engineer will be called to change the element to conform to the standard unless an overwhelmingly compelling reason for deviating from the standard is present. Changes to incorporate standards can be expensive and complicated after the design stage, so it is important to consider them at the appropriate time.

This concludes the basic guidelines needed to design adequate mine plant systems. Because of the infinite variety of design elements and the changing nature of technology, these guidelines are not hard and fast in terms of specific rules. They do, however, provide the basic fabric over which the mine plant design can be developed.

17.3.3 PLANT LAYOUT METHODOLOGY

Plant layout methodology differs from the above discussion in several fundamental ways. First, the methodology puts into practice the guidelines outlined prior to this point. Secondly, the methodology focuses on the procedures needed to bring mine plant concepts to fruition.

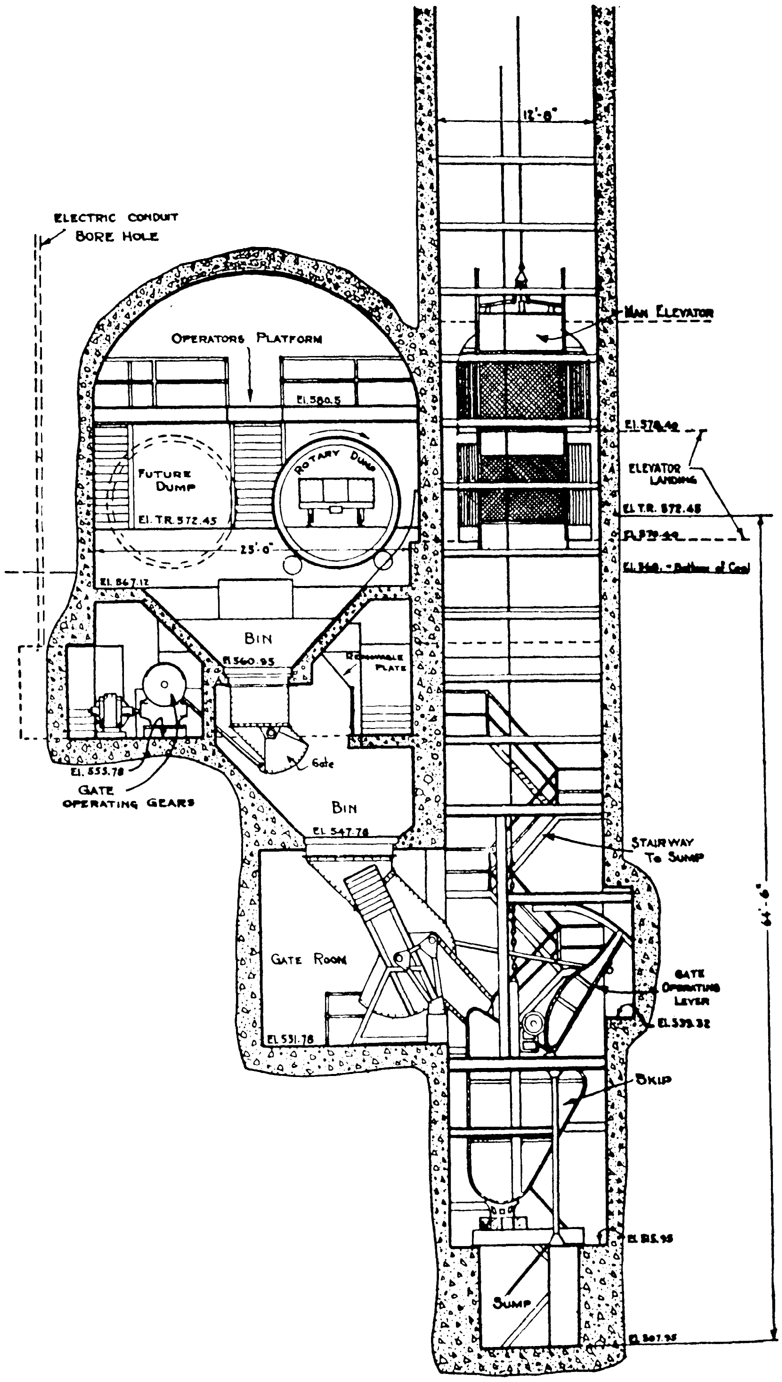

Fig. 17.3.7. Typical drawing from *Mine Plant* (used by permission of SME-AIME). Shaft loading pocket to hoist 100 fifteen-ton skips per hour, Buckeye Coal Co., Nemacolin, PA.

Basic mine plant layout is centered on devising a plan to balance the required operational goals of the company or business with the cost, time, and technical constraints of the project at hand. This plan is composed of numerous design and analysis steps that can be used again and again as needed. These steps are reviewed during the initial stages of mine development or project analysis when a planning team or engineering team is estimating the basic costs needed for extraction and ore processing.

The first type of mine plant layout always occurs in the initial efforts after one or more deposit access sites are identified. In this stage, a "thumbnail" sketch of the expected operations is laid out for all the potential opening sites. These expected operations are the product of initial mineral production and processing considerations, such as whether the ore is to be concentrated or milled onsite, or the mined material should be washed (either onsite or off), or whether there will be an onsite power plant or power is available from a local generating station, and so on. These considerations surface during the exploration program and are raised by the technical and marketing teams prior to the actual detailed engineering efforts. The engineer will note any special cost considerations for any one of the opening sites, if necessary. The sketch will encompass all known plant operations of major importance for all three plant areas.

From the thumbnail sketch, the engineer and others can begin the painstaking work of design—and with it—estimating costs of construction. The design consists of developing specifications for each subsystem, given the guidelines provided earlier. The costs can be obtained in the form of request for proposals to construction and design firms or developed from in-house resources. It may be necessary to develop detailed plan and construction drawings to fully support basic plant layout. At this time, the engineer will begin to piece together each supporting element based on the guidelines mentioned earlier. Firms experienced in the design and construction of particular elements (slopes and shafts, processing plants, grade work, etc.) are called to provide detailed plans along with quoted prices for completing such elements. Other firms capable of supplying equipment are contacted to provide quotes on specific items required by the design layouts.

During this stage of plant layout and design, the primary role of the engineer or planner is one of coordinator and compiler. It is his/her job to ensure that all elements required of the design are covered with detailed specifications and that these specifications coincide with other components within the overall design. It is not uncommon to spend a considerable amount of time modifying submitted designs, changing specifications to obtain a more efficient and cost-effective layout.

Once the basic parameters are satisfied, filling in the details between component systems becomes one of redesigning in relation to the overall plant layout and the differences between each component system. For example, power required for the site must be sufficient to run all operations, from the mine to the plant to the area lights. The power system should interface with each substation, breaker box, transformer, and other switching gear. Or, for example, water supplies must be adequate to support bathing and processing needs, sewage, and treatment needs, and be able to handle peak demands. Water must be filtered and treated before release into the environment. Each system has to be looked at before the mine plant can be pieced together.

The rule of thumb in determining the hierarchy of design after the initial plans are made can be simply stated as beginning from "the ground up," that is, the first system to focus in is the one most basic to operations. This progression of design is followed throughout until each system has been covered. For example, roads, ponds, and land contouring are the basic components of the surface plant. From this base, power lines, disconnects, and substations are added. The next system would be the fresh/process water system, followed by the supply/material yards, buildings, slopes, shafts, boreholes, hoists, fans, etc. Although each component system can be designed by individual teams, allowances must be made for limiting parameters of prior systems.

Within the auspices of the plant layout, the design engineer team begins to place the physical and structural components of the design to the actual plant site when all the components of the system are blocked out and defined. Especially important is the integration of the shaft plant and surface plant areas (the shaft collar, hoisting system, etc.) as well as the interface between the shaft and underground plant areas (sumps, power boreholes, skip stations, etc.) that must consider geologic stability. Where recognized areas of rock or strata weakness, or other unsuitable surface or subsurface areas are identified, the plans must be altered to work around or mitigate these circumstances.

In considering the layout of each necessary mine plant item, care must be given to human factors, cost, efficiency, and risk in the layout. For example, one does not lay out a design which results in putting a hazardous chemical storage depot next to an active travelway. For further clarification, thought and planning in the layout should consider (1) normal traffic patterns for employees, mobile equipment, customers, and vendors; (2) placement of aerial and underground pipelines and cables; (3) patterns of material flow to minimize health and environmental hazards (dust, water contamination, trash, etc); (4) orientation of facilities to minimize construction costs (excavation, etc.); and (5) placement of systems to take advantage of—or not be affected by—prevailing weather conditions.

Underground plant layout requires additional consideration for the confined space dimensions, the hazardous geologic conditions, and the dependency on artificial environmental systems to maintain a safe working environment (see the discussion on unencumbered space in 17.2.1.2). These additional considerations are not present in the surface plant design and require considerable practical experience on the part of the engineering design team.

Where materials and ore transportation systems enter the mining environment there is a tendency to underdesign the long-term nature of the transition area. For example, skip pockets, surge bins, sumps, or other systems that must endure the heavy operation imposed by life-of-mine duty are sometimes designed without consideration for changeouts, upgrading, or preventive maintenance activities.

Mine plant layouts, whether surface, shaft, or underground, are generally placed on drawings called schematics, plats, or layouts. All of these types of drawings orient the items placed on it to an exact scaling and position. In all cases, common sense and experience can help to reduce any inadvertent shortcomings.

The methodology of mine plant layout can be summed up as a straightforward application of good technical judgment when piecing together a "jigsaw" puzzle of interconnecting systems.

Chapter 17.4
CONSTRUCTION OF DEVELOPMENT OPENINGS

KOT F. UNRUG

17.4.1 LOCATION AND DESIGN OF VERTICAL SHAFTS

17.4.1.1 General Considerations

Shafts are the most important capital openings of deep mines, providing all services for underground operations including fresh air, transportation of ore and supplies, personnel traffic, power (electricity and compressed air), communications, water supply, and drainage.

Depending on the depth of the mine, shaft sinking may consume as much as 60% of the mine development time. Because of this, a proper choice of a method to minimize sinking time and assure uninterrupted operation is of great importance. In determining the shaft diameter and hoisting depths (the latter especially for three-dimensional or multiseam deposits), future mining needs have to be evaluated beyond the first stage of the project. Generally speaking, it is better to overdesign the shaft in the first stage of the project life span than later to face a bottleneck, preventing an otherwise feasible increase of production or requiring the sinking of a second shaft. If shaft extension is foreseen, part of the area in the shaft cross section can be used for this operation without affecting operation of the shaft, serving production from any upper levels.

Technical data required for the design of the shaft consists of a project outline and determination of the approximate shaft location. The outline of the shaft project should contain a section describing its purpose and justifying selection of the shaft site. Also included in the outline should be a short description of the characteristics of the shaft and its function; the hoisting gear; the shaft capacity, diameter, and depth; the type of shaft lining; the main pipelines and cables; number and functions of shaft insets; the depth of the shaft sump; and the quantity of airflow through the shaft, with corresponding drawings and cost specifications.

Excavation design requires the gathering of pertinent data and solving particular elements of the design, the most important of which are

1. Description of the geologic column in the form of a table identifying the rock strata, their geotechnical parameters, and groundwater levels together with water heads, calculated inflow, and degree of chemical contamination, if any.
2. Determination of the shaft diameter, with justification.
3. Choice of shaft sinking technology and its justification.
4. Description of the shaft lining and a list of lining sections with their thicknesses.
5. The shaft foundations (footings), their locations and dimensions.
6. The shaft collar, its depths and foundation, thickness and construction material, kind and number of openings with their function, and dimensions and elevations.
7. The shaft sump, its depth, structural characteristics, pumping arrangement, and cleaning system.
8. Surveying data for particular shaft elements,
9. Calculations comprising ground and water pressure acting on lining, resulting lining thicknesses, shaft insets with their dimensions, and airflow capacity.
10. Timetable of construction, with such elements as preparatory works, shaft sinking, lining erection, shaft equipment installation, and liquidation of construction arrangements.
11. Cost specifications.
12. Drawings of the general mine layout, with shaft location, plan of shaft site (construction stage), and shaft cross section with an outline of equipment and compartments.

GEOLOGIC COLUMN AND GEOMECHANICS PROPERTIES OF ROCKS. Reliable geologic information based upon core drilling near the shaft site is required for shaft design. In a virgin area, more detailed investigation is required than on a site where shafts previously were sunk nearby.

The package of hydrogeologic tests is usually based on the determination of the lithological character of rocks along the geologic column; the number of water levels, their depths and thickness; the hydrostatic pressure in particular water levels; coefficients of filtration of particular water levels; indicated water inflow to shaft from particular water levels; and chemical characterization of the various water levels. The geomechanics package contains a description and granulometric analysis of unconsolidated strata, if applicable, angles of repose or internal friction, specific gravity, porosity and fracture description, rock quality designation (RQD), inclination of strata, and uniaxial compressive and tensile (Brazilian) strengths. Geophysical logging usually includes neutron density, self-potential, and resistivity.

An exploration hole is drilled 35 to 100 ft (10 to 30 m) from the shaft axis. Such a distance ensures that test results from the drillhole correspond to conditions in the shaft, without the hole itself having a detrimental effect on the sinking operation (e.g., interconnecting water-bearing levels, resulting in an erroneously high hydrostatic pressure). Since the hole is a major source of information for shaft sinking, it must be placed with utmost care and under the supervision of a geologist. Core and water samples should be preserved in their natural state for testing.

DETERMINATION OF WATER INFLOW INTO SHAFT. A shaft face intersecting a water-bearing stratum will collect water similar to the way wells collect water. Water inflow must be controlled by pumping; consequently, a depression cone is created around the shaft. When certain parameters are defined, water inflow into the shaft during sinking can be predicted. They include (in SI units) the coefficient of filtration K in m/day; head of the water table H in m; head of the depressed water table h in m; radius at the depression cone R in m; radius of shaft r in m; and depression $s = H - h$ in m. The inflow often has a decisive influence on the choice of sinking method (Fig. 17.4.1). There are several inflow relationships.

1. An inflow q in m^3/day into the shaft through the walls (free water level) is calculated from

$$q = 1.36\, K \frac{H^2 - h^2}{\log (R/r)} \tag{17.4.1}$$

2. An inflow into the shaft through the walls for water level with a head is

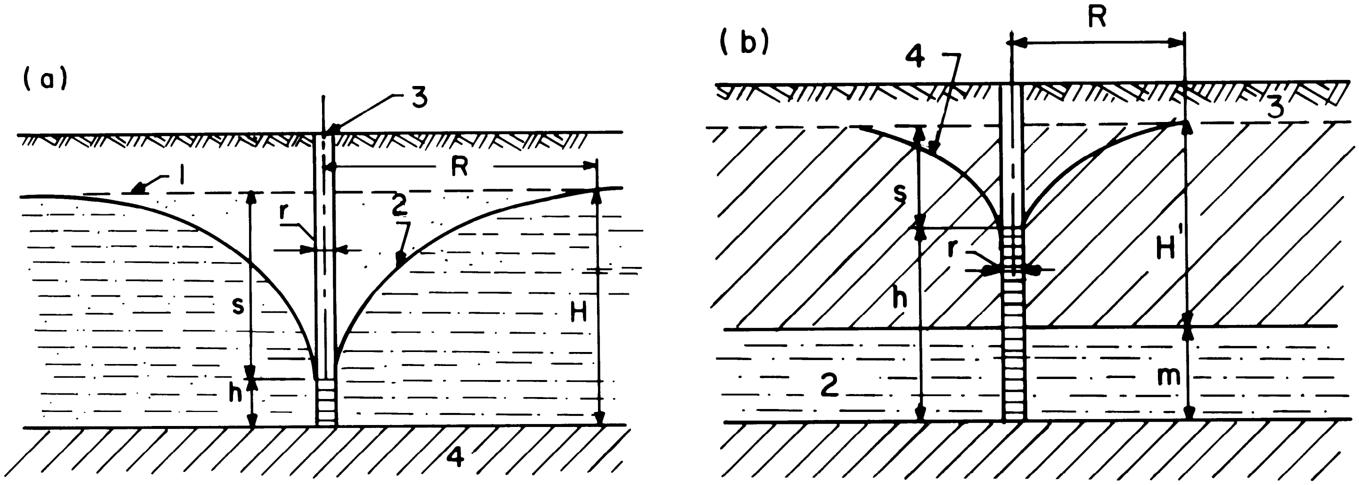

Fig. 17.4.1. Schematic of drawdown groundwater. (After Walewski, 1965.)

a) water-bearing strata with free ground level
1. initial groundwater level
2. drawdown water level
3. depression well
4. nonpermeable strata

b) water-bearing strata with head
1. nonpermeable upper strata
2. water-bearing strata
3. initial head of groundwater
4. drawdown water level

$$q = 2.73\ K\ m\ \frac{H' - h'}{\log\ (R/r)} \qquad (17.4.2)$$

where m is thickness of the nonpermeable strata.

3. Inflow through a flat bottom is

$$q = 4K\ r\ s \qquad (17.4.3).$$

4. Inflow into the shaft through the shaft walls in fissured rocks and free water level (simplified formulas) is

$$q = 2\pi\ K\ H\ \sqrt{r\ s} \qquad (17.4.4)$$

5. Inflow for this same condition but with a head is

$$q = 2\pi\ K\ m\ \sqrt{r\ s} \qquad (17.45)$$

The above formulas correspond to stabilized (equilibrium) inflow. Initial inflow will be greater.

SHAFT SITE SELECTION. The number of shafts in a mine depends directly on the daily production rate and the dimensions of the mining area. To obtain a minimum cost per ton of production, it is essential that an optimum balance between capital expenditure and operating costs be found.

Two Shafts—For a simple two-shaft mine, the location of a production/personnel/material/intake shaft is considered first, followed by the location of the ventilation shaft. Shafts can be located (see Fig. 17.4.2) in the central part of the property or on the footwall side of a deposit, with its major axis in the strike direction.

A central location of shafts in the mining area is most advantageous because transport costs (production, supplies, personnel) are minimized, and ventilation airflow routes to the production faces are also minimized. However, a central location causes losses of minable reserves within safety pillars and under the surface facilities at the mine site. In tabular deposits, with one-seam mining at moderate depths, it is the most effective system.

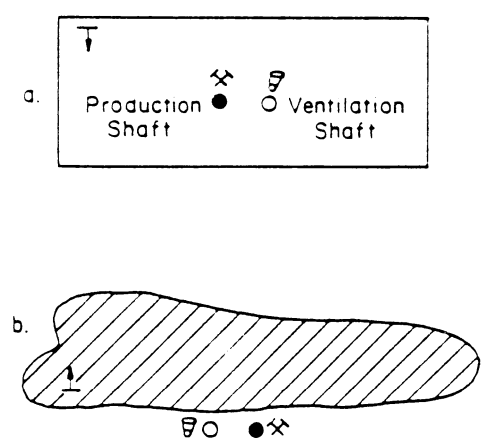

Fig. 17.4.2. Shaft locations for a two-shaft mine (a) centrally located and (b) on the footwall side of a steeply dipping deposit with its major axis in the strike direction. (After Jawien and Suchan, 1980.)

A side location (Fig. 17.4.2b and 17.4.3) increases the costs of development and transport by about 50% when compared with a central location (Fig. 17.4.2a), with simultaneous lengthening of ventilation airways. However, no part of the reserves is affected by the extensive shaft pillars that become essential for three-dimensional deposits at greater depths.

Three Shafts—Three shafts are required when the mining area is spread to the extent that a two-shaft arrangement is insufficient to provide the required ventilation. In such a layout, the intake shaft should have a larger cross-sectional area (e.g., 23 to 27 ft, or 7 to 8 m, in diameter), and ventilation shafts

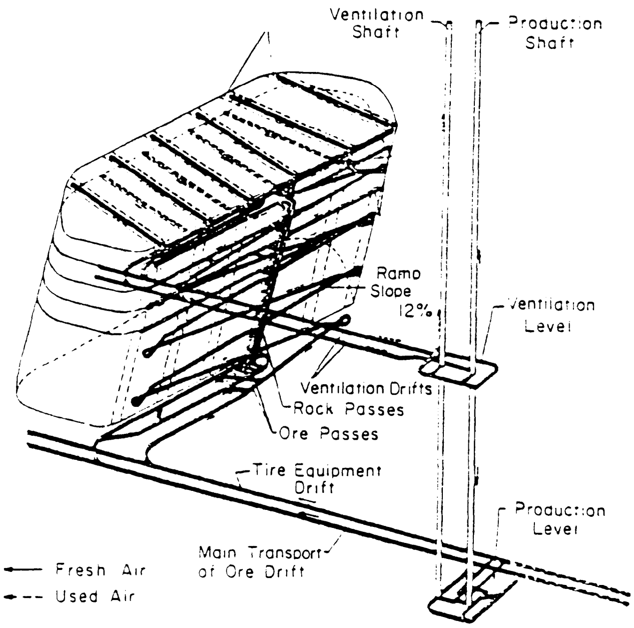

Fig. 17.4.3. Additional development resulting from side-shaft location for a magnetite ore deposit.

should be smaller (18 to 20 ft, or 5.5 to 6.0 m, in diameter). A centrally located intake shaft may also serve as a production and personnel/material shaft. Peripheral ventilation shafts should be placed along the strike direction when the mining property is two to three times longer in this direction than along the dip (Fig. 17.4.4a). In the case of a separated three-dimensional deposit elongated in the strike direction, the main production shaft is sunk in the footwall in the middle of the deposit. Ventilation shafts are located outside, on both ends of the deposit (Fig. 17.4.4b). When the mining area is elongated in a direction along the dip, the production shaft and one ventilation shaft are located in the middle, while the third shaft (second ventilation shaft) should be in the part of the deposit that is closest to the surface (Fig. 17.4.4c).

Four Shafts—A four-shaft system is necessary when the mine has a larger area and planned production is roughly double the size of a two-shaft mine. All four shafts should be approximately the same diameter and will have the following functions: (1) one production/intake shaft, (2) one personnel/material intake shaft, and (3) two ventilation shafts. The first two shafts should be centrally located, while the ventilation shafts will be close to the limits of the property, along the strike direction.

As was demonstrated for a three-shaft layout (Fig. 17.4.3b), a similar principle is applied to locate four shafts in the case of three-dimensional deposits. Another variant is possible when ventilation shafts are in the footwall side close to the highest part of the deposit. When the mining area is elongated in the direction of the dip, shafts may be located in the configuration with three shafts in the central area (production, personnel/material, and ventilation) and the fourth (a ventilation shaft) in the upper part of the deposit.

17.4.1.2 Selection of Shaft Diameter

The lateral cross section of the shaft is found graphically according to

1. Lateral dimensions of the hoisting conveyances and other installations (such as a ladderway), maintaining adequate distances between each and the lining.

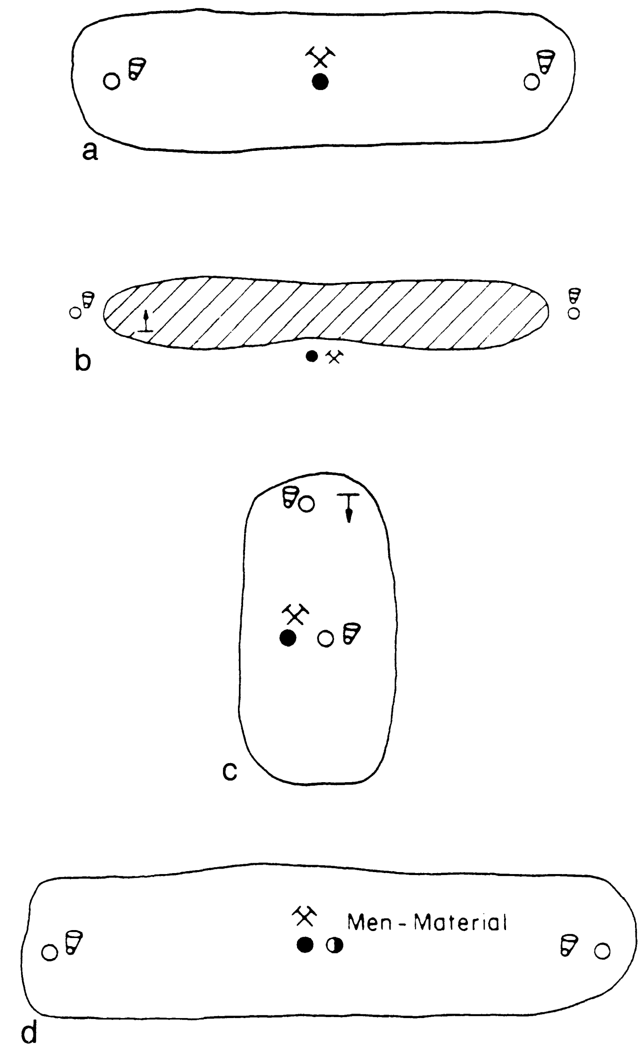

Fig. 17.4.4. Shaft locations for three- and four-shaft mines. Three-shaft layouts: (a) elongated deposit with major axis parallel to strike; (b) steeply dipping deposit with major axis parallel to strike; (c) elongated deposit with major axis normal to strike. Four-shaft layouts: (d) elongated deposit with major axis parallel to strike (after Jawien and Suchan, 1980).

2. Designed amount of airflow to fulfill ventilation requirements.

The required useful load Q in tons (tonnes) of the hoisting conveyance, generally a skip, for the planned daily production W in tons (tonnes)/day through the designed shaft is calculated for new production as follows:

$$Q = \frac{k\ W\ t}{3600\ T} \tag{17.4.6}$$

where k is irregularity factor = 1.15 for two or more vessels and = 1.25 for only one vessel, t is overall time of one cycle in seconds = $t_1 + t_2$ (t_1 is hoisting time and t_2 is brake time), and T is working hours of the hoist per day.

In SI units, the useful volume of the skip P in cubic meters is then

$$P = \frac{Q}{\gamma} \tag{17.4.7}$$

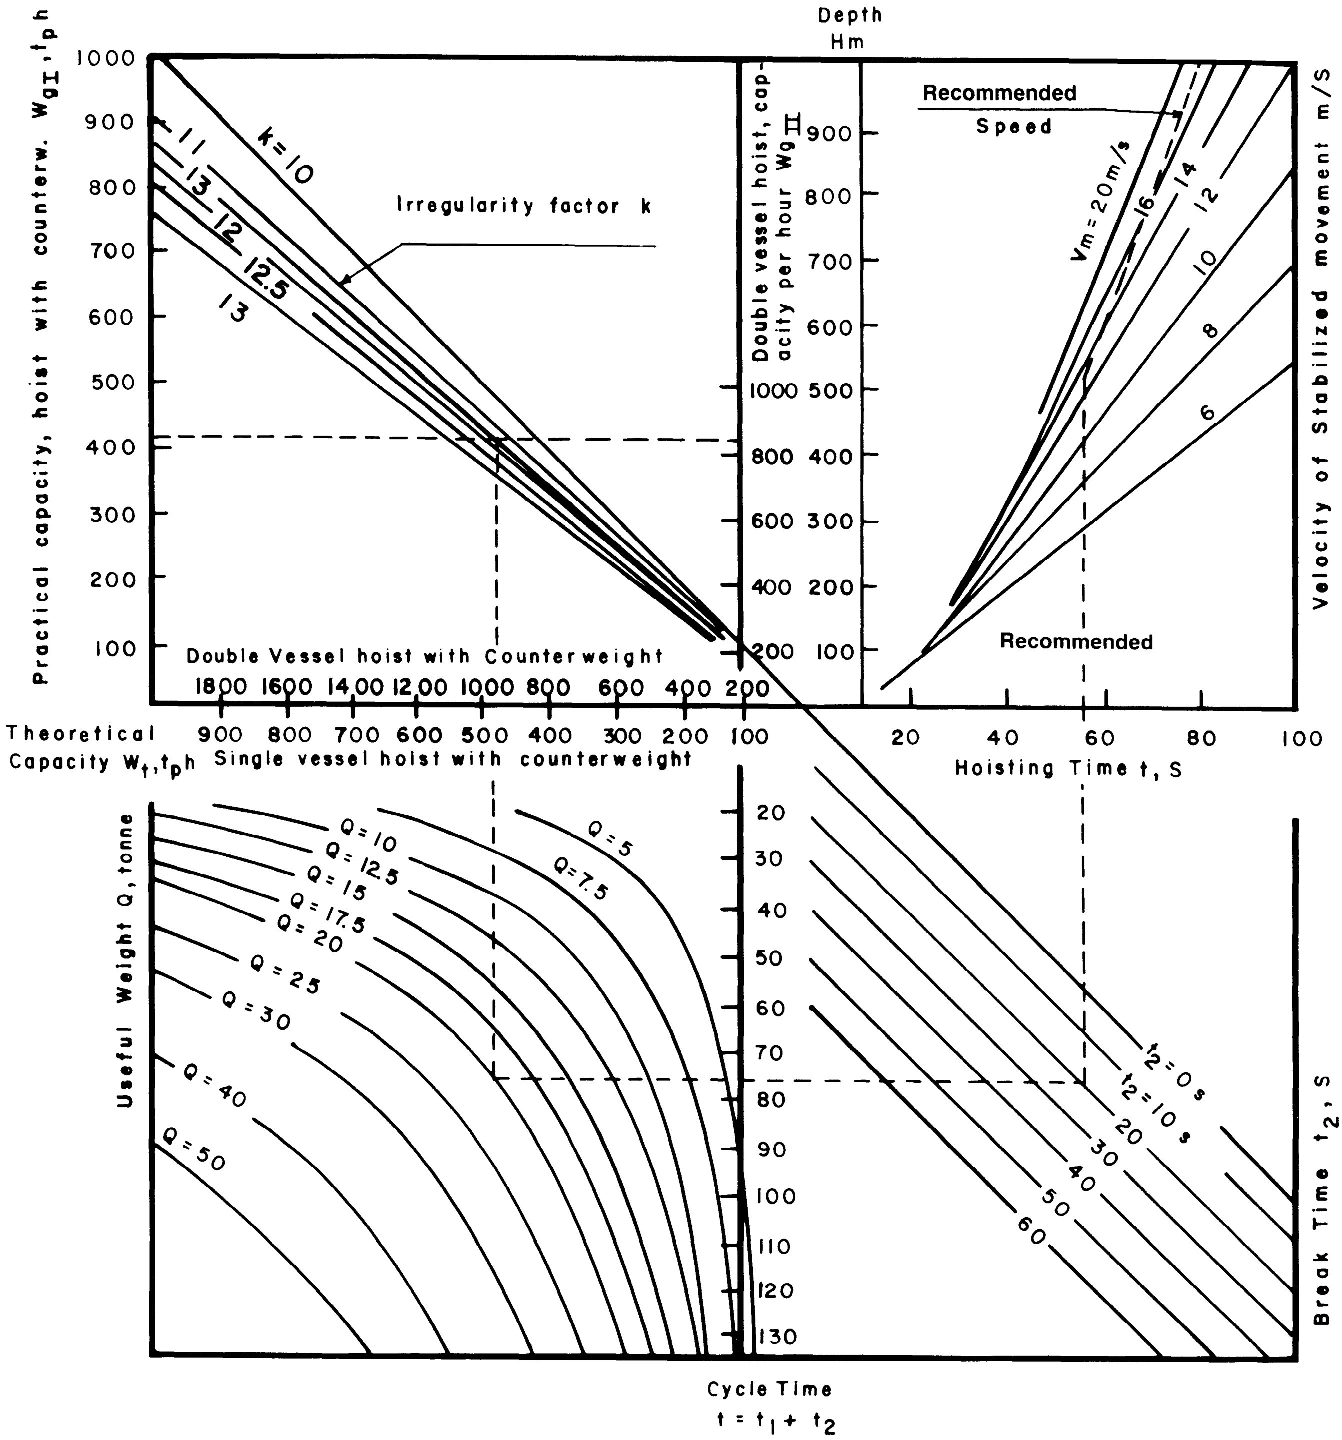

Fig. 17.4.5. Diagram for determination of single- and double-conveyance hoist capacity. Conversion factors: 1 ton = 0.9072 t, 1 fpm = 0.005 m/s.

where γ is bulk density of the hoisted material in t/m^3. For coal, γ = 0.8 to 0.85 and for stone, γ = 1.4 to 1.5.

Based on calculations and taking into consideration design principles and constraints, a graph for fast determination of the main hoisting parameters has been constructed (Fig. 17.4.5).

17.4.1.3 Shaft Linings

The lining of the shaft serves two purposes: support of shaft equipment and support of the walls of the excavation. Depending on ground conditions, wall support may require an additional

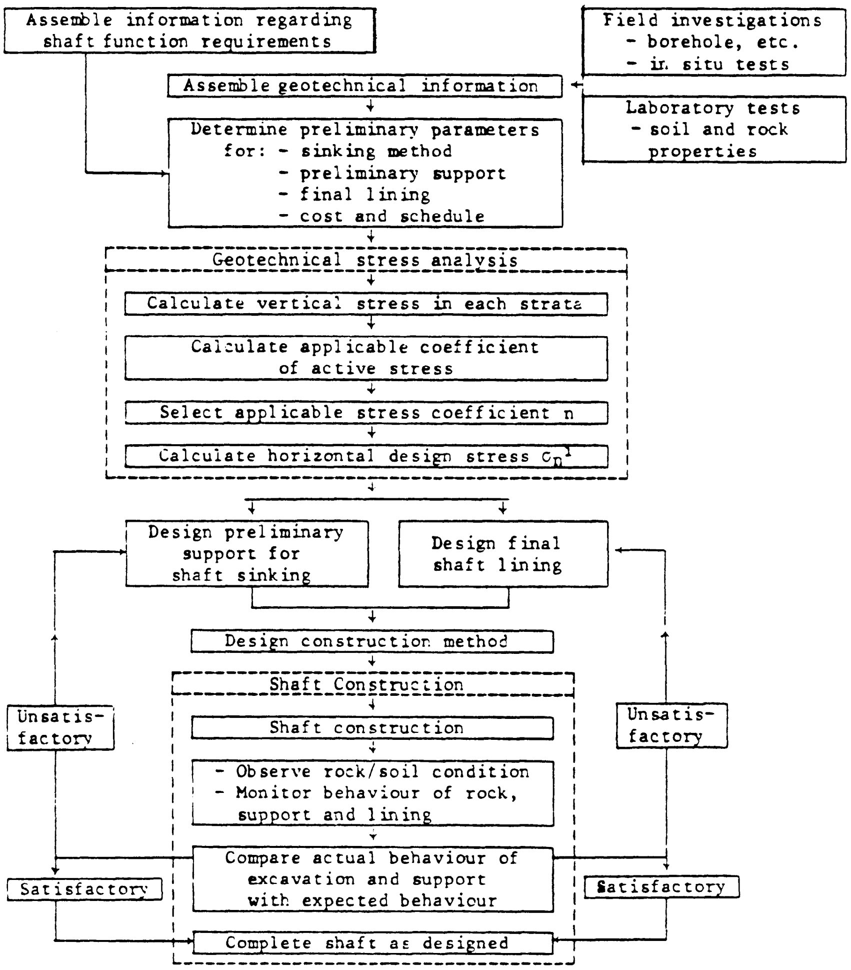

Fig. 17.4.6. Flow diagram for shaft ground support and lining design. (After Roesner et al., 1984.)

thickness of lining over the minimum 8 in. (200 mm) needed for fastening shaft equipment. In short life-span shafts sunk in competent rock, a rectangular shape with timber support is still commonly used. In modern large projects, however, round (or elliptical) shafts with concrete lining are the design used almost exclusively. Such a shape reduces airflow resistance, makes the sinking process easier, and permits taking full advantage of the structural features of concrete. Where possible, concrete lining with its numerous advantages is used over formerly popular materials such as brick and concrete blocks. Its placement is mechanized, resulting in high sinking rates as well as lower cost. Concrete strength can be adjusted according to need (2800 to 7100 psi, or 20 to 50 MPa), and watertightness of the lining can be achieved within aquifers with moderate head. In difficult ground conditions associated with high water pressure, cast iron tubbings with concrete mantle and welded steel lining are applied, usually in conjunction with one of the specialized methods of shaft sinking (see 17.4.3.2.). If mining within the shaft pillar is planned (deep multilevel coal mining), then a special elastic shaft lining is designed, consisting of two layers separated most often by a bitumen envelope. Such construction prevents deformation of the inner structural lining caused by shifting of the subsiding rock strata.

CALCULATION OF GROUND PRESSURE ACTING ON THE LINING OF CIRCULAR SHAFTS. The design procedure for shaft ground support and permanent lining is given in Fig. 17.4.6. When designing a new shaft, experience gained from data obtained during sinking of a nearby shaft should be used, provided that geologic conditions remain similar. Otherwise, only the results of geotechnical investigations obtained from the pilot hole are usually available. For complete treatment of geomechanics, see Section 10.

For temporary support, the safety factor need not be higher than one. For permanent linings, a higher safety factor is required, taking into account work conditions of the lining and its life span.

PRIMARY STRESSES. The vertical stress σ_v is proportional to the weight of overburden and is calculated from the relation,

$$\sigma_v = \Sigma \gamma h \tag{17.4.8}$$

where γ is density of the rock stratum, and h is thickness of the rock stratum.

Horizontal stresses may vary substantially from one location to another within the range of a minimum value, derived through elastic theory (Poisson's ratio), to a maximum value resulting from active or residual tectonic stress. From a practical standpoint, primary stresses may influence to some degree the level of the secondary stresses acting on shaft support. The pressure is caused by the overstressed zone of rock in a post-failure state developed around the shaft, resulting from the primary stress concentration. In most of the mining fields where primary stresses were measured, the horizontal to vertical stress factor is two to three, at a depth of less than 1500 ft (500 m).

STRESS DISTRIBUTION AROUND THE SHAFT. The stress distribution around the shaft differs in practice from the idealized solution derived from the elastic theory. Factors that influence stress are existing fracture pattern in rock, its anisotropy, shaft diameter, method of sinking (drill-blast or boring), time of exposure without support, type of temporary support used, and delay in installation of permanent lining. Additionally, the variety of strata penetrated by the shaft and their individual strength characteristics further complicate the stress analysis. For engineering purposes, however, a simplified approach is adequate where extreme pressure conditions, critical for shaft lining design, are assumed.

CALCULATION OF HORIZONTAL PRESSURE. Horizontal pressure appears when the strength of rock is reached by stress building up around the excavation and the limit of elastic deformation of the rock is exceeded. Then the fractured zone around the shaft spreads outward until the new equilibrium is achieved. Outside this zone, rocks are in an elastic state of deformation and hence self-supporting. The fractured (clastic) zone around the excavation tends to deform towards the center of the shaft and has to be controlled by an adequate support. In weak unconsolidated strata of a young geologic formation (usually at the upper part of shaft), ground pressure can be substantial, especially when combined with the head of the aquifers. In consolidated rock material, however, remaining in the elastic state of stress and deformation, no pressure is expected above the critical depth at which the stress reaches the strength of rock at the perimeter of the excavation. Some strata intersected by the shaft may be strong, thick, and therefore rigid. Such strata carry the load of the above weaker rock layers; thus there is no transfer of stress of the clastic zone from above the strong stratum to the weak rocks below this stratum. Such strata are also called cantilever strata. Their presence in the geologic column should be identified, and if they are below the critical depth, their influence on pressure distribution is significant. To act as a cantilever, the rock stratum has to satisfy the requirement (in SI units),

$$E\,I >= 206\,\sigma_t\,h^3 \qquad (17.4.9)$$

where E is elastic modulus in MPa, I is moment of inertia of section area of the rock stratum in m^4, σ_t is tensile strength of the rock in MPa, and h is thickness of the rock stratum in m. Above the first cantilever (if such exists), ground pressure is calculated in cohesiveless soils with $\phi = 5°$ and $c < 10$ kPa:

$$\sigma_h = \sigma_v\,Ka \qquad (17.4.10)$$

where σ_v is vertical stress in MPa, Ka is coefficient of active stress (ratio of horizontal to vertical stress), and $\sigma_h/\sigma_v = (1 - \sin\phi)/(1 + \sin\phi) = \tan^2(45° - \phi/2)$. In cohesive soils ($\phi <$ 25° and $c > 10$ kPa), the horizontal stress can be calculated from the equation,

$$\sigma_h = \sigma_v\,Ka - 2c\sqrt{Ka} \qquad (17.4.11)$$

where c is cohesion.

WATERTIGHT SHAFT LINING. The technical limit of water inflow for the conventional method of sinking is approximately 132 gpm (0.5 m^3/min). However, even a smaller inflow creates considerable problems and requires special arrangements to control it. Water seeping into the finished shaft causes corrosion of steel installations, requiring costly and troublesome replacement. Therefore, it is essential to minimize water inflow into the shaft unless it is controlled through a specially arranged drainage system, preventing a buildup of hydrostatic pressure behind the lining.

Over the years, different systems for control of water inflow have been tried. The most effective have proven to be those that take advantage of the energy of water itself to seal the lining. Quite often, water around the shaft is chemically aggressive to the concrete, so the lining can deteriorate when not insulated. Presently, the available system that is most effective, cheapest, and easiest to install is based on polyethylene (PE) or other insulation membrane sheets welded in the shaft. Double PE, 0.02-in.- (0.5-mm-) thick sheets have proven easy to handle and very successful for water insulation of concrete lining. A PE diaphragm is placed between the shaft wall and the concrete lining. In this case, the concrete does not need to be watertight, but it satisfies design strength requirements. Conversely, the PE insulation does not have any mechanical support function, but it provides 100% watertightness. Besides the desirable effect of a dry shaft resulting from this, deterioration of the lining associated with water seepage through concrete is also prevented.

Roesner et al., 1984, recommend the following method of determining the coefficient of the active stress for the calculation of horizontal stresses acting on the shaft excavation in cohesionless soils, cohesive soils, and rocks.

The single factor used for calculation of the coefficient of active stress Ka is either calculated from the readily obtainable friction angle ϕ_o (for soils) or the strength factor f (for rocks) (Table 17.4.1.).

The relationship between apparent friction angle and strength factor is (in SI units) ϕ_o = arctan f (for rocks) and f = tan ϕ (for soils), where ϕ_o is apparent friction angle (rocks) in degrees, ϕ is friction angle (in soils) in degrees, f is strength factor $= \sigma_c/10$, and σ_c is uniaxial compressive strength in MPa.

Very often the rock mass property is described either by the rock mass rating RMR or by the quality index Q (see Chapter 10.5). If either RMR or Q is known, the coefficient of active stress Ka can be read directly from the graph, Fig. 17.4.7.

Once the coefficient of the active stress Ka is established by either method, then the apparent coefficient of active stress Ka' is calculated by multiplying Ka by the appropriate stress coefficient n (Table 17.4.2.).

The stress coefficient n takes into account the influence of original tectonic forces n_o, the influence of the shaft diameter n_1, the influence of the shaft station n_2, the influence of the dip of the strata n_3, and finally the influence of the hydrostatic pressure on the lining (seepage coefficient) n_5.

By using the adjusted coefficient of active stress Ka' in the formulas for the horizontal stress, the horizontal design stress may be calculated from relations $\sigma'_h = \sigma_v Ka'$ for cohesionless soils, $\sigma'_h = \sigma_v Ka' - 2c\sqrt{Ka'}$ for cohesive soils, and $\sigma_h' = \sigma_v Ka'$ for rocks.

The detailed procedure is shown in Table 17.4.3.

From the same graph (Fig. 17.4.7), the indicated safe unsupported height between the permanent lining and the shaft bottom can be established and the ground support method can be selected (Table 17.4.4.).

The range of the maximum unsupported height varies from 45 to 75 ft (15 to 25 m) and is governed not only by the rock quality but also by mining regulations.

If preliminary ground support is installed, the relationship between Ka' and the unsupported height is no longer valid.

Depending upon the type and rigidity of the preliminary support, the stability conditions of the shaft excavation wall may improve; therefore, the unsupported height of the shaft can be increased accordingly.

CALCULATION OF THE LINING THICKNESS. The compressive strength and elastic moduli of concrete are given in Table 17.4.5. The coefficient of lateral deformation $\upsilon = 1/6$, and the

Source: Modified after Roesner et al., 1984.

coefficients of work conditions for the lining are given in Table 17.4.2.

The thickness of the shaft lining d_i in m may be found from the relation (in SI units)

$$d_i = a\left(\sqrt{\frac{R_c}{R_c - np\sqrt{3}}} - 1\right) \qquad (17.4.12)$$

where a is shaft radius in light of lining in m, R_c is allowable stress of the concrete in MPa (see Table 17.4.5.) n is coefficient of lining work conditions (see Table 17.4.2.), and p is calculated outside pressure acting on the lining in MPa.

Based on Eq. 17.4.12, a diagram for determination of concrete lining thickness has been constructed (Fig. 17.4.8).

17.4.1.4 Shaft Collars

The shaft collar is the upper part of the shaft extending to the first footing and, of necessity, must be anchored in competent rock. The dimensions of a collar, such as its depth, cross section, and thickness, depend on the shaft function, character of overburden rocks, hydrologic conditions and resulting water and ground pressures, sinking method, and additional loading conditions when applicable (in a vertical direction from the headframe and horizontally as a reaction from the foundations of nearby structures).

The shaft collar of the production/intake shaft must be planned with an outlet from the ladder compartment and a connection for a heated air intake in the winter or cooled air in the summer (when required by climatic and mine conditions). Additional outlets as needed accommodate water pipes, compressed air lines, and electrical and communication cables.

The collar of a ventilation shaft always has a connection to the ventilation drift conducting exhaust or intake mine air to the main fan if located on the surface. Additional outlets may be provided to meet special needs (e.g., outlets for water pipes, air lines, cables). In hoisting shafts, the collar must be designed to provide support for the headframe. When overburden is composed of strata with low-strength parameters, placement of the headframe to provide firm support from the collar is the most desirable solution. The base of the headframe can rest on the collar wall, provided allowance is calculated for the additional load (Fig. 17.4.9a), and the collar is constructed as a foundation. It can also be placed on steel beams fastened in the collar wall (Fig. 17.4.9b).

When a large hoist is installed at the top of the headframe, additional foundations outside the collar wall are needed. For smaller hoists, a round tower is designed, similar to an extension of the shaft and integrated with the reinforced concrete collar (Fig. 17.4.9c) at a certain depth below the ground. Since the required wall thickness of the shaft tower is 7 to 24 in. (0.2 to 0.6 m), the diameter of the collar must be adequately increased.

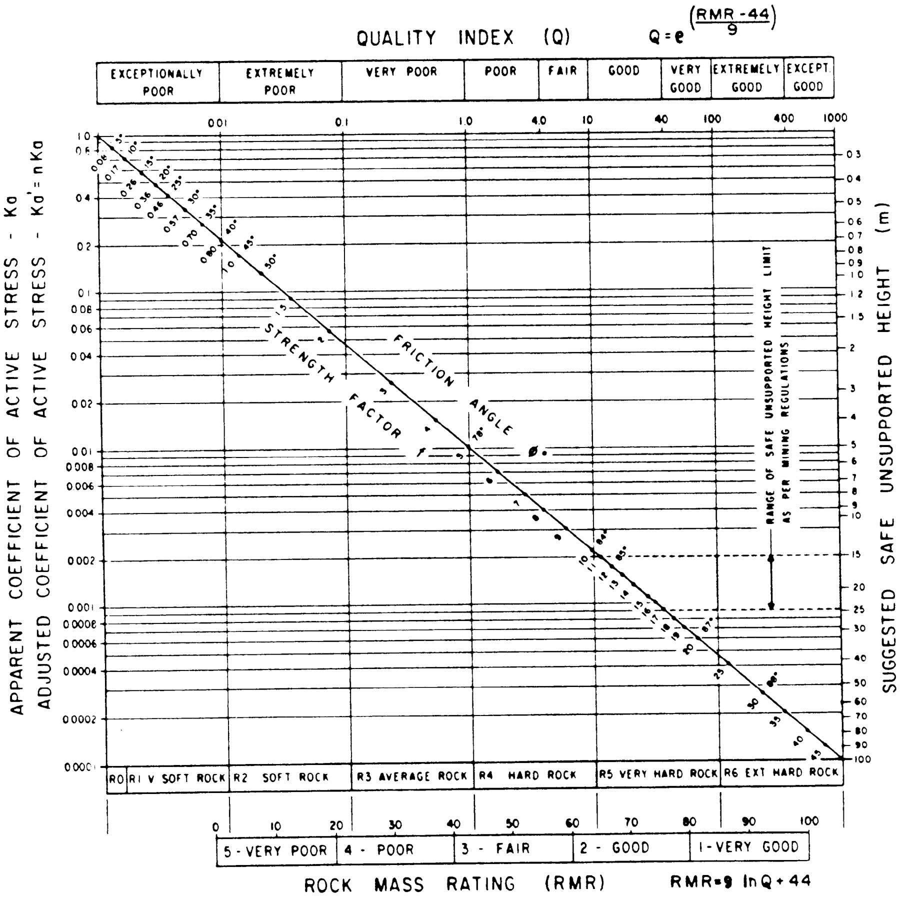

Fig. 17.4.7. Empirical strength factor criterion for ground support during shaft sinking. (After Roesner et al., 1984.) Conversion factors: 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

The tendency now is to use multirope friction hoists installed on top of the shafts (Fig. 17.4.9d), so this design solution is often used in new projects.

The lining of the collar is made of construction material, similar to that for the rest of the shaft, but it is thicker because of additional loads and the weakening structural influence of multiple outlets and connections. Additionally, the collar is exposed to changes in temperatures and to dynamic loading in both vertical and horizontal directions, caused by movement of conveyances in the shaft.

Collar linings can be constructed of concrete blocks, concrete, precast reinforced concrete elements, or high-strength bricks. Reinforced concrete is chosen for large and eccentric loads existing, for example, as in steep strata. Collars usually have a step-down shape (Fig. 17.4.10), with a footing foundation at the bottom. The first step must be deeper than frost penetration.

Choice of a collar shape depends on ground and load conditions. The first lining step is usually 3 to 5 ft (1 to 1.5 m) and sometimes up to 7 ft (2 m) thick; the next step is usually 2 to 3 ft (0.6 to 1 m) thick or approximately two times the thickness of the actual shaft lining. Wall thickness of the third step, if such is planned, should be somewhere between the ground step and the regular shaft lining. The foot of the collar is placed in firm stratum, 7 to 10 ft (2 to 3 m) below the overburden. Its shape is often double-conical to better transfer the load to the surrounding rock.

The influence of foundations adjacent to the shaft supporting such structures as headframe coal silos, etc., on the shaft collar lining can be evaluated using a graphical system recommended by Cimbarievich (1951) (Fig. 17.4.11). When the distance is less than the minimum distance l_o, the additional load must be found from a stress distribution diagram, which may require that the collar dimensions be increased.

Calculation of Collar Lining Thickness. In practice, the collar thickness is chosen according to structural needs, following the recommendations described above. Actual stresses are then calculated and the safety factor is evaluated.

The shaft in Fig. 17.4.12a shows the load distribution over the shaft head lining, with horizontal and vertical stresses unevenly distributed due to eccentric loading of the headframe. The shaft head is assumed to be an independent, hollow cylindrical, thick-wall foundation, with a footing. A conservative assumption is made that there is no friction between the lining and the surrounding ground. The four headframe legs carry the vertical forces P_1, P_2, P_3, and P_4. The resultant force and its coordinates are then calculated. Several design solutions of shaft collars are shown in Figs. 17.4.13 through 17.4.15.

17.4.1.5 Shaft Insets and Sump Design

Insets of Hoisting and Ventilation Shafts. Insets of ventilation shafts without hoisting gear must be designed to minimize airflow resistance. The size of an inset for a hoisting shaft depends on the width and number of skips and cages being hoisted on this level, number of decks in the cages, and maximum length of supplies to be delivered. Additionally, an inset sectional area is checked for ventilation requirements. (The recommended

air velocity is 800 fpm or 4 m/s for production shafts, and 1575 fpm or 8 m/s for ventilation exhaust shafts.) Within the inset, other openings must be provided as abutments (basements) for pushers and swinging platforms, drifts for simultaneous entrance and departure by personnel from multideck cages (if required), niches for control equipment, bypass around the shaft, etc.

Determination of the height of an inset (Fig. 17.4.16) is governed by the maximum length of material to be transported (e.g., rails, pipes).

17.4.1.6 Loading Chambers

Skip shafts and production levels are connected by a system of openings, the functions of which are interrelated and serve to accommodate the flow of material. Their shape and dimensions are dependent on skip size and loading system, as well as the types of mechanical and electrical service to the system.

Insets and sumps for shafts equipped for hoisting (Figs. 17.4.17 and 17.4.18) are more complicated than those of ventilation shafts. The sump in this case must house reverse sheaves for the bottom rope, end supports for stiff guides or weights for rope guides, and in the case of a skip hoist, must be equipped to catch and handle materials that fall.

The sump must also be of sufficient depth to assume adequate leeway for the hoisting conveyance below its lowest allowable position during operation. At the bottom, the sump must also provide space to store water flowing into the shaft and pump it into the central dewatering system. Fig. 17.4.18 shows an arrangement for a skip hoist loading level. Depending on the skip loading system and horizontal transportation arrangement, loading facilities may be required that incorporate the following:

1. Rail horizontal transport. (a) Tippler chamber or unloading ramp chamber (for Granby cars), batchers chamber, and skip chamber (so-called stiff system). (b) Tippler chamber or unloading ramp chamber, retaining bunker, loading devices chamber, batchers chamber, and skip chamber (so-called elastic system).

2. Belt horizontal transport. This system consists of unloading chamber, retaining bunker (vertical or horizontal), loading chamber, batchers chamber, skip chamber, retaining bunker, loading chamber, drift with belt scales, and skip chamber (also elastic system).

17.4.2 TECHNOLOGY OF SHAFT SINKING

17.4.2.1 Classification of Sinking Methods

Engineering properties of rocks and hydrogeologic conditions are the basis of the classification of sinking methods, with the main division on the conventional and special methods.

Table 17.4.3. Determination of Horizontal Design Stress

Soil/Rock Type	Friction angle ϕ	Cohesion intercept c(kPa)	Strength factor f	Coefficient of active stress $Ka = \sigma_h/\sigma_v$	Adjusted coefficient of active stress Ka'	Vertical stress σ_v (kPa)	Horizontal stress σ_h (kPa)	Horizontal design stress $\sigma_h{}^1$
Cohesionless	$\phi \geq 5°$	$c < 10°$	—	$\dfrac{1 - \sin\phi}{1 + \sin\phi}$	5) $Ka \cdot n$	2) $\sigma_v = \Sigma\gamma h$	$\sigma_h = \sigma_v \cdot Ka$	$\sigma_h{}^1 = \sigma_v \cdot Ka'$
Cohesive soil	$\phi < 25°$	$c \geq 10°$	—	$\dfrac{1 - \sin\phi}{1 + \sin\phi}$	5) $Ka \cdot n$	2) $\sigma_v = \Sigma\gamma h$	3) $\sigma_h = \sigma_v \cdot Ka$ $-2c\sqrt{Ka}$	3) $\sigma_h{}^1 = \sigma_v \cdot Ka^1$ $-2c\sqrt{Ka^1}$
Rock	$\phi > 25°$	$c \geq 10°$	1) $f = \sigma c/10$	$\dfrac{1 - \sin\sigma_o}{1 + \sin\sigma_o}$ $\phi_o = \arctan f$	5) $Ka \cdot n$	2) $\sigma_v = \Sigma\gamma h$	4) $\sigma_h = \sigma_v \cdot Ka$	4) $\sigma_h{}^1 = \sigma_v \cdot Ka'$

1) See Table 17.4.2, Stress coefficients n.
2) Below the water table, net hydrostatic pressure σ_w must be added to the submerged density of soil to obtain total σ_v
$\sigma_w = \gamma_w \cdot$ net water head $\cdot\ n_5$
3) In cohesive soils, the critical depth h at which pressure begins to act is calculated from equation
$h = 2c/\gamma\ Ka$
4) In elastic rocks, $\sigma_v = 0$ and $\sigma_h = 0$ to the depth $h < h_{critical}$

$$h_{critical} = n_4 \cdot \sigma_c/(2_{\gamma av}\ n_o n_1 n_2 n_3)$$
$$\gamma_{av} = (\gamma_1 h_1 + \gamma_2 h_2 + \cdots \gamma_i h_i/(h_1 + h_2 + \cdots h_i)$$

NOTE: R_c, allowable stress, is obtained by application of safety factor-3

NOTE: The above dry weights per cubic yard of concrete are based upon a specific gravity of 2.64 for sand and 2.66 for stone or gravel. The Engineer will adjust aggregate proportions to compensate for volume due to entrained air as necessary to maintain the specified cement factor. The air content, by volume, shall be 5.5% plus or minus 1.5%.

(1) All class AA concrete shall contain a water-reducing admixture meeting requirements when the ambient air temperature at the time of concrete placement is 70°F or less. When the ambient air temperature at the time of placement of class AA concrete is 71°F or more, the concrete shall contain a water-reducing and retarding admixture. At the direction of the engineer, water-reducing and retarding admixtures may be required or allowed for ambient air temperatures of less than 71°F. The type of admixture used shall not be changed for concrete placed during any individual contiguous pour, unless permitted.

(2) For prestressed members, 5000 psi expected at or prior to 28 days.

(3) Slumps less than the minimum listed herein will be permitted by the engineer provided satisfactory results are obtained.

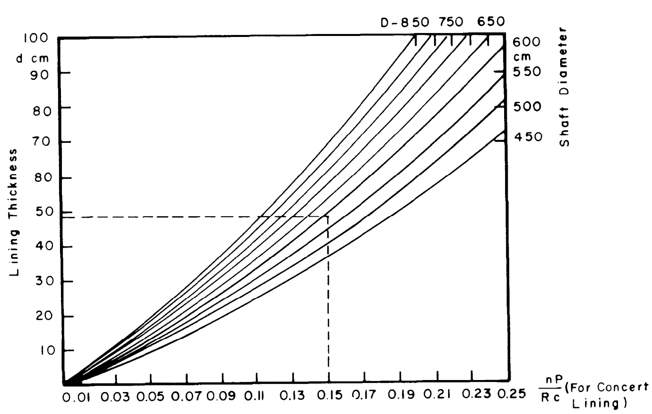

Fig. 17.4.8. Diagram for determination of lining thickness (concrete). Conversion factor: 1 in. = 2.54 cm.

Conventional methods consist of repeating cycles of face advancing and erecting of lining without any previous ground stabilization. Conventional methods are applicable in good- and fair-quality rocks with limited water inflow to the shaft not exceeding 130 gpm (0.5 m^3/min).

Special methods of shaft sinking are used in

1. Strong rocks but with an extensive fracture pattern, resulting in a substantial water inflow of more than 130 gpm (0.5 m^3/min).
2. Coherent, weak, plastic, and flowing ground.
3. Loose, water-bearing grounds (e.g., flowing sands, silts).

17.4.2.2 Conventional Drill and Blast Method

Taking into account the order of the main components of the sinking operation with the conventional method, the following classification can be employed:

1. Sinking with non-simultaneous face advancing and erecting of permanent lining, the so-called *series system.*
2. Sinking with simultaneous face advancing and permanent lining erection in certain distances behind the face, the so-called *parallel system.*
3. Advancing the face with simultaneous lining erection in the same shaft section, the *simultaneous system.*

Shaft beams, guides, etc., are usually installed following the advance of the permanent lining, although sometimes also after completion of the shaft lining (when a shaft boring system is employed).

In the series system, a shaft is sunk in sections, with length depending on the rock quality (between 100 and 170 ft, or 30 and 50 m). In a particular section, the face is advanced first with the temporary lining, and then when sinking is suspended, the permanent lining is constructed. This system does not assure a fast sinking rate, nor does it require a high capital expenditure, so it is used for sinking of shafts with smaller diameters and small and moderate depths.

The parallel system is characterized by a simultaneous advancing face and erection of permanent lining, but in various shaft sections. A temporary lining is required too. This system is applied for deep and large-diameter shafts, where the high capital (equipment) investment cost can be paid over the life of the project.

The simultaneous system can be further subdivided into (1) series-simultaneous and (2) parallel-simultaneous. In the *series-*

Dimensions in meters. (After Unrug, 1985.) Conversion factor: 1 ft = 0.3048 m.

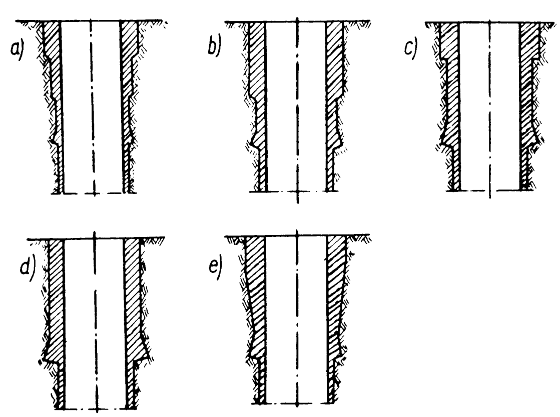

Fig. 17.4.10. Different shapes of shaft collars. (After Unrug, 1985.)

simultaneous system, face advance and lining are completed in one cycle, being done one after another. The lining is erected either upwards (e.g., brick lining in short segments), or downwards (e.g., underhanging tubbing lining or timber lining), eliminating temporary lining. The *parallel-simultaneous system* consists of simultaneous face advancing and permanent lining with segments 12 to 25 ft (4 to 8 m) long in competent rocks without temporary support, or with temporary support in weak, unstable rocks.

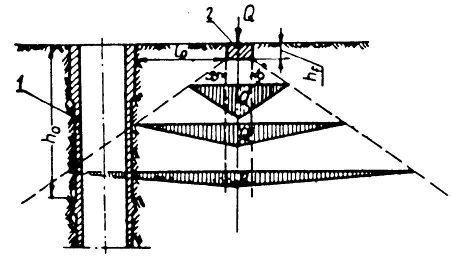

Fig. 17.4.11. Simple geometric method for determining additional load acting on the shaft collar lining from nearby foundations. A zone of influence is defined by lines drawn at 35° from the vertical at the base of the foundation. The effect of additional foundation loading may be considered negligible when the horizontal distance from the shaft to the foundation l_o is greater than $(h_o - h_f)$ tan 55°, where h_o is depth of the shaft collar, and h_f is depth of the foundation. (After Unrug, 1985.)

Another group of sinking methods is based on utilization of a central borehole for removal of muck (shaft sunk to the existing mine level).

Shafts can be sunk to the final depth or only to depths required in the first stage of mine development. Extension of the shaft to the next level should be synchronized with reserve depletion at the upper level, ensuring uninterrupted production. Shafts can be extended by sinking or raising.

PREPARATORY WORK. Shaft sinking is preceded by preparatory work as follows:

1. Determination of geologic and hydrogeologic conditions usually by drilling a hole or by examining an existing exploratory hole close by.
2. Preparation of technical documentation pertaining to surveying and permitting.
3. Construction work involving site preparation and construction of shaft head.

Site Preparation—The shaft site should be secure from flooding (above 100-year water level). Site preparation consists of

1. Construction of roads and material storage areas (open and covered).
2. Grading of the terrain (when required, this could also be done during sinking, using muck material as a fill) for further construction of mine facilities.
3. Water supply for drinking, industrial uses, and fire extinguishing. When a water line is not available, an adequate supply has to be built in compliance with existing regulations. When wells are drilled, they should be located outside the drainage cone of the shaft. Water pumped from the shaft should be utilized as well. The required daily supply is 20,000 to 26,000 gal (80 to 120 m^3) of plant water and 10,000 to 16,000 gal (40 to 60 m^3) of tap water. The fire tank should be 20,000 to 26,000 gal (80 to 100 m^3) capacity. An adequate ditch for storm water should be planned.
4. Electrical power supply can be provided in two stages: for preparatory work, from small (to 260 kVA) transformers, and during sinking when more power is needed, from larger units (e.g., 1200 kVA at 500 V). The transformer station should

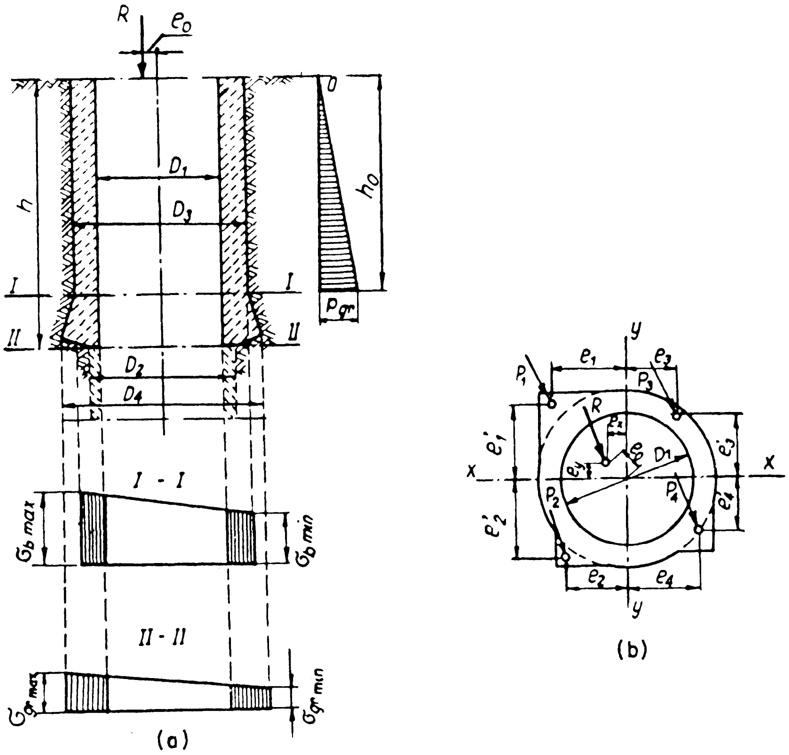

Fig. 17.4.12. Load distribution on shaft collar lining [*p*—forces, *e*—coordinates of forces, *R*—resultant force, *D*—shaft diameters]. (After Walewski, 1965.)

have two independent sources of power, and when that is impossible, a diesel generator is required for emergency use. Requirements include:

a. Provision of covered storage for construction materials and ramp for unloading heavy machinery.

b. Hook up to telephone lines.

c. Construction of temporary buildings for shaft sinking and foundations for head gear.

d. Installation of sinking equipment (hoists, etc.).

e. Surveying of elevation of shaft collar, with markers of main shaft axes and north direction (Fig. 17.4.19).

Temporary Buildings—Temporary buildings should be located in a way that will not interfere with permanent buildings to be constructed. For shaft sinking, the following is needed:

1. General use building, housing an office, bathhouse, first aid room, heating and cooling units, warehouse for small equipment. (When permanent mine facilities are available, such temporary facilities are not required.)

2. Lamp-house, complying with existing Mine Safety and Health Administration (MSHA) standards.

3. Mechanical and blacksmith shop for minor repair work and sharpening bits.

4. Sheds housing compressors (with foundation under particular machines) with outside tank for compressed air and cooling water tank.

5. Transformer station, housing transformers, high- and low-voltage switches, and an electrical shop. Sometimes high-voltage transformers are located outside; then the low-voltage switch-board is placed in the compressor building to avoid loss of cables.

6. Shed beside the headframe, approximately 32 to 64 ft (10 by 20 m), where concrete, mucking, and other equipment is placed.

7. Material shed, basically for cement storage and other construction materials (approximately 20 by 40 by 40 ft (6 by 12 by 12 m).

8. Winch building for the shaft stage.

9. Fan housing, approximately 13 by 13 ft (4 by 4 m).

10. Flammable supplies warehouse (fire resistant structure).

11. Hoist building, depending on machine size, approximately 16 by 33 ft to 40 by 40 ft (5 by 10 to 12 by 12 m).

12. Storage for 200 to 400 lb (100 to 200 kg) of explosives and 500 to 1000 detonators, when current supply is secured, and where not, a larger storage area is needed.

13. Living accommodations for sinking crew, depending on needs.

SHAFT COLLAR CONSTRUCTION. Shaft collar sinking and construction depend on geomechanical and hydrologic conditions. In the case of loose water-bearing rocks, one of the special sinking methods has to be used. In good ground conditions, an ordinary method is applicable to sink the collar to its whole depth, 26 to 40 ft (8 to 12 m).

In favorable ground conditions after the collar is constructed, further sinking of the shaft down to 160 ft (50 m) can proceed with the application of provisional equipment. This allows for installation of specialized sinking equipment and other required work, for example, grouting.

During collar construction, rock is excavated by means of jackhammers, mechanical excavators, or explosives. Muck is removed by suitable construction machines, and where beyond their reach, by bucket and mobile crane.

DRILLING AND BLASTING IN SHAFTS. Properly done, drilling and blasting work is supposed to ensure:

1. Correct size and shape of planned excavation.

2. Even surface of the face that makes easier mucking and drilling of the next round.

3. Uniform size of broken rock for effective mucking operation.

4. Safe and economical operation.

In shafts, a selection of high explosives is generally used so that in case of excessive methane liberation, adequate blasting

Dimensions in cm. Conversion factor: 1 in. = 2.54 cm.

material is available to ensure safety. Electric caps with millsecond delays are used.

The theory and practice of explosives and blasting is covered in Chapter 9.2.1.

Consumption of Explosives—The *unit consumption* (or *powder factor*) q is the amount of explosives in lb (kg) required to excavate 1 yd^3 (1 m^3) of solid.

It has been established that:

1. For practical purposes, it can be assumed that q is independent of the area of the shaft cross section S, provided that $S > 24$ yd^2 (20 m^2).

2. The unit consumption of explosives depends on the hole length; with a constant hole utilization factor (see Eq. 17.4.13), the minimum q is achieved in holes with length 8 to 10 ft (2.5 to 3.0 m) in shales and 7 to 8 ft (2.0 to 2.5 m) in sandstones (with other parameters constant) (Fig. 17.4.20).

3. With increase of hole diameter, q decreases.

4. Unit consumption decreases with the increase of hole utilization factor.

5. With q approaching its optimum value, the intensity of rock breaking increases.

6. q depends on the physical properties of the rock and is 20 to 30% less in shales than in hard sandstones.

Hole Utilization Factor—During shooting, rock material does not separate from the solid at the bottom of the hole. The *utilization factor* h is defined as follows:

$$\eta = \frac{l_o}{l} \tag{17.4.13}$$

where l_o is effective hole length utilized, and l is total hole length. The difference l-l_o represents hole length that was not utilized. An optimum factor h, which characterizes a proper selection of drill and blast parameters, assures a good sinking rate.

In the coal basin of Donieck, USSR, in carboniferous rocks where many shafts were sunk, research gave the following results (Walewski, 1968):

1. The ratio h increases (with other conditions unchanged) to a maximum, corresponding to an optimum unit consumption q, and then decreases.

2. The ratio grows with an increase of hole diameter (cartridge diameter).

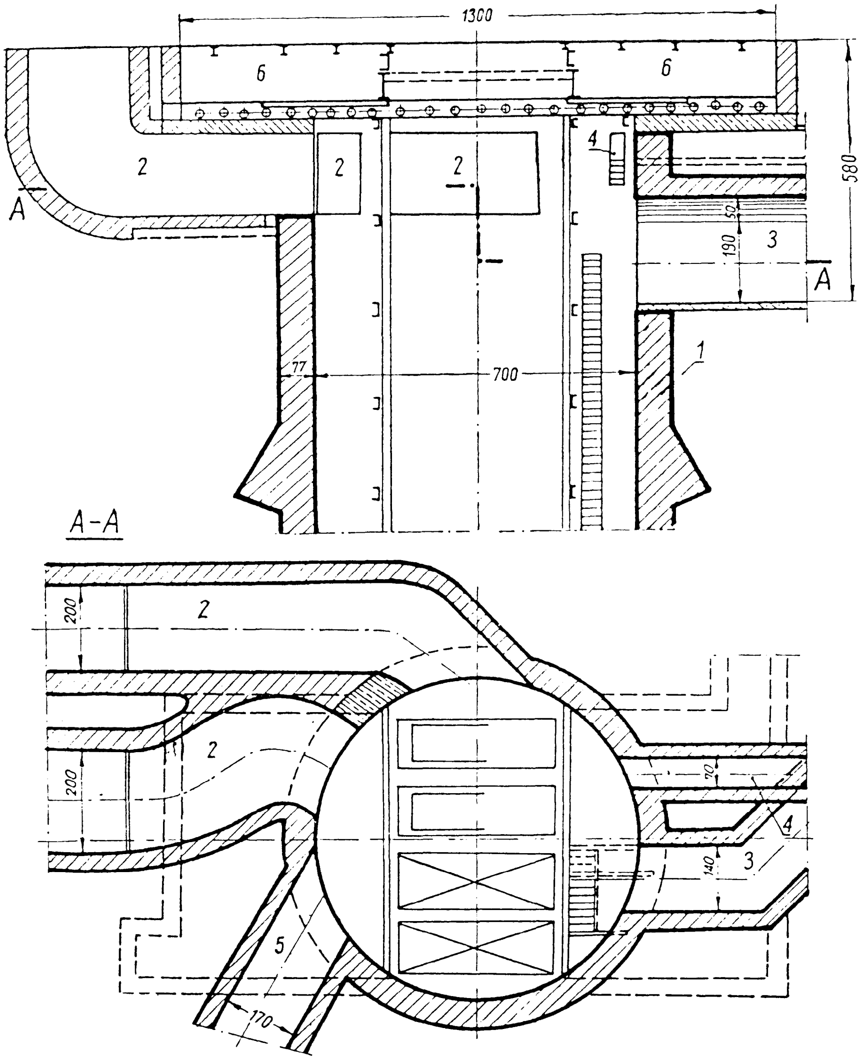

Fig. 17.4.14. Design of production shaft head 23 ft (7 m) in diameter.

3. outlet from ladder compartment
4. cable channel
5. channel for water pipes and compressed air
6. basement for fire closings

Dimensions in cm. Conversion factor: 1 in. = 2.54 cm.

3. A maximum value is achieved with an optimum length of holes. When the holes are too long, the shooting effect diminishes; in the upper part of the hole, crushing of the rock is not sufficient, while in the deeper part, the material is crushed excessively.

4. The factor increases with the growth of the hole loading factor until it reaches its optimum value (one has to remember that the hole loading factor decreases with a hole cartridge diameter increase).

Hole loading factor a is the ratio of the length of the hole filled with explosives to the entire length. In practice this relationship is as follows:

Hole diameter, in. (mm)	1.26 to 1.42 (32 to 36)	1.77 (45)
Factor *a*	0.6 to 0.7	0.45 to 0.5

Research on number of holes has shown that:

1. The number of holes does not depend on depth in the range of 10 to 12 ft (3 to 3.5 m).

2. The number of holes per unit area of shaft face does not depend on face area S when $S < 24$ yd^2 (20 m^2).

3. The hole number decreases 1.8 to 2.0 times when the hole diameter is 1.8 in. (45 mm) and 2.5 to 3.0 times when the diameter is 2.2 in. (55 mm). The use of shaft jumbos able to drill larger holes is therefore recommended (Fig. 17.4.21).

An empirical formula developed for hard rock gives the number of holes N as

$$N = 0.234\,A + 22 \qquad (17.4.14)$$

$$N = 2.55\,A_1 + 22 \qquad (17.4.14a)$$

where A is area of shaft face in ft^2 or A_1 is area of shaft face in m^2.

Hole Length—Hole length is different from hole depth; it is the shortest distance between the free face and the end of the hole. (Hole inclination creates this difference.) The length of holes has to be justified in three respects:

1. Length as a factor being determined by geologic and mining conditions (e.g., rock type, water inflow, diameter).

2. Length being determined according to the applied drilling and shooting technology (e.g., drilling equipment, explosive material).

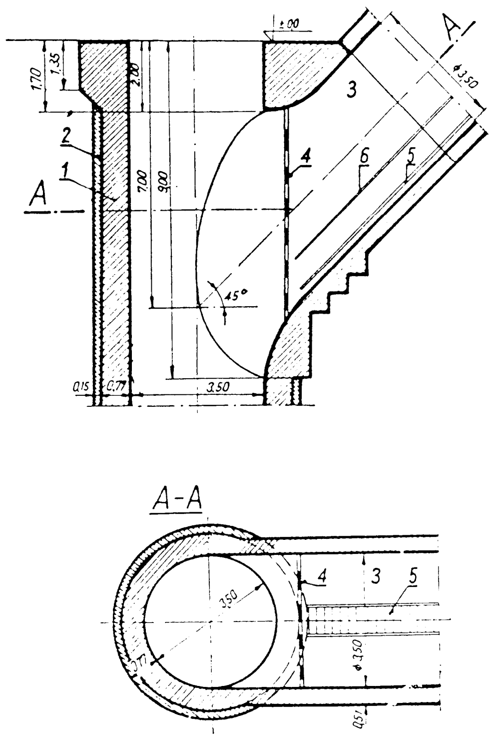

Fig. 17.4.15. Design of ventilation shaft head 12 ft (3.5 m) diameter.

Dimensions in cm. Conversion factor: 1 in. = 2.54 cm.

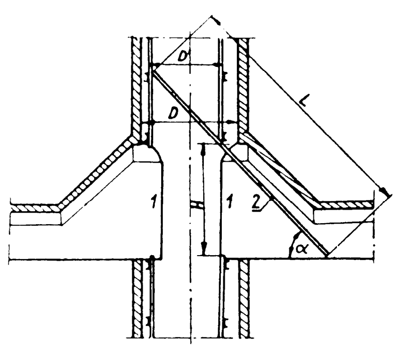

Fig. 17.4.16. Inset height calculation. *L* is maximum length of transported material, α is angle from level, *D* is shaft diameter. For α = 45°, *D′* = 0.7 *D,* which is the free space between shaft beams. *H* = 0.7 (*L* – *D*).

3. Length of holes determined according to the organization of shaft sinking, which consists of a sequence as follows: drilling + mucking/hoisting + lining. Shorter holes are chosen when one cycle per shift is planned rather than one per day. The most desirable will be the length that assures that a unit advance with minimum time and cost is achieved.

An optimum hole length should be found from the minimum cost principle. The main cost contributors are drilling of holes, explosives, and mucking, depending on the depth of round.

Fig. 17.4.22 shows the timing of particular operations vs. hole length.

An important consideration when choosing hole length is any deviation from the planned shaft section; for example, for holes 6.5 to 8 ft (2 to 2.5 m) long, this deviation is 2 to 3.5%, and for holes 13 to 16 ft (4 to 5 m) long, the deviation reaches 5 to 10%. Most records in shaft sinking have been achieved with hole lengths of approximately 10 ft (3 m). For carboniferous rocks such as shales, an optimum length is about 10 ft (3 m); for sandstones, about 8 ft (2.5 m). The sinking cycle time, dependent on hole length, must be considered when planning the length of holes.

It should be emphasized that the above calculation, essential during the designing stage, has to be verified by actual sinking conditions and can be changed as required.

Drilling Round—The drilling pattern has a strong influence on sinking performance. It should ensure:

1. Accuracy in the shape of the excavation.
2. Clean separation of rock from the bottom of the excavation (shaft face).
3. Even and sufficient comminution of rock.
4. Avoiding cutoffs of neighboring active holes.
5. Avoiding damage to nearby shaft installations.

The drilling pattern depends on such factors as the shape of the shaft section, rock strength, cleavage, dip of strata, water inflow, and hole loading structure.

In circular shafts with small and moderate strata dip, holes are placed on concentric circles, drawn from the center of the shaft. The number of circles is three to five, depending on the shaft diameter (Fig. 17.4.23).

The central hole is vertical and shorter, about two-thirds the length of the other holes. This hole initiates conical excavation by cut holes and is especially recommended in strong rocks.

Holes of the first (central) circle, so-called wedge holes inclined towards the shaft center, are shot first to open an additional free surface and to make easier and more efficient the work of the remaining external holes. They are drilled with an opposite (outward) inclination of 65 to 75°. Four to ten holes are drilled for the first circle. The ends of four holes are intended to create a square with sides of 7 to 12 in. (180 to 300 mm). For a larger number of holes, a circle 1.3 to 2 ft (400 to 600 mm) in diameter is used. In general, the harder the rock, the more first-cut holes are required.

Holes of the next two, three, and sometimes four circles crush and lift the excavated material.

The diameter of circles when the cartridge is 1.25 in. (32 mm) is dependent on the shaft diameter *D:*

1. With three circles, use 0.37, 0.66, and 0.93 *D.*
2. With four circles, use 0.35, 0.54, 0.7, and 0.93 *D.*
3. With five circles, use 0.27, 0.43, 0.6, 0.73, and 0.93 *D.*

The ratio of the hole number in particular circles is

1. For three circles: 1—2—3
2. For four circles: 1—2—3—4
3. For five circles: 1—2—3—4—5

When cartridges 1.78 in. (45 mm) in diameter are used, holes are placed usually in three or four circles with these diameters:

1. For three circles, use 0.3, 0.6, and 0.95 *D*
2. For four circles, use 0.25, 0.48, 0.72, and 0.96 *D*

The ratio of hole number in particular circles is then for three circles, 1—3—6, and for four circles, 1—2—3—5.

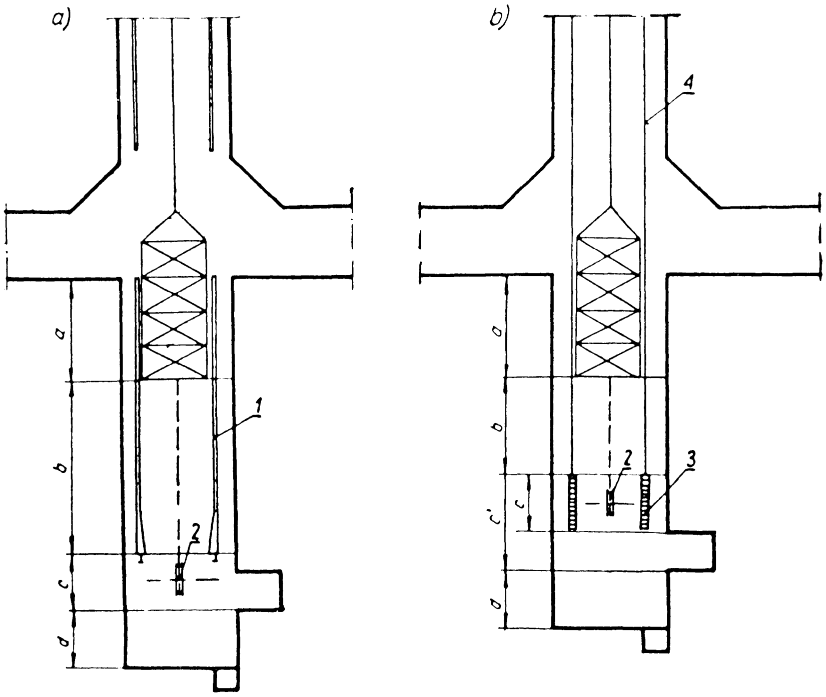

Fig. 17.4.17. Determination of shaft bottom depth (a) in personnel shaft using stiff guides (1), and (b) for material hoisting using rope guides (4). Space must be allowed for return sheave (2) and rope guide weights (3). Then depth (in m) = *a+b+c+d,* where *a* = (*n* – 1) *w, b* = (1–1.5) *w, c* = 2–10 m, and *d* = 3m, *n* is the number of cage floors, *w* is the distance between floors, *v* is the maximum hoisting speed in m/s, *b* is the freeway (max. 35 ft or 10 m), and *c* is the sheave clearance in m. (After Walewski, 1965.) Conversion factor: 1 ft = 0.3048 m.

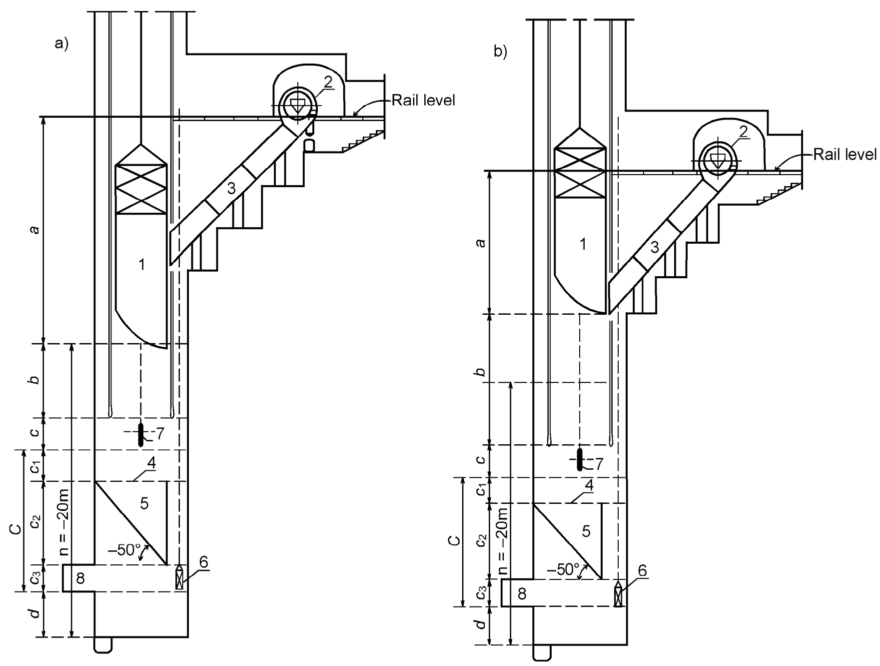

Fig. 17.4.18. Determination of shaft bottom depth in a skip shaft (a) for material hoisting and (b) for personnel hoisting. In this case, depth = *a+b+c+d,* as in Fig. 17.4.17, but a includes additional clearance for the skip (1), tippler (2), and batchers (3); and *c* includes clearance for the protecting grill (4), spillage bunker (5), auxiliary hoisting bucket (6), and return sheave (7); *d* is the sump pump chamber (8). (After Walewski, 1965.)

The inclination of holes varies from 65 to 85°, and the further they are from the center of the shaft, the more vertical they are.

The distance between adjacent holes on a circle should not exceed 2.6 to 3 ft (0.8 to 0.9 m) for 1.26-in. (32-mm) and 1.4-in. (36-mm) cartridges; for a 1.77-in. (45 mm) cartridge, it should be in the range of 3.28 to 4.92 ft (1 to 1.2 m). The last circles of so-called rib holes are supposed to leave the shaft wall smooth. They consist of holes drilled toward the shaft wall, 65 to 85° (less inclination for weak rocks and more for stronger ones). In very weak rocks, they can be slightly inclined toward the center of the shaft as are all the others.

Rib holes are placed in a circle with a diameter of 2 ft (0.6 m) less than the shaft diameter in rocks with a coherence factor of f = 2 to 8 and 1 ft (0.3 m) for rocks with f = 9 to 20. The distance from the shaft wall has to be such that in rocks with $f < 8$, holes should not project from the design shaft section, and in rocks with $f > 8$, they should protrude about 4 to 8 in. (100 to 200 mm) outside the shaft contour. The distance between rib

Conversion factor: 1 ft^3 = 0.0283 m^3.

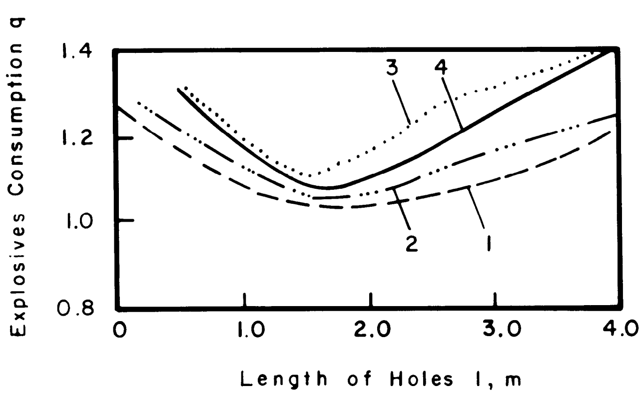

Fig. 17.4.20. Dependence of unit consumption of explosive q = kg/m^3 on length of blastholes (for shales):

1. $\eta = 0.55$
2. $\eta = 0.65$
3. $\eta = 0.75$
4. $\eta = 0.85$

Conversion factor: 1 ft = 0.3048 m.

holes in moderate-strength rock is 3 to 4 ft (0.9 to 1.2 m) and in strong rocks 2.23 to 3 ft (0.7 to 0.9 m). Sometimes it is necessary to place them as close as 7 to 12 in. (0.2 to 0.3 m).

When strata have a dip of more than 45°, the wedge holes are located along the strike, decreasing utilization of holes along the stratification (Fig. 17.4.24).

Overbreakage will be larger on the side of the hanging strata. The distance of the rib holes from the shaft contour on the dip side is 0.75 to 1.2 ft (0.25 to 0.4 m) in moderate-strength strata

Conversion factor: 1 ft = 0.3048 m.

and 0.15 to 0.25 in strong rocks. In inclined strata, the rock being blasted tends to form a pile on one side of the shaft. It creates difficulties in stationing buckets and in mucking operations.

In rectangular shafts, blasting holes are distributed similarly to horizontal drifts. The most typical and effective systems are the wedge and pyramidal ones (Fig. 17.4.25). A step pattern is used for conditions of larger water inflow (20,000 gal/hr or 80 m^3/h). The deeper part works as a sump for a pump.

Another development in drilling patterns, originating in the Scandinavian countries, is based on a central larger diameter hole (or holes) drilled parallel to the axis of the shaft (tunnel). This is possible only with application of the drilling jumbo, and in shafts, requires special organization of the drilling. Such a relief (burn cut) hole provides an additional free surface and increases the efficiency of blasting, reducing the consumption of explosives. This method was tested in hard rocks of the Canadian Shield for extension of an existing shaft 550 to 1350 ft (180 to 443 m) deep, where the powder factor was 5 to 5.4 lb/yd^3 (3 to 3.2 kg/m^3).

An example of the drilling pattern for a shaft 30 ft (9 m) in diameter in high-strength siltstone (Fig. 17.4.26) shows the distribution of holes and a schematic of the wiring of electric caps. Table 17.4.6 lists other data.

Shooting features include back initiation of shot holes, electric millisecond caps with consecutive delay steps in particular circles (with this same delay in each circle), a three-ring connecting system of electric caps (to diminish the probability of misfire), lighter shooting, and separate shot cables (exclusively for shooting).

A wedge cut was chosen for this round (Fig. 17.4.26). The largest charges were in lever holes (II, III, IV circles) and the smallest in wedge and rib holes (I and VI circles). Blastholes are charged with dynamite (381 lb or 173 kg/round). Millisecond fuses are initiated in six series, one after the other. Four workers load holes; one of them is the firemaster. The cartridge with the cap goes into the hole first. Each shotfirer makes the connections for his circle. Then the firemaster checks connections and makes the main one, to the shot cables. Afterwards, the shot firers go to the surface, and the resistivity of the wiring is measured. Shooting is done with a high-capacity shot lighter. The blast is supposed to crush the rock and lift it and, in this process, increase its volume by the swell factor.

By visual inspection, the shooting effect can be assessed. A centrally located pile of muck implies a correct shot. Piles on the side of the shaft indicate misfires there, or nonuniform hole charges. Since the bottom of the shaft is covered with muck, it is difficult to find misfires. A basic safety precaution in the shaft is to watch for misfires. When localized, an additional shot hole is drilled parallel to shoot out the remnant stump of rock and blasting material in the unfired hole.

Drilling of Shot Holes—Blastholes can be drilled with sinker percussive drills, hand-held or mounted on a special shaft jumbo. Sinkers are self-rotating, compressed-air or hydraulically driven with air or water flushing.

There are two organizational systems: (1) *series,* in which the drilling starts from the shaft center toward its perimeter after completion of mucking, and (2) *parallel,* where mucking and drilling are done at the same time. Drilling starts from the perimeter towards the shaft center. A shaft jumbo can be used only in the series system. A series system is used in smaller shafts when a Cryderman or similar type of mucker is used. This system assures precision in blasthole drilling.

The parallel system is sometimes chosen in large cross-sectional shafts where cactus grab cabin muckers start to clean the sides of the shaft moving towards its center. Drilling is done in the cleaned area. Owing to parallel drilling and mucking, some time saving can be achieved; however, it is at the expense of drilling accuracy. Blastholes can be drilled individually or by groups of drillers. In the first case, approximately 25% of the time is lost in changing bits. In the second, one shaft area is divided according to the number of drillers; each group drills in one sector holes of a certain depth only. Bits are changed only when they get dull (usually after two to four holes). Then the drilling rod is changed (lengthened), and work is done in the next sector. Wooden sticks secure holes against muck.

Drilling equipment is delivered in a special bucket or basket to the shaft bottom. An elastic hose with quick coupling is connected to the main steel compressed air tubing. At the end of the elastic hose, there is a distributor with multiple outlets and valves for particular drills. Drilling is a labor-intensive operation, which takes about 16% of the cycle time.

Shaft drill jumbos have been developed to mechanize blast hole drilling (Fig. 17.4.27). These permit the drilling of larger-diameter holes more precisely, faster, and deeper.

Loading of Blastholes and Shooting—Before the drilling of blastholes is finished, the shotmaster installs caps in the cartridges in a secure, fire-resistant shelter a minimum of 60 ft (20 m) from the shaft. These cartridges are carefully lowered in a special soft-lined container. The shot firer is responsible for appropriate loading of holes. The shot firer checks the hole and then loads the first (charged with a cap) cartridge and puts the first stemming in top of it. Further loading is done by the rest of the crew.

Wedge holes have zero-delay caps. The next circles have millisecond caps. Detonating wires should be well insulated. To

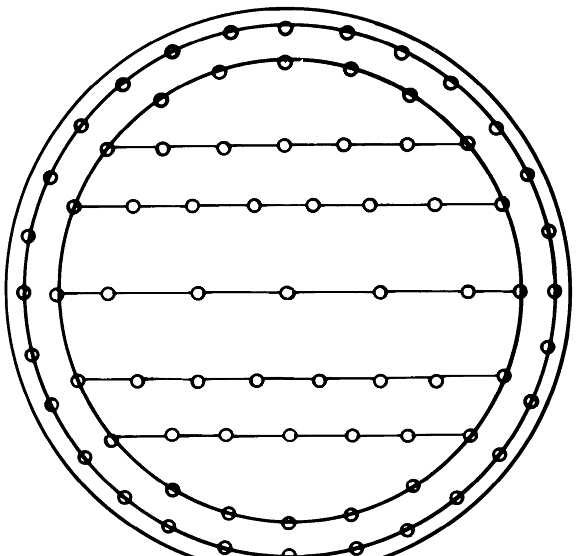

Fig. 17.4.24. Example of drillhole distribution in shaft sunk in inclined strata.

prevent the hazard of stray current, the ends of wires are short circuited until they are connected to the shot cable.

A clay-sand mixture is used as stemming. In wet shafts, flooding to a 10-in. (250-mm) depth substitutes for stemming. Loading time for one hole is about 6 to 8 minutes and for the whole round, about 60 to 90 minutes. Caps of detonating cartridges can be connected in series, in parallel, or in a mixed manner. Connection in series is the simplest method but also the least reliable. Failure of one cap means a misfire of all the holes.

A mixed connection is done in such a way that a group of holes is connected in series, and particular groups are connected parallel to the main shot cable. An example of a mixed connection is shown in Fig. 17.4.28.

When connections are completed, face lights are pulled up on the stage. The shot master is the last to leave the face. Firing is done by a shot lighter from the surface.

SHAFT VENTILATION. Shaft ventilation is carried out by fan and vent tubing, as described in Chapters 11.6 and 11.7.

MUCKING IN SHAFTS. Mucking in shafts is the most time- and effort-consuming operation, accounting for as much as 50 to 60% of cycle time. Table 17.4.7. gives different factors influencing mucking efficiency. Fig. 17.4.29 shows a schematic of sinking phases with an Eimco 630 loader. Fig. 17.4.30 illustrates the section through a shaft sunk with a cactus grab loading unit.

Mucking efficiency is dependent also on the degree of rock fragmentation and the height of the bucket. For mechanical mucking, medium-sized fragmentation, approximately 5 in. (125 mm), is most efficient.

Generally, in a muck pile after a shot, 70 to 80% of the material is fine fragmentation, and the rest is composed of larger fragments.

Muckers—Several types of muckers are in use depending on shaft shape, size, depth, and location, as listed below:

1. Scrapers, used in rectangular shafts and very large-diameter shafts (underground bunkers).

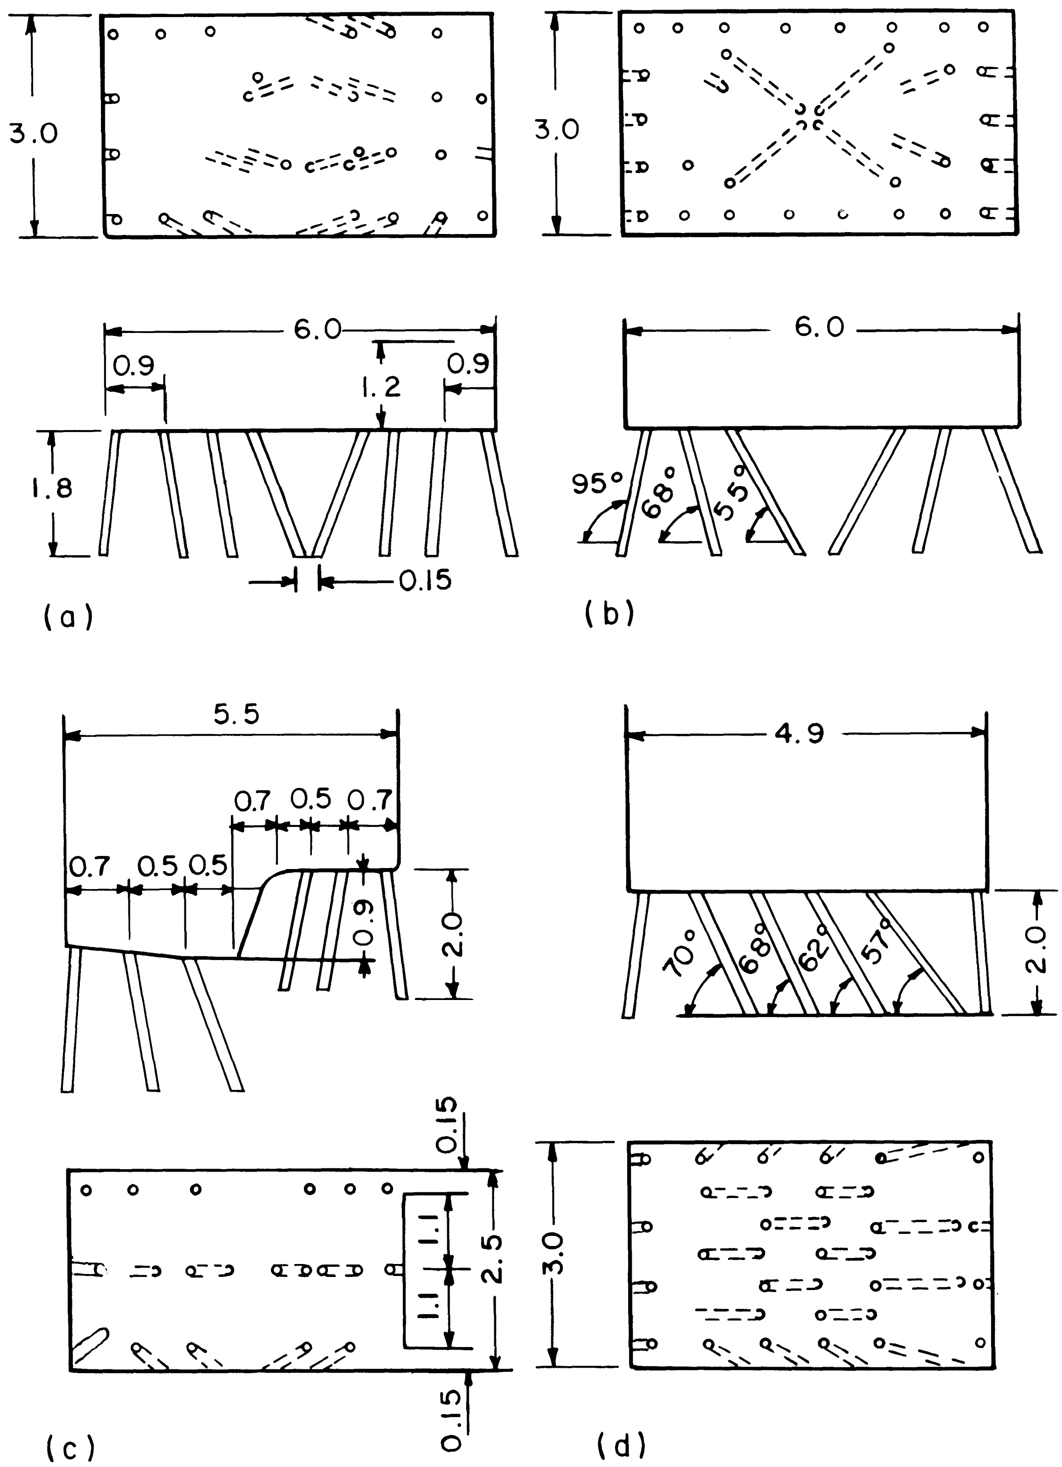

Fig. 17.4.25. Examples of hole distribution in rectangular shafts.

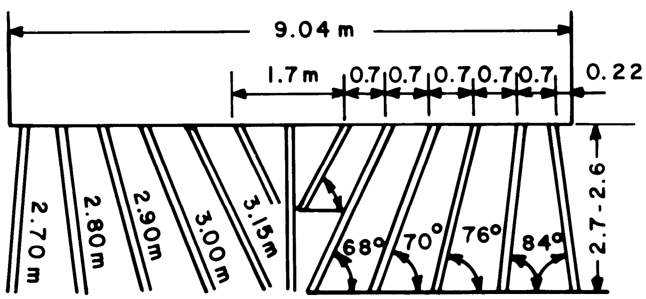
Conversion factor: 1 lb. = 0.4536 kg.



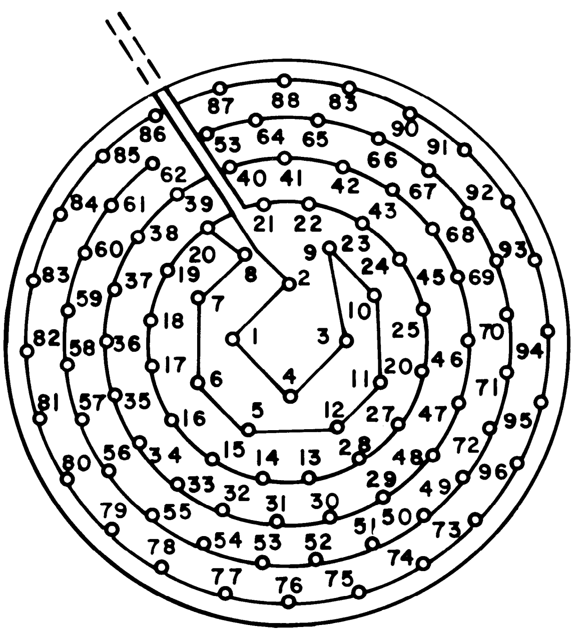


Fig. 17.4.26. Drilling pattern for shaft 27.5 ft (9.04 m) in diameter. Conversion factor: 1 ft = 0.3048 m.

2. Overshot loaders on caterpillars (e.g., Eimco 630).
3. Cryderman muckers.
4. Cactus grab (light).
5. Cactus grab (heavy, on central pivot).

A variety of systems is used. Some are driven by an operator (e.g., Eimco), some are hand-guided at the face when hanging from a platform, and some are attached to the shaft wall (Cryderman) and operated from a control cabin. Heavy cactus grab units have a rotating arm on a central pivot below the stage. The largest muckers are 1.3 yd^3 (1 m^3) capacity. Generally, large-capacity muckers are used for deep shafts with large diameters, where a high level of equipment investment is justified. Muckers can be electric, pneumatic, or hydraulically driven.

Determination of Mucker Capacity—The theoretical mucking efficiency P_t in yd^3 (m^3)/hr is

$$P_t = 3600\, k \frac{V_b}{t} \tag{17.4.15}$$

where k is the fill factor (0.8 to 0.9 for sandstone and 1.1 to 1.2 for shales), V_b is bucket volume in yd^3 (m^3), and t is mucking time in sec.

The mean actual efficiency is found by calculating the actual mucking time and all time losses for unproductive activity such as mucker lowering time to work position, time of temporary support erecting when mucking has to be suspended, and time for final cleaning.

DEWATERING OF SHAFTS. Most shafts intersect one or more water courses, so shaft dewatering is an essential part of sinking.

The characteristic features of shaft dewatering consist of changing water inflow, changing pump head, water containing rock and mud particles, and periodic changes in positioning dewatering devices.

Dewatering can be considered either as limiting water inflow into the shaft or pumping water out of the shaft.

Water inflow into the shaft can be diminished by initial drainage of the rock mass, sealing of the water courses, or by tapping the water.

For dewatering the face, the following devices are used:

1. Rock kibbles and special water kibbles.
2. Face pumps.
3. Combination of face and stationary pumps.
4. Combination of hanging and stationary pumps.
5. Submersible pumps.
6. Airlifts.

Dewatering with Kibbles—Removal of water with the muck being hoisted is the simplest dewatering system. A small portable pump is usually driven by compressed air with a head of 55 ft (18 m) water and output of 40 to 132 gal/hr (0.15 to 0.5 m^3/h) (it could also be any other type of electric pump approved for shaft face conditions).

Usually a kibble (bucket or skip) exclusively filled with water is periodically hoisted up, depending on the need.

A limit of the kibble dewatering system derived from the condition not to flood the face during shooting and ventilating is given by the formula (in SI units):

$$q > 0.8\, D^2 (kl + 0.1)/t \tag{17.4.16}$$

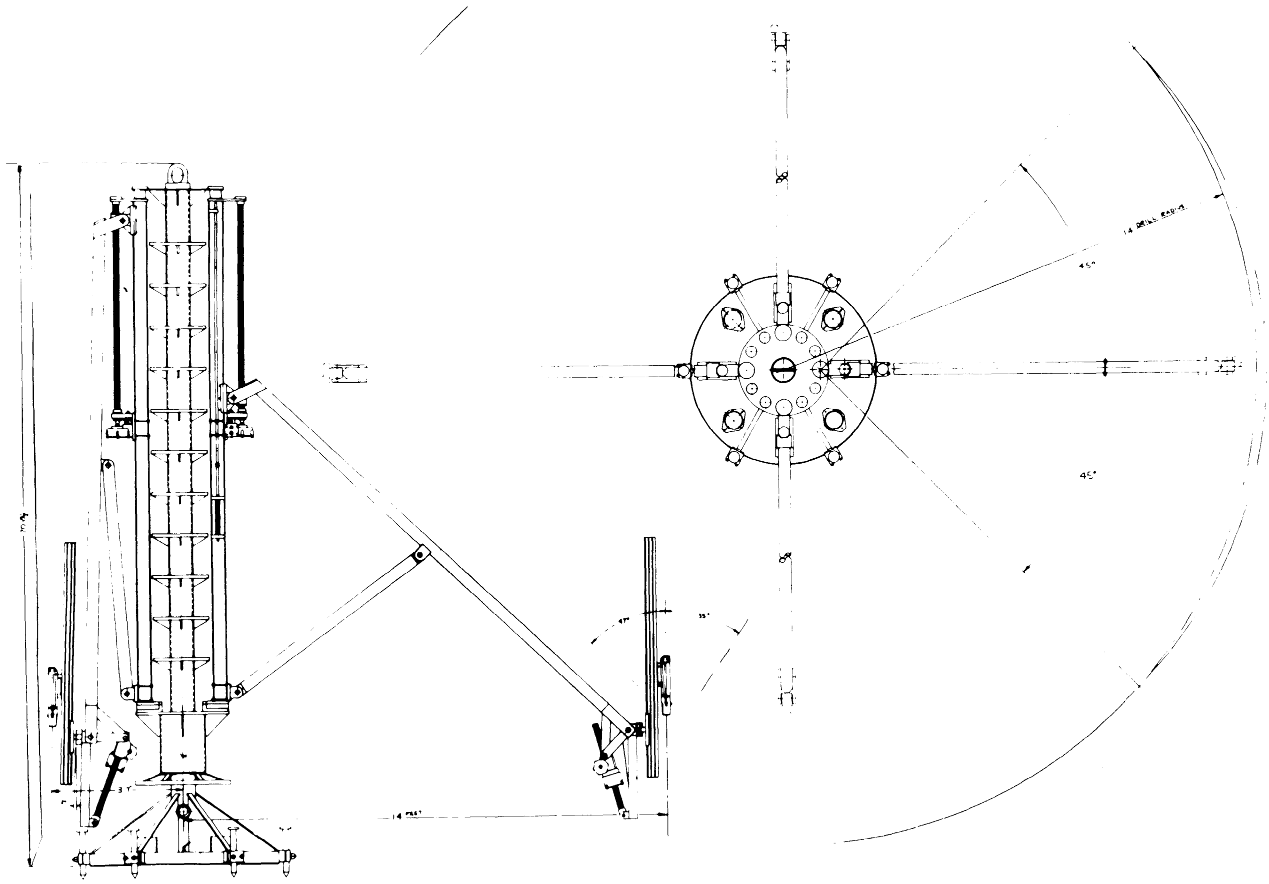

Fig. 17.4.27. ASJB-3B Shaft Jumbo (courtesy: Acme Machinery Co.). Conversion factor: 1 ft = 0.3045 m.

where q is water inflow in m^3/h, t is pumping time in coordination with blasting work in h, k is the coefficient characterizing the size of voids in the muck (0.5 to 0.6 for hard rocks and 0.3 to 0.4 for weak rocks), D is kibble diameter in m, l is depth of blasthole in m, and 0.1 m is the allowable water table level in the shaft.

Table 17.4.9. shows the amount of water inflow that can be controlled by dewatering with kibbles, depending on kibble capacity and the number of kibbles hoisted per hour. For example, from European practice, it is known that the limit for this system of dewatering for shafts down to 490 ft (150 m) deep is 800 gal/hr (3 m^3/h).

Face Pumps—Face pumps work on various principles. Compressed-air-driven membrane pumps are particularly effective in handling dirty water as it gathers in the shaft face and therefore are often used.

Hanging Pumps—Hanging pumps are used to control larger inflows, and when required, heads of 600 to 1200 ft (200 to 400 m). An advantage of these pumps is that they can be easily lifted up during shooting.

Dewatering with Airlifts—The airlift pump is powered by compressed air. The two main systems for these pumps are (1) parallel, where the air pipe runs beside the water pipe, and (2) concentric, in which arrangement the air pipe is inside the water pipe.

Airlifts require substantial submersion, so they are applicable in dewatering flooded shafts. They can handle dirty water, even quicksands.

Intermediate Pumping—When sinking a deep shaft, intermediate pumping has to be applied. The number of stages depends on the depth. On levels chosen as stages, overflow chambers are built. Pumping in stages can be arranged in the following systems:

1. The face pump delivers water to the overflow chamber, and from this it is pumped up by stationary pumps to the surface or to another chamber.
2. The hanging pump delivers water to the overflow chamber from where the stationary pump sends it upward.
3. The face pump pumps water to the overflow chamber where an airlift delivers it up to the surface.

SHAFT LINING CONSTRUCTION. The following factors determine the type of lining: hydrogeologic conditions, shaft function, planned lifetime, shape of shaft section and its depth, availability of construction materials, and construction cost.

When choosing a shaft lining, geotechnical properties of the rock and hydrologic conditions are decisive in most cases. However, the chemical activity (corrosiveness) of the water can also be an important consideration. Since modern new shafts often have automatically operating hoisting gear (moisture sensitive), they should be dry. Main shafts are usually planned for the entire mine life span, so they should be constructed to minimize repairs and maintenance time.

TEMPORARY LINING. Temporary support is placed to protect the crew and equipment against falling rocks from the exposed shaft wall before a permanent lining is placed. Temporary support is used when the face is advancing, leaving a longer lift

Factor	1.0	0.9		0.8		0.75

Conversion factors: 1 ft = 0.3048 m, 1 ft^2 = 0.0929 m^2, 1 gpm = 3.786 L/min.

up to 20 to 120 ft (6 to 40 m) of unlined shaft. Work at the face is then suspended, and the temporary support is dismantled, allowing positioning of a concrete form.

When removal of the temporary lining creates safety problems, it can be left and concrete poured over it.

Numerous systems of temporary lining are in use. One of the most popular types is shown in Fig. 17.4.31. Steel rings in profile are assembled and suspended from round, 1-in. (25mm) steel hangers. Each ring consists of six to eight separate segments bolted together with the possibility of a diameter change to fit the excavation. Boards, iron grates, or sheets are placed behind the rings. The first ring is supported by pins (into the shaft wall), placed every 4 to 5 ft (1.2 to 1.5 m) around the shaft perimeter and every five to six rings vertically. Wooden wedges are driven to make the rings tight.

Permanent Lining—According to the shaft design and environmental conditions, several different permanent lining systems can be applied: (1) timber, (2) brick or concrete blocks, (3) concrete monolithic, (4) reinforced concrete, (5) tubbing (cast iron and precast elements), (6) shotcrete, various systems (e.g., with mesh), or (7) anchor bolts. Quite often, the lining consists of a combination of the above listed types.

Timber Lining—In contemporary shafts, timber lining is very seldom used, and when it is, only in auxiliary shafts with a short life span (interlevel blind shafts).

Timber lining can be "full" with sets lying one on top of the other in more difficult ground conditions, or in better conditions, on posts with the distance of particular sets 2 to 5 ft (0.5 to 1.5 m). In both arrangements, every 25 to 45 ft (8 to 15 m), bearing beams are set, placed in nests 2 to 2.5 ft (0.5 to 0.7 m) deep. They are wedged to get the entire structure tightened into the surrounding rocks (Figs. 17.4.32 and 17.4.33).

Brick Lining—Brick lining was popular before the mechanization of shaft sinking. There are some characteristic features of this lining such as simplicity and ease of construction, ability to carry load immediately, ease of repairs, and resistance to corrosive waters (Fig. 17.4.34) that can be advantageous in certain conditions.

Among the disadvantages of brick lining are the following:
1. Time- and labor-consuming erection.
2. Low strength.
3. High cost (when labor is expensive).
4. Substantial permeability.

Concrete Block Lining—Concrete block lining is a type of improved brick lining possessing a decreased number of seams and the higher strength of a concrete shaft wall. This lining is also less labor-intensive when compared to brick lining.

Monolithic Concrete Lining—This is the most popular shaft lining. It has many advantages when compared to other types, such as:

1. The possibility of complete mechanization of the construction process with slip or switch forms and by transporting concrete through the slickline.
2. Good bond between the lining and shaft (rock) wall such that shaft footings (foundations) are not needed.
3. Decreased labor intensity (three to six times) and costs (30 to 40%) compared to bricks.
4. High strength, resulting in less required excavation.

Disadvantages are
1. Less resistance to corrosive water.
2. Sensitivity to rock mass movement.
3. Inability to take load immediately after placement.
4. Difficulty of repairs.

In ordinary conditions, a moderate-strength (2400- to 3500-psi, or 17 to 25 MPa) concrete is sufficient for lining purposes. It is made of natural aggregate and Portland or slag cement (3500 to 5000 psi, or 25 to 35 MPa). The concrete mix is prepared in the vicinity of the shaft (in a mechanized concrete plant) and sent down the shaft by one or two pipelines (sticklines). The minimum lining thickness is 8 in. (200 mm) and the maximum 32 in. (800 mm). There are several technologies of construction. When sinking in series, short segments of shaft, 13.1 to 16.4 ft (4 to 5 m) in length, are lined with the application of a collapsible steel form, which is relocated after the concrete sets. Lining made in that way is not a monolith but consists of segments with seams (Fig. 17.4.35).

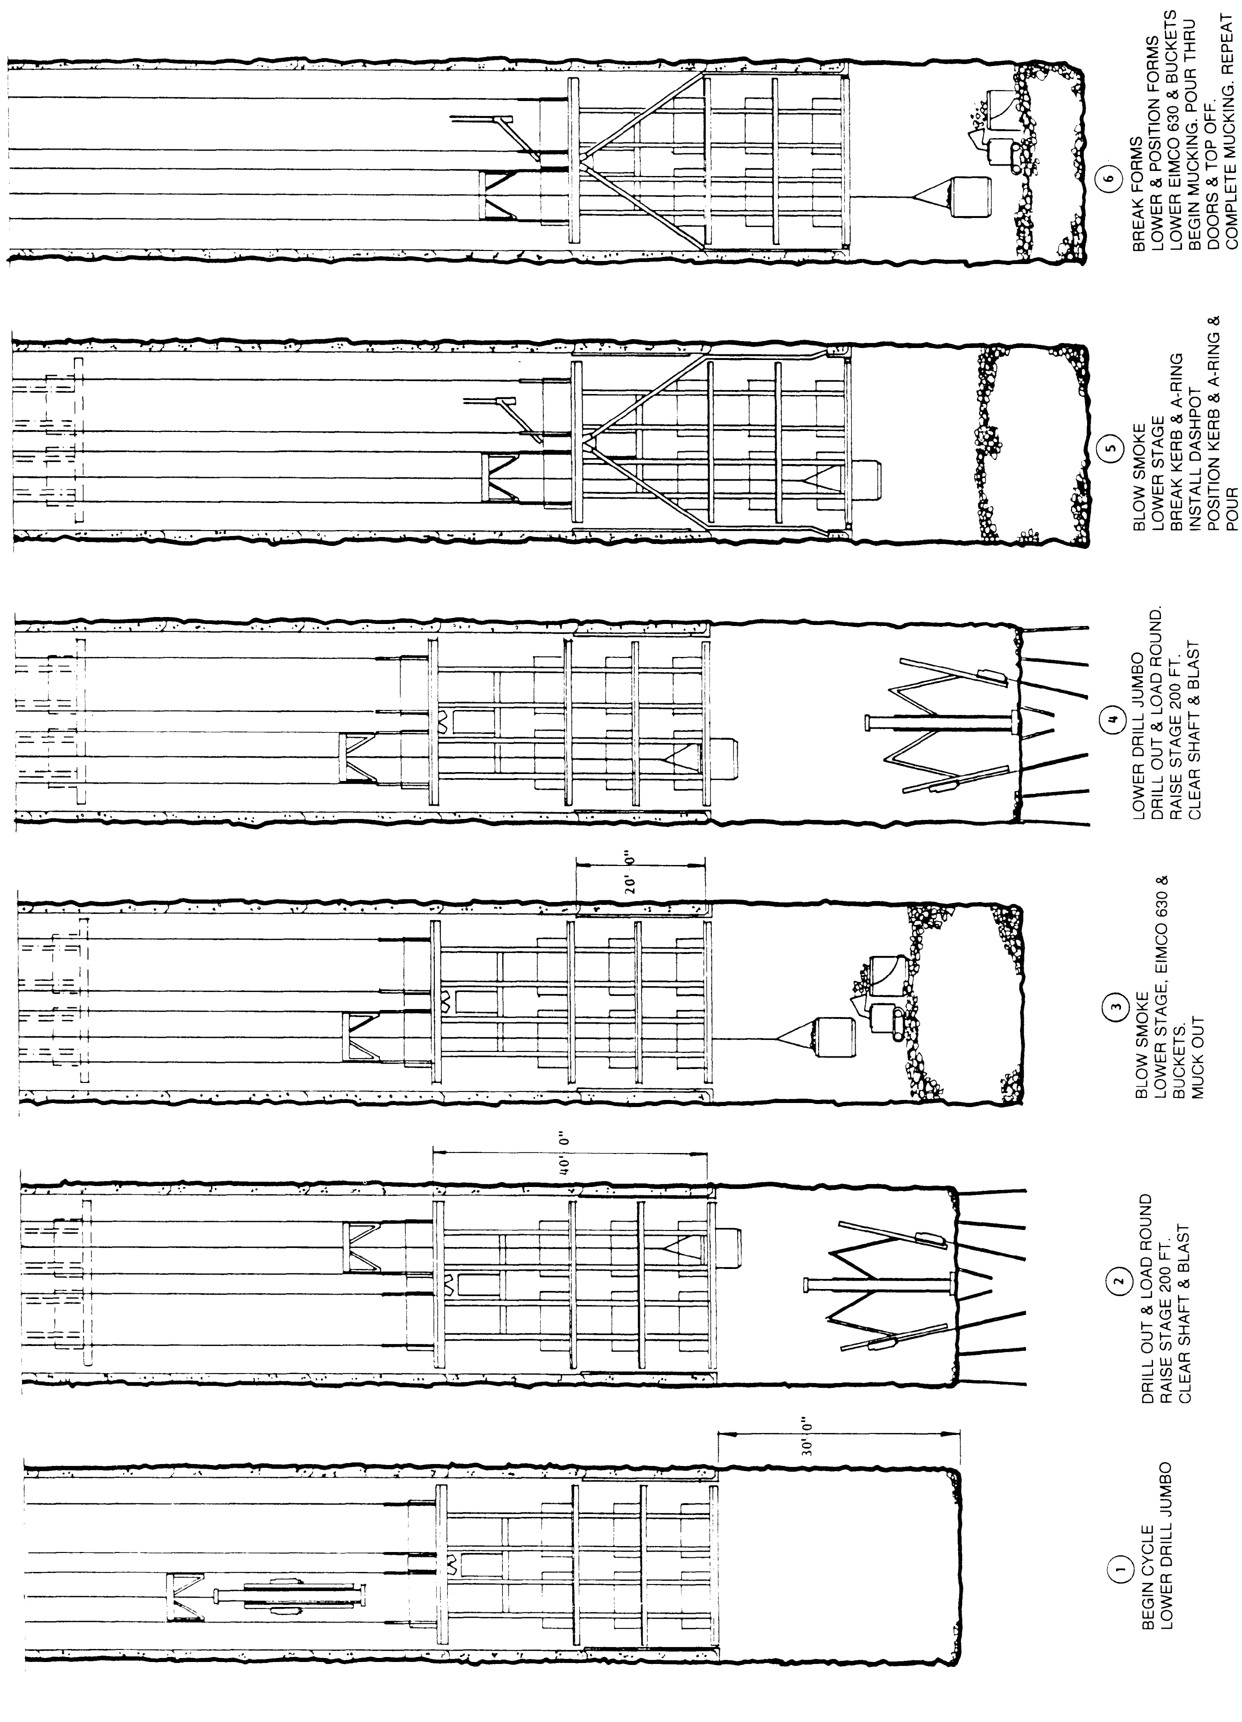

Fig. 17.4.29. Schematic of sinking operations. (After Hynd, 1982.) Conversion factor: 1 ft = 0.3048 m.

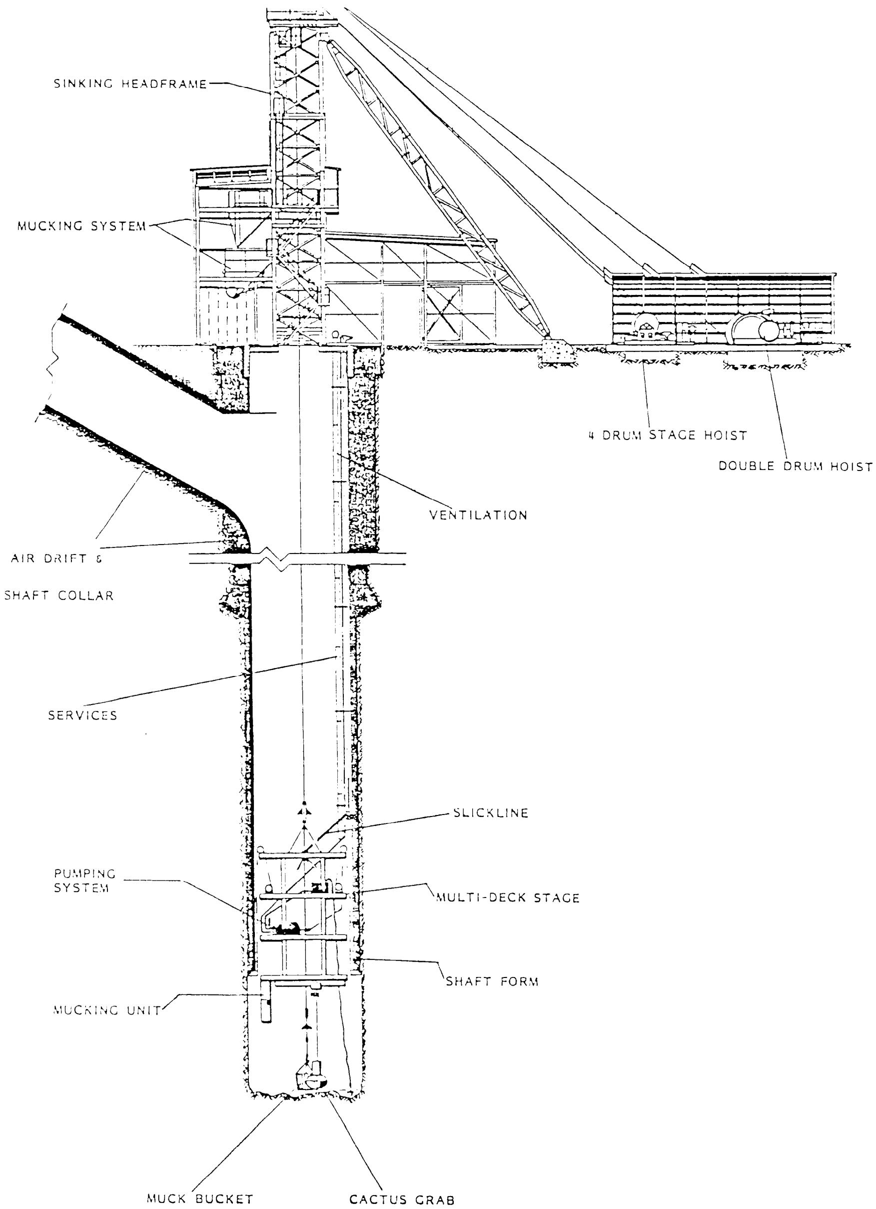

Fig. 17.4.30. Typical shaft sinking arrangement. (After Hynd, 1982.)

Table 17.4.8. Allowable Water Inflow, When Dewatering Is Done with Kibbles (Buckets)

Number of kibbles hoisting n/h	Water inflow (m^3/h) when controlled with kibbles of capacity m^3			
	1.0	1.5	2.0	2.5
5	2.25	3.4	4.5	6.75
10	4.5	6.8	9.0	13.5
15	6.75	10.2	13.5	20.3

Conversion factor: 1 ft^3 = 0.0283 m^3.

When the shaft is sunk in long lifts, a sliding concrete form can be applied. As a result, longer sections of monolithic lining are obtained.

Shotcrete Lining—Shotcrete lining can be made in a few variants, such as regular shotcrete, shotcrete with rock bolts, reinforced concrete, and reinforced concrete with bolts.

Shotcrete lining is applicable in dry shafts in rocks with good strength. Especially in blind shafts of smaller diameter where the use of concrete forms is limited, shotcrete is very useful. Shotcrete has some very attractive technical features such as very good binding with rock, tightness, and high strength due to low water/cement (w/c) ratio.

Shotcrete, however, is more often used in combination with rock bolts and mesh. The last two are generally installed as a temporary support, prior to or after the first shotcreting. Finally, shotcrete covers the mesh pinned to the shaft wall with bolts and creates a strong but thin shell of lining.

Rock Bolt Lining—Rock bolt lining is used primarily in salt mine shafts. Salt has creep characteristics and by flowing toward the opening, will exert an excessive pressure on a rigid shaft lining.

Two main systems are in use in such conditions. When salt rock is in good shape, no lining is required for ground control. In the presence of laminations and an overall tendency to weathering that creates worse conditions, rock bolts and mesh made

Table 17.4.9. Applicability of Special Methods of Shaft Sinking

	Method	Rock Mass	Thickness of Water-bearing Strata (m)	Water Inflow	Range of Depth (m)	Approximate Rate of Advance m/month	Comments
1.	Pile wall a) wooden b) sheet pile wall (steel profiles or pipes)	Quicksands, soils (saturated with water without stones and rock fragments)	2–6 6–10	limited	6–15 down to 30	2–5 6–10	Required presence of impermeable strata of clay, into which the piles could be driven to lock water in above water-bearing strata
2.	Concrete pile wall drilled or driven piles	Quicksands, soils, loose rocks (sands, gravels), clays saturated with water (also with stones)	10–20	any	25–30	8–10	Concrete pile wall can be used as a foundation for a shaft headgear.
3.	Caisson method a) Without pumping water in flow rocks b) With steady pumping in weak and loose water bearing rocks	Uniform flowrocks or loose rocks (sands gravel), clays, without intrusion of hard rock or boulders	10–15	not limited up to 0.3 m^3/min	down to 30, in special cases more when vibrators or compressed air applied	10–20	Flat-lying strata required or with little dip. Presence of the clay strata below water-bearing zone 2–3m thick is necessary.
4.	Caisson with compressed air	Loose or noncoherent water bearing strata	8–30	moderate	down to 40	20–30	Maximum air pressure in the face chamber 3–3.5 atmospheres
5.	Depression of groundwater level	Mid and coarse solids and gravels with coefficient of filtration 10–100 m/day. Fractured competent rocks.	20–30	great	around 100–150	15–20	Not supposed to be applied in clay rocks, quicksands, and alternating packages of permeable and not permeable rock.
6.	Chemical grouting	Sands with clay content not exceeding 10–15%. Coefficient of filtration 2–80 m/day. Also competent rocks with small tissue	a few	moderate	unlimited		Usually used as an additional interventional method
7.	Grouting (cement)	Competent rocks, with tissues and cracks filled with water (sandstones, shales, mudstones, limestones), and coarse sands and gravels	not limited	mid and large, up to about 10 m^3/min	any	10–15 in good conditions 20–30	Not recommended in flow rocks or quicksands, with water flow velocity more than 80 m/day, or in presence of caverns and large voids
8.	Grouting with clay	Water-bearing rocks with large cracks and voids	not limited	not limited	not limited	10–15	Can be used in presence of aggressive waters. Usually is used combined with grouting (cement).
9.	Bitumination	Competent rocks with large cracks and voids, also gravels	20–30	mid and large	down to about 40		Used as an auxiliary method for local sealing of the rocks with high flow velocity and aggressive waters.
10.	Freezing of the rock mass	All types of water-bearing rocks	10 to 1000	not limited	down to 1000	differs depending on depth, sinking frozen rocks up to 50 m overall less due to length of freezing method	Most reliable method, however, costly and time consuming because of expensive and time-consuming preparation works. (drilling of the freezing holes freezing themselves).
11.	Shaft drilling	Weak, water-bearing strata	several hundred	not limited	to 600		Thickness of competent hard rocks not supposed to exceed 10% of overall thickness of water-bearing strata.

Conversion factors: 1 ft = 0.3048 m, 1 ft^3 = 0.0283 m^3.

from synthetic materials (e.g., plastic, which does not corrode) are used. This same support system in salt is applied in insets, chambers, and other capital openings.

17.4.2.3 Specialized Methods of Shaft Sinking

CLASSIFICATION. Special methods of shaft sinking are used when the following conditions are encountered:

1. Incompetent, water-bearing rocks (e.g., quicksand).
2. Weak, unstable, soil-type rocks.
3. Competent fractured rocks, with high water inflows above 130 gpm (0.5 m^3/min).

There are numerous special methods varying among themselves in applicability because of environmental conditions and range of depths. The characteristics of these are given in Table 17.4.9.

2. seam.
Conversion factor: 1 ft = 0.3048 m.

WOODEN PILE WALL. The initial diameter of the shaft collar D_g (Figs. 17.4.36 and 17.4.37) should be established according to the following:

$$D_g = D + 2(d + 2b + c + f) \qquad (17.4.17)$$

where d is permanent lining thickness, b is width of guide rings, c is thickness of driven piles, and f is thickness of guide beams.

SHEET PILE WALL (STEEL). Construction of a steel sheet pile wall is shown in Fig. 17.4.38.

CONCRETE (REINFORCED CONCRETE PILE WALL). Two currently used methods of placing a concrete pile wall are piles driven with an outer steel tube with a diameter of 20 in. (520 mm), and drilled piles, with or without slurry, leaving diameters 20 to 48 in. (520 to 1200 mm). The outer steel pipe is forced into the ground by a pile driver, whereas drilled piles are made by means of a drilling rig. Where the ground does not assure stabil-

ity of the side wall, a slurry is used to prevent failure of the hole. The concrete used for piles has a low water/cement ratio (approximately 0.4). To assure tightness of the concrete, it is placed in batches and compacted with a rammer.

Piles driven beside each other (Fig. 17.4.39), cutting into the side of the fresh concrete of the neighbor pile, create a tight wall, preventing water and loose rock from penetrating the excavation (Fig. 17.4.40). For longer pipes, steel reinforcement is used. The limit of depth for this method is around 120 ft (40 m).

CAISSON METHOD. To permit advance of the caisson with weight Q and resisted by friction F, the following conditions have to be fulfilled (in SI units).

1. With water being pumped out: $Q > F$
2. Without pumping water: $Q > F + G$

$$Q = \frac{\pi(D_2^2 - D_1^2)}{4}\gamma H + B \tag{17.4.18}$$

a. Weight Q^1 of caisson partly submerged to depth H is $Q^1 = Q - G$, where G is calculated,

$$G = \frac{\pi(D_2^2 - D_1^2)}{4} H_w\,\delta_w + V_B\,\delta_w \tag{17.4.19}$$

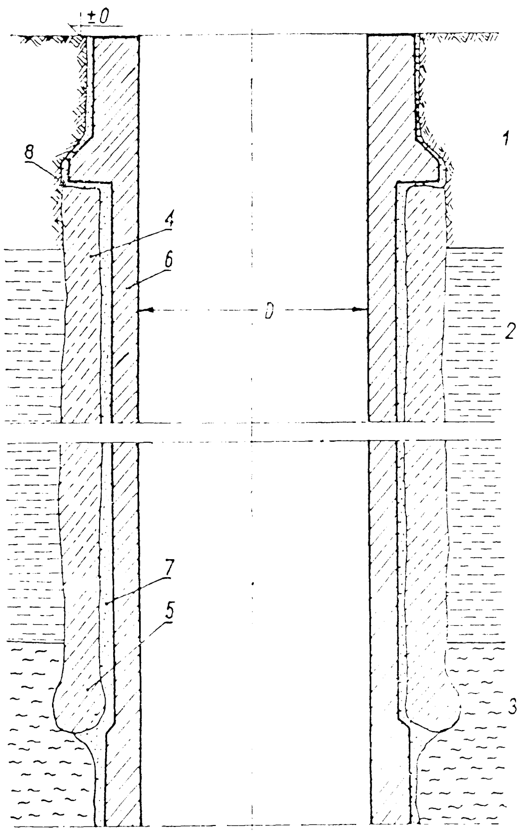

Fig. 17.4.40. Vertical section through the shaft.

2. water-bearing ground
3. nonpermeable clay strata
4. pile wall
5. base of the pile
6. shaft lining
7. inner layer of concrete
8. upper end of the pile wall.

where D_1 is inner diameter in m, D_2 is outer diameter in m, H is height of caisson in m, H_w is height of submerged part of caisson in m, B is weight of cutting toe in t, V is volume of cutting toe in m^3, δ_w is specific gravity of water in t/m^3, and γ is specific gravity of lining material in t/m^3.

b. Friction force, *F:*

$$F = \sum_{i=1}^{i=n} F_i = \pi D_2 \sum_{i=1}^{i=n} h_i \, f_i \qquad (17.4.20)$$

where f_i is friction force per unit in a particular strata in t/m^2, and h_i is thickness of particular strata thickness in m (Fig. 17.4.41).

For shallow caissons, the recommended value of friction force per unit area is in the range of 2.25 to 2.5 t/m^2 (when the depth of caisson does not exceed 75 ft or 25 m).

If either condition, $Q > F$ or $Q > F + G$, is not fulfilled, then the caisson will not sink and special methods are required, such as (1) some means to diminish friction between the lining and ground, or (2) additional load Q provided by ballast or jacking.

It is possible to diminish the friction by injecting water at 30 to 45 psi (210 to 320 kPa), or more than hydrostatic pressure, through the holes in the cutting toe.

Caisson Method With Compressed Air. The range of application of this method is limited to about 90 ft (30 m) because the maximum air pressure should not exceed 50 psi (350 kPa). Decompression to avoid the bends associated with working in a pressurized atmosphere is required for face crews. Compressed air in the caisson forces water back into the ground; therefore, face operations are in dry conditions. The pressure should be so adjusted that water will stay about 4 to 25 in. (100 to 400 mm) away. In this method, a lock chamber or chambers are required for transfer of the crew and for materials handling.

The thickness of roof at the working chamber is calculated according to the maximum pressure with a safety factor of 1.5. It is always a very solid reinforced concrete structure.

The lock dock has usually more than one chamber to accommodate hoisting facilities, personnel traffic, and materials handling.

To assure proper sinking, the vertical force downwards must be larger than the combined effect of friction and the vertical force acting upwards caused by positive air pressure in the caisson.

In the Moscow (USSR) coal basin, the caisson method with compressed air was often used, with rates of advance in sinking of (mean) 60 ft (20 m)/month and (maximum) 150 ft (45 m)/month.

Sinking Method With the Depression of Water Table. Design consideration for application of this method must be preceded by:

1. Choice of the most suitable way for depression of the water table in given conditions.
2. Determination of the number, spacing, diameter, and depth of the wells.
3. Calculation of the radius of the depression cone, amount of water to be pumped out, and the height of the remaining wet portion of the water-bearing strata.
4. Equipment, hardware, and pumping facilities.
5. Choice of the auxiliary method to go through the wet remainder of the water-bearing strata.

To lower the water table in the area of shaft sinking, the following system can be applied:

1. Pumping water from three to six depression wells drilled around the planned shaft perimeter, placed on a circle about 12 ft (4 m) larger than the diameter of the shaft excavation.
2. Draining water through drillholes to existing openings in the mine below.
3. Draining water through drillholes to water-absorptive strata (e.g., dry sands under water-bearing strata).

The first of these systems is the one most often used.

Wells. Wells are drilled with 14 to 20 in. (300 to 500 mm) diameters, without drilling mud. They are spaced uniformly around the future excavation. Within the range of the water-bearing strata, they are equipped with filters perforated by round or elongated holes 0.2 to 0.35 in. (5 to 10 mm) in diameter, spaced in a checker design, with an outside screen having eyes 0.015 to 0.035 in. (0.4 to 0.9 mm) in diameter, sized against entry of sand particles. Generally, the construction of the filter must be suitable for the character of strata to be drained.

Submersible drainage pumps have a wide capacity range, varying up to 92,500 gal/hr (350 m^3/h).

Calculations for well efficiency are based on principles of flow through porous media. The objective of the design is to determine a pumping regime to achieve a dry-out zone surrounding the shaft. This is created by the cumulative effect of the depression cones around particular drainage wells (Fig. 17.4.41). The movement of water through a porous media is given by the Darcy formula,

$$V = K\frac{dh}{dl} = Ki + K\frac{h}{l} \qquad (17.4.21)$$

where V is mean velocity of flow per unit time through a unit area or mean filtration velocity in m/s; $h = h_2 - h_1$, or the difference of water levels in the ground (depression) created by pumping water or head loss during flow; l is distance in which head loss appears in m, K is the coefficient of filtration (permeability factor) in m/s; and $i = \frac{h}{l} = \frac{h_2 - h_1}{l}$, or head loss over a unit distance (hydraulic gradient), which is a dimensionless quantity.

The coefficient of filtration K may be expressed in the following units: ft/day (m/s, cm/s, m/day). It has a characteristic value for a particular rock, depending upon the rock structure, grain size, etc.

The best drainage results are obtained in coarse and mid-size sands with K = 30 to 300 ft/day (10 to 100 m/day). Within the feasible range of drainage methods, it will successfully compete with other methods in terms of costs. It could be combined with the caisson method (with compressed air) to allow lowering the air pressure in the working chamber.

One of the negative features, especially in fine sand, is the carrying away of silt particles entrained in the water being pumped. This can cause substantial subsidence effects. An application of adequate filters can help to control a siltation problem.

SHAFT SINKING WITH APPLICATION OF GROUTING METHOD. Based on geologic data, the following decisions have to be made prior to the start of the project:

1. Choice of the grouting system, including whether grouting will be done from the surface or from the bottom of shaft; determination of the grouting depth; and determination of the length of the grouting sections.
2. Determination of the number of grouting holes and their respective distances, diameters, depth and angle of dip, and applicable drilling method.
3. Construction and calculation of the grouting plug.
4. Grout type to be used, its density and admixtures.
5. Injection system and required equipment.
6. Determination of working pressure to be applied in particular sections, and approximate calculations of grout consumption.
7. Number of control holes and their locations.
8. Set of drawings corresponding to the above list of problems.

Necessary hydrogeologic information should contain:

1. Number and characteristic of water horizons.
2. Chemical analysis of water flows and determination of their degree of corrosiveness.
3. Flow velocity.
4. Coefficient of filtration.

GROUTING SYSTEMS. Properly performed grouting seals the rock mass in the vicinity of the shaft, making sinking possible by a conventional method. Grouting is performed from the surface when the water-bearing strata are relatively thick and close to the surface, or from the shaft face when the strata to be grouted are located at such a depth that it is not feasible to drill long holes from the surface. Basically, grouting is most successful in water-bearing, competent, but fractured rocks. Grout fills the fractures and cracks, creating a sealed zone around the shaft to be sunk and protecting it against water inflow.

Grouting for sealing is often applied to improve tightness of the lining in existing shafts and to eliminate the voids behind the

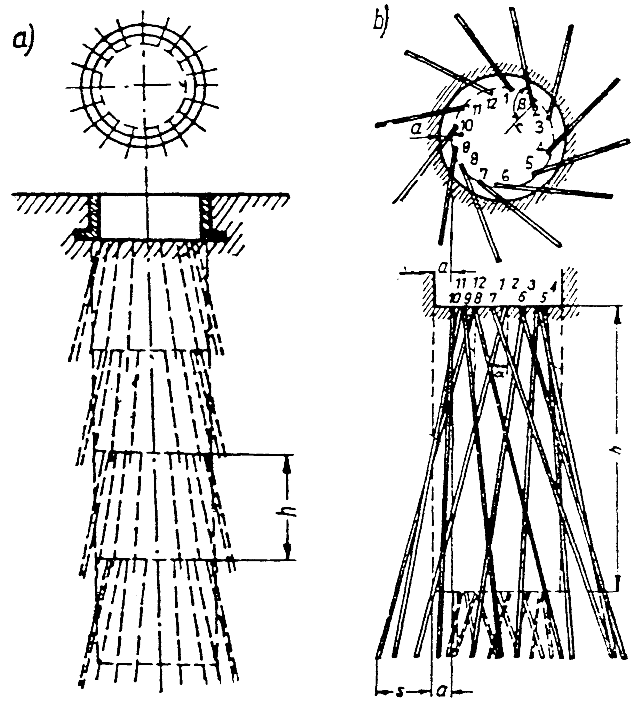

Fig. 17.4.43. Schematic of grout hole distribution drilled from the face.
a) general schema
b) sketch of one section with diagonal holes.

lining, as well as to seal rocks in the immediate vicinity of the lining.

GROUTING FROM THE SURFACE. Grouting holes with an initial diameter of 3 to 5 in. (75 to 150 mm) are drilled vertically around the future shaft on a circle with a radius 10 to 12 ft (3 to 4 m) larger than the excavation diameter.

The diameter of the holes should be as small as possible to minimize drilling cost and to maintain a sufficient velocity of grout flow to avoid sedimentation of cement particles. The distance between the holes usually is in the range of 6 to 12 ft (2 to 4 m) (Fig. 17.4.42). Basically, holes are without casings, excluding parts in loose rocks (usually near the surface). The entry to the hole has a cemented guide pipe 10 to 15 ft (3 to 5 m) long.

Depending on the thickness of the zone to be grouted, one or more grouting sections are chosen. The practical length of the section is 75 to 150 ft (25 to 50 m). In rocks with uniform fractures, distribution, and porosity, longer sections are used.

About 24 hours after the upper section is grouted, the hole is redrilled, in relatively soft grout; it is extended by the length of the next section and then grouted. After the drilling holes are flushed with water until clear, water comes out from the hole. Holes should be straight, and with their greater depth, any deviation should be recorded.

GROUTING FROM THE SHAFT FACE. This system (Fig. 17.4.43) is recommended when water-bearing strata occur below 300 ft (100 m) and when their thickness does not exceed 210 ft (70 m). The length of sections vary between 36 to 75 ft (12 to 25 m).

Holes are drilled along the length of grouting section, usually by means of heavy drill hammers or small rigs when space allows. Holes are directed at an angle in the vertical plane to get the hole bottoms 3 to 6 ft (1 to 2 m) away from the future excavation.

To increase the probability of encountering fractures by the hole, they are also tilted in a tangential direction (Fig. 17.4.43b). The distances between the hole entries are 2.5 to 4.5 ft (0.8 to 1.5 m). Spacing between the circles of holes is 4.5 to 6 to 9 ft (1.5 to 2 to 3 m).

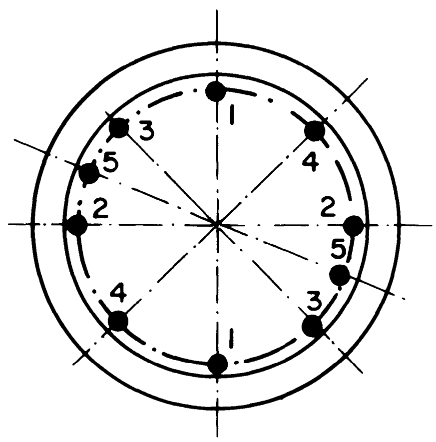

Fig. 17.4.44. Sequence of drilling and grouting opposite holes in pairs.

The number of holes drilled depends on the rock character, shaft diameter, and hydrogeologic conditions. Practically, it varies from 10 to 20 to 30. The initial drillhole size is 2 to 3 in. (50 to 75 mm); the end size is 1 1/4 to 2 in. (30 to 50 mm). The sequence of drilling and grouting is as follows:

1. The first one-half of the total number of holes is drilled and grouted; during hardening of the cement, the second half is drilled and grouted.

2. All holes are drilled and grouted, one after another, starting with the hole with the largest water inflow.

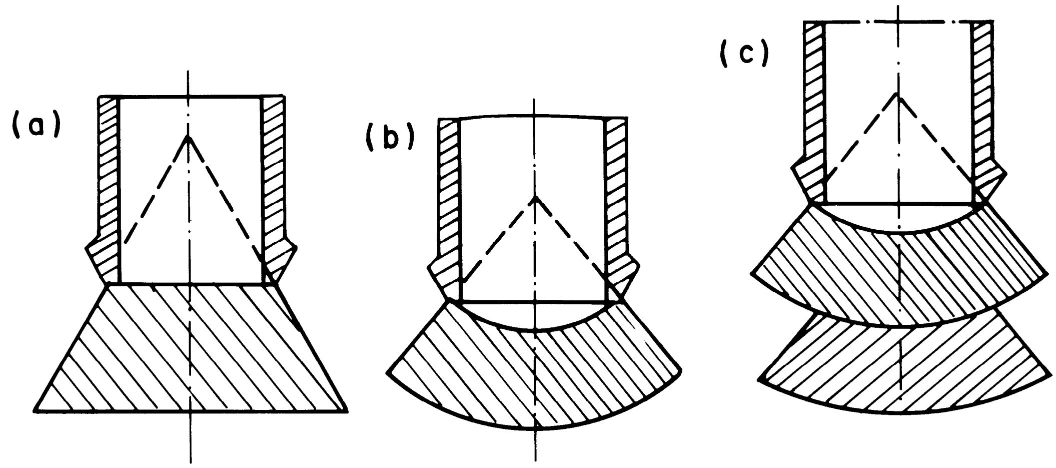

Fig. 17.4.45. Shaft grouting plugs.
a) flat
b) spherical, one stage
c) spherical, double stage.

3. A pair of holes lying on opposite sides are drilled and grouted; then the pair lying in the plane perpendicular to the first one is processed, etc., as in Fig. 17.4.44.

This system is the one most often used, being recognized as the best, because of the initial maximum distance between the holes, diminishing the probability of grout penetration from one hole to another.

The entrances of the grout holes are equipped with entrance pipes with diameters of 2 to 3 in. (50 to 75 mm) and lengths of 4.5 to 6 ft (1.5 to 2.0 m).

GROUTING PLUG. Grouting plugs are put in the shaft bottom to prevent water and grout inflow into the shaft. Entrance pipes to the holes are secured firmly by grouting them in the plug. The plug can be either natural or artificial.

Natural Plug—The natural plug is composed of a protective layer of grouted rock 9 to 15 ft (3 to 5 m) thick, depending on the strength of rock and expected pressure (water and grout).

Artificial Plug—An artificial plug is used more often and is constructed of concrete or reinforced concrete. It is constructed on the shaft bottom, 6 to 12 ft (2 to 4 m) from the water-bearing strata. When grouting is completed, the plug is demolished with explosives, and sinking proceeds through the cemented section, but again is suspended 6 to 12 ft (2 to 4 m) above the end of the grouted zone. The shaft lining is constructed and the procedure with the plug is repeated until the shaft passes the whole water-bearing zone.

During sinking of the shaft through the grouted zone, test drillholes are required to monitor hazardous water inflow. Artificial plugs can be flat, spherical, or multistage (Fig. 17.4.45). Appropriate design calculations are required.

CONSTRUCTION METHODS FOR ARTIFICIAL PLUGS. The construction method depends on the volume of water inflow to the shaft. When an inflow is small enough that it can be controlled by pumps, a wooden chest with a volume of about 35 ft^3 (1 m^3) is set on the shaft bottom (Fig. 17.4.46), with holes about 1.2 in. (30 mm) in diameter allowing water to enter. In the chest, a vertical drainage pipe is installed with a diameter larger than the suction pipe of the pump, and about 3 ft (1 m) longer than the thickness of the plug. On the shaft bottom, a layer of gravel 2 to 3 ft (0.6 to 1.0 m) thick is placed for water filtration. Through the drainage pipe, the suction pipe of the pump is lowered so that during the plug construction water inflow is controlled.

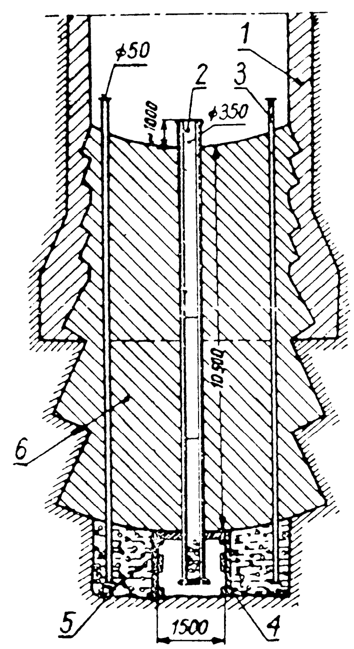

Fig. 17.4.46. Construction method with grouting plug.

2. drainage pipe
3. grouting pipes
4. wooden chest with holes
5. gravel or crushed stones
6. double-stage concrete plug.
Dimensions in mm. Conversion factor: 1 in. = 25.4 mm.

When the plug has hardened, a gravel layer is grouted through pipes previously installed within the plug. Then the grouting holes are drilled through the entrance pipes already installed in the upper part of the plug (during placing of concrete).

When the water inflow is too great to control with pumps, an underwater plug is placed. Concrete is pumped on the shaft

Table 17.4.10. Selection of Grout Density Depending on Water Absorbability of Grouting Hole

Absorbability L/min	Weight Proportions			
	Cement	Sand	Water	Proportion of Cement and Sand to Water
0.0–0.001	1	0	12	1:12
0.001–0.01	1	0	10	1:10
0.01–0.1	1	0	8	1:8
0.1–0.5	1	0	6	1:6
0.5–1.0	1	0	4	1:4
1.0–3.0	1	0.5	3	1:2
3.0–5.0	1	1.0	2	1:1
5.0–10.0	1	2.0	1.5	1:0.5
over 10.0	1	3.0	2.0	1:0.5

Conversion factor: 1 gal = 3.786 L.

bottom through tubing to form layers 3 to 3.5 ft (0.3 to 0.4 m) thick. (It is important to keep the outlet of the rising tubing below the concrete surface.)

SELECTION OF THE CEMENT AND GROUT PARAMETERS. Selection of cement depends on:

1. Character of water (salty or fresh).
2. Mineralization and chemical corrosiveness.
3. Value of the filtration factor.

A proper choice is made on the basis of results obtained from chemical analysis and pumping tests.

DENSITY OF GROUT. The choice of the grout density depends on water absorbability measured in the hole. It may be determined by pumping clear water for a 20-min period to the grouting hole with a head exceeding 45 to 75 psi (300 to 500 kPa) hydrostatic pressure.

Water absorbability in L/min can be determined by (in SI units),

$$q = \frac{Q}{Hh} \tag{17.4.22}$$

where Q is water volume being pumped in L/min, H is water head in m, and h is vertical height in m of the hole section where water absorbability is measured. Selection of grout density vs. water absorbability is shown in Table 17.4.10.

In the presence of salty water, this same salt concentration in water is used to prepare grout. The grout density depends on the character of the discontinuities in the rock mass and the applied grout pressure. This density changes over wide limits ranging from 3 to 50%. When larger cavities are encountered, then a thick grout (with sand fillers) is first pumped in, followed by a thinner mixture consisting of water-cement only. Similarly, for larger fissures, the recommendation is first to inject dense grout (25 to 30%), while for rock with small cracks, thin grout (3 to 5%) is preferable. The density of grout must be changed to match the absorbability of the hole.

In rocks with very small fissures where grout cannot penetrate well even under high head, special chemicals are used to decrease friction. To increase absorbability, small explosive charges sometimes are used in the holes.

To decrease absorbability and lessen the cost of the grouting operation, clay-cement grout is used with the cement-clay proportions of 1:2, 1:3, and 1:4, and solutions of cement-clay-sand with corresponding proportions of 1:1:1.5 or 1:1:2, respectively. By using clay-cement grout, cement is spared without sacrificing tightness of the rock mass.

It is advisable before planning a grouting operation to carry out a study and laboratory examination of rock samples to determine an optimum grouting regimen.

The hardening time of cement should be selected to allow grout preparation and injection to the desired radius of penetration. From an engineering standpoint, only the volume of injected grout is justified that seals the rock to meet minimum design requirements. This has a special meaning in cases of high rock permeability, when a substantial loss of grout may easily occur, thus raising the cost of shaft sinking. Admixtures speeding the time of setting up the cement are required to limit the range of grout penetration into large fractures, especially in the presence of water flow.

EQUIPMENT USED IN GROUTING OPERATION. The main components of the grouting setup are:

1. Cementation pumps (two units) for grout injection.
2. Mechanical mixers where grout is prepared.
3. Grout tanks.
4. Flexible pressure hoses.
5. Injectors.
6. Other hardware (pipes, valves, manometers, tools, etc.).

Cementation pumps are able to change head and output over wide ranges. Piston or plunger pumps with a capacity of 18 to 40 in./min (0.2 to 1 m/min) are commonly used at working pressures up to 2200 psi or (15 MPa). These may have electric or compressed-air drive.

When the grouting operation is carried out at substantial depths, the hydrostatic pressure of grout being prepared on the surface can be sufficient. Otherwise, cementation pumps are essential.

GROUT PRESSURE. The applied grout head should be established separately for each section of cementation. When grouting is done from the surface, the maximum pressure p in Pa is given by the formula,

$$p = H\gamma\, k \tag{17.4.23}$$

where H is depth counted from the surface to the top of the strata in m, γ is density of rocks = 1.5 to 2.0 t/m^3, and k is coefficient of cohesion of the strata above the grouting zone = 2 to 3.

When grouting from the shaft bottom, the required pressure has to be found by taking into account the strength of the shaft lining. In practice, a grout pressure is set 150 to 450 psi (1 to 3 MPa) higher than the hydrostatic head. Control calculations to ensure that the lining is not threatened should be done. Also recommended is the observation of the shaft lining during injection. Observation is done in control pipes with plugs installed in the lining, 9 to 15 ft (3 to 5 m) above the shaft bottom. Prior to injection, a tightness test of the installation is done with the pressure 1.5 times the maximum scheduled. Following that, the grout hole is flushed with water to clean out silt and clay until the return water is clean. Then the grouting operation begins. When grouting is terminated, the cutoff valve is closed, and the grouting installation, when not immediately used for another hole, should be flushed with water to prevent the grout from solidifying in the pipes.

After 24 hours, a grout hole can be drilled again. In the case of water outflow, the grouting procedure is repeated. Often, one injection may not be sufficient and one or more additional treatments is required.

CONTROL OF THE PROCESS. Effectiveness of the process is assessed by measuring the water inflow to the shaft after grouting and by examining the rock core obtained from the control diamond drillholes.

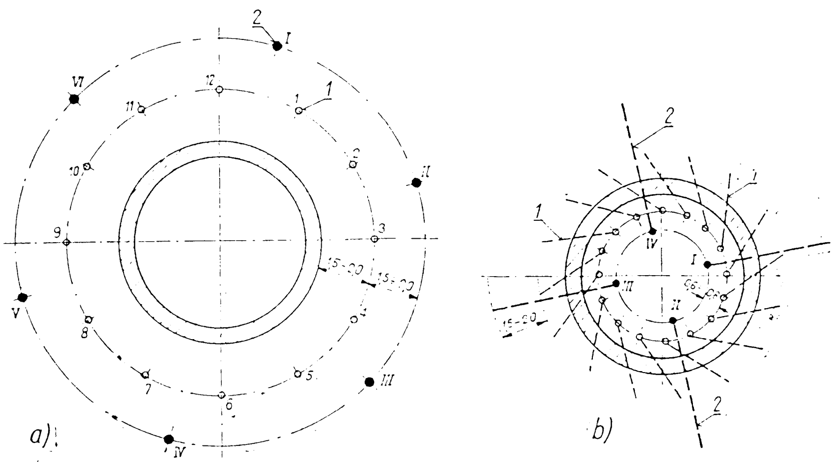

Fig. 17.4.47. Location of control holes.
a) for grouting operation from the surface
b) for grouting from the shaft bottom
1. grouting holes
2. control holes
The depth of the control holes is the same as the depth of the grouting holes. Dimensions in m. Conversion factor: 1 ft = 0.3048 m.

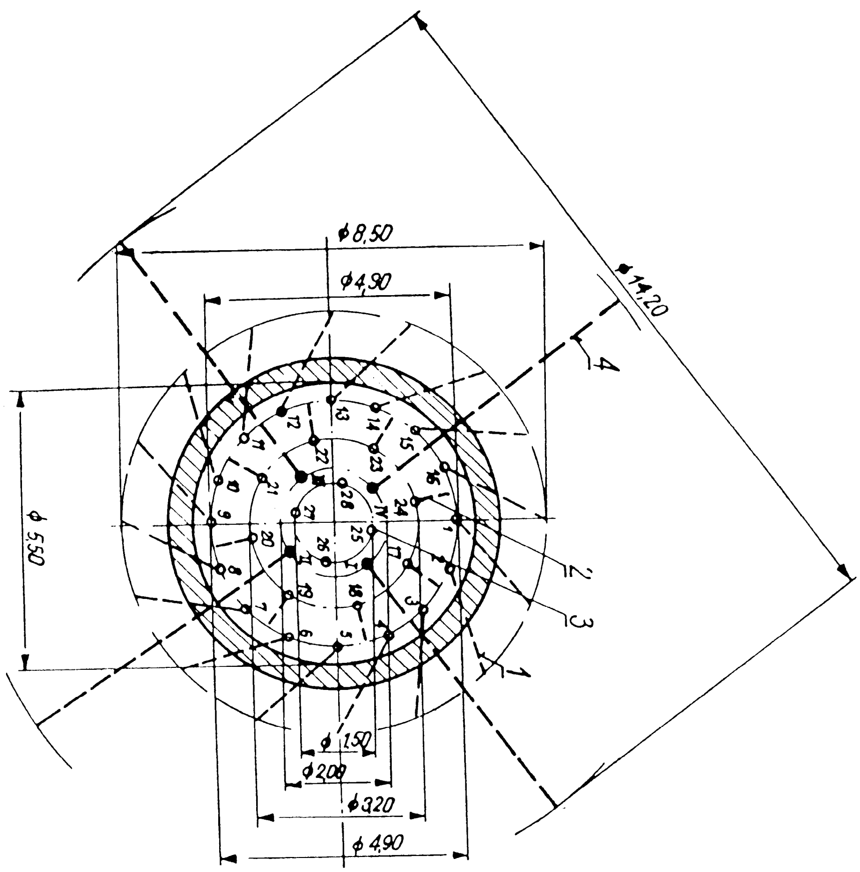

Fig. 17.4.48. Schematic of distribution of grouting and control holes in 18-ft (5.5-m) diameter shaft. Dimensions in m. Conversion factor: 1 ft = 0.3048 m.

The grouting operation is successful when control holes prove that water absorbability within the grouted rocks is less than 0.04 gpm/ft (0.05 L/min/m).

Control holes, where the grouting operation is carried out from the surface, have diameters of 3 to 4 in. (80 to 100 mm) and are located on opposite sides, between grouting holes, in a circle with a diameter of 9 to 12 ft (3 to 4 m) larger than the circle of grouting holes (Fig. 17.4.47a).

When grouting from the bottom of the shaft, control holes are drilled in a circle within the grout holes circle at a distance of 2 to 2.6 ft (0.6 to 0.8 m) (Fig. 17.4.47b).

Shown in Fig. 17.4.48 is an example of the hole plan for grouting carried out from the shaft bottom with a 36-ft (11-m) height for grouting sections.

GROUT CONSUMPTION. Grout consumption per 1 ft (0.3 m) of shaft varies widely and depends on the fissility of the rocks and the grouting system. The approximate mean figures for grout consumption for designing purposes that can be used are as follows: for sandstone, from 1.1 to 5.5 tons/ft (3.3 to 16.5 t/m); for dolomite, from 0.7 to 1.5 tons/ft (2.2 to 4.4 t/m); for chalk, about 1.3 tons/ft (4.0 t/m); and for diabase from 0.2 to 0.3 tons/ft (0.6 to 1.0 t/m).

EXCAVATION OF CEMENTED ZONE. The excavation method in the cemented zone is similar to the conventional method of shaft sinking. However, the depth of the blasting holes should be limited to 3 to 5 ft (1 to 1.5 m). In addition, the size of the charge in a particular hole and the overall charge being blasted should be reduced.

Explosives consumption can be estimated as follows: (1) in sandstone, about 2.5 lb/yd^3 (1.3 kg/m^3); (2) in shale about 2.2 lb/yd^3 (1.1 kg/m^3), and in coal about 1.2 lb/yd^3 (0.6 kg/m^3).

Excavation proceeds only to a certain depth in the grouted zone. When approaching the limit of the zone, an outgoing hole has to be drilled (through a valve) to test for the existence of water hazards.

SHAFT LINING. In spite of the long-lasting effect of properly done grouting, there is always a possibility of some water penetration in the shaft. Therefore, the permanent lining for the grouted zone should be watertight.

SHAFT SINKING PERFORMANCE AND COSTS. For a grouting operation, an average of 35 to 50% of the overall time is required for sinking within the water-bearing strata being grouted. The mean monthly advance is in a range of 25 to 50 ft (8 to 15 m)/ month. An approximate cost of sinking in water-bearing strata is about 30 to 50% more than the cost of sinking in normal conditions.

COMPLEMENTARY GROUTING. The complementary grouting of a shaft lining in the void between the lining and rocks, as well as in the rock itself in the vicinity of the shaft, is always done after shaft sinking in difficult hydrogeologic conditions, and especially when the freezing method has been used. In this method, a consolidation of the rocks disappears with thawing of the water and with a substantial change in stresses due to volumetric changes that often cause new cracks in the lining.

Complementary grouting is beneficial also after sinking with the normal method when tightening of lining, filling voids, or strengthening of rocks is required for better service conditions at the shaft. It is also used to improve conditions in existing shafts where, due to multiple causes (corrosion, vibration from shaft vessels, subsidence, etc.), the lining tightness has deteriorated.

A longer section of the shaft to be grouted is divided into smaller sections, with heights of 50 to 75 ft (15 to 25 m). These sections are grouted downwards, but in each of them, grouting goes from bottom to top. In every section on the circles 3 to 6 ft (1 to 2 m) apart and in a vertical direction, grouting holes are drilled with a 1.2- to 2-in. (30- to 50-mm) diameter and with depths depending on need from 2 to 6 ft (0.7 to 2.0 m), locating the holes in a checkerboard pattern. Holes in the circle are 3 to 6 ft (1 to 2 m) apart.

Grout pressure should exceed the hydrostatic water head but should not exceed the critical pressure for the lining. Assuming short-term loading, the safety factor for the lining can be lowered to 2 or 1.5.

If the first grouting operation is unsuccessful, it is repeated. Tubbing segments have special holes with plugs for grouting purposes. Grouting in shafts is usually conducted from a hanging platform.

The grouting operation is considered satisfactory when the water inflow in the shaft does not exceed 6.5 gpm (25 L/ min).

FREEZING METHOD. A suitable design procedure requires solution of the following problems:

1. Calculation of the wall thickness of the frozen rock cylinder.

2. Calculation of the diameter of the circle where freezing holes are located, their number, depth and spacing, and the number and distribution of surveying and control holes.

3. Selection of the drilling system for freezing holes, specification of equipment, choice of freezing pipes and their diameter, and assessment of time required for drilling.

4. Design of a temporary shaft head with a freezing basement.

5. Planning of the freezing procedure in active and passive periods, with specifications of freezing temperature, heat balance, required efficiency of freezing installation, and freezing time.

6. Determination of the system and time of thawing and liquidation of freezing holes.

7. Initial planning of freezing technology, shaft sinking and lining, and complementary grouting.

Calculation of Thickness of Frozen Rock Wall—An artificially created cylinder of frozen rock around the shaft creates a kind of lining, shielding the inner space against water and unstable rock. Thickness of the frozen rock cylinder e_c in m, for shallow and moderate depths is calculated for external pressure p in MPa, from the Lamé formula (in SI units):

$$e_c = r\left(\sqrt{\frac{k_c}{k_c - 2p}} - 1\right) \qquad (17.4.24)$$

where r is shaft radius of the excavation in m, and k_c is allowable stress of the frozen rock in MPa. The allowable stress of the rock is 50% of its compressive strength in the mean range of freezing temperatures.

In well-defined and favorable conditions, the allowable stress can be increased to 75% of the rock compressive strength. Because of the creep characteristics of ice, the compressive strength of frozen rocks is a time-dependent value.

For calculation of the thickness of the cylinder of frozen rock, the mean temperature of the rocks should be taken. The temperature within the wall of frozen rock changes, from a minimum value just beside the freezing hole to a maximum (around 32°F or 0°C) on the outer wall limit.

The outside pressure p is calculated according to guidelines given in 17.4.1.3.

The cylinder of frozen rock, when properly created, permits sinking a shaft of moderate depth even in long sections using temporary lining. This is desirable because there are fewer seams between lining sections. The concrete lining length made in one pass changes from several feet (meters) to about 60 to 75 ft (20 to 25 m), depending on the strength of the frozen rock mass, overall depth, and effective temperature (Fig. 17.4.49).

The thickness of the cylinder of frozen rock at greater depths within the plastic zone is calculated from the Domke formula:

$$\frac{e_c}{r} = 0.29\,\frac{P}{k_c} + 2.3\,\frac{P}{k_c} \qquad (17.4.25)$$

The other condition that is to be fulfilled is $p < P < k_c$, where $p = H\gamma_m$ in MPa is the vertical pressure (dead load) of the cylinder of frozen rock at depth H, with mean density γ_m, and with allowable compressive stress k_c. When the above conditions are met, it means that e_c has been properly chosen.

For greater freezing depths, another design concept of frozen rock thickness is recommended. It is usually impossible to arbitrarily change the freezing temperatures because of multiple limitations. At this pressure level, frozen rock creeps according to the Maxwell or Bingham rheological model. *R'c is* adequately evaluated due to the exposure time of the unsupported shaft wall, that is, the interval between excavation and installation of lining.

Lieberman (1962) has proposed the following formula for determination of frozen wall thickness e_c in these conditions (in SI units) (Fig. 17.4.50):

$$e_{c_{max}} = r\left(\frac{\gamma H}{e^{R'c}} - 1\right)s \qquad (17.4.26)$$

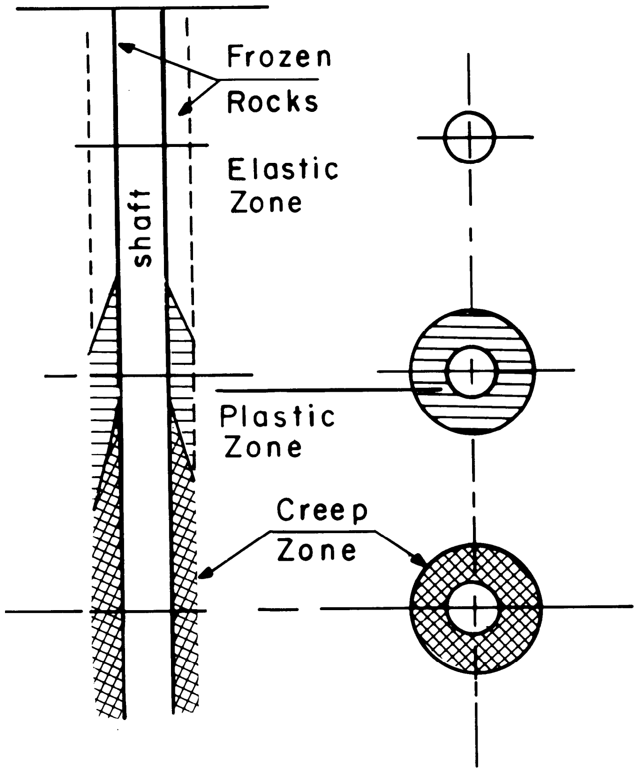

Fig. 17.4.49. Idealized schematic of state of stresses in cylinder of frozen rocks with growing depth.

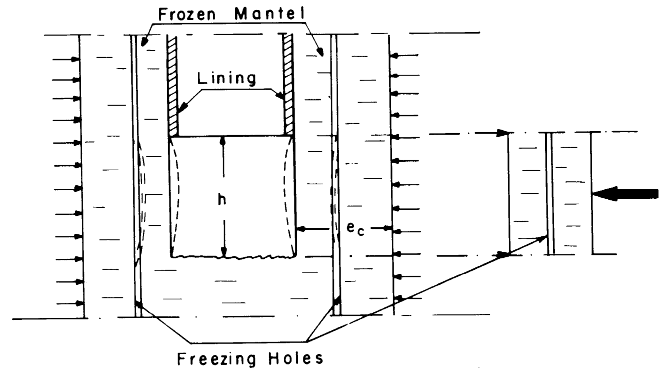

Fig. 17.4.50. Sketch of creep (bending) on frozen cylinder wall at great depth.

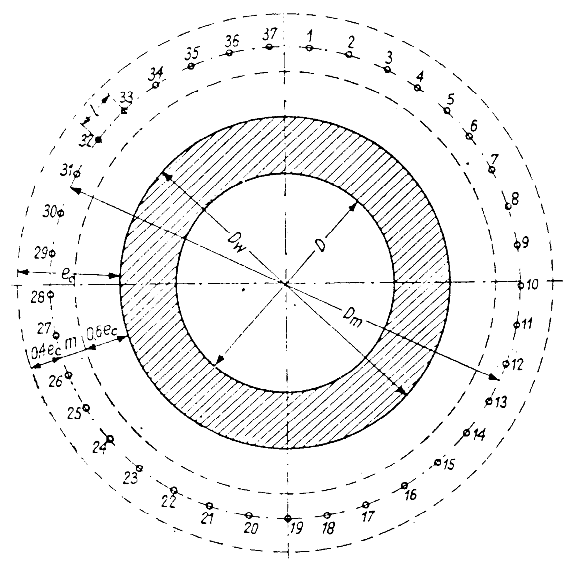

Fig. 17.4.51. Arrangement of freezing holes around the shaft.

Table 17.4.11. Creep Characteristics of Frozen Soil Materials

Type of Material	Compressive Strength R_c, MPa at Varying Temperature 14°F (−10°C)	5°F (−15°C)	−13°F (−25°C)
Clean ice	1.2	1.8	2.1
Clay, silt with organic matter	—	3.0–6.0	—
Clay, silty fine sand	5.5	7.2	3.5
Fine and medium-grained sand saturated with water	8.7	13.3	15.3
Quartz sand	12.0	15.0	20.0

Conversion factor: 1 MPa = 142.2 psi.

where h is height of excavated section in m, s is safety factor = 1.1 to 1.2, e is the natural logarithm = 2.718. Find h in m from the expression,

$$h = e_c \frac{R'_c}{\gamma H} \tag{17.4.27}$$

The author recommends the following procedure in applying the preceding formulas: Because of technological and economic limits, a practical thickness of frozen cylinder is assumed to be 15 to 17 ft (5 to 5.5 m). Then the allowable height of excavation h is calculated. When the assumed thickness $e_c > e_{max}$ from the above, then there is no restriction on the height of excavation. In these formulas, H is measured to the shaft bottom.

FREEZING HOLES, CONTROL AND TESTING HOLES: DIAMETER OF THE CIRCLE OF FREEZING HOLES. Centers of holes are placed on a circle with diameter D_m in ft (m) (Fig. 17.4.51), calculated as follows:

$$D_m = D_i + 2(0.6\, e_c + m) \tag{17.4.28}$$

where D_i is diameter of the excavated shaft in place with thickest lining in m, e_c is thickness of frozen cylinder in m, and m is a correction taking into account the vertical deviation of the freezing holes in m. The factor 0.6 represents nonsymmetrical (in a horizontal, radial direction) growth of the frost cylinder, 0.6 in the direction toward the center of shaft, and 0.4 toward the outside boundary where heat flow losses are greater. In practice, the diameter D_m is larger, at least 6 ft (2 m) more than the shaft diameter in excavations with freezing depths to 250 ft (80 m). For a depth of 450 ft (150 m), D_m is at least 8 ft (2.5 m) greater, and below 450 ft (150 m), no less than 10 ft (3 m).

Some well-trained crews are able to drill freezing holes at a depth of 1500 ft (500 m) within a cylinder with a 3-ft (l-m) radius.

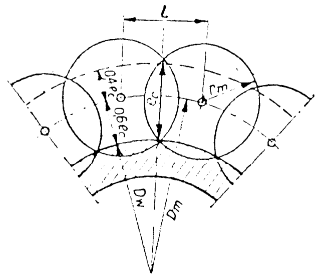

Fig. 17.4.52. Cylinders of frozen ground around the freezing holes.

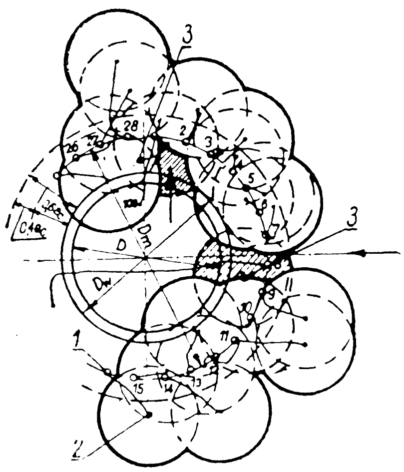

Fig. 17.4.53. Map of frozen rock cylinder with freezing hole locations and their deviations on the control horizon.
1. inlets of freezing holes
2. bottoms of freezing holes on control level
3. additional holes.

DISTANCE BETWEEN FREEZING HOLES. The spacing of freezing holes is taken from practical experience and varies between 35 and 44 in. (0.9 and 1.1 m); however, for deep freezing with turbulent flow of brine, spacing can be increased to 50 in. (1.25 m) (Fig. 17.4.52).

Basically, hole spacing should be arranged such that the chord of overlapping circles will be equal to the calculated thickness of the cylinder of frozen rock e_c.

The diameter of the frozen column around the freezing holes at a temperature of –1° F (–15°C) is assumed: in sandy rocks, 9 ft (3 m); in clay and silt rocks, 7.5 ft (2.5 m); and in rocks with water flow and large coefficient of filtration, 6 ft (2 m). The number of freezing holes is calculated from $n = p\,D_m/l$ (Fig. 17.4.52).

DEPTH OF FREEZING HOLES. When the freezing depth does not exceed 180 ft (55 m), the bottom of the hole should reach 6 to 15 ft (2 to 5 m) below the water-bearing strata. In inclined strata or when the total depth is greater, holes are drilled 15 to 30 ft (5 to 10 m) below it.

ADDITIONAL FREEZING HOLES. Verticality of freezing holes is measured every 150 ft (50 m), and results are plotted on a plan of the whole cylinder of frozen rock (Fig. 17.4.53).

If deviation of holes causes the cylinder of frozen rock not to close (assuming radius r_m of frost around the hole), drilling of an additional hole or holes is required. Emphasis should be put on accuracy of drilling to keep to a minimum the number of required additional holes.

CONTROL HOLES. To provide information about the freezing process, additional control holes are drilled along a radial line drawn in the middle between two freezing holes. Control holes are drilled 1.8, 3, and 10 ft (0.5, 0.9, and 3.0 m) from the freezing-hole circle toward the outside and 1.3 and 4.3 ft (0.4 and 1.3 m) toward the shaft center. These holes are filled with brine and are used for temperature measurements on different levels. They are cased in steel pipes with welded bottoms.

A water-level observation hole is drilled inside the frozen cylinder, usually in the center of the shaft. It has a casing without a bottom, and at levels corresponding with water tables, it has perforations with filter screens. Observations of changes in the water table are taken in that hole. It also plays an important role in stress relief, allowing water entrapped within the frozen cylinder to flow up into the hole. Otherwise, volumetric changes during the freezing process would increase the pressure.

DRILLING OF FREEZING HOLES. The most important problem during the drilling of freezing holes is to assure verticality of holes. Contemporary, modern rotary drilling rigs, when operated by an experienced crew, can maintain verticality within acceptable tolerances. Freezing holes are drilled with mud fluid of specific gravity 1.15 to 1.25. To shorten the time required for drilling of many (sometimes 40) holes, two or three rigs are used at a time.

FREEZING HOLES EQUIPMENT. Every hole is equipped with two columns of tubing.

1. Outside: the freezing pipe itself has a diameter of 4 to 6 in. (102 to 152 mm) and is constructed of steel with inside connectors so it is smooth on the outside and has a welded bottom.

2. Inside: The inner tubing has a smaller diameter of 1.25 to 2 in. (32 to 51 mm), is made of steel or polyethylene (PE) pipe, and has inside diameter and wall thickness of 3 in. and 2.25 in. (75 by 43 mm), respectively. Polyethylene pipes are used because they have several advantages over steel. They are cheaper and easier to install (by unwinding from a reel), have lower thermal conductivity, and the specific gravity of the PE is close to the specific gravity of the brine, resulting in less suspended weight (Fig. 17.4.54). Freezing brine flows at high velocity down the inner pipe. It rises more slowly in the annulus, absorbing heat from the surrounding rocks.

There are two distinct flow regimes: laminar and turbulent. For great depths and more difficult freezing conditions associated with the presence of clay rocks and organic matter (e.g., lignite), turbulent flow is recommended. It assures a more uniform heat flow from the rock to the freezing hole, making it less dependent on depth.

Laminar flow, which is adequate for moderate depths, exhibits a distinct difference in velocity of brine flowing down (2 to 4.5 fps, or 0.6 to 1.5 m/s) and upward (0.25 to 0.67 fps, or 0.08 to 0.2 m/s). Brine circulation initially cools the rocks and later freezes them, creating rigid columns 6 to 9 ft (2 to 3 m) in diameter. There are large differences in the thermal conductivity of rocks, resulting in differences in freezing time, varying from two to eight months. For greater freezing depths, larger-diameter freezing pipes are required. The ratio of diameters between the outer and inner pipes has to be chosen for particular freezing depths and estimated heat transfer rates. This keeps the cost of energy (freezing compressors, pumps) to a minimum and also ensures an installation capable of freezing the rock in the scheduled time interval.

Complete tightness of joints among individual segments of freezing pipes is necessary. Any brine leak will thaw the rock,

7. outflow pipe to inflow brine tank.

and in extreme cases, can cause catastrophic inflow of outside water and flow of rock to the shaft. It is also impossible to freeze rocks contaminated with brine without substantial lowering of the temperature, which in turn is limited by the capacity of the particular freezing station. Therefore, during installation of freezing pipes, every column 150 ft (50 m) or longer is hydrostatitally tested.

When the whole column is lowered to its final position, casing pipes are removed. The space between the wall of the hole and the freezing pipe is then filled with dense drilling mud.

SECTIONAL FREEZING. Sometimes water-bearing strata underlie strata of competent rocks. In this case, freezing is required only at particular depths; however, double inner-pipe installation is necessary. A brine circuit is designed to enable control of a return flow from particular holes (visually), and the flow-alarm gage in the tank gives a warning signal when the brine level goes down, indicating a break of the freezing pipe and escape of brine into the rock mass. Such a hole has to be immediately shut off (valve on inflow line).

FREEZING CELLAR. The collars of freezing holes with pipes connecting them with the distributing ring, shut-off valves, and thermometers are installed all together in a so-called freezing cellar.

A freezing cellar is designated either as (1) *temporary,* to speed up construction time (it will be demolished when the permanent shaft headframe is installed); or (2) *permanent,* considered a part of the permanent shaft headframe, requiring a longer construction time. An example of freezing cellar design is given in Fig. 17.4.55.

FREEZING OF ROCK MASS. Freezing media used as refrigerants are

1. Ammonia (NH,): assures a freezing temperature of –4°F (–20°C) with one stage and –40°F (–40°C) with two stages of compression, and is used in most cases.

2. Carbon dioxide (CO_2): provides a freezing temperature of –58°F (–50°C).

A schematic of an ammonia freezing station is shown in Fig. 17.4.56. It is a one-compression-stage system, and the freezing temperature is around –4°F (–20°C). The ammonia system is closed. Compression raises pressure to 150 psi (1 MPa), with a simultaneous increase of temperature to 167°F (75°C). Through the oil separator, the compressed ammonia goes to the sprinkle condenser, where it is cooled down with water (about 54°F, or 12°C) to a temperature of around 68°F (20°C). At this temperature, gaseous ammonia changes to a liquid, and, passing an expansion valve, the pressure (150 psi or 1 MPa) is reduced to 7 to 20 psi (50 to 140 kPa), expanding and boiling. Because of this rapid evaporation, the temperature drops to –4 to –13° (–20 to –25°C). Vapors of ammonia travel through the coil pipe within the evaporator filled with brine, which cools the brine. Then the ammonia returns to the intake of the compressor and the cycle starts again.

BRINE CIRCUIT. A water solution of calcium chloride ($CaCl_2$) is used almost exclusively for temperatures not lower than about –49 to –58°F (–45 to –50°C). For lower temperatures, lithium chloride solutions can be used (e.g., the Yarbo shaft, Saskatchewan, Canada). Most often used is an aqueous solution of $CaCl_2$, with a specific gravity of 1.25 to 1.26, and a freezing point of –29 to –36°F (–34 to –38°C). The brine circuit begins with the outflow brine being heated up (about 5°F or 3°C) in a rock mass and returning (through a collector ring or an outflow tank on the shaft gear and main pipeline) back to the heat exchanger, where it is cooled down. Here the cycle starts again.

FREEZING PERIODS. Two main periods of freezing can be distinguished, the active period and the passive or maintaining period.

During the active period, a frozen mantel of design thickness is created around the future shaft. To achieve the designed capacity of the freezing station, two to three aggregates are installed together to provide the required heat efficiency. During an active period, all units work at full capacity. The passive period starts after the frozen mantel is created and lasts through the sinking, lining, and assembling of the shaft installations. During the passive period, usually only one unit works while the others stand by as a reserve.

HEAT BALANCE CALCULATIONS. The volume of frozen rock V has to be found. It is calculated as a sum of the volumes of the cylinders in particular strata of different physical properties.

The volume of each stratum is the sum of the volume of rock material (solid) and the water volume remaining in rock pores.

The water content of the rock depends on the rock porosity and in competent rock also on the fracture and pore volumes. The required data are obtained from rock tests.

The amount of heat Q_o in Btu (kcal), which is to be extracted to cool down the rock mass from the initial temperature t_i to the mean freezing temperature t_m, is

$$Q_o = Q_1 + Q_2 + Q_3 + Q_4 \tag{17.4.29}$$

where Q_1 is heat in kcal to be extracted from the rock mass to lower the initial temperature of the solids to the mean freezing temperature, Q_2 is heat in kcal to be extracted to cool down the water in pores from initial temperature to temperature 32°F (0°C), Q_3 is heat in kcal to be extracted to change water at temperature 32°F (0°C) into ice at constant temperature, and Q_4 is heat in kcal to be extracted to cool down ice at initial temperature 32°F (0°C) to the final freezing temperature. The mean initial rock and water temperature is approximately 50 to 54°F (10 to 12°C).

18. outflow pipeline of warmed up brine.

The above heat components are calculated by applying calorimetric formulas that take into account the dimensions of particular rock cylinders with their corresponding content of solids and pore water, the specific gravity of those components, heat capacity of rock and water, latent heat of change of water into ice at 32°F (0°C), heat and density of ice, and the temperature difference achieved by freezing. The required net capacity of the freezing station can be calculated, as well as the heat loss in the rock mass and in the installation. The size of the freezing station is based on heat exchange during the active freezing period.

HEAT LOSSES. There are two kinds of losses in the freezing process: (1) loss in the rock mass as a result of the steady flow of heat from outside the frozen mantel, and (2) losses in the freezing installation, because of imperfect insulation. The gross capacity of the freezing station is equal to its net capacity minus heat losses in the rock mass, plus heat losses in the equipment.

TIME OF ACTIVE FREEZING. The time of active freezing of a rock mass depends on the rate of frost penetration radiating outward from the hole to reach a radius r_m, assuring a sufficient thickness e_c of frozen mantel, measured midway between the two holes.

The frost penetration velocity for sands is about 1 in./day (25 mm/day) and for clays about 0.2 to 0.25 in. (10 to 15 mm/day) (Pokrowskij, 1962).

The freezing velocity in practical terms for a given set of rock mass parameters and hydrologic conditions depends mainly on the net capacity of the freezing station.

From actual records, the time of active freezing is about 2 to 4 months for a freezing depth as great as 750 ft (250 m), and about 9 to 10 months when the freezing depth is around 1500 ft (500 m).

A nomograph (Fig. 17.4.57) allows the determination of the active freezing time for a frozen mantel with a required thickness, depending on brine temperature, spacing of freezing holes, initial temperature, and coefficient of thermal conductivity. The nomograph shows an example of water-saturated sand with a thermal conductivity of 0.13 in./hr (3 mm/h), with an initial temperature of 46°F (8°C) with a hole spacing of 4 ft (1.2 m) and brine temperature of –13° (–25°C) for a required thickness of frozen mantel 9 ft (3 m).

PASSIVE PERIOD OF FREEZING. During this period, the already frozen mantel of the rock mass should be maintained at the designed freezing temperature during the entire period of sinking and lining of the shaft. The required capacity of the freezing station during this period is smaller, just sufficient to balance heat losses. In practice, during the passive period, one-half to one-third of the initial capacity is sufficient.

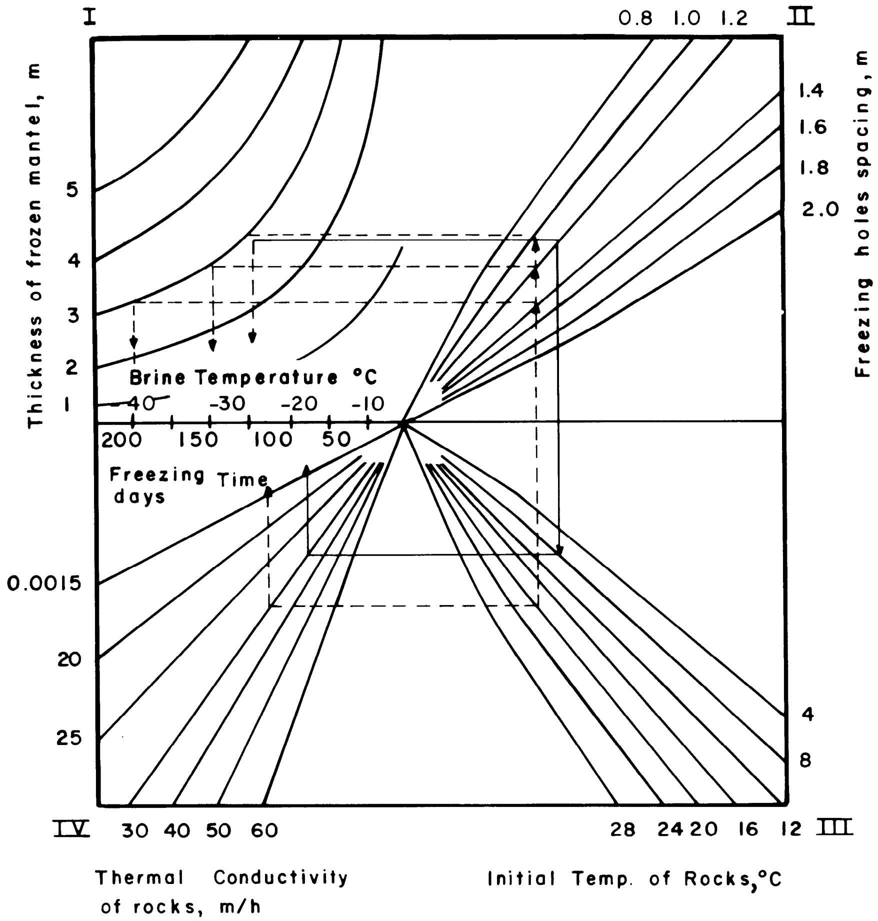

Fig. 17.4.57. Nomograph for determination of time required to create a frozen mantel with given thickness, depending on brine temperature, hole spacing, natural rock temperature, and thermal conductivity of rocks. Conversion factors: 1 ft = 0.3048 m, °F = 1.8°C + 32°.

Computer numerical modeling methods are applicable for heat transfer calculations and are often used in design of shafts sunk with application of the freezing method.

EXCAVATION OF FROZEN GROUND. Methods of excavation are similar to those under normal conditions; however, when explosives are used, special care is required because of the proximity of the freezing holes and the potential danger of their destruction. When the core of a shaft is not frozen, a cactus grab or other mechanical mucker can dig the shaft bottom. When the rock is partly frozen or too hard to be excavated, hand-held drill hammers with chisel picks are used; however, these working conditions are very unhealthy. In hard frozen rock, the drill and blast method is used with limitations as follows: the minimum distance between the freezing holes and the blastholes should be 5 ft (1.5 m), and the depth of the blastholes should not exceed 3 to 6 ft (1 to 1.7 m) in shafts of large diameter having a density of 0.5 to 1.5 holes/10 ft^2 (/1 m^2).

Explosives consumption is estimated as follows: (1) in alluvial overburden rocks, 0.5 to 1 lb/yd^3 (0.25 to 0.5 kg/m^3); and (2) in sandstones, sandy shales, and limestones, 2 to 3 lb/ yd^3 (1 to 1.4 kg/m^3).

The newest excavation system, which avoids exposing workers to unhealthy conditions at the face and permits good performance without disturbing freezing holes, was first developed in Poland (Lubin copper basin) in the early 1970s. A specially designed shaft miner was built from coal shearer parts. This system proved itself in several shafts. A system developed later utilized a roadheader cutting system in a similar arrangement.

17.4.2.4 Extension of Shafts by Raising

The use of conventional raising methods to drive vertical openings has decreased; however, under some conditions, especially for smaller mines, it remains the most attractive solution.

Development of raise boring machines and raise climbers has limited the application of conventional raising to short raises. This method of shaft extension is possible only when the lower level has been developed from another shaft or slope. Raising is recommended when there is no possibility of sinking due to a lack of free space in the existing shaft and a lack of room on the production level for production purposes.

Hydrogeologic and geomechanic conditions, however, limit the applicability of the raising method. It can be utilized only in competent rocks of high and medium strength, without fractures, and without a large water inflow.

The advantages of raising include:

1. Raising is independent of mining production so its influence on mine performance is minimal.
2. Loading of muck into buckets is avoided.
3. Blasting effectiveness is greater.
4. No water pumping is required.

The disadvantages of raising include:

1. The height of raising is limited to about 300 to 360 ft (100 to 120 m).
2. Ladder climbing is an inconvenience for personnel and the transport of materials to the face.

3. There is a potential hazard of pieces of rock falling from the face.

4. There is a potential threat of muck jamming in the chute compartment.

5. Surveying is difficult (deviation is possible).

6. There is time and cost involved in preparing the opening for raising purposes.

A raise must have three compartments—chute, hoist, and ladder—and must have a brattice installed from the bottom of the ladder compartment up to the safety platform placed below the working platform. The chute compartment is of solid construction and is lined tightly with thick 2-in. (50-mm) planks (lagging) to withstand the high-side pressure of the muck. For long raises, a rebound niche is made every 100 to 170 ft (30 to 50 m) in a sidewall of the raise.

Working platforms in raises are made with timbers strong enough to withstand the load of piled-on muck and are supported by steel girders or wooden beams with strength adequate to support the weight of muck, equipment, and workers. For carrying steel beams, a safety factor of six is recommended.

Safety platforms are of a lighter construction, lined with 2-in. (50-mm) lagging laid on beams of adequate strength.

There are two entrances with hatches, one in the ladder and one in the hoisting compartment. The distance between the working and safety platforms cannot be less than 5 ft (1.5 m) or more than 10 ft (3 m). The chute compartment should be filled with rock when it has rebound platforms in niches, and only an excess of muck is removed by opening the bottom damper. In hard rock, a raise face can be advanced up to 15 ft (5 m) without lining, and in weaker rocks, proportionally less. When a lining consists of timber sets, every third set has to be inserted in sockets in the shaft wall. When full timber lining is used, curb sets support at least each platform of the ladder compartment. The chute compartment is guarded by a railing to prevent accidental falls of personnel and larger pieces of rock. For ventilation, a hole 8 to 12 in. (200 to 300 mm) in diameter is drilled in the center of the future shaft. It is cased within the limit of the sump of the existing shaft and projects above the water level in a sump.

Three raising methods are used, depending on the size of the shaft and the geomechanical rock properties. They are as follows:

1. Raising shafts with small diameters up to 12 ft (4 m) is done full diameter with a temporary lining. A permanent lining is erected later. Good rock conditions are required (Fig. 17.4.58).

2. In competent rock, with medium strength, regular-sized and small-diameter shafts are raised full diameter, but in short cuts with immediate construction of a permanent lining.

3. Shafts of diameter greater than 12 ft (4 m) in competent rock of high and medium strength are first raised upward at reduced diameter; then the small shaft is widened downward to the required size. This is the most common method (Fig. 17.4.59).

MECHANICAL RAISE CLIMBERS. Mechanical raise climbers have been developed primarily for application in hard-rock mining. The most popular of this kind is the Swedish Alimak raise climber. The machine runs on a guide rail that incorporates a pin rack. The segmented guide rail is fastened to the side of the excavation with rock bolts. Figure 17.4.60 shows the different stages of system operation. The Alimak method has the following advantages over conventional systems:

1. Permits the driving of very long raises, vertical or inclined, straight or curved.

2. When traveling to the head of the raise, personnel are well protected in a cage under the platform.

3. The miners work from a platform that is easily adjusted for convenient height and angle.

4. Risks involving gases are reduced, as the raise is ventilated after blasting with an air-water mixture supplied in the raise climber.

5. All equipment and material required can be taken to the head of the raise in the raise climber.

6. Timbering is avoided, and if needed, rock bolts, with or without a screen, are used for support.

7. The raise climber can be used for areas up to 85 ft^2 (8 m^2).

The disadvantage is the cost of the raise-climber system, which cannot be justified for short raises; therefore, the most frequent application is in mines where driving raises in hard rock is part of the mining method. A new development is the change of pneumatic drive to electric for long raises. Performance data from recent applications can be summarized as follows.

Three ore passes were excavated with dimensions of 7 by 7 ft (2.1 by 2.1 m), with a combined length of 1097 ft (334 m) and a maximum length each of 427 ft (340 m). One was a stope fill/ventilation/service raise with this same cross-sectional area and length of 315 ft (96 m), and one a main ventilation/service raise 7 by 14 ft (2.13 by 4.26 m) and length of 314 ft (96 m). The raise was completed in 11 months for an average advance rate of 160 ft/month (49 m/month). The peak advance was 312 ft/month (95 m/month). Work was performed by a two-worker crew on a 2 shift/day, 6 days/week schedule. Costs in 1989 dollars, including contract labor, operating supplies, and services for the raise excavation, including setup and tearing down of equipment, was \$197/ft (\$646/m) of advance. Muck load out and haulage was an additional \$17/ft (\$56/m) of advance. The excavation rate increased slightly for an advance beyond 150 ft (50 m). These costs do not include the excavation required for Alimak equipment setup and do not include ground support in the raise. Neither do they include mine engineering and surveying, mine overhead, etc.

17.4.2.5 Raise Boring

Raise boring is one of the newest technologies in shafts and raises, maturing through improvements made during the three decades since its initial application. Steady increases in technical parameters of raise boring, such as diameter, length, and advance per unit time, followed research on system principles and improvements in performance of the critical components. Large-diameter holes or shafts can be drilled vertically or inclined. The costs of raise boring have been substantially reduced due to improvement of the cutters, the average life of which has been extended fivefold in the last fifteen years.

Raises are being utilized as a part of multilevel mining systems for orepasses and ventilation, as coal mine ventilation shafts, and also as full-sized shafts, primarily in coal mining.

Excavating rock by a continuous boring system has several advantages over the conventional drill-and-blast methods, especially in vertical excavations such as shafts and raises, where it eliminates the hazards associated with the presence of workers at the face. In industrialized countries, reducing the skilled labor required in conventional shaft sinking and raising is an important factor in cost reduction. The continuous action of raise boring usually assures faster completion of the project than conventional blast and drill methods. Boring does not disturb the surrounding rock, and therefore, most often there is no need for support or, alternatively, only minimum support is required for the finished hole. A perfectly round shape makes the hole inherently stable, and its smooth walls reduce resistance for ventilation as well as for passing ore. Provided conditions are right, the cost advantage over other systems is clearly apparent for long raises and for shafts.

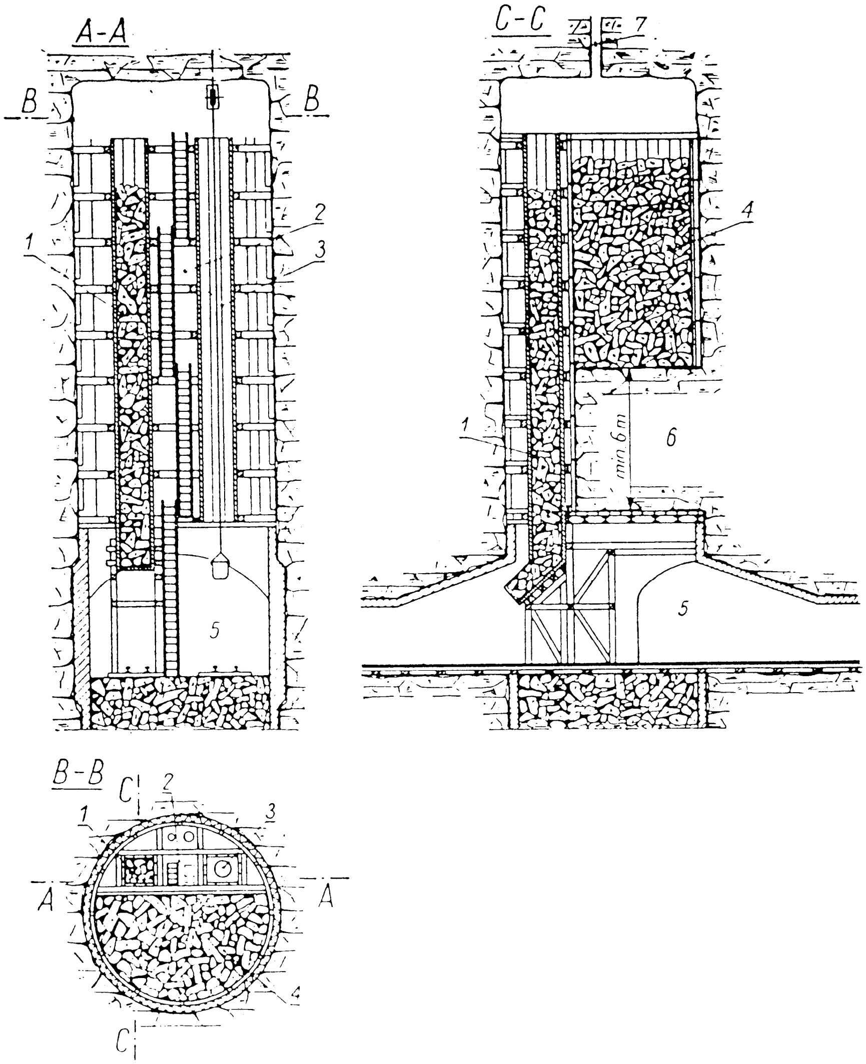

Fig. 17.4.58. Raising method with full diameter of the shaft, with temporary and a later-erected permanent lining.

5. lower shaft station
6. protective shelf
7. ventilation hole (to sump of existing-upper shaft).

Conversion factor: 1 ft = 0.3048 m.

The disadvantages of a continuous boring system include a general requirement that rock conditions be similar within the length of the raise bore. Another disadvantage is that drilling in very hard rock is slow, and costs rapidly increase. Also access to upper and lower levels is necessary, or in other words, raise boring requires a pre-existing level. A raise-bored rock mass has to be dry. The initial cost of the rig is also high.

EQUIPMENT AND SYSTEM DESCRIPTION. Raise boring equipment is produced in the United States, in other industrialized western countries, and in the USSR. Machines that are designed primarily for soft rock are applied mainly in European coal fields. US manufacturers produce machines for hard- and soft-rock conditions as well.

There is a large variety of machines available that are designed for certain sets of rock conditions and nominal sizes and lengths of the finished hole. Typical characteristics of the machine specify the pilot-hole diameter, drill pipe diameter, reaming torque, type of drive (ac, dc, or hydraulic), its rpm and power (hp or kW), and type of gear reducer with corresponding rpms. Additional specifications are the pilot-hole thrust and feed rates, reaming pull, size of drill pipe, base plate and derrick dimensions with characteristics (especially important for underground application), and finally the type of transporter/erector, if applicable, and the water and air consumption.

Raise boring machines (RBMs) operate on the principle of first drilling a small pilot hole and then reaming the hole, in one or more stages, to the desired size. The modes of operation are shown in Fig. 17.4.61. The most frequently used is a conventional scheme with the pilot hole down and reaming upward. However, in some mining systems, box-hole drilling upwards in one stage is chosen.

The RBM consists of several parts (Fig. 17.4.62). The rig itself is composed of a rigid plate and a structure on which are assembled drilling, hydraulic, and electrical equipment. The rig has its own crawler driven by compressed air, or it is mounted on rail wheels for haulage. The rig can be disassembled and hauled in underground service tire vehicles. A pilot hole is drilled through the stem with stabilizers and a conventional drilling bit (Fig. 17.4.63). Drill rods have outer/inner diameters in a range of 8 to 12-7/8 in. (20.3 to 31.4 mm) to 4-3/4 to 5-7/16 in. (12.06 to 13.1 mm). The length of the sections for underground application is usually 5 ft (1.5 m), dictated by clearance restrictions. Connections are made with tapered thread joints that have to be kept absolutely clean.

The purpose of the stabilizer is to assure directional accuracy of the pilot hole. Several types are in common use. They are of a larger diameter than drill rods, with strips of tungsten carbide welded vertically or spirally on the outside, bringing the outer

6. tubing compartment
7. drillhole for ventilation (to the sump of existing upper shaft).

dimension close to the hole diameter. These stabilizers are used for reaming up. Other types, for pilot holes and reaming down, have more clearance, allowing cuttings to pass.

Once the pilot hole penetrates to the mine opening, the pilot bit and stabilizer are removed. After necessary servicing, the stabilizer is mounted on the drill stem and the reamer is put in the place of the small pilot-hole bit. Starting the hole (collaring) is a critical operation, and damage to the cutters or bit body can occur due to the uneven surface. The tension on the stem has to be adjusted to allow starting the hole without a highly variable, dynamic load acting on the drilling components. The stem is the longest at this stage of drilling and, therefore, prone to maximum elongation and twist. The design of the reamer depends on the final size of the hole and the number of reaming stages. Structural analysis is required and is usually performed by computer, taking into account necessary balancing of the tool, achieved by optimum positioning of the cutters (Fig. 17.4.64). In the past, the primary body of the reamer was often supplemented with stages mounted below, resulting in a "Christmas-tree"-shaped tool (Fig. 17.4.65). Because of large torque requirements, this system is presently used only for shaft-sized holes, together with large non-rotating stabilizers. In another configuration, extensions are attached to the primary body. By doing this, an increase of the final diameter is achieved by adding more cutters in the same planes as the cutters on the primary body itself.

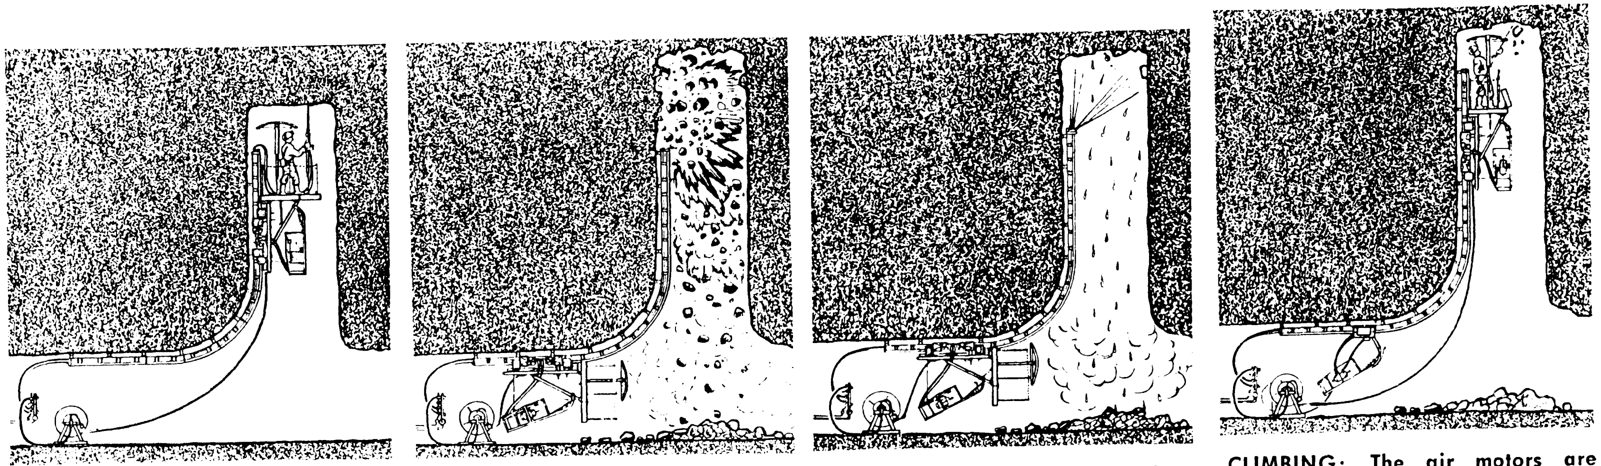
Geared reamers are being used for reduction of required torque when compared to conventional reamers. The bit turns at a slower rate than the drill pipe due to the gearing mechanism. Shaft reamers are used for very large-diameter holes. This is a separate machine that is installed after the standard-sized raise has been completed, and is used for enlarging the raise to the full diameter required. The shaft reamer stabilizes itself by side jacks pressing against the hole and develops both drilling load and torque reacting against the anchored portion of the machine. The cuttings fall freely down the previously completed raise. Shaft lining can be installed when drilling. A service hoist to the working level is, however, necessary for men and materials.

The accepted measure of drilling performance is the rate of penetration, which depends primarily on bit design. The cutting action has to match the rock properties to optimize drilling rate (Fig. 17.4.66). During the reaming operation, in addition to the cutters, the design of the reaming head also influences the raise boring performance. If no other source of information is available, an analysis of the wear of presently used cutters can help in the design of an improved cutting structure. Independent variables when drilling are rock properties, which are usually characterized by compressive, tensile (indirect), and shear strength measurements. The drilling tool should break rock primarily in tension and shear, because the strength of rock in these modes of loading is minimal. Strength alone does not determine drilling performance; additional factors intervening are rock ductility and abrasivity. For example, strong but brittle rock can have better drilling response than weak, clayish rock. Abrasivity is dependent on the mineral content of rock and is responsible for the wear of drilling tool elements in contact with the rock face and cuttings. The properties of the rock mass, such as joints, faults, and structural features, also influence drill response and, therefore, must be evaluated. The lowest drilling cost will occur at the point where both cutter life and rate of penetration are optimized.

One of the most important technological aspects of boring is the removal of cuttings. Research has shown that a layer of cuttings on the uncut rock reduces penetration up to 40%. In other words, the energy of drilling is spent on regrinding the cuttings rather than penetration of the intact rock. In raise boring, this situation is encountered during drilling of the pilot hole. Standard drilling technology with compressed air, air and foam, or drilling fluid is used for cuttings removal. During the reaming operation, cuttings simply fall down the hole.

Drilling load should be at the level required by the cutters to penetrate the rock and create fractures. Knowing the geometry of the cutting tool, it is possible to calculate the load exerted by particular cutters. Once the threshold strength of rock is reached, a further increase in drilling load does result in greater depths of penetration, but not in direct proportion to the increase of load. The general expression for this relationship is

$$D = W^d \tag{17.4.30}$$



DRILLING: Scaling and extension of guide rail is safely and easily carried out from the platform under the steel protective roof. Tubes in the guide rail are used for the supply of air and water to the drills.

BLASTING: During blasting the Raise Climber is well protected in the tunnel.

CLEANING: After blasting the face is cleaned with an air and water mixture sprayed through jets in a plate protecting the top of the guide rail.

CLIMBING: The air motors are controlled from the cage, and they are supplied with air via a hose connected to a reeling drum in the tunnel. ALICAB or ALITROLLEY Reserve and Service Lifts provide fast communication with the Raise Climber and is useful for the transport of men and material, or in the case of accidents.

Fig. 17.4.60. Stages of operation of the Alimak mechanical raise system (*courtesy*: Alimak Co.).

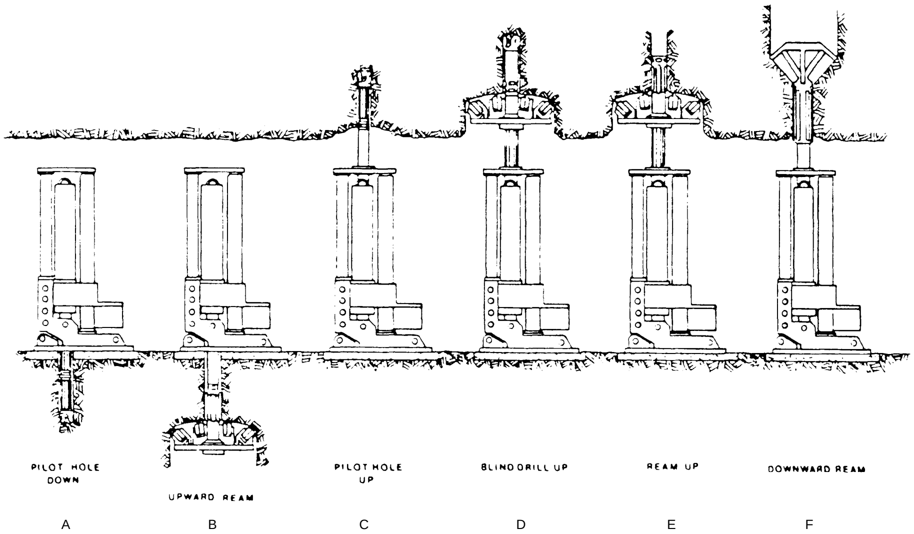


Fig. 17.4.61. Modes of operation in raise boring.

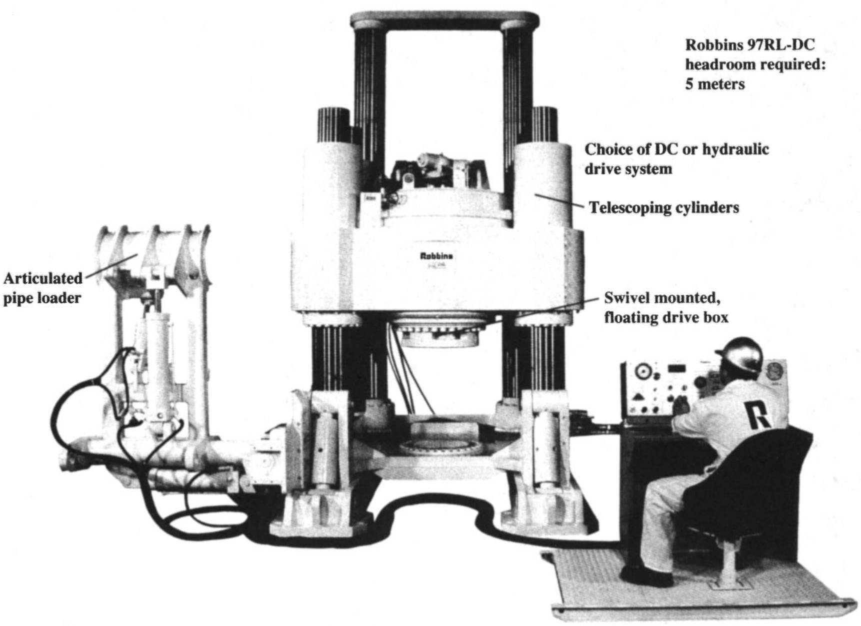

Fig. 17.4.62. Robbins 83RM-DC raise drill (*courtesy:* Robbins Co.).

where D is depth of penetration, W is the applied load, and d is a load exponent, which varies from 1.5 in soft rock to 1.0 in harder rocks.

During the reaming operation, the above equation is used for determination of load. The operator measures the rate of penetration over several minutes. He then adjusts the load and through several trials, finds the optimum load, above which the rate of penetration does not noticeably increase.

Rotary speed also affects the penetration rate. The higher the rotary speed, the faster the rate of penetration. However, restrictions other than the cutter-rock contact exist, namely, the wear of bearings and the tool itself. Vibration effects of uneven work by cutters result in wear of the drill pipe by rubbing against the wall of the pilot hole.

Table 17.4.12 lists the main parameters from several raise-boring projects.

METHOD SELECTION. The decision whether to drill raises from the top or bottom usually determines the access point. If only one end of the raise has adequate room, the machine must be put there. The extent to which raise boring will interfere with production must be evaluated. Location of the borer where less disturbance will be caused is preferred. Cost is also of major concern. Generally, drilling down and reaming up is cheaper than other configurations. Rock quality and its predicted response to drilling can influence the choice of direction as well.

LINING OF RAISES. In strong rocks without fractures, usually no support is needed. If support is required, shotcrete, rock bolts, with or without wire mesh, or steel lining can be applied. Shotcrete can be placed remotely or by workers from a cage. Rock bolts must be installed manually. Steel lining, required in unstable formations, is installed remotely, directly behind the reamer.

Conversion factor: 1 ft = 0.3048 m.

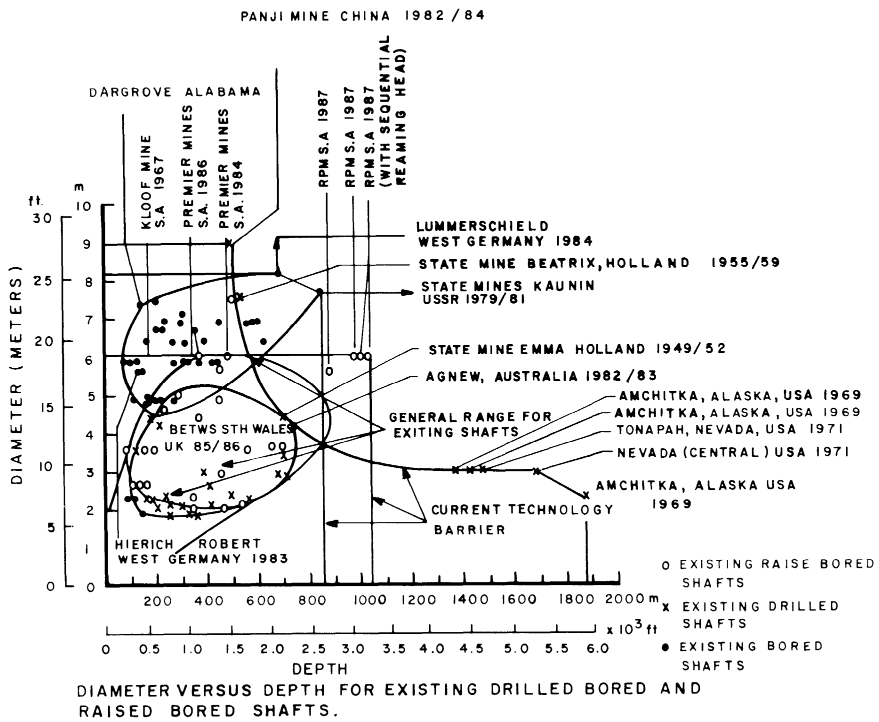

Fig. 17.4.67. Diameter vs. depth for existing drilled, bored, and raised-bored shafts. Conversion factor: 1 ft = 0.3048 m.

boring of shafts and large-diameter holes. In addition to classical mining, hydro and civil projects, a new application for the foundations of off-shore drilling platforms has emerged. Since conventional shaft sinking is the most hazardous work of all mining operations—and also, shaft conditions are among the most uncomfortable—methods eliminating human presence at the face are of great interest. Presently, two methods, shaft drilling and shaft boring, where applicable, can compete successfully with other conventional methods of shaft sinking. The cyclic nature of the mineral industry causes periods of activity in mine construction followed by periods of stagnation. Consequently, the rate of development of new technology and progress in existing technology is affected. Mechanical methods of shaft construction provide a good example of this process, as is the rate of their improvement.

The present state of technology permits shaft drilling to a depth of 3000 ft (1000 m) and up to 30 ft (10 m) in diameter (Figs. 17.4.67 and 17.4.68). Shaft drilling generally competes with conventional methods in weak and moderate-strength rock and can cope with the most difficult hydrogeologic conditions, which otherwise require application of expensive special methods. The most powerful rigs can even drill formations with compressive strength up to 42,000 psi (300 MPa).

Designing the drilling operation requires consideration of the following steps:

1. Choice of the drilling method according to the hydrogeologic conditions and geotechnical parameters of rock along the shaft profile. Next the drilling rig has to be selected based on the planned shaft diameter and depth, adequate cutters for the type of rock, stages of reaming, if any, and properties of drilling fluid.

2. Design of shaft head.

3. Selection of a type and technology of lining placement (buoyancy or casing type), determination of footing type and location, and fastening and sealing of lining in the shaft.

4. Design of the system of sealing water within aquifers, if present.

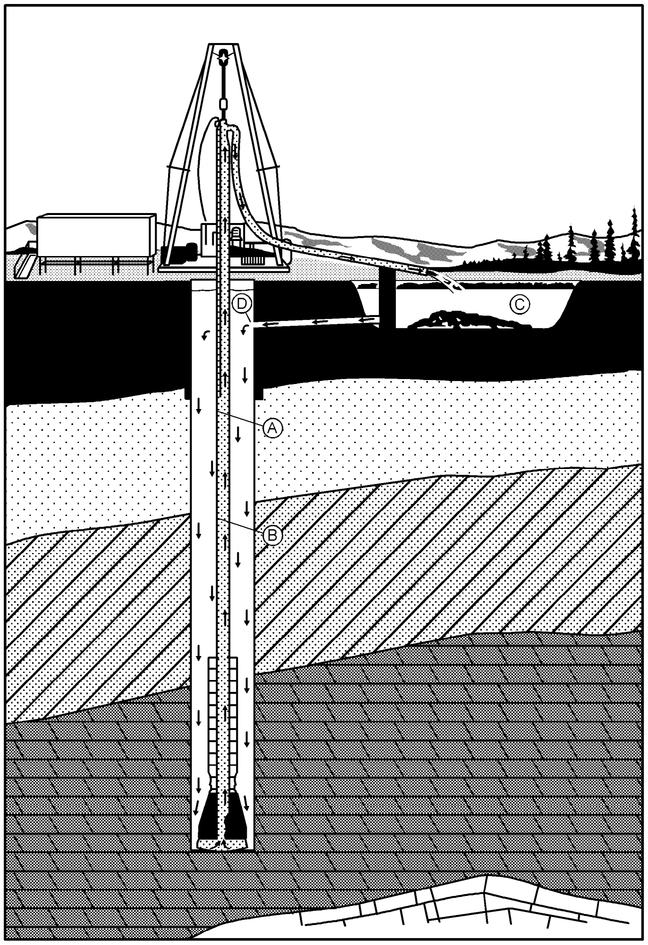

Fig. 17.4.68. Blind hole drilling system.

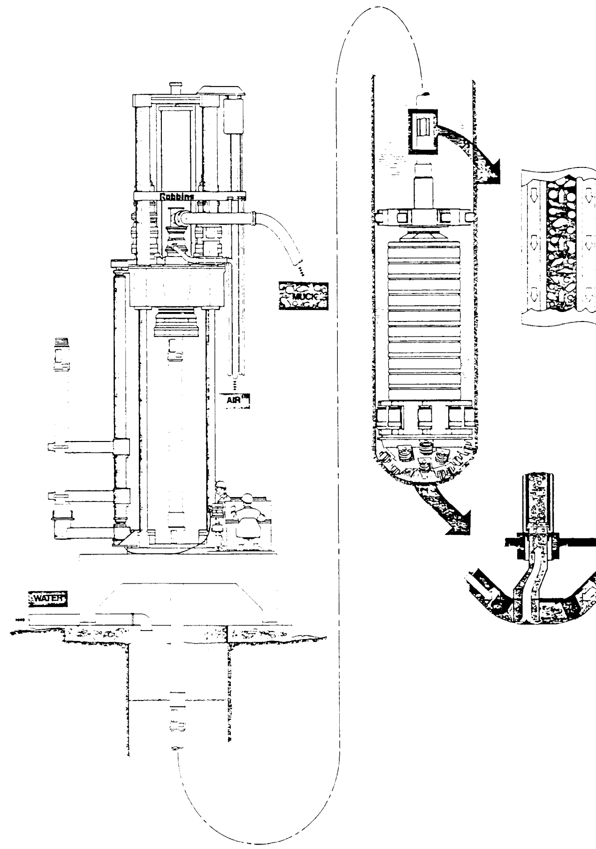

Fig. 17.4.69. Blind hole drilling rig (*courtesy;* Robbins Co.).

5. Organization of the drilling site, location of ponds for drilling fluid and a site for the fluid-making plant, and storage of lining components and materials.

DRILLING FLUID. The drilling fluid is a mixture of water and natural clay partly dispersed and partly colloidal, which by its hydrostatic head, keeps the wall of the hole in an equilibrium state and also transports chips of drilled rock and cools the bits. Ordinary drilling fluid should have a specific gravity of 1.15 to 1.25. Drilling fluid is prepared in mixers from which it flows to a tank and is pumped by slurry pumps to the shaft. During drilling, the shaft has to be filled completely with drilling fluid. To impose movement of the fluid, a compressed air airlift is used (Fig. 17.4.69). In small holes where the annular space between the drill string and hole wall is small, normal (right) circulation is applied. Air is injected in this space, and the drill fluid flows to the bottom through the drilling pipe, rising around it to lift cuttings to the surface. For large holes with a large sectional area of annular space between the drilling string and wall, the reverse system is used. Air-assisted, so-called reverse (or left) circulation systems, can be applied as single-, double-, and triple-wall pipe. In the simplest case, for example, a 3-in. (75-mm) pipe (if 13 3/8-in., or 33.4-mm, drill pipe is used) is run down the drill string, approximately 330 ft (100 m), sometimes to the end of the string. Compressed air is injected through the 3-in. (75-mm) pipe. When it rises in the annulus between the inner and drill pipes, it creates a mixture of air-drilling fluid of decreased density. The positive pressure of the drilling fluid (with unchanged density) in the shaft induces circulation with a resulting high flow velocity in the drill pipe, enabling transport of cuttings to the surface. The more viscous the fluid, the less the fluid velocity need be. Usually, the maximum particle load any system can carry is 5% of its volume.

A new development is termed pumped reverse circulation. Instead of air, a submersible pump is installed as a part of the drilling string. This allows an increase in the volume of circulating fluid (in drill pipe of 12.8-in. or 300-mm bore, 4000 to 5300 gpm, or 15 to 20 m^3/min) and consequently, better evacuation of chips from the face. To increase the size of cuttings transported, in addition to enlarging the flow volume, flow velocity can also be increased by restricting the cross-sectional area with skirts and shrouds at the very bottom of the hole. Here rock chips are lying exposed to unnecessary regrinding by the bit. Changing the angle of the sucking hole and adding chemicals to the drill fluid can also serve that purpose.

DRILLING EQUIPMENT. Originally, the drilling rigs used for large-hole drilling were converted heavy oil rigs. These were adequate when dealing with holes in a range of 10 to 12 ft (3 to 4 m), but for shafts of 15- to 25-ft (5- to 8-m) diameter, a rig had to be designed on a different set of principles. The rig must be able to produce large torque, and the required hoisting capacity must be very large. For example, CSD-300 is a rig manufactured by Hughes Micon, with six hydraulic motors producing 500,000 lb-ft (70 kNm) of torque. The power swivel is raised and lowered on hydraulic cylinders with a 2-million-lb (880-t) capacity (Fig. 17.4.70).

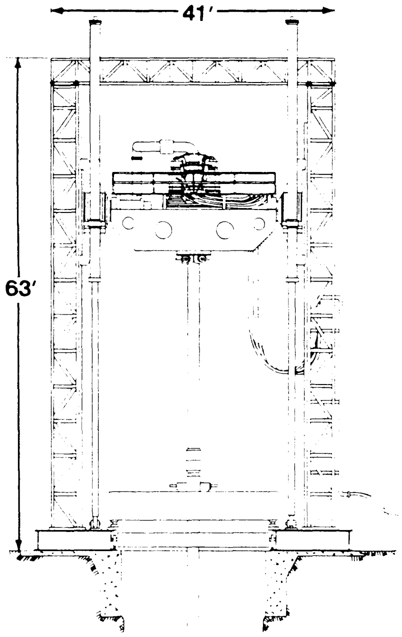

Fig. 17.4.70. CSD 300 hydraulic rig (*courtesy:* Hughes-Micon).

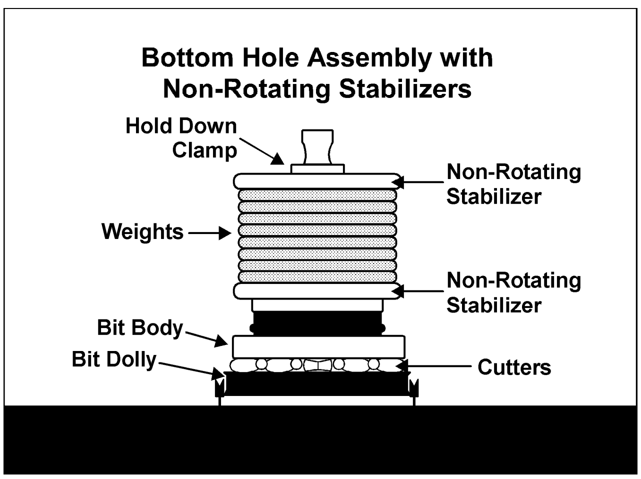

Fig. 17.4.71. 14-ft (4.3-m) diameter bottom-hole assembly.

Verticality of a large blind hole is a necessary condition that can be achieved by guiding the bit by a pilot hole or by the plumb bob effect of the very heavy end of the drilling string with large bit, weights, and stabilizers. For very-large-diameter holes, it may be necessary to use two or more passes with different sizes of bits.

Weights above the drilling structure serve several purposes other than assuring verticality of the hole. They produce the load required for bits to penetrate the rock and prevent reversal of stresses on the drill string by the flywheel effect, smoothing the dynamic reaction on the string from jerks and bumps caused by bits rolling over the rock with unevenly distributed strength. Two basic types of stabilizers are used, rotating and nonrotating. The first rotates together with the string and is often equipped with rollers (Fig. 17.4.71). Those rollers sometimes have cutting structures and work as reamers. Nonrotating stabilizers have an outer shell or pads that remain stationary while the inner core rotates. They are appropriate for softer rocks because they do not damage the shaft wall formed by weak material. Stabilizers assure vertical alignment of the hole by restricting lateral movement of the drilling bit. By using multiple stabilization, it is possible to drill shafts with an alignment of 1 in 1000.

Breaking of the rock at the base of the hole is achieved by cutters attached to the bit body. Great effort has been made over the last few decades to increase the reliability and life of cutters while permitting increased loading to be applied.

Milled steel-tooth cutters are most suitable for soft rock, producing large cuttings. This gives the potential for rapid rates of penetration, but the performance of the cutters diminishes rapidly as the teeth become dull.

Tungsten carbide cutters are more appropriate for harder rock or in particularly abrasive formations; they require substantially larger bit loading than other bit types and produce smaller chips. Their rate of penetration is slow, although performance remains steady throughout the life of the cutter. Disk or kerf cutters are not normally used for blind hole drilling because they tend to produce large chips that cannot be transported across the bottom of the hole and up to the surface. In soft and plastic strata, they can produce concentric furrows in the base of the bore with no excavation progress.

The cutters themselves are mounted in saddles that are attached to a fabricated steel body of the bit. Various basic shapes have been used, including flat-bottomed, conical, hemipherical, or a combination of shapes. There is not enough evidence to determine which shape is the most advantageous, because varying conditions in particular projects make such comparisons difficult. Some believe that flat-bottom bits drill straighter holes than do conical bits; however, the latter give a better rate of penetration in medium to soft formations.

LINING FOR DRILLED SHAFT. Types of permanent lining for drilled shafts depend on the character of rock formations intersected by the shaft. In strong rocks, minimum lining requirements exist; therefore, shotcrete usually is sufficient. In fractured zones, a combination of rock bolts with mesh and shotcrete can be applied. For shafts with hoisting installations, usually a minimum thickness of 8 in. (200 mm) of concrete lining is required, needed for the fastening of consoles for shaft beams. These types of lining must be installed from a hanging stage using conventional technology.

Permanent lining for water-bearing, weak strata can be made of reinforced concrete or steel, as a single (with stiffening rings) or double cylinder with concrete fill between the outer and inner segments. The work is performed at the surface and the lining is lowered to the shaft filled by drilling fluid.

In the floating method, a steel bottom is made (welded) beside the shafts, lined with 16 to 32 in. (400 to 800 mm) of concrete, and set afloat in the shaft. On this bottom, a first segment of lining 8 to 11.5 ft (2.5 to 3.5 m) high is welded. Extending the lining column with consecutive segments causes the weight of the lining to increase and, consequently, it sinks. Drilling fluid is displaced by lining with the equivalent volume. When the lining has positive buoyancy, by pouring water into it, the required balance can be achieved. The rate of lining placement is about 30 ft/day (10 m/day). If required by the depth of the shaft and the formation pressure, a double steel-cylinder lining with concrete filling the space between them can be made, just before sinking it into the shaft, using steel segments with the required curvature and automatic welders. The concrete inside the lining is usually made with application of the Colcrete method. Injectors are placed vertically with uniform spacing. The space is then filled with gravel, sand, and aggregate (mixed in the desired proportion), and cement of high quality is pumped into the stone skeleton through injectors, filling voids from the bottom up and pushing the air out. Vibrators are used for upgrading, compacting, and strengthening the concrete (5700 to 7100 psi, or 40 to 50 MPa, after 28 days). If for some reason, any difficulties appear during the sinking operation, the lining can be turned around, or filled with drilling fluid instead of water to make it heavier.

Another system of lining installation applies reel drum or hydraulic hoists to the lower segments of the lining 50 to 75 ft (15 to 25 m) high, without a bottom. This system is more appropriate for lighter single-cylinder lining, sufficient for conditions with lower formation pressure. After lining the entire length of the shaft, the annular space between the lining and the shaft wall is filled with cement-clay grout (proportion 2:1 and specific gravity 1.65 to 1.75) and is pumped upwards through the hoses from the bottom. The grout seals the contacts of the particular lining sections. When the grouting operation is completed and the grout has hardened to sufficient strength, the drilling fluid is pumped out from the filled shaft. If required, additional sealing can be done from the stage by grouting.

SHAFT BORING. Shaft boring is the newest and probably the least-mature technology of shaft sinking, even though this concept has been tried since the 1960s and earlier. Equipment in this category, called shaft boring machines (SBMs), could be considered as vertical tunnel boring machines (TBMs), with operating personnel traveling on board, and muck transportation and service facilities provided to the surface. The major problem encountered in this type of configuration is picking up the cuttings from the sump face for removal up the shaft. Wirth machines were quite successful with a pilot hole for free-muck removal to a lower (accessible) level. However, complete blind-hole operations have had only limited success, although the newest Robbins-Redpath machine seems to have a good potential for success. This machine has been developed utilizing experience gained with previous systems.

The SBM consists of a cutter wheel with a horizontal axis mounted on a carriage with vertical travel. The carriage is mounted on a slewing structure that rotates about the vertical axis of the shaft. The entire assembly is positioned in the shaft by an upper and lower gripper system that engages the sides of the shaft. Walking cylinders between the gripper assemblies allow the machine to advance up or down the shaft in increments. A clam-type mucking unit is mounted opposite the cutting wheel on the slew structure and loads directly from the shaft bottom into a hopper. A conventional mine hoisting system allows muck buckets to be lowered into the SBM to transfer muck from the hopper to the surface. The cutter wheel itself is fitted with disk cutters and is powered by two 261 kW motors. In the design of cuttings removal, all the advantages of disc cutters can be realized, similar to the TBM. All components of the machine fit through a 6- by 6-ft (2- by 2-m) opening, with the longest component approximately 17 ft (5.5 m) in length. The heaviest is 14 tons (13 t). This makes for easy transport and assembly and disassembly of the SBM, which can be employed even in remote locations (Fig. 17.4.72).

Carboniferous rock is probably the most suitable environment for an SBM. Formations which have a large amount of water inflow must be sealed by grout before the SBM begins boring.

17.4.3 SLOPES AND INCLINED SHAFTS

17.4.3.1 General Rules for the Design of Slopes

For shallow deposits, especially coal, *slopes* (also called *inclines* or *declines)* are more often chosen than shafts as the main entrance to a mine primarily because of their lower cost and shorter construction time. With belt transport of the coal or ore, a 15.5° slope angle is the maximum. Since a minimum of two entrances to a mine is required, slopes can serve as an intake airway while a ventilation shaft is raise bored from the mine level. As with a shaft, a slope provides all services for the mine such as main transport of production, personnel, materials and equipment, pipes, and cables (for power and communications); therefore, the cross section of the slope is designed to accommodate the required space. In coal mines, the main belt often is placed in an overhead compartment isolated from the rest of the cross-sectional area. Equipment, supplies, and miners are hoisted by means of the appropriate type of rail cars. Often the personnel walkway is also in a separate compartment to prevent exposure to the stream of intake air.

When comparing a slope with a shaft, the advantages of slopes are as follows. The beltway transportation system is uninterrupted all the way to the surface, either to the preparation plant or to the loading facility for surface transport. Slope construction is quite rapid and can be performed with mine personnel. In good quality rock, minimum support is required; often shotcrete with rock bolts is sufficient, providing additional insulation against the weathering of rocks. The main disadvantage of a slope is its increasing length with deposit depth, which makes shafts less expensive for depths exceeding about 1150 ft (350 m). However, for high-output mines, operating costs of a belt vs. shaft hoisting may still make the slope a more attractive solution, even for deeper mines.

A similar type of opening often encountered in hard-rock metal mines is a *ramp*. Ramps may be spiral or constructed as straight ramps with sharp turns. Their primary function is to connect adjacent mine levels and to allow for movement of rubber-tired haulage or tire equipment. Consequently, ramp floors have to be carefully designed and constructed to prevent tire wear on the vehicles. Good surveying of spiral ramps during construction is of great importance.

17.4.3.2 Ground Support

Slope portals at the surface are usually, as with tunnels, made of concrete. Depending on the configuration of the terrain, portals may be located at the highwall of the hill, as is practiced in Appalachian coal mines, or on even ground. In every case, they must be placed at a higher elevation than the surrounding area to avoid flooding. Further, slope entrances, similar to shafts, should be above the 100 years' flood level. Slopes intersect all strata of the overburden above the mine level, and ground support must be provided during construction and permanent service. Depending on the geotechnical parameters of rocks, support systems most often used are rock bolts, rock bolts with mesh, shotcrete, and steel arches. Selection of the support is also dependent on the technology of slope construction, size of its cross-sectional area, and utilization of slope. Principles of support selection, based on ground conditions, are given in Chapter 10.5.

17.4.3.3 Technology of Slope Construction

Technology of slope construction is similar to that of drift and tunnels; however, it is more difficult because the inclination of excavation makes the removal of muck more difficult.

A slope can be driven from the surface or upper level down, or inclined upwards if the lower level is already accessible. In rocks of compressive strength not exceeding 15,000 psi (110 MPa), roadheaders are recommended to achieve rapid progress and low cost per unit length of excavation. In rocks stronger

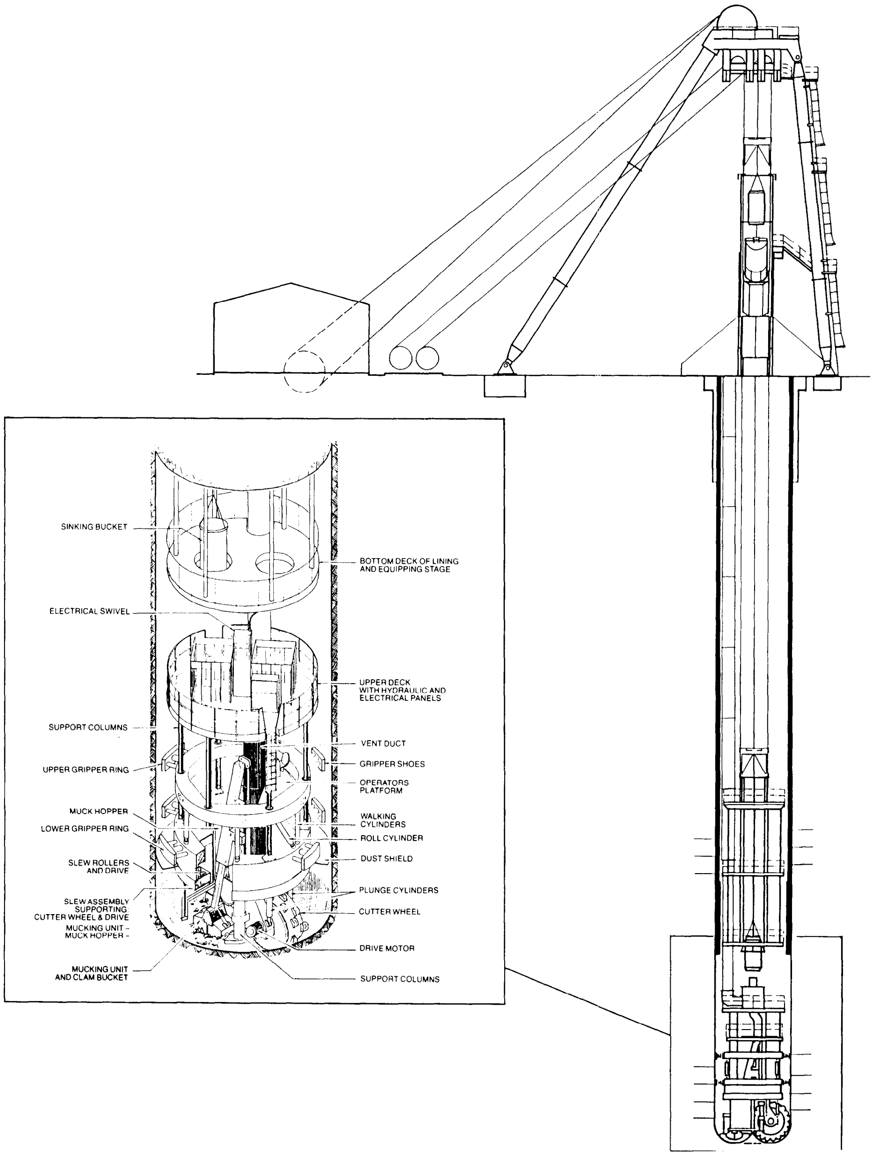

Fig. 17.4.72. Robbins shaft boring machine (*courtesy:* Robbins Co.).

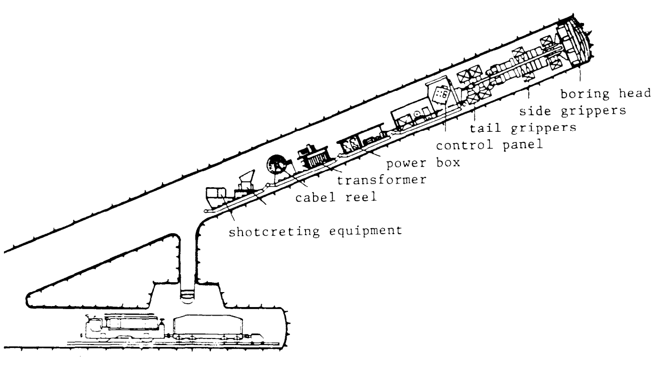

Fig. 17.4.73. Driving incline with tunneling machine (*courtesy:* Thyssen Schachtbaus Co.).

than indicated above, conventional drill-and-blast methods are usually used. In slopes where a circular cross-sectional area is required, and the total length justifies the high cost of equipment, a TBM can be applied (Fig. 17.4.73).

TECHNOLOGY WITH ROADHEADER CONFIGURATION. A boom-type roadheader cuts the face in a desirable shape, usually with an arched roof (Fig. 17.4.74). Laser beam guidance systems are used for maintaining direction along the excavation axis. Dust is controlled by exhausting tube ventilation and with water sprays installed on the cutterhead. The roof is supported by steel arches erected by a miner's boom with yoke. Steel arches can be left as the elements of permanent support or reused at the face area if another type of permanent lining is chosen (e.g., shotcrete). Muck is removed from the face by means of gathering arms on the apron of a roadheader. A conveyor at the back of the machine feeds another conveyor suspended on a monorail. A conveyor loading rail car, or cars, is periodically hoisted upward. During the car trip, the face loading system is shut down, and the apron of the machine then serves as a surge pile.

CONVENTIONAL CONFIGURATION IN HARD ROCK. The following machines are employed at the face: drill jumbo (two-boom), side loader (e.g., Eimco 633), face conveyor with impact roller crusher and loading stage for the next element of transport system (e.g., rail car), lifting cage, and shotcrete machine. Because this configuration is used in hard rocks that most often

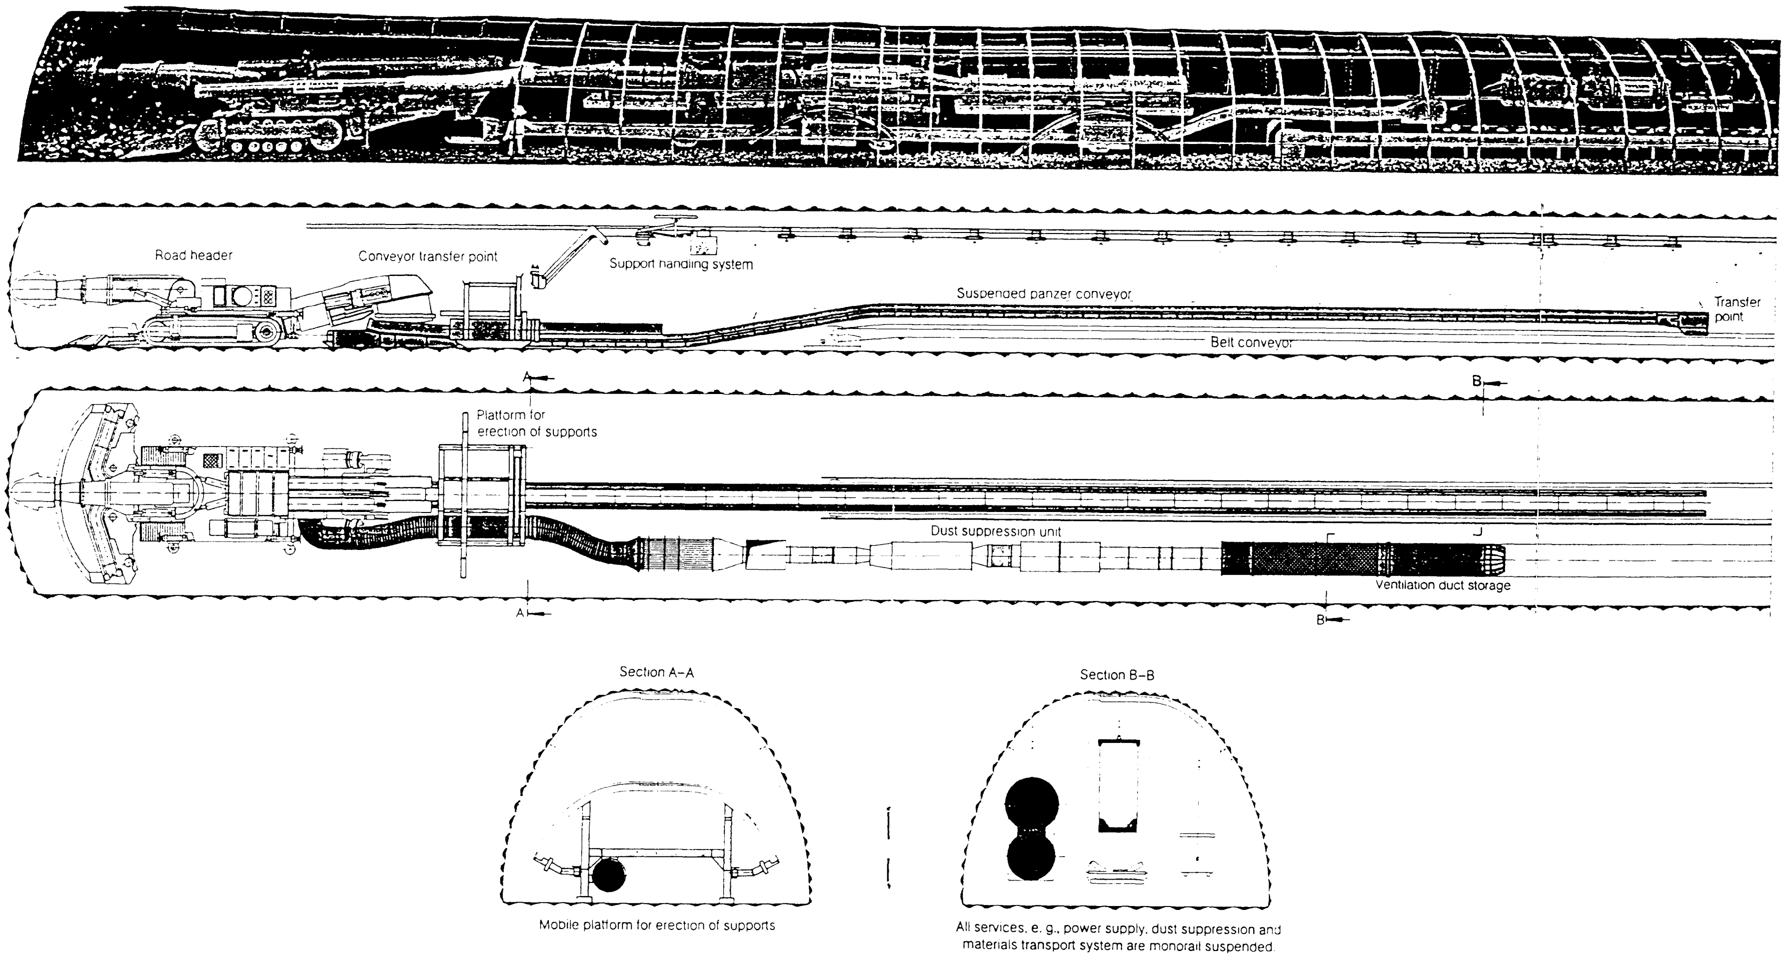

Fig. 17.4.74. Slope development with application of the roadheader (*courtesy:* Thyssen Schachtbaus Co.).

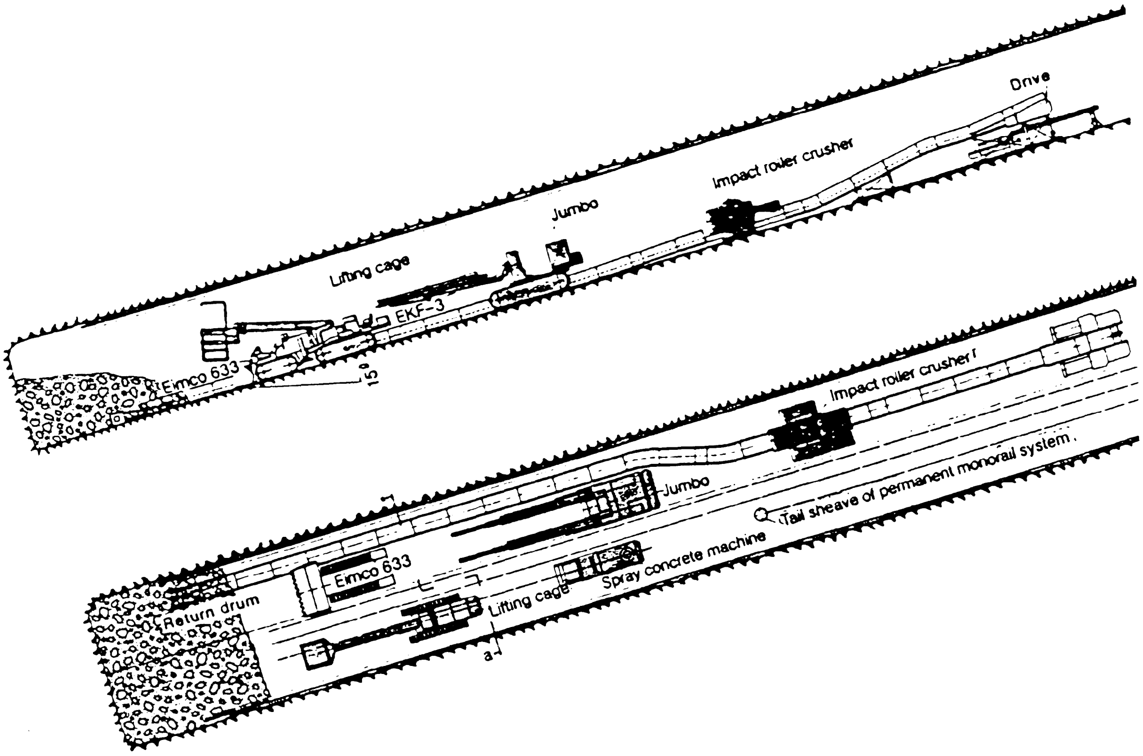

Fig. 17.4.75. Slope development with conventional drill-and-blast method. Development of a lower level by an incline, face equipment with drill jumbo and side-tipping loader (electro-hydraulic), steel support and sprayed concrete (*courtesy:* Thyssen Schachtbaus Co.).

are self-supporting, shotcrete is sufficient for temporary as well as for permanent support (Fig. 17.4.75). If water gathers at the face in excessive quantities (a small amount is beneficial for dust suppression), a face pump must be used. With a long slope, an additional unit is required to pump water to the surface (upper level).

Excavations with an angle of more than 45° are called inclined shafts. They are most often found as part of the materials handling system (orepasses) in hard-rock mining. At the present time, technology of construction is usually based on raise boring or drill-and-blast with application of a climbing platform as described in Segments 17.4.2.4 and 17.4.2.5.

17.4.4 SHAFT STATIONS

Types of shaft stations are diversified to the same degree as underground mines. Generally, the longer the life span of the mine and the larger its output, the more complex the shaft station becomes. The design considerations depend on the number of shafts within the station, type of deposit, mode of materials handling in the mine and in the shaft, water inflow, ventilation requirements, mining equipment, etc. Some typical solutions will be briefly characterized. Shaft stations in hard-rock mines with large production have several chambers that may have substantial dimensions. Those related to materials handling are skip loading pockets, retention bunkers (horizontal or vertical), pump chamber and main power station, explosives storage chamber, locomotive room, mechanical and electrical shops, miner station, dump chamber with bunker and sometimes primary crusher, and acclimatization chambers. If unit trains are the main mode of transportation, appropriate circuits are designed for empty and full trains. In cases of large water inflow in a deep mine, the pump station and sublevel water reservoirs will have large dimensions.

High-output coal mines operating in inclined seams, and consequently having primary development in rock (so-called rock structure), will have a design similar to that of hard-rock shaft stations. This is typical, for example, of European coal mines. US mines in the eastern coal fields operate in generally horizontal seams, where development with room and pillar mining equipment takes place exclusively in coal (so-called coal structure). As a result, shaft stations are developed within the limitations of the applied technology and often—due to the nearly exclusively used belt transportation—are quite simple. The geometry of such a shaft station resembles a set of main entries with larger pillars. Rail transport is limited to the handling of supplies and transportation of personnel. Service areas are arranged in particular entries.

17.4.4.1 Shaft Station Components

INSETS OF THE CAGE AND VENTILATION SHAFTS. The size of the inset of a cage shaft depends on the width and number of cages being hoisted on this level, number of decks in cages, and length of supplies to be delivered. Additionally, the inset cross-sectional area is checked for ventilation requirements. (The maximum recommended air velocity is 700 fpm (4 m/s) for production shafts and 1500 fpm (8 m/s) for ventilation exhaust shafts). Within the inset, other openings must be made, such as basements for car pushers and swinging platforms, basements for simultaneous entrance and exit of workers from multideck cages (if required), a niche for control equipment, passage to personnel station, by-pass around the shaft, etc. (Fig. 17.4.76).

Insets used only for ventilation purposes are less complex, due to their simple function.

10. chutes.

Dimensions in m. Conversion factor: 1 ft = 0.3048 m.

INSETS OF PRODUCTION SHAFTS WITH LOADING POCKET FOR SKIPS. Skip shafts and production levels are connected by a system of openings of interrelated function that accommodate the flow of material. Their shape and dimensions are dependent on the skip size and loading system as well as on the type of mechanical and electrical equipment in the system.

Depending on the skip loading system and horizontal transportation arrangement, there could be the following sets of openings for loading facilities:

1. For rail horizontal transport:

a. Dump (tippler) chamber or unloading ramp chamber (for Granby cars), batchers chamber, skip chamber (so-called stiff system) (Fig. 17.4.77).

b. Tippler chamber or unloading ramp chamber, retaining bunker, loading devices chamber, batchers chamber, skip chamber (so-called elastic system) (Fig. 17.4.78).

2. For belt horizontal transport: unloading chamber, retaining bunker (vertical or horizontal), loading chamber, batchers chamber, skip chamber, retaining bunker, loading chamber, drift with belt scales, skip chamber (also elastic system) (Figs. 17.4.79 and 17.4.80).

SHAFT STATION CHAMBERS. These chambers are an important link in the extraction process, transport, and energy supply. Because of their function, they are located in the vicinity of the main or auxiliary shafts.

The first group includes the main dewatering pump chamber, explosive storage, machine shops, fire extinguishing chamber, and crew station. Chambers serving the transportation system are the locomotive, car repair and cleaning, rectifiers, and dispatcher room. Examples of particular chambers are shown in

1 ft = 0.3048 m.

Figs. 17.4.81 through 17.4.83. Two examples of the general layout of shaft stations are presented in Figs. 17.4.84 and 17.4.86. Power distribution chambers include the main power distribution chamber, main switch chamber, and other energy-related openings.

The technology for construction of shaft station chambers is similar to that for tunnels of corresponding size. Ground conditions (mixed rock face) have great influence on sequencing of the excavation in layers. The conventional drill-and-blast method is usually used; however, continuous miners and roadheaders may also be used in weaker rock formations.

17.4.5 HORIZONTAL DEVELOPMENT OPENINGS

Primary and secondary horizontal openings play a major role in the development of a mine. This is well documented in statistics showing that out of the total length of development openings driven in 1980, 82% were horizontal openings, 16% were raises, and the rest were shafts, slopes, etc. (Martens, 1982).

Horizontal openings for primary development are applicable for mineral deposits in mountainous terrain. The deposit can be an outcropping (coal seam) or one that can be reached most conveniently by a horizontal tunnel (adit or drift) nearby. The cross-sectional area of the opening, as in the case of shafts and slopes (declines), must accommodate all required services for the mine (17.4.1.1). To meet large production and ventilation requirements, a cross section of large size is required. An alternative is the use of multiple openings, customary in coal mines. The shape of the cross section of the opening may vary from rectangular (in outcropping seam deposits such as coal) to any convenient shape (horseshoe, round) as dictated by ground conditions, construction technology, and required services of the capital opening.

Secondary development openings can be driven within the deposit, as is the practice in flat-lying coal seams (e.g., drifts, entries, crosscuts), or outside the deposit, as is generally practiced in three-dimensional ore bodies in metal mines (e.g., adits, tunnels, drifts). In the case of coal mines, there is no difference between secondary development and the production openings. The only difference is in the number of parallel entries, which can vary from seven to eleven mains and usually five to seven submains. The number of entries depends mainly on ventilation and haulage needs.

TECHNOLOGY OF CONSTRUCTION. Two major systems are in general use: 1) the drill-and-blast method, and 2) mechanical systems with the application of roadheaders, continuous miners, and tunnel boring machines. The drill-and-blast method is the most flexible system, relatively insensitive to changing rock conditions. The cross section of an opening may be changed in one step, or gradually, as may be needed in intersections and junctions of different size openings. Explosives remain the most energy-efficient means of excavating rock. Most of the energy available is utilized for rock breakage, and heat losses are minimum. The power factor per unit mass of rock obtained is 0.75 to 1.5 kWh (1 to 2 hp-hr)/ton of rock. By comparison with the most efficient for mechanical methods—a TBM with disk cutters—the corresponding factor is 2.25 to 3.75 kWh (3 to 5 hp-hr)/ton of moderately hard rock. Another advantage of the drill-and-blast method is that the capital cost is lower, by a factor of 3.5, as compared to TBMs.

Disadvantages of the drill-and-blast method are associated with the necessity for sequential drilling, blasting, mucking, and supporting of the excavation. The cyclic nature of that system is its limitation, especially with a single heading in which equipment and personnel not required for a particular operation at the face must remain idle. Another negative aspect is the hazard of handling explosives. A crew possessing higher skills is needed as compared with the TBM method, and the working environment is more physically demanding and hazardous. Finally, that part of the explosive energy that goes beyond the planned contour of the excavation often weakens the rock and produces overbreaks. This requires potentially hazardous scaling and increases the cost of support.

Depending on the face area, and whether it is uniform or mixed face (different rock strata in the face), full-face advance or in stages (with benches) is chosen. Drilling of blastholes for a larger face area is done with multiboom drilling jumbos, mounted on crawlers or on a rail carriage. For smaller cross sections, small jumbo or leg-mounted drills may be the optimum solution. Equipment selection is based on the minimum cost principle for the planned rate of excavation advance. Drilling patterns for different shapes of excavations are shown in Figs.

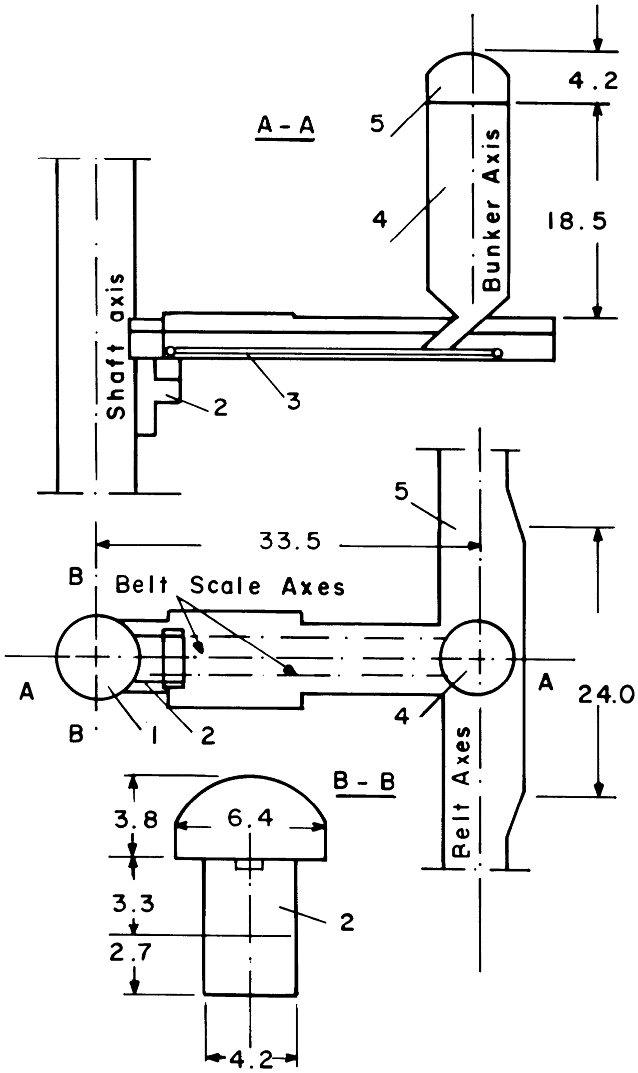

Fig. 17.4.80. Connection of production skip shaft with the opening of loading devices for horizontal belt transport system (elastic system with vertical retaining bunker).

1. skip shaft
2. skip chamber
3. belt scale
4. retaining bunker
5. unloading chamber.

Dimensions in m. Conversion factor: 1 ft = 0.3048 m.

17.4.87 through 17.4.89. V cut patterns are usually used in drifts of small face area, where only small drilling equipment is applicable. In larger drifts and tunnels, burn cuts are preferred. This requires larger equipment capable of drilling large-diameter parallel holes, which are left unloaded, providing additional free surface and thus increasing blasting effectiveness. There are a variety of drilling patterns, which are individually designed for the size of the excavation, the type of rock at the face, and the drifting technology applied. The planned contour of excavation should be followed as closely as possible, avoiding overbreaks. Therefore, a cumulative effect of blastholes should ideally reach this same surface, resulting in the designed size of excavation. There are also smoothwall blasting techniques that are based on adequate sizes of contour holes (smaller than other holes) with smaller charges. However, they require more precise drilling, affecting the rate of advance; therefore, this method is not as popular. Consumption of explosives per unit volume of solid rock varies substantially, depending on tunnel or adit size and rock strength. A similar relationship exists for the required number of holes per round. In other words, the stronger the rock, the more holes and more blasting material is needed per round. With other factors constant, for a larger face area, fewer holes are needed per unit area.

Mechanical systems of face advance are based on roadheaders or full-face borers continuously cutting the face. Technological improvements resulting in system availability and durability of cutters are gradually increasing possible applications of those systems for hard rock (Figs. 17.4.90 and 17.4.91). New-generation TBMs can cut even the strongest rock and successfully compete with drill-and-blast methods in terms of rate of advance. As in softer rock such as shales and weak sandstone, a mechanical system based on roadheaders has a clear advantage over conventional drill-and-blast methods. In a rock with moderate to high strength, careful evaluation is required of the advantages and disadvantages of both systems in order to make the proper choice. The capital cost of roadheaders and especially TBMs is high and can only be recovered over a considerable length of tunneling. Because of the very high cost of TBMs, they are seldom seen in US mining applications, whereas they are commonly used in civil construction. In coal mines of western Germany and England, main transportation tunnels have been successfully driven with TBMs (Table 17.4.13). They produce a smooth surface on the excavation, which is inherently more stable than those produced by blasting.

While TBMs have a full-face cutting head and thus produce circular openings, roadheaders mine the face with the cutterhead mounted on a hydraulically controlled boom. Therefore, any shape of cross section of the opening can be obtained. Within the new generation of roadheaders, there is a tendency towards heavier machines equipped with stiff box-type cutter booms supported by forward mounted cylinders. They operate with high torque and low RPM and are more powerful than the previous generation of machines. The roadheader principle of operation is based on the application of drag bits, which break rock in the shear and tensile modes, thus taking advantage of rock characteristics of least fragmentation resistance. The heaviest roadheaders equipped with special bits (picks) can cut rock up to 30,000 psi (200 MPa) (Trehelles et al., 1983). Roadheaders are very popular in Europe where mine development openings are usually made in rock. For instance, in Germany the average annual advance rate of roadheaders is more than twice that of conventional drill and blast headings at 10 to 15% lower cost per meter (Boldt, 1988). Two main types of cutterheads are in use, the in-line (milling) heads rotating on axis parallel to the boom and transverse (ripper) cutterheads. The latter work better in hard rock, while machines with in-line heads achieve a higher cutting rate in soft rock.

Bit consumption and cost depend on rock properties; cutter bit costs range for soft and nonabrasive materials up to $4/yd^3 ($5.20/m^3) (Kogelman, 1989). Roadheader production rate vs. rock strength is given in Fig. 17.4.91.

In the United States, the continuous miner is the most popular member of the rapid excavation family, because flat-lying seams in coal mines allow in-seam mine development. If possible to apply, this is the most economical development system, with the continuous miner applied in both development and production faces. In a weak-rock formation such as coal, shale, and salt, the continuous miner with drum cutting head is probably the most refined and most productive machine, widely applied in coal mines in North America, Australia, and South Africa.

MUCKING. A variety of possible configurations is available depending on the drifting system. Generally, side-casting or overshot loaders with track or tire undercarriage are used. In large tunnels, front-end loaders, arm loaders with flying conveyors, or backhoe shovels can be applied. Depending on equipment configuration, they discharge either to rail cars or use some sort of intermediate system, such as a hanging conveyor or shuttle car side casting to the rail cars. Beyond the face, muck transport in the tunnel can be either by rail cars or conveyor belt. The most practical and economical method is to apply the system that will be in service after the development stage is completed, during the exploitation stage of the mine (see Chapters 9.3 and 9.4). Some examples of equipment configuration are given in Figs. 17.4.92 and 17.4.93.

Support of the excavation has to ensure safety of the crew and the equipment. It is selected on the basis of rock conditions, technology of face advance, future function of the drift/tunnel, and existing regulations. In self-supporting rocks, only minimum support is needed, such as rock bolts, and even this is sometimes mainly to satisfy safety regulations. On the other hand, in unstable rocks, temporary support has to be installed at a minimum distance to the face to shorten delay time, and a permanent support of adequate strength must be erected following the face advance. Table 17.4.13 lists the support systems used for development drifts in reference to the engineering MBR classification. Clearly, the required type of support affects the equipment needed during the face advance. With the drill-and-blast method, the support is based on rock bolts, and if required, shotcrete will require a minimum number of machines in the face. If the support of steel arches is needed, the roadheader is usually employed where its boom yoke is used for erection of a roof arch. When rock pressure conditions make the installation of additional support necessary, it is erected at some distance to the face where it does not interfere with face activities. For instance, the initial

support (rock bolts or arches) can be shotcreted over or a structural concrete lining (with application of form) can even be poured for more difficult conditions.

Chapter 17.5
HOISTING SYSTEMS

FRED A. EDWARDS

17.5.1 INTRODUCTION

After a detailed technical feasibility study has indicated the commercial viability of exploiting an ore body using underground methods, an adequate planning and design process for mine access should begin. Two general types of access should be considered: (1) vertical to near-vertical shafts using hoists and cable-suspended conveyances, or (2) horizontal or inclined openings using rail, trucks, conveyors, or cable-operated conveyances.

Because a shaft often provides the most direct access over the longest period of time, there is an advantage to designing a shaft for maximum duty, consistent with economy. The current trend in shaft design is to provide multipurpose shafts. These shafts contain facilities for handling ore, waste, materials, personnel, services, manways, and ventilation.

During the process of identifying the purpose of the shaft, it should be realized that once a shaft is excavated and equipped, it cannot be enlarged easily in the future. Therefore, the shaft's initial and ultimate requirements must be defined during the design phase.

This chapter presents the information and criteria necessary to design or select a mine shaft hoisting system. Specific topics such as hoist selection, hoist rope details, headframe design, shaft furnishings and equipment, as well as shaft lining design, are included in the discussion. Ramps and tunnels are dealt with in a similar fashion in Chapters 17.4 and 24.1.

A *system* is defined as a group of units so combined as to form a whole and to operate in unison. Thus, when designing a shaft hoisting system, one must consider not only each part of the system separately but the interrelationships among the parts of the system in its entirety. For the purpose of this discussion, the shaft hoisting system has been divided into five main components: (1) hoist, (2) conveyance, (3) rope, (4) shaft, and (5) headframe (Fig. 17.5.1).

Following a description of each of the five main hoisting components, a segment describing a systematic procedure that can be used to design a shaft hoisting system is presented.

17.5.1.1 Design Parameters for Evaluating Alternative Modes of Access

The first step in evaluating an access system for a mine is to determine the principal purpose of the opening. The opening could be used for production, service, ventilation, exploration, development, or a combination of these. Next, duty requirements for the opening must be established. Questions include: how much ore and waste? how many personnel? how much material and supplies? how much air?

With this information, the basic design parameters, including the size of the opening, configuration, ground support, and inclination can be developed. This allows preliminary designs and comparative capital and operating cost estimates to be made between alternative systems.

Detailed cost analysis for the mine access cannot be carried out without additional design consideration involving the following items: (1) geology of the ground to be excavated, (2) strike, dip, plunge and depth of the ore body, and (3) hydrogeology of the strata to be penetrated. With the above information, the engineer is in a position to prepare conceptual designs and order-of-magnitude cost estimates.

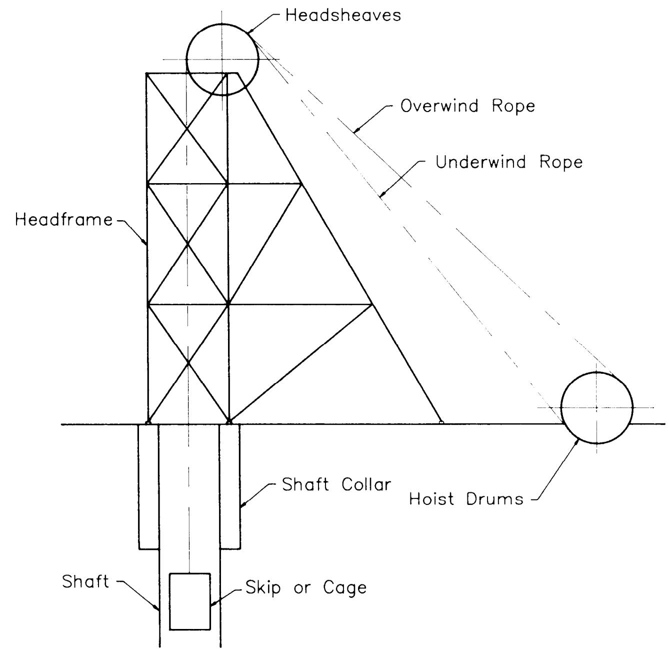

Fig. 17.5.1. Shaft hoisting system.

Outside influences on the cost of any new project must be taken into account. These are (1) the geographic location of the project, affecting cost of materials; (2) climatic conditions at the site, especially heavy rainfall, snow, extreme cold and high winds; and (3) availability of skilled manpower to carry out the work, noting labor relations in the area. While these items do not generally affect the design considerations, they affect the development costs for the access system.

After the above terms have been defined, trial calculations and alternate designs can be considered. During this process, the interrelationships among the major components of the system can be examined. Each trial design must be evaluated to ensure that it meets the design objectives. These objectives are concerned with capital costs, operating costs, dependability, efficiency, flexibility, suitability to the mining plan, and time to construct. This procedure of defining, examining alternate designs, and conducting evaluations is continued until an optimum solution is reached.

17.5.2 SHAFT HOISTING SYSTEMS

In this chapter, the major components associated with vertical to near-vertical shafts using hoists and cable-suspended conveyances are described briefly. The term shaft hoisting system is used to describe collectively the openings and the equipment being considered.

In addition to the five major hoisting components, Edwards (1988) has identified an additional 277 subcomponents. The number of subcomponents and their interrelationship with the main components are indicative of the complexity involved with the design of shaft hoisting systems.

A brief description of each of the above main components is now presented. In the following segments, information on the design and technical considerations to be examined when selecting a particular component is presented in more detail.

17.5.2.1 Hoists

There are two basic types of hoists in common use today. These are the *drum hoist* in which the hoist rope is stored on the drum, and the *friction hoist* in which the rope passes over the wheel during the hoisting cycle. Within each category there are several variations.

Drum hoists are usually located at some distance from the shaft and require a headframe and sheaves to center the hoisting ropes in the shaft compartment. Friction hoists may also be located directly over the shaft and, depending upon the wheel diameter, may require deflection sheaves to center the rope in the shaft compartment.

17.5.2.2 Conveyances

Conveyances used in mining operations are classified according to their use. Those for handling personnel and material are generally termed cages. Conveyances for handling broken ore or coal and waste are termed skips. Combination skip-cages are used in some areas. A counterweight may also be considered a conveyance.

17.5.2.3 Rope

When considering the complete shaft hoisting system, there are three common uses for steel ropes, with a particular construction applicable for each use. A list of ropes by use and most common construction follows:

Rope Use	Rope Construction
1. Hoist rope	Round strand
	Flattened strand
	Locked coil
2. Balance rope	Non-rotating
3. Guide and rubbing rope	Half-locked coil

17.5.2.4 Shaft

Brucker (1975) has provided two definitions that can be used to describe shafts for mining purposes: (1) a vertical, deep, restricted cross-section excavation, and (2) a vertical or inclined primary opening in rock that gives access to and serves various levels of a mine.

Primary openings can be further defined as those that are considered to be permanent and require a high degree of safety. Although the above definitions can be used to describe any type of shaft, they are somewhat general and do not provide sufficient information to allow the design and construction of a shaft as a useful structure for mining purposes.

There are several classifications that can be used to differentiate shafts by type. For the purpose of this discussion, four commonly used classifications are presented. Shafts can be classified (1) by purpose, (2) by configuration, (3) by ground support, and (4) by excavation method.

SHAFT PURPOSE. One of the first items to be examined when designing a shaft is to identify its intended purpose. When defined by purpose, shafts usually fall into the following categories:

1. Production: ore and waste handling.
2. Service: personnel and materials handling.
3. Ventilation: upcast or downcast airflow.
4. Exploration: for defining mineral deposits.
5. Escape: for emergency.
6. Combinations of the above.

SHAFT CONFIGURATION. Shafts may be classified according to their size and configuration. The most common shaft configurations for any size shaft are circular, rectangular, and elliptical. Size of a shaft can be small (32 to 160 ft^2, or 3 to 15 m^2), medium (160 to 2150 ft^2, or 15 to 200 m^2), or large (> 2150 ft^2, or 200 m^2), depending upon its service.

SHAFT GROUND SUPPORT REQUIREMENTS. Shafts may be classified according to the type of ground support to be used to maintain the stability of the shaft structure, for example, a timber shaft or concrete-lined shaft. Ground support applied to the shaft structure can be classified as temporary support or permanent support. Ground support requirements are thoroughly discussed in Chapter 17.4.

SHAFT EXCAVATION METHODS. Shafts may be classified by the excavation method used during construction. There are two types of excavation methods: conventional and bored. *Conventional shafts* are excavated with standard drilling, blasting, and mucking methods, in combination with various methods of ground support. They may be of any configuration or inclination. *Bored shafts* are excavated using a mechanical shaft boring machine (SBM). Several boring methods are available. Most methods remove cuttings from the collar of the hole. Some methods drop cuttings from the machine into the mine. All bored shafts are circular in configuration, with various methods of ground support. They may be of any inclination. Shaft excavation techniques are discussed in Chapter 17.4 and Section 9.

17.5.2.5 Headframe

Headframes may be constructed of wood, steel, or concrete. They are generally divided into two types:

A. With backlegs
   1. A-frame
   2. Four-post
   3. Six-post
   4. Other
B. Tower
   1. Ground-mounted hoist
   2. Tower-mounted hoist

17.5.3 HOISTS

Generally, the mine hoist selected and installed at a mine remains in position for the life of the operation. It is therefore imperative that the proper hoist be selected. In order to select the proper hoist, it is important to understand the basic design parameters, the various types of hoists available, and the relationship between the mine hoist and the other components of the hoisting system. Each major type of hoist is now considered separately (Fig. 17.5.2).

17.5.3.1 Types of Hoist

SINGLE DRUM. The single drum hoist may be used for balanced or unbalanced operation. When used for *unbalanced*

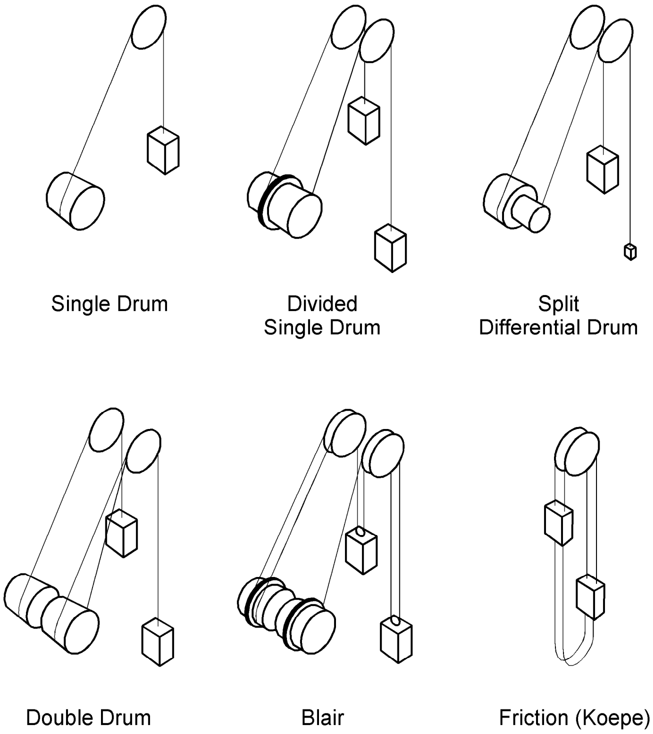

Fig. 17.5.2. Arrangements of various hoists.

hoisting, the cost of the electric drive becomes quite high for long hoisting distances and high tonnages. This is because the motor must have sufficient torque to handle the weight of the rope, conveyance, and payload.

In a *balanced hoisting system,* one rope winds off the drum as the other winds on. When used with a skip or cage in balance with a counterweight, a single drum hoist can service one or more levels since the location of the counterweight is not important. When used with two skips in balance, the single drum hoist is best used for single-level hoisting. Any rope adjustments to locate the conveyance must be done manually. For shallow shafts with one layer of rope, no dividing of the drum is required. For deeper shafts, the drum must be divided.

DIVIDED SINGLE DRUM. This type of hoist is used for deeper shafts with balanced hoisting when several layers of rope must be stored on the drum. Peak horsepower is less than with unbalanced hoisting because the skip weights are balanced. Since the payload and weight of the rope is not balanced, the maximum unbalanced load occurs when the loaded conveyance is at the bottom of the shaft.

SPLIT DIFFERENTIAL DIAMETER DRUM. The third type of single drum hoist available is the split differential diameter drum. This type of hoist is used with a conveyance and counterweight in balance. If the counterweight is wound on the smaller diameter drum, it moves less than the main conveyance, and rope adjustment problems are reduced.

DOUBLE DRUM, ONE DRUM CLUTCHED. Although more expensive than a single drum hoist, the double drum hoist with one drum clutched has certain advantages. With this type of hoist, it is possible to make quick adjustments to the ropes due to initial stretch. As a service hoist with cage and counterweight, this type of hoist can serve several levels efficiently. As a production hoist with two skips, the ropes can be adjusted to maintain balanced hoisting at any level in a multilevel operation.

DOUBLE DRUM, BOTH DRUMS CLUTCHED. The double drum hoist with both drums clutched has the added feature of allowing hoisting to continue in one compartment should something happen to the other compartment. This is an excellent feature if there is only one hoist available. This type of hoist is also favored during shaft sinking operations.

MULTIPLE DRUM, BLAIR TYPE. With this type of hoist, each conveyance is suspended from two hoist ropes that are each coiled on a drum. The advantage of this is that smaller diameter ropes and drums may be used. This type of hoist was developed in South Africa. There are no Blair-type hoists in use in North America. However, for very deep mines, they should be considered.

FRICTION HOIST, SINGLE ROPE, AND MULTIROPE. The Koepe or friction hoist was developed by Frederick Koepe in 1877. It consists of a wheel with a groove lined with friction material to resist slippage. The hoist rope is not attached or stored on the wheel. In early installations, the hoist was mounted on the ground, and a single rope was wound around the drum and over the headsheaves to the conveyances, in a balanced arrangement. In addition, a tailrope of the same weight per unit length as the headrope was suspended in the shaft below each conveyance. Thus the only out-of-balance load was the payload.

As hoisting loads became larger, the number of headropes and headsheaves increased to the point where it became more practical to install the hoist in the headframe directly over the shaft. In North America, many friction hoists are mounted in this way. In order to bring the rope centers in line with the compartment centers, deflection sheaves must also be installed in the headframe below the hoist.

17.5.3.2 Comparison of Friction and Drum Hoists

A friction hoist system differs from a drum hoisting system in performance as well as components. Therefore, when attempting to decide which type of hoist to use, it is necessary to compare the two complete systems rather than the two hoists alone. In addition to comparing the total capital costs of the hoist, headframe, ropes, conveyances, and shaft, it is necessary to consider operating costs, maintenance costs, reliability, power supply system, local custom, and individual preference.

Brucker (1975), Schulz (1973) and Tudhope (1973), among others, have discussed drum hoist and friction hoist applications. The following general statements help distinguish between these two hoisting systems: (1) double-drum hoists are the preferred hoist for shaft sinking; (2) double-drum hoists are the best choice for hoisting in two compartments from several levels; (3) drum-type hoists are best suited for high payloads from shallow depths; (4) the limitation on a drum hoist employing a single rope is the ultimate strength of the rope, because large ropes are difficult to manufacture and handle; (5) the depth capacity of drum hoists can be extended by using two ropes per conveyance (Blair-type hoist), and with this arrangement, Blair hoists can be used for depths exceeding those of either single-rope drum hoists or friction hoists); (6) friction hoists with multiple ropes can carry a higher payload and have a higher output in tons per hour than drum hoists within a range of depths from 1500 to 5000 ft (460 to 1520 m); (7) friction hoist mechanical operation is very simple, has a low rotational inertia, and is less costly than a drum hoist; (8) friction hoists have a lower peak power demand than drum hoists with the same output; and (9) the friction hoist can operate on a relatively light power supply.

17.5.3.3 Hoist Component Considerations

When selecting (or comparing) hoists, the components to be considered during the evaluation process include (1) drum, (2) bearings, (3) gearing, (4) brakes, (5) drive motor, and (6) control.

DRUM. For drum hoists, the drum must be designed to store the required length of rope, meet the statutory requirements concerning fleet angles and rope ratios, and must be sufficiently strong to withstand bending and crushing forces. The design of drums is well documented (Atkinson, 1973) but beyond the scope of this *Handbook.*

Drums may be plain faced or grooved. With plain-faced drums, a section of the drum is unavailable for carrying live turns of rope. However, with grooved drums, the entire face can be utilized.

There are three types of drum grooving available: (1) helical, (2) parallel, and (3) Le Bus (or antisynchronous). *Helical grooving* is a continuous spiral providing smooth winding with a single layer of rope. It can also be used with multilayer winding. *Parallel grooving* is made up of individual grooves evenly spaced over the drum width. This grooving is used for single layer winding only. *Le Bus grooving* is a combination of parallel and helical. It is deeper than helical and parallel grooves, thus providing better support. It is most suited for multilayer winding as it reduces rope whip at the crossover points.

For friction hoists, the drum must be sized to meet statutory requirements for rope-to-drum ratios and must be wide enough to carry the required number of ropes.

The tread of a friction hoist drum is lined with a friction material to resist slippage. In the past, this material was wood or leather. At present, polyurethane, PVC, or combination blocks are used.

BEARINGS. When there is a relative motion between two members of a machine, one of which supports the other, the supporting member is called a bearing. Bearings are classified into two general types: sliding bearings and roller bearings. *Sliding bearings* are those in which the surfaces are in sliding contact, and the supported member runs on a cylindrical, conical, or flat surface. *Roller bearings* have surfaces that are in rolling contact, and the supported member runs on hardened steel balls or rollers.

In some hoists, sliding bearings lined with babbitt are used for the hoist drum shaft, pinions, and headsheaves. During operation, the bearing surfaces are separated by an unbroken film of oil. Although sliding bearings are, in principle, the perfect type of bearing, they are being replaced by roller bearings. The advantages of roller bearings are their low coefficient of friction, economy of space, simplicity of lubrication, practical elimination of wear due to roller point contact, maintenance of accurate alignment, and their consistency in design and manufacture. For a hoist, roller bearings having a rated life of 300,000 hours are generally selected.

GEARING. The hoist may be driven by either ac or dc electric motors. Depending upon the hoisting speed, these motors may be connected to the shaft directly or through a gear drive. Low-speed motors may be connected directly; high-speed motors require a gear reducer drive.

With high-speed motors (300 to 900 rpm), power is transmitted from the motor to the hoist through coupling-connected single or multiple-stop, helical gear reduction drives. Beerkircher (1975) recognizes the following as consideration for the design and selection of a suitable gear drive: (1) size, type, speed, location, and number of motors; (2) size, type, speed, torque requirements, and location of hoist; (3) type of operating cycle; and (4) physical restrictions.

BRAKES. The braking system is required to decelerate, stop, and hold the hoist drum. This may be accomplished using electrical and mechanical braking systems, which must operate both under normal and emergency conditions.

Electric braking may be accomplished through regenerative braking, counter-torque braking, or dynamic braking. In regenerative breaking, the motor, when connected to a hoist operating on an overhauling load, performs as an induction generator, developing braking torque and returning energy to the system. With counter-torque and dynamic breaking, there is no energy returned to the system; instead, it is consumed and dissipated in the secondary resistance as heat.

When electric braking is used, and during normal operating conditions, the *mechanical brake* serves two purposes. Firstly, it helps to slow down the drum after the speed has been greatly reduced electrically, and secondly, it holds the drum at rest. Under these conditions, the mechanical brake does little work, and its design and operating characteristics can be fairly simple and straightforward. Under emergency conditions, however, the hoist must be stopped with the mechanical brake as quickly as possible, without damaging the hoist, brake, or conveyances.

In North America, there are three main types of brakes used: (1) the jaw, (2) the parallel motion, and (3) disk brakes. Disk brakes are used mainly on friction hoists, whereas jaw and parallel motion brakes may be used on both drum and friction hoists.

With the *"caliper-type" brakes,* two shoes are pressed against the periphery of the brake drum through the pull of a single or double draw bar acting through a series of linkages. The source of force can be a brake weight or a nest of springs. When not in use, the weight or springs are held open by a hydraulic oil cylinder. When the brakes are applied, oil flows from the cylinder to allow the force of the weight or springs to apply the brakes. The control of this flow is extremely important, as it determines the speed and amount of force to be applied.

The use of *disk brakes,* particularly with friction hoists, has increased. Two types of disk brakes are used. In one type, the brake is operated via a lever system and during emergency stops via a falling weight. This is similar to conventional post brake systems. With the other type of system, hydraulically operated, spring applied units are used. These units are mounted around the brake disk. The required number of units is determined by the total braking force required by the particular hoist. The braking control unit is similar to that used in drum hoists. The advantages of disk brakes are their relatively small dimensions, light weight, and ease of replacement.

CLUTCHES. Drum hoists used for unbalanced hoisting, or when operating from several levels, should have at least one of the drums clutch-connected to the drum shaft. With such a hoist, the clutched drum(s) is supported on the shaft through a sleeve bushing and the clutch is used to transfer the motor torque to the drum. In order to prevent the drum from rotating when it is unclutched, it is necessary that the clutch operating mechanism and the drum brake be interlocked.

The clutch is operated through a two-, three-, or four-arm *spider* that is attached to the turning drum shaft. These arms are perpendicular to the shaft and are shifted parallel to the axis of the drum shaft. A clutch ring with matching teeth on its entire periphery is bolted to the inside of the drum, and as the spider is moved, these two sets of teeth are free to engage at any point on the circumference of the drum. Driving torque is then transmitted from the clutch to the drum through the bolts used to hold the clutch ring to the drum flange.

DRIVE MOTOR. Staley (1936) describes four methods of providing power to drive the hoist: (1) electric power, (2) steam, (3) compressed air, and (4) internal combustion engine. Electric power is by far the most common method and is the only one treated here.

Table 17.5.1. Capital and Operating Cost Comparison Between M-G Set and Static Drive

	Type of Drive	
	M-G Set	Static Drive
Initial cost of system	100%	85% to 110%
Installed cost	100%	70% to 90%
Operating cost, kWh/ton	100%	90% to 92%
Power factor	0.8 leading	0.7 lagging
kW demand effect	100%	92%
Estimated maintenance time	100%	70%
Estimated downtime for major repair	100%	30%
Operating characteristics	No appreciable difference	
Technical competence required	100%	100%

Source: Muller, 1978.

The choice of electric motor drives lies between alternating-current motors and direct-current motors, with direct current being supplied from either a motor-generator (MG) set or from a silicon-controlled rectifier (SCR). The correct choice for a particular application is complex and requires advice from persons expert in this field. The principal factors to be considered in selecting a motor are the mechanical configuration, electric power system, and economics.

The ac motor has the advantage of having the lowest initial cost and can use the power normally supplied. However, it has a higher starting torque and is difficult to automate. The ac motor generally requires a gear train to drive the hoist.

The dc motor provides accurate and sensitive control, is easily automated, and has a lower starting torque. The dc motor may be directly connected to the hoist, thus eliminating the gear drive and the space requirements of such a drive.

The choice of power-conversion equipment is affected by the quality of the power system available, the ratio of the hoisting load (electrical) to the total plant load, and personal preference. Table 17.5.1 shows an operating and cost comparison of motor-generator sets and static drives for a mine hoist.

HOIST CONTROL. Control systems are required to monitor the speed and location of each conveyance moving in the shaft. Whenever a conveyance exceeds a preselected, safe, speed-distance profile, the control systems initiates an action to prevent the moving conveyance from striking a permanent obstruction regardless of its speed or direction of travel. In addition, control systems may be used to shut down equipment due to high operating temperatures, excess brake wear, rope slip, slack rope, loss of power, etc. Discussion with hoist manufacturers reveals that the control systems for friction hoists are more numerous and complex than for drum hoists.

Because a full discussion of all of the systems (and their variations) is beyond the scope of this presentation, it may be more useful to discuss the factors to be considered when reviewing various systems presented by suppliers. The three most important factors to be considered, according to Eastcott (1977), are (1) reliability, (2) simplicity, and (3) ease of adjustment.

17.5.3.4 Hoist Selection

The size of a hoist is expressed by the drum dimensions, horsepower rating of the motor, and rope pull. The following segments show how these factors are calculated.

Both drum hoists and friction hoists consist of two separate machines, each of which must be designed to produce the desired result. These types of machines are as follows: (1) mechanical (drum, drumshaft, gears, brakes), and (2) electrical (drive motor, controls). The *mechanical portion* of the hoist is designed to support the hoisting rope and its loads. The *electrical portion* of the hoist is designed to provide sufficient torque to turn the drum and raise or lower the rope, conveyance and payload.

In order to design and build a hoist, certain basic duty information is required, namely, (1) hoisting distance, (2) production rate (tons per hour), (3) maximum loads, and (4) types of guides (wood, steel, rope). It can be shown that for a given depth and production rate, there is an optimum load that results in the lowest cost for the hoist.

Due to competition among suppliers and the tendency for owners to purchase on the basis of lowest cost, it is possible that the selected hoist will not have any excess capacity for the drum and motor. This may mean that any change in the future, however slight, could not be accommodated. It is thus important that the purchaser provide the supplier with the following additional information: (1) ultimate use of shaft (men, materials, ventilation, exploration, proposed phasing of expansion); (2) surface plant layout (type of headframe, bin location, etc.); (3) underground layout (levels, station, loading pocket); and (4) type of power distribution system available.

Although the complete detailed design of a hoist is not possible here, the following segments provide sufficient information to allow the reader to determine the best type of hoist for a particular set of conditions, together with some indication as to the power and current consumptions involved.

In order to determine the dimensions, capacity, and size of the mechanical components, the designer must determine certain basic criteria. These include:

1. Hoisting speed, including acceleration, deceleration, and maximum speed.
2. Production rate, in tons per hour.
3. Maximum load to be hoisted.
4. Hoisting distance.
5. Weight of payload and conveyances.
6. Diameter of hoisting rope.

After this information is determined, the designer can then determine the capacity of the electric motor required to raise and lower the loads in the required time.

The order in which the data should be generated is as follows: (1) duty cycle times, (2) hoisting rate, (3) payload and conveyance weight, (4) rope size, (5) drum dimensions, and (6) RMS horsepower requirement.

These items are discussed in more detail in the following.

DUTY CYCLE. The *duty cycle* describes the total time it takes to move a conveyance from the bottom of its wind to the top. It is often depicted graphically as a time-speed diagram. In order to be complete, the duty cycle must include periods of time for initial creep, acceleration, full speed, deceleration, dumping, loading, and rest. The physical laws of uniformly accelerated motion are used to determine the time required and the distance traveled once values for acceleration rate, final velocity, and shaft depth are known.

The relationships between maximum speed, length of wind, and running time are summarized as follows (Fig. 17.5.3).

Accelerating time, seconds:

$$t_1 = \frac{V}{a} \tag{17.5.1}$$

Accelerating distance, ft or m:

$$\frac{Vt_1}{2} = \frac{V^2}{2a} \tag{17.5.2}$$

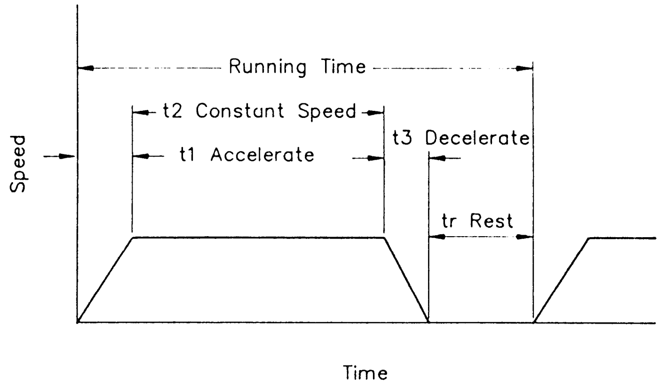

Fig. 17.5.3. Time-speed diagram.

Decelerating time, seconds:

$$t_3 = \frac{V}{r} \tag{17.5.3}$$

Decelerating distance, ft or m:

$$\frac{Vt_3}{2} = \frac{V^2}{2r} \tag{17.5.4}$$

Full-speed time, seconds:

$$t_2 = \frac{L}{V} - \frac{V}{2} \times \left(\frac{1}{a} + \frac{1}{r}\right) \tag{17.5.5}$$

Full-speed distance, ft or m:

$$L = \frac{V^2}{2} \times \left(\frac{1}{a} + \frac{1}{r}\right) \tag{17.5.6}$$

where a is acceleration in ft/s^2 or m/s^2, r is retardation in ft/sec^2 or m/s^2, t_1 is acceleration time in sec, t_2 is full speed time in set, t_3 is retardation time in sec, V is maximum speed in ft/sec or m/s, and L is length of wind in ft or m. Now if we call t_r the time at rest (loading and dumping),

Cycle time in seconds = $t_1 + t_2 + t_3 + t_r$

$$= \frac{V}{a} + \frac{L}{V} - \frac{V}{2} \times \left(\frac{1}{a} + \frac{1}{r}\right) + \frac{V}{r} + t_r \tag{17.5.7}$$

For initial estimating, the following assumptions may be used:

V, fps = $0.742L^{1/2}$ for drum hoists (0.410 $L^{1/2}$ m/s)
V, fps, = $0.790L^{1/2}$ for friction hoists (0.436 $L^{1/2}$ m/s)
a, fps^2, = $r = 2.2$ (0.76 m/s^2)
t_r = 20 sec for good skip loading and dumping conditions

Substitution of the above values in Eq. 17.5.7 gives the total cycle time for the hoisting operation:

Drum Hoist (English units)
Cycle time = 0.337 L + 21.388
Drum Hoist (SI units)
Cycle time = 0.612 L + 22.439
Friction Hoist (English units)
Cycle time = 0.359 L + 21.266
Friction Hoist (SI units)
Cycle time = 0.651 L + 22.294

The maximum velocities used above should not exceed the following values for different types of guides:

Wood guides 35 ft/sec (10 m/s)
Steel guides 50 ft/sec (15.25 m/s)
Rope guides 70 ft/sec (20 m/s)

In addition, the designer should check any statutory restrictions on velocity and acceleration in the jurisdiction (country or state) in which the hoisting system will operate.

PRODUCTION RATE. The required production rate (or hoisting rate as it is sometimes termed) for a skip hoist is expressed in terms of the average tons per hour hoisted. If the mill operates on a different schedule to the mine, the production rate must be adjusted to reflect the difference between hoisted tons per day and milled tons per day. In addition, the moisture content of the ore must be taken into consideration and included in the quantity of material to be hoisted.

At this stage the concept of hoist utilization factor should be introduced. In certain well-organized shafts, the utilization factor can be as high as 0.92 but a more normal figure is 0.70.

SKIP SIZE. After the cycle time and production rate are known, the payload requirements for the skip are derived simply as:

$$\text{Payload p} = \frac{\text{production rate}}{\text{no. of trips/hr}} = \frac{\text{production rate (tons/hr)}}{\text{cycle time (s)} \times 3600\text{ (s/hr)}}$$

The approximate weight of the skip can be derived from one of the following relationships:

$$= 0.5\text{ payload} + 1500\text{ in lb} \tag{17.5.8}$$

$$(0.5\text{ payload} + 680\text{, in kg}) \tag{17.5.8a}$$

or roughly, skip weight = $\frac{5}{8}$ payload.

Conveyance manufacturers should be consulted for more accurate figures.

ROPE SIZE. After the weights of the payload and the conveyance are known, the correct *size of rope* can be selected by applying the required (usually specified by statute) safety factor. The type of rope must also be considered and is covered in more detail in 17.5.5.

For initial estimating purposes, the size of the rope required may be selected by using the following relationships (de la Vergne, 1978).

1. For a depth of 4500 ft (1370 m) or less:

$$W = \frac{P(1 + s) \times 2000}{Ls - 4500} \tag{17.5.9}$$

$$\frac{P(1 + s) \times 1000}{Ls - 1370} \tag{17.5.9a}$$

where W is rope weight in lb/ft or kg/m, P is payload in tons or tonnes, s is mass of skip + mass of payload, Lu is maximum rope length that can be suspended in ft or m, and Ls is $Lu/5$ in ft or m.

2. For depths greater than 4500 ft (1370 m):

$$W = \frac{P(1 + s) \times 2000}{Ls - 1} \tag{17.5.10}$$

$$W = P(1 + s) \times \frac{1000}{Ls - 1} \tag{17.5.10a}$$

DRUM SIZE. Having determined the rope diameter, it is possible to establish a *hoist drum diameter.* Minimum allowable drum diameters are usually covered by legislation. In the United States, drum and sheave diameters must be

1. Not less than 60 times the hoist rope diameter for slope or inclined shaft applications.
2. Not less than 80 times the rope diameter if the hoist ropes are 1 in. (25 mm) in diameter or greater, or not less than 60 times the rope diameter if the hoist ropes are less than 1 in. (25 mm) in diameter for vertical shaft applications.
3. Not less than 100 times the diameter for locked coil ropes.

For drum hoisting, the drum width and center to center distance of the drums (for double drum hoists) must be calculated. The *drum width* may be determined from the following equation:

$$\text{capacity} = 0.252\ WN\,[D/d + 0.85\,(N - 1)] \tag{17.5.11}$$

where capacity is length of rope to be stored in ft, W is drum width in in., N is number of layers, D is drum diameter in in., and d is rope diameter in in. In SI units,

$$\text{capacity} = 3.024\ WN\,[D/d + 0.85\,(N - 1)] \tag{17.5.11a}$$

where capacity is length of rope in meters, W is drum width in cm, N is number of layers, D is drum diameter in mm, and d is rope diameter in mm.

The *center-to-center distance of the drums* can be calculated using the requirements for proper fleet angles (covered later) and knowing the center-to-center distance of the hoisting compartments being serviced.

In the case of tower-mounted friction hoists, the center-to-center distance of the compartments must be equal to or less than the drum diameter. If it is less, a deflector sheave must be installed below the hoist wheel to deflect the ropes on one side of the hoist into their correct position. In addition, the tail rope also has a natural bending radius that must be considered.

POWER REQUIREMENTS. After the duty cycle and rope size have been determined, it is possible to calculate the *hoist motor power* requirements. A quick, approximate method follows.

$$\text{HP required} = \frac{\text{foot-pounds work done per minute}}{33{,}000 \times \text{efficiency}}$$

$$= \frac{\text{payload in pounds} \times \text{speed in feet per minute}}{33{,}000 \times \text{efficiency}}$$

$$= \frac{\text{fpm} \times \text{tons} \times 2000}{33{,}000 \times \text{efficiency}} = \frac{\text{fpm} \times \text{tons} \times 2000}{\text{HP constant}} \tag{17.5.12}$$

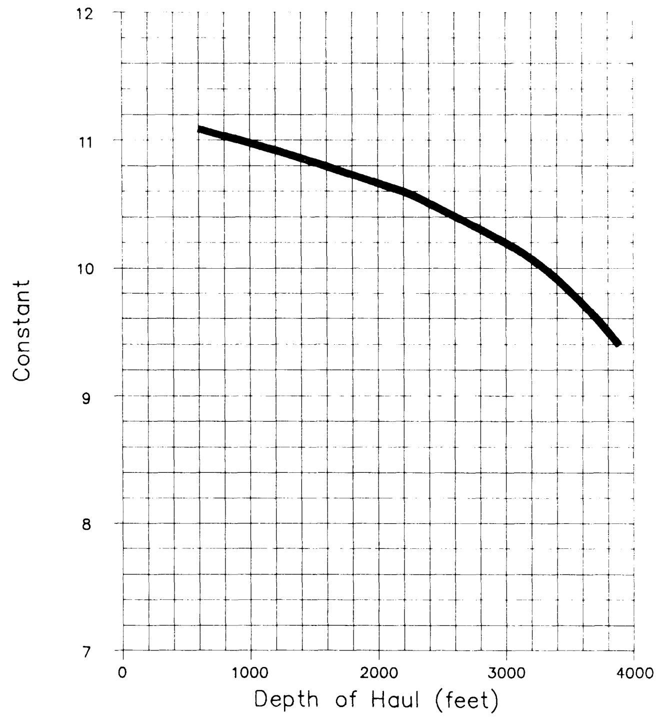

Fig. 17.5.4. Horsepower constant (Anon., 1948). Conversion factor: 1 ft = 0.3048 m.

$$\text{Watts required} = \frac{\text{watts}}{\text{efficiency}}$$

$$= \frac{\text{payload in kilograms} \times \text{speed in meters per second} \times 0.1020}{\text{efficiency}} \tag{17.5.12a}$$

Since the efficiency of the hoist varies according to depth, a graph has been developed from calculated data showing the variation in the constant for different depths (Fig. 17.5.4).

A more exact method of calculating the hoist motor horsepower is presented for both drum hoists and friction hoists as follows (Harmon, 1973).

Drum Hoist Horsepower Calculations— The equations needed to calculate horsepower at all points A through F, as shown on the horsepower vs. time cycle graph in Fig. 17.5.5, are as follows (in English units only):

1. Horsepower HP, required to accelerate the hoist system (motor inertia not included):

$$\text{HP}_1 = \frac{TSL \times V^2}{32.2 \times T_a \times 550} \tag{17.5.13}$$

where TSL is total suspended load and mass of hoist rotating parts to be accelerated $TSL = EEW$ (refer to Fig. 17.5.6) + SL + $2SW$ + $2R$, SL is skip load, SW is skip weight, R is rope weight, V is rope speed in fps, and T_a is total acceleration time (i.e., t_a to creep + t_a from creep to full speed).

2. The horsepower HP, regenerated into the electrical power system by suddenly decelerating is shown as a negative horsepower as it is created by energy pumped back into the power system (all terms the same as in Eq. 17.5.13):

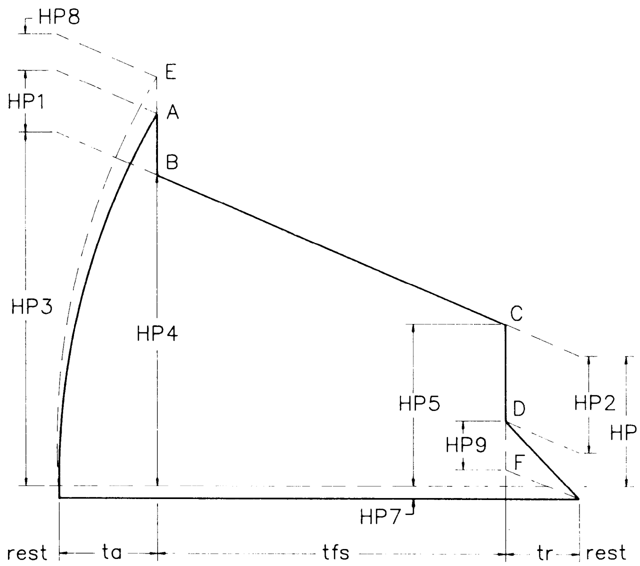

Fig. 17.5.5. Horsepower vs. time cycle, drum hoist (Harmon, 1973, p. 15-54).

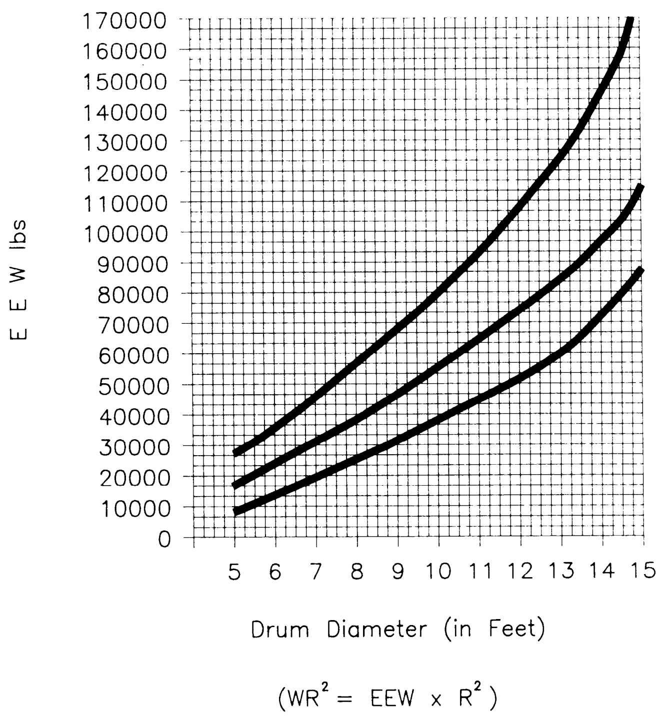

Fig. 17.5.6. Equivalent effective weight chart (EEW) (Harmon, 1973, Fig. 15-39). Conversion factors: 1 ft = 0.3048 in., 1 lb = 0.4536 kg.

$$HP_2 = -\frac{TSL \times V^2}{32.2 \times T_R \times 550} \tag{17.5.14}$$

where T_R is total retard time, i.e., from full speed to creep speed to stop.

3. Running horsepower at the shaft bottom without acceleration, that is, the horsepower to hoist a full skip load at the shaft bottom when traveling at full speed at that particular point in the shaft:

$$HP_3 = \frac{(SL + R) \times V}{550} \tag{17.5.15}$$

4. Running horsepower at the end of acceleration to full speed:

$$HP_4 = \frac{SLB \times V}{550} \tag{17.5.16}$$

where SLB is suspended load at shaft bottom =

$$(SL + R) - (V \times T_a \times \text{rope weight in lb/ft})$$

5. Running horsepower at the end of full-speed-run period and start of deceleration:

$$HP_5 = \frac{SLT \times V}{550} \tag{17.5.17}$$

where SLT is suspended load at shaft top =

$$(SL - R) + (V \times T_R \times \text{rope weight in lb/ft}).$$

6. Running horsepower at the end of deceleration:

$$HP_6 = \frac{(SL - R) \times V}{550} \tag{17.5.18}$$

7. The horsepower correction factor for motor and gearing efficiency is less than 100%:

$$HP_7 = \frac{SL \times V}{550} \times 0.176 \tag{17.5.19}$$

a. Peak accelerating horsepower of the hoist system:

$$A = HP_1 + HP_7 + \frac{HP_4 + 2HP_3}{3} \tag{17.5.19a}$$

b. Full-speed horsepower at the end of acceleration period:

$$B = HP_4 + HP_7 \tag{17.5.19b}$$

c. Full-speed horsepower at the start of deceleration period:

$$C = HP_5 + HP_7 \tag{17.5.19c}$$

d. Deceleration horsepower:

$$D = HP_2 + HP_7 + \frac{HP_5 + 2HP_6}{3} \tag{17.5.19d}$$

(1) Horsepower required to accelerate motor rotor (or armature):

$$HP_8 = \frac{0.6A \times 1.2}{T_a} \tag{17.5.20}$$

(2) Horsepower required to decelerate motor rotor (or armature):

$$HP_9 = \frac{-0.6A \times 1.2}{T_r} \qquad (17.5.21)$$

e. Total horsepower to accelerate the hoist system and motor rotor (or armature):

$$E = A + HP_8 \qquad (17.5.19e)$$

f. Total horsepower to decelerate hoist system and motor rotor (or armature):

$$F = D + HP_9 \qquad (17.5.19f)$$

8. Finally, equations to calculate the RMS horsepower requirement are as follows:
a. dc motors:

$$\text{RMS hp} = \sqrt{\frac{E^2 \times T_a + \frac{B^2 + C^2 + BC}{3} \times TFS + F^2 \times T_r}{0.75\ T_a + T_{FS} + 0.75\ T_r + 0.5\ \text{rest}}} \qquad (17.5.20a)$$

b. ac motors:

$$\text{RMS hp} = \sqrt{\frac{E^2 \times T_a + \frac{B^2 + C^2 + BC}{3} + TFS + F^2 \times Tn}{0.5\ T_a + T_{FS} + 0.5T_r + 0.25\ \text{rest}}} \qquad (17.5.20b)$$

9. As a check on calculations, the following equation can be solved:

$$\left(\frac{A}{2} \times T_a\right) + \left(\frac{B+C}{2} \times T_{FS}\right) + \qquad (17.5.21)$$

$$\left(\frac{D}{2} \times T_r\right) \cong \frac{SL \times \text{depth}}{0.85 \times 550}$$

The relation should agree to within 1 or 2% with the RMS horsepower calculation. This check is simply an approximation of the area under the horsepower vs. time-cycle diagram (Fig. 17.5.5) and represents work done, which is load times depth divided by 550 ft-lb/set-hp with an efficiency factor of 0.85 incorporated.

For unbalanced hoists, the only change is in the total suspended load *TSL*. In this case,

$$TSL = EEW + SL + 1SW + 1R. \qquad (17.5.22)$$

Friction Hoist Horsepower Calculations—Horsepower calculations for friction hoists are similar to those for drum hoists but a little simpler (several are identical). This is because the running horsepower after initial acceleration does not change as a result of a constant rope weight (head rope plus tail rope) during travel up the shaft.

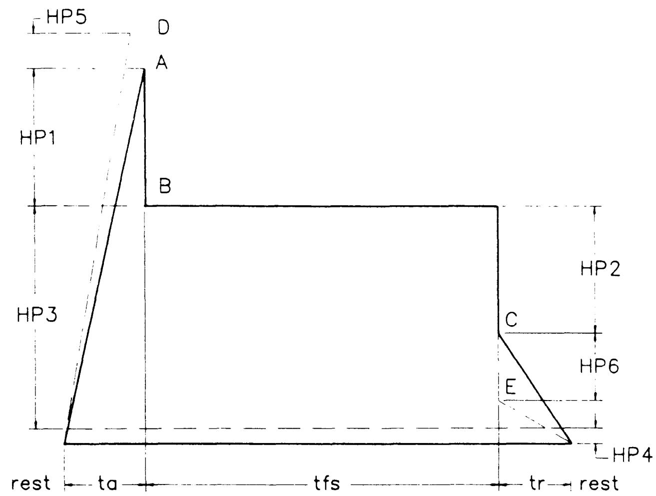

Fig. 17.5.7. Horsepower vs. time cycle, Koepe hoist (Harmon, 1973, p. 15-54).

The equations used to calculate horsepower requirements at all points (in English units only), A through E, as shown on the horsepower vs. time cycle graph in Fig. 17.5.7, are as follows:
1. Acceleration horsepower:

$$HP_1 = \frac{TSL \times V^2}{32.2 \times T_a \times 550} \qquad (17.5.23)$$

where $TSL = EEW + SL + 2SW + R$, and R = (depth × rope weight) per ft × 2 × no. of ropes.
2. Regeneration horsepower:

$$HP_2 = -\frac{TSL \times V^2}{32.2 \times T_r \times 550} \qquad (17.5.24)$$

3. Running horsepower at shaft bottom:

$$HP_3 = \frac{SL \times V}{550} \qquad (17.5.25)$$

4. Running horsepower at end of acceleration:

$$HP_4 = \frac{SL \times V \times 0.111}{550} \qquad (17.5.26)$$

The efficiency of the motor and drive system is greater than in the drum hoist:

$$0.111 = \frac{100 - 3}{E} \text{ where } E = 0.90$$

5. Summary calculations:
a. Acceleration peak of Fig. 17.5.7

$$A = HP_3 + HP_4 + HP_1 \qquad (17.5.27a)$$

b. Full-speed running horsepower:

$$B = HP_3 + HP_4 \qquad (17.5.27b)$$

c. Total retardation horsepower:

$$C = HP_3 + HP_4 + HP_2 \quad (17.5.27c)$$

(1) Running horsepower at end of full-speed run:

$$HP_5 = \frac{0.75A \times 1.2}{T_a} \quad (17.5.28)$$

(2) Horsepower required to retard motor rotor:

$$HP_6 = -\frac{0.75A \times 1.2}{T_r} \quad (17.5.29)$$

d. Total horsepower to accelerate hoist and motor rotor:

$$D = A + HP_5 \quad (17.5.27d)$$

e. Total horsepower to retard hoist and motor rotor:

$$E = C + HP_6 \quad (17.5.27e)$$

6. RMS horsepower
a. dc motors:

$$\text{RMS hp} = \sqrt{\frac{D^2 \times T_a + B^2 \times T_{FS} + E^2 \times T_r}{0.75\ T_a + T_{FS} + 0.75\ T_r + 0.5 \text{ rest}}} \quad (17.5.30a)$$

b. ac motors:

$$\text{RMS hp} = \sqrt{\frac{D^2 \times T_a + B^2 \times T_{FS} + E^2 \times T_r}{0.5\ T_a + T_{FS} + 0.5\ T_r + 0.25 \text{ rest}}} \quad (17.5.30b)$$

The check for Eqs. 17.5.23 through 17.5.30b is the following:

$$\left(\frac{A}{2} \times T_a\right) + \left(B \times T_{FS}\right) + \left(\frac{C}{2} \times T_r\right) = \frac{SL \times \text{depth}}{0.90 \times 550} \quad (17.5.31)$$

Example 17.5.1. Drum Hoist Calculation (Harmon, 1973) (in English units): Determine RMS hp of a hoist system using an ac motor and hoisting two 10-ton skips in balance in a 1000-ft shaft. Rope speed is 20 ft/sec. Skip-weight/skip-load ratio = 0.75. Acceleration rate is 2.0 ft/sec^2; deceleration, 2.0 ft/sec^2; rest period is 10 sec. The hoist uses two l-in. dia. round-strand ropes at 3.78 lb/ft. The hoist is a 15-ft dia. single-drum unit. The hoist duty cycle, in seconds, is

1. Accelerate to creep	1.0
2. Creep at 2.0 ft/sec^2	2.0
3. Accelerate to full speed	9.0
4. Travel at full speed	39.4
5. Decelerate to creep speed	9.0
6. Creep at 2 ft/sec^2	4.0
7. Decelerate to stop	1.0
8. Rest (load and dump)	10.0

Solution. Then T_a = 10 sec (1 + 3), T_r = 10 sec (5 + 7), T_{FS} = 39.4 sec (4)

$$HP_1 = \frac{TSL \times V^2}{32.2 \times T_a \times 550}$$

TSL: 1. EEW from Fig. 17.5.6 for 15-ft single drum is 110,000 lb
2. SL = 20,000 lb
3. 2 SW = 2 × 0.75 × 20,000 = 30,000 lb
4. 2R = 2 × 1000 ft × 3.78 lb/ft = 7560 lb

TSL = 167,560 lb

$$HP_1 = \frac{167{,}560 \times (20)^2}{32.2 \times 10 \times 550} = 376 \text{ hp}$$

$$HP_2 = \frac{-TSL \times V^2}{32.2 \times T_r \times 550} = 376 \text{ hp since } T_r = T_a HP_1 = -HP_2$$

$$HP_3 = \frac{(SL + R) \times V}{550} = \frac{(20{,}000 + 3{,}780) \times 20}{550} = 865 \text{ hp}$$

$$HP_4 = \frac{(SLB) \times (V)}{550}$$

$$\begin{aligned} SLB &= (SL + R) - (V \times T_a \times R \text{ per ft}) \\ &= (20{,}000 + 3{,}780) - (20 \times 10 \times 3.78) \\ &= 23{,}780 - 756 = 23{,}024 \text{ lb} \end{aligned}$$

$$HP_4 = \frac{23{,}024 \times 20}{550} = 839 \text{ hp}$$

$$HP_5 = \frac{SLT \times V}{550}$$

$$SLT = (SL - R) + (V \times T_r \times R \text{ per ft})$$

Since $T_a = T_r$, then ($V \times T_r \times R$ per ft) = ($V \times T_a \times R$ per ft), or SLT = (20,000 − 3780) + 756 = 16,976 lb

$$HP_5 = \frac{16{,}976 \times 20}{550} = 617 \text{ hp}$$

$$HP_6 = \frac{(SL - R) \times V}{550}$$

From HP_5 above, ($SL - R$) = (20,000 − 3780), or $HP_6 = \dfrac{16{,}220 \times 20}{550} = 591$ hp

$$HP_7 = \frac{SL \times V}{550} \times 0.176 = \frac{20{,}000 \times 20}{550} \times 0.176 = 128 \text{ hp}$$

$$A = HP_1 + HP_7 + \frac{HP_4 + 2HP_3}{3} = 376 + 128 + \frac{839 + 2(865)}{3} = 1360 \text{ hp}$$

$$B = HP_4 + HP_7 = 839 + 128 = 967 \text{ hp}$$

$$C = HP_5 + HP_7 = 617 + 128 = 745 \text{ hp}$$

$$D = HP_2 + HP_7 + \frac{HP_5 + 2HP_6}{3} = -376 + 128 + \frac{617 + 2(591)}{3} = 352 \text{ hp}$$

$$HP_8 = \frac{0.6A \times 1.2}{T_a} = \frac{0.6 \times 1260 \times 1.2}{10} = 91 \text{ hp}$$

$$HP_9 = -\frac{0.6A \times 1.2}{T_r}$$

Since $T_r = T_a = 10$ sec, $HP_9 = -91$ hp

$$E = A + HP_8 = 1{,}260 + 91 = 1{,}351 \text{ hp}$$
$$F = D + HP_9 = 352 + (-91) = 261 \text{ hp}$$

Check:

$$\frac{A}{2} \times T_a + \frac{B + C}{2} \times T_{FS} + \frac{D}{2} \times T_r \cong \frac{SL \times \text{depth}}{0.85 \times 550} \qquad (17.5.21)$$

Then

$$\frac{(1260 \times 10)}{2} + \frac{(967 + 745)}{2}(39.4) + \frac{(352 \times 10)}{2} \cong \frac{20{,}000 \times 1000}{0.85 \times 550}$$

or $6300 + 33{,}726 + 1760 = 41{,}786$ }
$\frac{20{,}000 \times 1000}{0.85 \times 550} = 42{,}780$ } less than 2% difference

Therefore, the check indicates that the solution will be accurate to within 2%.

The RMS hp for the ac motor

$$= \sqrt{\frac{(1351)^2 \times 10 + \frac{((967)^2 + (745)^2 + (967)(745))}{3} + (261)^2 \times 10}{0.5(10) + (39.4) + 0.5(10) + 0.25(10)}}$$

or approximately 1000 hp

Hence, for the skip load, skip weight, rope, and rope speed used in this example, a 1000-hp ac motor would be sufficient for this duty cycle.

Example 17.5.2. Friction Hoist Calculation (Harmon, 1973) (in English units): Determine the RMS hp for an ac drive running a friction hoist operating 5-ton skips in balance in a 1000-ft shaft with the following given information:

Given: 1. Hoist uses four l-in. dia. F.S. ropes at 1.80 lb/ft
2. Rope speed = 20 fps
3. Wheel diameter = 10 ft
4. Skip-weight/skip-load ratio = 1.2
5. Duty cycle T_a = 10 sec
T_{FS} = 39.75 sec
T_r = 8 sec
Rest = 10 sec

Solution.

1. HP_1:

$\frac{TSL}{EEW}$ (from Fig. 17.5.7)	= 37,000 lb
+ *SL*	= 10,000 lb
+ 2*SW* (2 × 1.2 × 10,000)	= 24,000 lb
+ *R* (1000 ft × 1.80 lb per ft × 2 × 4)	
TSL	= 14,400 lb
	85,400 lb

$$HP_1 = \frac{85{,}400 \times (20)^2}{32.2 \times 10 \times 550} = 193.5 \text{ hp}$$

2. $HP_2 = \frac{85{,}400 \times (20)^2}{32.2 \times 8 \times 550} = -241$ hp

3. $HP_3 = \frac{(10{,}000) \times (20)}{550} = 363$ hp

4. $HP_4 = \frac{(10{,}000) \times (20) \times 0.111}{550} = 40.3$ hp

5. $A = HP_3 + HP_4 + HP_1 = 363 + 40.3 + 193.5 = 596.8$ hp

6. $B = HP_3 + HP_4 = 363 + 40.3 = 403.3$ hp

7. $C = HP_3 + HP_4 + HP_2 = 363 + 40.3 + (-241) = 162.3$ hp

8. $HP_5 = \frac{0.75A \times 1.2}{T^a} = \frac{0.75(596.8) \times 1.2}{10} = 54$ hp

9. $HP_6 = \frac{-0.75A \times 1.2}{T_r} = \frac{-0.75(596.8) \times 1.2}{8} = -67.2$ hp

10. $D = A + HP_5 = 596.8 + 54 = 650.8$ hp

11. $E = C + HP_6 = 162.3 + (-67.2) = 95.1$ hp

Check:

$$\frac{A}{2} \times T_a + B \times T_{FS} + \frac{C}{2} \times T_r \cong \frac{SL \times \text{depth}}{0.90 \times 550}$$

$$= \left(\frac{596.8}{2} \times 10\right) + (403.3 \times 39.75) + \left(\frac{162.3}{2} \times 8\right) = \frac{10{,}000 + 1000}{0.90 \times 550}$$

$$= (2984) + (16{,}000) + (644) = 19{,}633$$

$$= \frac{10{,}000 \times 1000}{0.90 \times 550} = 20{,}200 \text{ hp}$$

$$= \frac{20{,}200}{19{,}663} = 1.0178,$$

or a difference of 1.78%, which is within the allowance of 1 to 2%; therefore, the solution is accurate.

$$\text{RMS hp (ac)} = \sqrt{\frac{D^2 \times T_a + B^2 \times T_{FS} + E^2 \times T_r}{0.5\ T_a + F_{FS} + 0.5\ T_r + 0.25 \text{ Rest}}}$$

$$= \sqrt{\frac{(650.8)^2 \times 10 + (403.3)^2 \times (39.75) + (95.1)^2 \times 8}{0.5\,(10) + 39.75 + 0.5\,(8) + 0.25\,(10)}}$$

$$= 458.9 \text{ hp}$$

17.5.3.5 Number of Hoists Required

Since most shafts are designed to be multipurpose (i.e., for ore, waste, personnel, materials), one of the first items to be considered is the number of hoists required to meet all the hoisting requirements. The best approach is to list all requirements, determining the daily hoisting time required for each. If the total is more than 24 hours, two hoists must be employed; or if close to 24 hours, compromises made. The items to be included in the list are as follows: (1) number of ore hoisting trips per day, (2) number of waste hoisting trips per day, (3) number of material trips per day, (4) number of man trips per day, (5) time required for hoist, shaft, rope, and conveyance inspections as required by law and good maintenance practices, (6) time required for internal movement of personnel, and materials, and (7) idle time, per day, per week.

After the number of trips has been determined, it is then necessary to calculate the length of time or duty cycle for each trip (see 17.5.3.4).

ORE HOISTING TIME. In order to determine the number of hours per day required to hoist ore, the following should be known: (1) planned tonnage to be hoisted daily, and (2) production rate for the skip hoist in tons per hour. This may be expressed as follows:

time required for ore hoisting (hours/day)

$$= \frac{\text{daily ore production (tons/day)}}{\text{hoist production rate (tons/hour)}} \qquad (17.5.32)$$

WASTE HOISTING TIME. Waste hoisting time is calculated in a similar manner as for ore hoisting. When calculating daily waste production, consideration should be given to using waste underground as backfill as this will reduce the daily waste hoisting requirements:

time required for waste hoisting (hours/day)

$$= \frac{\text{daily waste production (tons/day)}}{\text{hoist production rate (tons/hour)}} \qquad (17.5.33)$$

MATERIALS AND SUPPLIES HOISTING TIME. In order to determine the number of hours per day required to hoist materials and supplies, the following information should be known: (1) number of material and supplies trips per day, and (2) hoist duty cycle, defined as the total time it takes for the hoist to move a conveyance from one elevation to the next:

time required for materials and supplies (hours/day)

$$= \frac{N \times T}{3600} \qquad (17.5.34)$$

where N is number of material trips, and T is cycle time per trip in sec.

PERSONNEL HOISTING TIME. The projected daily employee requirement that must be lowered and raised through the hoisting facilities is either known or calculable. Using the daily manpower data, the hoisting time required for transporting personnel to and from underground is calculated after determining the cycle time, using Eq. 17.5.7.

In estimating the cycle time, consideration is given to the following: (1) cage capacity, (2) number of working levels underground to which personnel are to be transported, (3) hoisting speed to the first level, then between each level to conform with the mining regulations, (4) loading and unloading time (per level), and (5) idle time (per cycle).

MAINTENANCE AND INSPECTION TIME. Although statutory maintenance, inspections, and test requirements, as regulated by federal or local authorities, vary for each country and jurisdiction, the following procedures are carried out on most hoisting facilities:

1. Shaft and conveyance (including shaft signal) inspection—once per week.
2. Hoist (electrical and mechanical components) inspection—once per week.
3. Rope and rope attachments inspection—once per week.
4. Rope maintenance (including attachments)—once per month.
5. Electromagnetic test to ropes—once every three months.
6. Conveyance drop test—once every three months.

In order to allow maximum time for ore hoisting, it is normal practice at most major mines to carry out maintenance and repairs of a major nature on the weekend when the requirements for lowering personnel and material is at a minimum, unless such repairs are deemed necessary for the safe running of the facilities. However, statutory maintenance and inspections consume some of the time which would have been available otherwise for hoisting. For a typical mine, the average time lost for this activity can be approximated, as shown in Table 17.5.2.

Table 17.5.2. Hoisting Time Used For Maintenance and Inspection of Shaft and Equipment

Items	Time (h)	Remarks
Shaft, conveyance & rope inspection & signal bell test	1.5	Weekly
Sheave wheels inspection	0.5	Weekly
Hoist inspection	1.5	Weekly
TOTAL WEEKLY:	3.5	
Rope maintenance (lubrication)	4.0	Monthly
TOTAL MONTHLY:	4.0	
Electromagnetic test to ropes and attachments	2.0	Quarterly
Drop test	2.0	Quarterly
TOTAL QUARTERLY:	4.0	

Note: If the above is interpreted as unavailability of the hoists for production hoisting, then the average time lost per day at the typical hoisting facility can be taken as one hour.

INTERNAL HOISTING TIME. In some mining operations it is necessary to transfer personnel, materials, and equipment between levels using the shaft hoisting equipment. The work required to carry out these tasks is termed internal hoisting, and the time required to complete this type of hoisting can best be obtained through personal experience or by discussion with operators of similar mines.

IDLE TIME: HOIST UTILIZATION. It is a fact that it is not possible to plan to operate 100% of the time and that some idle time must be provided in any hoisting schedule. The amount of time to be allowed is generally a matter of experience on the part of the designer. However, the total operating time scheduled during planning stages should not exceed 70% of the total operating time available, that is, 16.8 hr/day (Harvey 1973a).

The hoist utilization factor H_u is defined as:

$$H_u = \frac{\text{No. of trips actually made in a month}}{\text{No. of trips possible on the basis of cycle time}} \qquad (17.5.35)$$

In certain exceptionally well-organized shafts, utilization factors as high as 0.92 have been achieved, but a more reasonable figure of 0.70 should be adopted. With multipurpose hoists, the utilization factor will be much lower.

SUMMARY. After the daily hoisting time for each of the above time subcomponents has been calculated and a hoist utilization factor estimated, a total daily hoisting time T can be determined. If this total is greater than 24 hours, two (or more) hoists are required:

$$T = \frac{T_o + T_w + T_s + T_p + T_m + T_i}{H_u} \qquad (17.5.36)$$

where T_o is ore hoisting time, T_w is waste hoisting time, T_s is materials hoisting time, T_p is personnel hoisting time, T_m is maintenance hoisting time, T_i is internal hoisting time, and H_u is hoist utilization factor.

17.5.4 SHAFT CONVEYANCES AND ACCESSORIES

The most common shaft conveyances considered are skips, cages, and counterweights. Accessories consist of loading pockets, spill pockets, and arrestor gear.

Skips are used to hoist broken ore and waste from the mine. Cages are used to raise and lower personnel, material, and equipment. Counterweights may be used in balance with either skips or cages. Loading pockets can improve the efficiency of hoisting systems by ensuring that the optimum amount of material is fed to the skip during each cycle. Arrestor gear is provided in the headframe and shaft bottom for friction hoist systems to protect personnel, the hoist, and the conveyances in the event overtravel occurs at the end of the hoisting cycle.

17.5.4.1 Description of Skip Hoisting

Skipping, as described by Souter (1973), consists of filling, hoisting, dumping, and returning to be filled again. The ore and waste may be crushed or uncrushed, filling may be volumetric or by weight, and the operation may be manual or automatically controlled. During filling, the skip is subjected to high dynamic loads, and depending upon depth, a certain amount of rope stretch occurs. Although chairing of the skip is possible, this practice can also result in higher impact loading, difficulties with slack rope, and the danger of leaving the chairs in the shaft, which could cause collision.

In order to permit hoisting at high speeds, skips are guided as they travel in the shaft. Difficulties with guides due to misalignment or loosening generally result in lower hoisting speeds and, correspondingly, reduced production rates.

Skips may be dumped at any point in the shaft, although the most common location is in the headframe. Dumping is usually accomplished by means of scrolls located at each side of the skip compartment at the dump. A roller on the side of the skip body (for swing-out body skips) or on the door (for fixed body skips) engages the scroll and causes the skip to be dumped. In the Sala-type skip, an air cylinder actuates the dump door.

17.5.4.2 Types of Skips

There are three main types of skips in use today: (1) the overturning, (2) the swing-out body, and (3) the fixed body.

OVERTURNING. The *overturning* or *Kimberley skip* consists of a bail frame, a shaft to support the skip, and the skip body itself. The skip body rests on the shaft. The skip is dumped through the action of a bull wheel, mounted on each side (at the top) of the skip body, engaging a scroll and causing the skip

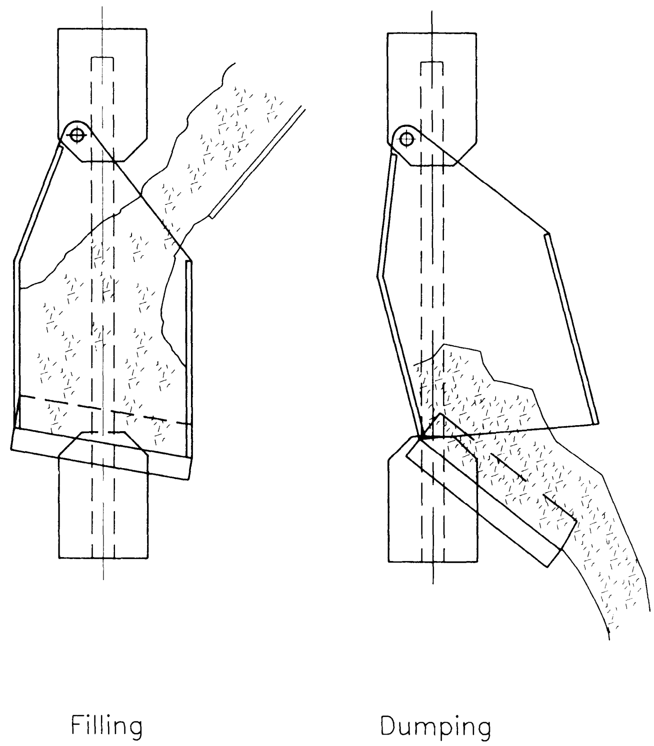

Fig. 17.5.8. Bottom dump skip, swing-out body (Penning, et al., 1977).

body to rotate around the shaft as the skip is being hoisted through the dump. The design of the tipping path is complex because the payload is being discharged as it moves along the path. The horizontal and vertical forces to be considered, according to Harvey (1973a), are dependent upon the rate at which the skip enters the dump, the inertia of the skip plus payload, the horizontal acceleration (which itself is dependent upon the angle of the tipping path), and the static forces.
