Preface

It was in 1918 that Robert Peele, assisted by 46 collaborators, edited the first edition of the classic *Mining Engineers' Handbook.* Like the second and third editions, released in 1927 and 1941, respectively, John Wiley & Sons, Inc., was the publisher. No doubt, there are a number of mining engineers in practice today who remember and still refer to Peele's highly regarded work.

By good fortune, in 1967, when a new handbook was sorely needed and Wiley declined to publish a new edition, the Society of Mining Engineers of AIME (now the Society for Mining, Metallurgy, and Exploration, Inc.) rose to the occasion. With Arthur B. Cummins as chairman of the Editorial Board and Ivan A. Given as editor, a first edition of the new *SME Mining Engineering Handbook* appeared in late 1973. Timely and authoritative, it has served the profession well for nearly two decades.

There is now need for a new and completely revised edition of the *SME Handbook.* Anticipating my coming retirement from The University of Alabama, I proposed to the SME editorial staff in 1987 that a second edition be published, and that I would be willing to serve as senior editor. Accordingly, we assembled an Editorial Board of 6 associate editors and 20 section coordinators, established a target release date of 1992, and set to work recruiting a collaborative team of 242 chapter authors. To the credit of all contributors — and under the resolute direction of first Marianne Snedeker and then Barbara Dygert, SME Managers of Book Publishing —this latest edition of the *SME Mining Engineering Handbook* is being published, on schedule, in 4 1/2 years!

In one of its first transactions of business, the Editorial Board grappled with a statement of purpose for the proposed Handbook:

> "By our thinking, a handbook is a comprehensive reference work, containing the distilled body of knowledge that characterizes a disciplinary field. While it may serve incidentally as an advanced textbook for students, its primary function is to provide professional practitioners with an authoritative reference and design source. In a field as practice-oriented as mining engineering, that is both a definitive and demanding charge.
>
> "To a lesser extent, the handbook should also serve nonprofessionals who seek technical knowledge of the field of mining. These include government officials, journalists, attorneys, economists, and other interested individuals.
>
> "It is the careful selection of pertinent subject matter and the manner and style in which it is presented, more than its organization, that distinguishes a handbook. However, the outline adopted for the revised *SME Handbook* benefits from a logical, generic subdivision of mining engineering knowledge; it is not unlike that of a comprehensive textbook. But the contents of a handbook are quite different, because design principles, relevant equations and tables, conceptual methods, illustrative examples, and case studies are stressed."

Intentionally, this statement of purpose has guided our labors throughout.

Further objectives related to subject-matter coverage and organization are as follows:

1. Appropriate attention is given to all branches of mining — metal, coal, and nonmetal — and to all locales of mining — surface, underground, and hybrid.
2. While major emphasis is placed on American mining, numerous references are made to practice abroad.
3. To facilitate international usage of the *Handbook,* mathematical and dimensional notations are cited in dual units, generally English first followed by SI in parentheses.
4. Appropriate references and/or bibliographies are grouped with each chapter for convenience.
5. Appendices follow the main body of the *Handbook.* They consist largely of tables of data, supplementing the text and useful for problem solving.

Credit for any eminence these volumes may attain belongs to the individuals who shared their knowledge, time, and expertise gratuitously. But recognition for a unique contribution properly goes to our professional organization, the Society for Mining, Metallurgy, and Exploration: it is the Society's enlightened policy of disseminating and publishing knowledge for the profession that makes this *SME Mining Engineering Handbook* possible.

Howard L. Hartman, *Senior Editor*

Introduction

Section 1 Introduction to Mining

HOWARD L. HARTMAN, SENIOR EDITOR AND SECTION COORDINATOR

Chapter 1.0
INTRODUCTION

HOWARD L. HARTMAN

It is appropriate in this opening section to introduce the broad topic of mining and mining engineering—the general subject of this entire *Handbook.* Hence, Section 1 in three chapters explores the history of mining, outlines the elements of mining, and discusses mineral engineering education. Coverage of history and education appears only in this section.

1.0.1.1 History of Mining

Contributions made by mining have played a much more significant role in the development of civilization than is generally conceded by historians or recognized by ordinary citizens. In modern society, mined products pervade all industry and the lives of all civilized people. Early man relied largely on stone and ceramics, and eventually metals, to fashion tools and weapons. Civilization was advanced by discoveries such as abundant supplies of high-quality flint in northern France and southern England and firesetting to break rock. Middle Eastern cultures flourished not only because of agriculture and trade, but also because of mineral-rich deposits nearby.

The earliest miners date back perhaps to 300,000 BC; their quest was for nonmetallic minerals (chert, flint, obsidian) suitable for utensils and eventually for weapons. Other rocks and minerals (ceramics, clay, salt, meteoric iron) attracted the miners for jewelry, cosmetics, construction materials, food seasoning, and coinage. At first, their excavations were confined to the surface, either pits or placers. But by about 40,000 BC, mine workings had been extended underground as short adits or shafts, and by 8000 BC as elaborate interconnected openings 300 ft (90 m) in depth.

Metallurgical separation of metals from their ores and their subsequent fabrication evolved gradually over the centuries, copper being the first liberated (c. 7000 BC) followed by lead, silver, gold, and iron. Man enhanced both the sophistication of his utensils and the lethalness of his weapons by an order of magnitude when his mineral frontiers first extended beyond the nonmetallics to the metallics. And the discovery and utilization of the first of the mineral fuels (coal) in the late 13th century AD carried civilization another quantum leap forward.

Much is learned both of mining development and human civilization when plotting a chronology of historical events. It is astonishing how well they correlate. In fact, one can track the major migrations of civilization westward and the discovery of the New World with the insatiable lust for mineral wealth.

1.0.1.2 Elements of Mining

Mining and mining engineering are similar but not synonymous terms. *Mining* consists of the processes, the occupation, and the industry concerned with the extraction of minerals from the earth. *Mining engineering,* on the other hand, is the art and the science applied to the processes of mining and to the operation of mines. The trained professional who relates the two is the *mining engineer;* he/she is responsible for helping to locate and prove mines, for designing and developing mines, and for exploiting and managing mines.

The essence of mining in extracting minerals from the earth is to drive (construct) an excavation or an opening to serve as a means of entry from the existing surface to the mineral deposit. Whether the openings lie on the surface or are placed underground fixes the locale of the mine. The specific details of the procedure, layout, equipment, and system used distinguish the mining method, which is uniquely determined by the physical, geologic, environmental, economic, and legal circumstances that prevail.

Using scientific principles, technological knowledge, and managerial skills, the mining engineer brings a mineral property through the four stages in the life of a mine: prospecting, exploration, development, and exploitation.

NOTE: Chapter 1.2 follows the outline of the *Handbook*, previewing in turn the six major parts of the volume, subdivided into 25 sections.

1.0.1.3 Mineral Engineering Education

The training of mining engineers was one of the first specialized fields in engineering education. Originating in 1716 at the academy in Joachimstal, Czechoslovakia, mining and mineral engineering education is now offered at institutions of higher learning on a worldwide basis. In the United States, 37 colleges and universities currently award ABET-accredited degrees in mining and related fields of engineering (ABET is the Accreditation Board for Engineering and Technology, Inc.).

Disciplines encompassed by the generic term *mineral engineering* include mining, geological, environmental, mineral processing, and metallurgical and materials engineering, Numbers of mining engineers graduating in the United States range from 200 to 800 per year (BS, MS, and PhD degrees).

Mineral engineering is a broad educational field, in part because accreditational standards for engineering education are extraordinarily wide ranging. In addition to mathematics, the basic sciences, and professional courses, mineral engineers must master a variety of engineering sciences ranging from electrical circuits to thermodynamics and strength of materials. At present, nearly all US undergraduate curricula are four years in duration, although increasingly the bachelor's degree is followed by a year or two of graduate study.

As mineral engineering grows ever more complex and technologically sophisticated, there is greater emphasis in the curriculum on computers, systems, and related topics. Likewise, there is a liberalizing effort underway to "humanize" and to stress social responsibility in the engineer's education.

Chapter 1.1
HISTORY OF MINING

WILLARD C. LACY AND JOHN C. LACY

1.1.1 A CHRONOLOGY OF EVENTS

History is much more than dates of political events; it is written in civilization's tools, weapons, workshops and factories, roads, bridges, canals, railways, laboratories, churches, housing and schools, laws, organizations, books, art and music, and medical and dental care. It is shaped by scientists, engineers, farmers, industrialists, and entrepreneurs. It is driven by economic concerns, fixed and circulating capital, supply and demand, wages and prices, expansion and contraction of markets, competition and monopolies, shortages, gluts, substitutions, trade cycles, crises, restrictions, diplomacy, and war. It has also been critically influenced by the availability to mankind of industrial minerals, metals, and fuels.

Table 1.1.1 attempts to list chronologically and geographically many historical developments, both those that have influenced the growth of mining and the mineral industries, and those that mining has influenced.

Viewing developments of mining technology purely on the basis of chronology, however, is misleading because technology advanced and declined in irregular geographic patterns throughout the world. For example, while Greek mining technology was well advanced by 500 BC, Britain remained in a primitive stage until Roman civilization arrived at the end of the 1st century AD, and Australia remained in a Paleolithic state until British colonization. Gunpowder, though in use by the 8th century in China, was not introduced in Europe until the 13th century, and still was not recorded as being used in mining until the 18th century. Steam as a source of power for pumping, first harnessed in the 17th century, was not effectively used in mining until a century later.

1.1.1.1 The Progress of Metallurgy

The earliest miners, dated back to perhaps 300,000 BC, were concerned with chert and flint for tools and weapons. Their quarries and pits led first to adits and shafts and finally to underground mining during the Neolithic Period (8000 BC to 2000 BC). Using crude stone picks and hammers, these early miners surprisingly reached depths of 300 ft (90 m) in the soft chalk of northern France and southern England. With this technology, mankind also directed its attention to metallic ores.

Metals were first appreciated only as stones, and from 7000 BC to 4000 BC, metallurgy centered on copper and gradually evolved from simple hammering to hammering and annealing, to melting and casting, and finally to alloying to produce desired characteristics of melt, hardness and flexibility. The pyrometallurgical technology of the West had its origin in the Near Eastern zone of ancient Anatolia (Turkey), Syria, Egypt, Iraq, and Iran. By the 6th millennium BC, these craftsmen were able to produce furnace temperatures of more than 1981°F (1083ºC) using forced draft, a technological breakthrough that launched the Metal Eras.

Ancient metallurgy entailed selection of compatible ores and fluxes and avoidance of incompatible ones. By the 2nd millennium BC, the eastern Mediterranean people were able to engage in mass production of copper, lead, and silver from oxide and sulfide ores and improve physical properties by addition of alloying elements. It was also found that by blending of ores from different localities, the metal product could be improved and controlled, and that ores containing iron-rich minerals, sea shells, or silicate minerals fluxed and aided the smelting process. Thus they were added if not already present in the ores.

Iron came into use as a byproduct of the smelting process for other metals in Anatolia where gossans were used as fluxes and iron formed as a part of the slag. China, however, was the site of great improvement in iron smelting and casting technology during 475 BC to 220 BC where pig iron was produced containing 3.5 to 4.5% carbon at a melting point of approximately 2282ºF (1250ºC). The Chinese also at this time developed new innovations in gilding bronze and inlaying of bronze and iron implements with gold and silver.

1.1.1.2 Mining Methods

The silver-lead mines of Laurium, near Athens, Greece, were first worked and abandoned by the Myceneans in the 2nd millennium BC, but opened again by the Athenians beginning about 600 BC. The earliest workings were open cast with short adits. Later, more than 2000 shafts were sunk and connected by drifts. Shafts were sunk in pairs with parallel drifts driven from them with frequent connecting crosscuts to aid ventilation. Stoping of ore bodies was either by overhand or underhand methods, and room and pillar methods were used for the larger stopes. Progress was slow, and it has been calculated that in shaft sinking a miner averaged about 5 ft/month (1.5 m/month).

It was in water-pumping devices that Roman mining showed the greatest advance. They drained the copper mines of Rio Tinto, Spain, and others as far away as Britain. The most important of these dewatering devices was the water wheel and the Archimedean screw.

The migrations of the Celts, originally from south-central Europe, was probably the single most important factor in the dissemination of mining technology throughout Europe. These migrations and general nomadic tendencies of the Celts not only spread knowledge of mining techniques, but many legal concepts can be traced to their tribal customs. The Celts, who permanently settled in the metal-rich areas of central Germany, became the Saxons and led the way to advances in mining during the Middle Ages, not only in their own country, but throughout Europe. They began mining at Schemnitz, Czechoslovakia, as early as AD 745; at Rammelsberg, Saxony, by 970; at Freiberg, Saxony, by 1170; and Joachimsthal, Bohemia, in 1515. Thereafter, when mines were opened in Spain and the famous silver mines at Konigsberg, Norway, Saxons skilled in mining and metallurgy were sent from Germany. By the 16th century the terms "miner" and "Saxon" had become almost synonymous.

Knowledge of mining technology was essentially a closely held craft that was dispersed by the mobility of miners. For example, the Celts that settled in Cornwall were the early tin miners. In 1240 a "tinner" fleeing England after having committed murder is reported to have taught the Germans to prospect for, mine, and concentrate metal ores; in 1562 the technology returned as Queen Elizabeth of England sent back to Germany for miners to introduce better mining and metallurgical practices in Devon and Cornwall. During the gold rushes of the 19th

Table 1.1.1. Chronology of Events Related to Mining

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
BC Paleolithic c.20,000 Late Paleolithic	c.40,000 Hematite mined for ritual painting (Africa) c.9500 Copper pendant. (Iraq)	300,000-100,000 Surface mining of flint (N. France, S. England) c.30,000 Use of fire, lamps, cave art, hunting with projectiles End of Ice Age c. 10,000 Gold ornaments		c.500,000 Use of fire (China)
c.9000 Mesolithic (Human Power)	c.8000 Development of agriculture (Egypt, Mesopotamia) c.7000 Burning of lime c.6500 Farming introduced (Greece) —Copper tools (Anatolia) c.6000 First pottery (Catal Huyuk) c.5000 Meteoric iron beads (Egypt) —Lead in use (Egypt) —Turquoise mining (Sinai) —Gold mining (Nubia) —Emerald mining (Red Sea) shafts to 300 m		c.6500 Farming introduced	c.8000 Development of agriculture (China)
c.4000 Neolithic—Chalcolithic	c.4000 Bronze casting (Egypt) —Copper smelting (Timna) c.3500 Wheel and plow invented (Mesopotamia) —Gold vessels (Iraq) —Stone quarrying (Egypt) c.3000 Bitumen mortar (Ur)	c.4000 Introduction of plow c.3500 Flint mines with shafts and galleries (France, Britain)		c.4000 Technology migration along trade routes
c.3000 Metal Age I Bronze	c.3000 Copper and stone artwork —Lost wax casting —Phoenician traders bring tin from Cornwall c.2700 Copper mined in Cyprus c.2600 Tin bronzes in use c.2500 Lead in use (Troy)	c.3000 Bronze weapons in use —Spread of copper mining —Gold from Ireland	c.3000 First pottery (Equador, Colombia) —Old Copper Culture, Lake Superior (US) —Hammering, annealing, grinding of copper (US)	c.3000 Bronze casting (Ban Chiang, Thailand) c.2800 Emperor Shen Nung discovers smelting (China)
c.2000 Metal Age II Bronze	c.2000 Pre-Hittites use iron —Silver separated from lead by cupellation (Anatolia) —Laurium Mine worked by Mycenians 1750 Hammurabi's code of laws (Babylonia) —Cu,Ag,Pb,Fe mined and smelted by Hittites c.1400 Gold mines of Nubia exploited —Use of bronze chisels 1280 Hebrew flight from Egypt taking metal technology		c.2000 First metalworking of gold (Peru)	c.2000 Gold and silver acupuncture needles (China) —Compound casting (China) —Coal dug and used as fuel —Miner lowest stratum of society (China) 1600-1400 Iron smelting and forging (Ban Chiang, Thailand)

Table 1.1.1. Chronology of Events Related to Mining (Continued)

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
Early Iron	c.1200 Jason uses fleece to recover fine gold c.950 Rio Tinto Mine operated by Phoenicians for silver c.670 Introduction of ironworking (Egypt) 650 First coins of silver and gold (Lydia, Turkey) c.600 Hanging Gardens of Babylon floored with lead 600-500 Bitumen mined (Baku) 510 Private leases granted at Laurium, royalties to citizens of Athens	c.700 Iron tools used in salt mining (Hallstatt, Austria)		c.800 Iron and bronze coins introduced (China) —Iron chains used for suspension bridges (China) c.600 Discovery of oil and gas while drilling for salt (China)
c.500				
Late Iron (Water Power)	c.500 Wootz steel made in India —Iron-making techniques spread to sub-Sahara 490 Athenian senate uses royalties from Laurium to finance naval construction 334 Alexander invades Asia Minor, conquers Egypt c.330 Aristotle writes *Meteorologica,* on how stones originate c.300 Theophrasus writes *Concerning Stones* (Greece) —Alchemy begins (Alexandria) 265 Punic wars begin for control of silver deposits of Iberia, Spain c.100 Water wheels in use—horizontal by Greeks, vertical by Romans	c.400 Celts mine placer tin in Cornwall using horn picks and wooden shovels with free miners	267 Platinum worked at Esmeraldas, Equador	c.500 Tombs contain gold (China) c.400 Steel weapons (China) 214 Great Wall commenced (China) c.200 Blowing of iron used 112 Opening of Silk Road
c.50 **AD**				
Greco-Roman	c.20 Romans use brass coins 23-79 Pliny writes books on earths, metals, stones, gems 117-138 Hadrian introduces strict regulations for treatment of miners —*Lex Metalli Vespacensis* recognizes miners rights, half to Crown —Villeinage introduced —Use of skilled artisans as miners c.220 Roman currency debased 320 Theodosian Code introduced (Roman Empire)	43 Roman invasion of Britain 112 Coal used by Romans in Britain, surface mines	c.0 Gold technology, lost wax method reaches Colombia	105 First use of paper (China) c.200 Iron casting a well developed art Han Dynasty, (China) 200-600 Gold and silver mining in China
500				
	528-533 Justinian compiles *Corpus Juris Civilis* in E. Roman Empire		c.500 American Indians use cinnabar and carnotite as decoration	c.500—Roman coins abundant (China)

Table 1.1.1. Chronology of Events Related to Mining (Continued)

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
Dark Ages	c.600 Use of windmills (Persia) —Gold and silver mines of Spain reopened by Moors c.800 Charlemagne renovates Roman mines in Italy c.1000 First Iron Age settlement in Zimbabwe	745 Mining begins at Schemnitz (Czechoslovakia) c.800 *Bergbaufreiheit,* right of free miner (Saxony) 938 Rammelsberg mine discovered (Saxony) 965 Gold strike in Harz Mountains (Saxony) c.990 Danelaw Courts of Aethelred II (England)	c.700 Gold working reaches Mexico c.900 Hopi Indians mine coal	c.710 Printing begins (China) c.900 Porcelain made (China) c.1000 Great age of Chinese ceramics and painting c.1045 First movable type (China)
c.1050				
Middle Ages	1185 Treaty of Bishop of Trent frees miners (Italy), expands miner's rights 1208 Mining customs announced in Trent (Italy) c.1215 Mining regulations of Massa (Italy) 1250 Forerunner of stock company in Genoa (Italy) 1298 Marco Polo writes *Description of the World,* includes formula for black powder (Italy)	1150 First adit in Ram melsberg 1170 Erzgeberge silver discovered 1195 Charter of Rights of Sovereign Princes recognizes discovery rights (Germany) 1198 Tin mines of Devon placed under supervision of warden (England) 1201 John I decree permits entry of unoccupied land for mining (England) 1210 "Sea coal" grant to monks of Holyrood Abbey by Wm. the Lion (Scotland) 1217 Forest Law of Henry III gave people right to use coal (England) 1219 Harz silver mining charter (Germany) 1238 First collieries established in Newcastle (England) 1240 Monks of Newminster Abbey granted rights to use "sea coal" for forge 1249 Iglau code (Moravia) 1250-1350 Energy crisis in Great Britain c.1250 Active coal mining at Liege, Belgium 1267 First recorded reference to steel (England) 1277 Oldest English brass 1288 Inquisition at Ashbourne defining miners' rights (England) c.1300 Philip **IV** frees serfs ending forced labor (France) —Coal diggings as trenches, irregular diggings, "bell pits;" coal raised in corves and windlass or backs of women (Britain)	1300 Indians in N. America learn to burn "black rock"	1275 Marco Polo arrives in China c.1300 Waterwheels used to power bellows (China)

Table 1.1.1. Chronology of Events Related to Mining (Continued)

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
		—Coal used by brewers and dryers 1305 Edward II issues stannary charters for Cornwall and Devon (England) 1306 Edward II prohibits artificers from using coal (England) 1307 Commission of Oyer and Terminer appointed to enforce proclamation of Edward II c.1340 Mining by pit and adit, vertical shaft and horizontal gallery, manual windlass or jackroll (Britain)		
	1344 Publication of *Las Siete Partidas* (Spain)	14th century Code of Freiberg (Saxony) 1356 "Golden Bull" of Charles IV recognizes free prospecting and working of discovery (German Empire) 1370 Human-powered water lifting devices used at Rammelsberg mine (Saxony) 1379 First tax on coal (England)		
	1387 Decree of Juan I permits mineral exploitation on land of others, ⅔ to Crown (Spain)			
c.1400 Rennaissance		1413 Charles IV claims sovereignty over all mines, tithe to Crown, damages to landlord (France) 1415 Great Barmote Court (England) 1450 Gutenberg's printing press (Germany) 1451 Funken separates copper and silver (Germany) 1454 Rag and chain pump installed at Rammelsberg		
	1463 Water-powered blast furnace in use at Ferriere (Italy)	c.1475 Mining tools: pick, hammer, wedge, wooden shovel —Two opposing water wheels used for driving hoist (Hungary)		
	1492 Columbus sails west (Spain)	c.1500 Windlass used for hoisting buckets or baskets —Surface haulage by panniers on horseback —Miners form guilds for mutual aid and benefit (England)	1492 Americas discovered	
	1509 Portugese defeat Saracen fleet closing Indian Ocean	1509 Watch invented by Peter Henle (Germany) 1516 Silver strike at Joachimstal (Czechoslovakia) 1550 First lift pump, Joachimstal (Czechoslovakia)	1521 Cortes enters Mexico 1524 Mining of copper in Cuba	

Table 1.1.1. Chronology of Events Related to Mining (Continued)

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
	1584 Philip II of Spain issues code of laws to govern overseas mining	1553 Railroads introduced in mining (Czechoslovakia) 1556 1st edition *De Re Metalica,* Agricola (Germany) 1558 English law prohibits cutting of trees for iron smelting 1563 Scottish parliament prohibits transport of coal outside of realm 1565 Hemp ropes replace iron chains at Rammelsberg (Saxony) 1568 Justices and barons of Exchequer rule ownership of gold and silver extends to privately owned land (England) 1590 Patent issued Dean of York for coking "pit coal" c.1600 Energy Crisis (England) —Sir Wm. Gilbert recognizes earth's magnetic field (England)	—Copper, tin, silver mined at Tazco, Mexico, by Spaniards 1545 Discovery of silver at Potosi (Bolivia) 1550 Mendoza's Mining Code (Mexico) 1554 "Patio" method developed at Pachuca (Mexico) 1574 Francisco Toledo's Mining Code (Peru, Bolivia, Chile, Argentina)	
1600 Rise of Science Coal Age		1600 Founding of English and Dutch East India Trading Co 1605 Furnace with covered crucibles to protect from noxious coal fumes introduced for production of sheet glass (England) 1610 Scientific Revolution in Europe begins: Kepler, Bacon, Galileo, Descartes, etc. —Patent to Wm. Wright for furnace to melt "bell metal" with coal (Germany) 1612 First use of reverbatory furnace (England) 1613 Bore rods in use in exploration for coal —Use of gunpowder in mining (Germany) 1614 Napier discovers logarithms (France) —Robert Mansell granted a monopoly for use of coal in glass manufacture (England) 1615 Salomon de Caus suggests raising water by expansive power of steam (France) 1619 Patent to "Dud" Dudley for smelting iron with "pit coal" (England) 1627 First use of drilling and blasting at Oberbeiberstollen mine, Schemnitz (Hungary)	1603 Philip II of Portugal issues code of laws to govern mining (Brazil) 1606 Charter granted to London and Plymouth Co. by James I specified royalties $1/5$ precious metals, $1/15$ copper 1609 Barba invents "kettle and cooking" process for silver ores (Bolivia)	

Table 1.1.1. Chronology of Events Related to Mining (Continued)

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
	1669 Steno writes *De Solium Naturalitar Contento* (Italy)	1630 First use of railway, Beaumont mine, Schemnitz 1640 Chimney tax imposed (England), repealed by Wm. III c.1650 Longwall mining introduced at Shropshire colleries, bord and pillar in N. England 1659 Papin's steam engine (France) 1660 Founding of Royal Society, chartered 1662 by Charles II (England) 1665 John Woodward writes "An Essay Toward a Natural History of the Earth and Terrestrial Bodies, Especially Minerals" (England) 1671 Railway and wagons used to convey coal from Ravensworth to Team Staith (England) c. 1675 Methane explosions in English coal mines 1689 Drilling and blasting introduced at Cornwall 1692 Lead smelted with coal 1694 British patent to extract tar and oil from stone 1698 Sir Humphery Mackworth employs coal in smelting copper (England) 1699 Thomas Savery reads paper to Royal Society on vacuum principle engine used at Grentwork mine, Cornwall	1636 Founding of Harvard College 1646 First successful use of blast furnace in N. America at Saugus, MA 1679 Coal discovered in Illinois 1692 Lead discovered in Mississippi Valley by Nicholas Perot 1693 Gold discovered at Minas Gerais (Brazil)	
1700				
		1709 Abraham Darby uses coke to smelt iron (England) —Kaolin mines established near Meissen, Germany 1712 Newcomen engine installed at Wolverhampton, Shropshire (England) 1713 Coke used at Coalbrookdale foundry (England) 1714 Henry II prohibits foundries from using coal (France) 1716 Mining school established at Joachinstal, Czechoslovakia 1718 Cornish tin mines dewater by pumping 1720 Zinc smelting at Swansea, Wales —"Bubble Act" limits stockholders to eight (England) c.1730 Cast iron used for mine pumps, pipes, and steam engine cylinders (England)	1718 SW Missouri lead mines commence work at La Motte mine 1727 Diamonds identified (Brazil) 1730 Brazilian diamonds declared property of Crown of Portugal	

Table 1.1.1. Chronology of Events Related to Mining (Continued)

Period—Stage	Near East—Mediterranean—Africa	Central and Northern Europe and Great Britain	North and South America	Australasia
		1740 Crucible steel method rediscovered by Huntsman (England) —Zinc produced on commercial scale (Wales) 1743 Marggraf publishes method to produce zinc (Germany) 1744 Gold mining in Russia 1747 Hutton writes *Theory of the Earth* (Scotland) 1749 Roebuck introduces lead chamber process for sulfuric acid manufacture (Britain)		
1750 Industrial Revolution (Britain) (Steam Power)	1752 Large-scale copper leaching at Rio Tinto (Spain) 1783 Tungsten discovered in Spain	1751 Crucible steel commercially established (Britain) 1759 Lebon's coal-gas patent (France) 1767 Cast iron rails for railroads introduced (England) 1769 Watt patents steam engine (England) 1770 Reverbatory furnace introduced (England) c.1770 Period of great advance in science: Priestley, Lavoisier, Volta, Watt, Harrison (Britain, France, Italy) 1774 Emancipation Act abolishing villeinage (Scotland) 1775 Abraham Werner inaugurates "Neptunist" school of geology at Freiberg (Germany) —Underhand cut and fill stoping used at Cornwall 1768-82 Watt and Boulton introduce double-acting condensing steam engine for dewatering Cornish tin mines 1781 Cornish pump introduced 1783 Henry Cort patents rolling mill (England) 1784 Henry Cort introduces puddling process for malleable wrought iron (England) 1789 Wheeled trams on light rails used underground (England) —Uranium discovered in pitchblende by Martin Klaproth (Germany) c. 1790 "Friendly Societies," forerunners of union, organize (England)	1770 Artur de Sa Mining Code for working mines at Minas Gerais (Brazil) 1771 Diamond Code (Brazil) 1783 Charles III (Spain) approves mining ordinances for "New Spain" 1785 Land Ordinance reserves 1/3 gold, silver, lead, and copper mines to Confederation (US) 1788 Benjamin Waterhouse begins course in geology and mineralogy at Harvard (US) 1792 Royal Seminary of Mining established in Mexico

century, the Cornish and German miners supplied mining technology throughout the world.

The first comprehensive record of mining and metallurgical methods was published in 1556 in Agricola's *De Re Metallica*, which describes mining and metallurgical technology as it had developed in the Ore Mountains of central and eastern Germany by the mid-16th century. Agricola's work was disseminated wherever there were miners, and its compendium of recorded knowledge provided a strong foundation for a rapid advance of mining education and technological advancement.

During Agricola's time, ground was broken by hammer and chisel (then and now the universal symbol for mining operations); fire setting was used in stoping rather than in driving, and then only when timber support was not required. Other notable advances were the first use of drilling and blasting at Schemnitz in 1727; the introduction of the pneumatic drill at Rammelsberg in 1876; and the replacement in hoisting of "kibbles" of wood bound with iron by hemp ropes first with wagons riding in cages hoisted by iron chains, then by wire rope in 1833 at Clausthal, Germany. Illumination evolved from tallow or oil-dip lamps used by the early Saxon miners, candles fixed in clay on helmets, ladders, or on rock faces by l8th-century Cornish miners, to 20th-century illumination provided by acetylene lamps and electric cap lights.

1.1.1.3 Milling and Smelting

The early miners and metallurgists were fortunate in having rich oxidized ores near the surface from which they could achieve adequate concentration by hand picking or simple washing. However, as grades declined and mineralogy became more complex with mineral grains finely interlocked, hand breaking and sorting were no longer possible. The most primitive mechanical grinding device used throughout Asia and the Near East was the Korean mill, a boulder rotating in a cupped stone. The arrastra, dating back to the Roman Empire, consisted of "drag stones" pulled over a circular paved area; the Chilean mill was similar except circular stone wheels were used in place of drag stone. Stamps came into use for primary crushing. All these devices were largely replaced by jaw and cone crushers and rod and ball mills about the turn of the 19th century.

The oldest method of concentration was by washing with water to remove light minerals and collect the heavy ones. This was accomplished by hand panning, rockers, or sluices with riffles or by passing the materials over a special cloth, as was the case with the fleece used by Jason and his Argonauts. The jig was the earliest mechanized gravity concentration device, developed about AD 1830, followed by the shaking riffled table. Magnetic separation was the second ore-concentration method to be developed in the 19th century.

Chemically induced concentrating began with amalgamation of gold on mercury-coated copper plates and dates back to the 4th century BC. Solution extraction on a large scale probably began with heap leaching and precipitation of copper at Rio Tinto, Spain, about AD 1752; solution of gold in cyanide solutions was known in Germany as early as 1805, but it was not developed as an ore treatment technique until 1887. It was this development that made the fine-grained gold of the Witwatersrand an economic source of gold.

Finally, the greatest breakthrough in the history of mineral beneficiation occurred at the turn of the 19th century when nearly simultaneously in Britain, Australia, and Italy, the technique of froth flotation evolved.

The mineral industry in the 20th century has been characterized by the recognition of economics of scale and development of technology for large-scale mining, bolstered by development of mineral flotation and hydrometallurgical techniques.

1.1.2 THE MINER'S CONTRIBUTION TO SOCIETY

The contribution of mining has played a bigger part in the development of civilization than is usually conceded by the historian or recognized by the ordinary citizen. In fact, products of the mineral industry pervade the lives of all members of our industrialized society.

Early man relied upon wood, bone, stone, and ceramics to fashion tools, weapons, and utensils. Civilization was advanced by the discovery of abundant supplies of high-quality flint in northern France and in the chalk beds of southern England. Culture after culture occupied the sites around the Acheuleum communities over a span of 200,000 years. Clay deposits supplied material for storage vessels as agriculture was introduced, and the metallic residues from pigments in the potters' kiln may have provided the first clue to these ancient peoples of the secrets of extraction of metals through smelting. Likewise, salt was recognized as essential in the human diet and, along with flint, became a prime medium of exchange that dictated early trade routes. During the initial development, the use of metallic minerals was in the form of pigments, decorative beads, and native metals that could be shaped into simple objects by hammering.

Most discoveries of these useful minerals were made by accident along trade routes. However, Egypt, which was not well endowed with mineral resources, sent out expeditions exploring for turquoise and gold as early as 4500 BC, resulting in an era of warfare for the acquisition of metals. The Mycenaeans followed by the Phoenicians broke this cycle of war and became wealthy, exchanging minerals for goods. These traders/prospectors sought deposits of silver, tin, lead, copper, and gold, acquiring them by barter rather than by conquest. By 1200 BC they had sea trade routes throughout the Mediterranean world, acquiring lead and silver from Spain, copper from Cyprus, and tin from Cornwall.

By 100 BC trade routes between China and the West, primarily for silk and spices, were well established. The roads passed through many countries and disseminated knowledge of "seric" iron (steel) and metallurgical technology to the known world. By 620, during the T'ang Dynasty, China had become the most advanced society in the world culturally and technologically. The fact that mining technology never fully developed in China can probably be attributed to Guatarma (563-483 BC), who taught that "suffering is caused by the craving for that which one has not," resulting in governmental policies that alternately discouraged and encouraged mining.

The discovery of copper on Cyprus c. 2700 BC resulted in the fabrication of tools, weapons, and household utensils made of metal and turned the island into an important trading center. Wealth poured into the island allowing for luxuries and artistic and religious development.

Work in the mines by the Greeks and Romans was first done by slaves, either prisoners of war, criminals, or political prisoners. Easily exploitable deposits were eventually exhausted and mine economics demanded mining skills. As a result, beginning with the reign of Hadrian (AD 138), the Roman Empire began to recognize a degree of individual ownership and permitted mining by freedmen in increasing numbers. There was gradual improvement of mining technology through the Roman Empire that accompanied replacement of slaves by skilled artisans, though villeinage was still practiced.

One legacy largely the result of Phoenician trading was to create a system whereby power and prosperity could thereafter be measured in terms of actual, exchangeable wealth. In this capacity, gold and silver throughout history have been universally accepted coinage. Thus debasement of the Roman denarius resulted in its loss of creditability as the standard of exchange, contributing to the fall of the Roman Empire, and by the end of the 6th century, the Latin West reverted to an agrarian economy and abandoned coinage and trade. The center of culture and technology shifted to the Byzantine and Islamic empires.

Charlemagne (768-814) recognized the need for metals and began the mining of lead, silver, and gold at Rothansberg, Kremnitz, and Schemnitz by enslaved captives. Charlemagne also reformed the coinage of his Holy Roman Empire, and these actions set in motion the establishment of new mints during the 10th century in Eichstadt (908), Cologne (960), Hildesheim (977), and Saxony (990), creating new and geographically dispersed demand for metals. Thus as Charlemagne's Empire gave way to more local kingdoms, a demand for precious metals had been created that aroused the spirit of enterprise and awakened interest in the development and use of metals; Europe saw a birth (or rebirth) of the traditions originally carried by the Celts of nomadic mining expertise. This rebirth was characterized as "bergbaufreiheit," or the rights of the free miner, whereby the poorest villein could become his own master merely by marking his own mining claim and registering its boundaries after making a discovery—subject to a tribute or royalty paid to the royal land owner. The miner thus ceased to be a serf and became a free man. The evidence of the foundation of this concept of self-initiation of rights to develop mineral ground includes a treaty initiated by the Bishop of Trent in 1185, where miners were invited to explore and mine that region of northern Italy as free men with rights of discovery; the charter of rights granted to miners by the various princes in the Germanic empire in 1209; and the results of the inquisition ordered by Edward II of England in 1288 to memorialize the ancient customs and practices of the miners within his realm. Thus the right of ownership based on discovery by a free miner became the foundation for mining laws carried by individual miners throughout Europe, then to the Americas, Australia, and South Africa.

Discoveries lured hordes of prospectors and miners, followed by farmers and merchants, eastward into Saxony and beyond to become settlers and developers of the land. Expansion east of the Rhine into the rich metalliferous province of Saxony resulted in discovery and development of mines at Schemnitz, Kremnitz, and Rammelsberg, and marked an awakening of metal mining, the revival of industry and trade, and the end of the Dark Ages in Europe. The metal from central Europe moved directly south to Venice and was largely responsible for the conversion of this poverty-stricken village of the 9th century into the richest port in southern Europe.

The affluence created by this industry had ultimate consequences in the arts, as Emperor Frederick II, supported by the wealth of Rammelsberg, became a noted patron of literature and science and contributed substantially to the Renaissance.

As mining extended underground, the free miner found that he could do little by himself, so he formed a partnership. As the operation grew, other men were required, and self-governing associations were born whose ownership and financial stake were supported by contributions memorialized in a "cost-book." The cost-book association formed the model for company organization before the practice of issuing stock as evidence of proprietorship. In the 13th century, the German cost-book association usually consisted of 16 able-bodied men. As the scale of operation increased, it was necessary to add additional participating shares, and Agricola notes in his time that the number of shares at Achneeberg was 128, of which 126 were private owners in the mine, one to the state, and one to the church.

Initially, production was divided among the shareholders, but as treatment and marketing became more complex, the sale became centralized. When a profit was made, it was divided among the "adventurers," but when losses were experienced the adventurers were required to contribute in proportion to their holdings or risk loss of their ownership. Rarely was any money set aside as a reserve, and consequently, a decline in metal prices or grade generally resulted in mine closure.

Growing demands for capital forced a search for outside capital, and gradually operators lost control to investors. The miners became contract workers. Guilds, originally organized by miners for charity and insurance, assumed objectives of industrial aggression.

When public financing in Britain was made possible through the enactment of the Limited Liabilities Acts of 1855-1862 and repeal of the Bubble Act that had limited stockholders to eight, British capitalists came to the forefront in financing mineral development worldwide. Goldsmiths assumed a banking function and issued printed receipts (or notes) payable to any bearer—the forerunner of present paper currency.

During the 18th century, iron metallurgy made great strides and made possible the Industrial Revolution in Britain. Village craftsmen evolved into the factory system and the "Friendly Societies" legally took on the function of the trade unions after 1825.

An industrial revolution is a period during which the economy of an underdeveloped country is transformed into an industrial economy, stimulated by availability of energy sources and metal resources. This change took place in Britain during the 18th and early 19th centuries and spread to France, the United States, Germany, Japan, Russia, Sweden, Canada, Taiwan, and

Korea in approximately that order. The developing technology was accompanied by a revolution in science and engineering, with empirical contributions from alert and observant workmen.

The machine age introduced by the Industrial Revolution of the late eighteenth century also required minerals as raw materials and as a source of energy. Industrial power thus became a measure of political and military power, and exploration for the acquisition of minerals resources extended to nearly all parts of the world. Nations' economies became interdependent. In an attempt to control the large-scale international flow of mineral resources, various commercial and political measures have been tried: monopolies, cartels, tariffs, subsidies, and quotas to name a few. The final result was that political and commercial control over mineral resources and their distribution played a leading role in both the maintenance and destruction of world peace (Leith et al., 1943).

No mention of coal mining appears in the historical record of the West until late in the thirteenth century. Early references are either to "quarries" or "drift" material. Development of coal mines in Britain, Europe, and the United States supplied energy that powered the industrial revolutions.

The structure of the coal industry traditionally was one of many small, low-capital, independent operators who supplied the retail and industrial markets, and a certain percentage of captive mines that supplied railroads, steel and electrical power requirements—all operating within their national boundaries. Depressed coal prices resulting from competition from oil and gas forced reorganization of the industry through aggregation by mergers and acquisition of small operations, mechanization, and a move to surface mining operations by larger companies able to afford this capital-intensive approach. This first occurred in the United States during the late 1950s and early 1960s, and internationally during the late 1960s and 1970s as coal markets were likewise expanded.

The petroleum industry not only shared in the technological developments, but along with coal was in a large part responsible for supplying abundant, cheap, and flexible energy and chemical raw materials. It created demand as well as responding to demand.

The story of aluminum is one of human ingenuity in the creation of a new metal, a new way of life, and a spate of new industries and technologies, as well as combined chemical, technological, and geological cooperation and discovery. Aluminum was not isolated as a metal until 1825 and has been in commercial production for only 100 years. Its discovery was made possible through development of the dynamo by Faraday and Edison.

Uranium, consistent with the history of copper and iron, was first used as a weapon. Its technology began in 1896 as a curious clouding of a photographic plate and evolved into a weapon, less than a half century later, of horrible destructive dimensions, first witnessed on the New Mexico desert in 1945 with the man-made thunder and lightning that was the atomic bomb.

Finally, fascination for gold has lured explorers, invaders, investors, settlers, and "con men" to all parts of the world. It has served, and continues to serve, as an international medium of exchange and a measure of a nation's wealth and financial stability.

1.1.2.1 Minerals and National Policy

With the final peace settlement after World War I, Germany lost 68% of its territory, all of its gold, silver, and mercury deposits, 80% of its coal mines and iron-producing capacity, and entered into a period of depression and starvation. The German economy managed to recover with imported ores and a high degree of technical skill and efficient labor.

The depression years of the 1930s resulted in economic nationalism and protective tariffs, and many markets were effectively closed. Since Germany and Japan were both dependent upon international trade, their standard of living plunged, and hunger, bitterness, and resentment flared. The Nazis came to power in Germany with promises of work, food, and prestige; rearmament began in 1933, and Japan followed suit shortly thereafter, leading the world into World War II (Lovering, 1943).

The world's mineral resources since the latter part of the 19th century have been primarily developed by Britain, the United States, the Soviet Union, Japan, West Germany, and France. These countries have furnished the necessary science, technology, and capital and have supplied the markets.

Local mineral wealth throughout history and social development has made first one nation rich and powerful, then another. The Phoenicians established worldwide trade and gained great wealth by developing and exchanging minerals for all manner of goods. Athens financed its ancient wars and "Golden Age" with silver from Laurium, Alexander funded his early conquests with gold from Macedon, the Romans expanded their Empire to acquire the silver of Carthage and the copper of Spain, and the Catholic crown of Spain became a world power by the exploitation of gold and silver from the New World. During the Middle Ages, Germany became the center of lead, zinc, and silver production and the leader in mining technology. Britain moved into the forefront during the Industrial Revolution of the 19th century and was successively the world's leading producer of tin, copper, lead, and then coal. Her resources were bolstered by those of a vast empire, and she became the wealthiest nation in the world. The greater resources of the United States subsequently supported its advance to become the richest nation; however, the future is already foreshadowed. Most of the Greek, German, and British high-grade mines are exhausted, and the United States is fast becoming dependent upon imports and preservation of peaceful world trade. Near East countries have experienced a rapid rise to great wealth based upon petroleum resources. This has been important in technological developments, but historically is of short duration. New discoveries of high-grade metal deposits are very likely in the Soviet Union and in China but less likely in the United States.

1.1.2.2 Future Contributions of the Minerals Industry

With few exceptions, no nation can achieve a high level of prosperity without a reliable source of minerals to supply its manufacturing industry. Through mining, emergent (Third-World) countries can finance growth progressively by the export of raw mineral resources, then by processing these raw materials prior to export, and finally by achieving progressive industrial development (Fig. 1.1.1).

Mineral reserves, upon which the future of the human race depends, occupy less than 0.1% of the continental areas. Unfortunately, we are not at present sufficiently skilled to determine exactly where they occur or how large they may be. They remain elusive targets.

Research in mining and metallurgical technology is essential. A new discovery may locate a mine, but a technological breakthrough can open up mines all around the world.

The economic evolution of society that began in Neolithic prehistory was based then, as it is now, on minerals, and has led man into modern times. The 104 elements of the periodic table, all but a few of which are recovered from widely spaced, often remote, mineral deposits using a variety of complex mining and metallurgical techniques, form the foundation of modern society.

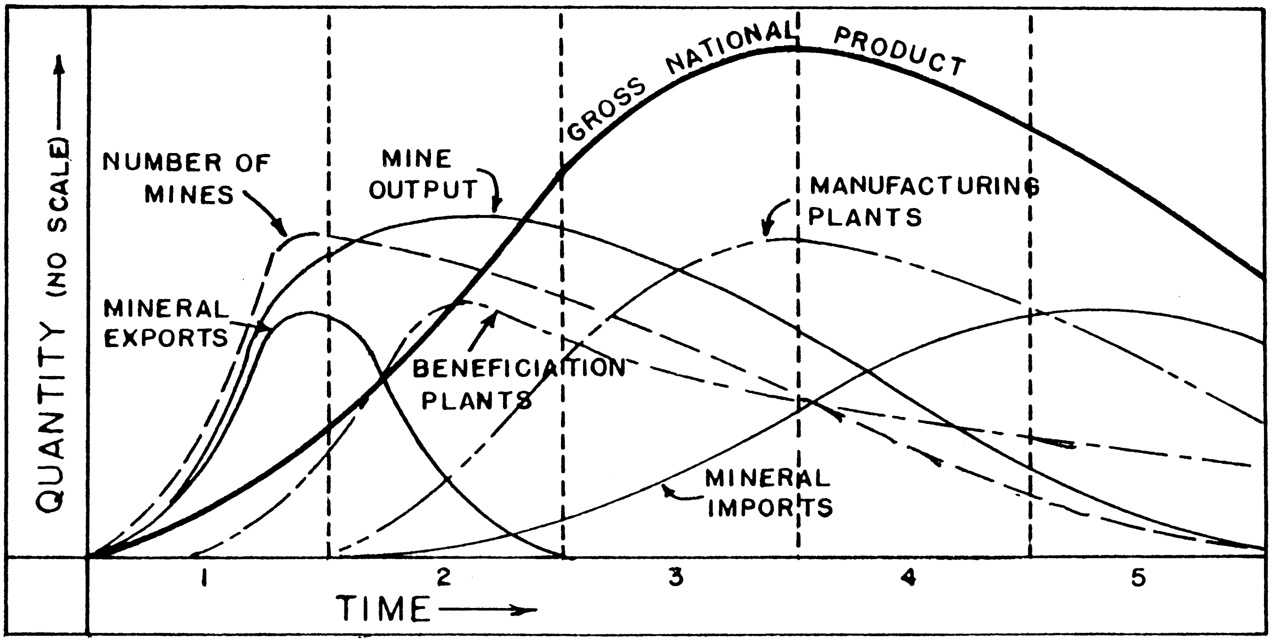

Fig. 1.1.1. Stages of mineral and metal production of an industrial country. (Modified from Lovering, 1943, p. 18.)

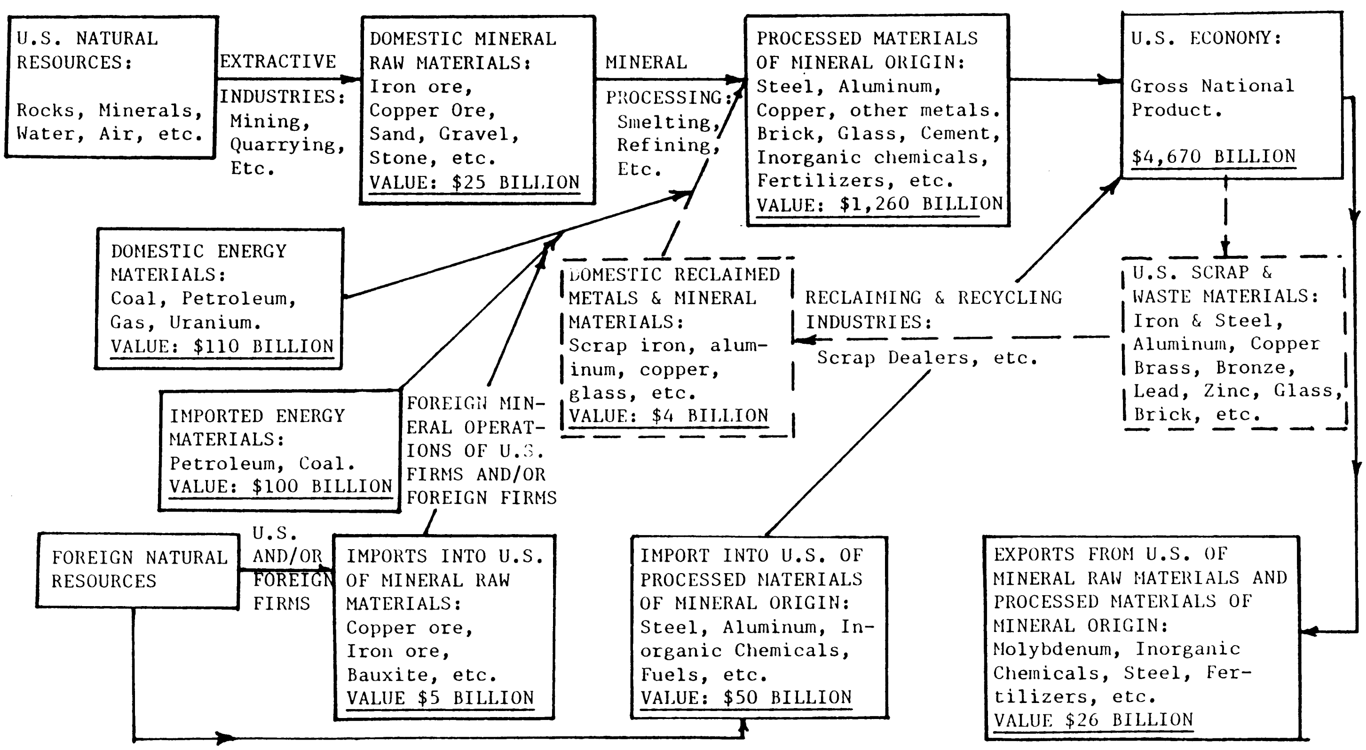

Fig. 1.1.2. The role of fuel and nonfuel minerals in the US economy (estimated values for 1990). (Modified from annual publications of the US Bureau of Mines.)

They provide its heat, light, shelter, transportation, communication, and food. The standards of living of the industrialized nations—which developing nations are striving to attain—are based upon minerals, and societies could not continue in their present state without them (Tables 1.1.2 and 1.1.3 and Fig. 1.1.2).

Mineral deposits within the border of any country represent potential national wealth: they can be transformed into actual

Table 1.1.2. Per Capita Consumption of Minerals in the United States (1970)

Commodity	Quantity	Major Uses
Steel	1400 lb	Transportation
Aluminium	44 lb	Kitchenware, buildings
Copper	20 lb	Electrical appliances
Tin	1 lb	Cans
Petroleum	3.4 tons	Transport, heating, industrial
Natural gas	2.5 tons	Heating, industrial
Coal	2.3 tons	Electricity generation, steel production
Salt	440 lb	Chemicals
Sulfur	70 lb	Fertilizer
Sand and gravel	4 tons	Roads, buildings

Modified from McDivitt and Manners.
Conversion units: 1 lb = 0.4536 kg
1 ton = 0.9072 t

Table 1.1.3. Source of Power (1987). United States Utility Companies Generated 2.5 Trillion Kw-Hr of electricity in 1987

Source of Power	kWh in Billions
Coal	1464
Nuclear power	455
Natural gas	273
Hydroelectric	250
Petroleum	118
Geothermal, others	12

material wealth (and contribute to the gross national product) only by being mined. Among the benefits to the state are an increase in employment levels (one mining job carries approximately a 5:1 multiplier effect), an enhanced level of self-sufficiency, and improved balance of trade. The latter results from fewer imports and greater exports of commodities mined, a spirited search for more minerals, a build-up of technical manpower levels by in-service training, attraction of overseas investment capital, and creation of national wealth (Gregory, 1980).

Chapter 1.2
ELEMENTS OF MINING

HOWARD L. HARTMAN

This chapter is both an introduction to the *Handbook* and an overview of the sections that follow. Each main segment of Chapter 1.2 correlates to one of the six major parts of the volume, and each subdivision to one or more of the 25 sections (corresponding part and section numbers appear in brackets following the headings). In this manner, it is possible to preview a portion or all of the *Handbook* or to identify where subject matter of interest is located.

The outline of this chapter and some of the material it contains first appeared in *Introductory Mining Engineering* by H. L. Hartman, and is used with permission of the publisher, John Wiley & Sons, Inc., New York, copyright © 1987.

1.2.1 PRELIMINARY TOPICS [Part I]

1.2.1.1 Introduction to Mining [Sec. 1]

History of Mining: The chronological development of mining technology bears an important relation to the history of civilization. In fact, as one of the earliest of man's enterprises, mining and its development correlate closely with human progress. It is no coincidence that the cultural ages of man are associated with minerals or their derivatives (e.g., Bronze Age, Nuclear Age). Today products of the mineral industry pervade the lives of all mankind.

Mining began with Paleolithic man, perhaps 300,000 years ago during the Stone Age, when flint implements were sought for agricultural and construction purposes. Primitive miners first extracted and fashioned the stone raw materials that they needed from deposits at the surface, but by the beginning of the New Stone Age (c. 40,000 BC), they began to mine underground as well.

Although records are nonexistent, human fossils and artifacts substantiate an early record of mining all over the world. Like other aspects of human civilization, mining originated in Africa; at first, it was done crudely and then with some technological sophistication. For example, early miners devised ways to chip and free fragments from the solid, to hoist ores by simple lifts, to illuminate their workings by torches and lamps, and even to ventilate underground openings.

Eventually, the first technological breakthrough that significantly advanced mining occurred in the breakage of rock in place. Fire setting, applying heat to expand rock and water to quench, contract, and crack it, was discovered by an unknown miner It was a revolutionary advance in geomechanics, one not surpassed in mining history until the deployment of explosives to break rock in the later Middle Ages.

Elements of Mining: A distinction is drawn between mining and mining engineering. *Mining* consists of the processes, occupation, and industry concerned with the extraction of minerals from the earth. *Mining engineering,* on the other hand, is the art and science applied to the processes of mining and to the operation of mines. The trained professional who relates the two is the *mining engineer;* he/she is responsible for helping to locate and prove mines, designing and developing mines, and exploiting and managing mines.*

The essence of mining in extracting minerals from the earth is to drive or construct an excavation, an opening to serve as a means of entry from the existing surface to the mineral deposit. Whether the openings lie on the surface or are placed underground fix the locale of the mine. The specific details of the procedure, layout, equipment, and system used distinguish the mining method uniquely determined by the physical, geologic, environmental, economic, and legal circumstances that prevail.

Using scientific principles, technological knowledge, and managerial skills, the mining engineer brings a mineral property through the four stages in the life of a mine: prospecting, exploration, development, and exploitation. Ever more advanced training is required for the professionals who direct mineral enterprises—which is the next topic discussed.

Mineral Engineering Education: Training engineers for the mineral industries is a specialized branch of the engineering profession. Originating at the academy in Joachimstal, Czechoslovakia, in 1716, mining and mineral engineering education is now offered worldwide. In the United States, 37 institutions of higher learning currently award accredited degrees in mining and related fields of engineering.

Disciplines encompassed by the generic term *mineral engineering* include mining, geological, environmental, mineral processing, and metallurgical engineering. Numbers of mining engineers graduating in the United States range from 200 to 800 per year (BS, MS, and PhD).

Mineral engineering is a broad educational field, in part because accreditational standards for engineering education are extraordinarily wide ranged. Additionally, mineral engineers must master a variety of engineering sciences, ranging from electrical circuits to thermodynamics and strength of materials. At the present time, nearly all US undergraduate curricula are four years in duration, but they are likely to be supplemented with a year or two of graduate study.

As mineral engineering grows increasingly more complex and technologically oriented, there is greater emphasis in the curriculum on computers, systems, and related topics. There is also a broadening effort underway to "humanize" and to add social responsibility to the engineer's education.

1.2.1.2 Mineral Economics [Sec. 2]

Because of their utility and value, minerals have been integral and essential to man's existence. Their uses are myriad: tools and utensils, weapons, ornaments, currency, structures, machines, and energy. Consequently, mining ranks with agriculture as one of man's two basic, earliest industries. And also like agriculture, mining is one of two human endeavors capable of generating new wealth (Beall, 1973).

Mineral wealth is, of course, neither abundantly nor uniformly distributed. Only a fraction of 1% of the earth's surface is

*The nomenclature used in the *Handbook* follows publications of the US Bureau of Mines and the Society for Mining, Metallurgy, and Exploration, Inc. (e.g., Thrush, 1968; Hustrulid, 1982).

underlain with mineral deposits that currently are of commercial value. Yet the annual mineral production (excluding petroleum and natural gas) of the United States currently exceeds 3.5 billion tons (3.2 t), valued at over $50 billion (Anon., 1984a). With value added in processing, the contribution of the mineral industry to the US gross national product approaches $300 billion, or approximately 8%. In developing countries, minerals' share of the GNP may reach 25%.

Consumption of minerals increased to such an extent in modern times that the United States alone has consumed more mineral products since World War II than were mined in the entire previous history of the world (Anon., 1983a). Since the Industrial Revolution, the average rate of increase in US mineral consumption has averaged 5%, and since 1950 the use of minerals has increased twice as fast as the total consumption of all other raw materials.

Currently, the United States leads the world in the mine production of bituminous coal, lead, molybdenum, natural gas, phosphate, salt, and sulfur. It also produces a significant amount (over 60%) of the copper, gold, gypsum, iron, and nitrogen that it consumes. But on balance, the United States has become a net importer of minerals: imports now exceed exports (on a dollar basis) by a 2:1 margin. We import 50 to 100% of 15 key minerals, including many critical to national defense or food production (e.g., aluminum ore, chromium, industrial diamonds, manganese, nickel, potash, tin). Growing US dependence on foreign sources for its mineral needs has both created a troubling defense concern and contributed to a soaring international trade deficit.

The shifting complexion of the US mineral industry has also raised environmental and conservation dilemmas for the nation. These issues are widely debated. Controversies often arise between profit-oriented mining corporations and conservation or wilderness groups, some of whom advocate extreme preservationism, not conservation. Increasingly, though, when new mining projects undergo environmental review, voices of reason prevail on both sides, allowing compromises to be reached without costly litigation or abandonment of objectives.

The uniqueness of mineral deposits accounts in large measure for the complexity of mineral economics and mining enterprise (Vogely, 1985; Strauss, 1986). Minerals are immobile and, unlike agricultural or forest products, cannot reproduce or be replaced. A mineral deposit may be viewed as a depleting or wasting asset whose production is restricted to the locality in which it occurs. These factors impose limitations on a mining company in the area of business practices and financing as well as in production operations. Because its mineral assets are continually being depleted, a mining company must discover additional reserves or acquire them by purchase to stay in business.

Other peculiar features are related to operations. Production costs tend to increase with the depth of the mine and the declining grade of ore, creating technological and financial problems with which every mine eventually is confronted. Financial hazards are great since estimates of the ore supply, market price, mining cost, or other factors may prove to be lacking in accuracy or sufficient detail.

The law of supply and demand likewise complicates the economics of the mining industry, because the price of minerals varies more sharply than the price of commodities manufactured by the consumers of raw materials. The output of minerals from byproduct producers and foreign sources can create an oversupply that depresses the market. Some minerals, such as precious metals, iron, and certain base metals, are recycled and in a sense never expended because of their utility as scrap. Reservoirs of scrap—lead is the extreme case at 50% of primary consumption—may depress the market, and stockpiles of strategic minerals maintained in the national interest may act as buffers. Certain minerals are exceptions to economic laws because their prices are fixed by government decree or private cartels. Official prices of gold, silver, and uranium historically have been regulated by statutes (although their market prices currently fluctuate in Free World markets), and cartels strongly influence the prices of industrial diamonds, mercury, oil, and tin. In addition, substitutes for a particular mineral may be developed, especially if the price of the mineral remains at a high level (e.g., aluminum for copper, plastic for metal). Market trading and speculation affect the prices of minerals as they do most other commodities.

Stockpiling of strategic minerals by the federal government became a common practice after 1939, and the practice was sharply increased after World War II. The Federal Emergency Management Agency is responsible for procuring certain minerals as part of the program of national preparedness and enters into purchase agreements with individual producers, at negotiated prices, to meet its stockpiling objectives. In recent years, US government stockpile purchases have declined under provisions of the Strategic and Critical Materials Stockpiling Act of 1979 (Dorr, 1987). The mineral industry has often been critical of the government's stockpiling policy, since sudden large purchases or sales from the stockpile can have drastic artificial effects on the price and demand for a commodity. Economists generally tend to favor private-sector management of inventories.

A final related aspect of mineral economics concerns financing and marketing of mines and mineral properties (also see Sec. 6). Mining enterprises are financed in much the same manner as are other businesses (Gentry and O'Neil, 1984; Wanless, 1984; Tinsley et al., 1985). Because of great financial risks, however, the expected return on an investment is higher and the payback period shorter in a mining enterprise. Mineral properties as well as mines are marketable. The selling price is determined generally by a valuation based on the report of qualified engineers; the value of future earnings may then be discounted to the date of purchase in computing the present value of the property.

1.2.1.3 Government Role and Influence in Mining [Sec. 3]

Governments and their agencies exert many influences on the mining industry. In the United States, these take the form of various statutes and regulations pertaining to land use, mineral rights, taxation (Sec. 2), quotas, tariffs, financial incentives, antitrust constraints, stockpiling (Sec. 2), safety and environment, and expressed or implied mineral policies.

Laws governing the acquisition of mineral rights in the United States have developed from the common law of England, the laws and statutes of the federal government, and the laws of the various states. Although the federal Mining Law of 1872 has been somewhat modified by later legislation, it remains the recognized and pertinent statute. It provides for the location of claims for mineral deposits located in the public domain, the performance of annual assessment work to retain rights to a claim, and the acquisition of title to claims. Certain nonmetallic minerals such as coal, gas, oil, phosphates, sodium compounds, and sulfur are exempted from this act and are governed by a leasing law, the Mineral Leasing Act of 1920. Uranium is subject to a leasing arrangement also, under the Atomic Energy Act of 1954. Many states have also enacted legislation to provide mineral rights within their boundaries.

A mining company is subject to the same forms of taxation upon income as any other business and, in certain states, to production, royalty, and severance taxes as well (Anon., 1983b).

In the federal corporate income tax law, however, the Internal Revenue Service wrote in two provisions that are advantageous to mining companies. The first is a depletion allowance, similar in effect to a depreciation charge, that permits a deduction from taxable income in recognition of the gradual exhaustion of ore. The second allows the deduction of exploration and development costs over a period of time.

Many imported minerals and processed metals are subject to tariff duty. The mineral industry, like manufacturing, has consistently sought import quotas or tariff protection from foreign producers, and the US government has generally recognized the importance of encouraging a strong domestic mining industry, notwithstanding other commerce policies generally supportive of international free trade.

The need for safety and environmental regulation arises because of some of the less favorable impacts of mining. Sometimes these are direct and obvious, but more often they are considered side effects. Typical impacts include (1) accidents and health hazards, (2) land-use and environmental impacts, and (3) economic-political-social-psychological effects.

Accident and health hazards in mining are of vital concern to the industry as well as to regulatory bodies of the government and the public at large. Mining practices are regulated by individual states and by the Mine Safety and Health Administration under Title 30 of the *Code of Federal Regulations,* based mainly on legislation enacted in the Coal Mine Health and Safety Act of 1969 and the Mine Safety and Health Act of 1977 (Anon., 1984b). While mining's safety record is among the poorest of all US industry, due in part to an inherently more dangerous environment, it has improved significantly since the 1960s. Greater industry diligence, government intervention, and union criticism are variously credited for the improvement. The consequences of poor health and safety practices in industry are costly, both in terms of loss or harm to life and property damage, and mining is beginning to exercise the initiative required to improve its record (Hansen, 1973).

Physical, chemical, and biological changes in the environment often result from mining. They are usually the most evident and serious of mining's side effects. Examples are disturbance of the surface, subsidence, water and air pollution, consumption of irreplaceable resources, threat to endangered species, and preemptive use of land (Parr and Ely, 1973; Brooks and Williams, 1973; Parr, 1982). Federal legislation (e.g., the Clean Water and Clean Air Acts of 1977, the Endangered Species Act of 1973) now requires the containment or correction of any of these effects that violate environmental standards. Conflicts over land use increasingly are being resolved in ways that provide for orderly, multiple use of the land; applicable legislation is contained in the Multiple Surface Use Act of 1955. Restoration of the surface following coal mining is now required under the federal Surface Mining Control and Reclamation Act of 1977.

Finally, there is a variety of indirect effects, often more subtle and less susceptible of measurement, that may be associated with mining. They are grouped into a third, omnibus category of economic-political-social-psychological effects (Weinreach and Fagan, 1975). Often they result from either initiation or termination of mining operations, when drastic changes occur in manpower-employment levels in nearby communities. The primary effects of opening a mine are largely beneficial, of course, but there may be deleterious secondary ones that create economic and political strains, require social readjustments, and cause psychological stress among the population. These are multiplied when a mine closes.

The anticipation of unwanted, indirect consequences is the most important and difficult challenge that mining confronts in managing its various side effects. Generally, a mining company writes a comprehensive environmental impact statement (EIS) prior to undertaking a mine development project. The National Environmental Policy Act stipulates that an EIS must be filed when "federal action" is involved, that is, approval of a lease, permit, right of way, or mining plan (Parr, 1982). In this way, cost/benefit analyses can anticipate mining's consequences in advance. Older mining operations face no such restraints, however, and consequently environmental abuses do exist in mined-out areas.

In spite of these direct and important involvements of government, many in the mineral industry rightly allege that the United States, as a nation, lacks a coherent, definitive mineral policy (Dorr, 1987). Long advocated by trade associations such as the American Mining Congress (Anon., 1988), a US national mineral policy in reality exists only in de facto form.

1.2.2 STAGES OF MINING [Part II]

The overall sequence of activities involved in modern mining can be expressed as *stages in the life of a mine.* There are four: prospecting, exploration, development, and exploitation. *Precursors* to actual mining, prospecting and exploration are closely linked stages, transitional, and often considered a combined activity (as they are treated here). Likewise, development and exploitation, which constitute *mining proper,* are inherently related. The great preponderance of the *Handbook* is devoted to these latter two stages.

Table 1.2.1 summarizes the four stages in the life of a mine, plus an evaluation step. Included are procedures, time durations, and cost ranges for each.

1.2.2.1 Stages 1 and 2: Mineral Prospecting and Exploration [Secs. 4, 5]

Prospecting, the first stage, is the search for metallic ores or other valuable minerals (coal or nonmetallics). Because mineral deposits are found at or beneath the surface of the earth, both direct and indirect techniques are employed, although geology is the basic science of all prospecting. In the United States, over the past 50 years, geology has accounted for three-quarters of all mineral discoveries (Derry and Booth, 1978).

The *direct method* of discovery, normally limited to surface deposits, consists of *visual examination* of either the exposure (outcrop) of the deposit or of the loose fragments (float) that have weathered away from the outcrop. *Geologic studies* of an area augment this simple, direct technique. By means of aerial photography and with topographic and structural maps of a region, the geologist gathers further evidence by direct methods to locate areas of ore deposition. Precise mapping of rock formations and their peculiar structures in the field, supplemented by analytic and microscopic studies of samples in the laboratory and aided by geologic inference, can enable the geologist to locate hidden as well as surface ore bodies.

A valuable scientific tool being employed in the *indirect search* for or exploration of hidden ore bodies is *geophysics,* a method that detects anomalies caused by the presence of mineral deposits through the analysis of gravitational, seismic, magnetic, electrical, electromagnetic, and radiometric measurements (Anon., 1983a). It is suitable for airborne, surface, and subsurface use. Three methods lend themselves to simultaneous application from aircraft: magnetic, electromagnetic, and radiometric. Geophysics applied from the air or space through remote sensing enables vast areas to be prospected and explored. On the ground and in logging boreholes, it provides more definitive information. The magnetic, electrical, electromagnetic, and radiometric meth-

Table 1.2.1. Stages in the Life of a Mine

Stage/ (Project Name)	Procedure	Time	Cost/Unit Cost
Precursors to Mining			
1,2. Prospecting and Exploration (Name: Prospect)	Search for ore a. Prospecting methods Direct: physical, geologic Indirect: geophysical, geochemical b. Locate favorable loci (maps, literature, old mines) c. Air: aerial photography, airborne geophysics Space: satellite d. Surface: ground geophysics, geology e. Spot anomaly, analyze, evaluate Define extent and value of ore (examination/evaluation) a. Sample (drilling or excavation), assay, test, log b. Estimate tonnage and grade Feasibility study: make decision to abandon or develop property a. Evaluate deposit (by formula or discount method), present value = annual cash flow discounted to the present	2-8 yr	\$0.5-\$15 million 10¢-\$1.50/ton (9¢-\$1.40/t)
Mining Proper			
3. Development (Name: Project)	Open up ore deposit for production a. Acquire mining rights (purchase or lease), if not done in Stage 2 b. Prepare budget, obtain financing c. File environmental impact statement, technology assessment, permit d. Construct access roads, transport system e. Locate surface plant, construct facilities f. Excavate deposit (strip or sink shaft)	2-5 yr	\$10-\$250 million or 25¢-\$5/ton (23¢-\$4.50/t)
4. Exploitation (Name: Mine)	Produce ore on large scale a. Factors in choice of method: geologic, geographical, economic, environmental, societal, safety b. Types of mining methods Surface: open pit, open cast, etc. Underground: room and pillar, block caving, etc. c. Monitor costs and economic payback (3-10 yr)	5-30 yr	\$5-\$50 million/yr or \$2-\$100/ton (\$1.80-\$90/t)

Source: Hartman, 1987.

ods are the most popular ground methods. *Geochemistry,* the microquantitative analysis of soil, rock, and water samples, and *geobotany,* the study of vegetational and plant growth patterns, also are employed as prospecting tools.

The second stage in the life of a mine, *exploration* determines as accurately as possible the size and value of mineral deposit, utilizing techniques similar to but more refined than those used in prospecting. The line of demarcation between the two is not sharp; in fact, a distinction between the two stages is usually not made. The locale in exploration shifts more from the air to the surface and subsurface, both with geology and geophysics. In addition, more positive information of the extent and richness of the deposit is obtained by representative and systematic *sampling,* subjecting mineral specimens to chemical, X-ray, spectrographic, or radiometric analyses. Samples are obtained systematically by chipping or trenching outcrops and by drilling and excavating below the surface; additionally, borehole logs may be taken by geophysics. These are several common drilling methods; diamond drills provide core samples, and rotary or percussion drills produce chips or cuttings. Coring is more useful but most expensive; rotary accounts for 70% of exploration drilling (Martens, 1982).

An evaluation of chip or core samples or logs enables the geologist or mining engineer to calculate the tonnage (extent) and grade (richness) of the deposit. He or she establishes the economic value of the ore, estimates mining costs, and assesses all other foreseeable factors in an effort to reach an accurate conclusion concerning the merits of a given deposit and the profits likely to be realized. This entire procedure consists of *reserve estimation and examination and valuation* of the mineral deposit. A complete ore estimate provides a breakdown of several categories of reserves (proven, probable, or possible), based on geologic and economic evidence. Many of the advanced phases of exploration constitute *project and mining geology.*

Discovery and location of an ore deposit have been likened to the search for the proverbial needle in the haystack. A mineral deposit is a geologic anomaly, while an ore deposit is a freak of nature. The odds against a mineral deposit evolving into a mine—of progressing successively from stages 1 to 4—are variously estimated as 1000 to 10,000:1 (Anon., 1980; Anon., 1983a).

The staggering costs involved in prospecting and exploration (Table 1.2.1) reflect these odds. Further, the complexity of search procedures and the need for a multidisciplinary team in mineral exploration have all but ruled out the solitary prospector as a viable alternative.

1.2.2.2 Mine Evaluation and Investment Analysis [Sec. 6]

At the conclusion of the prospecting and exploration stages in the life of a mine, a thorough *feasibility study* is conducted to determine the potential of developing the mineral deposit into a producing mine. The outcome of this study is a decision to abandon or proceed with the project.

The feasibility report produced is primarily an economic one, but legal, political, technological, geologic, environmental, and sociopolitical considerations are involved as well. In a typical study, all the information assembled by the exploration team of geologists and others is turned over to an evaluation group of engineers, mineral economists, and legal experts.

The formal feasibility study includes an economic analysis of the rate of return that can be expected from the mine at a certain production rate (Anon., 1983a). Some of the factors considered during such an economic analysis are

- Production
  - Reserve tonnage in the deposit
  - Mill recovery
  - Production rate, tons (tonnes) per day
- Costs
  - Exploration and development costs
  - Capital cost of the mine
  - Capital cost of the mill
  - Mining cost per ton (tonne)
  - Processing cost per ton (tonne)
  - Miscellaneous costs of operation
  - Royalties
  - Taxes (federal, state, and local)
- Revenues
  - Sale price of the metal or mineral
- Financing
  - Working capital necessary
  - Depreciation method used
  - Depletion allowance

In many cases, this information is processed by a computer to calculate the dollar value of annual gross sales, operating costs, operating income, depreciation, depletion, income tax, net income after taxes, cash flow, and after-tax rate of return on investment.

Each mining organization has a minimum acceptable rate of return. The cost of borrowing capital for the mine or of generating the needed capital internally within the company must be considered. If a company has a number of attractive investment opportunities, the rate of return from the proposed mine venture may be compared with the rate expected on a different mining venture elsewhere, or with some other business opportunity unrelated to mining.

1.2.2.3 Stage 3: Mine Development [Sec. 7]

In the third stage of mining, *development*, work is performed to open a mineral deposit for exploitation. With it begins mining proper. Access to the deposit must be gained either (1) by *stripping* overburden, the earth and/or rock covering the mineral deposit, to expose near-surface ore for surface mining; or (2) by *excavating* openings from the surface to more deeply buried deposits to prepare for underground mining.

In either case, certain preliminary development work, such as preparing an environmental impact statement, acquiring mineral rights and financing, and providing access roads and other transportation, power sources, ore processing facilities, dams, and waste disposal areas, nearly always precede the actual mining. These and other sequential steps in mine development are often programmed by operations research techniques such as CPM or PERT to conserve time and expense.

Stripping of the waste material overlying the ore body then commences if the mine is to be a surface one. The cycle of operations to break up and remove the overburden may be the same as that employed in exploitation of the ore, or it may differ, depending on the characteristics of the waste and the ore. Fig. 1.2.1 illustrates development for surface mining, using the open cast method. One or more bench faces are established, which permits mining on multiple levels.

Development for underground mining is generally more complex and expensive. It requires careful planning and layout of access openings for convenience, safety, and permanence. The principal opening to the surface is usually a shaft, which may be circular or rectangular in cross section, vertical or inclined (called a slope), and of sufficient size to allow passage for men and machines. In areas of high relief, horizontal openings called adits or tunnels may be used to reach the deposit. Mining of massive or steeply pitched underground deposits of minerals (usually metallic) is carried on from horizons, or levels, located at regular intervals in a vertical plane. The openings on each level consist of main arteries called drifts and numerous secondary, connecting crosscuts. Vertical openings (raises or winzes) or inclined ones (ramps) provide access between the levels. All these development openings connect with large exploitation chambers called stopes, from which most of the mine's mineral production is obtained (Fig. 1.2.2).

Coal and most nonmetallics in this country are often found in flat-lying, bedded deposits and are mined from systems of connected horizontal openings called entries or crosscuts and rooms or longwalls.

1.2.2.4 Stage 4: Mine Exploitation [Sec. 8]

Exploitation, the fourth and final stage of mining, is associated with the actual recovery in quantity of mineral from the earth. While some exploration and development work necessarily continues throughout the life of a mine, the emphasis in the exploitation stage is on production. Only enough development is done prior to exploitation to ensure that production, once started, can continue uninterrupted throughout the life of the mine. The transition through the four stages from prospect to producing mine for an actual case is shown in Fig. 1.2.3.

The mining method selected for exploitation is determined mainly by the characteristics of the mineral deposit and the limits imposed by safety, technology, and economics. Geologic conditions, such as deposit dip and shape and strength of the ore and wall rock, play a key role in selecting the method. *Traditional exploitation methods* fall into two broad categories based on locale: surface or underground. Surface mining includes mechanical extraction methods such as open pit and open cast and aqueous extraction methods such as placer and solution mining. Underground mining is usually classified into three groups of methods, including unsupported (e.g., room and pillar mining, sublevel stoping), supported (e.g., cut and fill stoping, square set stoping), and caving (e.g., longwall, block caving).

In addition to these traditional exploitation methods, novel or *innovative mining* methods are continually evolving. They are applicable to unusual deposits or employ unusual techniques or equipment. Examples are automation, rapid excavation in hard rock, underground gasification, and marine mining (see Sec. 22).

A scheme to classify the mining methods referred to in this *Handbook* is shown in Table 1.2.2. Distinctions are made on the basis of degree of acceptance (traditional or novel), locale (surface or underground), and class and subclass (extractive features). The table also provides information concerning application (commodities mined and relative cost).

Other topics covered in this section include mine surveying, systems engineering, computer methods, labor relations, management, and mine closure.

1.2.3 UNIT OPERATIONS OF MINING [Part III]

During the development and exploitation stages of all mining when natural materials-rock or soil, ore or waste-are extracted from the earth, remarkably standardized unit operations are employed. The *unit operations of mining* are the basic steps employed to produce mineral from the deposit, together with

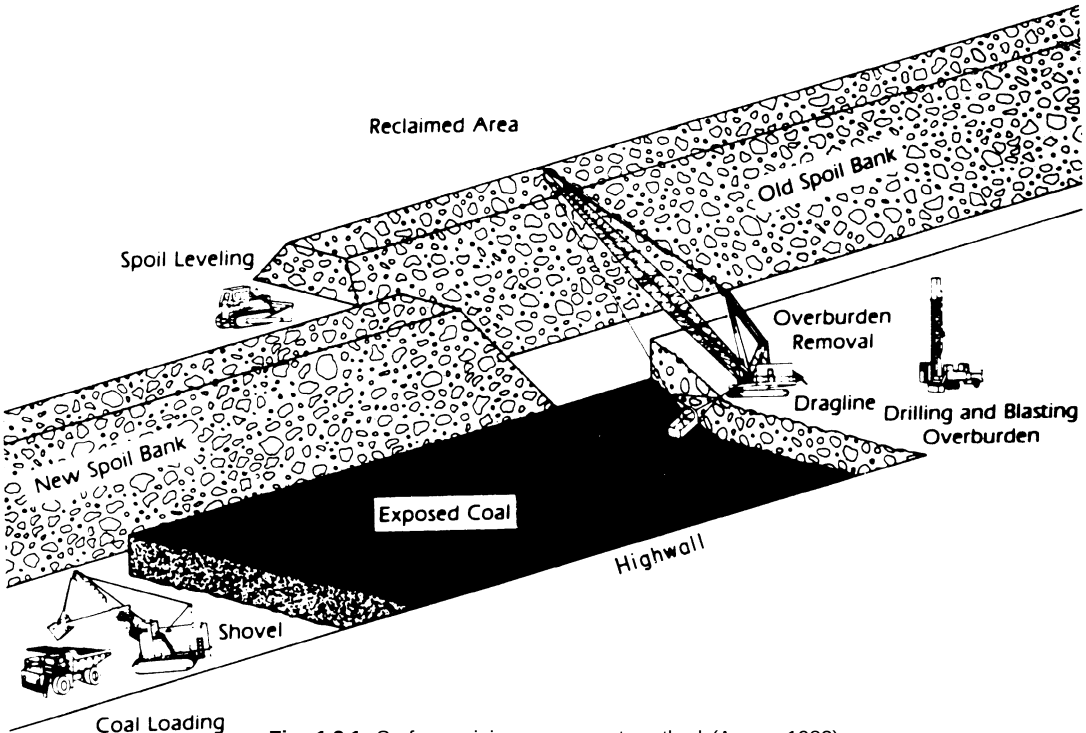

Fig. 1.2.1. Surface mining, open cast method (Anon., 1982).

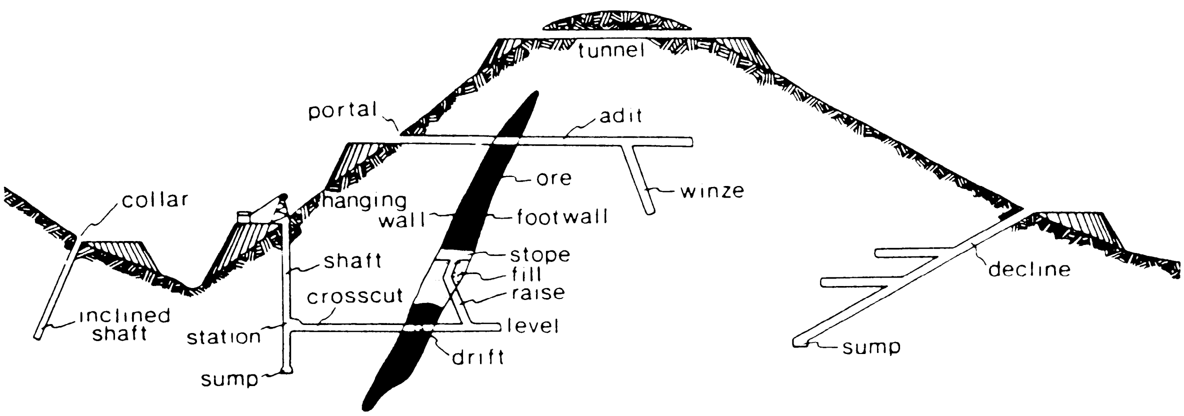

Fig. 1.2.2. Underground mining, stoping method (Anon., 1983a).

the auxiliary steps involved. Those steps contributing directly to mineral extraction are *production operations,* comprising the production cycle of operations. Those ancillary steps that support the production cycle are called *auxiliary operations.*

1.2.3.1 Production Operations [Sec. 9]

The production cycle employs unit operations that normally are grouped in two functions: rock breakage and materials handling. *Rock breakage* includes a variety of mechanisms but is usually accomplished by drilling and blasting, sometimes preceded by cutting in underground coal mining or replaced by channeling in quarrying. *Materials handling* generally encompasses loading or excavation and haulage (horizontal transport), with hoisting (vertical or inclined) optional. Thus the production cycle in mining consists of these unit operations:

General cycle = cut + drill + blast + load + haul + hoist

which may be abbreviated in many mines (especially noncoal or surface) to

Conventional cycle = drill + blast + load + haul

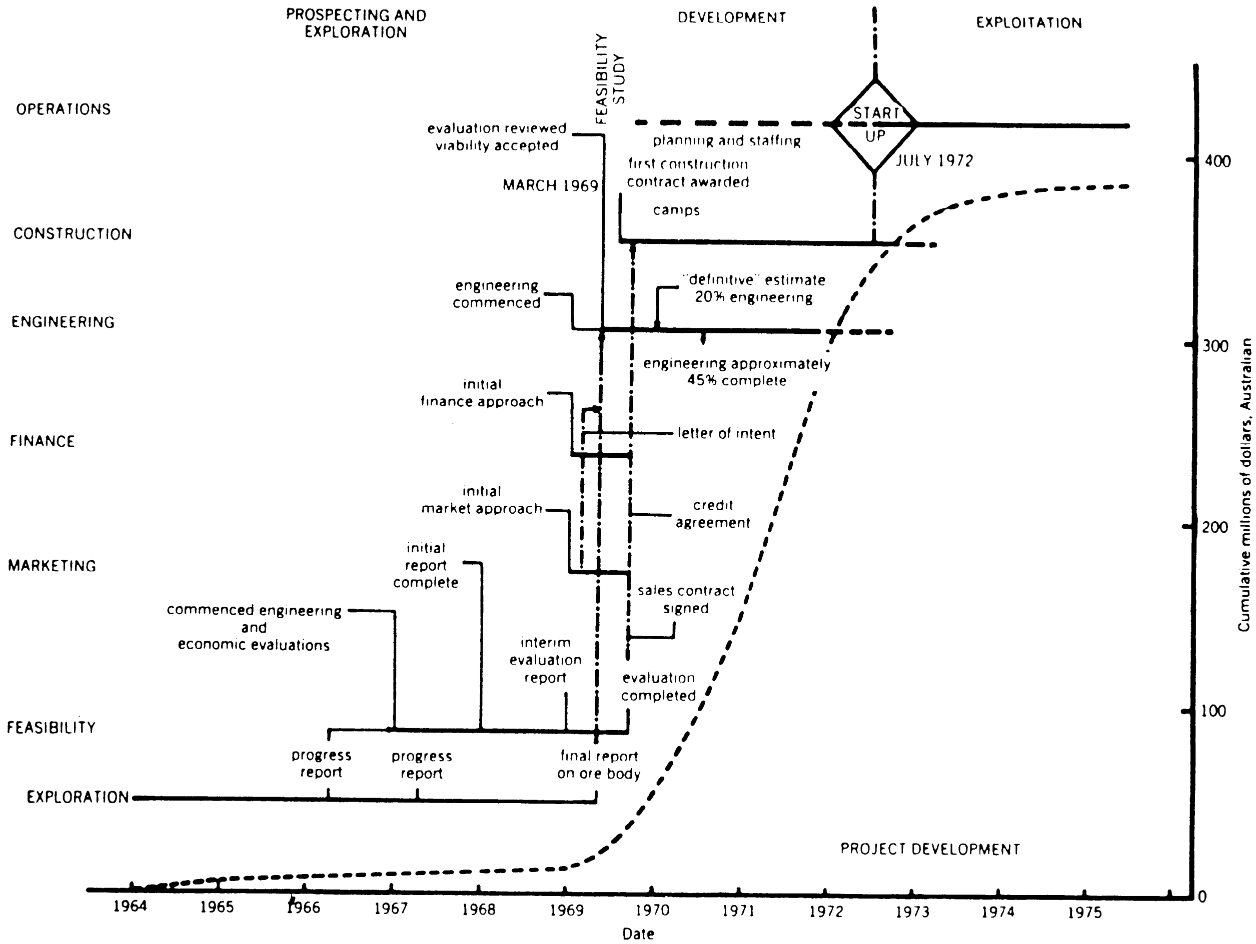

Fig. 1.2.3. Stages in the life of a mine. Relationship between planning steps during exploration and development and expenditures preparatory to mining a large copper open pit—Bougainville mine, Papua New Guinea. (Hope, 1971. By permission from Institution of Engineers, Barton, Australia.)

While production operations tend to be separate and cyclic in nature, the modern and future trend in mining and tunneling is to eliminate or combine functions and to increase continuity. For example, soil may be excavated by a machine (bucket wheel excavator) which requires no drilling or blasting. If loosening is necessary, it may be accomplished without explosives by ripping prior to loading. In coal or soft ores, continuous miners break and excavate mechanically and thus eliminate drilling and blasting; boring machines perform the same tasks in soft to medium-hard rock. The production cycle in these cases further simplifies to

Continuous cycle = mine + haul

The cycle of operations in surface and underground mining is distinguished mainly by the scale of the equipment. Specialized machines have evolved to meet the unique needs and conditions of the two regimes. In modern surface mining, blastholes several inches (tens of millimeters) in diameter are bored by mobile rotary or percussion drills for the placement of blasting agents or high explosives, essentially all now ammonium-nitrate based, when consolidated rock must be excavated. The charge is then inserted and detonated to reduce the ore or waste to fragments. The broken material is loaded by power excavators of the shovel, dragline, or bucket wheel type into haulage units—railroad cars, belt conveyers, or, most usually trucks—or cast on a waste (spoil) bank. Soil and coal are mined in a similar way, although blasting is often unnecessary. In quarrying dimension stone, the blocks are freed without blasting by channeling machines or saws.

In underground mining, the cycle differs little, although scaled-down equipment is usually employed. Smaller drillholes are bored for blasting, and compact loading machines and down-sized trains, trucks, shuttle cars, or conveyors are used to haul the ore or coal in or from the mine. To facilitate breakage in coal, salt, or potash mines where blasting is minimized to prevent methane ignition and excessive degradation, the process of cutting a kerf into the mineral face with a special machine precedes blasting. Hoisting by skip, cage, or conveyor may be the final operation.

In designing a production cycle for balanced operation, once individual machine capacities are established, the number of units (e.g., drills or trucks) can be determined from the required mine output. Ideally, the units of the system should be matched

Table 1.2.2. Classification of Mining Methods

Acceptance/ Locale	Class	Subclass	Method	Commodities	Relative cost, %
Traditional					
Surface	Mechanical	—	Open pit mining	Metal, nonmetal	10

in capacity so there is a uniform, uninterrupted flow of material from the working face to the surface disposal point (plant, loading pocket, or dump).

1.2.3.2 Auxiliary Operations [Secs. 10, 11, 12]

In addition to the productive phases of the actual mining cycle, certain auxiliary unit operations must be performed. Underground, these auxiliary operations consist of providing and maintaining adequate health and safety, roof support, ventilation and air conditioning, power supply, pumping, maintenance, lighting, noise abatement, communications, and handling of supplies. In surface mining, most functions remain the same, but slope stability, waste disposal, and land reclamation must be practiced instead of roof support and air contaminant control in place of ventilation.

Certainly the most important auxiliary operations in all mining-generically speaking-are (1) *health and safety,* (2) *ground control,* and (3) *atmospheric environmental control.* Specialized fields of engineering analysis and design (e.g., geomechanics for ground control) have matured around them.

In planning production cycles, most auxiliary operations are scheduled so as to support but not interfere with production operations. A few may be conducted as an integral part of the cycle if they are essential to health and safety or overall efficiency.

1.2.4 SURFACE MINING [Part IV]

Surface mining, in which excavation is carried on aboveground, is the predominant exploitation method, domestically and worldwide, producing in the United States nearly 85% of all minerals, excluding petroleum and natural gas (Pfleider, 1968). Almost all (96%) of the nonmetallic minerals, 87% of the metallic ores, and 60% of the coal in the United States are now mined from the surface-and the large preponderance by two methods (open pit or open cast mining). By their very nature, the mechanical extraction surface methods (except quarrying) are large-scale, mass-production techniques. The sheer magnitude of the volume or tonnage of material broken and handled in surface mining is staggering (over 12 billion tpy, or 11 Gt/a). In a recent year, surface methods account for 95% of all ore and waste extracted in US mining.

In importance, surface mining clearly ranks ahead of underground mining, if one compares tonnage or value of current annual production. In spite of its many attractions, however, there are some serious limitations to surface mining, not the least of which are depth, selectivity and flexibility, and environmental impact.

1.2.4.1 Surface Mine Development [Sec. 13]

Certain factors in mine development (Sec. 7) receive special attention in preparation for surface mining. Of the locational factors, climate is of more critical concern in surface operation than underground. Today, harsh climates at high altitudes or in northern latitudes rarely mitigate against surface mining, but they can be detrimental. Among natural and geologic factors, terrain, depth and spatial characteristics of the deposit, and presence of water are most important in surface mining. Among environmental factors, certainly antipollution and reclamation requirements rank highest as concerns in surface mining.

In the sequential steps of mine development, there are three that are unique to surface mining:

1. Initiation of a land reclamation plan, during and after mining, as part of the requirement to implement the EIS at the mine.
2. Provision of topsoil stockpiles and waste-disposal dumps.
3. Performing advanced stripping of overburden to gain access to the deposit.

They, too, must be incorporated into the development/exploitation schedule of operations. The major engineering design task in the development of a surface mine is planning the pit; three groups of factors are involved (Soderberg and Rausch, 1968; Atkinson, 1983):

1. *Natural and geologic factors:* geologic conditions, ore types, hydrologic conditions, topography, and metallurgical characteristics.
2. *Economic factors:* ore grade, ore tonnage, stripping ratio, cutoff grade, operating cost, investment cost, desired profit, production rate, and market conditions.
3. *Technological factors:* equipment, pit slope, bench geometry, road grade, easements and property lines, and pit limits.

Pit planning and design—partly because of the immensity of the scale of operations—is crucial to the success of a surface mine. It is predicated on several objectives and broken down into short-range and long-range planning. In both phases, the calculation of stripping ratios and pit limits is required.

Location of the ultimate pit limits is based both on technological and economic constraints. Equipment and method limitations govern absolute depth capability (see Fig. 1.2.1). The maximum allowable *stripping ratio,* a break-even ratio based solely on economics, is typically expressed in units of cubic yards (cubic meters) or tons (tonnes) of overburden per ton (tonne) of ore; it determines the areal pit boundaries. Magnitudes of the actual overall stripping ratio range from as high as 45-to-1 yd^3/ton (38-to-1 m^3/t) in coal mining to as low as 1:1 in metal and approach 0:l in nonmetal. Extensive calculations and computer plotting may be necessary to define both short-range and long-range objectives and limits in surface mining.

1.2.4.2 Surface Mining Methods [Secs. 14, 15, 16]

Two classes of methods are employed in surface mining: mechanical extraction and aqueous extraction. The former is by far the more prevalent (over 90% of US surface production), the latter being limited to applications where water is instrumental to exploitation.

Mechanical Extraction Methods: The *mechanical extraction class* employs mechanical processes in a nominally dry environment to free minerals from the earth. Four methods comprise this class: open pit mining, quarrying (of dimension stone), open cast mining, and auger mining.

In *open pit mining,* a thick deposit is generally mined in benches or steps, although a relatively thin deposit may be mined from a single face, as in quarrying, augering, or open cast mining. Any overburden must be removed by a stripping process before or during mining. In *open cast (or strip) mining,* however, overburden is removed, usually by casting into mined-out areas, and mineral (commonly coal) recovered in successive operations. Open pit or open cast mining is used to exploit a deposit near the earth's surface that has a relatively low stripping ratio, is preferably large in extent, and is reasonably uniform in value. These methods necessitate a large capital investment but generally result in high productivity, low operating costs, and good safety conditions. *Quarrying,* a highly specialized method and the only one intended to produce both a sized and shaped product, is slow, small scale, and (along with square set stoping) the most expensive of all mining methods. *Augering* is utilized in recovering coal from the highwall at the pit limit; it, too, is specialized but a low-cost method.

Broadly applicable, open pit and open cast methods employ a conventional mining cycle of operations to extract mineral: rock breakage is usually accomplished by drilling and blasting, followed by the materials handling operations of excavation and haulage. Quarrying and augering are specialized and less frequently used methods where breakage is achieved by alternative means and explosives are essentially eliminated.

Aqueous Extraction Methods: The *aqueous extraction methods* are uniquely reliant on water or an aqueous mixture during mining and processing to recover the valuable mineral by jetting, slurrying, dissolving, or melting. They are grouped in two subclasses: (1) placer mining or related methods and (2) solution mining methods.

Placer mining is used to exploit mineral deposits that are loosely cohesive or are nonconsolidated, such as sand and gravel or alluvium that contain a valuable heavy mineral in a free state. Native gold and platinum, diamonds, tin in the form of cassiterite, and titanium as rutile and ilmenite commonly are found in placer form. Two historical placering methods have been modernized and find application for a variety of mining purposes; they are hydraulicking and dredging. *Hydraulicking* (also called *hydraulic mining)* utilizes a high-pressure stream of water that is directed against an exposed bank, thereby undercutting it and causing it to collapse. *Dredging* accomplishes extraction of the ore minerals mechanically or hydraulically, normally from floating vessels. In both of these methods, if the objective is extraction, the valuable mineral constituent, generally heavier than the waste material, is removed from a water-base slurry by concentration. On a tonnage basis, however, both of these methods find widest application in mining fields other than placering and for many purposes other than mineral extraction (e.g., tailings transport, ore slurrying, overburden stripping, land reclamation, etc.).

Solution mining includes both *in situ techniques* and *surface techniques.* Examples of the former are salt wells, uranium dissolution, and the Frasch process to melt sulfur. Surface techniques principally involve solvent leaching of mineral values from heaps or dumps or an insoluble matrix or host rock.

Hydraulicking, dredging, and the solution mining methods are the most economical of all exploitation methods but can be used only for mineral deposits that are easily excavated and susceptible to aqueous (solution) attack. They employ unique and dissimilar cycles of operations and bear little resemblance to the mechanical extraction methods. Placer mining is applicable to the recovery of heavy minerals from shallow alluvial and other unconsolidated deposits; it lends itself to large-scale, continuous operation, especially dredging. Solution mining, on the other hand, is employed both for surface and deeply buried deposits of small size; hence it is a hybrid method. Generally, no personnel are exposed to underground operations, however, so it is properly regarded as a surface method.

Two nonmining applications of the aqueous methods are worth mentioning: channel dredging and creation of storage openings and waste repositories by solution mining.

A comparison of all surface methods is contained in Sec. 16.

1.2.5 UNDERGROUND MINING [Part V]

If the appeal of surface mining lies in its mass production and minimal-cost capabilities, then the attraction of underground mining stems from the variety and versatility of its methods to meet conditions too demanding and extreme for surface exploitation. True, underground mining cannot compete with surface mining today in its share of US mineral production. But the United States depends heavily on underground mining for certain essential and/or strategic minerals: all or most of its fluorspar, lead, potash, trona, and zinc come from underground mines, plus a significant part of its bituminous coal, gold, molybdenum, salt, and silver. Regardless, then, of present status and past trends, it seems safe to conclude that (1) underground mining still occupies an essential role in mineral exploitation, and (2) no drastic diminution in application is foreseeable.

While it is always risky to attempt to predict trends and the future, indications seem to favor an eventual return of underground mining to the prominence it once held. Reasons include (1) increasing deposit depths, (2) limited mobility of large surface machines, (3) ever-tightening environmental constraints, and (4) promising advances in underground rock-boring and continuous mining equipment. We have only to remind ourselves that the ultimate technological limit in all mining is depth, and that underground exploitation effectively postpones the inevitable. (Economics, of course, may impose a shallower limit than technology but never a deeper one.)

1.2.5.1 Underground Mine Development [Sec. 17]

In preparing a mineral deposit for exploitation, development in underground mining requires certain considerations that surface mine development does not. A review of governing factors indicates the least concern for locational criteria (climate, in particular, can almost be neglected, unless the mine requires heating or cooling). The most critical are natural and geologic factors: ore and rock strength, the presence of groundwater, and the rock-temperature gradient must be evaluated carefully (terrain is less important, because the surface plant is less extensive in underground mining). Social-economic-political-environmental factors can pose a plethora of problems in underground mining: a more skilled labor force must be recruited, financing may be more difficult because of the higher risk involved, and subsidence may occur.

The extent of access development performed prior to exploitation also differs. Surface mining requires considerable excavation if overburden exists, as is the normal case, and extensive surface area may be tied up with stripping activity and waste disposal prior to the commencement of actual mining. On the other hand, only limited excavation and relatively small openings are required in developing for underground mining. Overall excavation costs may not be too dissimilar, however, because of the vast differences in opening advance rates and unit excavation costs. Further, in underground mining, more careful attention must be given to siting, lifetime, and the construction scheduling of development openings.

All of the steps comprising the general sequence of mine development apply to and are usually performed in underground mining. One unique environmental feature—carried out as an auxiliary operation—is the necessity to provide an artificial atmosphere as a means of life support for the miners. The mine ventilation system utilizes access and production openings to distribute fresh air of the quality and quantity desired to all working places. Other than that requirement, underground development openings provide access to the mineral deposit in the broad sense, permitting entry of miners and materials (equipment, supplies, power, and water) as well as egress for the product mined and any attendant waste.

On occasion, underground development openings double for exploration purposes, and vice versa. Those openings driven in advance of mining can provide valuable exploration information and afford suitable sites for exploration drilling and sampling. Likewise, openings constructed for exploration purposes sometimes can be utilized later as development workings.

Mine development in the underground locale is more specialized, extensive, and expensive than on the surface. Development openings are classified (by rank order of importance) as primary or main, level or zone, and lateral or panel. Primary access is provided by a shaft, slope (decline or incline), or drift or adit (see Fig. 1.2.2). Secondary openings include crosscuts, laterals, raises, winzes, and ramps. Design factors to be taken into account in mine development are the type of mining method, production rate, mine life, and interval between levels. The overall physical plant required to conduct subsurface mining has three components: surface, shaft, and underground. Of these, the hoist plant is unique and a major task of engineering design.

1.2.5.2 Underground Mining Methods [Secs. 18, 19, 20, 21]

Mineral exploitation in which extraction operations are carried out beneath the earth's surface is termed *underground mining* (Hustrulid, 1982). Underground methods are employed when the depth of the deposit, the stripping ratio of overburden to ore (or coal or stone), or both become excessive for surface exploitation. Once the economics has been established, then the selection of a proper mining method hinges mainly on (1) determining the appropriate form of ground support, if necessary, or its absence, and (2) designing an appropriate opening configuration and extraction sequence to conform to the spatial characteristics of the mineral deposit.

Reflecting the importance of ground support, underground mining methods are categorized in three classes on the basis of the extent of support utilized. They are unsupported, supported, and caving, with individual methods differentiated by the type of wall and roof supports used, the configuration of production openings, and the direction in which mining operations progress.

Unsupported Methods: The *unsupported class* consists of those underground methods that are essentially self-supporting and require no major artificial system of support to carry the superincumbent load, relying instead on the walls of the openings and natural pillars. (The superincumbent load is comprised of the weight of the overburden and any tectonic forces acting at depth.) This definition of unsupported methods does not preclude the use of rock or roof bolts or light structural sets of timber or steel, provided that such artificial support does not significantly alter the load-carrying ability of the natural structure.

Theoretically, the unsupported class of methods can be used in any type of mineral deposit (except unconsolidated or placer) by varying the ratio of span-of-opening to width-of-pillar to achieve the desired mine life expectancy. Since the stable size of opening is determined by the depth and the mechanical properties of the ore and overlying rock, the safe span conceivably could range from a few feet (meters) to over 100 ft (30 m). Practically, the unsupported methods are not universally applicable and are limited to deposits with favorable characteristics. The unsupported class, however, is still the most widely used underground, producing over 80% of the ore and mineral from US subsurface mines.

Unsupported methods of mining are used to extract mineral deposits that are roughly tabular, flat or steeply dipping, and generally in contact with competent wall rock. This class consists of five methods: room and pillar mining, stope and pillar mining, shrinkage stoping, sublevel stoping, and vertical crater retreat mining.

Room and pillar mining is adaptable to regular flat-lying deposits, with the advance horizontal; support of the roof is provided by natural pillars of coal or ore that are left standing or recovered in a systematic pattern, and rooms are cut from access entries to provide working faces. When necessary, additional support is supplied by roof bolts or timbers. *Stope and pillar mining* (a stope is a large production opening) is a similar method used in noncoal mines where thicker, more irregular ore bodies occur; the pillars are usually spaced randomly and consist of waste or relatively low-grade ore, since the richer ore is extracted in the stopes. These two methods—room and pillar and stope and pillar—account for approximately 75% of all underground mining in the United States. In *shrinkage stoping,* mining progresses upward, with slabs of ore being broken along the length of the stope. The broken ore is allowed to accumulate in the stope to provide a working platform for the miners and is thereafter withdrawn through chutes into haulage drifts on the level below. *Sublevel stoping* differs from shrinkage by providing several working benches, aligned vertically or staggered, with breast (horizontal) mining on each bench. Long blastholes are drilled into the ore in a parallel or fanlike pattern to fracture the rock. *Vertical crater retreat (VCR) mining* is one of the few patented mining methods, originating from sublevel stoping. Large, parallel, vertical drillholes permit placement of nearly spherical explosive charges, the ideal shape for blasting; horizontal slices of ore are then broken into an undercut. The VCR method is applicable to ore of only moderate strength.

Unlike surface mining, there is little distinction in the cycle of operations for the various underground methods (except in coal mining), the differences occurring in the direction of mining (vertical or horizontal), the ratio of opening-to-pillar dimensions, and the nature of artificial support used, if any. Of the unsupported methods, room and pillar mining and stope and pillar mining employ horizontal openings, low opening-to-pillar ratios, and light-to-moderate support in all openings. Shrinkage and sublevel stoping and VCR mining utilize vertical or steeply inclined openings (and gravity for the flow of bulk material), high opening-to-pillar ratios, and light support mainly in the development openings.

Supported Methods: The *supported class* of underground mining methods consists of those methods that require substantial amounts of artificial support to maintain stability in exploitation openings and systematic ground control throughout the mine. Supported methods are used when production openings will not remain standing during their active life and when major caving or subsidence to the surface cannot be tolerated. In other words, the supported class is employed when the other two categories of methods—unsupported and caving—are not applicable.

Support systems for production workings are chosen to provide varying degrees of controlled wall closure and ground movement. Next to pillars, the most satisfactory form of support is backfill, which approaches 100% in its ability to support the superincumbent load without yielding. In certain instances, some yielding is acceptable and, in fact, preferable because artificial support cannot hold the superincumbent load. Heavy support systems of this type include timber stulls and cribs, timber or steel sets and trusses, and steel jacks, props, arches, chocks, shields, and canopies. Timber is weaker and yields more than steel (sometimes a desirable feature) but is readily available, flexible, workable, easy to install, and economical.

The supported class of mining methods is intended for application to rock ranging in competency from moderate to incompetent. (A competent rock is defined as rock that, because of its physical and geologic characteristics, is capable of sustaining openings without any heavy structural supports.) There is one major method in this class—cut and fill stoping—and two minor ones—stull stoping and square set stoping. They find application in metal (and nonmetal) mining but account for only a small percentage of US underground mineral production. All are vertical stoping methods.

Cut and fill stoping is usually employed for weak tabular deposits. As mining progresses, normally upward, sand, tailings, or waste backfill is placed in the stope to provide support for the walls. The ore, recovered in horizontal slices, is moved to chutes or orepasses mechanically, and the waste is usually distributed hydraulically. *Square set stoping,* a timbered-support method, likewise involves backfilling; however, it also relies on timber sets to support the walls during mining. These timber sets are assembled in a continuous support structure to form skeletal prisms that are subsequently filled with waste material for long-term support. Since it (with quarrying) is the costliest of all methods, it is generally used only in rich mines having very weak structure and is nearly obsolete today. *Stull stoping,* also a timbered method, is a small-scale, supported method using single timbers of rock bolts in narrow, tabular, pitching ore bodies. Cut and fill and stull stoping are intended for moderately competent rock, while square set stoping is suitable for the least competent rock.

The supported methods have declined in use in the decades since World War II (to an estimated 5% in US underground mines). Only cut and fill stoping lends itself to mechanization; consequently, costs of the other methods have risen relatively. Also the ranges of application of the unsupported and caving classes have tended to broaden in recent years, overlapping the former province of the supported class.

Caving Methods: The two classes of underground methods just discussed focus on maintaining exploitation workings open, essentially intact, for the duration of mining. If the ore and rock are sufficiently competent, unsupported methods are adequate; if ore and rock are incompetent to moderately competent, then supported methods may be used. There is also a class of methods in which the exploitation workings are designed to collapse; that is, caving of the ore or rock or both is intentional and the very essence of the method.

Caving methods may be defined as those associated with induced, controlled, massive caving of the ore body, the overlying rock, or both, concurrent with and essential to the conduct of mining. Subsidence of the surface eventually follows. There are three major caving methods: longwall mining, sublevel caving, and block caving. Longwall mining is used in horizontal, tabular deposits, mainly coal; the others have application in inclined, vertical, or massive deposits, almost exclusively metallic or nonmetallic. The caving class accounts for about 15% of US underground mineral production, a sharply increasing amount. In cost, this class includes a moderately priced method as well as the two cheapest of all underground methods.

Longwall mining is a caving method particularly adapted to thin seams, usually coal or nonmetallics at some depth. In this method, a face of considerable length (a "long" wall) is maintained, and, as the mining progresses, the overlying strata are caved, thus promoting the breakage of the coal itself. Widely used abroad, longwall mining for coal production is growing rapidly in popularity in this country. A different method, *sublevel caving,* is employed for a dipping tabular or massive deposit. As mining progresses downward, alternate slices of ore are mined out and the intervening layers of ore recovered by caving. The overlying rock is also subsequently caved. *Block caving* is a remarkable, large-scale, mass-production method that is highly productive, low-cost, and conceptually ideal for massive deposits that must be mined underground. A large block of ore, a few hundred feet (meters) to a side, is undercut and thereby caused to cave. As the block fragments and collapses, the ore is drawn off through chutes or loading points into haulage drifts. Block caving, with longwall, is the most economical of all underground methods because production is high and, except during the undercutting operation, manpower requirements are low. It is adaptable to weak or moderately strong ore and rock bodies and also to massive or dipping tabular deposits of considerable size that are cavable.

Because exploitation openings are deliberately destroyed in the progress of mining, the caving class is unique. Rock mechanics principles are applied to ensure that caving, in fact, does occur—rather than to prevent the occurrence of caving. In effect, the cross-sectional shape of the undercut area (i.e., the width-to-height ratio) is sufficiently elongated to cause failure of the roof or back. Further, development openings have to be designed and located to withstand shifting and caving ground, as well as subsidence that usually extends to the surface. Production must be maintained at a steady, continuous level to avoid disruptions or hangups in the caving action. Good mine engineering and supervision are indispensable to a successful caving operation.

The various underground methods are compared in Sec. 21.

1.2.6 SUPPLEMENTAL TOPICS [Part VI]

1.2.6.1 Novel and Innovative Mining Methods [Sec. 22]

There are several unique mining methods that are not included among the traditional surface and underground methods just described. They are termed *novel methods,* defined as methods that employ new or innovative principles or technologies, or exploit uncommon resources, and that are not yet widely accepted in practice.

The distinction between traditional and nontraditional methods is not as sharp as we might at first expect. Just as classical methods evolve, are modified or combined with other methods, or become obsolete and fall into disuse, so novel methods may in time receive the acceptance that warrants their reclassification into one of the traditional categories. Good examples are auger mining and solution mining, which a relatively short time ago were exploitation curiosities. Some of the novel methods examined are on the verge of winning wide enough acceptance to justify a change of status; others will sink into oblivion. Further, other methods, as yet only concepts or undiscovered, will most certainly emerge to supplement the novel methods now recognized.

How do novel mining methods originate? In past times, they evolved almost entirely from operating experience within the industry. That is not as true today. Technology transfer is occurring from other industries and endeavors. Military and space hardware and concepts frequently find application in diverse branches of industry, including mining. Also look for research and development within the mineral industry to contribute to the adoption of new methods in the future, both traditional and novel (e.g., VCR mining and mechanized sublevel caving both resulted from industry R&D).

Table 1.2.2 lists as examples nine current nontraditional mining methods and the mineral commodities to which they are applicable (relative costs are omitted because reliable data are lacking). They may be classified as to the likelihood of their eventual commercial application as (1) limited existing use, (2) promising but not yet in use, and (3) questionable or unlikely use. While some novel methods are intended for surface exploitation, all but one are applicable to underground mining. However, they all tend to be restrictive or specialized methods, limited as to conditions of use. Some comments on the principle, importance, and status of the major novel methods follow.

Existing Methods: 1. *Rapid excavation:* Still more concept than practice, rapid excavation is intended to replace the intermittent operations of rock breakage and materials handling in hard-rock mining with a system of continuous extraction. It seeks to develop boring-machine technology to achieve truly rapid advance and continuous operation in low-drillability rock. Not so much a mining method as an improved cycle and system of operations, rapid excavation offers revolutionary prospects in many fields of mining, including the boring of tunnels and shafts as well as raises. Truly continuous extraction and handling systems for hard-rock mining await a breakthrough and remain a distant possibility; but progress is being made, and the legitimacy of the goal is now widely accepted for both development and exploitation.

2. *Automation and robotics:* Evolving from cost-driven concepts of mechanization and automation, humanless or remote control in mining is especially attractive for reasons of safety. Widespread adoption depends upon more technological ruggedness, especially for the underground regime, which in turn should produce economic feasibility.

3. *Hydraulic mining:* Applications of water-jet and borehole-slurry technology are advancing slowly into various unit operations (penetration, fragmentation, and handling), toward a clear goal of an integrated mining system. Extension from coal to harder rock is a companion objective.

4. *Methane drainage:* Signs are favorable for rapid expansion of coalbed degasification throughout the underground coal-mining industry, in part on safety grounds but also with economic justification. Drainage from seams that are not actively being mined is equally attractive and coming to the fore as a competitive source of natural gas.

Promising Methods: 1. *Underground gasification:* Ripe with promise for difficult natural conditions, in situ coal gasification and combustion has been fraught with economic risk and technological difficulties. It involves the partial combustion of coal in place, generally through boreholes, with the collection of a low-quality gas at the surface.

2. *Underground retorting:* In situ oil shale retorting, in which pyrolysis of kerogen occurs in place, faces some technological uncertainties but, more serious, has yet to demonstrate economic viability. Unfortunately, its future is tied to that of the synthetic fuels industry, which presently is held economic hostage by the international oil cartel.

3. *Marine mining:* There are intriguing technological possibilities for mining rich unconsolidated nodule and mud deposits in the deep oceans. However, for deposits located in international waters, political and legal risks are too great until an acceptable treaty of the seas is negotiated. Exploitation appears much more likely for resources located within the so-called exclusive economic zone (EEZ) declared by the United States. Deposits of interest include cobaltiferous seabed crusts, massive sulfides, and deep offshore placers. Worldwide interest in the various marine resources is high.

Questionable Methods: 1. *Nuclear mining:* No applications are likely as long as radiation hazards are uncontained (and the Limited Nuclear Test Ban Treaty remains in effect), in spite of technological promise and economic attractiveness for certain fragmentation applications in underground mining.

2. *Extraterrestrial mining:* The furthest out of all the novel methods, colonization of outer space (most likely site: the moon) is a must to justify risky, untried extraterrestrial mining. Launching of a US space station would revive interest in the concept.

Other Methods: A variety of other emerging concepts in mining is also discussed.

1.2.6.2 Evaluation of Mining Methods and Systems [Sec. 23]

Earlier discussions dwelt on individual mining methods, or classes of methods, their characteristics and conditions. Finally, an overall comparison and evaluation and some selection procedures are needed, limited here to traditional methods.

Method Features: It is not possible to compare all the features associated with surface and underground methods, but one can note the principal advantages and disadvantages of the two locales.

1. *Mining cost:* Except in rare cases, relative costs (quarrying is an exception) are significantly less for surface mining; underground costs are higher but variable, with caving lowest and supported highest.
2. *Production rate:* All surface methods (except aqueous and quarrying) moderate to high; underground low to moderate (except high for caving and some unsupported).
3. *Productivity:* Surface much higher than underground in nearly all cases.
4. *Capital investment:* Generally small for aqueous and large for other surface, but larger for underground; surface equipment more expensive, but underground development costlier.
5. *Development rate:* More rapid for surface.
6. *Depth capacity:* Limited for surface (except for solution mining); range from limited (unsupported) to somewhat unlimited (supported) underground.
7. *Selectivity:* Generally low for surface, variable underground.
8. *Recovery:* Generally high for surface (except aqueous), variable from low to high underground.
9. *Dilution:* Generally less for underground (except for caving).
10. *Flexibility:* Underground tends to offer more flexibility than surface, although surface may be more adaptable to change.
11. *Stability of openings:* Generally higher for surface; more difficulty to attain and maintain underground.
12. *Environmental risk:* Substantially higher for surface, except that subsidence may be severe with underground methods.
13. *Waste disposal:* May be serious problem for surface, minor underground.
14. *Health and safety* (including atmospheric control): Vastly superior for surface.

Of the method features noted, the most important favoring surface mining are cost, production rate, productivity, recovery, and health and safety. Those supporting underground mining are depth tolerance, selectivity, dilution, environmental risk, and waste disposal.

Overall Considerations: Subjectively, we may conclude from the preceding comparison that, excluding depth limitations, surface mining is usually preferred over underground. There are certain significant factors that favor underground over surface mining, however, as noted previously, and these may govern in certain circumstances. Final judgment in a specific case awaits determination of costs and an economic analysis of competing candidate methods.

Cost Analysis: The ultimate basis for decision making in selecting a mining method is economics. Assuming that safety and technological considerations are satisfied, cost estimates are prepared for all candidate methods in order to make a final choice. Usually the process is performed in two stages: (1) if the deposit depth is shallow to moderate, compare approximate costs first for the general categories of surface vs. underground mining; and (2) once that has been resolved with some certainty, compare specific costs for promising, individual mining methods. Generally, direct mining costs including prospecting, exploration, development, and exploitation will suffice, but in some instances, consideration of all production costs (overhead, mineral processing, smelting, transportation, etc.) is necessary. Inherently, underground mining costs typically exceed surface mining costs by a margin of three to four to one. Relative costs in Table 1.2.2 provide an indication of the range.

Selection Procedures: A variety of procedures, including decision-making matrices, have been devised to aid in the selection of the most suitable mining method. Most are subjective (Peele, 1941; Young, 1946; Lewis and Clark, 1964; Hamrin, 1982; Hartman, 1987), but in recent years numerical techniques utilizing the computer have been developed (Nicholas, 1981). By permitting consideration of virtually an unlimited range of factors, a quantitative selection procedure is far more likely to result in the optimum choice.

1.2.6.3 Openings for Nonmining Purposes [Sec. 24]

Often, excavations in the earth are employed for purposes other than mineral extraction. These include both *civil and military works* in which the objective is to produce a stable opening of desired size, orientation, and permanence. Examples are vehicular tunnels, storage reservoirs, waste disposal chambers, and military installations. They are excavated using methods that are borrowed from mining. Since the objective is the excavation or opening itself rather than the mineral extracted, however, other kinds of conditions or circumstances may govern, such as time, shape, or life. Because the excavation technology is so similar to that used in mining, it is only mentioned here. Rather, attention is given to the variety of openings created, design criteria, and utilization factors.

Tunnels, Sewers, and Water Diversion Openings: The majority of civil construction is directed toward openings in this category. While tunnels serve several purposes, most today are driven for vehicular use (e.g., automobile, rail, subway). Sewers and water diversion openings are similar in size and appearance. Tunneling methods consist both of soft-ground and rock excavation, plus some specialized techniques such as cut-and-cover, shield, caisson, and immersed tube. Like mining, tunneling has become completely mechanized and employs continuous, rapid excavation technology whenever possible (tunnel boring machines, in fact, were originally developed for civil works). Governing factors in tunneling, again similar to those in mining, are safety and cost. Because of their greater permanence, however, civil openings tend to be much more expensive, to be more time-consuming to construct, and to require lining or more elaborate support systems.

Storage and Power Generation Openings: Underground openings constructed for storage and power generation purposes are generally larger than tunnels and hence less costly per unit volume of rock broken. In hard rock, because of their larger size, they must be excavated by conventional drill-blast techniques rather than by rapid excavation. In soft rock, susceptible to solution attack (e.g., salt beds and domes), large cavities can be constructed more readily and cheaply. Ground stability is of the utmost importance because of the long spans involved; lining and support systems are expensive to install and usually avoided by driving openings in competent rock. Underground storage is utilized for a host of materials, both solid and fluid, packaged and bulk. Gases stored include compressed air, methane (natural gas), helium, and nitrogen, generally under moderate to high pressure. Petroleum liquids and water are also stored in underground chambers. The newest application is for packaged storage, often of paper goods and records, warehouse inventory, and food stuffs. Power generation openings are usually constructed in conjunction with dams and hydroelectric projects, providing water-conveying pumped-storage facilities.

Waste Repositories: Like other large underground structures, waste repositories are located in competent rock to provide stability and to obviate the requirement of ground support. With the advent of the nuclear age and the need to dispose of dangerous radioactive wastes, underground repositories have assumed new prominence. Subsurface disposal of wastes of all kinds has been employed since the Industrial Revolution first created the need. Originally confined to wellbores, disposal in large chambers is now commonly practiced, often specially constructed to provide security for toxic and radioactive wastes. Disposal of high-level radioactive wastes from nuclear reactors poses a unique public health problem of national dimensions, one currently unresolved; underground repositories are presently the favored solution.

Military and Defense Installations: Underground facilities serve many military purposes, including materials storage, personnel protection, concealment, weapons testing and emplacements, and troop infiltration. Simple shallow structures are often adequate, but deeply buried ones may be necessary to withstand heavy bombardment or nuclear attack. Some large and very elaborate facilities, such as strategic factories, command headquarters, and submarine pens, have been constructed underground. Standard excavation techniques are employed to construct military installations, complicated by exacting specifications and the frequent need for secrecy and security.

1.2.6.4 Postmining Operations [Sec. 25]

All the steps in processing raw minerals that occur following extraction from the earth comprise *postmining operations.* They result in over a tenfold enhancement in value of US mineral production. It is not within the scope of the *Handbook* to treat postmining subjects at length, but they are introduced and their relationships established to the functions of mining proper.

Storage and Transportation: Materials handling as a unit operation continues beyond mining through processing. At each phase or transition, bulk-material storage and transportation must be provided. Bins, silos, hoppers, and stockpiles may be required for storage, with attendant transfer feeders, stackers, and reclaiming machines. Transportation occurs by rail, road, barge or ship, or conveyor (belt, hydraulic, or pneumatic). Design of these facilities is not often the responsibility of the operating mineral or metallurgical engineer, but selection is. Because of the specialized nature of the equipment, consultants, manufacturers, or engineer-constructors often provide the expertise.

Mineral Processing: It is termed cleaning or washing if the mineral is coal and milling or concentrating if it is an ore. Interfacing directly with mining, mineral processing requires close communication and coordination with the extraction activities. Almost continuous monitoring of the run-of-mine product as to tonnage and grade is mandatory; feedback control loops permit adjustments in mining practice to meet processing demands. Mineral processing today may be an intricate succession of treatment stages: comminution is followed by screening or classification, then by one or more beneficiation processes, and finally by agglomeration, dewatering, and drying. The treatment flowsheet is designed uniquely for the mineral commodity being processed. Disposal of wastes (tailings, culm, reagents) must always accompany mineral processing.

Chemical and Electrolytic Processing: Metallic ores often incur further processing during leaching, solvent extraction, ion exchange, electrowinning, and electrorefining. These traditional steps are classified as chemical and electrolytic processing, and the treatment plant to accomplish them may or may not be located at the mine or with the mineral processing facility. Environmental control is a necessary auxiliary operation for this step.

Sales and Marketing: Following one or more steps of processing, the final coal/mineral/metal product is ready for market. Many large organizations are vertically integrated, conducting their own exploration, mining, processing, and marketing. Smaller companies tend to be limited to a single stage of operations and must sell their product to others for processing and consumer marketing. Marketing practices vary for each of the three major mineral commodity groups—fuel, metal, and nonmetal—in accordance with the economic uniqueness of each industry (Strauss, 1986).

Chapter 1.3
MINERAL ENGINEERING EDUCATION

LAURENCE H. LATTMAN

1.3.1 INTRODUCTION

The educational disciplines covered in this chapter include mining engineering, geological engineering, environmental engineering, and metallurgical (and materials) engineering. The general term *mineral engineering* is here used to describe these fields, although mineral engineering is a separate program at a few schools. The boundaries between some of these disciplines are not sharply drawn, and what one school calls metallurgical engineering may largely overlap what another school calls mineral engineering. In addition, data on each of these areas of study are not equally complete or precise. For example, mining engineering enrollment information is extensive and accurate, whereas enrollment data on metallurgical engineering may be combined with materials engineering and thus may require interpretation. Nevertheless, general trends in enrollment at the undergraduate and graduate levels and changes in programs are available and worth noting.

There are today 37 accredited schools offering engineering degrees in the mineral fields (Table 1.3.1). The complete listing is issued annually by the Accreditation Board for Engineering and Technology (ABET), Inc. (Anon., 1987). A guide to mineral schools, giving faculty and enrollment data, is published by the Society for Mining, Metallurgy, and Exploration (SME), Inc. (Anon., 1988). Several schools report consideration being given to dropping or combining various mineral engineering programs, but no major changes were made in the 1987-1988 academic year. These considerations have been driven by significant enrollment drops since the early 1980s.

1.3.2 ENROLLMENT

1.3.2.1 Trends

While historically very cyclic, the most striking feature of enrollment trends in the past several years has been the decline. As shown in Fig. 1.3.1, the decrease in undergraduate enrollment in mining engineering has been steady since 1980–l981 and particularly rapid during 1983 to 1986. Graduate enrollment has remained essentially constant during that time. The numbers of graduating mining engineers (BS degrees) peaked in 1983-1984 and has been dropping steadily since. The projected graduates are expected to decrease through 1990-1991. In number, advanced degree graduates have remained close to constant.

A fact not brought out by Fig. 1.3.1 is that enrollments in mineral engineering have not dropped similarly at all schools. Some have kept enrollment reasonably steady, whereas others have had a very large drop-as high as 75% in some cases. Ashworth (1986) has given an excellent summary of mining engineering enrollment through 1985.

The data cited apply to mining engineering, but telephone discussions with colleagues indicate that all mineral engineering programs have had essentially a similar recent enrollment history.

Many schools report unused scholarships. Thus it is concluded that lack of financial support is not a contributor to the enrollment decline. Rather, it is almost universally attributed to an actual or perceived decrease in job opportunities for mineral engineers.

1.3.2.2 Types of Students

There appears to be a change, difficult to document, in the type of student enrolling in undergraduate and graduate mineral engineering programs. The number of international students is increasing. Anecdotal data on all mineral engineering programs indicate that from one-third to one-half of the undergraduate group are now international students, dominantly from Canada, the Pacific Rim countries, and Central and South America. Some schools state that they are actively recruiting international students.

At the graduate level, over one-half (perhaps 60%) of the students are international, and many do not plan to remain in the United States after graduation.

From this information, it is apparent that the numbers of US citizens in mineral engineering programs are probably decreasing at a faster rate than the total enrollment data alone indicate.

1.3.3 BASIC REQUIREMENTS FOR THE BACHELOR'S DEGREE

Most mineral engineering schools design their undergraduate programs to meet ABET criteria for accreditation. For the 1988-1989 academic year, program criteria have been developed for geological engineering; metallurgical, materials, and similarly named engineering programs; and mining and similarly named engineering programs. ABET notes that materials and similarly named engineering programs were separated from metallurgical and related engineering programs.

Details of accreditation requirements for any program can be obtained from ABET (Anon., 1987b). The requirements include faculty size and qualifications as well as curriculum needs in mathematics, basic sciences, and engineering sciences and design. The fundamental requirements are set by ABET and amplified by various professional societies. For example, SME-AIME formulates the program criteria for mining and geological engineering, expanding on ABET's basic requirements in science, humanities, laboratory experience, computer-based experience, etc.

Discussion of ABET accreditation criteria is continuous in academic circles, and the criteria commonly undergo modification. They should be carefully reviewed when seeking initial accreditation or renewal.

It is usually a principle in academe that a student should be held only to the graduation requirements contained in the school's catalog at the time that the student enrolled. This is to prevent changes prolonging the time required for a degree. Many schools, however, while not requiring students to change plans, strongly recommend such changes during the student's education, if these changes are part of new ABET criteria. This potential problem can best be resolved on an individual basis.

Individual program criteria are not discussed here as they change frequently and are available from ABET (Anon., 1987b).

Mineral Engineering	2
Mineral Processing Engineering	3
Mining Engineering	21

Source: Anon., 1987a.
[a] Combined with Materials Science and Engineering.
[b] Combined with Metallurgy, Metallurgy and Materials Science Engineering, and Extractive Metallurgy.

Clearly, faculty should take an active and progressive interest in these requirements through their professional societies as well as within their departments. Some recent program changes and trends are discussed in the next section.

1.3.4 SOME RECENT CHANGES IN EDUCATIONAL EMPHASIS

Many schools report changes in faculty thinking about undergraduate and graduate educational requirements in the mineral sciences. As is so often the case, many of these changes require new courses and can only be accommodated by dropping existing courses or creating a five-year undergraduate program. There is considerable reluctance by schools to force mineral engineering into a five-year program because of increased costs, possible further loss of student interest, and lack of support from industry.

The major single change, begun some years ago and continuing apace, has been the increased emphasis on computer training and application. Computers are now an integral part of mineral engineering and extend into reserve estimation, design, planning, automatic control, and operations. There is no doubt that computing and automation have made great changes in mineral engineering in the past decade and will continue to cause major curriculum changes for some years to come. It is considered impossible to graduate a well-educated mineral engineer today without significant understanding and skill in these areas.

In addition to the fundamental changes mentioned, there is increased concern in mineral engineering education today for coverage of the environment (including reclamation), some study of laws and regulations that have so major an impact on the industry, and at least an introduction to finance and management. These areas, while not new to mineral engineering education, are receiving increased emphasis. New courses are being added and are not infrequently being taught by persons outside the degree-granting department. Existing courses are undergoing major revisions.

To accommodate all these changes, particularly computer applications, automation, and environmental and reclamation emphasis, some standard older courses are being dropped. One school reports that students now enrolling in mining and geological engineering will no longer have to take a separate petrology course. Petrology will be subsumed under several other courses.

Obviously, mineral engineering education is undergoing great change with new and increased resultant demands on students, faculty, laboratory equipment, and space. The problem reported by many schools is that these increased needs come at a time of decreasing enrollment causing, in some cases, a reluctance on the part of central administrations of universities to fund such changes.

The changing emphases noted apply to graduate as well as to undergraduate programs. Schools report especially that these changes are clearly manifest in graduate research and thesis efforts. The traditional greater flexibility of graduate programs has, however, resulted in less major changes in degree requirements.

1.3.5 PROBLEMS OF MINERAL ENGINEERING EDUCATION

In common with all engineering education in the United States, mineral engineering education faces two pressing problems. These are a limited pool of potential students and a probable lack of qualified future faculty.

1.3.5.1 Pool of Students

Several recent studies have indicated that the United States faces a shortage of 300,000 to 500,000 engineers by the year 2010, if universities continue to attract only the traditional engineering student. The most obvious source of additional students is from an increase in the number of women and ethnic minority students entering the engineering profession. It is estimated that the number of women must be doubled and the number of ethnic minority members quadrupled to forestall the impending severe shortage of engineers. Detailed figures as to the needed increase to prevent a shortage of mineral engineers, in particular, are not available.

Nevertheless, it is clear that women and ethnic minority students must be attracted in increasing numbers to the mineral profession. Nearly all engineering schools have active recruitment efforts underway to increase participation of these groups, and the mineral engineering efforts are strong. Industry and professional societies have worked closely with the universities in sponsoring summer short courses, special high school programs and talks, literature, scholarships, and other efforts to recruit women and minorities. These efforts have resulted in some gains, but most mineral engineering schools feel that the efforts must continue to be strengthened and plan to do so.

1.3.5.2 Faculty Shortages

Another concern common to all engineering disciplines is a predicted shortage of qualified faculty. Because over one-half of current graduate students are international students, it is believed that inadequate numbers of future faculty will be available. Although most schools express concern about this problem, there does not appear to be a coordinated, or even a broad, effort to address it. In fact, the percentage of international students in graduate programs has been slowly and steadily increasing over the last several years. Some schools are aiding outstanding foreign graduate students to meet residency requirements and remain in the United States.

Although the great majority of schools seek young faculty holding the PhD degree, there is a growing recognition of the need to obtain help from experienced, part-time, older engineers as faculty members. Retired persons or engineers granted time by industry and government can be of very great help, but schools continue to be concerned about shortages in the traditional, young, PhD-holding faculty pool.

1.3.5.3 Funding Problems

Besides the two major problems discussed, many schools report concern about funding problems in mineral engineering. This concern is felt in two areas—faculty salaries and general support funds.

In some schools, mineral engineering faculty salaries have fallen behind those in more “glamorous” fields of engineering. Such disciplines as electronics, computer, and biomedical engineering are attracting more university salary support, perhaps at the expense of mineral engineering.

Also funds for new equipment, maintenance, and replacement equipment are in increasingly short supply. Concern over the impact of this on instruction and research is frequently expressed by academic people.

1.3.6 FUTURE OF MINERAL ENGINEERING EDUCATION

The section which follows is based largely on informal discussions with colleagues and does not necessarily represent a consensus of mineral engineering educators.

1.3.6.1 General Comments

Without doubt, computer use and instruction will increasingly become a part of course work in mineral engineering programs. The objective will be to give the student a firm familiarity and skill in computer application in addition to formal course work in computer science taken outside the mineral departments. The concentration of instructional effort appears to be on the increasingly powerful PCs and work stations, but some work with larger computers is included. It is believed by many faculty that some computer use will appear in at least one-half of all specialized courses taught in mineral engineering programs.

Automation, which includes process control of all types, is another area that will receive increased instructional and research attention. The object will be to give the student familiarity with the great potential of automation to increase efficiency and reduce costs. It is recognized that this is a specialized area of expertise, but an understanding of principles and general applications must be a part of the mineral engineering graduates’ background. Some departments indicate a strong interaction with chemical engineering departments in instruction in automatic process control.

1.3.6.2 Specific Needs

Foreign Exploration: As new mineral exploration efforts are likely to be concentrated outside the United States, those students who will work in exploration will need to receive training in the economic geology of the Pacific Rim countries and South America, for example. Such courses are already planned at some schools.

Environmental Education: Although environmental engineering and reclamation will become more and more a specialized profession, all mineral engineers will need some education in these important areas. Students specializing in these fields will have course work in such disparate areas as aquatic chemistry, hydrogeology, and air pollution. Legal and regulatory aspects of environmental problems are already covered in some courses. Schools report increasing industrial interest in students receiving such training. The entire field called *waste isolation* will become part of the mineral engineers’ background.

It is believed that course work in this area will require several instructors in each course because of the range and complexity of material covered. Also, graduate student research in environmental studies will become increasingly common. Several schools believe job opportunities in environmental and reclamation specialties are very inviting to increasing numbers of students. As shown in Table 1.3.1, there were 18 accredited programs in environmental engineering in the United States as of 1987, although all were not closely allied with the mineral field.

Materials: In many, but not all, schools materials, engineering has traditionally been combined with metallurgy or extractive metallurgy. Increasingly, materials science and engineering will become a stand-alone program. In this respect, ABET has established separate accreditation criteria for materials and similarly named engineering programs, and metallurgical, materials, and similarly named engineering programs. The rapidly expanding academic efforts in ceramics, polymers, and composite materials are in large part responsible for this change. Metals are no longer the dominant subject in many materials engineering programs. Extractive metallurgy really does not fit into the new materials engineering degree programs at all.

The outcome of what is essentially a reorganization will be different at various schools, and a realignment of departments is inevitable. Nevertheless, in some schools, there is a desire to have mineral engineers receive some familiarity with the new materials being developed, especially in their application to corrosion problems, grinding, transportation, etc. This is simply another example of the increasing range of subjects with which educators want mineral engineering students to have some mastery.

Special Subjects: Schools have expressed growing interest in their mineral engineering students having an introduction to such diverse subjects as budgeting, management, and public relations. Efforts in these areas vary widely among schools and are commonly driven by the concerns of one or two faculty members. There does not appear to be, however, an increasing interest in including them in graduate programs.

Graduate Studies and Research: Historically, a student specializes at the graduate level, and today the student's efforts are more and more controlled by perceived job opportunities. In addition to thesis research in traditional mineral engineering subjects, there is expected to be an increased graduate interest in the subjects given in this segment. Obviously, the input and desires of industry will play a key role in graduate students' efforts.

One other factor has lately appeared. Research funding, as for example, from the US Bureau of Mines and other federal agencies, has been curtailed. As a result, expensive graduate research has been diminished and more and more effort is going into less expensive research, particularly computer modeling. Faculty note this trend away from equipment-intensive research. It is a trend expected to continue.

Continuing Education and Technology Programs: A considerable amount of thinking and planning is going on in the fields of continuing education and engineering technology. There are nine accredited mineral technology programs in the United States (Anon., 1987c). Continuing education is commonly handled in-house by the large companies in the form of specialized training for their engineers, for example, in safety. Upgrading the education of practicing engineers in computer applications and instrumentation is carried out by short courses and, in some cases, by sending engineers back to universities for one or two terms. There is interest by schools in being involved in these efforts for engineers and technicians, and many discussions are underway. Televised courses to plants or offices are also being discussed as a way to reduce lost employee time but achieve the desired education. As yet these efforts in the mineral fields are not widespread or well established, but it is the consensus that they will become increasingly important. Educational institutions are developing continuing education courses in a wide variety of fields.

1.3.7 SUMMARY AND CONCLUSIONS

Clearly, mineral engineering education faces a period of significant change in the near future. This change is driven by a wide variety of factors, chief of which are

1. Declining enrollments at least for the foreseeable future.
2. In some cases, declining university financial support.
3. Some university plans concerning merging or elimination of programs.
4. Some splintering of existing programs such as separation of metallurgical and materials engineering and formation of new programs such as environmental engineering out of older programs.
5. Increased need to recruit women and ethnic minority students.
6. Coming possible shortage of qualified faculty.
7. Major changes in instructional efforts, such as vastly increased computer usage and education and automation and process control receiving strong new emphasis.
8. Calls for more instruction in areas of recent concern such as reclamation and environmental problems, knowledge of laws and regulations, and public relations, resulting in proposals to consider five-year programs.

Mineral engineering programs have traditionally been of high quality and are technically sound at American universities. The decisions made in the next few years may have a very significant influence on degree requirements and methods of instruction, but all educators contacted have insisted vigorously that the quality will remain very high.

There appears to be an increasing tendency for interaction among universities, to exchange data and information so that all mineral engineering programs may benefit from the thinking and experience of others.

Having completed the study for this chapter, the writer cannot help but be very optimistic that mineral industry education, although perhaps involving fewer programs, will continue to produce high-quality, well-trained, modern engineers for the profession. The next generation of engineers will have a significantly different education than its predecessors but will be a major strength to industry and the country.

Section 2 Mineral Economics

SCOTT G. BRITTON, ASSOCIATE EDITOR
MICHAEL RIEBER AND CHARLES W. BERRY, SECTION COORDINATORS

Chapter 2.0
INTRODUCTION

MICHAEL RIEBER

Mineral economics interfaces the mineral sciences and engineering with finance and economics in the analysis of appropriate questions facing the minerals and energy industries. Its practitioners include those trained in the earth sciences; mining, petroleum, and geological engineering; metallurgy and mineral preparation; as well as finance, information systems, economics, and statistics—most usefully in one or more combinations. Allowing for some overlap, three general areas may be identified: evaluation, economic analysis, and resource appraisal.

Evaluation begins with mine investment analysis (exemplified by Gentry and O'Neil, 1984) and process costing, for which the STRAMM Handbook (Anon., 1977) provides a well-known basis for mining and beneficiation. But it extends from property appraisal, often used for the determination of taxes and royalties, through the determination and comparison of transport costs (e.g., Rieber and Soo, 1977), and to benefit/cost analyses of externalities. Economic analysis, the subject of this section, is displayed in rigor and extent both theoretically and as applied to commodity classes in Vogely (1985), but it is implicit though apparent throughout Lefond (1983). The text edited by Vogely places minerals in their aggregative context with economic growth and trade, proceeds to the theoretical analysis of minerals and their markets, analyzes the structure and performance of the major mineral sectors, and concludes with policy issues: fuel, nonfuel, and environmental. Resource appraisal employs quantitative methods for the estimation of mineral and energy resources. It moves through geologic, geophysical, and geochemical properties to the identification of estimation procedures for mineral endowment and for the economic measure of stocks and flows of specific minerals (Harris, 1984). It can be used to estimate the probable amount of a specific resource remaining in a given region and has been used to project sites in a specific quadrangle with the highest probability of an economic occurrence.

Explicitly or implicitly, the tools of economics are used by all in the mineral industries. Resource appraisal seeks to exclude their implicit use by geologists in the estimation procedures, but explicitly includes it to obtain some of the final results. Among the economic tools required for evaluation procedures, the estimation of revenue and cost streams, the determination of the cost of capital, risk adjustments, the determination of the internal rate of return and present discounted value, and the analysis of the impact of taxes are familiar to all. Indeed, the very concept of a minable reserve has an economic component, as do the related concepts of mining grade, cutoff grade, mill head feed grade, concentration, and the rates of production and depletion. Smelter returns are not invariant with respect to market forces nor is the increasing production emphasis in the copper industry from open pit mining to leach-solvent extraction/electrowinning.

The economics interface exhibits irregularities in the area of economic analysis; in some cases, it has been abrasive. This is a function of the users, not the tools. Problems arise because of the subject matter. Economists, including some mineral economists, tend to be interested in (1) forecasting (supply, demand, price, and the cost of capital), (2) the structure of mineral and commodity industries and the competitive behavior of the firms comprising those industries, and (3) in public policy, especially as related to energy, the environment, and land management. At the more aggregate level, the issues include the relation between minerals and domestic economic growth, the development of mineral resources in the Third World, and international trade policy.

When performed by outsiders or academics, the results of these investigations have arguably not always been well received by the mineral industries. Some have been proven wrong; others have run counter to the natural optimism of any established industry. A few have been detrimental to the perceived interests of particular industries or firms. A common complaint is that the work does not fully comprehend the complexity and detail of the industry involved. There is merit in the complaints, especially when due to bias or ill-conception the results adversely affect the interests of a firm or industry. Nevertheless, it is not the economic tools that are at fault; more usually it is a logical consequence of the initial conditions or relationships assumed or estimated by the user. When externalities are important and when the benefits of an action or policy are received by some and the costs borne by others, even conceptually, agreement is rare.

Of necessity, everyone forecasts; history suggests that no one and no group has proven to be prescient. The difference between a formal and an informal forecast may simply be the time horizon, but is more closely related to the rigor with which the variables of interest are estimated and the basis for the decision upon which their inclusion is made (the defensibility in the statistical sense of the check list). At issue is whether addition or deletion of a fact or data series improves forecasting ability or reduces it, and how do we know? Errors arise due to faulty or incomplete data, a misunderstood change in basic industry relationships, or simply due to technical change. An econometric forecast, relying on a long period of stable relations among the variables to provide the basis for extrapolation, may provide a fine fit for the historical data, yet may prove incorrect in the face of major industry changes. Thus a benefit of formal forecasting is that the use of estimated models in the process of model building may force a more critical examination of assumptions and data than that which takes place in informal forecasting. Finally, the confidence limits of the forecasts are often neglected. Pin-point accuracy, a unique estimate, is not possible, and its use is misleading.

Competitive behavior and the structure of industry is widely investigated, not least by those companies with an interest in marketing and the market penetration of their product. Similarly, the economics inherent in the public policy issues and the aggregate relations between the mining industry and the national or international economies are widely discussed by academics, government personnel, and not least by industry representatives as seen, for example, in the articles and editorials contained in the *American Mining Congress Journal.*

If competitiveness is the watchword, economic as well as geologic factors are important. Grade-tonnage relationships are decisive in the long run, but that time horizon is usually longer than the planning period of a firm. In the interim, economic considerations are likely to be decisive. If the cutoff grades for Zairian and Zambian copper are higher than the Chilean and US mining grades, why are the former not the low-cost producers? Alternatively, if their mining grades were not so high, would the deposits be exploited?

Clearly, no study by outsiders is likely to utilize the wealth of detail or information available to onsite practitioners. But, the needed detail and the complexity of the relationships depend upon the issue to be resolved. Some broad relations, patterns, or trends may be clear only when details are aggregated. As both the level of aggregation and the degree of generality increase, the level of abstraction from reality also increases. For both economists and engineers, the world is not made up of a mass of special cases. The trick is to reduce the problem to manageable proportions, consistent with the desired accuracy of the result, without sacrificing anything essential to the result.

Mineral economics is inextricably associated with exploration, mining, mining engineering, processing, product sales, and residuals management. The chapters of this section comprise a relevant, analytical subset of these areas. The authors represent industry, government, and academia.

2.0.1.1 Chapter Overviews

The mineral economics section begins with Chapter 2.1, John Tilton's exposition of mineral supply, demand, and price formation employing the conceptual tools of the mineral economist's trade. For the economist, it is a useful review and check list. For the engineering nonspecialist, it is a lucid statement, with applications, of the theoretical underpinnings of practical analysis. Read in conjunction with the succeeding chapters, it bares their implicit theoretical assumptions and relationships.

Of the major elements that distinguish mineral economics from economics in general (derived demand for minerals, mineral substitution, co- and byproduct supply, recycling or secondary production from scrap, nondegrading stockpiles or inventories, a market structure often dominated by a few suppliers, depletion, and the importance of the time dimension), only depletion is omitted (it is covered in Chapter 2.4). Recognizing the diversity among the minerals and the need for familiarity with their production processes and markets, Tilton concentrates on the commonality of the economics principles needed for their analysis. From the firm to the industry level, the important elements of supply/demand analysis are explained as is the basis for their importance.

As most minerals are not directly consumed by final users but rather by processors or manufactures for final products, demand is treated as derived from the demand for the final products—a factor in the latter's production process. As it is the attributes of the minerals that are important, the role of substitution among minerals in subsequent manufacturing or use is highlighted.

The response of mineral supply to capital and variable costs over the several planning periods is next demonstrated. To this is added the often important role of co- and byproduct production of primary minerals and the secondary metals available from the recycling of scrap. In both supply and demand, but particularly the former, the role of market structure (the number and size distribution of firms) in price formation and the supply response to price changes is demonstrated.

The chapter concludes with two useful applications: the basis for mineral commodity market price instability, and the use of the incentive price technique for forecasting long-run mineral prices. The latter is the price level that ensures the industry level production capacity required to meet a specified or estimated level of demand.

The diversity of the minerals industry is displayed in Anthony Cammarota's commodity review (Chapter 2.2) of the nonfuel minerals of commercial importance in the United States. It provides the basic familiarity with the production processes and markets for individual minerals necessary for effective economic analysis. Some of the groups into which the individual minerals fall are familiar: base metals, precious metals, ferrous and their alloying metals, and the light metals (aluminum, magnesium, and beryllium). The nonmetallics fall into construction materials and agricultural commodity classes, both based on their demand characteristics. Two interesting categories are then presented; commodities produced principally as byproducts (gallium, arsenic, selenium and tellurium, germanium and indium), followed by a discussion of advanced materials (metals, ceramics, and polymers and their composites, e.g., aluminum-lithium alloys).

That diversity does not lead to singularity of the analytical approach to each commodity, even across commodity groups, is demonstrated by the format of the discussion. A general introductory segment shows the relevance to supply and demand of cost changes, economic cycles, environmental control impacts, and foreign competition. Individually, all commodities are discussed in terms of their location, supply sources, principal processing techniques, and byproduct credits as determinants of supply. Demand is related to the commodity attributes of use to their several consuming sectors. Market structure provides a relation between supply and demand. Transport costs help define market extent, the location of downstream processing, and are related to commodity exports and imports.

The chapter concludes with a discussion of import dependence. The analysis is in terms of the geologic, economic, and political reasons for the growing US dependence on imports for an increasing list of mineral commodities.

Mine management, production planning, and mine investment analysis all require a knowledge of present prices and the ability to forecast future prices. The publicly available price series upon which this depends, however, are often quoted in terms of refined products rather than ores or concentrates, and may be quoted differently on one or more international markets. Some mineral prices are quoted at several stages of processing; the quotations need not move in tandem in the short run. For both trade and planning purposes, it is necessary to understand how prices are determined and what they actually represent. In Chapter 2.3, Simon Strauss provides the required background for pricing and trading in metals and minerals.

Strauss begins with the generic issues: the effects of inflation on prices over time and the impact of volatile currency exchange rates on the prices of internationally traded minerals as separately seen by the buyer and seller. The body of the discussion is devoted to an analysis of the methods used to determine mineral market prices and why particular methods are used for different classes of minerals. Discussed separately, with examples, are the bases for pricing at various stages of processing, and the methodology for the determination of (and the reasons behind) producer pricing, prices as reported by independent agents, negotiated prices, and formal commodity market price formation.

Producers and some consumers prefer price stability. The reasons for this and some of the methods used to attain this end are outlined. Using the tin agreement as an example, Strauss shows the pitfalls in such stabilization efforts and why they are short-lived: market forces may be resisted, they cannot be abrogated. The chapter concludes with a view of the shifting focus of trade and processing towards the new sources of mineral mining.

John Whitney and Garth Sibbold (Chapter 2.4) present an overview, not a primer, of taxation in relation to mineral mining. Both federal and state taxes are discussed, the latter being necessarily generic rather than state specific. The context is cash flow analysis as, for example, the expected return on investment as used for project evaluation and the need for an after-tax determination of net present value or the internal rate of return for proper comparison across projects. Federal taxation with respect to exploration and development expenditures, depreciation, and depletion are emphasized. The interrelations between the taxes and business decisions are discussed. Importantly, the tax alternatives available are laid out with their implications for other tax payments shown.

State taxes—property, severance, income, sales, and use—are described along with their implications for both the mining industry and the taxing authority. The former react through adjustment of exploration, development, and production plans as well as by cutoff grades and delineation of minable reserves. The latter are concerned with the amount and predictability of tax revenues.

Any investment is risky. The length of time to profitability, the size of the investment relative to firm size, its front-end loading, and the inherent uncertainties of prices, costs, and political decisions put mine investment in the high-risk class. Chapter 2.5 by Dennis Arrouet, Investment Strategy for Mining Projects, defines the process of mining investment strategy for both US and foreign projects. Risk cannot be eliminated, but it can be identified, adjusted for, and ameliorated.

Market (product) risk arises because mineral demand is derived from that for the final goods containing or using the mineral. Country risk is exacerbated by the high profile of a mining project. Project risk is a function of the capital size, technical considerations, and the time horizons: to explore, to develop or build, to recoup the investment, to profit. Risk reduction is shown to depend on new corporate strategies: low-cost leadership, product and market differentiation, condensation of the time horizon, and a market structure that does not compete away legitimate economic rents.

As profitability must be shown, the discussion proceeds with several illustrative examples to demonstrate the calculations required to determine, given the uncertainties, if the rate of return on the project is adequate. The techniques used to compensate for risk are listed.

Projects require significant capital infusions, leading to an illustrated discussion of capital costs and their relation to the capital structure of the firm over the relevant period. Given the financing method, the means of calculating the contribution of project investment's risk to the firm's financial risk is demonstrated. This leads to the discussion and calculation of the acceptable level of risk-project and financial, as related to the firm's portfolio of projects.

Throughout, mine investment decisions are shown to be a process of the organization, one with steps to follow, check points, and a corporate ethos. Even failure, through painful, is shown to provide lessons. The chapter ends with two extremely valuable check lists: (1) a consideration of the various project participants, the suppliers of good, services, and finance; and (2) an extensive project check list.

Since biblical times, government stockpiles have been viewed by producers alternately as a source of additional demand bolstering prices, especially when excess supply threatens to depress prices, and as price depressing burdens overhanging the market when excess demand creates potential price and profit opportunities. As it is both a function and the nature of a stockpile or any inventory (whether voluntary for business purposes or involuntary due to production exceeding sales) to perform in this manner, irrespective of the objective for which the storage was created, this result is not surprising. In Chapter 2.6, J. Wayne Kulig and John Babey analyze the development of the US National Defense Stockpile, probably the largest and certainly the best known of the current stockpiles.

From the producer's standpoint, stockpile procedures and objectives; purchase and disposal provisions as they apply to mineral supply, demand, and price; purity considerations; and other restrictive provisions are important to the expectations of their industry and of their own firm. The changes in these considerations, 1939–1990, are the subject of the first part of the chapter. The changes have been extensive and intensive. For those who must plan with one eye on Washington, this history bears careful reading.

The final part of the paper includes a sectional analysis of the current (1990) Act, an analysis of its operation (who is responsible for what and what are the connections), and a precis of currently planned future developments to the Act. Two useful appendices provide the provisions of the Strategic and Critical Materials Stockpiling Act and the currently included materials.

Chapter 2.7 by William Holroyd provides an overview of some of the particularities encountered in the trading of minerals. Included are the types of sourcing and contracts, material quality, and financing. The importance of transport provisions, particularly for low value, bulk material, is shown. As trade is not necessarily direct from mine to processor or to manufacturer and need not be conducted for present or future cash payment, both barter and compensation trade are discussed. Finally, the role of minerals trading companies as both agents and dealers is assessed.

Chapter 2.1
ECONOMICS OF THE MINERAL INDUSTRIES*

JOHN E. TILTON

Mineral commodities are normally separated into three generic classes—metals, nonmetals, and energy minerals including oil and gas—and encompass a large number of different substances. Some are extracted from large open pits, others are dug out of underground mines or pumped from deep wells, and still others are processed from the sea. Extraction and processing can be relatively uncomplicated and inexpensive, though in most instances, sophisticated technology is necessary and the costs are high. Some mineral commodities are produced mainly as byproducts of other commodities. Some are recovered in large quantities from new and old scrap. Some are found in only a few locations and traded worldwide; others are produced in many different countries. Some are sold by numerous firms at fluctuating prices determined on competitive commodity exchanges, while others are produced by only a few firms and sold at stable producer prices.

Although this diversity makes the mineral industries interesting, indeed fascinating to study, it also poses problems. There is no general model or economic analysis applicable to all mineral commodities. Rather each mineral commodity must be considered individually, so that the analysis takes explicit account of its particular features.

This means that a single chapter cannot begin to cover comprehensively the economics of all mineral industries, and no attempt to do so is made here. Instead, we will concentrate on illustrating the usefulness of relatively simple economic principles, particularly those associated with supply and demand analysis, in understanding the behavior of mineral markets.

There is one particularly important conclusion that the following pages should make clear. The simple tools of economics can provide powerful insights into the operation and behavior of the mineral industries, but only if the analyst applying these tools has a firm understanding of the important technological and institutional relationships governing the market he or she is examining, and can tailor the analysis to take these relationships explicitly into account. Good analysis requires knowledge of both economics and the particular mineral commodity of interest.

2.1.1 MINERAL DEMAND

Mineral commodities rarely are final goods. Rather they are in demand because they possess certain qualities or attributes, such as strength, resistance to corrosion, or Btus, that are needed in the manufacturing of final consumer and producer goods. This means that mineral demand depends on the demand for final goods, and for this reason is often characterized as a derived demand. Since demand is really for a set of attributes, rather than for a mineral commodity per se, in many end uses one mineral produced can replace another. The importance of mineral substitution is highlighted in the discussion that follows on the major determinants of mineral demand.

*This article is a revised and updated version of another work (Tilton, 1985).

2.1.1.1 Major Determinants

Literally thousands of factors affect mineral demand-cold weather in the Northeast of the United States, perestroika in the Soviet Union, a decision by the French government to modernize part of its naval forces, a World Bank loan to Brazil to build a dam and hydroelectric power station. In analyzing mineral demand, it is not possible to take account of all possible determinants. There simply are too many. Moreover, the effects of most are so trivial they can be safely ignored, and indeed should be ignored to avoid needlessly complicating the analysis. The problem is deciding which features are of such importance they need to be considered. The answer depends not only on the minerals of interest, but also on the purpose and time horizon of the analysis. Technological change, for example, is not likely to alter greatly the demand for zinc over the next three months, but would require careful consideration for an analysis of zinc demand in the year 2020.

The choice of which factors to consider and which to ignore will to a large extent determine the quality of the analysis. In this regard, it is useful to review the determinants often considered in mineral demand studies.

Income: Mineral commodities are used in the production of consumer and producer goods. So changes in the output of these goods have a direct and immediate impact on mineral demand. In this connection, two types of changes in aggregate production or income are often distinguished: relatively short-run changes that come about largely as a result of fluctuations in the business cycle; and longer-run changes caused by secular growth and structural change in the economy.

As income is one of the most important variables affecting metal demand, its influence is almost always taken into consideration. In many studies, gross domestic product (GDP) or industrial output is employed for this purpose. More disaggregated measures of income are also used. For example, in assessing the demand for copper wire, we might use the production of electrical and electronic equipment to capture the effect of income fluctuations.

Own Price: A mineral commodity's own price is also normally an important determinant of demand. Demand tends to fall with an increase in price and rise with a decline in price. There are two reasons for this inverse relationship. First, a higher mineral price increases the production costs of the final goods in which it is used. If these costs are passed on to the consumer, demand for the final goods will fall. Second, and usually of greater consequence, firms may respond to the higher price by substituting another mineral commodity whose price has not risen. It is important, however, to note that mineral substitution takes time. New equipment is often necessary, personnel may have to be recruited or retrained, and production techniques must frequently be altered. Consequently, the initial effect on mineral demand of a change in a price may be quite modest, and a number of years may be needed before the full effect is realized.

Prices of Substitutes and Complements: The demand for a mineral commodity may be affected by prices other than its own. Most compete with other mineral commodities for their end-use markets, and so a change in the price of any such substitute can affect the demand for the others. The sharp rise in the world price of oil during the 1970s, for example, increased the demand for coal and natural gas.

In some instances, a fall in the price of one mineral commodity may actually increase demand for another. In such cases, we say the two are complements. For example, a fall in the price of steel tends to increase the use of tin plate, since tin plate is composed primarily of steel. This, in turn, stimulates the demand for tin.

As with changes in own price, changes in the prices of substitutes and complements affect mineral demand primarily by inducing firms to alter the nature of their production processes. Consequently, some time is required for the full impact of price changes on demand to be realized.

Technological Change: New technology can alter demand in several ways. First, it can reduce the amount of a mineral commodity required in the production of specific items. For example, new alloys and other technological developments have significantly reduced the amount of aluminum in a beer can.

Second, new technology can affect the ability of a mineral commodity to compete in particular end-use markets. This is nicely illustrated by the water-pipe market for home construction, where innovations in the production of polyvinyl chloride (PVC) plastic pipe have allowed this material to capture a sizable market share over the last 25 years. In the process, the demand for copper and other traditional pipe materials has suffered.

Finally, new technology can change the number and size of end-use markets. The advent of the automobile, for instance, gave rise to a major new market for petroleum, steel, and lead.

Since measuring technological change is difficult, some studies ignore this particular determinant. This may not be serious when assessing demand over a very short period, but over the longer term, it is much harder to justify its omission. Other studies simply assume that technological change is closely correlated with time. This allows the use of a time trend to capture the effects of technological change. While such a procedure may be acceptable in some situations, in most the influence of technological change is too random and discrete. The tremendous impact that electrolytic tinning had on the demand for tin was basically a once-and-for-all event. The effects of such major innovations are not likely to be closely correlated with time and should be explicitly and individually taken into consideration.

Consumer Preferences: Changes in consumer preferences affect the end-use markets in which metals are consumed. When preferences shift toward small cars, for instance, the demand for steel, copper, aluminum, and other metals by the motor vehicle industry tends to fall.

Consumer preferences vary over time and among countries for various reasons. The age distribution of the population, for example, can be important. Between the ages of 18 and 35, many individuals are engaged in setting up new family units and spend a relatively large proportion of their income on housing, automobiles, refrigerators, and other consumer durables.

Per capita income and the overall level of economic development also influence consumer preferences. The poor have to spend their limited incomes almost entirely on basic necessities, while the rich can indulge in more luxuries. The rich also tend to save a larger portion of their income. So a shift of income in favor of the poor is likely to reduce the amount of total income saved and invested. Since investment stimulates the construction, capital equipment, and other material-intensive sectors of the economy, such a redistribution may reduce mineral demand.

New technology, by making new and better products available, also causes shifts in consumer preferences. The rapid growth of the airline industry over the last 50 years has substantially increased the use of aluminum and titanium in this market, while reducing the consumption of steel in railroad passenger cars and ocean liners.

Finally, consumer preferences can change simply in response to shifts in personal tastes. In some instances, these shifts are influenced by advertising and psychological considerations that are not fully understood.

Government Activities: Government policies, regulations, and actions constitute another major determinant of metal demand (Chapter 3.2). This is perhaps most dramatically and starkly illustrated when government policies lead to war.

In peacetime, changes in government expenditures on education, defense, research and development, highways, and other public goods alter the output mix of the economy. Fiscal, monetary, and social welfare policies affect income distribution and the overall level of investment and economic growth. Worker health and safety legislation, environmental standards, and other governmental regulations may proscribe certain minerals in particular end uses.

2.1.1.2 The Demand Function

The relation between the demand for a mineral commodity and its major determinants, such as those we have just discussed, is given by the demand function. This economic relationship is often expressed mathematically. In some analyses, for example, demand during year t (Q_t^d) is assumed to depend on only three variables—income during year t (Y_t), own price during year t (P_t^o), and the price of its principal substitute during year t (P_t^s):

$$Q_t^d = f(Y_t, P_t^o, P_t^s) \tag{2.1.1}$$

Several things about Eq. 2.1.1 are worth noting. First, it recognizes only three variables affecting demand. In most situations, as we have seen, there are other important determinants that belong in the demand function.

Second, this equation considers only the immediate- or short-run effects on demand of changes in its determinants. For the income variable, this is not a serious shortcoming, since mineral demand tends to respond rather quickly to changes in the overall level of economic activity. This is not the case for prices. Producers take time to substitute one material for another and in other ways to respond fully to a change in a commodity's own price or that of its principal substitutes. This means that demand this year depends not only on prices this year, but also on prices a year ago, two years ago, and so on for as far back as past prices affect current demand.

Third, while Eq. 2.1.1 identifies important variables presumed to influence demand, it does not specify the nature of the relationship. Normally, a rather simple specification between demand and its determinants is assumed. A linear or log linear relationship, similar to those shown in Eqs. 2.1.2 and 2.1.3, are particularly popular, primarily because they are relatively simple and easy to estimate:

$$Q_t^d = a_0 + a_1 Y_t + a_2 P_t^o + a_3 P_t^s \tag{2.1.2}$$

$$\log Q_t^d = b_0 + b_1 \log Y_t + b_2 \log P_t^o + b_3 \log P_t^s \tag{2.1.3}$$

Unfortunately, such specifications entail rather strong assumptions about the nature of the demand function, whose validity is often difficult to assess.

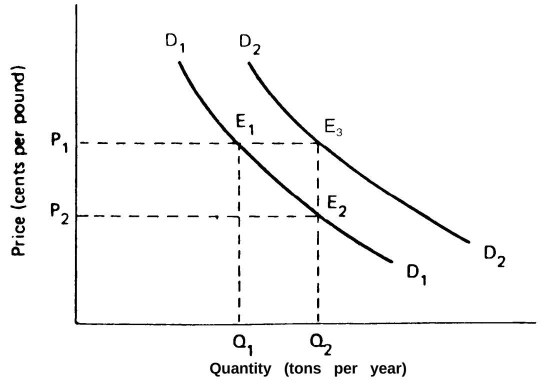

Fig. 2.1.1. Movements along and shifts in the demand curve.

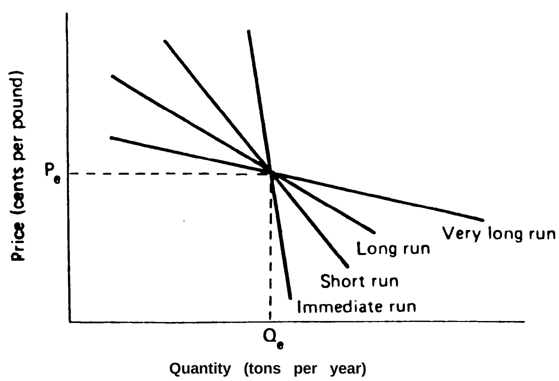

Fig. 2.1.2. Demand curve in the immediate, short, long, and very long run.

2.1.1.3 The Demand Curve

In analyzing mineral markets, we at times focus on one particular variable and try to assess how it alone affects demand. For example, if the US economy is expected to grow by 4% over the coming year, aluminum firms need to know how this will alter their demand.

Another variable of special interest is price, particularly a commodity's own price. The demand curve shows how much of a commodity can be sold at various prices over a year or some other time interval, on the assumption that income, the prices of substitutes, and other determinants of demand remain fixed at certain designated levels.

Normally, demand curves are drawn with a downward slope, like those shown in Figs. 2.1.1 and 2.1.2. Intuitively, one would expect demand to fall as price rises. Still, there can be exceptions. In special circumstances, the demand curve, at least over a significant segment, can be vertical (implying that consumers want a particular amount of the commodity, no more and no less, regardless of its price); horizontal (implying that above a particular price consumers demand none of the commodity while below that price their demand is insatiable); and upward sloping (implying that consumers actually increase their demand as price goes up). Such situations are rare, but when they do occur they are likely to be of considerable interest and importance.

Several other characteristics of the demand curve should also be noted:

1. A movement along the curve reflects the effect of a change in a commodity's own price. A change in any of the other variables influencing demand causes a shift in the curve itself. In Fig. 2.1.1, for example, demand can increase from Q_1 to Q_2 because price falls from P_1 to P_2, causing a movement along the curve DD_1 from point E_1 to E_2. Or the same increase can occur because the demand curve shifts from DD_1 to DD_2, causing the equilibrium point to move from E_1 to E_3. Such a shift in the demand curve can occur in response to a rise in income, a new technological development, an increase in the price of a substitute commodity, or a change in one or more of the other demand variables. In using demand curves, it is important to keep clear the distinction between a movement along the curve and a shift in the curve.

2. The same commodity may have many different demand curves. At the most aggregate level is the total demand curve, which indicates how much all buyers are willing to buy at various price levels. On the buyers' side of the market, we can define demand curves for individual buyers, for regional or national markets, for a country's imports, and for particular consuming sectors or industries. We can distinguish between the demand curve for consumers and the demand curve for speculators and hoarders. On the seller's side of the market, a similar breakdown is possible. So for refined copper, we can identify a demand curve for the world as a whole, for the United States, for the telecommunication sector, for AT&T, for speculative stocks, for US imports, for US exports, for US producers, for Cyprus Minerals Co., and so on.

3. The demand curve—and the demand function as well—indicate the demand for a commodity and not its consumption or production (even though the horizontal axis on the demand curve is sometimes identified as output). *Demand* is the quantity of a commodity that can be sold at a particular price in a given market over a year or some other time period. If the US government is selling tin from its strategic stockpile, or if speculators or other private stockholders are drawing down their inventories, production may be considerably below demand. Even in the case of a demand curve specifically for producers, production will be less than demand when producers are liquidating their inventories and more than demand when they are building up inventories. Similarly, consumption will be above demand when consumers and other buyers are decreasing their stocks and below demand when they are increasing their stocks.

Over a number of years, the differences between consumption, production, and demand are small and can safely be ignored. This is because inventory changes over, say, 10 years will largely cancel out, and any remaining differences will be small compared to cumulative demand over such a period. Usually, however, demand curves indicate how much of a commodity is needed over a year or shorter period, and so changes in stocks can cause sizable discrepancies among production, consumption, and demand.

4. The demand curve does not indicate how the effect of a price change varies with respect to time. Rather, it assumes, explicitly or implicitly, one specific adjustment period. In this connection, economists typically distinguish between (1) the *short run,* a period sufficient for firms to adjust output by altering their labor, raw material, and other variable inputs, and (2) the *long run,* a period long enough for firms to vary their fixed inputs, such as plant and equipment, as well as variable inputs.

In examining mineral markets, it is useful at times to consider what we will call the *very long run,* which provides time not only for all inputs to change, but also for the development and introduction of any new technology induced by price changes. At the other end of the spectrum, the *immediate run* is needed in addressing certain mineral issues. It provides so little time for adjustment that firms find it infeasible to alter their output. Only changes in inventories are possible. As illustrated in Fig. 2.1.2, the responsiveness of demand to price increases with the adjustment period.

Just how long the immediate, short, long, and very long runs are in practice is complicated by the fact that no one answer is valid for all situations. The lag between an infusion of variable inputs and increased output depends on the manufacturing process and may even vary over time for the same process. Similarly, new capacity can be built more quickly in some industries than others. Normally, we would not expect the immediate run to last for more than several months, and the short run for more than about several years. The shift from the long to very long run is more difficult to pin down. Some of the new technology induced by a price change may occur quickly, indeed within a year or two, but other developments may take decades.

The time dimension introduced by the immediate, short, long, and very long runs should not be confused with the time interval over which demand is measured. All of the curves drawn in Fig. 2.1.2 presume that demand is in tons per year. The very-long-run demand curve does not indicate how much of a commodity will be demanded over a very long period, for example, over the next 20 years. Rather, it indicates how much will be demanded per year in 20 years time as a consequence of a price change today, assuming prices stay at the new level and all other determinants of demand also remain unchanged.

Since neither of these conditions will hold for 20 years, it is best not to think of the very-long-run demand curve as showing annual demand 20 years from now. What it shows is the new equilibrium towards which demand is moving over the very long run in response to the price change. Long before this equilibrium is actually reached, price and other determinants will change again, causing the trend in demand to shift course and follow a new path towards a different equilibrium.

5. The downward-sloping demand curve, as commonly drawn, implies that the relationship between price and demand is continuous and reversible. Continuity means that the demand curve is smooth, like those drawn in Figs. 2.1.1 and 2.1.2, without any kinks or breaks. Reversibility means that if price, after an upward or downward movement, returns to its original level, demand will also return to its original level. In other words, one can move up and back down the same curve in response to price changes without causing the curve itself to shift.

For the immediate and short-run demand curves, reversibility seems reasonable. If the desired level of stocks that consumers and others wish to hold declines by a certain amount as price rises, the reverse is likely when price eventually falls. Mineral substitution that can occur in the short run by its nature involves changes that can be made quickly with minimal costs and disruption. After such a switch, it should be relatively easy to switch back to the original mineral commodity.

Reversibility is less likely with the long-run demand curve. Here mineral substitution will entail new equipment, lost production, and other conversion expenses. As a result, a firm will not switch back to a mineral product until its price falls considerably below the level at which its replacement became attractive. In the very long run, the assumption of reversibility is even more doubtful, for now price-induced innovations may substantially change the underlying technical and economic conditions governing the demand for a mineral commodity.

The assumption of continuity may also not hold, particularly for those commodities whose consumption is concentrated in a few major end uses. Over a wide range, price may rise with little or no effect on demand. Then at a particular threshold, an alternative becomes more cost effective in a major application, causing demand to drop sharply. Such discrete jumps or breaks may be found in both short- and long-run demand curves. They are particularly likely to characterize the very-long-run demand curve, as price induced innovations by their nature are discrete events. When they do occur, they can have a substantial impact on demand.

2.1.1.4 Demand Elasticities

In addressing many mineral issues, we need to know how sensitive demand is to a change in price. The measure economists use for this purpose is the elasticity of demand with respect to own price, or simply the *price elasticity of demand.* As Eq. 2.1.4 indicates, it is defined as the negative of the partial derivative of demand with respect to own price times the ratio of own price to demand. Since an increase in price normally produces a decrease in demand, this derivative is itself negative, making the price elasticity a positive number.

$$E_{Q_t^d,\ P_t^o} = -\frac{\partial Q_t^d}{\partial P_t^o} \cdot \frac{P_t^o}{Q_t^d} \tag{2.1.4}$$

$$= -\frac{\text{percent change in } Q_t^d}{\text{percent change in } P_t^o} \tag{2.1.4a}$$

For many, it is easier to remember the price elasticity of demand as the percentage increase in demand resulting from a 1% reduction in price, as shown in Eq. 2.1.4a. If the increase in demand is greater than l%, the elasticity is also greater than one, and we say that demand is elastic. When the elasticity is less than one, demand is inelastic.

Since the derivative of demand with respect to price is equal to the inverse of the slope of the demand curve, where two curves cross, the elasticity of demand will be lower for the curve with the steeper slope. This means that demand at the point where the curves intersect in Fig. 2.1.2 is most elastic in the very long run, and becomes increasingly less elastic in the long, short, and immediate runs. This, of course, is exactly what we would expect, for consumers have more opportunities to increase or decrease the usage of a material in response to a price change the longer the period they have to adjust.

If the relationship between demand and price is linear, as is assumed in Fig. 2.1.2 (and earlier in Eq. 2.1.2), the slope of the demand curve is the same at all points. This means that the price elasticity of demand decreases as one moves down the demand curve, and the ratio of price to demand falls. Consequently, other than at their intersection point, we must be careful in comparing the demand elasticities of two curves. The steeper curve will not necessarily have the lower elasticity everywhere.

At times, the relationship between demand and price is assumed to be linear in the logarithms, as in Eq. 2.1.3. In this case, the elasticity does not vary with the level of price and demand; a 1% decrease in price produces the same percentage change in demand over the entire demand curve. The latter, if drawn using logarithmic scales, is a straight line whose slope alone determines the price elasticity of demand. So one can easily compare the elasticities of two curves, even at points where they do not intersect. These properties make the logarithmic relationship popular in analyzing material demand. However, as stressed earlier, its use is appropriate only if there are good reasons to believe it reflects the true relationship between demand and its determinants.

Up to this point, we have considered only the price elasticity of demand. It is possible to define a separate elasticity for every variable affecting demand, though in practice we normally encounter only two others—the elasticity of demand with respect to the price of substitutes and the elasticity of demand with respect to income.

The elasticity of demand with respect to the price of a substitute, often called the cross (price) elasticity of demand, measures the percentage increase in demand for a material caused by a 1% increase in the price of a substitute. It too will be larger in the long and very long run than in the immediate and short run, since the opportunities to respond to a change in a substitute's price grow with the adjustment period.

The income elasticity of demand similarly measures the percentage increase in demand caused by a 1% rise in the GDP or some other measure of income. Since the demand for final goods, and in turn the demand for the raw materials needed to produce these goods, responds fully to a change in income rather quickly, the income elasticity does not increase with the adjustment period. There is consequently no need to distinguish among the immediate, short, long, and very long runs, as is the case for own and cross price elasticities.

Another distinction, however, is significant. Earlier, we noted that a change in income can be separated into two parts: a cyclical component caused by short-term fluctuations in the business cycle, and a secular component caused by long-term growth trends. Which of these is primarily responsible for an income change will affect the magnitude of the demand response and the size of the income elasticity.

The demand for many mineral commodities is particularly responsive to income changes caused by business cycle fluctuations. Metals and other materials, in particular, are consumed primarily in the capital equipment, construction, transportation, and consumer durable sectors of the economy, which use them to produce automobiles, refrigerators, homes and office buildings, new machinery, and other such items. These sectors boom when the economy is doing well, and they suffer severely when it falters. Since small fluctuations in the business cycle cause major change in their output and in turn the demand for materials, the income elasticity is normally greater than one when the business cycle is responsible for changes in income.

When income changes are the result of secular growth trends, the traditional and still very common presumption is that mineral demand grows or declines in direct proportion with income. The income elasticity of demand in such situations is thus one.

In recent years, this assumption has come under attack, in part because energy and metal consumption has not kept pace with income growth in many countries. As income grows, the desired mix of final goods may change, affecting mineral usage and causing the income elasticity of demand to deviate from unity. Indeed, Malenbaum (1975, 1978) and others writing over the last two decades on the intensity of material use provide a rationale for expecting just such a shift.

They contend that countries in early stages of economic development with low per capita incomes are largely agrarian. Their intensity of material use, defined as the amount of material consumed per unit of GDP, is quite low. As such countries begin to industrialize, they invest in basic industry, infrastructure, and other material intensive projects, which cause their intensity of use to rise. As development proceeds, the demand for factories, water and sewer systems, roads, housing, schools, and automobiles is gradually satisfied, and the composition of final production shifts away from manufacturing and construction and toward services. For this and other reasons, they believe the relationship between the intensity of material use and per capita income follows an inverted U-shaped curve similar to that shown in Fig. 2.1.3 for steel use in the United States. This implies that the income elasticity of demand is greater than one for developing countries operating on the rising portion of the intensity of use curve, and less than one for developed countries on the declining portion.[a]

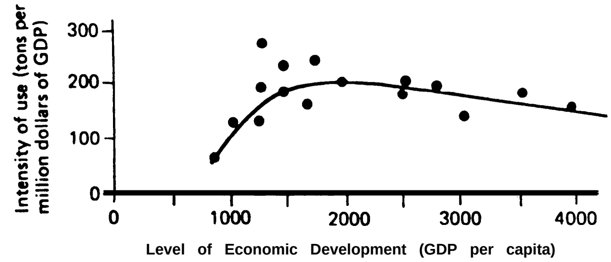

Fig. 2.1.3. Relationship between intensity of steel use and per capita income in the United States, 1888-1967 (Anon., 1974, p. 58). GDP is measured in constant (1963) dollars. Points shown in the figure are five year averages, through which a free hand curve has been drawn.

Canavan (1983), Radcliffe et al. (198l), Roberts (1985), and others have raised some serious questions regarding the intensity of use hypothesis, though most of the criticisms concern its use for forecasting. The evolution it anticipates as a country develops and per capita income rises in the importance of mineral intensive goods in overall GDP, while far from proven, certainly seems plausible.

In summary, the income elasticity of demand for mineral commodities depends on several considerations. When the business cycle produces a change in income, for metals and other mineral materials, the elasticity will normally be greater than unity. When secular growth causes change in income, the elasticity is likely to be greater than unity only if growth is concentrated in developing countries on the upward sloping portion of their intensity of use curve. It will be less than unity if growth is concentrated in developed countries on the downward sloping portion of their intensity of use curves.

Since the full impact of a change in income is quickly transmitted to the demand for mineral commodities, the income elasticity of demand is the same in the immediate, short, long, and very long run. This is not the case, however, for the elasticity of demand with respect to own price or the price of substitutes. With price changes, the longer the adjustment period, the greater the demand response. Consequently, these elasticities are often less than one in the immediate and short run and greater than one in the long and very long run.

2.1.2 METAL SUPPLY

Many mineral commodities, such as oil, coal, bauxite, and iron, are typically extracted as single or individual products. Others are produced as joint products. For instance, molybdenum and gold are often found in porphyry copper deposits, and nickel sulfide mines may produce copper as well.

[a]This assumes that part of any rise in income is accompanied by an increase in per capita income. It is possible, though unlikely, for income to increase solely as a result of population growth with per capita income remaining stagnant. In this case, there is no movement along the intensity of use curve and no change in the ratio of material usage to GDP. A 1% increase in income causes a 1% increase in material consumption, and the income elasticity of demand is one.

Where joint production occurs, main products, coproducts, or byproducts may be recovered. A main product is so important to the economic viability of a mine that its price alone determines the mine's output. A byproduct on the other hand is so unimportant its price has no influence on mine output. When prices of two or more joint products affect output, they are coproducts.

Once processed and consumed in the production of final goods, some mineral commodities, specifically metals, are often recovered and reused. Most of the gold ever mined, for example, is still in use. Recycling is called secondary production, not because recycled or secondary materials are inferior, but because the scrap from which they are made is not the original or primary source of the product.

This segment examines mineral supply, looking first at the primary production of individual products. It then considers how the recovery of byproducts and coproducts and secondary production supplement supply.

2.1.2.1 Individual Products

In examining mineral supply, we again want to concentrate on the few most important variables. Just which variables are worthy of consideration varies with the commodity, the source of supply, the time of adjustment, and other factors, and calls for considerable judgment on the part of the analyst. While no single list is appropriate for all situations, the following variables are often important.

Own Price: Firms have an incentive to increase their output up to the point where the costs of producing an additional unit just equals the extra revenue they receive from selling that unit. Consequently, a rise in the price of a mineral commodity normally increases its supply, while a fall in price reduces its supply.

In the short run, however, the response of supply to a price change may be constrained by existing capacity. It takes time to develop new mines, drill new wells, and build processing capacity, and so producers may need 5 to 7 years to respond fully to a price increase. An even longer time may be required to adjust fully to a price decrease. Extraction and mineral processing are capital intensive activities, requiring equipment and facilities with long productive lives. Firms will remain in production, despite a fall in price below average costs, as long as they are recovering their variable or out-of-pocket costs. Only when existing plants and equipment need to be replaced will they cease production.

Input Costs: The costs of labor and other inputs used in extraction and processing also affect profitability and, in turn, supply. For example, the rise in world oil prices during the 1970s sharply increased the costs of producing aluminum in Japan. Again the long lags in adjusting capacity to new conditions mean that the full effect of a change in costs on supply may take a number of years.

Technological Change: Advances in technology that reduce the costs of extraction or processing also affect mineral supply. For example, the mining of copper from large open pit porphyry deposits became feasible in the early years of the 20th century as a result of the introduction of the flotation process for concentrating such low-grade ores. Advances in excavating capability—more powerful blasting techniques, bigger trucks, and stronger shovels—have since helped keep low-grade deposits economic at constant or even lower real prices.

Strikes and Other Disruptions: Industry-wide strikes have in the past closed down the US copper industry and the Canadian nickel industry for months. Inadequate precipitation in the Pacific Northwest has curtailed hydroelectric power generation, and in turn aluminum production, in that region. Rebel invasions into the Shaba Province of Zaire, the world's largest producer of cobalt, have on several occasions disrupted world supplies of this important metal. Strikes, mine accidents, natural disasters, civil disturbances, and other such disruptions can affect the supply of a metal by interrupting either its production or transportation.

Government Activities: Government actions influence metal supply in a variety of ways. Environmental regulations and state-imposed severance taxes tend to increase costs and reduce supply. Abroad some countries require that mining companies purchase supplies from domestic producers, process ores and concentrates domestically, and employ nationals for managerial and technical positions, even though these restrictions may reduce efficiency and increase costs. Alternatively, governments may stimulate supply by subsidizing new mines or processing facilities.

Market Structure: Where a few firms or countries account for most of a mineral's production, they may maintain a producer price or, in the case of oil, a cartel price. As discussed later, this alters the nature of supply.

In addition, over the last 30 years, the number and importance of state-owned mining companies have grown. In their production and marketing decisions, such firms may be less concerned about earning profits than maintaining employment, foreign exchange earnings, and other public goals. If so, their market supply is likely to respond less to price signals, particularly to low prices during market recessions.

The relation between the supply of a metal and its principal determinants, such as those just discussed, is given by the supply function. Normally, it is expressed mathematically. Equation 2.1.5, for example, is the function for a metal whose supply Q_t^s depends on its price P_t^o, the wage rate paid by producers W_t, the cost of energy E_t, and strikes S_t.

$$Q_t^s = g\,(P_t^o, W_t, E_t, S_t) \tag{2.1.5}$$

This is a rather simple supply function. It does not consider technological change and certain other variables that often affect supply. It contains no lagged values of the price or cost variables, and hence takes account only of their short-run influence. Finally, its exact specification is not indicated.

The relationship between a commodity's price and its supply is often of special interest. It is portrayed by the supply curve, which shows how much producers will offer to the marketplace at various prices over a year or some other time period, on the assumption that all other variables affecting supply remain at some specified level.

The supply curve is normally drawn sloping upward, indicating that supply increases with price. This positive relationship seems plausible for reasons already mentioned, though it can be derived in microeconomics from the theory of the firm.

In special circumstances, however, the curve can, over the relevant portions, be horizontal (implying that sellers are willing to provide the market with as much as they have to offer at a particular price and with nothing below that price), vertical (implying that sellers will provide to the market a given quantity, no more and no less, regardless of the price), or downward sloping (implying that sellers will offer more to the market the lower the price).

Such behavior can occur for various reasons. Firms may maintain a producer price at which they are prepared to sell all of their available supplies. In other instances, a change in price may not alter the output because firms are already operating at full capacity. Some firms, for instance, state enterprises, may continue to produce at or near capacity, even though it would be more profitable to reduce output in order to avoid laying off employees. Some may even attempt to increase production when price falls if they feel responsible for maintaining their country's foreign exchange earnings.

While such situations do occur, they are unusual. Normally, the supply curve is upward sloping, and in this important respect differs from the demand curve. Other characteristics of the supply curve, however, are the same or similar to those discussed for the demand curve.

For example, a movement along the supply curve reflects a change in price, while a shift in the curve itself reflects a change in one of the other determinants of supply. There are also many different supply curves. For refined copper, for example, separate curves are possible for the supply of all producing firms, for the supply of US producing firms, for the supply of Cyprus Minerals Co., for the supply of US exports, for the supply of US imports, for the supply from US government stockpiles, and so on.

Supply reflects how much sellers are willing to offer in the marketplace, and so like demand should not be confused with consumption or production. Where the supply and demand curves intersect, the quantity desired by buyers and the quantity offered by sellers are equal, and at that price the market clears.

As normally drawn, the supply curve assumes that the relationship between price and supply is continuous and reversible. In practice, neither condition always holds. Some mines and smelters operate on a very large scale. When they begin or stop production, supply experiences a discrete jump. Similarly, when price goes up, it may induce higher wages, shifting the supply curve to the left, which makes it impossible to move back down the original curve. Alternatively, higher prices may stimulate new technology and lower costs, causing the supply curve to shift to the right. In this situation, should price return to its initial level, supply would be greater, not less, than originally.

The supply curve also assumes that metal producers have a certain amount of time to adjust to changes in price, input costs, and other determinants. Here, as with demand, it is useful to distinguish four adjustment periods and in turn four types of supply curves: the immediate, short, long, and very long run.

In the *immediate run,* firms do not have time to alter their rate of production. Consequently, supply cannot exceed current output plus available producer inventories or stocks. If demand is weak, they can build up inventories for sale at a later time. So the immediate-run supply curve is not everywhere vertical or nearly vertical, as one might first think.

Before assessing the general shape of the immediate-run supply curve, we need to distinguish two types of metal markets, producer markets and competitive markets, for the supply curve is different for each. Firms in producer markets quote the price at which they are prepared to sell their product. These markets, normally characterized by a few major sellers, have relatively stable prices, though when demand is weak, actual prices may fall below quoted producer prices as a result of discounting and other concessions. Steel, aluminum, and magnesium are a few of the metals sold in producer markets.

In competitive markets, price is determined by the interplay of supply and demand and is free to fluctuate as much as necessary to clear the marketplace. Many buyers and sellers are typically active in competitive markets, and price is often set on a commodity exchange, such as the London Metal Exchange (LME) or the New York Commodity Exchange (Comex). Tungsten, manganese, and silver are metals sold in competitive markets.

Producers are price takers in competitive markets and have no influence over the going market price. Nevertheless, they still control their own supply.

An immediate-run supply curve for producers selling in a competitive market is shown in Fig. 2.1.4a. At very low prices, it

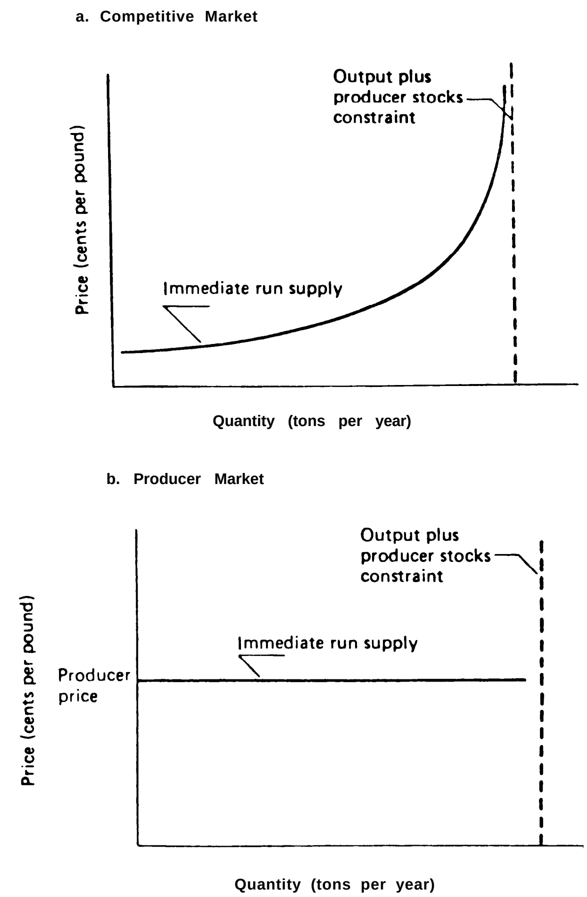

Fig. 2.1.4. Supply curves in the immediate run.

indicates that no supply is forthcoming as production is withheld from the market in anticipation of higher prices in the future. At some point as price rises, supply begins to come onto the market. Once this threshold is reached, supply at first expands greatly in response to higher prices as more and more current production is offered for sale. Eventually, however, further increases in supply must come from inventories. Since producers will deplete their stocks only at high prices, and since stocks can normally augment supply by only modest amounts compared to current output, the supply curve shown in Fig. 2.1.4a becomes quite steep at high prices, and finally vertical. As the curve approaches the constraint imposed by current production plus producer stocks, firms are unwilling or unable to add further to supply by drawing down inventories.

An immediate-run supply curve for a producer market is illustrated in Fig. 2.1.4b. It is simply a horizontal line at the producer price that extends from zero to an amount equal to current production plus the stocks producers are willing to sell. Since firms cannot increase their output in the immediate run, current production plus available producer stocks impose a constraint on supply. Figure 2.1.4b shows the curve stopping slightly before this barrier, as producers usually are not willing to sell all their available stocks.

The supply curve in Fig. 2.1.4b assumes that firms faithfully adhere to the producer price. If this is not the case, if some or all firms discount the producer price at times of weak demand, the curve is not perfectly horizontal, but instead drops somewhat at lower quantities reflecting these price concessions.

The curves shown in Fig. 2.1.4 indicate that, in both competitive and producer markets, metal supply is quite responsive to price until supply approaches current output plus producer stocks. At this point higher prices attract little or no additional supply into the market.

To assess the responsiveness of supply to price, economists use the elasticity of supply, defined as the partial derivative of supply with respect to price times the ratio of price to supply, as shown in Eq. 2.1.6.

$$E_{Q_t^s,\ P_t^o} = \frac{\partial Q_t^s}{\partial P_t^o} \cdot \frac{P_t^o}{Q_t^s} \tag{2.1.6}$$

$$= \frac{\text{percent change in } Q_t^s}{\text{percent change in } P_t^o} \tag{2.1.6a}$$

This measure reflects the percentage increase in supply produced by a 1% rise in price.

We say that supply is elastic when the elasticity is greater than one, and inelastic when it is less than one. Where the supply curve is vertical (as on the right side of Fig. 2.1.4a), or where it simply ends (as on the right side of Fig. 2.1.4b), supply is completely unresponsive to price and the supply elasticity is zero. Where the supply is flat or horizontal, supply is highly or infinitely responsive to price and the elasticity is very large.

In the *short run,* producers have time to change output but not capacity. So the supply curve is constrained by existing capacity rather than current production. If the industry is not operating at full capacity, this means the supply curves shown in Fig. 2.1.4 for both producer and competitive markets are extended in the short run by the amount of available idle capacity.

In the *long run,* new mines can be developed, wells drilled, and processing facilities built. Firms can also expand the capacity of existing operations. Consequently, the relatively flat or elastic portions of the supply curve encompass far more output than in the immediate or short runs. Only after all known deposits or fields are in operation does the supply curve stop or become vertical.

In the *very long run,* even the constraint imposed by existing deposits no longer holds, as firms have the time to conduct exploration and find new reserves. New technology may also permit the exploitation of new types of deposits.

So in the very long run, no barrier or constraint forces the supply curve to terminate or become vertical.[b] Consequently, the very-long-run supply curve, in contrast to the other supply curves we have considered, may be relatively flat or elastic over its entirety with no terminal point. In fact, for a number of mineral commodities sold in competitive markets, it may become more elastic at higher prices and quantities, because more costly sources of supply or deposit types are found in greater numbers and contain on average more metal. Large porphyry copper deposits containing about 0.4% copper, for example, are fairly abundant, and many have been found over the last 30 years. Should the price of copper reach the level needed to make such deposits attractive, supply would expand greatly.

The major differences just discussed among the four time-related supply curves are highlighted in Fig. 2.1.5a for competitive markets and in Fig. 2.1.5b for producer markets. It is particularly important to notice how the supply curves in both types of markets expand over increasingly greater quantities as the time permitted for adjustment increases, allowing first the output constraint, then the capacity constraint, and finally the known deposits constraint to be overcome. So in the very long run, no constraint on supply may exist, and supply may be elastic over the entire range of plausible outputs.

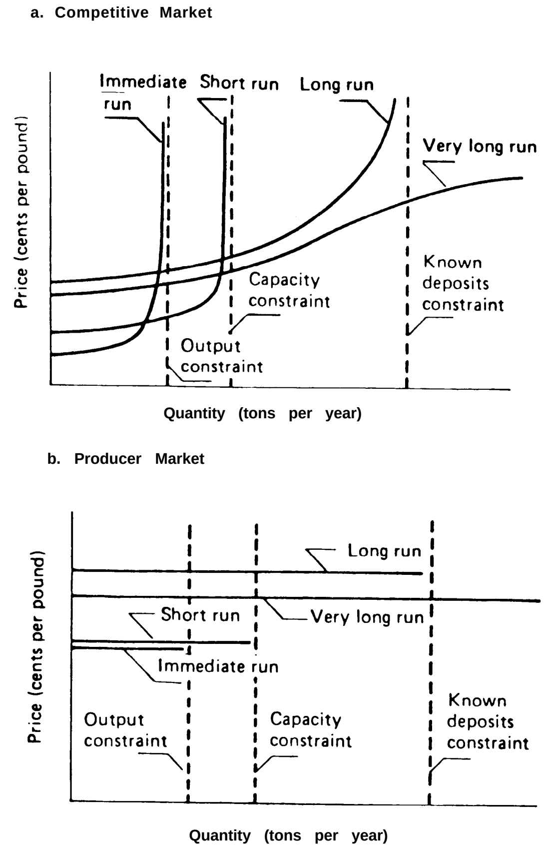

Fig. 2.1.5. Supply curves in the immediate, short, long, and very long run.

The relative vertical positions of the curves shown in Fig. 2.1.5 are based on certain presumptions about the influence of production costs on supply. In the case of producer markets, for example, we assume the producer price (which determines the height of the supply curve) is set on the basis of average total production costs at a standard or representative level of capacity utilization. These costs are likely to be similar in the immediate and short run, since capacity is fixed. In the long run, as new and presumably higher cost deposits are brought into production, average total costs will probably rise. In the very long run, though, new discoveries and the exploitation of new types of deposits should keep average total costs below those of the long run. Consequently, in Fig. 2.1.5b, the immediate- and short-run supply curves are drawn at about the same height, the very-long-run curve somewhat higher, and the long-run curve even higher.

Unfortunately, we still have much to learn about how producer prices are set and the extent to which they are actually tied to production costs. While average total costs may often be the major determinant, there are presumably instances when this is not so and when other factors are important. So the relative

[b]It is true that the earth is finite, and so the amount of oil, copper, and other minerals it contains is fixed. But the quantity of every mineral commodity found in the earth's crust compared to the amount supplied annually (which is what the supply curve relates to price) is so enormous that this ultimate constraint is not relevant here.

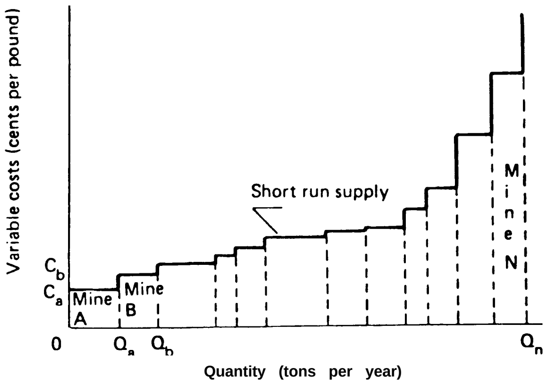

Fig. 2.1.6. Short-run supply curve derived from capacity and variable cost data.

heights of the curves in Fig. 2.1.5b should be considered simply as plausible and illustrative.

For competitive markets, the immediate-run supply curve is drawn below the short-run curve in Fig. 2.1.5a until output approaches the output constraint. Firms have two options available in the short run for reducing their supply—they can cut production in addition to building up inventories—and so are more likely to supply less at any particular price when demand is low.

The short-run curve, in turn, lies below the long-run curve until output approaches the capacity constraint. This is because firms in the short run, in contrast to the long run, have an incentive to continue production when price is below their average total costs so long as they are recovering out-of-pocket or average variable costs.

The long-run curve in Fig. 2.1.5a is also shown above the very long-run curve, for in the very long run the discovery of low-cost deposits and the development of new deposit types should reduce costs and in turn the price required to elicit any level of supply.

Economists have much more to say about the relationship between prices and costs in competitive markets than in producer markets. In the short run, according to microeconomic theory, competitive firms will have, as pointed out earlier, an incentive to produce and supply a commodity as long as price covers average variable costs. Since variable costs do not include the costs of capital and other fixed inputs, in the short run firms may remain in production even though they are losing money. This is because fixed costs must be paid whether a firm produces or not, and so losses are minimized by staying in the business as long as price is above variable costs.

This suggests that one might estimate the short-run supply curve for a metal sold in a competitive market by determining the average variable costs and capacity associated with each operating mine. This information can then be arranged as in Fig. 2.1.6, so that mine A with the lowest average variable costs *(OC_a)* and capacity *(OQ_a)* is shown first, mine B with the second lowest variable costs *(OC_b)* and capacity *(Q_aQ_b)* next, and so on. The resulting curve under certain conditions traces out a short-run supply curve. It approximates the short-run marginal costs curve for the industry, and shows how costs increase as the industry expands output by bringing back into operation mines with increasingly higher production costs.

While this procedure is used by mineral firms and others (Anon., 1987; Torries, 1988) and can provide useful insights into the nature of the short-run supply curve, it is predicated on several assumptions. All producers must have similar shutdown and start-up costs and share similar views regarding future price movements. Otherwise, some mines may remain operating while lower-cost competitors shut down because they have higher shutdown and start-up costs, or because their managers anticipate a rapid recovery of prices. In addition, governments must not provide subsidies or other public assistance when prices decline to keep marginal mines from closing. And, all producers must be primarily interested in maximizing profits. In practice, of course, these conditions may not be met. State-owned enterprises in foreign countries, for example, may remain in production even when the market price drops below their variable costs because employment and foreign exchange earnings are more important than profits. When this is the case, the actual short-run supply curve lies below that shown in Fig. 2.1.6.

Long-run supply curves for metals sold in competitive markets can also be derived using a similar procedure. The US Bureau of Mines (Anon., 1987), Torries (1988), and others have estimated the average total costs, including a competitive rate of return on invested capital, associated with all known deposits and their annual production capacity for copper and other metals. With this information, the industry's long-run supply curve is approximated in a manner similar to that illustrated in Fig. 2.1.6. Though, of course, the long-run supply curve is based on average total costs, not average variable costs, and must take account of all known deposits, including those that have not yet been placed into production.

Again this approach can provide useful insights into the nature of supply, but it does presume that undeveloped deposits will be brought into operation in order of their average total costs and only after price rises to a level that covers these costs. In practice, this is not always so. Some deposits come on-stream sooner because host governments are willing to provide expensive infrastructure and in other ways subsidize their development. On the other hand, political risk, heavy taxation, and other adverse public policies may delay the development of other deposits.

2.1.2.2 Byproducts and Coproducts

So far, we have taken account of only the primary supply of individual products. Often, however, particularly in the case of metals, two or more commodities are recovered from the same ore body. In such instances, as pointed out earlier, we can distinguish among metals mined as main products, coproducts, and byproducts. A *main product* is by definition so important that it alone determines the economic viability of a mine. When two metals must be produced to make a mine economic, both influence output, and they are *coproducts.* A *byproduct* is produced in association with a main product or with coproducts. Its price has no influence over the mine's ore output, though normally as we will see it does affect byproduct production.

Main product supply is quite similar to that for individual products discussed previously, and so is not considered further here. Instead, this segment, drawing on Brooks (1965), highlights the differences between the supply of byproducts and coproducts on the one hand and the supply of individual products on the other.

Before proceeding, however, we should point out that some metals, such as gold, silver, and molybdenum, are main products at some mines, coproducts at other mines, and byproducts at still other mines. To determine the total primary supply for such metals, one needs to assess main product, byproduct, and coproduct supply and then add them together. Moreover, gold and other metals may at some mines be a byproduct at times

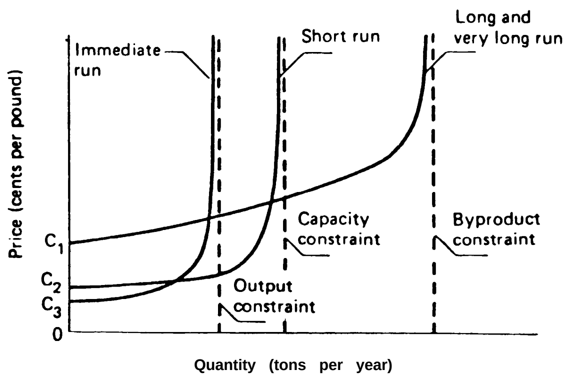

Fig. 2.1.7. Supply curves for byproduct metal in a competitive market.

and a coproduct or even main product at other times, if the price of gold and associated metals varies greatly.

Byproduct Supply: There are two important differences between the supply of byproducts and the supply of individual or main products. The first is that byproduct supply is limited by the output of the main product. The amount of molybdenum recoverable as a byproduct of copper production, for instance, cannot exceed the physical quantity of molybdenum actually in copper ore. As production approaches this constraint, the byproduct supply curve turns upward and becomes vertical. This is because a higher byproduct price does not increase the output of ore or of main product. Otherwise, it would not be a byproduct. So at some output, supply even in the very long run becomes unresponsive or inelastic to further increases in byproduct price.

This characteristic of byproduct supply is illustrated in Fig. 2.1.7. Both the long- and very-long-run supply curves, shown as the same curve, are quite elastic with respect to price until output approaches the byproduct constraint, which is imposed by main product output. Thereafter, little or no increase in supply is possible. Since normally byproduct producers are competitive firms, Fig. 2.1.7 shows the byproduct supply curve for only the competitive market. The same constraint, however, would apply in a producer market.

Since it is the price of the main product, rather than the byproduct, that stimulates supply in the very long run, through exploration and development of new technologies for exploiting alternative ores, the long- and very-long-run byproduct supply curves may actually be the same, as shown in Fig. 2.1.7. This, however, need not be the case. A high byproduct price, for example, may encourage new technology that allows a greater recovery of the byproduct. In this case, the byproduct constraint becomes binding at a greater output in the very long run, causing the long- and very-long-run byproduct supply curves to deviate from each other.

The constraint imposed by main product output shifts in response to changes in main product demand and supply. If the demand for copper goes up, for example, this causes the price and output of main product copper to rise, increasing the amount of ore from which byproduct molybdenum can be recovered. For this reason, the supply function of a byproduct should normally contain the output (or price) of the main product, in addition to its own price and the other important supply variables discussed earlier. Since changes in main product output are independent of the byproduct price, they reflect a shift in the byproduct curve itself, rather than a movement along it.

At times, main product ores may contain more of the byproduct than existing capacity can treat. This constraint, however, applies only in the immediate and short runs, as new capacity can be installed in the long run. Such a situation, where capacity limits byproduct supply in the immediate and short runs, is illustrated in Fig. 2.1.7. The immediate-run supply curve in Fig. 2.1.7 is further constrained by current output (plus available producer stocks), implying that the industry is not operating at full capacity. Otherwise, the output and capacity constraints would be the same, and the immediate- and short-run curves would both become inelastic at about the same output.

A second important difference between byproduct and individual (or main) product supply is that only costs specific to byproduct production affect byproduct supply. Joint costs, those necessary for the production of both the main product and the byproduct, are borne entirely by the main product and do not influence byproduct supply.

This means that byproduct supply curves for competitive markets, such as those drawn in Fig. 2.1.7, reflect the marginal costs of byproduct production exclusive of all joint costs. As a result, byproduct supply until production approaches the constraint imposed by main product output is often, though not always, available at lower costs than the same metal from main or individual product supply.

It is sometimes assumed that byproducts are basically free goods and that the byproduct supply curve is simply a vertical line at that output reflecting the amount of byproduct in the main product ore. For this to be true, however, two conditions must be satisfied: (1) the production of the main product must require the separation of the byproduct, and (2) no further processing of the byproduct must be necessary after separation. The first condition often is satisfied. It is the second condition that normally gives rise to specific byproduct costs. Byproducts will not be recovered and supplied to the market unless their price covers these specific costs. In Fig. 2.1.7, the lowest cost byproduct producer has specific costs equal to OC_1 cents per pound. Once byproduct capacity is in place, the market price can fall below specific costs and production will continue in the short run, as long as price covers the minimum variable or out of pocket costs specific to byproduct production (OC_2). In the immediate run, the price can even decline further (OC_3). Over the long run, however, capacity will not be replaced and byproduct production will cease if price remains below the minimum specific cost (OC_1).

Since byproduct production tends to occur first where main product ores are particularly rich in the byproduct mineral or are for other reasons less costly to process, the marginal costs specific to byproduct production usually rise with output. For this reason, the long- (and very-long) run supply curve shown in Fig. 2.1.7 has an upward slope over its relatively flat or elastic segment.

Coproduct Supply: Coproducts are in many respects between byproducts and main products. Their price influences mine output, but so do the prices of associated coproducts. Joint production costs must be shared, as no single coproduct can support them alone. This means that a coproduct's price must cover its specific production costs plus some but not all of joint costs.

Consequently, a coproduct's supply function includes its own price, the price of other coproducts, its specific costs, and joint costs, as well as possibly other factors. A change in any of these supply determinants, other than own price, causes a shift in the supply curve. An increase in specific or joint costs, for example, shifts the curve upward, while an increase in the price of an associated coproduct shifts it downwards.

Coproduct supply curves have the same general shape as those illustrated for individual products in Fig. 2.1.5. In the immediate, short, and long runs, coproduct supply is similarly constrained by current output, capacity, and known deposits.

Since a coproduct must bear only a part of joint production costs, supply may be available at lower costs than from main or individual product output. This reduces the height of the supply curve in competitive markets and possibly in the producer markets as well.

2.1.2.3 Secondary Production

Secondary production adds to the supply of some mineral commodities by recycling new and old scrap. *New scrap* is generated in the manufacturing of new goods. The aluminum sheet that remains after stamping the round tops for soft drink cans is part of the supply of new metal scrap. *Old scrap* comes from consumer and producer goods that have come to the end of their useful lives because they are obsolete, worn out, or for some other reason no longer of use. An empty soft drink can is part of old scrap supply. In recent years, the recycling of old scrap alone has accounted for about 20% of US aluminum consumption, 25% of US copper consumption, and 50% of US lead consumption.

Secondary supply differs in several respects from primary supply, particularly that for individual or main products. For example, secondary producers are for the most part highly competitive and rarely support a producer price. So in considering secondary supply, we need not be concerned with supply curves for a producer market.

In addition, it is the availability of scrap, rather than the availability of known deposits, that limits secondary supply in the long run. Since the important factors determining the availability of new and old scrap differ, secondary supply from these two sources are best considered separately.

Secondary Supply from New Scrap: The amount of new scrap available for recycling depends on three factors—current overall metal consumption, the distribution of this consumption by end uses, and the percentage of consumption resulting in new scrap for each end use. A rise in overall copper consumption, due to an increase in GNP or a change in consumer preferences, increases the availability of new copper scrap, causing both the constraint and the long-run supply curve for secondary copper metal produced from new scrap to shift to the right. On the other hand, improved manufacturing techniques that reduce the percentage of copper scrap generated in the manufacturing of electric wire or other fabricated products shifts the constraint and the curve to the left.

This means that the supply function for secondary metal from scrap, in addition to technological change and other determinants discussed earlier, should include a variable for the availability of new scrap. Often metal consumption is used as a proxy for the availability of new scrap. This is appropriate, however, only if its distribution by end uses and the proportion of consumption resulting in new scrap for each end use remain unchanged. Otherwise, these variables as well belong in the supply function.

The shape of the long-run (and very-long-run) supply curve for secondary metal from new scrap is shown in Fig. 2.1.8 and reflects the cost of collecting, identifying, and processing new scrap. The scrap which is the least costly to recycle will be processed first. These costs, given in Fig. 2.1.8 as OC_1 cents per pound, determine the point where the curve intersects the vertical axis. As most new scrap is relatively inexpensive to recycle, the slope of the curve rises from this point very gently over the range of possible outputs. Only as the constraint imposed by the availability of new scrap is approached does the supply curve turn upward.

The low cost of recycling new scrap compared to alternative sources of supply means all or almost all new scrap is recycled.

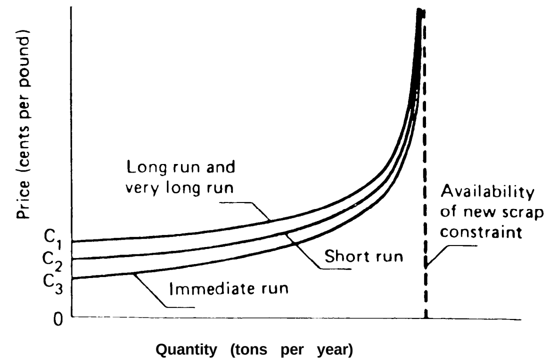

Fig. 2.1.8. Supply curves for secondary metal from new scrap in a competitive market.

So over the range of normal prices, little additional supply from new secondary is possible, making supply price inelastic. However, at very low prices, those approaching the cost of recycling new scrap, supply is—as Fig. 2.1.8 illustrates—quite elastic with respect to price.

The fact that almost all new scrap is recycled means that the constraints limiting supply in the immediate and short run, namely output and capacity, are not likely to differ significantly from the constraint in the long run imposed by the availability of new scrap. So although the immediate- and short-run curves lie below the long-run curve, they turn upward and become vertical at about the same output.

If current technology allows the full recovery of the metal content of new scrap, the very-long-run supply curve is also constrained by the availability of new scrap. In this case, it and the long-run curve coincide, as illustrated in Fig. 2.1.8. If this is not the case, if a high metal price induces over the very long run new technology that allows more metal to be recovered from the available scrap, the constraint on supply would be further to the right in the very long run. It would, however, not be eliminated. At some output the supply of secondary metal from new scrap, like that for byproduct supply, becomes inelastic to price even in the very long run and in this regard differs from the supply of individual and main metal products.

Secondary Supply from Old Scrap: The availability of old scrap during any particular year depends on (1) the flow of metal-containing products reaching the end of their service life during the year, and (2) the stock of metal-containing products no longer in use or service at the beginning of the year, but which have not yet been recycled. The number of old automobiles available for recycling, for example, includes those scrapped during the year as well as those scrapped in earlier years but which for one reason or another have yet to be recycled.

The flow of old metal scrap depends on the number and types of goods in use throughout the economy at the beginning of the year, their metal composition, their age distribution, the mean age at which they come to the end of their service life, and the frequency distribution around this mean. Since these factors together determine the flow of old scrap, they can be included in the supply function for secondary metal produced from old scrap in place of the latter.

The stock of old metal scrap depends on the accumulated past flows of products coming to the end of their service life. From this total, the quantities already recovered through recycling must be subtracted. This means that over time, the stock of old scrap will grow if the amount recycled is less than the incoming flow.

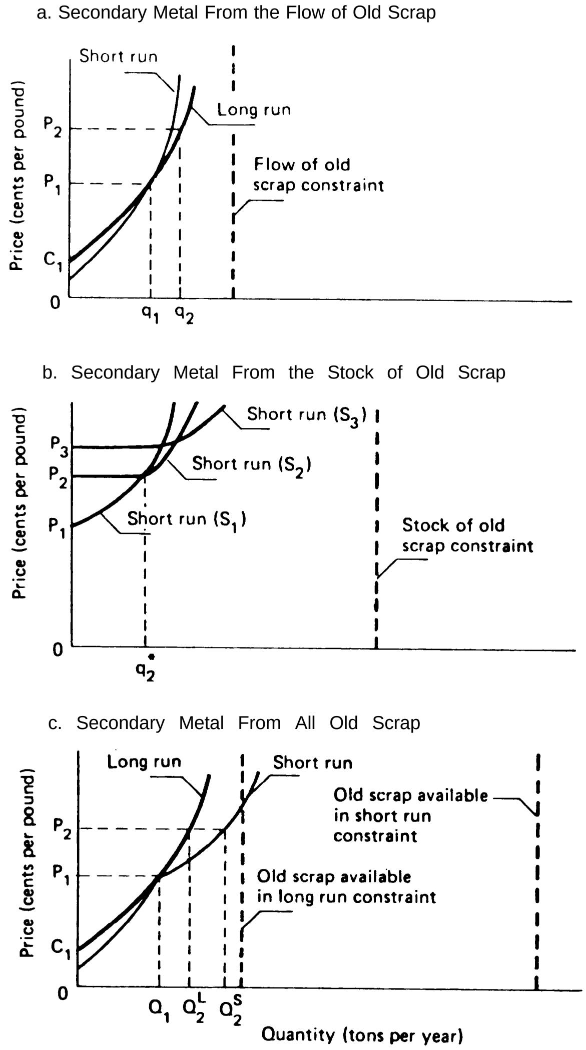

Fig. 2.1.9. Supply curves for secondary metal from old scrap in a competitive market.

Even though it depends on two flow variables—the accumulated flow of old scrap and the accumulated recycling of this scrap in the past—the stock of old scrap is as stated "a stock" and not a flow. Consequently, what is recycled this year is not available for recycling in the future. This has several important implications, and makes it necessary to distinguish between the supply of secondary produced from the flow and from the stock of old scrap.

A long-run supply curve for the former is shown in Fig. 2.1.9a. At the price P_1, this curve indicates that the quantity q_1 of the secondary metal is recovered from the incoming flow of old scrap. The remainder of the incoming flow of old scrap is not recycled, but rather added to the stock of old scrap available for recycling in the future.

The curve begins as the vertical axis at a fairly low price, reflecting the fact that some old scrap is of very high quality. It can be recycled at a relatively low cost (OC_1) per pound of contained metal. However, in contrast with new scrap, costs rise notably as more and more of the old scrap flow is recycled. This is because some scrap is scattered geographically, and so collection costs are high. Some is a mixture of various scrap types, requiring expensive identification and sorting techniques. Some is highly contaminated with rubber, glass, wood, and other waste material, making treatment costs high. Indeed, in some uses, such as lead in gasoline, the metal is so dissipated after use that recycling is simply too costly to contemplate. It is for such reasons that much of the old scrap flow is not recycled for many metals.

Fig. 2.1.9a also illustrates a short-run supply curve for secondary metal produced from the flow of old scrap. This curve is drawn beneath the long-run curve at prices below P_1, on the assumption that secondary producers will continue to operate and supply the market in the short run as long as they can cover variable costs. Since fixed costs tend to account for a relatively small share of total production costs, particularly in comparison with primary production, the short-run curve lies relatively close to the long-run curve.

At prices higher than P_1, Fig. 2.1.9a shows the short-run curve above the long-run curve, since producers at some output encounter capacity constraints. However, capacity tends to be more flexible in secondary than primary production. It is easier to raise output by increasing the number of shifts and by augmenting labor in other ways. For this reason, the short-run supply curve above the price P_1 is drawn quite close to the long-run curve.

This, though, need not necessarily be the case. Under certain circumstances, the short- and long-run curves may lie quite far apart. For example, at particularly high metal prices, certain products that account for a significant part of the total old scrap flow may become economic to recycle. The capacity to handle these products, however, may not exist, causing the short-run supply curve to become vertical considerably before the long-run curve.

Conversely, short-run supply can exceed long-run supply at relatively high prices, with the reverse being true at low prices, as a result of the "accelerated scrapping" phenomenon. The latter occurs when products close to the end of their service life are scrapped earlier than they otherwise would be as a result of high metal prices. For example, at times, old or obsolete machines are held in reserve for use during peak production periods, for emergencies, or are stored away and cannibalized for their parts. High metal scrap prices encourage the premature recycling of such equipment. When metal prices are particularly low, the costs of keeping such equipment in terms of the scrap revenues forgone are quite modest. This implies that in some circumstances, the constraint imposed by the flow of old scrap may not be invariant in the short run to price but rather may increase with price at least over a range.

So far we have focused entirely on secondary supply from the flow of old scrap. Fig. 2.1.9b illustrates three short-run secondary supply curves from the stock of old scrap. The first curve S_1 indicates that at the price P_1, no metal is recovered from the stock of old scrap. This price simply does not cover recycling costs. At higher prices, however, some of the available old scrap stock can be economically processed. At P_2, for example, the old scrap stock will produce an amount of metal equal to q^*_2.

Over the long run, however, this output is not sustainable, because the old scrap stock recoverable at costs under P_2 is depleted. So if price remains at P_2, the short-run curve soon becomes truncated in a manner similar to that illustrated by the curve S_2. Above price P_2 this curve lies somewhat to the right of the original curve, reflecting the fact that the flow of old metal scrap with recycling costs above P_2 has over the intervening years not been recycled, but rather added to the stock of old scrap. Below price P_2, however, the new supply curve S_2 indicates that no supply from the stock of old scrap is now forthcoming, as the material that can be recycled economically at this price has been exhausted. Similarly, if the price rises to P_3, the short-run supply curve will soon approach the shape indicated by the S_3. This means that normally there exists no long-run supply curve for secondary metal from the stock of old scrap.[c]

Although the size of the stock of old scrap does impose a constraint on the ultimate supply of secondary metal, this constraint is not nearly as binding as is the availability of scrap in the case of supply from the flow of old scrap or from new scrap. Long before the stock of old scrap is exhausted, processing is constrained by high costs. Most of the available old scrap stock has not been recycled precisely because at prevailing prices it has been uneconomical to do so. Other sources of supply—individual product, main product, coproduct, byproduct, secondary from new scrap—for the most part have been cheaper.

As Fig. 2.1.9c illustrates, the secondary supply curve from all old scrap can be derived by combining or, more precisely, by adding horizontally the secondary supply curve for the old scrap flow and for old scrap stocks. The long-run curve is simply that for secondary from the old scrap flow shown in Fig. 2.1.9a, as there is no long-run secondary supply curve from the stock of old scrap.

The short-run curve is derived by adding the appropriate short-run curve for the stock of old scrap, assumed to be the curve S_1 in Fig. 2.1.9b, to the short-run curve for the flow of old scrap. Since the short-run curve for the stock of old scrap intersects the vertical axis at P_1, implying that below this price no secondary metal from old scrap stocks is forthcoming, the short-run secondary curve for all old scrap below this price is simply the short-run curve for the flow of old scrap.

Fig. 2.1.9c highlights two interesting facets of secondary supply from old scrap. First, the constraint posed by the availability of scrap is actually less binding in the short run than in the long run. This, of course, is because the stock of old scrap, if exploited in the short run, is not available in the long.

Second, an increase in price, for example from P_1 to P_2, may actually produce an increase in supply that is greater in the short run than in the long run. In the short run, some of the stock of old scrap may be recycled, adding to supply. It is presumably for this reason that efforts to measure the price elasticity of secondary metal supply from old scrap (Bonczar and Tilton, 1975; Fisher et al., 1972) have found the elasticity to be greater in the short run than in the long run, which is just the opposite from what one normally finds with other sources of supply. However, as Fig. 2.1.9c indicates, this unusual result should be expected only if the market price is above the price at which secondary supply from old scrap stocks is forthcoming, that is, above the price P_1 in Fig. 2.1.9. When this is not the case, the figure suggests a change in price will produce a greater increase in supply in the long run than in the short run. Though as pointed out earlier, even here the phenomenon of accelerated scrapping can cause the response of supply to an increase in price to be greater in the short than the long run.

Nothing has been said so far about the immediate-run and very-long-run supply curves for secondary metal from old scrap, in large part because the curves are not particularly unusual. The immediate-run curve has the general shape illustrated for the competitive market in Fig. 2.1.5. At very low prices, producers will save much or all of their current production, in hope of higher prices in the future. As price increases, however, and

[c]It is possible that at very high prices, large reservoirs of old scrap might become economical to process. For example, at some price, certain metals found in dumps and landfills could presumably be extracted profitably. In such instances, the depletion of the available stock of old scrap could take a number of years, and make a long-run supply curve possible.

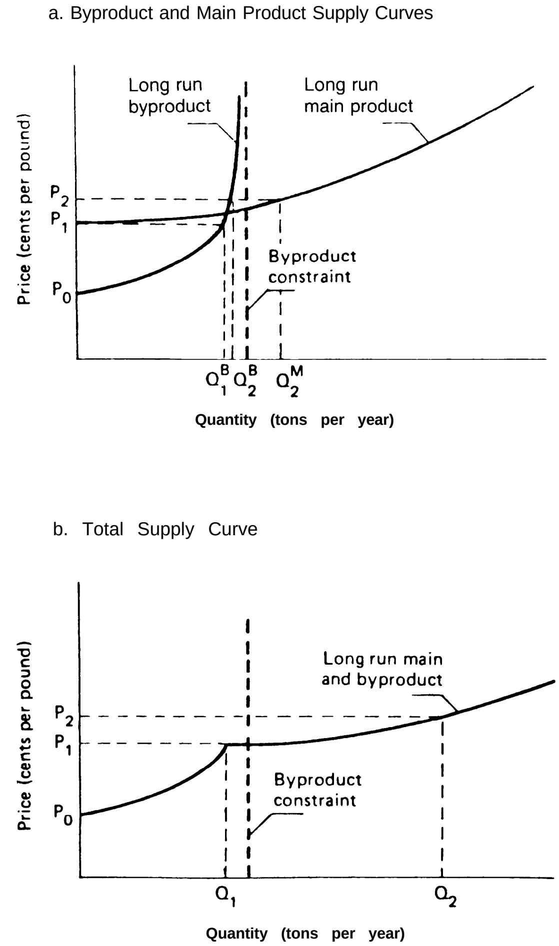

Fig 2.1.10. Total long-run supply curve for a metal produced as a byproduct and a main product.

supply approaches the constraint imposed by current production, the supply curve turns upward and becomes quite inelastic.

The very-long-run supply curve has the general shape of the long-run curve and is similarly constrained by the metal content of the flow of old metal scrap. Indeed, in some circumstances, the two curves may coincide. Where high metal prices, however, stimulate old scrap recovery technology and thereby permit a greater proportion of the flow of old metal scrap to be economically recycled at any particular price, the very-long-run curve will lie somewhat to the right, and perhaps below, the long-run curve.

2.1.2.4 Total Supply

Individual products, main products, coproducts, byproducts, and secondary from new and old scrap are all potential contributors to a mineral commodity's total supply. To derive the total supply curve, we must add horizontally the individual curves for all significant sources (in a manner similar to that just used to derive the secondary supply curve for all old scrap). For example, if the byproduct and main product supply curves for a mineral commodity are as shown in Fig. 2.1.l0a, and if other sources of supply are unimportant and can be ignored, the horizontal summation of these two curves gives the total supply curve shown in Fig. 2.1.l0b.

Among its many uses, the total supply curve provides an indication of the relative competitiveness of the different sources of supply and, in turn, their relative importance at different market prices. For example, byproduct production is initially the most competitive and cheapest source of supply for the commodity whose total supply curve is shown in Fig. 2.1.l0b. When market price is below P_1, it is the only source of supply. As the market price rises above P_1, however, main product production begins and becomes increasingly important. At the price P_2, main product supply exceeds byproduct supply.

In deriving the total supply curve, a question sometimes arises as to whether the secondary supply curve for new scrap should be included. New scrap, after all, is generated in the manufacturing process and depends on other sources of supply. If metal fabrication becomes more efficient and generates less new scrap, this does not mean total metal supply has declined.

Whether to include secondary supply from new scrap depends on the purpose for which total supply is being considered. In assessing the extent to which the United States is vulnerable to interruptions in supply from certain foreign producers, for example, we would not want to include secondary supply from new scrap. To do so would ignore the fact that this metal is generated from other sources of supply, and so would not be available in their absence. Including it would underestimate US dependence on foreign producers. On the other hand, in assessing the competitiveness of secondary metal markets, we would normally want to consider secondary supply from new scrap.

Regardless of how secondary supply from new scrap is treated, it is important that total supply and demand be consistent in this regard. If the demand curve takes account only of metal actually contained or embodied in final products, and excludes metal that ends up as new scrap and is recycled, then total supply should also exclude new scrap. Conversely, if demand includes the demand for all metal, including that which ends up as new scrap, then the total supply curve should include new scrap as well.

2.1.3 APPLICATIONS

This final segment illustrates the usefulness of the supply and demand principles examined in the preceding segments. It uses these concepts to analyze the problem of mineral market instability and the incentive price technique for forecasting long-run prices for mineral commodities.

2.1.3.1 Market Instability

Mineral markets are well known for their instability, for their feast-or-famine nature. In an effort to stabilize commodity markets, particularly for the benefit of producers in the developing countries, the United Nations Conference on Trade and Development (UNCTAD) has over the last 30 years pushed for the creation of an Integrated Program for Commodities. Among other measures, this program proposes to establish a common fund on which international commodity agreements can draw to support market stabilization measures. While the proposed program has encountered a number of difficulties, it does reflect the concern on the part of both producing and consuming countries over the instability that plagues mineral markets.

Nor is this instability new. One of the major driving forces behind the multiple mergers in the American steel industry at the turn of the last century, which culminated in 1901 with the creation of the US Steel Corp., possessing at that time some two-thirds of the country's steel-making capacity, was a desire to control the volatile steel market. Gyrations in steel prices during the 1880s and the 1890s had created severe problems for all producers.

A highly concentrated market structure where one or a few major producers dominate the market and set a producer price does not, however, eliminate market instability (though as we shall see, it does alter the ways in which market instability manifests itself). This is because the following three characteristics of short-run metal supply and demand, which are responsible for market instability, are present no matter how concentrated the market.

First, as output approaches the capacity constraint, total supply becomes increasingly price inelastic. In a competitive market, as shown earlier, the short-run supply curve turns upward and at some point becomes vertical. In a producer market, the curve simply ends when major producers no longer have sufficient supply to satisfy demand at the producer price.

Second, demand also tends to be price inelastic in the short run. So the slope of the demand curve is quite steep.

Third, demand is often highly elastic to changes in national income over the business cycle. The consumption of most metals and many other mineral commodities is concentrated in four sectors—construction, capital equipment, transportation, and consumer durables—whose output is particularly sensitive to fluctuations in the business cycle. During a recession, these sectors suffer far more than the economy as a whole. During a boom, their sales soar. As a consequence, the demand curve for most metals shifts considerably over the business cycle.

These characteristics of short-run supply and demand are illustrated in Fig. 2.1.11a for a commodity sold in a competitive market and in Fig. 2.1.11b for a commodity sold in a producer market. In both instances, it is assumed that supply comes from individual or main product production. This simplifies the analysis, but does not alter the conclusions, since total supply, regardless of the combination of sources from which it is derived, is at some output constrained in the short run by the available production capacity. As supply approaches this constraint, it becomes inelastic to price.

The two characteristics of demand—its low elasticity with respect to price and its high elasticity with respect to income-are portrayed in Figs. 2.1.11a and 2.1.11b by the steep slope of the demand curves and by the shifts in the demand curves over the business cycle. The curve DD_t reflects demand at the trough of the cycle, the curve DD_m at the midpoint of the cycle, and the curve DD_p at the peak of the cycle.

One of the important consequences of market instability for copper, tungsten, and other mineral commodities sold on competitive markets is the severe fluctuation in market price. It varies in Fig. 2.1.11a from a high of P_p at the peak of the business cycle to a low of P_t at the trough. The output that producers supply to the market also varies greatly, from a high of Q_p (approximately the maximum possible given the industry's production capacity) to a low of Q_t. At the latter level, producers are burdened with either shutting down much of their capacity or adding a large part of their output to their inventories.

Fig. 2.1.11a also indicates that when market instability is caused by shifts in the demand curve (rather than by shifts in the supply curve, which is more typical for agricultural commodities), the quantity sold and price move together. When one is down, so is the other. Consequently, total revenues and in turn profits tend to be highly volatile.

For mineral commodities sold in producer markets, the situation is somewhat different. If all firms faithfully adhere to one producer price, there is no price instability. Even if this is not the case, if some open or secret discounting occurs, or if the producer price is reduced when the market is weak, price instability will generally be less than in competitive markets.

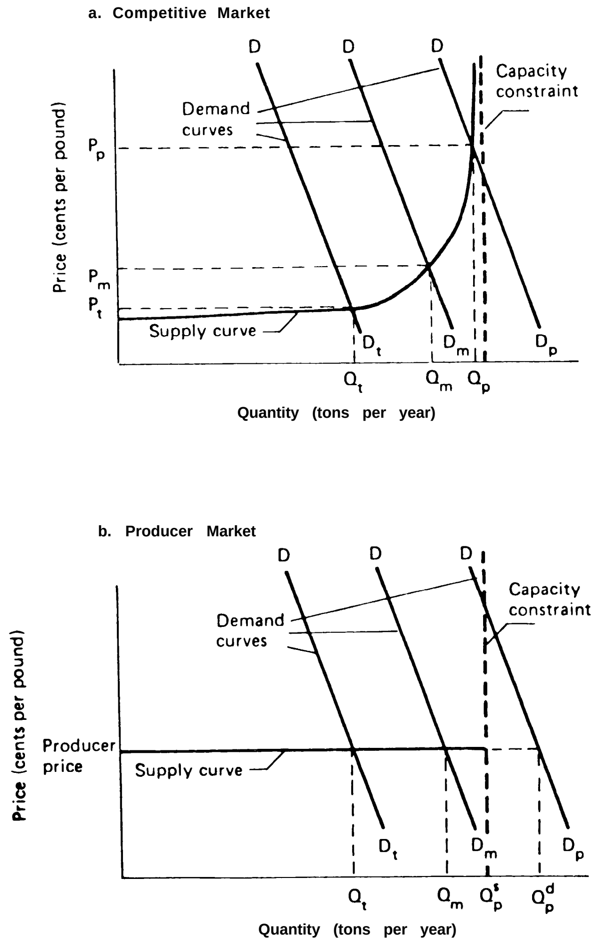

Fig. 2.1.11. Short-run supply and demand curves.

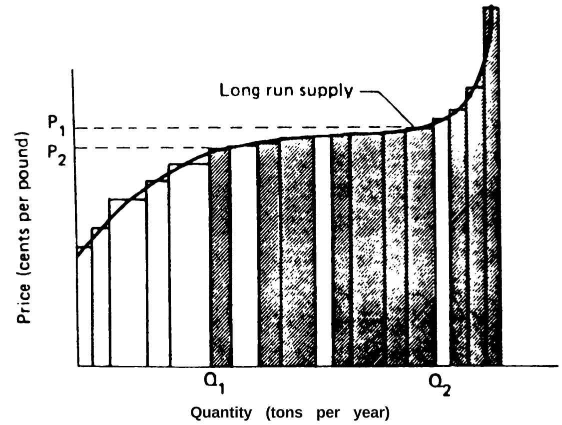

Fig. 2.1.12. Long-run supply curve for a metal with many underdeveloped deposits of similar quality. (Shaded areas represent known but undeveloped deposits.)

However, physical shortages, where the available supply is insufficient to satisfy demand at the prevailing price, can occur in a producer market. In Fig. 2.1.11b, for instance, the quantity demanded during the peak of the business cycle is Q_P^d while the maximum amount the industry can supply is only Q_p^s. The shortfall requires that producers allocate or ration their limited supply to customers.

Despite the greater price stability, firms in producer markets still suffer from sizable fluctuations in total revenue and profits over the business cycle as a result of the instability in metal demand and the impact that this has on sales. In these respects, the adverse effects of market instability are similar for firms in both producer and competitive markets.

2.1.3.2 Forecasting Long-Run Metal Prices

Firms studying the feasibility of developing new mines or of expanding existing facilities make forecasts of long-run commodity prices. Similarly, manufacturers contemplating the substitution of one material for another rely on price forecasts. Governments whose tax receipts and foreign exchange earnings follow trends in export markets and local communities whose economy depends on mineral production also have an interest in future price forecasts.

The incentive price technique is one method of making such forecasts. It assumes that over the long run, a commodity's price must approach that level that provides the necessary incentives to ensure production capacity just sufficient to satisfy demand.

As long as entry into the industry is not severely restricted, this condition is likely to be met. When market price is above the incentive price, new firms will enter the industry and existing firms will expand their capacity. The resulting increase in supply will eventually reduce price, and this downward trend will continue until the incentive price is reached and the expansion of existing capacity ceases.

Conversely, when the market price is below the incentive price, neither new firms nor established producers will be motivated to invest in new capacity. As existing facilities become obsolete and are retired from service and as demand grows over time the market price will rise. This upward movement will continue until the incentive price is reached and once again firms are willing to build new capacity.

Success in applying the incentive price technique lies in identifying the incentive price itself. While this can be extremely difficult for some mineral commodities owing to the nature of their long-run supply, it may be relatively simple.

Fig. 2.1.12, for example, portrays the long-run supply curve for a commodity produced largely as an individual or main product and sold in a competitive market. This curve is derived from the average total costs and annual production capacities associated with available deposits, both those actually in operation and those that are undeveloped but known to exist. The undeveloped deposits, denoted by the shaded areas in Fig. 2.1.12, are among the higher costs sources of supply, since lower cost deposits tend to be exploited first.

Because a very wide range of supply (from Q_1 to Q_2) is available in the long run over a narrow band of prices (from P_1 to P_2), the incentive price for the metal portrayed in Fig. 2.1.12 may be relatively easy to approximate. The long-run supply curve has a relatively flat segment, such as that shown, when a number of large deposits of comparable quality and costs are known to exist and so are available for development.

If this flat segment of the long-run supply curve is broad enough, it may cover all likely points of intersection with the long-run demand curve. The incentive price can then be approximated from the estimated average production costs, including an adequate rate of return on invested capital, associated with those marginal deposits determining the relatively flat and wide portion of the long-run supply curve.

Using this procedure, Radetzki (1983) has estimated that the incentive price for aluminum is between 80 and 100 ¢/lb (176 and 220 ¢/kg) and that for copper between 120 and 150 ¢/lb (265 and 331 ¢/kg) (both in 1980 dollars). At the time of his study, prices for both of these metals were substantially below these figures, allowing him to predict that aluminum and copper prices would rise over the long run.

The incentive price technique is a useful forecasting method when the incentive price itself is easily and accurately determined. In the following circumstances, however, this is not the case.

First, when entry into the industry is restricted and one or a few firms set a producer price, the long-run price may not approach the average production costs of the marginal deposits. In such situations, the determinants of long-run price are more difficult to identify and assess.

Second, the long-run supply curve may not have a broad flat segment. This depends on the quality differences among known deposits. If there is no tendency for a sizable number of large deposits to share the same quality—the same ore grade, ease of access, and processing costs—there will be no narrow price band over which large quantities of supply are forthcoming in the long run.

Third, even if the long-run supply curve possesses a broad flat segment, the range of possible intersection points with the long-run demand curve may fall outside this segment. Some forecasters, for example, are now suggesting that large porphyry copper deposits may not be needed in the foreseeable future, in part because the growth in copper demand has slowed in recent years, and in part because more copper supply will be coming from secondary and coproduct production. As a consequence, the long-run demand curve may intersect the long-run supply curve before the latter flattens out in response to the availability of porphyry copper deposits of comparable quality.

Fourth, the discovery of new deposits and especially the development of new technology can cause the very-long-run supply curve to lie appreciably below the long-run supply curve. Forecasting on the basis of the incentive price derived from the long-run supply curve will, as a result, substantially overestimate future price in some instances.

These considerations reflect violations of the four necessary conditions for obtaining reliable forecasts with the incentive price technique. It is important to consider whether these conditions are satisfied before using the technique to predict future metal prices.

Market instability and long-run price forecasting are only two examples of the usefulness of economic principles in analyzing mineral markets. Many other possibilities exist. We could, for instance, have assessed the market impact of a substantial release of tin from the US government stockpile, the effects of civil disruption in South Africa on the export price for platinum or coal, the consequences of seabed mining for land-based nickel producers, or the costs to domestic consumers of protecting the US steel industry.

The two examples, however, suffice to demonstrate the usefulness of relatively simple economic principles of supply and demand for the analyst investigating mineral markets and industries. The examples also indicate that these conceptual tools must be combined with specific knowledge about the nature of mineral supply and demand. It is not enough to know that the demand curve in most markets is downward sloping. Some idea of just how responsive or unresponsive demand is to price, and how this responsiveness varies from the immediate to the very long run, is essential. Some applications even require that the total demand be broken down into its various components, such as the demand for consumption, for inventories, and for government stockpiles.

Similar information is also needed on the nature of supply. To what extent, for example, does supply come from individual and main product output, from secondary production, from byproduct and coproduct production? How does market structure and the manner in which prices are determined affect supply? How responsive is supply to a change in price? How does this responsiveness change as supply approaches the constraint imposed by current production in the immediate run, by existing capacity in the short run, and by the availability of mineral deposits in the long run? How does the output or price of a main product affect the supply of its associated byproducts? How does secondary supply vary with metal consumption, prices, and the flow of old scrap?

No single set of answers to such questions is valid for all mineral commodities. The answers may even change for the same commodity, as technology and other conditions evolve over time. So the good analyst of mineral industries must know economic principles, but he or she must also know how technology, institutions, market structure, and government policies shape mineral supply and demand.

Chapter 2.2
COMMODITY REVIEW

V. ANTHONY CAMMAROTA, JR.

2.2.1 INTRODUCTION

Of the approximately 100 nonfuel mineral commodities produced worldwide, more than 70 are mined in the United States. Domestic production represents many thousands of operators, ranging from comparatively small but numerous sand and gravel producers to large but relatively few integrated multinational producers of steel, copper, aluminum, and other metals and chemicals. For some commodities, there is little or no US production. The focus of this chapter is on nonfuel minerals of significant commercial importance, with the emphasis on the US position in these materials.

Stone was probably the first mineral commodity used by man. From stone, man produced tools, weapons, and shelter. Stone continues to this day as the largest-valued mineral product in the United States. With time, man learned to use the metals that occur in nature in elemental form such as copper and gold (Muller-Ohlsen, 1981). Later man learned how to produce metals such as iron and bronze by heating certain materials. Increased metallurgical knowledge led to the production of other mineral commodities, such as aluminum that requires the use of electricity and titanium that involves complex chemical reactions and is carried out under an inert atmosphere.

In this period, cartel action of certain world petroleum producers caused energy price increases that profoundly affected the world economy, including minerals production and use. The economic performance of the minerals industry traditionally has been linked closely with the business cycle. As the price of energy increased, the industrial economy underwent tremendous structural change to lower manufacturing costs and conserve energy. For example, the automotive industry designed smaller automobiles to meet mandated fuel efficiency standards, making increased use of lighter materials such as aluminum, magnesium, and plastics and higher-performance steel alloys, in place of copper, zinc, and iron.

In the early 1970s, growth in the mineral industry contributed significantly to the economy (Hodel, 1986). However, in the mid-1970s the recession that followed the petroleum embargo and sharp energy price increases affected the mineral industry, especially the metals sector, more severely than the rest of the economy. Employment and production in the minerals industry fell, as did capacity utilization. For the remainder of the decade, growth rates in mineral production and consumption were lower than those which had been experienced in the years following World War II, and did not keep pace with the growth rates in the general economy. Concern for the environment became a major factor for the minerals industry during this decade. The high cost of environmental compliance, in addition to the increased cost of energy, made some facilities obsolete and forced them to close. Dependence on imports began to increase as the value of mineral imports as a percentage of Gross National Product increased from about 0.6% before 1970, to 0.8% in 1975–1976, and to 0.9% in 1977–1979.

The economic recession of the early 1980s saw mineral production, prices, and employment fall, especially in the metals sector. However, in the period of economic rebound that followed, the mineral industry recovered better than the economy. Foreign competition in metals increased. In addition to the higher energy cost, rising environmental regulation costs, and the recession, the US minerals industry has been affected by high labor cost, declining ore grade and reserves of some minerals, the relative value of the US dollar vs. other world currencies, and the trend of developing countries to process their own ores into industrial products and finished goods.

The United States has historically been a major producer of nonfuel minerals, and was the world's leader in aggregate value of production from about 1900 to the late 1950s when it was displaced by the USSR. In recent years the United States has been losing its world ranking in specific commodities, such as iron ore, steel, lead, potash, and zinc (Table 2.2.1). The United States has essentially maintained its rank in aluminum, cement, copper, phosphate rock, and sulfur, while increasing its position in gold by surpassing Canada.

US demand compared with the base period 1966–1970 is shown in Table 2.2.2 for selected commodities that are used in a wide variety of applications. In general, those commodities such as aluminum, columbium, germanium, rare earths, and platinum-group metals—which are associated with advanced material applications, which have substituted for other materials, or whose uses have benefited from changing demand patterns within the consuming industries—tend to show an uptrend in demand. However, commodities such as iron, manganese, molybdenum, cadmium, lead, and zinc, which are related to manufacturing and the steel industry, or those which have been particularly impacted by environmental constraints, tend to show a decline in demand. Some of this decline in demand can be attributed to increased US imports of finished goods such as automobiles. Agricultural chemicals, some ferrous-alloying metals, and copper have remained relatively flat. The reasons for these differences among commodities will be discussed in the subsequent segments.

The future supply of some minerals may be augmented through ocean mining (see Chapter 22.8). On Mar. 10, 1983, the United States declared an Exclusive Economic Zone (EEZ) that extends 200 nautical miles offshore. Exploration has uncovered many mineral occurrences including sand and gravel, gold, tin, platinum, titanium, zirconium, rare earths, copper, lead, zinc, cobalt, nickel, chromite, phosphate, and manganese. More than 70 coastal countries have taken advantage of EEZs to increase the area available to them for mineral development. In spite of the quantity of minerals that may be available in the EEZ, factors such as their location, extent, characteristics, extractive technology, and competition with land-based mineral extraction will ultimately decide the economic future of seabed mining. Offshore gold placers in Alaska appear promising, whereas offshore titanium and chromite-rich sands appear to be economically less appealing (Anon., 1987a). Although sand and gravel are low-value materials, marine deposits may be in a good competitive position because of land use restrictions that limit onshore development and the characteristics of marine sand (Anon., 1987b). Ferromanganese nodules and crusts in the deep sea contain copper, nickel, cobalt, and manganese, while polymetallic sulfide deposits contain the base metals.

2.2.2 COMMODITY DISCUSSION

2.2.2.1 Base Metals

The base metals are usually considered to be copper, lead, zinc, tin, mercury, and antimony, some of which have been known since ancient times. The ores of these metals usually are the source of a number of byproduct metals, such as precious metals and the minor metals such as arsenic, bismuth, indium, selenium, and tellurium. Base metals, both in elemental and chemical form, have an extremely wide range of industrial uses; copper, lead, and zinc are also used in very large quantities.

Copper: This metal is found in its elemental state, which accounts for its ancient use, but more commonly as sulfide or oxide minerals. The metal is recovered by smelting the sulfide ore to produce an impure blister and anode copper, which is then electrolytically refined to pure copper. In recent years, copper ores have been increasingly smelted in the countries where they are mined. Japan, however, smelts most of its copper from imported concentrate while Europe maintains a smelting industry that also relies significantly on imported concentrates.

Copper is the third most widely used metal, after iron and aluminum, owing to its combined properties of good electrical and thermal conductivity, corrosion resistance, and formability. Western Europe and the United States account for about one-half of world demand. Electrical and electronic uses of copper have continued to be a major growth area and now account for about three-quarters of the total demand for copper.

Copper is mined in approximately 60 countries throughout the world, with Chile, the United States, USSR, Canada, Zambia, and Zaire accounting for about 60% of production. The market economy countries contribute about 80% of world production. World copper mine production has more than doubled over the past 25 years, reaching about 9.4 million tons (8.5 Mt) in 1988. The US share of world mine production was maintained at about 25% through the 1960s, declined to about 14% by the mid-1980s as mine capacity developed in other countries, but recovered to almost 20% by the end of the decade. The largest growth in copper mine production, outside the centrally planned economies, has occurred in countries of South America, the Near East, and Oceania. Mine production in Chile has increased from 880,000 tons (800 kt) in 1975, to 1.54 million tons (1.4 Mt) in

1988, resulting in Chile and the United States vying as the largest copper mine producer.

In the early 1950s, eight privately owned North American and Western European companies controlled about 75% of market-economy country production. However, since that time, most mines owned by these companies in the less developed countries (LDCs) have been expropriated or nationalized. The result has been that more than 50% of world copper mine production is by government-owned or controlled corporations, and thus may not always be subject to the full impact of market forces.

World reserves of copper are estimated to total about 375 million tons (340 Mt), 85% of which are located in the market economy countries (Table 2.2.3). In the United States, massive porphyry copper deposits in Arizona, New Mexico, and Utah account for most of the reserves and production. Exploitation of these deposits became possible with the development in the early 1900s of the froth flotation process for concentrating sulfide ores. Subsequently, the tendency has been away from the small, high-grade deposits to the large porphyry deposits that are suitable for large-scale open-pit or underground mining methods. About 85% of domestic production is from open pits. While most of the ores are insoluble sulfides that are concentrated by flotation, oxide ores and tailings may be leached with sulfuric acid and the dissolved copper recovered through precipitation or solvent extraction and electrowinning.

Following the recession of 1982, world inventories of copper rose to record levels, and copper prices on the world markets

fell to levels that were below the average production costs in many countries. Consequently, domestic production declined by one-third from 1981 to 1983. Since that time, through restructuring, capital investment, and labor concessions, the US industry has reduced its production costs from 83¢/lb ($1.83 kg) in 1981 to 58¢ ($1.28 kg) in 1987, doubled its productivity, and become one of the most efficient and lowest-cost producers in the world.

Historically, copper smelting and refining have been done in the industrialized nations of the world. However, since 1980, in order to gain the added revenue of downstream processing and to avoid increasing transportation costs, some of the traditional concentrate exporting countries, including the Philippines, Mexico, and Chile, have been developing their own smelting, refining, and semi-fabricating industries. However, Japanese and European smelters and refiners, who lack their own ore resources and have invested heavily in foreign copper mines, still tend to dominate the world trade in copper concentrates. The newly industrializing countries, including the Republic of Korea, Taiwan, and China, have recently invested in smelting, refining, and semifabricating capacity.

Copper is one of the most extensively recycled metals. Copper from old scrap satisfies about one-quarter of US demand (Table 2.2.4). About 60% of the copper recovered from old scrap is consumed in the production of refined copper, the remainder mostly being consumed in alloy form in the production of brass and bronze.

Lead: Lead is mined in about 50 countries, and except for unique deposits in Missouri, Morocco, and the Republic of South Africa, lead is essentially a coproduct of zinc mining or a byproduct of copper and/or gold and silver mining. These complex ores are also the source of byproduct metals such as bismuth, antimony, silver, copper, and gold. Australia, Canada, China, Mexico, Peru, the USSR, and the United States traditionally supply about two-thirds of the world's lead mine production. In the United States, over 90% of the mine production comes from lead-sulfide stratabound deposits in Missouri.

Primary lead smelting is mainly a pyrometallurgical process, as is the refining process, except in Canada, China, Italy, Japan, Korea, and Peru, which have significant electrolytic refinery production associated with cheap coal or hydroelectric power or subsidized power. Secondary lead production is a significant portion of total lead production in several countries, most notably Japan, the United States, and the USSR. Worldwide, secondary lead accounts for over 40% of refined lead production (Anon., 1987c). Secondary production grew through recognition of the fact that lead is readily recyclable, mainly as spent lead-acid storage batteries of all types, while its dissipative uses in chemicals, paints, and gasoline additives declined.

Lead is the most corrosion resistant of the common metals, and, in terms of tonnage, lead ranks after aluminum, copper, and zinc among the nonferrous metals in total usage. About three-quarters of its use is in transportation, mainly in batteries, that make it less susceptible to recession than most other metals. Other uses are in lead alloys for the construction, electrical, and metal fabricating industries. Since the mid-1970s, its use as an antiknock additive in gasoline has substantially declined.

Zinc: Zinc ore is mined in about 50 countries, with about one-half the total coming from Australia, Canada, Peru, and the USSR. In the United States, most zinc is mined in Tennessee where the ore is relatively low grade and in Missouri where zinc is a byproduct of lead mining. Zinc concentrates, produced by flotation of sphalerite in the ore, are processed to produce metal by electrolytic deposition from a sulfate solution or by reduction and distillation in retorts or furnaces. For either method, concentrate is roasted to eliminate most of the sulfur that is recovered as sulfuric acid and sold mainly to the chemical industry.

Until recently, much concentrate produced in the LDCs was shipped to custom smelters, many of which were in Europe, for processing. However, the trend has been for smelters to be constructed within the mining country to achieve the value added. Countries such as India, Republic of Korea, Mexico, Peru, and Thailand have become new zinc metal producers or increased capacity significantly to become exporters of metal. Consequently, less concentrate is internationally traded, while more metal and zinc alloys find their way to the marketplace. The United States, which in the 1960s imported about 440,000 to 550,000 tpy (400 to 500 kt/a) of zinc in concentrate and derived almost 50% of its slab zinc production from foreign material, had by the late 1980s reduced its imports to less than 110,000 tons (100 kt), and only about 25% of its production of metal was from foreign material. During this same time many mine and smelter facilities closed due to environmental and technological factors, and, as a result, US reliance on imports of zinc materials (Fig. 2.2.1) rose from about 50% in the 1960s to 70% in 1988, mainly as metal.

About 60% of world zinc reserves occur in ores associated with coproduct precious metals, lead, and copper, while the remaining zinc reserves are ores in which zinc is the principal valuable component. In addition, it is conceivable that a potential exists for millions of tons of zinc to be recovered from sphalerite-bearing coals in the midcontinent United States.

Zinc metal uses are based on a number of properties, mainly its low melting point, that facilitates shaping by casting, its high electrochemical activity, whereby zinc provides cathodic protection for iron and steel and electrical energy in the ubiquitous zinc-carbon batteries, and its ability to alloy readily with copper to make brass. Galvanized steel products used in motor vehicles and construction account for zinc's greatest use, followed by zinc alloys for die casting, brass for a myriad of uses, coinage, zinc chemicals in agriculture, pharmaceuticals, and pigments, and zinc dust in paints and coatings for corrosion protection.

An important consideration in zinc mining and smelting is the extraction of valuable byproducts that can be credits in the production cost cycle. Most common byproducts include cadmium, germanium, lead, silver, and sulfur, although indium, gallium, copper, and gold may also be recovered. These elements are recovered during ore beneficiation or from residues generated in the zinc roasting and refining process.

Tin: Tin ore is mined in about 35 countries by both placer mining and by lode deposit mining, depending on the region of the world. About 75% of the total world production of tin ore comes from Brazil, China, Indonesia, Malaysia, Thailand, and the USSR. In the United States, there is no substantial amount of tin ore mined, with only a few small mines in Alaska and New Mexico. Almost all tin reserves occur in ores in which tin is the only or dominant metal; some coproducts include antimony, bismuth, columbium, and tantalum.

Until the 1960s, much of the tin concentrates produced in the LDCs was shipped to custom smelters, many of which were in Europe, for processing. However, the trend here, as with lead and zinc, has been for smelters to be constructed within the mining country to achieve the added value. Countries such as Australia, Bolivia, China, and Thailand have increased their smelting capacity in recent years and have become significant exporters of tin metal. As a result, less tin concentrate is traded internationally, and most trade is in tin metal. The United States has long had one primary tin smelter, located in Texas, which has traditionally depended on tin concentrates from several foreign countries, especially Bolivia and Peru. Secondary production of tin is derived from processing wastes and obsolete consumer products such as tin cans.

Up through the mid-1980s, Bolivia and Malaysia tended to be the leading suppliers of tin metal to the United States, but since then, Brazil and China have emerged as the major suppliers to the United States.

Tin metal uses are varied, and most tin uses are as a protective coating or as an alloy with other metals. The major applications are in tinplate, which is used extensively for food cans, and as an alloy with lead (solder), which is widely used as a joining material for metals, especially in electrical and electronic applications. Tin chemicals are used in fluoridated toothpastes, wood preservatives, heat stabilizers for making polyvinylchlorides, and marine paints as an anti-foulant for the hulls of ships.

2.2.2.2 Precious Metals

In addition to the traditional precious metals of silver and gold, the platinum-group metals including platinum, palladium, rhodium, iridium, ruthenium, and osmium are part of this group. Silver and gold have been used since ancient times for coinage, jewelry, and ornaments and as a storehouse of wealth. As monetary metals, their prices were controlled or manipulated by governments. With the demonetarization of gold and silver, their industrial applications have assumed increasing importance. The platinum-group metals have also undergone a change. These metals, sometimes called noble metals, were initially industrial metals used in catalysts and in corrosion resistant materials. In the 1980s, several countries began issuing coins made of platinum.

Silver: Silver is most often found associated with copper, gold, lead, or zinc ores. Although most of the silver in the United States is recovered from silver ores, approximately two-thirds of the world's silver reserves are estimated to be contained in copper, lead, and zinc deposits, with the remainder primarily in silver or gold deposits. Some silver has been found associated with certain aluminum or tin ores or with fluorspar.

Silver-bearing ores are mined using open pit or underground methods. Nearly all US mine production of silver comes from states west of the Mississippi River, mainly Nevada.

Worldwide, over 50 countries produce silver, with the largest producers traditionally being Australia, Canada, Mexico, Peru, the United States, and the USSR. Current treatment of silver-containing ores is almost entirely by a flotation process, which results in the recovery of silver from intermediate products of lead, zinc, or copper smelting. Gold and silver ores are generally treated by cyanidation, followed by precipitation of the metals from solution and electrolytically refined to pure metal.

The major primary silver-refining countries are Australia, Canada, Japan, Mexico, Peru, the United Kingdom, the United States, and the USSR. In the United States, most refiners of primary materials are located in the western states, while most secondary refiners are located in the eastern states, and along the west coast. Old scrap typically provides one-third to one-half of the annual US refinery production of silver. Price plays an important role in the quantity of scrap available for recycling.

Gold: From time immemorial, gold has played a prominent role in world economic and political events. Most of the gold mined or accumulated over the past 6000 years exists mainly in the form of refined gold held by governments as monetary reserve assets or by individuals in the form of jewelry, bullion coins, or small bars held as insurance against currency devaluation. In modern usage, gold is also consumed worldwide in numerous electronic, industrial, and dental applications, but more than three-fourths of the total annual demand goes toward the fabrication of jewelry and the minting of coins.

Although gold has been mined at one time or another in nearly every country in the world, deposits mined in the Republic of South Africa, beginning about 1886, have accounted for about 40% of the world's total cumulative production, estimated at about 3.3 billion troy oz (102.63 kt). By the late 1980s South Africa was producing about 40% of the world's annual production of over 50 million oz (1555 t); the second largest producer, the USSR, accounted for about 15%, followed by the United States with nearly 10%. In the United States, Nevada has been by far the nation's dominant producer during the 1980s.

As a consequence of the rapid and sustained increase in the world price of gold since the mid-1970s plus the development of a generally favorable margin between gold's market price and the cost of its production, exploration worldwide for new deposits has been both intense and highly successful. Gold exploration and mining is pursued by both individual miners and large multinational corporations with interests on several continents. Mining operations range from hand-dug pits and deep underground mines to highly mechanized surface lode or placer mines capable of handling large volumes of low-grade materials. Gold may also be recovered as a byproduct of various base metal deposits, principally copper. Recently, heap leaching, generally combined with open pit mining and relatively simple recovery methods, has become a popular and cost-effective method of extracting gold from very low-grade ores (Chapter 15.2). Crude or impure gold is refined to commercial specifications by chlorination or by electrolysis. Gold recovered in nugget or specimen form generally commands premium prices when sold in specialty markets. Substantial quantities of secondary material such as gold-bearing scrap are processed for recovery as a refined product; however, some material may also be reused directly as in local jewelry fabrication.

Gold is traded widely in all forms with substantial volumes traded daily for future delivery on various world commodity markets. Prominent gold trading centers, such as London, Zurich, New York, Hong Kong, and Singapore, account for much of the trading activity. However, clandestine or smuggled gold, can also account for a substantial portion of the daily movement. Gold contained in secondary or scrap products may be widely traded, especially during periods of heightened demand when prices tend to escalate.

Platinum-group Metals: The two most important metals of the platinum group (PGM) by quantity produced are platinum and palladium. PGM are concentrated in copper-, nickel-, and iron-bearing sulfide minerals in the Bushveld Complex in the Republic of South Africa and in copper-nickel sulfide deposits near Noril'sk in the USSR. Together, South Africa and the USSR account for almost all the world's reserves of PGM, with most of the remainder shared equally between the United States and Canada. In South Africa, PGM ores contain about 47% platinum, 32% palladium, 11% ruthenium, 7% rhodium, 2% iridium, and 1% osmium; while in the USSR, ores contain about 25% platinum, 67% palladium, 3% rhodium, 2% ruthenium, 2% iridium, and 1% osmium.

Together, South Africa and the USSR mine about 94% of the world's annual production of PGM. Almost all processing and refining is done within the borders of each country, although South Africa has historically relied on the United Kingdom for some of its PGM refining. In South Africa, the ore is processed in such a way as to produce byproduct copper, nickel, and cobalt, in addition to all the precious metals.

Secondary refining of PGM is extensive because of the high value of the metals. Secondary recovery is highest in the petroleum refining, chemical, glass, and the dental industries. Less recycling occurs from used automobile catalytic converters, electronic components, and jewelry. In the case of automobile catalytic converters and electronic components, the scrap is widely scattered and/or low in concentration, thus adding to the cost of processing and refining.

The PGM are refractory and chemically inert at elevated temperatures to a wide variety of materials, display excellent catalytic properties, and are attractive in appearance. These properties are the basis for the principal uses: as catalysts in the automotive, chemical, and petroleum refining industries; as corrosion-resistant materials in the chemical, electrical, glass, and dental-medical industries, and as beautiful objects and collectibles in the jewelry and investment industries. In the western world, 35% of the platinum is consumed annually in automobile catalytic converters, 30% in jewelry, 15% in investment, and the remaining 20% for all other uses. The investment uses of platinum came into being in 1982. In the case of palladium consumption, the electrical industry uses 50%; the dental industry, 31%; and all other industries, 19%. Rhodium usage is about one-tenth that of platinum, with about three-quarters going to automobile catalytic converters. About half of ruthenium usage is for electronics, one-third for electrochemical uses, and the remainder to other uses. For iridium, about one-quarter of the usage is evenly divided between the electrochemical industry and the petroleum refining industry, and three-quarters to other industries. Consumption of osmium is very low, mostly for the medical industry.

2.2.2.3 Ferrous Metals

Iron and steel are the fundamental metals of every modern industrialized country in the world. These commodities are critical to manufacturing, mining, construction, energy production, transportation, and agriculture. Iron is the least expensive and most widely used metal.

Iron: Iron ore is mined extensively in Africa, Australia, Canada, China, South America, the United States, and the USSR. Major world producers of iron and steel include the European Economic Community, Japan, the United States, and the USSR. About 98% of the iron ore produced in the United States is used for the manufacture of iron and steel. Most iron ore is mined from open pits. Continuously charging iron ore along with coke and limestone into a blast furnace is the primary method of iron production. In the United States, the main method used to convert molten blast furnace iron into steel is the basic oxygen furnace. Some open hearth furnaces are also used for this purpose.

US production of iron ore is based mainly on low-grade ore of the taconite type. These taconite pellets made up almost all US production in the 1980s, with very little direct-shipping ore being produced. In contrast, there was no commercial production of pellets 30 years earlier and direct-shipping ore made up almost three-fourths of US production. The change was brought about by depletion of reserves of direct-shipping ore and increased reliance on taconite to maintain production. Similar changes occurred in Canada and the USSR, but ore grades remain high in Australia, Brazil, India, and South Africa. Almost three-fourths of the world's production of iron ore is government-controlled.

The US iron and steel industry has reduced the amount of energy required per ton of raw steel production by about 20% between 1972 and 1988. During this period, the steel industry shifted its energy consumption away from coal and fuel oil toward natural gas and electricity. This shift occurred principally because of the increased fraction of steel produced by electric furnaces. Installation of heat recuperation systems has also reduced energy requirements.

About 99% of world demand for iron ore is from the iron and steel industry. Iron ore demand from steel production has declined because the proportion of steel produced in scrap-based electric furnaces has increased, adoption of continuous casting in integrated plants has resulted in higher yields, and a number of other technical advances have increased scrap consumption in the basic oxygen furnace.

Up to 10% of the tonnage of iron ore and agglomerates annually consumed in blast furnaces at US iron and steel plants is derived from secondary materials such as flue dust, mill scale, and steel-furnace slag. Ferrous scrap is also charged to blast-, steel-, and foundry-furnaces in varying amounts.

Manganese: The USSR is the world's largest producer of manganese ore. Manganese is an essential element in steelmaking and iron castings production. These industries, chiefly steelmaking, account for over 90% of manganese consumption. Manganese usage in the production of ferrous alloys is mostly as an intermediate product such as a manganese ferroalloy into which the ore is first smelted. Relatively small amounts of manganese are used in the form of metal to alloy with several nonferrous metals, chiefly aluminum. A variety of nonmetallurgical uses exist for manganese, mostly as natural and synthetic oxides and manufactured chemical compounds. Manganese dioxide is a key ingredient in dry cell batteries.

Smelting of ore into ferroalloys is becoming a more significant activity for ore-producing countries, especially Brazil and the Republic of South Africa. Among nonore-producing countries, France, Japan, and Norway are still leading world producers of manganese ferroalloys. The USSR is the world's largest producer of ferromanganese. Manganese smelting into ferroalloys has dwindled to a fraction of the scale once practiced in the United States. Since the late 1970s, imports of manganese in upgraded forms, such as ferroalloys and metal, exceeded those of manganese in ore.

The need for manganese in steelmaking and lack of significant economic domestic deposits make security of supply a national concern in such principal steel-producing areas as the United States, Japan, and Western Europe. The United States has been totally dependent since 1970 on foreign sources for ore products containing at least 35% manganese in addition to having lost most of its capability for producing manganese ferroalloys.

The strong reserve positions in 1990 of the Republic of South Africa and the USSR (Table 2.2.3) help explain the central importance of these two countries to present and future manganese supply. Currently, world trade in manganese is mostly either between market economy countries or between centrally planned economy countries, with relatively small flows between the two types of economies.

Manganese is not recycled per se, but rather is reprocessed mainly as a constituent of iron and steel scrap, steel slag, and aluminum alloys. These materials are recycled primarily for their contents of iron, slagging ingredients, and aluminum, respectively. The net effect on manganese supply is minor.

Chromium: Chromium is used primarily as an alloying element. It is also used in substantial quantities in the chemical and refractory industries. About one-half the chromium consumed in the United States is for the production of stainless steel. Other metallurgical uses of chromium include alloy steel (except stainless), superalloys (nickel, iron-nickel, and cobalt base alloys), and in copper, aluminum, and titanium alloys.

Chemical uses of chromium include wood preservation, pigments, plating solutions, and leather tanning. A small amount of chromium is used to make refractory bricks.

Chromium is mined in the form of the mineral chromite in about 20 countries, mainly the Republic of South Africa and the USSR. In the metallurgical industry, chromite is smelted in electric furnaces to produce ferrochromium that is subsequently used in iron-base or iron-containing alloys. Ferrochromium is also used to make chromium metal by an electrolytic process that is used for making alloys that do not contain iron. In the chemical industry, chromite is roasted with soda ash to produce sodium bichromate, the starting point for the manufacture of numerous chromium-containing chemicals. Secondary chromium from stainless steel scrap accounts for about 20% of US consumption.

Ferrochromium was originally produced in the major stainless steel producing centers of Europe, Japan, and the United States. Chromite-mining countries have installed ferrochromium smelters, while traditional producers have been closing excess capacity. This trend of vertical integration of the chromium industry in chromite-producing countries permits those countries to earn more from their resources.

Nickel: Nickel is primarily used in alloys with other elements, where it adds strength and corrosion resistance over a wide range of temperatures. About one-half the nickel used is for stainless steel. Other uses include electroplating, chemicals, superalloys, and magnets.

About 80% of the nickel reserves are found in laterite deposits, with the balance in sulfides ores. Laterites are highly weathered ultramafic rocks, which can contain nickel, cobalt, iron, and other elements. Typically, ferronickel is produced from laterite deposits with the attendant loss of any cobalt or other metals. Nickel sulfide deposits usually contain copper, cobalt, and sometimes platinum-group metals. Although most nickel reserves are in laterites, almost three-quarters of nickel mining is conducted on sulfide deposits that are readily amenable to concentration by flotation and can be reduced to metal using less energy than with laterite material. No effective method exists to concentrate nickel laterite ore early in the stages of processing.

Aside from small quantities of byproduct nickel produced from copper smelting, there is no US production of nickel. Secondary production, derived primarily from stainless steel scrap, provides about one-quarter of the total annual demand of nickel in the United States. Canada and the USSR are the largest producers of nickel, together mining and refining about 45% of the world's nickel. Australia mines and refines 11% and 6% of the world's nickel, respectively. Norway refines nickel matte produced in Canada and elsewhere. Indonesia and New Caledonia, which refine little nickel, together mine 15%. Japan has no mining capacity but refines 13% of the world total.

Cobalt: The primary use of cobalt metal is in superalloys. These alloys were developed for use in high temperature and corrosive environments. The major application of superalloys is in gas turbine engines for aircraft and industrial use. Cobalt is also used in cemented carbides for cutting and wear-resistant tools and in magnetic alloys for permanent magnets in electrical equipment. The chemical industry consumes significant quantities of cobalt in catalysts, in paints, as inorganic pigments and decolorizers for glass and ceramics, and in various other applications. The United States is a major cobalt consumer, using about one-third of the world's supply annually.

Cobalt is almost always mined as a byproduct of other more abundant metals, usually copper or nickel. More than one-half of the world's supply of cobalt comes from the copperbelt of Zaire and Zambia, where it is mined and refined by government-owned companies. The USSR is a major cobalt producer, mostly as a byproduct of its nickel mines, but is a net importer. Canada produces cobalt, also as a byproduct of nickel mining.

In terms of substitution, cobalt-base superalloys can be replaced by nickel-base superalloys in some applications, and cobalt levels can be reduced in some nickel-base superalloys. Magnetic alloys made of iron, neodymium, and boron can replace cobalt magnets in most cases.

A major transportation issue relating to cobalt is the export routes from Zaire and Zambia. Within Zaire, metals are transported over a complex system of rivers, roads, and railroads. Presently, Zairian cobalt is exported through the Republic of South Africa. Zambia is able to export its cobalt by railway to the port of Dar-es-Salaam in Tanzania. The political situation in southern Africa can have a tremendous impact on the supply, and therefore the price, of cobalt.

Presently, domestic production is limited to recovery of cobalt from scrap which meets almost one-fifth of US demand. Superalloy scrap generated during the making of superalloys, machining of engine parts, or from the replacement of components in jet engines is processed and reused in the production of new superalloys. Other sources of cobalt-bearing scrap are cemented carbide scrap, spent petroleum catalysts, and grindings from the production of cobalt-containing magnets.

Molybdenum: Molybdenum occurs in nature only in combination with other elements. The most common occurrence is molybdenite (molybdenum sulfide), which is widely distributed throughout the world. Commercial deposits have been identified in about 25 countries. About 90% of the total production comes from Canada, Chile, the USSR, and the United States.

As a result of the concentration of mine production capability, international trade in molybdenum materials consists primarily of exports from Chile, Canada, and the United States to industrialized nations that lack mine production. The major importers are West European countries and Japan. The United States exports more than 50% of its mine output, mostly as molybdenum concentrate or oxide.

Molybdic oxide is produced in several grades that are the precursors for all types of molybdenum salts and compounds, and it is also added to steel, cast irons, and superalloys, either with the furnace charge or to the molten bath, to make various alloys. It enhances hardenability, strength, toughness, and wear and corrosion resistance. Purified molybdenite concentrate is also used in the manufacture of molybdenum disulfide lubricants.

Columbium and Tantalum: Columbium (niobium) is a refractory metal used mostly as an alloying element in steels and superalloys. The largest demand for columbium in superalloys has been in a nickel-base superalloy which is used for a number of jet engine parts. Over 40% of the columbium consumed in the United States is used for construction purposes, such as high-strength steels in permanent structures. The next most important use of columbium is in the transportation and aerospace industries with about 25% of the total, followed by the oil and gas and metalworking industries. Tantalum is a refractory metal with approximately 60% of US consumption in electronic components, mainly capacitors. The remainder is consumed in the aerospace and other transportation applications, in the form of tantalum carbide in the metalworking industry, and in chemical processing equipment.

The major producers of columbium mineral concentrates are Brazil, Canada, and Thailand, while tantalum is produced mainly in Australia, Brazil, Canada, and Thailand. Tin slags containing columbium and tantalum are produced mainly by Brazil, Malaysia, and Thailand. Beginning in 1975, synthetic concentrates from the Federal Republic of Germany became an additional source material for columbium and tantalum production. The synthetic concentrates are produced from low-grade tin slags rather than from mined ore. The United States continues to be a major processor of imported feedstock to make columbium and tantalum end products. Brazil is the largest producer of ferrocolumbium for steelmaking. Large amounts of ferrocolumbium are also produced in Japan, the United States, the USSR, and Western Europe, using largely imported raw materials.

Australia, Brazil, and Thailand account for over 70% of the free-world production of tantalum feed material. Thailand is the major source, accounting for about 40% of total production. Thailand's production comes mainly from tin slags derived from the smelting of tin concentrates.

As domestic columbium and tantalum resources are of low grade and not currently commercially recoverable, the United States depends on imports for its columbium and tantalum feed material supply. Processing facilities in the United States are capable of producing about 50% of US demand for columbium products. However, columbium and tantalum processing is being increasingly conducted in countries in which the feed materials originate, such as in Australia, Brazil, and Thailand. Brazil and Canada account for 90% of total US columbium imports, and Thailand accounts for about 30% of total tantalum imports.

Tungsten: Tungsten ores are mined in approximately 30 countries covering nearly all continents. Occurrence of the tungsten-bearing mineral is usually in association with minerals of copper, tin, bismuth, or molybdenum. Most tungsten concentrate is converted to ammonium paratungstate, metal powder, tungsten carbide powder, ferrotungsten, or other tungsten chemicals before being consumed in end-use products. The exception is high-purity scheelite concentrate, which is added directly to steelmaking processes.

China has become a major supplier of tungsten materials to the United States, as US mine production declined drastically during the 1980s to just several hundred tons of tungsten per year. Accompanying this increase in imports from China, trade problems related to price and oversupply have developed requiring special agreements between the two countries. About one-third of the US supply is estimated to be derived from recycled material, mainly cemented tungsten carbide parts.

Because of tungsten's outstanding physical characteristics of high melting point and high density, a significant quantity is used as tungsten carbide in cutting and wear-resistant applications and is generally pressed and sintered (cemented) with cobalt powder for such purposes. The extreme hardness of cemented tungsten carbide at temperatures exceeding 1830°F (l000°C) makes it a preferred metalworking material for the cutting edge of machine tools. Mill products made from tungsten metal powder are used as lighting components and electrical contact points. Wrought tungsten metal is employed as heat and radiation shielding, welding electrodes, and heating elements. Tungsten is also used as an alloy constituent in stainless steels, superalloys and nonferrous alloys. Nonmetallurgical uses of tungsten chemicals include phosphors, catalysts, corrosion inhibitors, and fireproofing agents.

Vanadium: Vanadium occurs in uranium-bearing minerals of Colorado and Utah, in copper, lead, and zinc vanadates of Africa and with certain phosphatic shales and phosphate rocks in the western United States. Certain petroleum crude oils, especially those from South America, contain varying amounts of vanadium compounds. The vanadium is concentrated into the coke, fly ash, and boiler slag upon refining and combustion of the crude oils.

Most of the vanadium reserves are in deposits in which the vanadium would be a byproduct or coproduct with other minerals, including iron, titanium, phosphate, and petroleum. Vanadium is recovered domestically as a coproduct or byproduct from uranium-vanadium ores, and from ferrophosphorus slag as a byproduct in the production of elemental phosphorus.

The steel industry accounts for the majority of the world's consumption of vanadium as an additive to steel in the form of a ferrovanadium alloy. The addition of vanadium to steel produces a fine grained steel which exhibits greater toughness, hardness, impact and wear resistance, weldability, and good high temperature strength. The principal application of vanadium in nonferrous alloys is in a titanium alloy, which is important in the production of supersonic aircraft where strength-to-weight ratio is a primary consideration. Vanadium compounds are used in several permanent-magnet alloys containing cobalt, iron, and nickel. Vanadium metal and several vanadium compounds are used as catalysts in certain chemical and petrochemical reactions.

About one-half the total world reserves of recoverable vanadium is contained in titaniferous magnetite-ilmenite ores, certain magnetite-hematite ores, and titaniferous iron sands. The largest reserves of magnetite-ilmenite ores are in the Bushveld Igneous Complex of the Republic of South Africa and the Kachkanar Gabbro-Pyroxenite Massif of the USSR. Other countries with reserves of vanadium-bearing magnetite include Australia, Brazil, Chile, China, Finland, and India. About 6% of the total reserves are contained in crude petroleum and tar sands.

Silicon: Silicon never occurs free in nature but combines with oxygen and other elements to form oxides or silicates. Deposits of silicon-bearing minerals are widely distributed around the world.

Many countries produce ferrosilicon and silicon metal; however, Brazil, Norway, the United States, and the USSR account for over one-half of all production based on silicon content. Supply and demand of silicon-containing alloys and metal are related primarily to the requirements of the iron and steel, aluminum, and chemical industries, and prices are influenced by the cost and availability of transportation and energy. Ferrosilicon and silicon metal producers are generally located near a relatively inexpensive hydroelectric power source. Raw materials are usually obtained from within a 500-mile (805-km) radius of the plant. Economic factors such as accessibility to low-cost energy, transportation costs, and a ready market for the product determine resource development. Although US silicon resources are abundant, the United States imports ferrosilicon and metallurgical-grade silicon metal because smelting costs are lower in some other countries.

Most silicon is used as ferrosilicon for deoxidation and alloying in iron and steel production. Another significant portion of silicon demand is the silicon metal needed in the aluminum industry for alloying and to improve casting fluidity. The chemical industry uses silicon metal as the raw material for the manufacture of silanes from which silicones and semiconductor grade silicon are produced.

2.2.2.4 Light Metals

In the age of energy conservation and aerospace, light metals have achieved a prominent place in our industrial society. These metals are relatively new in their industrial applications, having been isolated in elemental form less than 200 years ago.

Titanium: The present mineral sources of titanium are rutile (93 to 96% titanium dioxide, TiO_2), ilmenite (44 to 70% TiO_2), and leucoxene, an alteration product of ilmenite, with up to about 90% TiO_2. Ilmenite is produced from both hard-rock and sand deposits, but rutile is currently produced only from sand deposits. A large proportion of the world's ilmenite production is upgraded by smelting or chemical processing to form high-TiO_2 slag or synthetic rutile.

Titanium dioxide pigment is produced commercially by either the sulfate or the chloride process, requiring either ilmenite or rutile, respectively. The major environmental concern in the titanium industry is the disposal of waste solutions from the sulfate pigment process that contain sulfuric acid and iron sulfate. To minimize this problem, US producers of sulfate process pigment operate waste treatment plants that neutralize such effluents with limestone and lime, and produce gypsum and iron oxide byproducts.

Principal world producers of ilmenite are Australia, Canada, Norway, the Republic of South Africa, the United States, and the USSR. Main producers of rutile are Australia, Sierra Leone, and the Republic of South Africa. Titanium metal is produced mainly by China, Japan, the United Kingdom, the United States, and the USSR. Scrap titanium generally accounts for about one-half the ingot production in the United States. Major producers of TiO_2 pigments are France, the Federal Republic of Germany, Japan, the United Kingdom, and the United States.

Because of the high strength-to-weight ratio of titanium alloys and their resistance to corrosion, titanium metal is an important strategic and critical material and is widely used for high performance military and commercial aircraft in both airframes and engines, in electric generating plants, and for a wide variety of chemical processing and handling equipment. Titanium metal is produced by highly sophisticated chemical processes and is more expensive than most other structural metals such as aluminum and steel. Only about 5% of the world's annual production of titanium minerals goes to produce titanium metal. The remainder is used primarily to make white TiO_2 pigment. Because of its whiteness, high refractive index, and resulting light-scattering ability, TiO_2 is the predominant white pigment for paints, paper, plastics, rubber, and various other materials. Other applications of titanium and its minerals include use in welding rod coatings, titanium carbides, ceramics, and chemicals.

Aluminum: Aluminum has been produced in commercial quantities only in this century. This versatile metal of widespread use is exceeded only by iron in world consumption.

Aluminum metal is produced in electrolytic cells by reduction of high-purity aluminum oxide (alumina), an intermediate-stage raw material produced by refining bauxite ore. Although the principal use of bauxite is in the production of aluminum, up to 15% of world production is consumed in refractories, abrasives, chemicals, or in alumina for nonmetallurgical uses. Since 1985, virtually all bauxite mined in the United States has been processed for specialty uses other than aluminum metal production.

The major producers of primary aluminum metal, including those in the United States, are dependent on imports for most of their bauxite and alumina. Large quantities of electrical energy supplied at a constant rate without interruption are required for the reduction of alumina to aluminum metal; thus aluminum smelters are built near sources of abundant electric energy. Until the early 1970s, aluminum metal production was located primarily in developed countries, close to sources of low-cost energy. When the cost of energy increased in the 1970s, metal production shifted to areas where the energy could still be obtained relatively cheaply. New major aluminum plants were built in Australia, Brazil, Canada, and Venezuela.

The United States continues to be the world's largest consumer of aluminum metal. Domestic production, however, has not been capable of meeting demand. Imports of aluminum ingot, semifabricated materials, and scrap supplement domestic production. Canada has traditionally been the largest supplier of metal to the United States. The largest domestic market for aluminum metal is the container and packaging industry. Aluminum metal is also widely used in transportation, building and construction, electrical applications, consumer appliances, and machinery and equipment.

While low cost and ease of fabrication contributed to the tremendous growth in the use of aluminum beverage cans, the recyclability of aluminum played an even more important role. Approximately 50% of all aluminum beverage cans are recycled in the United States. Cans have been the major reason behind the tripling of secondary aluminum production during the past decade (Table 2.2.4). Plastics and paper compete with aluminum for the container and packaging market. Aluminum's high strength-to-weight ratio has encouraged its use in the aircraft and aerospace industry. Aluminum's use in transportation has grown as manufacturers seek ways to reduce the weight of land vehicles to improve fuel efficiency.

Magnesium: Magnesium metal and magnesium compounds are produced from seawater, well and lake brines and bitterns, as well as from minerals such as magnesite, dolomite, and olivine. The largest tonnage use of magnesium in compounds is in refractories consumed primarily by the iron and steel industry. Magnesium compounds are also used in such varied materials as animal feed, cement, rubber, rayon, pharmaceuticals, and ceramics. Olivine, a magnesium-iron silicate, is used mainly as a foundry sand. The primary use of magnesium metal is as an alloying addition to aluminum. Aluminum-magnesium alloys are used in products such as two-piece beverage cans, automobiles, aircraft, and machinery. Magnesium metal and its alloys are also used as structural components in transportation equipment and in machinery.

China, North Korea, and the USSR account for almost one-half the world's magnesite production. China, Ireland, Israel, Japan, Mexico, the United Kingdom, and the USSR produce magnesium compounds from seawater. The United States is the largest producer of magnesium metal from seawater, brines, and magnesite, and with Norway and the USSR, accounts for about three-quarters of the world's magnesium output. Brazil, Canada, China, France, Italy, Japan, and Yugoslavia are the other magnesium metal producers.

Until the 1980s, the United States supplied most of its need for magnesium compounds with domestically produced material. With the decline in the US iron and steel industry in the late 1970s and the rise in the value of the US dollar, many magnesium compound producers shut down capacity or operated at significantly reduced capacities. Imports, principally from China and Greece, have replaced domestically produced magnesia in some of the refractory markets.

As the world's largest magnesium metal producer, the United States has been a net exporter of magnesium for many years. Domestic production, including secondary magnesium from scrap, have been sufficient to supply US demand, although the United States imports some magnesium, primarily from Canada and Norway.

Beryllium: This metal has become a necessary industrial metal only over the last 60 years because of its high strength, low weight, and high thermal conductivity. It is used in the form of metal, beryllium-copper alloys, or oxide. About two-thirds of consumption is in the form of copper alloys that have electrical, electronic, and aerospace applications. The metal accounts for about 20% of consumption in aerospace and defense applications, with the remainder being used in the form of beryllium oxide ceramics for electronics.

In the United States, beryllium resources consist primarily of bertrandite, while in the rest of the world the resource is beryl. Principal world beryl producers are Brazil, China, and the USSR, but the United States is the only integrated producer of beryllium products, including beryllium metal. Reserves exist in only about a dozen countries. Energy requirements for the production of beryllium materials are high, as processing requires the use of induction furnaces that consume large quantities of energy. Because of its high cost and potential health and environmental problems, beryllium materials are specified only when there is a clear technical and economic advantage over other materials.

2.2.2.5 Construction Materials

Construction materials are for the most part industrial minerals. They are high-volume, low-unit-value materials that are usually mined and consumed locally. Processing of the mined material to a usable product is usually a simple process. Imports tend to be a small part of supply and recycling represents a small but growing part.

Sand and Gravel: Sand and gravel, one of the most accessible natural resources, is used mostly for construction purposes, mainly as aggregate in concrete, as road material, and as fill. A significantly smaller volume of high purity sand known as industrial sand or silica sand is used in the glassmaking, foundry, abrasives, and oil industries. Because the uses, specifications, prices, producers, and consumers of construction sand and gravel differ substantially from those of industrial sand, the two types are treated separately.

Construction sand and gravel is a low-value product characterized by its "place value," a term that describes the importance of the location of the geologic deposit in reference to the market. The industry is geographically widespread and self-contained. Mine production is directly related to the amount of construction work in any area. But despite its low unit value, the construction sand and gravel industry in the United States showed a significant growth in production, from 209 million tons (190 Mt) in 1928 to about 882 million tons (800 Mt) in 1988. Annual sand and gravel production tonnage ranks second in the industrial minerals industry.

Construction sand and gravel is the only mineral commodity produced in all 50 states. In 1986, about 4300 companies with about 5800 operations were active in the United States. The individual operations range in size from those producing less than 11,000 tpy (10 kt/a), to those up to millions of tons annually. While most of the operations are relatively small, turning out one product or a limited range of products, most of the tonnage comes from large operations.

The total sand and gravel resources of the United States are very large. However, the geographic distribution and/or the quality of reserves and the environmental as well as zoning restrictions imposed by society are a very significant factor in determining if a particular deposit can be developed for production.

Sand and gravel are usually used together, but some uses require only sand or only gravel. Sand is used in mortar as concrete aggregates, plaster, gunite, and for snow and ice control, while gravel is used in drainage control and as covering and stabilizer on unpaved roads.

US consumption of sand and gravel almost equals that of production because of the very small export trade. The construction industry is by far the greatest consumer and, therefore, the primary factor that determines the demand and supply of sand and gravel for any given period.

The sand and gravel industry is a very competitive industry, largely because sand and gravel are abundant in most areas of the country. Production costs for sand and gravel are determined to a large extent by the cost of labor, equipment, energy, and water, in addition to the cost of compliance with the environmental and safety regulations. These costs vary depending upon the nature of the deposit, the geographic location, and the type and number of products produced. But despite the rising cost of labor, energy, and land value, the competition among sand and gravel producers has kept the relative cost of sand and gravel low. Increased operation costs have been somewhat offset by automation and other means of increasing operating efficiency. The availability of automated and therefore relatively expensive equipment is very important. For this reason, large companies are able to better compete in the sand and gravel business. Smaller, less efficient operations become less economical as operation costs, as well as costs associated with meeting various federal, state, and local regulations, continue to increase.

Stone: Despite the low unit value of crushed stone, the industry in the United States showed a tremendous growth in production, from 130 million tons (118 Mt) in 1928 to about 1.2 billion tons (1.1 Gt) in 1988, mainly due to rapidly increasing demand for railroad, highway, and other construction work. The amount of crushed stone produced is greater than that of any other mineral commodity mined in the United States.

The crushed stone industry is widespread and varies by size of operations, kind of stone, and type of material produced. The size of individual companies ranges from small independent producers with one quarry to large diversified corporations with 50 or more crushed stone operations, from which most of the production comes.

Reserves of stone have not been systematically investigated, partly because of the size of the undertaking and partly because a true measure of the total reserves available held by stone producers would have no particular value when compared with total potential resources, which are, on a national basis, unlimited.

Crushed stone in its different forms is used in a wide variety of applications in industries including construction, chemical, metallurgical, and agriculture. The most common use of crushed stone is for construction purposes. About 65% of the total US production of crushed stone is used as construction aggregates in residential and nonresidential construction and highway construction, of which 60% is unconsolidated aggregates and 40% is concrete and bituminous aggregates.

About 12% of the total crushed stone, mostly limestone, is used for cement and lime manufacturing and 2% for agricultural purposes. The remaining 21% is used for a wide variety of applications ranging from metallurgical flux to manufacture of glass, ceramic pottery, paper, and as fillers and extenders in asphalt, paint, rubber, plastics, and abrasive. A growing amount of limestone is being used in removal of sulfur oxides from stack gases, primarily from coal-burning electric generating stations, and for mine dusting to enhance mine safety by reducing explosion risk of highly combustible coal dust.

Cement: Portland cement is produced by nearly 2000 plants in more than 130 countries around the world. China is the world's largest producer followed by the USSR, the United States, and Japan. Together these four countries account for nearly two-thirds of the world's production. Portland cement is produced by pulverizing clinker consisting essentially of hydraulic calcium silicate and containing various forms of calcium sulfate. Limestone comprises about 85% of the raw material for making cement. World cement capacity was about 1.3 billion tons (1.2 Gt) in 1988, 40% of which is concentrated in Asia, with China and Japan accounting for one-half the total. In the United States, production capacity has been declining since 1985. The decline is attributed to closure of older, less efficient, more energy intensive plants that can no longer compete with more modern plants, both domestic and foreign.

Because cement is a high-bulk low-cost item, it was not always regarded as a commodity that would be traded internationally. However, due to the cyclical nature of cement consumption, many producers in highly developed countries found that domestic demand was not keeping pace with supply, thereby resulting in excess capacity in their own countries. Because of this overcapacity, they began to seek outside markets for their cement. Generally, lesser developed nations with little or no capacity were targets for their excess cement. Some developing countries, notably Mexico and Venezuela, became major producers and exporters. In the early 1980s, however, massive plant construction activity in Middle Eastern countries, and parts of Africa and Asia, made these countries more self-sufficient in cement production. This, coupled with plant construction and modernization projects in North America and Western Europe, contributed to excess world capacity.

The United States has the fastest growing and most stable market of all cement-producing nations and thus has been the growing target of foreign cement producers. Because plant construction is designed to serve strategically defined markets, the cost of transportation becomes an integral part of the planning process. It is uneconomical for cement to be transported long distances overland, thereby causing terminals to be constructed to serve as transfer points to supply markets that cannot traditionally be served by plants. Terminals located near water make it possible for producers to serve more distant domestic markets. At the same time, these terminals make it easier to bring in low-cost imports, thereby increasing the industry's reliance on foreign cement to meet their customer's needs. Shipment of cement from one country to another has become quite prevalent. It is estimated that almost 77 million tons (70 Mt) of cement is traded by world exporting countries each year. The United States is the largest recipient of imported cement receiving about one-quarter of the total. Portland cement manufacturing is one of the most energy intensive of all US industries. Shortages of petroleum and natural gas and escalating fuel costs in the 1970s caused producers to shift to coal and petroleum coke. In addition, countries such as Mexico that provided low-cost fuel to cement manufacturers became international competitors for cement.

Gypsum: Gypsum is the most common of the naturally occurring sulfate minerals, usually associated with limestones, shales and sandstones, marls, and clays. Crude commercial gypsum is generally high-grade material, the major portion of which can be utilized with no beneficiation.

About 80 countries are known to produce gypsum. Because of its wide distribution and plentiful supply, most of the world's production is consumed domestically. Exceptions are Canada and Mexico which export significant portions of their production to the United States; Thailand and Australia which export to much of the southeast Asia market; and Spain which exports principally to the United States and the Scandinavian market.

Crude gypsum is marketed for use in cement, agriculture, and fillers. Commercially calcined gypsum is a manufactured hemihydrate product produced by partial calcination of gypsum. Commonly called plaster of paris, when water is added to form a paste, it quickly sets and hardens to form gypsum again. In most industrialized countries, the major use of gypsum is in the manufacture of prefabricated wallboard products. In developing countries, most gypsum is used in crude form for manufacturing cement. The United States is the leading producer and consumer of gypsum. The domestic gypsum industry is a large, integrated industry in which a few large companies are predominant. These companies operate gypsum board plants with captive mines as a domestic raw material source, but imports of crude ore from Canada and Mexico are substituted for domestic crude gypsum for those plants located on the eastern and western seaboard.

Asbestos: Asbestos is mined in approximately 30 countries. The leading producer of asbestos is the USSR, which accounts for 60% of the world asbestos production. Other countries with significant asbestos production are Brazil, Canada, China, Italy, the Republic of South Africa, and Zimbabwe. The United States accounts for only 1% of the world asbestos production.

Chrysotile, the most common variety of asbestos, is mined in more than 25 countries, with Canada and the USSR accounting for over 70% of the world's production. The Republic of South Africa is the only country producing significant quantities of amosite and crocidolite, two other varieties of asbestos.

Asbestos is used in asbestos-cement products, coatings and compounds, friction materials, packing and gaskets, paper, plastics, roofing materials, and textiles. The properties of asbestos that make it useful in this wide variety of products are high-strength, good chemical and thermal stability, high flexibility, low electrical conductivity, and large surface area.

The largest markets for chrysotile are in asbestos-cement pipe, friction materials such as brakes and clutches, packing and gaskets, and roof coatings. These end uses account for over 80% of the US asbestos consumption. Crocidolite is used primarily in asbestos-cement pipe and accounts for only 1% of total US asbestos consumption.

Domestic demand for asbestos is satisfied primarily by imports, mainly from Canada. Demand for crocidolite is filled through imports from the Republic of South Africa.

Concern over possible health risks associated with asbestos exposure has resulted in an overall decline in the worldwide demand for asbestos in recent years. The most dramatic change has been in the United States, where there has been a tenfold decrease in asbestos consumption since the health issue was raised.

Asbestos consumption has declined in product categories where asbestos substitutes or alternative products are most readily available. These substitute materials are metal, mineral, organic, and glass fibers. In addition to direct substitution, manufacturers also are using alternative products, such as ductile iron pipe, reinforced concrete pipe, wood, or aluminum siding, to replace asbestos-containing products.

Lime: Lime, a manufactured product never found in a natural state, is produced by means of a process known as calcination of limestone or other high-calcium materials. Lime is a basic chemical used for many purposes and is produced in more than 70 countries. The USSR is the leading producer, followed by the United States, Japan, the Federal Republic of Germany, and Brazil. Lime is made from a variety of naturally abundant calcareous materials, such as limestone, marble, dolomite, chalk, shell, coral, aragonite, or byproduct sludge from paper mills, carbide plants, or other industrial plants. Lime in various forms is used in steel refining as a flux to remove impurities, in refractory brick furnace linings, and in a variety of metallurgical processes.

Environmental uses of lime include softening and clarification of municipal potable water, pH control and clarification in sewage treatment, neutralization of mine and industrial wastewater discharges, flue gas desulfurization serving utility and industrial plants, and stabilization of sludges from sewage and desulfurization plants before disposal.

Raw materials for lime manufacture are relatively inexpensive. The manufacturing process is energy intensive and thus expensive compared to raw material costs. The lime industry has one of the highest ratios of energy costs to total material costs found in any manufacturing process. The availability of economic and continuing supplies of fuel used mainly in the calcining operation has been one of the industry's principal concerns. In the past, rising oil and natural gas prices have driven the industry to increase energy efficiency and convert to lower cost fuel, especially coal.

The cost of transportation is also a large factor in the marketing of lime. Market areas and established end-use patterns are very critical to decisions on lime plant locations. Transportation costs restrict international trade in lime. When a demand for lime develops at a distance from an existing production facility, but near raw materials and a satisfactory energy supply, it is sometimes more economical to build a new plant rather than ship the material long distances.

2.2.2.6 Agricultural Commodities

Agricultural minerals, or fertilizers, are bulk commodities with worldwide trade patterns. No living organism can exist without phosphorus, potassium, or nitrogen. Phosphorus must be present in adequate amounts in living cells before cell division will take place. This nutrient has vital functions in photosynthesis, utilization of both sugars and starches, and in energy transfer processes.

Phosphate: Although phosphate minerals are common throughout the world, occurrences that can be profitably beneficiated to a marketable product are limited to Africa, China, the Middle East, the United States, and the USSR. China, Jordan, Morocco, the United States, and the USSR are the principal world producers of marketable phosphate rock. US production of phosphate rock is mainly in Florida. It is estimated that over 90% of production is used to manufacture phosphate fertilizer chemicals. The balance, principally produced by electric furnace smelting, is used to manufacture detergents and other industrial chemicals. Most of the countries with reserves have chemical complexes to convert phosphate rock into phosphoric acid and downstream fertilizers, that is, triple or single superphosphates or ammonium phosphates.

Potash: Potash deposits are not widely distributed throughout the world. Less than 20 countries have deposits of significant size and only two countries have large deposits. Canada and the USSR account for about 60% of the world's production from large, underground, bedded deposits of sylvinite. Most of the rest of the mines in the world are of the same type. Manufactured forms of potash are potassium sulfate and potassium nitrate.

Potash is traded widely and is used primarily as an agricultural fertilizer. Approximately 5% of the world's production enters the industrial chemicals industry. Potash is converted by the chloralkali industry into potassium hydroxide which is the gateway into industrial chemicals containing potassium.

There is a tendency for potash mines to be state-owned, which means that, when supply exceeds demand, the state-owned mines may continue production to maintain employment. LDCs tend to develop marginal mines to create employment, discourage imports, and earn foreign exchange from exports.

US imports of muriate of potash (sylvite) from Canada began in 1962 and have increased on a consistent basis to nearly 95% of total imports and nearly 90% of US apparent consumption. The Canadian mines are closer to the largest consuming region of potash, the US corn belt, than are the US mines. The US producers continue to export to Mexico and the Caribbean because of their natural geographical advantage to those regions. China, India, and Japan are completely dependent on imported potash. Canada, the Federal Republic of Germany, the German Democratic Republic, and the USSR supply most of the potash to the international potash market.

Nitrogen: The saline nitrate deposits of the Atacama Desert of northern Chile are the largest known geologic occurrences of mineralized nitrogen. With the phenomenon of world population explosion and increasing requirements for food and fiber during the past 150 years, nature's bank of available nitrogen has long been exceeded. Commercial production of fixed nitrogen as anhydrous ammonia (82.2% nitrogen) is now the principal source for global nitrogen fertilization. Fundamentally, the process of combining nitrogen from the air with a hydrogen source (usually natural gas) to produce anhydrous ammonia has changed little since commercialization in 1913.

Anhydrous ammonia production facilities are in place worldwide, particularly in countries having access to supplies of natural gas, the major feedstock. Naphtha, refinery off-gases, and condensates, together with coke and coal gases, are other feedstock sources. About 66 countries produce about 132 million tons (120 Mt) of anhydrous ammonia product annually. The People's Republic of China, India, the United States, and the USSR produce just over one-half the total.

Principal downstream nitrogen fertilizer products include anhydrous ammonia for direct application, urea, ammonium nitrate, ammonium phosphates, ammonium sulfate, and nitrogen solutions. About 20% of US anhydrous ammonia production is used for synthesis of nonfertilizer nitrogen products, including plastics, synthetic fibers and resins, explosives, and miscellaneous chemical materials.

2.2.2.7 Byproduct Commodities

These metals are produced as a byproduct of major commodities and therefore their production and supply do not necessarily reflect demand forces. Reserve data are tenuous, with their calculation based on typical content of ore mined for the major metal.

Gallium: Gallium is widely disseminated in the earth's crust; consequently, it is nearly always recovered as a byproduct during processing of ores to recover other metals. The principal materials in which gallium is found are bauxite, coal, phosphate ore, and zinc ore. Of these, gallium is commercially recovered mainly from the processing of bauxite to alumina and the rest from the processing of zinc ore. Although world gallium reserves of over 1.1 million tons (1 Mt) are available from bauxite, much of this bauxite will not be mined for many decades, and only about 40% of the available gallium is recoverable with current technology.

Gallium recovery facilities are centered in Europe, with France and the Federal Republic of Germany as the largest gallium producers. Japan and the United States lead the world in gallium arsenide (GaAs) crystal and device fabrication, with about 85% of the world gallium demand estimated to be in these two countries. The United States has been almost completely dependent upon imports of gallium and relies on the Federal Republic of Germany, France, and Switzerland to supply its demand.

Gallium has limited commercial applications in its metallic form. Its principal use is in the manufacture of semiconducting compounds, mainly gallium arsenide (GaAs) and gallium phosphide (GaP). These semiconducting compounds are used as substitutes for silicon-based devices in optoelectronic devices and integrated circuits. Opto-electronic devices are primarily employed as visual displays in consumer electronic and industrial equipment, as a light source or detector in fiber optic telecommunications systems, and as a power source for satellites. Integrated circuits are used principally in defense applications (Kramer, 1988). Most gallium applications require very high purity levels.

World demand for gallium was about 55 tons (50 t) in 1989, but with the rapid technological progress in GaAs integrated circuit development, the status of world supply and demand is changing dramatically. GaAs has advanced from a laboratory curiosity in the 1970s to a material with distinct applications and almost no effective substitute. Development of fiber optic telecommunications systems, the advent of sophisticated electronic military warfare systems, the widespread use of consumer electronics, and the need to process vast quantities of data in the shortest time possible have provided the impetus for implementing the large number of GaAs research and development programs that are currently underway.

Arsenic: Arsenic occurs commonly in sulfide deposits associated with copper, lead, zinc, cobalt, and gold, and may occur in coal as well. Most arsenic is recovered as a byproduct from copper or lead smelting, though increasingly it is being recovered from the roasting of gold-bearing sulfide concentrates. In general, arsenic is regarded as a troublesome impurity in smelting and refining, and thus high-arsenic source materials may be penalized at the smelter and refinery or avoided at the mine. Arsenic trioxide is produced in about a dozen countries, with France, Mexico, Sweden, and the USSR being the major producing countries.

From 1977 until 1982, there was a world shortage of arsenic trioxide, partly caused by environmental concerns. In the late 1980s, Belgium, Chile, and the Philippines have brought on new capacity. Some companies have actively sought out new sources of arsenic for processing, such as stockpiles of arseniferous dusts, accumulated from various stages of copper, lead, and zinc smelting.

Until 1985, the United States was a producer of arsenic trioxide as a byproduct of copper smelting, principally from imported high arsenic concentrates from the Philippines. The copper smelter and arsenic recovery plants in Washington were shut down because of difficulties in complying with air quality emission standards. Consequently, the Philippines became a new producer of arsenic trioxide in 1985 at its new copper smelter.

An estimated 97% of total western world arsenic production is marketed as trioxide. Most of this trioxide is used in making industrial chemicals, the most important of which is chromated copper arsenate (CCA), which is used as a wood preservative. The use of CCA has grown to be the largest single end use for arsenic trioxide. The next most important use for arsenic trioxide is in the manufacture of agricultural chemicals used in the production of cotton. In the United States, since the 1970s, the uses of inorganic arsenical pesticides have nearly all been phased out. Historically, inorganic arsenical pesticides have been a large end use for arsenic trioxide. There are minor uses for arsenic trioxide and arsenic acid in producing pressed and blown glass.

Arsenic in the form of metal accounts for about 3% of consumption. The major end use for arsenic metal is in copper and lead-base alloys, particularly in lead acid storage batteries to improve the strength of the lead posts and grids. Small amounts of high-purity arsenic metal, 99.999% arsenic or better, are used by the electronics industry in making products that contain gallium arsenide.

Selenium and Tellurium: These trace metals are recovered as byproducts, principally from the processing of copper ores. They accumulate along with the precious metal values in the slimes that are generated during the electrolytic refining of copper. The selenium and tellurium values are not recovered from copper ores processed by leaching technologies nor from copper concentrates processed by fire refining. Much of the selenium and tellurium initially present in the copper ores is not recovered, as concentration circuits are geared toward optimizing copper recovery and slimes circuits are optimized for recovery of precious metals. This is particularly true for tellurium, where recovery of the initial tellurium present in the ore may be less than 5%. Other potential sources of these materials include tellurides of gold and silver, which have been processed for tellurium, and coal resources which contain selenium and tellurium in association with sulfur. Belgium, Canada, Japan, and the United States account for the majority of refined selenium and tellurium production.

The principal uses for selenium are in electronics, where high-purity selenium is used as a photoreceptor on the drums of plain-paper electrophotographic copiers; in heat-stable reddish pigments used in plastics, glass, and ceramics; and in glass manufacturing as a decolorant. Other applications include its use as a feed additive for livestock, selenium being a necessary micronutrient yet toxic in high doses, and as an alloying element in metallurgical applications. Used photocopier drums and manufacturing scrap provide source material for the production of secondary selenium. Tellurium's principal use is as an alloying agent in the production of free-machining steels and copper alloys. It is also used in chemicals and rubber manufacturing and electronic applications including electrophotographic copiers. High-purity tellurium is of strategic significance in cadmium-mercury-telluride used as infrared detectors for military night vision systems.

Germanium: Those producers that currently recover primary germanium rely for the most part on germanium-rich residues derived from past or present base metal smelting operations, mostly zinc. Some germanium is also recovered from scrap. Germanium-rich residues as a byproduct of processing zinc ores mined in Tennessee are shipped to Belgium for germanium recovery and refining. Refined and semirefined germanium is also produced from domestic and imported raw materials in Canada, the Federal Republic of Germany, France, Italy, Japan, and Spain. The USSR and other centrally planned-economy countries produce and refine germanium from domestic sources.

The use of germanium in infrared systems and fiber optics has become the dominant market for germanium. Other applications for germanium include detectors, catalysts, phosphors, metallurgy, and chemotherapy.

Indium: Indium occurs as a trace constituent of other metal deposits, principally zinc, but also lead, tin, tungsten, and iron. It is usually recovered as a byproduct from residues generated in the refining of zinc, so its supply is therefore dependent upon the production of that metal. It is estimated that 90% of the US requirements for indium are accounted for by imports of highly refined indium metal or indium-rich residues and other materials, mainly from Europe. Canada is believed to be the world's largest mine producer of indium and is one of the few countries that processes indium-rich residues produced domestically. Indium-rich materials are usually sent to the major indium-refining countries for processing into high grade material. The major refiners are in Belgium, France, Italy, Japan, and the United Kingdom.

The major use of indium in recent years has been for alloys and solders. Indium is also used in semiconductors, infrared detectors, and atomic indicators, and dental alloys.

2.2.2.8 Advanced Materials

While the metals and industrial minerals as mined or produced normally for commercial use are not usually considered advanced materials, they are the sources of the elements used to make advanced or high technology materials in our modern society. *Advanced materials* can be defined as those materials developed over the past 30 years or so, and being developed at present, that exhibit greater strength, higher strength:density ratios, greater hardness, and/or one or more superior thermal, electrical, optical, or chemical properties, when compared with traditional materials (Sorrell, 1987). Advanced metals, ceramics, and polymers, including composites of these, offer the promise of decreased energy consumption, better performance at lower overall system cost, and perhaps less dependence on imports of materials for which the United States has few or no reserves. Heretofore, materials from high-grade mineral ores, earth minerals, coal, and oil were used as is or processed to produce commodity materials such as metals, glass, ceramics, and plastics for industrial and consumer use. However, technology has now made it possible to design a product and develop new materials with properties needed to perform a specific function and often entirely new functions.

Some of the more important new metals and alloys are aluminum-lithium alloys, with lower density and greater strength than other aluminum alloys; amorphous alloys with superior strength and magnetic properties; magnetic alloys with greatly improved energy product and coercive force; superconducting alloys for high-intensity magnets; super-plastic alloys suitable for new forming processes; improved titanium alloys and coated alloys with greater oxidation resistance; and beryllium-copper alloys with high thermal conductivity and fatigue resistance.

By virtue of their superior heat resistance, wear resistance, and corrosion resistance, structural ceramics are potentially important materials for use in turbine engines, cutting tools, wear parts, and many other applications in which they would replace metals. Some of the important materials for structural ceramics are alumina, zirconia, yttria, thoria, and borides and carbides of silicon, boron, aluminum, and titanium. In general, the raw materials for these materials are abundant, with the possible exception of yttria.

A new class of polymeric materials with exceptional strength and heat resistance is emerging and is increasingly replacing metals in automotive, aircraft, and many other applications. These materials, reinforced with a variety of fibers, are being applied to both exterior and interior components of aircraft and are being evaluated for use in automobiles to replace sheet steel in the body and possibly as structural components.

Stronger, lighter-weight, more heat-resistant materials, such as metal matrix, ceramic matrix, and polymer matrix composites containing particulate, whisker, and fiber reinforcements, have been developed. New fibers of carbon, boron, silicon carbide, silicon nitride, alumina, zirconia, aluminum silicates, and polymers have broadened the range of materials and properties that can be substituted for traditional materials in aerospace equipment.

Electronic, optical, and magnetic materials will require appreciable amounts of relatively rare and less abundant materials, many of them byproducts of the metals already discussed. Among these are gallium, germanium, indium, cadmium, thallium, arsenic, bismuth, zirconium, hafnium, and the rare earths. Because of the byproduct relationship, their future production depends on the extent of major commodity reserves. Consequently, it is imperative that recycling systems exist to recover these materials from waste streams and scrap. Waste materials, such as coal fly ash from power generation and red mud from Bayer processing of bauxite, contain not only appreciable quantities of materials such as aluminum, titanium, and iron, but also valuable minor elements such as gallium and germanium.

2.2.3 US IMPORT DEPENDENCE

Fig. 2.2.1 shows the import dependence of the United States for a number of major commodities expressed as *net import reliance* (imports less exports plus adjustments for government and industry stock changes) as a percentage of apparent consumption. Since World War II, the United States has become increasingly dependent on imports of certain minerals (Cameron, 1986). For the commodities for which reserves are minor or nonexistent in the United States, import reliance is greater than about 75%, and, if recycling plays only a minor part, reliance is nearly 100%. Some commodities, especially cobalt, chromium, nickel, and tin are recovered to a significant degree from scrap, and thus import reliance is significantly lower as secondary production plays an important part in the supply picture.

Since about 1950, the US import dependence has increased substantially for a number of commodities, such as cement, iron and steel, potash, and copper, and to a lesser extent for iron ore, zinc, aluminum, and tungsten. Since the United States has ample reserves and production facilities for most of these commodities, the reasons for increasing import dependence must be sought in the economic and political area.

Prior to the 1980s, cement imports supplemented US production in peak demand years wherever shortages existed. During the 1980s, world consumption declined while US consumption continued to grow. Because of this sustained growth, a strong US dollar in the early part of the decade, cheap water transportation, and in some cases alleged foreign government subsidies and less stringent environmental constraints, it became more economical to import cement. Low cost energy in Mexico for an industry that is one of the most energy-intensive of all led to that country becoming a major US supplier.

The United States was a net exporter of iron and steel in the 1950s, but by the late 1980s was importing almost one-quarter of its needs. By the mid-1960s, Japan and Western Europe had built modern steel industries to compete with the US steel industry. At the same time, the US industry continued to operate aging plants with high labor costs. When steel demand fell in

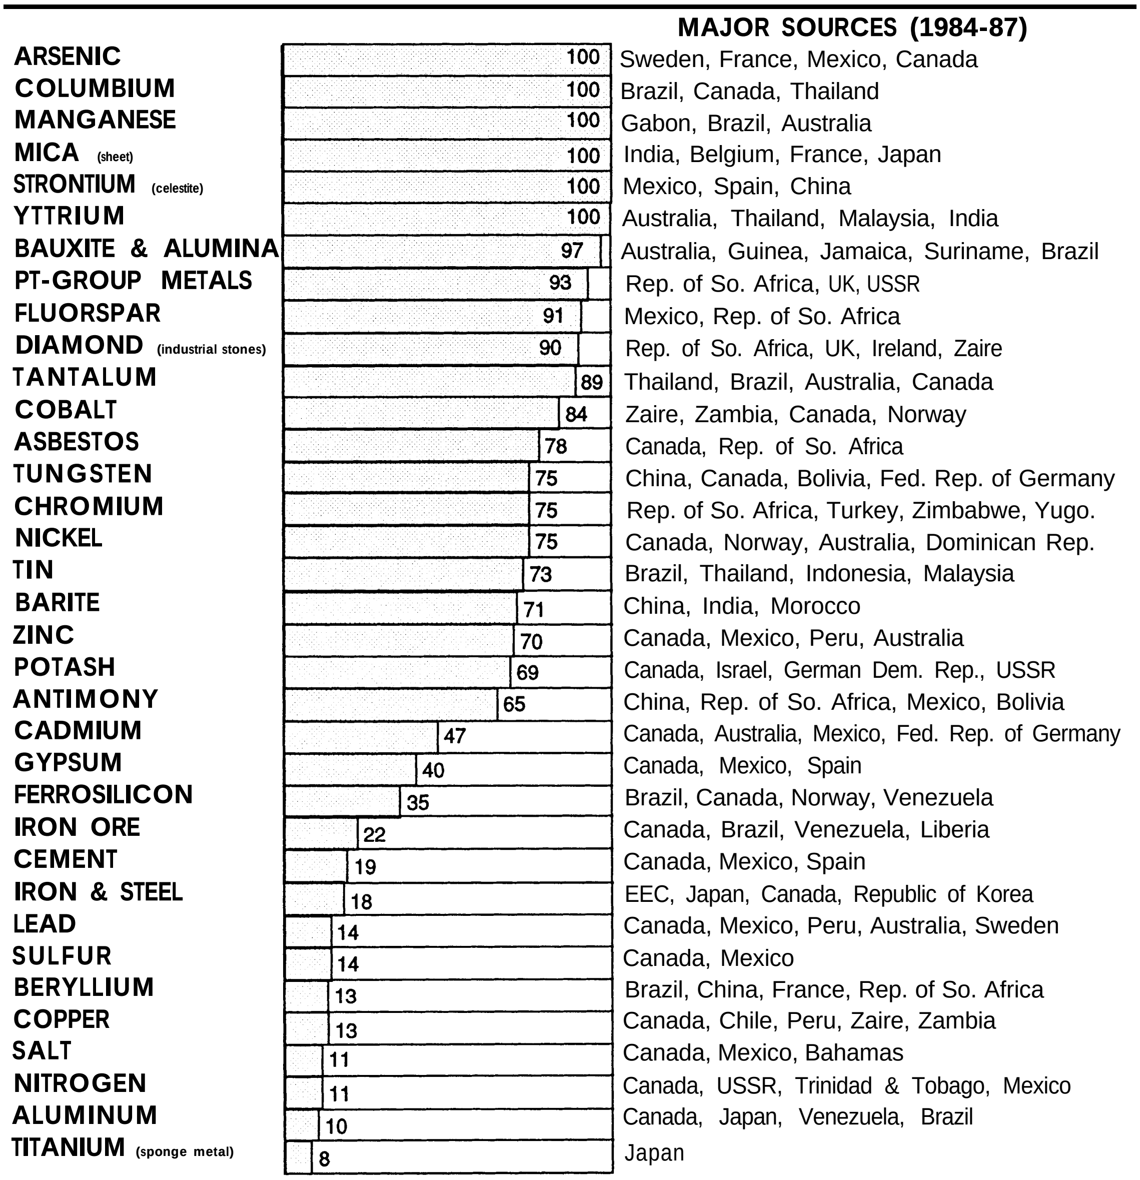

Fig. 2.2.1. 1988 net import reliance[a,b] of selected nonfuel mineral materials as a percent of apparent consumption[c] (Anon., 1989). [a]Estimated. [b]Net import reliance = imports – exports + adjustments for government and industry stock changes. [c]Apparent consumption = US primary + secondary production + net import reliance. Note: For a number of minerals, net import reliance data are withheld or incomplete. However, commodities for which sufficient data are available to indicate a significant degree of import dependency include: andalusite (Republic of South Africa), bismuth (Mexico, Belgium-Luxembourg, Peru, United Kingdom), gallium (France, Switzerland, Federal Republic of Germany, United Kingdom), germanium (Belgium-Luxembourg, China, France, Federal Republic of Germany), graphite (Mexico, China, Brazil, Madagascar), iodine (Japan, Chile, United Kingdom), ilmenite (Australia, Canada, Republic of South Africa) mercury (Spain, China, Algeria, Turkey), rhenium (Chile, Federal Republic of Germany), rutile (Australia, Republic of South Africa, Sierra Leone), selenium (Canada, United Kingdom, Japan, Belgium-Luxembourg), tellurium (Canada, United Kingdom, Peru, Belgium-Luxembourg, and vanadium (Republic of South Africa, South America, European Communities, Canada).

the early 1980s, US production was cut, and the strong US dollar in that period favored imports.

The increase in potash imports beginning in the mid-1960s came about from competition from large, low-cost Canadian mines coming onstream and exporting to the flourishing US agricultural areas. Canadian producers enjoyed a freight advantage in shipping potash to the US grain belt.

The United States evolved from a net exporter of copper through the mid-1970s to a significant importer. Increasing US copper demand coupled with the closure of a number of US mines and smelters due to environmental factors and economic pressures such as high labor costs and a strong dollar contributed to a higher degree of import reliance, which continued through the early 1980s.

The increase in US net import reliance for aluminum, iron ore, tungsten, and zinc has been less dramatic. Nearly all the primary aluminum metal produced in the United States relies on foreign bauxite. Until the 1980s, the US import reliance for aluminum metal was irregular, but with the decline in the 1980s of US smelter capacity due to high labor and energy costs, import reliance exhibited a steady increase. As a result, foreign competitors were better able to supply growing US needs.

Import reliance for iron ore has also fluctuated but was higher in the 1980s than in the 1950s. The depletion of high-grade iron ore reserves in the Lake Superior region was mainly responsible for greater US import dependence. Although the development of the taconite process allowed the use of lower-grade ore, the high impurity level in the pig iron product and environmental factors led to lower US production. In the meantime, many countries through international loans developed their own sizable reserves of high-grade ores that allowed them to enter the international market.

Tungsten dependence has been erratic, mainly because of its relationship to defense efforts and US strategic stockpile activity. With domestic mines operating during the 1960s and early 1970s, supply from US sources was adequate. As prices fell in the 1980s because of a world supply/demand imbalance, lower demand, and increased use of substitutes for tungsten carbide, US production facilities began to close and import reliance increased.

For zinc, total net import reliance has increased, but the reliance on imported zinc concentrate to feed US custom smelters gave way to a reliance on zinc metal imports as US smelters closed due to high costs, obsolescence, and environmental factors. As with a number of other commodities, import reliance was not a matter of lack of domestic resources, but rather one of international competition and political factors that discouraged investments in modern technology in the United States.

For further discussion of imports-exports, see Chapter 2.7.

2.2.4 INTERGOVERNMENTAL MINERAL COMMODITY ORGANIZATION

While most if not all mineral commodities have some type of trade or marketing development association to look after the interests of the industry, some commodities also have intergovernmental organizations with specific mandates. These types of organizations came into being after World War II with the establishment of the United Nations in 1945 and the United Nations Conference on Trade and Development (UNCTAD) in 1964. Developing countries through the auspices of UNCTAD have attempted to form international commodity agreements involving both producing and consuming countries with some type of economic provision for price stabilization through buffer stock management and export controls for bauxite, copper, iron ore, manganese, phosphate, and tungsten. The rationale behind these agreements was to provide an orderly market for these commodities such that developing countries could plan economic growth with assurance of foreign exchange for their commodity exports upon which many were dependent (Buck, 1986). However, the only agreement negotiated was for tin in 1956, with the establishment of the International Tin Agreement (Fox, 1974). In 1985, the buffer stock manager exceeded the financial ability of the implementing International Tin Council to support the tin price. As a result the tin market collapsed and the Council was in bankruptcy.

In the absence of effective economic commodity agreements, intergovernmental producer organizations sprang up for bauxite, copper, iron ore, and sulfur. CIPEC, the Conseil Intergovernmental des Pays Exportateurs de Cuivre established in 1967 by Chile, Peru, Zaire, and Zambia, is perhaps the most well known. Its objectives were essentially the same as for the tin agreement, but without formal economic mechanisms to achieve the end. These organizations also provide much information on the commodity, such as industry statistics worldwide. Committees on Tungsten and Iron Ore exist under UNCTAD as forums for discussion and data dissemination.

The International Lead and Zinc Study Group was formed in 1959, with the anticipation of concluding a commodity agreement. However, it was found that a study group whose function was to provide a forum for discussion, and to collect and disseminate data on the industry so that all members would be free to make their own market decisions, was an acceptable format. Hence market transparency became an objective of commodity groups, and it was this concept in the 1980s that led a number of industrialized nations to foster the formation of "classical" study groups for copper and nickel. In addition, tin-producing and consuming nations began negotiations in 1988 to form a similar organization for tin in order to continue the work of statistical reporting and intergovernmental consultation.

Chapter 2.3
PRICING AND TRADING IN METALS AND MINERALS

SIMON D. STRAUSS

2.3.1 INTRODUCTION

In any feasibility study for a metals or minerals project, an assumption must be made as to the prices at which the project's products can be sold. This is a difficult assignment. Prices of many mineral commodities are volatile, reflecting unpredictable shifts in the balance between supply and demand. Moreover, with some exceptions, the significant balance is that prevailing in the world market rather than any national market—for most mineral commodities are subject to a high degree of international trade.

Thus the mining engineer involved in the development of a mineral deposit needs to understand the pricing of the minerals that deposit will produce. Above all, he/she needs to recognize the perils involved in forecasting mineral prices. Even the most experienced and sophisticated observer of mineral markets is likely to err in predicting the future course of prices. This is true even though his/her studies have taken into account what appear to be all relevant factors.

Moreover, in projects involving mineral deposits previously unexploited, the forecast of prices must cover an extended period. Typically, a "greenfields" project requires several years for mine development, construction of production facilities, and provision of necessary infrastructure of transport and power supply. Following project completion, the price forecast will cover the years necessary to recoup the original investment and provide an adequate return. For most projects, this means that the forecast will cover a period of 10 to 20 years.

The yardsticks by which prices are measured are vastly different from the yardsticks with which engineers are familiar in the measurement of production, metallurgical efficiency, or labor productivity. Engineers are used to working with yardsticks that are constant—measurements of weight in pounds or kilograms; measurements of distance in feet or meters; measurements of time in seconds, minutes, hours, or days. Recovery of mineral content can be measured in percentages.

The yardsticks for prices are in terms of monetary currencies. The value of a given currency unit tends to change. Thus if the current price of a given mineral is the exact monetary equivalent of the price of that mineral 10 years earlier, it nevertheless has almost certainly changed. Due to the shifting tides of economic fortune, a given amount in dollars and cents today may be worth more or less than it was 10 years earlier. It will be worth more than 10 years ago if the economy has suffered deflation; it will be worth less than 10 years ago if the economy has suffered inflation. During the 20th century, with the exception of the severe depression of the thirties, the general trend worldwide has been inflationary.

To provide a specific illustration of the shifting value of currency units in relation to a mineral commodity, consider the price of copper in 1988 in the United States—it averaged $1.19/lb ($2.62/kg). Fifty years earlier, in 1938, the average price of copper was l0¢/lb (22¢/kg). Thus copper appears to have increased in price nearly twelvefold in 50 years. However, if these two prices are adjusted to allow for inflation, the comparison between them yields a very different picture. A common tool for making such adjustments is the US consumer price index. Taking this so-called CPI with the year 1967 equalling 100, the price of copper in 1938 is measured to have been 23.7¢/1b, not l0¢/lb. And the price of copper in 1988 is measured to have been 33.6¢/1b, not $l.l9/lb. In other words, by restating the prices in terms of a constant deflator, the change in the copper price over this 50-year period was not a gain of 1l00%, but rather 42%.

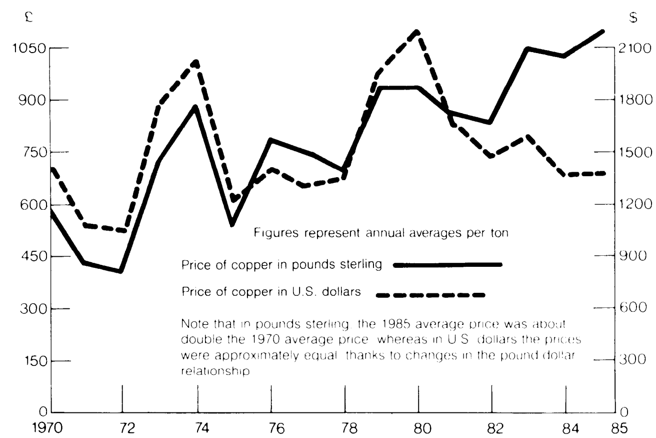

Fig. 2.3.1. London Metal Exchange prices for copper, 1970-1985, expressed in pounds sterling and US dollar equivalents (Strauss, 1986).

The mining engineer who is making a feasibility study of a mineral project obviously cannot be expected to study the broad economic picture. Therefore, his projection of price will be based on what the economists call "money of the day." If he is preparing his analysis in, say, the year 1992, his forecast of prices can appropriately be stated on the basis of 1992 dollars. If future economic trends significantly alter the value of the dollar, the presumption must be that roughly corresponding changes will occur in the prices of mineral commodities—although this may take time.

An additional difficulty in forecasting prices is that the currency of any given nation may lose or gain value at a different rate than the currencies of other nations. This has been particularly true since the early 1970s, when the system of fixed exchange rates instituted by the International Monetary Fund at the end of World War II gave way to a new era of floating exchange rates.

For most mineral commodities, the currency standard in the 20th century became the US dollar, as it was for many years the accepted denominator of international trading values. Thus prices stated in US dollars are the usual measuring stick for such significant minerals and metals as gold, copper, aluminum, nickel, zinc, lead, silver, tungsten, iron ore, sulfur, phosphates, potash, and talc, to name just a few.

But due to the change in the value of other leading currencies in relation to the dollar, it has frequently happened that a rise in the price of a commodity in terms of dollars may equate to a loss in the price of that commodity in terms of a different currency, say Japanese yen or German marks. See Fig. 2.3.1, especially after 1980, for an example of this. To further illustrate, between February 1985 and March 1987, the price of gold rose from \$299/oz (\$10.55/g) to \$409/oz (\$14.43/g), a gain of 37%. But during those 25 months, the value of the dollar fell in relation to other major currencies. In terms of Japanese yen, the price of gold declined by 21%, and in terms of German marks, it fell by 24%.

How then can one describe the gold market during those 25 months. Was the price rising? Most US citizens would say so. Was the price falling? That would be the verdict of the Japanese or the Germans.

The key point is that on any given day, however, the price of gold in the United States, Japan, or Germany was approximately equal—given the high value of the commodity, the ease with which it can be transported, and the absence of import duties. For other bulkier commodities, there may at times be significant differences in prices prevailing in particular markets. And where there are substantial barriers such as tariffs, quotas, or other limiting factors, on occasion a wide gap may exist between the price in one national market as distinct from other countries. However, with the increased trend toward freer trade and the continued improvement in transportation facilities, such isolated instances of large price differentials are becoming increasingly rare. One contributing factor to maintenance of fairly uniform pricing throughout the trading world at any given time is the information explosion resulting from widespread use of computers, fax machines, international telephone communications, and a vigilant trade press. Moreover, a substantial share of the world's mineral trade is carried on by international dealers or brokers who have a keen sense of market developments and hence will focus on sales in strong markets in preference to those where demand is lagging.

2.3.2 HOW ARE MINERAL PRICES DETERMINED?

The methods by which mineral prices are established differ widely. Unique patterns have evolved over the years in which minerals have been traded. Since there are literally hundreds of distinct mineral commodities being bought and sold, it is impracticable to attempt in this presentation to describe the prevailing procedures for each—or even for the 30 or so most widely used minerals in terms of volume or value.

Instead, an attempt is made to describe some of the more widely used methods of arriving at price.

In general, minerals are sold on the basis of weight, varying from carats for gem stones, ounces for precious metals, pounds or kilograms for the more valuable base metals, and on to tons (be they short, metric, or long) for less valuable metals, ores, and most of the industrial minerals. In some cases the price is stated on the basis of the metal content of certain ores rather than gross weight—thus, for example, tungsten is sold on the basis of units of tungsten contained in wolframite or scheelite concentrates.

For any given mineral, market transactions can occur at several stages of production. Thus there is a market for bauxite (the usual source of aluminum), for alumina (an intermediate product), and for aluminum. Prices are quoted for each of these three products and the trends are not necessarily the same. At times, aluminum metal may have been in short supply, but there may have been an abundance of bauxite.

One can identify at least four principal methods by which the minerals industries arrive at their selling prices. There is considerable difference of opinion among producers, consumers, traders, and public officials as to which is the best procedure. All express a desire to arrive at prices that are fair and reasonable and promote stability, yet they differ profoundly in their approaches.

The four broad procedures are

1. Prices established by a producing seller, who periodically announces the terms and conditions, as well as the prices, at which he/she will make sales. These are called producer prices.
2. Prices announced periodically by an independent agency, often a trade periodical, that makes regular surveys among both buyers and sellers to ascertain the basis at which actual transactions have taken place.
3. Prices negotiated directly between seller and buyer. Frequently, but not always, the result is contracts extending over a period of several years with provision for price adjustment under agreed conditions.
4. Prices established on futures markets or commodity exchanges. These facilities, open to all to trade, provide auctions by open outcry, comparable with securities exchanges.

For some commodities, the determination of price in some markets is by one procedure and in other markets by other procedures. For example, for many years in the United States, the price of lead was based on method 1. The major US and Canadian sellers, the chief suppliers of lead in the United States, periodically announced the price at which they would market their product. However, in the European market, the price of lead has long been customarily based on the quotation of the London Metal Exchange. In some of the developing countries of Asia and Latin America, sales of lead are frequently the result of method 3, negotiation between buyer and seller. In such negotiations, due attention is always given to the prevailing prices in the United States and Europe.

Some transactions take place in which two or more of the pricing methods play a role in a single transaction. Typical of these are the sale of copper, lead, zinc, or nickel concentrates by a producing mine to a so-called custom smelter, a processing facility which secures part or all of its feed from independent mines. Method 3 (direct negotiation between the miner and the custom smelter) is universally followed to set the treatment charges involved. These are characteristically stated in terms of an amount per ton of concentrate delivered, modified by credits for byproduct elements that are recovered and penalties for impurities. However, payment for the recoverable metal contained is based on a price determined either by methods 1, 2, or 4. For example, lead content may be paid on the smelter's selling price for lead (method l), a periodical's published price for lead (method 2), or the London Metal Exchange price for lead (method 4). Usually, these are the average price for the month in which the concentrate has been delivered to the smelter or for the month following delivery.

Perceived advantages and disadvantages of each method of pricing will influence both sellers and buyers as to which they select. Method 4 (trading on a commodity exchange) has not been found practicable for most mineral commodities even though it has become a highly acceptable price determinant for several key metals and has long dominated the field of pricing of leading agricultural commodities.

In the following, we discuss the salient characteristics of each of the four methods.

2.3.2.1 Producer Prices

In establishing a producer price, the seller takes into account his cost of production, his potential markets, the position of his competition, and the possibilities of increasing his market share. The competitive factor must always weigh heavily on his decisions.

Historically, there have been two instances of a mineral monopoly, a single significant seller in the world market. One was the Chilean nitrate of soda industry prior to World War I, and the other was the Greenland cryolite industry prior to World War II. In a sense, these two industries were in a position to name their own prices without considering competitive factors. Eventually, however, the very existence of this seemingly unlimited power sparked successful efforts to develop synthetic products that proved to be acceptable substitutes, and the apparent monopoly ended.

Although monopolies are rare, in the mineral field there have been numerous instances of what economists call oligopolies. These are markets dominated by a small number of powerful sellers. As examples of oligopolies, one might cite the aluminum, molybdenum, and nickel markets. As late as the middle of the 20th century, these markets were examples of producer pricing.

In the case of aluminum, a handful of companies accounted for the bulk of world production through the 1960s, notably Alcoa, Alcan, Alusuisse, Kaiser, Pechiney, and Reynolds. In molybdenum, the dominant seller was Climax, subsequently merged into the company now known as Amax. In nickel, the largest seller by far was Inco (formerly International Nickel Co.).

The pricing policies of these companies appeared to be designed for stability (in contrast with the volatile price behavior of such base metals as copper, lead, and zinc) at levels that would encourage maximum expansion of consumption. Indeed, in the third quarter of the century, the consumption of aluminum increased at an average rate of 8% compounded annually, while consumption of nickel and molybdenum both rose by about 6% compounded annually. These figures are for world consumption.

Expanding use of these metals was due to intensive research and promotion efforts by the dominant companies, as well as to the stable price structure. Since success attracts attention and imitation, in the long run what happened was that other corporations were encouraged to enter the aluminum, molybdenum, and nickel industries. Intensive exploration discovered previously unknown deposits in many areas (including byproduct resources of molybdenum in many copper deposits), financing was arranged, and new producers were launched.

With more sellers competing in the marketplace, gradually the ability of the previous major firms to control price was eroded. Stability of price gave way gradually to volatile behavior. By the 1980s, the prices of aluminum, nickel, and molybdenum rose and fell in response to market conditions much as had long been the case with other metals.

Producer pricing has coexisted with prices established on commodity exchanges in the case of copper, zinc, and lead. Producers of these metals have attempted to lessen the extreme swings in price on the exchanges at times in an effort to prevent a perceived threat of substitution by competing materials. When, as has happened, a material discrepancy has developed between the producer price and the exchange price, difficult market distortions have resulted. Increasingly the trend has been away from the producer price and toward the exchange-denominated price.

Two important categories of mineral commodities—the industrial minerals and the so-called minor metals—tend to be sold either on the basis of producer prices or prices as determined by trade periodicals or other independent sources. Recent price histories of representative nonmetallic minerals appear in Table 2.3.1.

Major industrial minerals tend to be bulk materials of relatively low unit value. They include sulfur, potash, phosphate rock, barite, gypsum, salt, fluorspar, diatomaceous earth, talc, and asbestos. An appreciable portion of their cost to the user is absorbed in transportation costs from mine to market. Keen competition prevails in these commodities, but they are considered unsuitable for listing on commodity exchanges because of low value and problems of establishing uniform quality standards.

Minor metals present a contrast: they have fairly high unit value but limited volume. Many are byproducts recovered in processing base-metal ores, for example, bismuth, cadmium, cobalt, germanium, indium, tellurium, and selenium. Antimony and mercury are two exceptions in that much of their production is derived from deposits in which they constitute the chief element of value. A problem arises in that output of the byproduct metals depends on the demand for the major base metals, whereas demand for byproduct metals does not necessarily coincide with demand for major metals. Hence markets for byproduct metals are at times subject to substantial excesses or shortfalls-with drastic effect on price. This price volatility would appear to encourage listing on commodity exchanges, but the prospective trading volume is too small to interest the exchanges.

Producer pricing is not feasible for the two traditional precious metals, gold and silver. Therefore, they have historically had prices established by other procedures. Huge supplies of gold and silver mined in the past exist as bullion, coins, jewelry, and works of art. These holdings dwarf the current newly mined product and exercise a dominant role in price determination. Because supplies of platinum group metals arise chiefly from two sources—the Soviet Union and South Africa—in the past, producer pricing arrangements have existed, yet increasingly the markets are being influenced by commodity exchange trading.

2.3.2.2 Independent Pricing Determination

Responding perhaps to consumer concerns over being subject to prices unilaterally determined by producers, in many minerals pricing is sometimes based on quotations as determined by a source that is neither seller nor buyer. In many but not all cases, this may be a trade periodical, such as *Metals Week* or *American Metal Market* in the United States or *Metal Bulletin* in Great Britain.

The prices quoted in these periodicals are based on canvassing producers, consumers, and merchants dealing in the specific commodity to determine the prices at which actual transactions have taken place at specific dates. The publication then reports these prices as averages for a given day, week, or month. Not infrequently, contracts are made between producer-sellers and consumer-buyers providing that the actual price for a given tonnage of metal or mineral will be the price as reported in the publication. Sometimes a seller will give buyers the option of paying either the seller's price or the periodical's average price, with the option to be decided in advance.

In addition to the trade press, other independent arbiters of price exist. One of the best known is the Handy & Harman daily silver quotation. Handy & Harman is a US silver refiner and fabricator, based in New York, that buys silver from producers and sells fabricated silver products to ultimate consumers. Each day, having determined the quantity of silver it requires to meet that day's sales commitments, Handy & Harman solicits bids from principal silver sellers to supply a matching amount of metal. Its price represents the clearing price at which it can obtain the amount it requires.

In London, a somewhat similar procedure is undertaken daily by the leading London bullion dealers to match inquiries from gold and silver buyers with offers from gold and silver sellers. Representatives of the firms meet at noon to review offers and bids received from worldwide sources. The consequence is announced as the official "fixing" for each of the two metals. Much of the world's commerce in the two metals is based on this daily announcement, although since the mid-1970s, attention is also paid to prices as announced in Zurich, Tokyo, Singapore,

Table 2.3.1. US Prices for Nonmetallic Minerals, 1973–1985

Year	US Gross National Product Deflator Price Index = 100	Barite, $	Boron, $	Diatomite, $	Gypsum, $	Phosphate Rock, $	Salt, $	Sulfur, $
1973	49.5	16.66	88.18	65.04	4.60	6.24	6.82	17.56
1974	54.0	16.77	108.03	83.77	4.86	12.10	7.87	28.42
1975	59.3	17.70	115.74	88.18	5.04	25.35	9.85	44.91
1976	63.1	25.63	121.25	95.90	5.51	21.26	8.62	45.72
1977	67.3	22.33	130.07	109.13	6.12	17.39	9.85	44.38
1978	72.2	22.71	141.09	122.36	6.87	18.56	11.13	45.17
1979	78.6	28.08	184.08	138.89	7.53	20.04	11.03	55.75
1980	85.7	32.39	186.28	160.94	9.18	22.78	16.15	89.06
1981	94.0	39.64	205.03	180.78	9.40	26.63	15.17	111.48
1982	100.0	41.53	221.56	194.00	9.33	25.52	15.31	108.27
1983	103.8	42.69	221.56	203.93	8.68	23.97	14.80	87.24
1984	108.1	36.19	229.28	212.74	8.75	23.99	15.19	94.31
1985	111.7	30.86	229.28	230.38	9.15	23.50	15.43	104.68
Change 1973-85	+125.7%	+85.2%	+160.0%	+254.1%	+98.8%	+176.6%	126.3%	+486.1%

All prices are in $US per ton material, f.o.b. shipping point.

and other bullion-trading centers, as well as to the prices prevailing on the New York Commodity Exchange.

In the case of tungsten, two independent sources of price determination have been established. *Metal Bulletin* in London has long been the source of quotations for tungsten content of scheelite and wolframite concentrates, the form in which most of the world's tungsten production is traded. In addition, as a consequence of meetings arranged under United Nations auspices, a so-called International Tungsten Indicator price is calculated, based on details of tonnages sold and prices paid provided by both buyers and sellers, stated in price per unit (1%) of tungsten content (in US dollars).

2.3.2.3 Negotiated Prices

In many transactions, the applicable price paid for a metal or mineral is the consequence of direct negotiation between buyer and seller, rather than the use of a price previously established by the seller or previously published by an independent agency. The use of negotiated prices is particularly common in the case of long-term contracts covering the supply of raw materials to a processing facility.

Thus, for example, a mine supplying iron ore to a steel mill or one supplying chrome or manganese ores to a ferroalloying plant will typically negotiate the price of its product with the consumer. Because the material involved is bulky and because transportation arrangements must be worked out on the basis of a regular schedule, it suits both the buyer and the seller to commit themselves to a long-term arrangement.

The contract specifies the quality of the product to be delivered: the seller can only offer material of the particular characteristics contained in the deposit it is exploiting. The buyer needs to be certain that his processing facility will receive raw material it can handle efficiently. There is thus a community of interest between the two.

In the price negotiation, each party is cognizant of the other's requirements. The buyer knows that if the price involved is inadequate to insure continued operation by the mine, he may lose a suitable supply of raw material for his plant. To guard against adverse consequences of major inflationary trends on his supplier's operating costs, as a rule he will agree to a provision for price escalation in the event labor, fuel, supply, or transport costs change drastically. The seller has to recognize that if he makes excessive price demands, the buyer will look for alternative sources. Therefore, possible competition influences the seller's negotiation stance.

Concentrates of such base metals as copper, lead, zinc, and nickel are normally sold through long-term contracts negotiated between a miner and a smelter—or perhaps by a miner and an intervening trading firm that then sells to a smelter. In such negotiations, the discussions center about the processing charges for smelting and/or refining of the concentrates. A separate matter is the determination of the value of the recoverable metal content. This is calculated either on the basis of published prices in trade periodicals or on official quotations from the commodity exchanges. The payment for the concentrates is the consequence of deducting the processing charges from the calculated value of the recoverable metals.

Buyer-seller negotiations also frequently determine the price paid in transactions involving nonmetallic industrial minerals—for example, chemical companies purchasing sulfur or other materials required in fertilizers and similar products. Major construction projects are also likely to negotiate on a long-term basis for cement, building stone, and other required minerals.

2.3.2.4 Commodity-Exchange Pricing

Prices of a few important nonferrous metals are either determined on or largely influenced by transactions on commodity exchanges, the two most widely known being the London Metal Exchange and the New York Commodity Exchange. There are other exchanges in operation that trade in metals, but these two are the ones most frequently referred to in the metals trade. The number of metals listed for trading in London and New York changes from time to time. When this chapter was written, London was trading in aluminum, copper, lead, nickel, tin, and zinc. New York was trading in aluminum, copper, gold, and silver. On the New York Mercantile Exchange, platinum and palladium were being traded.

Some description of exchange trading is essential for an understanding of the role played. Essentially, such trading represents an auction at which contracts for a given commodity are offered for sale during prescribed hours of each business day. Trading on an exchange is open to anyone with an appropriate credit rating, but the actual transaction must be conducted through a firm or individual that is a member of the particular exchange.

Exchange contracts specify a standard quantity of the commodity being traded. For example, the London copper contract is for 25 t (metric tons); the New York copper contract is for 25,000 lb. The quality of the metal that constitutes acceptable delivery under an exchange contract is carefully specified. Brands that are produced by known refiners must be approved for listing by the exchange before they can be traded.

Offerings made on the exchange floor are for delivery at a specific time. London contracts are traded for the prompt or “cash” position, requiring immediate delivery or for future delivery on a specified date. New York contracts specify the month of delivery.

Under exchange contracts, the seller may deliver any acceptable brand he chooses at any warehouse site approved by the exchange. This latter option is of great significance since the London exchange has approved warehouses not only in Britain but also at major ports throughout the European continent and even in Singapore. The New York exchange has approved warehouses scattered throughout the continental United States.

If the buyer takes delivery at a warehouse location that is inconvenient for him, or if the brand tendered is not one that he normally consumes in his plant, as a rule he can arrange to make an exchange for a more suitable warehouse site or a more desirable brand through the member firms, but this may involve paying a premium identified as “exchange for physical.”

However, in the vast majority of exchange transactions, physical delivery is not made. Instead, the buyer of a contract may sell or the seller of a contract may buy back the quantities involved in the original transaction prior to the effective date of the contract. What then is the purpose of the transaction? Simply to establish a known price to cover the seller’s output or the buyer’s raw-material costs.

As an illustration, assume a secondary copper smelter buys scrap material to be delivered to its plant in 30 days. After delivery, an additional 45 days may be required for processing. The price of copper may rise or fall substantially between the date of the original purchase and the date, 75 days forward, when metal is available for sale. By selling an equivalent amount of copper on the exchange the day the scrap material is purchased, for delivery 90 days forward, the secondary smelter has fixed the price it will receive based on the position of the market at the time it bought its raw material. When the recovered metal is available, it is sold to a consumer based on the then prevailing price and the outstanding exchange contract is bought back. These two latter transactions offset each other, so the net outcome is based on the original exchange sale even though no delivery is made on the exchange.

In addition to the large volume of exchange transactions based on this type of hedging, there are also trades made by speculators who believe they can realize capital gains through purchasing when a rise in price is probable or through selling when a fall in price seems imminent. Speculators are not actually involved in the metals business. They are as apt to trade in orange juice or hog bellies as they are in aluminum or gold. They too have no interest in holding supplies of metal per se. Therefore, in the great majority of instances, they either liquidate their positions prior to maturity or, alternatively, liquidate nearby positions and roll the contracts forward to more distant dates.

Obviously, much more could be spelled out in regard to exchange transactions—volumes have been written in regard to their operations (see the bibliography for some sources). Because of space limitations, however, a brief summary is all that is offered here.

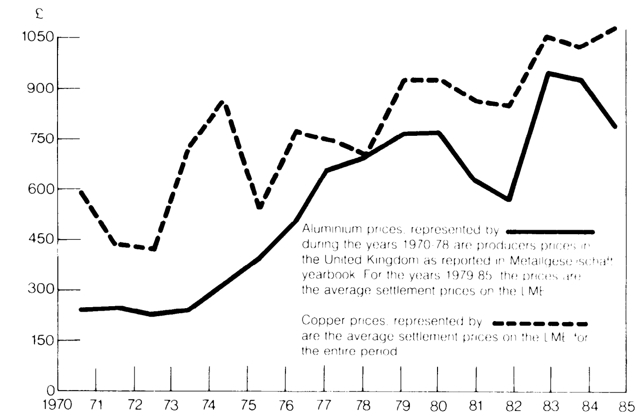

Fig. 2.3.2. Average prices for aluminum and copper, 1970-1985, stated in pounds sterling per ton (Strauss, 1986).

The key to the trend of prices on commodity exchanges is the perceived balance between supply and demand. If supply exceeds demand, inventories will rise and prices will fall. If demand exceeds supply, inventories will fall and prices will rise. The trend of production costs does not immediately affect prices on an exchange.

It is different with a producer price. Costs are an important price determinant. Thus after making an expensive wage settlement, a producer will try to increase its price. By contrast, when a wage settlement is reached, no matter how costly, the commodity-exchange price of the product will tend to fall because the market perceives that the risk of a strike and a reduction in supply has been averted.

As an example, before aluminum had been listed for trading on the London Metal Exchange, the producer price of aluminum was increased in 1975—even though at the time there was a serious economic slump under way. The rationale was that an expensive wage contract had just been concluded. After trading started on the London Metal Exchange during the recession of the early 1980s, the price of aluminum fell sharply—despite further wage increases (Fig. 2.3.2).

Producer prices are still quoted for some metals traded on commodity exchanges, but their significance has diminished. Many producers of the metals traded in London and New York believe that the volatility of prices is increased by the exchange mechanism. Yet they are reconciled to living with the prices quoted on the exchanges and have modified their former marketing strategies to take the exchange prices into account.

2.3.3 EFFORTS TO STABILIZE PRICES

Volatile mineral prices create problems for producers, consumers, and governments. Ore has been defined as mineralized rock that can be profitably extracted. At a given price a deposit may be profitable; at a lower price it will not be. Therefore a mine operator’s estimate of ore reserves is dependent on price and the very existence of his enterprise can be threatened by a sharp fall in price.

Consumers who produce products containing minerals need to establish their own selling prices. Frequent changes in those prices are resented by the buying public. Hence consumers deplore constant fluctuation in the cost of essential raw materials-particularly those raw materials that constitute a large part of their total costs.

Governments—particularly governments of developing countries that depend on mineral exports for a large share of their foreign-currency revenues and of their tax incomes—find it hard to plan their budgets in the face of widely fluctuating mineral prices.

Not surprisingly, therefore, repeated efforts have been made to stabilize mineral prices. Sometimes these efforts are made by private-sector producers of minerals; sometimes they are made by governments through commodity agreements. With few exceptions, these efforts have ultimately been unsuccessful because market forces have proved more powerful than the most ingeniously contrived stabilization schemes.

Perhaps the most extensive and longest lasting of the formal inter-government stabilization arrangements was that undertaken, beginning in 1956, by the International Tin Council. Although the number of member governments varied from time to time, during most of the three decades of ITC operation, there were over 20 tin-consuming and 6 or 7 tin-producing countries formally allied with this undertaking.

The stated objectives of the ITC were to avoid persistent disequilibrium between production and consumption of tin and the accumulation of burdensome stocks, to stabilize employment in the tin producing and consuming countries, to maintain steady export revenues for the producing countries, and to minimize price fluctuations.

Producing and consuming country members shared equally in decisions, but on major issues a two-thirds majority was required, ensuring that approved measures were acceptable to some members from both groups. Individual members had voting rights proportional to their production or consumption.

The Council set both floor and ceiling prices for tin, with the objective of keeping the actual price in the trading zone between floor and ceiling. These prices were subject to periodic reviews and the underlying agreement was itself renewed every five years.

The mechanism by which the Council undertook to keep the price within its desired trading range involved buffer stocks, financed by contributions from the producing-country members, and export quotas to be invoked if demand and prices were weak. Some consumer countries eventually made voluntary contributions to the buffer-stock fund, thus increasing available resources.

The buffer stock was operated by a manager who was instructed to buy tin in the open market if prices dropped toward the stipulated floor and to sell tin if prices rose toward the ceiling. The initial funds raised when the Council began operations were equivalent to about 25,000 tons (22,700 t) of tin, about one-sixth of the then current rate of world production.

During the 29 years of its existence, the floor and ceiling prices inexorably moved higher, reflecting worldwide inflation trends. In this period of time, the floor price was never lowered; the tin-agreement mechanism worked like a jack that steadily ratcheted the price upward. There were two consequences—one was that production of tin by nonmember countries was encouraged; the other was that consumption of tin was discouraged. World tin consumption in the 1980s was roughly at the same level as in the 1950s, whereas consumption of all other base metals had increased sharply.

By 1985, the buffer stock manager had not only exhausted all the funds available from member contributions, he had borrowed heavily using the buffer stock as a collateral to buy still more metal. In the lackluster economic situation then prevailing, supply exceeded demand, and stocks continued to build. In October, operations of the stock were suspended, the price of tin collapsed to levels far below the floor price, and the Council's inability to meet its obligations resulted in staggering losses of hundreds of millions of pounds to lenders and London Metal Exchange member firms. The banks had loaned funds and the traders had assumed that the member governments would stand behind the Council's obligations. They did not. Litigation resulted that continued until 1990, when settlements were made that mitigated a fraction of the losses.

The tin agreement was undertaken in good faith by member governments that operated with the best of intentions. It worked for a while, but eventually ran afoul of the market because good intentions are not enough. Consuming countries, wanting to help the producing nations that were for the most part poor countries with limited resources, had been persuaded to agree to unrealistic floor prices based on the costs of production at the most marginal mines. Once the target was set too high, trouble was inevitable in the long run.

There have been discussions of intergovernmental price stabilization arrangements for several other minerals—copper, bauxite, manganese, tungsten, and iron ore to name a few—but none have gone beyond the talking phase. The collapse of the tin agreement has reduced the interest in similar schemes.

Of course, history has been replete with efforts to stabilize prices through private arrangements. Under existing anti-monopoly legislation in many industrialized countries, such efforts would today be illegal.

One exception that perhaps proves the rule is in the field of gemstones. A high proportion of the world's supply of diamonds is marketed by a group called the Central Selling Organization (CSO), controlled by De Beers, a prominent South African diamond-mining firm. With its affiliates, De Beers today accounts for perhaps somewhat less than one-half of world production of gem and industrial diamonds. A large part of the balance of the production is bought by the CSO for classification and subsequent resale.

De Beers is well financed, able to hold substantial inventories, and prepared to adjust its own production as demand fluctuates. Competitive producers have come to recognize that to market diamonds in competition with De Beers could lead to sharp price declines that, in turn, would destroy the attraction that diamonds possess as long-term investments. They have therefore been willing to dispose of their output through the Central Selling Organization. A case in point is provided by the major Australian diamond deposits developed by firms independent of De Beers in the early 1980s. Originally, the operators planned to do their own selling but before actual production began, they agreed to sell all gemstones and 75% of industrial stones through the De Beers mechanism.

At the time this is written, the diamond market is firmly under CSO control with prices stable—although not inflexible. Public confidence in diamonds as investment has been maintained. Revenues realized by developing countries from their diamond exports have been stabilized. Nevertheless, in the United States, the cartel is considered illegal, but efforts to institute legal proceedings have been unavailing since neither De Beers nor CSO maintains offices within the United States.

The nonmetallic minerals have been less subject to severe price volatility than the metals. As previously commented, they are not traded on commodity exchanges and hence are rarely the target of speculators. Furthermore, the nature of consumption of nonmetallics is different from that of the metals: demand tends to be steadier and less subject to short-term cyclical economic trends. Because most of them sell at low prices in relation to bulk, the threat of substitution by competitive materials is much less pronounced. Indeed, for most of the industrial minerals, the level of world consumption has shown steady but not spectacular gains in line with population trends and overall industrial activity. Hence forecasts of nonmetallic mineral prices can be made with greater confidence than is the case with the metals.

2.3.4 SOURCES OF PRICING INFORMATION

Mining engineers need reliable information about prices. For current prices, the best sources are the three publications already mentioned, *Metals Week* and *American Metal Market* in the United States and *Metal Bulletin* in Great Britain. Commodity exchange quotations are available on a daily basis in the *Wall Street Journal* in the United States and the *Financial Times* in Britain and also in some metropolitan dailies, but these publications carry only limited information about prices of minerals not traded on commodity exchanges.

Other professional and trade publications carry price information (e.g., *Engineering and Mining Journal, Skillings Mining Review),* but it tends to be less current than the data appearing in the five periodicals mentioned.

When long-term historical pricing data are needed for feasibility studies or basic understanding of macro-economic trends, useful tabulations can be found in the yearbooks published by the US Bureau of Mines, the American Bureau of Metal Statistics, and a private German organization, Metallgesellschaft of Frankfurt A.M. The latter is particularly helpful if data are desired for prices within some of the principal consuming countries stated in terms of local currencies.

The World Bureau of Metal Statistics publishes excellent information on production, consumption, and trade in metals, but its yearbook does not contain tabulation of prices. However, it has perhaps more data on production and trade in minerals between the market-economy countries and the nations of the Communist bloc than any other source. Much of the production information is perforce based on informed estimates since official statistics have not been provided by many of the governments of the Communist bloc.

Further discussion of the marketing and sale of minerals is contained in Chapter 25.5.

2.3.5 TRADING IN MINERALS

As commented in the opening paragraph of this chapter, most minerals are subject to a high degree of international trade. This is the consequence of the erratic distribution of viable mineral deposits around the globe. For example, among the commodities that have highly concentrated production, one might cite platinum-group metals (primarily produced in the Soviet Union and South Africa), cobalt (Zaire, Zambia, and Canada), columbium (Brazil), phosphate rock (United States, Soviet Union, and Morocco), and asbestos (Soviet Union, Canada, and Zimbabwe).

Even in the case of minerals that are somewhat more widely distributed—such as tin, nickel, bauxite, and copper—the extent of international trade is huge because much of the production is concentrated in countries that are not large consumers while much of the consumption takes place in countries that have limited production potential. Western Europe and Japan are examples of the latter. Highly industrialized, they have only meager viable mineral resources and must depend on import sources to provide the mineral raw materials they require.

Particularly illustrative of the extent of international trade in minerals is the position in iron ore. Deposits of iron ore are to be found in every country, but the quality and quantity of these resources vary enormously. Great Britain, Germany, and Japan in their early stages of industrial development exploited their domestic iron-ore resources, but the best of these deposits have been long since depleted. Today these countries are huge importers of ore. The United States was at one time a net exporter of iron ore, thanks to the resources of its Mesabi Range, but since World War II has become a major importer.

Among the market economy countries, the largest iron-ore producers in the last three decades have been Brazil and Australia. Although they have substantial domestic iron and steel industries, the bulk of their output is exported. Since they are located at considerable distances from their potential customers, they have developed superb port loading facilities served by huge bulk-carrying freighters to transport their ores to the major consuming centers.

For many of the mineral-exporting countries, a major thrust has been to encourage the development of domestic processing facilities. Thus, rather than export copper concentrates, the preference has been to develop domestic smelting and refining facilities so that exports will be in the form of refined copper or even, perhaps, fabricated copper products. The economics of downstream processing are complex; considerations such as availability of fuel, skilled labor, and transport facilities between mines and processing plants may result in costs that exceed the charges offered by foreign processors—particularly if the initial capital cost of building a new facility is high.

A further complication has been the fact that the raw-material importing country may be encouraging its domestic processors through high duties on refined product and no duties on raw material imports. Thus a considerable share of the world trade in minerals remains in the form of raw materials rather than semi-finished or refined products.

Nevertheless, the long-term trend has been toward an increase in processing in the country where the minerals originate. This has been particularly true for ferroalloying materials. Prior to World War II, most of the trade in manganese and chrome was represented by ores. By the 1970s, a major share of international commerce in these two elements was in ferromanganese and ferrochrome. Indeed, one of the principal manganese exporters—India—prohibited the export of ore at one time and permitted only export of ferromanganese.

Although much of the international minerals trade is carried on through direct contracts between the minerals producer and the minerals consumer, a very large share—perhaps an increasing share—is carried on through the intermediation of trading firms. These enterprises, headquartered in Tokyo, London, New York, Frankfurt, Brussels, Zug (Switzerland), Helsinki, Paris, or other metropolitan centers, maintain offices or agencies in all of the principal producing and consuming centers. They deal in a whole range of minerals and are familiar with customer requirements of quality and physical characteristics. They understand the mechanics of dealing in foreign exchange and of commodity exchange trading. The key to their success lies in their access to information about both production and consumption developments.

Following the break-up of the colonial empires and the granting of independence to most of the developing nations, public-sector companies have taken over the operation of many mineral properties previously owned by private foreign investors. The governments involved have taken an active interest in the marketing of the mineral products. This has introduced a new element into minerals trading because on occasion foreign-policy or social considerations have replaced strictly commercial factors in determining where and how minerals are to be sold.

In the long run, however, market forces will predominate in determining what will happen to mineral prices and where the bulk of mineral trading will occur.

Chapter 2.4
TAXATION AND DEPLETION

JOHN W. WHITNEY AND GARTH H. SIBBALD

2.4.1 INTRODUCTION

Federal and state tax laws create a complex framework within which the cash flow analysis of a mining project or operation is conducted. Two important components of federal tax law are the capital recovery provisions of the depreciation and depletion regulations. The other important elements of federal taxes are the actual income tax provisions and the minimum tax provisions. Anyone who works for profit needs to be aware of tax concepts in order to determine how they will impact the amount and timing of generated cash flows. The purpose of the chapter is to emphasize the importance of tax planning and to show the effects of taxes in investment evaluation. This chapter describes the federal tax rules that apply to mining and different kinds of state taxes that affect mining operations.

Tax planning requires the legitimate use of all current laws, regulations, and court decisions to reduce taxable income. This is referred to as tax avoidance and enables companies to reduce their taxable income to the minimum allowed by the host country's legal system. Thus careful tax planning permits the retention of a maximum amount of cash for the company to use in its own endeavors.

It is necessary to include the effects of income tax in project analysis. This allows one to evaluate projects in terms of the net-after-tax return on total investment. There are several technical reasons for inclusion of the effects on income taxes, but the most important is to ensure a realistic estimate of the expected return on investment. For example, proposals that involve a mix of foreign and domestic operations will be subject to different tax rates and tax rules than either wholly foreign or wholly domestic corporations. Also there may be alternatives that require choices between projects that are wholly foreign vs. projects that are wholly domestic. In either case, it is necessary to analyze the project returns on an after-tax basis to avoid unrealistic rate-of-return comparisons.

The two most important US tax elements for preliminary financial analysis are depreciation and depletion. Although treatment of these two elements is relatively straightforward, the choice of the depreciation method will often depend on the anticipated mine life, the discount rate, and expected profitability. This is the reason that it is important to have a clear understanding of how depreciation and depletion are calculated and how they interact to affect the net present value and the internal rate of return.

Two categories of expenses, (1) exploration and (2) development, incurred by mineral exploration companies are given special tax treatment. Treatment of these two categories for tax purposes is summarized in this chapter. It is also important to emphasize here that oil and gas exploration expenditures are treated somewhat differently from exploration expenditure for other minerals. This chapter does not provide an analysis of the treatment of expenditures incurred in exploration and development of oil and gas.

Investment strategy and mine financing are discussed in Chapter 2.5 and Section 6.

2.4.2 FEDERAL INCOME TAXATION

2.4.2.1 Exploration Expenditures

Exploration expenditures are defined as expenses incurred by a mining organization in determining the location and quality of mineral deposits that had not previously been commercially exploited. As a general rule, exploration expenditures are capitalized and recoverable through depletion. Taxpayers do have the option to deduct a significant percentage of the exploration expenses in the year they are incurred and then recapture these expenses when the production stage is reached or when the property is transferred.

Two relatively separate stages in the exploration process can be identified, (1) the pre-exploration and (2) subsequent exploration activities. *Pre-exploratory costs* include the costs of reconnaissance, that is, the cost of surveying wide areas to find specific areas of interest. The Internal Revenue Service has ruled that pre-exploratory costs incurred in a project are to be related to the property ultimately acquired; these costs may be allocated on an acreage-based formula. This allocation of costs serves to establish part of the cost basis for the property.

Exploration expenditures are high-risk investments that are essential for the growth and long-run existence of the mining industry. For tax reporting purposes, exploration expenditures are those expenditures, excluding cost of depreciating property, that are paid or incurred by the taxpayer before the beginning of the development stage for the deposit. The *development stage* is deemed to begin when mineral deposits are determined to be of sufficient quality and quantity to reasonably justify commercial exploitation by the taxpayer.

Exploration costs include all expensable costs incurred prior to entering the development stage. These costs include such items as core drilling to ascertain the existence of commercially marketable ore and underground shafts, drifts, and crosscuts for the same purpose. Exploration costs also include the cost of labor, administrative overhead, depreciation of equipment used in exploration, and support facilities.

The taxpayer may elect to capitalize all exploration costs to be recovered from depletion. Under this option, exploration costs are capitalized and included with property costs to establish the cost basis of the property. This cost basis is then used to determine the appropriate cost depletion rate for the mineral deposit.

Exploration costs also may be deducted currently instead of capitalizing them. If this option is taken, the costs must be recovered when the mineral deposit has reached the producing stage. The amount of expenditures during the exploration stage that is deductible depends upon when the expenditures were incurred. Pursuant to the Tax Reform Act of 1986, expenditures made after 1986 are subject to a 70% current deductibility limitation. For expenditures incurred after 1984 but before 1987, deductibility is limited to 80%; for taxable years subsequent to 1982 but before 1985, the corporation can deduct 85% of exploration expenses. The remaining balance can be deducted ratably over the 60-month period beginning with the month in which the costs are paid or incurred.

There are two possible methods for recovering exploration costs: (1) they may be recorded as income in the first year of production, or (2) they may be recovered by disallowing the depletion allowance until the cost is recaptured.

If the taxpayer elects to recapture exploration costs through income, he/she should include in gross income for the taxable year an amount equal to the adjusted exploration expenditures applicable to the mineral property in the year that it reaches the producing stage. The amount so recorded in gross income is then capitalized as part of the cost basis of the mineral property and will be recoverable through depletion.

If the exploration expenditures are not included in income in the first producing year, they must be recaptured directly through the allowance for depletion. The deduction for depletion with respect to the property will be disallowed until recovery of the total amount of depletion expenditures that has previously been expensed.

2.4.2.2 Development Expenditures

Mine development expenditures include those necessary to gain access to an ore body in the preproduction stage, but after the existence of ores in commercially marketable quantities has been disclosed. Development expenditures also include those expenditures necessary to extend production in an existing ore body.

Development expenditures may be either deducted currently or deferred and amortized as ore is sold. Unlike exploration expenditures, development expenditures are not subject to recapture so that it is advantageous to classify expenditures as developmental rather than exploratory.

For development expenditures incurred in taxable years beginning after 1982, the amount currently deductible is limited to 85% of the expenditure. The remaining 15% must be capitalized and recovered over a five-year period. For expenditures incurred after 1984, the amount to be capitalized is increased to 20%. The capitalized development costs, however, are not part of the basis of the property for depletion purposes. For expenditures incurred after 1986, the amount allowable as a deduction for domestic mine development must be reduced by 30%. The amount not allowable as a deduction for any taxable year after 1986 may be amortized over a 60-month period beginning with the month in which the costs are paid or incurred.

2.4.2.3 Depreciation

Depreciation is the periodic write-off of the costs of items of property and certain other long-lived tangible assets. It denotes a periodic cost allocation against revenue of such tangible assets as buildings, machinery, and equipment. Depreciation is also the process by which the capitalized cost of a fixed asset is deducted from taxable income.

The cash flow analysis is primarily concerned with the tax savings that are a result of capital recovery provisions, and the *net present value* of the tax savings. The method used to calculate depreciation for tax purposes determines the value of the resulting tax savings.

The modified accelerated cost recovery system (MACRS) is mandatory for most tangible depreciable property placed in service after Dec. 31, 1986. Under MACRS, the cost of eligible property is recovered over a 3-, 5-, 7-, l0-, 15-, 20-, 27.5-, or 31.5-year period. The class-life of an asset determines its recovery period, the method of depreciation used, and the applicable convention.

The cost of property in the 3-, 5-, 7-, and l0-year classes is recovered using the 200% declining-balance method over three, five, seven, or ten years, respectively. The cost of 15- and 20-year property is recovered using the 150% declining-balance method over 15 and 20 years, respectively. Instead of the applicable depreciation method, taxpayers may elect to claim straight-line MACRS deductions over the regular recovery period.

In addition to the normal depreciation methods, mining companies may also use the ore-reserve or units-of-production method. This method of computing depreciation is similar to the cost depletion computation, except that a different cost basis is used in determining the depletion unit.

2.4.2.4 Depletion

Definition: Congress has recognized the unique risks and special nature of the mining industry by granting it a percentage *depletion allowance* that is not limited to the cost basis of the property. In general, annual depletion deductions are allowed only to owners of an economic interest in mineral deposits or standing timber.

In the case of mineral resources, the allowance for depletion may be calculated either upon the adjusted depletion basis of the property (cost depletion) or upon a percentage of gross income from the property (percentage depletion). The Internal Revenue Code requires taxpayers to use the method that yields the largest deduction for any taxable year. It is based on the concept that mineral deposits are wasting assets that are difficult to replace.

Cost Depletion: Cost depletion is based upon the cost of mineral property, the number of units of mineral or contained metal sold during the year, and the number of units of mineral or contained metal remaining in the deposit at the end of the year. The basis that is established for cost depletion in any one year is the undepleted cost basis of the mining property at the beginning of the year.

The cost depletion allowance for any year is determined in the following manner. First, the undepleted cost basis of the property must be determined. Then subtract the accumulated depletion to date from the original cost basis of the property. This must be divided by the total number of units of mineral remaining at the end of the year plus the number of units sold during the year. The result is then multiplied by the number of units sold during the year to determine the cost depletion allowance for the taxable year. The applicable relationship is

$$CD_n = \left(CB - \sum_{i=0}^{n-1} D_i\right)\left(\frac{U_n}{U_n + U_r}\right) \tag{2.4.1}$$

where CD_n is cost depletion allowance in year n, CB is the original cost basis of the property, $\sum_{i=0}^{n-1} D_i$ is accumulated depletion taken in the preceding years (both cost and percentage), U_n is units of metal sold during year n, and U_r is units remaining at year end (units of metal contained in ore reserves).

Each taxpayer who claims and makes a deduction for depletion of mineral property must keep a record of the cost basis for the mineral property and a record of the sum of depletion credits previously taken. No further deductions for cost depletion will be allowed when the sum of the depletion credit equals or exceeds the cost basis of the property.

Percentage Depletion: Percentage depletion is an allowance expressed as a percentage of the gross income from the mine and varies in amount with the type of mineral (see Table 2.4.1). The percentage depletion allowance is limited to 50% of the taxable income from the property before the allowance is deducted. One of the favorable aspects of the percentage depletion allowance is that it is not limited by the cost basis of the property.

The percentage depletion for year n is calculated by multiplying the applicable percentage depletion allowance for the min-

Table 2.4.1. Statistory Depletion Rates for Various Minerals

1. 22%
   a. Sulfur and uranium; and
   b. If from deposits in the United States, anorthosite, clay laterite, and nephelite syenite (to the extent that alumina and aluminum compounds are extracted therefrom), asbestos, bauxite, celesite, chromite, corundum, fluorspar, graphite, ilmenite, kyanite, mica, olivine, quartz crystals (radio grade), rutile, block steatite talc, and zircon, and ores of the following metals: Antimony, beryllium, bismuth, cadmium, cobalt, columbium, lead, lithium, manganese, mercury, molybdenum, nickel, platinum and platinum group metals, tantalum, thorium, tin, titanium, tungsten, vanadium, and zinc.
2. 15%–If from deposits in the United States
   a. Gold, silver, and copper;
   b. Oil shale (except shale described in paragraph 5); and
   c. Domestic iron ore; for tax years beginning after 1983, the corporate statutory percentage depletion deduction for such minerals is to be reduced by 15% of the excess of the percentage depletion deduction over the adjusted basis of the property as determined at the end of the tax year and without regard to the depletion deduction for that year.
3. 14%
   a. Metal mines [if paragraph (1)(b) or (2)(a) does not apply], rock asphalt, and vermiculite; and
   b. If paragraph 1b, 5, or 6b does not apply, ball clay, bentonite, china clay, sagger clay, and clay used or sold for use for purposes dependent on its refractory properties.
   c. Foreign iron ore; for tax years beginning after 1983, the corporate statutory percentage depletion deduction for such minerals is to be reduced by 15% of the excess of the percentage depletion deduction over the adjusted basis for the property as determined at the end of the tax year and without regard to the depletion deduction for that year.
4. 10%
   a. Asbestos (if paragraph 1 b does not apply), brucite, lignite, perlite, sodium chloride, and wollastonite. The depletion deduction for coal (including lignite) is 10%, but for tax years beginning after 1983, the corporate statutory percentage depletion deduction for such minerals is to be reduced by 15% of the excess of the percentage depletion deduction over the adjusted basis of the property as determined at the end of the tax year and without regard to the depletion deduction for that year.
5. 7.5%
   a. Clay and shale used or sold for use in the manufacture of sewer pipe or brick, and clay, shale, and slate used or sold for use as sintered or burned lightweight aggregates.
6. 5%
   a. Gravel, peat, pumice, sand, scoria, shale (except shale described in paragraph 2b or 5) and stone (except stone described in paragraph 7).
   b. Clay used, or sold for use, in the manufacture of drainage and roofing tile, flower pots, and kindred products; and
   c. If from brine wells, bromine, calcium chloride, and magnesium chloride.
7. 14%
   All other minerals, including, but not limited to, aplite, barite, borax, calcium carbonates, diatomaceous earth, dolomite, feldspar, fullers earth, garnet, gilsonite, granite, limestone, magnesite, magnesium carbonates, marble, mollusk shells (including clam shells and oyster shells), phosphate rock, potash, quartzite, slate, soapstone, stone (used or sold for use by the mine owner or operator as dimension stone or ornamental stone), thenardite, tripoli, trona, and (if paragraph 1 b does not apply) bauxite, flake graphite, fluorspar, lepidolite, mica, spodumene, and talc (including pyrophyllite), except that, unless sold on bid in direct competition with a bona fide bid to sell a mineral listed in paragraph 3, the percentage shall be 5% for any such other mineral (other than slate to which paragraph 5 applies) when used, or sold for use, by the mine owner or operator as rip rap, ballast, road material, rubble, concrete aggregates, or for similar purposes. For purposes of this paragraph, the term "all other minerals" does not include:
   a. Soil, sod, dirt, turf, water, or mosses;
   b. Minerals from seawater, the air, or similar inexhaustible sources; or
   c. Oil and gas wells.
   For purposes of this subsection, minerals (other than sodium chloride) extracted from brines pumped from a saline perennial lake within the United States shall not be considered minerals from an inexhaustible source.

Source: Section 613(b) of the Internal Revenue Code.

era1 by the gross income from mining less royalty payments. The amount of 0.5 times taxable income before depletion must be calculated to determine whether this limits the allowable percentage depletion. This is illustrated by the following relations:

$$PD_n = (MPDA)\ (GIM_n - RP_n) \qquad (2.4.2)$$

If

$$PD_n > (0.5)\ (TIBD) \qquad (2.4.3)$$

then

$$PD_n = (0.5)\ (TIBD)$$

where PD_n is the allowable percentage depletion for the mineral sold during the year, *MPDA* is the mineral's percentage depletion allowance (e.g., copper at 15%), GIM_n is gross income from mineral sales in year *n*, RP_n is royalty payments, and *TIBD* is taxable income before depletion.

2.4.2.5 Alternative Minimum Tax System

For taxable years beginning after Dec. 31, 1986, the Tax Reform Act of 1986 replaces the old "add-on" corporate minimum tax with a new alternative minimum tax. The new *alternative minimum tax* is based on a much broader income base than the regular tax because the preferential treatment accorded many items for regular tax purposes is not allowed in the alternative minimum tax system. This system has separate but parallel rules for several significant calculations, including depreciation, amortization and depletion, net operating losses, and foreign tax credits.

The corporation's regular taxable income is the starting point for the calculation of the alternative minimum tax. The amount of taxable income is recomputed to reflect certain adjustments required for determination of the alternative minimum tax. Some of the major adjustments are to depreciation, mining exploration and development costs, and depletion. Alternative minimum taxable income is taxed at the corporate rate of 20%.

Depreciation: For purposes of calculating alternative minimum taxable income, depreciation of most property is based upon use of the 150% declining-balance method over the class life of the property, switching to the straight-line method when it results in a larger allowance. However, if the taxpayer uses straight-line depreciation for regular tax, he must also use that method for the alternative minimum tax.

Most assets used in the mining industry have class lives of 10 years. Equipment used in smelting and refining of metal generally has a class life of 14 years. For regular tax purposes, these assets would generally be depreciated using the 200% declining-balance method or the straight-line method over a 17-year life. An election will allow the l0- and 14-year lives to be used for regular tax purposes, thereby reducing the adjustment necessary for computation of the alternative minimum tax. However, for the depreciation of buildings, the straight-line method must be used for both alternative minimum tax and regular tax purposes.

Exploration and Development Costs: Mining exploration and development costs that are expensed must be computed under 10-year straight-line amortization for purposes of the alternative minimum tax.

Depletion: The excess of percentage depletion allowable for regular tax over the adjusted basis of each piece of property at the end of the taxable year (determined without regard to the depletion deduction for the current taxable year) is treated as a preference item for purposes of computing the alternative minimum tax and must be added back in the calculation of alternative minimum taxable income.

2.4.3 STATE TAXES

The major types of state taxes affecting mineral production operations are property taxes, severance taxes, income taxes, and sales and use taxes.

2.4.3.1 Property Taxes

A *property tax* is an ad valorem tax levied by the taxing authority against the "value" of the property in question. Property taxes can be levied by cities, counties, states, or other taxing authorities such as school districts.

They can be levied against either real or personal property or both. Many states do not have a general state property tax authority and leave property taxation to the counties and local divisions. Many states have a board of equalization, a body which attempts to equalize taxes so that the tax burden is equitably imposed in each of the counties or other divisions within the state.

Real property is taxed in all states; however, some states do not tax personal property, and intangible personal property is exempt from taxation in most jurisdictions.

The amount of property tax to be paid depends on the tax base and the tax rate. Valuation, usually carried out by local or state assessors, determines the tax base. The tax rate, usually expressed in "mills per dollar," is applied to the assessed valuation.

Property is generally assessed at its "fair market value." The *fair market value* is the value which a willing buyer would pay to a willing seller in a "arm's-length" transaction, that is, in a situation in which neither is under any compulsion to buy or sell, and each is reasonably well informed as to the facts having a bearing on value. Other terms used to describe fair market value are "market value" and "cash value." All of these terms mean virtually the same thing.

There are essentially three methods that property appraisers (assessors) use to determine the fair market value of a piece of property. They are the (1) comparable sales approach, (2) replacement-cost method, and (3) capitalization of income method. A variant of the capitalization of income method is the net present value method. With the comparable sales approach, the assessor uses recent sales of comparable property to determine what it would cost to replace the property with a new piece of like property. Then the assessor subtracts depreciation based on the age of the property in question. Under the capitalization of income method, the present value of the annual net income of the property is determined by using a rate of return acceptable to a normal prudent investor. The figure is then capitalized to produce the market value of the property. For example, if the net income of the property is $12,000/year, and the acceptable rate of return to a prudent investor is 12%, the capitalized value of the property is $100,000.

The net present value method is similar to the capitalization of income method, but is based upon projected future operating income. There is a growing trend to use the net present value method for mine property assessment. There can be problems with this method because future mine income is based on metal prices that fluctuate widely from year to year. Projected after-tax cash flow over a mine's life, based upon mineral reserves and historical performance, is discounted using an appropriate capitalization or discount rate. The mine value is the sum of annual discounted after-tax cash flows over the mine life. For example, if the after-tax cash flow of a property is projected to be $12,000/year, 10% is an acceptable rate of return, and reserves for 5 years remain, the net present value for the current tax year is $10,908 + $9,912 + $9,012 + $8,196 + $7,452 = $45,480.

Although in many states, the state constitution and statutes allow property to be assessed at 100% of fair market value, in practice, property is often assessed at something less than 100%. This lesser assessment rate usually varies from 25% to 50% of market value. The assessment rate is referred to as the *assessment ratio.* After the assessment ratio is applied to the property, the tax is levied.

With mineral properties, the valuation of surface improvements, machinery and equipment, and land poses few problems. On the other hand, estimating the value of a mineral deposit itself is not easy. Two main approaches have been used to value ore bodies. One is to base the value of the ore body on its annual proceeds. Production may be that of the year under consideration or an average level over several preceding years. The valuation basis of the ore deposit may be gross proceeds, net proceeds, or some other criterion based on production. Gross proceeds is generally the value of the ore as reflected by the sale price if it is an arm's-length transaction with no deductions for costs of producing the ore. Net proceeds is the value as reflected by the sales price less allowable costs of production. For example, the costs of producing, transporting, refining, and selling the ore are generally considered to be allowable deductions. The property tax is then levied on the assessed value of the proceeds at the prevailing rate for the locality in question. This approach does not include in the valuation any mineral reserves to be extracted in the future, but provides a "realized value" basis for assessment.

An alternative approach is to use the present value of the projected future earnings of the mining operation to represent the value of the ore body. This application of the net present value method requires assumptions regarding mine life, rates of return, and future minerals prices. This type of tax is difficult to administer due to the many poorly defined technical variables that must be included. The principal advantage to taxing authorities of levying a property tax on the present value of mining operations is that it provides a steady source of revenue. The main disadvantage is that it discourages exploration for and development of reserves ahead of actual mining operations. This approach often results in “double taxation” on the equipment and facilities used in the operation. States that have used this method have experienced declines in their mining sectors over the years because it does discourage ore reserve development.

A direct ore reserve tax represents a fixed cost to the property owner. Ore reserve taxes clearly discourage ore reserve development. A tax on the capitalized value of income has the same negative implications although not to the same extent. In states where this latter type of tax has been applied, mine operators have tended to develop only the minimum amount of ore needed to sustain ongoing operations. The lack of long-range ore development due to the reduced ability of mine operators to adjust their output can be inefficient and may lead to premature mine closures during adverse economic periods. Often such mine closures are permanent because the lack of developed reserves makes it difficult for the mining company to justify the financing necessary to reopen the mine.

The net proceeds type of property tax was developed to overcome some of the foregoing problems. This type of tax applies only to operations that are active and that are profitable on a defined basis. The net proceeds property tax is beneficial because it encourages both ore reserve and mine development. However, in states with a corporate income tax, it may result in double taxation of the profits from mining unless there are specific exemptions.

Because taxes on real and personal property represent a fixed cost regardless of profitability, some states permit exemptions for certain classes of personal and/or real mine property. Such exemptions may be justifiable because mining is capital intensive and because the exemptions increase the amount of ore extractable from the mine by reducing fixed costs. Often the loss of primary property tax revenues is more than compensated for by secondary tax revenues and employment benefits.

2.4.3.2 Mineral Specific Taxes

A *severance tax* is a state tax imposed on the severing of natural resources from the land and is based on the value or quantity of production. In some states, this type of tax is given a different name. Instead of being called a severance tax, it may be called a mine license tax, an excise tax, a net proceeds tax, a production tax, or a royalty tax, depending on the label chosen by the legislators of the particular state. In all cases, however, the tax is based on actual output or production.

These types of taxes are usually calculated either as a flat rate per unit of production (sometimes called a “unit” or “specific” severance tax), or as a percentage of the value of the resource produced (sometimes called an “ad valorem” or “percentage” severance tax). The tax base for an ad valorem severance tax is generally either the gross or net value of resources produced or sold.

With a unit severance tax, there may be an escalation clause such that the tax increases with inflation. Ad valorem severance taxes automatically vary with the value of the mineral. Severance tax payments are altered by exemptions, credits, and exclusions in many states. There may be exemptions for minimum levels of production, credits for payments of ad valorem property taxes, and exclusions for small producers.

States differ widely in the definitions of value they use for calculating the base for an ad valorem severance tax. The tax might be imposed on the value of the resource in the ground (net proceeds), at the point of severance (gross proceeds), or after processing and preparation for shipment. The value is greater at each succeeding point. A severance tax based on gross sales value, or value f.o.b. mill, corresponds to the case where the resource is valued after processing and preparation for shipment. A tax based on gross proceeds generally corresponds to the case where the resource is valued at the point of severance. One way to estimate this value would be to deduct processing costs, transportation costs, certain production taxes, rentals, and royalties from the value at the point of first sale. A tax based on net proceeds corresponds to the case where the relevant value is the value in the ground. To estimate value in the ground, all costs of production, including mining costs, would be deducted.

The chief advantages of a tax of this type relative to many property taxes on ore bodies are that it does not discourage exploration for and development of additional ore reserves and it does not require ‘valuation’ of the ore body with all the attendant difficulties that entails. On the other hand, a severance tax does not create a steady stream of revenue since it requires an operating mine coupled with production or ore sales. Furthermore, an output-related proceeds tax will raise the cutoff grade of ore that will be mined, resulting in a waste of low-grade ore.

The net proceeds tax is preferable to other types of severance taxes from a conservation point of view. If a progressive net proceeds tax were imposed, mining operations might seek to enter lower tax brackets by reducing their rates of recovery; but a purely proportional net proceeds tax should have no effect on the rate of recovery. Indeed, a proportional net proceeds tax should have less effect on the production decisions of a mining operation than a property tax or any other type of severance tax.

Severance taxes offer some advantages from the standpoint of ability to pay. They are due only when a mining operation is actually producing, so there is no penalty if there is a strike or shutdown for market-related reasons. In contrast to property taxes, severance taxes offer opportunities to achieve a more nearly uniform distribution of revenues among areas of the state; and a mine located in a district that lacks other business activity is not so likely to be disadvantaged. A net proceeds tax is optional if ability to pay is an important policy criterion because the tax base most closely approximates profits. Only profitable operations will be required to pay taxes. The least satisfactory type of severance tax from an ability to pay standpoint is a high unit tax. With unit taxes, it often happens that an unprofitable operation whose output has a relatively low unit value is taxed at a higher percentage rate than a more profitable mine of comparable size with higher valued output.

A unit severance tax simplifies administrative problems because the rate schedule depends only upon the amount produced. A severance tax based on the value of output is easily determined if there is a market sale, but in some cases there may be no market transaction. Some barite mines, for example, are part of a vertically integrated drilling-fluids service company. In such cases, it is necessary to determine an accounting price for the barite, causing tax administration to become more complex.

Revenue generation is much more unpredictable and volatile with a severance tax of the net proceeds type than with other severance taxes. During periods of low minerals prices, profits and tax revenues also tend to be low. In addition, severance taxes do not help cope with covering pre-operational costs as well as property taxes do. If there is reliance on severance taxes, in the early stages of mine development, tax revenues may be below the levels needed to finance new services required by the community where the mine is being built.

2.4.3.3 Corporate Income or Occupation Taxes

The *income tax,* like the net-proceeds-type severance tax, is based on the profits of mines with certain statutory deductions and adjustments. The income tax is advantageous from the mining operator's point of view because it is assessed only if the operator makes a profit. The income tax has the least effect on direct and indirect costs. Further, it does not affect the cutoff grade of ore. Therefore, maximum ore recovery is promoted. Both the federal and many state governments impose an income tax.

The most significant income tax paid by mining companies is the federal income tax. Several provisions of the Federal Tax Code specifically relate to the minerals industry. These include the depletion allowance and expensing privileges for exploration and development costs. A percentage depletion allowance represents a deduction over the above recovery of actual costs equal to a fixed percentage of gross receipt and is generally viewed as an allowance for the reduction in asset value as mineral resources are removed. The mineral industry is also provided special tax treatment of costs associated with exploration and development. Exploration and development costs may be expensed as incurred. Most operations benefit from the expensing privilege for exploration costs, but only economically profitable operations benefit from expensing of development costs.

State corporate income taxes are applied to net income (income less statutory deductions). Most states use the federal definition of net income, often with certain adjustments, but the tax rate is much less than the federal rate. Items which are usually deductible in computing net income include business expenses, interest paid or accrued, uninsured losses, bad debts, a reasonable allowance for depreciation, charitable deductions, and net loss carryovers. Most states using the federal definition of net income would also allow the federal depletion allowance. States using a different tax base may or may not allow a deduction for depletion. Rates vary from state to state.

Some states allow deduction of federal income tax liabilities. If a mining operation is in the 34% tax bracket, this deduction effectively reduces the company's tax base by about that amount for state income tax purposes. The actual amounts are determined by application of a simultaneous equation.

Corporations doing business and having income in more than one state are generally taxed by the state in question on both income allocated to the state and an apportioned part of total US income under the unitary tax concept. Apportionment is generally standardized among the various states that adopted the "Uniform Division of Income for Tax Purposes Act" and is based upon a formula relating in-state tangible assets, compensation paid, and sales receipts to total tangible assets, compensation, and sales. In general, nonbusiness income, such as rents and royalties and capital gains from transactions in real or tangible personal property, is allocated wholly to the state in which the tangible property is located or from which it was sold. Interest and dividend income is allocated to the state that is the taxpayer's commercial domicile. Normal business income is apportioned among the states in which the taxpayer does business, irrespective of whether each such state imposes a corporate income tax.

The greatest disadvantage of the income tax from the state's point of view is that it does not provide the predictable, steady stream of revenue that the property tax provides. On the other hand, states can encourage mining development through the use of tax incentives such as deductions for exploration and development costs as well as liberal depletion deductions.

2.4.3.4 Sales and Use Taxes

The purpose of the *use tax* is to prevent users from purchasing property from states having no sales tax or a lesser sales tax and bringing it into a state with a higher sales tax. The use tax eliminates this advantage. Items subject to use taxes are generally not subject to *sales taxes* as well, because most states allow a credit for sales or use taxes paid to the state in question or to another state. For example, assume that a mining company is located in state A, which has a retail sales tax of $0.05/dollar. State B's sales tax is only $0.03/dollar. If the mining company purchases office equipment in state B for use in state A, state A would charge a use tax for the difference, that is, in an amount of $0.02/dollar.

Sales and use taxes produce revenues prior to production start-up and so may help defray the costs of new services early in the project life. Sales and use taxes raise the cost of mine construction and equipment and raise the cost of mine operation. To the extent that costs are increased, there will need to be compensating increases in minable grade of the deposit, and the ore reserves that are minable may be reduced. Such taxes also increase the cost of exploration. In areas where mines are already in operation, increases in sales and use taxes may cause a reduction in modernization and expansion and, to the extent that operating costs are increased, may cause mines to close sooner than they would in the absence of the tax.

Another disadvantage of a sales or use tax is relatively high administrative costs. Revenues from this type of tax tend to fluctuate through investment cycles, reaching their highest levels in years when capital spending by the mining industry is strong.

Sales or use taxes will, however, generate a steadier and more predictable revenue stream than income or net proceeds taxes. Because tax payments are not necessarily directly tied to profits, sales or use taxes do not satisfy most equity criteria as well as income taxes do.

Chapter 2.5
INVESTMENT STRATEGY FOR MINING PROJECTS

DENNIS ARROUET

Investment decisions in the mining industry, as in any other, normally focus on numerical methods comparing alternative investments. While these methods are important, the process of investment strategy, making the investment, and operating a project during its economic life, involves much more. Many key people in various disciplines provide varying degrees of input over the life of the project, and their input can play a major role in the investment strategy process. This chapter reviews principles and concepts covering investment within a home country and in foreign countries, showing how these many and disparate elements blend together and change over time. It is complemented by coverage in Section 6, Mine Evaluation and Investment Analysis.

2.5.1 MINING INVESTMENTS

Investments in the mining industry have many characteristics not found in most other industries. These include the following.

2.5.1.1 Finding or Exploration

Either generative or opportunistic exploration must be funded for a company to get/renew investments that will be profitable in the future. These programs, which may be structured as individual efforts, partnerships, or joint ventures, take time to develop good prospects/projects.

2.5.1.2 Size

In the past, projects had high ore grades and were easily mined and processed. In the latter part of the 20th century, the norm for mining projects was lower-grade deposits, large-scale mining, and processing using high technology equipment. Often these projects required infrastructure to make them feasible. As a result, mining became highly capital intensive. Projects costing in the hundreds of millions of dollars are more and more common.

2.5.1.3 Life

Projects generally have very long lives. Many years pass between first finding ore-grade material, proving up the reserves, planning the project, and construction. Additional years must pass before capital costs are recouped, and thereafter even more years are needed for equity investors to make an adequate return.

2.5.1.4 Product

By their nature, mining projects produce a major product, although byproduct or coproducts are often produced. In general, the product produced in the mining process is not sold to the final customer. Rather, this raw product is often sold to others who, after adding value to it, may or may not sell to the final customer. As a result, demand for "raw" mining products is "derived" and therefore subject to price and volume swings in addition to those generated by the final customer.

2.5.1.5 Profile

Projects are usually "high" profile wherever they are located because they are "natural resources." In some countries, they often get much more media and political coverage than they might elsewhere. If this situation exists, or may come to exist, attitudes and business ground rules can change very quickly; what appears to be a good investment one day can quickly become less attractive.

2.5.2 INVESTMENT STRATEGIES

Historically, mining investors explored, developed, and operated until the deposit was exhausted. The only question was proving up enough ore to support a profitable investment. While this strategy has been and can be successful, it assumes little change during the life of the project.

Recent dramatic changes in the price and volume of mining products, operating costs, and government attitudes, among other considerations, have led to the reexamination of a once successful strategy. Under the newer thinking, general approaches to a successful mining investment now include these strategies.

1. *Cost Leadership.* The objective is to have all operating costs for a project below that of average costs in the industry. Low costs result from a combination of ore grade, mining difficulty, dilution, economies of scale, development of the operation including infrastructure, technology, low cost of utilities and materials, location relative to markets, and access to low-cost transportation.
2. *Differentiation.* Here, the product offered is high valued and special to the market served.
3. *Focus.* The objective is to fulfill a market need ignored by others in the industry.
4. *Coattails.* When an industry has a single or few competitors, the "new entrant" may be accepted; economic return to the dominant producer(s) can be better (but less than before the new entrant), if the dominant producer(s) cede portions of the market and maintain price leadership rather than lower price to stop the new competitor.
5. *Volatility Exploitation.* The emphasis is on low fixed costs and low start-up and shutdown costs. As a result, in periods of high prices, a mine may be operated very profitably. While this strategy may apply to a good mining project that has successfully operated for many years, investors may be able to buy shut mines at very low cost, operate the property for a short time, and have a very attractive investment. Alternatively, developing ore bodies with these quick in-and-out-of-operation characteristics could prove profitable, depending on circumstances and assumptions.

2.5.3 CALCULATION METHODS

The evaluation of a mining investment starts with the concept that the rate of return over future periods measures the financial productivity of capital. In other words, a return of *x%* or more would be adequate for an investor. Return has been defined many ways over the years. Some of these measures and their peculiarities are detailed in the following.

Modern financial theory for measuring return on investment uses an interest factor to equate cash inflow (outflows) in different time periods. Thus $1 invested at 10% increases to $1.10 at the end of the first year, $1.21 after the second, etc. Similarly, $1.21 received two years hence has a present value of $1 today, "discounted" at 10%.

Mathematically,

$$FV = S_1 (1 + i) + S_2 (1 + i)^2 + \ldots \tag{2.5.1}$$

$$PV = \frac{S_1}{(1 + i)} + \frac{S_2 +}{(1 + i)^2} \ldots \tag{2.5.2}$$

where FV is future value, PV is present value, S is cash inflow (outflow) per period, and i is interest or discount rate. Thus investment returns are calculated by equating cash outflows for investment to cash inflows from operations (revenues less all cash operating costs, interest, taxes, maintenance and capital expenditures, debt repayment), discounted at an appropriate interest rate.

Example 2.5.1.

Project data (in million dollars)

Investment year 1 = $10, year 2 = $10	$20
Operating cash flow year 3, 4, and 5 = $10	$30
Depreciation—life	3 years
—amount	$20
Debt financing	none
Capital investment after start up	none

Solution.

Depreciation per year	$6.7
Average investment. Investment less one-half total depreciation	$10
Average operating cash flow per year	$10
Average net income. Average operating cash flow per year less average depreciation per year	$3.3

	Investment and Operating Cash Flows	Present Value: $1 discounted at 10%*	Present Value: Revalued Cash Flow
Year 1	(10)	0.909	(9.2)
2	(10)	0.826	(8.3)
3	10	0.751	7.5
4	10	0.683	6.8
5	10	0.621	6.2
			3.1

	Investment and Operating Cash Flows	Discounted Cash Flow: $1 discounted at 17.8%	Discounted Cash Flow: Revalued Cash Flow
Year 1	(10)	0.849	(8.5)
2	(10)	0.721	(7.2)
3	10	0.612	6.1
4	10	0.519	5.2
5	10	0.440	4.4
			0.0

*Discount factors assume revenue received once per year. Year 1 equals 1 divided by 1.10; year 2 equals 1 divided by 1.21, etc.

Returns

Accounting

Return on investment	$\frac{\text{Average net income } 3.3}{\text{Investment } 20.0}$	= 16.5%
Return on average investment	$\frac{\text{Average net income } 3.3}{\text{Average investment } 10.0}$	= 33.3%
Payback:	Years needed for cash inflows to equal cash outflows	2 years

Interest

Present value	10% interest rate	= $3.1
Discounted cash flow return		= 17.8%

The controversy over what measure to use has largely been resolved in favor of the discounted cash flow method. Each individual or organization may use one or a number of these return measures to increase communication of "return" to the many parties involved with the investment decision. Which measure(s) parties use relates to factors peculiar to their own circumstances.

The sophisticated decision maker knows that behind these precise calculations are tangible and intangible data that are uncertain. To cope with this uncertainty, decision makers use a number of techniques including the following:

1. *More Accurate Forecasts.* A worthy objective, but uncertainty is not addressed.
2. *Higher Cutoff Rate.* With a higher cutoff rate, a degree of risk is recognized as part of an investment. However, the probability of returns exceeding the threshold is not recognized.
3. *The Base and Most Likely Case.* Returns are calculated using "averages" for input variables. The base case is presumed to be conservative, that is, low risk by implication. The most likely case is moderate risk.
4. *"What If" Scenarios.* A series of returns are calculated using averages for all but one variable. For example, the base case return is run at sales increases/decreases of 5%, l0%, and 15%. While this methodology shows the sensitivity of returns to change in specific variables, the likelihood of these events is not quantified.
5. *Simulation.* Probability curves on each input variable are developed based on estimates of those most knowledgeable in a given area, for example, operating cost, selling price, etc. Thereafter, a probability is randomly selected from each probability curve and then used to calculate a discounted cash flow rate of return. Then the process is repeated many times. The probability of all anticipated returns can then be graphed as shown in Figs. 2.5.1 and 2.5.2. Then assessing the project and comparing it to other projects is easier and more meaningful.

2.5.4 COST OF CAPITAL

For an investment to add value, it must earn more than the cost of capital—the cost of debt and equity each weighted based upon the proportions of debt and equity the corporation targets for its capital structure over the investment period.

While there are several models for calculating the cost of capital, each at best is an estimate. The capital asset pricing model that follows is the most widely used formulation. *For debt cost,* calculate interest on incremental debt with a maturity similar to the investment less tax savings generated by deducting

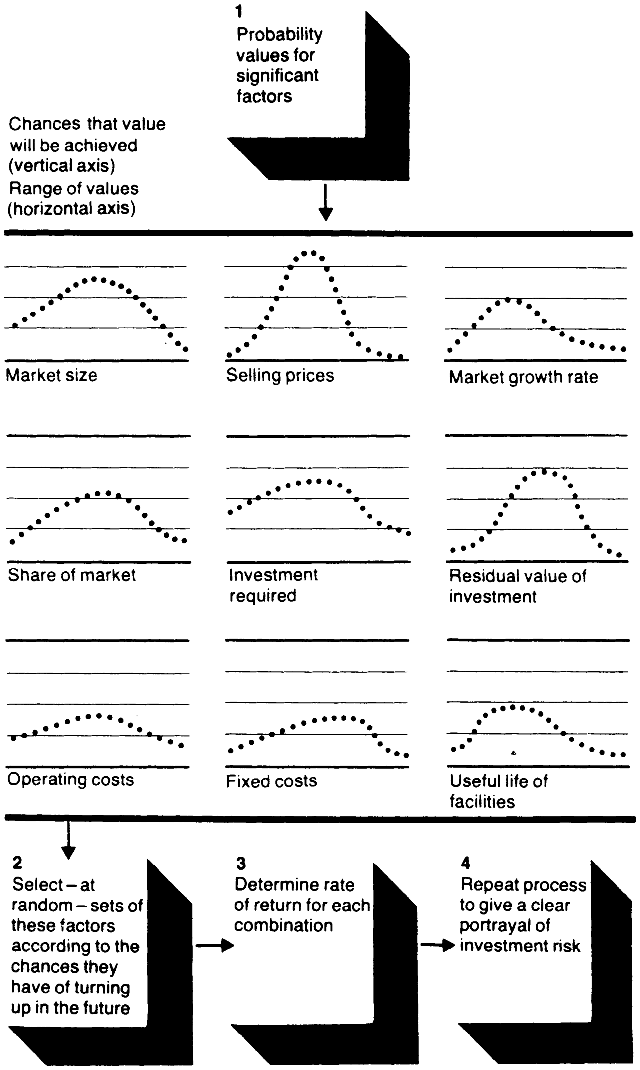

Fig. 2.5.1. Simulation for investment planning (Hertz, 1979).

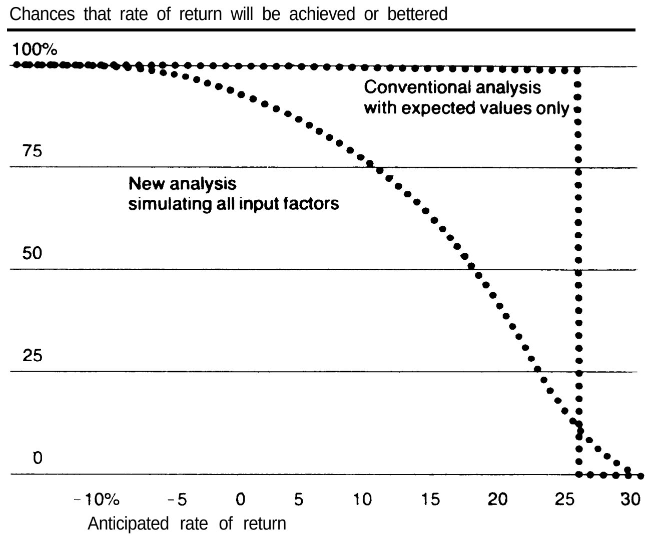

Percent return	Probability of achieving at least the return shown
0%	96.5%
5	80.6
10	75.2
15	53.8
20	43.0
25	12.6
30	0

Fig. 2.5.2. Anticipated rates of return under old and new approaches (Hertz, 1979).

interest from taxable income. *For equity cost,* calculate the risk free rate of return, the yield on government securities, plus an equity risk premium, for investing in equities. The yield on government securities compensates debt investors for the "real" interest rate plus the expected inflation rate. The equity risk premium compensates the equity investor for added risk and is equal to the expected equity market return less the risk-free rate multiplied by the riskiness of the stock or the beta. Betas are calculated by running linear regression analyses between past returns for a stock and past returns for the market. Then the volatility of the stock is compared to the volatility of the market. Thus a stock with a beta of 1.20 is 20% more volatile than the market. Betas are published by Value Line, Merrill Lynch, and other financial institutions.

In one of the classic studies of long-term investment returns, Ibbotson and Sinquefield (1989) calculated the risk and return of stocks, bonds, and treasury bills and the rate of inflation for 1926–1987. According to this study, the historical (1926–87) arithmetic average equity risk premium of stocks vs. government bonds was 6.8%. Since the equity risk premium is the average annual difference between the rates of return of stocks and government bonds, it is possible to use this factor in calculating a firm's equity cost regardless of the absolute level of interest rates. Specifically, the equity risk premium is multiplied by an individual stock's beta and the result is added to the current risk-free rate of government bonds to determine that company's equity cost.

Example 2.5.2.

Project Data

Risk free government interest rate		9%
Interest rate on new borrowings		10%
Income tax rate		40%
Expected return on equity market		15%
Beta		1.5
Capital mix over investment horizon	debt	40%
	equity	60%

Solution.

	Cost *(%)*	Weight	Weighted Cost
Debt	10% – 10% (0.4)	40%	2.4%
Equity	9% + (15% – 9%) 1.5	60%	10.8%
	Cost of Capital	100%	13.2%

Investment decision making involves more than just deciding to make a project expenditure or not. The process involves determining the amount of acceptable project risk, the financial capability of the investing organization, and the risk profile of each investment in its portfolio. Every situation needs to be analyzed separately.

The corporate objective is to maximize earnings (over the cost of capital) commensurate with acceptable risk. However, at some point in a corporation's life cycle, the risk profile is altered due to price and volume changes, competitor actions, etc. These dynamic changes in the corporation's risk profile are also present in the risk profile of an individual project.

A project's risk exposure is usually greatest prior to completion. But the exposure varies over time, as one would expect, according to the initial risk profile of the project and subsequent changes in the dynamic variables affecting the project. The project's risk profile is superimposed on that of the company, and the relative size of the project will affect its potential impact on the entire company. Upon completion, the project will have a proportionate impact on the overall risk profile of the company and, ideally, the periods of adverse returns on the project will not coincide with the periods of financial difficulty for the rest of the company. Otherwise, a restructuring of the project and/or the company may be necessary. Thus, the corporate decision-making process must explicitly integrate the project risk profile with the corporate profile.

The decision process also encompasses the entire life of an investment. The find, invest, and hold strategy implies one investment decision. However, in a more volatile world, knowledgeable decision makers keep track of the value of their investment with a view to capturing excess valuation. This "recapture" changes the capital structure and the risk profile. It may be done, for example, through the sale of a partial or whole interest in the investment; the excess can be used to adjust the risk profile of the project and thus the corporation and to create new value by developing or buying undervalued investments, repaying financial commitments or paying shareholders.

2.5.5 DECISION MAKING

Decision making for a mining investment is a process. It involves decisions within many separate disciplines that are then linked together. The initial economic decision is to invest or not to invest and thereafter to grow, maintain, or disinvest.

Good communication within the organization and with outside consultants is extremely important. It speeds decision making and it minimizes misunderstandings. But often it is overlooked as a key element that helps the decision process progress smoothly.

Also poor negotiation with outside parties can lead to major problems and unforeseen penalties. The process is critical to every aspect involved in a project. Experienced personnel have a better understanding of what to expect, how to act, and what to demand. They pay attention to:

1. *Organizing Their Positions.* They plan for changing negotiation strength, interference by others in the organization, insufficient internal communication, etc.

2. *Empathizing with Others.* They place themselves in another's position to understand different ways of thinking; they recognize the need for "saving face."

3. *Determining the Role of Government.* They try to understand the politics, the role for private enterprise in the country, status of businessmen, government involvement in negotiations, etc.

4. *Focusing on the Decision-Making Process.* They weigh economic and political criteria, the role of personal relations and personalities and the amount of time assigned to negotiations by others.

As the decision-making process approaches the go/no-go decision, senior management and finally the board of directors become more and more involved. By this time, all work is reviewed to check for consistency, risk, and possible omissions or areas that need more work pending the final decision. "Due diligence" is an investigatory safeguard and is particularly important. It covers reserve verification, project risks, projected capital and operating costs and their variability with volume, competitive assessment, market analysis, and financial analysis. The due diligence process is normally conducted again when, and if, potential equity investors and/or project finance are needed. Then money providers are given up to date factually correct data on the project together with a discussion of potential risks.

2.5.6 PROJECT FAILURES

While failure only happens to others and will not occur in a well-planned project, history teaches us that financial failures do occur, often despite the best plans. Indeed, the risk of failure may increase in the future. First, a number of metal and non-metal mining products that have been relatively price stable now show more significant price volatility (e.g., gold, aluminum, iron ore). Second, low price cycles are relatively longer at lower levels—at least recently—thereby increasing financial stress. Third, increased costs per unit of production and relatively higher interest rates make financial returns more difficult to achieve. Finally, the frontiers for "new" mineral deposits are increasingly in remote areas.

The causes for financial failure of investment in projects can include one or more of the following:

1. Delays in completion causing delay in revenues.
2. Unplanned capital cost overruns.
3. Technical failure.
4. Failure of contractor(s) and supplier(s).
5. Increased price or shortage of raw materials.
6. Estimated grades and amounts unavailable due to insufficient drilling, complex geology, errors, unforeseen faults, rock competences, etc.
7. Technical obsolescence.
8. Operating failure.
9. Loss of competitive position in the market.
10. Uninsured casualty losses.
11. Force majeure.
12. Refinancing risk.
13. Increased taxes, direct and indirect.
14. Foreign exchange, artificial rates, availability, etc.
15. Government interference, changes in laws, rules, regulations.
16. Expropriation.
17. Poor project management.

In hindsight, project failures fit into "nice" categories shown previously. Unfortunately, during a project's demise, the vision is rarely clear. While a check list can be helpful, even in retrospect the root causes are often overlooked. These root causes include:

1. The risk profile for each business variable (reserves, capital and operating costs, competition, etc.) changes during the life of the project.

2. Sponsors often neglect the vested interests of the project decision makers, whose future may be enhanced by a project go ahead, especially when excessive optimism is expressed.

2.5.7 PROJECT STRUCTURE AND PARTICIPANT CHECK LISTS

In order to minimize the downside risk of a project, it is important to focus on certain key issues at the outset. These issues, which relate to the structure of the project and the operational aspects of the project, are summarized in the following in check list format (also see Fig. 2.5.1).

2.5.7.1 Direct Owners

Parent or holding company structure can have undesirable impacts on financing, taxes, risk profile, future restructurings.

2.5.7.2 Ultimate Owners/Completion Guarantors

Completion guarantors could include third parties such as suppliers, offtake purchasers, and governments (particularly in the case of project infrastructure).

2.5.7.3 Domestic Bank Lenders/Guarantors

Domestic bank credit or lending is a major feature of most project financings. Domestic experience with other projects, local practices, etc., can assist in getting the optimal finance package. In addition, domestic institutions can help support the project with foreign lenders.

2.5.7.4 Foreign Bank Lenders/Guarantors

Foreign lenders include all lenders not domestic to the project. Many of these institutions are chosen to lead a project financing if they are well established domestically. In large financings, representation by institutions from many countries is encouraged in less-developed areas. The theory is that the local governments will not expropriate, embargo funds, etc., for fear of reduced funds being available to the country.

2.5.7.5 Guaranteed Lenders

These are generally export credit agencies, regional development banks, other foreign government lenders, institutional lenders, and occasionally debt participants in leveraged leases. The parties advance funds under guarantees or standby letters of credit, which take the project risk and charge a guarantee fee. Concessional rate and term financing is generally achieved in this way, since lenders in this category will not accept project risks.

2.5.7.6 Equipment Suppliers

Use of equipment from different countries should be evaluated. Prices and terms are often more attractive from one country vs. another.

2.5.7.7 Lessors

Leveraged leasing is often used as part of a project financing. Amount and terms will determine the use of leases.

2.5.7.8 Offtake Purchasers

Marketing arrangements can be a critical part of the credit supports needed to finance a project, especially where floor prices or minimum offtake levels are needed to meet debt service. Involving purchasers and lenders or their advisors in the early stages of market planning can be critical.

2.5.7.9 Engineering Consultants/Contractors

Consultants often establish the technical, marketing, and financial feasibility of major projects Sometimes an overall project feasibility consultant is used, but the trend has been towards using specialists.

2.5.7.10 Auditors

Auditors (for accounting and taxes) can provide useful information on the proposed ownership and financing structures. If off-balance-sheet accounting treatment is planned, auditors should be involved early in the project.

2.5.7.11 Legal Counsel

Project development inevitably involves lawyers. Their areas of involvement include agreements with customers, major suppliers, consultants, financial institutions, investors, other partner/venture owners, governments, etc. In most situations, lawyers should have prior mining project experience.

2.5.7.12 Financial Advisors

Investment banks, merchant banks, and commercial banks have undertaken advisory roles to determine the optimal financing for mining projects. For a fee, they will screen, select, and negotiate terms and conditions with financial institutions supplying funds. In some cases, they will supply their own funds.

2.5.7.13 Federal, State, and Local Governments and Their Agencies

Numerous approvals are necessary to obtain a mining lease to construct and operate a mine. Approvals are normally needed before loan drawdowns, and all are required before completion supports are released by lenders. Lenders want to minimize the chance that government intervention will frustrate a project's completion and operation.

2.5.7.14 In-house Expertise

Skills are needed in the areas of geology, mining, milling, metallurgy, operations, maintenance, taxes, legal, financial, governmental, etc.

2.5.8 PROJECT CHECK LIST

Relative to this check list, see Fig. 5.2.2.

2.5.8.1 Technical Considerations

1. Land and minerals: lease, ownership, title, royalties, special arrangements.
2. Reserves: geologic setting, ore types, geologic reserves vs. mineral reserves, proven vs. probable reserves, drilling data, sampling, methodology of reserve calculation.
3. Mining plan: forecasts of grades and material movements, geotechnical test results, equipment to be used, personnel requirements and availability, design assumptions.
4. Processing plan: plant layout, equipment needed, manpower requirements and scheduling, power requirements.

5. Infrastructure: water/power supplies and service availabilities, transport facilities, maintenance workshops, labor housing.

6. Construction: realistic scheduling allowing for weather, terrain, personnel requirements, infrastructure needs, labor agreements.

7. Environment: studies, reports, approvals needed. Limitations and controls affecting: air, water, solid and liquid waste, land, noise, ecology, power, hospitals, schools, roads, community services.

2.5.8.2 Products and Markets

1. Customer buying considerations: spot or term contracts, price—negotiated,tied to other factors such as cost escalators, f.o.b., c.i.f., exchange rate fluctuations and adjustments, volume minimums and maximums, quality premiums and penalties, chances to sell upgraded products, service, engineering, credit, transport.

2. Customers: number and size, location and growth prospects, relationships with other suppliers.

3. Past and prospective price and volume patterns through a complete economic cycle for domestic and world product market served. Usage changes due to obsolescence, use of competitive materials, technological innovation.

4. Competition: existing and potential.
   a. Who are they? What are their strategies for the future?
   b. Current capacity utilization and planned expansions.
   c. Price discipline, price leaders, relationship of price and inventory levels, use of contracts, terms and conditions.
   d. Cost curve for the industry—compare to prior and projected prices.
   e. Project strengths and weaknesses vs. competition.

5. Government regulations on export, approvals, tariffs.

6. Potential product liability.

2.5.8.3 Operating Considerations

1. Management: experience, responsibilities and pay of key people.

2. Labor: skills, availability (now and in the future), union considerations including strikes, prior work practices, pay, incentive compensation, production bonuses.

3. Machinery and equipment: operating availability and costs, flexibility to expand capacity, technical and economic obsolescence.

4. Materials: availability, lead times, cost volatility, purchasing practices.

5. Health, safety, security, and employee rights.

6. Maintenance: onsite vs. offsite workshop, availability of special parts and skilled labor, scheduling.

7. Inventory: amounts and locations, on-site and/or at suppliers.

8. Industry norms: reasons for under/over performance, programs to enhance, maintain or upgrade vs. norms.

9. Environment: studies, reports, approvals needed. Limitations and controls affecting air, water, solid and liquid waste; land; noise; ecology; power; and hospitals, schools, roads, and community services.

10. Equal opportunity employment.

2.5.8.4 Financial Considerations

1. Capital availability: sources, currencies, cost, terms, conditions. Need for refinancings.

2. Capital tied up in assets such as in accounts receivable and inventory, investment in facilities where services can be supplied by others.

3. Repayments: schedules, formula and interrelation with price, volume and margins.

4. Interest rates: variability and protective options.

5. Fees: front-end and continuing.

6. Taxes: land, use, income, royalties, special, direct, indirect.

7. Insurance: costs and coverage.

8. Leases: terms, and conditions on operating and financial leases.

9. Employee costs (other than wages): medical, dental, pensions and other contractual benefits, funding assumptions and requirements.

10. Foreign exchange: availability, quotes, special transactions.

11. Inflation: inclusion in capital and operating costs.

12. Capital additions and replacements.

13. Cost of outside services, travel, and home office.

Chapter 2.6
THE NATIONAL DEFENSE STOCKPILE

J. WAYNE KULIG

2.6.1 INTRODUCTION

The current Strategic and Critical Materials Stock Piling Act of 1979, as amended, provides for the acquisition and retention of strategic and critical materials in a National Defense Stockpile (hereafter referred to as the Stockpile). The stated purpose of the Stockpile, found in Section 2 of the Act, is "to decrease and to preclude, when possible, a dangerous and costly dependence by the United States upon foreign sources for supplies of such materials in times of national emergency."

The National Defense Stockpile, as planned, should be sufficient to sustain the United States through a three-year national emergency. The Stockpile does this through its inventory of strategic and critical materials and through activities that encourage the conservation and development of scarce domestic materials.

The Stockpile and its related efforts at conservation and development are part of this nation's industrial base and part of its national defense arsenal. The existence of the Stockpile is a visible sign to our allies and our adversaries that this nation has the reserves to sustain the industrial base during an extended national emergency.

To better understand the US Stockpile program and the foundation of its policies, we should first review the history of the Stockpile in the United States.

2.6.2 A BRIEF HISTORY OF THE STOCKPILE

Throughout the history of the Stockpile in the United States, two factors, other than its central purpose, stand out: the far-reaching impact of establishing a stockpile and the changing nature of the program.

Although the National Defense Stockpile is maintained for defense purposes, its presence affects more than the defense sector. Purchases and disposals of Stockpile commodities directly affect the US and the international mining and minerals industry. In fact, the stockpiling program has been a recognized factor in the national economy.

Another salient feature of the Stockpile program is its variability. The Stockpile is not static, but continually shifts to meet projected demands. Throughout its history, the Stockpile has been adjusted to adapt to changing conditions. Changing projections of defense need, obsolescence of materials resulting from new technology, development of new sources of supply, and changes in Stockpile policy regarding the adequacy of the Stockpile have kept the program in a constant state of review.

2.6.2.1 Need for a Stockpile

Although the United States has considerable mineral resources, it is far from being self-sufficient, particularly in time of war. The advent of World War II dramatically brought to the attention of the US government and the US public the need for a cache of materials that could be drawn on in an emergency.

Prior to the war, a law permitting stockpiling was already on the books. In 1939, Congress had enacted legislation that provided for acquisition of certain strategic and critical materials. Shortly thereafter, the 76th Congress had allocated $70 million in appropriations and advance contract authorizations in anticipation of a loss of important imports that could occur if Japan conquered parts of Asia or if war broke out in Europe. Little material was accumulated for a stockpile under that act, and when the war broke out, materials were needed badly for immediate use rather than for stockpiling.

During the war, the United States found itself short of some important commodities and was forced to resort to substitution and rationing to ensure a sufficient supply of commodities to support the war effort. Some valuable resources, such as energy supplies and equipment, were diverted for use in stepping up domestic mineral production of items in short supply. Thus, at the close of the war, the United States was ready to adopt a more formal concept of stockpiling.

2.6.2.2 Stock Piling Act of 1946

At the close of World War II, with the renewed interest in a stockpile, the US government sought new legislation for ensuring a constant supply of strategic and critical materials in case of a national emergency. Congress prepared to revise the 1939 provision in favor of provisions that would better meet the needs of national security. But the proposed new provisions brought a host of considerations that had to be adequately addressed.

One consideration was that of who should control the Stockpile. The question stemmed from what purpose the Stockpile should serve. The expressed purpose was that of providing for a national emergency, so the military seemed to be the logical controller.

Another issue that arose was whether the Stockpile should be a factor for consideration in international, political, and economic policy and whether it should function in compliance with international raw materials controls and price stabilization agreements. In this case, the Department of State should be involved.

Then, again, the domestic ramifications of establishing a Stockpile and meeting the needs of the US mining industry had to be considered. These subjects were of importance to the Departments of Commerce and the Interior.

After much debate, a stockpiling act was created that reflected a compromise among the interested parties. The Secretaries of War, Navy, and Interior were authorized "to . . . determine, from time to time, which materials are strategic and critical . . . and to determine, from time to time, the quality and quantities of such materials which shall be stockpiled."

Responsibility for performing some major functions of the Stock Piling Act was originally given to the Army-Navy Munitions Board and then to the National Security Resources Board. Later, the responsibility was shifted to the Treasury Department. A few years later, partially as a result of a Hoover Commission study, the functions that were being carried out by the Treasury were merged with the newly created General Services Administration (GSA) that was to be a major focal point for federal procurement. Operational responsibilities transferred to the GSA included the following:

1. Purchasing strategic and critical materials, as directed.

2. Storing, securing, and maintaining strategic and critical materials.

3. Arranging commercial refining or processing of materials, as directed.

4. Rotating and replacing materials as necessary to prevent deterioration.

5. Conducting Congressionally authorized disposals of excess materials that were no longer needed.

The Act also contained a provision to prevent undue disruption of the usual markets of producers, processors, and consumers by preventing Stockpile materials from being released indiscriminately. The Stock Piling Act was signed by President Truman on July 23, 1946.

While the Act in itself was straightforward, it engendered a number of complex problems. Soon after the Act was made official, a question arose as to what objectives the Stockpile should meet. The Stock Piling Act had stated that the Stockpile was to be used for national defense purposes. National defense included consideration of the following requirements:

1. Military requirements—materials needed by the military to carry on a war.

2. Domestic nonmilitary requirements—the essential civilian and war-supporting needs of industry and the civilian population that must be met to successfully carry on the war. These requirements assumed substitution and conservation measures would be in effect.

3. Export requirements—the usual peacetime exports to friendly countries.

After vigorous discussion, a "factoring system" was adopted in 1950 to determine the estimated availability of wartime supplies. A comparison with requirements helped determine what materials and what quantities should be stored. The system took into account the possible military accessibility to critical materials, political dependability of potential foreign suppliers, concentration of supplies of needed materials, and other miscellaneous factors, such as vulnerability to sabotage.

Of course, the concept of Stockpile objectives was a long-term issue. More immediate was the question of what to begin purchasing to start meeting those objectives. The major question was whether to work for balance in the Stockpile by purchasing materials that were needed to meet the quantity requirements or by purchasing materials that were readily available.

The original appropriation for the Stockpile was $100 million. With this beginning, the Munitions Board created an ideal procurement schedule. Their plans were subject to self-imposed policies. During the early postwar period, the Munitions Board purchased items conservatively. Any commodity price higher than one and one-half times the prewar price was considered too high. Even when the price was right, the Board did not buy material needed for industrial consumers.

Right after the war, business was active and materials were generally in demand. Prices were high for many items on the Stockpile list. So, as a result of the Board's acquisition policies, procurement was slow during the program's first year. Of the $100 million appropriated, $33 million remained unobligated at the end of the fiscal year.

Closely linked with the early purchasing decisions was the debate over the "Buy American" Act of 1933. The Act stated that only materials or supplies produced in the United States could be acquired for public use unless buying US materials was "inconsistent with the public interest" or the cost was "unreasonable." Under the Act, domestic producers were allowed up to one year for delivery and were normally exempt from the requirement of giving bond to guarantee delivery. Moreover, a 1937 Treasury Department ruling stated that domestic bids were supposed to be accepted if their price was not more than 25% over the nearest foreign bid.

One of the expressed purposes of the Stock Piling Act was to "encourage the conservation and development of sources of these materials within the United States . . ." But President Truman had dealt a blow to the "Buy American" Act on July 23, 1946, when he signed the Stock Piling Act into law. The President stated that he felt the "Buy American" provision of the Stock Piling Act would increase the cost of stockpiling, hamper our foreign economic policy, and deplete domestic reserves of strategic materials.

In the early years of stockpiling, many purchases were made from foreign sources, for two basic reasons. For one thing, two-thirds of the materials to be stockpiled were not produced in the United States. Of the listed materials that were available in this country, many could not be mined and processed economically. Purchasing those materials would have raised costs more than the specified 25%. On the other hand, foreign procurements were important early in the program because the strategy was to purchase some of the foreign-made materials and have them in stock in case an unexpected emergency again cut the United States off from foreign sources.

Naturally, senators and representatives who favored development of domestic mining industries took a dim view of the foreign purchases for the Stockpile. So did the miners, who had originally opposed the stockpiling legislation because they believed it could undercut their business. They, and the Department of Interior, rejected the notion that vigorous domestic mineral production would actually weaken national security by depleting important domestic resources. On the contrary, some congressmen fought for high Stockpile objectives as a means of stimulating domestic mining and regional economies. They felt that stockpiling alone was not enough to ensure readiness, and so they encouraged development of US mining as a supplement.

Two other procurement issues that had to be considered were the quality of material that should be stored and the form in which it should be stored. On the issue of quality, the question was the degree of impurity that was acceptable in stockpiled materials. At first, only materials of the highest purity were accepted for stockpiling on the grounds that in an emergency they could be mixed with available lower-grade materials to produce an acceptable product.

Obviously, this limitation was not palatable to those who advocated the interests of the US mining industry. Interior Secretary Harold Ickes argued that insistence on highest purity would "discourage the utilization of domestic ores, particularly those of a marginal character." In addition, Congress charged that the specifications were deliberately set high to exclude domestic materials from the Stockpile. The Preparedness Subcommittee of the Senate Committee on Armed Services insisted that the adherence to the concept of "universal applicability," that is, stockpiling only the purest materials because they would be suitable for any use, was unrealistic. They suggested stockpiling various qualities for a variety of end uses, thereby enabling more domestic materials to qualify for inclusion in the Stockpile inventory.

Initially, however, the argument for highest purity won, although this standard was later relaxed.

Regarding the issue of form, the question revolved around whether materials should be stored in their raw form or, for example, in upgraded forms or alloys that would be ready for use. On one hand, it was argued that stockpiling raw materials would be less expensive, would ensure a supply of raw materials for whatever was needed, and would prevent waste, if, for instance, some alloys became obsolete. The counter argument proposed by the Department of Interior was that storing already processed materials would save time, labor, and other resources if a war actually occurred. During wartime, having a stock of already processed materials would prevent the necessity of diverting valuable labor and natural or economic resources from the war effort to process raw materials into forms needed for the military effort. Ultimately, however, the decision was made to continue stockpiling primarily raw materials.

2.6.2.3 Defense Production Act

When the Korean War began, Congress recognized the need to expand production of materials quickly to meet the emergency. This necessity led to the Defense Production Act of 1950, an act that gave the President expanded powers for production emergencies. Among those powers were the following:

1. Encouraging banks to lend money and extend credit to speed production and deliveries of defense-related materials.
2. Authorizing broad direct lending to speed government contracts for production of strategic and critical materials.
3. Purchasing metals, minerals, and other raw materials for government use or resale.
4. Encouraging development and mining of critical and strategic minerals and metals, as long as those minerals and metals were not sold below the current US market price.

Naturally, use of such authority benefited the domestic mining industry and eventually created one of the major alternate sources of materials for the Stockpile.

In addition to these powers, the President was also authorized to subsidize domestically produced materials; process, refine, transport, and store such materials; and expand and modify government-owned industrial facilities and upgrade private facilities. A later amendment, approved June 30, 1953, points up the success of these expanded powers. The President was permitted to transfer to the existing National Stockpile those materials that had been accumulated under the Defense Production Act. Indeed, the act had created a "stockpile" of its own.

Besides these existing Stockpiles, legislation enacted by Congress in 1954 resulted in another "Stockpile." To increase foreign consumption of surplus US agricultural products, Congress authorized the sale of these products for foreign currencies that could be used to purchase strategic and critical materials for a "supplemental stockpile." In effect, the United States was able to get rid of bulky, short-lived farm products that were costly to store and receive in return needed strategic materials that were longer-lasting and less expensive to store. Releases from this supplemental Stockpile were restricted, as were releases from the National Stockpile.

This Act also gave rise to the Barter Program. Under the Act, the Commodity Credit Corporation (CCC) was permitted to barter agricultural commodities that it owned for strategic materials, creating, in essence, a fourth major Stockpile. Actually, the Barter Program was not primarily intended for acquiring strategic and critical materials; it was intended to reduce costs and storage of short-lived surplus agricultural commodities by exchanging them for more durable metals and minerals.

Between 1950 and 1954, barter was used when possible to acquire necessary materials for the Korean conflict. Beginning in 1954, however, materials obtained through barter were placed in the CCC inventory and, when Public Law 480 was modified in 1956, transferred to the supplemental stockpile.

2.6.2.4 Accelerating the Stockpile Program

Unquestionably, the Defense Production Act was a major factor in expanding the Stockpile program. Prior to the original stockpiling legislation, Congress, in 1939, had allocated $70 million in appropriations and advance contract authorizations. Between 1939 and 1950, Congress had appropriated $1,535 million (including contract authorizations) for stockpiling, but only $895 million had actually been spent. The rest of the money was tied up in long-term contracts for future deliveries. Within a 14-month period during 1950 and 1951, Congress increased authorizations for the program, totaling nearly $3.5 billion.

By the end of fiscal year 1955, major appropriations for Stockpile procurement had ended, though some Stockpile objectives remained unfulfilled. Within the first five years after its enactment in 1950, the Defense Production Act had become a major source of materials for filling National Stockpile objectives.

Particularly noteworthy in this regard were the expansion programs created under the Defense Production Act. Through various procurement and financing techniques, as well as other incentives, these programs created new industries and expanded existing industries. Some of the programs instituted were

1. *Contracts, loans, and grants.* Agencies of the government entered into over $8 billion in contracts, grants, and loans for defense production. Over 90% of the commitments were made by GSA.
2. *"Put" contracts.* These contracts gave the contractor the option to deliver to the government that part of his production that he could not sell on the open market at or above a stipulated option price.
3. *Reopening old facilities.* Government-owned mining, smelting, and refining facilities originally built during World War II and later deactivated were rehabilitated and put into operation.
4. *Purchase regulation programs.* Basically, these programs were government commitments to purchase from any qualified producer who delivered specified material to a designated receiving point, on a first-come, first-serve basis, until the program limit was fulfilled or the expiration date was reached.

Many suppliers saw these programs as an important commercial outlet. Previously nonexistent domestic industries flourished under them, only to vanish when the programs were curtailed or finally completed by 1962.

2.6.2.5 From Shortage to Surplus

The Stockpile expansion programs that were begun in response to the Korean War created an unprecedented buildup of stockpiled materials. These programs continued long after the war ended in 1953. Within the same time period, the expansion of the nuclear age, with its completely different theories and strategies of warfare, changed the philosophy of stockpiling materials. These two factors laid the foundation for an era of Stockpile surplus.

Certainly, discord over Stockpile policy was not new. As we have seen, the program was plagued since its inception by disagreements over how stockpiling should be conducted. In August 1955, the Assistant Secretary of Defense, Supply and Logistics, sent a letter to the Director, Office of Defense Mobilization (ODM), in which he pointed out that the Joint Chiefs of Staff had recently approved a revised objectives plan based on a three-year war instead of the five-year war. Nothing came of his concern at the time, but the issue resurfaced in October 1957. The new Director of Defense Mobilization appointed a Special Stockpile Advisory Committee to advise him of the adequacy of Stockpile policy. On Jan. 28, 1958, the committee submitted its report to the Director, ODM. Among their most important recommendations were the following:

1. That the current government Stockpiles virtually eliminated the possibility of raw material shortages.

2. That the correct government inventory plus production in accessible areas could support an expanded defense industry for several war years.

3. That a nuclear war would require fewer materials than a limited war.

4. That instead of raw materials, the Stockpile should contain more finished items and supplies for survival, relief, and rehabilitation.

5. That Stockpile planning should be revised to meet shortages for a three-year emergency; provisions should also be made for major military and atomic energy programs.

6. That the Director, Office of Defense Mobilization, should have more authority to dispose of surplus materials.

On June 11, 1958, the Director, Office of Defense Mobilization, ratified most of the advisory committee's findings when he signed Defense Mobilization Order (DMO) V-7. The order became effective on June 30, 1958.

Major policies delineated in the order were

1. Strategic Stockpile objectives should be reduced from a five-year war to a three-year war; Stockpile objectives should be adequate for a limited or general war.

2. Commitments for deliveries beyond the maximum Stockpile objectives should be cancelled when possible.

3. Disposals of excesses should be made only if they do not disrupt US domestic markets or US international relations.

In effect, the order reduced current Stockpile objectives by 40%, thereby creating surpluses in a number of commodities.

In response to DMO V-7, terminations of or reductions in outstanding contracts for defense materials were implemented, and obligations declined progressively year by year. Although these contracts did not generally contain termination clauses for government convenience, they could usually be cancelled by negotiation. And by the close of fiscal year 1962, natural attrition had further reduced outstanding contracts. Commodities included agar (seaweed gelatin), hog bristles, castor oil, coconut oil, cryolite, opium poppy seed, pyrethrum, quinine, titanium, and zirconium ore.

Disposals, on the other hand, did not proceed quite so smoothly. The original V-7 order provided for retention of materials to meet not only current objectives but also anticipated increases in objectives. A revised order issued in 1959 further restricted disposals by adding a requirement for review of any proposed disposal of excess materials by the Departments of Interior, Commerce, State, Agriculture, and Defense, as well as any other concerned Federal agencies. Inevitably the necessary review and approval process greatly slowed disposals. Fear of disrupting foreign or domestic markets, based on the original V-7 order, was often cited as the basis for vetoing proposed disposals.

The total value of disposals under this order was about $550 million, divided about equally between the National Stockpile and the Defense Production Act Stockpile. Disposal items from the National Stockpile totaled approximately $276.5 million and included hog bristles, coconut oil, rubber, and tin. Disposals from the Defense Production Act Stockpile totaled approximately $273.7 million and included aluminum, copper, and nickel.

Perhaps the greatest impetus to such disposals was the shake-up of the Stockpile program that occurred after Jan. 30, 1962, when President Kennedy announced at a news conference his assessment of the Stockpile program. Kennedy stated that, ". . . this excessive storage of costly materials [is] a questionable burden on public funds, and in addition a potential source of excessive and unconscionable profits."

In February 1962, the President created an Executive Stockpile Committee under the chairmanship of the Director, Office of Emergency Planning. Members were drawn from Cabinet-level government agencies, namely the Departments of State, Defense, Interior, Commerce, and Labor, and the General Services Administration. The President's committee recognized the magnitude and importance of the Stockpile disposal problem. In this regard, they made a series of recommendations, including the following:

1. Develop a program to provide the public with appropriate information about Stockpile surpluses.

2. Present maximum Stockpile objectives should be used to determine the surplus.

3. Defer disposals when they might inadvertently upset the economies of foreign countries and thus cut the US off from needed imports.

4. Give priority to cash sales of surpluses to commercial sources.

5. Reuse surpluses for other government functions only when those surpluses could not be disposed of.

6. Pass legislation to speed up disposal of Stockpile surpluses.

The rationale behind some of those recommendations is clear. The first recommendation took into account the disastrous effect of rumors upon the national economy. Rather than let the public speculate about Stockpile surpluses, partly because such information had been classified in the past, the committee chose to inform them. The second recommendation sprang from the committee's belief that the present Stockpile objectives were adequate, despite recurring suggestions to develop new objectives to meet the needs of a nuclear or a conventional war.

The final recommendation sought to correct what the committee saw as defects in existing legislation. The committee felt that the DPA had too many restrictions on Stockpile sales and on trading surplus items to upgrade Stockpile materials. The Strategic and Critical Materials Act, on the other hand, was considered too restrictive about disposals. What the committee preferred was the Agricultural Trade Development and Assistance Act of 1954, which allowed supplemental Stockpile materials to be sold or exchanged with National Stockpile commodities. It also recommended more flexibility in the interchange of materials among the different "Stockpiles" to make disposals easier and improve Stockpile management.

In addition, the National Stockpile and Naval Petroleum Reserves Subcommittee, under the chairmanship of Senator Stuart Symington, initiated a series of hearings on the Stockpile that began on Mar. 28, 1962, and concluded on Jan. 30, 1963. In October 1963, the committee published the reports of the hearings.

Chief among the subcommittee's findings was the conviction that the assumption of a three-year conventional war was unrealistic because it would be useless in fighting a nuclear war. On the other hand, survival and rehabilitation items for such a war should be stockpiled, and many of these items were lacking. The surpluses created by this proposed change in objectives should be disposed of, but maximum caution should be used to avoid disrupting the usual markets and US employment. The committee's final recommendation, however, was the most salient one—that all inventories of strategic and critical materials be consolidated so they could be uniformly acquired, stored, and disposed of.

2.6.2.6 Changing the Face of the Stockpile

The reevaluation of the Stockpile during the early 1960s set the stage for changes in Stockpile policy. In March 1973, the

National Security Council analyzed all aspects of the Stockpile. Their analysis was the basis for new guidance regarding Stockpile objectives for individual materials, issued by President Nixon on Apr. 16, 1973. The guidance assumed that

1. The new Stockpile would be used for defense purposes only; the planning period would be for the first year of an emergency.
2. Theaters of war would exist simultaneously in Europe and Asia.
3. Imports of supplies would be available for all years of an emergency from all noncommunist countries outside the war zone.

Obviously, these assumptions reflected confidence that strategic and critical materials would not be inaccessible in wartime. In his April 16th message on the Stockpile, the President had stated that, ". . . [because the US] economy and technology are dynamic, our capability to find substitutes for scarce materials is far greater today than in the past . . . [The United States is] now able to meet defense requirements for materials during possible major conflicts without imposing an excessive burden on the economy or relying on an enormous stockpile, as was once necessary."

Clearly, the policy trend was toward reduction of the Stockpile, a complete reversal of the acceleration policy promulgated in the early 1950s. The July-December 1973 edition of the Stockpile Report to Congress reported that, "As of December 31, 1973, total quantities of the Stockpile grade materials on hand in all Government-owned inventories with the exception of jewel bearings, were in excess of the Stockpile objectives for all of the materials now in the National Stockpile."

In fact, from July to December 1973, disposal sales of excess strategic and critical materials from all government inventories totaled $734.7 million, the largest sales effort since 1966. Of this total, $646.2 million represented sales from the national and supplemental Stockpiles, $87.2 million came from sales from the Defense Production Act inventory, and other sales accounted for the remaining $1.3 million.

That same year, control of the Stockpile planning policy changed hands. On July 1, 1973, a Reorganization Plan abolished the Office of Emergency Preparedness that ran the Stockpile. Its functions were transferred to the President and later reassigned to other agencies. The General Services Administration was made responsible for emergency resources planning, resources allocation, resource crisis management, and Stockpile materials policy. The Federal Preparedness Agency was created in GSA and made responsible for those functions.

In August 1976, the President issued new Stockpile policy guidance, based on the results of an interagency study of stockpiling policies and procedures. The new policy required a stockpile that could support US defense requirements

1. During a major war over a three-year period.
2. Assuming large-scale industrial mobilization and increased materials demands.
3. Providing for a wide range of basic civilian economic needs to ensure a healthy wartime economy.

The new policy also contained stipulations regarding Stockpile planning, including provisions to

1. Maintain current data and planning factors.
2. Develop an "Annual Materials Plan," a plan that will respond to changes in national security, budgetary considerations, domestic markets, and international events.

The new policy became effective Aug. 23, 1976; new goals were announced on Oct. 1, 1976.

The Stockpile program underwent another change in 1979 when President Carter signed the Strategic and Critical Materials Stock Piling Revision Act on July 30. This Act was the second major revision since the 1946 Act, which rewrote the original 1939 Stock Piling law.

One important feature of the revised Act was that it shifted Stockpile administration again. On July 15, 1979, the Federal Emergency Management Agency (FEMA) was officially created. The Stockpile policy functions previously delegated to GSA were transferred, with the entire Federal Preparedness Agency, to FEMA. Management functions, such as purchases and sales of materials, storage, security, maintenance, rotation, and refinement and processing of materials, remained with GSA.

In addition to changing the manager, the revised Act also accomplished the following:

1. Established the National Defense Stockpile Transaction Fund to receive money from the disposal of excess Stockpile materials. Monies from the fund, if authorized by Congress, were to be used only to buy new materials or transport newly acquired materials.
2. Encouraged the uses of barter to acquire and dispose of Stockpile materials.
3. Reaffirmed the statement that the Stockpile is to be used only for defense purposes.
4. Specified that the Stockpile must be sufficient to sustain the United States for a period of not less than three years in the event of a national emergency.

The revision of 1979 eventually set the wheels of change in motion. On Mar. 13, 1981, President Reagan announced a new major purchase program for the National Defense Stockpile. Reagan stated that, "It is now widely recognized that our nation is vulnerable to sudden shortages in basic raw materials that are necessary to our defense production base."

At the time, the Stockpile contained 61 family groups and individual materials. These materials could be categorized as follows:

1. Twenty-four group and individual materials with inventories equal to or greater than Stockpile goals.
2. Thirty-seven group and individual materials with inventories less than the goals. Of these materials, 14 goals were over 50% filled.

To fill these gaps, the administration set up priorities for purchasing materials to ensure that urgently needed ones with high defense uses and large goals were purchased first. Priority materials included refractory grade bauxite, cobalt, medicinals, nickel, platinum group metals, rubber, tantalum, titanium, and vanadium. Congress appropriated an initial $100 million from the Transaction Fund for fiscal year (FY) 1981 purchases. In fact, purchases of cobalt, bauxite, iridium, tantalum, and quinidine sulfate were made during FY 1981.

Disposals were also an important issue. On Aug. 13, 1981, President Reagan signed the Omnibus Budget Reconciliation Act (Public Law 97-35). The Act authorized disposal of antimony, asbestos (amosite and chrysotile), diamond stones, diamond industrial crushing bort, iodine, mica (muscovite splittings), phlogopite splittings, muscovite film first and second qualities, muscovite block (stained and lower), mercuric oxide, mercury, silver, and vegetable tannin wattle to be sold over a three-year period from 1982 to 1984.

Also included in the Budget Reconciliation Act were several amendments to the Strategic and Critical Materials Stock Piling Act. Most significant was the new Section 11, which required Congress to submit an Annual Materials Plan (AMP) each year with the President's budget. The AMP, developed through an interagency effort, was supposed to include planned expenditures for acquisitions and anticipated receipts from sales. The plan was required to cover the next fiscal year and the assumptions for the succeeding four fiscal years.

The Annual Materials Plan process was conducted within the framework of the AMP Steering Committee, an advisory group to the Director of the Federal Emergency Management Agency. The AMP Steering Committee was chaired by FEMA and included as designated member representatives of the Departments of Agriculture, State, Commerce, Defense, Energy, Interior, and Treasury, and GSA, OMB, and NSC. The AMP was developed in a way that balanced National Defense Stockpile requirements against the need to avoid undue market disruption and to conform to budget limitations.

The AMP process began within the Office of Resources Preparedness of FEMA, which provided a list of goals, shortfalls, excesses, and priorities to GSA. After an evaluation of the market outlook, the Office of Stockpile Transactions of GSA proposed quantities of commodities for acquisition or disposal. After FEMA review, the proposals were sent to the Strategic Implications Subcommittee and the Market and International Political Impacts Subcommittee, which furnished suggested revisions to the full AMP Steering Committee.

The Strategic Implications Subcommittee was chaired by the Department of Defense and included, as other designated members, the CIA, the Department of Energy, and FEMA. The subcommittee's primary function was to determine whether any of the materials proposed for the AMP would be affected by anticipated changes in defense requirements.

The Market and International Political Impacts Subcommittee was cochaired by the Departments of Commerce and State with the other designated members being the Departments of Defense, the Treasury, and the Interior, and FEMA, and GSA. This subcommittee evaluated, case-by-case, the effects that Stockpile acquisitions and disposals would have on domestic and international markets. The subcommittee examined significant trends and areas in which Stockpile activities could lead to undue market impacts and affect the normal market participants, as cited in the Stock Piling Act. The subcommittee also determined the international economic and political impacts of Stockpile acquisitions and disposals. In particular, the subcommittee determined the impact that Stockpile activities could have on earnings of international producers and producer countries, on international trade patterns, and on international agreements.

The results of these analyses were presented to the AMP Steering Committee, which developed a recommended AMP. The AMP was submitted to the Director of FEMA for approval and then to the NSC for review. At the same time, an information copy was provided to the Office of Management and Budget. Any revisions to the initial AMP each year were made jointly by the NSC and FEMA. The AMP was then submitted to the Committees on Armed Services of the Senate and the House of Representatives.

In 1982, two other important policies were created, each one affecting the Stockpile. On Apr. 5, 1982, President Reagan transmitted to Congress a report related to the National Materials and Minerals Policy, Research and Development Act of 1980. The President stated that, "It is the policy of this administration to decrease America's minerals vulnerability by taking positive action that will promote our national security, help ensure a healthy and vigorous economy, create American jobs, and protect America's natural resources and environment."

To put this policy into action, the President endorsed the following actions:

1. Continuing to inventory federal land to determine its mineral availability and potential. The President wanted to open appropriate public lands for mining and to develop deep seabed mineral resources as well.

2. Using tax incentives in the Economic Recovery Act to encourage private research with wide general application to materials problems and increased productivity.

3. Carefully disposing of excess Stockpile items while acquiring needed items. To enhance acquisitions and disposals, the President encouraged the use of exchange and barter.

The other important policy was separately created in November 1982, when President Reagan issued a directive stating that, over a 10-year period, chromite and manganese ores in the Stockpile were to be upgraded into high-carbon ferrochromium and high-carbon ferromanganese. The intent of the directive was to help sustain the processing capability necessary to national defense. The idea was that maintaining this capacity would reduce the time required to convert Stockpile materials to ferroalloys in an emergency.

Careful management of the Stockpile continued to be an important issue in subsequent years. On Nov. 14, 1986, the National Defense Authorization Act for FY 1987 (PL 99-661) was enacted. Among its provisions were the following:

1. No action may be taken before Oct. 1, 1987, to implement or administer any change in a Stockpile goal in effect on Oct. 1, 1984, that results in a reduction in the quality or quantity of any strategic and critical materials to be acquired for the National Defense Stockpile.

2. Uses of the Stockpile Transaction Fund are extended to include transportation of commodities, storage, development of specifications, upgrading expenses, testing and quality studies of Stockpile materials, material and mobilization studies, and other reasonable requirements for management of the Stockpile.

3. A seven-year ferroalloy upgrading program is required to convert Stockpile chromite and manganese ore to 374,000 st (339 kt) of high-carbon ferrochromium and 472,000 st (428 kt) of high-carbon ferromanganese, effectively putting the President's 1982 directive into law.

In addition, the Act required the Secretary of Defense to submit to the Congress a report describing, inter alia, the war emergency situation that should serve as the basis for planning and management of the National Defense Stockpile. This requirement reflected the Senate Committee on Armed Services' concern that a 1985 Stockpile goal study performed by the National Security Council had been inadequate. Evidence provided by the General Accounting Office, the various Administration agencies, and private individuals indicated that the National Security Council had used "an optimistic wartime scenario."

Based on the National Security Council Study, a proposed modernization program of the National Defense Stockpile of Strategic Materials was sent to Congress. The plan called for the inclusion of two types of materials in the Stockpile, those that would be unavailable during a long war and a reserve of materials already in the Stockpile to provide extra protection against materials shortages during a war.

Congressional opposition and evidence presented before the Armed Services Committee caused the proposed plan to be heartily rejected. Instead, the committee members made recommendations of their own, including the following:

1. Amending Section 2 of the Strategic and Critical Materials Stock Piling Act by restating (a) "that the intent of Congress is that the National Defense Stockpile be used to serve the interest of national defense only and not be used for economic or budgetary purposes" and (b) "that the quantities of materials stockpiled under the Act should be sufficient to sustain the United States for a period of not less than three years during a war emergency that would necessitate total mobilization of the economy of the United States for a conventional global war of indefinite duration."

2. Transferring management of the Stockpile to the Secretary of Defense. The Secretary would be responsible for acquisition, storage, security, maintenance, disposal, refining, rotation, processing, and upgrading Stockpile materials; for budgeting for Stockpile operations; and for managing the National Defense Stockpile Transaction Fund.

3. Requiring the Secretary of Defense to submit an annual report of his recommended requirements for the National Defense Stockpile based on total mobilization of the US economy for a three-year conventional global war. The Secretary would also be required to provide the National Emergency Planning Assumptions used to determine the Stockpile requirements.

The proposal to return control of the Stockpile to DOD represented a departure from previous policy since control had been in the hands of civilian agencies, namely FEMA and its predecessors, the Office of Emergency Preparedness and the Office of Civil and Defense Mobilization, since the 1950s. At the time, the House adopted the recommendations as part of H.R. 1748, but the Senate did not concur. So more time was allotted to determine whether the Stockpile could be efficiently managed by FEMA and GSA.

In addition to provisions on stockpiling goals, the Transaction Fund, and ferroalloy upgrading, PL 99-661 actually added certain amendments to the existing Strategic and Critical Materials Stock Piling Act. A particularly important one was the new Section 6A, which required the President, by Feb. 15, 1987, to designate a single federal official to be the National Defense Stockpile Manager and perform the functions of the President under the Stock Piling Act. The designated official ". . . shall be an officer who holds a civilian position to which the person was appointed by the President, by and with the advice and consent of the Senate." The official was to be known as the "National Defense Stockpile Manager." To comply with Section 6A, President Reagan, on Feb. 13, 1987, named Julius W. Becton, Jr., Director of FEMA, National Defense Stockpile Manager.

Becton's appointment was short-lived, however. On Feb. 25, 1988, President Reagan issued Executive Order 12626, designating the Secretary of Defense as National Defense Stockpile Manager. Essentially, control of the Stockpile was being shifted from civilian to military hands, as had been suggested earlier in H.R. 1748. That same year, the National Defense Authorization Act for FY 1988 and 1989 expanded the powers of the Stockpile Manager by adding provisions to the new Section 6A of the Strategic and Critical Materials Stock Piling Act. The new provisions required the President to delegate most presidential functions to the National Defense Stockpile Manager. The Stockpile Manager, however, could not authorize special releases from the Stockpile, initiate research and development of Stockpile commodities, or determine whether certain imported commodities should be prohibited.

2.6.3 THE STOCK PILING ACT

The Stock Piling Act reflects current philosophy about the Stockpiling program. (For a complete text of the Act, see Appendix A.) Highlights of the implementation of the Stock Piling Act of 1979, as amended, are summarized in the following.

2.6.3.1 Materials to be Stockpiled

The National Defense Stockpile Manager, per delegation by the President, makes the ultimate determinations as to which materials are strategic and critical. He also determines the quality and quantity of each such material. Section 3 of the Stock Piling Act provides Congressional guidance as to how these determinations are to be made.

The Stockpile is not an inventory of finished products but is rather comprised of materials necessary to meet military, industrial, and essential civilian needs during a crisis. The form of the material stockpiled should reflect (1) handling and processing capabilities of US industry and (2) defense requirements during a national emergency.

The classification of materials as strategic and critical changes over time as underlying assumptions and new technology dictate the obsolescence of materials such as silk and talc and the emergence of new materials such as germanium. The Stockpile is generally comprised of materials that are raw or refined rather than finished. (For a list of materials currently in the Stockpile, see Appendix B.)

2.6.3.2 Quantities of Materials to be Stockpiled

The Stockpile's Annual Materials Plan (AMP) contains an operations forecast of the Stockpile during the fiscal year and the succeeding four fiscal years. The Stock Piling Act requires the report to include "details of planned expenditures . . . and of anticipated receipts." Estimates are provided for both disposals and acquisitions.

Each year, by February 15, the President should submit a new AMP to the Congress, as required by Section 1 l(b) of the Act.

2.6.3.3 Method of Acquisition and Disposal

Stockpile goals indicate the magnitude of Stockpile requirements for given materials. Section 6(b)(2) provides that efforts shall be made to avoid undue market disruption to the "maximum extent feasible" for both acquisitions and disposals.

Section 6(b) of the Stock Piling Act stipulates that Stockpile acquisitions and disposals must, to the maximum extent feasible, utilize formal advertising or competitive negotiation procedures. The Stockpile's contract managers must draft their solicitations for acquisitions in accordance with the established federal procurement practices and the agency regulations.

2.6.3.4 Barter and Other Stockpile Transactions

Section 6(c) of the Act permits and encourages the use of barter for accomplishing Stockpile transactions. In recent years, excess Stockpile materials that are authorized for disposal have been transferred at fair market value as payment to contractors who are upgrading ferroalloys. Industrial diamonds, iodine, tin, and vegetable tannins, for example, have been used as payment.

Should the President determine that he cannot acquire or dispose of Stockpile materials in accordance with established federal procurement practices, he may elect to waive the applicability of any provision that controls or limits an acquisition or disposal. This waiver provision requires the Stockpile Manager to provide the Armed Services Committees of the Senate and House of Representatives with a written notice at least 30 days before proceeding with the transaction. The notice must include the reasons for not following established procedures.

2.6.3.5 National Defense Stockpile Transaction Fund

The Transaction Fund, or T-Fund, was established as of 1979 in the US Treasury as a separate fund under Section 9 of the Act. Moneys received from the sales of Stockpile materials are deposited into the T-Fund in the Treasury where they remain until expended. By earmarking the money in the Transaction

Fund, Congress helps ensure that funds will be available for restructuring and upgrading the Stockpile.

Moneys in the Transaction Fund are restricted in the Act to a limited number of specific uses. These uses include the acquisition of strategic and critical materials, transportation related to such acquisitions, storage, development of current specifications, the upgrading of existing Stockpile materials to meet current specifications, testing and quality studies of Stockpile materials, and studying future materials and mobilization requirements for the Stockpile.

2.6.3.6 Operational Expenditures for the Stockpile

National Defense Stockpile operating expenses are authorized by Section 5(c) of the Act. This section provides for appropriation of moneys to provide for the transportation, processing, refining, storage, security, maintenance, rotation, and disposal of materials. Now that the Stockpile is part of the Department of Defense, operating expenditures are a portion of the agency's appropriation for Operations and Maintenance.

2.6.3.7 Congressional Oversight of the Stockpile

The Committees on Armed Services of the Senate and House of Representatives oversee the National Defense Stockpile. The President and the Stockpile Manager must notify these committees in writing if the Stockpile Manager does any of the following: (1) releases materials for national defense purposes; (2) waives competitive procedures for acquisition or disposal actions; (3) waives the disposals for domestic use requirement; (4) revises the quantity of any Stockpile material goal by more than 10 percent. The Act specifies additional reporting requirements concerning: (1) information on foreign and domestic purchases of materials; (2) information on acquisition and disposal actions by barter; and (3) the financial status of the National Defense Stockpile Transaction Fund and anticipated acquisition appropriations for the following fiscal year.

Congress must legislate any disposals from the Stockpile. Section 5(b) of the Stock Piling Act requires that all disposals, whether by direct sale or by barter, be authorized to include the commodity's name and quantity. The only exceptions are for rotational sales, for sales of excess materials with a limited shelf life that might deteriorate if the disposal were delayed seeking authorizing legislation, and for releases ordered by the President in time of national emergency or for the national defense.

2.6.3.8 Specialized Leasing Authority

The Act provides a special leasing authority for use in Stockpile operations. Subsection 6(e) permits the President to "acquire leasehold interests in property, for periods not in excess of 20 years, for storage, security, and maintenance of materials in the Stockpile."

2.6.3.9 Special Disposal Authority of the President

In addition to the normal disposals authorized by Congress for excess materials, the President, under Section 7 of the Act, has authority to release materials from the Stockpile for use, sale, or other disposition. The President may order release of materials whenever he determines such release is necessary for the national defense.

This provisional authority has been utilized sparingly in response to situations that have not been national emergencies but are of concern or impact on national security.

The President has ordered releases pursuant to Section 7 for mercury for atomic weapons production when mercury was not available through commercial sources in 1956 and also in 1959. In 1973, quinine was released for sale to pharmaceutical manufacturers with unfilled defense orders so they could meet Vietnam requirements. As recently as 1979, chrysotile asbestos was released to meet specific defense contract deficiencies caused by international supply problems.

2.6.4 FUNCTIONS AND ORGANIZATION OF THE DEFENSE NATIONAL STOCKPILE PROGRAM

Operation of the Defense National Stockpile Program is conducted through the Defense National Stockpile Center (DNSC). Under the policy guidance of the Assistant Secretary of Defense for Production and Logistics, Operations, management is provided by the Directorate of the Defense Logistics Agency. The DNSC is composed of two major separate entities, the Primary Level Field Activity (PLFA) and the Secondary Level Field Activities (SLFA). (See organization charts, Appendix C.)

2.6.4.1 Primary Level Field Activity

The Primary Level Field Activity has its headquarters in Washington, DC, and is staffed by approximately 100 people. The PLFA includes the Office of the Administrator; Office of Counsel; Office of Management and Systems Support; Office of Planning and Market Research; and the Directorates of Stockpile Contracts; Quality Assurance and Technical Services; and Stockpile Operations.

The Administrator, who heads the PLFA, reports to the Director, DLA. The Administrator oversees all functions of the PLFA and the Secondary Level Field Activities. He ensures that all programs are operating effectively to achieve program objectives. He is assisted by the Deputy Administrator, who acts for the Administrator whenever necessary.

The Office of Counsel provides legal advice and services to the Administrator and all staff elements on matters involving or affecting the DNSC. Such services include analyzing the legal impact of proposed and new legislation, helping to formulate acquisition policy and procedures, and providing advice on the legal aspects of establishing internal controls.

The Office of Management and Systems Support keeps accounting and inventory records for the Stockpile Transaction Fund and for the quantity of materials sold and purchased by the contracting officers. The staff provides property accountability; supplies and services; mail, telecommunications and audit-report response; space management; management studies; and personnel services.

This office also maintains and periodically updates an international mailing list of persons or firms interested in selling strategic and critical materials to or buying excess commodities from the National Defense Stockpile inventories located at various depots around the country.

The Office of Planning and Market Research plays a major role in determining the market limitations on buying and selling materials. It evaluates proposed and current purchases and disposals of Stockpile materials and considers whether these actions are feasible and what effect they will have on the worldwide markets. The Office also recommends, evaluates, and monitors potential and actual domestic mining and processing projects approved for funding by Defense Production Act (DPA) appropriations.

The Office has a legislative affairs group that monitors and comments on proposed legislation affecting the Stockpile and reports the Stockpile program's progress semiannually in the Stockpile Report to Congress.

The Directorate of Stockpile Contracts acquires Stockpile materials and contracts for services needed for upgrading existing materials and for repairing and maintaining storage facilities. When authorized, the Directorate also disposes of excess Stockpile materials to producers, consumers, trading firms, or other government agencies.

One important program is the initiative to sustain a domestic ferroalloy furnace and processing capability that is vital to national security. Calendar year contracts provide for the upgrading of the Stockpile's chromite and manganese ore at a combined cost of more than $60 million/year.

This Directorate also manages the William Langer Jewel Bearing Plant at Rolla, ND. This plant is the only facility of its kind in the Western Hemisphere. Its purpose is to maintain a US capability for the manufacture of jewel bearings and related items to ensure a domestic source of supply in a national emergency. The plant is a government-owned facility, operated under contract by the Bulova Corp. Skilled personnel, 60% of whom are of Chippewa Indian descent, shape, polish, and drill synthetic sapphire and ruby raw materials into jewel bearings for Stockpile requirements and for sale to defense contractors. Each year, from 500,000 to l,000,000 jewel bearings, valued at more than $l,000,000, are purchased for the Stockpile.

Two of the metals that the division has purchased recently for the Stockpile are beryllium and germanium. Beryllium, a lightweight, high-strength metal vital in nuclear and aerospace technology, is produced by a domestic firm. Germanium is a hard, glassy, brittle metal closely related to silicon. It is used in lenses for night-vision optics and has been obtained from domestic and foreign firms.

The Directorate of Stockpile Contracts administers legislatively mandated grants to construct facilities for scientific research on strategic materials. It also sells excess silver to the US Treasury to be minted into bullion and commemorative coins. In recent years, the Treasury has used more than $100 million worth of Stockpile silver and lowered inventory holdings by more than 30 million oz (933 Mg).

The Directorate of Quality Assurance and Technical Services ensures the quality of all materials acquired for the Stockpile by sampling and testing these materials for conformance with the purchase specifications and contract requirements. The Directorate also develops sampling, testing, and analyses procedures and acceptance/rejection criteria for use by quality assurance personnel in the secondary level field activities. These procedures are used for materials accepted into the Stockpile by acquisition or upgrade.

The Directorate also conducts semiannual inspections of materials in the Stockpile to ensure their readiness. These inspections are especially important for the more sensitive materials or those materials subject to deterioration, such as quinidine sulfate and natural rubber. Some materials are also selected for special quality assessment tests and analyses. This testing determines the effect of long-term storage on the quality and usability of the commodities.

This Directorate, through its secondary level field activities, acts as the contracting officer's representative for most field operations involving commodities.

The Directorate of Stockpile Operations Management manages the Stockpile storage space, assuring safe storage, security, and maintenance of Stockpile commodities. This Directorate takes care of and secures all storage depots and sites. It develops and administers an equipment preventive maintenance system and maintains a nationwide equipment usage and inventory system. It also develops and implements plans for moving Stockpile materials and for maintaining the quality of commodities in the inventory.

For the secondary level field activities, the Directorate develops storage, handling, and packaging methods and publishes instructions for receiving, safeguarding, and shipping various materials. It also offers technical advice and assistance on storage and handling methods to other government agencies and private industry.

Environmental protection is an important concern. The Directorate of Stockpile Operations Management has overseen the removal of radioactive wastes from several storage sites to the Nuclear Regulatory Commission (NRC)-licensed burial sites. The soil and nearby waterways were thoroughly tested for radioactive thorium and were certified as safe by the NRC.

The Directorate determines the long-term environmental effect of materials stored outdoors. Tests are devised to discover the extent to which certain materials can leach into groundwater and surface water and to find out whether acid rain can cause some substances, such as lead, to leach into the surrounding soil.

Since the Directorate is concerned about the health of depot workers, it maintains high industrial hygiene standards. It also administers the pilot Baseline and Annual Medical Surveillance Program to guard employees' health. The program requires employees to be medically and physically examined before they begin working with the Stockpile and to be reexamined annually to be certain they are continually capable of performing the job safely while wearing any necessary protective clothing or devices.

2.6.4.2 Secondary Level Field Activities

The Secondary Level Field Activities consist of three zones and their respective storage depots. Each zone supports the NDS mission for a specific geographical area within the United States. The Defense National Stockpile Center maintains 94 storage sites around the country, staffed by approximately 200 people.

Each zone has an *Administrator* who guides and supports all Stockpile activities within that zone. The Administrator formulates and controls zone funding allotments and carries out the zone contracting program.

The *Quality Assurance Division* of each zone inspects, samples, and tests Stockpile materials within the zone, following procedures and instructions provided by the PLFA. The *Storage Operations Division* manages the operations of the depot properties and is responsible for commodity shipments, receipts, control, and proper storage.

2.6.5 THE FUTURE OF THE STOCKPILE

What will be the future of the Stockpile? This question is especially pertinent as the NDS enters a new stage as part of the Department of Defense (DOD). Current projections for the Stockpile involve changing priorities to make the Stockpile more responsive to defense needs. Program changes and advancing technology will continue to affect the content of the Stockpile as well as its funding.

2.6.5.1 Modernization

A primary objective is to modernize the Stockpile to make sure it can support both the military and civilian requirements in case of a national emergency. The modernization program is to be conducted in two phases. The first phase will be directed at making the Stockpile useful for accelerating and sustaining military production during a national emergency. This phase will be guided by the recommendations contained in the Secretary of Defense's annual report to the Congress on Stockpile requirements.

The second phase of modernization is expected to begin in FY 1992 and to be carried out over the next five to ten years. This phase will aim at changing the character of the Stockpile to meet the needs at that time. Changes will reflect refinements in military requirements and consideration of civilian requirements. The purpose is to support national security efforts in a future national emergency.

2.6.5.2 Consultations

A second program priority will be to consult more with Congress and private industry to receive expert suggestions on policy and program direction. DOD will work closely with the House Armed Services Subcommittee on Seapower and Strategic and Critical Materials to determine long-term objectives for the NDS program. DOD also plans to consult with industrial experts regarding technical information on special low-volume, highly critical advanced materials.

2.6.5.3 Research and Analysis

DOD has begun a series of research projects to determine future Stockpile requirements and thus appropriate objectives for its modernization program. Among the projects are

1. Analyses of possible conflict scenarios to determine the full range of potential threats to national defense.
2. Analyses to determine essential civilian requirements during a defense emergency.
3. Updating databases containing material consumption ratios, emergency operating capacities, and domestic and foreign production capacities for strategic and critical materials, a task that will be made difficult by budgeting constraints.

2.6.5.4 Proposed Change in Financial Policy

Currently, Section 5(b) of the Stock Piling Act prohibits selling excess Stockpile materials when the balance in the Transaction Fund exceeds $100 million. This cap on disposals was intended to encourage acquiring or upgrading Stockpile materials whenever sales of excess materials brought in additional money. The National Defense Stockpile Manager has proposed that the Section 5(b) cap be rescinded.

Rescinding the Section 5(b) cap would allow the National Defense Stockpile Manager to keep a balance in the Transaction Fund that could be used to build up the Stockpile in case of threats to the national defense. In response to warnings of an impending emergency, the Stockpile Manager could amend the Annual Materials Plan under Section 5(a)(2) of the Stock Piling Act. After notifying the Senate and House Committees on Armed Services, the Stockpile Manager would be allowed to use the existing balance in the T-Fund to acquire or upgrade materials to make up for any shortfalls in the Stockpile.

2.6.5.5 Meeting the Challenges Ahead

Of course, the future goals and policies of the National Defense Stockpile are speculative. Decisions made by the Congress and by DOD will determine its future direction. One thing, however, is certain. The Stockpile cannot remain static but must continually change to meet changing needs.

As we have seen, new trends in technology and in military strategies can render existing policies and stores of materials obsolete. If the Stockpile is to serve as an essential resource to America's defense system, it must adapt accordingly. The major objective of the National Defense Stockpile, then, is not stability but adaptability. With careful foresight, flexibility, and good management, the Stockpile will serve this country well in the coming decades, a symbol of America's strength and readiness.

For reports on the program status and questions regarding commodity/material specific activities involving contracts for acquisition, disposal, upgrading, storage, or testing, the reader should contact the Administrator, Defense National Stockpile Center, Defense Logistics Agency, 1745 Jefferson Davis Highway, Crystal Square 4, Ste. 100, Arlington, VA 22202.

APPENDIX A.
STRATEGIC AND CRITICAL MATERIALS STOCK PILING ACT

(50 U.S.C. 98 *et seq.)*
As amended by the National Defense Authorization Act
for Fiscal Year 1991 (P.L. 101-510)

SEC. 1. This Act may be cited as the "Strategic and Critical Materials Stock Piling Act."

FINDINGS AND PURPOSE

SEC. 2. (a) The Congress finds that the natural resources of the United States in certain strategic and critical materials are deficient or insufficiently developed to supply the military, industrial, and essential civilian needs of the United States for national defense.

(b) It is the purpose of this Act to provide for the acquisition and retention of stocks of certain strategic and critical materials and to encourage the conservation and development of sources of such materials within the United States and thereby to decrease and to preclude, when possible, a dangerous and costly dependence by the United States upon foreign sources for supplies of such materials in times of national emergency.

(c) In providing for the National Defense Stockpile under this Act, Congress establishes the following principles:

(1) The purpose of the National Defense Stockpile is to serve the interest of the national defense only. The National Defense Stockpile is not to be used for economic or budgetary purposes.

(2) The quantities of materials to be stockpiled under this Act should be sufficient to sustain the United States for a period of not less than three years during a national emergency situation that would necessitate total mobilization of the economy of the United States for a sustained conventional global war of indefinite duration.

MATERIALS TO BE ACQUIRED: PRESIDENTIAL AUTHORITY AND GUIDELINES

SEC. 3. (a) Subject to subsection (c), the President shall determine from time to time (1) which materials are strategic and critical materials for the purposes of this Act, and (2) the quality and quantity of each such material to be acquired for the purposes of this Act and the form in which each such material shall be acquired and stored. Such materials when acquired, together with the other materials described in section 4 of this Act, shall constitute and be collectively known as the National Defense Stockpile (hereinafter in this Act referred to as the "stockpile").

(b) The President shall make the determinations required to be made under subsection (a) on the basis of the principles stated in section 2(c).

(c) (1) The quantity of any material to be stockpiled under this Act, as in effect on Sept. 30, 1987, may be changed only as provided in this subsection or as otherwise provided by law enacted after December 4, 1987.

(2) If the President proposes to change the quantity of any material to be stockpiled under this Act, the President shall include a full explana-

tion and justification for the change in the next annual material plan submitted to Congress under section 11(b).

(3) If the proposed change in the case of any material would result in a new requirement for the quantity of such material different from the requirement for that material in effect on Sept. 30, 1987, by less than l0%, the change may be made by the President effective on or after the first day of the first fiscal year beginning after the explanation and justification for the proposed change is submitted pursuant to paragraph (2).

(4) In the case of a proposed change not covered by paragraph (3), the proposed change may be made only to the extent expressly authorized by law.

(5) If in any year the reports required by sections 11(b) and 14 are not submitted to Congress as required by law (including the time for such submission), then during the next fiscal year no change under paragraph (3) may be made in the quantity of any material to be stockpiled under this Act.

MATERIALS CONSTITUTING THE NATIONAL DEFENSE STOCKPILE

SEC. 4. (a) The stockpile consists of the following materials:

(1) Materials acquired under this Act and contained in the national stockpile on July 29, 1979.

(2) Materials acquired under this Act after July 29, 1979.

(3) Materials in the supplemental stockpile established by section 104(b) of the Agricultural Trade Development and Assistance Act of 1954 (as in effect from Sept. 21, 1959, through Dec. 31, 1966) on July 29, 1979.

(4) Materials acquired by the United States under the provisions of section 303 of the Defense Production Act of 1950 (50 U.S.C. App. 2093) and transferred to the stockpile by the President pursuant to subsection (f) of such section.

(5) Materials transferred to the United States under section 663 of the Foreign Assistance Act of 1961 (22 U.S.C. 2423) that have been determined to be strategic and critical materials for the purposes of this Act and that are allocated by the President under subsection (b) of such section for stockpiling in the stockpile.

(6) Materials acquired by the Commodity Credit Corporation and transferred to the stockpile under section 4(h) of the Commodity Credit Corporation Charter Act (15 U.S.C. 714b(h)).

(7) Materials acquired by the Commodity Credit Corporation under paragraph (2) of the section 103(a) of the Act entitled “An Act to provide for greater stability in agriculture; to augment the marketing and disposal of agricultural products and for other purposes” approved Aug. 28, 1954 (7 U.S.C. 1743(a)), and transferred to the stockpile under the third sentence of such section.

(8) Materials transferred to the stockpile by the President under paragraph (4) of section 103(a) of such Act of August 28, 1954.

(9) Materials transferred to the stockpile under subsection (b).

(b) Notwithstanding any other provision of law, any material that (1) is under the control of any department or agency of the United States, (2) is determined by the head of such department or agency to be excess to its needs and responsibilities, and (3) is required for the stockpile shall be transferred to the stockpile. Any such transfer shall be made without reimbursement to such department or agency, but all costs required to effect such transfer shall be paid or reimbursed from funds appropriated to carry out this Act.

AUTHORITY FOR STOCKPILE OPERATIONS

SEC. 5. (a)(l) Except for acquisitions made under the authority of paragraph (3) or (4) of section 6(a), no funds may be obligated or appropriated for acquisition of any material under this Act unless funds for such acquisition have been authorized by law. Funds appropriated for such acquisition (and for transportation and other incidental expenses related to such acquisition) shall remain available until expended, unless otherwise provided in appropriation Acts.

(2) If for any fiscal year the President proposes certain stockpile transactions in the annual materials plan submitted to Congress for that year under section 11(b) and after that plan is submitted the President proposes (or Congress requires) a significant change in any such transaction, or a significant transaction not included in such plan, no amount may be obligated or expended for such transaction during such year until the President has submitted a full statement of the proposed transaction to the appropriate committees of Congress and a period of 30 days has passed from the date of the receipt of such statement by such committees. In computing any 30-day period for the purpose of the preceding sentence, there shall be excluded any day on which either House of Congress is not in session because of an adjournment of more than three days to a day certain.

(b) Except for disposals made under the authority of paragraph (3), (4) or (5) of section 6(a) or under section 7(a), no disposal may be made from the stockpile (1) unless such disposal, including the quantity of the material to be disposed of, has been specifically authorized by law, or (2) if the disposal would result in there being an unobligated balance in the National Defense Stockpile Transaction Fund in excess of $100,000,000.

(c) There is authorized to be appropriated such sums as may be necessary to provide for the transportation, processing, refining, storage, security, rotation, and disposal of materials contained in or acquired for the stockpile. Funds appropriated for such purposes shall remain available to carry out the purposes for which appropriated for a period of two fiscal years, if so provided in appropriations Acts.

STOCKPILE MANAGEMENT

SEC. 6. (a) The President shall-

(1) acquire the materials determined under section 3(a) to be strategic and critical materials;

(2) provide for the proper storage, security, and maintenance of materials in the stockpile;

(3) provide for the upgrading, refining, or processing of any material in the stockpile (notwithstanding any intermediate stockpile quantity established for such material) when necessary to convert such material into a form more suitable for storage, subsequent disposition, and immediate use in a national emergency;

(4) provide for the rotation of any material in the stockpile when necessary to prevent deterioration of such material by replacement of such material with an equivalent quantity of substantially the same material;

(5) subject to the notification required by subsection (d)(2), provide for the timely disposal of materials in the stockpile that (A) are excess to stockpile requirements, and (B) may cause a loss to the Government if allowed to deteriorate; and

(6) subject to the provisions of section 5(b), dispose of materials in the stockpile the disposal of which is specifically authorized by law.

(b) Except as provided in subsections (c) and (d), acquisition of strategic and critical materials under this Act shall be made in accordance with established Federal procurement practices, and, except as provided in subsections (c) and (d) and in section 7(a), disposal of materials from the stockpile shall be made by formal advertising or competitive negotiation procedures. To the maximum extent feasible—

(1) competitive procedures shall be used in the acquisition and disposal of such materials; and

(2) efforts shall be made in the acquisition and disposal of such materials to avoid undue disruption of the usual markets or producers, processors, and consumers of such materials and to protect the United States against avoidable loss; and

(c)(l) The President shall encourage the use of barter in the acquisition under subsection (a)(l) of strategic and critical materials for, and the disposal under subsection (a)(5) or (a)(6) of materials from, the stockpile when acquisition or disposal by barter is authorized by law and is practical and in the best interest of the United States.

(2) Materials in the stockpile (the disposition of which is authorized by paragraph (3) to finance the upgrading, refining, or processing of a material in the stockpile, or is otherwise authorized by law); shall be available for transfer at fair market value as payment for expenses (including transportation and other incidental expenses) of acquisition of materials, or of upgrading, refining, processing, or rotating materials, under this Act.

(3) Notwithstanding section 3(c) or any other provision of law, whenever the President provides under subsection (a)(3) for the upgrading,

refining, or processing of a material in the stockpile to convert that material into a form more suitable for storage, subsequent disposition, and immediate use in a national emergency, the President may barter a portion of the same material (or any other material in the stockpile that is authorized for disposal) to finance that upgrading, refining, or processing.

(4) To the extent otherwise authorized by law, property owned by the United States may be bartered for materials needed for the stockpile.

(d)(1) The President may waive the applicability of any provision of the first sentence of subsection (b) to any acquisition of material for, or disposal of material from, the stockpile. Whenever the President waives any such provision with respect to any such acquisition or disposal, or whenever the President determines that the application of paragraph (1) or (2) of such subsection to a particular acquisition or disposal is not feasible, the President shall notify the Committees on Armed Services of the Senate and House of Representatives in writing of the proposed acquisition or disposal at least thirty days before any obligation of the United States is incurred in connection with such acquisition or disposal and shall include in such notification the reasons for not complying with any provision of such subsection.

(2) Materials in the stockpile may be disposed of under subsection (a)(5) only if the Committees on Armed Services of the Senate and House of Representatives are notified in writing of the proposed disposal at least thirty days before any obligation of the United States is incurred in connection with such disposal.

(3) The President may acquire leasehold interests in property, for periods not in excess of 20 years, for storage, security, and maintenance of materials in the stockpile.

SPECIAL DISPOSAL AUTHORITY OF THE PRESIDENT

SEC. 7. (a) Materials in the stockpile may be released for use, sale, or other disposition-

(1) on the order of the President, at any time the President determines the release of such materials is required for purposes of the national defense; and

(2) in time of war declared by the Congress or during a national emergency, on the order of any officer or employee of the United States designated by the President to have authority to issue disposal orders under this subsection, if such officer or employee determines that the release of such materials is required for purposes of the national defense.

(b) Any order issued under subsection (a) shall be promptly reported by the President, or by the Officer or employee issuing such order, in writing, to the Committees on Armed Services of the Senate and House of Representatives.

MATERIALS DEVELOPMENT AND RESEARCH

SEC. 8. (a)(l) The President shall make scientific, technologic, and economic investigations concerning the development, mining, preparation, treatment, and utilization of ores and other mineral substances that (A) are found in the United States, or in its territories or possessions, (B) are essential to the national defense, industrial, and essential civilian needs of the United States, and (C) are found in known domestic sources in inadequate quantities or grades.

(2) Such investigations shall be carried out in order to-

(A) determine and develop new domestic sources of supply of such ores and mineral substances;

(B) devise new methods for the treatment and utilization of lower grade reserves of such ores and mineral substances; and

(C) develop substitutes for such essential ores and mineral products.

(3) Investigations under paragraph (1) may be carried out on public lands and, with the consent of the owner, on privately owned lands for the purpose of exploring and determining the extent and quality of deposits of such minerals, the most suitable methods of mining and beneficiating such minerals, and the cost at which the minerals or metals may be produced.

(b) The President shall make scientific, technologic, and economic investigations of the feasibility of developing domestic sources of supplies of any agricultural material or for using agricultural commodities for the manufacture of any material determined pursuant to section 3(a) of this Act to be a strategic and critical material or substitutes therefor.

(c) The President shall make scientific, technologic, and economic investigations concerning the feasibility of—

(1) developing domestic sources of supply of materials (other than materials referred to in subsections (a) and (b) determined pursuant to section 3(a) to be strategic and critical materials; and

(2) developing or using alternative methods for the refining or processing of a material in the stockpile so as to convert such material into a form more suitable for use during an emergency or for storage.

(d) The President shall encourage the conservation of domestic sources of any material determined pursuant to section 3(a) to be a strategic and critical material by making grants or awarding contracts for research regarding the development of—

(1) substitutes for such materials; or

(2) more efficient methods of production or use of such material.

NATIONAL DEFENSE STOCKPILE TRANSACTION FUND

SEC. 9. (a) There is established in the Treasury of the United States a separate fund to be known as the National Defense Stockpile Transaction Fund (hereinafter in this section referred to as the "fund").

(b)(1) All moneys received from the sale of materials in the stockpile under paragraphs (5) and (6) of section 6(a) shall be covered into the fund.

(2) Subject to section 5(a)(l), moneys covered into the fund under paragraph (1) are hereby made available (subject to such limitations as may be provided in appropriations Acts) for the following purposes:

(A) The acquisition of strategic and critical materials under section 6(a)(1).

(B) Transportation, storage, and other incidental expenses related to such acquisition.

(C) Development of current specifications of stockpile materials and the upgrading of existing stockpile materials to meet current specifications (including transportation, when economical, related to such upgrading).

(D) Testing and quality studies of stockpile materials.

(E) Studying future material and mobilization requirements for the stockpile.

(F) Activities authorized under section 15.

(3) Moneys in the fund shall remain available until expended.

(c) All moneys received from the sale of materials being rotated under the provisions of section 6(a)(4) or disposed of under section 7(a) shall be covered into the fund and shall be available only for the acquisition of replacement materials.

(d) If, during a fiscal year, the National Defense Stockpile Manager barters materials in the stockpile for the purpose of acquiring, upgrading, refining, or processing other materials (or for services directly related to that purpose), the contract value of the materials so bartered shall—

(1) be applied toward the total value of materials that are authorized to be disposed of from the stockpile during that fiscal year;

(2) be treated as an acquisition for purposes of satisfying any requirement imposed on the National Defense Stockpile Manager to enter into obligations during that fiscal year under subsection (b)(2); and

(3) not increase or decrease the balance in the fund.

ADVISORY COMMITTEES

SEC. 10. (a) The President may appoint advisory committees composed of individuals with expertise relating to materials in the stockpile or with expertise in stockpile management to advise the President with respect to the acquisition, transportation, processing, refining, storage, security, maintenance, rotation, and disposal of such materials under this Act.

(b) Each member of an advisory committee established under subsection (a) while serving on the business of the advisory committee away from such member's home or regular place of business shall be allowed travel expenses, including per diem in lieu of subsistence, as authorized by section 5703 of title 5, United States Code, for persons intermittently employed in the Government service.

REPORTS TO CONGRESS

SEC. 11. (a) The President shall submit to the Congress every six months a written report detailing operations under this Act. Each such report shall include—

(1) information with respect to foreign and domestic purchases of materials during the preceding 6-month period;

(2) information with respect to the acquisition and disposal of materials under this Act by barter, as provided for in section 6(c) of this Act, during such period;

(3) information with respect to the activities by the Stockpile Manager to encourage the conservation, substitution, and development of strategic and critical materials within the United States;

(4) information with respect to the research and development activities conducted under sections 2 and 8;

(5) a statement and explanation of the financial status of the National Defense Stockpile Transaction Fund and the anticipated appropriations to be made to the fund, and obligations to be made from the fund, during the next fiscal year; and

(6) such other pertinent information on the administration of this Act as will enable the Congress to evaluate the effectiveness of the program provided for under this Act and to determine the need for additional legislation.

(b) Not later than February 15 of each year, the President shall submit to the appropriate committees of the Congress a report containing an annual materials plan for the operation of the stockpile during the next fiscal year and the succeeding four fiscal years. Each such report shall include details of all planned expenditures from the National Defense Stockpile Transaction Fund during such period (including expenditures to be made from appropriations from the general fund of the Treasury) and of anticipated receipts from proposed disposals of stockpile materials during such period. Any proposed expenditure or disposal detailed in the annual materials plan for any such fiscal year, and any expenditure or disposal proposed in connection with any transaction submitted for such fiscal year to the appropriate committees of Congress pursuant to section 5(a)(2), that is not obligated or executed in that fiscal year may not be obligated or executed until such proposed expenditure or disposal is resubmitted in a subsequent annual materials plan or is resubmitted to the appropriate committees of Congress in accordance with section 5(a)(2), as appropriate.

DEFINITIONS

SEC. 12. For the purposes of this Act:

(a) The term “strategic and critical materials” means materials that (1) would be needed to supply the military, industrial, and essential civilian needs of the United States during a national emergency, and (2) are not found or produced in the United States in sufficient quantities to meet such need.

(b) the term “national emergency” means a general declaration of emergency with respect to the national defense made by the President or by the Congress.

IMPORTATION OF STRATEGIC AND CRITICAL MATERIALS

SEC. 13. The President may not prohibit or regulate the importation into the United States of any material determined to be strategic and critical pursuant to the provisions of this Act, if such material is the product of any foreign country or area not listed as a Communist-dominated country or area in general headnote 3(d) of the Harmonized Tariff Schedule of the United States (19 U.S.C. 1202), for so long as the importation into the United States of material of that kind which is the product of such Communist-dominated countries or areas is not prohibited by any provision of law.

ANNUAL REPORT ON STOCKPILE REQUIREMENTS

SEC. 14. (a) The Secretary of Defense shall submit to Congress an annual report on stockpile requirements. Each such report shall be submitted with the annual report submitted under section 11(b) and shall include—

(1) the Secretary’s recommendations with respect to stockpile requirements; and

(2) the matters required under subsection (b).

(b) Each report under this section shall set forth the national emergency planning assumptions used in determining the stockpile requirements recommended by the Secretary, based upon total mobilization of the economy of the United States for a sustained conventional global war for a period of not less than three years. Assumptions to be set forth include assumptions relating to each of the following:

(1) Length and intensity of the assumed emergency.

(2) The military force structure to be mobilized.

(3) Losses from enemy action.

(4) Military, industrial, and essential civilian requirements to support the national emergency.

(5) Budget authority necessary to meet the requirements of total mobilization for the military, industrial, and essential civilian sectors.

(6) The availability of supplies of strategic and critical materials from foreign sources, taking into consideration possible shipping losses.

(7) Domestic production of strategic and critical materials.

(8) Civilian austerity measures.

(c) The President shall submit with each report under this section a statement of the plans of the President for meeting the recommendations of the Secretary set forth in the report.

DEVELOPMENT OF DOMESTIC RESOURCES

SEC. 15. (a) Subject to subsection (c) and to the extent the President determines such action is required for the national defense, the President shall encourage the development of domestic sources for materials determined pursuant to section 3(a) to be strategic and critical materials-

(1) by purchasing, or making a commitment to purchase, strategic and critical materials of domestic origin when such materials are needed for the stockpile; and

(2) by contracting with domestic facilities, or making a commitment to contract with domestic facilities, for the processing or refining of strategic and critical materials in the stockpile when processing or refining is necessary to convert such materials into a form more suitable for storage and subsequent disposition.

(b) A contract or commitment made under subsection (a) may not exceed five years from the date of the contract or commitment. Such purchases and commitments to purchase may be made for such quantities and on such terms and conditions, including advance payments, as the President considers to be necessary.

(c)(1) Descriptions of proposed transactions under subsection (a) shall be included in the appropriate annual materials plan submitted to Congress under section 1l(b). Changes to any such transaction, or the addition of a transaction not included in such plan, shall be made in the manner provided by section 5(a)(2).

(2) The authority of the President to enter into obligations under this section is effective for any fiscal year only to the extent that funds in the National Defense Stockpile Transaction Fund are adequate to meet such obligations. Payments required to be as a result of obligations incurred under this section shall be made from amounts in the fund.

(d) The authority of the President under subsection (a) includes the authority to pay—

(1) the expenses of transporting materials, and

(2) other incidental expenses related to carrying out such subsection.

(e) The President shall include in the reports required under section 11(a) information with respect to activities conducted under this section.

NATIONAL DEFENSE STOCKPILE MANAGER

SEC. 16. (a) The President shall designate a single Federal office to have responsibility for performing the functions of the President under this Act, other than under sections 7 and 13. The office designated shall be one to which appointment is made by the President, by and with the advice and consent of the Senate.

(b) The individual holding the office designated by the President under subsection (a) shall be known for purposes of functions under this Act as the “National Defense Stockpile Manager.”

(c) The President may delegate functions of the President under this Act (other than under sections 7 and 13) only to the National Defense Stockpile Manager. Any such delegation made by the President shall remain in effect until specifically revoked by law or Executive Order. The President may not delegate functions of the President under sections 7 and 13.

(d) During any period during which there is no officer appointed by the President, by and with the advice and consent of the Senate, serving in the position designated by the President under subsection (a) or during which the authority of the President under this Act (other than under sections 7 and 13) has not been delegated to that position, no action may be taken under section 6(a)(b).

APPENDIX B

Materials with Stockpile Requirements
As of September 1989

Aluminum Metal Group
Aluminum Oxide
Antimony
Asbestos, Chrysotile
Bauxite, Refractory
Beryllium Group
Bismuth
Cadmium
Chromite, Refractory
Chromium Group
Cobalt
Columbium Group
Copper
Cordage Fibers
Diamond Group
Fluorspar, Acid Grade
Fluorspar, Metal Grade
Germanium Metal
Graphite Group
Indium
Iodine
Jewel Bearings
Lead
Manganese Dioxide
Manganese Group
Mercury
Mica Group
Morphine
Natural Insulation Fibers
Nickel
Platinum Group Metals
-Iridium
-Palladium
-Platinum
-Rhodium
-Ruthenium
Pyrethrum
Quartz Crystals
Quinidine
Quinine
Rayon Aerospace Fiber
Ricinoleic/Sebacic Acid
Rubber
Rutile
Sapphire and Ruby
Silicon Carbide
Silver
Talc Block and Lump
Tantalum Group
Thorium Nitrate
Tin
Titanium
Tungsten Group
Vanadium
Vegetable Tannins Group
Zinc

Other Non-Stockpile Materials in Inventory

Asbestos Crocidolite
Celestite
Kyanite
Mica (stained and lower)
Rare Earth
Talc (ground)

Chapter 2.7
RAW MATERIAL TRADE: MINE TO MARKET

WILLIAM G. HOLROYD

2.7.1 INTRODUCTION

The mining and production of industrial raw materials—be it as a mineral, an ore, or a fuel—is only the beginning of the process to deliver the product to the marketplace. While a sale represents an agreement between the seller and buyer, there are many steps leading to the finalization of the sale which, if performed well, result in a satisfactory conclusion for both parties.

A producer anxious to increase market share must sooner or later address the export market where different terms and conditions apply. Although the responsibility for sales may fall under the responsibility of an experienced member of the company's marketing and sales department, or to a mining engineer who has recently moved from the field to management, those responsible for the marketing and sales development of raw materials should be aware of the rules of trade for domestic and international markets.

The following is a check list that will serve to identify some of the important items relative to the aspects of raw material trade: what should be understood under the terms of the sale, what must be identified, how delivery can be effected, and where further information is available. For discussions of other topics related to trading, see other chapters of Section 2, especially 2.2 and 2.3, and also Chapter 25.2.

2.7.2 SOURCING

Anytime a new industrial raw material is to be brought into a market, a feasibility study will define what products are presently being sourced for that market. Given the trend towards basing a finished product on multiple-sourced raw materials, producers will find eager consumers awaiting news of newly mined products and happy to provide details of how the product is expected to be produced as well as delivery expectations.

Producers should not be surprised to find their products competitive on another continent, even though they may have difficulty being competitive within their own. Geographical locations with proximity to water will greatly assist this situation.

2.7.3 TRANSPORTATION — DOMESTIC US

The ability of any industrial raw material to compete in a marketplace is often a function of inexpensive transportation. This reflects on the ability of the producer to take advantage of various modes of transport to offset any geographical disadvantages, in order to reach their domestic markets.

The geographical statistics of the United States are impressive: slightly over 3.5 million mi^2 (9.0 M km^2) is packed into an area that runs almost 3000 mi (4800 km) from the farthest coastal points east to west. Fortunately for raw material suppliers and consumers alike, the country is split down the middle by the third largest river system in the world: the confluence of the Mississippi, Missouri, and Ohio Rivers.

This natural water roadway acts as a massive feeding and distribution system to/from New Orleans, one of the busiest ports in the United States, and provides access to a total of 14,500 mi (23,300 km) of navigable waterways, which includes an inland waterway system that links Cincinnati and Pittsburgh in the northeast, Minneapolis/St. Paul and Chicago in the north-central region, and Tulsa to the west, as well as the Intercoastal Waterway System between Brownsville, TX, and St. Marks, FL.

Transportation of raw materials within the United States is accomplished through the selection or combination of truck, rail, or water transport. In discussing bulk raw materials, it is generally accepted that highway truck transport, for distances over 1000 mi (800 km), will not compete with rail.

Truck transport is traditionally used to ship construction type materials whose sources are usually close to the population areas they supply. Truck transport offers the advantages of flexibility, not only of prompt loading but also direct delivery and discharge to whatever area the buyer desires.

The statistics on the rail transportation network are as impressive as the geography of the United States: 18 major class 1 rail companies (those having revenues of over $50 million/yr) plus slightly over 300 medium-sized and short rail-line companies provide almost 233,000 mi (375,000 km) of rail mile arteries. Some 140,000 of these miles (225,000 km) are owned by the 18 major rail companies.

In 1980, the Staggers Rail Act allowed rail carriers pricing flexibility on railroad transportation, and, more importantly, the rail carrier did not have to allow access to other railroads to use their rail lines. The outcome of this was a reduction in rates for large point-to-point volume bulk commodities and an increase in rates for lesser volume traffic.

The newer and smaller mineral producer was then unjustly compensating for the lower-revenue-higher-volume bulk commodities. Upon appeal, the Interstate Commerce Commission (ICC) can grant trackage rights to one carrier over another carrier's lines if it is determined that shippers on that line are in an adverse position. This allows the raw material producer more freedom to negotiate with two or more carriers.

Deregulation of the trucking industry, which took place in 1982, did much to bring rail rates down to compete with trucks in the 500- to l000-mi (800- to 1600-km) radius. Although the railroads have a trailer-on-flat-car (TOFC) rate that competes very favorably with truck rates below 1000 mi (1600 km), these rates are usually only competitive for packaged goods.

Barge transport is an extremely economical way of moving bulk commodities. For instance, the cost in 1990 to deliver a full barge containing approximately 1350 lt (1370 t), loaded in New Orleans to a 9-ft (2.7-m) draft, would cost approximately $7.50/lt ($7.38/t) to the Pittsburgh area and approximately $5.50/lt ($5.41/t) to the Chicago area.

While rail rates are generally fixed for a tonnage volume or for a period of time, barge rates are susceptible to market conditions: for example, the US government may decide to store grain in barges and pay three times the generally accepted storage rate. This has the combined effect of not only removing barges from the waterway network but also immediately increasing barge rates. Alternatively, rather than return empty, barges may accept a back haul at reduced rates.

In recent years, there has been a trend toward rail lines attempting to buy out barge lines in order to act upon the concept of offering a "full transportation service." This has come about also because of the Staggers Rail Act, which for the first time allowed companies to own more than one transportation mode.

The following table, reflecting costs in effect for different transportation methods during the year 1990, clearly illustrates how the use of marine transport, sometimes combined with that of rail, will provide a producer with greater access to a market area.

Transportation Method	Transportation: Unit Cost, ¢/ton-mile (¢/t-km)	Total Cost, $/ton ($/t)	Effective Market Area mi (km)
Truck	12 (8.2)	$7.00 (7.72)	60 (97)
Rail	5 (3.4)	$7.00 (7.72)	140 (225)
Marine (barge)	1 (0.7)	$7.00 (7.72)	1000 (1609)
Marine (ship)	< 1 (< 0.7)	$7.00 (7.72)	6000 (9656)

2.7.4 TRANSPORTATION-EXPORT

Any producer desirous of increasing sales through wider market penetration will need to approach the export markets for their products. This will involve a different type of transportation system than that utilized for domestic shipments: the use of ocean vessels to deliver the goods.

The rental of a vessel, or a portion of the vessel space, is known as a charter party, which can take several forms:

1. "Voyage charter," covering one cargo at a time moved between one or more ports.
2. "Time charter," covering the hire or use of a vessel for specific periods of time.
3. "Contract of affreightment," covering the hire of the vessel for more than one cargo, usually with the cargoes being carried between the same ports or defined geographic areas.

Fortunately, decisions related to when and how to charter are usually handled by an ocean freight "broker," who acts either on behalf of the charterer or the vessel owner. Qualified ocean freight brokers are registered with the Association of Ship Brokers.

2.7.5 STATISTICAL PROCESS CONTROL

SPC (statistical process control)—which became the "buzzword" in the 1980s—will be an inherent part of every production system in the 1990s and beyond. An American professor, W. Edwards Deming, exported the use of statistics in production to Japan in 1950. Since that time, the use of statistical controls has enhanced the consistency and uniformity of many of the Japanese products that we have come to know so well.

Deming refers to SPC as "quality control at the source," where each worker acts as his own inspector in the production process, by being provided the statistical tools to monitor a particular activity, in order to prevent the manufacture of bad parts or waste material.

The concept of SPC can be applied to any production process. For raw materials, this could mean the gathering and plotting of data that are normally available in the quality control department, covering the testing of samples taken at specific intervals during the product process. A pattern is defined that will point out any trends or cycles of quality. Any definition of points or trends above the norm indicates problems in the processing system.

While variation is a simple fact of nature and particularly true for raw materials, random influence variation must be eliminated in order to guarantee the supply of a quality product to the market.

The implementation of an SPC system within any raw material production process will assure customers that the producer is working diligently towards controlling variation in order to prevent the production of an off-grade product.

Producers should not be surprised that a consumer requests to view and audit their SPC system: this is a positive step and indicates a desire of the consumer to enter into a relationship of longer term and to become a "partner" in guaranteeing quality.

2.7.6 CONTRACTS

Once seller and buyer have agreed that a raw material will be able to meet the quality required and will be delivered at an acceptable price, then the general terms and conditions should be recorded in contract form. This serves not only to protect the interests of all parties but, more importantly, sets down what has been agreed.

A contract in raw material trade is usually made up of four parts:

1. *Description of the Material.*

This usually incorporates a definition of the material and grade, which is producer-oriented, as well as a material specification, which is the buyer's requirement for product quality. A proper description should include any desired minimum/maximum chemical and physical characteristics, plus any ancillary data (specific gravity, loss on ignition, moisture, etc).

2. *Quantity to be Shipped.*

This is defined as an exact tonnage number, with a percentage variance at either the seller's or the buyer's option. Shipment of precise tonnages are difficult due to differences in methods of transport, and variances provide comfort to both parties.

This section also defines the date when a shipment is to be made and/or when it is to be delivered.

3. *Price and Payment Terms.*

In addition to describing the cost of the raw material in a defined currency, the price should also give a definition as to where the transfer of title takes place. This is simply done through the use of either one of the terms FOB/CFR/CIF (named port), which are INCOTERMS (described in detail at the end of this segment).

This part of the contract also defines in what form the material is to be shipped: in bulk or in bags (with exact weight described as well as construction of the bags) or in any other mode of packaging.

Payment terms for domestic shipments usually stipulate a procedure for initiating payment to a bank, or directly to the seller, by cheque or telegraphic transfer. Export shipments are normally channeled through banks, where the buyer establishes a "letter of credit" between its bank and the seller's bank, and payment is provided for once the seller has met the terms and conditions defined in the contract.

4. *Quality and Quantity Assurance.*

This final section of the contract outlines the procedures employed to assure quality and quantity at load port and at port of destination. Since the transport involves third parties whose only connection to the transaction is the carriage of goods, an independent company is hired at the port of loading and unloading to sample and analyze and report on the quality of the material. The quantity loaded and discharged is also independently verified.

Costs for the quality and quantity assurance are normally shared between seller and buyer.

There are several well-known US and international companies who act as independent "superintendent" quality and quantity verifiers:

Andrew S. McCreath & Co.
Commercial Testing and Eng. Co.
Ste Generale de Surveillance (SGS)
Inspectorate Griffith
Alfred H. Knight

No discussion on contracts would be complete without a definition of INCOTERMS. International commercial transactions can be risky business: misunderstandings, disputes, and litigation are time consuming and costly. In 1936, the International Chamber of Commerce organized a reliable set of international rules for the interpretation of trade terms. Through their use, any uncertainties due to different interpretations of the terms used in various countries can be avoided or considerably reduced.

The current amendment, INCOTERMS 1990, incorporates changes in transportation techniques and renders them compatible to electronic data interchange (EDI). They are presented in a format which allows the seller and the buyer to follow a step-by-step process to determine their respective obligations.

The terms are grouped in four different categories:

Group E Departure	Seller makes the goods available to the buyers at the seller's own premises.	
	EXW	Ex Works
Group F Main Carriage Unpaid	Seller is called upon to deliver the goods to a carrier appointed by the buyer.	
	FCA	Free Carrier
	FAS	Free Alongside Ship
	FOB	Free On Board
Group C Main Carriage Paid	Seller has to contract for carriage, but without assuming the risk of loss of or damage to the goods or additional costs due to events occurring after shipment and dispatch.	
	CFR	Cost and Freight
	CIF	Cost, Insurance, and Freight
	CPT	Carriage Paid To
	CIP	Carriage and Insurance Paid To
Group D Arrival	Seller has to bear all costs and risks needed to bring the goods to the country of destination.	
	DAF	Delivered at Frontier
	DES	Delivered Ex Ship
	DEQ	Delivered Ex Quay
	DDU	Delivered Duty Unpaid
	DDP	Delivered Duty Paid

Any party desiring to use these rules should specify that their contracts will be governed by "INCOTERMS 1990."

2.7.7 CURRENCY

As a general rule, the US dollar is the common currency in which most industrial raw materials are denominated. Barring an unlikely devaluation of the dollar by the United States government, this eliminates the need for the US-based producer to be concerned about receiving a lower value for his commodity. However, since exchange rates do have a tendency to fluctuate based on a country's economic and competitive position during the course of a contract or a shipment, it is possible that either the buyer or seller will make a gain (or a loss) on the value of their shipment in terms of their domestic currency.

2.7.8 COUNTERTRADE

In Colonial times, barter on the United States frontier represented commercial exchange for furs and wheat in compensation for rum and whale oil. Today companies specializing in barter execute both multitrader and international transactions for goods or services, where no money is exchanged and deliveries are covered in one contract.

Given the complexities of today's trade of raw materials, *counterpurchase* has emerged as the most popular form of countertrade since barter relies upon a coincidence of identical needs. Counterpurchase includes as a condition of the sale, where the seller agrees to purchase goods or services from the buyer. The cost of the transaction is tied to the value of the raw materials sold.

Compensation, otherwise understood as buy-back, is similar to counterpurchase except that the products received in the transaction are resultant or connected, instead of their being unrelated to those sold.

A recent innovation has been the establishment of barter-exchange companies where reciprocal trade is established through trade dollars, which are units of account denoting the right to receive, or obligation to pay, in goods or services available from the participating members of an exchange.

What this means is that a mining operation requiring a new jaw crusher could transact with a barter exchange company that in turn would arrange to receive a specific tonnage of raw mineral from the mining company, including some cash, in exchange for the desired equipment. This type of transaction is gaining popularity but requires time and patience to satisfy all parties involved.

Any countertrade operation requires a thorough understanding by both the seller and the buyer of what they are getting into.

2.7.9 ROLE OF TRADING COMPANIES

One of the important questions that any producer must answer early in developing a marketing plan is "who will and how will the marketing be handled?" One method is through the use of professional marketing organizations, sometimes known as *traders* who act on behalf of either the producer, the consumer, or for their own account to deliver a wide variety of raw materials to the marketplace.

Since the first initiatives of commerce, producers have utilized the services of a middleman to market their goods or have appointed an agent to act on their behalf to introduce and market their goods to a particular market. Whatever the choice, the overall purpose is the same: to supply the product at an equitable price, within the shortest time, for the economic benefit of both parties.

Once a producer has decided that its goals will be accomplished by working through a trader, what relationship with that trader does it choose?

If the producer decides that it wants someone to work alongside to introduce its raw material to the market, then it has chosen a long-term approach where the trader acts as agent.

In the long run, this usually yields a higher return, as well as providing two other important benefits:

1. The preservation of the identity of the producer's product.
2. The promotion of the producer's good name.

In deciding on an agency relationship, the mineral producer must also accept that the mineral trader will be working as its extended arm in the marketplace, and the producer must be prepared for not only joint decisions regarding the marketing strategy but also joint visits to key accounts.

There are other advantages that an agency relationship brings to the producer of minerals, and these are related to the overall concept of a mineral trading organization, which is that of a fully integrated team taking a product from the mining center and delivering it all the way to the consumer market, sometimes via an interim processor, at a competitive price.

To accomplish this, the producer can expect the trading organization to possess:

1. A professional marketing and sales personnel team.
2. Frequent contacts with consumers at both the technical and commercial levels.
3. Intimate technical and commercial knowledge of the products being sold.
4. Established success in all segments of the industry served.
5. The strength of a diverse customer base.

There are circumstances under which the industrial mineral producer may find it to its advantage to sell its mineral directly to a mineral trader and, by consequence, have little involvement in the market development.

For instance, during the early 1970s, the majority of mineral sand producers in Australia benefited from the practice of selling off their zircon or rutile mineral sands stockpiles to traders, thereby improving their year-end financial position. From that point on, the mineral trader acted as principal to bring those minerals to the marketplace. In the process, the mineral sand lost its identity and, more often than not, the producer later competed with its own product in the market.

Today the major mineral sand producers are represented worldwide by mineral trading organizations, and both the consumer and the producer now benefit from a stable pricing and fully integrated distribution system, tied in with regular tonnage allocations. In fact, during the rapid increase in spot prices for zircon mineral sand during the last two years, traders assisted the consumer markets by entering into the trade of spot tonnages and prevented further price escalations, which might have pushed consumers into looking at substitute materials.

Another example of the mineral trader functioning as principal is in the area of industrial raw materials originating from the People's Republic of China. Although the Chinese, through the independence of their provinces, have attempted to align themselves through so-called "exclusive contracts" with trading companies or with their own foreign-based offices, few of these arrangements have worked in practice. This may be due to the fact that China has far too many official selling agencies: sometimes as many as six agencies compete with each other to sell the same mineral from one Chinese province.

In other cases, consumers have experienced difficulties when dealing directly with the Chinese due to contract interpretations and unexpected delivery delays and quality questions. Mineral traders have served this market well by being able to bridge many of these differences and offsetting some of the problems against other contracts.

In other countries, there are circumstances under which a producer may have financial considerations for selling his minerals directly to a mineral trader. As in the case of a chromite mine in the Philippines, the trader performs the important role of acting as a party to financing the operations of the mine by establishing a letter of credit for a defined tonnage. This letter of credit is then taken to a Philippine bank, and monies are advanced to meet production tonnage.

There are many trading companies involved in the marketing and distribution of raw materials. Producers should fully investigate a trading company's expertise in the markets they serve, with particular emphasis on knowledge of materials and markets competitive with the producer's raw materials.

2.7.10 INFORMATION SOURCES

There are many excellent publications that cover the subject of minerals, ores, fuels, and other industrial raw materials. In addition to covering specifics relative to new mine or market developments, most are issued on a monthly basis and contain valuable up-to-date market price information. Government agencies are also good sources of information on raw materials but may be limited to specific import and export data.

Industrial Minerals (published by Industrial Minerals Div. of Metal Bulletin Inc. of UK) 220 Fifth Ave. New York, NY 10001 Tel: 212-213-6202	Considered by many to be the monthly "textbook" on nonmetallic industrial minerals, their worldwide producers and markets.
Engineering and Mining Journal 29 North Wacker Dr. Chicago, IL 60606 Tel: 312-726-2802	Monthly magazine providing world coverage of all types of mining projects and mineral prices.
Skillings' Mining Review First Bank Place Duluth, MN 55802 Tel: 218-722-2310	Weekly magazine devoted to iron ore mining and markets.
Pit & Quarry 750 Old Oak Blvd. Cleveland, OH 44130 Tel: 216-243-8100	Monthly magazine devoted to the rock and quarry stone industries.
Mining Engineering 8307 Shaffer Parkway Littleton, CO 80127 Tel: 303-973-9550	Monthly magazine published for members of the Society for Mining, Metallurgy, and Exploration, Inc.
Ceramic Industry 5900 Harper Rd. Solon, OH 44139 Tel: 216-498-9214	Published monthly and devoted to more traditional refractory and advanced ceramics.
Ceramic Bulletin 757 Brooksedge Plaza Dr. Westerville, OH 43081 Tel: 614-890-4700	Monthly magazine published for members of the American Ceramic Society.
US Bureau of Mines Minerals Information Office Washington, DC 20241 Tel: 202-634-1001	Published bimonthly periodical *Minerals Today* as well as import commodity summaries.
Arundale Mineral Intelligence Letter Arundale & Associates 351 E. Thomas Rd. Phoenix, AZ 85012	Distributed without charge to those who are interested in, or involved with, the broad field of "minerals intelligence."
INCOTERMS 1990 ICC Publishing Corp. 156 Fifth Ave. New York, NY 10010 Tel: 212-206-1150	International Chamber of Commerce guide explains the respective obligations of buyer and seller.
International Bulk Journal Ranmore House Ranmore Rd. Dorking, Surrey RH4-H4E, UK Tel: 44-306-887433	Published monthly journal devoted to the shipping and port handling of a variety of raw materials.

CIM Bulletin 1210-3400 De Maisonneuve Blvd. W. Montreal, PQ, Canada H3Z 3B8 Tel: 514-939-2710	Monthly magazine published for members of the Canadian Institute of Mining, Metallurgy and Petroleum.
Mining Journal 60 Worship St. London EC2A 2HD, UK Tel: 44-71-377-2020	Weekly newsletter providing timely information on mine development, production, technology, equipment contracts, and company financial news.
Coal 29 North Wacker Dr. Chicago, IL 60606 Tel: 312-726-2802	Monthly magazine devoted to coal mining, processing, and markets.
Minerals Engineering Pergamon Press Inc. Maxwell House Fairview Park Elmsford, NY 10523	Monthly international journal covering developments in mineral processing and extractive metallurgy.

Section 3 Government Role and Influence in Mining

JAN M. MUTMANSKY, ASSOCIATE EDITOR
THOMAS V. FALKIE, SECTION COORDINATOR

Chapter 3.0
INTRODUCTION

THOMAS V. FALKIE

In bygone days, the mineral engineer spent most of his/her time on the technical aspects of designing, building, and managing mineral operations. In the last few decades, mostly since the 1960s, increasing amounts of engineering manpower and time are spent dealing with federal, state, and local government agencies, laws, and regulations. It is not possible to plan, design, build, or operate mines, mills, smelters, or even office buildings without detailed consideration of government regulations and permitting requirements dealing with environment, worker health and safety, etc.

The four chapters of this section provide an overview of the social, legal, political, environmental, and health and safety aspects of mineral enterprise. The section sets the stage for the working engineer/geologist in industry, government, consulting, or academe and points the direction for more detailed study in each of these areas.

Chapter 3.1, Social-Legal-Political-Economic Impacts, describes how government works in a general way and how it applies to mining. It also discusses the socioeconomic and political aspects of mineral policy and how and why there are many constituencies to be considered, not only in mineral policy but in the actual process of planning mines.

Government plays a strong role in every facet of mineral development from exploration through mining, processing, and consumption. While there is no coherent US mineral policy and probably never will be, the mineral industry is profoundly affected by laws, regulations, and other government actions on land use, worker health and safety, environment, taxes, fiscal policy, and many other policy areas.

The chapter also discusses the importance of mining to our country's well-being and to our standard of living. Virtually everything we eat, every metallic object, most of our building materials, the cars we drive are all made from minerals or use metallic or nonmetallic or energy minerals in some way. This is taken for granted by large segments of the public. Even worse, some people believe that mineral production can be curtailed without affecting our standard of living.

The practicing engineer must deal with government and the public in every facet of his or her career. Not only must the engineer understand how government functions, but he or she should also get involved in the legislative and policy process.

Chapter 3.2, Mining Law, describes in detail provisions of the Mining Law of 1872 and other statutes and regulations dealing with mining on the public lands. The odds are very high that the mineral professional will be involved with the public lands sometime in his/her career because about one-third of the area of the United States (about 730×10^{12} acres) is owned or controlled by the federal government. In addition, the states and

Indian tribes control large amounts of land and mineral rights. Significant amounts of minerals are produced from the public lands, and these lands include much of the most geologically promising areas of our country. It is also true that increasing amounts of public lands are becoming "off-limits" to mineral exploration and development by various land-withdrawal actions of government. Perhaps two-thirds or more of the public lands is unavailable or severely restricted. About one-quarter is slightly to moderately restricted. The land withdrawal problem is not discussed in this chapter but is mentioned in Chapter 3.1.

Chapter 3.3, Health and Safety Standards, shows why and how mine health and safety laws and regulations were developed, how they are structured, and how the enforcement system works. The discussion is general, and the reader will find specifics in other chapters dealing with design and engineering. Over the past century, no subject has brought more negative attention and more controversy to the mining industry. The health and safety record of the industry has improved, but there is need for even more diligence. In fact, health and safety considerations affect virtually every design or operating decision connected with mining. Every step of the mining process, whether it be materials handling, ventilation, equipment operation, roof control, or other activity, is regulated by very detailed federal and state laws, and these laws are enforced by equally detailed procedures. This chapter provides an introduction to these standards.

Chapter 3.4, Environmental Consequences, introduces the reader to some of the major federal environmental laws dealing with clean air, clean water, land reclamation, waste disposal, preservation of animal species and antiquities, and other aspects of environmental protection. Every environmental law has some effect on mining, although the Surface Mining Control and Reclamation Act of 1977 was the first major federal regulatory law aimed specifically at mining. That law, incidentally, applies to underground and surface mining. Every one of these laws has spawned many regulations and requires extensive engineering efforts in order to obtain permits from various governmental agencies. Once again, details on many of these will be found throughout the design and engineering chapters of this *Handbook.*

The status of these laws and regulations is under constant change. Therefore, the reader should use this chapter as a guide and should always refer to the *Federal Register* for updated information.

This section will help mineral professionals at all levels and furthermore should be required study material for university students in all mineral-related fields.

Chapter 3.1
SOCIAL-LEGAL-POLITICAL-ECONOMIC IMPACTS

JOHN J. SCHANZ, JR.

3.1.1 INTRODUCTION

The impact of government permeates all facets of the operational, financial, and managerial life of a mine or a company. As a consequence, there are few topics found in this *Handbook* that are free of its imprint. This chapter is totally devoted to examining in general the breadth of government impact. The following chapters present in detail three major domains of government involvement in mining—federal control over the public lands, health and safety, and environmental standards and regulations.

Any individual or an employee of a private firm annoyed by this intrusion into his, her, or its, internal affairs can be excused for occasionally wondering, "Why do we need government to start with? It's nothing but trouble!" A moment's reflection usually recalls to mind that we do need government, and in fact the public wants government to exist. Government is not merely a nuisance and a nonproductive element in our society, despite irritation with regulation, taxes, or police powers. But these activities are the unavoidable accompaniments of providing what are known as *public goods.*

A classic example of a public good is national defense. It is not usually practical for the individual, the town, or even a state to provide for its own security and defense against a foreign enemy. As a consequence, society relies upon some form of central government, in our case the federal establishment. Numerous other examples of public goods, provided by both local and national government, come to mind: the formation or construction of courts, schools, parks, roads, and so on. In some cases, there is disagreement as to whether a good or service should be provided by public or private means. Private vs. public power production has been debated for decades. But an industrial society, unlike a rural or agrarian one, does not function cheaply and efficiently in the absence of public goods.

This chapter will first concern itself with how government functions. Without an awareness of this, one cannot really understand the policy and decision process that ultimately impacts the operation of a mine in both positive and negative ways. Some of the broader public policies with respect to mineral resources and mining are then recapitulated.

There is an array of broad social concerns of government to be considered. For example, there are needs relating to the work force directly employed by the mining company—health and safety are prime examples. When government deals with the national budget, monetary or fiscal policy, domestic and foreign trade, aid to domestic industry, or foreign policy, it will unavoidably at the same time do things of consequence to the mineral industries. Many of these economic issues are placed in a somewhat broader public policy context than in the seven chapters of Section 2. There, economic matters are explored primarily from the perspective of the individual firm or the mining industry at large.

The regulatory role of government is important. Mining on the public lands, health and safety, and environmental matters deservedly draw considerable attention. So they are examined in the following separate chapters of this section. But there are also the regulations and controls on how land is used in general, including private lands. Water laws and water allocation are extremely important to mining—and both federal and state governments are involved. Government also provides a whole array of support functions from information gathering to pilot plant construction using experimental technologies.

Finally, the question must be addressed as to what this means to the engineer in performing his tasks throughout his career. Obviously, the visibility of governmental impacts tends to expand as the engineer moves from workplace to the executive suite. But for many decisions from beginning to end, he or she will have to learn how to factor in regulations, added costs, and other forms of government involvement into the engineering process. To do this, however, involves constantly facing an element of uncertainty over time.

The task of the mining engineer is an international one. Thus it would be ideal if this chapter could address the many forms government involvement can assume in foreign lands. However, the limits of space preclude this, so the United States is the focus of attention.

3.1.2 STRUCTURE OF GOVERNMENT

Federal, state, and local governments through statutes (1) create institutions and administer them, (2) establish regulations relating to the conduct of individuals and organizations and enforce them, and (3) collect taxes and allocate the receipts. Much of this is described in general terms in the following subsections. The federal government is the primary focus of attention. However, it should be recalled that similar, but not identical, organizations and processes are encountered in the lower jurisdictions. Obviously, too much space would be required to cover each state, and much would be redundant. However, in those cases where the state or local government is the primary actor, this will be incorporated into the discussion.

3.1.2.1 Legislatures

The statutes and the budgetary support to accomplish the various designated tasks originate in the legislature. This, of course, must be accompanied by sufficient tax revenues to pay for the costs of performing them. But it is quite possible for the Congress of the United States to pass legislation and not immediately provide for it in its budget or not appropriate tax monies to pay for it. Many water projects have been authorized but not (or never) built for years for lack of an appropriation. In this fashion, Congress receives credit for approving of something, but then shows an unwillingness to divert scarce funds to the cause. This may happen when the administration and the legislature are of different parties. The executive branch has the leverage to get something proposed and approved, but then watches its program languish for the want of adequate money.

The Process: All legislative initiatives, whether proposed by members on their own in the public interest, for their constituencies, or on behalf of the current administration, have to be converted into a bill for submission. The drafting of this document is a critical step because it establishes the objective and dimensions of the intended statute. Once it enters the legislative process, it is subjected to constant proposals for modifications both large and small. The best chances for success are for legislation in which the member has particular expertise and where the bill will pass through committees where he has some leverage.

The beginning of the legislative drafting is frequently an inconspicuous event. The member of Congress may not necessarily want publicity because it invites more attention than desirable from those wishing to influence the content of the bill. Competing or opposing members may be tempted to take the initiative away from him or her. Staff doing the ground work will call upon those, both inside and outside of the Congressional family, who they know have expertise in the area or political savvy. This is an advantageous time for interested parties to be involved.

Bills customarily originate in the Senate or the House according to the nature of the bill; for example, money bills start in the House. But bills on the same issue may be drafted and submitted by members of both bodies. The bills will be assigned to the committee(s) having jurisdiction over these matters. This gives the legislative leaders some leeway as well as leading to competition among committees.

The committee leadership has important leverage in deciding when the hearings will be held on a bill, how much time will be devoted, and what happens after the hearings. Who will appear and the topics to be discussed are carefully programmed. Anyone can request time to appear, but the time available is limited. So many have to be satisfied with making a written submission for the record.

While hearings can influence the content of proposed legislation, in most cases this is not the primary goal. Rather the committee is intent on “making a record” on the various viewpoints. The committee members, as well as other members, are careful to get their position on the record by statements and questions of witnesses. The transcript will be reviewed and edited carefully by all involved. This document provides information to those who did not attend. Most importantly, if the bill becomes law, the hearings documents will help show the “intent of Congress.” This may not always be explicit in the language of the bill itself.

If the bill is to become law, it must be voted upon by the subcommittee(s) or committee(s) having jurisdiction. Once again, the chairman has leverage in deciding whether the bill has merit and has a real opportunity to become law. A member can display his responsiveness to his constituency’s concerns by drafting a bill. He may even obtain a hearing on the legislation. But only a small proportion of the bills ever justify the time needed to get them to a final vote.

A crucial step is the “mark-up” sessions held by the committee. This is the moment when the other members have an opportunity to alter the bill as originally drafted. At this point, the lobbyists representing various interest groups will apply their persuasiveness to modify or to get votes for or against. The final version is likely to be not only a compromise of interests but considerably modified from its original construct. Substitute bills may even appear.

If the bill is finally passed, it moves on to the floor of the House or Senate. If passed by a subcommittee, the bill must survive another review by the parent committee, as well as surveillance by the main committee chairman, before moving along. Once the bill arrives at the floor, it is subject to more debate and possible amendment as well as a number of parliamentary procedures that will determine whether a vote will be taken at all.

Once passed, the bill must then move to the other chamber of the Congress. That chamber then has an opportunity to review the legislation, debate it, amend it, and approve or reject it. Quite commonly, a bill from one chamber will encounter a similar but not necessarily identical bill that has survived the entire process in the other chamber. The bill received from the other chamber may replace its own legislation and be voted upon. Or the chamber may approve its own version and the two versions are referred to a conference committee of representatives from both chambers. This group then seeks to arrive at a version acceptable to both sides, which is then referred back to both chambers for a final vote.

The final hurdle is the president. He may sign it, let it become law without his approval, prevent it from becoming law by not signing before the session ends, or veto it and return it to Congress. In the latter case, both chambers must override his veto with a two-thirds majority for it to become law.

Beyond Legislation: The role of the legislature does not end with the passage of a statute. Oversight of the implementation of a program or enforcement of a regulatory regime is common. If budgets and appropriations are involved, then the oversight is to determine the manner in which the funds are being expended.

The legislature may also engage in hearings and investigations on matters of interest. This may be prompted by a concern that laws are being violated by individuals, firms, or members of administrative agencies. Or it may be exploratory in nature to determine if action is needed or legislation should be formulated.

Congress is a part of the policy process but is constrained on how far it can go. As a nonoperational unit, it cannot execute its own wishes; this is done by an administrative or management agency. It is also impossible for Congress to draft a document that can stand alone as *the national policy*. Any national policy is in essence the composite of the acts of Congress and the implementation of those pieces of legislation by the responsible agencies.

One of the most challenging aspects of legislation is how far the legislature can, must, or should go in specifying how the statute is to be implemented. Broadly stated objectives may lead to little action or so much discretion that the intent of the legislature is not achieved. Overspecification allows the responsible agency little flexibility in adjusting to circumstances and may require them to be concerned more with procedure than substance. And in most cases, the legislature may not have the technical ability to formulate regulatory detail or to foresee what will be faced by an administrator on a daily basis. How to address the many variables in the reclamation of surface mined lands had to be faced in formulating the language of the Surface Mine Control and Reclamation Act (SMCRA). Even in its final wording, Congress recognized that it was most relevant to coal mining but not to all the other forms of surface mining.

Once the legislature has acted, this places limits upon the future actions of the administrative and regulatory agencies. Executives and regulators frequently have considerable discretion in the conduct of their offices. But it is important for them to recognize how far that discretion can reach without coming into conflict with the letter of the law.

The engineer in design and in operations encounters regulations and procedures that are reflective of prior actions by legislatures. In many cases, these are in response to actual laws, and conformance is a legal requirement. But there may also be some freedom, official discretion, or appeal permitted under the law. So familiarity with the details of legislation can be useful to the engineer.

The mine executive comes into broader contact with the consequences of legislation, from tax burdens to constraints on how the firm or the mine can be operated. Here familiarity with the law and legislative process is important. Background information and reasoned personal arguments placed in the hands of legislators and their staff can be important when they are timely. Testimony and submissions to committee hearings are useful, but their impact may be limited. When actual voting begins, political sensitivity peaks, and the time for more data is passed.

There is a tendency among those not familiar with Washington to feel that legislators would perhaps perform "better" if they were "more informed about the real world." However, each member of Congress has available personal staff who are assigned areas in which to keep informed; numerous people attached to the committees to which they belong, among them technically trained professionals; and four well-manned support agencies created to respond to requests for help from any member or committee from both the majority and minority sides. In addition, there are all those individuals from the outside world eager to inform them of the "truth." In reality, the legislator may frequently be a victim of more knowledge than is possible to digest.

The committees that are more frequently interested in matters relating to mining in particular are the Senate Committees for Energy and Natural Resources and for Environment and Public Works, and the House Committees on Energy and Commerce, Interior and Insular Affairs, and Science, Space, and Technology. Within these main committees are subcommittees that focus on more specialized matters. The subcommittees are particularly important in the House with its larger membership.

3.1.2.2 Executive Branch Agencies

The administrative agencies are in the executive branch of government created for the purpose of administering, managing, and regulating. They perform not only the functions of government designated by the Constitution but also those subsequently made a part of our public laws by the Congress. Only the president and vice president are elected. All others are either appointive positions filled with the advice and consent of the Congress or employees hired from funds appropriated by the Congress.

Budgets: The Congress for certain activities includes specific funding as part of its legislation. But for most of the continuing activities of the administration, annual funding legislation is required. This funding must not only provide for specific activities mandated under existing laws (e.g., payment of social security to those eligible), but also for the various functions of the administrative agencies where there is some discretion as to what will be done (e.g., how to conduct research to keep domestic mining viable).

The budget proposal to be made to the Congress each year by the Executive Office of the President is coordinated through the Office of Management and Budget (OMB). This consists of the budgets proposed by each segment of the administration's organization to perform their obligatory programs and also monies to engage in new activities supported by the Executive. This budget is coupled with estimates of the federal income during that period from various sources including existing or proposed tax revenues. For new programs or changes in old programs, as well as the necessary changes in taxation, the Executive Branch will propose the enabling legislation and will appear before Congress to support their proposals.

The Congress, in turn, designs its own budget and makes its own estimates of income. Since the Congress's priorities do not necessarily match those of the president, the various amounts do not necessarily match those coming from the Executive Branch. The budget committees proposals are reviewed, modified, and adopted by Congress to provide guidelines for all of the Congressional committees as to the monies likely to be available. By September 30, the Congress attempts to pass bills originating from the appropriation committees to provide money to the Administration for the coming fiscal year. If the deadline cannot be met, stopgap funding is provided through the use of a "continuing resolution." In recent years, this has been relied upon frequently, in effect, short circuiting the customary authorization and appropriation process.

Each branch of government then has available to it an actual amount of money. How closely this matches what was originally requested can vary considerably. Congress may have added things to be done, not funded others, and/or altered the total. But much of the budget is assigned to broad categories of activity, allowing the agency considerable freedom on exactly what is done.

Where not constrained by Congress, a large department may also make determinations as to which bureaus or offices will receive more or less than previously and how these funds will be allocated or left to the discretion of that agency's manager. Some funds may not be immediately allocated by a departmental secretary or comparable official but kept under his control for later disbursement.

The OMB reenters the picture at this point. Once the appropriations are received, then the OMB becomes an overseer as to how the funds are spent. This provides on one hand, the need to keep overall expenditures in line with the amounts appropriated. But on the other hand, it also allows the Executive Branch to control to considerable extent how its various agencies operate and keep in tune with the overall objectives of the Executive. Historically, the importance of the OMB has varied as administrations have changed. At one extreme, its functions have been straightforward monitoring and auditing of the expenditures made for various purposes, that is, management *of the* budget. But the OMB also can be used as a potent policy management tool by the president, that is, dealing in management *and* budget. In recent years, OMB has been an influential part of how the federal government actually functions.

Policy Making: What is the policy-making process for the administrative side of the government? Even a rather small government agency will refer to its "policies." This usually involves procedural matters relating to how that office performs its assigned functions.

But as one moves up through the successive layers of government, the term "policy" changes meaning. The US Bureau of Mines may adopt a policy relating to the research it will undertake using the funds made available to it. This has a real impact on the research that is conducted. The Secretary of Interior, at the same time, may be making even broader policy decisions on the overall emphasis of his departments on the matters at hand. These have less to do with procedure and daily management but can be consequential. Above all of this, there still remains the overarching national policy objectives of the president and his staff advisors.

An awareness of the many facets of the total policy formulation process underscores how complex the federal policy fabric may become. This is why identifying the origins of "a policy" may be difficult. One finds many who claim they do not make policy but merely implement or enforce it. In fact, policy evolves from many places—from those below making suggestions and recommendations to their superiors as well as by senior officials setting general guidelines to be followed by those below them.

Regulation: One of the major roles of central government is regulatory. Many people prefer and one can find many nations that have taken the stance of "the less the better." But there are many societies where a strong hand by government is applied as well as welcomed by the people. Regulation is likely to be considered to be beneficial if individuals or organizations are not able to, or will not, control their actions in a manner that respects the interests of the populace at large.

Thus we find that the inspection of food or instituting other forms of health regulation is generally accepted as being a proper role for government. But as the regulatory regimes expand their domains, public resistance is likely to grow apace and to demonstrate the merit of regulatory rulings is more difficult. For example, an antitrust ruling may be more debatable than defining potable water qualities.

For the most part, it has been considered prudent to separate regulatory activities from the other functions of government. In some cases regulatory bodies may be a part of departments with other functions, but they are kept operationally separate from the other agencies. For example, the Federal Energy Regulatory Commission is a separate entity within the Department of Energy. A few examples of visible, independent regulatory offices are the Consumer Product Safety Commission, Federal Communications Commission, Interstate Commerce Commission, Occupational Safety and Health Administration, Public Health Service, and the Securities and Exchange Commission.

The various parts of the administrative or Executive Branch of the federal government are the ones with which people and firms are most familiar. They serve and regulate in a variety of ways which provide almost daily contact, both welcome and unwelcome, admired or ridiculed. The individual, while free to complain to the "proper authority" usually feels that there is little that he can do. Businesses, however, do seem to have better access and may very well have more influence on the manner and effectiveness of the functioning of federal and local government.

Administrative or regulatory agencies do not simply decide how they will operate away from public view. A significant part of their official activity is made a part of the public record. Many meetings must be held in a manner which provides public access. The more important procedures and rules they establish frequently require advance notification, public hearings, or periods for written comment to be considered before they can go into affect. Individuals and firms should be alert to use this access to its fullest extent in their own self-interest.

The most visible branch of government to the mining engineer is the Department of Interior and its various departments such as the Bureau of Land Management, Bureau of Mines, Geological Survey, Mineral Management Service, and the Office of Surface Mining. Other Executive Branch agencies with which mining companies have frequent contact include, among others, the Department of Defense, Department of Energy, Environmental Protection Agency, Federal Energy Regulatory Commission, Federal Trade Commission, International Trade Commission, Mine Safety and Health Administration, and the Securities and Exchange Commission.

3.1.2.3 The Judiciary

The Judiciary is the branch designated to interpret the Constitution and the laws provided by legislators, to ascertain if the other two branches are functioning in accord with these documents, to resolve conflicts, and to assign proper penalties or relief when the law is violated or inequities are identified. There are many layers to the judiciary, from local traffic courts to the US Supreme Court. The functions also vary from original hearing through subsequent appeal and as to what body of law for which they are responsible.

Given its place in the structure of our government, one does not think of the judiciary as part of the policy process. But that does not suggest it is solely a reactive body. To the contrary, the judiciary in many instances has a very powerful impact on the way in which things are accomplished.

With the respect to the legislatures and the executive branches, the judiciary is charged with ascertaining if these bodies are functioning properly within the provisions of the appropriate constitutions as passed or subsequently amended by the representatives of the people. This establishes the basic ground rules as to authority and procedure for all parts of government. If the judiciary finds a violation, then that action can be reversed by the court. If the legislature has taken the improper action, then it must find another way to accomplish its goals that is acceptable to the court or take the more difficult route of a constitutional amendment.

Administrative agencies must not only perform in accord with the Constitution but also be in conformance with any legislation passed by the legislatures that relates to them. This means that responsible officials of the government may be subject to suits filed against them charging violations of the law or nonconformance to the procedures they have established to execute that which the law charges them to do.

In some cases, the impact of the courts on the engineer may be quite significant. If the courts find that a government agency or a firm is not in accordance with the law, a regulation, or a procedure, the court may specify what needs to be done by government or industry to come into conformance. For example, under the requirement that an Environmental Impact Statement (EIS) should consider various alternatives for the development of the nation's natural resources, the court may decide that not all alternatives have been adequately considered or that the technical details are insufficient to make a judgment among them.

In some cases, the law is not sufficiently specific or clear. Then the court may decide what was the intent of the Congress or what the meaning of the certain language should be. The implementation of the Mining Law of 1872 has been refined by over a century of legal effort dedicated to interpreting legal "words of art." There has also been a need to develop practical ways to enforce the law, such as how to determine whether or not "valuable" minerals are present within a mining claim.

3.1.2.4 Interrelationship of Mining and Government

In the early stages of the emergence of an industrial economy, the natural resource industries are likely to be a major focus of attention in national affairs. In this respect, the public and government are particularly solicitous of the agriculture sector—perhaps as a reflection of a basic concern about adequate supplies of essential food and clothing items. In the US government, we find a separate Department of Agriculture, separate Congressional committees for agriculture, and a complex fabric of farm policy developed over many decades.

This is not to suggest that the mining sector has not experienced its own mix of supportive government activity, but it is of a different magnitude. We find that there are some specialized bureaus and subcommittees. The kinds of policies and actions they generate is reviewed in the next section.

Importance of Mining: The minerals industry has sought over the years to publicize its fundamental importance to the nation's industrial economy. This is probably appreciated to some degree by most of the public. But the extractive industries lack visibility in that their output is not usually an end product as perceived by the final consumer. People drive automobiles, not the separate materials in the assembly; turn on electrical appliances, not burn coal; and wear a garment, not the machine that made it. As a consequence, except in periods of shortage or wartime, public concern about mining and processing tends to be localized rather than having a national focus of concern. Moreover, as an industrial economy matures, manufacturing, commerce, services, and other economic activities expand while segments of the primary resource industries, despite growing in absolute terms, may diminish in relative size. As this occurs, mineral enterprises may tend to become "just another part of industry."

It is important to be aware of the modest size of the extractive industries—fuels, metals, and nonmetallics—compared to the rest of the economy. Collectively, using Bureau of Mines historical data, they have provided a fairly predictable proportion of the nation's national product since 1920, varying from 2 to 9% between the top and the bottom of the business cycle. This cyclic behavior reflects the fact that minerals are closely tied to the consumption of capital goods by basic industry. But in 1989 despite a healthy economy, the value of US fuel and nonfuel mineral production is estimated to have been approximately $128 billion or 2.4% of the Gross National Product (GNP). This was at the lower limit of the long-term average situation because the mineral commodities were experiencing price declines in the decade of the 1980s. Also the structure of the US economy had been changing over the previous two decades.

It is also informative to separate out the value of the three subsectors of mineral production. The role of domestic metals output has shrunk relative to the national economy as well as compared to total mineral output. Despite the considerable attention to energy conservation by the public and industry, the fossil fuels still command a high unit value and remain the dominant member of the mineral industries. Finally, the nonmetallic group has in recent years moved ahead of the metals in terms of gross value of annual output. In 1989, the estimated individual contributions to GNP were fuels 1.8%, nonmetallics 0.4% and metals 0.2%. The total work force in extractive industries in 1988 was about 753,000.

As noted previously, there tends to be a public perception of national importance concerning the agriculture sector. However, in 1989, gross farm income contributed 3.6% to GNP, about 1% higher than minerals. There were 3.0 million workers on the nation's farms out of a total US civilian labor force of about 122 million in 1988. These numbers are somewhat larger than those for mining, but do not necessarily suggest great political leverage. But one must recognize that the various activities of agriculture are widespread and found in almost every county of the country. Mining operations, in contrast, are found in a more limited number of locales, and they are not relatively important in many states. Thus mining's immediate impact has always been highly regional or localized.

The decline in some parts of the mining sector since 1974 has been particularly devastating. From a high of 167,200 in 1974, the metal mining and smelting work force in 1988 was only 49,500. This reduced its proportion of the US nonagricultural work force to less than 1.0%. Congress has expressed its concern about how this has an adverse economic impact on many local communities and in some cases entire states. But its response in the way of actual remedial measures tends to be tempered by consideration of any such actions on the work force in other industrial sectors as well as on the consuming industries and public.

Legislative proposals to assist mining are judged within the context of overall industrial or economic policy. The two dimensions are not always complimentary; for example, assistance to mining may mean that raw material prices and consumer products will become more expensive. The political resolution of this kind of conflict may not always be the one sought by the mining industry.

3.1.2.5 Other Jurisdictions

The engineer's or mine executive's attention should not or cannot be totally absorbed by consideration of the federal government's actions. Administrative activity, support, regulation, and involvement in mining by government extends over many jurisdictions. Thus we have local or municipal, county, state, federal, and international institutions. To mine minerals and sell them triggers interaction at many political levels. Security by local police, road maintenance by counties, state taxation, or international agreements on trade are just examples of the many kinds of government involvement that go beyond the federal establishment. To function, an engineer may have to obtain a local permit, conform to state labor laws, deal with a regional federal environmental office, and/or ship to a foreign destination that will apply a tariff to his product at the port of entry. Obviously, to be unaware of or to ignore any of the particulars of how these jurisdictions function and interact is a serious oversight on the part of the engineer that can negate all of the value to be found in the technical competence of his work.

Previously, it was described how the mine and the entire mineral industry must compete for attention with all other sectors of the economy in dealing with the federal government. It is noted that this does not necessarily work to mining's advantage. However, the economic importance of mining can escalate as one moves down to the smaller jurisdictions. Local governmental actions taken concerning taxation, land regulation, fiscal policy, and other domains may recognize more fully the particular needs or problems of mining. The consequences of a mine opening, declining employment, or a closing are important, can get attention, and will generate support. To pursue these opportunities requires the same familiarity with process and a sensitivity to good timing that is suggested for company or individual involvement with the federal government. But the specifics are quite different and vary widely from one operating location to another. This suggests considerable preparation is in order for the engineer, and that may have to be repeated throughout his or her career.

3.1.3 CREATION AND IMPLEMENTATION OF POLICY

The fact that various kinds of policies are created, interpreted, and altered at all branches and levels of government is discussed in the previous section. Now we turn to the policy formulation process itself as it relates to the mining industry in broad national terms. The mineral policy of the United States is the cumulative set of actions that the various branches of government have taken over time and the manner in which these have been subsequently interpreted and implemented.

Occasionally government may set for itself a specific or clear-cut objective. The Mining and Minerals Policy Act of 1970 is an example. The key paragraph states in essence that the United States will develop a sound and stable minerals industry, it will pursue orderly and economic development of its mineral resources, it will foster mineral research, and it will seek to lessen the impact of mining upon the physical environment. The actions of the government a few years later with respect to energy, while not quite as simple and direct as with the Mineral Policy Act, were rather uniformly directed toward reducing the national dependency on imported petroleum. But time has demonstrated that despite the clarity of the goal set for the nation, achieving it is a different matter.

It is perhaps better to visualize the national mineral policy to be a complex matrix of legislation, orders, and regulations developed gradually by incremental steps. In many cases the individual elements may even be in conflict with one another. Nor does this matrix stay fixed over time-new objectives are added and the manner in which goals are pursued is changed.

The following chapters in Section 3 discuss major components of current national mineral policy. These are the character of our current implementation of the Mining Law of 1872, how we now seek to enhance mine health and safety standards, and how mining is being impacted by national efforts to mitigate environmental consequences of mineral extraction and processing. None of these various elements that constitute our national policy has remained unchanged over the years since each was first introduced into the policy matrix.

3.1.3.1 Serving Many Publics

Whenever a bill is drafted, an executive order circulated, or a regulation proposed it immediately becomes apparent how many "publics" are impacted. Thus there is a national interest, a regional interest, a state interest, and a local interest to be served. Coupled with that there are the various participants in industrial enterprise: stockholders, managers, workers, suppliers, and consumers. Nor are the enterprises themselves monolithic in that they can be large or small as well as domestic or international in character. The members of these various publics will want policies to enhance their situation.

It is quite apparent that, in some fashion, a democratic government needs to arrive as often as possible at policies that benefit more publics than those experiencing extensive negative impacts. It is not often that the Congress will experience the comfortable situation of a strong public mandate and considerable support among its entire membership. Rather, most legislation that emerges must deal with the totality of society and the many interactions that may be involved. From the drafting of legislation designed to address the problems of a constituency or a particular public to having a law signed by the president is a process of resolving conflicts, compromising, and building a consensus that will provide a majority affirmative vote.

The Congress in its efforts tends to gravitate toward not what any one individual would view as the "best" answer to a national need but rather to what might be described as the "least painful" alternative. This is most likely to occur when many members find no serious objection to what is being voted upon, and those who are most directly concerned find more advantages than disadvantages in the final version being proposed for enactment. If this is not the case, Congress may simply choose not to act at all.

While Congress may often be the first to have to deal with the many publics in arriving at national policies, the executive and judicial branch are also similarly affected. Either in serving the intent of Congress or performing their assigned administrative roles, the departments and agencies of government will submit their orders and regulations to public scrutiny before putting them into effect. The various publics will once again react from their own economic or personal viewpoints. While directed or restrained by the statutes which prompt the actions taken, the officials involved will attempt to respond to the extent possible. This is essential if their subsequent efforts to implement the policies are to be both successful and efficient in practice.

The administrative agency with which the mining industry has had the closest involvement over the years is the Department of the Interior. It itself is a microcosm of the many interests that go to make up the national interest. In addition to the Geological Survey and the Bureau of Mines, well known to all mineral specialists, there is a diverse group of other agencies involved in both technical and land management matters (e.g., the Bureau of Land Management, Bureau of Reclamation, Fish and Wildlife Service, National Park Service, Bureau of Indian Affairs, and Mineral Management Service).

Each one of Interior's agencies is involved in a different set of existing or potential uses for the lands and resources of the United States. Various kinds of land uses can be compatible, but more frequently there are likely to be conflicts and competition among them for exclusive use. To illustrate, a proposal for a new dam and reservoir may remove land from use for mining, hunting, parks, grazing or farming, and wildlife protection. Even among the consumers of water, there may be controversy because the past patterns of water supply will be altered.

Not only are the various parts of Interior charged with being responsible for different user groups and representing their viewpoints, they may also come under the jurisdiction of different committees of Congress. Obviously, an oversight hearing before a House Subcommittee on actions taken by the Secretary of Interior will have quite a different thrust depending upon whether it is the Subcommittee on Energy and Power, Mining and Natural Resources, National Parks and Public Lands, or Water and Power Resources.

Despite the efforts of the Congress and the Administration to arrive at policies and their implementation that minimize the conflict between the various publics involved, a challenge to the legality or the equity of the law itself or how its being employed may still be made. The courts are the final haven for expressions of opposition. At this point, the law itself may be struck down, its manner of implementation may be altered, or inequities in its impact may be resolved. As a consequence, national mineral policies are not fully defined until the various elements have either avoided challenge in the courts or have been further refined by judicial decisions.

3.1.3.2 Industrial and Economic Policy in General

In this chapter, we are particularly interested in the mineral policies of the United States. But it is important to recall that the mining industry, in addition to when it is intentionally considered as a separate sector, is also impacted by the broader economic and industrial policies of the nation. During the late 1970s and early 1980s, many of the difficulties experienced by domestic mining were in part a reflection of the fiscal and monetary policies of the United States. These policies, and changes in them, were reflections of general concern about the economic and industrial welfare of the United States. While it was recognized that the mining sector might be affected in a variety of ways, the policies were actually neutral with respect to mining.

During the extended battle against inflation and high interest rates from 1977 through 1982, a strong US dollar emerged as result of the various fiscal and monetary strategies used. Not solely, but to an important degree, this made the output of US mines more expensive than foreign output because the exchange rate for other currencies lowered the comparative cost of their output. In their own self-interest, US and foreign raw-material consuming industries bought less of US origin. Subsequently, inflation eased, the dollar became cheaper in currency exchanges, and US mines introduced cost-reducing measures. The mining industry found itself in an improved condition. But the policies pursued to protect the national economy, while of real significance to mining, never were influenced to any major degree by what was good or bad for mining per se.

National industrial policy, as was described for mineral policy itself, is the composite of many laws, executive decisions, and regulations. Taxation and trade policy are of perennial importance to industry. When it first became apparent that US industry seemed to be falling behind other nations, such as Japan, in our ability to do as well as we had in the past in international competition, our aging plant and low investment rate were blamed. The Accelerated Cost Recovery System (ACRS) was introduced in 1981 to correct the situation. ACRS allowed industry to depreciate equipment faster for tax purposes than previously. This would act as a stimulant. There was also introduced a 10% investment tax credit (ITC) for the purchase of certain machines and equipment. It is believed that capital investment in industry and in mining probably did show a positive response.

But Congress may also be motivated to remove incentives that it had previously approved. The ACRS and ITC were removed in the changes that were made in the Tax Reform Act of 1986. This Act was designed to restructure the tax system with respect to rates, incentives, penalties, complexity, and other features that resulted from the product of many years of Congressional tinkering with the tax laws on an item-by-item basis. On balance it was to be "tax neutral" and not change the total revenues to be received in the future by the Treasury. Efforts were made to replace any lost tax incomes with increases in taxes elsewhere. Generally speaking, while industry benefited from the lower rates it had to pay, the removal of tax "shelters" and industry tax incentives tended to be negative from the viewpoint of industry. However, incentives targeted for the mining industry in particular were left largely untouched.

Energy Policy as an Example: The energy policy considerations and actions of the 1970s and 1980s are also an excellent example of how policy can become multifaceted. Prior to 1970, most individuals would have viewed the national energy policy as being for the largest part government actions directed toward assuring a reliable supply of domestic energy over time. But a United States, which no longer had a surplus capacity to produce petroleum, that faced a series of interruptions in supply in the 1970s and a tenfold increase in the price of crude oil, had to make decisions on a much broader front.

It was quite apparent that future energy policy had to concern itself with demand as well as supply. The questions to be answered were abundant. In the event of interruptions in the flow of petroleum products, should government resolve the shortages with allocations or let the market and the consumer adjust to the higher prices on their own? Should taxes on fuels be used to influence consumers' energy-buying habits? Should the poorer segments of the population be insulated from these economic shocks? How could more energy-efficient equipment be made available and then actually bought by energy users? Should tax incentives be employed to encourage this to happen? If so, what kinds of energy savings and capital investments should be eligible? Should standards be set for energy consumption, for example, miles per gallon for vehicles or controlling the design of buildings?

A similar array of questions surfaced on the supply side. Since the immediate problem was the national reliance on petroleum imports, should policy focus on this in particular or on energy supply in general? With respect to petroleum itself, should there be an emergency stockpile of oil? If so, how should it be created, how large should it be, and how should it be used? Should there be new incentives for the exploration, development, and enhanced recovery of domestic oil? Or would it be better to begin to direct the national effort toward reducing dependency on crude oil in general? If so, of the more abundant energy forms that should be encouraged, should the other familiar fossil fuels to be used directly or converted into synthetic hydrocarbons? Or would it be better to tackle the more difficult task of shifting toward the renewable forms of energy created from current solar influx? In all of this, how should the government be involved-basic research, applied research, development, demonstration, or commercialization? Did the oil supply threat justify subsidizing these new supply initiatives?

As a mineral or energy policy matrix becomes more complex, it spills over into other areas of social concern. Had past policies concerning encouraging home ownership or improving national transport unintentionally accentuated our energy problem? Should we change these policies in the interest of energy? Should energy pricing which had been rewarding more consumption be inverted so that those who used less would pay less per unit? Improved air and water quality were relatively new national goals and are closely tied to energy use. Should new, more stringent standards be reexamined in the interest of easing the energy supply problem? There had been a growing effort to set aside public lands in a variety of ways that reduced their availability for extractive purposes. Should access to the tidelands, continental shelves, and onshore public lands be improved so that any remaining energy resources could be located and developed?

3.1.3.3 Current Mining and Mineral Policies

World War I demonstrated clearly that industrial capacity and the raw material supplies to support it were the "sinews of war." Many authors in the next 30 years devoted attention to what nations or combinations of nations had the capability of entering into a major, worldwide conflict. World War II confirmed this, and the combatants relied upon strategic plans that included assuring supplies for themselves while denying them to the opposition. Despite the richness of its resource base, the United States recognized its vulnerability in certain minerals not produced domestically in adequate amounts. These are known as *strategic and critical materials.*

As a consequence, one of the primary focuses of national mineral policy for a half century has been to stockpile these materials that were viewed to be of critical importance to have on hand in a national emergency (see Chapter 2.6). The strategic goals of the stockpile, the materials stocked, and the quantities stocked have been modified frequently since the first Stockpiling Act was passed in 1946. Management was handled for many years by the General Services Administration but is now in the Department of Defense. As of Mar. 31, 1990, 66 commodities were in the stockpile, and the inventory was valued at $9.7 billion.

A companion element in assuring national security is the Defense Production Act of 1950. This authorizes materials allocation in an emergency and provides for loans and guarantees to companies to expand capacity and facilitate production. In addition, the government itself could become involved in purchasing and resale of material supplies.

However, anticipation of emergencies is not sufficient in the absence of a functioning raw-materials supply industry. Four pieces of legislation stand out in this respect: the Mining Law of 1872, discussed in detail in Chapter 3.2; the special tax provisions for mining discussed in Chapter 2.4; the Mineral Policy Act of 1970; and the National Materials and Minerals Policy, Research, and Development Act of 1980. Each of these is directed specifically to encourage the mining sector and is not a part of the broader economic and industrial policies of the nation. The Mining Law provides access to the public lands for mineral exploration and development at modest cost, and the holders of claims can eventually obtain fee title to the land. Certain mineral resources, in particular the fossil fuels found in large sedimentary basins, were removed from this "location" system by the Mineral Leasing Act of 1920.

In the mid-1920s, the Congress addressed the problem of the taxation of mineral deposits. A minable deposit can be either discovered by a mining firm and developed or purchased after discovery by someone else. The value of a given discovery can exceed by many times the directly related expenditures of the successful explorationist, but not necessarily his total expenditures, or money spent by those who are less successful. Even after discovery, the actual size and ultimate market value of the deposit is not known with accuracy. The Congress devised the concept of permitting either cost or percentage depletion for arriving at the taxes to be paid by the mine operator. This not only avoided the problems of estimating a property value but provided an encouragement for further exploration to replace depleted deposits. The tax schedules and the mineral commodities eligible have been changed over the years, but this still remains a part of the federal tax laws.

The Mining and Minerals Policy Act of 1970 quite clearly expressed the general concern of Congress that the domestic mining industry should not be allowed to atrophy. Its Section 2 is quite specific:

> Sec.2. The Congress declares that it is the continuing policy of the Federal Government in the national interest to foster and encourage private enterprise in (1) the development of economically sound and stable domestic mining, minerals, metal and mineral reclamation industries, (2) the orderly and economic development of domestic mineral resources, reserves, and reclamation of metals and minerals to help assure satisfaction of industrial, security and environmental needs, (3) mining, mineral and metallurgical research, including the use of our natural and reclaimable mineral resources, and (4) the study and development of methods for the disposal, control, and reclamation of mineral waste products, and the reclamation of mined land, so as to lessen any adverse impact of mineral extraction and processing upon the physical environment that may result from mining or mineral activities.

In the 1970s, the world experienced a general period of economic growth that had not been anticipated by the international mining industry. Demand for raw materials exceeded the capability of existing mines and plants to meet it. The resulting shortages, hoarding, and higher prices generated widespread concern that the world was facing persistent shortages. However, new capacity was developed and the growth in demand slowed from its frenetic pace.

However, the United States continued to be concerned that it was not paying sufficient attention to what is needed to maintain its competitive edge in producing materials but also to participate in the development of new materials. The National Materials and Minerals Policy, Research, and Development Act of 1980 was a reflection of this concern. Unlike the Mineral Policy Act, this legislation for the first time had a strong emphasis on research and development. The Act involves all materials used by industry, the military, and individuals, not just those that result from mining per se. It attempts to provide a framework for materials policy decisions by the executive and encourages government support for materials research and development. By the end of the Reagan administration, the effectiveness of the Act had not been demonstrated.

The foregoing presents some of the broader aspects of governmental policy formulation. It also provides illustrations of policies that are broad in character or those specifically designed for the mining industry. But the mining engineer's daily work is probably more influenced by a much larger array of laws and specific governmental activities. These are reviewed in the following discussion.

3.1.4 SPECIFIC AREAS OF GOVERNMENT INVOLVEMENT

In this part, we demonstrate the sweep of government influence on the mining process from exploration to abandonment, and how every facet of engineering, supervision, and management is touched to some extent by government. The subject is far too extensive to be presented in a comprehensive fashion here. But it is important that the engineer be alert to the diversity of laws, procedures, and regulations that are relevant to his tasks. Government may be involved in some fashion in matters as diverse as what information may be requested from a prospective employee to the disposal of used lubricants. This section provides some general guidance as to the many ways in which government may impact mining. But more specific references should be consulted as appropriate for detailed information.

3.1.4.1 Work Force

A century ago, an employer was fairly free to operate his mine, plant, or business as he wished. Today companies, particularly the larger ones, are much more constrained in what they can do and in some cases are directed as to what they must do. Federal regulations, frequently coupled with state requirements, are encountered from hiring to retirement. Some of the more important ones and their major purpose are summarized in the following.

Labor/Management Relations: This aspect of employment was the earliest to receive attention. The Clayton Act of 1914 dealt with strikes and picketing. In 1926, the subject of collective bargaining appeared in the Railway Labor Act of 1926.

As the union movement grew, the Norris-LaGuardia Act of 1932 sought to define and protect what were lawful union activities. The National Labor Relations Act of 1934 established the National Labor Relations Board and dealt with the conduct of labor unions. Union practices and collective bargaining were dealt with further in the Taft-Hartley Act of 1947. The Labor-Management Reporting and Disclosure Act of 1959 established a "Bill of Rights" for union members.

Civil Rights: Explicit concern by government about civil rights first appeared with the passage of the Civil Rights Act of 1964. This was subsequently followed by the Equal Opportunity Act of 1982. In addition to this, there are Presidential Executive orders, such as the one relating to affirmative action. State laws are an integral part of these government efforts to assure that employment is not influenced by religion, race, age, color, or sex. Affirmative action goes one step further in directing that efforts be made to correct for past discrimination in hiring.

Wages and Hours: An early piece of legislation in this category was the Fair Labor Standards Act of 1938 and its subsequent amendments. The minimum wage laws, both state and federal, are constantly being revised to reflect the changing cost of living and the nature of the work force. In addition, statutes define the maximum permissible hours that can be worked and the schedule of compensation for various types of overtime.

Other Compensation: Employees also receive compensation beyond that related to actual hours on the job. Originally, compensation to a worker injured on the job was obtained, as in other injury claims, through reliance on the courts. This is now handled through reliance on state laws that provide for appropriate compensation and associated hearings and appeals.

When an employee loses his job with a firm, the states now provide temporary compensation while he seeks other employment. In support of this, the federal government permits 90% of amounts paid into state unemployment funds to be deducted from their federal unemployment tax obligation.

Income is now provided the individual after retirement from full-time employment. The Social Security System was first established in 1935. It has become the foundation stone for most workers' retirement planning. But its benefits are not restricted solely to retirement due to age but may also may be paid in connection with death or disability at an earlier age.

Pension plans established by companies have grown more numerous and comprehensive over the years. This, however, has prompted considerable attention by government in recent years and some legislation. How pension funds are to be managed, the protections to be offered the worker, the equity held by the employee, and the disposition of retirement funds when a company fails or is merged with another firm are all important issues. These will almost certainly be further explored and defined in the years to come.

Training: During periods of economic stress in general or in particular economic sectors, the federal or state governments frequently attempt to ease the stress of job relocation through offering special training, for example, the Job Training Partnership Act.

Safety: In the general area of industrial safety, the passage of the Occupational Safety and Health Act in 1970 was important. But more specific federal involvement in mine safety has a long history. At one time this was an important facet of the work of the Bureau of Mines. But today, mine safety is handled by a separate agency, and the key document is the Mine Safety and Health Act. This topic is discussed in depth in Chapter 3.3.

3.1.4.2 Economic

The most significant things that the federal government does on the economic front are those related to the economy in general. How broad-based fiscal or monetary decisions can impact mining has been illustrated previously. But the federal and state governments can also take actions that separate out the mining industry for special attention. In the area of taxation and property evaluation, this may be quite important to the profitability or even the survival of a mine. A favorable position on depletion allowances is an economic plus while a new or higher severance tax is negative.

Direct Assistance: Most governments, including the United States, may direct special attention toward "infant" or depressed industries and small firms in general. In its more mature state, the United States has less need to be concerned about "infant" industries. But much of the economic encouragement, or subsidization, that still is evident in mining originated in the last century when the mining sector was in its infancy. In this century, the light metals emerged, and the federal government was very much involved in how aluminum, magnesium, and beryllium evolved into mature industries. The post-World War II expansion of uranium mining and processing was also dominated by the government, but this was more motivated by national security concerns than economic.

When a particular extractive industry gets into difficulty, it has not been unusual for the federal government to step in with assistance, quotas, or tariffs. Domestic oil producers and independent oil refiners have been insulated from the impacts of imports in recent decades. In 1958, the United States became concerned about the viability of domestic lead and zinc mining. Imports of lead and zinc were limited by quotas, and other measures, such as assistance to exploration, were introduced. The program continued until 1965 and then was discontinued as the economy strengthened.

Marketing and Trade Practices: Federal and state governments also concern themselves with the manner in which goods are priced and sold. The initial legislation in this area was the Federal Trade Commission Act of 1914 to prevent unfair or deceptive practices. There are companion state laws with respect to fair trade in 46 states, and much of the burden now falls upon them. Most of the mining industry is not affected on a daily basis by these laws and regulations because products are transferred within firms or sold as intermediate goods to other industries for further processing or manufacture. But some large-volume industries and those that sell directly to final consumers may receive particular attention to their pricing and marketing practices. Steel, cement, and petroleum products are examples.

Monopoly and Antitrust: Closely related to trade practices is the body of law that deals with monopoly conditions in any industry or the concentration of market power among a few firms. The first of these was the Interstate Commerce Act of 1887 to control the railroads. This did not relate to mining itself but was to impact the cost of transporting mined products in the years following. Broader legislation to provide public protection against monopolies and conspiracies, including their dissolution, appeared in the Sherman Antitrust Act of 1890. This was further defined by the Clayton Act of 1914 that dealt with such matters as price discrimination and fixing, concerted action by firms, exclusive contracts, mergers and acquisitions, and interlocking directorates. The Robinson-Patman Act of 1936 also deals with discrimination.

At first, and still to a major extent, the US Justice Department and the Federal Trade Commission are the agencies most concerned about monopolies or other restraints on competition. However, in more recent years, the states have also become active in enforcement.

International Trade: We have noted that the United States, in common with other industrial nations, tries to optimize the use of its indigenous natural resources. In pursuing this goal, industrial nations may institute tax preferences, provide various forms of subsidies that will reduce production costs, and may even introduce trade barriers that lower domestic access to materials of foreign origin to the advantage of domestic producers.

There can be advantages to low-cost raw materials from other nations. Material consumers benefit from receiving what they need at lowest cost. Moreover, no western industrial nation is able to satisfy totally all of its needs. Stockpiling can help meet emergency needs of critical materials, but this does not help in meeting peacetime requirements. So the national interest is also served by seeking to have diverse and competing sources of that which we cannot produce as well ourselves.

However, our viewpoint as an exporter can be quite different. Mining companies seeking to market abroad do not welcome the tax preferences, subsidies, and market barriers used by potential consumer countries to protect their own producers. These are viewed as unfair and discriminatory. Obviously, it is most difficult to interfere in the policy affairs of other nations. But retaliatory acts are taken, and trade wars erupt.

There are no international institutions that can control international matters as directly as we are able to do internally. But an effort to arrive at least some measure of control has been attempted by the General Agreement on Tariffs and Trade (GATT) signed in 1947 and the creation of an International Trade Organization (ITO).

This kind of intergovernmental cooperation must be created from the top down. First, there is establishment of the general objectives, then definition of the kinds of trade restrictions of concern, and finally consideration of the particulars as they relate to individual commodities and circumstances. The need to reach agreement naturally tends to narrow the definitions of what constitutes trade restrictions and what remedies are considered appropriate. GATT is subjected to review at infrequent intervals called "Rounds." It is important to international mineral trade, but it functions primarily through persuasion.

The formation of "common markets" by governments has also become important. These reflect close trading relations among groups of countries and are an attempt to lower barriers and to enhance the collective economic well-being. The European Economic Community (EEC) is the most important of these. In 1992, the EEC has agreed to have its common market begin to function as though it is a single market. That effort by these important materials-consuming nations plus the free trade agreement between Canada and the United States, two major mineral producers, will be events of considerable significance in the future of mineral trade.

3.1.4.3 Regulatory

Many of our laws in effect prohibit certain activities by individuals or firms. But even then, this requires further monitoring and enforcement. Other statutes permit activities but restrict them or control how they can be accomplished. This process of regulation of the activities of industry has become of increasing importance to mining.

The mining industry now recognizes that its activities will be monitored much more closely in the future than in the past. Violations of that which is prohibited by law are likely to incur penalties. But more importantly, regulation has brought with it a whole new framework of seeking official approval or permits for each aspect of the mining process beginning with exploration and persisting to abandonment. The steps involved in this process before federal and state government requirements are satisfied customarily number in the dozens.

Not only are numerous permits or other forms of approval required, but in many cases there are administrative procedures to be followed as work progresses. Performance standards may be specified as to what is done by the firm. Onsite inspection to assure conformance is also a common part of the regulatory process. How pervasive regulation has become is readily apparent in many of the *Handbook* chapters such as those concerning public land operations, health and safety, and environmental control.

An enumeration of what is now involved in environmental protection is informative. The modern era of environmental control began with the passage of the National Environmental Protection Act in 1970. Not only did this impact industry, but it also instituted the requirement that government agencies themselves would have to prepare environmental impacts statements with respect to each of their proposed programs or activities. In the same year, the Environmental Protection Agency (EPA) was formed to coordinate the public control of private actions on a national and regional basis.

The authority for governmental involvement in environmental protection is drawn largely from the following federal statutes:

Clean Air Act
Clean Water Act
Noise Control Act
Solid Waste Disposal Act
Toxic Substances Act
National Resource Conservation and Recovery Act
Comprehensive Environmental Response, Compensation and Liability Act (Superfund)
Endangered Species Act
Federal Lands Policy and Management Act
Antiquities Act
Wilderness Act
Surface Mining Control and Reclamation Act
Coal Leasing Amendments Act

One needs to remain aware that there are also state environmental protection acts of a general nature as well as more specific laws. Chapter 3.4 provides a more detailed discussion of environmental regulations and mining.

3.1.4.4 Government in Support of Industry

In reviewing the various impacts of government on mining, it may appear that they tend to be mostly negative or disruptive in some fashion. While it is generally agreed that government in pursuing its assigned tasks or legal obligations can create problems for individuals and firms, we should also recognize that industry obtains considerable support from government.

A mining firm operating in a developing country or in the frontier area of any country soon recognizes what government does provide elsewhere. This is known as the *infrastructure*—the roads, the transport, the utilities, the security, the education, and the public amenities we take for granted in developed areas. These must be provided by the company itself in isolated regions.

In addition, a developed area has an established commercial sector. Housing, food, services, and other needs are provided by other firms and people. Not only does this remove a burden from the firm, but these profit-making enterprises, plus the public at large, share in the tax burden of paying for the public goods provided by local and national government.

Government may also be capable of providing specialized technical services or problem-solving agencies. Advanced education or vocational training may also be developed by government entities to meet local needs.

Another area of importance to government is its involvement in research of all kinds. This can be either doing the research in-house or the providing of financial support to industry, research organizations, or educational institutions. An important issue in this respect is at what point in the research process is the government most effective, how can it be assured that it achieves a net addition to the research effort, and how does it transfer results to the ultimate user. In some cases, government has even created quasi-corporations to function on an interim basis until private firms can take over a permanent role.

A sometimes overlooked aspect of government support, and perhaps an undervalued one, is the information services that government provides. At the federal level, the Bureau of Mines, the Geological Survey, the Department of Energy, the Bureau of Standards, and the National Aeronautic and Space Administration are all recognized organizations for research activity and financial support. But they are also prolific sources of specialized or general information such as maps, characteristics of materials, new technology reports, or industry statistics, all at little or no direct cost to the mining industry.

3.1.4.5 Land and Water Resources Allocation

Much of the early history of American mining involved the private lands of the eastern part of the United States. The property owner had title to both the surface and the minerals below. An arrangement for the recovery of mineral values was a contract between the property owner and the miner. In addition, the landowner possessed riparian rights to the water flowing through his land. He could use the water, the stream, and the bed in whatever way suited his needs. It has only been in recent years that these freedoms have been somewhat restrained because of concerns about air and water pollution and reclamation of the surface after mining.

As American mining grew and spread westward, and as the older mining regions of the east declined in more recent years, the industry has had to deal more and more with the subsurface ownership of mineral rights and surface ownership by the federal government. Coupled with that, obtaining the rights to scarce water supplies in the west is entirely different than in the east. In the west, water rights are a reflection of use rather than of property ownership. Those who use and become dependent upon water from a stream establish a legal right to that quantity of stream flow in the future. Consumers along the entire water course must respect these rights no matter where they are located. Moreover, the prior possessor of a water right may transfer or sell all or a portion of it to others.

All of industry, including mining and processing operations, is dependent upon water. Thus any new western mining operation must include an adequate water supply in its planning. This means dealing with the established governmental and legal institutions for water allocation found in each state. Generally speaking, tradition has favored agricultural uses of water, municipal needs have ranked next, and industrial requirements have not receive any special advantages. To some extent, this reflects a fear that in an open market for water, industry could outbid other users for water supplies. This does not suggest that mining has been excessively constrained by a lack of water, but it does underscore the fact that the engineer must be prepared to cope with the established systems of water allocation.

In dealing with public lands, the prospector a century ago was offered a preferred position to entice him to explore. Today, as the competition for the use of land has increased, the private owner still retains for the most part the option of selling or leasing to mining interests because of the higher dollar value that may represent. But the variety of land use demands now being made upon the public lands are not necessarily resolved by what is the highest present value per acre. Rather a judgment is made by public land managers as to where the greatest social return may be realized. One criterion might be to maximize the income to government. But the aggregate social return is not always readily measured solely in terms of dollars and may have to reflect qualitative measures as well. In most decisions, there is also in the final analysis significant reliance on the political process. That is, regardless of the motive behind voter preferences, in the opinion of their elected representatives, what do a majority of the public want?

A part of the public land allocation process has been the dedication of blocks of land for particular purposes. An effort is sometimes made to appraise the mineral potential of such lands. But what might be discovered in unexplored areas is difficult to substantiate. However, the more visible value of land as a pristine wilderness, its attraction as a park, or its demonstrable value for agriculture, wildlife preservation, or military purposes give these uses an advantage in these land use decisions.

Even the extraction of minerals on private lands is not totally free of government involvement. The police powers of government extend into matters relating to conflicts in land use. Fortunately for mining, most of its operations tend to be in relatively isolated locations. But when mining is near population centers, or as human settlement encroaches upon mineralized lands, conflict often appears. This means that mining has to contend with such legal issues as what constitutes a public nuisance, zoning decisions which may preclude mining operations, or condemnation of land for public use. Originally, these conflicts tended to arise between adjacent uses of the surface of the land, but now less specific aesthetic and environmental concerns may also enter into the legal actions taken.

3.1.4.6 Socioeconomic Consequences of Mining Operations

Both industry and government try to anticipate and prepare for the social, economic, and environmental effects of the development of new mining and processing operations. The new economic benefits are for the most part welcomed. But there is also the downside when mining operations eventually cease. In addition to the positive and negative economic and environmental consequences encountered during the life of a mine, there can also be considerable social strain placed on a community in many phases. Governments are fearful of the costs to be faced and uncertain of their revenues. Industry, on the other hand, is trying to make a new venture successful and does not welcome unexpected financial burdens or public restraints. Both mine and local government managers must anticipate these public vs. private stresses that accompany mining and plan how to cope with them independently and cooperatively.

Life Profile of a Mine: Each of the four stages in the life of a mine and its closure has different socioeconomic impacts. They are

1. Exploration is first and the least intrusive. It involves only a small work force for limited periods of time.
2. The period of mine development and of plants for associated surface activities (if any) is perhaps the most disruptive event. It lasts only a few years, but at its peak on a monthly or quarterly basis, it can involve the largest number of people. The work force is to a considerable degree transient in character.
3. The period of mine and plant operation is the longest, often two decades or more, and most likely to be a relatively stable period. It usually provides the greatest economic rewards to the community.
4. The final stage is abandonment for any of a variety of reasons. Obviously, this is a negative event on both economic and social counts.

Key Factors in Planning for New Mine Development: The opening of a "greenfields" mine and plant in the United States today is a relatively uncommon event. Mine extensions and plant expansions are more frequent. As a consequence, there is limited recent experience upon which to plan for greenfields operations. However, in the early 1970s, attention was directed toward the vast coal resources of the west.

For the western communities involved, the prospect of new coal mines, and perhaps associated power plants or synthetic fuel plants, was initially welcomed by those eager for economic expansion. Others preferred their lives to remain largely unchanged. Some communities with populations of a few thousand near several new mine and power plant projects were engulfed by thousands of construction workers. Much of the anticipation turned to anxiety about these events.

Now that these events have largely run their course, it is possible to provide some guidelines about what is likely to occur when a new mine or major expansion occurs. The following discussion draws to a considerable extent on unpublished reports prepared for regional clients during those years by Browne, Bortz, and Coddington, a Denver consulting firm.

First, each event is unique and complex, and what will occur cannot be anticipated precisely. The severity of the impact to be experienced is controlled to a large extent by the amount of surrounding development that already exists. A mature, economic region can absorb a new mining operation with little dislocation. But for an isolated community, the consequences can for a time seem overwhelming. If no prior settlement exists, then the entire burden may fall upon the company unless the state or federal government steps in to assist.

For public administrators, with the help of company engineers and managers, it is important to scope the size and timing of the events that are about to happen. The size of the mine, the type of mine, the mineral commodity to be extracted, and the associated surface processing facilities are important variables as to the number and type of workers that will be required, how long they will stay, and the associated needs and services beyond the operation itself. Much of this will seem mundane to company engineers, but city planners may not be aware that it does make a difference if it is a copper open pit, a coal stripping operation, or an underground mine. If there will also be associated surface activity, planning must reflect whether it is a mill, preparation plant, smelter, power plant, or a synthetic fuel plant.

For areas where infrastructure is not fully developed, as in parts of the Rocky Mountain west, the following are offered as useful parameters.

1. For some mining plus surface plant developments, the construction work force may number in the thousands and needs to be estimated by the company(ies). For a mine alone, it will be much smaller. This means a large temporary increase in local employment, with associated demands on housing and all types of public services. The group of workers will change somewhat throughout the period because the type of workers needed shifts as development progresses.

2. Local hiring can be important for many of the less-specialized jobs. This may not reduce the need for inward migration because the jobs they leave need to be filled. However, a previously active area may develop an indigenous work force for activities of this type.

3. Construction workers will tend to live in mobile homes, recreation vehicles, or rental houses, or to commute from other locations.

4. Depending of the size of the community, there may be a need for approximately 0.2 to 0.6 additional service workers plus family to support each construction employee.

5. The permanent operating work force for a mine and plant is much smaller and usually numbers in the hundreds. Again a company estimate to fit the specific situation is needed.

6. Operating personnel intend to stay and will tend to buy or rent permanent housing close to work. But this depends upon the quality of the community and the cost. More will be married, and they tend to have slightly smaller families.

7. Permanent personnel have a greater impact on the economy because they may require from 0.4 to 1.0 service workers and their families, depending upon the services already present.

8. Retail and service establishments must increase but not as much as might be expected. The pressure created by the higher paid jobs at the new installation will tend to raise the local wage level, the cost of housing, and property taxes.

For the local government officials of a small community, the foregoing situation is a difficult one. The construction force will need housing, but only of a certain type and for a limited period. An unknown number may commute. They might overload the roads, the schools, and public and private services. But overreaction and too much expansion is dangerous because these numbers will then diminish rapidly.

Once the operating era begins, the situation changes. Needs will be larger per person and more stable. But it is tempting to overestimate the magnitude of secondary effects on employment and services. The local purchases by the company of services and supplies may be disappointing. Corporate headquarters will likely be elsewhere, and purchasing may be done for more than one location. Some or all of the profits from operations may also flow out of the community. Government revenues will increase from the additional taxes generated by business and a larger population. But in some cases, the boundaries of local jurisdictions separate the public incomes from where public expenditures are needed. Also many expenditures may need to be made early based on anticipated needs and incomes before revenues are actually in hand.

The Magnitude of Change: Fairly sophisticated economic models can be constructed for mature local economies and can approximate the complex interactions that will result from a new mine and plant. For smaller communities, simpler projections are usually sufficient to translate company and community planners raw data into population increases, the multiplier effect on total employment, and the acceleration of incomes resulting from the new dollars spent in the local economy. But in both cases, past experience suggests that the resulting projections tend to be too high and unanticipated events or conditions are the rule rather than the exception.

In retrospect, western communities that were affected by the coal expansion are likely to assess the net economic result as positive. The negative facets, such as coping with higher rents and higher labor costs, were unexpected and the gains were less than hoped for. The immediate turmoil created by the inflow of new workers did subside, and the long-term socioeconomic effects eventually proved manageable.

In addition to the general parameters presented, some quantitative orders of magnitude connected with new mines are useful. Based on actual experience during that period, a typical new Rocky Mountain underground coal mine capable of producing 1.5 million tons (1.4 Mt) annually involved a four-year development period requiring over 500 people. As the beginning of mining approached, the approximately 450 permanent workers would begin to arrive, with the peak employment being reached in the third year when both development and operating people were present.

The company might invest $200 million in the mine and transport facilities. The community then had to find the means to accommodate the mine workers and their families, approximately 1750 individuals. Their presence generated an additional 225 jobs and families. New housing requirements amounted to about 550 units, mostly single-family. School enrollment jumped from 700 to 1100. Retail trade increased l0%, personal incomes 12%, property values 12%, and total county population by 13%.

This is a single mine in a small community. To place it into a larger context, the experience of Gillette and Campbell County in Wyoming is an informative case study.

As of 1981, there were 11 employment centers in Campbell county related to old and relatively new coal mines. These consisted of seven coal mines, two mining company headquarters, a power plant, and the local operations of the Burlington Northern Railroad. Coal mine employment was approximately 2400.

The statistical comparisons below capture how much had happened to Campbell County and Gillette, its major city, in the preceding six years.

	1976	1981
Mining Employment[a]	1,676	4,795
Construction Employment	1,782	3,413
Manufacturing Employment	102	160
Transport and Utility Employment	481	870
Trade Employment	1,597	2,922
Financial Services, etc., Employment	182	379
Services Employment	835	2,671
Public Administration Employment	NA	466
Total Employment	6,655	15,676
Occupied Housing Units	5,810	10,000
Retail Sales (Millions $)	50	148
Bank Deposits (Millions $)	105	256
Property Values (Millions $)	305	1,000
Building Permits	475	807
School Enrollments	3,342	6,492

Source: Browne, Bortz, and Coddington, Inc., Denver, CO
[a]Combined oil and gas, coal, and uranium.

Along with all of these fundamental economic activities of the county, there are many other things related to living that must be accommodated. The number of hospital admissions went from 1418 in 1977 to 2685 in 1980, increasing the occupancy rate from 51 to 83%. Cases filed in county court went from 840 in 1974 to 7008 in 1981. Almost 90% of those in 1981 were noncivil offenses.

Those planning for how the 1980s would affect Campbell County anticipated that growth would continue but at a less frantic pace. But they did not anticipate the dramatic decline in the world oil price in 1986 and the sudden demise of the boom in western energy: an effective demonstration of the fragility of projections. This suggests that all parties at interest, both private and public, must be flexible enough to withstand the unanticipated.

The joint company and community projections and planning that precede new projects must be monitored, at least annually, by tracking the events that follow the mine opening. The projected snapshots of the future become obsolete rapidly. Slowing of expected growth or unfavorable signs of trouble must activate actions to mitigate the effect of these new trends both on the mine and the community. Certainly, any company wants to be optimistic when planning a new project so as to generate community support. However, this does not negate the need to invest in backup plans as insurance against any difficulties if events take a turn for the worse.

Abandonment Phase: Despite its inevitableness, the abandonment of a mine is not a precisely predictable event. Mining may persist in one location for over a century, but it can also end in a matter of a few years. As technology changes, what is economic to produce and what the consumer wants can alter the viability of an operation. Newer mines appear elsewhere, and established mines face increasing costs and the obsolescence of equipment and methods. Even depletion of the minable reserves is uncertain because detailed examination of a deposit is usually made as needed to extend the mine plan.

A mine closing can be expected to be a stressful situation for most of the employees. For those in the community who were dependent upon providing goods and services to the mine and the employee families, there is a similar impact. As is the case in the opening phase, how significant this is for the county, region, and state depends upon the size and maturity of the total economy. A closing of a zinc mine in New Jersey or an iron mine in Pennsylvania is a local event, while a single molybdenum mine is more important to the whole state of Colorado.

Sometimes the decline of a given extractive industry can have major impact on a whole region. The sharp reduction in the mining of anthracite over a period of two decades involved northeastern Pennsylvania's major industry. The economic impact and social disruption this caused was felt for many years. More recently, the decline in iron ore mining in Minnesota, uranium mining in New Mexico, and energy production in several areas has been of concern to entire states.

Because mining is often found in less well-developed locations, an abandonment may leave a population stranded without sufficient economic activity. A century ago, this created the ghost towns that have become tourist attractions today. But in modern times, government takes a more active role in cushioning the impact of the decline or termination of mining and processing. Unemployment compensation, retraining, relocation, and enticements for new businesses to locate locally are all part of this strategy.

Companies today are also more involved than in the past with displaced workers. A mining company is reluctant to close a mine when there are still recoverable resources present. Both the resources and the past investment may be totally lost. Operations may even continue for some time at a loss. But eventually the economic drain and future outlook dictate a closing. Companies may keep employees on the payroll as long as possible, provide severance pay, or offer relocation counselling.

However, this can be a difficult time in government/company/labor relations. The decision may appear abrupt to local government and the workers. They would naturally prefer to see the operation continue. From the company viewpoint, it is reluctant to postulate abandonment of a mine prematurely because of the impact it will have. A closing is usually a last resort and rarely a reversible situation or one that the company wishes to see prolonged. How well management and individual engineers are able to clarify the circumstances that lead to abandonment is important. This may provide a better environment for cooperative efforts to mitigate the economic damage and shorten its duration.

The economic impact that occurs may at least be anticipated and addressed. But the sociological aspects are more subtle and difficult to handle. Some of the skills employed in mining and processing are not readily transferable to other jobs. This means that moving to another job means a reduction in pay. But on the other hand, many workers from open pit or stripping operations can move rather readily to a variety of construction operations. Also, many tasks in mineral processing plants are sufficiently similar to those in the chemical or other manufacturing industries that retraining and relocation are not too difficult.

Experience has shown that many workers once established in a community are reluctant to move for a variety of reasons. This may mean that job opportunities elsewhere are refused, and the family remains where it is. The wife may become the major source of income, and the family resources tend to remain less than they had been. The consequences affect the entire family in many ways, and the community begins to experience the resulting health and social problems and costs this creates. There are no ready solutions to this problem, and they persist for many years.

Technical aspects of mine closures are considered in Chapter 8.7.

3.1.5 IN CONCLUSION: GOVERNMENT AND THE ENGINEER

Mining has traditionally been characterized as a high-risk venture. The mining engineer has been trained to deal with the uncertainties and hazards of mining. No matter how carefully a property has been examined prior to mining, the deposit's geology will not be known in minute detail, and the quality of deposition will vary spatially. Mining conditions will not be uniform, and adjustments will have to be made as operations progress. Efforts are made to factor these variables into the economic feasibility studies made prior to mining. This may be done statistically, through using conservative assumptions, or in other ways. Nonetheless, many mines may successfully extract minerals from the ground but may not be financial successes.

The corporate decision makers are also aware that unpredictable economic conditions external to the mine are an unavoidable business risk. These can also be addressed in a variety of ways. Risk is introduced into the property evaluation prior to investment. The financing used can be fitted to variable income levels, break-even points and cutoff grades can be designed to accommodate possible changes in output, and conservative assumptions can be made about minimum and average price conditions. Larger corporations can seek refuge in the protection of large numbers. As Herbert Hoover noted in his book on mining in 1909, the prudent mine executive recognizes the risk of failure in one mine but would expect to be successful in the aggregate if he/she has ten.

3.1.5.1 Government as a Source of Uncertainty for Mine Management

Despite the capability of the mining executive or the individual engineer to recognize and deal with the risks and hazards that are a part of mining, they may find the uncertainties that originate in the behavior of governments a less familiar situation. As is apparent in the various discussions in this chapter, every aspect of mining is touched by government policies, regulations, or prohibitions. Relations with the labor force can be influenced, new costs may appear, or both foreign and domestic markets may be affected. At one moment, government actions may be supportive of domestic mining, but the next day they may be advantageous to competitors at home or abroad.

Perhaps the most frustrating aspect of government rules and policies is that they do not remain static. A corporate decision tends to be made on the basis of policies and regulations at the time the decision is made. Once done, it may become deeply imbedded in how the mine is operated, the ore or mineral is processed, or to what market output is directed. Yet the policies and regulations may change continuously over the several decades that the mine operates. Adjustment, if not actually impossible, is difficult and costs money. Unfortunately, the resulting objections raised by industry often tend to appear dogmatic and unresponsive to public needs. Although their actions may appear capricious, thoughtful politicians would like to feel that their actions are durable and dependable. But the pressures of social and political change often preclude that being the case.

This situation demands that management as well as engineers involved in planning future operations need to weave government as a variable into their work and their decisions. Initial plans are best drafted employing current laws, regulations, and policy. But these plans should then be reviewed using assessments on how the government posture could possibly change within reasonable bounds over time. Such scenarios can provide rough measures of sensitivity to the effect of future government actions and plans. Projects can then be adjusted to minimize this impact. This should be just as much a part of engineering design and management decisions as the careful examination of technology, costs, and prices. Finally, approval or disapproval of a project at the board of directors level may once again assess these tangible and intangible political elements before a decision is made.

Investment decisions naturally tend to be somewhat influenced by current economic conditions. If prices have been dropping, then pessimism colors profit expectations and extra caution appears. Rising prices will have the opposite effect. This occurs despite the fact that all businessmen know prices behave cyclically and do not continue to rise or fall indefinitely. To a degree, the same is true on the world political scene. Leaderships change, and the policy pendulum swings between relatively conservative and liberal viewpoints. But there are bounds to these swings that are not likely to be exceeded, and reversals should be anticipated.

This does not suggest that persistent trends or basic changes should be ignored. For example, it is not likely that the regulatory presence of the federal government will revert back to what it was decades ago. The environmental controls that have appeared in the last 20 years will likely continue to change and may become more responsive to cost considerations, but they will not disappear. The mineral policies when we were a pioneer nation, or even those of mid-20th century America, will not likely have the same public appeal in the 21st century.

3.1.5.2 The Engineer's Role

Most mining engineers may have once been inclined to view their professional careers as being largely apolitical. There are always a few individuals who opt at some point to become active in political party affairs or to be a spokesperson for the mineral industry's interests before government bodies. But a general sense of political detachment may no longer be wise for engineers. Government is a pervasive force in the affairs of industry, and the daily existence of mining and all of its employees is affected. The engineer must be sensitive to law, regulation, and policy. This is different than suggesting that the engineer must now become a political advocate or activist, but rather that he must be capable of assessing governmental and political behavior in the context of his job.

The individual engineer can also be a participant in the legislative and policy process itself. As a professional, he has competence and experience to offer to the politician and the government official. As a citizen and as an engineer, he should not be reluctant to communicate his views to his elected representatives through personal communication. Members of Congress have attested to the fact that personal communications are effective. It should be noted that this is apart from sending form letters used in campaigns by organized groups or when an engineer is acting as a representative of a company or an industry.

Providing professional advice to legislative assistants as they draft bills can be extremely helpful if the opportunity presents itself. The earlier the technical input by engineers, the better. But it is important that the information should be provided in a form relevant to current legislative or policy purposes. Offering technical and objective testimony in a digestible form at a hearing or in response to a proposed administrative order can also be useful. Participating in studies by scientific or engineering organizations requested by government is important. Those in government are particularly receptive to any timely inputs they feel are not tainted by political objectives. Such information is welcomed because it is rare. Those in government need to be adept in recognizing the motives of all those who are eager to offer guidance. Even then, as public servants, they listen but will react accordingly.

Chapter 3.2
MINING LAW*

CLAYTON J. PARR

Mining law is essentially a branch of the law of real property. It concerns the acquisition of property for extracting contained minerals, and the rights, privileges, and duties that fall upon the holder of the property once the rights are acquired. Accordingly, this chapter focuses on the procedures to be followed in acquiring state, federal, Indian, and private lands, and defines briefly the nature of the rights obtained.

This discussion is not intended to be the basis for legal decisions. Rather, its purpose is to provide the engineer with an understanding of basic principles and procedures. For a detailed treatise on mining law, reference can be made to the *American Law of Mining,* 2nd ed., a six-volume set edited by the Rocky Mountain Mineral Law Foundation.[1] Coverage is extended in this section to the United States and to US law only.

The law changes constantly, especially that based on federal and state statutes, and the reader is cautioned to be alert for subsequent modifications of statutes, regulations, and case law.

3.2.1 PRELIMINARY LAND-STATUS CHECK

After completion of area reconnaissance, or perhaps after receipt of a submittal, a specific and more localized target area will often become of interest. Usually, an intensive exploration program comprising detailed surface mapping, sampling, geophysical prospecting, and drilling will be required before the mineral potential of the ground can be properly evaluated. Before an investment of this magnitude is made, however, it is advisable to obtain rights to mine ore from the property. Otherwise, knowledge of the exploration activity might greatly inflate land values, or speculators or competing mining concerns might step in. The first step in a land acquisition program is a land-status check to determine whether the lands are available and, if so, from whom they can be obtained and by what means. Further discussion of this subject is provided in Chapter 7.1.

3.2.1.1 Bureau of Land Management Records

In those states that contain large areas of federal land, basically the western states, the primary information source is the records of the Bureau of Land Management (BLM). These may be examined at the land office having jurisdiction over federal lands in the area of interest. The records for Montana and North and South Dakota are kept at the Billings, MT, land office; Wyoming, Nebraska, and Kansas, at Cheyenne, WY; New Mexico, Oklahoma, and Texas, at Santa Fe, NM; northern Alaska, at Fairbanks, and southern Alaska, at Anchorage; Utah, at Salt Lake City; Nevada, at Reno; Arizona, at Phoenix; Oregon and Washington, at Portland; and Colorado, at Denver. There are two land offices in California, at Sacramento and Los Angeles. Records for other states are kept in Washington, DC, at the office of the director, Bureau of Land Management. At the land offices, most of the pertinent records are available for perusal by interested parties, but one unfamiliar with the system should seek assistance from land-office personnel.

Essentially, the examiner of the federal land records should ascertain what lands are owned by the federal government and their status. It also is advisable to note how lands no longer owned by the federal government were disposed of and when. Some federal lands have been conveyed out of federal ownership with a reservation of all or some of the minerals to the United States.

The first records that should be examined are the *master title plats* made up for each township that show all lands, minerals, and other rights owned by the federal government, all lands and rights that have been conveyed out of federal ownership, and reservations made by the United States in patents or other conveyances out of federal ownership. Withdrawals, rights-of-way, national forests, Indian reservations, military reservations, and acquired lands also are shown. Those lands affected by a particular action are outlined on the plat by lines of various weight and composition, and abbreviated symbols indicate the status of the parcels.

A second plat, the *use plat,* gives information regarding mineral leases, oil and gas leases, applications, and other current uses.

The master title plat book is accompanied by a *historical index* listing chronologically all past and present actions that affect title to the federal land. The index provides references that can be used to locate copies of the official documents.

The *control document index* contains microfilms of patents and other control documents. It is especially useful in determining if minerals were reserved by the government in a patent.

Other records available in the BLM land office are the *serial register* books, often accessible on computer display screens, that summarize the actions taken in connection with certain entries or classifications of federal land, and *case files,* that contain all correspondence and instruments relating to any particular serial number.

Information regarding unpatented mining claims may be found by checking the geographical index maintained for that purpose, that lists claims by township, range, section, and quarter section. More detailed information can then be obtained by referring to case files in which detailed information on such claims or group of claims is kept.

3.2.1.2 State Records

Often the check of BLM records will show that certain parcels in the area of interest have been conveyed to the state. For this reason, and because lands may have been otherwise acquired by the state, an examination of state land records must be made. They can be found at the office of the agency having jurisdiction over state lands, usually in the capitol city.

Most states have plat books similar to those of the BLM that show lands owned by the state and their status. Like the federal government, the state might have issued patents or other instruments conveying the land into private ownership, possibly with reservations of minerals. The plat books will usually indicate

*This chapter is a revised version of materials in the first edition prepared by Clayton J. Parr and Northcutt Ely. Grateful acknowledgment is given to Robert G. Holt and Daniel A. Jensen for valuable assistance in preparing these materials.

[1] References in this chapter are listed numerically.

whether mineral leases have been issued covering properties of interest. Inquiry should be made of state land-office personnel to learn how such information can be ascertained. It also should be determined whether any special-use permits or leases, such as grazing leases, affecting the surface are in effect.

3.2.1.3 County Records

Information regarding title to privately owned lands must be obtained from the records of the county in which the land is situated. To obtain a quick indication of apparent ownership, the records of the county treasurer or assessor, which show to whom ad valorem property taxes are being assessed, can be examined. County assessors keep abreast of title transfers and generally will be billing the current owner for the taxes. Even if the records do not reflect current ownership, however, discussion with those whose names are given generally will yield up-to-date information.

If time permits, a more accurate indication of ownership can be obtained from the county recorder's files. The recorder must keep an index of all instruments recorded. Usually the index is by name of the grantor and grantee. Except in sparsely populated counties, this index is not very useful in obtaining a rapid indication of land ownership in a large target area. Many states also require that a tract index be kept, which is keyed by legal subdivisions. Examination of the tract index will show chronologically all recorded transactions affecting title to a particular piece of property, and should reveal the current record titleholder and the existence of mineral interests. Some county recorders keep indexes of mining claims by area. These are very helpful, but are not to be relied upon to show all claims. County records will also reveal judgments or liens, overriding royalty conveyances, and other encumbrances.

3.2.1.4 Surface Check

The final step, but certainly not least in importance, is a field examination. If the land is public domain open to mining location, the ground must be examined to determine whether any claims have been located thereon. BLM and county indices are usually not current and they are often not complete or accurate. Also, notices recorded with the BLM or with the county recorder might not be discovered during a record search or, even if discovered, might contain inadequate or incorrect descriptions.

If claim markers are observed, the notices should be examined and the contents carefully noted. The field examiner also should check the claim markers to determine whether the boundaries are adequately marked and to plot the area covered by the claims. Any excavations, prospects, drillholes, or other evidence of geological or mining activities should be carefully examined and described. Any evidence of assessment work should be noted, as should the contents of any assessment affidavits in view.

If claims are found to have been made, it will be necessary to check county and BLM records to see if affidavits of annual assessment work have been filed. If within the time permitted by state law, no notice of performance of annual assessment work for the year expiring noon the last preceding Sept. 1 has been recorded, or if a copy of the recorded document has not been filed in the state office of the BLM by Dec. 30 of that same year, the lands might be open to location. All data acquired from the examination should be reviewed by an attorney to determine whether the claimant has complied with applicable laws regarding the location and preservation of the claims.

The field examiner also should make note of any other uses being made of the surface, such as industrial, residential, or agricultural.

3.2.2 FEDERAL LANDS

Federal lands can usually be placed in one of several categories depending on how the lands have been classified. These classifications are important in determining whether mining rights can be obtained, and if so, by what procedure. The basic categories are defined in the *American Law of Mining,* 2nd ed.:[2]

> "Public lands" means any land and interest in land owned by the United States within the several states and administered by the Secretary of the Interior through the Bureau of Land Management, without regard to how the United States acquired ownership, except: lands located on the Outer Continental Shelf, and lands held for the benefit of Indians, Aleuts, and Eskimos. "Public lands" includes "public domain lands" and "acquired lands.". . . . Generally, public lands do not include submerged lands.
>
> "Public domain," within the meaning of this title, denotes those lands which are or were subject to the public land laws of the United States. It includes lands initially acquired by the United States by cession, purchase, and treaty, as well as lands acquired by other methods where the latter have expressly been declared by Congress to be public lands or public domain.
>
> "Public domain lands" are defined by the US Department of the Interior to be "original public domain lands which have never left Federal ownership; also lands in federal ownership which were obtained by the Government in exchange for public domain lands or for timber on public domain lands.
>
> "Acquired lands" are defined by the Department of the Interior as "lands in Federal ownership which were obtained by the Government through purchase, condemnation, or gift, or by exchange for such purchased, condemned, or donated lands, or for timber on such lands. They are one category of public lands." Notwithstanding the characterization of acquired lands as a component of public lands by this definition, the mineral developer or prospector will find that the public land laws are generally inapplicable to acquired lands.
>
> The Department of the Interior defines "reserved lands" as "federal lands which are dedicated or set aside for a specific public purpose or program and which are, therefore, generally not subject to disposition under the operation of all the public land laws." Reservations are frequently mistaken for withdrawals because reserved lands are usually withdrawn.
>
> A withdrawal segregates particular lands from the operation of specified public land laws, making those laws inapplicable to those lands. Lands may be withdrawn from all or any part of the public land laws, including the mineral location and mineral leasing laws. Withdrawal is a frequently used technique of the government when its purpose is to preclude disposition or a particular use of a given tract of land. The breadth of the statutory definition, especially its use of the term "reserving," creates a temptation to equate withdrawals with reservations; however, the traditional distinction discussed in the text continues to be honored.

Severed Lands: The federal government has conveyed the surfaces of many lands, but has retained rights to all or certain named minerals. This is known as a severance of the mineral and surface estates, and such lands can be described as severed lands. Procedures for acquisition of the minerals are dependent upon the type of disposition that was made.

3.2.2.1 Mining Law of 1872

The Mining Law of 1872 is an embodiment of custom established by early western miners. The law is based fundamentally on two principles: (1) one can acquire mineral rights to land by making a discovery of valuable minerals thereon, and (2) a person who has made such an acquisition must continue to develop the minerals on the land to retain possession. Under this law, land is "claimed" for minerals by marking boundaries on the surface. Thus a claim is "located." The Mining Law of 1872 and subsequent modifications thereto often are commonly referred to as "the general mining laws."[3]

Lands Subject to Location: Federal lands that are locatable are unappropriated public domain and withdrawn or segregated lands that have by special provision not been segregated from application of the mining laws. Location can be made in Alaska, Arizona, Arkansas (except lead), California, Colorado, Florida, Idaho, Louisiana, Mississippi, Montana, Nebraska, Nevada, New Mexico, North Dakota, Oregon, South Dakota, Utah, Washington, and Wyoming.[4] Lands in national forests in these states are locatable, but not lands in national parks and national monuments, except where specifically authorized by law. Lands in Indian reservations, military reservations, and acquired lands, are not locatable.

Qualifications of Locators: Mining locations can be made by citizens of the United States and aliens who have declared their intention to become citizens.[5] Corporations organized under the laws of the United States or any state are considered citizens without regard to the nationality of shareholders and can locate and hold mining claims if empowered to do so under state law. By special statutory provision, certain employees of the Bureau of Land Management are disqualified,[6] but the Secretary of the Interior has, by administrative action, also excluded all full and part-time employees of the department, except members of advisory boards and councils.[7]

The proscription against location of claims by aliens is enforceable only at the instance of the United States. Hence, as a general rule, the fact that a mining claim is owned in whole or in part by an alien cannot be used by a private party as the basis for acquiring a dominant interest or for challenging validity.[8] Defective title of an alien is cured upon transfer to a citizen or upon a declaration of intent by the alien to become a citizen. The required declaration of intent usually is manifested by the filing of an application for citizenship.

Minerals Obtainable Under Location Law: The Mining Law of 1872 provides that "all valuable mineral deposits" in lands belonging to the United States shall be free and open to exploration and purchase.[9] There are two questions in determining what constitutes a "valuable mineral deposit" subject to appropriation under the general mining laws. First, is the particular mineral locatable and, second, is the mineral deposit valuable?

Theoretically, a particular *kind* of mineral is valuable and hence locatable if there is a market for it. A *valuable mineral* also has been defined as "any substance found in the earth having sufficient value to warrant the cost of its extraction."[10] Because of the unrestricted definition, the Location Law came to be applied to deposits of common nonmetallics, such as sand and gravel.[11] By special enactment at a later time, building stone and saline deposits were made locatable.[12]

The number of locatable minerals has been substantially reduced, however, by the Mineral Leasing Act of 1920 and the Common Varieties Act of 1955. The 1920 Act provides that oil, gas, coal, potassium, sodium, phosphate, oil shale, native asphalt, gilsonite, solid and semisolid bitumen, bituminous rocks, and deposits of sulfur in Louisiana and New Mexico can be acquired only by lease.[13] The 1955 Act foreclosed future locating of common varieties of sand, stone, gravel, pumice, pumicite, and cinders[14] ("stone" has been interpreted to encompass building stone and limestone). Excluded from the Act, however, are deposits of minerals with "some property" giving them a "distinct and special value." These are to remain locatable.

There is much uncertainty as to which characteristics are sufficient to give a deposit distinct and special value, and the issue has been the subject of many adjudications by the Department of the Interior (DOI). One writer summarizes by saying that "locatable common substances must have 'an exceptional nature' or be so unusual, exceptional or unique as to add to its value for uses over and above normal uses of the general run of such deposits."[15] Characteristics such as unique fracturing features, superior cleavability, unusual purity, unique use, and high price might be sufficient in a particular case, but as a practical matter, there is no way to be sure. As a result, substantial risk of loss of investment and possible liability for trespass exists whenever deposits of such materials are claimed and mining subsequently is undertaken.

Prediscovery Right—Pedis Possessio: The task of modern-day exploration geologists is complex. New mineral deposits most often are found far beneath the surface, and actual penetration of mineralized zones may occur only after long, multiphase exploration programs. There can be no appropriation under the mining laws until a discovery of valuable minerals has been made, but in most cases the prospector will find indications of mineralization, such as geophysical anomalies, long before the deposit can be proved out. It has long been recognized that a person actively exploring an area should have some protection against preemption by others of the land that he/she is exploring until he has had the necessary time to make a discovery of minerals in place. The doctrine of *pedis possessio* was formulated to provide such protection.

Under the doctrine, a qualified person who peaceably and in good faith enters vacant unappropriated public domain in search of valuable minerals may exclusively hold the place where he is working against others having no better right, as long as he remains in continuous exclusive occupancy and diligently and in good faith prosecutes work toward making a discovery.[16]

Because of *pedis possessio* rights, it is common for prospectors to set up claim monuments before making a discovery. It must be emphasized, however, that claims located before discoveries are made are simply convenient delineations of areas in which the locator claims the exclusive right of exploration. Each must be supported by a discovery of minerals in place before it becomes legally perfected under the mining laws.

Whether a prospector can successfully assert rights of *pedis possessio* will depend on the facts of the particular case, but in every case there must be (1) actual physical occupancy of the ground, (2) diligent bona fide work directed toward making a discovery, and (3) exclusion of others.[17] Although the requirements can be stated quite simply, it is difficult to prescribe with certainty what actions must be taken in the field to satisfy them.

It is common practice to locate a large block of claims over and around an area where deposits of valuable minerals are suspected. Locators of such blocks have attempted to maintain exclusive possession on the theory that work being done on some of the claims constitutes constructive possession of the remainder. This theory has met with little success, however, and as a result, little security is had under *pedis possessio* in the absence of actual physical possession of each claim.[18]

The occupancy must be more than mere presence. The occupant must be actively working toward making a discovery. Mere preparations for exploratory work may not be sufficient unless the activity directly precedes actual drilling or digging. The sufficiency of radiometric or geophysical testing is doubtful.[19]

It is difficult to state any hard and fast rule as to what conduct will be sufficient to establish that work is being directed toward making a discovery. If, however, the claimant is acting in good faith and is utilizing the most appropriate exploration method under the circumstances, his chances of overcoming a challenge by a third party should be good. Actual penetration of the earth in an attempt to uncover minerals in place provides the most security. It is most important, however, that exploration work be taking place on each claim.

The requirement of physical occupancy of the ground is usually satisfied as a result of the work in progress. Exclusion of others, however, requires positive action, because *pedis possessio* rights are lost if an adverse claimant is permitted to enter the property peacefully. *Pedis possessio* protects against "forcible" entry. Thus it is necessary that the intruding party be denied entry. If a confrontation occurs, and the party being denied entry resorts to force to gain such entry, he need not be successfully excluded. One simply yields to force, and then resorts to his legal remedy. No statements should be made, however, that indicate acquiescence.

It has been suggested that denial of access may be made by signs, written or verbal notice, or other reasonable means.[20] If no other means are available, such methods should be used for whatever protection they might offer. If it is possible, however, especially in a land-rush situation, the area should be patrolled and entry denied all trespassers. If problems are anticipated, legal counsel should be engaged beforehand so that necessary preparations can be made for obtaining a restraining order.

Pedis possessio provides only tenuous prediscovery protection. It is unclear in a given situation what conduct will satisfy the requirements and, as a result, much litigation has resulted.

Discovery: Even though the particular mineral of interest is subject to acquisition under the mining laws, it also is required that there be a valuable deposit of the mineral within the land desired to be located. That is, the geologic setting must be such that the deposit is of sufficient grade, quality, and amenability to render the ground valuable because of its mineral content. If so, there has been a "discovery" in the legal sense, and a valid mining claim can be located.

A discovery is essential to the acquisition of rights under the federal mining laws.[21] A temporary, but highly tenuous, right to exclusive possession can be obtained through *pedis possessio,* but there must be a discovery of valuable minerals before the locator will have perfected a legally valid mining claim.

The definition of "discovery" under the mining law has been and continues to be a subject of controversy. The basic legal standard for discovery is the so-called prudent-man test, which reads:

> (W)here minerals have been found and the evidence is of such a character that a person of ordinary prudence would be justified in the further expenditure of his labor and means, with a reasonable prospect of success in developing a valuable mine, the requirements of the statute have been met.[22]

Hence the test is not whether the individual claimant feels he is justified in further expenditure of labor and means, but whether the hypothetical reasonable man would be so justified.

Imperfect as the objective prudent-man test is, it became the universally accepted standard of determining discovery. In 1933, however, the DOI formulated a modified standard applicable to discovery determination by the United States, the so-called "marketability test:"

> (T)he mineral locator or applicant, to justify his possession, must show that by reason of accessibility, *bona fides* in development, proximity to market, existence of present demand, and other factors, the deposit is of such value that it can be mined, removed, and disposed of at a profit.[23]

Thus the marketability test focuses on the economic value of the deposit as a whole. In *Coleman v. US,*[24] which involved a deposit of building stone, the court upheld the marketability test on the ground that it is merely a facet of the prudent-man test.

The stringency of application of the discovery test varies according to the identity of the adversaries and the nature of the controversy. The standard is applied with much more strictness, for example, when the existence of a discovery is challenged by the BLM in connection with a patent application than when lack of discovery is alleged by a rival locator. A critical fundamental difference is that application of the marketability test per se is limited to "controversies between a mining claimant and the United States or between a mining claimant and someone other than a mining claimant, claiming under the United States."[25] Thus courts can reach different conclusions based on the same set of facts. The BLM has listed six categories in the order of decreasing discovery requirements: [26]

> A. Building stone and saline placer, where it has to be shown that the land is chiefly valuable for building stone or salines.
>
> B. Mineral patent applications.
>
> C. Claims, located on deposits of commonplace materials where the existence of an actual market has to be shown which were located prior to July 23, 1955 . . .
>
> D. Claims in conflict with nonmineral (agriculture) entries or located in areas where condemnation proceedings may be required.
>
> E. Mining claims located on lands involved in multiple use procedures under Public Laws 167, 357, 359 and 585.
>
> F. Disputes between rival mining claimants.

Even though the scope of applicability of the test is uncertain, as a result of these decisions, every locator should be prepared to defend his discovery under the standards imposed by the marketability test. Hence, the locator should begin building his case at the time he exposes minerals and should continue to do so for as long as the claim is held. He should gather and retain as much data as he can about the character and extent of the deposit and its economic value. Because of the variability of the test and the difficulty in applying the accepted definition to field conditions, one can rarely be confident that he has a discovery unless he is actually mining the deposit at a profit.

It is well established that discovery contemplates an actual physical exposure of mineral-bearing rock in place within the limits of a claim.[27] Discovery of float rock or other surface indications will not suffice. Geophysical and geologic data sufficient to establish a strong inference of mineralization are not sufficient standing alone. In several cases, however, it has been held that, as against a rival locator, radiometric readings plus corroboration based on sampling and assays of nearby exposures and a strong geologic inference of projection of the sampled zone, will be sufficient.[28] In *Ranchers Exploration & Dev. Co. v.*

Anaconda Co.,[29] the court held that discovery of ore in place on one claim can be sufficient to support a discovery on an adjacent claim if projection of the ore-bearing zone across the boundaries can be demonstrated. In determining this, the court weighed evidence of geologic inference based on the opinions of miners, geologists, and other experts. As against the United States, geologic inference alone is not enough to demonstrate a discovery, but it may help establish the further elements of a discovery with regard to an exposure of rock in place.[30]

There is an oft-repeated statement in mining contests brought by the government that information sufficient to justify additional exploration is not enough to show a reasonable probability of developing a paying mine. This was emphasized in the decision in *Converse v. Udall,*[31] where the court stated, "(T)he finding of some mineral, or even of a vein or lode, is not enough to constitute discovery—their extent and value are also to be considered."

From the standpoint of the field engineer, the objective should not be so much to understand the intricacies of the law relating to discovery, but more to appreciate the necessity of fortifying the claim by amassing as much information as possible, both geologic and economic, tending to show that the deposit is valuable. The existence of a discovery always is subject to challenge until a patent issues, and when a challenge is made, the success of a lawyer's defense of the claim will be dependent on the facts with which he or she has to work.

Choice Between Lode and Placer: The location law authorizes two types of claims, lode and placer, depending upon the character of the deposit. It requires that lode claims be made "upon veins or lodes of quartz or other rock in place bearing gold, silver, cinnabar, lead, tin, copper, or other valuable deposits."[32] However, "all forms of deposit, excepting veins of quartz, or other rock in place" must be located as placers.[33] Hence the locator must decide into which category his deposit falls before making his location.

Congress apparently was drawing a distinction between the traditional gold placer in unconsolidated alluvial material along stream beds, as opposed to the common vein, or lode, found in solid rock. Many deposits, however, do not clearly fall into either category, and consequently, the choice can be difficult at times.

The most frequently quoted definition of a lode is given in *Eureka Consol. Mining Co. v. Richmond Mining Co.,*[34] where the court stated: "The term lode, as used in the Acts of Congress, is applicable to any zone or belt of mineralized rock lying within the boundaries clearly separating it from the neighboring rock." Placers have been defined as "merely superficial deposits, occupying the beds of ancient rivers or valleys, washed down from some vein or lode,"[35] and as "deposit(s) of valuable minerals found in particles in alluvium or diluvium, on beds of streams."[36]

On the basis of these and similar definitions, which emphasize the form of the deposit rather than its mode of origin, it has been held that blanket-type deposits of nonmetallic minerals, such as phosphate and distinct stratigraphic units of intermittently mineralized limestone can be lodes.[37] Deposits of uranium contained in a horizontal sandstone have also been characterized as lodes.[38] It has been held by some courts, however, that badly distorted near-surface blanket deposits of minerals in place are placers.[39] Generally speaking, certain recurring factors are considered by the courts. Thus, if the rock is in place and bounded on either side by other rock in place, it is likely to be a lode. If the ore is on top of the ground, has broad lateral continuity, is weathered and has no cover except perhaps for a thin veneer of soil, it is likely to be a placer. Although in many instances the choice is difficult, some comfort can be derived from the knowledge that the courts have exhibited an inclination to uphold the choice of the first locator in the event of a dispute.[40]

A placer location does not establish rights to lodes within its boundaries. Hence, up to the time of patent, lodes within an unpatented placer claim are subject to appropriation either by the placer claimant or third parties. It is generally accepted that the locator of a placer claim may cover the same ground with lode claims without invalidating his prior claim. Most often the junior lode claims are located full size, but there is a mix of opinion as to whether lode claims located over valid placers are limited to a width of no greater than 50 ft (15.2 m) plus the width of the vein.[41] A lode location made by a third party over a valid placer claim without consent of the placer owner, however, may be invalid by reason of its being located in trespass.[42]

An included lode can be acquired at the time of patent, but a known lode that is not so acquired remains subject to separate location.[43] If no reference to an included lode is made in the patent, however, a strong presumption exists that the placer does not contain a known lode, and a subsequent locator must show by clear and convincing evidence that a valuable lode deposit was known to exist when the application for patent was made.[44]

Although the customary sequence is location first of placer claims and then location of lodes, there is authority supporting the proposition that placer claims can be located over prior valid lode claims, or over known lodes.[45] Such location would presumably be subject to the same consent requirements described previously if the junior location were made by a third party. A patent of the prior lode claim, however, would vitiate the placer claim because the lode claim will include all placers upon issuance of a patent.

Placer claims located over patented lode claims are invalid.

Size and Shape of Mining Claims: A lode location may not exceed 1500 ft (457.2 m) in length along the vein or lode (sideline), nor more than 300 ft (91.4 m) on each side of the vein (endline). A smaller claim may be located if desired. The endlines should be parallel to each other,[46] although they do not have to be perpendicular to the sidelines. It has been held, however, that nonparallel endlines do not invalidate a claim, although they do deprive the locator of extralateral rights if the endlines diverge in the direction of the dip of the vein.[47] The claims can overlap previously located claims as long as the discovery is made on unappropriated land. However, only the unappropriated ground is held over a senior locator whose claim is overlapped.

A placer claim can be no larger than 20 acres (8 ha) for an individual, but associations, or groups of persons, can locate up to 160 acres (64 ha) in a single claim, based on 20 acres (8 ha) per individual in the association.[48] A corporation is considered to be a single person. On surveyed land, placer locations must conform as nearly as practicable to rectangular legal subdivisions.[49] Legal subdivisions of 40 acres (16 ha) may not be subdivided smaller than into l0-acre (4-ha) tracts. If the legal subdivision contains more than 20 acres (8 ha) per claimant because of discrepancies in the public land survey, up to 5 acres (2 ha) of excess are permitted.[50]

Care must be taken to ensure that all individuals in an association have a true ownership interest in the venture, because the interest held by a so-called "dummy locator" can be invalidated.[51]

Location Procedures: The federal law requires only that there be a discovery of a vein or lode within the limits of a lode claim, and that the claim be marked on the ground so that its boundaries can be readily traced.[52] Other requirements for location are to be established by regulations made by the miners of each mining district that are not in conflict with the laws of the United States or of the state or territory in which the mining district is situated.[53] State governments have supplanted local mining districts with regard to the enactment of location requirements.[54] Hence the laws of each state must be examined to determine requirements concerning the manner of posting and recording notices of location and the manner of marking the boundaries of the claim.

State law generally requires that there be (1) posting of a location notice, (2) marking of the boundaries of the claim, (3) performance of the required discovery work, and (4) recording of the location notices or a location certificate. Once the location notice is posted, the remaining order in which these steps are performed is not important as long as they are all performed within the time permitted.[55]

The federal mining laws do not require posting of a notice of location, but the Secretary of the Interior has, by regulation, provided posting procedures and has described the contents of the notice and the place and manner of posting.[56] This regulation suggests that the discovery notice ties in with some permanent landmark, such as stone monuments, blazed trees, etc.; the regulation also states:

> (T)he claimant should state the name of adjoining claims or, if none adjoin, the relative positions of the nearest claims, should drive a post or erect a monument of stones at each corner of his surface ground, and at the point of discovery or discovery shafts should fix a post, stake or board, upon which should be designated the name of the lode, the name or names of the locators, the number of feet claimed, and in which direction from the point of discovery, it being essential that the location notice filed for record, in addition to the foregoing description, should state whether the entire claim of 1500 ft is taken on one side of the point of discovery, or whether it is partly upon one and partly upon the other side thereof, and in the latter case, how many feet are claimed upon each side of such discovery point.

Under the laws of some states, the notice posted on the claim must simply contain the name of the claim, the name of the locator, and the date of discovery. More detailed information may be required on a recorded location certificate. In other states, the recorded notice is a copy of the posted location notice, and both must contain detailed information regarding the location.[57] Once the location notice is posted, the land is withdrawn from location by others as long as the locator performs the required acts of location within the prescribed time and has a valid discovery.

The boundaries of a claim are established by markings on the ground, and these markings control over descriptions in the location notices or deeds. Federal law requires that a location be distinctly marked on the ground so that its boundaries can be readily traced.[58] In each state, the minimum requirements for marking the boundaries are set out by statute. These statutes should be checked to determine what type of monument must be posted and how extensively the boundaries must be marked. Usually, as a minimum, a monument must be placed at each corner of the claim. Once a discovery is made and the location monument is erected, most states allow a set period of time for completion of location requirements. The notice of location, or a separate certificate of location, usually must be recorded within the same period of time.

Discovery work differs from discovery of valuable minerals. The former is a diligence requirement having as its purpose the discouraging of non bona fide locators by requiring a minimum amount of work on the claim. Performance of the work does not constitute a discovery of valuable minerals.[59] With the exception of Washington, which requires discovery work in the form of labor to develop placer claims, all states have now eliminated the requirement that physical discovery work be performed, although some allow it as optional and others require the filing of maps in lieu of physical work.[60]

Requirements imposed by state law usually are very detailed and sometimes seemingly without rationale, but nevertheless, they should be complied with as nearly as possible. It must be kept in mind that any procedural defect can be seized upon by a competing locator as a means of obtaining priority.

State laws requiring recordation of notices or certificates of location must be complied with. In addition, a copy of the notice or certificate of location, in the exact form of that recorded if the state requires recordation and otherwise in form required by BLM regulations, must be filed with the appropriate state BLM office within 90 days after the date of location.[61] Failure to make the BLM filing causes the claim to be void.[62]

Once the boundaries are marked and the location monuments erected, the claimant need not maintain or restore the monuments, if they are obliterated without his fault, to preserve his possession as against rival claimants.[63] If the monuments are obliterated after patent issues, the patent description controls. Prior to patenting, the location markers should be maintained because the boundaries of the claim are determined by the markings on the ground.

Amendment: If a location notice contains defects, a corrective amended notice can be filed without making changes on the ground.[64] If the notice is so defective that it is void, an amendment will not defeat the priority of an intervening locator (junior locator). Boundary changes can be made to include new unappropriated ground by filing an amended location notice and changing the boundary markers. Prior to the posting of location markers, a locator can swing his claim around the point of discovery to better orient the claim along the vein.

Rights of the Locator: The owner of a valid mining claim has the right of exclusive possession of the claim as against other locations as long as he complies with the acts of Congress and local statutes. Claims are real property and cannot be taken away by the United States without just compensation.[65] Except in situations where a purely legal issue is involved, such as where required filings have not been made, claims cannot be declared invalid without a hearing.[66] Actual fee title to a claim remains in the United States until patent issues.

The owner of an unpatented lode claim is entitled to all veins or lodes within the limits of his claim, not subject to extralateral rights of another, and he can proceed to mine them for his own exclusive use and benefit. He can use the surface as required for his mining operations. The owner of a placer claim has similar rights to any placers within the boundaries of his claim.

Extralateral Rights: The locator of a valid lode mining claim acquires the right to "all veins, lodes and ledges throughout the entire depth the top or apex of which lies inside of such surface lines extended downward vertically, although such veins, lodes or ledges may so far depart from a perpendicular in their courses downward as to extend outside the vertical sidelines of such locations.[67] The apex of a vein is its top (or the highest point), the terminal edge from which the vein extends downward in the direction of the dip.[68] The rights of a claimant to follow a vein or lode beyond the boundaries of the claim are known as extralatera1 rights. Such rights are confined to the area between two hypothetical vertical planes that extend through the parallel endlines.

Extralateral rights are acquired only if the location is a lode claim. The vein or lode must be rock in place, and it must be essentially continuous in its downward course. Some offset along faults or thinning of ore zones is permissible, but if the vein disappears or loses its identity so that it can no longer be traced, the rights cease. If the deposit is horizontal, no extralateral rights are acquired.

An entire stratigraphic unit, such as a limestone bed, can be a lode to which extralateral rights will attach if it is mineralized throughout. Such a unit is referred to as a “broad lode.”[69]

Ideally, a lode claim would be located along a vein outcropping at the surface in nearly a straight line. In most instances, however, the course of a vein is difficult to define on the surface and, as a result, the locator often does not, or cannot, orient his claim so that the apex intersects both endlines. By judicial decision, however, the rule has been adapted to cover a variety of situations.

If the apex of a vein passes through both sidelines of a location, and the sidelines are parallel to each other, the sidelines become endlines for the purpose of determining extralateral rights to the vein.[70]

No extralateral rights are acquired if the endlines diverge in the direction of the dip of the vein. Some courts have held that extralateral rights are acquired if the endlines converge, but only within the converging endlines to the point of intersection.[71]

If the apex of the vein crosses one side and one endline, the extralateral rights are bounded by a plane extending perpendicularly downward through the endline through which the vein passes, and a plane parallel therewith dropped downward perpendicularly through the point where the vein crosses the sideline.[72]

If the vein enters and leaves the claim through the same boundary line, it has been held that extralateral rights are obtained within vertical planes drawn parallel to the endlines at the points where the vein crosses the sideline.[73]

If the vein crosses only one boundary line, or is contained wholly within the boundaries of a claim, extralateral rights apparently will be bounded by vertical planes parallel to the endlines drawn at the point or points where the vein terminates.[74]

If the apex of the vein on its course is split or divided by a boundary line of a location, or if the vein is wider than the location itself, the senior locator is entitled to extralateral rights to the entire vein.[75]

Extralateral rights are not restricted merely to the discovery vein; the locator also acquires extralateral rights to any hidden or secondary veins, the apexes of which lie within the claim’s boundaries. It is the discovery vein, however, that determines which lines are endlines and which are sidelines. Otherwise, the extent of extralateral rights to the secondary vein are determined in the same manner as are those extending to the discovery vein.[76]

The mining law provides that “where two or more veins intersect or cross each other, priority of title shall govern, and such prior location shall be entitled to all ore or mineral contained within the space of intersection; but the subsequent location shall have the right-of-way through the space of intersection for the purpose of the convenient working of the mine. . . .”[77] If two veins unite, the prior locator obtains rights to the vein below the point of union and to the space of intersection.

At one time, lawsuits concerning extralateral rights were common, but now they occur rarely. Such litigation generally was bitter, prolonged, and exceedingly costly. A good practice is to enter into vertical sideline agreements with adjoining claim owners limiting each party to the mining of ore directly beneath the surface of his claims.

Tunnel Sites: The location law provides for acquisition of minerals encountered in a tunnel run for the development of the vein or lode for the discovery of mines.[78] The owners of such a tunnel have the rights of possession of all veins or lodes within 3000 ft (914.4 m) from the face of the tunnel on the line thereof not previously known to exist. The rights acquired are the same as if the vein had been discovered from the surface, so the tunnel claimant’s right to a vein is limited by the maximum dimensions of a lode claim: 1500 ft (457.2 m) along its length and 300 ft (91.4 m) on each side of the vein. If a vein is encountered, the tunnel claimant can delineate the boundaries of his rights by locating on the surface.[79]

In effect, a tunnel locator segregates a 3000-ft (914.4-m) square measured from the face of his tunnel for so long as he is diligently working on the tunnel. His rights are not dependent upon an initial discovery, and they have priority over surface locations made by others after commencement of the tunnel. Failure to prosecute the work on the tunnel for six months constitutes an abandonment of the tunnel locator’s rights.

Procedures for the initiation of the tunnel rights are defined in regulations promulgated by the Secretary of the Interior.[80] A monument must be placed at the face of the tunnel upon which a notice must be posted giving the names of the parties or company claiming the tunnel right, the actual proposed course or direction of the tunnel, the height and width thereof, and the course and distance from such face or point of commencement to some permanent well-known object in the vicinity. The tunnel claimant must establish the boundary lines of the tunnel by stakes or monuments placed along its lines for a length of 3000 ft (914.4 m) from the face. In addition, a copy of the notice must be filed with the recorder for the district in which the claim is located and, to this, must be attached a sworn statement stating the amount expended by the tunnel claimants, the extent of work performed, and the bona fide intent to prosecute work for the development of the vein or lode or for the discovery of mines.

Tunnel sites are rare.

Mill Sites: The mining law permits acquisition of land for nonmining purposes in plots up to 5 acres (2 ha) that are referred to generally as mill sites. Three type of mill sites are recognized: (1) nonmineral land not contiguous to a vein or lode can be occupied by the claimant for mining or milling purposes, and the mill site can be patented with the lode claim; (2) nonmineral land not contiguous to a vein or lode claim can be appropriated for a mill site by the owner of a quartz mill or reduction works, and separate patent can be obtained; and (3) nonmineral land can be acquired by the proprietor of a placer mining claim for mining, milling, processing, beneficiation, or other operations in connection with the placer claim, and patent can be obtained at the time patent is acquired for the placer claim.[81]

By custom, mill sites are staked in the manner provided for lode claims. The mill site does not have to be any required shape, as long as its area does not exceed 5 acres (2 ha). It may consist of one or several pieces of ground.[82]

Land obtained for a mill site must be nonmineral in character up to the time of patent.[83]

A mill site must be used for mining and milling purposes. The statute has been interpreted broadly, however, and apparently requires only that some step in or directly connected with the process of mining or some feature of milling be performed upon, or that some recognized agency of operative mining or milling, occupy the mill site.[84] Thus it has been recognized that the construction of substantial improvements for the conveyance and utilization of water from or to land in connection with mining operations, the construction of storage or shop buildings required for mining operations, ore-storage facilities, and, of course, an actual mill, are proper uses.[85] It is likely, although not certain, that a mill site can be used for waste dumps.[86] The DOI has disapproved of a mill site solely for the use of transporting water.[87]

Land which has been entered for a mill site cannot be kept indefinitely without being used for its intended purpose. Moreover, unless steps toward putting it to use are clearly under way, a patent will not issue.[88]

Although the statute is unclear on the issue the DOI apparently does not impose a numerical limit to the number of dependent mill sites that can be acquired for a single mining claim. Conversely, a group of mining claims will not necessarily justify the acquisition of an equal number of mill sites. An applicant must show a sufficient and satisfactory need for more than one mill site in an area and must show need for the entire 5 acres (2 ha) in any individual mill site.[89]

Patents generally are applied for at the time patent is sought for the supporting lode or placer claim. It may be obtained by an independent application, however, if good faith is manifest in its use or occupation in connection with the lode, and no adverse claim exists.[90]

Annual Assessment Work: The rights acquired by locating a valid mining claim are terminable by others unless the claim is maintained. The federal mining law requires that not less than $100 worth of labor be performed or improvements made each year to keep the land encompassed by the claim closed to acquisition by other claimants.[91] The requirement applies to both lode and placer claims.[92] The law also provides that local mining districts (i.e., the states) can make regulations not in conflict with the laws of the United States regarding the amount of work necessary to hold possession of a mining claim.[93]

The assessment work year commences as 12 o'clock noon local time, Sept. 1. Assessment work need not be performed during the assessment work year in which the claim is located.

There is substantial uncertainty with regard to what type of work will satisfy the annual labor requirement. Basically, the work must be performed in good faith, and it must tend to develop the claim and facilitate the extraction of minerals from it.[94] Hence the work should be part of a development plan for a known deposit, as distinguished from exploration work done for the discovery of a new deposit.

It is the reasonable value of the labor that is considered and not necessarily the amount paid for it. The amount paid, however, is an important factor in determining the value of improvements.[95]

Construction of mining excavations, such as surface pits, tunnels, shafts, or other workings, generally will satisfy the requirement. Construction of buildings and replacement of machinery and equipment usually will suffice if the facilities are close to the claim and are directly related to the mining of ore. Construction and maintenance of roads for access to and from claims is a popular mode of improvement but it, too, must be related to the development of the claim. Milling and processing facilities generally will not suffice. Some courts have held that the expense of a watchman or caretaker can be used if the mine is only temporarily idle and mining equipment and materials must be protected from loss or damage, but other courts have held that such expenditures do not apply.[96] The diversion of water for use in mining generally will be satisfactory.[97]

Drilling is perhaps the most widely used form of annual labor. Such drilling should be part of a development program and not simply exploratory.

In 1958, Congress passed legislation that specifically permitted geologic, geochemical, and geophysical surveys in satisfaction of annual labor requirements.[98] Such surveys must be conducted by qualified experts, and they must be verified by a detailed report filed in the county office in which the claim is located. The report must set forth fully (1) the location of the work performed in relation to the point of discovery and boundaries of the claim; (2) the nature, extent, and cost thereof; (3) the basic findings therefrom; and (4) the name, address, and professional background of the person or persons conducting the work. Such surveys may not be used for more than two consecutive years or for more than a total of five years for any one mining claim, and the surveys must not be repetitive. The surveys should be performed on the ground. Doubt has been expressed whether radiometric testing, standing alone, is authorized.[99]

The required report can be submitted with the affidavit of labor to the county recorder, either as an appendage or as an integral part of the text of the affidavit.

The federal statute says that where claims are held in common, the annual expenditure may be made upon any one claim. Because of a statement of judicial dictum by the court in *Chambers v. Harrington,*[100] it has become common belief that the claims must be contiguous before work done on one will inure to the benefit of the others, and, in fact, BLM regulations so state.[101] Certainly the case is much stronger if the claims are contiguous, but it seems also to be well established that work done off the claims or upon a claim not contiguous to the others can satisfy the requirement as long as the work benefits the noncontiguous claims.[102] To avoid uncertainty, however, separate work should be done on each group of contiguous claims if possible.

Group assessment work should be made as part of a plan tending to develop all claims in the group, and the value of the work done must be at least $100 for each claim in the group.

Assessment work may be performed by the owner or his agent, by someone in privity with him, by someone who holds an equitable or beneficial interest in the property, or by someone who intends that the work inure to the benefit of the owner.[103] A co-owner who fails to contribute his portion of the expenditures forfeits his interest to the other owners if they follow a statutory procedure for giving notice.[104]

Each of the western states has a statute prescribing the information that must be contained in the affidavit, or "proof," of annual labor and the time within which it must be filed.[105] Six states require that the affidavit be filed within a specified time after the closing of the assessment year. The time periods are 90 days in Alaska and Montana; 30 days in California, Utah, and Washington; and 60 days in Idaho. Two states require that the affidavit be filed within a specified time after completion of the work. Twenty days are allowed in Oregon and 60 in Wyoming. In Nevada, the deadline is Nov. 1, and in Arizona, Colorado, and New Mexico, on or before Dec. 30 of the year in which the time expires for doing the work.

The owner of the claim must also file with the BLM a notice of intention to hold, an affidavit of assessment work, or a copy of a detailed report concerning the performance of geologic, geochemical, or geophysical surveys.[106] The filing must be made at the office where the certificate or notice of location is recorded as well as at the BLM state office. The BLM filing must be made on or before Dec. 30 of each year following the *calendar* year in which the claim is located. Thus, even though assessment work is not required in the ensuing calendar year for a claim located after Sept. 1 and before Dec. 31 in a given year, the BLM filing must nonetheless be made. Copies of the same document must be filed in both the recorder's and the BLM office, and the notice must set forth the BLM serial number assigned to the claim or provide other information constituting a description of the location of the mining claim sufficient to locate the claimed lands or the ground.[107]

A notice of intention to hold is ordinarily filed only when assessment work is not required for the assessment work year ending on Sept. 1 of the year in question, either because the claim was located during the prior calendar year after Sept. 1, or because a deferment of assessment work has been allowed by the BLM.[108] The notice can be in the form of an instrument, generally in the form of a letter, signed by the owner, a reference to the BLM deferment decision, or a reference to a pending decision for deferment.[109]

Failure to make required BLM assessment work filings on time and consistent with statutory requirements, including the requirements that the exact same form of instrument be filed with the county recorder and that the BLM file number for the claim be shown, will cause the claim to be conclusively deemed to have been abandoned, or in effect become void. [110]

Although not required by statute, BLM regulations require the filing of notices of intention to hold mill sites and tunnel sites on or before Dec. 30 of each year.[111] Forfeiture does not occur, however, unless the delinquent filing is not made within 30 days after notice from BLM of failure to make a timely filing is received.

In most states, the recorded affidavit constitutes prima facie evidence of performance of the work or making of the improvements described therein. It must be emphasized that the mere filing of an affidavit does not give protection if the work has not been done, and the signer of a false affidavit could be charged with perjury. Even if an affidavit is not filed, however, a locator can prove the performance of the required annual work by other evidence. The affidavit also can be supplemented by other evidence that work was done. [112]

Annual assessment work should be planned well ahead so that a determination can be made whether the contemplated work program will fulfill the requirements. Complete detailed records should be kept of all work done.

Failure to perform annual assessment work (as opposed to failure to make the required annual filings) does not result automatically in loss of the claim. The effect is to open the claim to relocation by others. If, however, the original locators, their heirs, assigns, or legal representatives resume work upon the claim before the relocation is made, the claim is no longer subject to relocation as long as the requirements are thereafter met. The claimant need not make up delinquent work for years past.

A locator can abandon a claim by voluntarily leaving it and concurrently intending not to preserve or reestablish his rights. A locator who has abandoned his claim cannot later revive his rights by resuming assessment work.[113] Abandonment, however, is very difficult to prove. A federal regulation provides that the BLM may take action to cancel a claim if a mining claimant fails to comply substantially with the requirement of an annual expenditure of $100 in labor or improvements on a claim. [114]

Patent Applications: If a discovery has been made, the claim has been properly located, and $500 worth of labor has been expended or improvements made upon the claim by the owner of his predecessors, the claim owner who meets citizenship requirements is eligible to apply for a patent.[115] With respect to a placer claim, there must be a discovery on each 10-acre (4-ha) tract within the claim.[116] Detailed procedural requirements for obtaining a patent are prescribed in Title 43, *Code of Federal Regulations,* Pt. 3860 (1987). These procedures have been summarized as follows: [117]

(1) The claimant must file an application in the proper office under oath, showing compliance with the law, together with a plat and the field notes of the claim or claims, showing the boundaries, which must be distinctly marked on the ground.

(2) Prior to filing the application, the claimant must post a copy of the plat, with a notice of his intended application, in a conspicuous place on the land embraced in the plat, and must file an affidavit of at least two persons that such notice has been duly posted, together with a copy of the notice, in the proper office.

(3) When the application, plat, field notes, notice and affidavits have been filed, the manager of the land office is required to publish a notice of the application for a period of 60 days in a newspaper to be designated by him as being published nearest the claim, and to post the notice in his office for the same period.

(4) At the time of filing his application, or at any time thereafter within 60 days, the applicant is required to file a certificate of the office cadastral engineer that $500 worth of labor has been performed or improvements made upon the claim by the applicant or his grantors, that the plat is correct, with such further description, by reference to natural objects or permanent monuments, as will identify the claim. The applicant must also furnish an accurate description of the claim to be incorporated in the patent.

(5) At the expiration of 60 days, the claimant is required to file his affidavit showing that the plat and notice have been posted in a conspicuous place on the claim during the period of publication.

A patent applicant is advised to engage the services of an attorney to process his application. The procedures are very detailed, and many delays can result from errors occurring because of unfamiliarity with the rules and regulations.

Before the applicant submits his application for patent to the land-office manager, he must obtain a correct survey, unless the claim is a placer claim on surveyed land. Application for survey is submitted to the state director of the BLM for the state in which the claim is situated, who after an initial review will then issue an order for a survey to the qualified mineral surveyor who has been designated by the applicant. [118] The surveys are conducted under authority of the cadastral engineer. A nominal fee of $5/acre ($12.50/ha) or fractional part of an acre of a lode claim and $2.50/acre ($6.25/ha) or fractional part of a placer claim must be paid as a purchase price for the patent. [119]

For many years after enactment of the Mining Law of 1872, the issuance of mineral patents was fairly routine and commonplace. Because of ever-increasing vigilance on the part of federal land-administration officials, however, it is now difficult to obtain a patent. They are issued only in cases where clearly there is full compliance with the law. The most important requirement is that of showing a valid discovery. The stringency of the test for discovery varies in different settings, but it is applied most strictly in connection with a patent application. If the BLM field engineer concludes that no discovery exists, contest proceedings can be initiated to invalidate the claim. Hence, an application for patent should be made only after careful consideration of the circumstances.

Within 60 days after commencement of publication of notice of application for patent, an adverse claim can be asserted by a person alleging a right to all or a portion of the surface ground of a mining claim sought to be patented. These are referred to simply as "adverses." An adverse might be filed, for example, by another claimant whose boundaries overlap those of the patent applicant. Within 30 days after an adverse claim is filed, the party must commence proceedings in a court of competent jurisdiction to determine the question of the right of possession.[120]

At any time prior to the issuance of patent, a protest may be filed against the patenting of a mining claim based upon any ground tending to show that the applicant has failed to comply with the law on any matter essential to a valid entry.[121] The protestant cannot acquire title to the land in question, but he can defeat the efforts of the applicant. The disposition of a protest is discretionary with the BLM through the local office in which the claim is located. The land-office manager can either dismiss the patent or order a hearing to determine the character of the claim and whether there has been due compliance with the mining law.[122]

Contest Proceedings: BLM can contest the validity of a mining claim at any time prior to patent "for any cause affecting the legality or validity of any entry or settlement or mining claim."[123] The usual basis for a contest is lack of discovery. A contest can be initiated at the instance of the BLM or after request by another governmental agency. Such requests most often are made by the US Forest Service. Contests may be initiated when the land has been requested by a federal agency for another use, after investigation in connection with a patent application, upon discovery that minerals properly removable only by lease are being mined, where there is conflict with a nonmineral user (for example, a grazing permittee), or where the claim is being used for a nonmining purpose. Discovery may be challenged under the Common Varieties Act,[124] but an adverse determination does not invalidate the object claims. After the contest is initiated, a hearing is held before an administrative law judge. The decision of the administrative law judge can be appealed to the Interior Board of Land Appeals.[125]

3.2.2.2 Mineral Leasing Act of 1920

Leasable Minerals: Under the Mineral Leasing Act of 1920, [126] deposits of oil, gas, coal, potassium, phosphate, sodium, oil shale, gilsonite, native asphalt, solid and semisolid bitumen, bituminous rock, and sulfur in New Mexico and Louisiana have been made subject to disposition through lease. The 1920 Act has had its most extensive application in connection with leases for oil and gas. Federal oil and gas law is a subject beyond the scope of this section, and the Leasing Act is discussed only as it relates to minerals traditionally extracted by mining methods. The reader is referred to *The Law of Federal Oil and Gas Leases*, 2nd ed., edited by the Rocky Mountain Mineral Law Foundation, for a thorough treatment of that subject.

Lands Available for Leasing:[127] With certain special exceptions, lands withdrawn by Executive Order for use as military bases, bombing ranges, and similar purposes; lands within other classified areas; lands within naval-petroleum and oil-shale reserves; Indian lands; lands in incorporated cities, towns, and villages; submerged lands; and lands in national parks and monuments are unavailable for leasing under the Act. Other federal lands not previously disposed of under any other public-land laws are available for leasing. Public domain lands administered by agencies other than the Interior Department can only be leased after consultation with the agency.[128]

Qualifications to Lease: Leases may be held only by adult, native-born, or naturalized citizens of the United States, domestic corporations and associations of citizens. [129] A US corporation whose shares are owned in whole or in part by aliens can hold leases if their country grants similar or like privileges to citizens or corporations of this country. [130] The regulations require that corporations reveal the names and citizenship of shareholders owning or controlling more than 10% of its stock.[131] Associations of adult US citizens can hold leases.[132] A partnership as such cannot take and hold leases, but an application submitted by a partnership is considered and treated as an application or offer by an association. [133] Municipalities are eligible to lease coal, oil, oil shale, or gas. [134]

Procedures: Authority to issue prospecting permits and leases has been delegated to the land-office managers of the BLM. Applications for leases or prospecting permits are filed in the land office having jurisdiction. Detailed and precise information must be contained on applications. A person not familiar with procedures should obtain forms from the land office and should consult with land-office personnel or a lawyer regarding procedures.

Acreage Limitations: [135] To prevent excess holdings of mineral lands under lease, limitations have been imposed on the total acreage that can be held by a person, a business association, or a corporation under the Leasing Act. The same acreage limitations apply to leases issued under the Acquired Lands Act, but acreage held under the two acts is considered separately.[136]

A person, association, or corporation may not hold in any one state more than the following acreages under lease or permit: coal, 46,080 acres (18,650 ha) per state, 100,000 acres (40,500 ha) total; sodium, 5120 acres (2070 ha) per state; phosphate, 20,480 acres (8290 ha) total; sulfur, 3 permits or leases per state, 640 acres per lease; potassium, 52,100 acres (21,050 ha) under permits and 25,600 acres (10,360 ha) total; oil shale, 5120 acres (2070 ha) per lease, one lease maximum; gilsonite, 7680 acres (3100 ha) per state; and tar sands, 246,080 acres (99,590 ha) per state.

Both direct and indirect holdings are included in computing acreage holdings. A person holding indirectly as a member of an association or corporation will be charged with his proportionate part of the corporation's or association's accountable acreage, unless he holds less than 10% of the stock or other instruments of ownership or control. [137] A party owning an undivided interest is chargeable with his proportionate part of total lease and permit acreage. An assignee remains chargeable with acreage pending approval of an assignment. [138] Acreage held, owned, or controlled in common by two or more parties may not exceed in the aggregate an amount equivalent to the maximum number of acres permitted for one lessee or permittee.[139] If a contract is entered into for the development and operation of leased land, both parties are charged with their proportionate interests in the total acreage.

The chargeability of options is discussed specifically in reference to oil and gas leases,[140] but the statutes and regulations are not clear as to whether the rules regarding options apply to leases for minerals other than oil and gas. Since options generally are described as "interests" constituting chargeable acreage holdings, [141] it is likely that the same rules would apply. Thus option acreage is charged to both the optionor and the optionee until exercised, whereupon the charge is only to the optionee. If an optionee holds an option to only a portion of the optionor's holdings, he nevertheless is chargeable with the full acreage if he has the power under the option to prevent further alienation of the balance of the optionor's interest during the option period or to otherwise effectively tie up the optionor's interest.

Interests creating acreage chargeability also include record title interests, overriding royalties, working interests, operating rights, any agreement covering such interests, and any claim or any prospective advantage or benefit from a lease, and any participation or share in production or profits which may derive from the lease.[142]

If it is determined that a party's holdings exceed the applicable acreage limitation, an application for or assignment of an amount in excess will be denied, and any interest held in violation of the acreage limitations may be cancelled or forfeited.[143]

Prospecting Permits. The Secretary of the Interior is authorized to issue prospecting permits to unclaimed and undeveloped lands for phosphate, sodium, sulfur, potassium, and gilsonite. A permit gives the holder the exclusive right to prospect on and explore the lands involved. They are issued to qualified applicants on the basis of priority in time of filing for a term of two years. With the exception of sodium and sulfur, permits can be extended an additional two years (four years in the case of phosphate). Permittees may not remove commercial amounts of minerals.

Preference Right Leases: A permittee who makes a discovery of a valuable deposit of minerals is entitled to a preference-right lease of all or part of the lands in the permit in reasonably compact form. The hard-rock prudent-person discovery test has been adopted in the regulations as the determinant of whether there has been a discovery of a valuable deposit.[144] Before a sodium, sulfur, or potassium preference right lease is issued, the land must be shown to be more valuable by reason of the presence of these minerals than it is for other uses.[145]

Competitive Leases: Lands available for leasing where prospecting and exploratory work is unnecessary to determine the existence or workability of a deposit are leased through competitive sale. Sales are arranged upon receipt of a proper application from a qualified party. After notice, sales are by sealed bids or at public auction, which may be preceded by sealed bids.[146]

Areas: Individual phosphate, sodium, and potassium leases and permits cannot exceed 2560 acres (1035 ha). No sulfur lease or permit can exceed 640 acres (260 ha). Leasing tracts for coal are of such size as the Secretary of the Interior finds appropriate and in the public interest.[147] Lands in a lease or permit must be in a reasonably compact form.[148]

Royalties and Rentals: By statute, royalties cannot be less than 12½% of the value of the coal removed from a surface mine, but they can vary as determined by the Secretary on coal removed by underground mining.[149] Current regulations provide for an 8% royalty on coal removed from underground mines.[150] Rentals are not less than $3.00/acre ($7.50/ha) per year.[151] Overriding royalties on coal leases cannot exceed 50% of the federal royalty except under certain special circumstances.[152]

The yearly rental for phosphate leases may not be less than 25¢/acre (62$/ha) for the first year, 50¢/acre ($1.25/ha) for the second and third, and $l/acre ($2.50/ha) for each year thereafter.[153] Royalties are fixed by the Secretary of Interior in advance of offering the lease, at not less than 5% of the gross value of the output of phosphate.[154]

Each lease for minerals other than coal and hard-rock minerals will contain appropriate conditions fixing a minimum annual production of the lease deposits beginning with the sixth year from date of the lease or payment of a minimum royalty of $3.00/acre ($7.50/ha) per year in lieu thereof.[155]

Sodium and potassium royalties are set by the Secretary at an amount not less than 2% of the quantity or gross value of the output at the point of shipment to market. Rental payable in advance is set at 25¢/acre (62¢/ha) for the first calendar year or fraction thereof; 50¢/acre ($1.25/ha) for the second, third, fourth, and fifth, and $l/acre ($2.50/ha) per annum thereafter during the period of the lease.[156]

A yearly rental of 50¢/acre ($1.25/ha) or fraction thereof is prescribed for sulfur leases. A royalty of 5% of the quantity or gross value of the output of sulfur at the point of shipment to market is provided for in preference right leases.[157]

Duration of Leases: Both preference right and competitive leases for phosphate, potassium, and gilsonite are issued for indeterminate periods, subject to readjustment on renewal at the end of the first 20-year period.[158] The holder of a sodium or a sulfur lease has a preferential right to renew for successive periods of 10 years.[159]

Bonds: A surety or personal bond is required prior to the issuance of a prospecting permit or lease. The amount of the bond is set on a case-by-case basis subject to minimums set in the regulations.[160]

Special Provisions Related to Coal: A complex procedure is followed before coal leases are issued. Regional coal teams comprising representatives of federal, state, and local agencies make recommendations for regional coal-leasing targets and participate in lease tract delineation, ranking, and scheduling.[161] All new coal leases are issued by competitive bidding either after a regional lease tract designation process in completed or after receipt and review of applications submitted by private parties under special circumstances. A lease sale may not be held unless the lands containing the coal deposits have been included in a comprehensive land-use plan or land-use analysis, and unless the sale is compatible with and subject to any relevant stipulations, guidelines, and standards set out in that plan or analysis.[162] After areas for potential leasing are identified, numerous reviews and consultations with governmental officials and others are held before tracts are approved for leasing under the regional tract designation process.[163] Leasing or application may be approved if the federal coal is needed to maintain an existing mining operation, to supply coal for contracts signed prior to July 19, 1979, or to prevent bypassing of federal coal.[164]

For coal leases issued after Aug. 4, 1976, diligent development, defined as the production of 1% of the removable coal reserves in a lease, must be achieved by the end of the 10th lease year. Leases issued prior to that date are burdened with a similar requirement where they are readjusted. If the leases are included in a *logical mining unit* (LMU), a unit compromising properties logically developed or part of a single mining operation, the 10-year period begins to run (1) from the effective date of the LMU, if the LMU contains a federal coal lease issued prior to LMU approval, but not readjusted after Aug. 4, 1976, and prior to LMU approval, (a "non-readjusted pre-1976 lease"); or (2) from the effective date of the most recent federal lease issuance or readjustment prior to LMU approval, for an LMU that does not contain a nonreadjusted pre-1976 lease.[165] As to an LMU, the quantity of coal that must be mined within the 10-year period is 1% of the estimated federal and nonfederal recoverable coal reserves in the LMU. Once production is begun, it must be continued through the production of 1% of the recoverable coal reserves in the lease or land during each of the first two years of production and a rolling average of that amount over continuous three-year periods.[166] The authorized officer may suspend the continuous operation requirement in certain circumstances and may also upon application suspend the requirement upon the payment of advance royalty in lieu thereof.[167]

3.2.2.3 Mineral Deposits Within Acquired Lands

Leasing Act Minerals: In 1947, Congress enacted the Mineral Leasing Act for Acquired Lands.[168] Acquired lands have been defined as (1) those in federal ownership that have never been "public domain," and (2) those lands that once were public lands but have been disposed of and subsequently reacquired by the United States by purchase, condemnation, or donation.[169] The Act authorized and established procedures for leasing deposits of coal, phosphate, oil, oil shale, gas, sodium, potassium, and sulfur on lands acquired by the United States, except those acquired for the development of mineral deposits or reported as surplus pursuant to the provisions of the Surplus Property Act of 1944, or lands within incorporated cities, towns, and villages, national parks or monuments, lands set apart for military or naval purposes, or tidelands, or submerged lands.[170] Acquired lands are not subject to the Mining Location Law.

Leases on acquired lands are issued under the same conditions as contained in the Mineral Leasing Act of 1920. The head of the executive department, independent establishment, or instrumentality having jurisdiction over the lands containing such deposits must consent to the lease, and he or she can prescribe conditions in the lease felt necessary to ensure the adequate utilization of the lands for the primary purpose for which they have been acquired or are being administered.[171]

Nonleasing Act Minerals: Section 402 of Reorganization Plan No. 3, 1946,[172] transferred the functions of the Secretary of Agriculture relative to leasing and other disposals of nonleasable minerals in certain acquired lands to the Secretary of Interior. The Act of Sep. 1, 1949, authorized the Secretary to lease non-leasing act minerals in certain lands added to Shasta National Forest. [173] The authority provided by the Acts has been broadly construed as being applicable as well to nonleasing-act minerals in all lands acquired by agencies of the DOI.[174] Pursuant to this authority, and other authority related to other designated areas, [175] the Secretary has promulgated regulations establishing procedures for leasing minerals not subject to the Mineral Leasing Act of 1920 in the subject acquired lands. [176]

Nonleasable minerals in acquired lands subject to the jurisdiction of federal agencies other than the Interior or Agriculture departments are leasable only as specifically authorized by statute.

Prospecting permits including not more than 2560 acres (1030 ha) are issued to the first qualified applicant for a period of two years, and may be extended for a period not to exceed four years. [177] Upon discovery of a valuable deposit of minerals, the permittee is entitled to a preference-right lease.[178]

No applicant may hold more than 20,480 acres (8290 ha) under prospecting permit and lease, of which not more than 10,240 acres (4140 ha) may be held under lease. The Secretary may authorize an additional 10,240 acres (4140 ha) upon an adequate showing of need. A lessee cannot hold in excess of 10,240 acres (4140 ha) of leased land for the mining of any dominant single mineral, nor shall any person at any one time hold more than 20,480 acres (8290 ha) under permit and lease in any one state.[179]

Except for preference right leases, lands containing valuable mineral deposits will be leased only to the qualified person offering the highest bonus in competitive bidding. Rentals are $l.00/acre ($2.50/ha) per year. Other terms and conditions of the leases, including the royalty rates, are established on an individual-case basis. [180] The lease will be issued for a period not exceeding 20 years, with right of renewal for successive periods, not exceeding 10 years each, at the discretion of the Secretary.[181]

3.2.2.4 Multiple Mineral Development Act of 1954—Public Law 585

Prior to Aug. 13, 1954, mining claims could not be located on land subject to prior dispositions under the mineral leasing laws. Public Law 585, commonly referred to as the Multiple Mineral Development Act, which became effective on that date, authorized the location of mining claims on lands that at the time of location are included in a permit or lease issued under the mineral leasing laws or an application for permit or lease and on lands known to be valuable for leasable minerals. [182] Conflicts may still exist between mining claims and leases in existence prior to that time. [183]

The Act attempts to provide for multiple use of land subject to both mining claims and mineral leases. A holder of a mining claim must conduct his operations, so far as reasonably practicable, in a manner that will avoid damaging any known deposit of any leasing-act mineral, and in such a manner as will not endanger or materially interfere with any existing surface or underground improvements, working or facilities that may have been made for the purpose of leasing-act operations.[184] Operations conducted under a lease on land covered by an unpatented mining claim or mill site shall likewise avoid damage to any known deposit or any mineral not reserved from the mining claim or mill site, and to any existing mining facilities.

If a leaseholder or mining claimant feels that his operations cannot be carried on without endangering or materially interfering with another operation, petition can be made to a court. If the court finds that one of the operations cannot be conducted without such interference, it can permit the operation to continue upon payment of fair compensation for the injury or damage.[185]

The Act also provides for a determination of rights to leasable minerals under preexisting mining claims.[186] A Mineral-Leasing-Act applicant, offeror, permittee, or lessee can obtain a determination of validity of claims to leasable minerals, asserted by the owners of unpatented mining claims located prior to Aug. 13, 1954. After proper service of notice, the mining claimant's rights are determined at a hearing.

3.2.2.5 Undersea Resources

The threshold question that must be answered before rights to undersea resources can be acquired is whether the area of interest is under state or federal jurisdiction. The Submerged Lands Act of 1953, the result of conflicting claims by state and federal governments to the mineral wealth of offshore lands, gave the coastal states ownership of all lands lying within three geographical miles (4.84-km) of their coastlines. [187] Historic boundaries to the extent of three marine leagues (9 miles or 14.5 km) were permitted in the Gulf of Mexico. Only Texas and Florida have been able to take advantage of the three-league boundary provision. [188]

The seaward limits of state jurisdiction are to be measured from the "coast line," defined as the "line of ordinary low water along that portion of the coast which is in direct contact with the open sea and the line marking the seaward limit of inland waters."[189] Since no definition of the "the seaward limit of inland waters" was given, it was left to the courts to define the baseline with more certainty. In 1965, the United States Supreme Court adopted the boundary definitions set forth in the 1958 Convention on the Territorial Sea and the Contiguous Zone.[190] Since that time, there has been litigation in Alaska, California, Louisiana, the Atlantic Coast states, and elsewhere regarding specific boundaries with respect to islands, coves, bays, and the like.[191]

Thus lands from the point of mean high tide to the three-mile (4.84-km) limit (three-league limit in the Gulf of Mexico) are subject to the jurisdiction of the coastal states, and reference must be made to state statutory materials to determine the method by which minerals in such lands can be acquired.

The Outer Continental Shelf Lands Act of 1953, a companion measure to the Submerged Lands Act, authorized the Secretary of the Interior to lease offshore lands owned by the federal government for the purpose of mineral development.[192] The Secretary is authorized to grant competitive oil, gas, sulfur, and other mineral leases covering any area of the outer continental shelf owned by the United States and not already under lease or withdrawn. The outer continental shelf is defined in the Act as the subsoil and seabed of that part of the continental shelf that belongs to the United States and is subject to its jurisdiction, control, and power of disposition, which, of course, excludes the coastal lands owned by the states. Thus the inland boundary of the federal offshore land subject to the Act is governed by state ownership, while the seaward boundary is a matter of international law.

The seaward boundary, as presently defined, was established at the 1958 United Nations Conference on the Law of the Sea at Geneva, Switzerland, and was subsequently ratified by the United States. It defines the continental shelf as "the seabed and subsoil of the submarine areas adjacent to the coast [and islands] but outside the area of the territorial sea, to a depth of 200 m (660 ft) or, beyond that limit, to where the depth of superjacent waters admits of the exploitation of the natural resources of the said areas."[193] Thus the boundary varies according to the limit to which exploitation of undersea resources can be achieved.

This, of course, is a matter of technology, commodity prices, and world economics.

It should be noted that the legal definition of the continental shelf has little, if any, relationship to the geologic definition. The legal definition may include areas that would be known to geologists as continental slope, continental rise, and continental borderlands. In any event, the definition covers a vast area of land. As applied to the United States, the legal definition of continental shelf, using the 200-m (660-ft) cutoff, encompasses some 850,000 mi^2 (1,360,000 km^2), an area equal to roughly one-fourth of the United States.[194]

Pursuant to authority given by the Act, the Secretary has promulgated regulations providing for the issuance of oil and gas and sulfur leases after competitive bidding. These are contained in Part 200 of Title 30, *Code of Federal Regulations,* Part 200.

Sulfur leases are issued in much the same manner as oil and gas leases. Leases are awarded on the basis of sealed competitive bonus bids. The size of the lease is determined by the Secretary, and the term is for not more than 10 years and so long thereafter as sulfur may be produced from the area in paying quantities, or drilling, well reworking, plant construction, or other operations for the production of sulfur are being carried out. Royalties and rentals are determined by the Secretary, but the royalty can be no less than 5% of the gross production value.[195]

The Secretary is also authorized to grant leases on the outer continental shelf to qualified persons offering the highest cash bonus bid for any mineral other than oil, gas, and sulfur. Any person may submit a request to the director of the Minerals Management Service that such offshore minerals as gold, chromium, tin, titanium, salt, phosphate, and sand and gravel be offered for lease. The Secretary may also voluntarily offer such leases. The primary lease term is 10 years for sand and gravel and not less than 20 years for all other minerals. The lease can be continued thereafter for as long as production continues. Leases are subject to such royalty, rental, acreage, and other terms and conditions as the Secretary may prescribe.[196]

Finally, the Act provides that any person authorized by the Secretary may conduct geological and geophysical exploration in the outer continental shelf so long as it does not interfere with operations under an existing lease and is not unduly harmful to aquatic life.[197]

For years, the nations of the world have struggled over how to regulate appropriation of the deep seabed and the minerals contained therein. These minerals represent a vast resource, particularly for the mineral needs of the future (see Chapter 22.8, Marine Mining). For example, 10% of the entire floor of the Pacific Ocean is thought to be covered by manganese nodules, potato-sized oval rocks generally found at depths between 10,560 and 19,800 ft (3200 and 6000 m). These nodules contain over 20 elements, with an average metal content of 24.4% manganese, 14.0% iron, 1.9% nickel, 0.5% copper, and 0.35% cobalt. These strategic metals are particularly important to the United States, which imports almost all of its manganese and cobalt, most of its nickel, and much of its copper requirements.[198] The cost, however, to develop a single mine site to exploit these deep-sea minerals has been estimated at $2.5 billion.[199]

Since the 1960s, the United Nations has attempted to enact an international Law of the Sea Treaty, based on the principle that the mineral resources of the deep seabed are the common heritage of mankind. The treaty would allocate jurisdiction of deep seabed mineral resources to the coastal nations that would develop the minerals in accordance with treaty standards and pay over to an international fund, for assistance to the less-developed countries, a portion of the revenues derived from mineral development. To date, a vast majority of countries has adopted and signed the Law of the Sea Treaty, but the United States, for various reasons unrelated to mining, has not.[200] Instead, the United States enacted the Deep Seabed Hard Mineral Resources Act of 1980.[201]

The Act is designed as an interim measure to allow deep seabed exploration and mining until such time as an international Law of the Sea Treaty is ratified by the United States. If such a treaty is ratified, the Act will be superseded; if not, the Act will permit regulated deep seabed mining on a permanent basis. By its terms the Act pertains to the "deep seabed," which is defined as the seabed (and the underlying 33 ft or 10 m of subsoil) lying outside the "continental shelf' as defined earlier under the Outer Continental Shelf Lands Act.[202] The Act prohibits exploration for or commercial recovery of deep seabed minerals unless licensed to do so by the federal government or by a foreign government that grants reciprocal rights to United States citizens under a similar regulatory scheme. This prohibition does not apply to scientific research, mapping, random sampling, or the design, construction, or testing of exploration or commercial recovery equipment and facilities.[203]

Exploration licenses and commercial recovery permits may be issued by the Administrator of the National Oceanic and Atmospheric Administration, the agency charged with regulating deep seabed mining. Subject to environmental considerations, the applicant chooses the size and location of the area for exploration or mining. Exploration licenses have a primary term of 10 years, with discretionary extensions.[204] Detailed procedures and rules regarding exploration licenses are set forth in administrative regulations.[205] The application fee for an exploration license is presently $100,000.[206]

Any person holding a valid exploration license can apply to the Administrator for a commercial recovery permit covering all or part of the exploration area. A commercial permit authorizes the holder to recover, own, transport, use, and sell deep seabed minerals.[207] In order to allow a time period for ratification of a suitable international treaty, the 1980 Act prohibited the issuance of any commercial recovery permits before Jan. 1, 1988. Commercial permits have a term of 20 years and so long thereafter as minerals are recovered in commercial quantities.[208] Detailed procedures and rules regarding commercial permits and operations have been set forth in administrative regulations.[209] The present fee for a commercial recovery permit is $100,000.[210]

Applicants for an exploration license must file a detailed exploration plan, while applicants for a commercial permit must file a recovery plan describing the technology and environmental protection measures to be employed. All applicants must show they have the requisite financial responsibility and technical capability to operate according to the submitted plan. All leases must include requirements to assure diligent development, including a requirement that commercial recovery be underway within 10 years from the permit date unless an extension is granted by the Administrator for good cause.[211]

The Act contains provisions designed to protect deep-sea miners' investments should the United States ratify a treaty having terms inconsistent with the Act.[212] But the Act expressly disclaims any financial responsibility by the government in the event an investment is impaired through the ratification of such a treaty.[213] These facts, along with the extremely high cost of deep-sea operations, political instability in many parts of the world, low-metal prices, and, in the absence of a treaty, the legal uncertainty of mining rights in international waters, indicate that deep seabed mining is not likely to occur soon.[214] There are also concerns over how to conduct large-scale seabed mining without wreaking havoc on the economies of the land-based producers of the same metals.[215] The ability to conduct deep seabed mining has been proven from a technological standpoint.

Sooner or later, such mining will surely occur, with the first mines likely to be located beneath the deep waters of the north Pacific between Hawaii and the west coast of the United States.[216] Most authorities agree, however, that despite earlier expectations, deep seabed mining will not likely occur before the next century.[217]

3.2.2.5 Materials Act of 1947

The Materials Act of 1947 authorizes the Secretaries of Interior and Agriculture to dispose of mineral materials, specifically including, but not limited to, common varieties of sand, stone, gravel, pumice, pumicite, cinders, clay, and petrified wood, in lands under their respective jurisdictions, if such disposal is not otherwise authorized by law.[218] The Act also authorizes disposal of minerals found on lands which have been withdrawn in aid of the function of a federal department or agency other than the DOI, or a state, county, municipality, water district, or other local-government subdivision or agency, with the consent of such federal department or agency or such state or local government unit.[219] Regulations promulgated by the Secretary of Interior under the Act are found in Title 43, *Code of Federal Regulations,* Group 3600 (rev. June 13, 1970); and by the Secretary of Agriculture in Title 36, *Code of Federal Regulations,* Secs. 251.4 and 251.4a.

The Act does not authorize a Secretary to sell minerals found on lands in any national park or national monument or on lands held for the use or benefit of Indians.[220] Disposal from BLM lands cannot be made from lands on which there are valid existing mining claims.[221] Sales from national forest lands can be made from lands subject to a claim located before and after July 23, 1955, if the disposal will not materially interfere with the rights of the mining claimant.[222]

Materials can be sold upon the request of any interested party or upon request of an authorized officer. Mineral materials not exceeding 100,000 yd^3 (76,460 m^3), or weight equivalents can be acquired by negotiated sale with the authorized officer, if it is impracticable to obtain competition, and if a negotiated sale is in the public interest.[223] If the materials are to be used in connection with the development of federal lands or in connection with a public-works improvement program on behalf of the federal, state, or local government agency, and the public exigency will not permit the delay incident to advertising, negotiated sales can be made for a sum not exceeding $10,000.[224] Sales of up to 200,000 tpy (180 kt/a) may be made to lessees under a US-issued mineral 1ease.[225] Otherwise, the sale is by competitive bidding.

The materials to be sold are designated in the notice of competitive bidding, which must be advertised in a local newspaper and in the office where the bids are to be submitted. The materials are appraised, and the sale will not be complete unless the bid equals or exceeds the appraised value.

All contracts are subject to the continuing rights of the United States to use the surface and to issue leases, permits, and licenses involving the use and occupancy of the surface, provided that such subsequently authorized use shall not endanger or materially interfere with the purchaser's production or removal of the materials under contract. Performance and reclamation bonds must be provided, and lands mined under the Materials Sales Act must be restored after completion of the mining operation.[226]

Deposits of the listed minerals having some property giving them distinct and special value remain locatable under the mining laws. It is extremely difficult to determine whether a particular deposit of minerals has those characteristics. If it does, the deposit technically is not subject to disposal under the provisions of the Materials Act. Nevertheless, because of the BLM's policy of interpreting the distinct and special-value exception strictly, more security will be gained in most instances by acquiring the minerals under the Materials Act rather than under the Mining Location Law.[227] Certain materials not considered to be common varieties because of their distinct economic or commercial value are block pumice, cement grade limestone, metallurgical and chemical grade limestone, and gypsum.[228]

A mining claimant risks prosecution for trespass and is liable for damages to the United States if he removes materials from a claim later held to be invalid. To be weighed against these considerations, however, is the possibility that a person who discovers a deposit of substantial value might not be the high bidder at a competitive sale.

3.2.2.6 Indian Lands

If, during a preliminary land-status check, it is determined that some of the lands of interest are Indian lands, great care should be taken to obtain as much information as possible regarding the specific status of the lands so designated. The superintendent of the particular Indian agency having jurisdiction has custody of pertinent land records. These include all leases, deeds, patents, assignments, and related documents. Duplicates of all instruments affecting the title to Indian lands should be available at the Bureau of Indian Affairs (BIA) Office, Washington, DC.[229]

Lands which are classified as Indian lands by the US government fall generally into one of two categories: tribal lands and allotted lands.

Allotted lands are those allotted to individual tribal members under the general Allotment Act of 1887.[230] Pursuant to the Act, certificates of allotment containing restrictions against alienation were given to individual Indians. These gave the holder the right to exclusive possession and equitable title to the land.[231] Title to allotted lands was to be held in trust for the benefit of the allottee by the United States for a period of 25 years. This period has been extended, however, and much of the allotted lands still are held in trust. Because of the trust arrangements, any dealings with regard to allotted lands must be carried on with both the allottee and the BIA. Allotments were no longer made after passage of the Indian Reorganization Act of June 18, 1934.[232]

Tribal lands are defined as those within the boundaries of a reservation that have not been allotted and in which no vested rights exist.[233] They are administered for the use and benefit of all Indians constituting the tribe. Dealings regarding tribal lands must be carried on with both the tribe and the BIA.

Indian reservations are parts of the public domain that have been set aside by proper authority for use and occupation by a group of Indians.[234] The boundaries were determined by treaty, executive order, or act of Congress. Hence title is held by the United States, and the Indians have the right of use and occupancy. Governing control rests in the tribal councils, subject to much supervision by the BIA.

Indian tribes have periodically claimed aboriginal property rights to lands historically occupied by the tribes. In the case of *Tee-Hit-Ton Indians v. US,*[235] the Supreme Court held that original or aboriginal Indian title can be extinguished at the will of Congress without compensation, provided no recognition has previously been given by the federal government to such right of occupancy.[236] The tribes enjoy full use and occupancy of such lands. These rights are enforceable against all but the federal government.[237]

Neither the general mining laws nor the federal leasing laws are applicable to reservations.[238] Hence, unless the United States reserved mineral rights in the grant of the reservation, special procedures must be followed to obtain mineral rights. If minerals were reserved by the United States, they are subject to acquisition under the general mining laws.[239]

Legislation enacted by Congress in 1934 and 1938 greatly simplified the law relating to acquisition of mineral rights on Indian lands. Section 17 of Indian Reorganization Act of 1934[240] provided that the Secretary of Interior could issue a charter of incorporation to any tribe that made application, which charter could convey to the tribe comprehensive powers of management and disposition of its property. After a trial period, chartered tribes could lease lands for mineral purposes, subject to Secretary approval. The issuance of minerals by chartered tribes is governed by provisions of the charter.

Congress subsequently enacted the Act of May 11, 1938,[241] which permitted the leasing of unallotted land for mining purposes by authority of the tribal council or other authorized spokesmen for the Indians with Secretary of the Interior approval. The Act excepts from its coverage the Crow Reservation in Montana, the ceded lands of the Shoshone Reservation in Wyoming, the Osage Reservation in Oklahoma, and the coal and asphalt lands of the Choctaw and Chickasaw tribes in Oklahoma.

Authorization for the leasing of tribal lands must come from the tribal council or other authorized representative of the tribe. However, the local superintendent of the BIA has the responsibility for handling formal procedures. Regulations governing the leasing of minerals in Indian lands are contained in the *Code of Federal Regulations.*[242] Leases may be issued not to exceed 10 years and as long thereafter as minerals are produced in paying quantities.[243] Leases for oil and gas must be offered for sale at a public auction or upon sealed bids, but leases for other minerals can be negotiated and approved without advertisement and sale.[244]

The Superintendent of Indian Affairs may, upon the consent of tribal authorities, issue prospecting permits for minerals other than oil and gas. These permits, however, do not give the permittee any preference right to a lease, unless specifically provided.[245]

Leasing of allotted lands was authorized by the Act of Mar. 3, 1909.[246] Under this Act, the allottee can lease the land allotted to him for mining purposes subject to approval of the Secretary of the Interior. Rules and regulations implemented pursuant to the Act of Mar. 3, 1909, are found in the *Code of Federal Regulations.*[247]

Leases on allotted lands for minerals other than oil and gas can be negotiated. Permission must first be obtained from the superintendent to negotiate with the allottee, or his heirs or devisees, as the case may be. The superintendent then decides whether it is in the best interests of the tribe and the allottee to negotiate privately. If his conclusion is negative, competitive bidding procedures will be followed. Otherwise, contact then can be made with the allottee with whom negotiations are carried on. The agreed terms are subject to approval by the superintendent and to pertinent regulations. Leases for oil and gas must be offered for sale at public auction.

Congress has enacted a series of statutes, each applicable only to a single tribe or tribal group, providing for a simultaneous termination of federal supervision over the trust and restricted property, both of the tribe and its individual members, and cessation of the federal services theretofore furnished to such Indians. Generally, the effect of this legislation is to give the tribe complete responsibility for the sale or encumbrance of all property, real and personal, held in trust by the United States for the tribe. Some of the statutes call for the transfer of title to a trustee, who can then dispose of such property and distribute the proceeds among the members of the tribe.[248]

Congress has recently enacted legislation that specifically authorizes the tribes to enter, with the approval of the Secretary of Interior, joint venture or operating type agreements.[249] The significance of this act, known as the Indian Mineral Development Act of 1982, lies in the fact that mineral developers may now use two separate and independent alternatives for development of Indian land. They can deal with the BIA using the traditional leasing methods described previously or they may enter into a "joint venture, operating, production sharing, service, managerial, lease, or other agreement" directly with the Indian tribe, subject to BIA approva1.[250]

When approving or disapproving a privately negotiated agreement for mineral development of Indian lands, the Secretary of Interior is required by the Act to determine whether the agreement is in the best interest of the Indian tribe. In making this determination, the Secretary must consider the potential economic return to the tribe; the potential environmental, social and cultural effects on the tribe; and the provisions for resolving disputes that may arise between the parties to the agreement.[251] According to the US 9th Circuit Court of Appeals, a tribe may rescind an agreement at any time prior to secretarial approval.[252] Therefore, all parties to a mineral development agreement should be aware that there is no agreement until Secretarial approval is received.

3.2.2.7 Alaska Native Lands

Special laws govern the acquisition of mineral rights from native groups in Alaska. Most of the lands owned by the Alaska Natives were granted to them as shareholders in Native corporations under the authority of the Alaska Native Claims Settlement Act (ANCSA).[253] Unlike most other lands reserved or granted to Native Americans, the lands conveyed to the Native Corporations pursuant to ANCSA are not subject to restrictions against alienation. The decision of a Native corporation to enter into an exploration agreement or to lease or sell any of its lands does not require the review or approval of the DOI. These lands are, in essence, private lands over which the Secretary of the Interior exercises no control.

Four different types of Native corporations were created to receive lands pursuant to ANCSA. They are regional corporations, village corporations, group corporations, and urban corporations. Village, group, and urban corporations receive only the surface estate in lands conveyed to them. The subsurface estate in those lands is acquired by the regional corporation for the region in which the village, group, or urban corporation is located.[254] Regional corporations acquire both the surface and the subsurface estates to lands conveyed to them.[255] Where the regional corporations are precluded from acquiring the subsurface estates to corporation lands, they are entitled to acquire the subsurface estate to certain in lieu lands, the surface owner of which may be the federal government, the state government, or some third party.[256]

Prior to the enactment of ANCSA, a significant number of Native reserves existed in Alaska. Pursuant to ANCSA, village corporations for villages located within these former reserves were granted the option to acquire lands within their reserve.[257] These village corporations are granted surface and subsurface rights to the lands within their former reserves.[258]

Because Native corporations exercise complete freedom to enter into agreements respecting their lands, an exploration and development agreement between a mining company and a Native corporation can theoretically be structured as any other agreement with a private landowner. Therefore, the opportunity exists for a mining company to obtain exploration and development rights to Native lands in Alaska, unencumbered to a large extent by the governmental restrictions attached to other Native lands.

3.2.2.8 Conflict with Surface Rights

During the preliminary land-status check, it should be determined, if possible, whether there has been a severance of the surface and the mineral estates of the subject property. Although private lands can be affected by severances, they most often occur when the states or the federal government dispose of the surface and retain the minerals. In the event a severance has been made, the rights of the surface owner must be considered before the lands are entered for minerals exploration and development. Where the minerals have been reserved by the United States, the rights of the surface owner are governed largely by statute. Thus, whenever a land status check reveals such a severance, further inquiry should be made to determine the statutory authority under which it occurred.

The Stockraising Homestead Act of 1916, which is the most common governing statute, provides for nonmineral entry and patent of stock-raising lands, provided that the patent contains a reservation to the United States of all minerals in said lands and the right to prospect for, mine, and remove the same.[259] That Act also establishes the rights of others to enter upon the potential land to develop the minerals.[260] Entry for prospecting purposes or to locate claims can be made without obtaining prior approval from the surface owner.[261] The right is specifically given to enter the land and prospect for coal and other minerals, providing that the prospector does not injure, damage, or destroy the permanent improvements of the stock-raising homestead entryman or patentee. The mineral prospector must pay for any damages to crops that occur as a result of his prospecting activities. To the extent permitted by the confidential nature of the prospecting activities, it is advisable to make an agreement with the surface owner as soon as possible. His interest in the property and improvements thereon should always be respected.[262]

Once a party acquires from the United States the coal or other mineral deposits in any such land, or the right to mine and remove the same, he is given the right to reenter and occupy so much land as may be required for mining. Before such activities are undertaken, however, the miner must (1) secure written consent or waiver of the homestead entryman or patentee, (2) make an agreement for payment of damages to crops or other tangible improvements with the entryman or owner, or (3) execute a bond or undertaking to the United States for the benefit of the homestead entryman or owner.[263] Any person who prospects for, mines, or removes by strip or open-pit mining methods, any minerals from any land included in a stock-raising or other homestead entry or patent must also compensate the entryman for any damage caused to the value of the land for grazing.[264]

The DOI has concluded that common varieties of sand, stone, pumice, pumicite, and cinders in lands patented under the Stockraising Homestead Act are subject to the Materials Disposal Act of 1947, with the exception of sand, gravel, and ordinary rock, which have no value separate from the soil itself.[265]

Multiple Surface Use Act of 1955: In 1955, Congress enacted the Multiple Surface Use Act[266] to curtail nonmining use of the surface of mining claims. The Act provides that any mining claim located after July 23, 1955, "shall not be used, prior to issuance of patent, for any purposes other than prospecting, mining or processing operations and uses reasonably incident thereto," and that rights under any mining claim thereafter located will be subject, prior to the issuance of patent therefore, "to the right of the United States to manage and dispose of the vegetative surface resources thereof and to manage other surface resources thereof (except mineral deposits subject to location under the mining laws of the United States)."[267]

The Act also provides that any such mining claims will be "subject, prior to issuance of patent therefore, to the right of the United States to use so much of the surface as may be necessary for such purposes or for access to adjacent land. " Any use of the surface of the mining claim by the United States, however, must not "endanger or materially interfere with prospecting, mining, or processing operations or uses reasonably incident thereto."[268] A mining claimant is authorized to cut and use timber from the claim and to use sand and gravel for mining purposes.[269]

As a result of the legislation, the owner of mining claims located subsequent to July 23, 1955, is entitled to use the surface only as necessary for his operation, and his claim is subject to surface-management activities of the federal government until patent.

A procedure is established in the Act for determination of surface rights on claims located before July 23, 1955.[270] After notice and response, a hearing is held to determine the validity and effectiveness of the claimant's interest in the mining claim. At that hearing, the claim can be contested on various grounds, including lack of discovery, but the effect of a determination adverse to the claimholder is simply to restrict his surface rights as specified in the statute. The claim is not invalidated.

Holders of claims located prior to July 23, 1955, although not necessarily subject to surface management by government agencies, cannot use the surface for nonmining purposes.[271]

3.2.3 STATE LANDS

States have acquired ownership of lands within their boundaries by various means, which are important because they may impact a particular state's ability to grant mineral rights, procedures to be followed in obtaining such grants, and conditions and limitations to them.[272] Most state lands that are of interest to mineral developers were acquired by grants from the United States. Other important categories of state lands are those comprising the beds of navigable streams and offshore submerged lands three geographical miles (4.8 km) seaward from the ordinary low waterline. Large areas in many of the western states are state owned through grants of specific numbered sections of the public land survey.

Often an examination of records in a state land office occurs by reason of notations of BLM records of transfers by the United States to the state. The state records may show that the state in turn conveyed ownership to a private citizen. Such conveyances might have reserved minerals in the state.

State land office records, of course, vary from state to state, but many have plats showing state-owned lands, including lands in which the state owns minerals only. If a particular tract of interest has passed from state ownership, the document by which it was conveyed and the statutory authority for the conveyance should be reviewed to determine the nature of the estate that passed and any reserved rights in the state.

Authority to grant mineral rights in state lands stems from state constitutions and statutes.[273] To determine the procedures that govern the granting of mineral rights, inquiry should be made of the agency that administers state lands. Most states have a leasing system for minerals, although Alaska, Arizona, Colorado, Idaho, Maine, and Oregon utilize some form of location as a part of the process of obtaining a 1ease.[274]

The regulations of the particular state involved must be examined to determine eligibility requirements. Corporations, for example, might have to be qualified formally to do business in the state before being eligible to lease state lands. Whether an alien or a corporation whose stockholders are aliens can hold state leases must also be ascertained. Acreage limitations might also exist.

Some states issue leases directly, others go through a prospecting permit phase with a preference right lease being issued only if minerals are discovered by the permittee. Leases other than preference right leases might go to the first qualified applicant, or they might be issued upon competitive bidding. When leases are relinquished or terminated, it is common to put them up for competitive bid, and if there are no bidders to make them available to the first qualified applicant.

Minerals are generally classified into groups such as metalliferous minerals, coal, uranium, industrial minerals, etc., with lease terms designed accordingly. Like all leases, the key provisions are the royalty, rental, and lease term clause.

State leases often require approval of mine plans by the administering agency. Performance and reclamation bonds are also commonly required.

3.2.4 PRIVATE LANDS

3.2.4.1 Geologic and Geophysical Trespass

Before entering privately owned land to conduct geologic and geophysical investigations, permission of the surface owner and the minerals owner should be obtained, both to establish good relations and to avoid possible liability for trespass. If unauthorized geologic or geophysical tests are made, the prospector might be liable to the landowner under the theory of geophysical trespass. In connection primarily with oil and gas exploration, geophysical information is acquired over very large areas. When entry upon the land is made for these purposes, without the permission of the owner, or where the permission given by the owner is exceeded, the courts have in some cases held the prospector liable for trespassatory damages. The landowner has the right to have the mineral potential of his land remain unknown unless he is paid a fee or gives permission to someone to enter and gather such information, and if the right is violated he can obtain damages for the reasonable value of the information that was obtained. In addition, if a geophysical trespasser publishes information to a third person that is untrue, the value of the land is disparaged, and the landowner can recover an amount equal to the reduction in value of the 1and.[275]

The theory of geophysical trespass could apply as well to hard-mineral exploration. For this reason, the consent of the owner should always be obtained before land is entered for prospecting.

3.2.4.2 Ownership of Minerals

Questions can arise as to who owns a particular type of mineral in fee lands. There are many situations where there has been a conveyance of the land in question with reservation of minerals using wording that is not necessarily all inclusive. There has been much litigation, for example, over the issue of whether a reservation of "oil and gas and other minerals" includes such minerals as sand and gravel, geothermal resources, or minerals that were not recognized to be valuable at the time the conveyance was made.[276] In one line of Texas cases, the issue was whether minerals that could only be extracted through destruction of the surface were encompassed in a prior reservation of minerals.[277] If the mineral involved is near surface and of widespread occurrences and there has been a severance of the mineral and surface estate on the land involved, state law should be examined to determine whether the surface owner has any claim to ownership of the mineral in question.

Questions can also arise whether the owner or lessee of a particular mineral in lands also has rights to associated minerals. A good example of such a problem is provided by claims of the owner of oil and gas right to methane gas found in coa1.[278] In *U.S. Steel v. Hoge,*[279] the Pennsylvania Supreme Court held that methane gas within a coal seam is owned by the owner of the coal, but the issue is still open in other jurisdictions.

3.2.4.3 Agreements

Agreements pertaining to private mineral lands differ from those involving state and federal lands in that the terms are extremely variable (see Chapters 6.4 and 6.6). Terms of agreements relating to governmental lands generally are established by statute and regulation, whereas terms relating to private lands are established by negotiation. The same principles that apply to agreements relating to private lands, however, apply to agreements with owners of mining claims and to a lesser extent to agreements with the holders of mineral leases. Transfers of mineral interests in private lands can be made in many different ways, and a variety of terms can be included in any particular agreement. Nevertheless, both the vendor and the vendee have certain basic objectives that they should seek to obtain through the agreement terms. These transactions can be structured with respect not only to lands that have passed from public ownership ("fee lands"), but also to mining claims and governmental leases that are held by private citizens or business entities. All such interests are described in this chapter as private lands. Further discussion of this subject is available in Chapter 7.1.

Most transactions fall into one of several basic categories. These are an outright purchase, a purchase with the reservation of royalty, a lease, and an option to lease or purchase. If the property owner is in the mining business, the deal may be structured as a "farmout agreement," where the new party earns an interest by spending money on development and then participates as a joint venture partner with the owner.

Private lands usually become of interest because preliminary studies indicate that an area has mineral potential. The immediate objective of the mining company, then, is to gain access to the land so that detailed exploration can be carried on. Because such activities might inflate the value of the land, however, the company usually desires to obtain mineral rights beforehand to as much land as possible in and around the area of interest.

Because of the high cost of exploration, the company desires that the initial outlay for land acquisition be as small as possible. It is desirable, therefore, to defer payments and to make them contingent on production. For the same reasons, it is in the company's interest to be able to terminate future payment obligations after having had sufficient time to evaluate the property.

Perhaps the best agreement for achieving these objectives is the option—an agreement by a vendor to give the vendee the exclusive right to accept the terms of the vendor's offer for a set period of time. The option can be to purchase or to lease. The terms of the sale or lease are established at the time the option is granted, and if the optionee exercises the option, he binds himself to the preestablished terms and conditions. An option must be coupled with an agreement giving the optionee the right to enter and explore the land during the option period.

The advantage of an option is that it permits the mining concern to examine the property without undue expense and without fear of losing it to another. If the findings are negative, the option can simply be released or permitted to expire. The disadvantage to the mining concern is that the terms of the lease or sale are negotiated on the assumption that favorable indications of mineralization will have been found in the event the option is exercised. The economic terms may accordingly be less favorable to the company.

The main advantage of an option to the landowner is that it forces the optionee to conduct exploration without delay before the option expires. The landowner may not gain this benefit, however, if he options the ground to a speculator, who might simply hold the land hoping for its value to increase. The landowner should receive reasonable consideration for the option, and he should restrict the option period to an amount of time sufficient for the company to evaluate the land thoroughly.

Outright purchases of land are rare because they require an advance outlay of capital by the mining company without sufficient knowledge of the land's value. It might occasionally be advantageous to the vendor, however, to seek an outright sale with a reservation in himself of a royalty interest. This permits him to get an immediate return with the possibility of substantial royalty income later. He will not, however, have the power to force rapid development of the property. It is that same lack of control by the owner that provides an incentive to the company to make an outright purchase.

Perhaps the most common type of mineral transaction is the mineral lease. The terms of such a lease are extremely flexible, and they can be tailored to the interests of both the lessor and the lessee.

The lessor can usually demand a bonus payment for a lease, especially if other companies are interested in the property.

The lessor wants to ensure that the lessee does not simply tie up the land without benefiting it, and so he should attempt to insert some provision that has the effect of pressuring the lessee to take steps toward development. There are several approaches. The lease can provide for the payment of delay rentals if there is no production from the property within a specified period of time. The same effect can be achieved by providing for periodic increases in rental payments. Another common practice is to require the lessee to make yearly minimum expenditures for exploration, or to perform a set amount of work, such as a minimum number of feet (meters) of core drilling.

The lessor also can assure himself of some return before mining operations are profitable by requiring the periodic payment of a minimum advance royalty during the term of the lease. Minimum royalty payments can be credited cumulatively against future royalty payments, but often are credited only in the year of payment.

The lessor also can require an express-development covenant, which obligates the lessee to be reasonably diligent in commencing mining operations and in continuing thereafter. Breach of such a covenant by the lessee will permit cancellation of the lease or possibly recovery of damages. If the property has known ore reserves, the express-development covenant can be made more specific. For example, the lessee can be required to produce a certain number of tons per month. In the absence of an express-development covenant, the courts have recognized that the lessee has an implied obligation to use reasonable diligence in commencing mining operations.[280] A delay-rental or minimum-royalty provision might negate the obligations of the lessee to carry out diligent development, because the lessor in effect receives a substitute for production.

It is important to the lessee, however, to keep initial payments small so that the money can be put into exploration. Deferred increased payments usually are acceptable because, by the time they become due, enough information will have been obtained either to justify the outlay or to cause termination.

The lessee also desires a long primary term so that there will be sufficient time to evaluate the property and get it into production if minerals are encountered. On the other hand, the lessor will often set a shorter primary term, 5 to 10 years, with extensions to be contingent upon production.

The heart of any mining-lease agreement is the royalty provision. It is by receiving a share of the minerals produced that the lessor fully realizes the value of his property. The wording of the royalty provision will be governed by the type of mineral or minerals involved, and the royalty percentage, although arrived at by negotiation, generally will be influenced strongly by the royalty schedule in common use in the area at the time.

Because of the variety of products that can be sold from a mining operation, the term "net smelter returns" is currently less favored. It is common to see a reference to the royalty as being a percentage of "net proceeds," meaning the proceeds received from a buyer of product produced from the mine, no matter what its form. Products may be in the form of ores, concentrates, leachates, precipitates, or in the case of gold and silver, nearly pure dore' bars. The purchase may be a gold refinery rather than a smelter. Clarity should be provided in stating the point at which the valuation is made, and the costs that may be deducted. If gold dore' bar is produced at an onsite mill, the royalty would ordinarily be based on the value of that product rather than on the value of the concentrate or other gold-bearing material prior to its entering the final stage furnace. Deductible costs then would be those incurred in shipping and further treating that product into refined gold.

A good rule of thumb in this regard is to consider the salable product to be that which is produced at a milling or other beneficiating facility constructed as part of the mining operation. Deductible costs then would be those incurred in shipping, treating, and selling that product to third parties. Clearly, that rule will not work in all cases because the operator might send the product before sale for further treatment on a contract or "tolling" arrangement, or it might perform upgrading or refining at its own facility offsite. Careful drafting of the royalty provision in light of the particular mineral involved can reduce the likelihood of problems arising from such factors. (Mineral sales are discussed in Chapters 2.3 and 25.5.)

Another common form of royalty is the net profits royalty where, instead of a percentage of proceeds, the owner is given a percentage of profits. Ideally, the lessee simply subtracts all of his costs from revenues and gives the owner a percentage of the profits realized when and if they ever occur. In this way, the owner shares the risk that the operation will not be profitable. Because returns are deferred and are keyed to recovery of costs by the lessee, the net profits percentage paid to the owner is much higher than what a net smelter or net proceeds royalty would be. It is common, for example, for a lessee to offer a 15% net profits royalty in place of a 5% net smelter returns royalty.

The timing of net profits revenues to the owner is dependent upon whether preproduction costs can be recovered in full prior to the realization of net profits or whether they are to be recovered on an annualized amortization basis. Other important factors to consider in a net profits royalty provision are the degree to which the lessee can charge offsite overhead and the basis for charging personnel and equipment that are used in part for other operations. The lessee will usually want to charge an interest factor to reflect the costs of invested funds. Net profits royalties are often the basis for disputes, so they should be drawn with great care.

Revenues received by the lessee may be those paid by the purchaser, such as a smelter or refinery, that are based upon current published market prices, or they can be based upon various contractual provisions that might vary considerably from prevailing market prices. Product may be sold, for example, months before it is actually produced. The owner has the choice then of tying his royalty revenues to whatever the lessee negotiates, or he can tie his revenues to market price at the time of production by so specifying in the lease. There are obviously risks either way, both to owner and lessee.

If the desired property is already held by a mining company, the owner might prefer to have the ability to participate actively in a mining operation rather than just to be a royalty owner. The parties might therefore form a "joint venture," a special type of partnership formed for a single purpose, or the interested party might first be given the opportunity to "earn in" by spending a set amount to achieve ownership of a proportionate interest in the property. The earn-in agreement is just a modified form of the exploration and option agreement described earlier. The earning party can drop out at any time, thus giving up the option, or he can spend the required amount and thereby earn a vested interest in the property. The vested interest can be a 50% interest, or it can be over or under that amount.

Once the earn-in is completed and the acquired interest vested, then the parties will usually form a joint venture pursuant to a joint venture or joint operating agreement. One party is designated as the operator with responsibility for preparing and carrying out plans and budgets and the other, the nonoperator, pays his share of approved budgets. A management committee is usually formed of representatives of the operator and nonoperator. The party with a majority interest usually has voting control.

A key provision in any joint venture agreement is that which states the consequence of a party's election not to fund his share of an approved budget. The nonparticipating party can be diluted on a proportionate basis to a minimum interest of say l0%, or he can forfeit his participating interest. It is common in either case to convert the nonparticipating party's interest to a carried net profits interest.

A vital part of any joint operating agreement is the accounting procedures that govern how the operator will charge his costs. Those dealing with offsite overhead and shared equipment, facilities, and labor are key provisions in the accounting procedures.

Royalties for large-volume, low-unit-value commodities, such as sand and gravel, are often based upon tonnage or cubic yards (cubic meters) removed. Royalties on most other commodities are generally based upon the amount received from sale, less certain expenses incurred prior to the time of sale. Defining the point at which such deductible costs arise is critical in preparing a royalty provision. It can be set at the mine mouth, thereby allowing deduction of transportation and treatment costs from that point on, or more commonly, at the outlet of a mill or other treatment facility. This arrangement is the traditional net smelter returns royalty where the royalty is based upon the amount paid for concentrates of a smelter less smelter treatment charges and deductions, and transportation costs incurred by the operator in moving the ore from the mill to the smelter. If the ore is sold to a mill, the same procedure applies except that transportation costs are those incurred between mine and mill.

It is important to the lessor that the lease provide that charges be competitive with those of other comparable mills or smelters if the lessee sells to a mill or smelter in which the lessor owns an interest (a non-arm's-length transaction). The same is true if the transportation is performed by the lessee.

In some instances, particularly as to precious metals, the lessor may wish to take a share of production in kind, rather than a percentage of proceeds.

If a large-scale mining operation is begun, it is desirable for the company to have exclusive title and not to be obligated to make indefinite payments out of production. For this reason, it is common practice to negotiate an end price for the lessee's entire interest. Often, if a sizable ore body is uncovered, the lessee simply will pay off the lessor before production begins.

The lease should contain a *force majeure* clause so that the lessee will be excused from certain obligations under the lease if he is prevented from performing because of events beyond his control.

The lessor will desire provisions requiring the lessee to comply with all applicable environmental protection and other laws and regulations, to indemnify the lessor for any claims by third parties, and to have adequate insurance coverage.

A termination clause also should be inserted permitting the lessee to terminate all obligations under the lease upon the giving of notice, usually 15 or 30 days. Conversely, the lessor should be given the right to terminate the lease upon breach by the lessee within a specified time after giving notice to the lessee requiring him either to comply with the contract or face termination.

Provisions allowing for commingling of ores and concentrates and for use of the leased lands in connection with mining on adjoining or nearby lands are desirable.

If the consideration is substantial, the lessor should be required to warrant his title. The warranty should extend to compliance with location, assessment work, and BLM filing requirements with respect to unpatented mining claims. In all cases, the lease should be reviewed for its tax implications and tailored to the needs of the parties involved.

Since the lessor is assessing the terms of the lease in light of the regulation and resources of the particular lessee, the lessor will desire that any assessment by the lessee be conditional upon the lessor's consent, not to be unreasonably withheld.

Sample lease forms and royalty provisions can be found in Vol. 4, *American Law of Mining,* 2nd ed.[281]

Chapter 3.3
HEALTH AND SAFETY STANDARDS

KENNETH P. KATEN

3.3.1 INTRODUCTION

Throughout the centuries of documented mining activities, perhaps the subject of most concern to the public pertains to safety aspects. However, in recent years, concerns for the environmental effects of mining and the health effects of industrial processes on the work force have equaled the long-standing concern for safety. These three facets, and the manner in which the mining community addresses each, constitute the primary sources from which the public derives its perception and image of the industry. Consequently, it is incumbent upon every member of the mining community, and particularly directors and managers of mining companies, to undertake their responsibilities in such a manner that will at all times include appropriate concern for these elements in their decisions and actions.

The purposes for discussing health and safety standards in a mining engineer's handbook are (1) to provide some historical perspective to the developments in these areas, (2) to outline the intent and requirements of applicable federal legislation, and (3) to provide some guidance in meeting the obligations and responsibilities that this legislation confers upon mining personnel. While focusing on those pieces of legislation that apply on a national level, it is beyond the scope of this work to address the many similar developments in each state in which mining takes place. However, adherence to the standards promulgated in these various states is equally important to compliance with the federal standards.

For further discussion of the subject of health and safety programs, see Chapters 11.0 and 11.1.

3.3.2 BACKGROUND OF HEALTH AND SAFETY DEVELOPMENTS

3.3.2.1 Statistics

Purpose: Although much has been written about mine health and safety, only in recent decades has there been a structured effort to accumulate meaningful data on accidents and injuries. Documents relating to this subject are numerous and varied in their approach to the topic. Most, however, share the common thread of analysis of safety statistics in order to demonstrate the necessity of understanding the scope of the safety situation before attempting to ascertain cause or source of accidents.

Safety experts recognize the value of accurate information in measuring the safety performance of a mine and the manner in which it relates to the occupations and operations therein. In addition to providing a basis for measuring safety performance, statistical information is valuable in isolating elements that are causative factors in accidents. This type of information, along with accident analyses, provides the basis for several approaches in furthering the reduction of accidents. For instance, with this type of data, engineers, supervisors, and workers can develop an awareness of hazards and develop the means to eliminate, reduce, or avoid them. Governmental agencies make use of statistical information to focus on areas in which research may offer a solution, or to develop an inspection strategy that will provide the most assistance in addressing identified hazards. Mining equipment manufacturers can design equipment to eliminate a particular hazard that has become apparent through statistical analysis of accidents related to their products. Application of this type of information is valuable in planning stages; for example, in the layout of the mine and facilities, design engineers can increase safety as well as economy by planning layout or location to remove hazards wherever possible rather than add protective safety equipment at some later time. Finally, training instructors can use statistical data to develop training strategies to address hazards or accident-causing procedures that are unique to or prevalent at a particular site.

Review: From late in the 19th century, records relate the most tragic accidents that occurred and the number of associated fatalities. However, it was not until the creation of the US Bureau of Mines in 1910 that consistent and comprehensive records became available. It is reasonable to assume that, prior to 1910, even without substantiation from accurate records, mine accidents probably claimed thousands of lives each year. Fig. 3.3.1 indicates the magnitude of the situation in the earlier part of the 20th century as well as the progress that has been made in the intervening years. The data in Figs. 3.3.2 through 3.3.5 delineate more precisely developments in the last 16 years based on injury rates that compare the fatalities and all injuries in the coal and metal/nonmetal sectors as a function of the number of exposure hours of miners.

Injury rates are generally expressed in two categories to provide an indication of the rate at which accidents occur and how serious in nature they may be. The frequency of occurrence, or *incidence rate* (IR), represents the number of injuries sustained in any particular category per 200,000 hr of exposure, that is,

$$IR = \text{number of cases} \times 200{,}000/\text{hr of exposure} \qquad (3.3.1)$$

The 200,000-hr exposure represents the number of hours that 100 miners would experience in an average work year.

Although most attention centers on incidence rates, the second category, *severity measure* (SM), provides an indication of the relative seriousness of injuries sustained at a site. This statistic derives from the number of days lost from work and days of restricted work activity, adjusted for the same amount of exposure as indicated above. Thus,

$$SM = \text{sum of days} \times 200{,}000/\text{hr of exposure} \qquad (3.3.2)$$

In the absence of a definitive number of work days lost due to a particular accident, especially in the case of a fatality or permanently disabling injury, the most widely accepted standard is the schedule provided by the American National Standards Institute (ANSI). In this standard, a fatal or permanent disabling injury carries an assignment of 6000 lost workdays, while other injuries that result in loss of limb or body parts carry a specified number of days (Table 3.3.1) to be charged regardless of the number of days that may have actually been lost. It is important to note that, in many cases, the actual days lost may vary significantly

Table 3.3.1. Tabulation of Scheduled Charges of Lost Workdays Caused by Injuries

A. For Loss of Member-Traumatic or Surgical

Fingers, Thumb and Hand

Amputation involving all or part of bone	Thumb	Fingers: Index	Fingers: Middle	Fingers: Ring	Fingers: Little
Distal phalange	300	100	75	60	50
Middle phalange	—	200	150	120	100
Proximal phalange	600	400	300	240	200
Metacarpal	900	600	500	450	400
Hand at wrist, 3000					

Toe, Foot, and Ankle

Amputation Involving All or Part of Bone	Great Toe	Each of Other Toes
Distal phalange	150	35
Middle phalange	—	75
Proximal phalange	300	150
Metatarsal	600	350
Foot at ankle, 2400		

Arm

Any point above elbow, including shoulder joint	4500
Any point above wrist and at or below elbow	3600

Leg

Any point above knee	4500
Any point above ankle and at or below knee	3000

B. Impairment of Function

One eye (loss of sight), whether or not there is sight in the other eye	1800
Both eyes (loss of sight), in one accident	6000
One ear (complete industrial loss of hearing), whether or not there is hearing in the other ear	600
Both ears (complete industrial loss of hearing), in one accident	3000
Unrepaired hernia	50

from this standard, but the standard enables a comparison of the severity of accidents from site to site.

The trend in the number and rate of fatal accidents indicated in Fig. 3.3.1 is fairly clear upon analysis and, though there is some minor year-to-year deviation, shows consistent improvement. The same can be said for accidents that result in disabling injuries, although advances in medicine and treatment may claim some credit for this reduction. Due to the nature of these types of accidents, these figures tend to be more reliable than the number and rate of nonfatal and nondisabling accidents, the recording of which varies with interpretation of reporting requirements.

3.3.2.2 Health and Safety Laws

Intent: As with the passage of any statute, the theoretical intent of statutes relating to mine health and safety is remedial in nature. Public concern for the well-being of the nation's miners has prompted Congress to act on several occasions during the course of this century, beginning in 1910 with the formation of the Bureau of Mines (Public Law or P.L. 61-89). This legislation formed the first federal governmental body to become directly involved with the safety of miners. It also included provisions for investigation of accidents, research in the areas of mineral extraction and safety, teaching accident prevention, and training for first aid and mine rescue. Public Law 77-49 in 1941 provided for safety inspections of mines and gave federal inspectors the right of entry in order to conduct these inspections. In 1947, Public Law 80-328 created safety standards for bituminous coal mines, but had no enforcement provisions and expired after one year.

The year 1952 saw enactment of the first Federal Coal Mine Safety Act, which encompassed all underground coal mines employing more than 15 people. This act provided for enforcement of federal standards under a state plan and mandated annual inspections, delineated safety standards, and provided for issuance of orders of withdrawal in instances of imminent danger. The passage in 1961 of P.L. 87-300 authorized study of the causes and prevention of injuries and health hazards in metal and nonmetal (M/NM) mines and included provisions for access to information by federal officials. Public Law 89-376 extended the coverage of the 1952 law to small mines and included language for the withdrawal of miners in cases of repeated and unwarrantable failures to comply with safety standards. The Federal Metal and Nonmetallic Mine Safety Act of 1966 established annual inspections for this sector of the industry and established a procedure for the development of additional standards. Shortly following its passage came the Federal Coal Mine

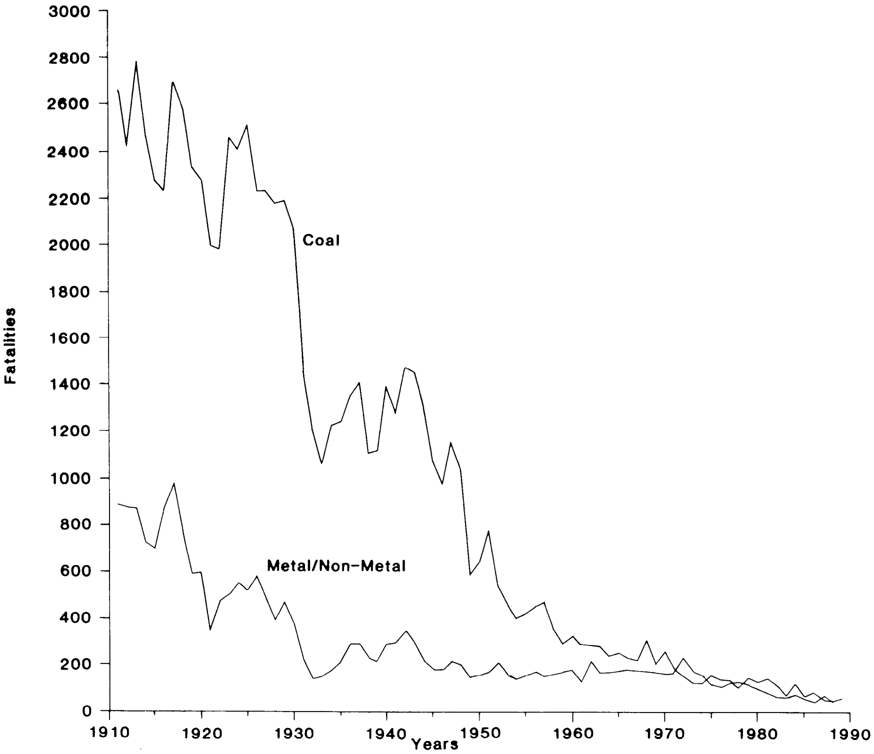

Fig. 3.3.1. Fatal injuries in the US mining industry, 1911-1988. *(Source:* Mine Safety and Health Administration.)

Fig. 3.3.2. Coal fatality rates, 1973-1988. *(Source:* Mine Safety and Health Administration.)

Health and Safety Act of 1969 (Anon., 1969) that included surface mines in its coverage and eliminated state-plan enforcement of standards. Noteworthy in this piece of legislation were mandated annual inspections, civil penalties for violations, and criminal penalties for knowing and willful violations. This act was then amended in 1977 (P.L. 95-164) to place coal, metal, and nonmetal mines under a single law, to eliminate advisory standards in the metal/nonmetal sector, and to mandate miner training.

Provisions: Viewing the intent of any legislation as curative or remedial, one can derive the sense or purpose of the various provisions as elements that, taken in sum, will provide guidance

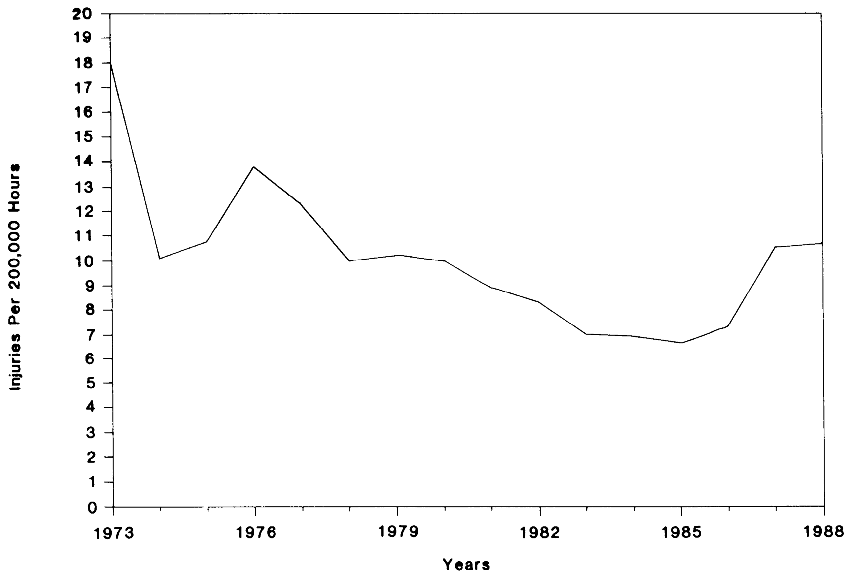

Fig. 3.3.3. Coal all-injury rates, 1973-1988. *(Source:* Mine Safety and Health Administration.

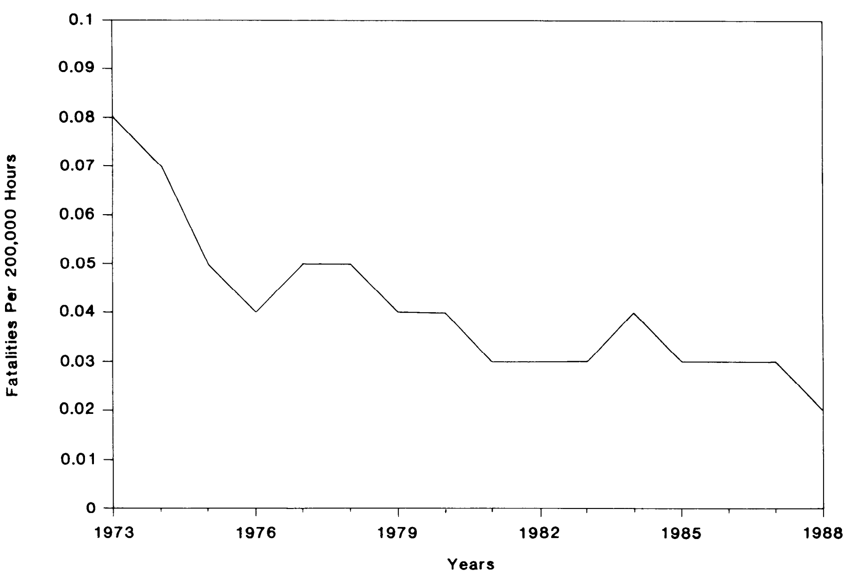

Fig. 3.3.4. Metal/nonmetal mine fatality rates, 1973-1988. *(Source:* Mine Safety and Health Administration.)

as to how we as a society feel that we should address a given situation. It is in this light that we view the provisions of the predominant piece of health and safety legislation, namely, the Federal Mine Safety and Health Amendments Act of 1977 (Anon., 1977), hereinafter referred to as "the Act."

Developing health and safety standards plays a central role in addressing the respective aspects of mining. In the statement of findings and purpose of this Act, Congress specifically stated in Section 2(g) that one of the purposes of the Act was to establish interim health and safety standards, to direct the Secretaries of

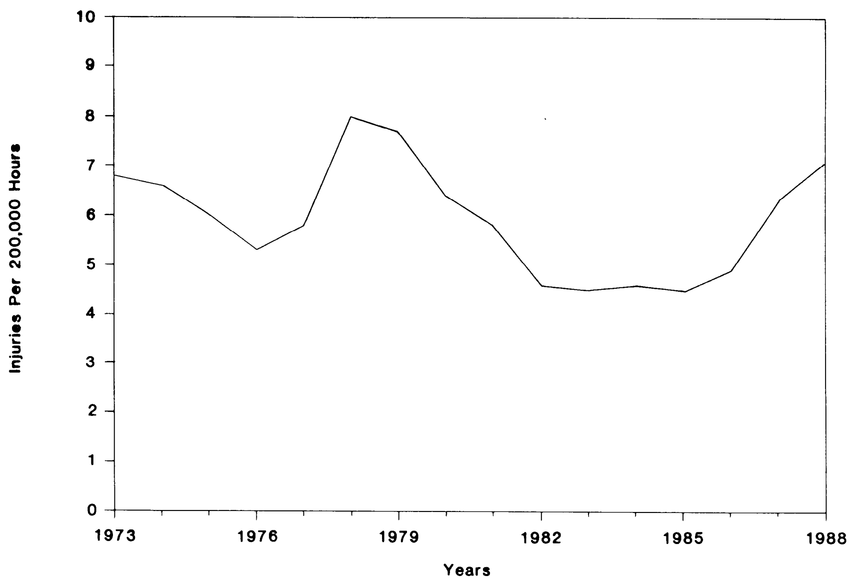

Fig. 3.3.5. Metal/nonmetal mine all-injury rates, 1973-1988. (Source: Mine Safety and Health Administration.)

Labor and of Health, Education and Welfare to develop improved standards, to cooperate with the states in development and enforcement of other mine health and safety programs, and to improve and expand research and development as well as training programs.

In Title I of the aforementioned legislation are provisions for development, promulgation, or revision of the interim standards for the protection of life and prevention of injuries in coal or other mines. Since a reading of this portion of the Act provides the details and procedures for these actions, it would be redundant to review them in this text. In general, these provisions charge the Mine Safety and Health Administration (MSHA), as agent for the Secretary of Labor, to develop improved standards in matters of mine health and safety and invest it with the rule-making authority to do so.

Title II of the Act contains Interim Mandatory Health Standards for all underground coal mines. Regulations contained in Title 30 of the *Code of Federal Regulations,* 30 CFR (Anon., 1988), implement this portion of the Act and contain these interim standards as well as those which have been since promulgated for surface coal mines and all metal/nonmetal mines. Although similar in many respects, health regulations for coal mines and metal/nonmetal mines are separate, as indicated in Table 3.3.2. This table lists the various parts of Title 30 and the respective area that each part addresses.

Interim mandatory safety standards for underground coal mines are contained in Title III of the Act, and Part 75 of 30 CFR implements these statutory provisions. Regulations promulgated since passage of the 1969 Act dealing with surface coal mines and surface areas of underground mines comprise Part 77 of the Code. Parts 56 and 57 of this same code contain the standards for metal/nonmetal surface and underground mines, respectively. In addition to these mandatory health and safety standards, Title 30 contains regulations that address the many related health and safetv topics, as indicated in Table 3.3.2.

3.3.2.3 Regulations and Standards

Types:

Mandatory—Many of the regulations contained in the aforementioned parts of 30 CFR are mandatory and provide no latitude in their observance, except as specified by paragraph 101(c) of Title I of the Act, with procedures outlined in 30 CFR, Part 44, Rules of Practice for Petitions for Modification of Mandatory Safety Standards.

Although there has been significant discussion in recent years regarding the concept of performance-oriented standards, most of the present standards are specific in their wording. Standards that are performance-oriented state the goal to be achieved by the standard and allow mine operators to use whatever techniques or means of compliance that best suit the circumstances of mining situations. An example of such a standard would be that of a coal mine operator maintaining the airborne dust at a level not to exceed a concentration of 2.0 mg/m^3 in order to prevent the development of coal workers' pneumoconiosis (CWP). However, present standards include this requirement, in addition to the specifically stated requirements for minimum air quantities and velocities, line brattices, distances of line brattices from the working face, cross-sectional areas available for air passage on the return-air side of the brattices, requirement of a specified water pressure, number of water sprays, etc.

Performance-oriented and specifically worded standards each have advantages and disadvantages. An advantage of performance-oriented language is that mine operators have greater latitude to employ the techniques that best suit the particular operation and are most economical. The disadvantage is that it may be difficult to determine whether any such method does, in fact, achieve the goal of the regulation at all times.

Specifically worded standards have the disadvantage of limiting all mining operations to the same approach regardless of

Table 3.3.2. Title 30—*Code of Federal Regulations* Health and Safety Topics

Part(s)	Subject
11	Respiratory protective devices
15-17	Explosives and related articles

the circumstances that exist at the various sites. This approach tends to limit technological developments and provides little latitude to mine operators. On the other hand, standards of this nature are usually easily measured or observed and have the benefit of being "tried and proven" in most situations.

Many of the existing regulations, in addition to being specifically worded, are based on the ability to measure some parameter(s) in order to ascertain the performance of the mining company in complying with the standard. This approach relies on measurement-based standards to inform mine operators of compliance responsibilities in exact terms. An example of this type of standard is the requirement that electric transformers installed on the surface be totally enclosed, or be at least 8 ft (2.4 m) aboveground, or be surrounded by a fence at least 6 ft (1.8 m) high and at least 3 ft (0.9 m) from any energized parts. This type of standard not only has the advantages of providing mine operators with guidance as to what constitutes a safe installation, but frequently provides alternative means of achieving the safety goal. Safety inspectors find that this type of standard is most easily overseen because of the absolute nature of the measurement that can determine compliance or lack thereof.

Although measurement-based standards are becoming more prevalent and may be desirable in some cases, there are many situations that require the use of experience or judgment in determining what constitutes not only compliance with a particular regulation, but, more importantly, what will provide the proper measure of safety to personnel. Equipment-guarding standards are examples of experience or judgment-based regulations. For example, wording of these standards generally requires guarding of exposed moving parts that may be contacted by persons and that may cause injury.

Advisory—The bulk of regulations for the mining industry is mandatory in nature, but there are some that can be categorized as advisory and are generally labeled as criteria or are worded in such a manner that the verb "should" replaces the verb "shall" in the wording of the standard. The purpose of this type of regulation is to provide guidance or options for mine operators in determining the means of compliance to achieve the desired safety goal.

Development of Regulations and Standards: Existing regulations for the metal/nonmetal and coal sectors have developed from several sources, but in most cases derive their origin from interim standards. In the case of the regulations governing metal/nonmetal mines, advisory committees composed initial standards that were later published as proposed rules and finalized after public hearings and comment, as prescribed in the Administrative Procedures Act of 1946 (5 U.S.C., 1976) (Anon., 1976). The coal regulations, having evolved over a greater period of time, were part of the interim standards in the 1969 and 1977 Acts and continue to be revised with advances in technology and experience with their use and administration.

The Administrative Procedures Act outlines the framework for formal rule-making as it applies to the development of all regulations. In addition to this, Title I of the 1977 Mine Health and Safety Act provides language and direction regarding regulations that pertain specifically to the area of mine health and safety.

The procedures in each of these statutes include, as a minimum, publishing the proposed rule in the *Federal Register,* a public comment period, opportunity for any member of the public to request a public hearing, and publication of the final rule in the *Federal Register*. In the 1980s, MSHA added an earlier stage by publishing an advance notice of proposed rule-making (ANPRM) to provide for more participation from the mining community prior to the development of a proposed rule.

Elements that comprise standards in each regulation are derived from diverse sources, but most have an engineering origin, especially those standards that are measurement-based. Accident statistics, known or accepted safety and engineering standards, epidemiological data, experience, and data from research or specific studies are all used as sources in developing standards that are incorporated in proposed rules.

In most cases, safety regulations are structured in such a manner as to provide several "lines of defense" for a particular hazard in order to prevent a catastrophic development should one facet or line of defense fail. Viewing the Act and implementing regulations in this manner, we can ascertain the tiers of safety for any one of several situations. For example, in preventing methane explosions in underground coal mines, the first and most obvious means of prevention includes provisions for separation of intake and return airways, minimum air quantities for adequate dilution, and specified levels of tolerance for methane to prevent the accumulation of explosive amounts. A second line of defense, accompanying these methods of prevention, constitutes eliminating man-made sources of ignition, such as prohibition of smoking and requiring electrical equipment to be approved by MSHA as permissible for use in gassy atmospheres. Thirdly, training and certification requirements for supervisory, inspection, and electrical maintenance personnel (certified persons) ensure that those persons entrusted with the inspection of conditions and maintenance of electrical equipment are knowledgeable about detecting hazards and proper means of prevention. Regular instruction for machine operators (qualified persons) who check for methane during the course of the performance of their work provides further protection against dangerous accumulations of methane.

Should there be a set of circumstances in which a face ignition occurs, additional "lines of defense" serve to eliminate or mitigate personal injuries. For example, rock-dusting requirements reduce the potential of initiating or propagating an ignition beyond the immediate area of the face. Regulations governing the designation and maintenance of escapeways provide a means of egress in the event of a development that exceeds the capability of the personnel in any area of the mine.

Mine Plans—Recognizing the uniqueness of individual mining operations, Congress made provision in the interim mandatory safety standards of the Act for mine operators to develop safety plans for various situations. MSHA has generally continued this approach in regulations that it has subsequently developed.

The mine-plan concept allows personnel at individual mines to develop safety plans for the design, construction, and operation of safety systems and procedures that take into consideration the mining conditions and equipment that are peculiar to the site. Once an operator has developed a plan and MSHA has approved it, that plan becomes the established regulation for the facet of the operation that the plan addresses.

There is great merit in and reliance placed upon the mine-plan approach to safety regulation, particularly in the coal sector. Since this approach allows mine personnel to develop the safety plan which is most appropriate for the mining conditions and equipment at a site, the plan can better address site-specific hazards and better protect the miners exposed to those hazards. In recent years, however, there has been a trend to make the plans more generic or broad-based and less unique to each operation. Though this development may have the benefit of providing an easier means by which to oversee compliance, it has the disadvantage of imposing requirements that may not be as appropriate as those that would pertain to site-specific hazards.

Examples of plans that are commonly compiled for coal mines include slope and shaft sinking, ground control, roof and rib control, ventilation system and methane and dust control, training, fire fighting and escape and evacuation, smoking articles search, self-rescuer storage, mine rescue, and emergency assistance and transportation. In each of these cases one can see the need for adaptation to local or peculiar situations that a generalized mandatory standard would find difficult to address.

Although the metal/nonmetal sector does not have the breadth of involvement in developing these sorts of plans, there is involvement in the development of training plans that can address the site-specific nature of hazards.

Variances—As mentioned earlier, Congress provided means by which mine operators could request exception to or variance from a mandatory safety standard. This sole exception allows the Secretary of Labor, that is, MSHA, to modify the application of any mandatory safety standard upon petition by a mine operator, if one of two tests can be met. (Noteworthy is the fact that there are no provisions for variances from mandatory health standards.) The first test is that the alternative or proposed method of achieving the safety result will at all times guarantee no less than the same measure of protection afforded miners by the existing standard. This approach evidently recognizes the fact that emerging technology could outpace the development of safety regulations and that, in some cases, alternatives will provide at least the same degree of, if not greater, safety to the miners.

The second criterion or test allows alternative means of complying with mandatory standards if application of a particular mandatory standard would result in a diminution of safety to the miners. Here, again, it appears that Congress recognized the fact that a standard that generally promotes safety may result in a lessening of safety to miners when applied in some situations.

In developing a petition for modification of a safety standard, an operator can receive guidance from Part 44 of 30 CFR that outlines the procedures for this approach. When considering filing a petition for modification, mine operators should consider the fact that they bear the burden of showing that the proposed alternative meets one of the two tests. Petitioning for modification of a safety standard is historically a lengthy process and involves a thorough study of the situation and proposed alternative by MSHA before issuance of a decision.

Enforcement: Regulatory oversight in the mining sector ranks among the most intensive in modern society. In passing the 1977 Act, Congress specifically charged the Secretary of Labor, that is, MSHA, to "make inspections of each underground coal or other mine in its entirety at least four times a year and of each surface coal or other mine at least two times a year." These inspections are supplemented by many others that depend on the type and condition of a mine, safety or health complaints that may be filed by miners, allegations of discrimination, accidents, previous citations, and several others.

Enforcement actions stemming from an inspection vary and may range from issuance of a single civil penalty (104-a of the Act) citation to closure orders for imminent-danger situations (107-a) or for unwarrantably failing to comply with regulatory provisions (104-d). Regardless of the type of enforcement action, the violative condition must be abated within the period of time specified in the citation. Failure to abate a violative condition within the timeframe specified in a 104-a citation may result in a 104-b closure order that will remain in effect until the situation is rectified.

Citations are civil actions that require correction of the violative condition within the abatement period specified in the citation and payment of a monetary penalty, as outlined in the 30 CFR Part 100 criteria.

Orders, however, require cessation of work activities in the affected area and immediate abatement of the condition. Furthermore, these enforcement actions usually result in greater civil penalty amounts. In the case of either a citation or order, should the violative condition result from knowing or willful violations of safety or health standards, managers may be subject to individual civil or criminal penalties in addition to the aforementioned corporate civil penalties.

Should a citation or order be issued as a result of an inspection or investigation, mine operators have the option of discussing the enforcement action with MSHA officials in an informal conference. Further options include paying the amount of the civil penalty or contesting the citation or amount of the proposed penalty. These formal contests begin with a hearing before an administrative law judge and can proceed, upon appeal by either party, as far as the Supreme Court.

3.3.3 HEALTH AND SAFETY ORGANIZATIONS/ AGENCIES

3.3.3.1 Governmental

Although MSHA and the various state agencies are perhaps the highest-profile organizations involved with health and safety, they are by no means the only ones in existence. On the national level, in addition to MSHA, are the Occupational Safety and Health Administration (OSHA), the US Bureau of Mines (USBM), the National Institute for Occupational Safety and Health (NIOSH), and the National Institutes of Health (NIH).

Although not all these organizations conduct inspections or enforce regulations per se, those that do not are active in conducting research and surveys that serve as underlying bases for development of new or revised standards and regulations.

State mining agencies play various roles, depending on the respective statutory requirements. Their roles generally include, but are not limited to, inspections, training, mine rescue, and mine accident analysis. In general, despite some overlap, the national and state governmental agencies complement each other's activities to the general benefit of all miners.

3.3.3.2 Nongovernmental

In addition to the federal and state health and safety inspectorates, there are numerous other entities whose primary interest is the health and safety of mining personnel. These organizations, many voluntary, contribute significantly to the health and safety efforts on a grass-roots level and are of extreme value in the public comment stage of the rule-making process. Many mining companies have safety departments to oversee safety systems and procedures and, frequently, conduct inspections in the same manner as governmental inspectors. Insurance companies that underwrite coverage for mining activities employ safety inspectors or consultants to ascertain conditions and practices at a prospective client's operations and regularly inspect the insured operations to determine whether those operations observe appropriate safety measures on a regular basis.

In addition to organizations whose activities pertain to inspections, there are a number of associations whose primary or subsidiary purpose is the health and safety of miners. The National Safety Council, the American Conference of Governmental Industrial Hygienists, the Society for Mining, Metallurgy, and Exploration, Inc., the American Society of Safety Engineers, the Mine Inspectors Institute of America, the Holmes Safety Association, and the Smokeaters Association are perhaps the best known, but there are many other state, local, academic, and manufacturing organizations that are equally dedicated to the health and safety of mining personnel.

3.3.4 ECONOMICS OF HEALTH AND SAFETY STANDARDS

Recent data indicate that the cost of accidents is a major factor in the economics of many mining operations. Cost elements directly included in or attributable to lost-time accidents include the immediate loss of production due to the accident itself and rendering of first aid, wage compensation, medical treatment and hospital care, benefits for injuries resulting in death or disability, investigations of fatal or serious accidents, and loss of production associated with these investigations. These costs for fatal, disabling, and lost-time accidents are included in Figs. 3.3.6 through 3.3.9.

Other costs associated with safety may not be attributable to accidents, nor readily apparent or calculable. Among these are civil penalty assessments, lost revenue associated with closure orders, the cost of legal appeals and tort liability litigation, loss or damage of equipment, and post-accident reduction of productivity levels due to replacement of injured miners with less-experienced personnel.

It is equally important to recognize that the employer is not the only economic victim as a result of an accident. If a miner is injured, in most cases there is decreased primary income accompanied in some cases by physical impairment and attendant inability to enjoy normal activities. Additionally, there is the possibility of decreased future primary earning power as well as possible secondary financial losses.

Correlation of accidents, injuries, and property damage indicates that for each fatal, disabling, or lost-time injury, there are 10 accidents resulting in minor injuries, 30 cases of property damage, and 600 near misses. This information underscores the fact that, in addition to the concern for the well-being of personnel, it is in the best interest of all parties to conduct operations safely to help ensure the economic viability of the producing company and its employees.

3.3.5 ASPECTS OF HEALTH AND SAFETY STANDARDS

3.3.5.1 Engineering

In the industrial sector, and particularly in mining, the uncompromising need for a safe workplace cannot be overstated. As mentioned earlier, redundancies of safety systems are routinely used in order to prevent catastrophe in the event of malfunction of any one system or line of defense.

In the construction of safety-system requirements and procedures, perhaps the most prevalent aspect is engineering. Most of the standards that comprise the regulations derive their origins from some aspect of the engineering sciences. For example, understanding ventilation requires knowledge of hydraulics and fluid flow; roof control, the properties of materials, and beam theory; electrical safety, the basics of electrical power generation, distribution, and protective circuitry; and fire prevention and fighting, the elements of combustion theory. Indeed, the modern engineer has the challenge, opportunity, and responsibility to participate fully in establishing safety regulations that are based on sound engineering theory. Furthermore, engineering validation of many standards can help ensure their credibility and subsequent compliance by all members of the mining community.

3.3.5.2 Training

In addition to the need for a safe workplace, studies indicate that training has a tremendous opportunity to produce safety dividends. These same studies indicate that more than 80% of accidents and injuries are the result of unsafe acts or omissions on the part of personnel. This in no way should be seen as an indictment of any segment of the industry, but rather as evidence of the need for and value of timely and relevant training.

Present mining regulations, as articulated in 30 CFR Part 48, require initial safety training of miners before they assume their duties as well as annual retraining in general safety practices and procedures. Additionally, before miners embrace a new task or operate a new piece of equipment, the employer must instruct each such employee in the various safety and operational aspects of the soon-to-be-assumed responsibility.

A common industry practice that provides regular reminders consists of daily or weekly "tool-box" training. Although not required by regulation, this form of training usually takes place at the beginning of a work shift. Using this approach, a supervisor, member of the safety department, or member of the work crew reviews safety regulations or practices that apply to the particular work site. Presentations may vary and may include such approaches as a group discussion of circumstances relevant to the work site, a review of accident information and discussion of preventative measures, and a demonstration of procedures for particular work tasks or dealing with unusual geologic conditions.

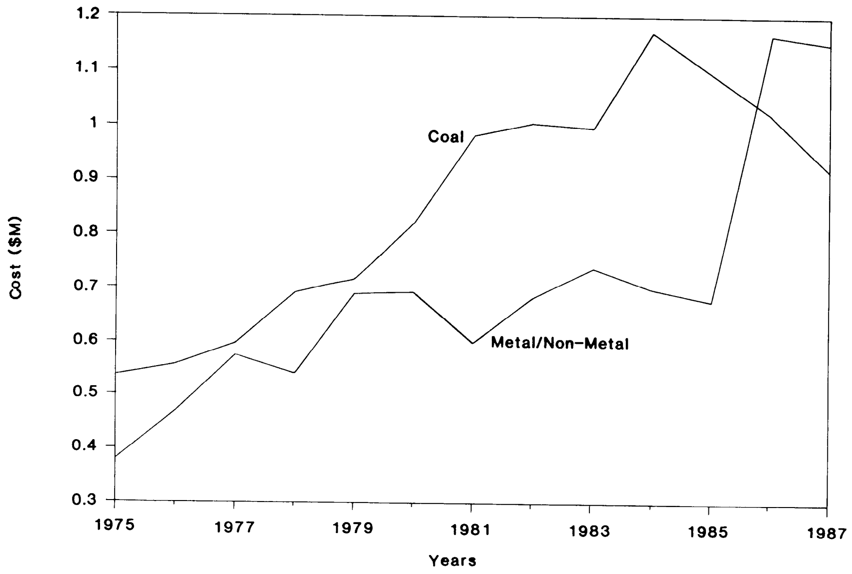

Fig. 3.3.6. Average cost per fatality in underground mines. *(Source:* US Bureau of Mines.)

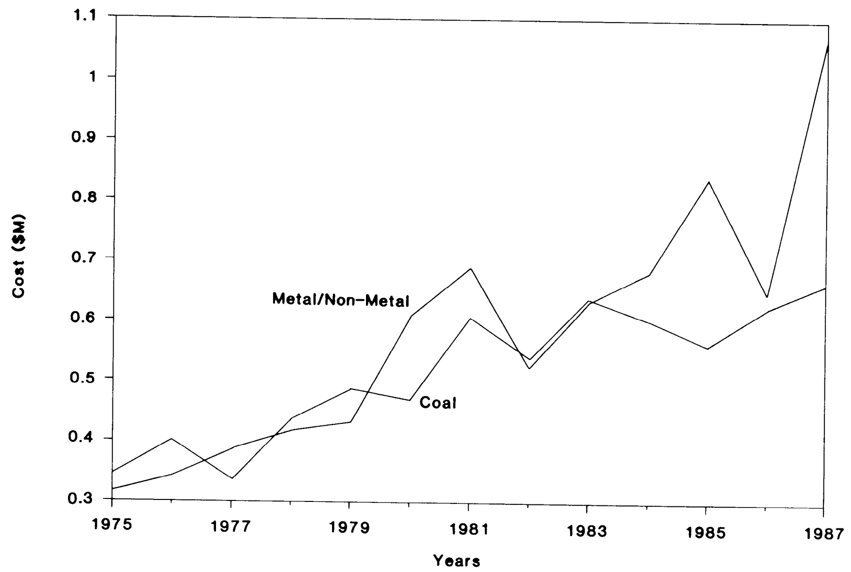

Fig. 3.3.7. Average cost per fatality in surface mines. *(Source:* US Bureau of Mines.)

The dialogue and feedback that result from interactive training are most beneficial to the overall safety effort. Not only will training sessions of this nature educe greater interest on the part of the participants, but will promote greater safety awareness and improve morale long after the class has ended.

3.3.5.3 Maintaining Safe and Healthful Conditions

Systems installed to provide a safety or health benefit must occasionally be inspected, calibrated, or maintained in some manner to ensure their proper function. Inspections to ensure

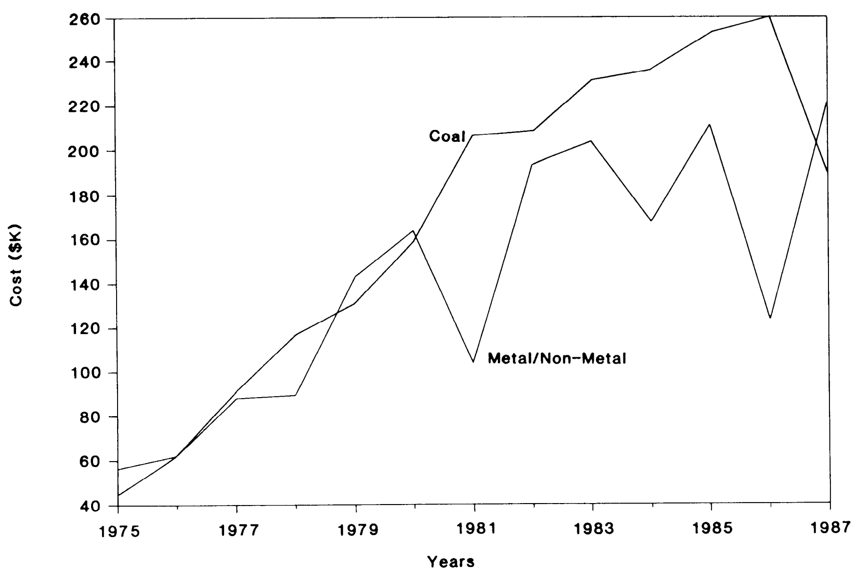

Fig. 3.3.8. Average cost of permanent disability in underground mines. *(Source:* US Bureau of Mines.)

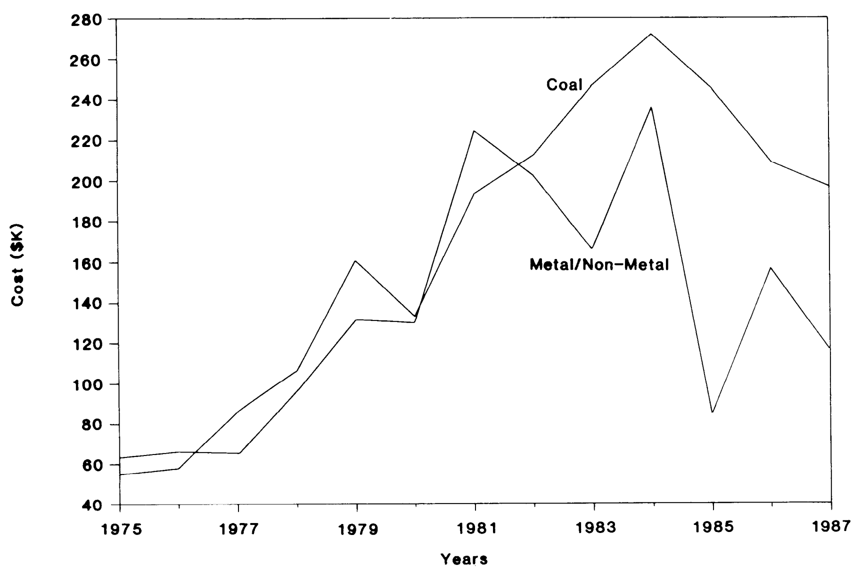

Fig. 3.3.9. Average cost of permanent disability in surface mines. *(Source:* US Bureau of Mines.)

safe working conditions and equipment are basic elements in safety programs. The fact that inspections comprise such an important role in maintaining a safe working environment is good reason for their inclusion in regulations as mandatory requirements. These types of requirements include examinations of pre- and on-shift conditions, escapeways, ventilation equipment, fire-fighting and suppression equipment, electrical equipment, hoisting equipment, etc. Where examination and maintenance of equipment is involved, equipment manufacturers often recommend the intervals at which these functions are to be performed, but the majority are outlined in mandatory health and safety standards.

The basic construction of these types of regulations provides for examination, testing or calibration, and subsequent reporting or record-keeping on the part of the person responsible for conducting the activity. Along with the activity itself, development of a record can allow personnel to establish or discern trends that will provide information for preventative or remedial action. So important are some of these records that failure to report or record, or falsifying a document provides the basis for a civil penalty citation and, possibly, criminal indictment of the responsible person(s).

Along with the examination and reporting of a condition comes the requirement and, indeed, responsibility to take the appropriate corrective actions to remedy any detected unsafe or unhealthful situation. Remembering the intent of the safety legislation as being remedial in nature, it is incumbent upon mine operators to take whatever action is necessary and appropriate to ensure the health and safety of their employees.

3.3.6 CONTROL OF HAZARDS

3.3.6.1 Primary Goal of Standards

Inasmuch as the stated purpose of safety legislation is "to protect the health and safety of the Nation's coal or other miners" (P.L. 95-164, 1977) (Anon., 1977), one must view the goal of the resultant regulations as fulfilling this intent. Consistent with this philosophy, in its statement of purpose, the Act also requires the Secretary of Labor "to develop and promulgate improved mandatory health or safety standards" (Anon., 1977) to achieve the goal.

Due to the nature of the rule-making process, development of such standards is not only a lengthy process but also one filled with controversy. For instance, in many cases there is sincere disagreement about what constitutes an "improved" standard. Further, does improving a standard necessarily involve converting from experience- or judgment-based to measurement-based standards to remove subjectivity from the compliance determination decision? In order for the rule-making process to have accurate, documented, and applicable information, it requires input from responsible elements in the community. What better source of information than the mining engineers who comprise the technical/engineering aspect of mining and who are trained to understand and recognize the many implications of health and safety requirements?

3.3.6.2 Means of Control

Whether a hazard be a safety or health concern, mine operators are ultimately responsible for its correction or abatement. In many situations, curative action is outlined in the regulations and thus leaves little room for disagreement as to whether any action was, in fact, sufficient to correct or abate the condition. Regardless of the number and detail of published regulations, however, the sheer number of hazardous situations that could arise renders the construction of prescribed actions impossible. Therefore, it is left to the mine personnel to assess any such situation and determine the appropriate course of action to pursue in its remedy.

The means of control that could be utilized to effect abatement of unsafe or unhealthful conditions consist of three primary categories: engineering controls, administrative or procedural controls, and personal protective devices.

Where engineering controls are involved, the mining engineer obviously has the greatest opportunity to participate in, and perhaps influence, the decision-making process about how best to proceed. For example, in providing proper ventilation, diluting and removing methane or other unwanted gases, and controlling respirable dusts, selection of equipment and configuration of the delivery system are paramount considerations. Although regulations require powered fans, prescribe minimum quantities of air, and establish threshold levels of action for various unwanted gases, it is left to the mining company to determine the type and size of equipment as well as the design of the ventilation system. Further, once having selected and installed safety equipment, it falls to the mine operator to effectively maintain it in such a manner that it will fulfill its function. Similar situations exist in the areas involving ground control, electrical systems, materials handling, fire prevention, use of explosives, etc.

Procedural controls are categorized with administrative actions in that they constitute some type of action on the part of the miner or supervisor. In this sense, they consist of learned actions or responses that are a function of training. With the great variation in types and kinds of mining equipment that are used in the industry from region to region, mine to mine, and even within the same mine, it is imperative that personnel be instructed in the proper and safe use of that which is applicable to the particular work site.

The third means of control that can provide safety and/or health protection consists of personal protective devices. In contrast to engineering controls that require no or little action or choice on the part of the individual, these devices, as indicated by their classification, require the individual to wear or make use of the device in the proper manner in order to derive the intended safety or health benefit. Although many safety experts prefer engineering controls, there are situations in which personal protective devices provide additional or necessary protection, especially in cases where technology does not yet provide an engineering solution or where exposures are of short term or on infrequent bases.

3.3.7 FIRST-AID AND MINE-RESCUE STANDARDS

Recent decades have held numerous accounts of mine disasters around the world that focused on the rescue efforts for survivors or recovery efforts of victims and the mine itself. In each of these cases, volunteers who comprise the rescue teams conduct these rescue efforts, with oversight or coordination from company and governmental personnel.

Perhaps less heralded than the mine-rescue teams, but equally important at every mine site, are the first-aid personnel who perform not only in disaster situations but also on a more routine basis. Although transportation and communication facilities are more capable of expeditiously rendering formal medical attention than in previous decades, the ability to provide first aid remains a vital requirement at every mine.

In order to ensure that these capabilities are available and current at each mine, MSHA has developed regulations to address these items. The regulations governing mine-rescue team availability, equipment, and training constitute Part 49 of 30 CFR, while Part 48 contains the first-aid training requirements. In some states, mining laws require the presence of an emergency medical technician (EMT) at the mine site to ensure first-aid capability at all times.

As a result of these regulations, we in the United States have several means of providing first-aid and mine-rescue capability. Individual mining companies remain the most prevalent source of trained mine-rescue teams, but several states' regulations require that the state itself maintain teams at various locations where they will be within an hour's traveling time of the mines in that particular state. Private companies, whose primary role consists of mining-related health and safety efforts, also constitute a source of trained rescue teams. These types of companies usually contract their mine-rescue services to mining companies in their locale.

3.3.8 CONCLUSION

Through developments in technology, the evolution of health and safety legislation and regulations, and a greater awareness of the need for health and safety considerations, mine safety improvements in the United States in the 20th century have been appreciable. These improvements are most noteworthy in the reduction of personal injuries and the achievement of more healthful workplaces.

Recognizing these developments is an important step in providing the philosophical approach to a constantly improving level of achievement. However, it is only with the commitment of all participating entities to maintain safe and healthful workplaces and to carry out activities in accordance with trained procedures that we will continue to improve our performance and safety record and prevent adverse occupational health exposures.

Chapter 3.4
ENVIRONMENTAL CONSEQUENCES

L. MICHAEL KAAS AND CLAYTON J. PARR

3.4.1 INTRODUCTION

L. MICHAEL KAAS

The development, operation, and ultimately the closure of any mining and mineral processing facility are profoundly influenced by the environmental laws and regulations promulgated by government organizations at the federal, state, and local levels. The purpose of this chapter is to provide a review of the evolution of these laws and regulations at the federal level that has occurred in recent years and its effect on the mineral industry.

The body of environmental laws and regulations is large and complex. For example, the Office of Surface Mining, Reclamation, and Enforcement (OSMRE) regulations implementing the Surface Mining, Reclamation, and Control Act of 1977 (SMCRA) comprise nearly 700 pages in the *Code of Federal Regulations* (CFR). Existing environmental laws are frequently amended and significant new laws are passed by the Congress. Regulations are constantly changing as witnessed by the hundreds of pages of new or revised regulations that are proposed or finalized weekly by regulatory agencies. These regulations are published daily in the *Federal Register* (FR). Finally, the environmental laws and regulations are subject to legal interpretation and influenced by thousands of court decisions.

While this chapter provides a useful introduction to environmental law for the minerals engineer, it is not intended to be a substitute for competent legal counsel. The old adage that a physician who treats himself has a fool for a patient may have a direct parallel in the field of environmental law. The engineer who tries to be his own environmental lawyer may have a fool for a client.

References to environmental protective measures may be found elsewhere in this *Handbook* (e.g., Chapters 7.3, 12.1, 12.2, and 12.3 and Section 11).

3.4.1.1 Rise of Environmental Awareness

Few aspects of minerals resource development have experienced changes as drastic and rapid as those in the field of environmental regulation. These changes reflect the increased public awareness of environmental issues during the 1960s. That awareness emerged in response to many and varied influences such as the earlier conservation movement, the publication of Rachel Carson's *Silent Spring,* and the euphoria that followed the successes in the US space program. This awareness ultimately led to the first Earth Day, Apr. 22, 1970.

The 1960s have been called the "Decade of the Environment." We became convinced as a nation that we could develop whatever technology might be necessary to protect and restore the environment and that we could afford whatever the costs might be. Indeed, we simply could not afford not to take whatever precautions that might be necessary to protect the environment on Spaceship Earth for generations to come.

The crowning achievement of the 1960s was the passage of the National Environmental Policy Act of 1969 (NEPA). This act stated that it was national policy "to create and maintain conditions under which man and nature can exist in productive harmony, and fulfill the social, economic, and other requirements of present and future generations of Americans."[1] NEPA laid the groundwork for the decade of the 1970s, which could be called the "Decade of Environmental Law." During the decade, numerous landmark federal environmental statutes were passed by Congress and transformed into regulations by their implementing agencies. The most prominent of these laws were the Clean Air Act of 1970, Federal Water Pollution Control Act of 1972 (known as the Clean Water Act), Resource Conservation and Recovery Act of 1976, Surface Mining Control and Reclamation Act of 1977, Federal Land Policy and Management Act of 1976, Endangered Species Act of 1973, Toxic Substances Control Act of 1976, Clean Air and Water Act Amendments of 1977, Uranium Mill Tailings Radiation Control Act of 1978, and Archaeological Resources Protection Act of 1979. Numerous other environmental statutes were passed by Congress and state and local governments.

The growth of environmental laws and regulations continued throughout the 1980s reflecting the continued broadbased political support for the national commitment to protection of human health and the environment. Major statutes passed during the 1980s included the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (also called Superfund), Superfund Amendments and Reauthorization Act of 1986, and Water Quality Act of 1987 (amendments to the Clean Water Act).

The strength and support for the environmental movement was underestimated by some early skeptics. Today there is no doubt about the high level of national commitment to a cleaner and healthier environment. The tremendous nationwide response on the 20th anniversary of Earth Day, Apr. 22, 1990, demonstrated the strength of that commitment. That concern has reached global proportions with the realization that protection of air and water quality frequently transcends political boundaries.

3.4.1.2 Impact of Mineral Development on the Environment

There is no question that the development of mineral resources does impact the environment. With proper precautions, these impacts can usually be eliminated or can be minimized in terms of severity or duration. However, for nearly two centuries, this nation developed its mineral resources with few environmental controls. Many of the mineral industry's harshest critics have delighted in pointing out the legacy of environmental disturbances created by past mining and mineral processing activities. In Appalachia, over 5000 miles (8000 km) of streams are polluted by acid drainage from abandoned coal mines (Fig. 3.4.1.1). Thousands of unreclaimed coal strip mines dot the landscape in coal country (Fig. 3.4.1.2). Hundreds of thousands of acres (hectares) of land are underlain by abandoned mine workings and face subsidence hazards. Over 50 billion tons (45 Gt) of solid waste have been produced from hard-rock mining, primarily in the western states (Fig. 3.4.1.3). Dozens of identified sites containing hazardous waste from metal mining and processing

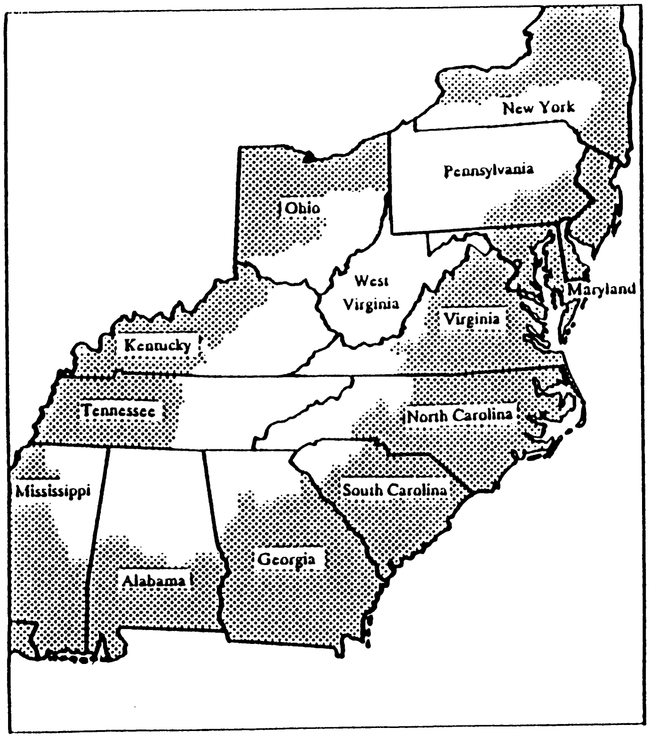

Fig. 3.4.1.1. Coal mine drainage contaminates streams in an extensive area of Appalachia.

operations pose myriad problems ranging from soil and water contamination (Fig. 3.4.1.4) to airborne particulate and toxic gas emissions. Cleanup of many sites with the most onerous of these problems is being conducted under the Environmental Protection Agency's Superfund program and OSMRE's Abandoned Mine Land Reclamation Program.

It is easy for critics of mineral resource development to forget that most of these adverse impacts predate the current laws and regulations. Today's modern mines and processing plants have adopted new technologies, sometimes at great expense, that will help insure that future generations will not have to face many of these same environmental problems. However, it is also important to realize that much still needs to be learned about the potential for long-term adverse environmental impacts such as those associated with mineral waste materials or about shorter-term impacts of some newer production methods. For example, the rapid expansion of heap and dump leaching methods utilizing large quantities of acid or sodium cyanide for recovery of copper and precious metals has led to public concern for the prevention of groundwater contamination and wildlife kills. The increased use of full-extraction coal mining methods such as longwall mining has triggered other concerns relating to land disturbance and aquifer damage caused by subsidence. These concerns and others are the targets of emerging regulatory and legal developments that will place new controls on disposal of mining and beneficiation wastes, give added protection to groundwater resources, and control airborne toxic substances.

And yet, as the world population grows and standards of living improve, the worldwide demand for minerals will continue to increase. The nation, and indeed the world, will continue to deplete high-grade, shallow mineral resources. Deeper and lower-grade mineral deposits will be mined. The new mining methods and new processing techniques required for exploitation of these resources could pose new types of environmental disturbances. Improved environmental technology will be needed to insure that potential environmental hazards can be avoided and that the goals of producing necessary minerals and maintaining environmental quality can be achieved.

3.4.2 MAJOR FEDERAL ENVIRONMENTAL LAWS AND REGULATIONS

L. MICHAEL KAAS

3.4.2.1 National Environmental Policy Act of 1969 (Public Law 91-190)

The National Environmental Policy Act of 1970 serves as the fundamental national charter for environmental protection. The purposes of the Act are "to declare a national policy which will encourage productive and enjoyable harmony between man and his environment . . . and to establish a Council of Environmental Quality."[2] Although short in length when compared with other major environmental statutes, NEPA has had a profound impact on the governmental decision-making process. The Act's importance stems from its requirement that all agencies of the federal government must "include in every recommendation or report on proposals for legislation and other major Federal actions significantly affecting the quality of the human environment, a detailed statement by the responsible official on the environmental impact of the proposed action."[3] Although mineral resource development is traditionally the domain of the private sector, the need for permits from federal agencies or the involvement of federal lands means that it is unlikely that many mining projects will escape the requirement for preparation of an *environmental impact statement* (EIS). One major exception to this is the area of mineral exploration, which does not require an EIS. The regulations that have been promulgated under NEPA begin in Part 1500 of Title 40 of the *Code of Federal Regulations* (40 CFR § 1500).

Title I declares that it is national environmental policy for the federal government "to use all practicable means and measures, including financial and technical assistance, in a manner calculated to foster and promote the general welfare, to create and maintain conditions under which man and nature can exist in productive harmony."[4] The following requirements are placed on all federal agencies:

1. Utilize a systematic and interdisciplinary approach in planning and in decision making that may have have an effect on the environment.
2. Develop methods and procedures that insure that environmental values are considered in the decision-making process.
3. Prepare environmental impact statements of proposed federal government actions.
4. Develop alternatives to recommended courses of action in any proposal involving unresolved conflicts.

Title II of the Act creates the Council for Environmental Quality (CEQ) in the Executive Office of the President. The principal functions of CEQ are to advise the President on government programs and policies that affect the environment and to issue regulations for implementation of NEPA by the federal agencies. The most significant of these regulations pertain to the EIS process.

Environmental Impact Statement Process: Because of the likelihood of most new mining projects having "significant ef-

Fig. 3.4.1.2. Unreclaimed strip mines pose environmental and public safety hazards.

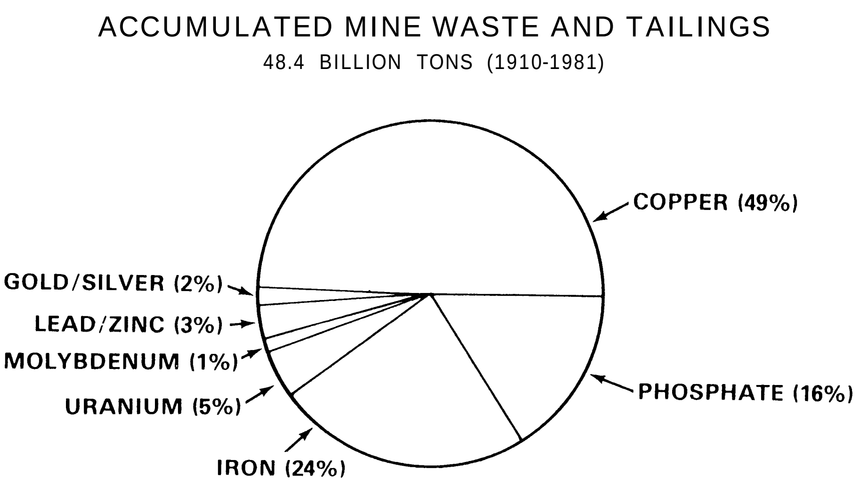

Fig. 3.4.1.3. Over 50 billion tons (45 Gt) of hard-rock mining and beneficiation waste has accumulated during this century.

fects" on the quality of the environment and involving some type of "major Federal action," it is important to understand the EIS process.[5] It is equally important to begin planning at an early point in the life cycle of the project for eventual EIS preparation by the federal agencies involved. Failure to do so may result in a longer and/or more costly approval process.

NEPA states that the EIS is to be prepared by the agency, not the applicant for a permit. To facilitate compliance with the EIS requirement, most agencies have specialized staffs in place to prepare the EIS and administer the process. When an agency is in doubt about whether or not an EIS is required, it may elect to have the applicant prepare, at his expense, an *environmental*

Fig. 3.4.1.4. The Yak Tunnel, part of the California Gulch Superfund Site, drains acid, metal-laden water from the Leadville, CO, mining district.

assessment (EA).[6] The EA usually involves a very comprehensive data-gathering effort including baseline environmental analyses. The list of data types is extensive, including geologic, hydrologic, botanical, zoological, archaeological, historical, cultural, sociological, and economic. If the agency ultimately decides that an EIS will be required, it will utilize data collected during the EA in its preparation.

It is not uncommon for several federal agencies to be involved in the approval of a mining project. In such cases, the agencies can agree jointly to prepare the EIS. In this case, one of the agencies may be designated as the lead agency with supervisory responsibility for EIS preparation. At the request of a lead agency, any other federal agency with special expertise may be asked to be a cooperating agency. A scoping process is used to insure that the significant issues of concern to the participating agencies are identified and their scope determined.

When a number of major actions are expected to occur in a given geographic area, such as during the opening of a new mining district, the agency or agencies involved may choose to prepare a regional EIS. This approach enables the cumulative impact of the expected actions to be considered and may result in a more efficient process overall. As a result, it is possible that some actions included in the region may not require a separate EIS unless they involve a project or site-specific impact not considered in the overall regional statement.

The format of the EIS is prescribed in the CEQ regulations. A brief description of the format follows:

1. *Cover Sheet.* A list of the responsible agencies including the lead agency and cooperating agencies. Title of the proposed action. A one-paragraph abstract. Designation of the statement as a draft, final, draft supplement, or final supplement. Name, address, and telephone number of a contact for additional information. Date by which comments must be received.

2. *Summary.* An accurate summary of the EIS including major conclusions, areas of controversy, and issues to be resolved.

3. *Table of Contents.*

4. *Purpose and Need.* A brief discussion of the purpose and need to which the agency is responding by preparation of the EIS.

5. *Alternatives Including the Proposed Action.* The main section of the EIS. Presents the environmental impacts and alternatives in detail and in a comparative form. Includes a no-action alternative. Sharply defines the issues and provides a clear choice among the options. Identifies the agency's preferred alternative.

6. *Affected Environment.* Describes the environment of the affected area at a level of detail necessary to understand the alternatives. Presents data and analyses commensurate with the magnitude of the impacts.

7. *Environmental Consequences.* Describes the environmental impacts of the alternative courses of action, including the proposed action. Provides the scientific and analytic basis for comparisons of alternatives. Describes the relationship between short-term uses and longer-term productivity. Discusses irreversible or irretrievable commitments of resources involved in the proposal.

8. *List of Preparers.*

9. *List of Agencies, Organizations, and Persons to Whom Copies of the Statement Are Sent.*

10. *Index.*

11. *Appendices.* Supplementary material prepared in conjunction with the EIS (optional).

After preparation of the draft EIS has been completed and before the final EIS is prepared, the agency must obtain comments from any federal agency that has jurisdiction by law, has special expertise in any environmental impact, or is authorized to develop and enforce environmental standards. Comments must also be sought from any state or local agency authorized to develop environmental standards. When the effects of the proposed action may be on an Indian reservation, the tribe's comments must be obtained. At least 45 days must be allowed for comments. The length of the comment period may be extended by the agency.

Diligent efforts must also be made to involve the public in the EIS process[7] and to obtain public comment. Public notices must be provided for hearings, public meetings, and the availability of documents such as the draft EIS. When a proposed action is of local concern, notices are sent to state and area-wide clearinghouses, community organizations, and interested persons, and published in local newspapers and through other local media. Agencies must hold public hearings or meetings whenever appropriate. These hearings are a particularly important part of the EIS process if the proposed action is—as most mining projects are—controversial.

Company strategies for public involvement vary from its active solicitation to its discouragement. However, there appears to be growing sentiment favoring a proactive position with the public. Successful permitting of a number of highly controversial minerals projects has been attributed to the companies actively seeking early public involvement so that citizens' concerns are identified. Once the public's concerns are identified, they frequently can be satisfactorily addressed in the EIS process and through public education activities.

Completed draft and final EISs are filed with the Environmental Protection Agency (EPA) which publishes a weekly notice of their availability in the *Federal Register* (FR). No decision on a proposed action can take place until 90 days after publication of the notice for a draft EIS or 30 days for a final EIS. These deadlines can run concurrently.

Once comments have been received, the draft EIS is modified to address the comments. The agency must respond to each comment. The comments and the agency's response are included in an appendix to the final EIS.

When the permitting agency has reached its decision, it must prepare a concise public Record of Decision (ROD).[8] The ROD must clearly state the decision. It must also identify the alternatives considered, stating which one(s) were considered environmentally preferable. Finally, it must state whether all practicable means have been taken to minimize environmental harm.

More detailed discussion of the EIS process is contained in Chapter 7.3.

3.4.2.2 Surface Mining Control and Reclamation Act of 1977 (Public Law 95-87)

The Surface Mining Control and Reclamation Act of 1977 was the first piece of legislation specifically aimed at elimination of environmental problems associated with mining. These problems included "destroying and diminishing the utility of land for commercial, industrial, residential, recreational, agricultural, and forestry purposes, by causing erosion and landslides, by contributing to floods, by polluting the water, by destroying fish and wildlife habitats, by impairing natural beauty, by damaging the property of citizens, by creating hazards dangerous to life and property, by degrading the quality of life in local communities, and by counteracting governmental programs and efforts to conserve soil, water, and other natural resources."[9]

After nearly a decade of legislative conflict among industrial, environmental, and governmental organizations, SMCRA was signed into law on Aug. 3, 1977. Since its passage, the Act has subsequently been amended many times by other pieces of legislation. It created a nationwide framework for regulating active surface coal mines and the surface effects of underground coal mining (Title V).[10] It includes detailed environmental protection standards and reclamation requirements, establishes a state or federal permitting and enforcement system, and restricts mining in certain areas or under certain circumstances. SMCRA provides a means for reclaiming previously mined areas where little or no reclamation had been carried out prior to the Act (Title IV).[11] To pay for the cost of this reclamation effort, the Abandoned Mine Reclamation Fund was established, and taxes on both surface and underground coal production were created to generate needed revenues. The Office of Surface Mining, Reclamation, and Enforcement, a unit of the Department of the Interior, was created to implement the Act (Title II).[12] OSMRE was to assist the coal-producing states in the development of approved regulatory programs and to provide oversight on those programs once established. The regulations that have been promulgated under SMCRA begin in Part 700 of Title 30 of the *Code of Federal Regulations* (30 CFR § 700).

SMCRA was passed at the very time the nation was recovering from a serious energy crisis. There was widespread recognition that mining of the extensive US coal reserves would be necessary to meet a significant portion of future energy requirements. The concern of the environmental community as reflected in the Act was that future coal production would be conducted with ". . . appropriate standards to minimize damage to the environment the productivity of the land and to protect the health and safety of the public."[13]

Since its passage, implementation of SMCRA has been fraught with seemingly endless court challenges, Congressional hearings, and protests by environmental interest groups. Much of this conflict has stemmed from the rigid requirements that force the use of specific reclamation practices without regard to regional differences and that allow only limited flexibility for innovative reclamation approaches and subsequent land use.

State Programs: Any state in which there are or may be coal exploration or surface coal mining and reclamation activities on nonfederal and non-Indian lands may assume exclusive jurisdiction or "primacy" over their regulation.[14] To gain this authority, the state must have an approved regulatory program. If a state chooses not to conduct such a program or if its program is not approved or is withdrawn, OSMRE must promulgate and implement a federal regulatory program for that state. Currently, 23 states have approved programs, and 11 have federal programs.[15] Similarly, under Title IV, the states must also submit a state reclamation plan for administering an abandoned mine land reclamation program. A synopsis of each state program or the federal program applicable to that state is given in the *Code of Federal Regulations.*

Federal Lands: Title V requires that the Secretary of the Interior promulgate and implement a regulatory program for federal lands except Indian lands.[16] When federal lands are located in a state with an approved state program, the federal program is, at a minimum, to include all of the requirements of the approved state program. States with approved state programs may enter into cooperative agreements with OSMRE to assume regulatory authority over surface coal mining on federal lands within the state.

Indian Lands: Title VII requires the Secretary of the Interior to study the regulation of surface mining on Indian lands so that all surface coal mining on these lands complies with the requirements of the Act.[17] A federal program has been established for the Indian lands. OSMRE, the regulatory authority, consults with the Indian tribes, the Bureau of Indian Affairs, and the Bureau of Land Management on various aspects of the program.

Lands Unsuitable for Mining: Title IV requires that each state establish a planning process that designates state and private land areas as unsuitable for mining.[18] Similarly, federal lands may be designated unsuitable. Individuals also have the right to petition the appropriate regulatory authority to have an area designated as unsuitable. Once an area has been designated as unsuitable, OSMRE cannot issue a mining permit involving that area.

States must designate lands as unsuitable if postmining reclamation is not "technologically and economically feasible."[19] In addition, lands may be determined unsuitable if mining would "be incompatible with existing state or local land use plans or programs;"[20] damage "important historic, cultural, scientific, and esthetic values;"[21] "result in a substantial loss or reduction of long-range productivity of water supply or of food or fiber products;"[22] or "could substantially endanger life or property."[23]

The Act states that federal lands may be designated unsuitable for mining as a result of a land review. Federal lands within the National Park System, National Wildlife Refuge Systems, National System of Trails, National Wilderness Preservation System, Wild and Scenic Rivers System, and National Recreation Areas are designated as unsuitable. With some exceptions, mining is also prohibited in national forests. Mining is prohibited if it would adversely effect any publicly owned park or place included in the National Register of Historic Sites. In addition, it is not permitted to mine within 100 ft (30 m) of the outside of the right-of-way of any public road or cemetery or within 300 ft (91 m) of any occupied dwelling or public building, school, church, or community or institutional building.

Coal mining can be permitted within land designated as unsuitable if the mine operator has valid existing rights such as where "substantial legal and financial commitments"[24] in such an operation were in existence prior to Jan. 4, 1977. The concept of valid existing rights is to prevent taking of a person's property that would entitle the person to just compensation under the 5th and 14th Amendments to the Constitution of the United States.

Permitting: Title V of the Act establishes a permitting system for all surface coal mining operations.[25] Permits are issued by the regulatory authority for five years with the right of successive renewal. Longer-term permits may be issued under certain circumstances. Permits terminate after three years if mining has not been started.

A permit application along with the application fee are submitted to the appropriate state or federal program office. The application requires extensive information identifying the applicant, operator, and any property owners or lease holders. Owners of adjacent properties are also identified. The applicant's prior, existing, and pending mining permits must be included, and any suspensions, revocations, or bond forfeitures during the last five years must be explained. The applicant must also file a listing of any violations of the Act and any air and water quality environmental protection violations associated with coal mining. Additional information includes details of the mining plans, a description of the probable hydrologic consequences, climatological data, maps, cross sections, and drill logs of the coal deposit, and a soil survey if mining will involve prime farmland. The applicant is also required to place a public notice of his application in a local newspaper for four weeks. The advertisement must clearly state the location of the proposed mining operation and the location where the application is available for public inspection.

A reclamation plan, blasting plan, and certification of public liability insurance must also be submitted by the applicant for a mining permit. The reclamation plan identifies the location of the land proposed for mining, the uses of the land at the time of the application, any previous mining history, the capability and productivity of the land to support other uses, and the proposed use of the land after mining and reclamation. The detailed reclamation procedures, cost estimate, and timetable must be provided. Steps taken to protect surface water and groundwater systems and to comply with air and water quality and health and safety laws and regulations must be stated.

Performance Standards: Title IV sets forth a list of minimum environmental protection performance standards that are applicable to all surface coal mining and reclamation operations.[26] General standards require such operations to:

1. Maximize the utilization and conservation of the coal resource so as to minimize future land disturbance.
2. Restore the land to a condition capable of supporting premining uses or higher or better uses.
3. Restore the approximate original contour of the land.
4. Stabilize surface areas and spoil piles to control erosion and air and water pollution.
5. Remove, segregate, protect, and replace topsoil or other strata shown to be more suitable for supporting vegetation.
6. Restore the topsoil or the best available subsoil for supporting vegetation.
7. Utilize special handling for the various soil horizons present in prime farmland.
8. Create approved water impoundments that are stable and that protect water quality.
9. Conduct augering to maximize coal recovery, sealing auger holes to prevent drainage.
10. Minimize disturbances to the prevailing hydrologic balance on and off the mine site.
11. Construct stable and revegetated surface disposal areas for mine wastes, tailings, and coal processing wastes.
12. Refrain from mining within 500 ft (152 m) of active or abandoned underground mines to prevent breakthroughs.
13. Design, operate, maintain, and abandon coal waste disposal areas in accordance with standards and criteria.
14. Treat, bury, or dispose of acid-forming, toxic, or combustible waste materials to prevent water contamination or spontaneous combustion, and develop contingency plans to prevent sustained combustion,
15. Use explosives in accordance with existing state and federal laws and regulations.
16. Proceed with reclamation efforts in an environmentally sound manner and as contemporaneously as practicable with mining operations.
17. Construct and maintain access roads so that erosion, siltation, water pollution, damage to fish and wildlife or their habitat, or damage to public or private property will be prevented.
18. Refrain from road construction that will seriously alter the flow of streams or drainage channels.
19. Revegetate disturbed lands with diverse, effective, and permanent species native to the area.
20. Assume responsibility for successful revegetation for a period of 5 full years after revegetation work is completed and for 10 full years in areas or regions with 26 in. (660 mm) or less annual average precipitation.
21. Protect offsite areas from slides or damage occurring during the mining and reclamation operations.

22. Place excess spoil material in such a manner to assure stability and proper drainage and prevent erosion.

23. Meet other criteria to achieve reclamation, taking into consideration physical, climatological, and other site characteristics.

24. Use the best technology currently available to minimize disturbances and adverse impacts on fish, wildlife, and environmental values.

25. Provide a natural barrier to slides and erosion.

Title IV also establishes minimum performance standards for underground coal mining operations.[27] Many of the performance standards are identical to those just described for surface mining. The Act does provide that regulations should consider the distinct differences between surface and underground coal mining. The general standards that are unique to underground mining are summarized:

1. Prevent subsidence causing material damage to the extent technologically and economically feasible, except where the mining technology used requires planned subsidence in a predictable and controlled manner.

2. Seal openings between the surface and underground workings when they are no longer needed for operations.

3. Fill or seal exploratory holes and return, to the maximum extent technologically and economically feasible, mine and processing waste to the mine workings.

4. Protect offsite areas from damages resulting from mining operations.

5. Eliminate fire hazards and other hazards to public health and safety.

6. Locate openings of drift mines in acid- or iron-producing coal seams so that they prevent gravity discharge of mine water.

The regulations implementing the performance standards set forth in the Act are not included here because of their length and detail. The reader is directed to the appropriate sections of the *Code of Federal Regulations* for the specific standards that apply to his or her situation. Permanent performance standards are provided for coal exploration activities,[28] surface coal mining and reclamation activities,[29] and underground mining activities.[30] The regulations also provide special performance standards for auger mining,[31] anthracite mines in Pennsylvania,[32] operations in alluvial valley floors,[33] operations on prime farmland,[34] mountaintop removal,[35] special bituminous coal mines in Wyoming,[36] coal preparation plants not located within the permit area of a mine,[37] and in situ processing.[38]

Performance Bonds: Under Title V, once an application has been approved but before the permit has been issued, the applicant must provide a performance bond.[39] The bond provides an incentive for the applicant to complete the required reclamation. The amount of the bond is determined by the regulatory authority and is based on the reclamation requirements. It must be sufficient to assure completion of the reclamation plan if the work had to be performed by the regulatory authority in the event of forfeiture. The minimum amount of the bond for the area under one permit is $10,000.

Release of the performance bond requires that reclamation be completed along with the period of time for which the mine operator is responsible for successful revegetation as specified in the performance standards.[40] To obtain release of a bond, the operator must file a bond-release application and advertise the application and the location of the mining operation in a local newspaper for four weeks. He must also send letters of notification to adjacent landowners and local authorities. Copies of these letters and the advertisement are included with the application for release. The regulatory authority will then inspect the reclamation work and determine if the performance bond or any part of it is to be released.

Enforcement: Inspections and fines for violations are the major enforcement tools provided by the Act. Inspections of the mining operation are conducted on an irregular schedule with a partial inspection occurring monthly and a full inspection occurring quarterly.[41] In addition to inspections, the operator is required to keep appropriate records, submit monthly reports to the regulatory authority, and make the records available to inspectors and the residents of the mining area. If an inspection identifies a violation of the Act that poses imminent danger to the health and safety of the public or could cause significant and imminent environmental harm, a cessation order will be issued. A notice of violation will be issued if the violation does not pose an imminent danger to the public or the environment. Both cessation orders and notices of violation must describe the violation, the remedial action required, and the time limit for correction of the violation.

Failure to comply with the terms of the mining permit or violations of any other provision of Title V of the Act results in fines not to exceed $5000 for each violation. Each day of continued violation may be considered a separate violation. The operator may request a hearing prior to the assessment of the fine. Any person who willfully and knowingly violates a condition of a permit or fails or refuses to comply with any cessation order can be punished by a fine of not more than $10,000, or by imprisonment for not more than one year, or both. A pattern of repeated violations or failure to comply with the requirements of the permit may result in either suspension or revocation of the permit.

3.4.2.3 Resource Conservation and Recovery Act of 1976 (Public Law 94-580)

Management of solid wastes, including those generated by the minerals industry, is regulated under the authority of the Resource Conservation and Recovery Act of 1976 (RCRA). RCRA was designed to provide "cradle-to-grave" management of land disposal of solid waste to protect health and the environment. Along with the Clean Air Act and the Clean Water Act, Congress viewed RCRA as the third critical environmental law needed for protection of the air, land, and water. The regulations that have been promulgated for solid waste management under RCRA begin in Part 240 of Title 40 of the *Code of Federal Regulations* (40 CFR § 240).

RCRA uses a very broad definition of *solid waste* that includes "any garbage, refuse, sludge from a waste treatment plant, water treatment plant, or air pollution control facility and other discarded material, including solid, liquid, semisolid, or contained gaseous material, resulting from industrial, commercial, mining, and agricultural operations, and from community activities."[42] Regulations further define solid waste to include any "discarded material" that is not excluded by regulation or by a specific variance granted by the EPA or an authorized state.[43] A "discarded material" is defined as any material that is abandoned, recycled or "inherently wastelike."[44] A material is "abandoned" if it is disposed of, burned, or incinerated, or accumulated, stored, or treated prior to or in lieu of abandonment.[45] A material is a solid waste if it is "recycled" in a manner constituting disposal, by burning for energy recovery, by reclamation, or by speculative accumulation.[46] The only type of recycled materials that are clearly not solid wastes are those directly "used or reused as ingredients in an industrial process to make a product" or "used or reused as effective substitutes for commercial products," or those recycled in a closed-loop manner "to the original process from which they are generated without first being reclaimed."[47] A material is "inherently wastelike" if the EPA so defines it by regulation.[48] These interlocking definitions of solid waste result in the EPA regulating a universe of materials, some of which may not be commonly understood to be wastes in a particular industry or company.

Solid waste management facilities are described under an equally broad definition and include "(A) any resource recovery system or component thereof, (B) any system, program, or facility for resource conservation, and (C) any facility for the collection, source separation, storage, transportation, transfer, processing, treatment or disposal of solid wastes including hazardous wastes, whether such facility is associated with facilities generating such wastes."[49]

The result of these broad definitions is that essentially all mining, minerals processing, and materials recycling operations fall under the jurisdiction of the Act. Some waste materials commonly found in minerals production operations such as used oils, solvents, and machine shop wastes are already regulated under RCRA. Waste streams associated with mining and beneficiation operations such as mine overburden, mine waste rock, leaching residues, and mill tailings are not currently regulated. A regulatory program for these wastes is under development by the EPA with implementation expected in the mid-1990s.

The EPA has categorized those production stages that take place after beneficiation as *processing.* Typical mineral processing operations include smelting and refining. Most wastes generated during mineral processing are subject to regulation as hazardous wastes. However, the final regulatory status of 20 large-volume mineral processing wastes is expected to be determined in 1991.[a]

Two major parts of RCRA are particularly important. Subtitle C (Subchapter III) deals with hazardous waste management. Subtitle D (Subchapter IV) deals with nonhazardous waste management. Each of these subtitles is described in the following.

Hazardous Waste Regulation: A *hazardous waste* is defined by Subtitle C of RCRA as "a solid waste, or combination of solid wastes, which because of its quantity, concentration, or physical, chemical, or infectious characteristics may (A) cause, or significantly contribute to an increase in mortality or an increase in serious irreversible, or incapacitating reversible, illness; or (B) pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed."[50]

The regulations include lists of specific hazardous wastes.[51] A solid waste is also defined as hazardous if it exhibits one or more characteristics including ignitability, corrosivity, reactivity, or EP toxicity.[52] The latter characteristic is determined by the Extraction Procedure (EP) Toxicity Test, which is described in the regulations.[53] The EPA has proposed a modification for the EP Toxicity Test, the Toxicity Characteristic Leaching Procedure (TCLP).[54]

Mixtures of solid wastes and listed hazardous wastes are also considered hazardous wastes unless the listed hazardous waste was listed "solely because it exhibits one or more of the [four] characteristics of hazardous waste" and "the resultant mixture no longer exhibits any characteristic of hazardous waste."[55]

Certain mining wastes are specifically designated as not being hazardous. These include "mining overburden returned to the mine site"[56] and "materials subjected to in-situ mining techniques which are not removed from the ground as part of the extraction process."[57] Other waste "from the extraction, beneficiation and processing of ores and minerals (including coal), including phosphate rock, and overburden from mining of uranium ore" were temporarily excluded.[58] More will be said about this exclusion later in this discussion.

Standards are included in the regulations for hazardous waste generators,[59] transporters,[60] and owners and operators of hazardous waste treatment, storage, and disposal facilities? In general, those participating in any of these types of activities are required to obtain an EPA identification number. A uniform manifest system is to be used for shipment, transport, and receipt of any hazardous waste. The extensive regulations for owners and operators of hazardous waste treatment, storage, and disposal facilities cover design, operation, and maintenance of the facility; contingency plans and emergency procedures; detection and correction of releases from the facility; closure and post-closure requirements; and financial requirements, to name just a few of the provisions.

Nonhazardous Waste Regulation: The management of *nonhazardous solid waste* is covered under Subtitle D of RCRA. The Act required the EPA to provide technical and financial assistance to state, regional, and local authorities for the development of solid waste management plans. The primary target of this subtitle was municipal waste. The EPA was required to develop criteria for sanitary landfills. All solid waste was to be disposed of in sanitary landfills. Open dumps were prohibited.

Guidelines for solid waste management plans were to be developed by the EPA and periodically reviewed. Rather than a rigid set of federal regulations as exist for hazardous waste, these guidelines were designed to provide flexibility. They were to consider "the varying regional, geologic, hydrologic, climatic, and other circumstances under which different solid waste management practices are required in order to insure the reasonable protection of the quality of the ground and surface waters from leachate contamination, the reasonable protection of the quality of the surface waters from surface runoff contamination, and the reasonable protection of ambient air quality."[62] They were also required to consider the "characteristics and conditions of collection, storage, processing, and disposal operating methods, techniques and practices, and location of facilities where such operating methods, techniques, and practices are conducted, taking into account the nature of the material to be disposed."[63]

At this writing, the future of the EPA's regulatory program under Subtitle D is less than clear. Many feel that the provisions of Subtitle D need to be strengthened and made more specific to individual waste types. However, the flexibility provided by Subtitle D is particularly important because the EPA has announced its intention to regulate mining and beneficiation wastes under this Subtitle.[64] The current status of the development of these regulations is described in the following.

Potential Changes in Mining Waste Regulation: Mining, beneficiation, and mineral processing wastes constitute nearly 40% of the nation's solid wastes generated annually by municipalities, industries, and agriculture. However, RCRA recognized the special characteristics of most of these wastes, namely that they are large in volume and generally low in toxicity. The Act required the EPA to study these wastes before developing regulations. Specifically, the Act required that "the Administrator [of the EPA], in consultation with the Secretary of the Interior, shall conduct a detailed and comprehensive study on the adverse effects of solid wastes from active and abandoned surface and underground mines on the environment."[65] In addition, it required that "the Administrator [of the EPA] shall conduct a detailed and comprehensive study on the adverse effects on human health and the environment, if any, of the disposal and utilization of solid waste from the extraction, beneficiation, and processing of ores and minerals, including phosphate rock, and overburden from uranium mining."[66] In 1980, Congress

[a] At this writing, the actual regulatory status of solid wastes in the minerals industry is complex and in a state of flux. The reader is cautioned to check carefully the current status of mining, beneficiation, and large-volume mineral processing waste regulations to see what new regulations may apply.

amended RCRA. One section of these amendments, the Bevill Amendment,[67] specifically excluded "solid waste from the extraction, beneficiation, and processing of ores and minerals" from regulation under Subtitle C, pending completion of the studies mentioned previously.

Because of the complex problems associated with the disposal of wastes such as mine overburden, mine waste rock, leach residues, mill tailings, and smelter slags, the development of regulations moved very slowly; however, the pace of regulatory developments has accelerated in recent years. In 1985, the EPA submitted a report to Congress entitled *Wastes from the Extraction and Beneficiation of Metallic Ores, Phosphate Rock, Asbestos, Overburden from Uranium, and Oil Shale.* This report partially met the requirements for the studies of mining and mineral processing wastes required by RCRA. In July 1986, EPA issued a regulatory determination in which it found that regulation of mining and mineral processing wastes as hazardous wastes under Subtitle C of RCRA was not warranted and that it would develop a regulatory program under Subtitle D. This determination was viewed as an important victory by the mineral industry. Although EPA originally intended that the regulatory determination would apply to all mining and mineral processing wastes, subsequent court decisions have caused EPA to narrow its scope to only mining and beneficiation wastes. It now appears likely that these wastes will be regulated by EPA and the states in the mid-1990s.

A 1988 court rendered an opinion that Congress had not intended that the mining waste exclusion under the Bevill Amendment should include all wastes from primary smelting and refining. It also decided that the term "solid waste from the . . . processing of ores and minerals" in that Bevill Amendment should include only those wastes from processing ores and minerals that meet undefined criteria for large volume and low hazard. The court directed EPA to immediately list six waste streams from aluminum, copper, lead, and ferroalloy smelting as hazardous. In September 1989, EPA published its final rule reinterpreting the Bevill exclusion for "solid waste from the . . . processing of ores and minerals."[68] In this ruling, EPA also established the criteria for designating wastes as large volume and low hazard.

In January 1990, EPA released another final rule which applied the revised interpretation and resulted in only 20 large-volume, mineral processing wastes being retained within the Bevill exclusion.[69] Included in this group were such wastes as lead smelter slags and phosphogypsum from phosphoric acid production. These wastes will be subject to study as required in RCRA. The study could lead to the final regulatory determination for mineral processing wastes within a year. As a result of these actions, all other mineral processing wastes are now subject to regulation under RCRA's Subtitle C as hazardous wastes.

3.4.3 MAJOR FEDERAL ENVIRONMENTAL LAWS AND REGULATIONS (cont.)

CLAYTON J. PARR

3.4.3.1. Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (Superfund)

The Comprehensive Environmental Response, Compensation, and Liability Act (commonly referred to as "CERCLA" or "Super-fund") focuses upon discharges of hazardous substances.[1] Such hazardous substances can exist in mine water, leachate (including natural leachate from waste piles), mill tailings, and chemicals used in various stages of mining, mineral processing, and mine-related activities.[2]

Ongoing mine- and mill-related discharges of hazardous solid wastes are covered by the Resource Conservation and Recovery Act. CERCLA applies to discharges of "hazardous substances" at inactive sites occurring through the effects of natural processes on discarded materials.

CERCLA also applies to accidental spills or releases of certain hazardous substances that are not subject to reporting and cleanup requirements of other laws.

CERCLA is enforced by the US Environmental Protection Agency, but it also involves state agencies.

Inactive Sites: Mine operators may encounter CERCLA-governed inactive sites on owned property or property that is being acquired. Old tailings disposal areas in particular are high risk.

The definition of *hazardous substance* is extremely broad, covering generally materials that present a substantial danger to the environment or public health. The term includes certain hazardous substances and toxic pollutants designated under the Clean Water Act, Solid Waste Disposal Act, Clean Air Act, and Toxic Substances Control Act. A list of substances designated as hazardous by EPA is published in Title 40, Code of Federal Regulations (CFR), Part 302.

The most common situation encountered at mine sites involves deposits of wastes, such as mill tailings, with hazardous substance constituents that through action of the elements can pollute surface water or groundwater. Some near-surface sites can emit dangerous gases or particles that can enter the body through respiration. A few materials, such as PCBs, are dangerous to the touch. Petroleum, including crude oil and any fraction thereof that is not otherwise specifically listed or designated as a hazardous substance, natural gas, natural gas liquids, liquefied natural gas, or synthetic gas usable for fuel, are excluded.[3]

CERCLA requires that persons in charge give notification of any facility where hazardous wastes have been treated, stored, or disposed of that could threaten the environment, unless the site has already been identified through the RCRA notification procedures. Sites are also identified by EPA through its own investigations.[4]

Once a site is identified by EPA as a possible source of discharges of hazardous substances, further evaluation procedures are governed by the National Contingency Plan (NCP)[5] The NCP also establishes the framework for site investigations and for removal and remediation. EPA has the authority to request information concerning use, transportation, or generation of hazardous substances.[6] In a final rule promulgated on Mar. 8, 1990, EPA adopted changes to the NCP (1) to implement regulatory changes necessitated by the Superfund Amendments and Reauthorization Act of 1986; (2) to clarify existing NCP language; and (3) to reorganize the NCP to coincide more accurately with the sequence of response actions.[7]

A preliminary assessment is performed to determine whether a serious problem exists. Through a mathematical evaluation methodology, known as the Hazard Ranking System (HRS), sources, pathways, and receptors are assessed.[8] If the score and resulting ranking are sufficiently high, the site is placed on the National Priorities List (NPL), a listing of approximately 1200 sites throughout the United States that have been evaluated as needing to be cleaned up.[9] A remedial investigation/feasibility study (RI/FS) is then conducted to determine appropriate remedial alternatives and objectives. After a remedial action is selected, which can involve stabilization or removal, work begins.

CERCLA is designed to put the obligation to pay for all of this expensive work on those who were responsible for putting the hazardous substances at the site in the first place or who now own the land upon which the site is located. If no responsible party can be found, or if the cleanup must proceed before the responsible parties can be tagged with the liability, funds can be used from the federal Hazardous Substance Superfund.[10] Reimbursement is then sought from the responsible parties. Governmental entities and private parties can also obtain reimbursement from the fund or from responsible parties.[11] Claims are not recoverable where the release of a hazardous substance is federally permitted, which can include releases authorized under state permits issued pursuant to delegated federal programs.[12]

Potentially Responsible Parties (PRPs) may include present or former owners or operators of the facility or the property upon which the hazardous wastes have been stored, treated, or disposed of; the generators of the hazardous waste; and parties who accepted the hazardous waste for transport and selected the facility.[13] The unique, and most frightening aspects of CERCLA, involve the scope of the liability of the PRPs. Because the liability is retroactive, a PRP can have enormous financial responsibility for activities that took place decades ago when the hazardous waste generating activity did not conflict with any then applicable laws. Although the law provides for contribution among responsible parties, liability is joint and several, thereby exposing any one of the responsible parties to an obligation to pay for the entire remedial action even though only a small fraction of the problem can be directly attributed to that party. A strict liability standard is applied, meaning that no negligence or willful misconduct need be shown.[14]

Completion of remediation cleanup of the site that removes the threat does not end the matter. CERCLA also provides for liability of responsible persons for damages for, injury to, destruction of, or loss of natural resources, including the reasonable costs of assessing such injury, destruction, or loss resulting from a release or threatened release of a hazardous substance.[15] This element of the law addresses more long-range effects of the discharge on such things as land, fish, wildlife, biota, air, water, groundwater, drinking water supplies, and the like that are controlled by the United States or any state or local government.[16] Natural resources damages cannot be recovered with respect to damages and releases that occurred wholly prior to enactment of CERCLA.[17]

Because of the immense liability that can be imposed upon an owner of a property under CERCLA, an examination for possible sites containing hazardous substances should be made before an acquisition is completed.[18] Under the "innocent landowner defense," liability can be avoided if it can be shown by a landowner that, at the time the facility was acquired, the purchaser did not know and had no reason to know that any hazardous substance which is the subject of a release or threatened release was disposed of on, in, or at the facility.[19] This requires that an appropriate inquiry has been undertaken at the time of acquisition into the previous ownership and uses of the property consistent with good commercial or customary practice in an effort to minimize liability. A thorough examination by trained professionals is needed to show such an appropriate inquiry.

Accidental Spills: Upon the occurrence of a spill or other actual release of a reportable quantity of a hazardous substance, the person in charge must immediately notify the National Response Center (NRC) at US Coast Guard headquarters in Washington, DC. The reportable quantity, as prescribed in Section 302 of Title 40, CFR, may be as little as 1 lb (0.5 kg) or as much as several thousand pounds (kilograms) per 24-hr period. The person in charge is the individual or entity with power to direct the activities of persons who control the mechanisms causing the pollution.[20] A responsible person who fails to notify under CERCLA is liable for civil and criminal penalties.[21]

Certain substances and types of releases are exempted from reporting requirements. Among these are petroleum, crude oil, natural gas, natural gas liquids, and releases exempted from reporting under RCRA. The petroleum exclusion includes refined petroleum products.

A release includes "spilling, leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping, leaching, dumping or disposing into the environment (including the abandonment or discarding of barrels, containers, and other closed receptacles containing any hazardous substances" or pollutant or contaminant)."[22] Since it is only releases "into the environment" that are covered, a hazardous substance spill onto a concrete floor of an enclosed building or structure need be reported only if the substance escapes the building structure in a reportable quantity.[23]

The owner or operator of the facility from which the release has been made has the responsibility to clean up. If that does not happen, EPA may issue an administrative order or seek an injunction ordering a responsible party to mitigate or clean up the release.[24] EPA may also go ahead with the cleanup (a remedial action) and then seek reimbursement of costs from the responsible party.[25] Cleanup is performed pursuant to the National Contingency Plan.[26] Such "remedial actions" are designed "to prevent or minimize the release of hazardous substances" or pollutants or contaminants so they do not migrate to cause substantial damage to present or future public health or welfare or to the environment.[27]

The owner/operator with responsibility for such costs includes the entity with legal possession of and operating control over the facility, and other individuals or entities such as parent corporations that actively control the daily operations of the subsidiary; lenders or other secured creditors who take possession and participate in management of the facility; passive owners, such as lessors, even if they do not participate in facility management or in the disposal of hazardous substances; and individual officers and controlling shareholders who actively participate in management of the facility.[28]

SARA/EPCRA: The Superfund Amendments and Reauthorization Act of 1986 ("SARA") enacted the Emergency Planning and Community Right-to-Know Act ("EPCRA" or "SARA Title III") as a free-standing law. EPCRA's purpose is to encourage state and local emergency planning regarding chemical releases, and to develop a bank of information for residents and local governments on potential chemical hazards in their communities. That bank of information is collected from owners and operators of subject facilities pursuant to the reporting requirements of EPCRA. EPCRA's reporting requirements include (1) emergency release notification under Section 304;[29] (2) community right-to-know reporting under Sections 311 and 312;[30] and (3) toxic chemical release reporting under Section 313.[31]

The Environmental Protection Agency has developed a list of "extremely hazardous substances" under EPCRA. The list is codified at Title 40, CFR, Part 355, Appendix A. Under Section 304, facilities must immediately notify state and local planning committees of the release of a reportable quantity of either a CERCLA "hazardous substance" or an EPCRA "extremely hazardous substance." This requirement is closely related to but slightly different from the accidental release reporting requirements under CERCLA. Currently, the major difference in reporting requirements is that releases of "extremely hazardous substances" need be reported only to state and local officials, while releases of "hazardous substances" must be reported to the National Response Center (to satisfy CERCLA reporting requirements) *and* to state and local officials (to satisfy EPCRA emergency release notification requirements). EPA is currently involved in rulemaking that would eliminate the confusion caused by these different notification requirements.[32]

Owners and operators otherwise required (under the provisions of the Occupational Safety and Health Act, or OSHA) to prepare or have available Material Safety Data Sheets (MSDS) for "hazardous chemicals" under OSHA (codified at Title 29, CFR, Section 1910.1200) must annually submit either the MSDS or a list of such chemicals present at a facility above specified threshold levels to state and local committees and to the local fire department. In addition, subject facilities must submit annual inventory forms to the same governmental entities providing aggregate information on the maximum and average amounts and general location of hazardous chemicals present at a facility above specified threshold levels.[33]

Subject facilities must submit to EPA and designated state officials a toxic chemical release inventory form ("Form R") annually on July 1.[34] Form R covers all types of releases to all environmental media. The list of toxic chemicals is codified at Title 40, CFR, Part 372 (Subpart D). Data provided to EPA under the provisions of Section 313 is available to the general public on a computerized database. Facilities subject to Form R reporting are, among other things, manufacturing facilities under Standard Industrial Classification Codes 20-39. Although the mining and milling of natural resources falls outside of those Codes (i.e., Standard Industrial Classification Codes 10 through 14), many mining operations, such as metal mining, also include manufacturing operations (e.g., smelting and refining), which brings them within the scope of this reporting requirement.

3.4.3.2 Federal Water Pollution Control Requirements

The initial inquiry as to environmental regulations concerning water pollution must be directed to federal law, and particularly to the Water Pollution Control Act Amendments of 1972[35] as amended by the Clean Water Act of 1977[36] (collectively referred to here as the Act). This long and very complex piece of legislation establishes the basic procedural and technical requirements applicable to the discharge of water as a consequence of any mining or milling activity.

The basic thrust of the Act is to improve water quality by regulation of discharges of pollutants into navigable waters at the source. Thus the addition of any pollutant to navigable waters from any point source except in compliance with the Act is unlawful.[37]

The term *point source* is defined as follows:

> [A]ny discernible, confined and discrete conveyance, including but not limited to any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, or vessel or other floating craft, from which pollutants are or may be discharged.[38]

The term *navigable waters* is so broadly defined in the Act and in the regulations that any discharge from a point source, whether intermittent or continuous, that enters surface waters, or tributaries of surface waters (even if not flowing), should be presumed to be covered.[39]

The Act also provides for the adoption of standards applicable to the discharge of pollutants into publicly owned treatment works.[40]

Responsibility for administering the Act initially rests with EPA. As described in the following, individual states can take over certain administrative and enforcement responsibilities under the Act.

Effluent Limitations: Regulations applicable to discharges from point sources at mining operations are designed to protect water quality by limiting the concentrations of certain pollutants and by limiting the level of acidity in whatever quantities of water that are discharged from point sources. Those levels are determined by evaluating the level to which the quantities of pollutants can be limited through the application of available technology.[41]

Existing sources have been permitted under requirements that have become more restrictive over time.

Since the most modern technology can be incorporated into new construction, the restrictions for discharges from new sources, as would be expected, are the most stringent. New sources are thus to be governed by effluent limitations based upon standards reflecting application of "the best available demonstrated control technology, processes, operating methods, or other alternatives."[42] Where these "new source performance standards" have yet to be developed, as is the case with some of the mining discharge categories described in the following, the most stringent limitations that have been developed are applicable to new sources, with the subsequently developed standards to be imposed over time as permits are renewed.

Standards of performance for new sources located in a particular state may be applied and enforced by the state, if the procedures and the laws of the state require the application and enforcement of standards of performance to at least the same extent as is required by the federal law.[43]

Ore Mining and Dressing Point-Source Category: Effluent limitations promulgated by EPA for the ore mining and dressing point-source category are set forth in Part 440, of Title 40, CFR.[44] Separate regulations are set forth for each of 12 subcategories of ore. These are (1) iron, (2) aluminum, (3) uranium, radium, and vanadium, (4) mercury, (5) titanium, (6) tungsten, (7) nickel, (8) vanadium (mined alone), (9) antimony, (10) copper, lead, zinc, gold, silver, and molybdenum, (11) platinum, and (22) gold placers.

The regulations are applicable to mines and mills producing and processing ores in the various subcategories. The term *mine* is defined in the regulations as an

> active mining area, including all land and property placed under, or above the surface of such land, used in or resulting from the work of extracting metal ore or minerals from their natural deposits by any means or method, including secondary recovery of metal ore from refuse or other storage piles, wastes, or rock dumps and mill tailings derived from the mining, cleaning, or concentration of metal ores.[45]

The regulations are directed to waste water discharged from mines as mine drainage. The term *mine drainage* means any water drained, pumped, or siphoned from a mine.[46]

If drainage from mines or discharges from mills are polluted, treatment will be required to reduce the concentration to permitted levels before it can be discharged to navigable waters. Because the quantity of mine water is dependent upon many factors beyond the control of the mine operator and is unrelated or only indirectly related to mine production, discharge restrictions are expressed in terms of concentration (with the exception of pH units) rather than units of production.

The term *mill* is defined as a

> preparation facility within which the metal ore is cleaned, concentrated, or otherwise processed before it is shipped to the customer, refiner, smelter, or manufacturer. A mill includes all ancillary operations and structures necessary to clean, concentrate, or otherwise process metal ore, such as ore and gangue storage areas and loading facilities.[47]

Mill water that may have become polluted is that water used in ore and product washing, dust suppression, grinding and classification, heavy-media separation, flotation, and equipment and floor washing. In addition, boiler blowdown and noncontact cooling water, such as bearing cooling water, have been identified as possible sources of stream pollutants.

Mineral Mining and Processing Point-Source Category: Effluent limitations promulgated by EPA for the mineral mining and processing point-source category, which includes minerals generally classified as industrial minerals, are set forth in Part 436 of Title 40, CFR.[48] Separate regulations are given for each of 21 subcategories, and EPA contemplates that standards eventually will be promulgated for 38 subcategories of mineral types or classes. Minerals for which effluent limitations have been published are crushed stone, construction sand and gravel, industrial sand, phosphate rock, gypsum, asphaltic minerals, asbestos and wollastonite, barite, fluorspar, salines from brine lakes, borax, potash, sodium sulfate, Frasch sulfur, bentonite, magnesite, diatomite, jade, novaculite, tripoli, and graphite.

The regulations are directed toward limiting the pollutants from mine drainage, transportation of the ore to the processing plants, and waste waters from the processing plant itself, including transport water, ore and product washing water, dust-suppression water, classification water, heavy-media separation water, flotation water, solution water, air-emissions control-equipment water, and equipment and floor washdown water.[49]

Coal-Mining Point-Source Category:[50] Effluent limitations promulgated by EPA for the coal-mining point-source category are set forth in Part 434, Title 40, CFR. Separate regulations are provided for each of three subcategories:

1. The Coal Preparation Plant and Coal Preparation Plant Associated Areas Subcategory is applicable to facilities where coal is cleaned, concentrated, or otherwise processed or prepared in order to separate coal from its impurities and is loaded for transfer to a consuming facility and associated areas such as coal preparation plant yards, immediate access roads, coal refuse piles, and coal storage piles and facilities.

2. The Acid or Ferruginous Mine Drainage Subcategory is applicable to mine drainage resulting from the mining of coal of any rank that, before any treatment, has either a pH of less than 6.0 or a total iron concentration of more than 10 mg/L.

3. The Alkaline Mine Drainage Subcategory is applicable to mine drainage resulting from the mining of coal of any rank that, before any treatment, has a pH of more than 6.0 and a total iron concentration of less than 10 mg/L.

4. The Postmining Areas Subcategory is applicable to discharges from reclamation areas until the performance bond issued to the facility under the Coal Surface Mining and Reclamation Act has been released by the appropriate authority.

The regulations define *active mining area* as:

> the area, on and beneath land, used or disturbed in activity related to the extraction, removal, or recovery of coal from

its natural deposits. This term excludes coal preparation plants, coal preparation plant associated areas and post-mining areas.[51]

Postmining area is defined as: (1) a reclamation area or (2) the underground workings of an underground coal mine after the extraction, removal, or recovery of coal from its natural deposit has ceased and prior to bond release.[52]

The term *mine drainage* means any water drained, pumped, or siphoned from an active mining area or a postmining area.[53]

Parameters are established for four pollutants typically discharged into streams from coal mining operations. These are total iron, total manganese, total suspended solids, and pH.

State Areawide Waste Treatment Management Plans: Under Section 208 of the Act,[54] the governor of each state, in compliance with regulations published by the Administrator, must identify each area within the state that has substantial water-quality control problems. A continuing areawide waste-treatment management planning process is to be prepared for each such area and will be applicable to all wastes generated within the area involved. Areas within a state, including federal lands, that are not so designated by the governor will, by operation of the provisions of Section 208, be ultimately designated and made subject to areawide waste-treatment plans.[55]

The waste-treatment planning process must provide for control or treatment of all point and nonpoint sources of pollution, including in-place or accumulative pollution sources, to protect both groundwater and surface-water quality.[56] Each plan is (1) to include a process to identify mine-related sources of pollution including new, current, and abandoned surface and underground mine runoff, and (2) to set forth procedures and methods (including land-use requirements) to control such sources to the extent feasible.[57] So-called "best management practices" will be established to control nonpoint-source pollution. Best management practices are those selected by an agency to meet its nonpoint source-control needs. They include structured and nonstructured controls and operation and maintenance procedures, and they can be applied before, during, and after pollution producing activities.[58]

Section 208 plans have significance for mining operations because no permit under Section 402 of the Act will be issued for any point source that is in conflict with an areawide waste treatment plan.[59] In addition, control over nonpoint-source pollution, such as would occur from storm runoff or from leach dumps, is provided for by the Act, even though the Section 402 permit requirements directly relate only to point sources.[60]

State Water Quality Standards: Under Section 303 of the Act,[61] each state also must adopt interstate and intrastate water quality standards applicable to water in the state. Water quality standards are essentially water-use classifications generally based upon the quality criteria for water developed by EPA. Typical water quality programs assign each body of water one or more classifications, based upon existing quality and uses, such as public water supply, recreational, aquatic life, industrial, and agricultural.[62] For such standards to be achieved or maintained, it is necessary to regulate effluents entering those waters from industrial operations. Therefore, a discharge of pollutants from a mining operation is evaluated to determine whether this discharge will allow achievement or maintenance of the state water quality standards.

Section 303(d)[63] requires that each state further identify the waters within its boundaries for which the effluent limitations required under Section 301 of the Act are not stringent enough to implement any water quality standard applicable to any such waters. Maximum daily load limits are to be established for those pollutants for which the effluent limitations are inadequate. Consequently, a mining operation located on water so classified may have to meet more stringent effluent limitations than otherwise would be imposed.[64]

Permit Requirements: As is indicated from the foregoing discussions, the degree of water pollution control required at any given property is determined both by the water quality standards to be achieved in the area and by the effluent limitations that are imposed by regulation. Permit conditions are designed to assure that the discharge meets such requirements. When necessary to meet water quality standards, treatment standards, or schedules of compliance established pursuant to state law or regulation, more stringent limitations may be imposed than are required by the Act.

These substantive aspects of the Act are imposed upon mining operations by means of a permit system; a permit is required for any discharge of pollutants subject to the Act, which establishes the National Pollutant Discharge Elimination System (NPDES).[65]

NPDES permits must be acquired for all existing and new sources. A permit is not required for discharges made to a publicly owned treatment works, but, in such instances, the discharger must comply with applicable pretreatment standards.[66]

The Environmental Protection Agency has recently promulgated NPDES permit application procedures for discharge of storm water "associated with industrial activity" pursuant to Section 402(p) of the Act.[66a] The term "associated with industrial activity" includes storm water discharges from "[f]acilities classified as Standard Industrial Classifications 10 through 14 (mineral industry) including active or inactive mining operations."[66b] If storm water from these facilities is "contaminated by contact with . . . any overburden, raw material, intermediate products, finished product, byproduct or waste products located on the site of such operations," then storm water discharges from the facilities must be permitted.[66c] Under these new regulations, facilities may choose to apply for general, group, or individual permits.[66d]

Permits are issued on such conditions as the Administrator determines are necessary to carry out the provisions of the Act, and they can be extremely stringent. Specifically, the permits must comply with published state and federal effluent limitation requirements. Federal requirements are based upon determinations of the minimum concentrations of certain pollutants that can be achieved through the application of varying levels of pollution control technology. Effluent limits under permits may also be influenced by limitations imposed to improve or maintain water quality in the drainage system involved. It is through this means that water pollution is controlled, and the overall objectives of the Act are ultimately achieved. The nature of such requirements is discussed in the following paragraphs.

The permit program established under Section 402 of the Act may be administered by the state for discharges into navigable waters within its jurisdiction, if a proposed state plan is submitted to and approved by the Administrator of the EPA in accordance with the standards established by the Act.[67] The Administrator, however, retains the power to review permit applications and to object to the proposed issuance of a permit.[68] In such an event, the state may resubmit the permit, revised to meet the objection, or request a hearing. If neither step is taken, the Administrator may issue the permit with such modifications as he deems necessary to effect compliance with the Act.[69]

A separate permit application must be submitted for each facility that is discharging separately. Therefore, more than one permit may be required for a particular mining operation. One NPDES permit, however, may cover several discharge points from the same facility or operation.

Current procedures for obtaining NPDES permits (applicable in states not having an approved plan for state administration) are set forth in Part 124, Title 40, CFR. State programs are patterned after the federal regulations.[70] Details of permit contents are presented in Part 122 of Title 40, CFR.

A new discharger must apply for a permit at least 180 days before discharge begins, unless the Regional EPA Administrator approves a later application date.[71] The application must be submitted on an appropriate form.

No action will be taken on an application to the EPA until the applicant provides the Regional Administrator with a certification from the state or interstate water pollution control agency having jurisdiction over the discharge point of origin that the discharge will comply with any applicable effluent limitations or water quality standards. Any certification must set forth any applicable effluent limitations, standards, and monitoring requirements needed to insure compliance with state regulations.[72]

Public notice is given of each application, and a draft permit is prepared for comment.[73] If a sufficient degree of public interest is found or if a request is made, a hearing will be held.[74] EPA has 90 days to comment on a state-issued permit.[75] If EPA objections are not met, EPA can take over and issue the permit.[76]

An environmental impact statement will not be required prior to issuance of a permit for an existing source, but it may be required in connection with permits for new sources.[77] Preparation of an EIS will expand the time required for obtaining a permit.

An adjudicatory hearing will be held if a request is made and if the Regional Administrator determines that the request sets forth material issues of fact or that a hearing is necessary or appropriate.[78]

Permits must contain any special conditions deemed necessary to assure compliance with applicable effluent limitations or other water quality requirements, including schedules of compliance, treatment standards, record keeping, and monitoring requirements (including those set forth in the state certification).[79]

Permits are issued for a fixed term not exceeding five years. Short-term permits of less than five years may be issued where there are special circumstances.[80]

If the operator of a point source fails to obtain a permit or violates the permit conditions, EPA may issue a compliance order or bring a civil action against the violator.[81] Civil penalties of up to $25,000 per day of violation may be imposed for discharges without a permit or in violation of a permit.[82] Any person negligently violating the Act or any condition or permit issued by EPA or by a state is subject to criminal sanctions and may be punished by fine of not less than $2500 nor more than $25,000 per day of violation, by imprisonment for not more than one year, or both. Willful violations trigger penalties of not less than $5000 per day of violation, or imprisonment not to exceed three years, or both.[83] Conviction of subsequent violations is punishable by a fine of not more than $50,000 per day and/or two years' imprisonment.[84]

Violation of the Act, of any conditions or limitations set forth in a state or federal permit, or of any compliance order, which violation is not willful or the result of negligence, is subject to civil penalties assessed administratively by EPA.[85]

Hazardous Substances: Section 311 of the Act[86] provides for the designation of hazardous substances other than oil by the Administrator of EPA, and the imposition of penalties for the unauthorized discharge of such substances. Hazardous substances are elements or compounds other than oil which, when discharged in any quantity into or upon navigable waters of the United States, present an imminent and substantial danger to the public health or welfare, including, but not limited to, fish, shellfish, wildlife, shorelines, and beaches.[87]

The Administrator must make a determination whether any substance designated as a hazardous substance can be removed after discharge.[88] The unauthorized discharge of any hazardous substance determined not to be removable creates liability for monetary penalties based on the quantity of such hazardous substance that is released.[89]

The discharge of any hazardous substance into navigable waters in harmful quantities is prohibited.[90] The quantity of a substance that constitutes a harmful quantity is determined by the Administrator of EPA and shown in Part 117 of Title 40, CFR. Any such discharge must be reported to the EPA, National Response Center in Washington, DC, by the person in charge, failing which, a penalty of a fine or imprisonment can be imposed. Penalties of not more than $5000 will be assessed for each discharge.[91] The penalties are based upon the toxicity, degradability, and dispersal characteristics of the substance or the number of units of measurement discharged. The owner causing such discharge is also liable for the costs of removal of the hazardous substance.[92]

Regulations designating hazardous substances promulgated by EPA are contained in Part 116, Title 40, CFR. The list of substances designated as hazardous includes many chemicals common to mining and milling operations. Consequently, unauthorized discharge of such substances through direct release or through breach of a tailings pond could result in liability for the penalties provided in the Act.

Regulations may also be promulgated by the Administrator, establishing best management practices for hazardous pollutants to control plant-site runoff, spillage or leaks, sludge or waste disposal, and drainage from raw material storage.[93] Such controls must be required in any NPDES permit.

Discharges of Oil: Discharges of oil in harmful quantities are prohibited.[94] Harmful quantities are those that "cause a film or sheen upon or discoloration of the surface of the water or adjoining shorelines or cause a sludge or emulsion to be deposited beneath the surface of the water or upon adjoining shorelines."[95]

Any prohibited discharge must be reported to the Natural Response Center in Washington, DC.[96] Civil penalties are prescribed for violation of oil pollution regulations.[97]

A spill prevention, control, and countermeasure (SPCC) plan is required of any facility that has a buried oil-storage tank with a capacity of greater than 42,000 gal (159 kL), a nonburied oil-storage unit of more than 1320 gal (5 kL), or any single container greater than 660 gal (2.5 kL).[98] The plan must be certified by a registered professional engineer and must contain the procedures, methods, and equipment that will prevent the discharge of oil spills to navigable waters. No plan need be submitted to the EPA, but it must be available for inspection at any time.[99]

The plan is required of any onshore facilities not related to transportation. Facilities which, due to their location, cannot reasonably expect to discharge oil onto navigable waters are exempt from preparing an SPCC plan. The regulations establish penalties for oil spills.[100]

Toxic Pollutants: Section 307(a) of the Act establishes a list of 65 pollutants considered to be toxic.[101] Included are the following that could be encountered in mining and milling operations:

1. Antimony and compounds.
2. Arsenic and compounds.
3. Asbestos.
4. Beryllium and compounds.
5. Cadmium and compounds.
6. Chromium and compounds.
7. Copper and compounds.
8. Lead and compounds.

9. Mercury and compounds.
10. Nickel and compounds.
11. Selenium and compounds.
12. Silver and compounds.
13. Zinc and compounds.

The Administrator is authorized to add pollutants to or remove pollutants from the list from time to time. Effluent standards or prohibitions for toxic pollutants set forth in EPA regulations may be incorporated in an NPDES permit.[102]

At the time of this writing, EPA has established special toxic effluent standards for only six pollutants, which do not include any of those listed previously.[103]

Regulations also may be promulgated by the Administrator, establishing best management practices for toxic pollutants to control plant-site runoff, spillage or leaks, sludge or waste disposal, and drainage from raw material storage.[104] Even though such sources are more in the nature of nonpoint sources, effluent controls requiring best management practices will be included in NPDES permits.

3.4.3.3 Dredge and Fill Permits

Section 404 of the Water Pollution Control Act[105] authorizes the Secretary of the Army, acting through the Chief of the Corps of Engineers, to issue permits for the discharge of dredged or fill material into the navigable waters of the United States at specified disposal sites. Guidelines for the selection of disposal sites are to be developed by the Administrator of EPA in conjunction with the Secretary of the Army.[106]

Regulations prescribing the policy, practice, and procedure to be followed by the Corps of Engineers in connection with applications for permits for the discharge of dredged or fill material into navigable waters are contained in Chapter II, Title 33, CFR. Guidelines prepared by the Administrator of the EPA for the selection of disposal sites are available in Part 230, Chapter I, Title 40, CFR.

Although Section 404 refers to navigable waters, regulation of the discharge of dredged or fill material under Section 404 has been applied by the Secretary of the Army to all waters affected by the Water Pollution Control Act, referred to as "waters of the United States." This term is defined in the regulations as including

> (a) The term "waters of the United States" means
>
> (1) All waters which are currently used, or were used in the past, or may be susceptible to use in interstate or foreign commerce, including all waters which are subject to the ebb and flow of the tide;
>
> (2) All interstate waters including interstate wetlands;
>
> (3) All other waters such as intrastate lakes, rivers, streams (including intermittent streams), mudflats, sandflats, wetlands, sloughs, prairie potholes, wet meadows, playa lakes, or natural ponds, the use, degradation or destruction of which could affect interstate or foreign commerce including any such waters:
>
> (i) Which are or could be used by interstate or foreign travelers for recreational or other purposes; or
>
> (ii) From which fish or shellfish are or could be taken and sold in interstate or foreign commerce; or
>
> (iii) Which are used or could be used for industrial purpose by industries in interstate commerce;
>
> (4) All impoundments of water otherwise defined as waters of the United States under the definition;
>
> (5) Tributaries of waters identified in paragraphs (a) (1) through (4) of this section;
>
> (6) The territorial seas;
>
> (7) Wetlands adjacent to waters (other than waters that are themselves wetlands) identified in paragraphs (a) (1) through (6) of this section.
>
> Waste treatment systems, including treatment ponds or lagoons designed to meet the requirements of CWA (other than cooling ponds as defined in 40 CFR 123.1 l(m) which also meet the criteria of this definition) are not waters of the United States.[107]

As a result of this broad definition of waters of the United States, activities conducted throughout all of the interior of the United States are subject to the jurisdiction of the Corps of Engineers under Section 404, if such activities involve the discharge of dredged or fill material into virtually any standing or moving body of water or their tributaries, whether or not they are perennial and adjacent wetlands. Moreover, intermittent streams and isolated standing bodies of water that are not a part of a tributary system to interstate waters or to navigable waters, are included. Most importantly, wetlands, wherever occurring, come within the definition. Consequently, a mining operation may be subject to permit requirements under Section 404 if it deposits any material into a drainage channel or depression where water exists or may periodically accumulate or flow.

The most pervasive impact of Section 404 on mining operations occur in connection with wetlands, which are defined as follows:

> (b) The term "wetlands" means those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas.[108]

Wetlands have become vital areas of concern because of the broad range of wildlife that they support and because of the key role they play in the natural ecosystem. Their protection constitutes a significant, but important, extension of Corps jurisdiction beyond matters related to commerce on navigable bodies of water.

Discharge of Dredged or Fill Material: Section 404 refers to the discharge of dredged or fill material. *Dredged material* is any material excavated or dredged from waters of the United States.[109] A *discharge of dredged material* occurs when there is addition of dredged material to a specified discharge site located in waters of the United States and the runoff or overflow from a contained land or water disposal area.[110] The term does not include plowing, cultivation, seeding, or harvesting for the production of food, fiber, and forest products.

Fill material is any material used for the primary purpose of replacing an aquatic area with dry land or of changing the bottom elevation of a water body.[111] It does not include any pollutant discharged into water primarily to dispose of waste, as that activity is regulated under Section 402 of the Water Pollution Control Act.

A discharge of fill material occurs when fill material is added into waters of the United States, including the placement of fill that is necessary to the construction of any structure in a water of the United States; the building of any structure or impoundment requiring rock, sand, dirt, or other material for its construction; site-development fills for recreational, industrial, commercial, residential, and other uses; causeways or road fills; dams and dikes; artificial islands; property protection and/or reclamation devices such as riprap, groins, seawalls, breakwaters, and revetments; levees; fill for structures such as sewage treatment facilities, intake and outfall pipes associated with power plants and subaqueous utility lines; and artificial reefs.[112] The term does not include plowing, cultivating, seeding, and harvesting for the production of food, fiber, and forest products.

The list of activities for which a permit is required illustrates that there are many surface activities related to the operation of mines located near waters of the United States as defined in the Act that could trigger the requirement for a permit under Section 404. Such activities would include the construction of bridges, the placement of culverts, the alteration of natural stream channels, the laying of utility pipelines, the construction of diversion dams, the construction of bulkheads along stream cuts, the placement of waste dumps, the excavation of open pit or strip mines, and most importantly, the disturbance of any wetlands.

General and Individual Permits: Recognizing the difficulty of issuing separate permits for all such discharges, the Secretary of the Army has established a system that provides for the issuance of individual and general permits. Specific statutory authorization to issue general permits on a state, regional, or nationwide basis for any category of activities involving discharges of dredged or fill material has been given to the Corps of Engineers.[113]

A general permit has been issued for discharges of dredged or fill materials into certain kinds of waters and watercourses.

General permits, described in Part 330 of Title 33, CFR, have been issued as of the date of this writing for 26 specified authorized activities.[114] Some of these are important to the mining industry.

One permitted activity directly related to mining pertains to structures, works, and discharges associated with surface coal mining activities permitted under the Surface Mining Control and Reclamation Act of 1977, provided that the appropriate district engineer is given the opportunity to review the permit application and the district or division engineer makes a determination that the individual and cumulative adverse effects on the environment from the structures, work, or discharges are minimal.[115]

Another permitted activity important to mining covers discharges causing the loss or substantial modification of less than 10 acres (4 ha) of waters of the United States, including wetlands, into (1) nontidal rivers, streams, and their lakes and impoundments, including adjacent wetlands, that are located above the headwaters, and (2) other nontidal waters, including adjacent wetlands, that are not part of a surface tributary system to interstate waters or navigable waters of the United States.[116] Prenotification of the district engineer is nonetheless required for such discharges that cause the loss or substantial adverse modification of 1 to 10 acres (0.4 to 4 ha) of such waters, including wetlands.[117] The term *headwaters* means the point on a nontidal stream above which the average annual flow is less than 5.0 ft^3/sec (0.039 m^3/s), using the mean annual area precipitation, area drainage basin maps, and the average runoff coefficient, or by similar means.[118] For streams that are dry during long periods of the year, district engineers may establish the headwater point as that point on the stream where a flow of 5.0 ft^3/sec (0.039 m^3/s) is equalled or exceeded 50% of the time. The surface area of a lake is determined at the ordinary high-water mark.

To rely on the general permit for these remote activities, a number of specific conditions must be met including requirements that no significant disruption of the movement of aquatic life indigenous to the waterbody occur, that the structure of fill be properly maintained, and that management practices listed in the regulations[119] be followed. The general permit does not remove the necessity of complying with applicable local or state laws.[120] Other categories of discharges covered by a general permit include (1) survey activities including core sampling, seismic exploratory operations, and plugging of seismic shot holes and other exploratory-type boreholes; (2) outfalls and associated intake structures subject to NPDES permits; (3) dredged or fill material placed as backfill or bedding for utility-line crossings; (4) material discharged for minor bank stabilization; (5) minor road-crossing fills, including all attendant features, both temporary and permanent, that are part of a single and complete crossing of a nontidal water body; (6) fill placed incidental to the construction of bridges, except approach fills and causeways; (7) the repair, rehabilitation, or replacement of any previously authorized currently serviceable fill, or of any currently serviceable fill discharged prior to the requirement for authorization; and (8) discharges into waters other than wetlands that do not exceed 10 yd^3 (7.6 m^3) as part of a single project provided the material is not placed for the purpose of stream diversion. Once again, any such discharges must be performed in accordance with conditions and limitations set forth in the regulations application to the general permit.[121]

In addition to the general permits granted under the regulations, the District Engineer of the Corps of Engineers may issue general permits for certain clearly described categories of structures of work requiring permits, including discharges of dredged or fill material.[122] After such a local general permit has been issued, individual activities falling within those categories will not require individual permit processing, unless the District Engineer determines, on a case-by-case basis, that the public interest requires individual review. Appropriate conditions will be included in such general permits.

The Water Pollution Control Act requires that such general permits cover activities that will cause only minimal adverse environmental effects when performed separately and will have only minimal cumulative adverse effects on the environment.[123] Thus, if the cumulative effect of discharges made under a general permit begin to have a severe adverse effect on the aquatic environment, further restrictions may be required.[124]

The division engineer has discretion to modify, add regional conditions, or modify general permits on a case-by-case basis based upon concerns for the aquatic environment as expressed in the guidelines published by EPA.[125] This authority may be significant in cases where the proposed activity is controversial.

Six principal exemptions from permit requirements are provided for in Section 404. Of importance to the mining industry is an exception from Section 404 regulation for construction and maintenance of temporary roads for moving mining equipment.[126] In such road construction, best management practices must be followed to insure that flow and circulation patterns and chemical and biological characteristics of the navigable waters are not impaired, that the reach of the navigable waters is not reduced, and that any adverse effects on the aquatic environment will be otherwise minimized.

Exceptions also exist for discharges in connection with the maintenance, including emergency reconstruction of recently damaged parts, of currently serviceable structures such as dikes, dams, etc., and discharges for the purpose of construction of a temporary sedimentation basin on a construction site that does not include placement of fill material into navigable waters.[127]

Procedures: Procedures for processing Section 404 permits are established under Part 325 of Chapter II, Title 33, CFR. Unless an approved state plan is in effect, applications for permits are made to the District Engineer of the Corps of Engineers in charge of the district where the proposed activity is to be performed.[128] Forms are provided. Public notice will be made of the application.[129]

An important consequence of a requirement that an individual permit be obtained is that NEPA review is triggered. An environmental impact analysis can be expected in nearly all instances. If the district engineer believes that the proposed activity would significantly affect the quality of the human environment, he must either prepare an environmental impact statement or cooperate with other agencies that may act as the lead agency in preparing the EIS for the project.[130]

If water quality certification for the proposed activity is necessary under Section 401 of the Water Pollution Control Act, certification must be given by the state or appropriate interstate water pollution control agency prior to the issuance of a permit to the effect that any discharge will comply with applicable effluent limitations and water quality standards.[131]

Applications for permits for the discharge of dredged or fill material at specific disposal sites are reviewed in accordance with guidelines promulgated by the Administrator of the EPA.[132] Permits can still be issued, however, notwithstanding that they would be denied if the guidelines alone were applied. The EPA and the Department of the Army have recently entered into a Memorandum of Agreement (MOA)[133] which provides guidance to agency field personnel on the implementation of certain guideline requirements. The MOA primarily focuses on standard individual permits under Title 33, CFR § 325.5(b)(l). EPA and the Corps must adhere to the guidance provided in the MOA when considering mitigation requirements for standard permit applications. The MOA will be used by the agencies in their review of standard individual permit applications received on or after Feb. 7, 1990, for compliance with EPA guidelines. The Administrator of the EPA has the authority to prohibit the specification of the defined areas as a disposal site, if he determines that the proposed discharge will have an unacceptable adverse effect on the municipal water supply, fishing areas, wildlife, or recreational areas.[134]

After review of the application in accordance with the regulations and the holding of a public hearing, the District Engineer decides whether or not the permit should be issued and what conditions are to be attached.[135]

Permits may authorize both the work and the resulting use.[136] Authorizations continue in effect until they automatically expire or are modified, suspended, or revoked. Authorization for the existence of the structure or other form of alteration of the waterways is usually for an indefinite duration; authorizations for construction work or activity, however, will specify time limits for accomplishing the work or activity.[137]

The District Engineer has authority to modify, suspend, or revoke a permit "as may be made necessary by considerations of the public interest."[138]

Administration by States: Administration of individual and general permit programs except as to waters used or reasonably susceptible to use to transport interstate or foreign commerce, may be undertaken by the states upon obtaining approval of a state plan meeting specified requirements.[139] States with approved programs, nevertheless, must transmit a copy of each permit application and a copy of each proposed general permit to the Administrator of the EPA for comment, except for certain categories excepted by the Administrator.[140] If the Administrator objects to the issuance of a permit, a public hearing will be held on request of the state. Within 30 days after the public hearing or 90 days after the objections are made and no public hearing is requested, if the state does not resubmit the permit revised to meet the objections, the Chief of the Corps of Engineers may issue the permit revised in accordance with the objections.[141]

Control Through Section 208 of Areawide Waste-Treatment Plans: Control of the discharge or placement of dredged or fill material into navigable waters may also be accomplished through state areawide waste-treatment plans promulgated under Section 208.[142] If such a program is approved and the state is also administering an approved program under Section 404, an operator conducting activities involving the placement or discharge of dredged or fill material into navigable waters in accordance with approved best management practices need not obtain an individual permit or comply with a general permit.[143]

3.4.3.4 Safe Drinking Water Act

The Safe Drinking Water Act[144] requires that national health standards be established for water quality in public water systems.[145] Under the Act, primary drinking-water standards and standards applicable to public water systems are imposed, maximum contaminant levels are established, and monitoring and sampling requirements are dictated. States have the primary enforcement responsibility if they adopt regulations and set up enforcement procedures. A mine facility would have to comply with the Act if it provides water where there are more than 15 service connections, or if the system regularly services an average of at least 25 individuals daily (including miners) 60 days out of the year.[146]

The Act also contains provisions relating to the protection of underground drinking water through control of underground injections, which may endanger underground drinking-water sources.[147] EPA has promulgated regulations that establish minimum requirements for state underground injection-control programs. The regulations apply to "well injections," which includes drilled, bored, or driven wells and dug wells having depths greater than the largest horizontal dimension.[148]

Five separate classes of wells are described in the regulations.[149] Class III wells cover wells into which fluids are injected to extract minerals. Examples are underground in situ leaching wells and Frasch process sulfur wells.[150] Permits are required for Class III wells from the state permitting agency.[151] Various conditions designed to protect groundwater, such as preventing leakage into aquifers and ensuring careful plugging and abandonment, are incorporated into the permit.[152] An entire project may be covered by a single permit.[153]

Class I wells are those that dispose of hazardous or nonhazardous wastes beneath the lower-most formation containing an underground source of drinking water within a one-quarter-mile radius of the wellbore.[154] Class I wells, like Class III wells, must be permitted.[155]

Miscellaneous types of wells, some of which are particular to mining operations, are included in the general Class V category. Examples include sand backfill and other backfill wells used to inject sand, mill tailings, or other solids into mined-out portions of underground mines; wells used for solution mining of conventional mines such as stope leaching; injection wells used in experimental technologies; and injection wells used for in situ recovery of lignite, coal, for sands, and oil shale.[156] Class V wells are subject to regulatory requirements, but they are not necessarily required to be permitted, depending upon state law.[157] Owners and operators of such wells are required to provide notice to the appropriate authority that they exist and to provide certain information about them.[158]

Wells being used at a mining operation for the subsurface emplacement of fluids, such as solution-mining wells, would be covered under the regulations. Excavations such as tailings ponds and wastewater settling pits from which contaminated water can percolate into underground water systems are not directly regulated under the Act.

The primary enforcement responsibility under the Safe Drinking Water Act rests with states. The Act provides that states prohibit underground injection, not authorized by a permit or rule, and that no underground injection be permitted that will endanger drinking-water sources.[159]

3.4.3.5 Air Pollution Control

Emissions from facilities such as conveyor belts, washing plants, crushers, and concentrators, as well as fugitive dust from mining and materials handling activities, cause mining operations to be subject to certain requirements under federal and state air pollution control laws.

Federal controls over air pollution have been established under the Clean Air Act of 1970, as amended by the Clean Air Act Amendments of 1977 and 1990. The Clean Air Act Amendments of 1990 ("1990 Amendments") added a comprehensive program to regulate emissions of toxic air pollutants (Title III), created a new permit program (Title V), significantly revised nonattainment provisions (Title I), and strengthened the existing enforcement provisions. This Act, in turn, has resulted in the adoption by many states of extensive air pollution control legislation under the state delegation provisions of the federal law. The four aspects of the Act having the most significant impact on mining operations are the provisions relating to (1) implementation plans for national primary and secondary ambient air quality standards, (2) permit requirements, (3) standards of performance for new stationary sources, (4) emission standards for hazardous air pollutants, (5) air toxics standards, and (6) restrictions preventing significant deterioration of clean air areas.

Implementation Plans for National Primary and Secondary Ambient Air-Quality Standards: The program for adopting implementation plans for national primary and secondary ambient air quality standards has several stages. The first is the designation of air quality control regions in interstate or major intrastate areas for the attainment and maintenance of ambient air quality standards (NAAQS).[160] Achievement of improved air quality under the Act is measured on the basis of conditions in the designated air quality control regions.

For the purpose of establishing national primary and secondary ambient air quality standards, the Administrator of EPA publishes a list that includes each air pollutant that has an adverse effect on public health or welfare and the presence of which in the ambient air results from numerous or diverse mobile or stationary sources.[161] The Administrator then issues air quality criteria for each air pollutant on the list, including information on conditions and factors relating to the impact on public health or welfare.[162] The Administrator also publishes information on air pollution control techniques, including data on available technology, costs of installation and operation, energy requirements, emission-reduction benefits, environmental impact of the emission-control technology, and alternative methods of prevention and control of air pollution for each pollutant.[163]

National primary ambient air quality standards and national secondary ambient air quality standards are established by EPA for each air pollutant for which air quality criteria are issued.[164] Primary ambient air quality standards establish minimum permissible concentrations of a pollutant that are necessary to protect the public health. Secondary ambient air quality standards establish a minimum level of air quality that must be obtained in order to protect the public welfare, including such considerations as conditions of vegetation, wildlife, odor, and other factors which, although not constituting dangers to public health, do adversely affect the general quality of life. Essentially, the standards set the maximum amount of each pollutant that will be permitted in the atmosphere.

Primary and secondary air quality standards have been established for particulate matter, sulfur dioxide (SO_2), nitrogen oxides (No_x), ozone (O_3), carbon monoxide (CO), and lead (Pb).[165] Mining operations are most concerned with particulate matter because that category covers fugitive dust.[166] The primary and secondary NAAQS for particulate matter now applies to particles equal to or less than 10 µm in aerodynamic diameter referred to as PM-l0.[167]

The states determine how national air pollution objectives are to be reached. After the promulgation of a national primary or secondary ambient air quality standard for any air pollutant, each state must adopt and submit to EPA a plan that provides for implementation, maintenance, and enforcement of such primary or secondary standards in each air quality control region (or portion thereof) within the state.[168] These are referred to as state implementation plans, or SIPs. If such a plan is approved by EPA after application of the rigid standards set forth in the Act, the state is given responsibility for the enforcement of those provisions of the plan that will insure that the air quality standards are attained and maintained. If the state's plan is not approved, EPA will adopt regulations setting forth an implementation plan for the state. Such implementation plans may require installation of extensive pollution-control equipment at existing sources, so that emissions will be reduced to the extent necessary for the attainment of the national air quality standards.

Few existing mining operations are affected by the air quality standards achievement programs because they are generally located outside nonattainment areas, and those that are, by this time, are at least generally aware of the nature of implementation programs and their impact. State programs for the achievement of air quality standards do, however, have an impact on the construction and operation of new sources.

Permit Program: Title V of the 1990 Amendments adds a new uniform federal permitting program. Sources must obtain permits if they emit 100 tons per year ("TPY") or more of any air pollutant or 10 TPY of any hazardous air pollutant (or 25 TPY of any combination of any hazardous air pollutant). Moreover, sources which are located in certain nonattainment areas may need permits if they emit as little as 10 TPY of a criteria pollutant.

Under Title V, sources are required to prepare and submit permit applications by November 1995. States which have received primacy from the EPA to operate the permit program have up to 18 months to review the permit applications and act on the applications. The permit application must include a schedule for compliance with the emission standards, including periodic compliance certifications. Permits are to be issued for a fixed period, not to exceed five years.

The permit program includes many unique aspects including permit "shield" provisions. The states may draft their permit programs so that compliance with the permit constitutes compliance with other Clean Air Act provisions. The permit program also requires the imposition of permit fees sufficient to recover direct and indirect costs of the states permit program. Under proposed regulations, the EPA presumes that the appropriate permit fee should be at least $25 per ton of regulated pollutant (which is defined very broadly). The fees are to be imposed on the first 4000 tons of regulated pollutant (e.g., up to $100,000); however, the fees may be larger if the source emits more than one regulated pollutant or the state chooses not to restrict fees to the 4000-ton limit.

Standards of Performance for New Stationary Sources: Of more direct concern to the mine operator are the requirements that affect new operations. One or more of the facilities at such an operation may be considered to be a new stationary source, the emissions from which must meet federal standards of performance (NSPS).

A new source is any building, structure, facility, or installation that emits or may emit an air pollutant, the construction or modification of which is commenced after the publication of regulations or proposed regulations establishing an emission standard applicable to such a source.[169] An existing source can be considered to be a new source subject to applicable performance standards if it is modified to the extent that the methods of operation are changed so as to result in an emission increase or the emission of an air pollutant not previously emitted.[170] New source performance standards are to be established for new sources that contribute significantly to air pollution that causes or contributes to the endangerment of the public health or welfare.

The Administrator of EPA is required to publish a list of categories of stationary sources and to publish regulations establishing federal standards of performance for new sources within each such category.[171] A standard of performance establishes allowable emission limitations for categories of stationary sources.[172] The standards are based on the degree of emission reduction achievable through the best technology the Administrator determines has been adequately demonstrated. If the Administrator concludes that it is not feasible to prescribe or enforce a standard of performance, he may instead promulgate a design, equipment, work practice, operational standard, or combination thereof, that reflects the best technological system of continuous emission reduction that the Administrator determines has been adequately demonstrated.[173]

Of the categories of new stationary sources for which standards of performance have been promulgated as of the date of this writing, the only categories of obvious direct concern to underground mining operators are those for portland cement plants, coal preparation plants, metallic mineral processing plants, phosphate rock plants, and nonmetallic mineral processing plants, contained in subparts F, Y, LL, NN, and OOO of Part 60, Title 40, CFR.

The Act provides that states may implement and enforce standards of performance for new sources if the state develops a plan found to be adequate by the Administrator of EPA.[174] However, EPA still retains authority to enforce any applicable standard of performance.

The Clean Air Act itself does not require specifically that permits be obtained for new sources. The owner or operator has the legal responsibility for compliance with an applicable standard, and he must comply with regulations that contain extensive requirements relating to reporting and data gathering. A permit for a new source, however, will be required under state new-source permitting authority or under state programs for the implementation of primary or secondary ambient-air standards for all new or modified sources with the potential (design capacity) to emit 100 TPY or more of a given pollutant.

If the affected facility is located in a state not having an approved new-source review program, an owner or operator subject to the performance standards must notify EPA of the anticipated startup date of an affected facility not more than 60 days or less than 30 days prior to such date.[175] The EPA must also be notified of the actual date of initial start-up within 15 days after such date.[176] Extensive records must be kept concerning the emissions and the effectiveness of emission-control equipment.[177]

Within 60 days after the maximum production rate is achieved, but not later than 180 days after initial start-up, performance tests for the affected facilities must be conducted and the results thereof sent to EPA.[178] Compliance with the new-source performance standards is to be determined by the application of performance tests specifically set forth in the regulations.[179]

In nonattainment areas (areas wherein any air pollutant exceeds any national ambient air quality standard for such pollutant), new major emitting facilities cannot be built unless SIP requirements are met and there first is secured an offset (greater than one to one) to existing emissions.[180] Under the 1990 Amendments, offset requirements may range from at least one to one to as high as two to one, depending upon the extent to which pollutant levels exceed the standard in the area.[181] The sources must also be controlled to a level reflecting the lowest achievable emission rate (LAER), which is the most stringent emission standard in any SIP (unless it is shown to be unachievable) or the lowest emissions any source in the same category has achieved in production.

Emission Standards for Hazardous Air Pollutants: Section 11a of the Clean Air Act gives authority to EPA to set national emission standards for hazardous air pollutants.[182] Hazardous air pollutants are those to which no ambient air quality standard is applicable and which, in the judgment of the Administrator of EPA, may cause or contribute to an increase in mortality or an increase in serious irreversible, or incapacitating reversible, illness.[183] In contrast to the provision authorizing establishment of ambient air quality standards, this section of the Clean Air Act does not require that the pollutant come "from numerous or diverse mobile or stationary sources;"[184] Only stationary sources must comply.[185]

The Administrator is directed to prescribe emission standards or design, equipment, work practice, or operational standards for each hazardous air pollutant that he identifies on a list, which standard establishes the level that provides an ample margin of safety to protect the public health from such hazardous air pollutant.[186] They are referred to as NESHAPs (National Emission Standards for Hazardous Air Pollutants). After the effective date of any such emission standard, no person may construct any new source or modify any existing source that will emit a hazardous air pollutant in violation of the standards.[187] Existing sources must comply with the standard 90 days after the effective date, unless waivers or exemptions are obtained in accordance with the Act.[188]

Regulations of EPA prescribe that permission of EPA must be given prior to the construction or modification of a stationary source that emits hazardous air pollutants.[189] Within 60 days of receipt, EPA must notify the owner or operator of its approval or its intent to deny approval of construction or modification.[190]

States may be given authority over implementation and enforcement of standards for hazardous air pollutants upon submission and approval by the Administrator of an adequate plan. However, the Administrator is still empowered to enforce applicable federal emission standards.[191]

Emission standards for hazardous air pollutants have been established for radon 222 emissions from underground uranium mines and from licensed mill tailings, asbestos, beryllium, and mercury.[192] Emission standards have also been established for such hazardous air pollutants as arsenic, benzene, vinyl chloride, and radionuclides.

Air Toxics: Title III of the 1990 Amendments completely revised the NESHAP provisions of Section 112. Under the air toxics provisions, the Clean Air Act establishes a list of 189 toxic air pollutants that are to be primarily regulated through technology-based standards.[193] Sources subject to regulation include "major" and "area" sources. Major sources are those sources that have the potential to emit 10 tons or more of any hazardous pollutant (or alternatively any source that emits 25 TPY of any combination of any hazardous pollutants). Area sources include any stationary sources that are not major sources, other than vehicles.

The EPA is required to publish a list of sources it proposes to develop standards for and regulate by Nov. 15, 1991. These sources are to be subject to standards that represent the maximum available control technology (MACT).[194] The EPA is to prepare a standards promulgation schedule and the first round standards must be promulgated by Nov. 15, 1992. All standards are to be promulgated by November 2000.

New sources must generally comply with the new standards immediately. If construction of the new source began after the standards were proposed then the source is allowed up to three years to comply if the final standard is more stringent than the proposed standard. Generally, existing sources have three years after promulgation to comply with the standard. Certain sources, including sources of mining waste, may obtain a compliance extention of up to three additional years.

In setting emission standards, the EPA is allowed to develop less stringent standards for existing sources. For existing sources the emission standard must be at least as stringent as the emission control that is achieved in practice by the best controlled similar sources. The 1990 Amendments include a savings clause that preserves any standards developed under the NESHAP program prior to November 15, 1990. Like the NESHAP program, states may develop programs under Section 112 to obtain enforcement authority for the air toxics program. Since the radionuclide rule has been the subject of judicial challenge, the 1990 Amendments retain the radionuclide standard for some sources and suspend the standard for other sources.

Enforcement: Violation of provisions of the Clean Air Act may result in the issuance of a permanent or temporary injunction or imposition of a fine or imprisonment.[195]

The Administrator or the state, upon the approval of the Administrator, may require the owner or operator of any emission source to monitor and sample emissions, to maintain and provide records thereof, and to permit inspection of the premises in which an emission source is located.[196]

Prevention of Significant Deterioration of Existing Air Quality (PSD): Special provisions have been enacted to prevent significant deterioration of the air quality in areas where the quality of the air is better than required under national ambient air quality standards.[197] Such zones may be classified by the states into areas based on degrees of air quality deterioration, measured by concentrations of sulfur dioxides and particulates, to be permitted therein. EPA has also promulgated allowable amounts for nitrogen oxides based on the same classification scheme.[198] In other areas, referred to as nonattainment areas, the objective is to reduce pollution to levels consistent with national ambient air quality standards.

Areas are to be classed as I, II, or III depending upon the maximum allowable increase of sulfur dioxide, particulate matter, and nitrogen oxides over the baseline concentration of such pollutants to be permitted in the area.[199] Generally, class I areas include National Parks, National Wilderness Areas, National Monuments, and similar regions of unique beauty. Most areas are class II, where limited growth can be permitted. Class III areas are those where industrial development can occur. All state air quality control regions not designated as class I initially have been designated as class II. All areas redesignated as class I under regulations in effect prior to passage of the Clean Air Act Amendments of 1977 retain that status.[200] An area which as of Aug. 7, 1977, exceeded 10,000 acres (4047 ha) in size and was a national monument, a national primitive area, a national preserve, a national recreational area, a national wild and scenic river, a national wildlife refuge, a national lakeshore or seashore, and a national park or national wilderness established after Aug. 7, 1977, which exceeds 10,000 acres (4047 ha) in size may be redesignated only as class I or II. An area may not be designated as class III if such redesignation will cause or contribute to concentrations of any pollutant that exceed any maximum allowable increase or maximum allowable concentration permitted under the classification of any adjoining area.[201] Thus areas adjoining class I areas are not likely to be redesignated as class III.

Once an area has been designated, no "major emitting facility" may be constructed therein without a permit from the state, or from EPA if the state does not have an approved PSD plan.[202] To obtain a permit, the owner or operator of the facility must demonstrate that emissions from the construction or operation of such a facility will not cause or contribute to air pollution in excess of any maximum allowable increase or maximum allowable concentration of sulfur oxides, particulates, or nitrogen oxides more than one time per year and that the proposed facility is subject to the best available control technology for each pollutant subject to regulation under the Act.[203]

Best available control technology (BACT) requires the achievement of an emission limitation based upon the maximum degree of reduction of each pollutant subject to regulation under the Act emitted from a major emitting facility that the permitting authority determines, on a case-by-case basis, is achievable for such a facility through the application of production processes and available methods, systems, and techniques.[204]

Major emitting facilities are specifically designated categories of stationary sources of air pollutants that emit, or have the potential to emit, 100 TPY or more of any air pollutant and any other source with the potential to emit 250 TPY or more of any air pollutant.[205] The designated categories include coal-cleaning plants with thermal dryers, portland cement plants, phosphate rock-processing plants, and taconite ore-processing facilities. Although not specifically named in any of the 28 categories, mining operations contiguous or adjacent to such facilities may be included.[206] Both new operations and major modifications of existing operations can be considered major emitting facilities.[207]

Whether a facility is a major emitting facility is determined by its capacity to emit a pollutant under its physical and operational design, which includes air pollution control equipment and restrictions on hours of operation or on the type of material combusted, stored, or processed.[208] Thus, even though uncontrolled emissions may be more than the threshold limits for categorizing a facility as a major emitting facility, it will be considered to be a major emitting facility only if its controlled emissions will exceed those limits.

Unless a major emitting facility is exempted, the owner or operator must satisfy rigorous air quality review standards and conduct ambient air quality monitoring and additional impact analyses as part of the permitting process. Such requirements, as described in the regulations,[209] can constitute a significant burden. Generally, a full year of monitoring of all listed pollutants that a source would have the potential to emit in significant amounts, or as to major modifications in amounts constituting a significant net increase, is required.[210]

Of importance to the mining industry is an exemption applicable to fugitive dust. Fugitive dust is not considered in determining whether a source is a major emitting facility, unless the source is one of the 28 listed sources or is being regulated by a new source performance standard or national emission standard for hazardous air pollutants in effect as of Aug. 7, 1980.[211] Fugitive emissions are those emissions that could not reasonably pass through a stack, chimney, vent, or other functionally equivalent opening.[212] Fugitive dust may include emissions from haulage roads, wind erosion of exposed soil surfaces and soil storage piles, and other activities in which the soil is removed, stored, transported, or redistributed.

Copies of permit applications received by a state are transmitted to the Administrator of EPA for review by federal officials to insure that the proposed emitting facility will not have an adverse effect on air quality in class I areas. A permit will not be issued unless the owner or operator demonstrates that emissions of particulate matter, sulfur dioxide, and nitrogen oxides from the permitted facility and secondary sources established in the same area as a result of the facility will not cause concentrations exceeding maximum allowable increases.[213] A variance may be obtained if emissions of sulfur dioxide from the source exceed the allowable increments within specified limits for a period of exposure of 24 hr or less on not more than 18 days during a year.[214]

Once the permissible increment for increases in pollutant concentration over the baseline concentration in a PSD classified area are utilized, including contributions by unpermitted minor sources and mobile sources, then no additional discharges will be permitted.[215] Thus many PSD areas ultimately will be closed to any additional industrial activities that cannot be carried on without the discharge of sulfur dioxide or particulates.

3.4.3.6 Federal Surface Management Regulations Concerning Unpatented Mining Claims

Under federal mining laws (see chapter 3.2), a person has a statutory right to enter upon and use available public lands for mineral prospecting, exploration, development, and extraction. This statutory right, however, carries with it a responsibility to conduct such activities in a way that will prevent undue degradation of the land and will ensure that reasonable reclamation takes place. The federal government has adopted various regulations to accomplish these objectives. The pertinent regulations are contained in Titles 36 and 43, CFR. These regulations do not preempt, but are supplemental to, state laws and regulations relating to mining operations and reclamation,[216] so the operator must also be familiar and comply with applicable state and local regulations, including applicable zoning provisions.[217]

The geographic location of the unpatented mining claim determines which group of federal regulations must be followed. Separate regulatory programs have been established for claims located on land administered by the Bureau of Land Management (BLM) and land administered by the Forest Service. Other regulations may apply if the land is within a designated wilderness study area. The regulations apply not only to unpatented mining claims but to tunnel claims and unpatented millsite claims as we11.[218]

BLM-Administered Land: If the claim is located on BLM-administered land and is not within a designated wilderness study area, exploration and mining activities are governed by regulations contained in Title 43, CFR subpart 3809. Increasingly stringent regulations are imposed on the operator according to the extent of anticipated surface disturbance. The applicable regulations can be divided into three rather distinct categories.

Casual Use—If the intended activity amounts only to "casual use," no notification to or approval by the BLM is required. The operator is free to conduct casual-use activities at will and without notice, so long as they are carried out in a way that will prevent unnecessary degradation of the land.[219] "Casual use" is defined as activities ordinarily resulting in only negligible disturbance of the surface of the land. Activities are generally considered casual use if they do not involve the use of explosives, mechanized earthmoving equipment, or motorized vehicles in areas designated as closed to off-road vehicles.[220]

Surface Disturbance of Five Acres or Less—If the annual cumulative surface disturbance from activities on the claim will exceed casual use but will be kept to 5 acres (2 ha) or less (including disturbance associated with establishing access to the claim), the operator is required to notify the BLM in writing at least 15 days prior to the commencement of operations. Approval by the BLM of the proposed activities is not required, although consultation with the BLM may be required if the activities include the construction of access roads.[221] The written notice, which may be in the form of a letter, must include the name and address of the claimant and the operator; the names and BLM serial numbers of the mining claims on which disturbance will occur; a statement describing the activities that will take place, including their location, the approximate commencement date, the location of access routes to be constructed, and the type of equipment to be used; a statement that reasonable measures will be taken to prevent unnecessary degradation of the land during operations; and a statement that appropriate reclamation will be completed as set forth in the regulations.[222] No reclamation bond to recover the cost of reclaiming the land is required, but once reclamation has been completed the operator is required to notify the BLM so that an inspection of the area can be made.[223]

Generally, the 5-acre (2 ha) provision will allow most exploration activities and perhaps limited extraction activities to take place without having to file anything more than a written notice with the BLM, provided the disturbed area is reclaimed in the manner required by the regulations.[224]

Surface Disturbance of More Than Five Acres—When more than 5 acres (2 ha) of surface will be disturbed by the contemplated activities, a "plan of operations" must be submitted to and approved by the BLM prior to commencement.[225] While no special form is required, the plan of operations must include the name and address of the claimant and operator; the names and BLM serial numbers of the mining claims involved; a topographic map showing existing and proposed access routes; a description of the proposed operations, describing the timeframe and manner in which they will be conducted; a listing of measures to be taken to prevent undue degradation of the environment and to accomplish reclamation of the land as required in the regulations; and a statement of measures to be taken to maintain the area during extended periods of nonuse.[226]

Once the plan is submitted, the BLM has 30 days to review and act on it. The BLM can respond to the plan in any of several ways. It can (1) approve the plan, (2) require additions to or modifications of the plan, (3) determine that an environmental impact statement is required and delay action on the plan until 30 days after completion of a final EIS, (4) delay acting on the plan while the BLM complies with provisions of the Endangered Species Act or the National Historic Preservation Act, or (5) take an additional period of time (up to 60 days) to complete the review.[227] The same process must be followed if the operator decides to significantly modify the plan after its initial approval.[228] It should be noted that all information and data submitted by the operator will be available for public examination in accordance with the Freedom of Information Act unless the information is specifically identified by the operator as containing trade secrets or confidential commercial or financial information.[229]

The regulations require that while final approval is pending, the BLM approve on an interim basis any operations that may be necessary for timely compliance with state and federal laws, subject only to conditions needed to prevent undue degradation of the land. Such state and federal laws would include those relating to assessment work, discovery work, claim staking, and the like.[230]

Before a plan of operations encompassing land not previously covered by an approved plan can be approved, the BLM must conduct an environmental assessment of the proposed operation to identify the environmental impacts of the proposed activities, determine whether an EIS is required, and assess the adequacy of the operator's proposed reclamation measures.[231] This assessment will be performed during the 30-day review period. If the plan is approved the BLM may, at its discretion, require the operator to furnish a bond in an amount determined by the BLM to cover the estimated cost of reclaiming the land. No bond is required if the operations will cause only minimal disturbance to the land.[232]

All exploration and mining operations, whether casual, under notice, or by plan of operations, must be carried out so as to prevent unnecessary or undue degradation[233] of the land and must be completed in compliance with specific regulations relating to air and water quality, solid wastes, fisheries, wildlife and plant habitat, cultural resources, and survey monuments.[234] The BLM may monitor and inspect any such operations to ensure compliance with the regulations. If the operator is found to be in noncompliance with the regulations or with the provisions of an approved plan, the BLM can issue a notice of noncompliance. Failure to remedy the problem as specified in the notice of noncompliance may subject the operator to a court order prohibiting further operations and to monetary damages.[235]

Finally, any operator adversely affected by a decision of the BLM has the right to appeal the decision. An appeal is made first to the BLM State Director of the applicable state and thereafter, if necessary, to the Interior Board of Land Appeals. An appeal will not be considered unless it is made within 30 days after receipt of the adverse decision.[236]

Requirements for Claims Within BLM Wilderness Study Areas—A "wilderness study area" is an area of public land designated by the BLM as having wilderness characteristics, making it a candidate for inclusion in the federal government's wilderness preservation system.[237] Wilderness study areas are managed in a manner that will not impair their suitability for preservation as wilderness. The applicable regulations are designed to achieve this management objective[238] and are very similar to those established for activities requiring a plan of operations as discussed previously.

Subject to certain exceptions, before any exploration or mining operation on claims located within a wilderness study area begins, a plan of operations must be submitted to and approved by the BLM. The regulations expressly require submission and approval of a plan of operations if the proposed activity will involve the construction of access facilities, the destruction of trees greater than 2 in. (50 mm) in diameter at the base, the use of mechanized earthmoving equipment, the use of motorized vehicles in certain areas closed to such use, the placing of portable or fixed structures on the land for more than 30 days, the use of explosives, or the changing of a water course. On the other hand, no plan of operations is required for activities involving limited geophysical testing, the occasional removal of mineral samples, the use of motorized vehicles in permitted areas, or the making of minor improvements to existing access routes.[239] Additionally, no plan is required for ongoing operations that were in existence on Oct. 21, 1976, unless and until the operation is enlarged or is found by the BLM to be causing unnecessary degradation to the environment.[240]

In reviewing the plan of operations, the key issue is whether the proposed activities will impair the suitability of the area for preservation as wilderness. In analyzing that issue, the BLM can approve or reject the plan or require modifications or additions to preserve the wilderness character of the land.[241] The required contents and approval procedure for the plan of operations are substantially the same as those established for claims not within a wilderness study area. The same is true with respect to interim approval to conduct assessment work and the like, plan modifications, bond requirements, environmental assessments, treatment of confidential information, monitoring and inspection procedures, noncompliance remedies, and appeal rights.[242] The reclamation requirements for operations conducted within a wilderness study area are similar to but substantially more stringent than those pertaining to operations conducted outside of wilderness study areas.[243] Additionally, the operator must notify the BLM if operations are suspended for more than 30 days (except for seasonal suspensions) and must reclaim the site within one year after operations cease (unless additional time is allowed for good cause).[244]

Forest Service Administered Land: If the unpatented claim is located within a National Forest, exploration and mining activities are governed by regulations found in Title 36, CFR, Part 228, subpart A. The purpose of the regulations is to provide for exploration and mining activities while minimizing adverse environmental impacts on the forest resources.[245] The Forest Service's regulatory scheme is similar to that established for BLM nonwilderness areas.

Insignificant Surface Disturbance—Forest Service regulations do not use the term "casual use," but they do similarly provide that activities that will result in only insignificant surface disturbance can be conducted without notice to or approval from the Forest Service. Insignificant disturbance activities include such acts as using vehicles on existing roads, removing small mineral samples on an occasional basis, prospecting to the extent that it does not significantly disturb surface resources, marking and monumenting mining claims, and conducting subsurface operations with insignificant surface effects. Operations that do not involve the use of mechanized earthmoving equipment or the cutting of trees are also considered insignificant and are exempt from notice requirements.[246]

Notice and Plan of Operations—Prior to commencement of any action that might cause "significant disturbance of surface resources" (a term not defined in the regulations), the operator is required to notify the Forest Service.[247] The notice must identify the area involved, the nature of the proposed operations, the access route, and the method of transportation. The Forest Service then has 15 days to determine whether a plan of operations will be required. If the Forest Service decides that the proposed activity will likely result in significant surface disturbance, an approved plan of operations will be required.[248]

The plan of operations, if required, must include the name and address of the claimant and operator; a map showing the proposed area of operations, the existing and proposed access routes, and the approximate location of anticipated surface resource disturbance; and a description explaining the proposed operations and how they will be conducted, the type of existing and proposed access routes, the means of transportation to be used, the time period during which the proposed activities will take place, and the environmental protection measures to be taken.[249]

After receipt, the Forest Service has 30 days to consider the plan of operations and notify the operator of its decision. The Forest Service can (1) approve the plan, (2) require changes in or additions to the plan, (3) delay any decision for an additional period of time (up to 60 days), (4) delay any decision until a final EIS, if necessary, has been completed, or (5) conclude that no plan is required for the proposed operations.[250]

All mineral operations, whether conducted pursuant to a plan or otherwise, must be conducted so as to minimize adverse environmental impacts on forest resources and must comply with applicable state and federal environmental standards. Activities must also comply with specific environmental provisions relating to air and water quality, solid wastes, scenic values, fisheries and wildlife habitat, roads, and reclamation procedures as set forth in the regulations.[251]

The Forest Service follows provisions similar to the BLM's with regard to completion of an environmental analysis during the approval process, interim approval to conduct assessment work and the like, procedures for modifying an approved plan, bond requirements, treatment of confidential information, inspection procedures, noncompliance remedies, and appeal rights.[252]

Unlike the BLM, the Forest Service does not have a separate regulatory scheme for lands under wilderness review. Operations within Forest Service wilderness study areas are subject to the same requirements as operations outside of such areas, but wilderness study area operations must be conducted in a manner that will not impair the wilderness character of the land.[253] It can be expected that the Forest Service will carefully consider the nonimpairment requirement in any review of activities to be conducted on wilderness study lands.[254]

3.4.3.7 Federal Lease Operating Regulations (Other than Coal)

Operations for the extraction of hard minerals other than coal, conducted on federal lands under lease, permit, or contract from the federal government (which excludes mining claims), are governed by operating regulations set forth in Part 23 of Title 43, CFR.

Regulations[255] provide for the protection and conservation of nonmineral resources during operations for the discovery, development, surface mining, and onsite processing of minerals under permits, leases, or contracts issued pursuant to the Mineral Leasing Act of 1920[256] and the Mineral Leasing Act for acquired Lands.[257] No definition of surface mining is given in the regulations, but it is assumed for purposes of this discussion that surface activities incident to underground mining operations are subject thereto.

These regulations also establish the procedures to be followed by BLM in reviewing applications for permits or leases under the Mineral Leasing Act.[258] When such an application is submitted, a technical examination is made of the prospective effects of the proposed exploration or surface mining operations.[259] As part of the technical examination, a determination is made whether special measures are needed (1) to preserve and protect nonmineral resources, including recreational, scenic, historic, and ecological values; (2) to prevent air and water pollution; (3) to isolate toxic materials; or (4) to accomplish surface reclamation.[260] After the technical examination is completed, special provisions are drawn up setting forth such special measures that need to be taken. These requirements are made known to the applicant before the permit, lease, or contract is issued, and, if accepted, they are incorporated therein.[261] If the lands are under the jurisdiction of an agency other than the Department of the Interior, environmental protection requirements proposed by that agency generally will be attached to the lease, permit, or contract.[262]

These special requirements are referred to as stipulations, and they become part of the lease, permit, or contract. They may set forth detailed requirements pertaining to all aspects of environmental protection and surface reclamation.

Compliance with general objectives is achieved primarily through review by the mining supervisor of a mining plan, which must be approved before operations can be commenced. After approval, mining and milling must be performed in accordance with the plan. A mining plan must show, in detail, the proposed mining operations to be conducted. A mining plan must include the following information:

1. A statement of proposed methods of operating, including a description of the surface or underground mining methods.
2. A description of proposed roads or vehicular trails.
3. The size and location of structures and facilities to be built.
4. An estimate of the quantity of water to be used.
5. Identification of pollutants that are expected to enter any receiving water.
6. A design for the necessary impoundment, treatment or control of all runoff water and drainage workings so as to reduce soil erosion and sedimentation and to prevent the pollution of receiving waters.
7. A description of measures to be taken to prevent or control fire, soil erosion, pollution of surface water and groundwater, damage to fish and wildlife, and hazards to public health and safety.
8. A statement of the proposed manner and time of performance of work to reclaim areas disturbed by the operations.[263]

In most instances, provisions of the permit or lease will require revegetation of areas affected by the operations.[264]

A performance bond must be provided to assure that required environmental protection and reclamation activities are performed.[265]

After approval of the mining plan and commencement of operations, a report is required each year from the operator, containing a description of the operations that have been performed and a description of the reclamation work that has been done, including grading, backfilling, and planting.[266]

Failure of the lessee to take action in response to a notice of noncompliance with the terms of the lease or with the mining plan can result in suspension of operations and/or cancellation of the lease.[267]

As far as day-to-day planning and operation of a mining facility is concerned, at least when such operation is conducted on lands held under federal lease, the environmental protection requirements imposed by the lease terms and by the mining supervisor are the most significant. Close attention should be paid to requirements that are imposed, and close coordination should be maintained with the mining supervisor at all times.

3.4.3.8 Preservation of Historical and Archeological Data

Prior to the commencement of construction on any project licensed by the federal government, a cultural resources inventory may be required. Such inventories are authorized or required under the National Historic Preservation Act of 1966,[268] the Antiquities Act of 1906,[269] the Act of May 24, 1974,[270] and Executive Order No. 11593 issued May 13, 1971. If the study reveals that the project may cause irreparable loss or destruction of significant scientific, prehistorical, historical, or archeological data, a mining project could be delayed while additional studies are performed. Discovery of important historical or archeological data could preclude permitting or licensing of the project altogether.

3.4.3.9 Endangered Species Act of 1973

Section 7 of the Endangered Species Act of 1973[271] provides that all federal departments and agencies shall take such action as is necessary "to ensure that actions authorized, funded or carried out by them do not jeopardize the continued existence of . . . endangered species and threatened species or result in the destruction or modification of habitat of such species which is determined . . . to be critica1."[272] The Secretary of the Interior identifies endangered or threatened species through rulemaking.[273]

Every federal agency must assure that any action it takes will not jeopardize the continued existence of an endangered or threatened species or result in the destruction or modification of habitat of an endangered or threatened species if the habitat is determined by the Secretary to be critical. They must consult with the Fish and Wildlife Service of the Department of the Interior and the Department of Commerce in order to assure that actions do not cause such jeopardy or destruction.[274]

If in the course of preparation of an environmental impact analysis, it is determined that a threat to an endangered or threatened species might result from the contemplated project, special protective measures, including prohibition of the proposed action, if necessary, must be adopted. This becomes more and more of a possibility as additional species of plants, fish, and wildlife are classified as endangered or threatened. An exemption is possible under extraordinary circumstances upon action taken by a National Review Board and the Endangered Species Committee.[275]

Failure of a federal agency to take such action as is necessary to protect the endangered or threatened species does not mean that the proposed action can take place without restrictions. The law permits lawsuits to be brought by any citizen to enjoin any person who is alleged to be in violation of any provision of the Endangered Species Act or any regulation issued under the authority thereof or to compel the Secretary of the Interior or the secretary of Commerce to apply the protective regulations adopted pursuant to the Act.[276]

3.4.4 STATE AND LOCAL GOVERNMENT ENVIRONMENTAL REQUIREMENTS

CLAYTON J. PARR

To date, this chapter has focused primarily on federal laws and regulations pertaining to environmental protection at mine sites because of their general applicability. There is, however, another body of law peculiar to each state that will govern the conduct of mining operations within its boundaries. In addition, counties or municipalities also can adopt laws and ordinances affecting mining.

At the earliest possible stage in mine development, it is most important to learn of the environmental protection requirements that may exist in the state wherein an operation is contemplated. Ideally, this inquiry should begin at the earliest exploration stage. Of particular importance are permits that must be acquired before exploration and/or production operations can commence. General information regarding such matters usually can be obtained through inquiry to the state agency having jurisdiction over mining operations. Often there will be some sort of office of industrial promotion in a state that can give helpful assistance in this regard. Detailed questions as to compatibility between state and federal laws, procedures for variances, and other such subjects often are best directed to an attorney.

The following paragraphs are a brief checklist of the types of laws and regulations that may be in effect in a particular state.

3.4.4.1 Environmental Impact Assessment Procedures

Some states have adopted legislation similar to NEPA that requires an environmental impact assessment prior to the taking of action by a state agency on an operation that may have a significant effect on the environment. California, for example, requires that an environmental impact report be prepared by state agencies prior to approval of an activity involving the issuance of a lease, permit, license, or certificate that may have a significant effect on the environment.[277] An EIS prepared in accordance with NEPA often will satisfy the state requirements.[278]

3.4.4.2 Water Pollution Control

Most states have enacted legislation prohibiting the pollution of waters in the state and requiring that discharges that might cause pollution not be made in the absence of a valid permit issued by a state agency or board.[279] Such laws often will govern discharges not subject to the Federal Water Pollution Control Act, such as discharges that do not enter surface waters and nonpoint source discharges. Separate legislative schemes may apply to discharges affecting groundwaters.[280] Separate state water discharge requirements may exist even if the state administers the program related to NPDES permits. Since the NPDES program, when administered by EPA, requires state certification of the quality of water being discharged, requirements in excess of those under the federal law may be imposed.

In those states where water rights are obtained upon application to the State Engineer, the State Engineer may impose environmental protection requirements with respect to the construction and operation of diversion and storage facilities.

3.4.4.3 Air Pollution Control

Bodies charged with the responsibility for air pollution control have been established in all states to comply with the Clean Air Act. The emission requirements imposed by the state can be more stringent than those imposed under the federal law and can apply to types of emissions not covered under federal law. State laws and regulations often dictate that no new source of air pollution be operated without a permit. The permit will set maximum discharge levels and generally will require that an emission monitoring system be set up.

3.4.4.4 Solid Waste Control

Disposal of solid wastes such as garbage or construction debris often require a permit.[281] Few states specifically deal with tailings disposal and waste dumps through solid waste control. However, more activity in that area can be anticipated, particularly in light of special studies that are to be conducted on the adverse effects of solid wastes from active and abandoned surface and underground mines on the environment under the Resource Conservation and Recovery Act of 1976.

3.4.4.5 Reclamation

Surface reclamation requirements have been adopted by many states, although some relate only to surface-mining operations.[282] State coal mining regulations must conform to the Coal Surface Mining and Reclamation Act of 1977. Such regulations generally require that a reclamation plan be submitted and approved prior to the commencement of mining operations, that reclamation meet certain general standards, and that a bond be provided to insure that the reclamation is performed when mining is completed. The conduct of all phases of mine operations can be influenced on a day-to-day basis by such surface-reclamation requirements.

3.4.4.6 State Lease Requirements

Mining conducted on state lands generally will be subject to environmental protection requirements spelled out in the lease terms. Such leases usually require prior approval of a mining plan before the commencement of operations and compliance with state environmental protection laws and regulations.

3.4.4.7 Noise Abatement

Some states have adopted legislation for noise control. Under such laws, noise-emission standards may be adopted to limit the noise that can be emitted by particular products or categories of noise-emission sources. Because of noise emitted by crushing and milling operations, a permit or variance may be needed under such a law before operations can be commenced.

3.4.4.8 Construction Permit

Approval of construction permits can be conditioned upon compliance with environmental protection requirements. A permit for a large installation, such as a concentrator, might impose numerous requirements with respect to dust control, ventilation, water discharge, noise abatement, and aesthetics.

3.4.4.9 Zoning

It is quite likely that the zoning laws of a county or municipality, within the boundaries of which an operation is sited, will have a bearing thereon. Some states have enacted comprehensive land-use plans.[283] If the lands have been zoned for a use other than mining, it will be necessary to seek rezoning. Even if mining is permitted, it usually will need to be conducted in accordance with zoning regulations that provide for environmental protection.

Federal Surface Management Regulations Concerning Unpatented Mining Claims

216. *See* 43 C.F.R. § 3809.3-1(a) (1988).
217. A good overview of the various state regulations can be found in *American Law of Mining,* Vol. 5, § 173.03. For a discussion of zoning and other land use controls as they relate to mining, see § 174.
218. 43 C.F.R. §§ 3802.0-5(e), 3809.0-5(d) (1988). The regulations concerning operations on Forest Service lands do not specifically include tunnel claims. *See* 36 C.F.R. § 288.3(d) (1989).
219. 43 C.F.R. §§ 3809.1-2, 3809.2-2 (1988).
220. *Id.* § 3809.0-5(c). As an example of the legal interpretation of "casual use," a federal court has held that an operator who lived on his claim, cut trees, violated health codes, littered, discharged wastewater, raised animals and a garden, and excluded the public by fencing off the access road and posting "no trespassing" signs was clearly not making casual use of the land as contemplated in the regulations. *See* Bales v. Ruch, 522 F. Supp. 150, 155-57 (E.D. Cal. 1981).
221. 43 C.F.R. § 3809.1-3(a) and (b) (1988).
222. *Id.* § 3809.1-3(c).
223. *Id.* §§ 3809.1-9, 3809.1-3(d)(5).
224. *See* Kimball, D., III, 1983, "Impact of BLM Surface Management Regulations on Exploration and Mining Operations," 28 *Rocky Mountain Mineral Law Institute*, pp. 509, 526. A plan of operations may be required if the activities will take place in certain specified environmentally sensitive areas. 43 C.F.R.
225. 43 C.F.R. § 3809.1-4(a) (1988). Unless the operations constitute "casual use," a plan of operations is also required if the claims are located in certain specially protected environmental areas such as lands within or proposed for inclusion within the wild and scenic rivers system, certain lands within the California Desert Conservation Area, wilderness areas, areas closed to off-road vehicle use, and designated areas of critical environmental concern. *See id.* § 3809.1-4(b).
226. *Id.* § 3809.1-5.
227. *Id.* § 3809.1-6.
228. *Id.* § 3809.1-7(b). Procedures also exist for the BLM to request at any time that the operator modify the approved plan of operations. *See id.* § 3809.1-7.
229. *Id.* § 3809.5(a). Examples of information that may be specified by the operator as confidential (if provided at all) would include such items as the outline, location and extent of the mineral deposit, and the location of exploration pits and drill holes. *See* 36 C.F.R. § 228.6 (1989) (discussing confidentiality with respect to claims on Forest Service land).
230. 43 C.F.R. § 3809.1-6(d) (1988); Kimball, *supra,* at 530.
231. 43 C.F.R. § 3809.2-l (1988).
232. *Id.* § 3809.1-9.
233. "Unnecessary or undue degradation" is specifically defined in the regulations. See *id.* § 3809.0-5(k).
234. *See id.* § 3809.2-2.
235. *See id.* §§ 3809.1-1, 3809.1-4(e), 3809.3-2, 3809.3-6.
236. See *id.* § 3809.4. For further information regarding BLM surface management regulations governing nonwilderness areas, see 43 C.F.R. subpart 3809 (1988), *American Law of Mining,* Vol. 5, § 173.05[4][a][ii], and Kimball, *supra,* at 520-37.
237. See 43 C.F.R. § 3802.0-5(c) (1988) and *American Law of Mining,* Vol. 1, ch. 15 (discussing wilderness areas and the wilderness system).
238. See 43 C.F.R. § 3802.0-2(a) (1988).
239. *Id.* §§ 3802.l-l, 3802.1-2.
240. *Id.* § 3802.1-3. "Undue and unnecessary degradation" is defined in the regulations. *See id.* § 3802.0-5(l).
241. *See id.* § 3802.1-5. Ongoing operations that existed on Oct. 21, 1976, are subject to a lower level of scrutiny. Such operations do not generally necessitate a plan of operations and need only prevent undue or unnecessary degradation of the environment. Post-1976 operations generally require a plan of operations, must prevent unnecessary degradation, and must also prevent any impairment of the area's suitability for wilderness. *Id.* § 3802.0-6.
242. *See id.* §§ 3802.1-4 to 3802.6.
243. *Compare id. §* 3809.0-5(j) *with id.* § 3802.0-5(a).
244. *Id,* §§ 3802.4-7, 3802.4-8. For further information regarding BLM surface management regulations governing wilderness study areas, see 43 C.F.R. subpart 3802 (1988), *American Law of Mining,* Vol. 5, § 173.05[4][a][iii], and Kimball, *supra,* at 538-53.
245. 36 C.F.R. § 228.1 (1989).
246. *Id.* §§ 228.4(a)(l) and (2). As an example of how the courts have interpreted "significant disturbance of surface resources," a federal appeals court has ruled that the presence of a cabin, an uncompleted mill building, a tool shed, a shower, and an outhouse on an unpatented mill-site claim located within a National Forest constituted significant surface disturbance within the meaning of the Forest Service regulations. *See* U.S. v. Brunskill, 792 F.2d 938, 939, 941 (9th Cir. 1986).

Part II
Stages of Mining

Section 4 Mineral Prospecting and Exploration

HOWARD L. HARTMAN, SENIOR EDITOR
WILLARD C. LACY, SECTION COORDINATOR

Chapter 4.0
INTRODUCTION

WILLARD C. LACY

A mining operation begins with prospecting and exploration-stages with long periods of investment and high risk of failure. However, success in exploration ultimately determines survival of the mining industry.

Prospecting and exploration may discover evidence of a mineral occurrence and outline its size and character, but ore deposits that support mining are "made" through the collective efforts of project geologists, geophysicists, geochemists, metallurgists, engineers, chemists, lawyers, and even politicians (Joralemon, 1975). Some deposits may go through multiple cycles of rejection and recommendation, discovery and development, decline and abandonment, rediscovery and development, etc., as economic, technological, or political conditions change or geologic understanding is improved. Peters (1987, p. 233) graphically illustrates the normal life cycle of a mine and the position of exploration in the cycle (Fig. 4.0.1).

During the past fifty years, mineral exploration has evolved from comparing evidence of mineralization of prospects with that of known deposits to a more quantitative science employing many facets of geochemistry, geophysics, multispectral sensing from space, computer data storage, analysis, modeling, and most importantly, a better understanding of ore genesis. This modern approach to exploration began in the late 1940s and continues to develop. Exploration efforts peaked in the 1960s with emphasis upon the search for porphyry copper deposits, Mississippi Valley lead-zinc deposits, and volcanogenic massive sulfide copper-lead-zinc deposits. It peaked again in the middle and late 1980s with emphasis upon micron-size disseminated gold and epithermal and stratiform precious metal deposits.

Revival and augmentation of the concepts of continental drift and its effects on continental plates, sea floor spreading, subduction zones and related fault systems, observation of actual sea floor metal sulfide deposition, and precious metal deposits forming in hot spring environments have suggested potential target areas and revealed deposit characteristics that enabled discovery of new varieties of deposits in newly recognized environments.

The object of mineral commodity search shifts with development of geological concepts and search techniques, changing markets, price fluctuations, and developments in mining and

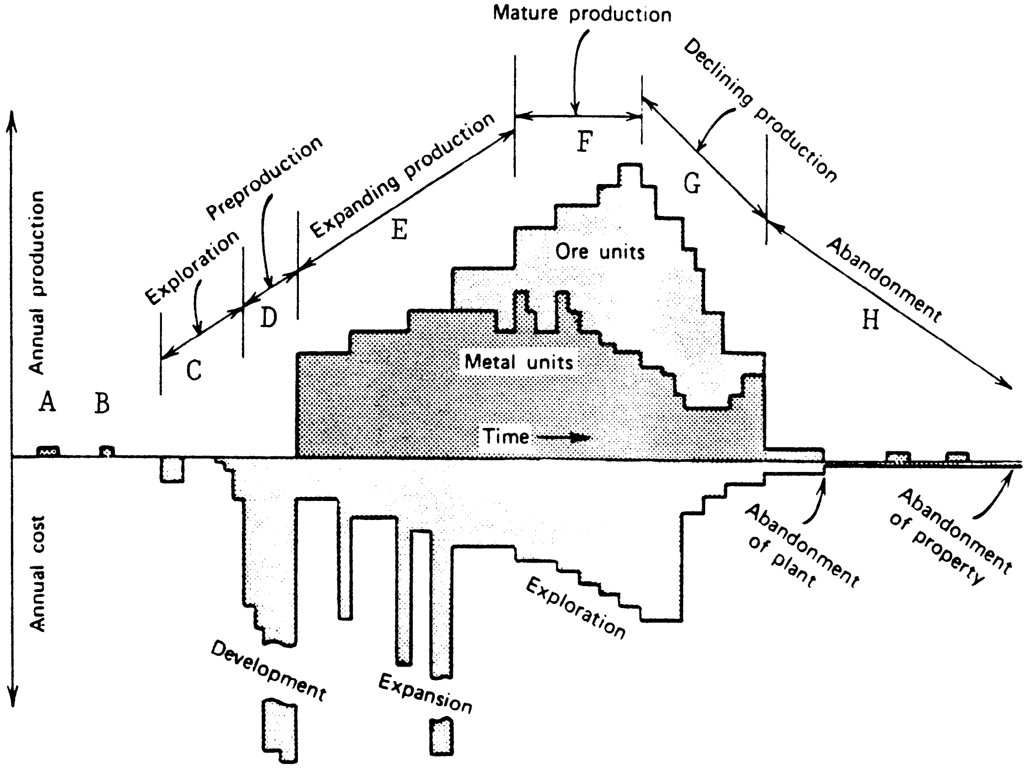

Fig. 4.0.1. The life cycle of a mine. A. Discovery of the district. B. Repeated examination by geologists and engineers. C. Recognition of potential of a major ore body. D. The preproduction interval: preliminary estimates, financing, testing, development, staffing. E. Expanding (youthful) production: payment of dividends, repayment of debt, vertical and horizontal growth. F. Mature production: innovation, verification of limits of ore, local exploration, cost reduction. G. Declining (old-age) production: sale or lease of assets, "outside" exploration, mining of pillars, cost reduction. H. Mine abandonment: salvage of machinery, custom milling, treatment of dumps, lessee operations, land restoration. (Peters, 1987. By permission from John Wiley & Sons, New York.)

metallurgical technology. This is well demonstrated by the commodity gold (Fig. 4.0.2). Exploration for gold in the United States lacked enthusiasm until discovery of the Carlin micron-size disseminated gold deposit in 1962, combined with freeing of gold price control in 1971, and development of heap-leach and carbon extraction techniques for gold recovery. These developments sparked the "gold rush" of the 1980s. In contrast, copper exploration suffered from an oversupplied market, depressed prices, and restrictive environmental legislation. Exploration and discoveries declined.

While changing economic factors, technological developments, and new market demands have created new target areas and revived old ones, restrictive legislation continues to reduce areas available for search and development and to increase governmental controls.

4.0.1 DEFINITIONS

In this section, the term "ore" is used in its broadest sense to include economic metallic mineral deposits, industrial mineral deposits, and energy mineral deposits.

In North America, the terms "prospecting" and "exploration" are often considered equivalent, but there is the implication that prospecting is less technical and usually carried out by an individual. Company departmental groups engaged in the search for mineral deposits are referred to as "exploration departments," which may on occasion employ or finance practical "country-wise" individuals to search given areas, "prospecting" for surface evidence of mineralization.

In this presentation, *prospecting* is considered as a part of exploration–the direct search for surface indications of ore mineralization. *Exploration* includes all activities involved in the discovery and evaluation of a mineral deposit, establishing the size, grade, initial flowsheet, and annual output of the new extractive operation (Bailly and Still, 1973, p.5-2). At an operating mine, the search for additional ore bodies, discussed in Section 5, may also be referred to as exploration.

"Discovery" of valuable mineral is the foundation of the US Mining Law of 1872. It is a prerequisite to mining claim validity. Initially, "discovery" was legally defined as the finding of sufficient quality and quantity of mineralization that a person of ordinary prudence, with a reasonable hope of success, would be justified in further expenditure of labor and means-the "prudent man" test. However, at present the Department of the Interior and the courts have modified their definition of discovery to a more stringent test, a "marketability" test. In order to establish discovery, the locator must demonstrate the existence of a mineral deposit that can currently be mined, treated, and marketed at a profit-an "economic discovery." The US Revenue Act of Feb. 9, 1919, uses discovery as practically synonymous with "development." This leads to a "Catch 22" situation where tenure may be required before capital for development can be acquired, yet development is required for tenure.

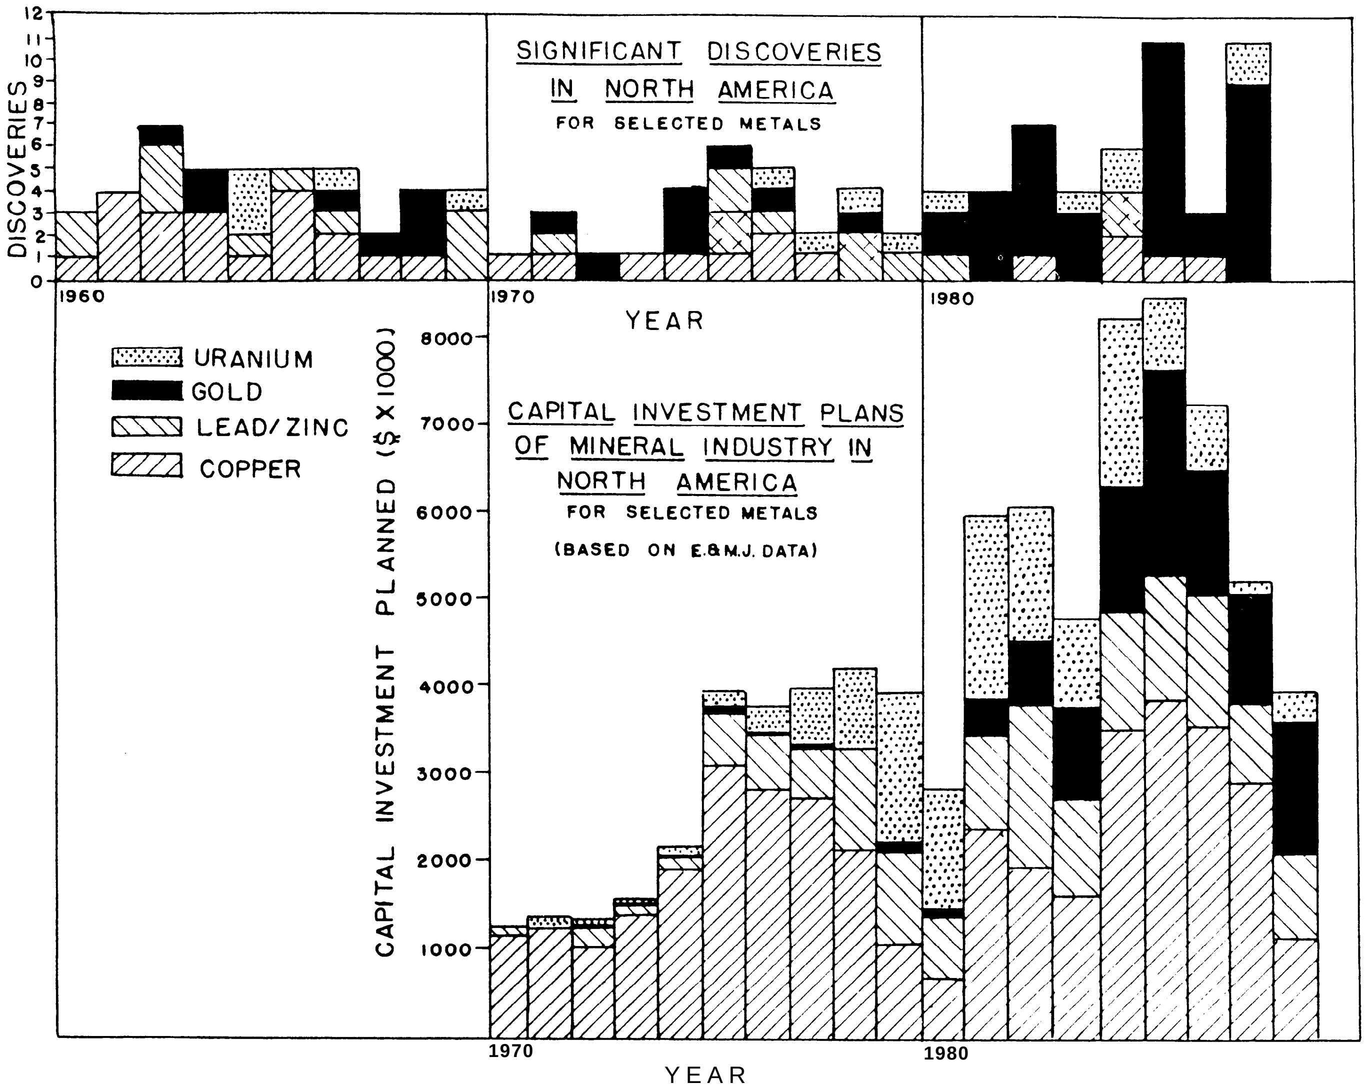

Fig. 4.0.2. Significant ore deposit discoveries in North America for selected metals, and capital investment plans projected by North American industry (source of data: *Engineering and Mining Journal, Mining Engineering,* Cook, 1986).

Lack of agreement among persons within the mineral industry as to the definition of "discovery" results from different objectives. What may be considered as a successful discovery to one company may not be acceptable to another.

MacKenzie and Bilodeau (1984) state, "A discovery is considered to be made when the deposit which ultimately forms the basis for development is first encountered by drilling (or other means). . . . An economic discovery is one which realizes a total revenue of at least $20 million and a rate of return of at least 10%."

Miller (1976, p.840) is much more restrictive, stating, "Within the modern corporate system an ore discovery is a mineral deposit which can be brought into production within a five-year period. A technical success is the discovery of a mineral deposit which is subeconomic into the indefinite future . . . exploration geologists can be judged successful only on their rate of ore discovery, not on the basis of technical successes."

Cook (1986, p. 87) recognizes "significant discoveries" as deposits of a size and grade that would yield more than $500 million in gross revenue, using average metal prices for the past five years. "World class discoveries" consist of those deposits that are continuously operated and consistently return a profit even during periods of low metal prices, that are large enough to significantly affect a medium-sized corporation's profits, and that rank in the lower one-third cost per unit metal produced for all similar deposits.

In this discussion, *discovery* refers to the first encounter with mineralization that can be developed into a profitable mine under normal economic conditions.

An exploration program may find a "prospect"—interesting surface indications of mineralization that bear investigation. This may develop into a "geological," "geochemical," or "geophysical" discovery when sufficient data are gained to locate the probable presence of an economic mineral deposit. An "economic discovery" can be achieved when (1) capital for development can be raised within a reasonable period of time, (2) tenure and ownership will be respected (the mining claims will qualify for patent), (3) a reasonable profit margin can be projected, (4) technology for mining and treatment exists or can be developed within a reasonable period of time, and (5) there is social and political acceptance of the mining activity. An economic discovery results from the collective efforts that go into the making of a mine.

4.0.2 ANALYSIS OF SIGNIFICANT MINERAL DISCOVERIES: 1950 to 1990

4.0.2.1 Performance by Commodity

During the 1950s and 1960s, base metal search and discovery dominated mineral exploration. Successes stemmed from refined geological and geophysical models, in particular—relating to fluid flow through geologic formations, recognition of alteration halo patterns, positioning of deposits relative to geotectonic plates, and refinement of search techniques.

Models of porphyry copper deposits were developed by exploration and research geologists of several major mining companies and consultants, and the distribution of deposits was recognized as being associated with subduction at plate margins and associated with crustal breaks. This encouraged extension of search and resulted in many new discoveries. Refinement of induced polarization geophysical techniques enabled recognition and evaluation of disseminated sulfides under alluvial and/or post-mineralization cover.

Localization of volcanogenic massive sulfide copper-lead-zinc deposits along interplate environments led to discoveries along the cratonic margin in southeastern Canada and northeastern United States from Michigan to Maine. Exploration for these deposits was assisted by refinements in aeroelectromagnetic methods.

Mississippi Valley type lead-zinc deposits were related to fluid-flow models, to basin margins, and to reef distribution in limestone units. This led to a rash of discoveries and recognition of the Viburnum Trend in southeastern Missouri.

The roll-front model of sandstone uranium deposits resulted in many discoveries in the 1960s and 1970s on the Colorado Plateau and adjacent areas, and the energy crisis of the 1970s stimulated search for uranium in Canada that was rewarded by large high-grade discoveries along the Proterozoic unconformity of the Canadian Shield.

Search for precious metals was stimulated by the French "run" on gold reserves of the US Treasury, discovery of the Carlin micron-size disseminated gold deposit in 1962, freeing of gold price controls in 1971, and development of low-cost extract techniques. Genetic models relating deposits to hot spring and epithermal environments, detachment fault zones and peraluminous intrusives of the western United States, and to stratiform Proterozoic environments in eastern Canada have led to many discoveries that dominated success statistics during the 1980s (Fig. 4.0.2).

Lag time between discovery and development of deposits is reflected in capital investment plans, which may be seen in Fig. 4.0.2. Between the time of initial detection of base metal deposits and planned major capital expenditures for development is an average period of about ten years. Uranium and gold deposits, on an average, require shorter preproduction periods and lower capital investment. Albers (1977, p.73) suggests an average of seven years' preproduction period from geological, geophysical, or geochemical discovery for all mine types, ten years for copper deposits, five years for uranium deposits, and three years for gold deposits. These figures lack sufficient numbers to give statistical validity, but they are indicative.

Table 4.0.1 Principal Techniques Responsible for Ore Body Detection in the United States and Canada, 1940-1976

	USA[1]	Canada[2]
Discoveries	63	122
Geological inference	73%	32%
Conventional prospecting	4%	37%
Geophysical	3%	25%

4.0.2.2 Performance by Search Technique

A comparison of ore deposit detection according to methods responsible for their detection is shown on Table 4.0.1

Direct observation of surface evidence or ore mineralization—conventional prospecting—is declining in importance except for some precious metal deposits that have very subtle surface indications, search for deposits in remote or underdeveloped portions of the world, and search for deposits of those elements or minerals that have had limited past search history. The prospector has become much more sophisticated in his recognition of evidence of mineralization and has become aware of current theory and search techniques.

It has become increasingly difficult to assign any discovery to a single exploration technique. The successful programs utilize search by all appropriate techniques.

4.0.2.3 Discovery Costs

Various estimates have been made as to the average costs for making discovery of an ore deposit (Cook, 1986; Albers, 1977; Derry and Booth, 1978; and MacKenzie and Bilodeau, 1984). Such approximations lack general agreement as to what constitutes a discovery and involve uncertainties as to expenditures. They do, however, present an order of magnitude and permit comparison between areas of search and target size. Figures need to be composited over ten-year periods to accommodate preproduction periods. Table 4.0.2 presents estimates of average discovery costs for finds with anticipated gross metal value in excess of $500 million in the United States, Canada, and the entire Non-Communist World, and in excess of $20 million in Australia.

A comparison of these statistics on a basis of estimated minimum acceptable gross revenue vs. cost of discovery (Fig.

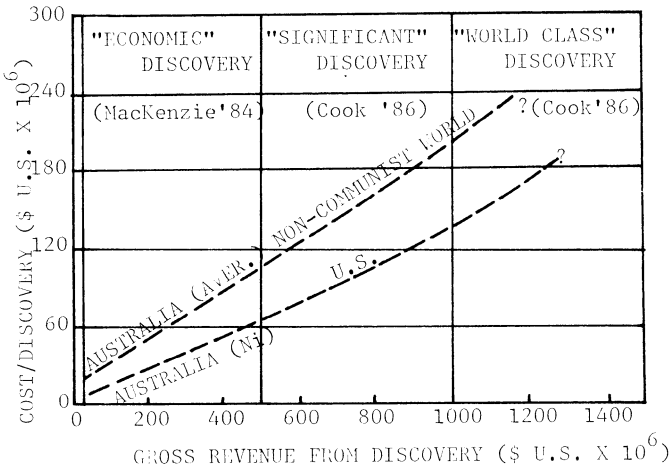

Fig. 4.0.3. Average discovery costs relative to minimum acceptable gross revenue of ore deposit discoveries (Cook, 1986; MacKenzie and Bilodeau, 1984.)

Table 4.0.3 Distribution of Exploration Costs in United States and Canada, 1980-1983

	USA	Canada
Geological inference	15.6%	20.3%
Geochemistry and conventional prospecting	18.5	14.3
Geophysics	4.6	12.2
Drilling	30.6	33.6
Cost per staff (excluding summer students) in 1980 U.S. dollars	130,000	140,000

Source: Barber and Muessig, 1984, 1985.

4.0.3) suggests that discoveries cost between 14 and 20% of minimum acceptable gross revenue from the deposit. Some company exploration success costs consistently beat these average costs, while others seldom realize success despite substantial expenditures. This appears to be a function of management of exploration programs (Chapter 4.6).

Distribution of costs in exploration programs in the United States and Canada for the period 1980 to 1983 is shown in Table 4.0.3.

4.0.3 FORECAST

Madigan (1984), paraphrasing Wallace Platt, wrote:

> "Where mineral is first found, in the final analysis, is in the minds of men. . . . When man no longer believes more minerals are left to be found, no more minerals will be found, but so long as mineral seekers remain with a mental vision of a new field to cherish along with freedom and incentive to explore, so long will mineral fields continue to be discovered."

Continued research on ore genesis will reveal new environments of mineral and metal concentrations, and new search and production technologies or escalation of prices may allow extraction of previously uneconomic concentrations.

The search for specific mineral and metal commodities will change as markets are modified and different technologies develop. For example, miniaturization and satellite communications have allowed less metal to do more, but, at the same time decrease in metal demand in some parts of the world may be compensated by increased Third World demand. New public transportation systems, local, national, and international, surface and underground, may require large quantities of steel and alloy metals—far in excess of the "railroad era." New mineral and metal commodities may become critical in supply—development of super-conductors may demand large quantities of elements yet to be determined. High-temperature engines using hydrogen fuels may require special ceramic materials replacing metal parts.

Limiting parameters for development and search include supplies of energy, environmental effects, restrictive legislation, excessive taxation, and social pressures. The latter may force ore search to less populated areas.

Cook (1986) foresees that exploration objectives for major natural resource companies will be directed toward (1) world-class discoveries and/or small, high-unit value, low capital-cost deposits that can be profitable even under most adverse market conditions, and (2) polymetallic deposits, particularly those amenable to open pit extraction.

With a willingness to seek and accept new mineral occurrence patterns, and with the aid of improved technology and support from management and government, we should be able to extract the most from our traditional ore hunting grounds; but it may be time also to reexamine the refractory ore deposits, to examine the more remote areas, and to review the more esoteric metal sources.

Chapter 4.1
GENERAL PRINCIPLES

WILLARD C. LACY

4.1.1 INTRODUCTION

Design and conduct of successful exploration programs involve forecasting, defining of corporate and business objectives, determination of strategy and tactics, scheduling, and budgeting—all carried out within limitations of corporate, local, state, and national policies and procedures. Advanced planning and assessment of budget and personnel needs and financial and technical capabilities save wasted efforts. Instructions such as, "Go find us a mine, then we will decide what to do with it," makes the job of the explorationist difficult and fails to focus search. On the other hand, requirements that are too restrictive may condemn the program.

Some companies have established policies of acquisition of deposits through purchase, thus avoiding uncertainty and risk of exploration. Such a policy is shortsighted in terms of long-term survival of the mining industry. All new mineral concentrations are found through prospecting and/or exploration and made into mines through man's creativity.

4.1.2 OBJECTIVES

The principal objective of mineral exploration is to find an economic mineral deposit that will appreciably increase the value of the company's stock to the stockholder on a continuing basis or enrich the explorer. Bailly (1972, p.31) suggests that objectives in acquisition or discovery of new ore reserves and mineral resources are to maintain and increase profitability of production assets of mine/mill operations and supply raw material to the treatment plant, and to create new assets and profit centers by product and/or geographic diversification.

Each organization involved in exploration defines its own objectives in terms of mineral commodities and geographic locations, acceptable size, life and profitability, and acceptable risk and expenditure. The exploration program should be designed to find and acquire a maximum number of acceptable mineral deposits at a minimum cost and within a minimum time period.

Exploration is an economic activity—a form of investment for the future or insurance. Companies undertake the cost of searching for new deposits with hope of finding deposits that can either be sold or developed at a substantial profit. If they are successful, they should realize a rate of return on their exploration investment that more than compensates for their cost of capital and the high risk associated with exploration activities.

4.1.3 STRATEGIES

Prospecting and exploration strategies vary widely, dependent upon the mineral commodity sought, the geologic and climatic environment, political and social restrictions, and available resources. Bailly (1972) outlines possible strategies for acquisition of mineral deposits: (1) acquire a producer, (2) acquire developed reserves, (3) develop a known deposit, (4) explore known deposits, and (5) explore for new deposits—(a) near known deposits, (b) in a mining district, (c) in a mineral belt, or (d) in a favorable virgin area. All of these approaches have been successful.

4.1.4 TACTICS

Most exploration programs focus progressively on areas of decreasing size, using methods increasing in cost per unit area, with declining risk of failure. These include (1) "conventional prospecting" consisting of the search for directly observable natural features commonly associated with ore mineralization, or literature and geologic research with selection of geologically favorable localities; (2) multistage coverage of the area selected involving detailed geologic mapping, geochemical and/or geophysical coverage, and/or use of special techniques; and finally (3) a drilling program and/or underground exploration by shafts, drifts, and crosscuts. Emphasis upon each stage or technique depends upon the character of the deposit under investigation, the commodity sought, the human and economic resources available, previous experience of the explorer, and results obtained in earlier stages in the exploration.

Bailly and Still (1973) outline stages of a regional exploration program and detection methods in Figs. 4.1.1 and 4.1.2.

Analysis of satellite data and computer modeling are not generally direct ore-finding tools, but may be integrated with geological, geophysical, and geochemical data to improve the efficiency of the exploration program. They can lead to a better understanding of the relationships and controls of mineralization and increase the probability of making a discovery.

Ore deposits are detected by individuals and the importance of the human resource cannot be overemphasized. Local knowledge, detection methods, and time and money are of little value if the explorationist fails to recognize or misinterprets favorable indications, or management lacks courage or technical resources to proceed.

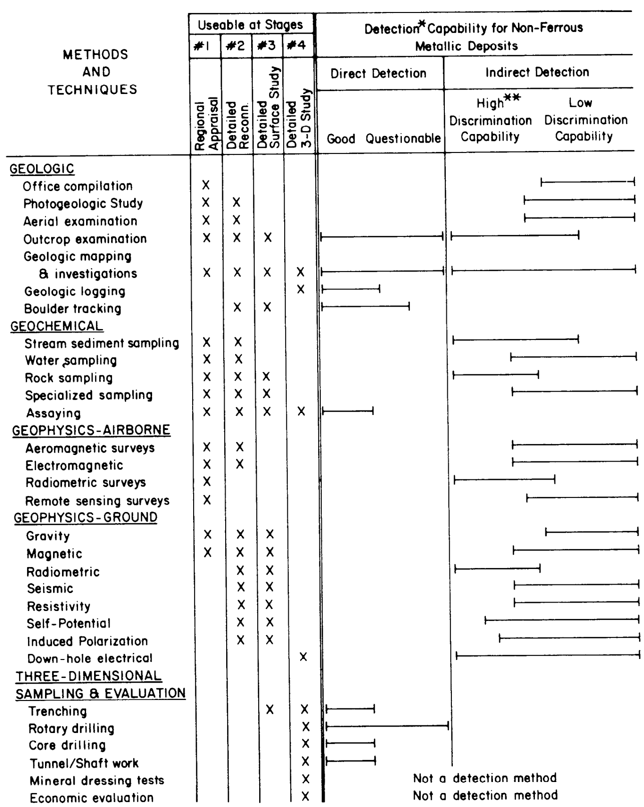

Fig. 4.1.2. Main exploration methods and techniques (scientific aids) (Bailly and Still, 1973).

* Detection refers to the ability to detect a deposit if is there Indirect detection refers to a geological, chemical or physical response showing a deposit may be the cause of the response; this is in opposition to direct evidence of the presence of a deposit.

** Discrimination with regard to indirect methods refers to the ability to determine if a certain response (anomaly) is due to a deposit or to another cause.

Chapter 4.2
FORMATION AND CLASSIFICATION OF MINERAL DEPOSITS

SPENCER R. TITLEY

4.2.1 INTRODUCTION

The knowledge of where and how ores form has been sought by geologists for many hundreds of years since the earliest of the "modern" expositions on the subject by Agricola in the 16th century, and for many centuries before that time, by "natural philosophers." The growth of knowledge about formation of mineral deposits through this period of time has resulted in continuous attempts at classification of ores, each successive attempt building upon accumulated knowledge, as ore bodies continue to be discovered and as detailed knowledge of geologic environments and processes has grown from research in the field and laboratory. Thus knowledge about the formation of ore bodies and their classification have moved on parallel tracks, hypotheses related to formation contributing to modification of existing schemes of classification. In the late 20th century, knowledge of the genesis of ores continues to expand at an ever accelerating pace, and corresponding modifications of classification schemes continue to be proposed.

At a very fundamental level, mineral deposits represent the results of processes that act to concentrate elements in mineral form or in anomalous concentration in other minerals. In those places where the concentration is sufficiently great that such rocks or minerals can be extracted from the earth at a profit, these deposits are called *ores.* The concentrations represent geochemical anomalies within the earth's crust, and their study in this context has led and continues to lead to the development of fundamental scientific information concerning evolution and modification of our planet.

In the study and classification of ores, we search for common, intrinsic, evolutionary, or environmental properties of occurrence of groups of these special rocks and minerals that allow definition and establishment of occurrence of classes or like-kinds of mineral deposits. It is a demonstrated fact that anomalous occurrences of minerals and metals, as well as rocks, *can* be classified in certain important and practical ways. However, discovery and recognition of like properties of genesis and environment of formation of ores, leading to hypotheses of classification, are not merely intellectual exercises. Ore classifications that relate environments and processes (as well as geological time) have immense practical and scientific value for they serve to direct and guide both continuing scientific research and the exploration for undiscovered ore bodies.

4.2.2 OVERVIEW OF ORE GENESIS

Modern knowledge concerning where and how ores form has evolved to its present state as a result of studies of mines, ore bodies, and regional geology during the past century. Although many of our current ideas stem from concepts of much older vintage, the expansion of knowledge about ores dates from the early part of the 20th century with the last half of the century witness to an explosion of knowledge. This growth of understanding is due to many things. The numbers of geologists studying ores during this century has increased from, perhaps, a few hundred to thousands. Further, only since about 1950 has our capability to measure many chemical and isotopic properties of ore systems and rocks been realized and the results of such studies, focused on ore deposits, have tested many early ideas and revealed clearly many hitherto unknown phenomena. And only during the late decades of the century has new knowledge allowed us to ascribe a meaningful association of ore formation with planetary and crustal evolution.

Mineral deposits represent geochemical anomalies in the sense that they are sites of, usually, significant concentration of elements that are ordinarily dispersed in crustal rocks. This concentration takes place in one of two fundamental environments, at the earth's surface, or within the crust, as an end result of one of three primary processes.

The most widespread and common of the processes is the dissolution of chemical components of rocks, their transport in solution and the precipitation of those components as ore minerals at some specific site (trap) of deposition, usually controlled by a chemical contrast or change in chemical environment. It is this localized site of chemical contrast, together with the channeling of metal-bearing fluids into it that results in metal or mineral concentrations. The process takes place at both air- or water-rock interfaces, for example the earth's subaerial surface or the ocean floor, and at deeper levels in the crust. The process of solution-dominated ore genesis is fundamental and makes no distinction as to kind and source of solution, nor of metal or mineral-component source, nor of specifications concerning traps of ore minerals. In view of the complex nature of the crust and its many environments, together with varied sources of fluids and metals, there are clearly many complex combinations of process and environment; the characteristics of such ores reveal a great variety of associations of rocks and different metals.

The second primary process involves the transport of particulate matter at the earth's surface. Certain valuable minerals, which occur in rocks, such as gold, platinum, and gems, are dense, or hard, or chemically inert and survive chemical weathering to be transported in hydrologic systems and reconcentrated. Both water under the force of gravity, and the density contrasts between the mineral in water, combine to move such minerals to sites where localized physical features of containment of the hydrologic system bring about concentration by changing hydraulic competence. The process results in placer deposits that concentrate at contemporary surfaces. Modern streams and wave action are currently producing placers; the process, however, has taken place since water washed over rocks, and there are important placer deposits of gold of great geological antiquity that survived by being buried after formation.

The third important process involves the formation of certain igneous or metamorphic rocks. Chemical and mineralogical evolution of such rocks is attended by the formation and segregation of special groups of ore minerals (e.g., platinum, chromite, and magnetite), which are concentrated at specific places and at specific stages of the processes. Resulting concentrations of these minerals occupy predictable parts of layers of igneous rocks or occur within certain facies of metamorphic rocks. In the case of igneous rocks, the mineral concentrations occur as distinctive flows in volcanic successions, or as layers within magmas that cooled at deep crustal levels. Metamorphism results in chemical changes that move water, resulting in metal concentrations identifiable with certain levels of intensity of the metamorphic processes.

4.2.3 SOME CLASSIFICATION SCHEMES OF THE EARLY AND MID-20TH CENTURY

The understanding of ore genesis is an evolving phenomenon and can be traced with some accuracy in reviewing the nature and rationale of various classification schemes of the past century. For, as concepts change, so does the classification. In order to appreciate the relevance of the direction in which studies of ores has progressed, it is important to know of the early ideas of ore genesis to understand where we have been.

As a knowledge of where metal ores occurred was developed through the 18th and 19th centuries, largely as a result of the industrial revolution, the westward movement of European cultures, and the search for wealth, the first serious attempts at classifying ores ensued. Such attempts were integral parts of broader theories of evolution of the earth and represented polarization of ideas of those who believed, on the one hand, that geological phenomena had their sources within the earth (plutonists) and those who held to terrestrial evolution controlled by events in a primeval ocean (neptunists). It is a curious fact that changing ideas based upon geologic evidence developed during the past century have brought us to a current point of view that both of these early ideas, albeit extensively modified and extended, may be uniquely applied to specific kinds of ores. Without regard to geologic time, it appears to us now that ores formed as a consequence of both, processes acting *within* the earth and processes acting at submarine or subaerial *surfaces.*

Many recent (late 19th and early 20th century) ore deposit classifications stem from Posepny (1898, 1910), whose ideas were extended and modified by Lindgren (1913, 1933) into a classification that remained broadly applicable to many mines and districts in the western hemisphere in the late 20th century. However, the classification has not endured without challenge, and many of its parts have required modification as knowledge of the occurrence of ores has advanced. As is true of the development and use of many classification schemes, it may not be the classification that is at fault; rather it may be its unreserved and unquestioned acceptance, and the way in which it is applied and used by the clientele. Adherents to any classification scheme dealing with natural phenomena are invariably faced with situations in which no category exists to exactly place or identify a phenomenon, or in which detail about a known feature only partially satisfies criteria for a particular class. With only few changes of substance, but in some cases many changes and augmentations in detail, Lindgren's classification has been modified through the years by various authors to accommodate newly recognized characteristics of certain kinds of ore bodies. Graton (1933) and Buddington (1935) split and expanded Lindgren's fundamental depth zones of his classification of hydrothermal deposits to accommodate some otherwise intractable ore styles; Ridge (1972), Park and McDiarmid (1974), and, most recently, Guilbert and Park (1986) have further detailed and expanded the Lindgren classification internally without modification of its fundamental structure. Although Lindgren's classification is conventionally viewed as based upon environments of formation (and he detailed the nature of those environments in a way that had not been previously done), it is actually premised upon processes. Survival of the basic framework of the classification as a fundamental statement about the occurrence of ores is testimony to Lindgren's perceptive mind; the scheme is outlined in the following.

A Classification of Ores Based Upon Processes

I. Deposits produced by mechanical processes of concentration.
II. Deposits produced by chemical processes of concentration.
  A. In bodies of surface waters.
  B. In bodies of rocks.
    1. By concentration of substances contained in the geological body itself (e.g., metamorphism, weathering).
    2. Concentration effected by introduction of substances foreign to the rock (e.g., circulating waters, igneous emanations, directly or indirectly).
  C. In magmas by processes of differentiation.

Source: Modified from Lindgren, 1933.

Lindgren's classification represents but one of many of his time that attempted to categorize ores and that reflected views of different workers. (For an excellent discussion of this subject, see Stanton, 1972, pp.7-35.) Among other significant contributions were those of Niggli (1941) whose framework of igneous rock types encompassed ores based on mineral-metal associations, and of Schneiderhohn (1941) whose classification is premised primarily on processes and secondarily on ore associations. It may be noted that in Schneiderhohn's classification, outlined below, the framework is based upon processes either related to specific geological environments (intrusive rocks and magmas) or to specific processes themselves (i.e., "pneumatolytic"). Further, the mineral-metal associations are those of generally compatible geochemical associations.

A Classification Based Upon Processes and Associations

I. Intrusive and liquid-magmatic deposits (Process).
II. Pneumatolytic deposits (Process).
III. Hydrothermal deposits (Process).
  A. Gold and gold-silver associations.
  B. Pyrite and copper associations.
  C. Lead-silver-zinc associations.
  D. Silver-cobalt-nickel-bismuth-uranium associations.
  E. Tin-silver-tungsten-bismuth associations.
  F. Antimony-mercury-arsenic-selenium associations.
  G. Iron-free associations.
IV. Exhalation deposits.

Source: Schneiderhohn, 1941, modified from Noble, 1955.

Development and application of classifications tend to be strongly provincial, reflecting the particular region or peculiar environment in which geologists work and gain experience. As Lindgren's classification evolved from wide experience in cordillera of the western hemisphere and was widely applied during a time when exploration of the cordillera was active, it is no surprise that strongly held views of processes related to magmatism, as a fundamental driving force of ore formation, came into ascendancy in this region in the first half of the century. Notwithstanding that fact, opposing views were expressed and caution counseled by some workers, notably Van Hise (1903), against uncritical adoption of all aspects of the magmatic theories. Van Hise noted that evidence for metal and solution source was not convincing in any genetic context and that magmatism was not by any means necessarily the sole agent of ore concentration. Testimony to the strength of prevailing opinions at that time is that Van Hise's work may be viewed as having been virtually

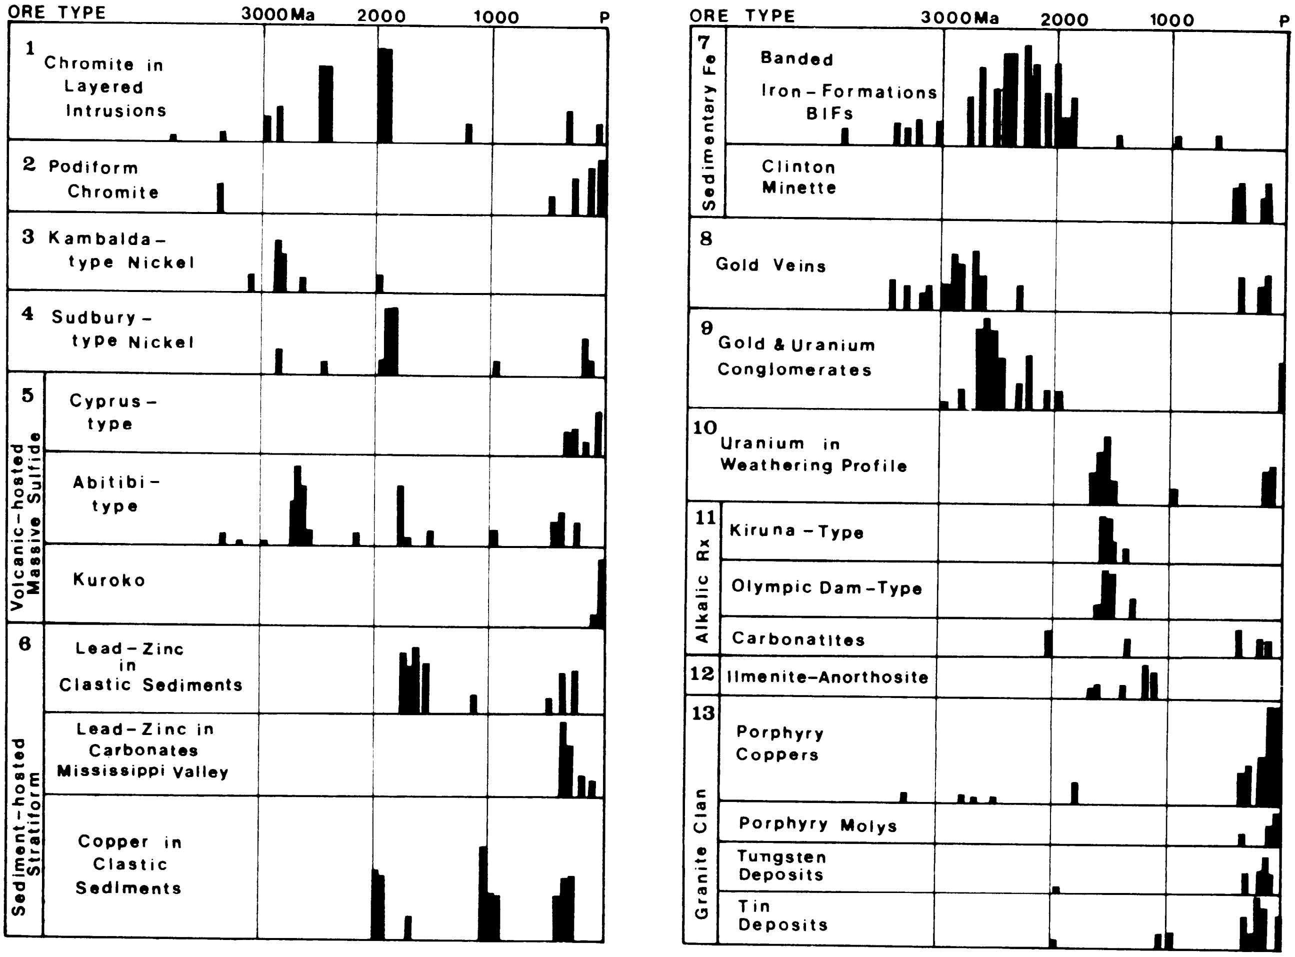

Fig. 4.2.1. Distribution of ore metal deposit types and metal production in geologic time. "The width of each vertical bar represents an interval of approximately 50 million years. The length of each bar is a geological estimate of the percentage of ore formed during that 50 m.y. as related to the total estimated tonnage—the sum of all of the bars *for that type of deposit*—for all geologic time. (From Meyer, 1988; reproduced, with permission, from the *Annual Review of Earth and Planetary Sciences,* Vol. 16. © 1988 by Annual Reviews Inc.)

sunk in a sea of igneous hydrothermalist notions. However, close review of Lindgren's (1933) classification and writings reveal that although he appears to have held strongly to magmatic concepts of formation of metallic ores, he expressed many reservations concerning the origin of metals and waters that formed them, and he clearly set apart certain industrial rocks and minerals.

4.2.4. SIGNIFICANT ADVANCES IN KNOWLEDGE OF THE LAST HALF OF THE 20TH CENTURY

Several important advances and discoveries of the past 40 years constitute bases for a reconsideration and modification of some earlier classification schemes. First, early schemes evolved in the absence of quantitative methods of dating ores; only since about 1955 have radiometric age dates of ores and rocks entered the literature in significant numbers to view *temporal* aspects of ores. A second point stems from this work. Meyer's (1981, 1988) treatises on variations of ore occurrence through geologic time discuss temporal patterns of metal concentration that bear importantly upon genetic classifications and environment (Fig. 4.2.1). A third important factor is the (now) widespread acceptance of the notion that metal sulfides form by various hydrothermal processes at and near the surface of the ocean floor (Routhier, 1963; Derry, 1973). This view, that ores *could* form at an ocean floor surface, was a fundamental working hypothesis applied by many geologists in Europe, Japan, Canada, and Australia for several decades before it was widely accepted in the magmatic-hydrothermal-dominated perspectives of many ore geologists in the United States. Nevertheless, following general and widespread acceptance of the kinds of ideas expounded by Routhier (1963) and Derry (1973), the important sea-floor environment and surficial hydrothermal and related processes still remained detached or isolated from existing and evolving ore classifications.

The period of intellectual evolution of the 1970s was a time when the geology of Precambrian shields was first expounded in a modern geochemical and petrochemical sense (Anon., 1969). There shortly followed significant papers reviewing the place of ores in such settings in Africa (Annhaeuser, 1974, 1981). Uniqueness of the greenstone environments was established as had been the environments of formation of Precambrian iron ores (James, 1954). King and Thompson (1953) suggested the Proterozoic, stratigraphically conformable massive sulfide ores at Broken Hill had been metamorphosed *after* metal deposition rather than formed by metamorphism, and Kinkel (1962) related some massive sulfide ores to sea floor volcanism. In North America, the importance of submarine volcanic processes in greenstone metallization in formation of greenstone ores had been developed with examples by Goodwin (1965), and the environment of concentration of many of these ores was at a contemporary surface. Although Gilmour (1971) proposed a classification of the massive stratabound sulfide ores, the stratabound ores of many geological environments remained isolated from the "mainstream" as classifiable phenomena in "traditional" overviews of ore occurrence.

In the 1970s, many workers attempted to group ores on the basis of their tectonic settings (Sillitoe, 1976), as revealed through the new knowledge of plate tectonics. These new insights of crustal evolution lent themselves to the appreciation of ore genesis in the context of global tectonics (Mitchell and Garson, 1981; Sawkins, 1984). Consequently, the long-recognized *geographic* distribution of mines and districts was given sense and significance from the perspective of *tectonic* environment; for example, the styles of mineral deposits on cratons became more fully understood in a *regional* and *evolutionary* sense as were metal deposits along active continental margins and in island arcs. Hypotheses of processes and environment were advanced in the context of what were perceived to be the effects of subduction of oceanic crust beneath continents or collision of crustal blocks; the sense and importance of continental extensional or compressional tectonics achieved stature in the study of region-wide structural ore control, and integration of knowledge of evolution of Precambrian rocks and ores has now led to assessment of crustal tectonic processes as they relate to these old rocks. The sorting of ore deposits in the context of this tectonic framework serves a useful purpose as most of the environments are not time dependent; the search for ores that may be unique to a specific environment is based solely upon recognition of that environment in the geological record and the assessment as to whether specific metals were concentrated at that time. Such a classification is outlined in the following.

A Classification of Ores Based on Tectonic Settings

I. Deposits formed in continental hot spots, rifts, and aualacogens.
II. Deposits formed on passive contental margins and in interior basins.
III. Deposits formed in oceanic settings.
IV. Deposits of subduction-related settings.
V. Deposits of collision-related settings.
VI. Deposits related to transform faults and lineaments in continental crust.

4.2.5 A CLASSIFICATION BASED UPON ENVIRONMENT AND PROCESS

Classifications of ore deposits may be created to meet various purposes. In the foregoing, examples have been described and shown that focus largely upon genetic considerations and various lithologic, mineralogic, or tectonic associations. In the following discussion, an outline of ore occurrence will be set forth that is developed upon first, one or the other of two fundamental environments in which ores were originally concentrated (within bodies of rocks or the crust, or at or near a contemporary surface), and secondarily upon processes of concentration. At this writing, the nature of processes that formed some ores and the events that modified them remain uncertain in many instances, as do the environments in which they are presently interpreted as having evolved. Consequently, the placing of some ore bodies into such a classification remains problematical. However, the scheme of classification and the contrasting environments are fundamental and lend themselves to a system in which specific kinds of ore occurrence can be moved to different parts of the format, as different concepts of environment or processes are developed and proven, without changing its basic structure.

4.2.5.1 Environments of Ore Formation

The most easily observed and studied environment is that of the modern surface. This surficial environment, in many different forms and compositions, has existed since formation of the planet and simply constitutes that surface between rock and atmosphere and rock and water. It has been a significant environment of chemical change involving at the one extreme, chemical modification and erosion (oxidizing and acid), and at the other extreme deposition of particulate matter or chemical precipitates (mostly non-oxidizing and acid to alkaline). At the subaerial surface, processes postdate diagenesis; at the submarine surface, processes predate or are synchronous with diagenesis. Many important ore types and ores, essentially synsedimentary or synvolcanic and including some of the largest known concentrations of base and precious metal mineralization known, have been formed in this environment; if they have survived subsequent erosion, they have a common property. The ores occur at an unconformity or disconformity, or within specific strata in the geologic column, and they are grossly concordant with their footwalls. They will be, or have been, modified by the same tectonic or thermal processes that may subsequently modify their crustal environment. Appreciation of this style of occurrence has a high practical value in prospecting as it focuses search toward and within *strata*, or to discernment and prospecting of *unconformities.*

The other environment is that *within* rocks of the crust. Except for ores of magmatic segregation and perhaps pegmatites of granites, these ores are fundamentally epigenetic, that is, they were deposited *after* lithification of their host. The environment is not always specifically restricted to rocks at depth, and it may connect with the surface where, in some cases such as supergene chemical enrichment, processes may act through some feet to 100s of feet (meters to 100s of meters) below it. Whereas ores of this environment, within the exceptions noted, are mostly discordant, they may also be concordant where certain properties of the rocks of the column, such as permeability or "reactivity" of specific strata, are amenable to fluid flow or act as chemical traps for mineral precipitation; they may thus be considered as stratabound. Further, physical modification of rocks below the surface, by surface-related processes, into mineralization traps such as deep karsts and caves, reveal the complex and important interaction between geologic processes acting in both environments.

4.2.5.2 Processes of Mineral Concentration at the Earth's Surface

Fundamental natural processes act to concentrate minerals and certain metals at contemporary surfaces. The effects of these same processes may be observed to result in different mineralization styles because of the different environments in which they take place. For example, hot springs moving through oceanic rocks and surfacing in the thermally insulated environment of the deep ocean result in different products from those of hot springs acting in the subaerial environment. These processes are briefly described below.

Subaerial Weathering: This process acts continuously at contemporary surfaces, but is most important at the atmosphere-land interface. Fundamentally, it is the chemical process that changes mineral, and thereby, rock compositions. Three products evolve; relatively insoluble components of silicate rocks such as clay and bauxite, concentrates of insoluble minerals, and soluble components of rocks that are removed by circulating waters.

Subaerial Chemical Precipitation: Some metallic components released to solution during weathering are reprecipitated in mineral form at various deeper levels (i.e., 10s of feet or meters beneath the surface). Most noteworthy of such mineral groups that form at shallow levels are those minerals of deposits of supergene nickel. They form as a result of weathering of Ni-rich ocean crust and tend to be stratigraphically controlled by levels of soil formation. The supergene concentration of lead and silver at shallow levels is widely recognized. The supergene concentration of copper, gold, and some silver, however, takes place at many levels, some of which are deep (i.e., 100s of feet or meters); controls of this process are chemical and generally related to water-table position, rather than to stratigraphic positions.

Erosion, Transportation, and Deposition: These processes proceed from weathering of rocks and involve the transportation of generally dense, insoluble phases (minerals) of rocks into those concentrations controlled by hydraulic competency, the placer deposits. The erosion of precious metal minerals, together with other dense and resistant minerals such as magnetite, monazite, rutile, and zircon, have resulted in placer deposits in a variety of sedimentological settings; the chemically reducing atmosphere of the Archean is believed to have been an agent that precluded chemical destruction of uraninite, which is concentrated in some fossil placers with gold, and the principal resource of diamonds and other gems lies in placer concentrations developed from weathering of their primary sources. Settings of placer deposits range from streams, through beaches to alluvial fans and deltas. Although placer deposits are abundant and widespread in geologically young sediments, formation of placer deposits has been a time-enduring process, and many buried and indurated placers, such as the gold of the Witwatersrand of South Africa, are of major economic importance.

Water Circulation at the Ocean-Water, Atmosphere-Land Interfaces: This process, most importantly developed in the tidal-flat environment, has been proposed as important in ore formation. Processes acting in this, the *sabkha environment,* have been proposed, although not without controversy, to have resulted in precipitation of important bedded copper ores such as those of the Zambian copper belt (Renfro, 1974). The sabkha process, which takes place in regions of extreme aridity and little topographic relief, involves evaporative pumping of subsurface water through evaporites and decomposing algal mats. The mats are reducing and sulfur-rich, forming metal traps that concentrate metals as sulfide minerals. Biogenic processes acting *within* the algal mats of this environment have also been suggested to be important in concentrating gold in the Witwatersrand strata of South Africa (Pretorious, 1976).

Submarine Precipitation: This important process is believed responsible for the formation of major deposits of ferrous and base metals, as well as gold, across a spectrum of submarine environments. Included are the major iron deposits of the world and the largest deposits of stratiform lead-zinc-silver ores such as Mt. Isa and Broken Hill in Australia; large strataform deposits of copper such as the Kupferscheiffer of Europe may be included as well. Submarine precipitation is also responsible for formation of sea-floor "manganese" nodules. Source of metals is likely diverse and ranges from metals contained in ocean waters to metals introduced into the environment from basin or ocean-floor volcanic hot springs along deeply penetrating faults. The metal concentrating processes may be controlled solely by chemical contrasts in the ocean-floor environment, such as redox changes, or they may be controlled by the existence of chemical or biogenic traps such as the presence of carbonate or sulfide at or near the ocean floor.

Processes at the Crustal Surface Related to Thermal Activity: Localized thermal contrasts developed from emplacement of magmas in continental or ocean crust or from other unknown causes result in the flow of metal-bearing water. In both crustal settings, the water emerges at the surface as hot springs; in continental settings, the hot springs are important sites of deposition of precious metals, mercury, arsenic, and antimony. In oceanic settings, they give rise to concentrations of base and precious metals at rises and spreading oceanic ridges.

Sea-floor springs related to deeply penetrating normal or down-to-basin faults, such as those with rifts may be sources of metals in some reducing sediments such as black shales and some of the important shale-hosted Pb-Zn-Ag (Cu) ores. In such ore-forming environments, metal concentration from additions of hydrothermal fluids may accompany sedimentary diagenesis, and the process may act within the accreting sedimentary section and close to although beneath the contemporary surface. Thermal activity and associated hot springs related to sea-floor volcanism are agents of the process of formation of the important class of volcanogenic massive sulfide ores of Kuroko type in Japan and likely many similar deposits that have formed in similar oceanic setting since the Archean. Stockwork sulfide deposits of the Cyprus type, developed in ophiolite complexes are of problematical origin in the context of their location with respect to the plane of the sea floor, but appear to have had connection with ocean water. However, massive sulfide bodies enclosed in associated pillow lavas appear to be related to sea-floor volcanic activity.

4.2.5.3 Processes Acting Beneath the Earth's Surface

Within the crust, the process of metal concentration takes place from the flow of metal-bearing fluid and precipitation of minerals in some kind of trap, and from the results of metal-bearing waters excluded by crystallization of magmas or recrystallization of rocks. The crustal environments in which fluids are believed to be important agents of ore formation extend from near-surface regions to depths that are unknown, but possibly as deep as 6 mi (10 km); bodies of igneous rocks containing synmagmatic ore minerals form at unknown depths within the crust, possibly as deep as 12 mi (20 km), and metamorphism that results in recrystallization and generation of ore fluids is, likewise, thought to be a deep-seated phenomenon, although there are few criteria by which such depths may be reliably estimated.

Processes Involving Supergene Fluids: Apparently demonstrable supergene fluids; that is, fluids whose immediate origin was at the surface, have been agents of secondarily enriched metals, especially in copper deposits. In the oceanic or basinal environments, fluids that have carried and precipitated metals within oceanic crust may have had their immediate origin in waters of those basins and have been important in high temperature systems. It is not specifically clear that such waters should be classified as supergene, but in the context considered here, their immediate, not penultimate, origins have been from sources above the relevant surface.

Processes Involving Hypogene Fluids: The presence of hydrous minerals in ore deposits, the presence of fluid inclusions in ores, and the evidence from theoretical chemistry point unequivocally toward water-based solutions as a significant agent of metal transport and deposition in many intracrustal ore deposit environments. Hypogene fluids are of high temperature (hydrothermal solutions) and may be inferred from isotopic evidence to have had many different origins peculiar to specific deposit types or to terranes in which deposits occur. Thus fluids may have their sources in igneous plutons, in the included water of sediments in basins, from formation waters derived from sedimentary rocks, from water excluded by dehydration reactions during metamorphism, and from meteoric waters recirculated by thermal and gravity-related processes in shallow crustal environments. Many of these fluid sources (and by inference some metal sources) are distinctive in the context of tectonic environments. For example, basin brines are believed to be important in formation of epigenetic ores in craton settings; magmatic sources inferred to be important in pluton-centered ore systems of cordillera of subduction or collisional settings; and metamorphic fluids important in forming epigenetic ores in the old (Archean) greenstone terranes.

The results of hydrothermal processes in forming ores change across the thickness of crust in which the processes act. Recognition of these changes led Lindgren to outline his hydrothermal depth zone classification and others to modify it. Thus *telethermal* and *epithermal environments* were the shallow cave and open fault systems in which filling of open space by ore minerals was the dominant process of deposition, *mesothermal* the intermediate *environment* characterized by filling and replacement, and the *hypothermal* zone, the deep *environment* dominated by replacement. With the passage of time in which countless numbers of ore deposits have been studied with sophisticated techniques of measurement, the depth zone aspect of the classification of hydrothermal ores has become less distinct and certainly less definable in a rigorous sense than when proposed 60 years ago; many hydrothermal systems transgress the boundaries originally established by Lindgren and others. And we have yet to discover geobarometers that would reliably establish depths of ore formation over much of the proposed range of hydrothermal activity. Nonetheless, the criteria set forth by Lindgren still remain as observable and reliable phenomena to assert for the most part that mineralization in many ore bodies may belong to deep or shallow parts of hydrothermal ore systems.

Processes Related to Magmatic Segregation: Platinum Group Metals (PGM) are enriched in mafic (iron and magnesium-rich) volcanic rocks; in certain mafic intrusions, they have been concentrated by the processes of mineral segregation during crystallization of magma. Deposits of this group are related to Layered Mafic Intrusions, most noteworthy of which is the Bushveld Complex of South Africa. In this body, platinum occurs in such concentration that mines of the Complex are profitable solely because of their platinum content; the Complex is also a significant source of chromium and vanadium, also concentrated in minerals by the process of cooling and segregation of these unusual magmas.

Other metals occur as products of segregation in igneous rocks of other compositions. Magnetite and ilmenite occur as segregated products in gabbros. Granitic rocks, locally anomalously rich in tin, niobium, and tantalum, are sources of extensive tin placers in southern Africa, southeast Asia, and northeastern Australia; in a comparable way, nickel is enriched in some mafic and ultramafic rocks. In old terranes, these lithologies host primary concentrations of nickel sulfides and oceanic igneous rocks, which when weathered, give rise to secondarily enriched and economic deposits of nickel silicates.

Granitic Pegmatites, the Link between Hydrothermal and Magmatic Processes: The pegmatites of intermediate to felsic igneous rocks represent late stage differentiates of granitic magma, rich in alkalies, large lithospheric ions, water, and other volatiles, which cooled to form a specific genetic class of ores. The magmatic-hydrothermal processes are inferred from the presence of minerals of granitic rocks and the presence of hydrous silicate minerals in these bodies.

Metamorphism: The effects of heat and pressure on old rocks at deep crustal levels were becoming increasingly recognized as potentially important in ore genesis by the late 1980s. Formation of granulites and consequent dehydration of the protoliths are suspected to have contributed in some ways to solution of metals and their transportation from deep to shallow levels in the crust.

In addition to effecting solution of and transportation of metals, a further important result of metamorphism has been that of tectonic transport of ores formed as part of the protolith. Examples of this are seen in folded and distended concordant lenses of sulfides in many geologically old terranes, especially where dynamothermal processes have taken place.

4.2.6 SUMMARY: DEPOSITS OF METALLIC ORES

The foregoing has outlined characteristics of processes as they have operated to form some typical styles of ore bodies in different settings. The intent of presentation of this classification has been to provide an overview of ore formation based upon the gross dichotomy of environments. The outline of ores in the framework of contemporary surfaces is presented here in a first attempt at such a classification. The outline of ore occurrence within the crust is an extension of Lindgren’s proposals.

A fundamental aspect of ore search and development planning revolves around the question of *where* ores were formed and what is their style of occurrence. Importantly, what is the likely shape of an ore concentration, and how far is it likely to persist? Fundamentally, does one view a fault system and an igneous pluton as the basic criteria of ore search in a specific terrane, or does the exploration geologist search across strata and along unconformities? Viewed from this perspective, the process of ore formation may in many instances assume a secondary level of importance; hydrothermal processes may be important in each of the two environments considered, but the results of those processes are controlled by the environment in which they take place. The classification is shown in format style in Tables 4.2.1 and 4.2.2.

4.2.7 INDUSTRIAL MINERALS AND ROCKS

A great variety of rocks and minerals are valuable to man because of certain physical properties or compositions. They are considered here and distinguished from the foregoing discussion of metals and ores because of their general “nonmetallic” nature. And although it is a misnomer in some respect, these commodities have been loosely referred to in that context, as the “nonmetallics” (Bates, 1959). Perhaps the most important and consistent distinction between these commodities and the metallic ores is the (relatively) higher cost of processing of ores compared with that of most of the industrial rocks and minerals.

Although this class of commodities contains within it some that are scarce, for the most part the class comprises naturally occurring materials that are relatively more common than metallic ore minerals, and that may be used with little additional processing beyond transportation to their point of consumption. Viewed in a very general way, rocks and unconsolidated materials are mined in bulk and by virtue of this character are attended

Table 4.2.1. Environments and Ore-forming Processes at or Near Contemporary Surfaces

Processes / Environments	Chemical Weathering (Leaching)	Subaerial Chemical Precipitation	Erosion, Transportation, Deposition	Subaerial/ Submarine Precipitation	Submarine Precipitation	Volcanic Processes	Hydrothermal Processes
Subaerial Surfaces	Bauxite, Clay, Mn, Fe Laterites	Ni Laterites, U Calcretes				Sulfur, magnetite, hematite in volcanic flows	Hot Springs, Hg, As, Sb, Ag, Au
Alluvial, Fluvial Environments			Placer deposits, Precious metals, U, Gems, Resistates	Reduction in algal mats, Base metals, Au, Ag, U			
Lacustrine Environment, Playas				Brines, Borax, U			Hot springs, B, Sb, Hg(?), U(?)
Platform, Low-High Tide Sabkha Environ				Base metals, Au/Cu ores (Zambia?)	Cu ores, Pb/Zn ores (Kupferschiefer?)		
Shelf Environment					Carbonate facies Banded Iron Fm, Shale-hosted Pb/Zn	Algoman Banded Iron Formation	
Euxenic Environment of Basins, Rifts					Pyritic black shale Birmingham Iron, Shale-hosted Pb/Zn	Algoman Banded Iron Formation	Hot springs, Au, Fe, Ni, Ag, Cu, W, Sn
Cratonic Basins					Superior-type Banded Iron Formation		
Abyssal Plains > 4.5 km (2.7 mi) Depth					Deep-sea nodules Mn Fe, Ni, Cu, Co		
Marginal Basins Extensional Environment					Volcanogenic Massive Sulphides	Volcanogenic Massive Sulphides Greenstones, Kuroko	Sea-floor hot springs
Ocean Ridge, Spreading Center							Cyprus-like deposits, Cu

by transportation costs that compose a significant component of their value. Viewed from the perspective of their occurrence, these materials have more value as a consequence of their location than from their intrinsic properties. In contrast, the value of many of these commodities, specifically certain minerals such as diamonds, mica, asbestos, and clay, is in great part dependent upon the quality of the product as it occurs or as it is mined or found, and because their bulk is small compared with that of rocks, the site component of their value is less critical than that of rocks and unconsolidated materials. These characteristics of rocks and minerals have led to a useful and widely applied classification scheme developed by Bates (1959, 1960), who separated these materials into two groups as shown in Table 4.2.3.

In a very general way, group 1 of the classification comprises rocks and unconsolidated materials; group 2 is minerals. From this separation, Bates further selects unit and place values for classification of the industrial rocks and minerals, examples of which are contrasted in Table 4.2.4.

Notwithstanding the economic-geographic basis of this classification, it nonetheless provides a realistic geologic separation of materials allowing a sensible geologic approach to their formation, occurrence, prospecting, extraction, and occurrence. The generally low intrinsic value of rocks stems from their widespread occurrence, common habits, ease of extraction, and negligible processing costs; the higher value of minerals results from their more restricted geographic occurrence, their relative (to rocks) scarcity, and processing costs.

Chapter 4.3
GEOLOGIC PROSPECTING AND EXPLORATION

WILLIAM C. PETERS

4.3.1 INTRODUCTION

Geology provides the framework in which mineral exploration and the integrated procedures of remote sensing, geophysics, and geochemistry are planned and interpreted.

A systematic exploration program is directed toward a mineral discovery that will be evaluated as a *prospect.* "Prospect" may carry several connotations. A geophysicist or geochemist may apply the term to an encouraging anomaly that bears additional investigation. In this discussion, a prospect is a site of recognized and potentially economic mineralization that has not yet come into production as a mine.

The evaluation of a new prospect may be done by the discoverer's own organization, by joint venturers in mine development, and by purchasers of the mineral property. Prospect evaluation and the ensuing feasibility studies are heavily geologic, but they are directed toward the specific economic and engineering considerations of mine development and production. As such, they are discussed most fully in Sections 5 and 6.

4.3.2 GEOLOGY IN THE EXPLORATION SEQUENCE

An initial requirement in exploration is to have a mental image of the *target*—the deposit being sought. Throughout history, prospectors have used a knowledge of known deposits as guidelines in their search for new deposits; in modern exploration, this is identified as the building of an *exploration model.* The exploration model applies to a favorable geological environment and a target with an expected response to the methods and techniques of exploration. The model will necessarily be revised and redirected during exploration. An exploration objective that allows for a discovery among several kinds of deposits will make use of several models.

Exploration may be done as a comprehensive "grassroots" program in a large and geologically attractive region. It may be done within the narrower limits of a specific district having a particular need for a new ore body or a recognized potential for ore discovery.

4.3.2.1 Grassroots Exploration

Grassroots or regional exploration follows a sequence of *reconnaissance, target selection, target investigation,* and *prospect evaluation,* as generalized in Fig. 4.3.1. In a preliminary design or generative stage, a strategic plan is made in relation to an economically acceptable objective, a cost and time budget, one or more exploration models, and the geologic nature of a selected region. The region itself may be selected in regard to uninvestigated terrain within a discernible association between geology and existing mineral deposits. This can amount to a recognized metallogenic province such as the Colorado Mineral Belt (Fig. 4.3.2), the Carlin Trend of gold deposits in Nevada, or the Mother Lode system of quartz-gold veins in California. The region may also encompass a large area with few known deposits but with potentially favorable geologic conditions involving lithologic and structural sequences or even plate tectonics features.

The reconnaissance stages provide for a stepwise screening by geological, geophysical, and geochemical methods in which areas of little or no apparent promise are rejected and the remaining work is focused on progressively smaller and more significant areas of manageable size. Primary reconnaissance, the coarsest stage in screening, amounts to an examination of the entire region for areas with some combination of exposed or indicated geologic attributes that relate to the exploration model. These are selected as favorable areas for further reconnaissance. Secondary or detailed reconnaissance is a process of finer screening for target areas that fit, or have the capability to fit, the exploration model. The reconnaissance stages, beginning with a selected region of several thousand to more than 40,000 mi^2 (100,000 km^2), may reduce the terrain under consideration to something on the order of 40 mi^2 (100 km^2) in a favorable area. A favorable area may then be reduced to less than 20 mi^2 (50 km^2) in a selected target area.

In the target selection stage, detailed surface studies in the target areas provide for the identification of specific targets on the order of a few square miles (square kilometers) or less. During the subsequent target investigation stage, work converges on the target with the highest priority, and the target is explored in its subsurface extent by drilling and sampling. The aim is to discover a body of ore mineralization. In the prospect evaluation stage, the discovery is appraised as a potential ore body, and an acceptable prospect is then approved for feasibility studies, environmental baseline data collection, and eventual development into a mine.

Reality seldom mirrors this neat scheme. A grassroots exploration sequence may be telescoped in various ways. With a stratigraphy-associated exploration model or within a region having considerable postore cover, subsurface work with drillholes may begin much earlier, even as a part of reconnaissance. The discovery of a potential ore body, considered as taking place during the target investigation stage, may actually happen at some point along the way, perhaps during a target area investigation. In the idealized sequence, the region reduces to a single target. In actuality, no target of sufficient interest may be found. Conversely, a number of targets may be selected, and these are investigated in an order of priority based on their relative strength.

As shown in the "data" path in Fig. 4.3.1, data from rejected targets and areas amount to exploration experience; these are collected for use in planning subsequent exploration. New information that can affect the geologic assumptions and interpretations made in prior stages, or even in the exploration model itself, may also come to light; this, shown in the "revisions" path, is used in a reconsideration of earlier decisions that were made and areas that were selected or rejected.

4.3.2.2 District Exploration

In district exploration, as opposed to grassroots exploration, a more limited area of 400 mi^2 (1000 km^2) or less will have been preselected for detailed reconnaissance and a search for targets. There may be a need for a specific kind of new ore body in

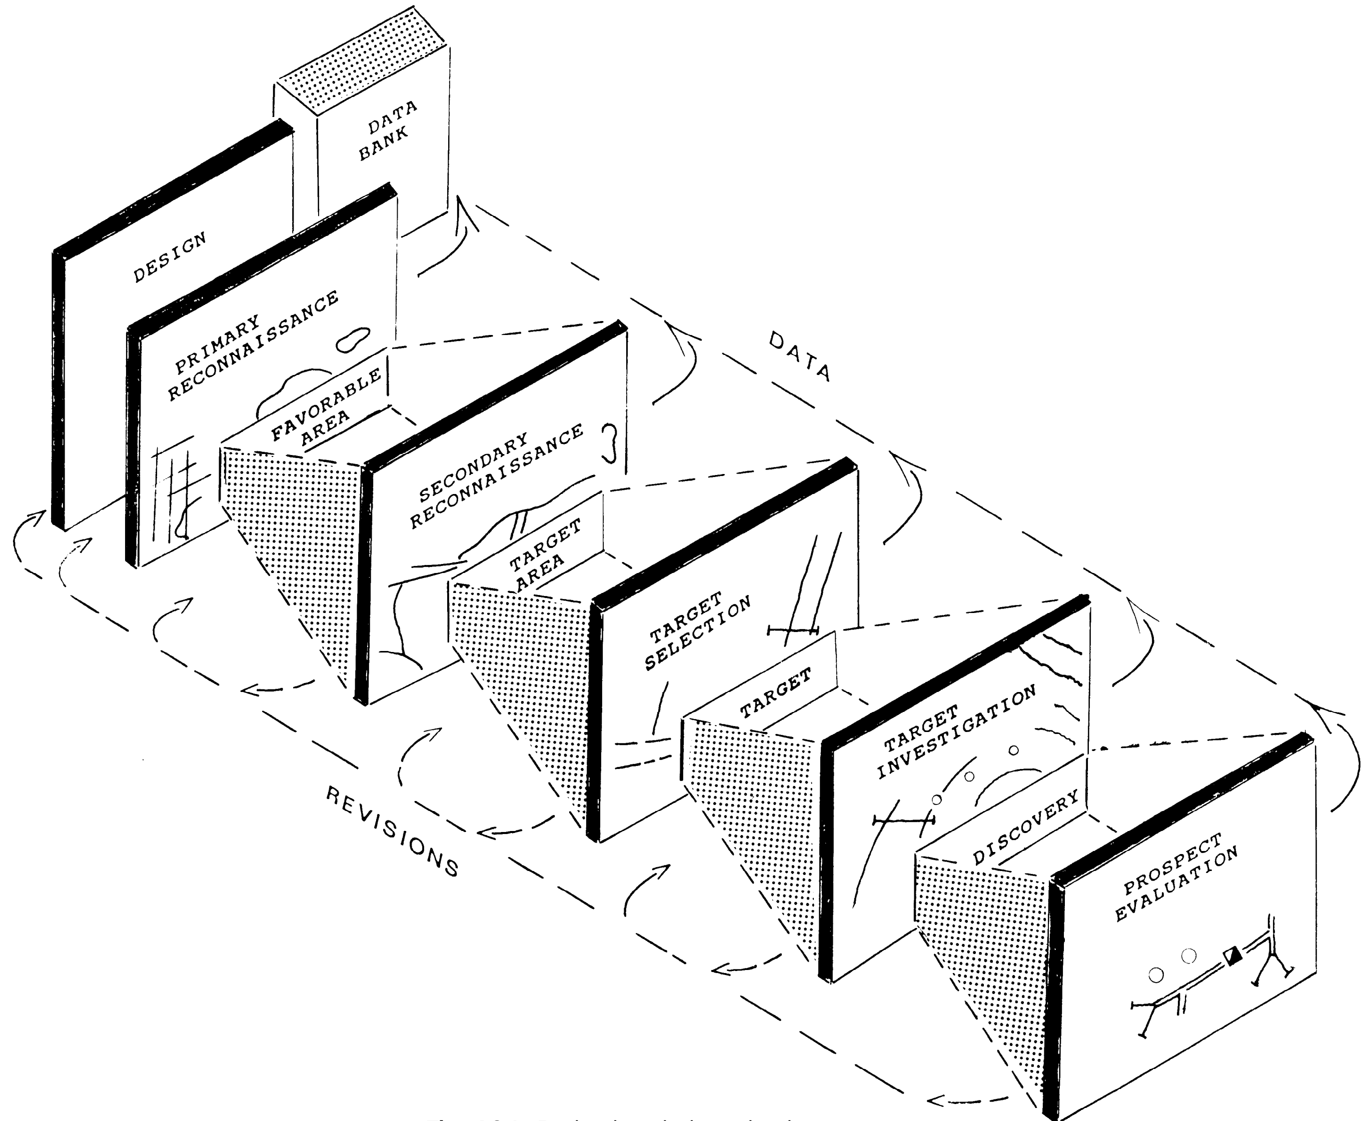

Fig. 4.3.1. Regional geologic exploration sequence.

relation to a mineral-using industry or a near-depleted mine. There may be a newly recognized potential for a significant discovery within an established mining district. This can derive from improved economic and technologic conditions for the mining of a particular commodity, from a perceived application for new exploration technology, or from the identification of important geologic ore controls in similar deposits and analogous terrain.

A district hitherto characterized as having small-scale mines may now be prospected once more in search of larger scale mineralization or for stratigraphically as well as structurally controlled ore bodies. The district may also be "elephant country" where major ore bodies have been mined. Here the search is directed to the discovery of less-apparent and "blind" ore bodies that may have formed at some depth beneath the present surface or that lie beneath unrelated postore lithologic units.

District exploration may take on an intense "gold rush" aspect when it follows the discovery of a new ore body—essentially a new exploration model—in the immediate area. In some instances, such exploration may be overly thorough. It then amounts to what has been termed "saturation prospecting" where an entire district is explored in detail as though it were actually a target area.

District exploration, discoveries, and the identification of potential ore bodies are commonly repeated by several groups and over long periods of time. With newer economic situations and geologic interpretations, information from the rejected targets, uneconomic discoveries, and mines of a prior cycle of exploration will then provide guidelines for the next cycle.

Geologic exploration, whether done in a grassroots or district sequence, relates field observations to the geologic conditions provided in the exploration model and to its expected signatures of geological, geophysical, and geochemical anomalies. Conditions and anomalies are tested in accordance with the model in successive areas and targets until one or more significant discoveries are made, or until the program is abandoned.

4.3.3 EXPLORATION MODELS

Mineral deposits can be expressed in terms of descriptive empirical models, genetic conceptual models, and more compre-

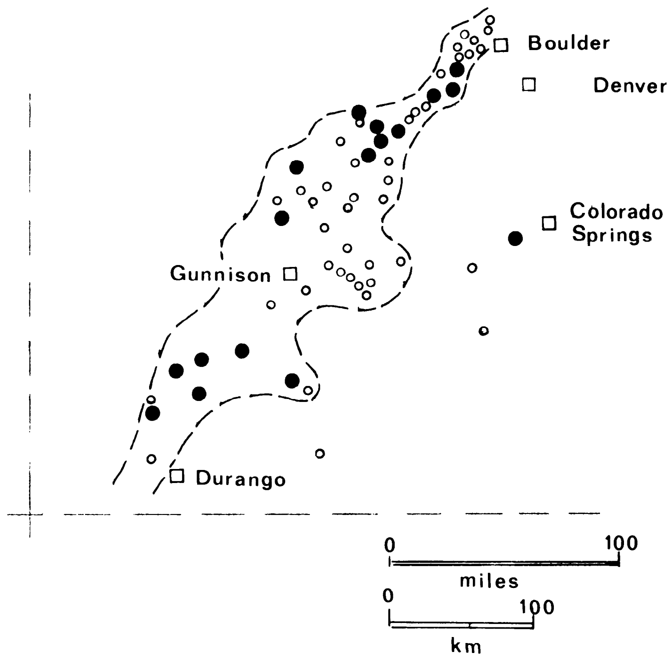

Fig. 4.3.2. Colorado Mineral Belt. Principal mines and mining districts associated with Laramide Tertiary intrusive porphyries and northeasterly shear zones.

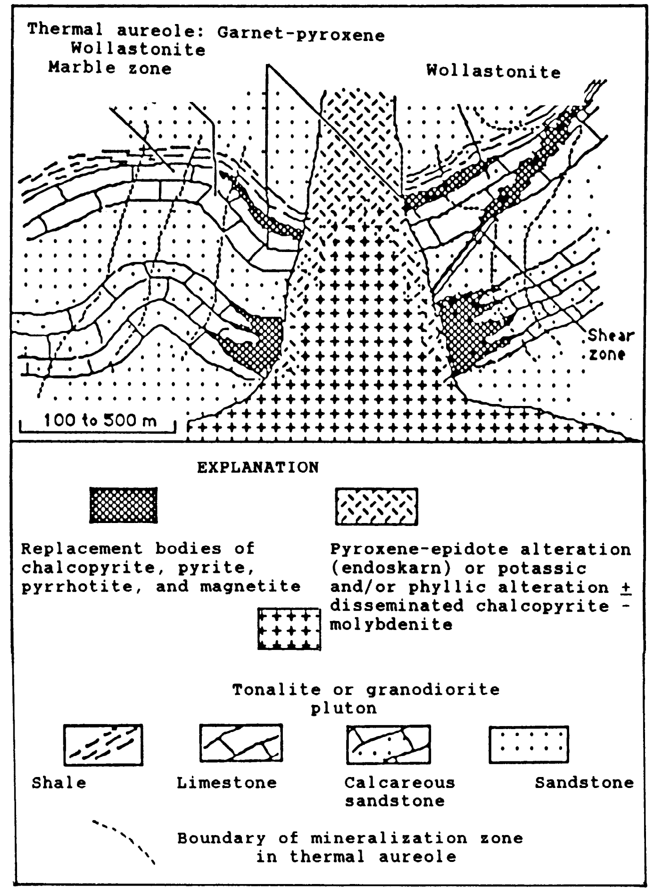

Fig. 4.3.3. Empirical model, illustration: copper skarn. (Cox and Singer, 1986, p. 87).

hensive exploration models. An exploration model is a body of geologic information taken from known deposits and used as target-recognition criteria in a particular program and a particular terrain.

Traditional prospectors have long used direct and indirect knowledge of known ore deposits as guides to new ore bodies. When formally assembled, this amounts to an empirical model describing the target ore body. An empirical model is a thorough compilation of data and observations taken from a group of similar mineral deposits. Empirical modeling relates the type of deposit to a range of geological characteristics, but it does not make specific use of genetic interpretations or concepts. The models are commonly named in relation to deposits such as an alluvial gold placer, a beryllium-lithium-bearing pegmatite, a polymetallic massive sulfide, a volcanic-hosted gold-silver ore body, or a copper skarn ore body (Fig. 4.3.3). Simplification and generalization are inherent; otherwise there would be an inordinate number of separate models, one for each of the individual deposits considered.

Summarized empirical and descriptive models for major types of mineral deposits have been compiled as guidelines to prospectors by the US Geological Survey (Cox and Singer, 1986) and the Geological Survey of Canada (Eckstrand, 1984). In these, examples are cited for each type of deposit, and each model is described in relation to its geological setting, characteristics, and typical conditions of tonnage and grade. The geologic setting is directed to the type, texture, and age of the host rock and associated rocks, to the tectonic situation, and to the association with other kinds of deposits. Deposit characteristics are given in reference to the form of the deposit, to its mineralogy, structural associations, attendant mineral zoning and wall rock alteration patterns, and to its weathering features and geochemical signature.

Taken with concepts on the genesis of a certain type of deposit, an empirical model evolves into a genetic or conceptual model in which the geologic processes associated with the deposit's attributes are identified. A conceptual model is designated according to a deposit prototype such as "Mississippi Valley lead-zinc" or according to group classifications such as "volcanogenic massive sulfide deposits" or "hot spring gold deposits" (Fig 4.3.4).

A conceptual model, accepted with the detailed empirical criteria for recognizing its attributes and associations, provides the fundamentals for an exploration model. An exploration model is formulated in respect to a specific target, or family of targets, that fit the overall geology of the region, an acceptable size and grade of deposit, and the capabilities of the organization. It relates the directly compelling and indirectly permissive characteristics of the expected target to the most appropriate geological, geophysical, and geochemical detection methods, and it provides a basis for designing a sequence of exploration steps and decisions.

Exploration models have an acknowledged limitation. They are drawn from ore bodies that have already been discovered rather than from those that are yet to be found in new terrain. Thus a model will be too restrictive unless it is open to modification as information is gathered during the exploration program. Some of the geological relationships in the model may depend on several alternative genetic concepts; the model must be flexible enough to accommodate the multiple working hypotheses. Assumptions about the area's geology and styles of ore mineralization will change as well. All of this requires feedback to the

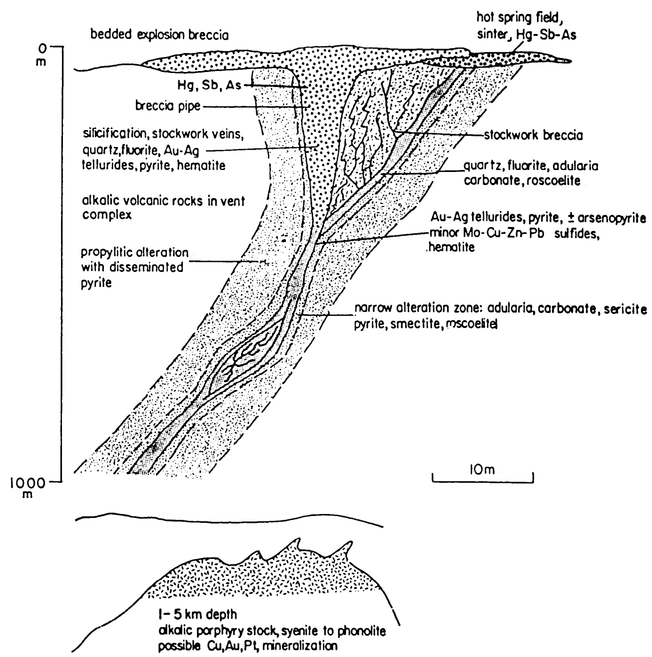

Fig. 4.3.4. Genetic model, schematic illustration: volcanic-hosted, alkalic gold-silver deposit (Bonham, 1988, p. 267). Conversion factor: 1 ft = 0.3048 m

model, with a provision for revising the choice of appropriate recognition criteria.

Mineralization found during the investigation of a specific target may be in an appropriate regional and local pattern but in a different geologic association from that expected on the basis of the guiding model. The remaining and more definitive exploration will then be guided by a model that has been changed to account for another or entirely new type of ore body. This was done in the exploration program that led to the discovery of the Olympic Dam copper-uranium-gold deposit in South Australia. The target investigation was based on an effective series of regional and area investigations, but the initial drillhole intersected significant mineralization associated with sedimentary breccias rather than with an anticipated basalt. Additional drilling and the discovery of economic mineralization in the principal ore body was then guided by a new model.

The format taken by exploration models does not follow a particular standard. It may involve descriptive text, tables and matrices of geologic characteristics, diagrams, and mathematical expressions of correlation between geologic character, tonnage, and grade. A deposit targeted for detection is also expressed in terms of its expected geophysical and geochemical signatures. As models in themselves, these are taken in geologic context and included in the exploration model.

The mass of data that must be processed and displayed in an exploration model is commonly handled by computer. In this regard, another family of models can also be used in selecting areas and designing programs for prospecting. These are computer-processed mathematical models that deal with the probability for certain types of ore deposit to occur as a geostatistical "mineral endowment" within a selected area (Harris, 1990) or to be recognized in a given search pattern (De Geoffroy and Wignall, 1985). One form of computerized exploration modeling, that of "Prospector" and related systems, uses the procedures of artificial intelligence. It accepts a series of actual and simulated data that would be obtained in prospecting, relates this to a network of exploration models for a chosen kind of deposit, and imitates the decision process of a geologist in evaluating the favorability for ore occurrence within a specific target area (Johnson and Keravnou, 1985).

In addition to the geologic models used in exploration, there are models for related purposes. A detailed geologic model of the specific ore body is fundamental to the evaluation and development of a mining project (Chapter 5.5), and models are basic to geostatistical ore reserve estimation (Chapter 5.6).

4.3.4 METHODS OF GEOLOGIC EXPLORATION

Methods of geologic exploration comprise the techniques and procedures of conventional prospecting, interpretation of airborne and satellite imagery, field geologic mapping, and subsurface investigation. Geochemical and geophysical exploration methods and laboratory analytical support are integrated with geologic methods throughout an exploration program.

Exploration is first a matter of using broad-scale geologic reconnaissance to find areas that could reasonably contain a suitable target, then of using more detailed geology to find the target itself (if one exists) and finally a matter of zeroing-in on the bull's eye—an ore body. Whether in extensive grassroots exploration or in more restricted district exploration, the stepwise coarse-to-fine screening provides for the work to be concentrated in the specific areas with a geological identity that most closely fits the exploration model. An initial investigation of an entire region or district in uniform detail would be inordinately costly; the need for time and money increase markedly during subsequent target investigation and delineation.

Geologic maps and geologic mapping are fundamental to exploration. They provide the framework for conventional prospecting, the basis for recognizing geologic target conditions, and the context for designing and interpreting geophysical and geochemical surveys in the stepwise sequence from reconnaissance to detail.

4.3.4.1 Conventional Prospecting

The procedures of conventional prospecting—looking for direct indications of ore mineralization in outcrops and in sediments and soil—are those of the traditional prospector. They remain a part of systematic exploration, and they are now carried out with the support of newer field and laboratory techniques. Conventional prospecting has a spatial aspect that relates to mapping; thus much of the field traversing used in geologic mapping during exploration can also be categorized as "conventional prospecting."

Some of the most direct indications of ore mineralization are associated with prior prospecting and mining, as shown in the character and pattern of old workings. An array of pits and caved adits on a hillside can reflect the trend of an unexposed vein or a bedded zone of mineralization. The succession of material in an old mine dump can indicate the nature of deeper ore mineralization and its lithologic associations. Relative sizes and mineral compositions in a series of mine dumps can give evidence of an ore body's structural attitude, depth of oxidation, and zoning sequence. Old placer workings may have a distribution that relates to undiscovered primary mineralization.

Conventional prospectors have long been aware of the colors and textures shown at the surface by weathered ore mineralization. They have made use of gossan and capping, the characteristic red, brown, and yellow accumulations of cellular limonitic material derived from the leaching of sulfide-bearing veins and disseminated ore bodies. Other guides to ore mineralization in weathered outcrops relate to such colors as the greens and blues of oxidized copper minerals, the black of oxidized manganese minerals, and the yellows and greens of silver halides. These traditional guides to ore have an expanded modern aspect in the applications of geochemistry and laboratory mineralogy to the identification and interpretation of gossans and weathered outcrops.

Prospectors have been drawn to topographic "ledges," the ridges and knobs that may be associated with vein quartz and silicification, and to aligned depressions made by collapse and slumping during the oxidation of ore bodies. Coalbeds that have oxidized and burned in the zone of weathering will also be reflected in a thinner remnant exposure and a surficial zone of slumping. With aerial photography, these geomorphic features, however subtle, continue to be used in ore search.

The tracing of mineralized "float," fragments of ore, gossan, and ore-associated rock that have been eroded and transported from a source area, is a long-recognized conventional practice in prospecting. It is now done with the support of geochemical rock sampling, definitive mineral identification, and the color patterns apparent on aerial photographs. Geomorphic and paleogeographic studies can be involved. A dispersal train or fan of rock and mineral fragments is generally from a source "uphill," but it may also relate to the more recent erosion of an earlier accumulation in ancestral drainages and divides. Even patterns of human occupancy have a place in the tracing of mineralized float; stones in farm walls would have come from less than half way to the next wall. This served as a guide to the discovery of the Tynagh zinc-lead ore body beneath several feet (meters) of glacial drift in Ireland.

The tracing of ore boulders in glaciated terrain served as a guide to the discovery of the Outokumpu copper deposit in Finland, and it is a longstanding practice of conventional prospecting in Scandinavia and Canada. It can now be associated with geochemical prospecting in glacial till, the sampling of the till-bedrock zone in shallow drillholes, and the recognition of specific patterns in glacial drift.

Panning for gold and other heavy minerals in alluvium is a longstanding and still-valid way of collecting geological information and of tracing relatively stable ore minerals to a placer deposit or to an exposed source in a specific drainage basin (Chapter 15.1.1). In modern practice, the sites, such as stream junctions and former stream channels, are selected and mapped on aerial photographs. Heavy mineral panning is now supported by mechanical, electromagnetic, and electrostatic separation techniques and by microscopic examination and instrumental mineralogical analysis. In geochemical exploration, panning is a technique associated with stream sediment and heavy mineral sampling, as described in Chapter 4.5.

The age-old practice of digging pits and trenches into placer deposits and through soil and weathered zones to obtain geologic information and samples is as valid as ever, but it is now done with bulldozers, backhoes, and lightweight drilling machinery. Stream channel depths can be outlined in advance by geophysical methods, and the sites for trenching and drilling are sometimes determined by using hammer-activated seismic equipment to indicate shallow bedrock.

4.3.4.2 Logistics

Four-wheel-drive vehicles are the standard means of field access for conventional prospecting and systematic exploration in relatively open desert and brush country. In remote and less accessible terrain, air transportation is applicable. Even though the cost of operating fixed-wing aircraft and helicopters is high, the alternative of slow surface travel from a distant base camp would often be more costly and would lessen the time spent in actual field geologic work. A common procedure is to establish a base camp at a site that can be serviced by ground transport or by a fixed-wing aircraft and then use a helicopter for access to field sites, cleared landing areas, and temporary "fly camps." In an extended exploration program, a base camp can also be the site of a mobile geochemical laboratory and a microcomputer-equipped workstation in a network that provides field geologists with maps, sample data, and information in direct contact by telephone line with other computers in laboratories, data-handling services, and principal offices.

Helicopters serve conventional prospecting and systematic exploration by providing "fly-over" confirmation for photogeologic interpretation and by giving views of minor but significant terrain features, hydrothermal alteration zones, and old prospect workings in a varied perspective that most aerial photography could not match. Helicopter-borne methods of geophysical prospecting can be incorporated as well. Throughout an exploration program in all but the most densely wooded terrain, a helicopter pilot can place geologists and equipment on sites and near significant outcrops for sampling and field traversing.

4.3.4.3 Scale of Exploration Work

The scale chosen for the recording and study of conventional prospecting data, geologic information, geologic field mapping, and geophysical and geochemical work depends on the extent of the exploration model and its associated features. In reconnaissance, the scale must be large enough to show the relevant geology without too much exaggeration, and yet it must be small enough to give a synopsis of regional patterns in preference to the more intricate geologic detail that comes with larger-scale mapping in target areas.

Primary reconnaissance is done at 1:100,000 (USGS intermediate scale maps) or smaller. In North America, primary reconnaissance in a grassroots exploration program often begins with geologic maps, photogeologic studies, and field mapping at a scale of 1:250,000 (1 in. = 4 mi). A government topographic map sheet at this scale covers an area on the order of 7000 mi^2 (18,000 km^2). Field observation sites can be plotted within a spacing of 0.6 mi (1 km) and related to enough topographic and cultural detail to be located again.

After primary reconnaissance has reduced the area to smaller areas of further interest, the appropriate data for secondary reconnaissance are transferred to a more detailed set of topographic and geologic maps, aerial photographs, and overlay sheets at a scale of 1:24,000 (1 in. = 2000 ft), 1:25,000 or, in some instances, 1:50,000 or 1:62,500 (USGS 15-min quadrangles). The increase in scale from that of primary reconnaissance is on the order of five to ten times; a lesser increase in scale would not be likely to bring out more detail. At 1:25,000, additional observations can be recorded at intervals of 170 ft (50 m); traverse lines for geology, geochemistry, and geophysics can be shown; and individual mine workings, local stratigraphic changes, and local structure can be discriminated well enough to proceed from reconnaissance investigations into more detailed investigation of the target areas.

The scale of geologic work in target areas is likely to be in the range from 1:5000 or 1:6000 (1 in. = 500 ft) to 1:10,000 or 1:12,000 (1 in. = 1000 ft). At this level, prospect pits 30 to 60 ft (10 to 20 m) apart can be shown by separate symbols, and a dike or fault zone several feet (meters) in width can be shown without exaggeration as a single fine line. The succeeding step in mapping within a more closely defined target will often be at 1:1000 to 1:2400 (1 in. = 200 ft) or 1:2500; at this scale, the smaller significant features associated with individual deposits can be shown.

Once a specific site for drilling and trenching has been designated, it may be mapped at a still larger scale such as 1:500 or 1:600 (1 in. = 50 ft) so that the results of sampling as well as the stratigraphic and structural detail can be plotted in their exact locations on maps and cross sections. In the trenches and pits themselves, there may be a need to plot the sample data in even more detail at a scale such as 1:100.

4.3.4.4 Airborne and Satellite Imagery

Because reconnaissance work begins with a synoptic view, it can begin at the scale of satellite and airborne imagery. Imagery includes direct photography and the images derived from other remote sensing data obtained from spectroradiometric channels or bands in the visible and infrared spectral wavelengths and in the wavelengths of microwave and radar systems. Geologic methods in remote sensing are related to geophysical prospecting (Chapter 4.4.) The response is, however, more from the land surface than from depth. Remote sensing has an additional relation to geobotanical patterns, a consideration in geochemical prospecting (Chapter 4.5.) The geologic exploration procedures are essentially those of image analysis, interpretation, and photogeologic mapping.

Satellite Imagery: The most widely used sources of satellite remote sensing imagery have been from the Landsat series of the Earth Observation Satellite Co. (EOSAT) and from the French SPOT series of spacecraft. Both have worldwide coverage from which spectral radiance data in individual scenes can be obtained in computer-compatible tape (CCT) and photographic form.

In the Landsat series, multispectral scanner (MSS) and thematic mapper (TM) data are obtained for ground scenes of 115 × 115 mi (185 × 185 km). MSS provides imagery at a ground resolution of 260 ft (80 m) from two spectral bands in the visible spectrum and two bands with wavelengths that correspond to the infrared portion of the spectrum just beyond the visible zone (Fig. 4.3.5). The thematic mapper on Landsat 4 and 5 provides additional imagery at a ground resolution of 100 ft (30 m) and a higher sensitivity from reflectance in six spectral bands, four in the visible and near infrared range and two in the short wave or middle infrared range. The thematic mapper also provides imagery at a ground resolution of 400 ft (120 m) in a thermal infrared band. Further Landsat missions are planned to have a stereocoverage capability, with a ground resolution of 33 ft (10 m) in the visible and near infrared spectral region, and a ground resolution of 200 ft (60 m) in several thermal infrared bands.

In addition to providing a thorough view of landscape patterns reflecting geologic structure, multispectral scanner imagery displays variations in the radiance given by rocks, soils, and vegetation in each spectral band. By comparing the data from a number of bands at their different wavelengths, types of land surface cover and lithology can be recognized.

The difference in reflectance between two MSS wavelength bands can also indicate a strong spectral absorption associated with ferric iron oxide staining in hydrothermally altered areas. The thematic mapper has the increased capability of differentiating between carbonate and silicate rock assemblages and identifying hydrothermally altered areas characterized by the presence of hydroxl-bearing minerals such as kaolinite, sericite, montmorillonite, and alunite.

Landsat data can be previewed on microfiche cards and can be obtained from EOSAT as computer-compatible tapes or disks and as derived photographic images. Landsat tapes and disks have a higher resolution than the derived images because they are a direct record of the sensor data; they can be processed into images, enhanced to highlight specific data, and enlarged to scales of 1:50,000 for accurate map making or 1:24,000 for geologic field work. Photographic products are 1:1,000,000-scale black and white film negatives and positives from single bands and 1:1,000,000 and 1:500,000-scale film positives composited from several bands in "false color." Paper prints can also be obtained as enlargements at 1:500,000 and 1:250,000 scale.

SPOT is a commercial French satellite system that obtains data for ground scenes of 38 × 38 mi (60 × 60 km) with a capability of stereoscopic viewing. A high-resolution sensor operates in two modes. One mode provides a ground resolution of 66 ft (20 m) for three spectral bands in the visible and near infrared wavelengths. A panchromatic mode provides black-and-white imagery with a ground resolution of 33 ft (10 m) in a single broad band.

SPOT products are available as computer-compatible tapes and derived photographic images. Precision processing of the tape data can provide accurate topographic maps at a scale of 1:50,000 and a field mapping base at a scale of 1:12,000. The photographic products are black and white or color composite transparencies and prints at scales of 1:400,000, 1:200,000, and 1:100,000.

For geologic reconnaissance study, the most widely used Landsat and SPOT products have been black and white prints of specific band imagery and color (false color) composites of three bands. In most color composites, vegetation appears in shades of orange and red, water in black, and soil and rocks in shades of green, gray, red, orange, and brown.

Geologic features can be accented in several ways. Imagery with minimal cloud cover can be selected for times of year when partial snow or vegetation conditions bring out subtle differences in structure or lithology. The data from tapes and disks can also be processed by photographic darkroom techniques, by optical diffraction techniques, or by computer in order to emphasize certain features having geologic context. Computer-aided processing of Landsat and SPOT data makes use of smoothing, filtering, and sharpening techniques. The resulting enhanced images are provided by contrast stretch, by edge detection, and by ratioing–showing the difference in spectral reflectance values between two wavelength bands.

In additional techniques, high resolution black-and-white SPOT imagery is merged with thematic mapper imagery, and topographic or geophysical data are merged with satellite imagery. The display of processed data can range from a computer-drafted isoline map or a sheet of superimposed characters in various densities for each pixel (resolution-size picture element) to a color-photographic rendition of images created and modified in a video display. A certain amount of preprocessing involving geometric correction, scene shifting, and map gridding (geocoding) can be obtained from EOSAT and SPOT. Additional processing can be done by a user with an adequate computer facility or can be obtained from one of several dozen service companies that deal specifically with the custom handling and interpretation of remote sensing data for mineral exploration.

Although Landsat and SPOT multispectral data provide the most widely used satellite imagery for reconnaissance, there are other sources of useful satellite imagery. These involve remote sensing data from other American and foreign satellites and also photography from manned spacecraft.

Shuttle multispectral infrared radiometer (SMIRR) and shuttle imaging radar (SIR) have applications to geologic reconnaissance. Satellite-borne radar is able to penetrate the persistent cloud cover and forest cover of areas such as in the tropics, and it can obtain signals with 80 to 130 ft (25 to 40 m) ground resolution relating to bedrock and its structural patterns beneath several meters of desert sand cover. Limitations exist, however,

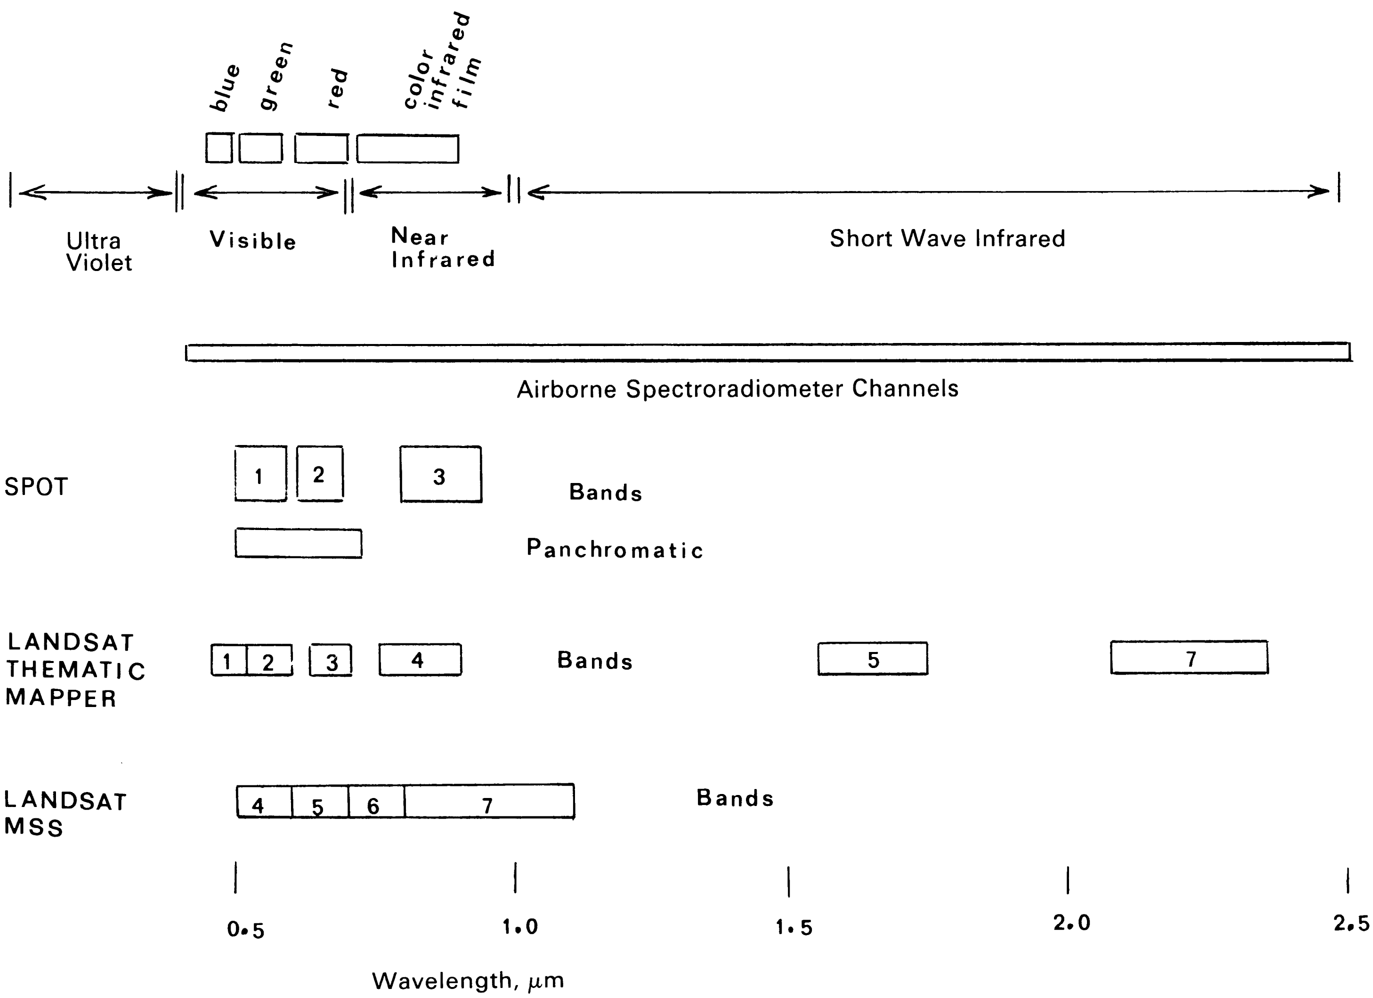

Fig. 4.3.5. Spectral zones and band designations, Landsat and SPOT. TM band 6 is at 10.4 to 12.5 μm in the thermal infrared zone.

in its discontinuous geographic coverage in relatively narrow swaths. Additional satellite-borne radar coverage is represented in Japan's marine observation satellite (MOS), which also furnishes stereo imagery in the visible wavelengths and imagery in the thermal infrared band. The ERS-1 satellite (1992) of the European Space Agency and Canada's Radarsat (1994) are designed with sensors to include radar imagery at 80 to 100 ft (25 to 30 m) ground resolution.

Geologic reconnaissance can make use of the spectacular and high-quality photography of some large areas on the earth provided by the Skylab and the later space shuttle missions. In these photographs, ground resolution is on the order of 30 ft (10 m) with black-and-white film and 60 ft (20 m) with color film.

Satellite imagery is of demonstrated value in reconnaissance work, but there are, as with all exploration tools, some limitations. Cloud cover and vegetation hide a great deal of terrain, and there are expanses of soil and sediment that mask geologic features. Still, vegetation responds in discernible ways to geochemical patterns, large structural features sometimes appear as "ghosts" through overburden, and satellite radar can penetrate some of the cloud cover. One of the most useful features of satellite imagery in comparison with aerial photography and aircraft-based remote sensing is its broader synoptic view of surface patterns and alignments in large areas—just what is needed in the early stages of reconnaissance.

The comparatively low resolution of satellite data, even in camera photography and in high-quality SPOT panchromatic images, prevents it from competing with middle to low altitude aerial photography and airborne remote sensing in detailed geologic mapping at a scale larger than that of reconnaissance. Vertical aerial photography in stereo coverage is the established "workhorse" of geologic mapping.

Aerial Photography: With aerial photography as with satellite imagery, we can obtain synoptic views that would not be possible on the ground. Photogeologic mapping is an established technique in reconnaissance; it provides for an economical and effective map in which geology is keyed to a certain amount of surface observation and "ground truth." Air photos also provide the base for more detailed field mapping. In target areas, geologic features are plotted on stereopairs of contact prints and on single photograph enlargements that are keyed to topographic maps.

There is hardly any upper limit to the scale at which aerial photographs can serve in geologic exploration. Government stereo pairs are provided in black-and-white contact prints and transparencies and to a lesser extent in color photographs at reconnaissance scales ranging from 1:120,000 to 1:20,000. For more detailed geologic mapping, enlargements of single photographs to several times the original scale can provide additional nonstereo prints without losing too much clarity for field work. Larger-scale photography, with stereopairs at a scale on the order of 1:6000 or 1:3000, is furnished for selected areas from new flying by air-photo contractors; these photographs can also be enlarged to provide high-resolution and corrected (orthophoto) prints at a scale on the order of 1:1000 or 1:500.

Whatever the scale of photography, there are certain places in which its use in geologic mapping is limited. Cloud cover may seldom, or never, permit good photography in some areas. Photography can be planned for the right season in areas of deciduous trees, but there are areas in which evergreen vegetation may be too dense in all seasons for an effective look at the ground. Topographic relief in some locales may be so great that the photographs are badly distorted for photogrammetric mapping unless taken from a very high altitude and therefore at a small scale.

Photogeologic work is done by interpreting contrasts and textures in tones and shades of gray and tints of color. Landforms are commonly quite distinct, and the stereoscopic view provided by adjacent photographs emphasizes even the most subtle variations in terrain. Quartzite, limestone, and felsic igneous rocks reflect a higher percentage of the incident light and have light tones; shale and slate show darker tones. A basalt flow or an amphibolite dike absorbs most of the incident light and appears very dark, as would be expected.

Geomorphic relationships, the shape, size, and distribution of topographic features, are the mainstay of photogeologic interpretation for exploration work. Linear and arclike alignments in stream courses, ridges, and vegetation can be related to known or suspected patterns of volcanic caldera features, intrusive boundaries, fault zones, folded beds, and unconformities. Most linear features are, however, labeled as “photo linears” until a field investigation can be made. A photo linear cutting across several tonal and textural zones may turn out to be a vein, a fault, a dike, the faint expression of a structural feature beneath alluvium or soil, or perhaps a fence line or an old road. A “hash” of linears in several directions may afford a significant geologic interpretation as a jointing pattern. It could also relate simply to livestock trails.

Most photogeology is done by direct study of the photographic prints. Aerial photography data can also be enhanced by some of the photographic, optical, and computer techniques mentioned for satellite imagery. These include selective filtering, contrast stretching, and edge enhancement. The final photogeologic map may also be integrated with other data such as topographic contours and geophysical and geochemical trends.

Color infrared (near infrared) aerial photographs provide additional coverage with considerable detail. They are widely available at 1:58,000 scale in the United States through the USGS National High Altitude Photography Program.

Airborne Scanning Systems: Side-looking airborne radar (SLAR) has poorer resolution than photography, but it is used in exploration, especially in areas where forest and cloud cover limit the effectiveness of aerial photography. Geologic features are not seen as such, but faint linear patterns may show up better at 30 to 60 ft (10 to 20 m) ground resolution in SLAR than with aerial photography. SLAR imagery of some one-third of the United States is available from the US Geological Survey as digital data and as 1:250,000 and 1:100,000 photographic imagery.

Airborne remote-sensing imagery has multispectral capabilities similar to those of the thematic mapper, but with data from additional spectroradiometric channels and at a closer resolution. Geographic coverage is still limited, but it is becoming available in mining regions. A system that has been tested over an extensive greenstone region in Western Australia scans a 2.5-mi (4-km) swath in the visible, near infrared, and thermal wavelengths to provide a 30-ft (10-m) ground resolution.

4.3.4.5 Geologic Field Mapping

Geologic mapping is fundamental to exploration, but the making of maps in uniform detail is not an objective. The level of geologic detail relates to the screening process in going from reconnaissance to target investigation. Areas of minimal interest, those that are to be rejected in screening, are mapped only in enough detail to support their designation as such. Areas mapped in considerably more detail are those with enough potential interest to warrant closer examination before deciding on their acceptance or rejection as target areas or targets.

Reconnaissance: The typical mapping base in reconnaissance field geology is a topographic map or an enlarged aerial photograph cut into sheets of manageable size. Working overlay sheets provide initial photogeologic information for “ground truth” checking in the field on apparent geologic unit boundaries, linear features, and known prospects and mines. Other overlay sheets may be used in the field to key-in the indications of available regional geophysical and geochemical data. Widely spaced traverse lines, commonly along ridges and drainages, are often plotted in such a way that information taken from actual outcrops can be differentiated from that which was projected or observed from a distance. Most of the geologic contact and boundary features in reconnaissance mapping will of necessity be designated as “approximate” or “inferred.”

In reconnaissance geologic mapping and in the more detailed mapping that follows reconnaissance, field notes with additional information and sample locations are taken in notebook or in a prepared computer-oriented form. Fig. 4.3.6 shows a portion of a reconnaissance field sheet with numbered locations of additional notes.

Target Areas: Temporary control surveys and base maps in target areas are generally made by the geologist, operating with a plane table or with a combination of compass triangulation and altimetry supported by traverses with tape, threaded “hip chain,” optical range finder, or pace. The traverses are related to patterns of outcrop or to a field grid. Field observations are recorded on enlarged topographic base maps with aerial photographs for reference or recorded directly on aerial photographs for transfer to a map.

In field mapping on aerial photographs, the data are transferred to topographic maps where they can be related to grid lines and survey monuments. Transfer is done with radial line plotting or with the use of camera lucida equipment in which the photo and map can be viewed together. Where the aerial photographs have been processed as orthophotographs to correct for topographic distortion, the geologic data can be transferred directly without further adjustment.

The ideal geologic mapping base would be a series of accurate and distinct contact prints of color aerial photographs in stereo pair with a supporting map at the same scale. In a more attainable situation, mapping is done on photographic enlargements cut to field sheet-holder size. Because enlargements cannot be viewed with a pocket stereoscope, a set of the original stereo pairs of photographs should also be taken into the field for concurrent study.

Mapping is sometimes done directly on the surface of the photo, with inked lines for geologic features and with needle holes through the photo for control stations. A more common practice is to draw the geologic lines and features on an overlay sheet of polyester drafting film that is keyed to reference points

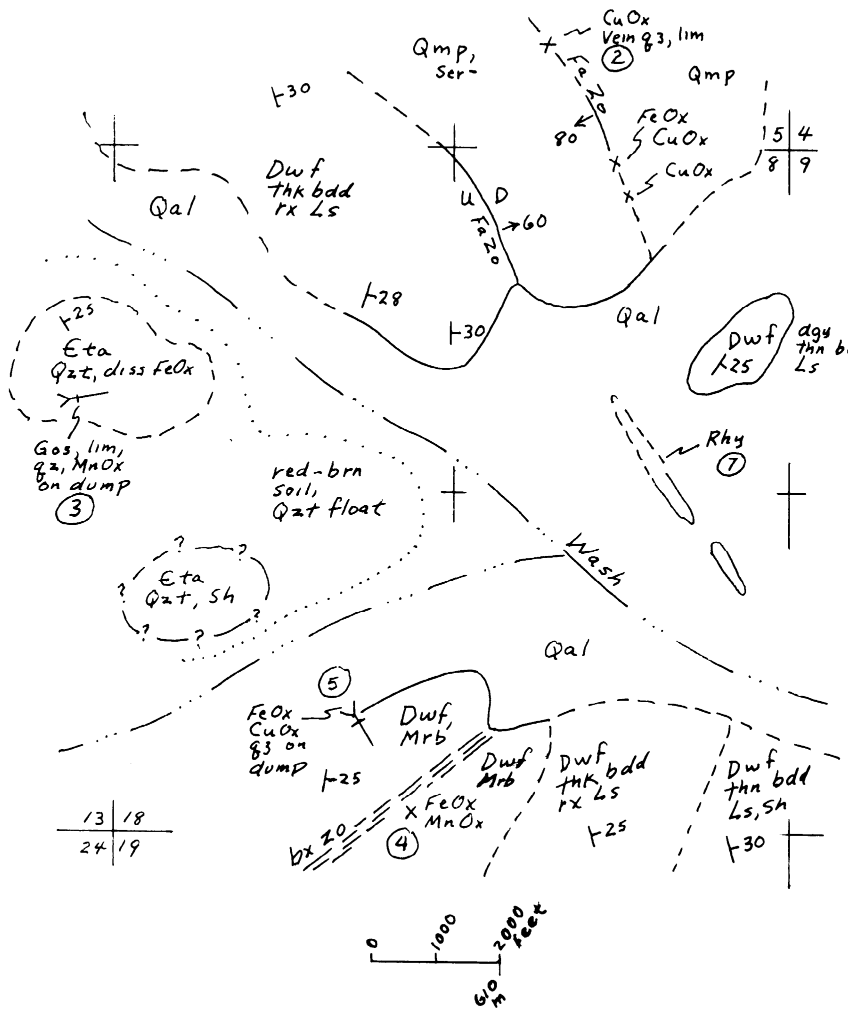

Fig. 4.3.6. Portion of a reconnaissance map field sheet.

on the photo. Additional overlay sheets are used to permit more information to be registered to the photo in the field.

In most practice with overlays, the photograph is left unmarked, and the geologic data are plotted on overlay sheets, as shown in Fig. 4.3.7.

Overlay 1. Outcrop boundaries; lithologic identifications; geologic contacts, notes on texture, color, and weathering; and the numbered location of additional notes.

Overlay 2. Structural data, including bedding attitudes, with notes on cleavage, schistosity, and rock fabric.

Overlay 3. Mineralization and alteration, with notes on geochemical sampling and with the locations of supporting field photographs of outcrops.

The boundaries of outcrops are drawn on the first overlay, and the rock types are identified by their field appearance rather than by their interpreted origin. This is a part of "outcrop mapping" or "multiple-exposure mapping," common practice in large-scale geologic work. Areas of abundant float or of a characteristic soil are outlined as well. Interpretation of the geologic conditions between outcrops is also done in the field, but it is distinguished from the directly observed outcrop data. The interpreted geology will evolve in critical areas with additional mapping, trenching, drilling, and sampling.

Geologic work provides the context for geophysical and geochemical exploration, but geophysical and geochemical surveys are often integrated with geologic field mapping as well. Lithologic units will commonly have a certain signature that can be interpreted and used for mapping in soil and alluvial cover between outcrops. A dike or an igneous contact may be traced by its magnetic or radiometric response in ground or airborne geophysics. A sedimentary formation with carbonaceous material or disseminated pyrite may have a characteristic response to induced polarization surveys. A key limestone bed may have a significantly higher resistivity than the surrounding beds. Soil samples taken across a projected lithologic zone will sometimes have a measurable higher trace-element background than those taken in surrounding terrain. Faintly visible areas of hydrothermal alteration may have a geochemical identity that can be incorporated into more detailed mapping.

4.3.4.6 Subsurface Methods

Pits, trenches, and shallow drillholes are common to conventional prospecting, geologic mapping, and geochemical exploration in areas of soil and alluvium. Deeper drillholes are ordinarily associated with the testing of indicated mineralization in the target investigation stage of exploration. Drilling is the characteristic step to discovery. Drillhole information is even more thoroughly associated with the delineation and sampling of ore bodies during prospect evaluation; as such, the specific methods of drilling and drillhole sampling are described in detail in Chapter 5.3.

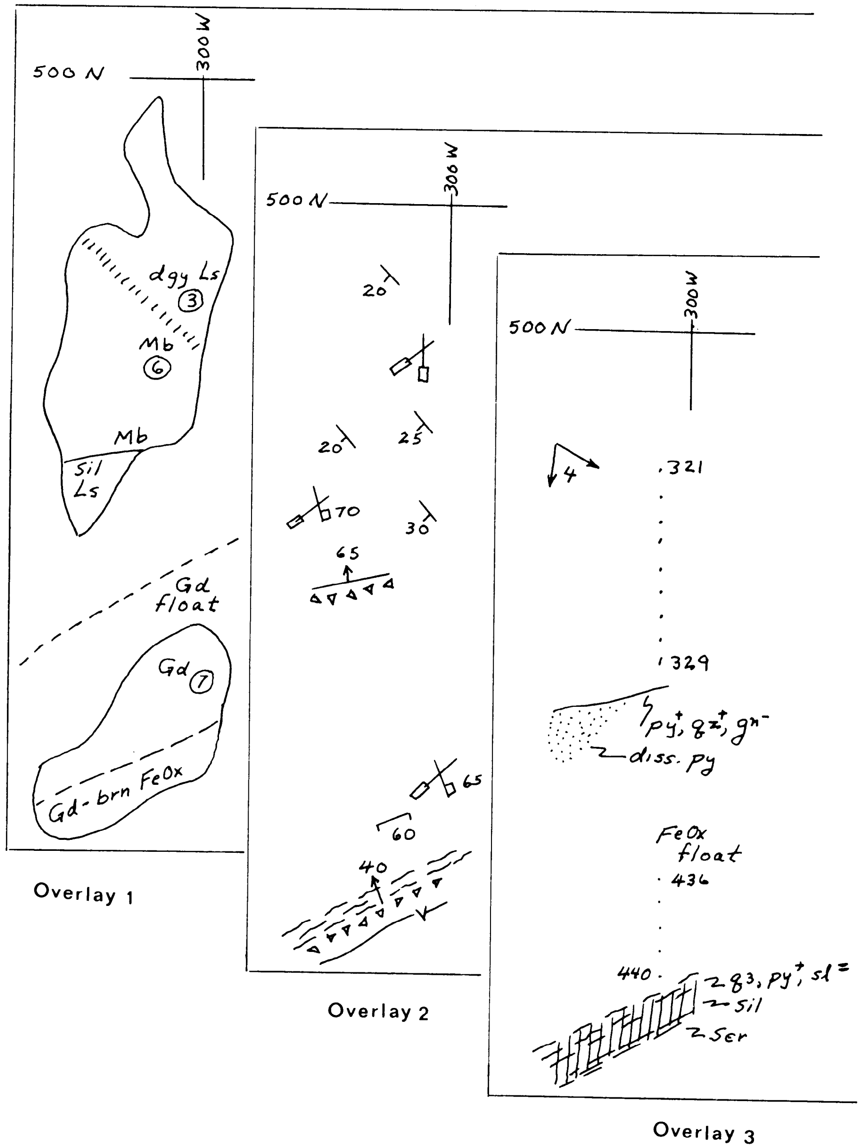

Fig. 4.3.7. Three overlay levels, geologic mapping field sheets. Lithology, alteration, and mineralization would be color-coded.

In systematic exploration programs, drillholes may also be appropriate to reconnaissance and to target area selection. In situations involving sediment-hosted mineralization concealed by younger rocks, "scout" drillholes at intervals of a few miles (several kilometers to tens of kilometers) are often a part of the search for indications of mineralization. In searching for Mississippi Valley-type deposits, for example, reconnaissance holes are drilled for stratigraphic information and for the recognition of significant facies changes and regional reef structures, as shown in Fig. 4.3.8.

4.3.4.7 Laboratory Support

Throughout an exploration program, laboratory work is integrated with the succession of field and interpretive geology. The analysis of geochemical samples (Chapter 4.5) and the assaying of ore mineralization (Chapter 5.4) are of such specific importance that they are treated in special chapters of this handbook. Mineralogical studies begin during reconnaissance, and they have an increasing role toward the stage of target investigation.

The field identification of minerals and rocks is done by hand lens at a magnification of 10 to 20 power and with a binocular microscope at magnifications on the order of 20 to 80 power. In this range, grain size, approximate mineral distribution, and texture can be determined. Laboratory study of mineral fragments and sections of rock and ore with the petrographic microscope provides for a closer determination of mineral associations and textures. Thin section petrography and polished section mineragraphy afford the determination of paragenetic sequences in ore mineralization and the identification of broader halos in mineralization and wall rock alteration. In these studies, microscopic characteristics are related to the geologic context of field observations—to the apparent sequence in lithogenesis, structural stages of folding and faulting, and stages of mineralization.

Laboratory petrographic work includes the study of fluid inclusions, bubbles or vacuoles of fluid, vapor, and solids in transparent and translucent minerals that can be observed in connection with a heating and freezing microscope stage. Geochemical (Chapter 4.5) and thermal studies of fluid inclusions

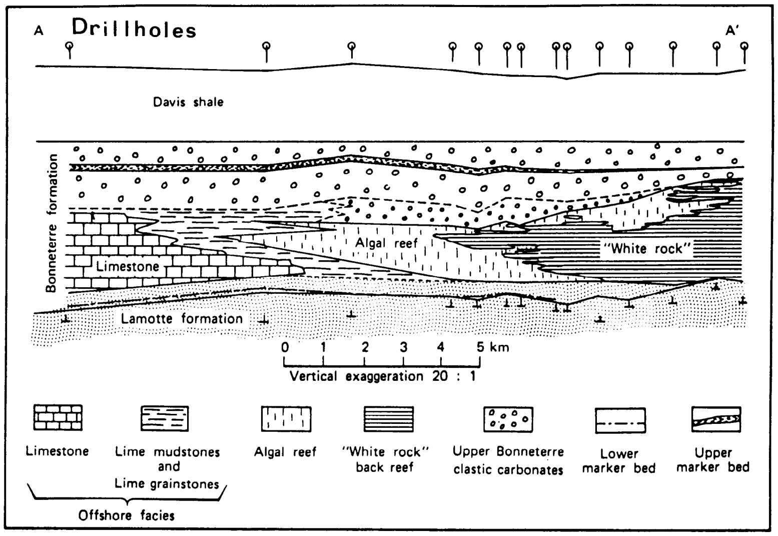

Fig. 4.3.8. Cross section with projected and interpreted data from reconnaissance drilling, Southeast Missouri (Gerdemann and Myers, 1972, p. 430). Conversion factor: 1 mi = 1.609 km.

are used as indicators of the source of ore mineralization and the relative temperature of ore deposition. In the exploration of a mining district, fluid inclusion studies in rock, soil, and gossan samples can provide vectors that point toward a thermal center from which the ore solutions migrated, differentiated, and deposited a sequence of ore minerals.

Combined mineralogical studies and instrumental analysis have a relation to field geology. Whole rock geochemical analyses are used in identifying the particular lithologic compositions associated with the targeted deposits and the accepted exploration model. X-ray diffraction analysis is especially applicable to the identification of fine-grained minerals in zones of alteration. Microprobe and scanning electron microscopy can be used to determine the composition and distribution of minute mineral grains and inclusions.

Some of the laboratory mineralogy and geochemistry relates to age dating and to the pattern of mineralization shown by radiogenic and stable isotopes. Radiogenic lead isotope patterns or signatures can be used to distinguish between a barren "ironstone" false gossan and the actual gossan derived from a sulfide-bearing ore deposit. Lead isotope studies can be used to determine whether the age and style of mineralization in a sample of bedrock or soil belongs to the principal target stage or to a less important stage. In the Coeur d'Alene District, for example, lead isotope signatures provide a basis for differentiating the principal ore mineralization of late Precambrian age from minor ore mineralization of Tertiary age.

4.3.5 EXPLORATION PROGRAM DESIGN

In the design stage of systematic exploration, a sequence of activities is set forth in relation to an exploration model and a designated region, both of which are taken from a compilation and study of existing geological information. The data and information involve regional and local studies and maps, airborne-satellite imagery, and the results of earlier exploration. Sources will range from company files-the in-house data bank-to the published literature and unpublished but available data.

The compilation of published geologic information in respect to the mineral deposits within a region begins with a search for titles and topics dealing entirely or in part with the specific geographic area, its type of geologic setting, and its expected association of mineral commodities. This job is commonly assisted by computerized information retrieval from extensive national and international databases devoted to geology and mining. By using a succession of geographical and topical key words, these can be accessed directly by personal computer, through libraries with search services, or by telephone and mail search centers such as the American Geological Institute's GeoRef Information Services and Research on Demand, Berkeley, CA, which has access to several databases. A reference book by Stark (1988) on sources of information for the mineral industries includes a listing of the principal geological bibliographies, indexes, and international databases.

Regional geologic information, databases, geologic maps, and metallogenic, geophysical, and geochemical maps are obtainable from national and state geological surveys and bureaus of mines. In addition to published information, these organizations can provide access to appropriate open-file reports, field investigation notes, and collections of drill core and cuttings.

Where an exploration program involves older and once-active mining districts, sources of geologic data-including some considerable detail on inaccessible workings-can be found in the archives of state historical societies. The American Heritage Center at the University of Wyoming, Laramie, provides access to an especially large collection of historic mining and geological archives; it holds a number of older mining company's exploration data banks, including the Anaconda Co.'s exploration collection of 1.8 million documents.

The compilation of geologic data for an extensive exploration program necessitates a painstaking evaluation of the material. Older maps may have been superseded by newer ones. Some data will involve projections and interpretations that are inconsistent with other data. Some geologic reports on earlier mined or "promoted" mineral deposits will be more subjective than factual. Faulty data that creep into the design stage can wreak havoc on an entire exploration program.

Aerial photography and remote sensing imagery can be obtained from governmental and commercial sources. In the United States, aerial photographs and NASA satellite and airborne imagery are primarily available from the US Geological Survey EROS Data Center in Sioux Falls, SD. Landsat spacecraft imagery is available from EOSAT, the Earth Observation Satellite Co. in Lanham, MD. Worldwide SPOT spacecraft imagery may be obtained from the SPOT Image Corp. in Reston, VA.

In designing a grassroots exploration program and preparing a format to be used in reconnaissance, the regional data will often be placed in a set of transparent overlay maps that can be studied in various combinations. A reconnaissance scale of 1:250,000 provides a suitable format in which topographic maps, satellite imagery, geologic maps, and a considerable number of government maps with gravity geophysics and airborne magnetic and radioactivity geophysics are available. Information from maps at other scales can then be photographically enlarged or reduced, and maps can also be digitized or obtained in digital form on tape and disk for computer-assisted drafting and plotting at the desired scale. The completed overlay maps can be arranged and studied as such. With maps that are stored and correlated in a computer, several levels of overlay data can also be displayed simultaneously on screen for study at various scales.

The set of maps will commonly have a topographic base sheet. Additional reference information may also be given on a property sheet showing existing mining claims and permit areas, and on an index sheet showing the location and scale of coverage available in more detailed geologic, geophysical, and geochemical surveys. Overlay sheets will include such information as:

1. Geology, simplified for clarity, with emphasis on metallogenic features such as structural zones, intrusions, and selected volcanic or sedimentary formations that can be related to the exploration model. Areas of "cover" by postore rocks and sediments may be shown on the same or another overlay sheet.

2. Satellite and airphoto information, showing significant linear features and remote sensing data on bleached and anomalous color zones.

3. Geophysical and geochemical information, with data points and interpretive isolines.

4. Mines, prospects, and ore mineral occurrences, with relative production and kind of ore.

Finally, a working overlay is used for developing interpretations and outlining areas for specific reconnaissance efforts. In the areas of further interest, the map sheets can then be enlarged for subsequent use in reconnaissance and follow-up detail.

The design stage in an exploration program serves its fundamental purpose of initiating a systematic sequence of tasks, but it carries an inherent load of geologic assumptions. The program and its guiding exploration model must be capable of revision as geologic information is gathered during reconnaissance, target identification, and target investigation.

The objective is a discovery of ore mineralization, a prospect that can be developed into a mine. Section 5 addresses the evaluation of prospects and the succeeding steps in feasibility studies and mine making.

Chapter 4.4
GEOPHYSICAL PROSPECTING

JOHN S. SUMNER

4.4.1 INTRODUCTION

The term *geophysical prospecting* should be taken here in a broad sense, including not only geophysical surveying as directly employed for the purposes of mineral discovery but also for subsurface geologic mapping by use of geophysical methods. In fact, more often than not, the exploration geophysicist provides supplemental geologic information about subsurface structure and lithology rather than making a direct discovery. The reasons for this more indirect use of geophysics is that, in the "apparent" sense, ore deposit physical property contrasts and geometric features are strongly diluted and distorted when measured through the overburden and wall-rock environment. And an ore body is often a smaller target. Thus direct mineral deposit detection, while very desirable, is not readily achievable. But geophysical methods still can provide critical information about the ore deposit environment even without direct detection capabilities.

The interpretive skills of the geophysicist are greatly improved by information about the physical property contrasts of the materials being sought. Although values from handbooks (Carmichael, 1984; Clarke, 1966) and textbooks (Dobrin and Savit, 1988; Telford et al., 1976; Parasnis, 1983) are useful in the absence of other information, actual mineral deposit physical properties really help in solving the problems of geophysical interpretation. A knowledge of the different physical property contrasts in an ore environment enables the geophysicist to choose the optimal, most effective prospecting method. In general, the geophysical methods used in mineral exploration give ambiguous results that are only resolved by knowledge of physical property contrast and/or the size and shape of the anomalous body. Body geometry and also its specific geometric relationship with the geophysical excitation and detection systems are very important factors in data interpretation, but these problems are solvable only after physical property contrasts are known.

Often more than a single geophysical method should be applied to an exploration problem to improve the odds for success. The principle of synergism applies whereby the total interpretive benefit can exceed the sum of individual contributions. For example, in the resistivity and the induced-polarization (IP) methods, IP contributes information about subsurface mineralization and the resistivity method provides geologic data, while the metal factor ratio is yet a third data set.

A geophysical anomaly can have different meanings, depending on the method being employed and the geologic environment of the survey. An *anomaly* is the difference between an observed response and normal response, given by the equation

$$\text{anomaly} = \text{observed response} - \text{normal response} \tag{4.4.1}$$

Certain small or background geophysical anomalies are to be expected, and they may have little or no exploration significance. Some geologic materials produce unwanted anomalies, while other geophysical anomalies are due to "geologic" or "cultural" noise or errors resulting from equipment limitations or erroneous assumptions of subsurface conditions.

As in any engineering or scientific measurement, an estimate of errors in geophysical values is an important aspect of a survey. Frequently, an error source is overlooked, and if it is large the survey will be adversely affected. The geophysical methods discussed in this chapter together with the basic physical characteristics and the type of applied fields are shown in Table 4.4.1.

The final result of geophysical measurements usually is a map or profile portraying the variation of the measured field in space. Geophysical measurements are taken at points, or "stations," whose location must be known with sufficient accuracy (1) to indicate how the measured quantity changes with location, (2) to determine certain corrections, and (3) to enable anomalous areas to be relocated at any time for future exploration work. Stations may be arranged in a regular grid or an irregular network. Station spacing is determined by the problem at hand—the expected size and depth of the sought-after feature or condition. In some surveys, particularly airborne surveys, data are continuously recorded along profiles. The spacing between profiles is also determined by the nature of the problem at hand.

The planning of a geophysical survey is one of the most important aspects of the prospecting problem. First, one must ask for the most probable geologic model of the target zone in terms of depth, body geometry, and physical property contrasts. Other factors such as terrain, survey costs, land ownership, condition of the environment, and equipment availability may be important. Also the planning geophysicist should not only examine the regional and local maps but should also visit the area to gain insight into the exploration problems. Only then can geophysical feasibility models be hypothesized and cost estimates made. Indeed, it may turn out that blind drilling is more cost effective than geophysical prospecting. To be truly objective and effective, the exploration manager should try to avoid hearsay or preconceived notions in employing geophysics to improve his exploration odds.

4.4.2 REGIONAL GEOPHYSICS

Focusing in on an exploration target is a matter of reviewing a series of scaled maps, first noting the various regional features and their interrelationships. The exploration geologist should not overlook the available regional geophysical maps in planning his exploration program.

4.4.2.1 Remote Sensing

Satellite imagery is available, with varying costs and quality, everywhere on earth. Geophysics has contributed its technology to the image processing and enhancements of satellite images (Mather, 1987), but remote sensing is not considered to be a geophysical surveying method in the very shallow penetrating (down to 0.4 in. or 1 cm) wavelength band. The conventional methods of remote sensing are discussed elsewhere in this section in Chapters 4.3 and 4.5.

High-altitude radar-equipped aircraft can map the earth's topography by using imagery and also side-looking airborne radar (SLAR), which is similar to aerial photography. L-band (390 to 1550 MHz) and P-band (225 to 390 MHz) radar can have penetrations of a few meters in nonconductive rocks and has been found to penetrate thousands of feet (meters) of glacial

Table 4.4.1. Geophysical Methods

ice. For example, the sands of the Sahara Desert have been scanned by radar to reveal ancient alluvial channels, incised when the climate was wetter.

4.4.2.2 Aeromagnetic Surveying

Most mineral deposits have some mappable magnetic expression, but few of these appear distinctly on a regional magnetic map. Nevertheless, the geologic trends related to districts and deposits should be examined for supplemental information. Most continental rocks are magnetized by induction, a fact that can be verified by careful examination of the magnetic map.

The earth's normal magnetic field varies from about 0.35 oersted in a horizontal direction at the magnetic equator to 0.65 oersted in a vertical direction at the magnetic poles. Rocks possessing ferromagnetic susceptibility become magnetized in the direction of the earth's field, and some rocks exhibit permanent or remanent magnetization that may be independent of the earth's present field. The earth's normal magnetic field will be disturbed near both of these kinds of rocks.

Magnetometers can measure the intensity of the earth's magnetic field to at least an accuracy of a gamma, or nanotesla (where the gamma is defined as 10^{-5} oersted), and this is quite adequate for regional exploration surveys. A map is prepared showing how the magnetic intensity varies over the area being surveyed, and this is the basis for interpreting the probable distribution of magnetic rocks in the earth's crust. Most magnetic surveys in large areas are conducted from an aircraft or a ship, and the relative cost is quite reasonable.

Magnetic Properties of Rocks: The magnetization of rocks is a complex subject, but for exploration purposes the most important and most common minerals to be considered are the magnetite-ilmenite series and, depending on its composition, pyrrhotite. The susceptibility of a rock to being magnetized in the earth's magnetic field varies almost directly with its magnetite content. In addition to the volume fraction of magnetite, susceptibility will vary somewhat with field strength, grain size, the presence of less common magnetic minerals, and the state of natural remanent magnetization. The relationship, in cgs units,

$$k = 300{,}000\ V_m \times 10^{-6} \tag{4.4.2}$$

is probably as satisfactory as any in relating rock susceptibility k to volume fraction magnetite V_m. Magnetite is a common accessory mineral in many igneous and some metamorphic rocks. Consequently, the magnetite content within one rock type may vary over a wide range, perhaps several percent, with attendant susceptibility variations. The "habit" of rock types in the survey region is empirically established by inspection of field data. The intensity of induced magnetization I_i of a rock due to susceptibility is given by

$$\vec{I}_i = k\vec{H}_o \tag{4.4.3}$$

where I_i is a vector quantity in the direction of the earth's magnetic field H_o. The total magnetization of a rock is the vector sum of the induced and remanent (permanent) magnetization:

$$\vec{I}_t = \vec{I}_i + \vec{I}_r \tag{4.4.4}$$

Unfortunately, I_r is seldom known, so that in practice a hybrid quantity is used that might be described as the "apparent induced magnetization." A thorough discussion of the influence of remanent magnetization on anomaly patterns is given by Hood (1963).

Processing Magnetic Data: The earth's magnetic field is not well ordered. It changes appreciably with time. Ordinarily, the time variations of magnetic intensity are gradual, especially at lower geomagnetic latitudes. Strong, abrupt variations in magnetic intensity sometimes occur and are caused by solar-related magnetic storms. At high geomagnetic latitudes, useful data seldom can be obtained during such events. The earth's magnetic field cannot be described simply, but it can be modeled, by using spherical harmonics, with a fair degree of accuracy. The earth's regional magnetic field can be removed from exploration data to create a more easily interpretable residual magnetic map. Topographic effects exist but seldom are evaluated because of the uncertainty in assigning effective susceptibilities for surface formations. Lightning strikes on topographic highs cause erratic remanent magnetic effects due to isothermal remanent magnetism. To create an interpretable map, the earth's total magnetic field is measured, variations with time and longer distances are removed, instrument readings converted to gammas, and the results are plotted.

Interpretation of Results: The objectives of a regional magnetic survey may be (1) the direct detection of magnetic minerals, (2) a means of extrapolating known geology beneath covered rocks, or (3) to give estimates of depths to basement rocks beneath a sedimentary basin. The interpretation procedure, therefore, will vary somewhat, depending on the objectives of the survey. The direct detection of magnetic minerals has important economic implications, because this category would include not only magnetic iron ore but also magnetite-chalcopyrite or pyrochlore occurrences in contact metamorphic deposits, magnetitic nickel ores, pyrrhotite in Cu-Zn-Ag and Ni-Cu massive sulfide deposits, and magnetite associated with gold in placers.

When used as an aid to geologic mapping, the magnetic map is often divided into "provinces" on the basis of the magnetic pattern. Broad areas of little relief often are underlain by sediments, a bird's-eye maple pattern is typical of flat-lying volcanics, and isolated equidimensional anomalies may represent intrusive plugs. Structural and lithologic trends frequently are reflected in the magnetic pattern of metamorphosed areas.

The success of this map interpretative procedure will depend on the geologic control available. The depth to basement and the structure in a sedimentary basin are of concern to exploration in such areas as the Blind River uranium district of Canada and the Southeast Missouri lead belt.

Once the foregoing type of qualitative interpretation has been accomplished, the isolated anomalies may be treated semi-quantitatively. The magnetic attraction for a wide variety of geometric shapes may be calculated and compared with observed data until an acceptable fit is achieved. The magnetic data can also be mathematically inverted to directly interpret the most probable body geometry for a given apparent susceptibility contrast. Magnetic data in itself cannot yield a unique solution for both the geometry and susceptibility contrast of the volume causing the anomaly without additional control, but the number of possibilities can be restricted by using the boundary conditions of geologic reasonableness. An older reference and atlas for use in interpreting total intensity magnetic anomalies has been prepared by Vacquier et al. (1951).

Further models of geologic conditions are given by Grant and West (1965), Nettleton (1976), and Dobrin and Savit (1988).

4.4.2.3 Regional Gravity Surveying

Gravity meters are capable of rapidly measuring the earth's gravity field to an accuracy of ±0.01 milligal, where the milligal is 10^{-3} cm/sec^2. After corrections to the observed data, a map or profile is prepared, which is the basis for interpreting the probable density distribution in the earth responsible for the gravity changes. Precision gravity surveys must be made from a position fixed with respect to the earth, but less accurate surveys can be made from boats, or even to within one milligal from aircraft (Hammer, 1983). Regional gravity surveys are those in which the station spacing is 0.3 mi (0.5 km) or greater.

Density of Earth Materials: The densities of rock types may vary with one or more of the following: compaction, porosity, saturation, texture, composition, age, fracturing, and burial depth. Hand-sample densities from outcrops or drillholes usually are the most practical source of density information. Sometimes the gravity data will permit an assignment of bulk density value.

Processing Gravity Data: Field gravity measurements require a number of corrections to remove nongeologic variations. First, it is necessary to remove real and apparent gravity variations with time, meter drift, and tidal effects. Variation in gravity due to station location and elevations are then taken care of.

The most important consideration in exploration surveys is to reduce the observed gravity in such a way that a high degree of relative, rather than absolute, accuracy is preserved. Exploration surveys are concerned with changes in geologic condition, so that changes in gravity rather than gravity itself are of primary interest. Regional surveys should be referenced to sea level. The reduction of observed gravity follows the formula

$$g_B = g_o - (g_t - kh - T - L) \qquad (4.4.5)$$

where g_B indicates that the reduced gravity is in the form of the complete Bouguer anomaly, g_o is observed gravity at a station with elevation h feet above sea level, g_t is theoretical sea-level gravity, k is elevation factor, T is terrain correction, and L is latitude correction referenced to the equator.

Drift and Tidal Corrections: Changes in gravity reading with time are removed by first observing a base station with a known gravity value. Unknown stations are then observed for a period of time, and finally either the original base or another station with a well-established gravity value is observed. The time interval between base station readings is sufficiently short that overall drift may be assumed to be linear with time. The station designation, time of observation, and meter readings are recorded. Each gravity meter has a scale constant C furnished by the manufacturer that expresses the value in milligal of each dial division on the meter. There are variations in calculation procedures, but effectively drift rate D in dial divisions per minute is computed from

$$D = \frac{(R_{b1} - R_{b2}) - (V_{b2} - V_{b1})/C}{t_{b2} - t_{b1}} \qquad (4.4.6)$$

where R is meter reading in dial divisions, V is accepted gravity value, t is time in minutes, and subscripts $b1$ and $b2$ refer to base station 1 and base station 2. If base stations 1 and 2 are the same, then $V_{b2} = V_{b1}$ and Eq. 4.4.6 is simplified. If they are different stations, then V_{b2} must be carefully established by replicate measurements (three or more) of the type next to be described. The gravity value at some unknown station n read during the interval between t_{b1} and t_{b2} is given by

$$V_n = V_{b1} - C\,[\,(R_n - R_{b2}) - D(t_n - t_{b1})\,] \qquad (4.4.7)$$

where V_n, R_n, and t_n are observed gravity, meter readings, and time of reading, respectively, at station n.

Theoretical gravity g_t, in gal, and the latitude correction L, which is the earth's normal gravity at sea level, are obtained by solving the Geodetic Reference System 1967 equations to obtain the Gravity Formula 1967, which is

$$g_t = (978.03185)\,(1 + 0.005278895\,\sin^2\phi) \qquad (4.4.8)$$

where ϕ is latitude. Eq. 4.4.8 may be differentiated to obtain the north-south change in gravity at any latitude. Gravity increases from the equator to the poles; therefore the latitude correction L is subtracted as one proceeds northward.

Elevation Correction: The elevation correction k, in milligal per foot, for a surface gravity station is given by

$$k = (0.09406 - 0.01276d) \qquad (4.4.9)$$

where d is the effective surface density in the survey area. For regional gravity surveys, the effective average density of the earth's crust above sea level is taken to be 2.67 g/cm^3. This yields an elevation correction factor of k = 0.05999 milligal/ft.

Terrain Correction: The terrain correction described previously assumes a plane for the earth's surface, but a terrain correction T may be required in hilly country. This correction is always positive because a hill is an excess mass above the station and a valley is a mass deficiency below. Both tend to reduce observed gravity. The correction is evaluated by approximating terrain with geometric shapes for which the gravity effect can be calculated. These may be the cylindrical and annular segments of Hammer (1983) or the vertical prisms and subdivisions thereof as described by Kane (1962) and which are amenable to the digital computer. In Kane's method, the mass within the prism is transferred to a vertical line element at the center of the prism for ease in computation.

Interpretation of Results: After the Bouguer gravity map or profile is prepared by applying the appropriate corrections in accordance with Eq. 4.4.5, variations may appear in the data due to very shallow or very deep density changes that are of no interest to the interpreter. Shorter wavelength anomalous variations are often referred to as "noise," and the longer wavelength variations are called "regional" effects. A discussion of techniques for removing or suppressing such variations is given by Grant and West (1965). When inconsequential variations are removed from a Bouguer gravity map, the result is generally known as a residual Bouguer gravity map, which shows the true shape and amplitude of local anomalies of interest.

The fact that there is no unique interpretation of gravity data has been adequately demonstrated by numerous investigations, but the situation becomes more acceptable if some geologic control or the concept of geologic plausibility is incorporated into the interpretive process. Simple geometric shapes can be postulated to approximate or model the inferred geologic conditions, then the gravity patterns of these shapes are calculated and compared to the residual (observed) gravity values. The model is readjusted until a reasonable fit to the residual gravity is achieved. A perfect fit of the observed and theoretical curves is no proof that a true shape has been computed. Appropriate references to this process include Nettleton (1976), Grant and West (1965), Talwani (1985), and Dobrin and Savit (1988). An alternative, more detailed interpretive method involves the mathematical inversion of the original residual gravity data set, as discussed by Parker (1975).

4.4.2.4 Aeroelectromagnetic (AEM) Surveying

Surveys of the electrical conductivity over broad portions of the earth have been very successful in revealing the presence of electrically conductive mineral deposits. Here the geologic environment is important: (1) rather flat or undulating terrain, (2) richly endowed (in mineral deposits), and (3) thin, concealing, but extensive covering overburden. Literally billions of dollars of massive sulfide ore bodies have been directly discovered in the Precambrian shield areas of the world by using the AEM reconnaissance method, and the ground follow-up geophysical surveying has been equally rewarding. Pemberton (1962) has reviewed AEM methods and equipment.

Fixed-wing aircraft are usually used for reconnaissance AEM surveying, employing either continuous wave frequency domain waveforms (Paterson, 1961) or pulsed time-domain (Palacky and West, 1973) techniques. The INPUT (induced pulse transient) method of A. R. Barringer, a Colorado consultant, has proved to be quite successful in regional exploration for massive sulfides, and Fraser's (1979) helicopter DIGHEM (digital helicopter electromagnetic) system gives useful near-surface resistivity information.

4.4.2.5 Airborne Radiometric Methods

Uranium, thorium, and potassium-40 occur naturally in earth materials, and because these elements are radioactive, their presence can be detected by radiometric surveys. Alpha, beta, or gamma particles may be emitted, but only gamma rays will penetrate a sufficient distance to be useful in airborne exploration. Gamma rays will penetrate several hundred feet (meters) through the atmosphere, but a few inches (centimeters) of earth are sufficient to attenuate natural radiation by half. Therefore, the radioactive elements or their radioactive daughter products must occur in outcrop to be detected. Gamma-ray detectors consist of a crystal that is activated to give off a minute flash of light (scintillate) upon being struck by an ionizing gamma particle. The crystal is coupled to a photomultiplier tube that generates an electrical pulse proportional to the intensity of each scintillation. "Total count" scintillometers give a readout proportional to the total number of flashes above a small threshold of intensity. Instead of a "total count" scintillometer, a pulse-height analyzer can sort out the flashes according to intensity and number. As a result, scintillation spectrometers are available to provide readouts of the source of radiation. The number of counts in each energy channel will be significantly less than the total count, so large crystals and slower, lower-flying aircraft are desirable. The uranium series presents a problem in that some of the daughter products have appreciable half-lives and are fairly mobile. Disequilibrium may result causing the indicated concentration of bismuth-214 to be out of proportion to the concentration of uranium-238 in the source material.

4.4.3 DETAILED GEOPHYSICAL SURVEYING

From closely-spaced measuring stations in a geophysical survey, exploration drilling can be planned. Detailed surveys generally have these stations spaced at 0.5 mi (0.9 km) or less, and ground-based rather than aerial surveying is required. Work can be done on the surface or in boreholes.

4.4.3.1 Surface Methods

The equipment requirements for surface geophysical surveying are similar to the airborne instruments, except for miniaturization. Power needs and power supplies must be small, and the device must be portable enough for one person to carry.

Gravity: The theory and practice of detailed gravity surveying is much the same as the regional work, except for the accuracy requirements. Whereas regional work can accept errors due to special and temporal variations that are ±0.2 milligal or less, detailed work will require errors to be less than ±0.02 milligal. This means that more precise location maps must be used and station elevations must be leveled to a precision of ±0.10 ft (30 mm). Also, closer drift loop control must be maintained and tidal variations watched closely.

New cryogenic and mechanical-optical gravimeters are in use that can measure gravity variation to within a microgal. These devices are proving useful in detecting small masses and subsurface voids such as caves or tunnels.

Some ores such as chromite, hematite, and barite have such a high density compared with the material that surrounds them that they can be located directly by detailed gravity surveys. Buried channels that might contain gold or uranium minerals can frequently be located by gravity or seismic surveys because the channel fill is less dense than the rock in which the channel has been cut.

Gravity surveys are employed in base-metal exploration for a number of purposes. In the southwestern United States, they have been used to find shallow bedrock structures such as the edges of pediments under alluvial cover. In the Canadian Shield, they have been carried out, along with shallow seismic surveying, to differentiate electromagnetic anomalies caused by massive sulfides from those caused by low-density, graphite-filled shear zones. Gravity surveys have also been useful for estimating tonnages in sulfide or iron deposits detected by drilling.

Interpretation of Detailed Gravity Surveys—Because residual gravity values can be stored in computer memory and operated on by digital filters, a number of different interpretational methods are available. The selection and use of these digital filters depend to a large degree on the type of geologic environment and the exploration problem at hand.

Two-dimensional Fourier transforms can assist in removing longer or shorter wavelength geologic effects from gravity data, as can wavelength filters. Directional filters can also select and quantify structural trends.

Upward continuation of gravity data tends to smooth the original data by attenuation of shorter wavelength anomalies relative to their longer wavelength counterparts, a regional consequence of the attenuation of anomaly amplitude with increasing distance from the source. Downward-continuation filtering tends to amplify the shorter wavelengths, so this method can be used for estimates of depth to the causative body. However, because the downward-continuation filters also amplify noise and errors, the method must be applied with caution.

Vertical and horizontal derivatives can also be readily computed for detailed gravity maps, so that certain sizes or shapes can be enhanced. Pseudomagnetic anomalies can be computed too, so that gravity and magnetic maps can be more closely compared. Most of these interpretive methods are discussed, with examples and references, in Dobrin and Savit (1988).

Magnetics: Thanks to electronic technology and related microprocessor instrumentation, truly portable, hand-held but completely automatic magnetometers are now a reality. Usually these instruments are of the proton-precession type, measuring the total magnetic flux density $|B|$ in a scalar sense. A particularly good explanation of field techniques and survey methods has been made available by Breiner (1973).

Because of their dipolar nature, magnetic anomalies and their interpretative methods are more complex than gravity methods, but magnetic resolution of subsurface bodies is much better. The improvement in resolution by magnetics is brought about by a concept in potential theory known as Poisson's relation (Garland, 1971) wherein it is shown that magnetic fields are higher in order than gravitational fields. Poisson's relation also allows magnetic models to be analytically calculated from gravity models. And conversely, a pseudo-gravity map can be computed from a magnetic map to allow a comparison with gravity data in the same area.

Detailed ground magnetic surveys are now quite simple to carry out and are therefore often supplemental to other ground survey methods. Usually the highest cost of a geophysical survey is logistics and transportation, and if these costs are borne by other survey methods, carrying an additional exploration tool such as the magnetometer is well justified.

Interpretation of Detailed Magnetic Data—In general, magnetic data can be interpreted either in a qualitative or a quantitative sense. Although it may seem that the qualitative approach would be simpler, this method is actually based on computed forward models so that the interpreter must have a "feel" for the data to be analyzed. In the qualitative method, one notes the half-width of anomalies because of the simple relationship that the half-width has to the depth to the body. Also magnetic gradients must be noticed and the relationship of the positive anomalies with their corresponding negative anomalies.

Talwani's (1985) method is probably the most widely used algorithm in potential field interpretation. It calculates the anomaly due to a prism or set of prisms of polygonal cross section and either an infinite (two-dimensional) or finite (three-dimensional) strike length. The three-dimensional Talwani method (Talwani, 1985) approximates the source by a set of thin laminae. Each lamina is, in turn, approximated by a polygon in plan view. The method is also applicable to topographic sources because the contours of topographic maps correspond to the boundaries of appropriate laminae. Plouff (1976) has modified Talwani's algorithm to model a stack of layers of finite thickness.

Table 4.4.2. Electrical Prospecting Methods by Source Field

Natural Field Source	Artificially Controlled Source
A. Magnetotellurics (MT)	A. Electrical resistivity (dc)
Telluric-MT (TMT)	B. Transient soundings (TEM)
Audio-frequency MT (AMT)	C. Induced polarization (IP)
Audio-frequency magnetic (AFMAG)	D. Electromagnetic (EM) induction
Telluric current	E. Ground-penetrating radar
B. Electromagnetic (EM) array profiling (EMAP)	F. Controlled-source audio-frequency magnetotelluric (CSAMT)
C. Self-potential (SP)	

Plouff's method overcomes the inaccuracy resulting from the inability to calculate the total field at the same levels as the source body.

Use of the inversion technique in interpreting data is probably more advanced in the magnetic method than in the gravity method today. The matrix method (Bott, 1967) divides the geometry into cells and seeks a numerical solution for a linear integral equation. Parker's (1975) inversion starts with a forward-modeled Fourier domain algorithm and derives an iterative scheme involving transforms to find the distribution of magnetization.

Several computational methods are useful in finding the depth to source, which is useful in finding basement structures. The Werner (Hartman et al., 1971) method uses deconvolution to solve the parametric unknowns of the source geometry. Power spectra of data can be compared with model spectra to find the key body parameters. Peters' (1949) half-slope method, although rather old, is quite simple and straightforward.

Electrical Survey Methods: Detailed electrical surveys have become very diverse over the past two decades, and the reader is referred to Sumner et al. (1967) for discussions of previously established methods. Some techniques (self-potential, telluric-current, and magnetotelluric) depend on naturally occurring electromagnetic (EM) fields. Other EM methods require electric currents or fields that are artificially introduced into the earth. The natural and artificial field methods are summarized in Table 4.4.2. Keller and Frischknecht (1966) reviewed the subject of EM methods very well.

In the broader sense, the electrical methods operate in segments of the electromagnetic spectrum shown in Fig. 4.4.1. Near-direct-current (dc) methods are on the left of the diagram, progressing successively to the gamma-ray region on the far right. Electrical and electromagnetic prospecting techniques generally operate in that part of the EM spectrum below 3×10^4 Hz (30 kc). In this range, radiation and propagation effects are small, and displacement currents are negligible. Thus the investigator is concerned principally with resistive and conductive coupling between circuits. The limiting factor is the skin depth, which is the depth in a medium at which the current density has diminished to $1/e$ (or about 0.368) of its surface value. No prospecting information is obtained from depths greater than the skin depth, and at these low frequencies, conductive bodies do not "reflect" electromagnetic radiation.

Electrical Properties of Rock—The specific resistance, or electrical resistivity, of earth materials depends strongly on the contained volume of water. Although the resistivity of minerals varies over many orders of magnitude, mixtures of minerals (rocks) in their natural environment are somewhat porous, and the pore spaces are occupied by water. Even rock and soil above the water table contains water that is bound to surface grains.

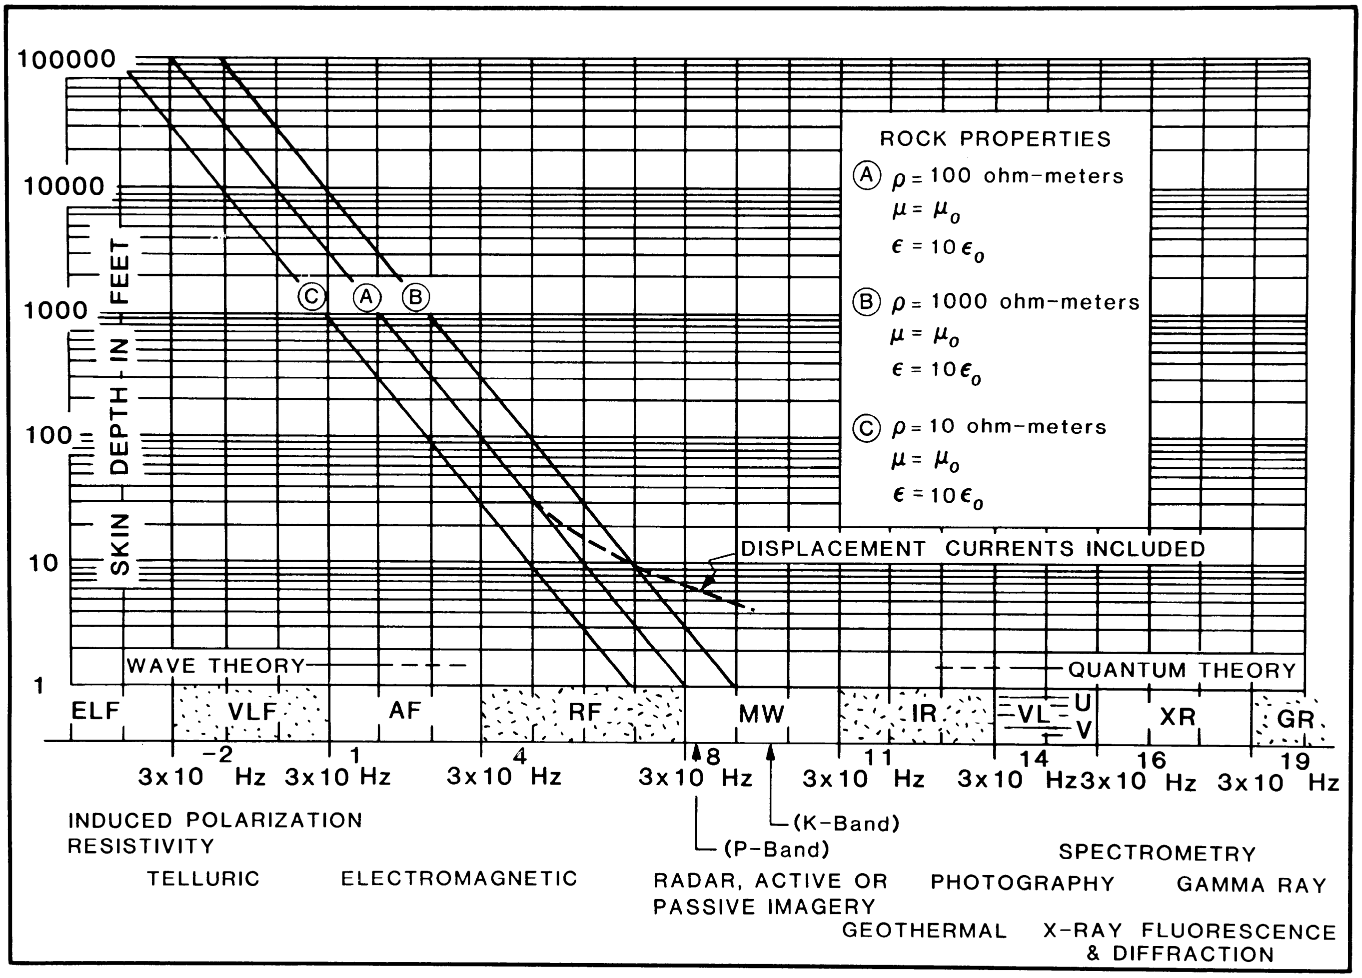

Fig. 4.4.1. The electromagnetic spectrum, skin depth, and the regions in which the different methods operate. Conversion factor: 1 ft = 0.3048 m.

The electrical conduction next to these particles is very high, and therefore it is difficult to detect the water table by resistivity methods alone.

The reciprocal of resistivity is conductivity, measured in mhos per meter. Metallic luster minerals, including magnetite and most base-metal sulfides, are very good conductors of electricity, particularly in the presence of groundwater.

Low-Frequency Electrical Methods—At frequencies below 10 Hz, the resistive coupling through the ground between the current and voltage circuits is dominant. It is necessary to have two voltage detection and two current insertion contacts with the ground for a low-frequency electrical measurement. The theory of low-frequency prospecting methods is discussed by Wait (1982). The electrode array configurations most commonly used for exploration are illustrated in Fig. 4.4.2.

If the values of *V, I,* and the electrode geometry and spacing are known, apparent resistivity of the earth is computed by the appropriate formulas, shown in Fig. 4.4.2. These formulas assume a homogeneous ground, hence the term "apparent." Variations in apparent resistivity plotted as the array is expanded are known as vertical electrical sounding (VES) curves, and depth to surfaces bounding contrasting resistivities can be computed by using a variety of different methods. An electrode array can also be used to traverse the target area, and the values of the resulting apparent resistivities can be plotted and contoured on a map. The dipole-dipole arrays can be used for both sounding and for profiling, and the resulting values can be plotted on an exploration cross section as a "pseudosection" of data (Fig. 4.4.2). The pseudosection is so named because it is not a true electrical cross section of the earth. A description of the electrical resistivity and the related field prospecting induced-polarization methods is given by Sumner (1976).

In the induced-polarization (IP) method, either a variable frequency or a square-wave pulse of current is applied to the earth. If polarizable minerals are present, the ground will become charged while current is flowing, and the resulting discharge can be measured by the voltage detection electrodes. In the frequency-domain induced-polarization method, the voltage differences between the low- (V_L) and high- (V_H) frequencies voltage determines the frequency effect *(FE)* such that

$$FE = (V_L - V_H)/V_H \qquad (4.4.10)$$

using one particular current value. Of course, a standard frequency difference such as one decade must be used for comparative purpose.

In the pulse (or time) method of induced polarization, the ratio of the secondary to the primary voltages is used to obtain the chargeability (M), as shown in Fig. 4.4.3b. Another common

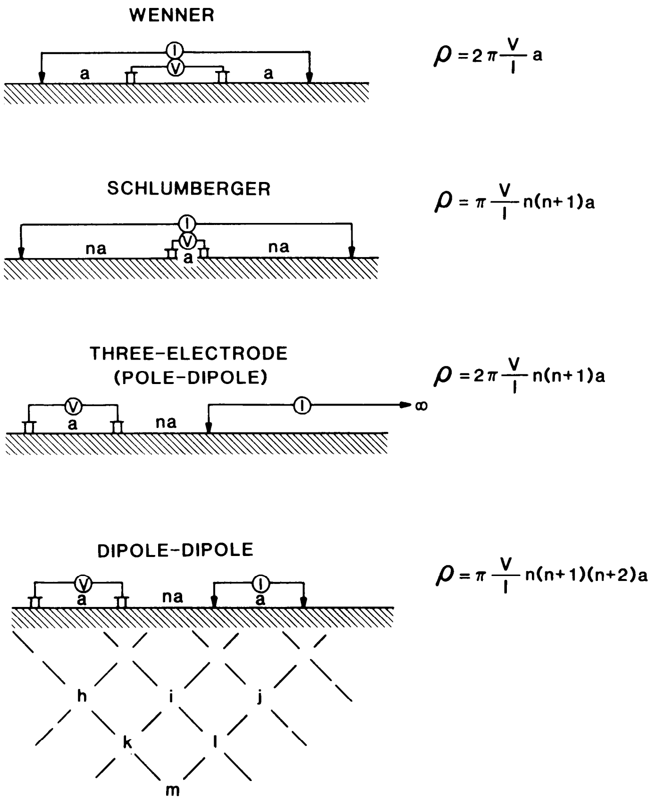

Fig. 4.4.2. Typical electrode arrays for resistivity and induced-polarization surveys (Sumner, 1976, p. 25).

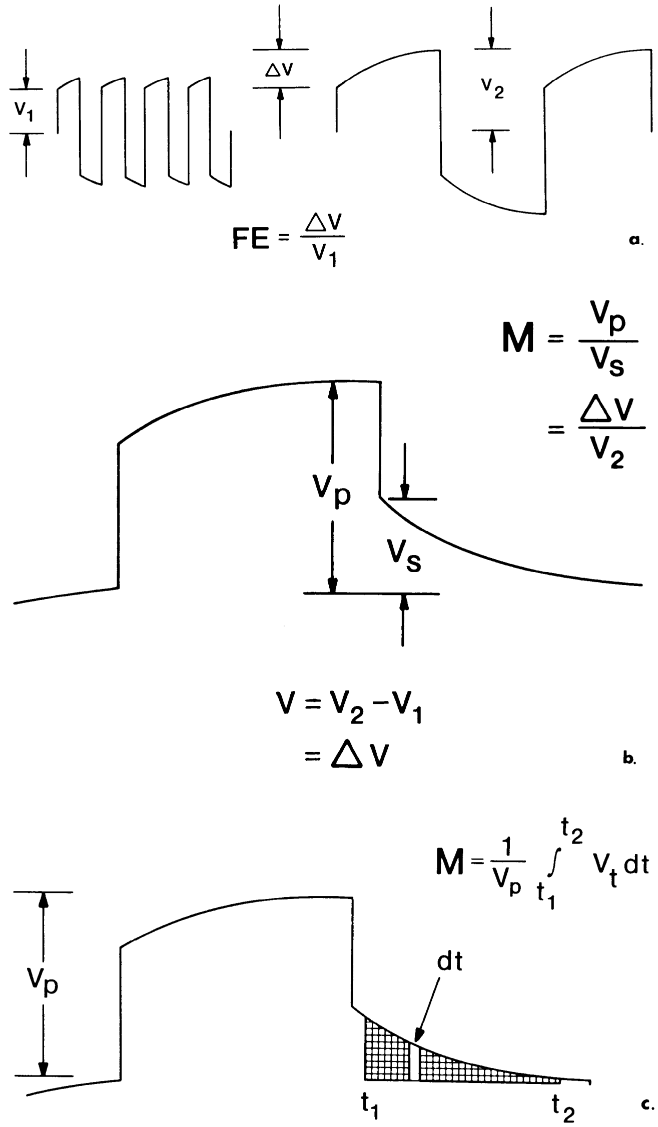

Fig. 4.4.3. Waveforms and parameters in the time and frequency methods of induced polarization. a. Frequency effect measurement. b. Time or pulse IP measurement: $M = V_S/V_P$. c. Chargeability M as an area under the discharge curve.

time-domain method is to measure the area under the decay curve that is also proportional to chargeability (Fig. 4.4.3c).

Complex Resistivity—Geophysicists have noted that the time and frequency induced-polarization methods are equivalent and differ mainly in field instrumentation. A third induced-polarization method measures the electrical phase shift between the transmitter and receiver to provide yet a third set of data. It has been pointed out (Zonge, 1975) that all three measurements can be combined to provide the most comprehensive electrical model of the subsurface.

Complex-resistivity measurements require rather sophisticated computerized instruments in the field, and it takes longer and thus costs more to make a reading. However, the interference by telluric noise is minimized, and it is possible to remove most of the unwanted electromagnetic effects that couple the transmitter and receiver systems. In fact, the electromagnetic response, which often obscures normal induced-polarization measurements, can be observed and interpreted to supplement the induced-polarization and resistivity interpretation.

Natural Source Electrical Methods—The signal source for natural field electromagnetic methods consists of naturally occurring fluctuations of the earth's magnetic field. This field is present everywhere, at any time, and contains a very wide range of frequencies. For exploration, the total range is from about 0.0001 to 10,000 Hz. Below 1 Hz, the field is due to solar-wind interactions with the earth's magnetic field and ionosphere, and above 1 Hz, the source is mainly terrestrial thunderstorm activity.

The self-potential (SP) method measures natural earth voltages existing at a nearly direct current level due to electrochemical action between minerals and solutions. The field survey method is very simple, requiring only a dc voltmeter and two ground controls as well as porous ceramic pots. The theory of Sato and Mooney (1960) is most widely accepted. The natural self-potential voltage of a shallow massive sulfide deposit is invariably negative and less than 1000 mV, although a 1700-mV potential anomaly was described over an alunite body by Kruger and Lacy (1949) at Cerro de Pasco in Peru.

The interpretation of natural-field electromagnetic methods involves recognition that electrical signal penetration into the earth is proportional to the electromagnetic skin depth. However, the magnetic component of the electromagnetic wave is virtually unaffected, so that their ratio gives a measure of apparent resistivity in much the way as making a dc resistivity sounding. A good treatment of natural-field electromagnetic methods is included in the volume by Nabighian (1988).

Controlled-Source Audio-Frequency Magnetotelluric Surveying—Starting initially as an outgrowth of the more academic magnetotelluric method, controlled-source audio-frequency magnetotelluric (CSAMT) surveying has become important in its own right. Basically, the long-wire transmitter is programmed to generate a series of increasingly lower-frequency signals. The portable receiver measures the electric field and the magnetic field at some distance from the transmitter. At a particular receiving station, the series of frequencies "sees" increasing depths of penetration, so these responses can be plotted vertically in serial fashion. Thus a line of receiver stations can yield a plotted parametric cross section of data that can be interpreted to give a geologic section. The controlled-source audio-frequency magnetotelluric method is fairly rapid to run in the field and thus is lower in cost. It has been applied to environmental problems as well as to mineral exploration. Most of the interpreted results appear to supplement knowledge of subsurface geologic structure and lithology rather than making a direct discovery of mineralization. The method is described rather completely by Zonge and Hughes (1988).

Prospecting with Inductive Electromagnetic Methods—All ground electromagnetic methods have two systems: one is the transmitter and one, the receiver. Beyond that similarity, comparisons cease because every imaginable configuration has been tried, and each has its advantage.

1. *The Slingram Method.* One of the most common systems is the Slingram or horizontal-loop method, the coils connected by means of conductive cable. The cable maintains a fixed distance, up to 600 ft (200 m), between the horizontal coils. The cable also allows phase measurements to be made between the transmitted signal and any secondary signals produced by a conductive body. The two coils are carried on traverses that are normal to conductive trends, and measurements are taken at about 75-ft (25-m) intervals. Interpretation is usually carried out by means of modeled type curves, and conductivities can be estimated by means of comparing phase ratios.

The Max-Min system is similar to the Slingram equipment but more sophisticated. The Max-Min data interpretation is well proven, and the equipment is capable of fairly deep (1000 ft or 330 m) exploration.

2. *The Dip-Angle Method.* In this method, sometimes called the vertical-loop method, the coils need not be electrically connected. The transmitter coil is held in a vertical plane pointed at the receiver. The receiver coil is then held nearly horizontal and rocked back and forth laterally to receive the dip angle (or more properly, the tilt angle) null. Two frequencies are used so that conductivity estimates can be made. Unlike the Slingram method, the dip angle (sometimes called the vertical loop method) is asymmetric, and a reversal of transmitter and receiver will give different readings.

In older dip-angle surveys, a large vertical loop was set in the center of a survey area, and one or two receivers covered a square area about 0.3 mi (0.5 km) on a side. This vertical loop transmitter coil configuration was also the basis for the early airborne electromagnetic survey methods, particularly the Inco and McPhar systems.

3. *The Crone "'Shootback" Method and Related Systems.* The dip-angle coil configuration was modified by Crone (1966) to switch the transmitter into a receiver and the receiver to a transmitter, so reversed readings could easily be taken. Also the transmitter plane could be made nearly horizontal with the plane of the coil pointed toward the receiver. Such a configuration removed topographic effects. To add to the versatility, a conductive cable could connect the coils together for phase comparisons.

4. *Turam Method.* With Turam, a long (0.3 mi or 0.5 km), grounded transmitting or large loop cable is used, and lines are surveyed adjacent to it. The two horizontal coils of the receiver are connected by a phase-comparison cable so that signal amplitude and in- and out-of-phase (quadrature) measurements can be made at the receiver site. It is also called the long-line system. An area of about 0.3 mi (0.5 km) on a side can be surveyed from one transmitter position, and two (or more) pairs of receiver coils can be used at one time.

5. *Helicopter Electromagnetic Systems.* Several helicopter-based electromagnetic systems have been used successfully for shallow exploration in the Precambrian Shield and in similar environments. On some the coils are fixed, on others the coils are "button on," and on yet others the helicopter dangles an elongated "bird" with the rigid coil system enclosed in an aerodynamic sheath. In the Dighem system (Fraser, 1979), the receiver coils are continuously electronically rotated, and signals from all of the transmitted directions are received and then unscrambled by onboard digital computers.

6. *Time-Domain Electromagnetic Systems.* A number of time-domain electromagnetic exploration systems similar to the airborne INPUT system have been employed over the past decade in the ground search for massive sulfides. Depending on affiliations of the original system designer, these have been called Utem, Sirotem, Zerotem, and so forth. The pulse electromagnetic system has the advantage over frequency-domain systems of "listening" to the received anomalous signal in virtually the absence of the transmitted signal and the geologic noise. There is also a claim by some that at longer time constants even an induced-polarization response is received.

7. Very Low Frequency Electromagnetic Systems. There are several very low frequency (VLF) radio transmitters operating continuously in countries over the earth. The signals are used for military purposes, mainly by submarines, and the frequency band is designed to have a refracted, ground-penetrating wave. On the 20-kHz band, the depth of penetration into earth material is such that exploration can be accomplished with only a finely tunable radio receiver. In some ways, the survey principle is similar to that of the dip-angle method in its simplicity, but additional electronic phase information is also obtained. Interpretation and contouring of data are sometimes done with reference to Fraser's (1969) article in *Geophysics.*

Although VLF frequencies are "very low" in the electromagnetic communication spectrum sense, they are very high as compared to frequencies normally used in geophysical exploration. As a result, VLF depth of exploration is small, because of the shallow skin depth (Fig. 4.4.1).

Seismic Methods: Reflection and refraction seismic methods depend on the velocities of acoustical energy in earth materials. Accordingly, these involve the creation and transmission of a short pulse of seismic energy and the broad-band recording of the arrival of the train of seismic pulses at distant locations. The time intervals after the initiating energy pulse instant must be determined with millisecond accuracy. Explosives or the impact of a mass furnishes the energy, and direction is accomplished by sensitive seismometers operating into electronic amplifiers and recording equipment. Wave (or optical) theory of travel time reflection, absorption, diffraction, and refraction are applicable to seismic interpretation. This involves quite different physical principles than with the potential methods discussed earlier.

Seismic methods have only been occasionally applicable to mining exploration problems. This is due to the vastly more complex mining geologic conditions, as well as costs. Thus there are few case-history examples of the application of seismic methods to mineral exploration. Most of the use by mining companies has been in engineering, environmental, and hydrologic applications.

Seismic exploration has been used to aid in the interpretation of other data by providing depth-to-bedrock information. For example, Bacon (1966) described basement profiling by refraction seismics as a method of correcting gravity exploration data. The buried alluvial channels of placer deposits can be traced by the refraction seismic method.

4.4.3.2 Borehole and Subsurface Methods

Surface geophysics has its subsurface counterpart in subsurface applications within the environment that is being searched. One of the important applications here is the in situ determination of physical property contrasts such as density, magnetic, electrical and electromagnetic, seismic and radiometric properties.

Gravity: In a compatible geological environment, underground gravity surveys can be quite successful (Sumner and Schnepfe, 1967). At Bisbee, AZ, the success ratio was about 0.8, using 14 diamond drills in the search for massive sulfides during the last years in the life of the mine.

Borehole gravity surveying is coming of age, and there are two or three instruments and as many contracting groups in the service industry. The borehole gravimeter is primarily a density-logging device, but it also "sees" anomalous masses near the borehole that can be overlooked in surface exploration. LaFehr (1983) has summarized borehole gravity exploration, applications, and interpretation in a succinct manner.

Borehole Electric Logging: Surface and underground electrical exploration methods have counterparts in borehole logging. However, there are major differences from the more well-known petroleum and water well logging systems. In mineral exploration, the holes are shallow in depth and smaller in diameter. Site access is often difficult, hole blockage is common, and proper equipment is not always available.

The types of logging that has been reported are

1. Resistivity logs.
2. Self-potential logs.
3. Induced polarization, resistivity, self-potential in combination, (a) single hole, multiple electrodes, (b) azimuth and radial surveys, (c) hole-to-hole tomography.
4. Magnetic vector and susceptibility logs.
6. Mise a la masse surveying.
7. Electromagnetic logging: (a) receiver coil down-hole, transmitter coil on surface; (b) both receiver and transmitter coils down-hole; (c) receiver and transmitter coils in adjacent holes; (d) down-hole Turam and gradient array surveys.

Uses of logs in mineral exploration are for physical-property measurements and for mineral exploration. To enlarge the sphere of detection, two or more holes can be used to separate the transmitting and receiving systems, in a method referred to as "tomography." The goal of tomographic surveys is to reconstitute the geologic section between drillholes by using all depths in each hole for transmitter and receiver.

Another means of gaining a larger sphere of detection from a drillhole is to insert current from a bottom hole electrode and to measure the electric potential along surface traverses radiating from the hole collar. This has been called the "azimuth array" or the "radial array" (Sumner, 1976).

4.4.4 COST OF GEOPHYSICAL WORK

The cost of performing geophysical surveys will vary over a wide range, depending on access, terrain, and the amount of detailed information required. Approximate relative costs per square mile (square kilometer) in units of 1980 US dollars are given in the tabulation for initial reconnaissance coverage of a "typical" area in Table 4.4.3.

Surveys in mining exploration are planned to suit the problem at hand and are not always used in a reconnaissance fashion.

Table 4.4.3. Costs of Geophysical Surveys

Method	Cost (in 1980 US$) per mi^2	per km^2
Radiometric	100- 200	50-100
Magnetic (ground)	100- 200	50-100
Gravity	200- 300	100-150
Electromagnetics	500-1000	250-500
Resistivity/induced polarization	700-1200	300-600

Table 4.4.4. Costs of Borehole Geophysical Surveys

Method	Cost (in 1980 US$) per ft	per m
Electromagnetic logging, discrete readings	1.00-1.50	3.00-5.00
Induced polarization, resistivity, discrete readings	1.00-2.00	3.00-5.00
Magnetic susceptibility, core log or cuttings	0.10-0.23	0.30-0.60
Radioactive logging, core or cuttings	0.10-0.25	0.30-0.65
Radioactive logging, downhole	0.50-1.00	1.50-3.00

Shallow seismic refraction surveys should be of a similar cost as resistivity and induced-polarization surveys. Reflection seismic surveys may require more elaborate equipment, especially for deep work. Costs of $150,000 per crew-month for reflection seismic surveys are not unusual.

Aeromagnetic surveys and aerial radiometric surveys are flown at costs of $20 to $30/line-mi ($15 to $20/line-km). Airborne EM surveys are almost always combined with aeromagnetic surveys at costs of at least $35 to $50/line-mi ($20 to $35/line-km). Helicopter costs would be much higher, especially for smaller surveys.

Drillhole logging costs vary with mobilization costs, hole depth, site access, condition of site, drill on or off site, hole condition, diameter, hole fluid, background physical properties, ambient noise, hole orientation relative to vertical cultural effects, facilities at hole, temperature and weather, method, contractor, type of accessory equipment, and number of holes to be logged. With careful planning, a reliable contractor and adequate equipment the data in Table 4.4.4 should apply.

Another approach to cost estimation is to allow $500 per day for operator and equipment, adding the cost of laborers and mobilization. On a per line-mile (line-kilometer) or per day basis, costs should be less but may be approximately of the same order of magnitude.

Chapter 4.5
GEOCHEMICAL AND OTHER PROSPECTING TECHNIQUES

J. ALAN COOPE

4.5.1 GEOCHEMICAL SURVEYS

4.5.1.1 Definition

Exploration geochemistry, or geochemical prospecting, includes any method of mineral exploration based on the systematic measurement of one or more chemical or chemically influenced properties of a naturally occurring material. The property measured is most commonly the trace concentration of some chemical element or group of elements. It may also include molecular and isotopic compositions and bacterial counts. The naturally occurring material may be rock, soil, stream sediment, glacial sediment, surface water, groundwater, vegetation, microorganisms, animal tissues, particulates, or gases including air.

4.5.1.2 Geochemical Cycle

Chemical elements, including the ore metals, are unevenly dispersed throughout the lithosphere and are continuously being cycled and redistributed under the influence of the earth's dynamic geological processes. The *geochemical cycle* (Fig. 4.5.1) diagrammatically illustrates the complex physiochemical changes and the variety of pathways that earth materials and their contained elements follow in response to these processes. It conveniently defines the major *deep-seated* and *surficial* geochemical environments.

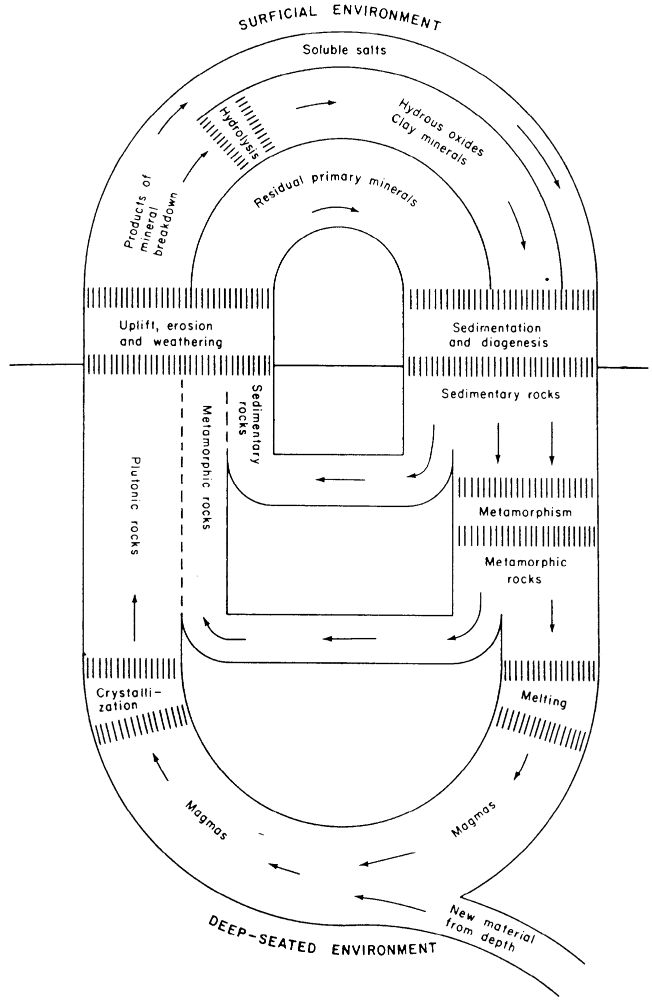

Fig. 4.5.1 Geochemical cycle (Rose et al., 1979).

4.5.1.3 History of Geochemical Prospecting

It is clear from historical records that the principles of geochemical exploration have been applied in prospecting over several thousands of years (Chapter 1.1). The prospector who panned for gold and traced the colors upstream to a bedrock source used mineralogical observations in a similar way to the modern geochemist, who utilizes sensitive chemical analyses to outline patterns of dispersion in the surficial environment. Boyle (1987) describes the working of placers for gold in the Preclassical Period. Geobotanical indicators were recognized as early as the 8th and 9th centuries (Boyle, 1967). The mid-16th century works of Biringuccio and Agricola describe the analysis of natural waters, springs, and their residues (Hawkes, 1957; Boyle, 1967).

Levinson (1974) records that modern methods of exploration geochemistry were first used in the early 1930s in the Soviet Union. Shortly thereafter, the methods were applied in the Scandinavian countries, particularly Sweden.

In North America, the earliest geochemical surveys were carried out between 1938 and 1940 by Lundberg in Newfoundland and in 1944 by Warren in British Columbia (Brummer et al., 1987). The first comprehensive geochemical exploration studies commenced at the US Geological Survey under the leadership of H. E. Hawkes in 1947 and at the Geological Survey of Canada with R. W. Boyle in the early 1950s. The Applied Geochemical Research Group was established at the Imperial College of Science and Technology in London in 1954 under the direction of J. S. Webb, and in France, research related to exploration geochemistry began in 1955.

The successful application and adaptation of geochemical exploration techniques in all parts of the world, the rapid development of analytical and computer technology, and improvements in field transportation have made geochemistry one of the more effective and widely applied exploration disciplines. Analytical capability is such that relatively rapid, sensitive analysis can be achieved for virtually all metals of economic interest. Continuing research is expanding our established capability to cost effectively detect and interpret dispersion patterns related to mineral deposits in a wide variety of often complex environments.

Through multielement analysis, geochemical data can reveal multiparameter signatures related to distinct geological units and processes. This capability, when applied to rock samples, permits geological correlation as well as the more precise delineation of otherwise invisible alteration features related to mineralization. When applied to soil and other types of samples, multielement data can help outline major geological units and identify

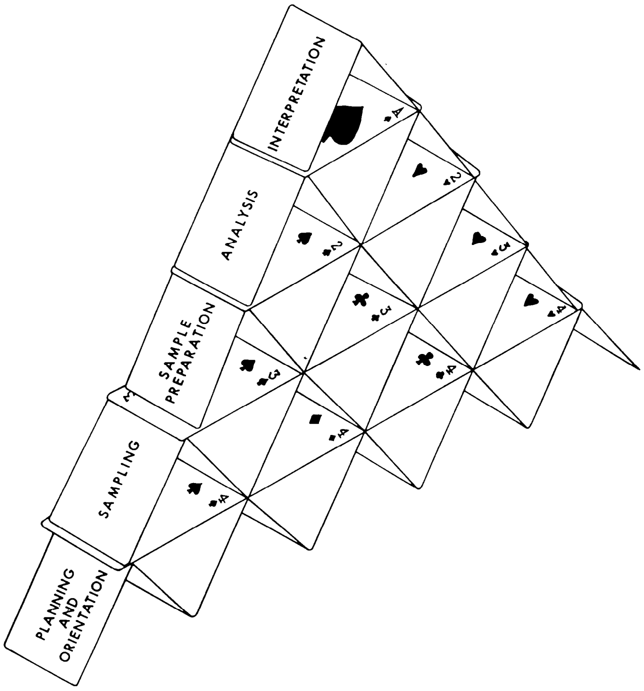

Fig. 4.5.2. The stages of exploration geochemistry related to a "house of cards" (modified after Lavin et al., 1986).

the presence of mineralization buried under extensive cover (Hoffman, 1987).

4.5.1.4 Geochemical Prospecting Methods

The various components of a geochemical exploration program can best be understood by reference to the "house of cards" (Fig. 4.5.2). This model clearly indicates the importance and interdependence of the various phases of a geochemical survey. Good design and planning (including orientation) and well-conducted sampling programs constitute the foundation of all sound geochemical exploration work (Closs and Nichol, 1989). Inappropriate sample preparation prior to analysis can destroy the integrity of the well-chosen sample. It follows that no matter how accurate and precise the techniques used for analysis or how advanced the statistical treatments and computer programs used for data handling and interpretation, this cannot resurrect the lost quality and representativity and restore the decreased probability of exploration success caused by poor planning, improper field sampling, or faulty sample preparation.

It is convenient to categorize geochemical prospecting methods into those utilizing sample media from (1) the surficial environment and (2) the deep-seated environment.

4.5.1.5 The Surficial Environment

Reference to the geochemical cycle (Fig. 4.5.1) indicates that the surficial environment is characterized by the processes of weathering, erosion, transportation, sedimentation, and diagenesis. In geochemical exploration practice, the overwhelming majority of samples are collected from media in this environment.

Experience has confirmed that the success of a geochemical survey in the surficial environment depends largely on the correct assessment of all the natural factors that influence the mobility and dispersion of the metallic elements of interest. These natural factors, which are described more fully in textbooks by Rose et al. (1978) and Levinson (1974; 1980), are (1) the physical and chemical properties of the elements or parameters of interest, (2) the nature of the geology and mineralization, (3) the geomorphological history of the field area, (4) the vegetation, and (5) the topographic and climatic conditions.

These factors are completely interrelated and any change in one condition—such as a geologic change from an acidic to a basic environment, a local climatic change caused by elevation or a topographic change from rolling to mountainous terrain-can significantly influence mobilities and the extent of the dispersion from any mineralization type. Consequently, procedures for sampling, sample preparation, and analysis that proved to be satisfactory in one field area may be inadequate and unreliable in an adjacent region.

The processes of oxidation, weathering, erosion, transportation, sedimentation, and diagenesis that characterize the surficial environment are much too complex to describe in detail in this summary. The physiochemical conditions determine whether the weathering products of mineralization disperse either in solution in a *hydromorphic* form or in a solid or *clastic* form. The low pH, high Eh conditions of the acid weathering environment (e.g., oxidizing massive sulfides) promotes the solubilization of many base metal and other elements and their more widespread hydromorphic dispersion in surface and ground waters. Alkaline conditions developed over a weathering limestone or in a semi-arid climatic condition prohibit or arrest this hydromorphic dispersion. In these conditions, the insoluble metal particles disperse mechanically to form clastic patterns. Figs. 4.5.3 through 4.5.6, (Rose et al., 1979) illustrate how clastic and hydromorphic dis-

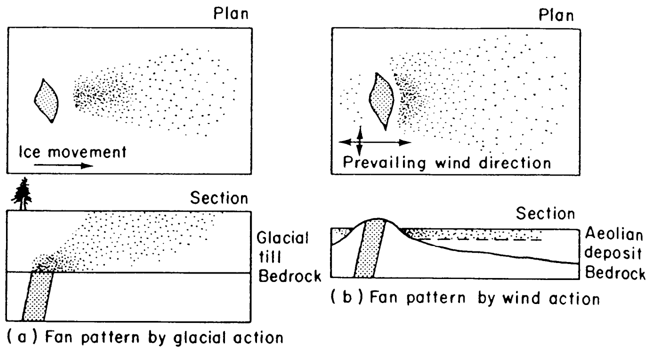

Fig. 4.5.4. Syngenetic (clastic) patterns in transported overburden (Rose et al., 1979).

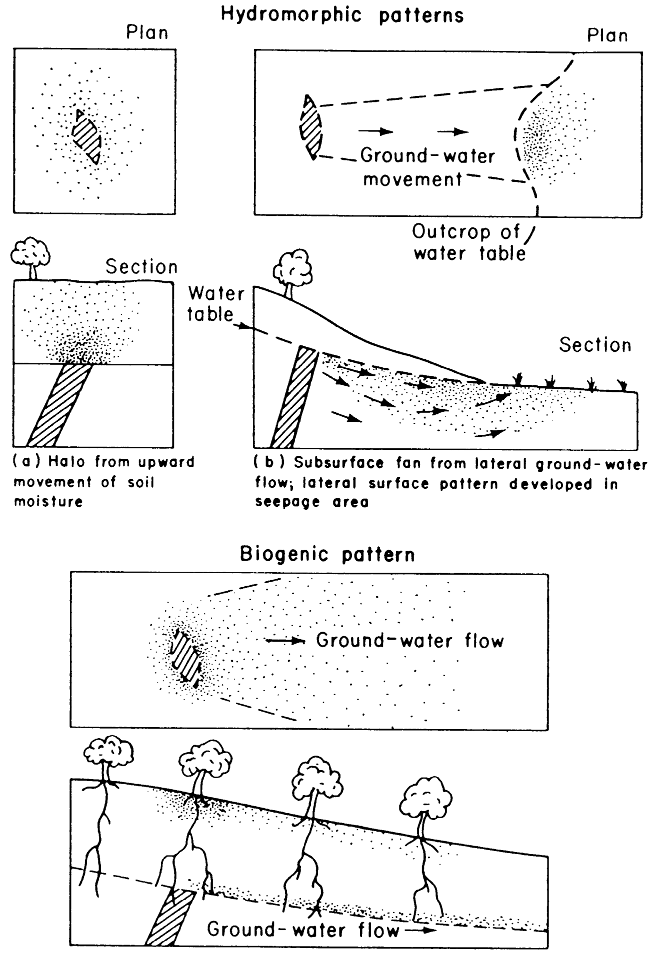

Fig. 4.5.6. Epigenetic patterns in transported overburden. Similar dispersion may also contribute to patterns in residual overburden (Rose et al., 1979).

persion can form syngenetic and epigenetic patterns in residual and transported overburden as well as providing one example of *biogenic* dispersion through the activity of vegetation. In some situations, *gaseous* dispersion can occur (e.g., radon escaping from a uranium deposit or SO, and other sulfur gases released during active oxidation of sulfides).

A general guide to the relative mobility of the common metallic elements under a variety of environmental conditions is shown in Table 4.5.1. A series of publications sponsored by the Association of Exploration Geochemists develops conceptual models based on conditions in Canada (Bradshaw, 1975), Scandinavia (Kauranne, 1976), the Basin and Range (Lovering and McCarthy, 1978), and Australia (Butt and Smith, 1980) that describe the principles and mechanisms of formation and configuration of anomalies and dispersion patterns revealed through geochemical exploration surveys in these regions.

The Orientation Survey: When contemplating a geochemical survey in a new region, the most reliable method of determining the extent and nature of dispersion patterns is to conduct an *orientation survey.* The objective of orientation sampling is to determine and outline the existence and characteristics of dispersion patterns or anomalies associated with mineralization and also background levels in similar environmental conditions. The specific sample media used are dependent on a knowledge of the field area, the prospecting problem, and, if available, previous experience, but may include any of the following: soils, stream sediments, surface waters, groundwaters, glacial sediments, lake sediments, rocks, vegetation or mull, gases or air, particulates, animal tissues, microorganisms.

The orientation survey commonly involves the collection of a number of relatively closely spaced samples over and in the vicinity of known, but preferably undisturbed, mineralization with the express purpose of outlining the dispersion patterns in the available sampling media. This information can then be used to select the most reliable sampling, sample preparation, and analytical techniques capable of detecting similar anomalies under similar environmental conditions. The detailed examination of the nature and shape of the dispersion patterns invariably yields information on the principal natural factors responsible for the observed distribution of anomalies. This is a significant aid in the development of interpretation procedures.

The accompanying table (Table 4.5.2) is a synthesis of the important parameters that can be derived from a properly planned and executed orientation survey. Based on this information, the optimum physical parameters (e.g., sample depth, sam-

Table 4.5.1. Relative Mobilities of the Elements in the Surficial Environment

Relative mobilities	Environmental conditions

ple interval, analytical technique, etc.) for routine surveying can be chosen that necessarily take into account the defined dispersion characteristics as well as the physical, logistical, and economic conditions pertaining to the project. Large samples should be taken to provide sufficient material for the full evaluation of the parameters listed in Table 4.5.2 and representative samples should be collected from nonmineralized areas to adequately define background conditions. Recommended procedures for orientation sampling, sample preparation, and analysis are outlined by Bradshaw (1975).

A survey conducted over gold-silver vein mineralization at Mt. Nansen in the Yukon Territory (Coope, 1966) illustrates the application of the orientation approach. Detailed profile sampling of soil and overburden exposed in a trench across virgin mineralization produced patterns of lead, antimony, and zinc as illustrated in Fig. 4.5.7. It is apparent from these patterns that the dispersion behavior of lead and antimony is similar but quite contrasting with the patterns for zinc. All metals have been influenced by downslope movement in the overburden, but the zinc pattern is compatible with dispersion in solution along the bedrock surface. Examination of the patterns also indicates that near-surface sampling (0 to 12 in., or 0 to 300 mm) would not reliably indicate the mineralized vein. It was concluded that a sample depth of 18 to 24 in. (460 to 610 mm) and a sample interval of one-half the anomaly width at this depth (15 ft or 5 m) were the optimum parameters necessary for routine surveying (Fig. 4.5.8). Observation of these sampling criteria led to the discovery of several, previously unknown veins.

The soil profile interval in an orientation survey over more extensive types of mineralization will be proportionately larger than the intervals chosen for narrow-vein type mineralization.

A stream sediment orientation survey can define the appropriate sample interval for reconnaissance surveying. In the example illustrated in Fig. 4.5.9, closely spaced samples were collected

Table 4.5.2. Parameters to be Derived from a Properly Planned Orientation Survey

Rock	Soil	Sediment	Water	Biogeochemical	Gas
Shape, extent, reproducibility, homogeneity, and controls of geochemical patterns (Rock to Gas)					
Most suitable indicator elements and best analytical methods (Rock to Gas)					
Reproducibility of sampling and analysis (Rock to Gas)					
Sampling pattern and density (Rock to Gas)					
Amount of sample required (Rock to Gas)					
Required field observations (Rock to Gas)					
Possible contamination sources (Rock to Gas)					
	Effects of topography, drainage, vegetation, geology (Soil to Gas)				
	Seasonal or temporal variations (Soil to Gas)				
	Optimum sampling depth or horizon (Soil and Sediment)				
	Optimum sampling fraction (size, heavy minerals, organic fraction) (Soil and Sediment)				
Sample material (rock,vein,etc)	Nature of overburden (Residual vs transported) (Mechanism and direction)	Correlation with Fe-Mn oxides	Optimum material (ground or surface)	Optimum species (distribution, ease of anomaly recognition, ease of sampling, and depth of root system)	Effect of soil type Effect of soil depth
Type of sample (grab, channel, etc)	(Soil profile development) (Depth variation of indicator elements)	Correlation with organic matter	Control of water flow Difference in aquifers		Effect of soil moisture
Effects of weathering					
Effects of alteration			Relation to recharge areas	Part of plant to be sampled	
Applicability of mineral separations (sulfides, biotite, limonite, calcite, etc)			Variation with depth	Effect of aspect (sunlight, shading) (Biogeochemical and Gas)	
			Variation with type of lake

both upstream and downstream of known molybdenum mineralization. With increasing distance from the deposit, the sample interval was progressively increased. Subsequent analytical results indicated the background level for molybdenum in the –80-mesh stream sediment fraction was 2 to 3 ppm Mo and that anomalous values extend downstream in the tributary sediments for approximately 1.2 mi (2.0 km) prior to being diluted by the background sediments in the main stream. In this area, therefore, sampling along the drainages at half this anomalous distance (0.6 mi or 1 km) with mandatory collection in each drainage immediately upstream of each tributary junction will satisfactorily indicate the presence of similar, or more extensive, molybdenum occurrences in a routine reconnaissance survey.

The sample intervals employed in stream sediment orientation surveys will vary according to the anticipated size of the target mineralization and the dispersion characteristics of the metals of interest. In areas where no previous experience exists, a short interval of 150 ft (50 m) over an initial downstream distance of 1000 ft (330 m) is recommended. This interval should then be progressively expanded with distance from the metal source to the limits of the known or anticipated dispersion pattern. Samples must also be collected from nonmineralized areas to establish the background range and sufficient material should be collected at each site to allow for the determination of optimum size fractions, analytical techniques, and other factors listed in Table 4.5.2.

Sample Collection and Handling: Effective sampling of all surficial media requires well-trained personnel capable of recognizing and describing the correct sample material and the sample site characteristics. Samplers should be able to recognize and, if possible, avoid situations where contamination from human activity or changes in the natural physiochemical conditions can

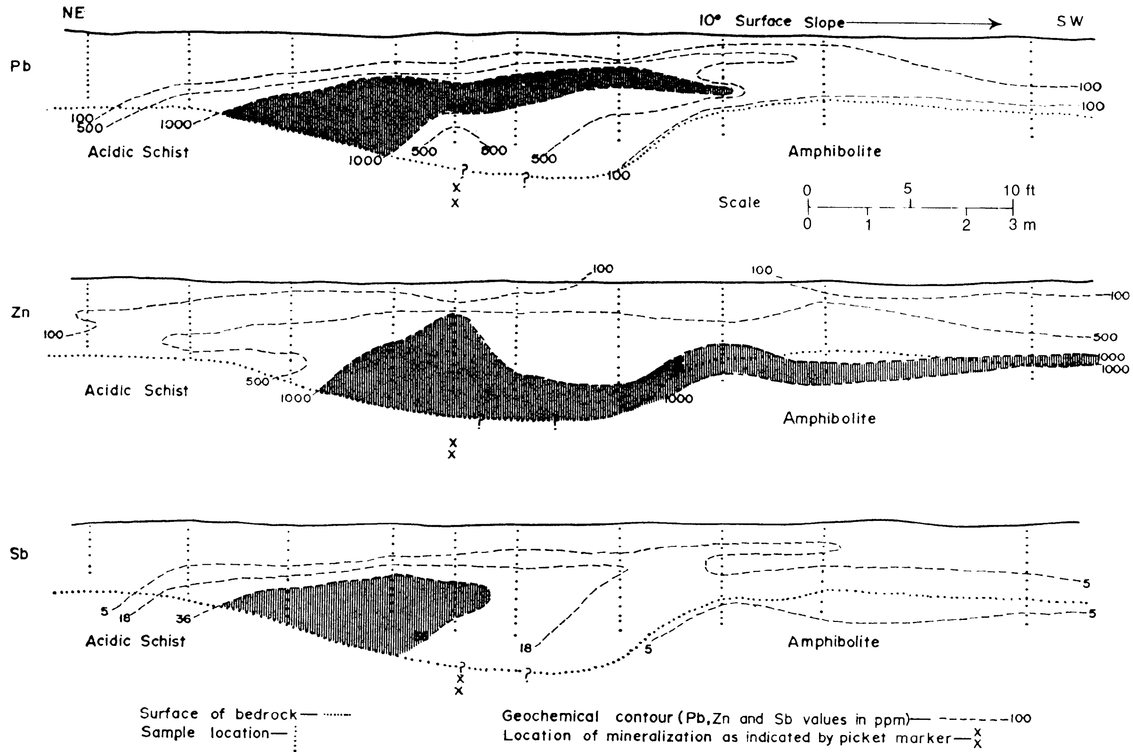

Fig. 4.5.7. Profile distribution of lead, zinc, and antimony over mineralized vein. Mount Nansen area, Yukon Territory (Coope, 1966).

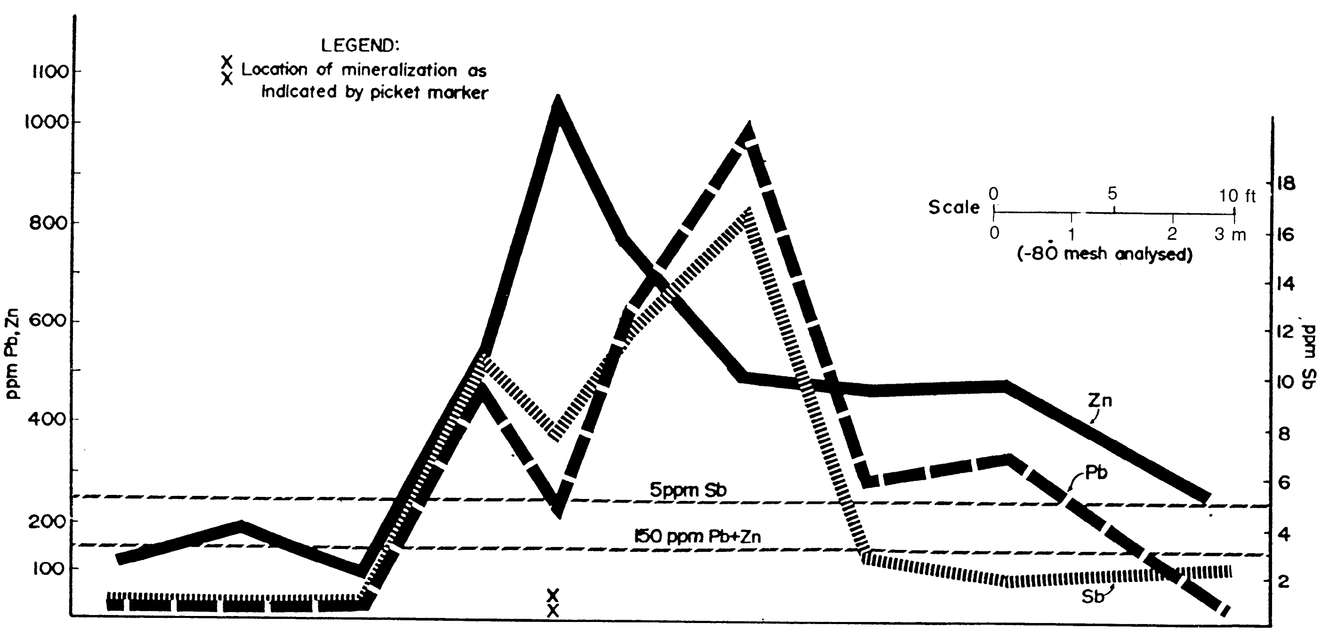

Fig. 4.5.8. Graphical representation of lead, zinc, and antimony over mineralized vein at 18- to 24-in. (460- to 610-mm) depth, Mount Nansen, Yukon Territory (Coope, 1966).

produce spurious or unusual results. In most situations, these sampling duties can be undertaken by trained technical personnel under the supervision of a geochemist or geologist with adequate geochemical exploration experience. In some surveys (e.g., where identification of the correct sample material is critical, as in biogeochemical or glacial till sampling programs), it is prudent

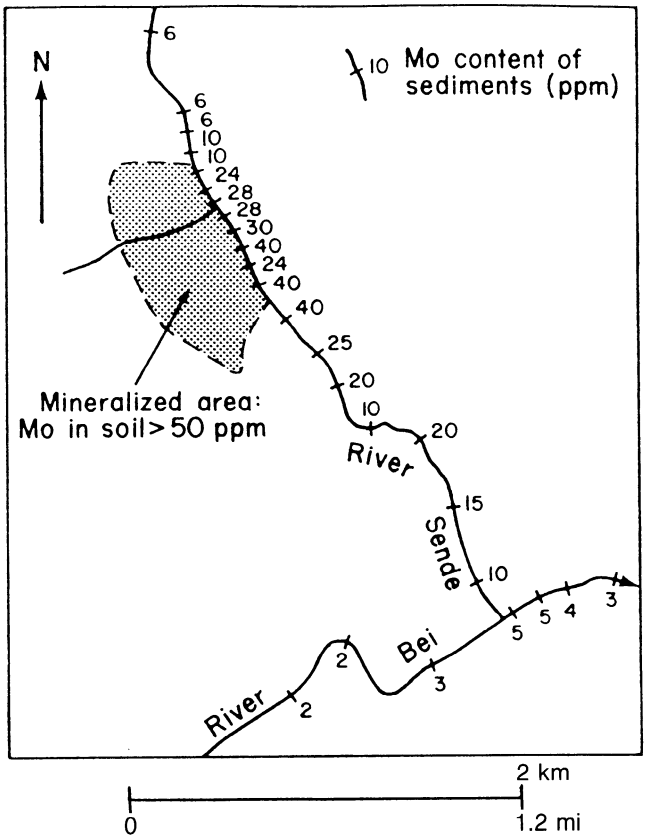

Fig. 4.5.9. Stream sediment survey of River Sende, Sierra Leone. Data on 80-mesh fraction (Rose et al., 1979).

to employ qualified specialists (e.g., botanists and Quaternary geologists) to conduct orientation surveys and instruct and supervise the sampling teams.

Sampling tools vary according to the medium and the field situation. Noncontaminating equipment is essential and care should be exercised in not only choosing noncontaminating steels for shovels, trowels, augers, etc., but in ensuring that lubricants and adhesives, weldings, and solders are metal-free too. This awareness of geochemical cleanliness extends to the dress of the sampler who should avoid wearing metal buckles, rings, etc., and handling coins which might lead to contamination by chipping or transfer of metal on fingers.

The same caution is necessary in the choice of sample containers. Kraft paper (with noncontaminating waterproof glue and closures), olefin, and plastic bag containers of appropriate size are frequently used. Kraft and olefin allow samples to be dried without transfer. Plastic bags are commonly used for larger samples. More rigid polypropylene and special glass bottles can be utilized in water sampling and a variety of sampling devices, many of them patented, are available for the sampling of gases and particulates.

Sample Media:

Soils—Soils vary considerably in composition and appearance according to their genetic, climatic, and geographic environment. Classified into residual and transported types according to their relationship to their substrate, soils are mixtures of mineral and biologic matter and may be distinctively differentiated into a series of soil horizons. Residual soils characteristically contain detectable dispersion patterns developed during the weathering of mineralization in the underlying bedrock, and these patterns are revealed by careful sampling of appropriate soil horizons. Transported soils present more difficult sampling problems, but meaningful sampling is possible in many areas once the genetic origins of the transported cover are understood.

With all but a few exceptions, soils are sampled along traverses or grids in the follow-up or detailed prospecting stage of a geochemical program. Orientation programs define criteria such as sample depth or soil horizon to be sampled, sample interval, and the size fraction for analysis. It is essential that these criteria be observed resolutely through the survey.

Stream Sediments and Waters—Stream sediment is one of the more commonly used media for geochemical reconnaissance surveys. The sediment at any point in a stream is a natural composite sample of erosional materials from upstream in the drainage basin and will include clastically, hydromorphically, and biogenically derived products from weathering mineralization. The length of anomalous dispersion trains will vary with the nature of the mineralization, source, and the physiochemical environment of the field area or drainage basin. In humid, actively oxidizing environments, dispersion trains from sulfide-rich base metal deposits may extend downstream for several miles.

Active stream sediment—that material constantly or most frequently washed by stream waters—is collected from the center of a drainage avoiding sites that may be contaminated or influenced by bank collapse. In most survey programs, approximately 500 to 1000 g (1.1 to 2.2 lb) of fine-grained material is collected from the upper few inches (tens of millimeters) of the sediment. Larger samples from deeper in the stream bed are collected from carefully selected sites if heavy minerals are to be examined. In all surveys in new areas, the critical parameters of sample interval, sediment size fraction, appropriate analytical procedures, significant anomaly contrasts, and background levels are determined through orientation surveys.

In the regional reconnaissance prospecting mode, stream sediment surveys can be designed to systematically cover areas up to several hundred square miles. Anomalous indications of mineralization can be followed up with more detailed sediment sampling to pinpoint source areas in more detail. Follow-up sampling of seepage areas is particularly effective in delimiting anomalous groundwater sources containing metal derived from oxidizing mineralization. If appropriate, soil sampling can be used to define suboutcropping mineralization in the anomalous source areas defined by the sediment survey.

Regional reconnaissance can also be achieved by sampling the waters of actively flowing streams where metal is dispersing in solution. A prospecting approach similar to the sampling of stream sediments is necessary, collecting waters in clean 500 or l000-mL (0.13 to 0.26-gal) polypropylene or glass bottles. Sampling of groundwater seepage sites is an integral part of stream water surveys. A few milliliters of acid is routinely added to the water samples after collection to keep the dissolved metals from adhering to the bottle walls. pH, conductivity and certain other measurements are commonly made at the sample site.

Lake Sediments and Waters—Lake sediments and lake water sampling have been developed into effective geochemical reconnaissance techniques in areas of Canada and Scandinavia where lakes are common, conditions are swampy, and/or where stream drainages are inaccessible or poorly developed. In low-relief regions, the lake sediment medium is dependent on the hydromorphic dispersion of metals into the lake environment through groundwaters and the adsorption of this metal onto hydrous oxides and the organic-rich muds being deposited on the lake bottoms. The sampling focuses on the collection of these organic muds using specially designed sampling devices. In more mountainous areas, fine-grained clastic dispersion into the lake sediment becomes a more important factor. In all areas satisfactory sample locations are found well away from lake shores and are reached using boats, float planes, or helicopters. Lake waters are commonly collected at the same sites as the lake sediments.

The lake sediment technique has successfully indicated the presence of uranium mineralization in Saskatchewan and base metal mineralization in the Northwest Territories, the Appalachians, and British Columbia (Coker et al., 1979).

Glacial Deposits—Extensive Quaternary glacial deposits occurring over most of Canada and the northern United States, northern Europe, and northern Asia have presented major challenges to exploration. As a better understanding of the origin and formation of these glacial sediments has grown, their blanketing presence has become progressively less formidable and effective exploration techniques have been developed.

Mineralized boulder tracing in glaciated regions is an established technique of the traditional prospector in Scandinavia and parts of Canada. In Scandinavia, dogs have been trained to assist the prospector by sensing SO_2 released from oxidizing sulfide boulders at shallow depths below the surface. In Finland, methods were developed for sampling tills in the 1950s, and this technique is now the preferred sampling method in most Finnish geochemical exploration programs. Esker sampling and till sampling for distinctive heavy mineral suites have been used for kimberlite and diamond prospecting in the Canadian Shield.

Approximately 70% of lodgement till is locally derived, and most of the early success with till sampling was in areas of shallow till cover (less than 30 ft or 10 m) where the sample medium is reasonably accessible. In the 1960s, lightweight percussion drills such as the Pionjar and Cobra models, were adapted to collect small samples of till from immediately above the suboutcropping bedrock to geochemically categorize anomalous geophysical features at depths of up to 70 to 80 ft (21 to 24 m) (Gleeson et al.,1971). Overburden drilling technology, particularly reverse circulation and sonic drilling, advanced rapidly with the utilization of larger drills in programs for uranium and gold deposits in glaciated areas. Because most types of gold deposits are not detectable by conventional geophysical methods, lodgement till sampling using overburden drills to depths of 330 ft (100 m) has been routinely used in prospecting for gold in the Canadian Shield through the 1980s. Large samples of till (approximately 20 lb or 10 kg) are recovered in these programs from which the heavy mineral fraction is separated and examined both visually and chemically for gold and other metals. The correct interpretation of these data is dependent on an understanding of the till stratigraphy and provenance of the transported material. The technique is expensive, with combined drilling, sample treatment, and analytical costs ranging from \$20 to \$30/ft (\$66 to \$98/m), but it is cost effective in this deep overburden-covered environment where other exploration methods have not been as successful in gold exploration. At least four significant gold deposits have been discovered in Canada by these overburden drilling methods.

In contrast with the heavy mineral sampling of tills practiced in Canadian exploration, Scandinavian explorers place a greater reliance on the 63-μm (–240-mesh) fraction of till. This fraction has successfully indicated the presence of several types of mineralization including gold.

Rocks—Rock sampling or lithogeochemical surveys in the surficial environment comprise systematic sampling of outcrops, trenches, drill cores, or cuttings within the zone of oxidation and weathering.

As with other types of geochemical surveys, the sampling procedures and the sample material collected in lithogeochemical work should be standardized as much as possible. However, considering the large number of variables that can be introduced by the processes of weathering and oxidation, the ideal of collecting similarly weathered material is sometimes impractical. Nevertheless, the geologist or the geochemist conducting the survey should ensure that individual samples at all sample sites are essentially comparable and that observed variations in weathering intensity are properly recorded for interpretation purposes.

Lithogeochemical sampling necessarily must take into account the geological environment and the type of mineral deposit of interest to the explorer. Very briefly, *syngenetic lithogeochemical patterns* can develop, for example, (1) in intrusives genetically associated with specific mineral deposit types, or (2) in volcanic stratigraphy where exhalative activity has dispersed detectable quantities of metals during the formation of volcanogenic massive sulfide deposits, or (3) in the vicinity of sedimentary deposits. The scale of sampling necessary for detection of these and other types of syngenetic genetic patterns will be determined by orientation surveys but may include the regional sampling of individual plutons or more detailed sampling of specific parts of an exposed stratigraphic section.

Epigenetic lithogeochemical patterns can develop in diffusion aureoles in the rocks hosting epigenetic mineral deposits, or as leakage aureoles along fractures and other structures that mark the pathways followed by hydrothermal or groundwater fluids prior to and subsequent to the deposition of the significant mineral deposits. Both these processes introduce the concept of mineral zoning of geochemical aureoles. The ratios of the different elements introduced during the mineralization period varies with distance from the principal deposit in accordance with the properties of these elements and the host rocks and the physiochemical conditions at the time of deposition. Leakage anomalies can extend for hundreds of feet or meters from a deposit whereas diffusion anomalies rarely exceed 100 ft (30 m). Several texts—Rose et al., (1979), Levinson (1974, 1980), and Govett (1983)—provide more detailed discussion and case histories of lithogeochemical surveys. The scale of dispersion, the presence of zoning patterns, and the sampling parameters for epigenetic geochemical patterns are determined by appropriate lithogeochemical orientation surveys.

It is clear that surveys designed to detect leakage anomalies will focus on a standardized collection of fault or fracture zones and, possibly, bedding structures. In contrast, the preferred lithogeochemical sample material for the detection of diffusion haloes is likely to be unfractured and the scale of sampling much more detailed. In all instances, geochemical analysis of lithogeochemical material has the potential of delimiting dispersion patterns associated with mineralization beyond visible alteration.

Vegetation and Humus—Early scientific observers dating from the 8th and 9th centuries recorded that the morphology and distribution of certain plants were affected by the presence of metals in the soils. Such visible variations in a plant species are referred to as *geobotanical indicators*. Many other plants, while not showing any visible variations, are capable of concentrating metals in their tissues and the presence of anomalous metals in the soils or groundwaters is often reflected in the metal content of leaves, twigs, or other plant organs. These invisible metal concentrations are known as *biogeochemical indicators* (Brooks, 1972).

The seasonal fall of leaves and needles transfers some of the accumulated metals to the surface soil where they are incorporated in the humus layer. Sampling of this *humus* (alternatively known as *mull, Ao,* or *Ah* material) by Scandinavians in the 1930s revealed its potential for geochemical prospecting. This is especially true in areas of transported material where the root penetration of the plant exceeds the thickness of this cover and

obtains nutrients from the underlying mineralized bedrock and groundwater.

In addition to the direct recognition of geobotanical indicators, the most attractive feature of vegetation sampling is the ability of biogeochemical and mull prospecting to "see through" thicknesses of barren transported overburden. Consequently, these techniques have been applied with varying success in glaciated regions of North America, Europe, and Asia and in areas like the southwestern United States where pediment, colluvial, and alluvial cover is extensive (Boyle et al., 1969; Chaffee, 1977).

Plants are complex organisms and so is their metabolism. Different species respond differently to the same conditions and, consequently, some species are more effective biogeochemical indicators than others. Deep-rooted plants (e.g., the mesquite) are much more effective prospectors of the deeper groundwaters than the shallow-rooted flora of the southwestern US deserts and are, therefore, preferred species in biogeochemical work. Nevertheless, shallow-rooted plants growing in transported cover may reveal meaningful patterns in some desert regions. Evapotranspiration has been suggested as a mechanism for movement of metals into the nutrient depth of these plants.

Some species preferentially concentrate metals in specific tissues such as leaves, twigs, bark, or wood. It is therefore very important to establish the most favorable tissues for sampling once a useful species has been identified. This complexity is accentuated by the fact that metal uptake may vary with aspect and degree of uptake commonly varies with the seasons (Table 4.5.3). In temperate forest regions, accelerated uptake and higher concentration commonly occurs during the spring growth following a dormant winter season. In hot desert regions, following the exhaustion of available near-surface water during the dry season, deep-rooted plants will tap the deeper, more metal-rich groundwaters.

These variables make biogeochemical sampling a very specialized exercise. The expertise of an experienced geochemist or botanist is essential during orientation studies and the supervision of vegetation surveys. Because of the seasonal variations, biogeochemical surveys must be completed quickly, and sampling in the spring and fall is generally avoided.

The same complexities do not affect the humus or mull medium. Dead tissues are not subject to seasonal variations and annual accumulation has an integrating effect. Weathering, leaching, and bacterial decomposition will work to diminish the metal contents, but signatures in mull are generally preserved. Dunn (1987) has pointed out that, with some species, sampling of bark (a dead tissue) can be an effective technique that is not subject to seasonal metabolic variations.

Animal Tissues—Animal tissues have not been used extensively as a geochemical medium. Warren et al. (1971) analyzed 96 trout livers from locations in British Columbia and identified a general correlation between the zinc and copper contents of these livers and known mineral regions. As part of an environmental monitoring program, the government of Ontario has sampled fish tissues for their mercury content. Recent work has investigated the use of the trace element content of bee pollen as an exploration tool. Variations in concentrations were noted showing a general relationship with known mineralization, but follow-up is complicated by the territorial wandering of the insects.

Microorganisms—Parduhn and Watterson (1984) and Parduhn et al. (1985) have demonstrated that the population of the common microorganism, *Bacillus cereus*, increases with natural increases in the base and precious metal content of soils in the vicinity of known mineral deposits. It has also been noted that the increased antibiotic resistance of these bacteria correlates with increased metal concentrations in soils (Watterson et al., 1986).

Gases and Air—Under certain conditions, mineral deposits produce gaseous emanations that can be detected by specialized measurements. Radon, for example, is produced during the radioactive decay of uranium and radium. Survey techniques measuring the alpha particle emissions during radon decay have been used extensively in the search for uranium. Helium is another gas produced during radiogenic decay and is considered by many to be also of deep-seated origin. Mercury-bearing minerals, which can include sphalerite and other sulfides, often release mercury vapor during oxidation. This vapor can be measured in soil gas directly or adsorbed mercury can be released from conventional soil samples by heating to 210° to 390°F (100° to 200°C) (Landa, 1978).

The oxidation of sulfides leads to the generation of SO_2, H_2S, and CO_2. Because of the consumption of oxygen in the oxidation process, the atmospheric proportions of CO_2:O_2 change in the vicinity of oxidizing sulfides and these imbalances can be measured in the soil gas.

Biogenic activity in the soil can produce CH_4, H_2, H_2S, and CO_2. Therefore, near-surface detection of these gases can be suspect. Methane is found at depth in several types of mines, but a genetic association with mineralization is not always clear. Recent studies in Sweden (Malmqvist et al., 1986) have identified an upward fluxing of GEOGAS in the near-surface sections of the earth. This GEOGAS enters the groundwaters as dissolved air. The circulating meteoric waters and changing pressure conditions in the subsurface cause the GEOGAS to rise as small streaming bubbles. The bubbles contain other gases and can also collect metallic ions and particles that can be trapped in collectors set out in the surface soil. Anomalous patterns in GEOGAS have been recorded over mineralization buried under thicknesses up to 100 ft (30 m) of transported cover.

Particulates—Solid particles down to the size range of large molecules are present in the atmosphere. Weiss (1971) developed an airborne geochemical prospecting technique in arid terrain for the collection of dust particles suspended in the atmosphere. The AIRTRACE and SURTRACE techniques of Barringer Research Ltd. have been designed to sample a variety of particulates in the lower atmosphere including spores, pollen, dust, microorganisms, organometallics, and hydrocarbon complexes. The collected particulates are analyzed using a laser pulse/inductively coupled plasma spectrometry (ICP) procedure in the laboratory. The same airborne platform can be equipped with a mercury sensor for real-time measurements. AIRTRACE has been successful in sensing gas and oil resources and has produced positive results over mineral deposits. Reproducibility of the technique in the search for mineral deposits is hampered by variable weather conditions and temperature inversions. The SURTRACE method is designed to overcome these climatic problems by sampling particulate matter from the surface microlayer of the ground using a helicopter-based or manually transported system.

Sample Preparation: Inappropriate sample preparation can completely nullify the careful work of the sampler who has invested time and expertise in the selection and collection of representative material. Furthermore, it is impossible to restore the integrity of the poorly prepared sample by enterprising analytical treatments and interpretational procedures.

Drying—Prior to mechanical treatment, nonlithified clastic and rock geochemical samples have to be dried. This can be achieved by exposure to the sun in some climates, but most samples are dried in drying ovens. Heating these ovens to temperatures in excess of 160°F (70°C) can lead to the loss of volatile elements that may be of value to the exploration program. Organic samples, including humus, may be dried in a conventional drying oven or in a microwave oven at temperatures not to exceed 160°F (70°C).

Sieving and Crushing—After drying, nonlithified clastic samples should be agitated and pounded to achieve complete separation of component particles without crushing. This can be done with a pestle and mortar or other suitable noncontaminating mechanical device that can be thoroughly cleaned between samples. In earlier geochemical prospecting work, orientation studies on soils, stream sediments, and other clastic materials revealed that the separation of — 80-mesh material for analysis was appropriate in many surveys. With some elements, such as those commonly concentrated in residual minerals and other elements dispersed in weathering products in arid/semi-arid environments, fractions coarser than 80 mesh give superior geochemical patterns with better contrasts. Some surveys in glacial till environments benefit from the analysis of the –240 mesh (63-μm) or even finer fractions (Shelp and Nichol, 1987). Careful size fraction analysis during orientation will not only indicate the most appropriate fraction for routine work, but the metal distribution throughout the sample reveals invaluable information on metal behavior for interpretation purposes. Sieves must have a noncontaminating composition. Those most frequently used are made from stainless steel or nylon mesh.

Heavy Mineral Separations—Heavy mineral separations from stream sediment, glacial till, and rock samples commonly utilize the liquids tetrabromoethane (sp gr 2.9) and methylene iodide (sp gr 3.3). Solutions of sodium polytungstate, with specific gravities ranging from 1.0 to 3.1 according to dilution, can also be used. Usually these liquid separations are carried out on coarser sample size fractions (e.g., -30 + 80 mesh), but separations can be made on material down to 200 mesh if the metal of interest is present in the finer size fractions. If necessary, heavy mineral concentrates can be further subdivided by electromagnetic separation into magnetic, paramagnetic, and nonmagnetic fractions.

Vegetation Samples—Ideally, *vegetation* and *humus samples* should contain no clastic material. Dust on leaves and twigs can be removed by rinsing with demineralized water, but humus material is rarely 100% organic. The presence of excessive clastic material (1) may dilute or contaminate the metal content of the organic material, and (2) adversely interfere with lower detection limits possible on organic material using the neutron activation analytical technique.

After drying at temperatures of less than 160°F (70°C) in a standard drying or microwave oven, vegetation samples are macerated in a Wiley Laboratory Mill to a –2-mm mesh size. This material is compressed into either 8.0- or 30.0-g pellets for direct analysis by neutron activation or can be ashed in a muffle furnace at 842° to 878°F (450º to 470°C) for approximately 15 hr. The plant ash is then analyzed in a similar manner to clastic sample material.

Rock Samples—Some surveys call for the analysis of specific minerals in rock samples. Such minerals may include magnetite, biotites, feldspars, and sulfides that may be concentrated by magnetic separation or with heavy liquids from the most suitable size fraction, after appropriate sample treatment.

Most rock samples collected in geochemical programs are analyzed for their whole rock or trace element contents. This requires crushing and pulverizing and, if the contained metals of interest are heterogeneously distributed (e.g., as with coarse gold), the principles of sampling theory must be observed. The pulverized whole rock product that is commonly analyzed has a grain size of less than 150 to 200 mesh. The sample is rarely reduced to this fine grain size in its entirety, but, as a general rule, the finer the sample can be crushed or ground prior to sample splitting, the more representative the split is likely to be. The emphasis on gold exploration in recent years has focused attention on sample heterogeneity. This has stimulated some significant developments in the design and adaptation of crushing and grinding equipment for improved sample preparation. In addition to sample representativity, the geochemist must be concerned with sources of contamination in the sample preparation equipment. Grinding plates and blades of different composition are available so that the obvious contamination from chrome steel, tungsten carbide, and other materials can be avoided. Similarly, loss of sample representivity through "smearing" of native copper, native gold, molybdenite, or other soft material on pulverizer plates can be avoided in many instances by the selection of alternative equipment with a different comminuting action.

Since sample weights analyzed in geochemical work are small (0.1 to 50 g or 0.0002 to 0.1 lb) compared with the original sample size, sample homogeneity is very important. Improved mixing can be achieved, when necessary, by careful blending and the pulverization of coarser fractions to the –200-mesh size.

4.5.1.6 The Deep-Seated Environment

Geochemical sampling in the deep-seated environment as defined in Fig. 4.5.1 is, primarily, rock or lithogeochemical sampling beyond the influence of surficial processes. Sample material is necessarily obtained from deeper underground workings or from drill cores. Syngenetic and epigenetic patterns of primary dispersion (see discussion of rocks) are the targets of such sampling and the sample selection, analysis, and data interpretation is often directly related to the current understanding of the genesis of the mineral deposit type of interest.

Gases, particularly helium, and other fluids, circulate in the deep-seated environment. Several surveys measuring helium in the near-surface (Eremeev et al., 1973) have been interpreted as

Table 4.5.4. Comparison of Some Characteristics of Analytical Methods

Method[a]	Capital, $	Multielement	Determinations per day	Comments
Colorimetry	1×10^3	No	20-100	Very simple; adaptable to field
AAS	2×10^4	No	500	Easy to set up; several elements can be determined on same solution but not simultaneously
ICP	$1\text{-}3 \times 10^5$	Yes	> 2000	Needs skilled analyst to supervise; computer; sample in solution
XRF	$1\text{-}5 \times 10^5$	Yes	> 1000	Needs skilled analyst to supervise; computer; analyzes solid sample
INAA	$0.8\text{-}20 \times 10^6$	Yes	> 3500	Needs skilled analyst to supervise; computer; analyzes solid or liquid sample

reflecting patterns related to the passage of the gas along deep-seated structural features in the earth's crust.

Widely spaced sampling of tills (one sample per 300 km^2 or 115 mi^2) in Finland has revealed patterns of elements believed related to deeper crustal features not immediately apparent from a study of the geological maps (Bjorklund, 1989). These Finnish surveys are illustrated in the segment 4.5.1.9. It is quite possible that these maps are highly significant in indicating how sampling of surficial materials can outline important structural patterns in the deeper crust. Such structural patterns very likely have influenced the migration of mineralized fluids and the crustal distribution of mineral deposits.

4.5.1.7 Analytical Techniques

A prime requirement for cost-effective geochemical exploration surveys is the availability of analytical procedures capable of high productivity, low detection limits, high precision, and acceptable accuracy. These criteria were met, in the 1950s, by a series of colorimetric analytical techniques with man-day productivities ranging from 20 to 100 samples per day. Technological developments have subsequently led to the introduction of atomic absorption spectrophotometry (AAS), inductively coupled plasma spectrometry (ICP), X-ray fluorescence (XRF), and instrumental neutron activation analysis (INAA) and a vastly increased productivity (Table 4.5.4). Along with the multielement capability of ICP, XRF, and INAA, these techniques provide accurate, precise determinations with detection limits of less than 5 ppb to 1 ppm for many of the elements commonly measured in exploration geochemical surveys. The inductively coupled plasma-mass spectrometer (ICP-MS) instrument is capable of even greater sensitivity, and other techniques including direct-current plasma (DCP), and ICP-atomic fluorescence analysis (ICP-AFS) are particularly well-suited for some element groups. The dc-arc emission spectrograph is still used for some geochemical work, but the method has lost ground to the other techniques that have been described.

In the minds of the inexperienced, the spectacular analytical capabilities of these instruments often overshadows the critical importance of the sample preparation and sample decomposition stages of sample treatment.

Table 4.5.6. Comparison of Six Stream-Sediment Analyses for Nickel

	Preparation		Digestion	Ni, ppm
	Crushing	Fraction		
Lab A	no	– 80	70% $HClO_4$	20
Lab B	no	– 80	1:3 HNO_3	60
Lab C	no	– 80	HNO_3/HCl	150
Lab D	no	– 80	1:1 HCl	320
Lab E	yes	–100	1:1 HCl	14
Lab F	no	–100	1:1 HCl	1120

Sample description: Stream sediment with 0.5% magnetite; magnetite contains an average of 0.28% Ni; 80% of magnetite is -80 mesh; 99% of sample is + 100 mesh and 96% is +80 mesh.
Source: Fletcher, 1987.

It was emphasized in the preceding section on sample preparation, that the most informative fraction of a geochemical sample may be the heavy mineral fraction, a relatively coarse fraction (– 30 + 80 mesh), a fine fraction (– 80 mesh), or a very fine fraction (– 240 mesh), depending on the material being analyzed or the particular property of interest in a sample. If an improperly chosen solid sample material is correctly analyzed by the XRF or INAA instruments, the results can be no better than mediocre in the context of the exploration program and may even be misleading.

Sample decomposition presents even greater complexities. The ICP and AAS methods require that elements of interest be introduced to the instruments in solution. This requirement can create both difficulties and opportunities.

The choice of method to take elements into solution requires careful consideration of the mineralogy of the material. Strong decompositions of a geochemical sample can be achieved through treatment with hot concentrated acids or by fusion. Some resistant minerals (e.g., chromite) may not be soluble in

Table 4.5.7. Summary of Decomposition Techniques

Decomposition	Reagents
Fusions	
acid fusions	$KHSO_4$, $K_2S_2O_7$
ammonium halide sublimations	NH_4I, NH_4Cl
alkaline fusions	Na_2CO_3, NaOH, $LiBO_2$, LiB_20_7
oxidative-alkali fusions	Na_2CO_3 or NaOH with KNO_3 or NA_2O_2
Acid digestions	
Hot strong mineral acids	$HF\text{-}HNO_3\text{-}HClO_4$, $HF\text{-}HClO_4$, $HF\text{-}HNO_3\text{-}HCl$
Partial decomposition	
Hot strong mineral acids	HF, $HCl0_4$, $HN0_3$, HCl, HBr, Aqua Regia
Partial digestions or leaches	
Nonselective extractions	
cold dilute inorganic acids:	0.1-1 *N* HCl
organic acids:	acetic acid (pH 5.5) oxalic acid
buffers:	NH_4-citrate NH_3OH (pH 2-8)
chelating agents:	0.05-0.25 *M* EDTA (pH 4-7) NH4-citrate-hydroxylamine hydrochloride (pH 8.5)
Selective extractions	
exchangeable metals:	NH_4-acetate; $MgCl_2$, $CaCl_2$, $BaCl_2$
organic matter:	H_2O_2; NaOCl; $Na_4P_2O_7$ or $K_4P_2O_7$
carbonates:	cold weak acetic acid
manganese oxides:	0.1 *M* hydroxylamine hydrochloride in 0.01 *M* $HN0_3$ (pH 2)
iron oxides:	
amorphous	0.175 *M* $(NH_4)_2\ C_2O_4$-0.10 *M* $H_2C_2O_4$ 0.25 *M* hydroxylamine hydrochloride
crystalline	0.02-1 *M* hydroxylamine hydrochloride -0.25 *M* acetic acid Na-dithionate Hydrazine chloride (pH 4.5) NH_4-oxalate 0.2 *M* oxalic acid in 0.1 *M* ascorbic acid
sulfides:	H_2O_2-ascorbic acid $KClO_3$/HCl followed by 4 *M* HNO_3

hot concentrated acids but are broken down by fusion (Table 4.5.5). Table 4.5.6 indicates that nickeliferous magnetite is more readily dissolved by hydrochloric acid than perchloric acid, nitric acid, or aqua regia.

Hydrofluoric acid is the only acid decomposition medium that will dissolve silicate minerals in the typical clastic or lithogeochemical sample. The amount of metal extracted by the strong decompositions achieved with nitric, hydrochloric, perchloric acids, or their mixtures is not total and will vary with the mineralogy of the sample (Table 4.5.7). In addition, as emphasized by Fletcher (1981, 1987), even with similar acid mixtures, extraction efficiency will vary with the acid, sample to acid ratio, and the duration and the temperature of extraction.

Of the fusion techniques, potassium bisulfate treatment does not result in a total extraction, but the alkaline, fire assay, and sublimation techniques can be effective in attacking resistant minerals and extracting specific elements.

Comparison of the quantities of metals extracted by techniques capable of different degrees of decomposition can be very informative. Metals in silicate lattices of rock-forming minerals commonly constitute the background or threshold level of the geochemical sample material. The mineralization component of an anomalous sample is generally contained in sulfides, iron or manganese oxides, or in adsorbed positions on clay minerals. The metal on the clays, and that contained in the sulfides and hydroxides, is more easily extractable than the background/threshold component contained in the rock-forming minerals. Stronger decompositions, which break down the rock-forming minerals, will effectively dilute the anomalous metal components by releasing the lower concentrations of metal in the background/threshold component. Partial decomposition techniques utilizing cold or weaker acids and other reagents that do not break down the rock-forming silicates enhance the more readily extractable mineralization component, resulting in a much greater contrast between the anomalous and background values in the survey.

In numerous geochemical surveys, therefore, the data from partial decompositions, or partial decompositions ratioed against total decompositions, can be much more definitive in target delineation than data from strong or total decompositions. Examples of selective, partial decomposition techniques are listed in Table 4.5.7. Canney and Hawkins (1958) and Bloom (1955) developed cold extraction colorimetric tests for cold-extractable copper (CxCu) and cold extractable heavy metals (CxHM) which are readily adaptable for field use. More recently, Viets et al. (1984) have described a separation technique from solution extracts allowing more sensitive multielement analysis of rocks, minerals, soils, and stream sediments, and Church et al. (1987) have made a comprehensive study of multielement partial extractions.

QUALITY CONTROL. The "house of cards" analog (Fig. 4.5.2) illustrates the relative importance of the various phases of a geochemical program. In addition to observing the basic principles of orientation, sampling, sample preparation and analysis, adequate assurance of analytical quality, representativity, consistency, and precision are essential when all data are evaluated.

Quality controls can be introduced at several stages in the geochemical program. Duplicate sampling of the designated sample material at the sample site produces two samples (*field duplicates*) that will give a measure of the combined variance in the sample material and the sampling procedure. Division of a sample prior to the sample preparation stage (*sample duplicates*) provides a measure of the sample homogeneity. Splitting of the sample after the appropriate sample preparation (*analytical duplicates*) will provide information on analytical variance and also sample homogeneity.

Specially prepared *standard reference samples* having known metal contents provide essential material for checking the precision and accuracy of an analytical laboratory on a batch basis and also for monitoring analytical drift with time when numerous batches are forwarded to the same laboratory over the life of a project. It is very important to know that analytical data collected at all stages of a project are comparable.

The usual practice of the routine addition of one of a suite of standard reference samples with every 30 routine or batch samples and the inclusion of sample and analytical duplicates at a similar frequency will provide a 10% quality control volume. Routine scanning of results from these standards and duplicates will give an immediate indication of unsatisfactory precision and accuracy and sample inhomogeneities. Since it is the objective of the geochemical laboratory to produce good and reliable data and maintain an ongoing, profitable customer relationship, quality control is the initial concern of both the laboratory and the client.

If irregularities are noted, the laboratory should be contacted immediately and the discrepancies discussed. Every reputable laboratory will have its own standard reference samples and other controls and should rerun samples without charge if the quality of its output comes into question. If erratic analytical results are experienced with the duplicate and batch samples but not with the standard reference materials, sample inhomogeneity ("nugget" effect) is indicated. Experienced commercial laboratory personnel can assist with these problems by utilizing special techniques designed to overcome sample inhomogeneities.

4.5.1.8 Interpretation Principles

Geochemical interpretation does not begin only after all samples have been collected, prepared, and analyzed. Interpretive methodologies develop progressively throughout a geochemical project. The patterns observed during the orientation program are directly related to the dispersion characteristics of the metallic elements, the nature of the overburden, and the overall general geochemical environment. Such recognition contributes to the formulation of interpretational procedures and this developing understanding impacts directly on the sampling, sample preparation, and analytical procedures that are selected for the geochemical program.

The cumulative experience of geochemical behavior gained from orientation surveys and case histories in a broad spectrum of environments has enabled geochemists to compile a series of *conceptual interpretation models* that pictorially represent dispersion behavior in a wide variety of landscape configurations. The simplified example in Fig. 4.5.10 illustrates the formation of geochemical anomaly as patterns related to natural factors within the landscape. Models like these have been developed for a wide variety of environments including those in the Canadian Cordillera and the Canadian Shield (Bradshaw, 1975), in northern Europe (Kauranne, 1976), in the Basin and Range (Lovering and McCarthy, 1978), and in Australia (Butt and Smith, 1980). The initial framework for the conceptual models came from the portrayal of landscape geochemistry by the Soviets as early as the 1930s and was adapted to synthesize geochemical data by Fortescue (1975, 1980). All have certain common features (Hoffman and Thomson, 1987):

1. A body of mineralization or another source that may mimic mineralization.
2. The relative distribution of bedrock, overburden, soil, groundwater, surface water, vegetation, and other factors.
3. Highlighted dispersion pathways related to mineralization and anomaly formation.
4. Each model portrays dispersion as a series of patterns related to and controlled by a variety of identifiable natural factors.

Fundamentally, geochemical interpretation involves the recognition of these patterns, the identification of the factors causing them, and the extrapolation of the patterns back to a mineralized or other source.

With the gradual acceptance of these concepts, *geomorphological mapping* through ground and air-photograph observations is proving to be an invaluable tool in the interpretation of geochemical patterns particularly in areas of mature landscapes.

The importance of the preferred emphasis on patterns of dispersion rather than the magnitude of the geochemical values in parts per million or parts per billion units can be illustrated by reference to Fig. 4.5.10. Precipitation and accumulation of hydromorphically transported metal in the seepage anomaly area adjacent the stream channel can invariably result in concentrations markedly higher than in the surface horizons of a residual soil anomaly on a well-drained slope. In such a situation, reference only to the magnitude of values would result in first priority for follow-up being assigned to the seepage anomaly, whereas recognition of the location and shape of the seepage anomaly would immediately indicate its origin and direct the interpretation to the source areas upslope.

In parallel with pattern recognition, geochemical interpretation requires a knowledge of the *"anomalous," "threshold,"* and *"background"* values of the elements of interest in the survey. The fundamental observations leading to the identification of these values come from the orientation survey. In the simplest orientation scenario, background values are not influenced by the presence of mineralization and in Fig 4.5.11 are represented by the relatively homogeneous areas of low values at the extremities of the hypothetical soil traverse. Anomalous values are, in this example, the higher values peaking a short distance downslope of the suboutcropping vein zone. Weaker mineralization, disseminated in the rocks on either side of the vein zone, also gives rise to anomalous, but less spectacular, values which are also influenced by the topographic slope. The upper limit of the background population is referred to as the threshold and it is clear that contouring this data at the threshold level will outline an anomalous pattern related to the mineralization in the bedrock.

Unfortunately, too many explorationists apply this simple concept of anomaly definition far too rigidly in all their exploration programs. This reflects an erroneous conception of the geochemical environment and totally ignores the geological influences on metal distribution and the basic principles of dispersion illustrated by the geochemical models.

The hypothetical example described (Fig. 4.5.1l), assumes no variation in bedrock type or environmental factors. For the majority of field areas, the simple scenario portrayed in Fig. 4.5.11 is the exception rather than the rule, and the introduction of geological and geomorphological complexities such as those shown in Fig. 4.5.12 can produce spurious anomalies.

During mineralization processes, some elements (e.g., sodium) may be leached from the host rocks by the mineralizing fluids. In such a situation, a depletion in values below the regional background for the element will cause an "anomalous low" that is geochemically and economically significant.

The interpretation of geochemical data and the correct identification of significant anomalies therefore requires a fundamental awareness of the geochemical environment as presented in the geochemical model (Fig. 4.5.10), a knowledge of the geology, structure, and other characteristics of the type of deposit sought, and an underlying understanding of the geochemical behavior of the elements of interest. This procedure is clearly described and illustrated with numerous actual examples in a workbook format by Levinson et al. (1987).

Over the past several years, geochemists have adapted *statistical methods* of evaluation to assist in geochemical interpretation. This has not been a simple evolution. As noted by Sinclair, (1987), "to attempt to carry out a blind evaluation of data by submitting them to any one of an increasing number of packaged software systems and expect a computer to do our thinking for us is patently wrong." Effective application of statistical methods, whether univariate or multivariate, requires not only the same full appreciation of the geochemical environment, the geology, and the chemistry of the elements as described in the proceeding paragraphs but also an understanding of the statistical technique being employed. In addition, this effectiveness is also dependent on correct design, representativity and quality of the sampling and analytical phases of the program. It is not difficult to appreciate that statistical treatment of a data set lacking in representativity and quality will primarily highlight error, to the virtual exclusion of relationships of geochemical significance.

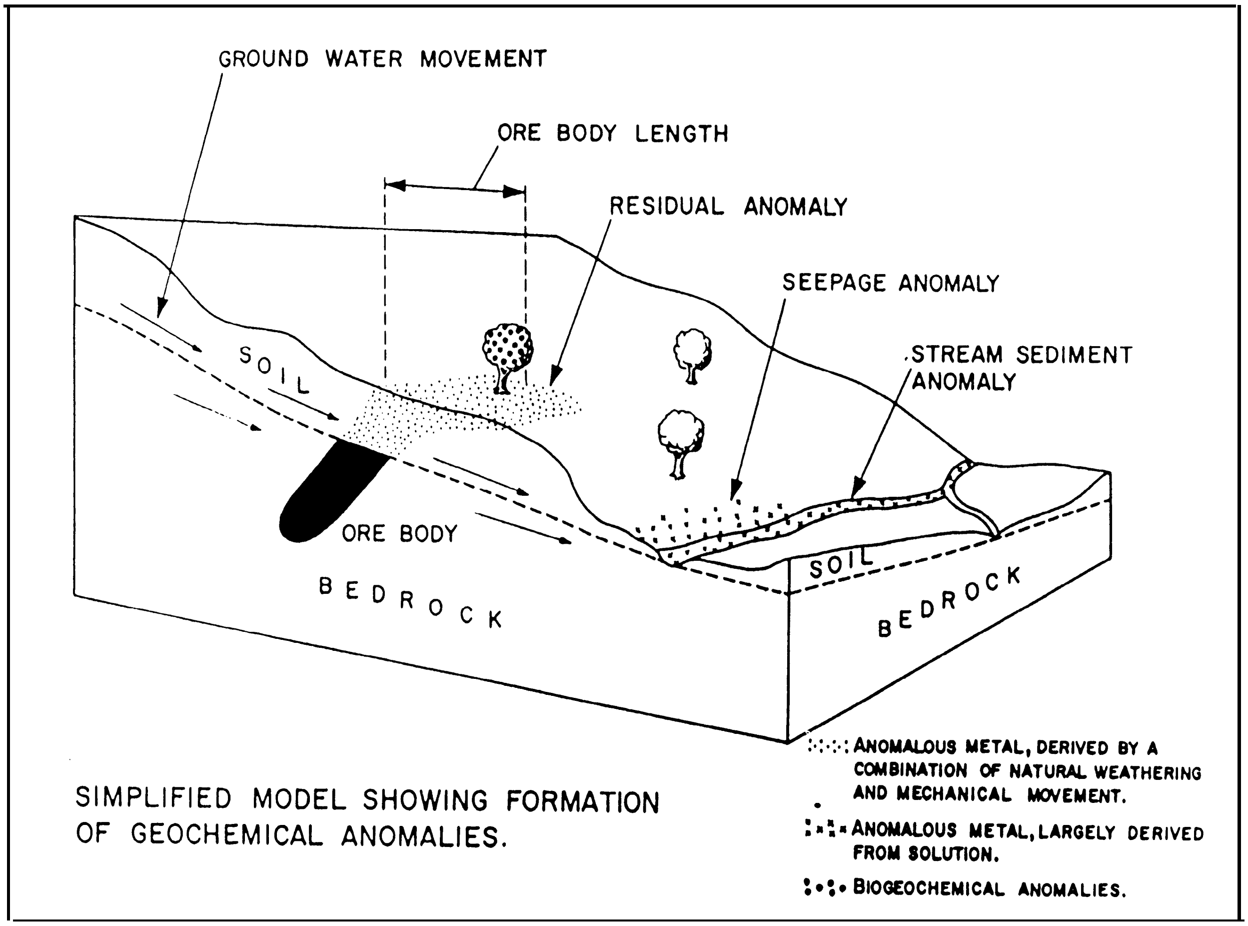

Fig. 4.5.10. Simplified model showing formation of geochemical anomalies (Hoffman and Thomson, 1987).

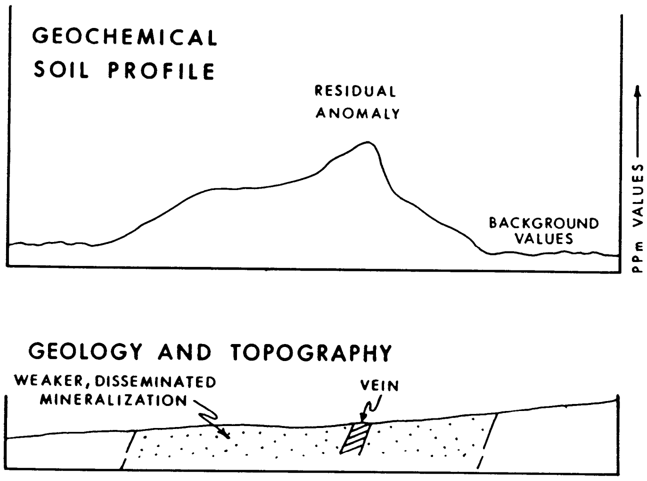

Fig. 4.5.11. Hypothetical soil profile across mineralized zone.

Given these essential understandings, statistical techniques provide useful and often powerful tools for geochemical data analysis. They can assist in explaining previously unrecognized characteristics in a data set and making significant patterns more consistent, larger, or otherwise more easily recognizable.

A basic assumption applied in the statistical treatment of geochemical data is that the data are unbiased and continuous. Most geochemical data are discrete, but fortunately, in practice these discrete values commonly are sufficiently abundant and close that they can be assumed to be continuous. Such is generally the case if the number of values is large and if the analytical uncertainty is small relative to the spread of the values. Because of this statistical assumption used in the analysis of geochemical prospecting data, other statistical approaches are continually being assessed (Kurzl, 1988).

A review of basic statistics is beyond the scope of this presentation, but a useful summary has been prepared by Sinclair (1987) and a more comprehensive treatment is covered by Howarth (1983).

Univariate statistics allow the geochemist to quickly become familiar with voluminous sets of data. Histograms and probability plots provide a means of displaying data and revealing internal complexity. A histogram (Fig. 4.5.13) has the obvious advantage of providing visual information on the total range of values, the existence of one or more populations, and possible thresholds separating background and anomalous values. Data grouped for purposes of constructing a histogram can be cumulated (from high to low values or vice versa) as for a cumulative histogram and plotted directly on probability graph paper (Fig. 4.5.14).

Probability plots, as described by Sinclair (1976), and the "PROBPLOT" computer program of Stanley (1987), have found

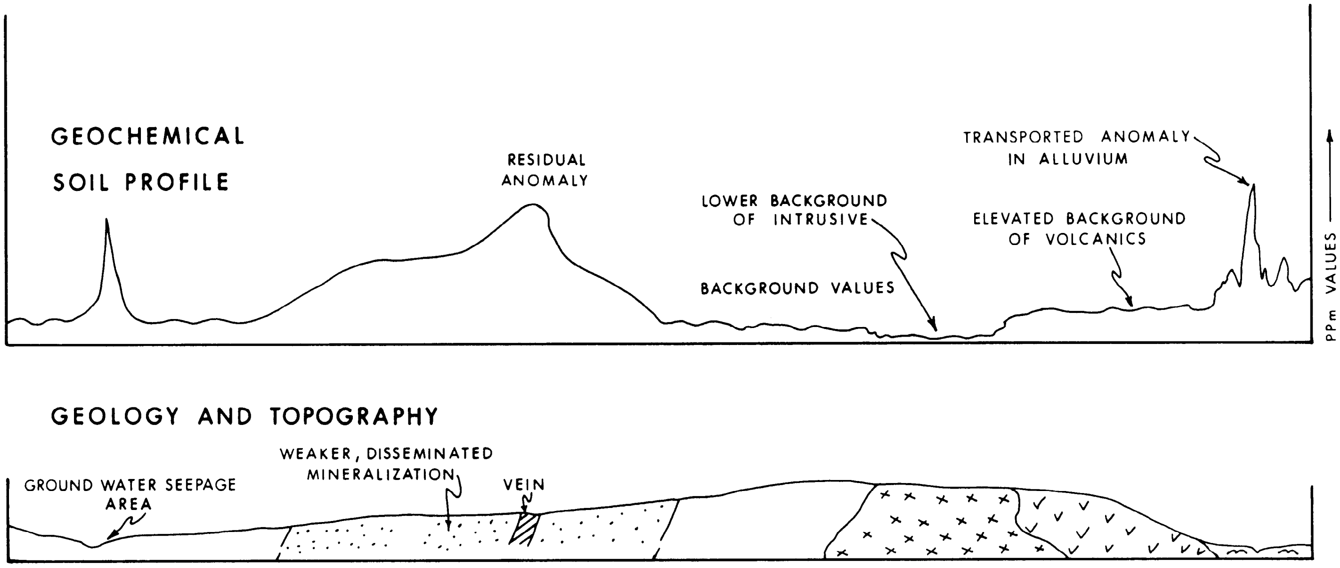

Fig. 4.5.12. Hypothetical soil profile illustrating spurious anomalies related to geological and geomorphological complexities.

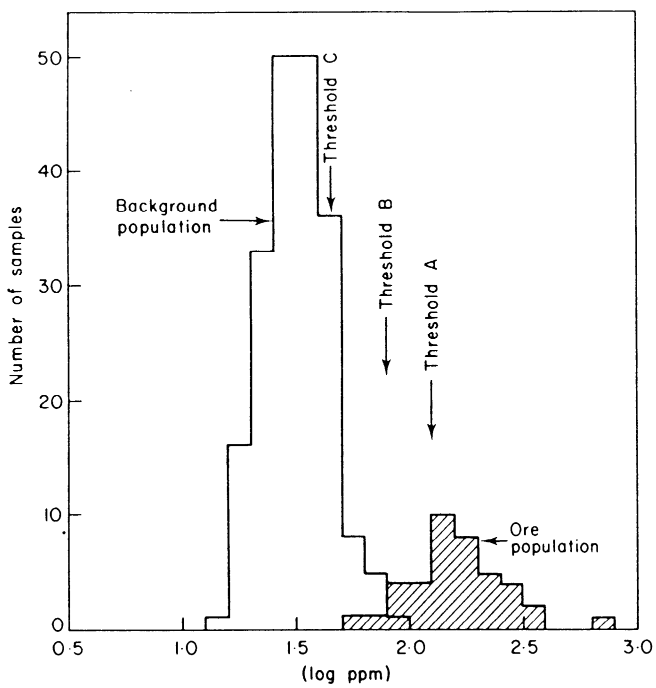

Fig. 4.5.13. Overlap of values in background and ore populations (derived as random samples from two log-normally distributed populations) (*Source*: Rose et al., 1979).

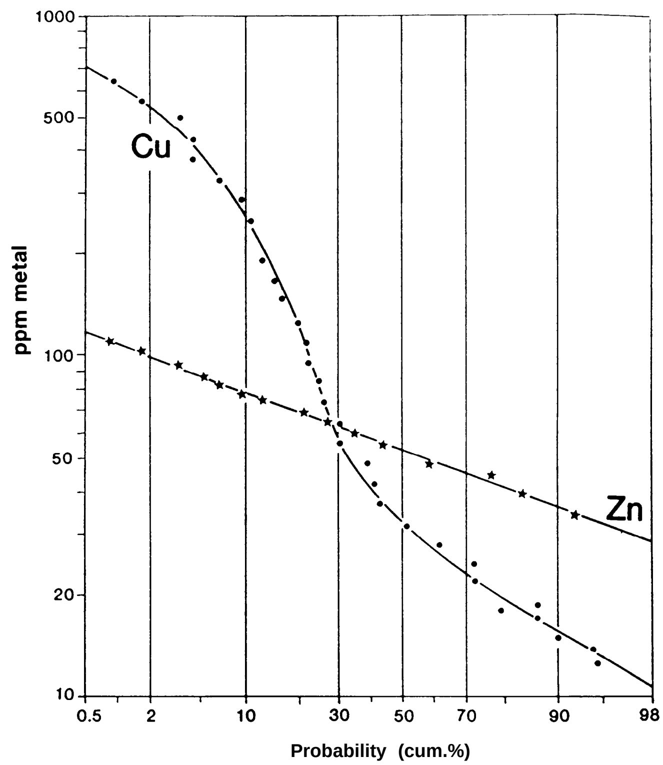

Fig. 4.5.14. Probability graphs (cumulative curves) for zinc and copper in B horizon soil samples over the Daisy Creek stratabound copper prospect, western Montana. Cumulated from high to low values (Sinclair, 1986).

widespread use in geochemistry and allow the partitioning of consistent populations and the estimation of threshold values. Depending on the statistical distribution of geochemical data, one ordinate of the probability graph paper is either arithmetic or logarithmic, and the other ordinate, the probability scale, is arranged such that a normal or log-normal distribution will plot as a straight line. This type of graph is a very sensitive method for recognizing the presence of multiple populations.

In this example shown in Fig. 4.5.14, the straight-line plot for zinc indicates a single log-normal population and the curved line for copper indicates the presence of more than one population. The inflection point of the copper curve can be interpreted from the probability plot to be at the 25 percentile (Fig. 4.5.15), indicating the curve to represent a mixture of 25% of the higher population A and 75% of the lower population B, both of which can be mathematically derived. The two populations overlap

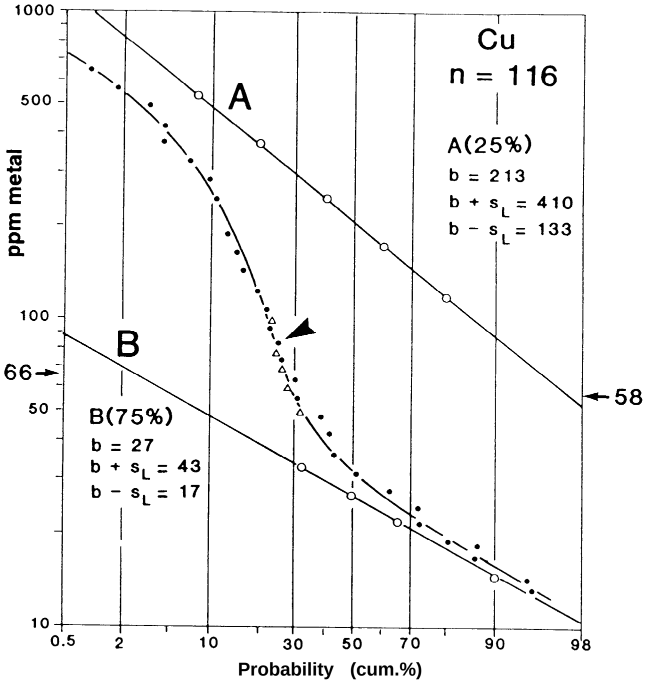

Fig. 4.5.15. Probability graph of copper in soils (from Fig. 4.5.14) partitioned into two ideal components, A and B. An arrowhead shows the interpreted position of an inflection point in the curve. Black dots are original data; open circles are construction points determined by the partitioning procedure; open triangles are check points determined by combining ideal populations A and B in their zone of overlap to compare with real data. Thresholds of 58 and 66 ppm are determined at the lower 2.5 percentile of A and the upper 2.5 percentile of B (Sinclair, 1986).

slightly, but it is clear that if populations can be defined in this way, an estimated or statistically calculated value can be identified that can be contoured or otherwise differentiated that will separate the populations for interpretation purposes.

Multivariate analysis is used to investigate complex interelement relationships and can include other types of exploration parameters based on geological, geophysical, or other data. A necessary prerequisite for more advanced multivariate analyses are correlation studies between pairs of variables (scatter diagrams, correlation coefficients) and between populations (analysis of variance). Based on this information, it is possible to investigate intra-element and between-sample relationships using a variety of techniques (principal component, factor analysis, cluster analysis, multiple regression, discriminate, and characterization analysis) (Howarth, 1983).

An example of the use of these multivariate techniques is the mineral resource assessment map produced as a result of joint collaboration of the geological surveys of Finland, Norway, and Sweden in the Nordkalott Project north of the 66th parallel. Discriminant and characterisation analysis methods were applied to integrate 20 geochemical, 5 geophysical, and 5 geological variables to produce a resource assessment map showing regional favorability for mineral deposits (Fig. 4.5.16). In addition, scores were calculated representing each of 13 metallogenic provinces, and the local favorability for the existence of each deposit type are shown as symbols in which size indicates favorability and color the most likely deposit model. The model areas are shown in Fig. 4.5.16 as irregular polygons.

4.5.1.9 Geochemical Atlases

Sampling of stream sediments, soils, and other media in geochemical exploration is usually conducted at relatively high densities. Early surveys at relatively wider spaced sample intervals (Holman, 1963) revealed geochemical patterns reflected, to a much greater degree, signatures related to the surface geological components with a relative diminution of the signal from anomalous mineralization sources. The publication of the Wolfson Geochemical Atlas covering England and Wales (Webb et al., 1979) vividly illustrated the influence of the geological component in a stream sediment survey at a density of one sample per square kilometer (per 0.4 mi^2). The Wolfson Atlas stimulated a number of additional large-scale geochemical mapping programs in Alaska, (Weaver et al., 1983), Germany, (Fauth et al., 1985), Newfoundland (Davenport, 1982), Great Britain (Plant and Slater, 1986), and Fennoscandia (Bolviken et al., 1986).

The Fennoscandinavian or Nordkalott Project involved the collection of several types of sampling media from the stream and glacial till environments at an average density of one per 25 km^2 (one sample per 9.65 mi^2). Data handling and presentation techniques developed as part of this program were very innovative (Fig. 4.5.17) allowing effective, broad-scale depiction of metal distributions that serve as a focus for more detailed geochemical prospecting surveys. In part, concurrent with the Nordkalott Program, the Geological Survey of Finland conducted a glacial till sampling survey covering the whole country at a scale of one sample per 300 km^2 (one sample per 116 mi^2). Again, using innovative data handling and data presentation techniques, these results revealed patterns that were not directly correlatable with mapped geological lithologies, but possibly reflecting deeper crustal structural patterns of metallogenic significance. Alignment of the geochemical patterns and significant mineral deposits (Fig. 4.5.18) supports this prediction (Bjorklund, 1989). The plotting of individual element results from the same sample database-one per 300 km^2 (one sample per 116 mi^2)— has also served as a focus for more detailed exploration (Fig. 4.5.19).

The low-density geochemical maps that have been described contain useful information for the agricultural, forestry, and environmental sciences as well as the geological sciences, and planning has begun for an International Geochemical Mapping Project which will include contributions from a large number of developed and less-developed nations (Darnley, 1988). It is clear that the project has the potential of generating invaluable information on the global distribution and relative concentrations of economically significant metals of fundamental interest to the mining industry.

4.5.2 OTHER PROSPECTING TECHNIQUES

4.5.2.1 Background

The remarkable advances in new technology over the past three decades have stimulated numerous avenues of research and the development of new methods that can be applied in mineral prospecting. Usually, each new method experiences a "breaking-in" period during which the technology is applied in a variety of situations leading to a better understanding of the properties being investigated and refinements in interpretation procedures.

Before these methods are described briefly, it is appropriate to note that certain well-established techniques of prospecting are still as effective today as they were in the earlier days of mining. Such techniques include the skillful use of *heavy mineral panning,* particularly in the search for gold, platinum, cassiterite, tungsten, barite, and other resistant metals and minerals of high specific gravity (Chapter 15.1.1). Although undocumented, panning may be responsible for the discovery of more ore and mineral occurrences than any other technique, and its application in the stream environment is well described in some older publications (e.g., MacKay, 1921, and Lindgren, 1911, in Boyle, 1987). The *ultraviolet light* or "blacklight" method is another established technique with specific application in the search for naturally fluorescent minerals such as scheelite, willemite, and fluorite.

4.5.2.2 Airborne and Satellite Techniques

Since the early 1970s, aerial photography has been supplemented by a variety of satellite- and aircraft-borne electronic imaging systems that can be used to map structural, lithologic, and alteration features. The era of satellite remote sensing for geology began with the launch of the ERTS-1 (later renamed Landsat 1) satellite on July 23, 1972. On board ERTS-1 was the Multispectral Scanner (MSS) that was the first satellite-borne electronic imaging system designed for the analysis of the earth's resources. MSS images provided a fairly coarse spatial resolution of 80 m in four regions covering visible and infrared light. Geologists quickly realized that they could use these data to map regional structures and, in some cases, limonite-stained rocks. Interest on the part of the earth-science community was great enough that government and industry geologists influenced the design of the Thematic Mapper that was first put in orbit aboard Landsat 4 in 1982. TM provides an improved spatial resolution of 30 m (98 ft) and coverage of longer wavelengths of infrared light. The longer wavelength infrared images collected by TM provide an ability to map hydrothermally altered areas by identifying high concentrations of clay in rock and soil. Nations other than the United States have also recognized the usefulness of satellite remote sensing. France recently launched SPOT-l (Systeme Probatoire d'Observation de la Terre) that provides spatial resolutions of 20 m (66 ft) for visible and near IR wavelengths and 10 m (33 ft) for a broad wavelength panchromatic band. SPOT has the additional capability of collecting stereo images.

Both governments and the private sector have produced airborne remote sensing systems which push the cutting edge of the technology forward. These systems are operated from aircraft much the same way as a conventional aerial camera. Systems such as the Jet Propulsion Laboratory (JPL)-developed Airborne Visible and Infrared Imaging Spectrometer (AVIRIS), and the Geophysical Environmental Research Inc.-developed Imaging Spectrometer (GERIS) are designed to map the mineralogy of the surface material. These systems produce images with spatial resolutions that vary from 5 to 30 m (16 to 98 ft) depending on the altitude of the aircraft. The Thermal Infrared Multispectral Scanner from JPL (TIMS) produces multichannel thermal (temperature) images that can be used to differentiate and map tectosilicates (particularly silica). Airborne remote-sensing systems provide data for both immediate use and means for determining which types of instruments will ultimately be mounted on satellites.

For more detailed information on remote sensing applications in geology and exploration, the reader is referred to the books by Drury (1987), Sabins (1987), and Siegal et al. (1980).

4.5.2.3 Fluid Inclusion Studies

Fluid inclusion studies have figured prominently in research in the composition of ore-forming fluids and the conditions of deposition of ore deposits. Spooner (1981) acknowledges that the studies, in combination with other techniques, have contributed very significantly to the better understanding of hydrothermal mineralizing systems.

A fluid inclusion in an ore or gangue mineral represents a fluid composition existing at some time during the history of a hydrothermal system. It can be anticipated that these compositions will vary with time and position as the hydrothermal system develops and matures (Roedder, 1967). Two types of fluid inclusion are recognized: (1) the *primary* inclusion entrapped during the growth of the host crystal and (2) the *secondary* inclusion in which fluids are entrapped after the growth of the host crystals and that commonly occur along microfractures. Secondary inclusions are the most numerous, and careful petrological observation is clearly a critical aspect of fluid inclusion studies.

Primary inclusions are frequently found in hydrothermal veins that have formed in open fissures. Their compositions vary considerably, but most fluids fall in the carbon-oxygen-hydrogen-sulfur plus sodium chloride (C-O-H-S + NaCl) system with the most prominent constituents being carbon dioxide (CO_2) and water (H_2O). Other species occurring in this system include carbon monoxide (CO), hydrogen (H_2), methane (CH_4), hydrogen sulfide (H_2S), and sulfur dioxide (SO_2). The salt composition ranges from zero to as much as 40% by weight consisting commonly of Na^+ but with variable but important amounts of K^+, Ca^{2+}, or Mg^{2+}.

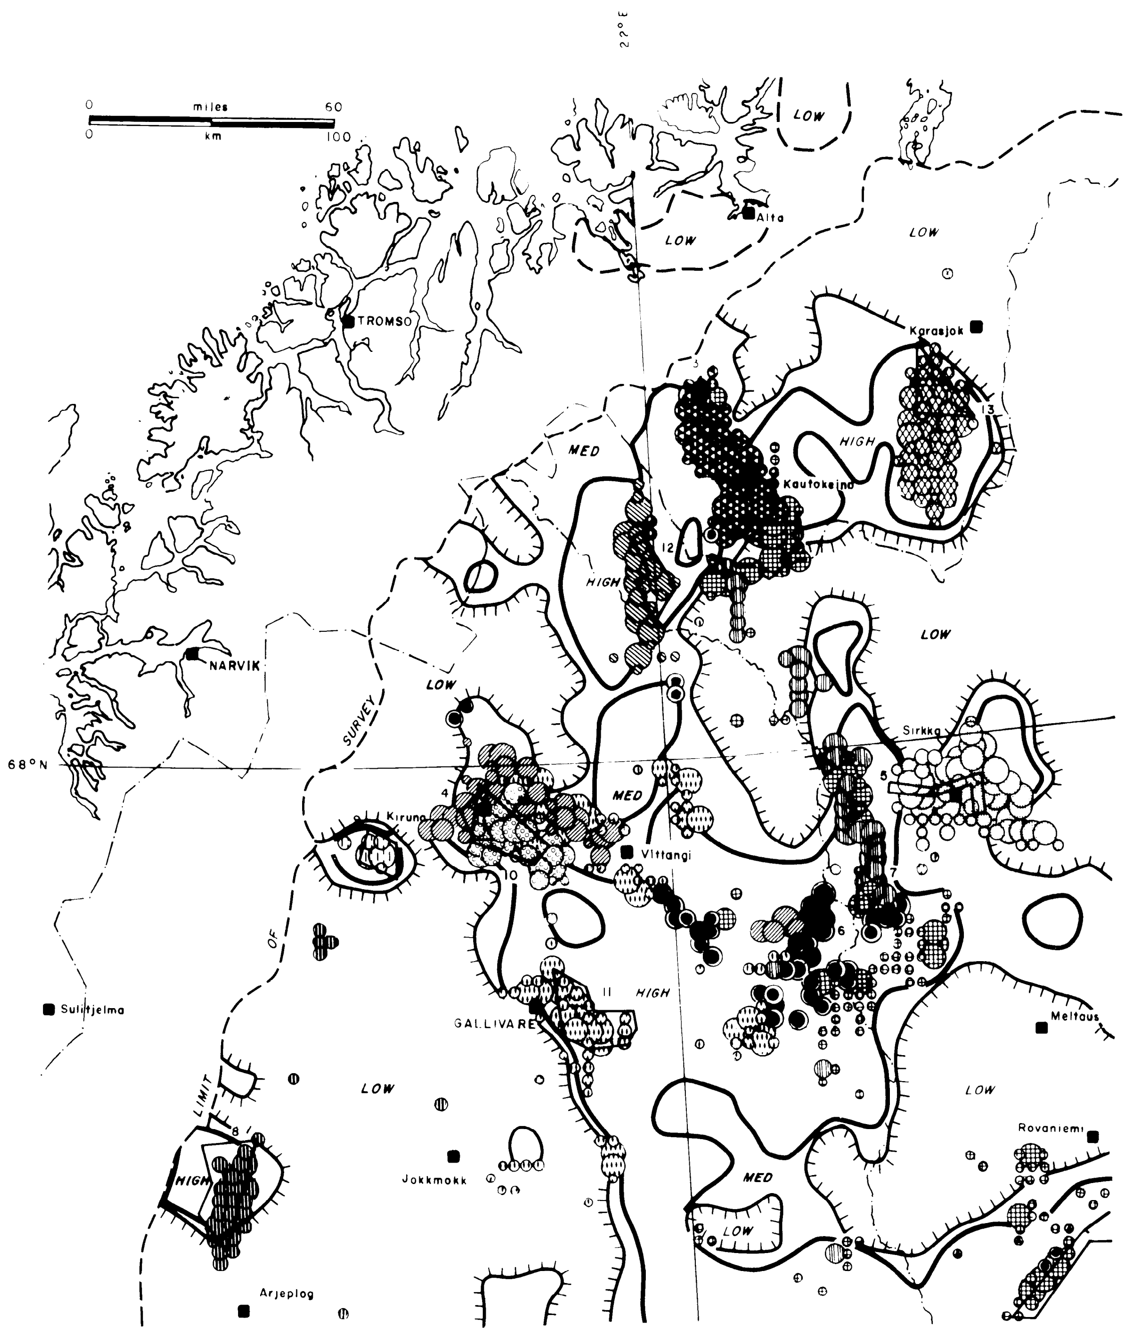
The fluid inclusion components are commonly distributed into immiscible gaseous and aqueous and, less frequently, solid phases. On heating, these phases homogenize and the temperature of homogenization correlates with the (minimum) temperature of the fluid at the time of entrapment. Consequently, by reference to phase diagrams for CO_2 and P-T diagrams for both CO_2 and H_2O, it is possible to determine the pressure and temperature of the ore-forming fluid by careful examination of primary inclusions. The study of inclusion compositions across a single vein or in a succession of veins can, therefore, indicate changes in composition (as well as temperature and pressure) of the parent fluid during the mineralizing period. Table 4.5.8 (Colvine et al., 1988) is a summary of fluid inclusion data for Archean gold deposits in the Canadian Shield and the Yilgarn Block of Western Australia. Homogenization temperatures range between 392° and 752°F (200° and 400°C) to cluster around 662°F (350°C), and calculated pressures range from 1.5 to 4.5 kb (equivalent to depths of 2.5 to 7 mi or 4 to 12 km). Compositionally, these fluids are of low salinity, aqueous with a moderate to high CO_2 density. Norman (1989) in studies of fluid inclusions from the Creede Mining District, has noted high H_2S concentrations associated with the precious metal deposits. Calculated temperatures of deposition at Creede and some other epithermal districts in the western USA are in the 482° to 536°F (250° to 280°C) range.

There is a huge bibliography of fluid inclusion studies, and the interested reader is referred to the publications of Roedder (1967, 1972, 1976) and Crawford (1981) for more detailed discussions of the technique, its application, and its contribution in mineral deposits geology.

4.5.2.4 Isotope Studies

In recent years, stable and radioisotope studies have expanded dramatically within mineral deposit geology and have found application in exploration. The object of these studies have been (Guilbert and Park, 1986)

1. To determine the composition and sources of ore-bearing fluids.
2. To determine the source of ore-forming components.
3. To determine the age of mineral deposits.



See legend top of next page.

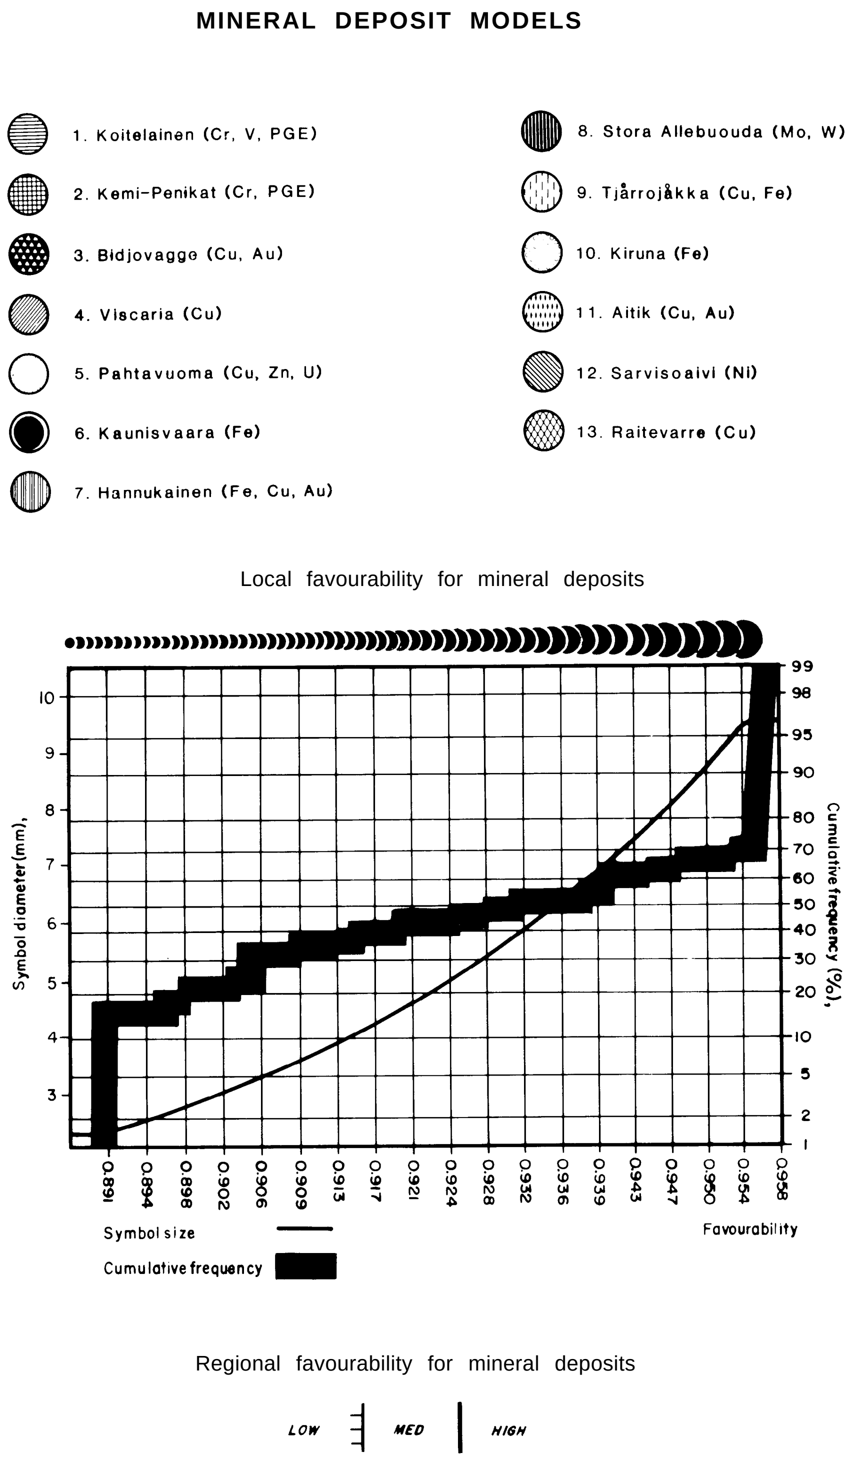


Fig. 4.5.16. Northern Fennoscandia mineral resource assessment map, northern Fennoscandia, regions and locations highly favored for mineral deposits *(Mineral Resource Assessment Map,* Northern Fennoscandia, Geological Surveys of Finland, Norway, and Sweden, 1986).

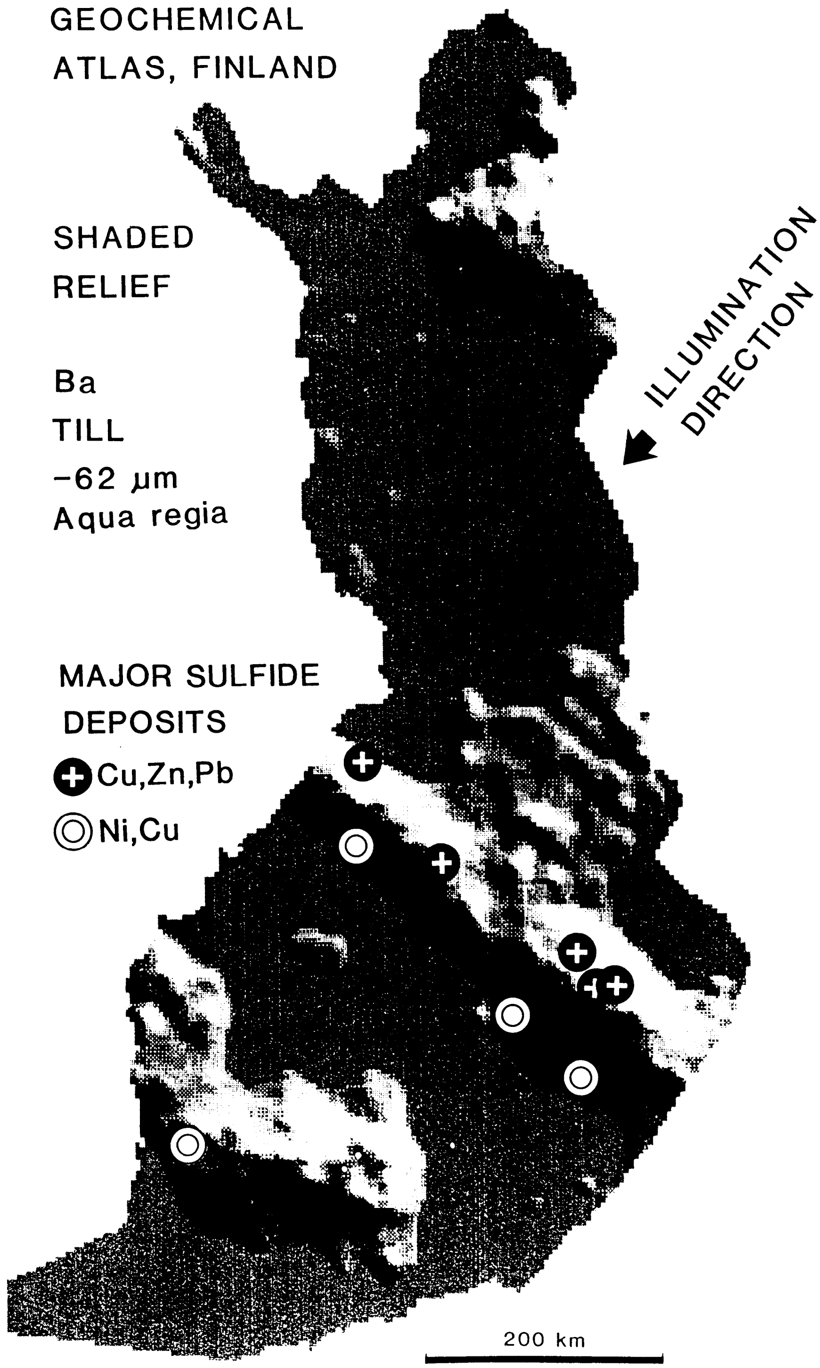

Fig. 4.5.18. Geochemical atlas of Finland. Alignment of geochemical patterns and significant mineral deposits (Björklund, 1989).

4. To help determine temperature and other conditions of deposition.

5. To establish the degrees of bacteriological involvement in certain ore-forming processes.

This expanded understanding of isotope behavior, aided considerably by improved technology, has led to the development of techniques of considerable promise for detailed prospecting.

Stable isotope investigations involve the study of the different properties of isotopes of the same element and assume that the abundance ratios of these related isotopes in geological materials have not changed over time. Since stable isotope ratios are influenced by natural processes, the understanding of this behavior can be indicative of how rocks and minerals associated in mineral deposits have been formed. The field is complex, with ratios being affected by natural processes of oxidation, reduction, precipitation, dissolution, evaporation, condensation, adsorption, desorption, diffusion, and biochemical activity. Stable isotope measurements on minute geological samples are now possible due to significant advances in laser and ion probe technology (Shanks and Criss, 1989).

When seawater is evaporated, the lighter isotopes of *oxygen* and *hydrogen* are enriched in the vapor, and consequently the $^{18}O/^{16}O$ and $^{2}H/^{1}H$ (or $\delta^{18}O$ and δD) ratios are decreased. $\delta^{18}O$ and δD values are increased relative to the vapor in the primary rainfall, and the lighter isotopes become enriched in meteoric waters progressively inland and polewards on all continents.

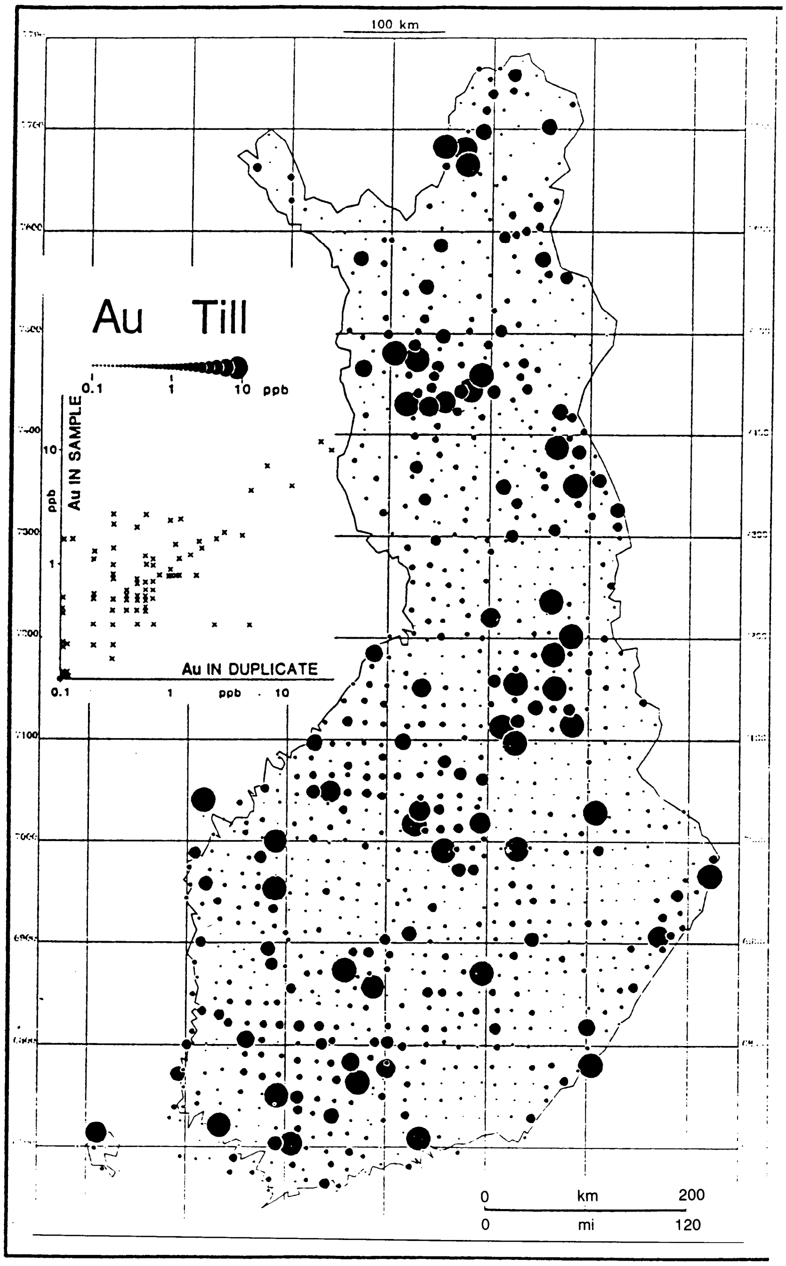

Fig. 4.5.19. Gold in till [-63 μm fraction], (— 240 mesh) *Geochemical Atlas of Finland* (Geological Survey of Finland).

Taylor (1967, 1974) incorporated these meteoric water variations into plots, which also define the fields of other waters in the earth's crust, viz., connate, metamorphic, magmatic, and seawater (or SMOW—standard mean ocean water) (Fig. 4.5.20). Fig. 4.5.21 shows variations in the $\delta^{18}O$ and δD ratios measured in various minerals associated with ore deposits. Comparison of Figs. 4.5.20 and 4.5.21 illustrates how oxygen and hydrogen isotope studies can provide information on the nature of the mineralizing fluids involved in ore formation. In practice, the interpretation of these ratios is complex, but their study is leading to an improved understanding and evaluation of mineral deposit environments.

The *sulfur isotope* ratio $^{34}S/^{32}S$ of a sample relative to the same ratio in the Canyon Diablo meteorite is referred to as $\delta^{34}S$. The $\delta^{34}S$ value for the meteorite (troilite) is zero and sulfides or igneous rocks having a $\delta^{34}S$ value at or close to zero are interpreted as being of mantle derivation. Biogenically derived sulfur is isotopically lighter and this characteristic has stimulated considerable investigations of the epigenetic or syngenetic origin of many types of mineral deposits. Other studies, necessarily integrated with careful geological observations, have illustrated many complexities related to diverse sources of sulfur and isotopic partitioning correlatable with changes in redox conditions, temperature, and sulfur concentration in the mineralizing fluid. Sulfur isotope variations in nature, from a paper by Ohmoto and Rye (1979), are shown in Fig. 4.5.22.

Radioisotopes are the product of radioactive decay of some preexisting element. Ratios of radioactive isotopes are affected only by time and the specific decay constant of the isotopes of interest. The ratios are unaffected by metamorphism or orogeny, biological activity, temperature, or intrusion and have important geochronological application. The most commonly used radioactive decay series are those of rubidium-strontium (^{87}Rb-^{87}Sr), uranium-thorium-lead (^{235}U-^{207}Pb; ^{238}U-^{206}Pb; ^{232}Th-^{208}Pb), and

Table 4.5.8. Summary of Fluid Inclusion Data for Archean Gold Deposits in the Abitibi Subprovince of Canada and the Yilgarn Block, Western Australia

Deposit or Area (Reference)	Fluid Inclusion data	Interpretation
Red Lake, Ontario Brown and LaKind (1986)	Primary low salinity H_2O-CO_2, higher CO_2 density, variable CO_2/H_2O ratios, T_h = 110° to 360°C, GOLD RELATED Secondary aqueous brine, T_h = > 350°C Secondary low salinity (< 10 equi. wt % NaCl), CO_2-H_2O, low CO_2 density	Possible fluid unmixing
McIntyre-Hollinger mine, Timmins, Ontario Smith et al. (1984)	Pseudo-secondary or primary H_2O-CO_2, T_h = 220° to 385°C, 3 to 24 mole wt % CO_2, CO_2 liquid phase homogenization, CO_2 density range 0.46 to 0.78 g/cm^2, GOLD RELATED Secondary CO_2-bearing aqueous inclusions, T_h = 160° to 215°C In graphite-bearing vein, pseudo-secondary to primary CH_4-$C0_2$-H_2O inclusions (> 26 mole % CH_4) Secondary CH_4-rich inclusions	Possible fluid unmixing; fluids buffered by QFM; depositional pressure 0.35 to 0.5 bars
Hollinger mine, Timmins, Ontario Wood et al. (1986)	Primary H_2O-CO_2, variable phase proportions; 1 to 4 equi. wt. % NaCl; 6 mole % CO_2; T_h = 225° to 355°C, mean 277°C; minor CH_4; CO_2 density 0.65 g/cm^3	Phase separation
O'Brien mine, Cadillac, Quebec Krupka et al. (1977)	Primary H_2O-CO_2 with constant phase proportions.	Early fluid homogeneous
	Coexisting secondary H_2O-CO_2; T_h of both types= 210° to 380°C	Late heterogeneous fluid
Sigma mine, Val d'Or, Quebec Robert and Kelly (1987)	Secondary H_2O-CO_2 inclusions with < 10 equi. wt. % NaCl, 15 to 30 mole % CO_2; T_h = 285° to 395°C	
	Coexisting H_2O-rich inclusions, 25 to 34 equi. wt. % $NaCl_1$, T_h = 60° to 295°C and CO_2-rich inclusions in healed fractures	Fluid unmixing intermittently
Yilgarn Block, Western Australia Ho et al. (1987)	Primary H_2O-CO_2 with both constant and variable phase proportions (20 to 30 mole % CO_2), < 2 equi. wt. % NaCl, T_h = 200° to 390°C	Early fluid, some unmixing
	Coexisting primary H_2O-rich and CO_2-rich in late vugs	Late fluid, heterogeneous

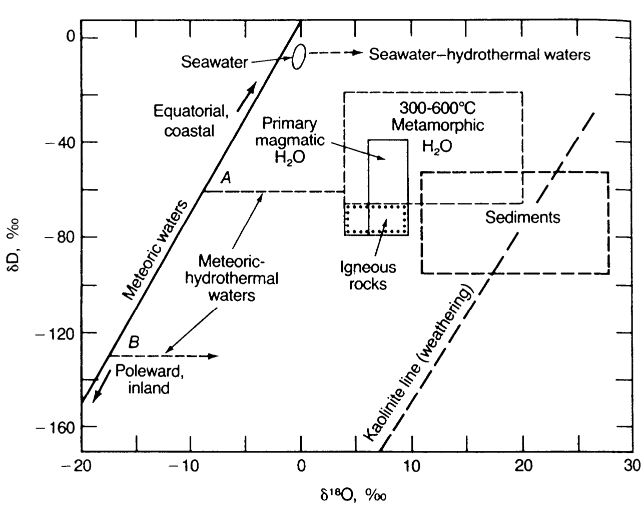

Fig. 4.5.20. Summary diagram of isotope composition of waters of different origins. Trends of ^{18}O shift due to water-rock interaction and exchange are shown for seawater and meteoric waters of compositions A and B (Guilbert and Park, 1986).

potassium-argon (^{40}K-^{40}Ar). Rubidium-strontium dating can be applied in the investigation of the source (mantle or crust) of the rocks related to mineral deposits and features of alteration. Potassium-argon dating is particularly applicable to determing the age of igneous rocks.

^{204}Pb is a stable isotope and the abundances of ^{206}Pb, ^{207}Pb, and ^{208}Pb have increased through the decay of uranium and thorium since the formation of the earth.

High-precision *uranium-lead* isotope analyses on zircon and titanite have been used extensively in dating rock units in the Canadian Shield and elsewhere. When combined with careful geological mapping and age dates from mineral deposits, these isotopic data provide a geochronological framework for determining the timing of mineralization episodes and the conditions of mineral deposit formation (Colvine et al., 1988).

Gulson (1986) reviews the growth and application of lead isotopes in exploration. This includes the development of the lead isotope method as a prospecting tool in the differentiation of significant gossans from false gossans in deeply weathered and oxidized terrain (Gulson and Mizon, 1979).

Lead isotope studies depend on the following assumptions (Richards, 1971):

1. At the time of the formation of the earth, there was a single set of lead isotope ratios throughout the earth mass, the so called primeval lead.

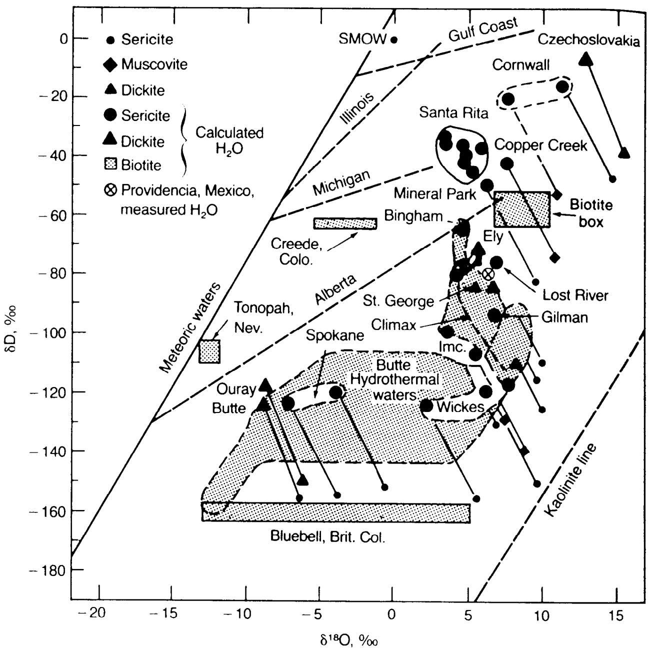

Fig. 4.5.21. Plot of δD vs. $\delta^{18}O$ for calculated hydrothermal waters from a variety of ore deposits, mainly from western North America. The stippled biotite "box" describes waters that would have coexisted in equilibrium with hydrothermal biotites from Ely, Bingham, and Santa Rita at 650°C. Also shown are the trend lines for oil-field formation waters from various sedimentary basins in the midcontinent of North America (Taylor, 1974).

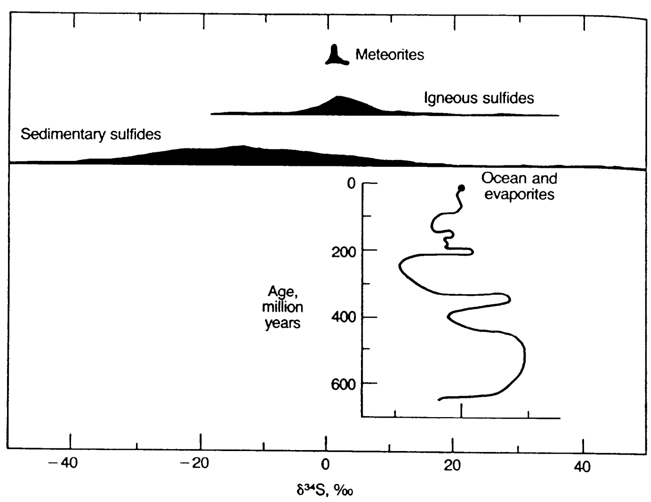

Fig. 4.5.22. Sulfur isotope variations in nature (Ohmoto and Rye, 1979).

2. Since then, all lead has been held in one or more closed systems with the proportions of uranium, thorium, and lead changed only by radioactive decay.

3. From time to time, batches of lead-bearing material have been removed from their source to form ore deposits, with negligible effect on what remains.

4. Ore leads so removed were not contaminated by other leads while traveling to the site of deposition; they reflect frozen original isotope abundances and ratios.

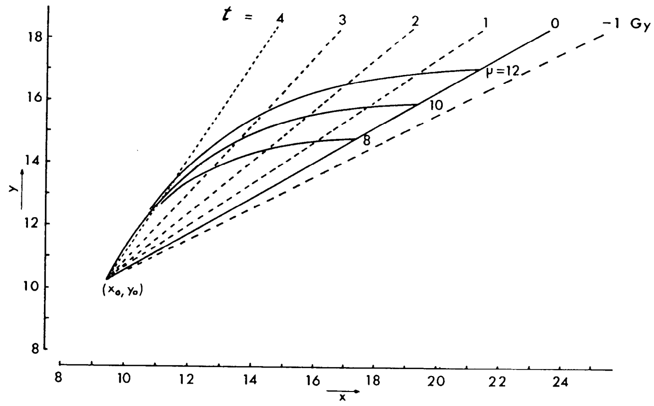

Fig. 4.5.23. Simple lead growth model. Growth curves for constant ($^{238}U/^{204}Pb$), variable time; straight-line isochrons for constant *t*, variable μ. Coordinates are $x = {}^{206}Pb / {}^{204}Pb$; $y = {}^{207}Pb / {}^{204}Pb$ (Richards, 1968, 1971).

The primeval lead value is calculated from the Canyon Diablo meteorite (which contains no uranium or thorium) at 4.55 billion years. Dating of leads is achieved by observing the positioning of measurements relative to growth curves of single stage leads and isochrons connecting points of equal geologic age (Fig. 4.5.23). An example of lead isotope ratios (and calculated age dates) plotting on a single stage growth curve is shown on Fig. 4.5.24.

4.5.2.5 Portable X-Ray Fluorescent Analyzers

Portable X-ray fluorescent analyzers (XRF) were initially developed in the 1960s (Bowie et al., 1965). The analyzers utilize a radioisotope source (Cf^{238}or Cd^{109}) to irradiate the sample material with gamma rays (Fig. 4.5.25). The resultant X-ray spectrum is selectively filtered, and the concentration of specific elements can be measured directly at the outcrop, the drill site, or the underground face.

The penetration of the sample surface by X-rays emitted by the radioactive source is very limited and generally less than 3 mm (0.1 in). The accuracy of any determination is, therefore, dependent on sample surface exposed to the detector. Measurements on unprepared rock surfaces, whether the sample is a rock face, a hand specimen, or piece of drill core is, at best, a qualitative measurement. To obtain quantitative results, it is necessary to homogenize and mix the sample through grinding and pulverization. The sensitivity of the portable XRF analyzers is generally inferior to the more conventional geochemical or assay techniques, but nevertheless, the positive identification of metals of interest in the field contributes to an increased prospecting effectiveness. The metals that can be identified and quantitatively measured by the portable analyzers include copper, tin, molybdenum, lead, zinc, nickel, iron, titanium, tungsten, barium, zirconium, and silver.

4.5.2.6 Laser Techniques

Excitation of minerals using a laser beam followed by the measurement of the resulting luminescent radiation is the basis of the *Luminex* exploration technique developed by Scintrex Ltd. for deposits of tungsten, zinc, molybdenum, gold, and other minerals. Ultraviolet sources are coupled with detectors particularly sensitive to responses from photoluminescent minerals. When mounted in a helicopter, the Luminex system can be used

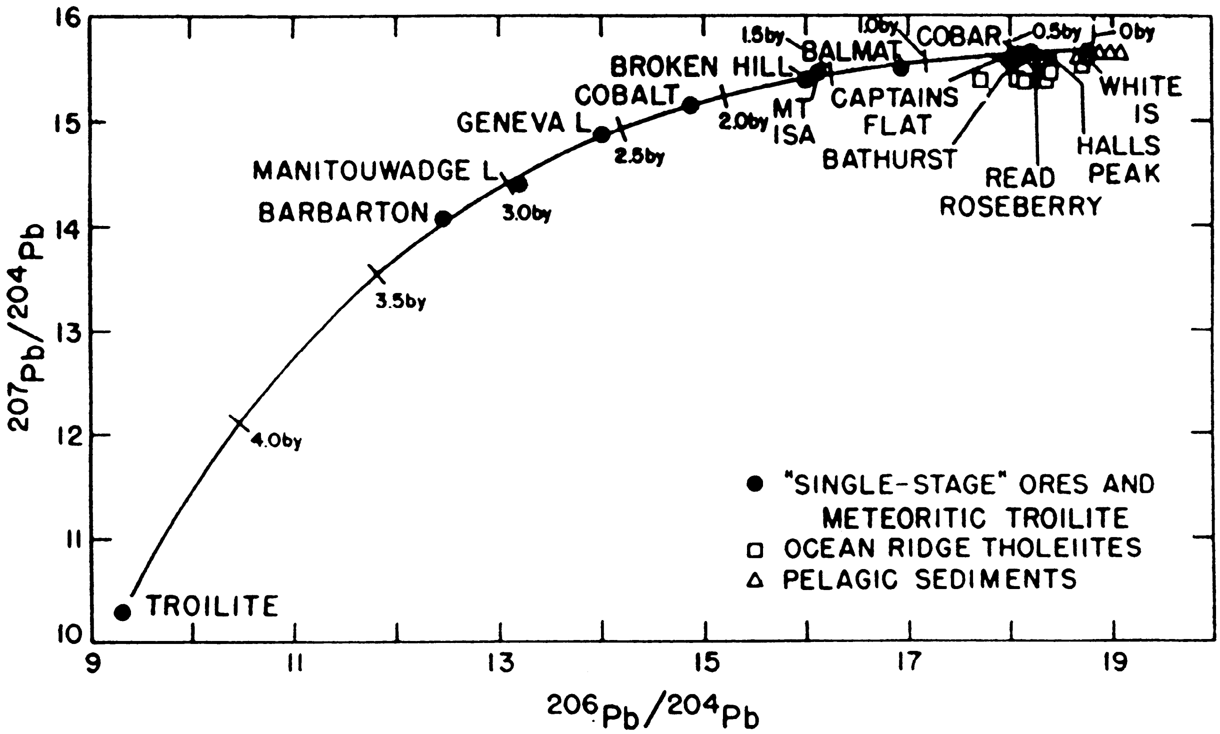

Fig. 4.5.24. Single-stage growth curve and lead isotopic ratios for uranogenic leads from selected ores, ocean-ridge tholeiites, and pelagic sediments. Parameters of the curve are: T_o = 4.43 b.y. (chosen to distribute errors in model-lead ages), ^{206}Pb / $^{204}Pb_0$ = 9.307, ^{207}Pb / $^{204}Pb_0$ = 10.294, and ^{238}U / ^{204}Pb = 9.58 (Doe and Stacey, 1974).

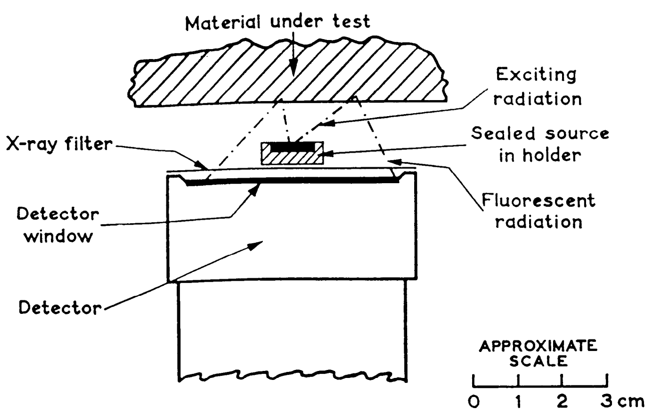

Fig. 4.5.25. Diagrammatic illustration of the relative positions of source, sample, filter, and detector of a portable radioisotope X-ray fluorescence analyser (Bowie et al., 1965). Conversion factor: 1 in. = 2.54 cm.

to detect and quantify responsive minerals occurring in outcrop, and it is probably the first of a series of prospecting methods that will be developed using laser technology.

ACKNOWLEDGMENTS

During the preparation of this summary, the author benefitted considerably from wise and pertinent comments from a large number of people. Sincere thanks and appreciation is extended to A.J. Bjorklund, D.W. Coulter, L.G. Closs, I.L. Elliott, W.K. Fletcher, G.J.S. Govett, H.E. Hawkes, W.C. Lacy, O.P. Lavin, PK. Theobald, I. Thomson, and E.F. Weiland. Mollie Uhl Eaton very efficiently organized the preparation of the manuscript, and Gary Moseley competently assisted with several of the illustrations. Their contributions are gratefully acknowledged.

Chapter 4.6
MANAGEMENT AND NEGOTIATIONS

THOMAS N. WALTHIER (DECEASED)

4.6.1 INTRODUCTION

Exploration success depends upon a supportive corporate environment financing a well-managed exploration group. Qualified people using the most modern technology are essential. Luck is a negligible factor.

D.L. Kyle (1984) stated, ". . . *on average*, the return on all exploration in a region, by virtue of discovery value, is not adequate when considering the risks involved . . . Thoroughbred mining companies, however, show an exceptionally good rate of return on this investment . . . by applying a totally professional approach . . ." This requires "money, experience, perseverance, technical excellence, imagination, ideas, flexibility, time, confidence . . ." The author analyzes exploration risk.

Eisenbeis (1975, p. 8) writes, "Because of the great odds in making an economic discovery, an exploration department could conceivably operate inefficiently and ineffectively for many years before it becomes evident to upper management. In contrast, a well-managed creative exploration group . . . may find one or two acceptable ore bodies with an expenditure equal to the unproductive group."

There have been lucky discoveries—stumbling across an ore-grade outcrop, cutting ore when the drill site was misplaced on a survey error, etc. This is different from a consistently successful record of discovery where luck is not a significant factor (see also Bailly, 1979a). This chapter discusses organization and management that foster a high success rate and a high return on exploration dollars.

4.6.2. ROLE OF THE CORPORATION

4.6.2.1 Corporate Dedication

The board of directors and the president/CEO must truly believe that exploration is an essential part of a mining company. Exploration is necessary to replace the ore that is being mined and is equally important to the company's growth through the discovery of new profit centers.

Exploration must be recognized and accepted as a high risk, entrepreneurial activity not usually compatible with other sectors of the corporate organization. However, "Large mining companies tend to be bureaucratic (and therefore inherently conservative) enterprises engaged in a high-risk business—exploration . . . Well established management rules, which may be effective for mine management, cannot easily be applied to exploration . . . This built-in tension in working styles has always provided difficult management situations" (Anon., 1986). Wooda11 (1984a) writes, "The single most critical requirement for successful mineral exploration is the chain of confidence linking financial investors and Boards of Directors to the scientists and field operators."

Exploration is to be looked upon philosophically as an *investment* in the company's future and not an expense, no matter what the account books say. Funds for exploration, or a dividend, are equally important considerations.

If the person in charge of exploration is not a corporate officer, it indicates less than optimum company commitment. For the same reason, the incumbent should report directly to the CEO. Vice president-exploration (VP-Exp.) is a suitable title.

4.6.2.2 Objectives

Exploration guidelines should be clearly established:

1. *What do we look for?* Commodities sought should have attractive future markets as well as compatibility with the company's growth plans and expertise; i.e., long-range planning is part of exploration, and vice versa.
2. *Where?* In political jurisdictions that possess acceptable investment climates and an attractive discovery potential.
3. *What are acceptable company risks?* In the technical, financial, marketing areas?

4.6.2.3 Size of Program

Availability of funds is the long-term (and usually short-term) limitation.

Funding via equity investors is limited in amount that can be raised and is not usually repeatable without short-term success.

Debt is rarely available to fund exploration.

Income from operating mines is the most secure source of long-term exploration funds.

Two other restrictions on size of the program are

1. Competent staff, especially supervisory staff.
2. Availability of good prospects.

A competent staff can generate more good properties than there are funds available to test them.

Exploration in remote areas, and in foreign countries, adds to the cost and reduces the effective amount of exploration that can be done on the same money. Supervision becomes more difficult and complex.

4.6.2.4 Transition from Exploration to Operations

Once a discovery is made, further testing becomes less and less an exploration process, whereas engineering factors become dominant. At some point, it is appropriate to transfer responsibility to a group with an operating orientation. This is a crucial time, and the CEO must devote much attention to make sure the transition is timely and smooth. It may not be easy.

The exploration group will have developed a paternalistic attitude toward "its" discovery and may resent operations taking over. The latter will have no sentimental attachment to the new deposit. They must search for uncertainties and deficiencies in the data that have to be resolved before they will assume responsibility for a production decision. This can appear to be (and may be) unnecessarily critical. Geological ore reserves are always larger than initial engineering minable reserves. Consequently, the size and even viability of the discovery may be hotly disputed.

Intimate knowledge of the underlying contractual agreements relative to the deposit are initially not known by the operators. Commitments may be overlooked, contractual deadlines missed. Accusations of mismanagement may pass between the two groups.

To facilitate the transition, the CEO must personally see to the gradual involvement of the operating group as a discovery emerges. A separate *Mine Development Group* has been found to be successful (Regan, 1971, pp. 33-39).

4.6.2.5 Budget

Annually, the company prepares a financial plan for the coming year, probably combined with a five-year plan. Based upon these projections, the board of directors and CEO allocate a certain sum to fund the next year's exploration, usually in consultation with the VP-Exp. Emphasis on certain commodities and allocation by countries is stated. The VP-Exp., with the various exploration managers, choose those reconnaissance programs and more advanced projects that optimize the promise of discovery within the funds allowed. Work plans are prepared with estimated costs. The final budget presented by the VP-Exp. is normally the last technical review. The CEO and board concentrate on the broad objectives and whether there is a balance among commodities, political distribution, and reconnaissance vs. advanced projects.

The overall magnitude of the exploration budget is limited by a combination of funds available, corporate philosophy, and alternative investment opportunities. Moreover, there are practical limitations: above a certain budget level, an exploration group appears to lose its effectiveness—likely because of increase in bureaucracy, dogma, overstaffing, and overorganization. Conversely, below a certain level of funding, exploration does not have enough exposure, ability to attract staff, acquire quality prospects, or persevere long enough (see also Bailly, 1973).

What is a minimum-sized program that has a reasonable expectation of success? Boyd (1967) and Morgan (1969) estimated a minimum of $1 to $3 million annually for five years were required. Adjusting these figures for inflation to current 1989 dollars raises the expenditures to about $3.5 to $10 million annually, or a total commitment between $15 to $50 million. Woodall (1984a) states, "The study showed that the average cost of finding an economic metal deposit (between 1955 and 1978) in Australia was A$38 million" (in 1980 dollars). Excluding Western Mining Corp. from the statistics, the average cost increased to A$54 million (Woodall, 1984b). He found that in Canada (1946-1979) the discovery cost calculates to C$20 million, Woodall adds that two to three times this may have to be spent to increase the probability of success to 90%. Assuming an efficient and effective exploration program, a cost of US$30 to $50 million per discovery is generally accepted today. A program of $10 million annually for five years should be more effective than $17 million for only three years or $2 million for 25 years.

When the board approves the budget, part of it may be only contingent approval—depending upon favorable results of the next ensuing phase of exploration.

It is important that the VP-Exp. have some freedom to shift funds between various reconnaissance programs and drilling projects. The money is shifted away from projects that deteriorate in potential into those with improved expectations. Without the authority to move money about quickly to meet changing priorities can so frustrate attempts to better-the-competition that the exploration program suffers significantly. Overall limits in the ability to shift funds may be set by the CEO (such as 5 to 10% of the total budget).

4.6.2.5 Accounting Practice

How expenditures for exploration and mine development are shown on the account books have a marked effect on the company's P&L statement, balance sheet, taxes, and cost of production.

Consider three companies exploring the same prospect (The Prospect). Company A has no operating income but raised $1 million selling stock. Companies B and C have operating mines, which were developed by borrowing $15 million in addition to selling $1 million shares. Operating revenue is $4 million and production costs $2 million. Tax rate is 50%.

Balance Sheets, Beginning of Year

	A	B	C
Assets			
Cash	$1,000,000	$ 1,000,000	$ 1,000,000
Mine (book value)	0	15,000,000	15,000,000
Liabilities			
Debt	0	15,000,000	15,000,000
Equity	1,000,000	1,000,000	1,000,000

During the year, companies A and C consider they have made a discovery at The Prospect after spending $100,000 and proceed to spend $900,000 more on "mine development" than is capitalized. Company B questions the viability of The Prospect after spending $1 million. The changes in financial positions (simplified—omitting depreciation, et al.) during the year are

	A	B	C
Revenue	0	$ 4,000,000	$ 4,000,000
Operating costs	0	(2,000,000)	(2,000,000)
Operating profit	0	2,000,000	2,000,000
Exploration expense	$ (100,000)	(1,000,000)	(100,000)
Taxable income	0	1,000,000	1,900,000
50% income tax	0	(500,000)	(950,000)
After tax profit	0	500,000	950,000
Mine development	900,000	0	900,000

Year End Balance Sheets

	A	B	C
Assets			
Cash	0	$ 1,500,000	$ 1,050,000
Mine (book value)	0	15,000,000	15,000,000
Mine development	$ 900,000	0	900,000
Liabilities			
Debt	0	15,000,000	15,000,000
Equity	900,000	1,500,000	1,500,000

All three companies have used acceptable accounting procedures. They differ because of the subjective decision of what constitutes a commercial discovery (see also Brown, 1983).

Normally, in the long run, all three companies will end up more or less the same. If the prospect is a "real" discovery, the same book value will eventually appear on all the books. (Company B will have to recapture prior "expenses" and capitalize them.) However, if the occurrence fails to prove commercial, it should disappear on all the companies' books, incurring, perhaps sizable, write-offs in companies A and C. However, company A or C can decide not to write off The Prospect, thereby showing a higher net worth and avoiding a difficult write-off, on the belief, or ruse, that The Prospect will be minable "someday."

The three companies were keeping their accounts consistent with their own needs, discovery criteria, and legal/accounting restrictions. In joint ventures, or with minority partners, the participants may have widely different views on what constitutes a discovery and how the accounts should be managed. Serious disputes can arise.

Once a mine is in production, exploration near the mine to extend reserves is expensed; it is no longer capitalized and is considered a mine production cost.

But how close is close to the mine? It is a subjective call whether exploration in the vicinity of the mine complex is "close enough" to be a production expense or outside exploration. If exploration close-in is nevertheless called "outside exploration," it will give the appearance of lower production costs plus a more aggressive exploration program. A guide is that if any ore that might be found would (probably) be processed in the existing milling facility, it should be considered "close enough."

4.6.2.7 Criteria of Successful Exploration

Evaluating exploration success is difficult because of the absence of measurable parameters. A team may use all the appropriate exploration procedures in the correct way, most of the money going "into the ground," yet fail to find ore. They are obviously not successful, but where is the problem and how to evaluate it? Even if successful, have they been sufficiently successful?

The immediately preceding accounting example illustrates some of the evaluation difficulties. Companies A and C each found a commercial discovery after spending $100,000. Company B, by its criteria, did not after spending $1 million—yet they have all found exactly the same thing. Is company B less successful?

The exploration industry in Australia (1955-1978) was studied as to cost, number of discoveries, and cost effectiveness of exploration (Mackenzie and Bilodeau, 1984). Woodall (1984a,b,c) compares this with a similar Canadian study, 1946-1977. Cranston (1980, p. 2) points out that in any such study, the number of tabulated discoveries is less than what eventually will be counted. He states, "As times passes, yet more ore bodies may turn out to be discovered during that interval and the recognized *size* of the currently known ore bodies discovered in those year may become even larger."

In summary, the average cost per discovery is, at best, a crude yardstick of the effectiveness of an exploration group compared to industry as a whole. There are many variables.

A comprehensive worldwide review of exploration expenditures, cost of discovery, etc., is covered in Tilton et al. (1988, Chap. 2).

As noted, the number of discoveries is often used to measure success. But are five small ore bodies worse, equal to, or better than one major discovery? Suppose the sponsoring company is only interested in the "big one;" is that realistic? How often can such a discovery be expected? A low success rate is built in by such corporate guidelines and is not necessarily a measure of incompetence of the exploration team. Likewise, profitability has been suggested as a guide, but the profitability of a mine depends on many important factors such as market price of the product, operating skill, grade, tax and royalty structure, etc., *none* of which measures exploration proficiency.

The best criteria of successful exploration are

1. Is enough ore being found to (a) replenish ore as it is mined and (b) generate new profit centers in line with desired corporate growth?
2. Is ore being found cheaper than buying equivalent reserves?
3. The cost of discovery per ton of ore, or unit of salable product, should not be a material burden on profitability.
4. During the exploration stage, are recognizable fatal flaws and weak links identified and resolved early before a lot of money is spent?
5. Is cooperation good with other corporate departments?
6. Are long-range corporate goals and needs known throughout the exploration staff and do they appreciate their role in achieving them?
7. Are exploration programs, and results, explained clearly and concisely to top management?
8. Is there good budget control?
9. Is morale good?
10. What percentage of (production) (earnings) (revenue) (growth) is derived from new discoveries within the last (5) (10) (?) years? If low, this shows something is wrong, but it begs the question of "why?"

4.6.2.8 Compensation

Small exploration companies will generally approach remuneration differently from a large, mature-operating mining company. In the former, exploration success is vital to survival. Cash is in short supply. Salary and fringe benefits will be lower but offset with noncash items like large stock options and deferred expenditures like discovery bonuses. The potential reward from success must be sufficient to entice quality people away from a more secure good salary, fringe benefits, and a comfortable retirement.

Exploration is not such a vital element in a large operating company. Base salaries and fringes will be standardized company-wide, based on industry averages. Stock options may exist but will extend down equally in all corporate departments, hence are not per se a reward *for discovery*. There might be an ad hoc reward for a significant discovery. If so, it most likely will be treated confidentially and hence is not a motivation to others.

In granting discovery awards, care must be taken to ensure that *all* employees who made a material contribution are recognized. Others may think they were contributors, but really were not. They will be upset at being omitted. Some companies take the easy way out and eliminate discovery bonuses because it is difficult to determine who should get what.

There is some evidence (Regan, 1971) that a policy of extra, or special, compensation for a discovery does not *motivate* top quality professionals although such incentives can attract excellent people to the company and help retain them.

To summarize, an anonymous exploration executive has said, "Successful exploration *requires* other things beyond a good exploration approach."

4.6.3 ROLE OF THE EXPLORATION DEPARTMENT

4.6.3.1 Staff

This will comprise "support" and "technical" people. The former consist of clerical, accounting, legal, etc., and are similar in background and training to those in most business departments, the management of which has been discussed many times. The rest of this segment, therefore, will concentrate on management of the technical staff.

4.6.3.2 Technical Staff

Qualifications: A strong background in the earth sciences is essential, with particular emphasis on descriptive geology of ore deposits plus up-to-date concepts on ore genesis. A thorough understanding of modern exploration technology is crucial. Knowledge of ore bodies should encompass many types and kinds as this expands the explorer's ken to the vast number of geologic processes that can concentrate minerals and metals into minable deposits. It minimizes parochial thinking. In addition, all the staff should have an understanding of the principles of geochemistry and geophysics and the fundamentals of mining methods and extractive metallurgy. There should be a good working knowledge of the laws and regulations governing mineral rights and mining in those areas where exploration is being carried out.

Exploration makes great use of geology, but in applying geology, its role is restricted solely to finding ore and making money. This is quite different from running a geological survey or speculating on the composition of the earth's core. See also Ohle and Bates (1981).

A dedication must exist to finding ore. Most of the person's professional career should have been spent involved in the discovery and acquisition of mineral deposits.

As Parker (1988) has said, "The individual explorer must be personally committed to the general exploration program and should work in areas with which he/she has geological familiarity."

Experience in mining operations is useful, but extensive exposure to operations accentuates an engineering desire for precision, certainty, and risk avoidance. These are not the dominating personal traits of a successful explorationist.

In addition to a good technical background, the mineral explorer should have an entrepreneurial flair. It is necessary to have the courage to commit, on a continuing basis, large sums of company money where only sparse and indirect evidence exist, relying upon experience and judgment that the potential rewards are compensatingly large. It demands a personality comfortable working in this environment. This does not imply the person is reckless and flamboyant. He is *not* a gambler, but a calculating risk taker employing the most modern technology and concepts to improve the possibility of discovery.

Bailly (1979b) discusses the personality of a successful explorationist. "Good exploration people are rarely among the best of earth scientists; they are just keen on using their . . . knowledge . . . to find new deposits." Bailly further quotes Drucker (1964) that the purpose of staffing is not to minimize weaknesses but to maximize strengths. People that perform well (i.e., discover ore) are *the key* people, even though they may have weaknesses-technical or personal.

Past participation in making a discovery is almost essential: "The more ore deposits you are involved in finding, the better you get at it" (Kohls, 1988; Bailly, 1979a).

Exploration *managers* are more difficult to find than good field people. Eisenbeis (1975) discusses this at great length. He quotes Katz (1954, p. 90) that the engineer (scientist)-manager must have three managerial attributes: technical, human, conceptual. "Human" means the ability to work as a group member and leader and inspire teamwork and enthusiasm. Conceptual skill is the ability to see the total picture (company goals, resources, and political structure) and be able to operate in that environment. The VP-Exp. is the key post that integrates the technically oriented explorers into the company environment. Fellows (1968) lists inherent conflict areas between managers and technical professionals. Some are

1. Professionals will not accept direction from low-ranking nontechnical people.
2. Technical people often look upon "management" as undisciplined politicians.
3. Even a technically trained manager must use diplomacy in giving directions to professional subordinates.

The single most important duty of the VP-Exp. is the selection of staff. "His main discovery contribution, therefore, is to select and to retain only *outstanding* people in order to obtain the best technical work management at all levels" (Bailly, 1973). [Emphasis added.]

Another critical task is "to ensure that a favorable idea-generating and idea-nurturing climate is maintained." This takes effort; it seldom occurs accidentally. It is easier in some companies than in others (Regan, 1971).

The top manager of exploration, the VP-Exp. must also be acutely aware of the corporation's tolerance for risk taking, which varies widely among companies, or with a change in management.

The VP-Exp. must also have the ability (and courage) to bring to a prompt end projects that were once exciting favorites that have lost their potential.

4.6.3.3 Delegating Authority

Much field work is done by geologists acting independently in widely scattered areas without good communication. This requires a large amount of delegation of authority and responsibility by the VP-Exp. and the regional exploration managers. Clear guidelines must be given on commodities to be looked for, acceptable terms for the acquisition of mineral rights, minimum size of deposit sought, what are acceptable risks, and what are the limits to the delegated powers. A large amount of travel by the supervisors will be necessary to preserve control.

Rose and Eggert (Tilton et al., 1988) have recognized two fundamental management styles in exploration groups: (1) exploration managers who dominate the scope and direction of the program and (2) exploration managers that lead a team of specialists. They conclude that the former appears to be more successful with the proviso that the manager must be competent or the whole thing fails. "Dominate" means inspiration and leadership, *not* deciding every minute detail.

Good morale is essential, both individually and as a group. "Good" morale equates with satisfaction in attempting to achieve the company's objectives. Lack of such commitment constitutes "low" morale. First, the corporate goals should be consistent, clearly defined, and surrounded with a sense of importance and urgency (Bailly, 1979b). Furthermore, Read (1962) and Shepard (1961) have concluded that unsuccessful groups historically are very dogmatic, highly critical of the company and of members within the group.

4.6.3.4 Special Considerations

Every mineral commodity has its unique set of technical, economic, and marketing factors that impact directly on what constitutes a commercial ore body. Base and precious metal deposits are fairly straightforward, with tonnage, grade, metallurgical recovery, and infrastructure availability the major considerations. Other minerals, especially the nonmetallics, may have very critical texture, impurity, color, or location restrictions that outweigh almost everything else in evaluating commercial viability. Do not start exploration for a new commodity until a thorough study has been made as to what special factors may dominate the assessment. Special knowledge, via consultants, usually is needed.

4.6.3.5 Control of Mineral Rights

There is nothing more embarrassing and unforgivable than to make an important discovery only to find it belongs to someone else (see Chapters 3.2 and 7.1).

Absolute legal ownership of the minerals must precede discovery, which means unequivocal control occurs very early in the exploration process.

The basic procedures for obtaining control are established by the laws and regulations of the country, especially the mining law. The rights and obligations of the explorer and miner must have been thoroughly understood. This requires a competent local legal advisor.

Mineral rights may be owned privately or by the government; similarly with the associated surface rights. Private mineral and surface rights may be owned by the same or different parties.

In most political jurisdictions, mineral rights are considered senior to surface rights, which means mining (and by inference, exploration) may proceed without consent of the surface owner. Courtesy, as a minimum, requires asking permission to trespass. However, the miner must compensate for damage to, or the loss of, the surface. The compensation may be set by law or it may be left for the parties to negotiate. Agreeing to the damage amounts should be established before exploration starts and loss occurs.

Private Ownership: Property ownership can be sold, leased, or passed on by inheritance. After several generations, ownership may be widespread with many heirs unknown. If surface and mineral rights are separate, the problem is compounded. However, surface rights usually incur property taxes, so at least the heirs that are paying taxes form a good starting point in tracing ownership. Separated mineral rights, in many areas, are not taxed, and the search for unknown heirs and owners (who are often ignorant of their inheritance) often approaches the impossible. Consult local legal counsel if there are procedures for extinguishing the rights of lost owners. Some countries (Ireland, for example) have started taxing mineral rights. If taxes are not paid, the mineral rights revert to the state. This quickly sorted out mineral ownership, which had been a horrendous quagmire in Ireland. The change was subsequently followed by an exploration boom.

Once ownership is determined, negotiations commence, culminating in a written contract giving the explorer the right to test for ore and, if found, conveys the irrevocable right to exploit the discovery. Compensation to the owner of the minerals is set out. See 4.6.5 for details. Compensation to a different surface owner should also be resolved at this time.

If a third party has obtained mineral rights directly from a government (see below), the ensuing negotiations will be carried out as if the third party were a private owner. The new group, however, will have to assume all the obligations and commitments that the third party agreed to with the government. Many governments allow the free transfer of mineral rights, but sometimes the transferee must show technical and financial competence.

Government-Owned Minerals: Minerals are available by either

1. Laying claim to a tract of land (maximum size specified) by posting notice in the field and recording a copy in the appropriate government office. This is called staking or pegging a claim. Annual work commitments and/or rentals are imposed to maintain the claims in good standing. The details of staking and maintaining claims can be complex and vary state to state and province to province. Seek local legal advise on the detailed procedures. Even minor variations in carrying out the procedures may void the claim. The law and procedures pertaining to staking, filing, and maintaining claims in the US are summarized by Pruitt (1987).

2. Issuance by the government of a concession to qualified applicants permitting exploring and mining. Laws and regulations itemize the conditions and obligations. Concessions can cover large areas measured in square miles (square kilometers) as opposed to individual claims that usually encompass a few acres (hectares). Because concessions tend to be large, there are usually stipulations that a certain percentage must be dropped after specified time periods, such as 50% every two or three years. Annual work obligations and rentals are common. The terms and conditions may be standard and spelled out, or they may be individually negotiated at the time the concession is requested.

A government may consider a parcel of ground to be so attractive that it will call for an auction, requesting interested parties from around the world to submit (sealed) bids. While this is common for oil, gas, and coal concessions, it is rare for hard minerals.

4.6.3.6 Water Rights

Almost every operating mine requires a secure source of process water. Water rights may be scarce and considered more valuable than surface rights, hence very difficult and expensive to acquire.

Rights to water may be privately or government owned. All available water may be already allocated to farms (irrigation), factories, and towns. If so, somebody's rights will have to be bought. An alternative can be to set up an exploration program to discover a new underground source. Even if successful, government authorities may have a strong voice in how the discovered water will be allocated.

As soon as a prospect begins to show signs of being commercially viable, start securing water rights via options to purchase, filing for an allocation of undedicated rights, or assessing the possibilities for discovering a new aquifer.

4.6.3.7 Land Records

Any sizable exploration program will generate a large number of documents covering staked claims, joint ventures, leases, concessions, and options to purchase or lease. There will be a bewildering assortment of terms and conditions and a variety of deadlines and commitment dates. An emerging valuable discovery can be lost if a commitment is overlooked.

A systematic procedure to monitor all obligations and contracts is essential. It should be the responsibility of one person. In some large companies, a separate land department is established. However, the person in charge of a field project must also be aware of all the obligations so that work commitments are completed in a timely manner and rental payments can be justified.

Deadlines, payment dates, and commitments should be programmed into a computer retrieval system such that they are flagged in adequate time for the field people to generate the data needed to justify the next commitment. Large monetary commitments may need more advance warning if higher management review and approval is necessary.

4.6.4 EXPLORING IN FOREIGN COUNTRIES

Exploring abroad is more complex than in the home country—and usually highly complex. It is also more expensive.

Much of what follows relates to the operating stage of a mine in the foreign country. However, it is almost always the exploration division that makes the initial contacts in the country. It bears the responsibility for making certain that activities in the country are properly organized for the entire period the company will be active there.

4.6.4.1 Selecting the Foreign Country

Two fundamental considerations are

1. The political and financial climate must be acceptable and appear stable for many years.

2. The geologic setting, and evidence of mineral, is promising for the minerals being sought.

Beware of countries that have been traditionally negative about foreign interests mining their national patrimony and then, suddenly, espouse an enthusiasm for it. Perhaps the change is real and lasting, but inbred attitudes can resurface rapidly and investment incentive laws be repealed. This can coincide when sizable profits are about to be remitted or with a change of government.

Assessing the political risk of a country as a place to invest is a very difficult task. It should not be the result of a few casual trips, a visit to a local attorney, banker, and your embassy plus touristic literature. It involves an in-depth analysis of the political scene, the country's history, and how that has influenced the current socioeconomic scene. Is the regime stable and likely to last? Is the economy strong? What are the people's *real* attitude on foreign investment? It is difficult to get up-to-date, informed, unbiased data and opinions on these issues. Coplin and O'Leary (1987) discuss how to collect objective data and various do's and don't's to arrive at a reasonable evaluation.

4.6.4.2 Initial Steps

Having chosen the country, the first chore is to find a good attorney. Then, in most countries, forget about exploration for six months to a year until all the formalities related to starting a mining business are taken care of.

Performing serious exploration on tourist visas can be a serious violation of the immigration laws. Start promptly to obtain proper work visas.

4.6.4.3 Selecting an Attorney

Recommendations can come from your embassy, home country law firm with international connections, branch of a foreign bank, CPA firm, or foreign firms operating there.

Qualifications include

1. Fluency in your language as well as the local one.

2. Comprehends how the laws and tax regime of his country must mesh with your home country for combined maximum benefit.

3. Is well respected for his legal ability.

4. Has easy access to top political officials of all major parties but officially is politically neutral and noncontroversial.

4.6.4.4 Corporate Structure

Determine which legal vehicles are recognized in the country, for example, branch of the home company, limited partnership, joint venture, corporation, etc. The one that is selected by top management will be on the advice of tax, legal, and financial experts and will have three objectives

1. Maximize remittable profits.

2. Minimize the *combined* tax burden of the foreign and home countries.

3. Management flexibility and control.

This is a very complex issue and may take months to resolve.

The corporate structure is not irreversible, but subsequent changes may incur large costs in capital transfer and corporate reorganization fees as well as legal costs. Deemed income may be assessed on the shifting of corporate assets, thereby incurring sizable income and VAT (value added taxes).

4.6.4.5 Foreign Investment Agreement

Some developing countries will enter into a contract with a potential foreign investor, guaranteeing certain financial conditions to encourage the investment.

These agreements are complex documents and tedious to negotiate, but are usually considered worth the effort.

Topics that may be included are

1. Guarantees will last for a period of time, say, 25 years, life of mine, etc.

2. Guarantees will cover a stated amount of foreign investment.

3. Specify a fixed income tax rate.

4. No additional, or discriminatory, taxes, fees, or charges will be imposed.

5. Right to foreign exchange at most favorable exchange rate on day of transaction to service debt, pay foreign bills, repatriate capital, and freely pay dividends.

6. Exoneration of customs duties and relief from bureaucratic delays.

7. Number, and work conditions, of expatriate employees.

8. The operation will be treated and governed as any other business in the country. The general commercial code, general labor law, etc., will govern. There will be no discrimination in regulation of the operation.

9. If restrictions are placed on the amount of product that can be exported, the price received on prescribed domestic sales will be no less than the net amount that could have been received from the most attractive sale abroad.

10. In case of expropriation, the conditions of compensation are spelled out, and specifically how the value is to be calculated.

Which terms are included and how inclusive they are will depend upon the skill of the negotiators as well as restrictions contained in the law or decree authorizing such agreements.

4.6.4.6 Staffing the Foreign Program

Qualifications: The qualifications of the domestic exploration staff apply equally here (see 4.6.3a), but more things must be considered.

Supervision will be less frequent.

In much of the world, infrastructure will be less developed. Service industries support will be poor or absent. Considerable time will be spent improvising or attempting to import goods and services, which in the home country can be accomplished with a local phone call.

Language differences may mean that only bilingual people can be employed; hence fewer candidates can be considered.

Living conditions (for example, housing, food, schooling, medical care) may be inadequate. Many spouses and children may not readily accept the environment. Some qualified job candidates will decline for these reasons. Any foreign assignment is disruptive to a family unit. Some people will "make do" for a while, but only a small percentage really enjoy it and make it a career.

Some companies feel strongly that their senior representative in a foreign country should be an expatriate, rather than a local citizen. This stems from a feeling that a national may have a conflict of interest between what is best for the company vs. what is best for the country or local employees. It is perceived that the local government can put more pressure on a national to take (or not take) certain actions, thereby compromising the company.

It may be that local citizens are not available, either because they are poorly trained or happily employed. In many cultures, manual work is demeaning to anyone with a college education. Local geologists may look upon field work as unacceptable manual labor.

In any event, expatriates may have to fill in.

Compensation: Since candidates and families ready, willing, and able to work overseas are harder to find, qualified ones are enticed and rewarded with higher remuneration.

A number of consulting firms keep records on overseas compensation packages currently in vogue with multi-national companies. They can tailor-make a program to meet your needs.

Overseas benefits are usually based on a percentage of a base salary, which is taken as the salary that would be paid for a comparable position at home.

Common benefits and perquisites are

1. Overseas bonus, calculated as a percentage of base salary (15% is a typical number).
2. Hardship premium (percentage of base), if applicable.
3. Reimbursement of income taxes over and above what employee would have paid in home country on base salary. Only company-derived income and perks are considered in calculation of the reimbursable amount.
4. Cost of living adjustment: a payment so the employee may approximate the same life style overseas as if at home.
5. Housing allowance: may be included in the foregoing, but housing must also be an appropriate standard for the people that represent the company.
6. Company-provided car. Because of import duties, vehicles may be two or three times more expensive. When driving conditions are difficult, a chauffeur may also be provided.
7. Tuition, books, lodging, and travel, if necessary, for children through secondary school. Costs are reimbursed for the closest home-language school that meets home country college entrance requirements.
8. Payment to transport household goods to and from the assignment.
9. Annual paid trip for the family back to home country for a vacation, often of one month's duration.
10. In case of serious medical problems, paid trip(s) to a medical facility meeting home country standards.

The foregoing benefits will at least double the cost of employment overseas. Not all of the foregoing are necessary if the country of assignment has a high-quality life style and a cultural background similar to the home country.

Employees are encouraged to take only as much salary in local currency as is needed for current living. The balance will be paid into a home country bank account. Paying split salaries can cause local accounting and tax problems; check with an appropriate legal and accounting counsel. The company is not responsible for foreign exchange losses if local currency is accumulated, nor is the company responsible for losses incurred on local investments (including any home purchase).

4.6.4.7 General Conditions

In many parts of the world, infrastructure is poor to essentially absent. Travel to the field can be slow and arduous. The geologic framework may be poorly known or incorrectly interpreted. In these cases, exploration will proceed slowly. Support facilities and exploration contractors may be missing. If local ones exist (for example, an assay house), the government may insist they be used instead of foreign facilities, no matter how poor the quality and reliability.

4.6.4.8 Discovery is Made

Prior to discovery, the local exploration manager (LEXM) has been the senior representative of the company, dealing with the top government officials and enjoying high-level business contacts and an attractive social life. When parent company executives visit the country to review the exploration developments, the LEXM is host and the focal point of the visit.

Then the important discovery is made.

Before long, an operations general manager (OGM) is appointed and stationed locally. The OPM becomes the senior representative of the company with all that it implies. The LEXM is lower in the management structure because of what has been built over and around him. Further exploration may be curtailed until the cash drain from building the new mine-mill complex is completed and exploration can be financed out of locally generated cash flow.

When resumed, exploration becomes an *expense* against mine revenue, increasing the costs of the new operating mining company. Because of this, the OPM will seek a strong voice in directing further exploration. The CEO may eventually have to become involved to resolve company in-fighting.. This scenario need not happen, but without cooperation among the LEXM, OPM, and VP-Exp., and an attentive CEO, the situation can get out of hand.

If the LEXM's morale deteriorates, he might be transferred to a new country. This is expensive and his local experience is lost. There is a practical limit to how many times this solution can be used. The LEXM can be brought home to the executive office as, perhaps, Assistant VP-Exp. This is expensive; local expertise has to be rebuilt, and it has limited repeat possibilities.

Something should be done, or the LEXM can be lost to a competitor.

The best solution is for the LEXM to be made part of, and truly treated as, a key member of the local company's *management team.*

This must have the full backing of the CEO, OPM, and the head of international operations. The LEXM can contribute significantly to the preproduction mine development, even should continuing exploration be deferred.

4.6.5 NEGOTIATIONS

Many transactions are involved in the exploration business that require extensive negotiations. Those that are most crucial are the negotiations related to the acquisition of mineral, water, and surface rights, and these are the subject of this subchapter.

All contracts involving mineral and surface rights must be written and signed by both parties before they are binding and effective. A precise legal description of the property is essential, and the whole agreement depends upon proof of clear and merchantable title.

While outright purchase contracts are made for mineral rights, the usual deal involves an option to either purchase or lease. The option period allows time to test the area and justify the previously agreed to purchase price or lease terms as well as a final verification of title.

A valuable guide is found in the *Landman's Legal Handbook—A PracticaI Guide to Mineral Leasing,* published by the Rocky Mountain Law Foundation (Anon., 1982). See also Maley (1983).

The Rocky Mountain Mineral Law Foundation has prepared a compendium on US mining laws, regulations, proceedings, and pitfalls entitled *American Law of Mining* (Anon., 1984). It is updated with yearly supplements. Since July 1955, the same

Foundation has sponsored annual sessions focusing on current legal problems facing the US mining industry. The results are published under the title *Rocky Mountain Mineral Law Institute.* The Foundation has also held two workshop sessions on all types of contracts used in the industry: lease agreements, drill contracts, consulting arrangements, joint venture contracts with a section on accounting practices, etc. These two publications entitled *Mining Agreements, Institutes I and II,* are more general in content and have application beyond this country (Anon., 1979, 1981) (also see Chapter 3.2).

4.6.5.1 Nature of the Mineral Rights Market

Mineral commodities are cyclical in demand with accompanying variations in prices. When prices are high, exploration for that commodity accelerates, and it will be concentrated in those areas with high discovery potential and a good investment climate.

The demand for the right to explore will surge and wane accordingly. The terms and conditions explorers will pay will fluctuate to the same rhythm. In a loose sense, there is a market for mineral rights. One has to meet the "going price" being offered by the other companies active in the area. This equivalency of offers is largely subjective as no two tracts of land are precisely the same in size or geologic attraction, but perceived relative equivalence of offers does exist nevertheless.

Appreciably more attractive acquisition terms can be obtained by exploring areas off the beaten track. This is offset by the usually much higher discovery cost, or political risk, in working in a virgin area.

4.6.5.2 Acquiring Partly/Fully Developed Ore Bodies

The asking price will be substantial, to reimburse for the high-risk early exploration that was paid out, plus the expectation of a reward for having made the discovery. A sizable down payment is usually involved, and the other financial conditions are higher than if unexplored ground were involved. A deal will be possible only if the seller's lowest acceptable price overlaps the buyer's highest evaluation.

The property may be sold in its entirety, or only partial divestiture may be under consideration.

Before the deal is consummated, the buyer will want time to do a "due diligence" evaluation. This allows time to verify title and confirm the previous work, especially ore reserve calculations and metallurgical recoveries. A determination will be made of what government clearances and permits are in hand and those that may be needed in addition. In short, verify what has been done, outline what has to be done, and determine if there are any weak links that must be resolved. Almost certainly a major consideration will be the potential for discovering considerably more ore.

The foregoing assumes that the prior work was done properly. Problems arise if that is not the case. The prospective buyer will not want to reimburse exploration costs that were poorly planned or incompetently carried out. Critical backup data may have been lost, or the results appear suspect, and the work has to be duplicated. If the property is attractive enough, reimbursement may just have to be considered part of the purchase price, attributing little if any value to the prior results.

A corollary is that owners of minerals should not test their property unless it is done in a professional manner by experts and all the results preserved in a businesslike way.

4.6.5.3 Acquiring Undeveloped Properties

These are properties possessing only indirect evidence of ore. The potential buyer will put up the front-end exploration money and take the high risk that something will be found. Substantial front-end payments are not justified until there has been time for exploration to indicate the existence of commercial mineralization. An option agreement provides the time to do the required exploration.

The duration of the option period (commonly in the three- to five-year range, but remote, rugged terrains, or the search for deeply buried ore may double this period). The amount and schedule of rentals, the size of work obligations, and the purchase price and manner of payment, or the lease terms, are negotiated and then incorporated into a formal contract.

4.6.5.4 Manner of Payment

Mineral properties can be paid for in several ways

1. Cash: *Lump sum.*

   Installments, usually tied to start-up of the mine with small interim payments.
2. Company stock of the buyer.
3. By royalty payments: kinds of royalties are

   Advance, before production starts, and these are in reality rentals; they may or may not be credited (in whole or in part) against future production royalties.

   Production, as ore is produced, a negotiated percentage of the value is paid to the previous owner.

   Minimum, no matter how small the production royalty is, a minimum payment is made regardless (monthly or annually).
4. Royalty cap: payments made until the aggregate equals a specified amount, whereupon further royalties cease.

Production royalties can be calculated as a percentage of the total price *received from the sale* of the ore mined. This is called a "gross revenue royalty." More typically, certain charges and costs are deducted, such as freight and insurance from mine to the buyer's facility, deductions and penalties for impurities, and subsequent treatment charges, sales taxes, etc. These are commonly referred to as *net smelter return* royalties, or NSR royalties.

Some owners believe they should be paid a royalty on the full mineral content in the ground, at prices quoted in current mining periodicals. This is mistaken because

1. Ore in the ground is an estimate only and not a precise measure at any specific extraction site.
2. There will be mining losses and dilution.
3. The mill will recover only a percentage of what is mined.
4. The price received by the mine will be less than the quoted price because of freight and insurance to the buyer's location, processing and refining costs, and attendant losses by the buyer. Published prices may not reflect discounts that are the reality of the marketplace.

Royalties may be based as a percentage of the profit made by the miner. Profit has to be carefully defined. It may be gross cash operating profits, but paper charges, like depreciation and amortization, may be deducted, or it may be a percentage of "taxable profits" where additional costs, such as corporate (general and administrative, G&A), can be deducted before calculating the royalty amount. Such royalties can be refereed to as net profits royalties (NPR) or net profits interest (NPI).

The mining company prefers NPRs because the owner shares only when prices are sufficient for both parties to enjoy the profits. In times of low prices, both parties suffer together. With an NSR, the owner may be enjoying high royalty payments while the mine operator is losing money. Care must be taken that the

NSR owner is not penalized because of poor mine management and excessive costs unnecessarily reducing profits.

It is a common rule of thumb that in a well-managed operation, a stated NPI percentage is equivalent to an NSR of about half that amount (i.e., 4% NSR equates to 7 or 8% NPI). Specific conditions can grossly distort this ratio.

4.6.5.5 Holding Costs

Some owners grant long-term leases or options at only nominal holding costs. Under such relaxed conditions, the lessee may let the property go unexplored and lie idle. No other party can be enticed to explore because of the double financial burden to the owner and the lessee. To prevent such stalemates and the deep storage of good mineral properties, the owner should insist on rentals or work obligations, increasing with time, to prevent long-term control of the property without an incentive to test and develop. The rentals and obligations should be high enough to foster testing in a prompt way but not so onerous as to deter reasonable people from making a deal at all. Knowledgeable consultants can be found to advise what are acceptable and reasonable terms.

4.6.5.6 Joint Ventures (JV)

This is an arrangement whereby a party who controls a tract of mineral rights joins with a technically and financially competent party to test and develop the minerals for their mutual benefit. In essence, the first party contributes the mineral rights (plus any relevant data, facilities, and expertise) while the other party(ies) contribute money and expertise. Superficially, it appears to be a partnership, but there are important legal differences. Some countries do not have the legal structure to permit forming a true "joint venture." A "partnership" can have significantly different tax consequences.

These are complex deals to negotiate. Both parties tend to be sophisticated and financially responsible. The bargaining can become complex.

The basic items to be negotiated are

1. How much money must be spent by the incoming party, over what time period, to earn what percentage interest? After earn-in period, both parties contribute their share of costs and enjoy their share of profits and cash flow. The earn-in may be staged so that after putting up $X, a permanent Y% equity has been earned. The contributing party may stay at that equity level, whereupon both parties contribute proportionately, or the farming-in party may elect to continue to fund 100% to earn a higher interest.

2. Who manages while the farm-in party puts up all the money? Generally, the financing entity can insist on the right to manage, but for a variety of reasons may let the noncontributor be the manager.

3. Qualifying expenditures must be carefully defined, especially nebulous charges like management fees, rental charge of company-owned equipment to the joint venture, corporate overhead, depreciation, etc.

4. If the JV is to be equally owned (50-50%), how are deadlocks and stalemates resolved?

Possible solutions in case of deadlock are

a. Major decisions (defined) require unanimous vote.

b. The manager can unilaterally invoke a budget no greater than % of the last approved budget, provided it must be large enough to preserve rights to the property.

c. Invoke arbitration.

d. Either party can set a price at which the other party must sell its equity or buy out the other party.

e. The right of first refusal to buy the other participant's interest at a third party's offering price.

f. The manager (or either party) can invoke a work plan and budget after certain procedural attempts at reconciliation. The other party has the choice of contributing or diluting. Dilution of equity interest tracks the percentage shortfall of its financial contribution compared to the other party's. There may be a point below which no further dilution occurs no matter what the financial shortfall. This residual interest effectively becomes a NPI. Alternatively, dilution below a certain percentage automatically reverts to 0%.

g. The manager automatically is replaced if it becomes bankrupt.

h. If a large exploration area is involved, small portions can be spun off and set up as special projects. Percentage ownership can be different and, so too, the manager. Special projects arise when one party wishes to concentrate exploration there while the other does not and is willing to dilute in this restricted portion.

i. Convert the joint venture into a corporation, with each party owning half the shares. Outside directors provide the swing votes.

A small company may be reluctant to enter a joint venture with a major company for fear that the financial disparity will end up in dilution for them, or somehow in their being squeezed out. It can be agreed that should the small company not be able to meet a cash call, it can request the large financially-strong company to advance the money on its behalf at some agreed interest rate (prime plus). This will be subject to preferential payback out of operating cash flow to the major. This carried advance may be all the way to production, or just to the stage where the project is "bankable," that is, the junior can borrow money from the banks with the project as collateral. It should be the responsibility of the major partner to prepare sufficient documentation of the viability of the project so that it truly is bankable by the junior.

4.6.6 SUMMARY OF EXPLORATION SUCCESS

Regan (1971) canvassed the North American mining industry and from the polled data selected the seven most successful exploration companies and the seven least successful during the period 1966-1970. The first group reported 12 major commercial discoveries during the period, the second group only one. The companies were analyzed, and executives interviewed, to see whether significant differences existed in their approach and methodology toward exploration. The results, abstracted and generalized in Table 4.6.1, appear equally germane today as in the 1960s.

Corporate organization was found by Regan to vary widely, and there was no discernable pattern distinguishing the two groups' organization charts. The same was true with accounting practices.

Disparity in budget size existed between the groups (five-year total for six of the seven most successful was $177 million vs. (estimated) five-year total of the seven least successful of $50 million. This must account for some of the difference in the number of discoveries, but the other factors seem surely to have influenced the discovery rates as well.

Table 4.6.1. Differences in Approach and Methodology of Successful and Unsuccessful Exploration Companies

Factors	Successful	Unsuccessful
Does a formal system (such as a Mine Development Group) exist between Exploration and Operations?	Yes	No
Is technical competence of staff stressed?	Definitely	Less so
Is long-range planning important?	Definitely	No, or less so
Does exploration deviate from company policies?*	Rarely	Variable, but tends to
Does top management dwell on exploration's past successes or failures?	Successes	Failures
Exploration morale	High	Low(er)
Interdepartmental communications	Well developed	Poorly developed
Annual budgets	Large	Medium to small

Section 5 Project and Mining Geology

HOWARD HARTMAN, SENIOR EDITOR
DONALD E. RANTA, SECTION COORDINATOR

Chapter 5.0
INTRODUCTION

DONALD E. RANTA

Every mineral project or mine is based on a geologic entity-an ore (mineral) deposit. A well-defined mineral deposit and its associated geologic characteristics are the only aspects of a project that cannot be altered. Mine plans can be modified to exploit the deposit using alternative approaches and yielding similar results. A variety of processing methods also are often available producing generally comparable results. Major modifications can be made to other aspects of the project without substantially changing project economics. However, all engineering and metallurgical aspects of a mine must be accommodated to the specific location and geologic characteristics of the deposit.

Geologic data and interpretations form the foundation for both mine evaluation and mine production by providing estimates of reserves and essential information for mine planning and process design or control. Proper geologic work requires a keen awareness of and an ability to anticipate the technical requirements of geotechnical engineers, hydrologists, mining engineers, metallurgists, and other specialists. Geologists are integral members of the project evaluation or production team. Presentation of pertinent data in a usable format and frequent communication of new geologic knowledge to the other members of the technical team are integral components of the geological program.

The ultimate objective of the exploration geologist is to find ore, of the project geologist it is to define the ore, and of the mine geologist it is to keep the mine in ore. Project geology follows sequentially after exploration, once a discovery of potentially economic mineralization takes place and evaluation and development proceed; mining geology begins upon the commencement of production, but also can be defined to include project geology. Project geology combines many of the elements of exploration and mining geology through the delineation of mineralization and estimation of reserves. Feasibility studies and development decisions involving large capital outlays require great accuracy in mineral deposit definition and reserve estimation. The greatest single cause of mine failure worldwide is unreliable reserve estimates. In addition, the project or mine geologist is expected to identify potential ground stability and hydrological problems.

Section 5, Project and Mining Geology, relates the procedures and goals required for sampling, assaying, geologic data collection, delineation, geologic interpretation, and reserve estimation of a mineral deposit. In Chapter 5.1 of this section, the general principles of project and mining geology are presented, including responsibilities, procedures, importance, and objectives. Responsibilities of a project or mine geologist include continuing evaluation of the mineral deposit; exploring for more reserves within the district; and contributing to the mine planning, metallurgical testing, land acquisition, land use planning, environmental, and other programs. Procedures for the collection, analysis and interpretation of a variety of critical geologic data are presented in Chapters 5.2 through 5.5. The most common methods of gathering geologic data are by mapping and sampling geologic features, both at surface and underground, when available, and by collecting and logging drillhole samples, as discussed in Chapters 5.2 and 5.3. Collection of samples manually or by drilling should provide material that is truly representative of selected portions of the original rock mass under study. In addition, geochemical surveys, geophysical surveys, mineralogical and petrographical studies, geotechnical investigations, and other studies often provide valuable insights in understanding the geologic setting of a deposit. Sample preparation and analysis, described in Chapter 5.4, are designed to produce analytical results that are accurate for the samples collected.

Interpretation of geologic and analytical data, discussed in Chapter 5.5, is essential in the understanding of a geologic setting, the determination of ore controls, the development of a geologic model, and the delineation of mineralization. Valid geological interpretation relies on reasonable assumptions and judgments as to the adequacy of sampling, assay quality, and geologic projections. Interpretative data has a major impact on mine operations through definition of the location, size, shape, attitude, tonnage, and grade of mineral reserves, as described in Chapter 5.6, and by providing other information on geologic characteristics of both ore and waste. The most important goals of project or mining geology are the accurate definition and estimation of reserves. Reserves are validated by detailed comparison with estimates produced by various alternatives such as manual, geostatistical, and computer-assisted conventional methods. Additional objectives are grouped in the broad category of providing information and support for other evaluation specialists or production engineers (Chapter 5.7). Three case studies are presented in Chapter 5.8 as examples of recent project evaluations. For a more extensive series of recent case histories of applied mining geology, the reader is referred to the SME volumes edited by Erickson (1984) Metz (1985), and Ranta (1986).

Section 5 focuses primarily on project and mining geology for metallic deposits, but, where appropriate, reference is made to placer deposits, as well as industrial minerals, coal, and other nonmetallic mineral deposits. The concepts, procedures, and goals presented are generally applicable to any type of mineral occurrence, and only the details of applying exploration and evaluation techniques may vary. Further information on the exploration and evaluation of specific types of mineral deposits can be found in Section 5 (Payne, 1973), *SME Mining Engineering Handbook,* 1st ed. Deposit types mentioned include sedimentary, disseminated, placer, coal and petroliferous solids, uranium, and miscellaneous minerals.

Chapter 5.1
GENERAL PRINCIPLES

WILLIAM C. PETERS

Mining takes place in geologic media, and the dictates of geologic conditions prevail throughout the life of a mining operation. The resident geologist evaluates the significant conditions and their impact on the mine.

Exploration geology, described in Section 4, is directed toward discovery of a mineral deposit and the recognition of a prospect that can be developed into a mine. Mining geology, beginning as project geology in the preproduction development stage of a mining sequence, is directed to the design, planning, and operation of the mine.

Project geology deals with a succession of feasibility studies and with subsequent mine preproduction development. It is commonly done within a project task force comprising geologists, geological engineers, mining engineers, metallurgists, and other technical specialists. With the completion of preproduction work, the project becomes a mine with a resident mine geologist or a geology department.

Relatively small mines operate with a single resident geologist or with a geologist in the engineering department. Major mines have geologists and supporting personnel in a staff department or a geology section in the engineering department.

The geology department or section at a major mine may comprise groups assigned to specific sectors within the mine and groups assigned to geological engineering, ongoing district exploration, and hydrogeological and environmental work. Ore reserve estimation may be done in the geology department, but it is more commonly within the scope of the engineering department where it is handled in cooperation with the geology department. Functions that may be assigned to the mine geologists or performed in cooperation with other departments are ore sampling and grade control (planning department) and analytical laboratory work (quality control department.)

The chief geologist ordinarily reports to the mine superintendent, to a technical services superintendent, or to the general manager of the corporation's local mining unit. The closest lines of communication are, however, to mine engineering and planning. The geology department at an individual mining unit commonly has an additional line of communication and responsibility to a manager of operating properties geology at the corporation's exploration division headquarters.

5.1.1 RESPONSIBILITIES: GEOLOGISTS

Project and mine geologists are essentially responsible for evaluating known ore bodies and finding more ore. Responsibilities also relate to geologic factors in the design, planning, and operation of a mine; to characteristics of the ore that is handled in the mineral processing plant; and to environmental concerns. In each of these, there are long-term (years), intermediate-term (months), and short-term (day-to-day) elements.

5.1.1.1 Ore Body Evaluation

The ore bodies that were outlined in earlier exploration work are verified and delineated during preproduction; their limits and changes in character are defined, and new ore reserves are sought. In this, continued development work, drilling, and sampling provide for geologic resources to be included in mining reserves as their classification is changed from possible to probable to proven ore and a mine plan is devised. The geologist's and engineer's periodic inventories of ore reserves are made with a number of geologic provisions, including provisions for the differing mineralogical zones in the minable ore and for alternative cutoff grades on the periphery of each ore body.

In the short term, geologists and the planning engineers are responsible for ore-grade control and for the designation of ore boundaries in stopes and benches. In Chapter 5.6, the estimation of ore reserves is covered in detail, with discussions of sample spacing, ore reserve models, methods of calculation, and classification.

5.1.1.2 District Exploration

One of the principal responsibilities of the mine geologist is to define and interpret the patterns of mineralization throughout the immediate district, as well as in the mine. The job is essentially that of district exploration for additional ore. Nearby prospects, mining operations, and exploration activity are evaluated. The need for district-wide exploration relates to the inevitable depletion of the ore bodies currently being mined, and the information becomes additionally important when a joint venture, lease, or purchase of mineral land is considered.

Supporting materials such as coal, aggregate, limestone for cement, stope fill, and siliceous ore for metallurgical purposes may be needed. The resident geology department evaluates the sources. Mine geologists have an additional exploration responsibility that extends beyond the district: the mine and its geologic setting can provide orientation survey localities for new exploration methods, and mine geologists are often called upon to advise exploration personnel on the targeting of similar deposits in other districts and regions.

5.1.1.3 Mine Design and Planning

The geologic factors involved in design, planning, and operations are identified and assessed. Where development is planned for new ground in untested geologic and geotechnical surroundings, or when changes in mining method are anticipated, the mine geologist's projections are especially critical. In the shorter term, there is a need for monitoring water and ground conditions throughout the mine, as well as a responsibility for geotechnical investigation and for immediate advice on problems with ground control or slope stability.

Where mineral processing methods are designed and planned, bulk samples from workings and drillholes are 'tested, and the samples have an inherent geologic context. Mineralogical zoning within the ore bodies is fundamental in this respect, and the zoning patterns reflected in the appropriate computerized model also relate to production goals and to forecasts of monthly and yearly recovery of metals or minerals. In the short term, the processing plant needs continuing advice on the changing characteristics of ore from active stopes or benches. Where ore blending or selective mining is practiced in order to give an acceptable mill feed, day-to-day geologic advice is needed at the mine and at the concentrator.

5.1.1.4 Land and Environmental Geology

It is the geologist's responsibility to evaluate land for mining and for supporting nonmining use. Areas with a potential for ore mineralization are designated for exploration and for future expansion of the mine, and nonmineral sites are identified for water supply, mine dumps, tailings disposal areas, plant installations, housing areas, and access routes.

Environmental baseline data, environmental permitting, compliance with environmental statutes, and the continued monitoring of land, water, air, and biota have geologic aspects. These functions, and the requirements for land reclamation and restoration during and following mining, are often handled jointly by the geology and engineering departments.

5.1.2 PROCEDURES IN MINING GEOLOGY

The procedures of project and mining geology deal in large part with the collection and interpretation of data: with a geologic database that is begun at the very outset of work in a project. As the mine geologic database grows, it affords a mine geologic model, a conceptual picture of the specific deposit-this becomes a basis for interpretations and a platform for projections. The initial geologic model of the deposit, like the geologic models used in exploration, is revised and expanded as more is learned about the deposit's limits and variations. In the maps, sections, and charts made from information in development workings and drillholes, the geologist can begin to recognize correlations and discontinuities that were missed or that could only be vaguely projected between the earlier exploration pits and drillholes. With further development and mining, the results of geologic mapping, logging, monitoring, and sampling can then be added to the geologic database and to an improved geologic model.

As mining continues, data become available on metallurgical recovery and on pumping, explosives and bit usage, and ground support. All of these have a geologic aspect, and all are relevant in some respect to the growing geologic database and the changing geologic model. A development in "new ground" is planned on the basis of the geological and geotechnical conditions mapped and monitored in "old ground."

Sampling of the mineral deposit and of the adjacent ground is a continuing procedure in mine geology. Geologic and geotechnical interpretations in themselves need to be supported by samples taken for petrographic study, mineralogical examination, and laboratory analysis. Ore sampling for assay and in relation to design, planning, and daily operations is done in the context of the mine geologic model and its mineralogical zoning pattern.

In long-term aspect, the sampling of drillholes and of exploration and development workings relates to successive estimates of ore reserves for eventual development and mining. In the short term, the sampling of production drillholes, blastholes, and broken ore is done for grade control and immediate mine planning.

The procedures of data collection and recording are given in Chapter 5.2. Methods of data interpretation, with descriptions of the database and interpretive models are discussed in Chapter 5.5. Detailed comments on sample collection are given in Chapter 5.3, and comments on sample preparation and assaying appear in Chapter 5.4. Case studies of geologic procedures and methods at specific mines are given in SME's three volumes on *Applied Mining Geology* (Erickson, 1984; Metz, 1985; Ranta, 1986).

5.1.3 IMPACT OF GEOLOGY ON MINE OPERATIONS

The impact of geology carries throughout mine operations. The geologist's responsibility is to provide the relevant information. The most distinct impact bears upon the ore that is to be developed and mined—its location, extent, attitude, and grade. A broader and more complex set of impacts relates to the development and mining operations themselves.

The relevant information is established from the current geological model and database. Then communication with the engineering and planning staff carries the collected geologic data into an active stream of information that pertains directly to the impact of geology on the mining operation.

Figs. 5.1.1, 5.1.2, and 5.1.3 show examples of impacting geology and its relation to operational factors in underground mining, open pit mining, and mineral processing. The impacting geology is related to data accumulated through mapping and logging, geotechnical testing, and the interpretation of geology-associated records.

In each example, the impacting geology is necessarily predictive—it is based on observations in known ground, but it is applied to new sites and conditions. The most critical predictions deal with projected changes in geologic conditions. A significant change in rock type or in the mineralogy of the ore would, for example, impact the entire sequence from mine development to the disposal of tailings at the mill.

Operations and Factors / Impacting Geology and Data		Drill and Blast, Excavate, Load, Haul, Crush, Convey					Waste Disposal and Restoration

Fig. 5.1.2. Impact of geology on open pit mining operations.

In the basic production cycle of drilling, blasting, loading, and haulage at an underground or open pit mine, geologic impact is related to rock type and texture, ore and gangue mineralogy, and fracture patterns, and it is related to geotechnical determinations of rock and ore characteristics and stress conditions. The relevant information is taken from mapping, logging, and testing and from the records of prior drilling and blasting performance under various geologic conditions. Where excavation is done by ripping or continuous mining, and where development involves raise boring or roadheader advance, the factors are similar, and the same geologic data are applicable.

Underground backfilling of waste, storage of broken ore in underground shrinkage stopes, and surface stockpiling and heap leaching are all affected by geologic conditions related to fragment size, shape, density, and mineralogy. Mineralogy is of special importance in the sense that the weathering and oxidation of ore and gangue minerals can cause plugging, corrosion, and cementation in the broken material.

In relating geologic impact to ground support and slope stability, the information taken from mapping and logging is combined with the information from geotechnical testing and monitoring. The requirement for geologic information is similar in caving methods of mining.

Rock type and texture are critical factors in the initial crushing and grinding stages of conventional mineral processing, but their impacts and the additional impact of changes in mineralogy continue throughout the successive stages in mineral processing. The mine geologist has an ongoing responsibility for communication with the mill engineer regarding changes in the geologic nature of the ore.

Operations and Factors / Impacting Geology and Data		Crush and Grind			Concentration			Leaching

5.1.4 OBJECTIVES IN MINING GEOLOGY

The ultimate objectives of the mine geologist are to keep the mine in ore and to see that geological conditions are taken into account throughout the life of the mining operation. The more immediate objectives are to fulfill these responsibilities at the current stage in the sequence of development and mining. The objectives, in both long- and short-term, are centered on an ore body or a group of ore bodies, a mine, and a related plant facility. But the objectives and the responsibilities have a broader spatial and temporal aspect as well: they pertain to the ore bodies and geologic conditions throughout a mining district, and they relate to an operation that goes from discovery and preproduction development to an eventual sequence of stages in mining.

5.1.4.1 Preproduction

During preproduction, a principal objective is to put specific dimensions on the geologic factors that were mapped, measured, and estimated during earlier feasibility studies. This amounts to the formulation of an initial database and geologic model. The focus is on mine design and on the defining of sufficient proven and minable ore reserves to support the initial capital investment. But there is more: preproduction work calls for putting dimensions on the geologic aspects of regulatory permitting, a plant site, a water supply, and supporting facilities for power, transportation, and mineral processing.

An associated aim during preproduction is to determine the pattern of geologic and geotechnical zones that will influence the subsequent stages in mining and processing. Bulk sampling and testing are important to this objective, and the initial work-

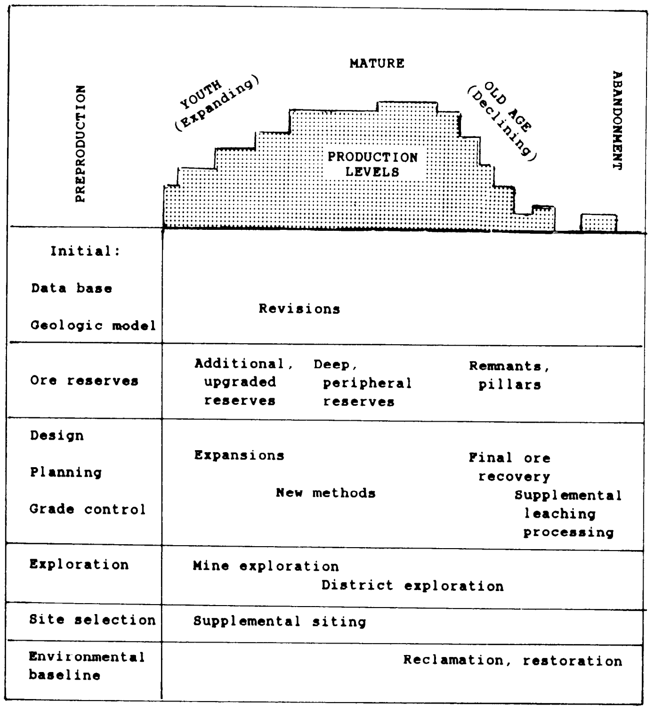

Fig. 5.1.4. Mining geology focus in the mine life cycle.

ings may have to be planned for this as well as for immediate mine development.

A broader objective is related more specifically to the long-term responsibilities that begin in preproduction and continue through the life of the mine. This objective is to establish consistent procedures in geologic investigation and data collection, with appropriate levels of detail, accuracy and precision. Then, as geologic parameters begin to develop, an adequate database is established for measuring the subsequent changes in geotechnical, hydrological, and environmental patterns.

5.1.4.2 Mining Life Cycle

A mining life cycle of youth, maturity, and old age can be characterized in spite of its variations from mine to mine. The life cycle can be as short as a few years, or the mine can be consistently productive during a century or more. It can be irregular, with idle periods and with periods of rejuvenation and expansion. Unlike the biological life cycle analogy, there can be resurrection; the graveyard of a former mining operation will often be recognized as an exploration target, and the subsequently rediscovered ore body begins a new mining life cycle.

In the characteristic mining life cycle, a mine passes from preproduction to successive stages of youthful expanding production, mature production, old-age decline, and abandonment. The focus of mining geology during the life cycle is illustrated in Fig. 5.1.4. At each stage, the mine geologist's immediate responsibilities and objectives are shared with longer-term objectives that relate to responsibilities in the later stages.

Youthful Stage Mines: In the youthful stage of a mining life cycle, the objectives of preproduction continue. Proven ore reserves are augmented from probable and possible reserves, and the limits of the deposit or group of deposits are sought and outlined. Grade control procedures, designed during preproduction, are now capable of being refined. The database, also designed earlier, now begins to fill out, to require massive data processing, and to provide stronger support for geologic projections.

A new objective for the mine geologist is to provide specific information for mine growth and expansion. This can involve site studies for new access through adjacent mines, new shafts and entries, a supplemental or extended pit, and an enlarged milling and waste disposal facility.

Mature Stage Mines: In the mature stage of a mine's life, the objectives continue to relate to grade control, ore reserve definition, and geologic information for mine planning, but there are additional considerations. In a mature mine, the apparent limits of the established ore reserves will commonly have been recognized. The workings are deeper and broader than before, and mining costs are higher. The complex outer zones of the main ore bodies are part of the picture, and the grade of the deeper and peripheral ore may be lower than that of the ore previously mined. The mining geologist's objectives are now governed by an economic squeeze.

The finding of roots to the deposit and the identification of extensions and associated deposits are now objectives. The geologic model and geologic data from earlier stages in the mine's life cycle come into full play. The economic squeeze in a mine's maturity can result in a need for raising the cutoff grade or for emphasizing higher-grade ore zones during times of low metal price. Conversely, improvements in metal price and in technology can permit the mining of lower-grade ore. In either event, changing economic conditions can bring about a change in mining method and a reassessment of economic ore reserves. The mine geologist must then provide for a delineation of different ore zones and an assessment of different geotechnical conditions in mining, access, and waste disposal.

District exploration intensifies, and it extends to prospects and even to relatively small ore bodies that could be developed and integrated with the existing plant. Exploration targets, in the district and outside, receive special attention by the mine geologist and by company exploration geologists.

Old Age Mines: A mine's old age may last through a number of years in the mining of dwindling ore bodies and pillars or in the mining of a steep-walled "ultimate" pit. The geologist's work in this stage involves a review of information collected in earlier stages, and the objectives at this point turn to a re-inventory of the remaining ore and an assessment of the geotechnical conditions for final mining in disturbed ground. The mine geologist may be concerned with an evaluation of workings for in-place leaching and with the evaluation of dumps and tailings for processing and leaching. Environmental restoration, stabilization of workings and waste, and the need for mined-land reclamation are now specific geologic concerns.

5.1.4.3 Planning for the Objectives

The geologist's continuing responsibilities and objectives require the building of an early foundation. The early foundation will be sketchy and speculative, but it amounts to a skeletal database and model that serve to identify the currently accessible geologic and geotechnical information that will be later required in a broader and deeper mining complex.

Provision for the massive data processing that will be required in the youth and maturity of a mine's life can be made at the outset of operations or during preproduction, even though the need does not seem to be immediately pressing. Determinations of the potential limits of ore mineralization at grades not now economic, the potential shape and mineralogy of the ore body borders, and the presence of additional ore bodies that may be incorporated in expanded operations—conditions of importance in the mature stage of a mine—require an established fund of data.

The needs of a mine in the stage of declining production or old age can be anticipated. This will include an assessment of values and of geological and geotechnical conditions in the final pit, in pillars, in dump leaching, and with in-place leaching operations. Geological and geotechnical data need to have been obtained during earlier stages of mining, before some of the workings and terrain became inaccessible. Mine abandonment, with the need for stabilization and environmental restoration, makes use of the geologic database that began during the preproduction period and extended through the mine's productive years.

The role of the project geologist and mine geologist requires an appreciation for the changes in design, planning, and operations that will take place in the mine. Performance of the role calls for the recognition of an ultimate geologic model, a conceptual picture of the conditions that will affect the geologist's objectives and procedures as the mine grows to maturity and is finally depleted of its ore.

Chapter 5.2
GEOLOGIC DATA COLLECTION AND RECORDING

A. J. ERICKSON, JR.

Mining is a physical endeavor that extracts some valuable mineral resource from the earth. To do this effectively, it is essential that management has as accurate as possible a characterization of mineral-zone geometry. A good understanding and clear representation of the shape, size, quality, variability, and limits—the geologic characteristics of the mineral zone—are needed at the evaluation, development, and productive stages of a project. This characterization requires a high-quality geologic database in order for the geologist, in a clearly supportive role, to provide management with the information needed for critical project decisions. The financial success of the mining venture is directly related to the completeness and accuracy of the geologic database and the quality and understanding of the characterization that describe the mineral zone. In an expansion of an earlier statement, the geologist who fails to provide the best geologic characterization based on data available at the time "is delinquent in his or her responsibility for providing management with the best possible information for intelligent decision making" (Barnes, 1980, p. 63).

This chapter deals with basic geologic data-collection principles, the first of the three essential geologic information processing steps—data collection, analysis, and interpretation. Chapter 5.5, to follow, deals with the latter two in the development of the geologic model and input into a database for resource estimation of the mineral zone.

5.2.1 GENERAL

Geologic data vary greatly within a single deposit and from deposit to deposit. This applies if we are concerned with metallic, coal, or nonmetallic commodities. Specific geologic features will differ considerably, and likewise the importance of any specific feature will vary from deposit to deposit. The geologist is faced with the task of collecting many types of geologic data. It is seldom known in advance which features are critical; therefore, he/she must collect detailed data on all features of potential importance. Data may be collected in a number of ways, such as by drilling, surface or underground mapping, geophysical or geochemical surveys, or in specific studies examining such features as structure, rock mechanic properties, alteration effect and distribution, or mineralogy.

A great deal of time, effort, and expense is required to collect data adequately. It is essential that data-collection systems be planned in advance so that all data and descriptions are systematically gathered to insure completeness and high quality. Data-collection systems should be on at least a region-wide, but preferably a company-wide, standardized system or format to assure consistency, accuracy, neatness, legibility, objectivity, and completeness. Fact must be discernible from inference. Personnel should be trained in the requirements imposed by the recording system. It does little good to have two people, biased by personal experience, making data recordings on the same outcrop or sample, the ultimate record suggesting two entirely different geologic units. Quantification of the geologic variable should be done wherever possible. This requires estimation which, although imprecise, is sufficiently accurate for comparison or correlation purposes and far superior to vague generalizations.

Geologic data are extremely important, costly to obtain, and essential for proper evaluation and mining. The data collection may be a one chance occurrence due to constraints imposed by mining or distance. A second observation of a critical area may be impossible as the drift or bench may be mined out or the core crushed for assay. The system used to collect the data should be designed to assure timely completeness, accuracy, consistency, quantification, objectivity, and legibility. If data is collected in this manner it will provide a useful record that is timeless in character. The practice of geology is not easy and requires a great deal of patience, diligence, discipline, and simply hard work, whether it be surface or underground mapping or core or cutting logging. A high level of professionalism is required. Further comments on these topics are clearly discussed by McKinstry (1948, Chapters 19 and 17), and should be reviewed.

5.2.2 REQUIRED DATA

Every effort must be made to observe, record objectively, and describe all geologic features that may be of importance in characterizing the size, shape, and variability of the resource under study and its associated environment. Broad categories of data to be collected routinely are location information and lithologic, mineralogic, alteration, structural, and rock competency data. As experience is gained in specific areas, deposits, or suites of rocks, the capability to subdivide various units into key subunits typically will be developed. This will enable the geologist to improve description, correlation, projection, and understanding of the genesis of the deposit. More importantly, it will allow for superior resource estimation and improve recommendations needed for management decision making.

Important details within each category appear in Table 5.2.1. Keys are careful observation and clear description.

5.2.3 RECOMMENDED EQUIPMENT

Equipment varies somewhat with individuals and projects; however, in addition to normal personal gear—hats, boots, lamp—items listed in Table 5.2.2 are useful equipment that should be on hand for either mapping or core logging. Ear plugs of appropriate design *must* be worn around equipment, particularly percussion drills, to prevent long-term permanent nerve damage and resultant hearing loss. Safety glasses are essential.

5.2.4 SYMBOLS

Geologic representation, geologic mapping, core logging, data compilation, and interpretation are heavily dependent on visual presentation as "geologists think and communicate best in pictures. The basis of almost all geologic work is the making of maps, plans, sections and the like. The graphical form is the most efficient way of displaying and explaining geological observations and ideas" (Dixon, 1979, p. 5). Standardization in the way geologic data are collected, recorded, or displayed is desirable as the concepts being portrayed are frequently difficult,

Table 5.2.1. Geologic Data Collection: Key Features

Location Data

Sample, map, mine, or drill location on each sheet. May include geographic data such as state, county, section, township, range, latitude, longitude, coordinates, elevation, mining district, mine, pit, bench, level, working, claim, claim corner, or any and all information that will clearly identify the unique location of the geologic data points. Data cannot be used if the geologist does not know where they came from.

Lithologic Data

Typical data to describe rock, sample, or unit. Should include color, texture, mineralogic characteristics, lithology, and rock type. Appropriate descriptive modifiers, stratigraphic information, if known, top and bottom data, age relationships, and general gross features as hardness, competency, and bedding characteristics. Subjective generic terms should be avoided unless well established or qualified to distinguish inference from observable facts. Primary sedimentary structure and sedimentological features such as bedding, laminations, casts, soft-sediment deformation, graded bedding, burrows, bioturbation, fossil content, or banding, foliation, and lineation, with appropriate attitudes, should be noted where possible.

Structural Data

Secondary structural features that post-date rock formation. Should include clear description and attitudes of joints, fractures, faults, breccias with quantitative description of selvages, gouge zones, fragment size, and healed or recemented character of breccias. Folds, dragfolds, crenulations, lineations, and foliation should be noted. Age relationships, mineralization association, and overall effect on rock mass are important. Weathering and oxidation intensity data are usually critical and commonly structure related but may be included with lithologic data. Quantification of structural data where possible is extremely important as they may play a key role in determining minability of a deposit.

Alteration Data

Nature, mineralogy, intensity, and distribution of features. This should include color, texture, mineralogy, intensity, pervasiveness, fracture control, stages, mineralization association, and overall effect on rock mass. Weathering and oxidation intensity are important but may be included with lithologic data. Quantification where possible is extremely useful as is description of age relationships of various alteration features.

Mineralization Data

Nature, intensity, mineralogy, and distribution of the desired resource. Should include primary and secondary classification, estimates of specific and total quantity of various minerals, intensity, character of veinlet, vein or disseminations, supergene features, weathering and oxidation intensity, and associated gangue mineralogy. Vein age relationships tied to mineralogy, alteration, or lithology provide important data in understanding both zoning and grade estimates and overall deposit genesis.

Coal Data

In addition to standard lithological and structural data listed above, logging of any and all features that aid in correlation, understanding the distribution of sedimentary facies, and construction of a depositional model of the coalbed(s) and coal-bearing sequence is important. Detailed descriptions of horizons immediately above and below the roof and floor are critical as are accurate measurements of depths and thickness of all units associated with the coal. Some key features include abundance and type of marine or freshwater fossils, slickenside in roof or floor rocks, the presence of roots representing old soil horizons, pyrite bands, nodules or streaks, siderite or ironstone nodules, and plant debris. Description of individual coalbeds, either the banded or nonbanded groups, requires careful measurement or estimates of the banded lithotypes, vitrain, clarain, durain, and fusain content (Stopes, 1919; Ward, 1984). A more practical system (Schopf, 1960) describes the thickness and amount or concentration of vitrain and fusain bands in a matrix of atrital coal. The latter is described by five luster levels that range from bright to dull. Nonbanded sapropelic coals, boghead and cannel end-members descriptions, rely on identification of these massive faintly banded fine-grained accumulations of algae or spores and usually require a microscope for adequate description. The nature of cleats, partings, bone, and shale layers needs description and careful thickness measurements to separate "net" from "gross" coal bed thicknesses. Coalbed description, while straightforward, requires some supervised training to ensure adequate data recording.

Other Features

Other features that may supply extremely important information with direct bearings on mining and/or metallurgy should be recorded. This may be reasonably objective as fracture frequency, rock quality determination measurements, longest and shortest unbroken core recovered in a run, or more subjective as an overall estimate of rock strength, friability, or competency. Metallurgically significant features such as hardness which affects grindability, grain size which controls grinding for particle liberation, or oxidation intensity which affects flotation recoveries, should be noted. Added testing is almost always needed here; however, geologic data collections should indicate these and other potential problem areas requiring specialized study.

Table 5.2.2. Geologic Data Collection: Useful Equipment

The following are items of equipment routinely used in day-to-day geologic work: (1) Compass, geologist's pick, hand lens, pocket tape, and several cloth survey tapes or chains (nonmetallic for safety), (2) a knife, protractor, or 6-in. (152-mm) plastic scales with imprinted protractor, dilute HCl, magnet, nail, survey spads, cement nails, sample tags, sample bags, marking pens, aluminum sheet holder, preferably end-opening with an end extractable pencil holder attached, and (3) sample ring for holding sample bags during chip sampling, pencils, pens, mapping sheets, or logging forms. A field vest with large pockets for samples and clipboard is helpful. Access to brushes and water buckets is important for core logging and spray bottles help. Extra core blocks are useful as is a good binocular microscope.

and varied symbolism may cause confusion. A simple line or symbol on a map is a powerful decision-influencing tool, may have innumerable connotations, and therefore, should be presented in a clear, self-explanatory way. Symbol standardization, a very difficult objective, helps in obtaining the desired clarity.

There is no single standardized set of geologic and mine-related symbols in use, but those listed in Tables 5.2.3 to 5.2.6 are commonly used in the United States. Many are utilized in other parts of the world as well. They were compiled from works by Dietrich et al. (1982), Peters (1987), Berkman and Ryall (1982), Reedman (1979), Lahee (1952), Compton (1962, 1985), and McKinstry (1948), and from personal experience. Additionally, the Geological Society of London's five-volume *Handbook* series by Barnes (1981), Tucker (1982), Fry (1984), Thorp and Brown (1985), and McClay (1987) are very useful and practical. This series covers both general and specific aspects of mapping, and data recording. The volumes are small and highly portable for field use. Blackadar et al. (1968) illustrate the Canadian

Table 5.2.3. Lithologic Symbols

viewpoint, and a number of chapters in Finkl (1988) cover symbology as well as other topics on field methods.

Worldwide standardization would be useful, country-wide strived for, company-wide very desirable, regional office-wide should be mandatory, and project-wide absolutely essential. The accompanying tables are not all inclusive but illustrate many commonly used symbols. Projects with multiple units of a similar nature frequently require the creation of additional symbols or combination of symbols. The possibilities are endless, but simplicity, clarity during reproduction, and practicality should be the guides.

Some systems use black for culture, lithology, and rock data, blue for structure, and red for mineralization. This practice is convenient, useful, and readily understood. Other systems use an extensive array of colors for various geologic features leading to either highly useful or totally confusing data collection. Still others collect all data in black, which is quite useful for modern copying technology. Any system should be well planned in advance, simple to learn and use, consistent, and well documented and should aid, not hinder, data collection and understanding.

5.2.5 ABBREVIATIONS

The extensive observations and descriptions essential in geologic work are commonly facilitated by the use of abbreviations. Standardization of these abbreviations is desirable because logs

and maps may be used by numerous individuals and therefore require some basic commonality. Additionally, long lag time may be involved between data recording and actual use. In addition to the commonly used w (with) or w/o (without), the list abridged in Table 5.2.7 from Chace (1956), with some additions, is fairly standard and used (at least in part) in the United States. Other lists appear in Compton (1962, 1985), Berkman and Ryall (1982), Blackadar et al. (1968), and Finkl (1988). Quantification of these abbreviations is achieved by the addition of superscripts or subscripts, as py^2 or py 2-10, which indicate estimates of 2% or 2 to 10% pyrite content in a rock. Cp_1 and py_2 indicate 1% and 2% chalcopyrite and pyrite, respectively, while cp:py = 1:2 or cp1:py2 indicates a ratio of chalcopyrite to pyrite of 1 to 2. Combinations are endless. The only requirement is that an explanation or legend describing the notation accompany *each* log, map, or project.

5.2.6 CORE AND CUTTING LOGGING

Drilling of one type or another provides much of the material for sampling and geologic analysis of natural resources. The core, rotary, or percussion drill provides the geologist with numerous surface or subsurface points to observe, describe, and sample, providing the facts to include in a geologic database for analysis and interpretation. Drilling is expensive and time-consuming, and in order to derive maximum benefit from the data obtained, an orderly standardized system of recording, commonly referred to as logging, is needed. When done to scale, commonly 1 in. = 20 ft (1:240) or sometimes 1 in. = 10 ft (1:120), this is actually mapping a long, narrow segment of the earth and some correctly refer to the process as core mapping rather than core logging.

Although frequently looked on with disdain and relegated to new, inexperienced geologists, good core logging is in fact a highly specialized skill requiring careful observation, clear accurate recording, and considerable personal discipline. Good drill logs are the primary record-keeping document of the geologist and are used repeatedly by individuals of varied technical disciplines. They must be clear, correct, and legible. The log records the basic data used in geologic analysis, interpretation, and resource calculations, the basis for economic evaluation and decision making.

Numerous types of logging forms exist, all allowing systematic data collection and comparison usually by means of columns for recording data. Data are recorded in the columns in varied ways—graphic, alpha, and numeric—depending upon purpose. Although varied in appearance and to some degree with project needs, all should contain the following broad classes of information, not uncommonly on several sheets or forms.

Location data, commonly referred to as header information, containing thorough location, bearing, inclination, scale, date, geologist, possibly down-hole surveys, hole size, and hole completion information such as casing record, plugging, and hole condition. Detailed geologic logs should provide space for recording depths, core recovery, perhaps rock mechanics data, lithology, alteration, mineralization, and possibly assays. All sheets should provide for hole and page number so separated sheets are not lost. Graphic columns for standardized symbols with adjacent room for notes are desirable. Note-taking should be brief, descriptive, employ standard abbreviations, and be quantified where possible. As an example, py_{10} or 10% py means approximately 10% pyrite to anyone, whereas “strong,” “weak,” or “much pyrite” usually means different things to different individuals. Logs should record as many as possible of the project’s important features listed in Table 5.2.1, using those symbols that are appropriate from Tables 5.2.3, 5.2.4, 5.2.5, and 5.2.6, with abbreviations from Table 5.2.7.

At some stage, generally early in the logging process, core is typically marked for sampling, splitting, and analysis. This should be done by the geologist familiar with the project to ensure that geologic units are appropriately sampled. Samples should be taken to reflect geologic changes and not taken across contacts. This ensures that analytical data reflect geologic variations. Occasionally, this may lead to some short samples; however, with core, the samples can be selected to allow later mathematical compositions to some equal sample length as desired.

Logging should be done to scale (multiple scales in the case of coal) and a separate summary log at a smaller scale, commonly 1 in. = 100 ft (1:1200), completed at the end of a hole. This allows the geologist to organize and simplify the detailed data and also his interpretation for more effective use. Reedman (1979) provides some practical discussion of logging, noting particularly the importance of recording attitude data on planar or linear features in relation to the core axis. He stresses the importance of summarizing observations into major units so the user is not overwhelmed by the meticulous detail normally recorded.

Two general types of formats in use are the graphic and narrative, and the data-entry style. There are combinations of both. Sheet sizes vary from 8-l/2 × 11 in. to 11 × 17 in. (216 × 279 mm to 279 × 432 mm) or sometimes larger. All can be designed adequately to do the job. Smaller 8-1/2 × 11 in. (216 × 279 mm) sheets are easier to handle while larger data-entry pad style allow easier numerical data entry but are somewhat cumbersome. Data-entry pad format requires considerable planning and standardized alpha, alpha-numeric, or numeric codes to be entered properly in appropriate columns to allow for key punch. It also requires a disciplined systematized data entry methodology that typically identifies a feature and then allows for an intensity estimate. The key is to decide what is needed, design a form to assure recording of the needed data, and train the staff in its use. An instructive method of logging coal cores, or any normal facing sedimentary sequence, is to wait until drilling of the hole is complete and then carefully log the core from the bottom up. This allows the geologist to observe the orderly change in the evolving sedimentary record, visualize the processes, and gain a better understanding of the depositional system responsible for the resource being evaluated.

If planned well, a generalized logging form should be usable from project to project within a company, requiring but little project specific modification. For specialized studies, standardized formats can be modified for the desired purpose. References by Call (1979), Perrin (1984), Ranta et al. (1984, 1984a), Atkinson and Erickson (1984), Ahrens (1984), Rowe and Hite (1984), Peters (1987), Goodwin et al. (1982), and Reedman (1979) provide additional discussions, descriptions, and philosophies on logging that are useful. Warnaars et al. (1985, p. 1563) discuss the importance of terminology, nomenclature, and abbreviation in logging and mapping in a paper published after a major deposit evaluation program in Chile. They also provide a good example of a data-entry style logging format. Ward (1984), Wallis (1978), and Merritt (1986) describe specialized requirements for coal logging and in particular of the need to record sufficient data to understand the stratigraphy essential to solving structural problems and the depositional environment influencing coal and associated noncoal distribution. Good detailed measurements and description of lithology, geologic structure, roof rolls, and slickensides in roof, coal, partings, mineral matter, and floor rocks is essential for coal work. Core photography is useful. Logging can be on a simpler form, as shown in Fig. 5.2.4c, or directly on data-entry coding forms, as illustrated by Ward (1984, p. 215). Alternatively, the coding for computer data handling can be done as a separate exercise after logging. Merritt (1983) is a well-illustrated practical reference that provides discussion of coal overburden/interburden characterization as it relates to mine planning, hydrologic, and environmental problems. Ferm and Smith (1980) and Ferm and Melton (1977) have compiled extremely detailed and comprehensive guides to cored rocks in the coal-rich Pittsburgh (Dunkard) and Pocahontas Basins in the eastern United States. These guides were published in an effort to rectify problems in inadequate description, misidentification, and the lack of uniform terminology by providing a standard basis for objective rock description and a uniform set of terms. Color photographs of core specimens of the common rock types in the basins are provided, and each is named and numbered according to a key that conveys information on lithol-

ogy, color, grain size, composition, structure, and bedding. Geophysical logging, discussed in the next part of this review, is an essential part of coal work.

Figs. 5.2.1 to 5.2.6 are examples of types of logging formats and are presented to show the degree of variability in style. The first group (Figs. 5.2.1 to 5.2.4) show narrative-graphic styles, first with a variable interval format and subsequently a fixed interval format more useful for logging cuttings from specific sample intervals. Logs in Figs. 5.2.1, 5.2.2, and 5.2.4 use 8-1/2 × 11 in. (216 × 279 mm) forms, whereas Fig. 5.2.3 logs are 8-1/2 × 14 in. (216 × 356 mm) forms. Finally, Fig. 5.2.6 illustrates 8-1/2 × 11 in. (216 × 279 mm) data entry style used with the log shown in Fig. 5.2.5d. Other data entry style forms shown in Fig. 5.2.5 are 11 × 17 in. (279 × 432 mm) or larger. Also shown, Fig. 5.2.6c, is an example of the first of several pages in one style of summary log. Effective summaries may also be made by compiling data on standard logging format in use on a project, but at a reduced scale.

All of the logs illustrated are adequate to record varying amounts of geologic data and could be modified to suit a specific project. These examples are representative and have been collected over a number of years from various sources. Company identity has been removed to ensure confidentiality.

5.2.7 GEOPHYSICAL LOGGING

Although not commonly used in typical hard-rock mineral applications, the use of in-hole electrical or geophysical logs, which record measurements of electrical, nuclear, or physical properties of rocks and adjacent fluids, is essential in coal and uranium resource evaluation. These logs, supplemented by good core or cutting logs that describe key features listed in Table 5.2.1, form the basis for geologic work and resource estimation in these industries.

Geophysical logging was developed to serve the special needs in subsurface, noncoring, work in the petroleum industry. The techniques have advanced to the status of an extremely useful, dependable, accurate, highly specialized discipline used in lithologic identification, correlation, depositional environment analysis, and formation evaluation. Only the use of logs for lithologic identification for correlation will be discussed here.

Numerous types or suites of logs are available, and descriptions of each can be found in a publication by Pickett (1971), which is particularly good yet brief, or more in-depth treatments by Asquith and Gibson (1982), the Schlumberger (Anon., 1972, 1974), or Dresser-Atlas (Anon., 1974 through 1979) sets of complementary interpretation manuals. BPB Instruments (Anon., 1981) has published a *Coal Interpretation Manual* that is useful, as are numerous papers by Reeves such as those in Argall (1979). The Plouffe (1981) summary is excellent, and the older Dodd and Eschliman (1972) review directed towards uranium work is good, as is Fitch (1990). Finally, Peters (1987) provides a useful short overview. Some supervised training in log interpretation is helpful and allows one to learn basic techniques quickly. A clear understanding of log heading, the multitrack nature of the logs, curve deflection direction, scales, and recording format is essential as there are a significant number of different log types, suites, and recording conventions.

Ward (1984), Chironis (1982), Wood et al. (1983), and Merritt (1986) provide discussions of use of various logs as well, and the summary which follows, primarily relating to coal, is largely abstracted from Chironis and Wood et al. Further, the work by Wood et al. provides a good discussion of various logging methods. The logs, when properly interpreted, provide a substantial quantity of useful geologic data, particularly on noncore holes. Some tools and measurements such as resistivity or spontaneous potential require fluid-filled uncased holes while variations in natural radioactivity, determined from the gamma log, can be measured in cased holes. In general, the systems provide the best information on porous, fresh sediments; however, variations in natural radioactivity associated with potassium-bearing clays and micas of hydrothermal alteration halos in crystalline rocks can commonly be clearly identified and mapped.

It is almost essential that suites of logs, such as gamma, spontaneous potential, resistivity, density, or other combinations, are obtained. The down-hole logging tool, sonde, typically is constructed to measure several properties, hence it provides multiple logs in a single pass.

Modern logging systems commonly supply output in the form of pictorial logs, "squiggly lines," and digital tapes or disks that feed directly into computer data processing and graphical output systems. Specific formats and products, some highly sophisticated in nature, vary with software vendor, client purpose, and need. In general, computer systems tend to provide a lithologic identification associated with the trace of varied geophysical logs, or at least space to append one manually for calibration, reconciliation, or simply as an additional set of of data to be used in geologic evaluation. Lithology determination and attendant correlation without the geologists or "mud log" can be erroneous and should be avoided.

A summary of logging techniques follows.

5.2.7.1 Spontaneous Potential (SP)

This is one of the most common logs found in all older work but not, unfortunately, with some modern coal-logging systems. The system measures natural currents developed in drillholes at lithologic contacts due to differences in salinity between borehole fluids and water in porous formations as the formation is invaded with the drill fluid. It is good for differentiating sand from shale, environmental analysis such as "fining up" sequences, but problems in distinguishing shale from coal are common.

5.2.7.2 Natural Gamma Ray

This method measures the natural gamma rays emitted by isotopes of uranium, thorium, and potassium. Coals and lignite are usually low in radioactivity, whereas the rock that usually surrounds coalbeds, shale, is high in potassium-rich clay and sometimes uranium minerals. Sometimes, however, uranium minerals from groundwater precipitate in the coalbeds, making the beds less apparent on the log and, additionally, limestone, like coal, tends to be low in radioactivity.

5.2.7.3 Bulk Density (Gamma-Gamma Density)

Interaction between induced gamma rays and electrons in the material surrounding the borehole is measured. Porous materials with light elements, such as coal and lignite, have a low apparent density on the gamma-gamma density log. This log alone may be used to identify thickness and structure of coal seams, but is even more definitive when used in combination with a caliper log that shows changes in hole size. Contract between high-density limestone or moderate-density sandstone with low-density shale or coal is quite clear.

5.2.7.4 Neutron Density

This method involves measurements similar to bulk density, except that the neutral tool emits a stream of high-energy neutrons that interact with hydrogen atoms. Because coal and lignite are hydrogen-rich and porous, and the pores usually are filled with water that is hydrogen-rich, these beds have a higher porosity index on neutron logs than associated shales or limestones.

5.2.7.5 Sonic (Acoustic) Velocity

This method measures the velocity of the compressional wave component of an acoustic signal between a transmitter and a receiver. The interval transit time is usually higher for coal than for surrounding rock. The more highly compacted coals have lower transit times. Lignite's range is 130 to 150 micro-sec/ft, while anthracite's is 120 or less. Accuracy is affected by variations in hole size and condition.

5.2.7.6 Resistivity (Electrical)

Resistivity measurements involve determining the current flow between an electrode in the logging tool and another electrode in the ground at the surface. Because coal is a poor conductor of electric current, it exhibits high resistivity values. Tight sandstone or limestone beds, however, may be confused with coal. Also the identity and thickness of a coalbed may not show up accurately, depending on the electrode spacing with respect to bed thickness. Newly developed focused resistivity tools can measure true coal seam resistivity and thus provide better resolution. Resistivity remains as one of the best logs for lithologic interpretation and correlation.

5.2.7.7 Laterolog (Electrical Conductivity, Induction Log)

This method, which measures the electrical conductivity of a bed, sends out the signal horizontally. High-rank coals exhibit low conductivity; poorer quality coals vary with ash content. Bed boundaries are likely to be more accurate than on the resistivity log but, as with the resistivity log, this log may confuse coal with tight sandstone or limestone.

Figs. 5.2.7a and 5.2.7b are summaries of typical log signatures or character to be anticipated from various lithologies during geophysical logging. Fig. 5.2.7a from Irving (1981) shows the highly irregular pattern commonly seen in actual logs, whereas Fig. 5.2.7b from Wood et al. (1983) is more stylized in nature. The suites of logs shown are slightly different.

Fig. 5.2.8a is a typical log from uranium deposit evaluation in Wyoming. Four curves are shown: two at different sensitivities recording the natural radiation, gamma rays in counts per second (cps) in the borehole environment, and one each for spontaneous potential in millivolts (mv), and for resistivity R in ohms. Deflection of the natural gamma curve to the right on the scale of 0 to 2000 cps is off the sheet, while the higher-range scale 0 to 100,000 cps clearly shows the nature of the uranium distribution, Measurements are taken at 1/2-ft (152-mm) intervals and then converted, through use of a constant (*K* factor) that is different for each instrument, to $\%eU_3O_8$. Modern logging systems perform this calculation automatically and provide printouts of the values. Periodic calibration with known standards, a test pit, and chemical analysis of core for U_3O_8 are essential to assure accuracy of the eU_3O_8 determinations. The two spikes, shaded, at 500 and 542 ft (152 and 165 m) on this log correspond to 3.5 ft (1.1 m) of 0.270% eU_3O_8 and 8.5 ft (2.6 m) of 0.171% eU_3O_8, respectively. The remaining two curves, *SP* and *R,* show the characteristic left or negative deflection of the *SP* curve and right deflection of the *R* curve corresponding to sandstone (stippled) horizons. Less deflection can be seen in the two curves adjacent to the shale or shaly (horizontal lines) horizon.

Fig. 5.2.8b is one of many types of logs displaying typical responses seen in eastern US coal work. In this case, gamma, density, and resistivity tracks or curves are illustrated. Sand and shaly sections can clearly be seen in the gamma and resistivity logs, the shale showing the higher natural radioactivity of potassium, thorium, and uranium concentrated in clays.

Coal is clearly identifiable due to the low radioactivity (gamma log), the low density shown on the density log, and the very high resistivity. Four coalbeds which have been shaded are identified on this log. Sandstone and shale horizons have not been differentiated, as in Fig. 5.2.8a.

5.2.8 GEOLOGIC MAPPING

Surface or underground mapping requires the same detail, uniformity, standardization, and systematic, unbiased, objective, data collection and recording as described in the previous section on logging. The general comments and philosophy described there apply to mapping as well. Note-taking, abbreviation, and symbology are best if they employ company-wide established methodology, reflecting common initial training of personnel involved. In addition to being consistent with logging, mapping data must be accurately located and tied to known, preferably surveyed, geographic locations.

Brunton compass and tape(s) are commonly used to construct ground outlines for data recording, to locate outcrops, and to tie in culture or survey control, and if done carefully, they will provide sufficient accuracy. This is a fairly straightforward procedure and consists of stretching a cloth measuring tape or tapes from or between known points and determining the bearing of the tape with a compass. This “tape line” is then plotted to scale in its proper orientation on the field note sheet and tick marks posted and identified each 10 ft (3 m) along the bearing of the tape line. Following this, offset measurements are taken at right angles to the cloth tape from the tape to the edge of the drift or pit bench. A small pocket tape is used to take these offset measurements at 10-ft (3-m) intervals along the cloth tape. Points corresponding to these offsets are then plotted on the field note sheet, connected, and an outline of the drift or edge of the pit bench is thus created for geologic note taking. Figs. 5.2.9a and b illustrate the methodology of developing a ground outline and shows some simple geologic notes.

Geologic field note-taking is commonly done on relatively large scale in typical mine-related work such as 1 in. = 20 ft or 1 in. = 50 ft (1:240 or 1:600). Smaller scales, 1 in. = 100 ft and 1 in. =200 ft (1:1200 and 1:2400), are also used, generally to collect data on overall resource setting or to simplify more detailed work in the mine itself. For regional work, scales of 1 in. = 1000 ft or 1 in. =2000 ft (1:12,000 or 1:24,000) may also be appropriate. Some variability is necessary, and the actual mapping scale used will depend on needs of specific projects. Advance planning here is useful. While detailed, 1 in. = 20 ft (1:240) mapping in a vein or massive sulfide deposit is desirable, attempting to get the same detail in a 15-million tpy (13.5-Mt/a) open cut coal mine or a 2-million tpy (1.8-Mt/a) underground coal operation would be inappropriate.

Mapping techniques are described in a number of good references, which vary somewhat in perspective. Proper supervised training is desirable. Peters (1987) provides considerable detail in a good description of general surface, surface open pit, and underground work. He describes an outcrop mapping system in which multiple acetate overlays (Fig. 5.2.10a), generally three, are superimposed over a base map or photo and used to take notes describing geology, mineralization, and alteration, respectively, for each outcrop. A similar system using photographically superimposed topography on orthophotos is described in more detail by Atkinson and Erickson (1984) in a volume that reviews the practice of mining geology at a number of properties such as the Santa Rita District, NM (Ahrens, 1984). The field manual by Compton (1962, 1985), provides good coverage of geologic mapping techniques as do the extremely useful Geological Society of London’s *Handbook* series previously mentioned. Earlier textbooks by McKinstry (1948) and Forrester (1946) remain the best sources on techniques in mine mapping. More recent articles by Rutherford et al. (1984), Ledvina (1986), and Krausse et al. (1979) describe the increasing use of geologic mapping in underground coal mines, stressing the importance of lithology and roof rock characterization. Data gained and properly used enhances geologic understanding, improves safety, and supports increased productivity and, ultimately, mine profitability. A report by Moebs and Stateham (1984) summarizes contract studies investigating the relationship between geologic factors and roof stability in coal mines. The work is well referenced and clearly identifies mine and core mappable geologic features that control roof stability. The reference, Finkl (1988), contains a number of sections on basic field principles from a construction site evaluation perspective and is useful. Volumes 69 and 70 in the *Benchmark Papers in Geology* series (Lacy, 1983) are compila-

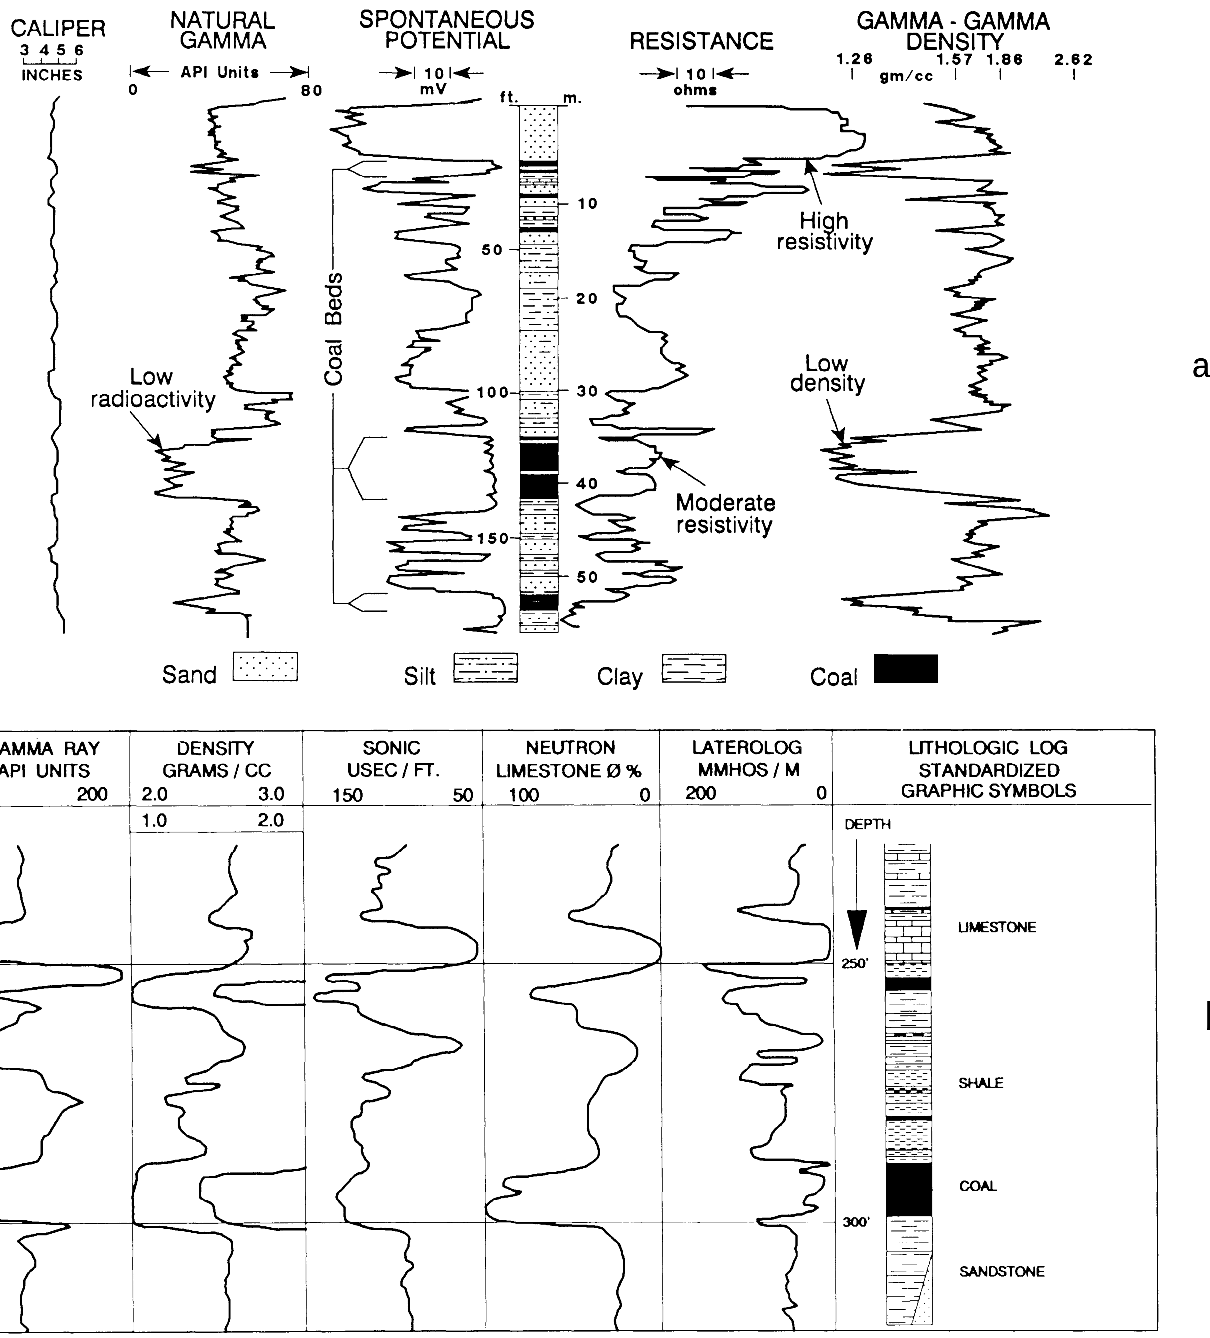

Fig. 5.2.7. Typical geophysical log characteristics for various lithologies. (a) is modified after Irving, 1981, while (b) is modified after Wood et al., 1983.

tions of key geologic papers in mining and exploration geology, and although abstracted and only partially reproduced, they are valuable as they identify key significant papers with bibliographies and provide many useful illustrations.

Early papers by Linforth (1910, 1933), McLaughlin and Sales (1933), Billingsley (1933), McLaughlin (1933), Sales (1941), or James (1946), although somewhat dated, clearly show techniques and discuss the importance of careful geologic mapping. A recent paper (Garmoe, 1984) is one of the few that contains a direct reproduction of an unedited, underground field sheet showing the technique referred to as the Anaconda method. The papers by Bakken and Einaudi (1986) and Einaudi and Bakken (1988) demonstrate the usefulness of detailed geologic mapping. In this study of the Carlin deposit, gold grade was

Table 5.2.8. Surface Mapping: General Points

Aluminum sheet holder for 8-1/2 in. × 11 in. (216 mm x 279 mm) gridded sheets, topographic bases, or airphoto base maps, are superior to bound notebooks as they allow sheet removal, filing, and reduce chance of data loss.

Adequate control is critical, and data must be tied with survey or Brunton and tape to known locations as survey points, claim corners, mine workings, key topographic features as ridges, valleys, stream junctions, and roads.

All maps need north arrows and coordinate data to determine orientation.

Data sheets must be clearly identified with location, scale, geologist, and date and, if an overlay system is used, all should be permanently attached to base map or photo and further identified with photo number.

Notetaking should be clear, legible, and accurate as "clear cut sketches indicate understanding . . . muddled mussy sketches denote confusion . . ." (Sales, 1941, p. 19.03). Keep sheets clean by keeping a folded piece of paper on which to rest hand during note taking in clipboard. Use sharp pencils.

Set up field sheet map index system in advance.

Use standardized notetaking, abbreviations, and symbols and post data collected regularly on base maps. Plot strikes and dips in their proper attitude. Plan ahead so outcrop outlines and notes complement and do not conflict with each other.

Table 5.2.9. Pit Mapping: Added Key Points

Safety: Be careful; pit benches and walls are frequently unstable and falls are common. Additionally, heavy equipment operators frequently are unable to see individuals close to the equipment. Be sure they know of your presence.

Use Brunton compass and tape to tie mapping to available survey points by drawing ground outline at toe of bench as in Fig. 5.2.9.

Clearly identify pit and bench location on 8-1/2 in. × 11 -in. (216-mm × 279-mm) grid sheets and use note-taking system parallel to one set of grid lines on paper or perpendicular to trend of workings.

Plan ahead and use systematic data posting. (Overlays may or may not be appropriate.) Plot lithologic data on one side of ground line, alteration on the other, mineralization close to actual location.

found to be correlatable with mappable alteration features, extremely useful information both from a genetic and a practical, day-to-day operating perspective.

Tables 5.2.1 through 5.2.10 contain summaries of some key points to be considered in geologic mapping on surface, in pits, or underground.

Fig. 5.2.10a from Peters (1987) illustrates the overlay system while Fig. 5.2.10b from Ahrens (1984) shows good technique in underground vein mapping. Figs. 5.2.11a and 5.2.11b from Peters (1987) illustrate multiple bench mapping with a minimum of detail and then simplified geologic note-posting, compilation on an office base map.

Table 5.2.10. Underground Mapping: Added Key Points

Be careful and constantly aware of the back, ribs, stopes, raise locations, and moving equipment. Test by light tapping with pick. Check for bad air. Keep a candle; if it will not burn in old workings there is insufficient air to breath adequately over sustained periods. Supervised training is mandatory.

Notesheet should be clearly identified as to mine, level, scale, dates, and geologist.

Tape and compass measuring should be tied to survey control usually located in the back of the workings. Control must be carried from drifts through raises and stopes to ensure proper location. This is time consuming but important. Ground outlines should be accurately drawn (Fig. 5.2.9).

A blotter paper in the aluminum sheet holder in addition to folded paper allows the geologist to keep notesheets clean and dry. A clean rag to dry hands and hat brim aids in keeping field sheets clean.

Mapping should be at waist height and ground outlines plotted by taking offset measurements from tape.

Colored pencils should be kept to a minimum of two to three colors as they frequently bleed when damp. Plan ahead in note taking.

Advance mapping should be on a day-to-day basis to allow ready access to clean drift walls. Old ribs should be washed or picked clean. A geologist cannot map what he cannot see

Notetaking should be clear and systematic with appropriate detail as needed. Too much detail, if uncluttered, is far superior to too little detail.

Advance should be posted on office base maps and dated shortly after mapping. Note sheets should be systematically filed for ready retrieval and use.

Isa, Qld.

Chapter 5.3
SAMPLE COLLECTION

ROBERT A. METZ

Whether for the evaluation of an exploration prospect or control of a mining operation, the process of sample collection can have significant effects on the outcome of those activities. The mathematical chances alone of collection on the order of a millionth (1:l,000,000) of a rock mass to evaluate its valuable mineral content (Bailly, 1968) would seem to dictate that the utmost care be used in that collection. It is paradoxical, then, that this function is often treated so casually in exploration and mining geology. The methods used may be carefully selected, but emphasis is often placed on obtaining data at minimum cost in the shortest possible time so as to expedite production or planning decisions. Procedures that should be rigorously followed often become mundane in practice due to their repetitive and often labor-intensive nature. Sampling personnel are not always highly paid, well-supervised, or thoroughly indoctrinated in the reasons for being meticulous in their work; also the equipment they use may not be in the best condition or have the best design to perform the tasks for which it was intended. Often the demands imposed by time, cost, and difficult working situations lead to the use of procedures and equipment that are more expedient than ideal. It is hoped, and apparently often true, that the number of samples and volume of material collected will be sufficient to compensate for variations and inconsistencies in the material being sampled. The history of mining contains abundant examples of failure due to erroneous or inappropriate sample-gathering methods or the misinterpretation thereof.

In following the trail from prospecting through discovery to a successful mining operation, the geologist will employ a number of diverse sampling methods, each applicable to the particular level of progress and scope of the project. In this day and age, seldom if ever are mines developed from an outcrop of ore alone. Some subsurface sampling must be done, usually by one or more methods of drilling. In event of a discovery, additional drilling, perhaps of a different type, must be done to determine the potential size, shape, and geologic character of the deposit.

At some point prior to mining, bulk sampling of the deposit is done to further determine mining and metallurgical properties of the deposit. These properties include not only the grade but the degree of homogeneity of mineralization and controls localizing the mineralization, rock hardness and strength, ore and gangue mineralogy and their variations, grain size of the ore minerals, and response to ore dressing processes as well.

Once the project progresses to becoming an operating mine, a different type of sampling program must be designed to monitor and control the operation for maximum profitability within the previously determined parameters, generally simplistically referred to as grade control. In actuality, many more factors than grade are usually involved, but most depend on a valid sampling of the material to be mined.

5.3.1 DRILLING METHODS AND EQUIPMENT

Sampling the subsurface usually involves one or more types of drilling, determined by the nature of the material to be sampled and the particular objective of the sampling. A number of different types will be discussed, although present-day mineral exploration and development work is virtually limited to the use of diamond core, rotary, or rotary-percussion methods (Peters, 1978; Waterman and Hazen, 1968; Sainsbury, 1979). For a discussion of drilling theory, see Chapter 9.1.

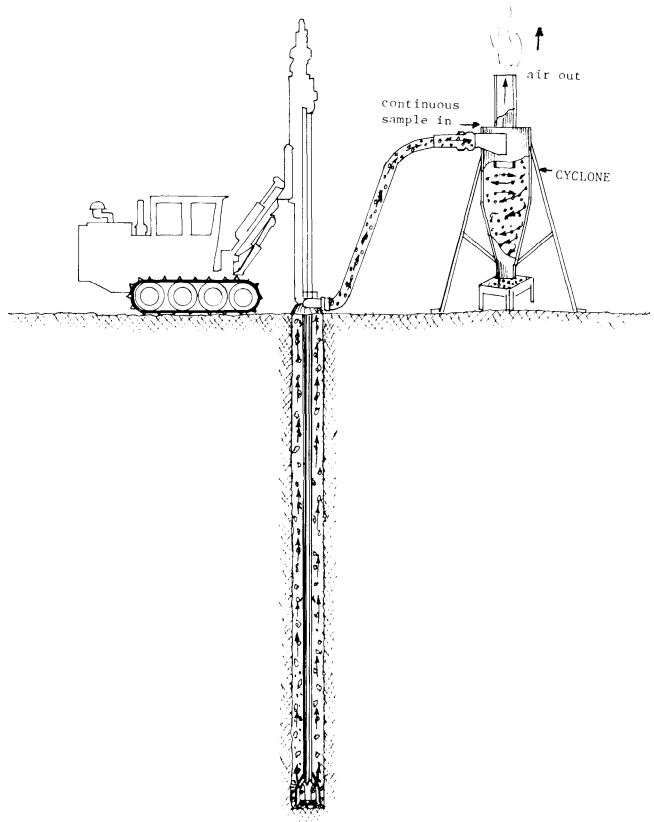

Fig. 5.3.1. Conventional rotary-percussion drill, bit, and cyclone.

5.3.1.1 Rotary-Percussion Drilling

One of the simplest, oldest, and least expensive methods, rotary-percussion drilling is essentially an evolutionary outgrowth of the single-jack driller whose arm has been replaced by a pneumatically or hydraulically driven hammer that transmits its force to a rotating drillbit through a string of hollow-drill steel or directly to the bit in the case of the down-hole hammer. Air, or sometimes water, is circulated through the drill-steel column to the bit to cool its surface and clean the hole of cuttings by forcing them along the outside of the column, hopefully to the collar of the hole (Fig. 5.3.1). Of no little importance is the power behind the circulating fluid. With air, the compressor should have the capacity in both volume and pressure appropriate for the situation. Insufficient volume will allow sorting in the fluidized column of cuttings and may result in heavy particles being left in the hole. Excessive airflow can cause excessive erosion of the hole walls and contamination of the sample. Drilling at high altitudes requires some special considerations and more powerful or multiple-stage compressors. If water is used, special arrangements must be made to allow sample cuttings to settle, minimize the loss of fines, and perhaps clarify and reclaim the water. For sample collection, the collar of the hole is usually fitted with casing and a tee connection to divert the fluidized stream of cuttings into a cyclone collector. At the end of each sampling increment, the bit is slightly retracted from the bottom of the hole and the fluid circulated until all the cuttings are removed.

This method can work well in certain situations where wall rock is competent, dry, and impermeable and drilling does not produce a great amount of fines that could be lost in the exhaust from the cyclone. Conventional rotary-percussion drilling is relatively fast and inexpensive, and equipment, particularly at an operating mine, is readily available and quite mobile, for example, blasthole drills.

However, the method has several disadvantages. Raveling of hole walls caused by vibration of the drill string or abrasion from cuttings can seriously contaminate or dilute samples. A small amount of moisture in the wall rock can be helpful by stabilizing the walls and reducing dust loss; often drillers will add a small amount of water or "mist" to the airflow to the bit to do just that. Large amounts of water flowing into a drillhole can cause serious difficulties, especially where clays are present. Swelling clay minerals can plug drillbits and adhere to hole walls, restricting and stopping airflow and/or rotation of the drill stem. Such problems can sometimes be alleviated by adding substantial amounts of water to air for circulation, but again the washing action of water either injected or from the wall rock is likely to erode the hole walls and produce an invalid sample. Fractured or permeable rock encountered in drilling will cause reduction in or loss of circulation to the surface as the drilling fluid and cuttings are spent into fractures and pores. Attempts at continuing drilling may eventually restore circulation, but any sample so obtained will be suspect; there is the additional danger of cuttings suspended in fractures settling around the drill stem and binding it in place when fluid flow is interrupted such as when adding or removing drill steel. It is generally not practical to install casing and continue with small-diameter drill tools, and the best course when circulation is lost is usually to abandon the hole. The exception would be if the desired object is the hole itself rather than a sample of the material it penetrated.

As drilling depth increases downward, the size of recovered cuttings decreases, resulting in a greater chance of losing values in fines from the sample. Nevertheless, conventional rotary-percussion drilling has a practical depth limit of 200 to 300 ft (60 to 90 m).

As mentioned, sampling by rotary-percussion drilling is relatively inexpensive due, in part, to the ready availability of equipment, the main function of which is usually blasthole drilling. This is particularly true in operating underground mines where compressed air and water supplies are installed. Sample collection is likely to be easier and the sample quality better where relatively short holes are drilled, especially when directed upward from the working and extraction of cuttings is aided by gravity. For "long holes," however, raveling of the hole wall will be exacerbated by the (usually) downward deflection of the drill stem.

By far the more common rotary-percussion drilling method for sampling uses a down-hole hammer (Fig. 5.3.2). Improvements in engineering and design have resulted in pneumatic drill hammers as small as $3^7/_8$ in. (85 mm) in diameter, which are attached to the bottom of a string of drill pipe, are activated by compressed air in the pipe, and transmit impact directly to the drillbit as the drill string is rotated. This method overcomes the disadvantage of the loss of force caused by compression of drill steel in conventional rotary-percussion drilling. Contamination and/or dilution of samples from the hole walls has been alleviated by development of dual-wall drill pipe and reverse circulation in which cuttings are forced up the center or the annulus of the pipe to the cyclone collector (Fig. 5.3.3). Although reduced, there is still the possibility of sample contamination from loose wall-rock caving, falling to the bottom of the hole, and entering the stream of cuttings. Innovations in down-hole hammer design now being tested are aimed at extracting cuttings directly from the bit face and forcing them through ports in the bit to the center of the drill pipe. If problems of bit plugging can be overcome, this concept should greatly improve sample integrity.

Initial reluctance of drilling companies to make the sizable investment in dual-wall pipe has been overcome by demand from clients for better samples, and the equipment is now universally available. At this time, reverse circulation is the most widely used method of sampling mineral deposits, and a great variety of drilling machines have been designed or adapted to work in almost any situation. The method's popularity is due to its speed, up to 825 fpd (250 m/day), and low direct cost, which generally ranges from about $5 to $15/ft ($15 to $45/m). Depth capability until recently had been effectively limited to about 650 ft (200 m), but demand has spurred modification and improvements in equipment to more than triple that capability.

Sample collection with reverse circulation drilling is relatively simple in theory (Fig. 5.3.3). Cuttings transported either through the center or the annulus of the drill pipe are retained in a cyclone collector. When the end of the sample interval is reached, the drill stem is retracted a short distance from the bottom of the hole and the airflow (or water flow) continued until it is judged that cuttings from that interval have been exhausted from the pipe. The flow is then shut off and cuttings dumped from the cyclone through a splitting device to reduce the sample size to a predetermined amount. A separate portion of the rejected sample is collected for geologic logging.

This procedure is not without problems as far as accurate sampling is concerned. The volume and pressure of the air (or other fluid) supply must first be adequate to force all of the cuttings out of the hole. This is especially important if the mineral sought has a high specific gravity. Most rigs designed for down-hole hammer reverse circulation drilling are equipped with suitable compressors, but conversion of rigs built for other types of drilling may not be. Excessive airflow causes excessive loss of fines from the exhaust stack on the cyclone; this also can be reduced by extending the length of the stack, which may produce dust leaks elsewhere in the system. By experimentation, an optimum arrangement can usually be found. Another source of sampling error can occur when the sample is dumped from the cyclone onto the splitting device. If this is not properly done, the material will billow up over the splitter and be lost from the splitting process. In some collection systems, the cyclone does not have a gate on the outlet, and the material collected flows continuously through the cyclone and splitter during drilling. Although this continuous flow may avoid the problem of spillage, it usually results in extremely dusty and often hazardous conditions around the machinery. Samples from the cyclone are commonly reduced in size by being passed through Jones or Gilson splitters (Figs. 5.3.4 and 5.3.5). The latter is an adjustable modification of the former, and both types have such a long history of use in the sampling process that their appropriateness is seldom questioned. However, some thought should be given

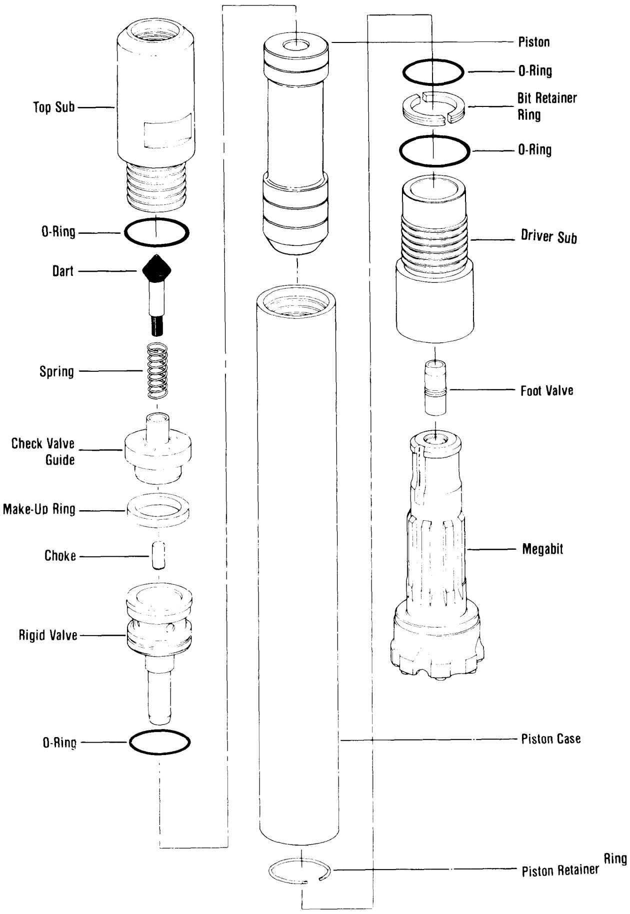

Fig. 5.3.2. Down-hole hammer (by permission: Ingersoll-Rand, Inc., left and Sandvik Mission Drilling Products Co., center and right).

to their correct use (e.g., level positioning, even distribution of the material being split, size of the slot openings relative to particle size of the material). With this simple and seemingly effective equipment, there are numerous ways to introduce bias into the final sample with only a little carelessness. Recently developed splitters such as the Accu sampler and SDI models (Figs. 5.3.6 and 5.3.7) are designed to avoid these biases and also to handle wet samples. Another type of splitter designed specifically for wet samples is shown in Fig. 5.3.8. Collection of wet samples dictates special care in washing equipment thoroughly between sample intervals.

In collecting wet samples, one is often overwhelmed by the volume and weight of the material and the problems of filtering and drying it for transport and handling. Spillage and loss of fines are valid concerns. Often the mineral sought, when in a finely divided, suspended state, will float on the water and may be lost from the sample. This is particularly true of gold and other precious metals that, due to their malleability, are easily suspended by surface tension. The problem is being addressed by a number of drilling companies and equipment manufacturers who have designed and produced a variety of stationary and rotating sampling devices intended to extract a representative proportion of the drill cuttings. However, the problems of spillage and properly cleaning the device, added to those of filtering out the water without losing values in the fines, in the author's opinion, make accurate and reliable sampling virtually impossible. These are problems that must be solved. Environmental concerns about air pollution and conspicuous dust plumes from pneumatic drilling have prompted regulations in some areas that essentially prohibit drilling with air conventionally. It is anticipated that this regulatory trend will continue and that drilling with water and collecting wet samples may eventually become mandatory procedures.

5.3.1.2 Rotary Drilling

Because of inherent elasticity or other unique physical properties, certain rock types cannot be drilled and sampled effectively with percussion equipment but are amenable to some type of rotary drilling, whether conventional or reverse circulation (Fig. 5.3.9). Most commonly, a tricone bit is used, but special situations may find the use of plug, fishtail, or drag bits more effective. Extracting and collecting the sample are essentially the same as with rotary-percussion drilling.

5.3.1.3 Diamond Core Drilling

Diamond core drilling generally provides the most useful and accurate samples of a mineral deposit and is the most versatile of all drilling methods (Peters, 1978). Whereas at one time, limitations of equipment produced small, fragmented samples, the refinements in wireline techniques and drilling fluids and additives since the 1950s have made it possible to core almost any kind of rock.

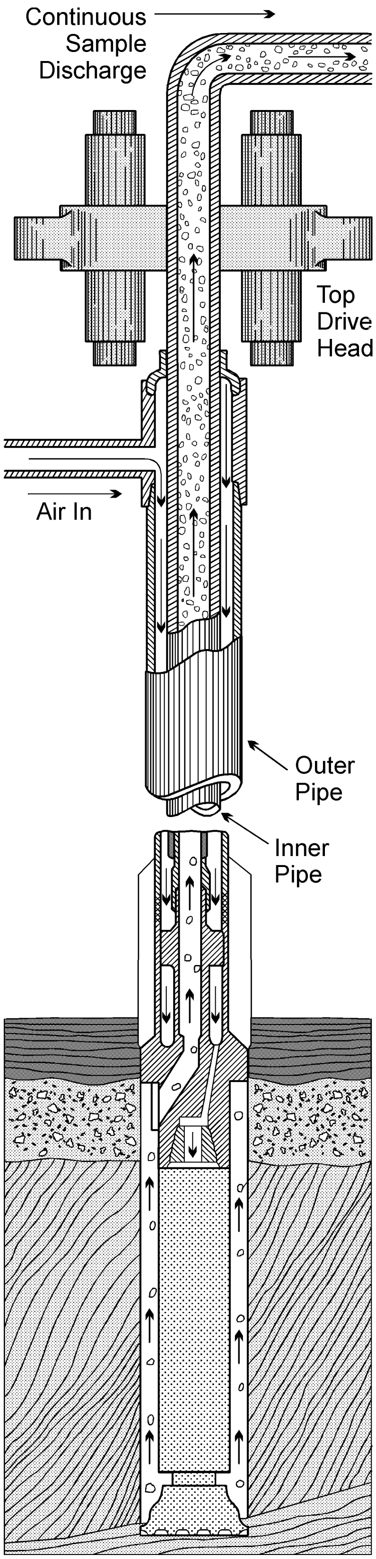

Fig. 5.3.3. Reverse circulation downhole hammer, pipe, sample recovery system. (By permission of Drilling Services Co.)

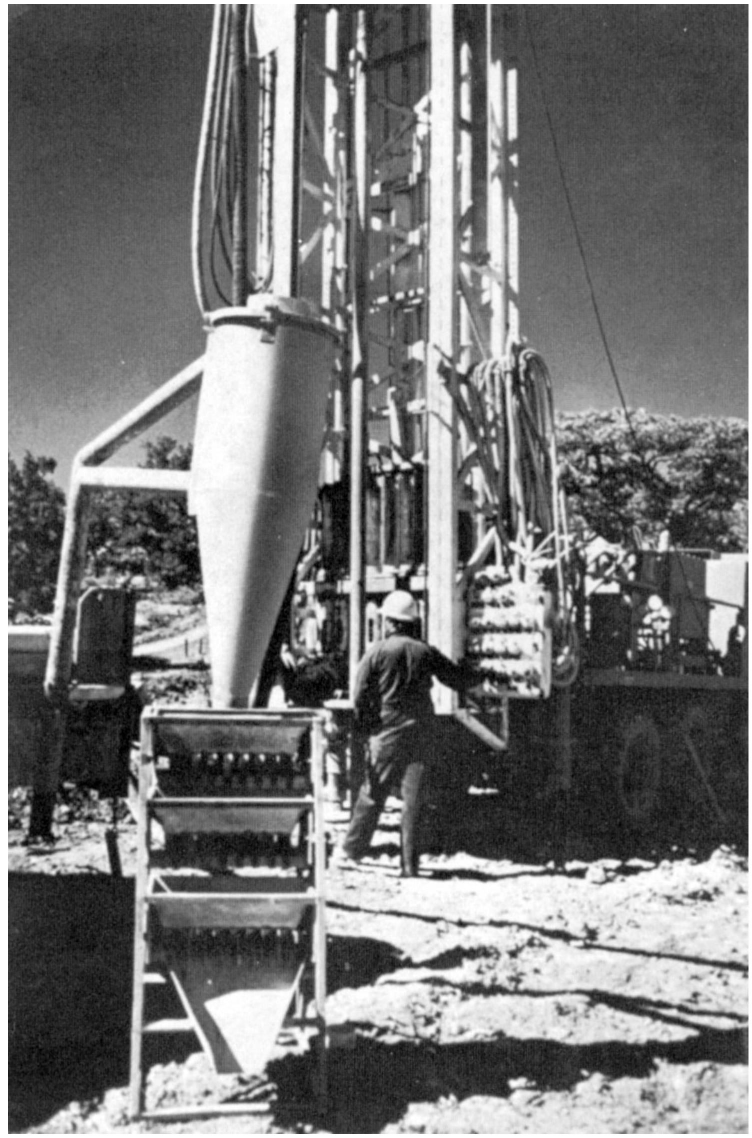

Fig. 5.3.4. Jones riffle splitter. (By permission of Drilling Services Co.)

The two methods of diamond core drilling are referred to as conventional and wireline. In drilling with conventional equipment, the core barrel is a fixed part of the drill rod string (Fig. 5.3.10) and can only be retrieved by retracting and removing all drill rods from the hole one at a time. This method has undoubtedly resulted in a great deal of core being destroyed over the years because of the reluctance of drill crews to pull the rods before finishing a run, especially in deep holes.

The wireline method uses a core barrel removable through the inside of the drill stem with a latching device on the end of a cable (Fig. 5.3.10). With this method, core can be retrieved at any desired point, usually in less time than with the conventional method, and drill rods need only be removed for bit changes, casing installation, etc. In general, wireline is the preferred method, but there are exceptions. Core diameters with wireline equipment are smaller than their conventional counterparts. In relatively shallow holes or in hard rock where bit changes are

Fig. 5.3.5. Gilson adjustable sample splitter. (By permission of Gilson Screen Co.)

frequent, there may be no time-saving advantage to using wire-line equipment.

Early conventional equipment using water as a drilling fluid commonly yielded core recoveries of less than 50% and led to numerous intricate methods of collecting sludge (material ground up by the drillbit and flushed from the hole outside the rods) samples and formulas for combining core and sludge assays to get the "correct" value. Even then, the results were often suspect and assays discounted as an extra safety factor. With the present variety of diamond bit designs and mud and polymer technology, 100% core recovery has become the rule rather than the exception, and sludge samples (fortunately) are rarely collected. The collection and use of sludge samples have the same inherent problems as those with cuttings from conventional rotary-percussion drilling. Sludge is usually believed to consist of the softer (and probably more mineralized) part of the material being drilled, but with the possibilities of losses into fractures or additions from caving walls, one can never be sure of what a sludge sample represents. Wireline tool design is believed to add stability to the coring process and also to increase core recovery.

Core sampling can also be problematic. Traditionally, core is manually split lengthwise with the aid of a mechanical splitter (Fig. 5.3.1), and one half is used for assays and the other half for "backup." However, a true split is rarely if ever achieved. This is particularly troublesome when the mineral sought occurs in friable fractured material at varying angles to the core axis. Another method, intended to obtain a more equitable split, is to cut the core lengthwise with a diamond saw; this works particularly well with hard, competent rock and more or less evenly disseminated mineralization. Other workers believe that the best course is to assay the whole core, thus avoiding bias from the splitting process.

The advantages of diamond core drilling over other methods include better geologic and geotechnical information (structure, controls, nature of mineralization, strength) and better material for metallurgical testing. Its main disadvantages are that it is slower and more costly than other methods and produces a relatively smaller sample. However, in recent years due to the amortization of drilling equipment and competition from

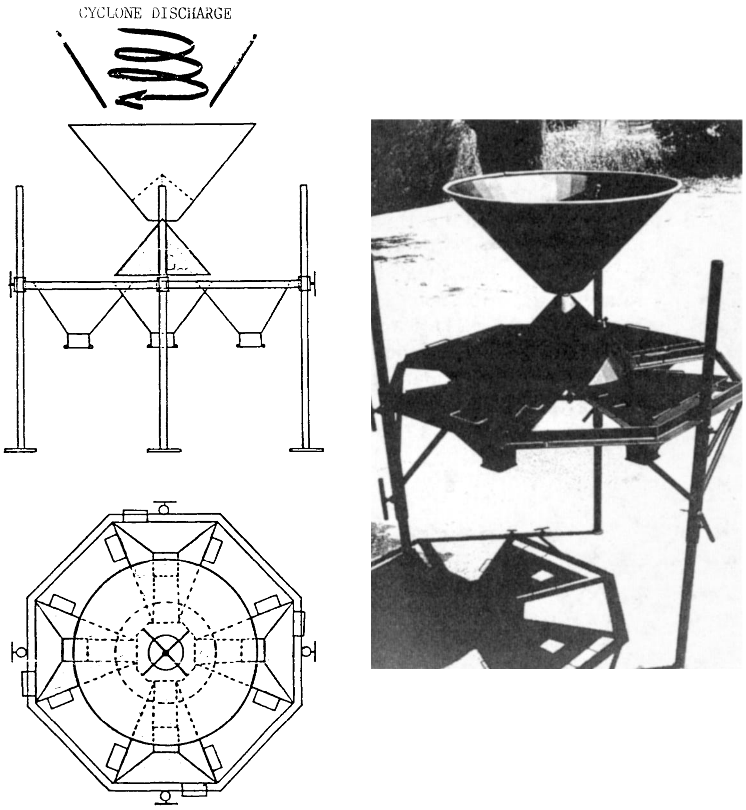

Fig. 5.3.7. SDI sampler. (By permission of Sampling Devices, Inc.)

reverse-circulation drilling, diamond drilling costs have dropped to about a third of what they were in the mid-1980s. Prices vary with circumstances, but rates of \$10 to \$15/ft (\$35 to \$50/m) are not uncommon.

5.3.1.4 Other Drill Sampling Methods and Equipment

The foregoing methods and equipment are virtually the only ones used in sampling hard-rock mineral deposits. A number of specialized types of drilling methods have been developed for sampling soft, unconsolidated materials such as alluvial or placer deposits. Many of these are based on the churn (or cable tool) drill method such as the Airplane drill, Banka or Empire drill, Keystone drill, and Becker hammer drill (Wells, 1973) (Figs. 5.3.12 and 5.3.13). The principles in all are the same: hollow casing is driven into the material to be sampled, leaving an inside core of relatively undisturbed material; the core is then attacked with a cable tool drillbit, broken up, and flushed, pumped, or otherwise lifted to the collar of the hole for sampling. The Keystone drill is a churn drill specifically designed for placer sampling; the Airplane drill is essentially a smaller version for use in areas of difficult access (Wells, 1973). The Banka or Empire drill is a prospecting drill, which uses the weight of the crew on a platform to drive the casing, rotation being accomplished by man or animal power; the drillbit and sand pumps are usually operated from the drilling platform. The Becker hammer drill, developed in the 1950s, combines the foregoing techniques with those of reverse circulation; dual-wall drill pipe is driven by a pile driver while air or water is forced down through the annulus to lift the cuttings through the inner pipe. Measurements of the samples recovered and calculations of volume and value are quite specific and critical; examples are given by Daily (1983) and Wells (1973).

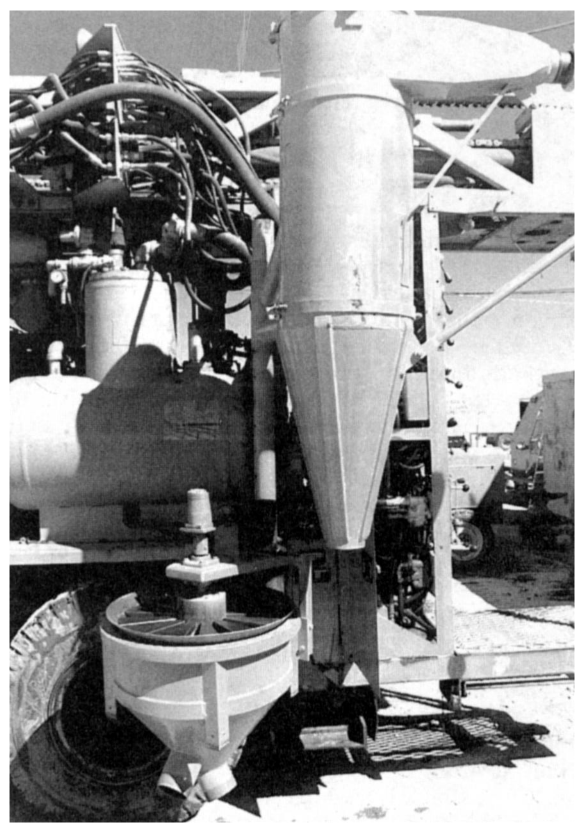

Fig. 5.3.8. Wet drill sample splitter. (By permission of Boyles Brothers Drilling Co.)

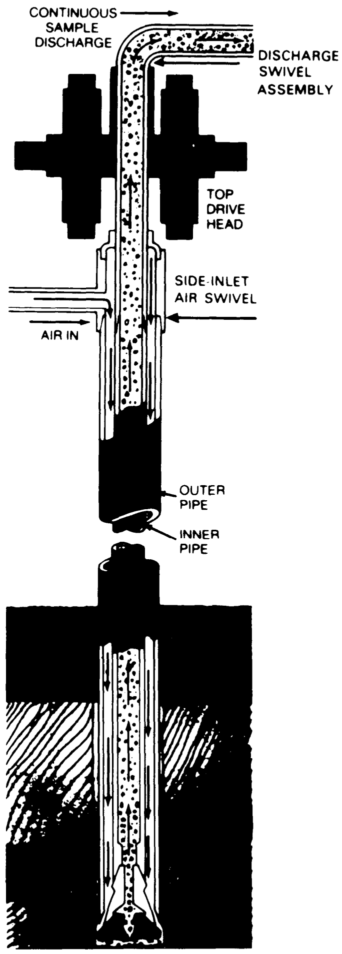

Fig. 5.3.9. Reverse circulation drilling system with tricone bit. (By permission of Systems for Drilling Inc.)

In special circumstances, a bucket drill can be used successfully, that is, in firm dry ground without large rocks. The "bucket" is a straight-walled cylinder many times larger in diameter than the drill stem, with radial excavating blades extending from the bottom where rubber flaps over wedge-shaped openings admit cuttings during drilling but seal the openings when the bucket is hoisted (Wells, 1973, pp. 39-41). Variations on this technique are rotary "clamshell" type excavators such as the "orange peel," which has several convergent tapered segments that can be closed to remove the sample. Sampling with these excavators has the inherent inability to remove all the loose material from the hole.

Large boulders can cause problems for all these methods by either blocking the drillbit, deflecting it, or being pushed aside. Ideally, the boulders would be cut by the bit and included in the sample, but this is probably seldom what happens. If numerous large boulders are known to occur in the deposit, this effect can be reduced by taking larger samples such as with a caisson drill (Fig. 5.3.14) (Hildebrand, 1976). A large-diameter caisson is driven by a combination of the rotational impact of a horizontally swinging arm onto a striker block and the weight of the equipment. The sample is removed at intervals from the inside of the caisson with a mechanical excavator and perhaps, ultimately, manually.

A recent innovation in drilling equipment, developed for water wells, is the Barber Dual Rotary (DR) system manufactured by Barber Industries. This system features two rotary drill heads: a lower one to advance carbide-tipped steel casing through unconsolidated material, and an upper one to advance a drill string connected to a down-hole hammer or tricone bit used to break up the core within the casing. The fragmented core material is flushed from the hole to a collecting cyclone by the air or other drilling fluid (Fig. 5.3.15). Reportedly, this equipment is successful in drilling through boulders as well as sands and gravels in unconsolidated alluvium and in materials with strong artesian flow. These features appear to be well suited to reliably sampling deposits such as placers with minimal loss or contamination of samples. However, any values contained in large fragments and reported in the samples from such deposits would not be recovered in normal placer operations.

Earth augers have been used in soft, relatively fine material (for example, placers) but present problems in sample removal and collection.

5.3.2 DRILLING PARAMETERS

In establishing a drill sampling program there are many factors to be considered, most of them having to do with the type of deposit involved. Different methods should apply to a high-grade precious-metal vein, a low-grade disseminated metal deposit, a specialty clay, coal seam, phosphate, or placer. A fair working hypothesis must be developed about the nature of the deposit sought, its geometry, competency, mineralogy, etc. The stage of the project is important as well, because a method used in the early exploration phases will probably not be suitable for development or production phases. If, for example, the stratigraphy is well known and the various rock types are readily discernible, reverse circulation drilling can provide adequate samples and geologic information. If the foregoing premises do not apply, diamond core drilling should be employed to provide the necessary information, at least until the geologic framework of the deposit is stabilized with some degree of confidence.

Other factors such as equipment availability and cost may dictate the use of a drill sampling method that is less than ideal for the project. If, for example, funds are critical and a standard percussion blasthole drill is readily available, one might drill a few holes "just to see if something's there." If that test meets with apparent success, it should be followed with a more accurate method. Checking such results is often done by "twinning" drillholes, but it must be realized that the sampled material from the "twin" holes will not be identical, and close agreement cannot always be expected. Caution should be used in mixing or combining results from different types of drill samples into a resource estimate. Too often an assay printed on a log or cross section becomes a "fact" on a par with all others, with no further consideration of its provenance. In the author's experience and in examples such as noted by Parratt and Bloomstein (1989), unintentional salting of samples occurred in rotary-percussion holes, and the apparent high-grade zones were disproved by subsequent diamond drilling.

The optimum drilling method for a deposit may change as the project makes the transitions from exploration and discovery through development to production. Early exploration drilling is usually done at locations chosen for specific geologic reasons. Following a discovery, a specific drillhole pattern or grid is followed to delineate and define the deposit with sufficient accuracy to determine its economic viability. Spacing of drillholes in the grid can be critical, and the optimum spacing can often be determined by the use of geology (Shaddrick, 1987) and geosta-

Right: Wireline drilling equipment that consists of (1) diamond drillbit, (2) diamond set reaming shell, (3) outer core barrel complete, (4) inner tube assembly, (5) overshot assembly, (6) wireline cable, (7) drill rod string, and (8) wireline hoist. (Reproduced by permission from *Diamond Drill Handbook,* 1980, pp. 55, 63.)

tistics (Call, 1979; Peters, 1978) as well as empirically. There have, of course, been deposits that in retrospect were found to have been drilled on a closer than necessary spacing, causing an undue front-end capital cost to the project. More noteworthy are the opposite situations where too large a grid spacing resulted in holes penetrating isolated pods of mineralization with insuffcient continuity between holes. Porphyry copper deposits may be adequately sampled by drillholes on a 250-ft (75-m) grid spacing, but a limestone replacement or skarn deposit may require a 50-ft (15-m) or less drillhole spacing for adequate evaluation.

Differences in mineralization grade in various rock types in a deposit should be taken into account in drillhole sampling if possible. Although generally practicable only with diamond core drilling, sample (assay) intervals should conform to geologic contacts to properly define the deposit. Even though the ore body may ultimately be mined on prescribed bench levels, assays can be averaged to represent those levels and the geologic controls can and should be used to determine those levels.

A deposit characterized by steeply dipping mineralized fractures can seldom be evaluated properly with vertical drillholes. In such deposits, preferred orientations of mineralized fractures should be determined as closely as possible and the drillholes oriented at a reasonable angle to crosscut the fractures.

Drillhole size is also an important consideration in sampling. If mineralization is expected to be relatively homogeneous and

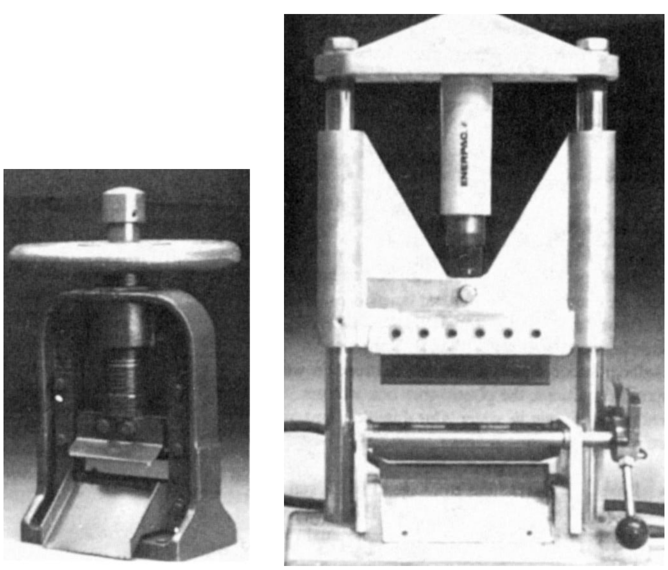

Fig. 5.3.11. Core splitters (manual, left; hydraulic, right). (By permission of Myhre's Exploration Products, Inc. *Catalog.)*

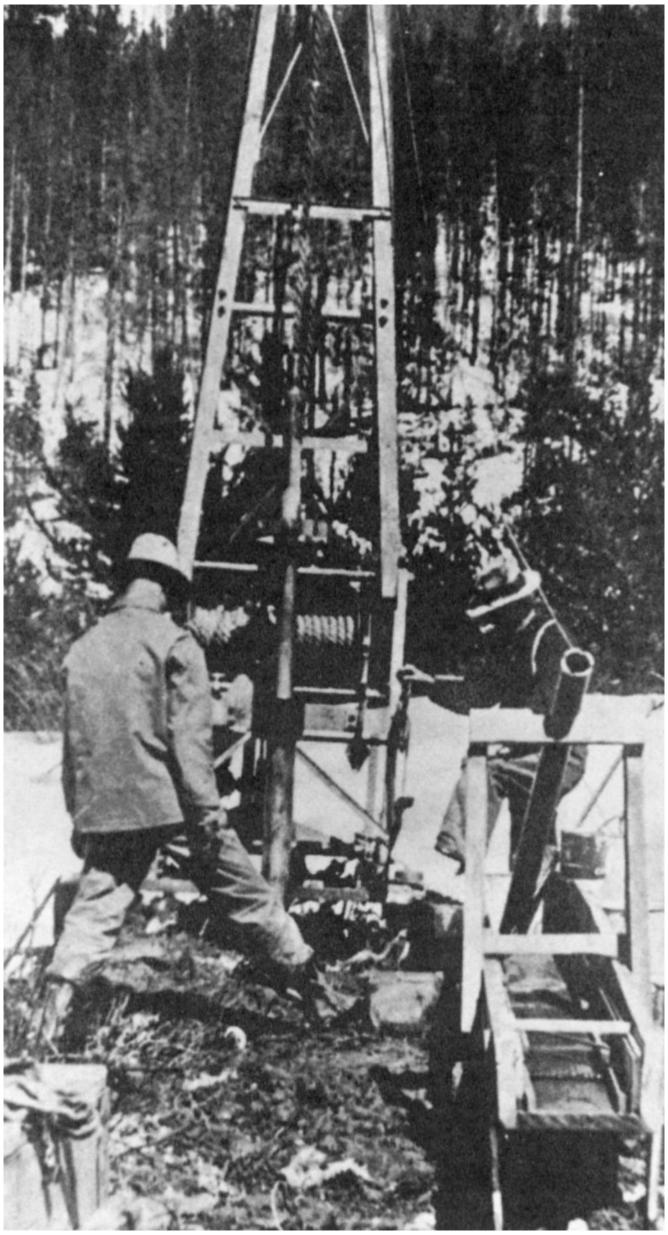

Fig. 5.3.12. Airplane placer drill (Wells, 1969, p. 51).

finely disseminated on closely spaced fractures within the host rock, adequate sampling may be done with BX size core (1.432-in. or 136.4-mm diameter). However, NX core can yield 1.7 times as much sample, a 5.5-in. (140-mm) diameter rotary-percussion hole 11 times as much, and a 12-in. (305-mm) diameter blasthole 50 times as much. The importance of adequate sample size for gold analysis was discussed in detail by Clifton et al. (1969).

With angle drilling for vein deposits as well as with relatively deep vertical drilling, it is important to know the location of the drillhole at points from which samples were cut. Such drillholes often deviate from their collar orientation as the result of wall-rock structure and composition (e.g., bedding, cleavage, foliation, alternating hard and soft layers, etc.) or excessive down pressure on the drill stem during drilling (McKinstry, 1948, p.

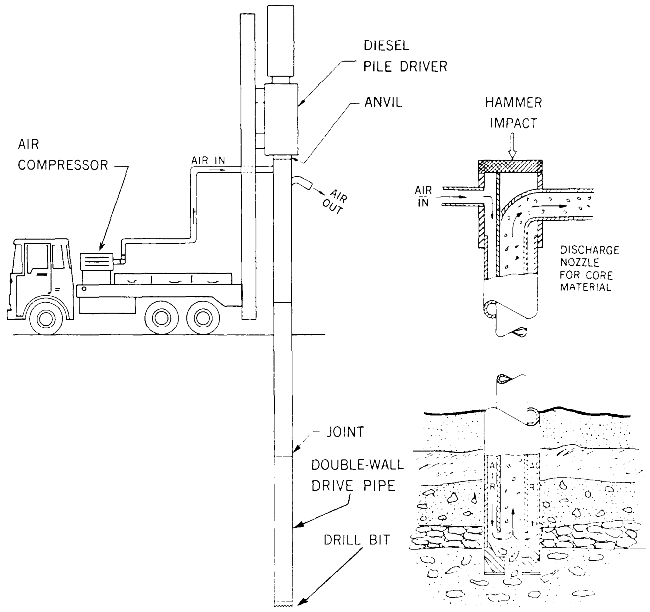

Fig. 5.3.13. Becker hammer drill. (By permission of Becker Manufacturing and Drilling Inc.)

96; Peters, 1978, p. 447). Over the decades, numerous methods of down-hole surveying have been used in diamond drilling to measure such deviations and determine the true location of the drillhole in space. Some methods such as that using simply a glass tube and hydrofluoric acid provide only the inclination of the hole at the point surveyed; others such as the Maas compass and "Tro-Pari" (Cumming and Wicklund, 1975) provide both azimuth and inclination data on the attitude of the hole but are affected by the magnetism of the wall rock. The Sperry-Sun Well Surveying Co. offers services and equipment that include multi-shot gyroscopic as well as magnetic compass devices that can provide an almost continuous survey of a drillhole, if desired. Although originally developed for oil-field drilling, presently available equipment is small enough for use in BX-size core holes (Table 5.3.1). Outgrowths of accurate drill surveying are the taking of oriented core samples (permitting measurement of true attitudes of geologic contacts, faults, veins, bedding, etc.) and directional and multiple-hole drilling. With the latter two, a targeted vein or formation can be sampled at depth at one or more specific locations, by the combined use of hole surveys and directional wedges or mud-powered bits such as the Dyna-drill or Navi drill (Fig. 5.3.16). Both Smith and Navi drill systems include a deviation device acting from the nonrotating part of the drill stem. The bit, turned by a motor powered by the force of the circulating fluid, continues to drill until the desired deflection has been achieved, while the drill string slides down the hole behind it. With the Smith Steerable System, azimuth and inclination are monitored on the surface by means of a "mud-pulse" telemetry system in the down-hole drilling unit. Although this system was developed mainly for the larger-diameter drilling in the petroleum industry, continuing refinements and miniatureization of the equipment suggest it may eventually be used more widely in the mining industry.

5.3.3 BULK SAMPLING

Once a reserve of economic-grade material has been proved, its continuity and availability to mining and metallurgical pro-

cesses should be verified by bulk sampling. By the time the project reaches this stage, a great deal should be known about its physical as well as its chemical characteristics from physical examination of samples and bench-scale metallurgical tests run on them. These presumed properties need to be confirmed by examination and testing on a larger scale. The earlier stage gives information on what and how many metallurgical ore types occur in the deposit (oxide, sulfide, mixed, polymetallic), their spatial distribution, and some clues as to their structural strength. A carefully planned program of collecting several tons to several thousand tons from different portions of the deposit judged to be representative of the various significant ore types is essential to designing a successful operation. These samples may be obtained from surface excavations, underground excavations, or drillholes as appropriate to the size, location, and geometry of the deposit.

Near-surface deposits such as a placer or certain types of nonmetallic deposits may be effectively tested from surface trenching or pitting. Such excavations should be accurately measured for assay checks and computation of tonnage factors. They should also be mapped in detail to document such factors as fracture spacing, intensity, and trends; facies changes; mineralization variation and trends; and size and distribution of fragments.

Underground bulk samples are usually collected by driving raises around a drillhole from the surface or mining a test stope in a "proved" ore area. That area must be carefully selected to be as representative as possible of the whole deposit, a very difficult condition to meet. Consequently, the sampling of more than one such area is desirable if not necessary. Assay comparisons between the bulk sample and the drillhole(s) it is intended to check are likely to show some discrepancy. A method of statistical comparison is given by Waterman and Hazen (1968).

Without the convenience of existing underground workings, the cost of underground bulk sampling may seem prohibitive and must be weighed against the cost of alternative methods or that of inadequate mine and process design. That design will depend greatly on the selection of the bulk sampling site(s).

A more comprehensive system of bulk sampling uses drill cores from various parts of the deposit. For this purpose, large-diameter core (6 in. or 152 mm, or larger) is most useful for

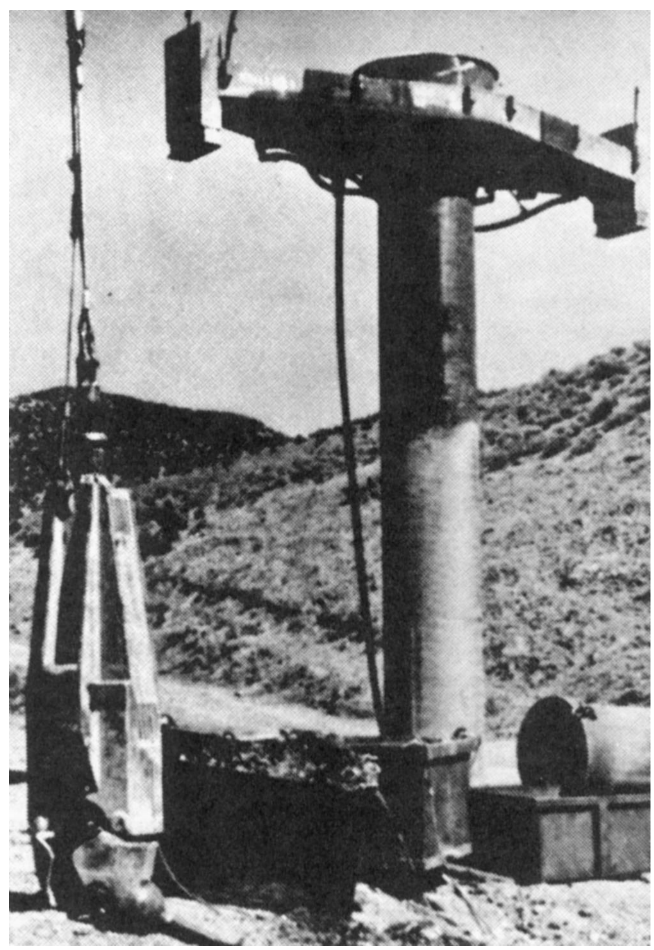

Fig. 5.3.14. Caisson drill. (Reprinted from *Mining Year Book 1976,* Colorado Mining Association, p. 131.)

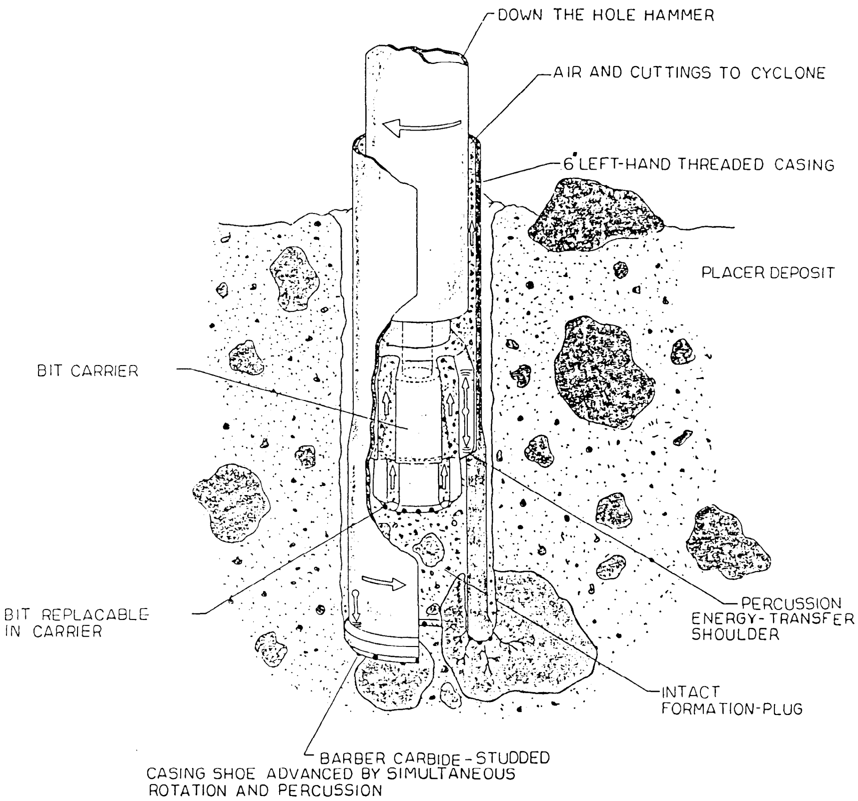

Fig. 5.3.15. Schematic diagram showing the Barber dual rotary drilling methods. (By permission of Barber Industries.)

obtaining metallurgical and geotechnical information. This system permits sampling all facies or ore types of a deposit rather than only what is hoped to be "typical." With a vein deposit, drilling wall rock can be started with noncoring equipment and converted to coring equipment as the vein intersection is approached. Ample amounts of wall rock should be cored to provide geotechnical data and address the problem of dilution as well. Bulk sampling with drill core does not provide first-hand inspection of material in place but does provide a greater amount and variety of information than other methods.

In the subject of bulk sampling, emphasis is often placed on obtaining samples of "typical" or average material. Sampling should also include some of the "worst case" or refractory portions of the ore body, especially if they are likely to be treated at an early stage of mining when achievement of production and profitability goals are especially important.

Placer deposits present a special challenge in the area of bulk sampling due to the often erratic distribution of values, great variations in particle size of material to be handled, and usual lack of consolidation. Dry land placers can be sampled with carefully excavated surface pits and trenches, hand-dug shafts, or by special techniques such as the caisson drilling method previously mentioned (Hildebrand, 1976). The subject is worthy of an entire chapter by itself; Hildebrand also discussed some of the problems to be dealt with, and Wells (1973) covered various methods and ways to address special problems and deposit types. It is especially important in bulk sampling of placers to retain any sample in its entirety without splitting for concentration by the same methods contemplated for production to provide a reliable estimate of value and recovery. Chapter 15.1 also discusses placer exploration.

Sampling industrial mineral deposits is a very specialized field, and techniques may vary from the simple use of a physical property such as specific gravity for a barite deposit to processing the sample through a series of microscopic and X-ray analytical tests. Often the purity of the sample (a bias in itself) must be estimated prior to the collection. Or, as in sampling a phosphate deposit, most of the analysis is done at the sample collection site. A comprehensive discussion of techniques, problems, and their considerations is given by Eyde and Eyde (1985).

Other specialized applications are discussed by O'Donnell and Jodrey (1985) and Greenberg et al. (1985).

5.3.4 GRADE CONTROL

During the transition from development to production, a method of grade control must be established, including correct and necessary sampling procedures. The procedures will vary with the type of deposit and, of course, be different for open pit and underground.

Presently, virtually all grade control in open pit mines is based on samples collected from blastholes on pit benches. Although a variety of techniques may be used, the best samples are obtained by using a wedge-shaped ("piece of pie") collecting pan whose vertical sides are radial to the hole and long enough to recover all particles ejected from the hole in that sector. The collector is placed against the drill collar before drilling starts and removed when the drillbit reaches the next lower bench level (blastholes are usually drilled a prescribed distance past that level to allow for caving and to assure optimum breakage). Results of such sampling give a good indication of the grade distribution of the material in situ, but that can be changed significantly by blasting, particularly if there are notable physical differences, for example, competency or fracture density, between ore and waste. What once may have been clearly separate ore and waste can

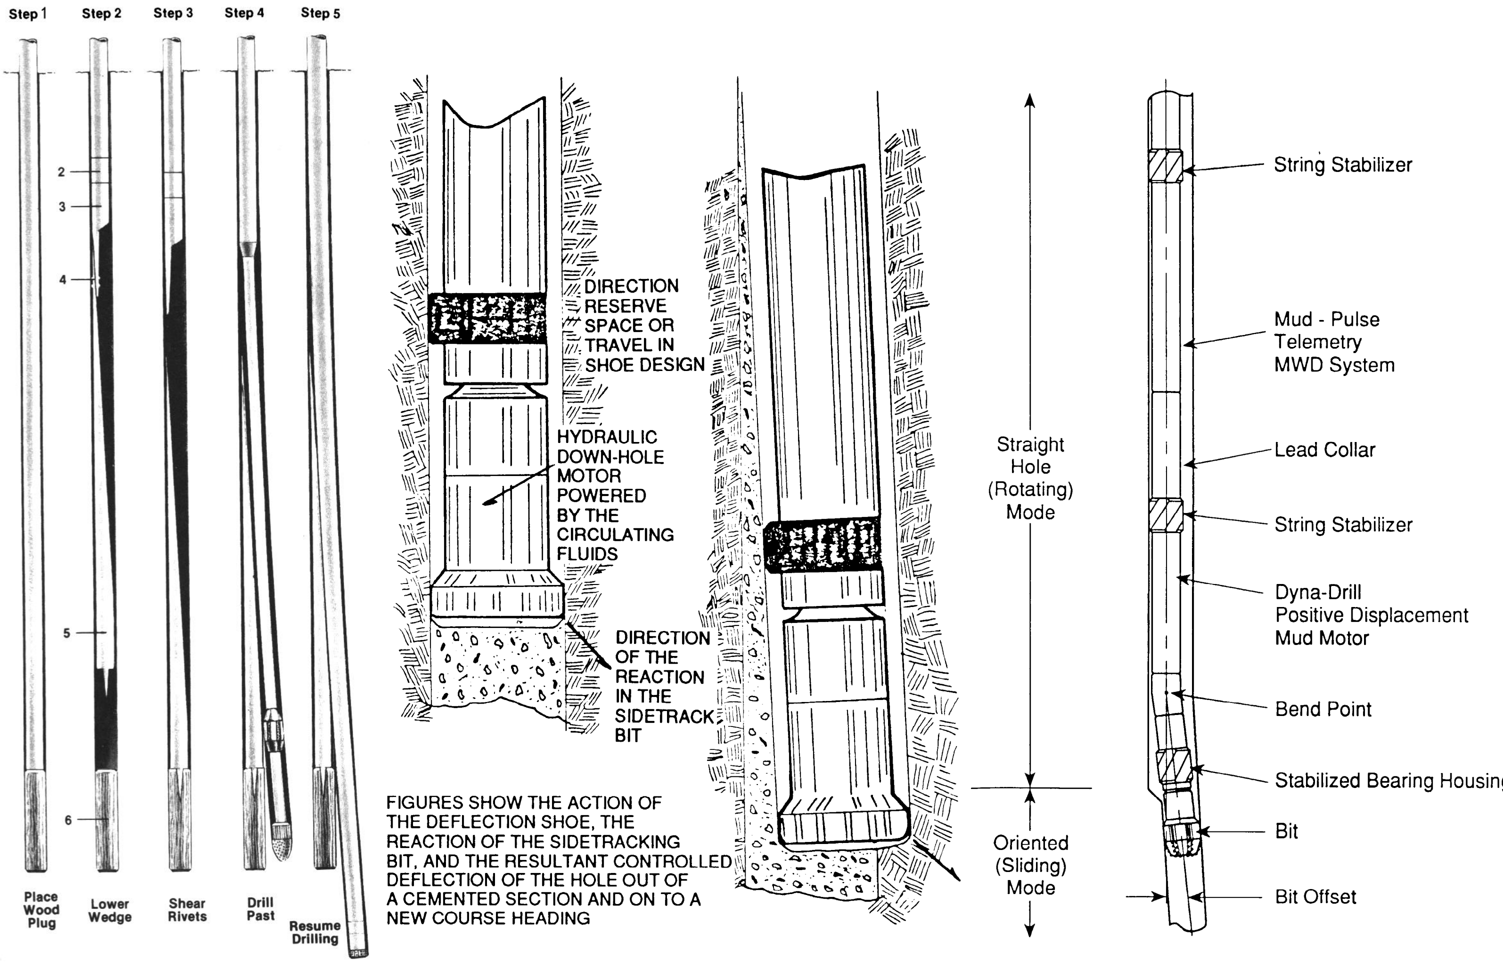

Fig. 5.3.16. Directional deflecting wedges (left), Navi-drill (center), and Smith Steerable System (right). (By permission of left, Boyles Bros. Drilling Co.; center, Christensen Boyles Co.; and right, Smith International.)

become so mixed during blasting that all is waste. If ore controls are well known, visual inspection of shot muck may suffice to redefine an ore-waste boundary, or the ore control engineer may decide to use grab samples to make that definition, a risky method. More refined selective mining techniques may be called for, and these should rely heavily on geologic input. Information gained from detailed mine level mapping can determine structural and lithologic controls and mineralization and thus ore grade and metallurgical ore types. Kornze et al (1985) and Clark et al. (1985) detail methods used in low-grade precious-metal and disseminated copper deposits, respectively.

Sampling for grade control in underground mines presents some more difficult problems, as often the material cannot be sampled until it is broken and essentially loaded and perhaps on its way to the mill or smelter. Grade control may be based on composite results from channel samples of a stope, drift face or back, muck piles, ore chutes, and car samples. Particular care must be taken with the last three because of the mineral particle segregation in fines vs. coarse material. Rogers (1985) and Ruge and Vera (1985) detail some of the intricate problems and variations encountered and methods used to resolve them at two quite different underground mines.

Grade control is usually thought of in terms of measuring the contained amounts of the metal or compound sought. However, in industrial mineral deposits, it often depends on detection and quantitative measurement of contaminants. Likewise, quality control in coal deposits depends on sulfur and nitrogen oxide contents of the products of combustion. In solution mining and tangentially Frasch sulfur production, grade control is accomplished by a complex system of computer monitoring, analysis, and regulation of solutions.

5.3.5 OTHER SAMPLING METHODS

The preceding discussion has covered the more common sampling methods currently in use, most of which are aimed at direct measurement of the sought-after commodity. For certain minerals, indirect methods are used. One of the better known methods developed from the uranium rush of the 1950s as techniques were devised to "assay" radioactive minerals in rock with Geiger counters, scintillometers, and subsequently gamma-ray spectrometers. Rotary-percussion drilling without concern for sample recovery followed by hole probing to detect zones of radioactivity was the method used and perfected because of the unique properties of uranium. Down-hole probing was refined to down-hole logging, providing precise electrical as well as radiometric measurements, particularly useful in prospecting evaporite deposits. Another down-hole sampling technique that has seen some limited use employs neutron activation analysis to assay material in situ. Evaluation of diamond deposits involves mechanically breaking down bulk samples and heavy media separation (Atkinson et al., 1985) in lieu of the earlier labor-intensive, less-quantitative method of panning alluvial or colluvial material. Mention has already been made of the drill-site sample processing and analysis in evaluating phosphate deposits; no doubt other similar techniques exist or will be developed.

Chapter 5.4
SAMPLE PREPARATION AND ASSAYING

GORDON E. GUMBLE, EDWIN V. POST, AND WALTER E. HILL, JR.

The sample preparation and assaying procedures discussed in this chapter apply equally to in-house facilities as well as commercial laboratories. They are applicable to samples derived from reconnaissance exploration through development drilling to mine operations.

The focus is on operations in metal mines; indeed, much worldwide mining activity at this writing is concerned with exploration for and development of gold deposits. The requirements for the preparation of samples of many gold-bearing materials are more stringent than those for many other metallic deposits. Thus the practices described here generally fulfill the requirements for most metallic mineral deposits.

The preparation and testing of coal samples is a specialized field. Most of the pertinent procedures have been published by the American Society for Testing and Materials (ASTM), and they are summarized in a later segment (5.4.3) of this chapter.

As is true for coal, the preparation and testing of samples of industrial mineral raw materials is highly specialized. For many products, the preparation and testing procedures are end-product sensitive; that is, the preparation and testing procedures to be used are controlled by the properties desired in the final product. One must attempt to select sample preparation and testing procedures that will produce a product comparable to one produced by the actual process procedures to be used. The book, *Industrial Minerals and Rocks* (Lefond, 1983), presents perhaps the best overall background on a wide variety of industrial mineral products, although little specifically on sample preparation and testing. Few additional general publications exist, and no specific guidelines can be given here, other than to suggest that sample preparation and testing procedures be established for individual deposits through frequent and close communication among the exploration and mining staff, laboratory personnel, mill managers, marketing staff, and end users.

5.4.1 SAMPLE PREPARATION

Sample preparation is the process of converting samples of geologic materials from the large sample collected in the field or mine into finely divided homogeneous powders suitable for chemical analysis or other testing. This is accomplished by the mechanical reduction of pieces of rock to a smaller particle size in a stepwise sequence, alternating with the reduction of sample volume or mass by an unbiased splitting process.

Error can be introduced in many ways during sample preparation. As a consequence, attention to detail and thorough cleaning of equipment between samples is necessary. The desired end result of sample preparation is a rock powder that contains the elements to be analyzed in the same concentrations and proportions as in the original sample received. The reduction in particle size will be affected by many factors, including particle shape, hardness, specific gravity, lubricity, malleability, residual moisture, and the quantity of clay minerals or organic matter present.

5.4.1.1 Sample Preparation Equipment

The equipment required to prepare mineral samples adequately for analysis depends to some extent on the nature and quantity of the samples, and even on the climatic environment. In hot desert environments, samples can be air dried adequately under the sun, and a laboratory with only a handfull of small samples to crush and pulverize per day could do an adequate job with a manual bucking board and muller.

Dryers: Electric- or gas-fired ovens are used to remove moisture or free-standing water from samples before crushing and pulverizing. An airflow is maintained through the oven to remove water vapor released from the samples. For routine assay purposes, oven temperatures are usually maintained from 220° to 285°F (104° to 140° C), the higher temperatures being used on clays, although the temperature should not exceed 100°F (37°C) if mercury is to be determined. The submission of larger and excessively wet drill cutting samples to high-volume minerals laboratories has started a trend towards drying rooms or buildings equipped to dry large quantities of samples.

Crushers:

Jaw Crushers—The first stage of crushing normally is accomplished in a laboratory-sized jaw crusher. Many designs still in production date back a half century or more, but the trend in redesigns or new designs is towards roller bearings, short stroke, and a high reduction ratio. Some of these can be choke-fed through a hopper with feed up to 4 in. (100 mm) across, and they will produce a —8-mesh (2.4-mm) product in one pass while the operator is attending to other duties. Jaw crushers have a relatively high productivity and reduction ratio and are generally easy to clean between samples.

Cone Crushers—Normally used in a second stage of crushing, cone crushers produce a uniform-sized product with a smaller percentage of fines, considered better for metallurgical testing, and most can crush to 10 mesh (2 mm). Cone crushers are not effective on clays, but work best on hard siliceous materials. They have a relatively low productivity and are difficult to clean, especially after clayey samples.

Roll Crushers—As an alternative to cone crushers for second-stage crushing, roll crushers have a higher productivity and can produce a —10-mesh (2-mm) product. However, they produce a poorly sorted product with a higher percentage of fines and are noisy, dusty, and difficult to clean. The feed to roll crushers must be sized to —3/8 or 1/2 in. (10 or 12 mm), and the feed rate must be controlled to prevent choking.

Hammer Mills—Hammer mills have a high productivity and the potential to produce a product suitable for splitting and pulverizing in one pass from feed as large as 4 in. (100 mm). However, they are extremely noisy, dusty, hard to clean, and subject to excessive wear when processing tough siliceous materials. Their product is not well sorted, typically consisting of a large percentage of fines with a small percentage of very coarse fragments. Hammer mills are more often used to crush clays, limestone, coal, and similar softer materials.

Splitters: At some point in the sample size-reduction process, it becomes impractical and unnecessary to further reduce the particle size of the entire sample. The sample volume is then reduced by half or more, depending on the procedure selected as appropriate for the material at hand, by using a sample splitter.

Riffle Splitters—The riffle splitter, or Jones splitter, is most commonly used for sample size reduction. The technique of splitting must be carefully monitored to insure that statistically valid splits are taken. Splitter chutes should be at least three times as wide as the diameter of the largest particles in the sample, and the delivery pan should be no longer than the distance across all of the chutes. The sample should be evenly distributed along the length of the delivery pan and should be poured along the center line of the splitter—not against one side or the other. The rate of pouring must be slow enough to avoid choking the chutes. The splitter must be cleaned between samples.

Rotating Sectorial Splitters—The most effective splitter, in terms of sampling error, is the rotating sectorial splitter (Allen and Khan, 1970). Various designs exist, most being adapted to splitting the product from rotary drill rigs and thus larger than appropriate for use in the laboratory. Shop-made laboratory-sized versions of the rotating sectorial splitter are in use in some sample preparation facilities. One design consists of a rotating circular table driven by a variable-speed motor at about 10 rpm. Four plastic cartons of 1-pt or 1-qt (1/2 or 1-L) capacity rest on the rotating table. The gaps between the cartons are covered by pieces of angle iron. The sample is fed from a feed hopper by a vibratory feeder.

Pulverizers: Once the sample is reduced to an appropriate weight (typically 1/4 to 1 lb, or 100 to 500 g), it is then pulverized to a nominal 100 to 200 mesh (150 to 75 µm). Two basic types of pulverizers are in common use: the plate or disk pulverizer and the vibratory ring mill.

Plate Pulverizers—Plate pulverizers reduce the particle size of samples through a shearing action as the sample passes between a fixed and a rotating plate. Two basic designs exist: horizontal shafts and vertical shafts. Some are designed only for intermittent use, whereas the more recent versions are extremely rugged and built for high volume work. Controlling the spacing between the plates (and thus the product size) has been a problem, and has required almost constant attention by the operator, but recent models of plate pulverizers have better mechanical or even pneumatic controls that maintain a constant plate separation. Plate pulverizers have a high productivity, they can pulverize a large sample, and are easily cleaned. However, they are dusty and their product is inhomogeneous, requiring thorough blending before assaying. Mikli (1986) does not recommend plate pulverizers for the final pulverizing of nuggety gold ores, as the plate pulverizer does not significantly reduce the particle size of gold nuggets. Plate wear is high, requiring frequent changing and refinishing or replacing of plates.

Vibratory Ring Mills—Two basic versions of vibratory ring mills are made. The first consists of a steel bowl with lid, the bowl containing a cylindrical steel puck plus one or two steel rings that surround the puck. The crushed sample is placed in the open space between the walls of the bowl, the puck, and the rings. The bowl is clamped in a housing which is made to oscillate around a vertical axis by an electric motor carrying an eccentric weight on its shaft. The oscillatory motion causes the puck and rings to revolve in a planetary pattern inside the bowl, thus grinding the sample.

The second version of this mill also consists of a bowl with lid but only a single grinding element, a discus- or "flying saucer"-shaped oblate spheroid of steel with a flat rim. The center of gravity of this steel element is off center so that when the bowl oscillates, the grinding element revolves in a planetary pattern within the bowl. Bowls of this style have a capacity of 1.8 to 11 lb (800 g to 5 kg) of sample, whereas the puck and ring bowls range from 0.1 to 0.9 lb (50 to 400 g) in capacity.

Vibratory ring mills exhibit the following advantages: they require no operator adjustment, produce a relatively homogeneous product that requires no further blending, create little dust, have a low noise level (because of a supplied noise-suppressant cabinet), and have a moderate productivity of some 12 to 20 samples per hour. The productivity depends on the character of the samples, with the lower productivity being achieved on high-clay samples, which require less than 1 min to pulverize, but several minutes' cleanup time between samples. Vibratory ring mills have been described by Mikli (1986) as the only type of pulverizer that actually can reduce the particle size of gold nuggets. However, to reduce the particle size of coarse nuggety gold or to pulverize a 4.5-lb (2-kg) or larger sample thoroughly to — 80 mesh (177 µm) or finer can require from 10 to 30 min and result in excessive bowl wear.

Table 5.4.1. Representative Sample Preparation Procedure

Dry Sample
(Typical wt. 2 to 10 lb, or 1 to 4.5 kg)
Crush
(Typical product 8 to 10 mesh, or 2.4 to 2 mm)
Riffle Split
(Retain 1/2 lb, or 250 g)
Pulverize
(Typical product 100 to 150 mesh, or 150 to 100 µm)

Blenders and Pulp Splitters: Pulps prepared on plate pulverizers require blending. The most common approach (although not the most effective) is to roll the pulp on a rubberized cloth. Taggart (1945, Sec. 19, p. 71) gives instructions for proper rolling: "Rolling is accomplished by drawing the corners of the cloth horizontally toward diagonally opposite corners, causing the sample to roll over and over on itself. If the corner is lifted instead of drawn horizontally, the sample merely slides along the surface of the cloth and no mixing occurs." Plastic sheeting should not be used for blending because of the static charges that build up, causing retention of some particles and difficulty in cleaning. Some question exists as to whether or not rolling actually is very effective in homogenizing a pulp.

A far superior alternative to rolling is the use of a mechanical blender. Large V-shaped blenders have been used to blend bulk samples for use as reference standards, but small sizes suitable for blending assay pulps are not common. Individual sample blenders are slow. A multisample mechanical wheel blender that meets the productivity requirements of a high-volume minerals laboratory has been described by Gilbert (1987).

Mechanical splitters for use on pulps exist, but they are expensive, slow, and require extensive cleaning between samples. A more effective approach is to roll the pulp on a rolling cloth into a "sausage," flatten the sausage to the height of the scoop being used, and then cut several increments from the sausage using a flat-bottomed vertical-sided scoop until the required weight has been withdrawn.

5.4.1.2 Typical Preparation Methods

The procedure given in Table 5.4.1 is typical of many minerals laboratories. It is inexpensive and assumes the sample is relatively homogeneous and the ore particles small.

People experienced with sampling for nuggety gold (or any ore with a potentially large nugget effect) generally collect larger

Table 5.4.2. Typical Sample Preparation Procedure Used on Nuggety Materials

Dry Sample
(Typical wt. 8 to 20 lb, or 3.6 to 9 kg)
Crush
(Typical product 8 to 10 mesh, or 2.4 to 2 mm)
Riffle Split
(Retain 4 to 10 lb, or 1.8 to 4.5 kg)
Plate Pulverize
(Product 40 mesh, 420 µm, or finer)
Riffle Split
(Retain 1 to 2 lb, or 450 to 900 g)
Pulverize in Ring Mill
(Typical product 100 to 150 mesh, or 150 to 100 µm)

samples and prefer a sample preparation procedure similar to that outlined in Table 5.4.2.

5.4.1.3 Selecting a Sample Preparation Procedure

Virtually every mineral deposit has its own eccentricities, and an individual sample preparation procedure must be developed for each, unless the deposit is known to be fine-grained and relatively homogeneous. A "safe" sample preparation procedure is given by Royle (1989, p. 40) based on a method originally developed by Gy (1977). Similarly, Pitard (1987) presents sampling nomographs that enable one graphically to analyze an existing sample preparation process and to develop an optimum protocol. Pitard markets programs for personal computers that describe tests to perform on gold ores of unknown characteristics and enable one to plot sampling nomographs from which an appropriate sampling protocol can be developed. In their Chapter 1, Sampling, Ingamells and Pitard (1986, pp. 1-84) present a good review of the necessity for intelligent sampling, both before and during the sample preparation and analytical stages.

5.4.2 ASSAY METHODS

Two basic classes of assay methods are available: geochemical and quantitative. Geochemical procedures typically are used in prospecting and the early stages of exploration when results of high accuracy and precision are not as necessary, but low levels of detection are required. Quantitative procedures are used during exploration drilling, sampling and analysis for ore reserve estimation, and subsequent stages of mine development and operation. Geochemical methods of analysis in the past have been considered semi-quantitative, but many of these now approach quantitative methods in accuracy and precision, and they offer the advantage of considerably lower levels of detection.

Whether establishing an in-house laboratory or selecting a commercial laboratory, there is no substitute for a chemist with experience in the analysis of earth materials. The wide variety of materials to be analyzed, constituents to be determined, and matrix compositions to be encountered pose a myriad of challenges to the minerals analyst. Many constructive comments on the art of geochemical analysis are given by Ingamells and Pitard (1986).

5.4.2.1 Wet Chemistry

Wet chemical methods of analysis have been and probably will continue to be the mainstay of the minerals laboratory, in contrast to nondestructive instrumental methods. Wet chemical methods have undergone significant changes with time, perhaps the most dramatic following the evolution of microelectronics and computers that allowed the development of instrumental methods of measurement.

Classical Volumetric and Gravimetric Methods: Volumetric and gravimetric methods of analysis now are used principally for the determination of the higher concentrations of various elements in ores and concentrates. Typical examples are the determination of calcium in limestone; iron in iron ores; ferrous iron in most mineral materials; copper, lead, zinc, etc., in ores and concentrates; and uranium in ores and yellow cake. Most classical methods of analysis are well-established. Many are given in references such as Furman (1962), Young (1971), and Dolezal et al. (1968).

Colorimetric Analysis: Colorimetric methods of analysis were used extensively in the mineral industry in the mid-1900s, especially in trace analysis for geochemical exploration purposes. More recently, colorimetric methods of analysis have been supplanted by instrumental methods such as atomic absorption and inductively coupled plasma spectrometry.

Colorimetric methods of analysis are based on the development of a colored compound in solution by the reaction of the element in question with a specific chemical reagent. One of the principal colorimetric methods still in common use is the thiocyanate assay procedure for molybdenum in ores and concentrates (Ingamells and Pitard, 1986, p. 523). Simple colorimetric methods of analysis useful in geochemical exploration in remote areas are ammonium citrate-soluble heavy metals (Bloom, 1955) and cold acid-extractable copper (Canney and Hawkins, 1958). Colorimetric analytical methods for tungsten and molybdenum produce results comparable with atomic absorption procedures, but they are not as rapid.

Instrumental Analysis: Instrumental methods of analysis have dominated minerals laboratories since the development of the atomic absorption spectrophotometer in Australia in the mid-1950s and the inductively coupled plasma emission spectrometer in the 1970s.

The atomic absorption spectrophotometer (AA) enables the analyst to measure the concentration of some cations down to a fraction of a part per million and with specialized attachments down to a part per billion. The AA instrument generally is specific for the element selected, although there are various interferences and operational nuances that the analyst must be aware of and either avoid or compensate for.

Principles of AA operation are given by Slavin (1968). Many methods of analysis are given in publications of the US Geological Survey and the Geological Survey of Canada as well as the *Atomic Absorption Newsletter* (now titled *Atomic Spectroscopy)* published by the Perkin Elmer Corp.

Inductively coupled plasma spectrometers (ICPs) were developed as modifications of existing direct-reading emission spectrometers or atomic absorption spectrophotometers. The direct readers became ICPs capable of measuring 30 or more elements simultaneously, whereas the AAs became ICPs that measure a number of elements sequentially, commonly utilizing more than one wavelength per element. Thus the simultaneous instrument is faster for routine work on similar materials, whereas the sequential instrument is more versatile. Most ICP instruments utilize the high energy of an argon plasma to excite atoms of various elements in a sample solution that is aspirated into the plasma. The excited atoms emit light that is passed through a spectrometer, wherein the energy of light emitted at various wavelengths is measured electronically and converted into the concentration of each element in the sample solution.

ICPs are supplanting AAs in many high-volume mineral laboratories because they allow the determination of a large number of elements in a short period of time, whereas the AA determines one or at best a few elements simultaneously. The accuracy and precision of ICP instruments and AAs are comparable, and the capital costs, considering the productivity, probably favor the ICP. The ICP can achieve detection levels as low or perhaps slightly lower than the AA, and in addition the ICP instruments have a linear response over some five to seven orders of magnitude of concentration of the element in question, a much broader operating range than the AA.

ICPs are used to determine both trace elements and major elements in most earth materials. A wide variety of digestion and separation procedures are used to prepare the sample for ICP measurement, many of them similar to AA digestion procedures. A large literature exists.

Several other instruments are used for specific determinations in minerals laboratories. Specific ion electrodes are used to measure the concentration of cyanide in dilute solutions as well as the content of fluorine, chlorine, and several other constituents in earth materials, and the fluorometer is the standard instrument for determining trace amounts of uranium.

5.4.2.2 Fire Assay

A fire assay is a chemical fusion method for separating, concentrating, and measuring the content of gold and silver in exploration samples, ores, and concentrates. The pulverized sample is weighed, mixed with a lead oxide-alkali carbonate flux and a small amount of reducing agent such as flour, and fused in a fire-clay crucible. The reduced lead collects the precious metals as it settles down through the melt. The molten charge is then poured into a mold to cool. The lead sinks to the bottom of the mold and is broken from the glassy slag when cool. The precious metals are separated from the lead by cupellation. The lead button containing the precious metals is placed in a cupel of bone ash or magnesia which is heated in the furnace under oxidizing conditions. The cupel acts as a semi-permeable membrane allowing the lead oxide formed from the button to be absorbed into the cupel, leaving the precious metals in a tiny bead on the surface of the cupel. The gold and silver are separated chemically and quantified gravimetrically or by instrumental analytical techniques.

Fire assay is the standard method of the industry. Details, theory, and variations of the method are described in references such as Bugbee (1940), Haffty et al. (1977), and Heady and Broadhead (1976).

5.4.2.3 Nondestructive Analysis

X-Ray: The X-ray diffractometer is used in some well-equipped minerals laboratories to determine the mineral species present in a sample by recording their characteristic crystallographic patterns. The instruments are not extensively used in mine and project assay work.

X-ray fluorescence spectrometry (XRF) is used for the rapid analysis of silicate rocks and the routine determination of the concentration of selected elements in exploration samples, ores, concentrates, and mill products. XRF analysis is most satisfactory when applied to a continuing series of samples of similar matrix. The method is subject to matrix effects and interelement interferences, most of which can be corrected for in the comprehensive computer software that accompanies all modern instruments. XRF instruments require for calibration previously analyzed standards similar in bulk composition to the unknowns. The instruments are capable of excellent precision, but without proper calibration and intelligent operation, they can be rather inaccurate.

Radiometric Analysis: Radiometric analysis is used to measure the concentration of uranium in its ores by simultaneously counting the beta and gamma radiation emitted by the sample.

Multispectral radiometric analysis provides a determination of the concentrations of the radioactive elements uranium, potassium, and thorium, all of which will provide a positive response to a simple gamma ray detector such as a Geiger-Mueller counter or a scintillometer.

Neutron Activation Analysis: Neutron activation analysis (NAA) is available principally through commercial laboratories with access to nuclear reactors. Most of the laboratories offering commercial NAA analyses of earth materials at reasonable cost are Canadian-based. NAA is indicated when (1) a conventional technique does not have acceptable limits of detection for the element of interest, (2) the sample is unique and cannot be consumed in analysis, (3) only a small quantity of sample material is available, or (4) conventional methods of analysis are unacceptable because of interferences or inherent instrumental errors. The sample typically is pulverized, loaded into a plastic capsule (rabbit), and introduced to a reactor in which it is bombarded by neutrons. After recovery of the capsule from the reactor, the radioactivity induced in the sample is measured and analyzed, thus giving a measure of the concentration of each element present in the sample. NAA currently has much application in the analysis of vegetation or mull for trace amounts of gold, and in the analysis of the platinum-group elements and the rare earth elements.

5.4.3 COAL PREPARATION AND ANALYSIS

The procedures used in the preparation of coal and coke samples for analysis are similar to those for rock samples. The ASTM standard method of preparing coal samples is No. D 2013-86, published in the *Annual Book of ASTM Standards*, Pt. 05.5 (Anon., 1989). The principal difference in coal sample preparation is the use of lower temperatures and, indeed, even air drying to preclude oxidation as much as possible. Crushing and pulverizing is accomplished with much the same equipment as used on rocks. However, samples are pulverized only to —60 mesh (250 µm), and only 0.1 lb (50 g) is retained for analysis.

A variety of tests are available for coal samples. Some of these include sieve analyses, washability, Hardgrove grindability, moisture, sulfur, ash content, carbon and hydrogen content, and calorific value. Two of the most common determinations are proximate and ultimate analyses. A proximate analysis, as described in ASTM Standard Method D 3172-73, covers the determination of moisture, volatile matter, and ash, as well as the calculation of fixed carbon. According to ASTM (Anon., 1989, Method D 3172-73, p. 1), the results of a proximate analysis are used to establish the rank of coals, to show the ratio of combustible to incombustible constituents, to evaluate the coal for beneficiation and other purposes, and to provide a basis for buying and selling.

An ultimate analysis, according to ASTM Standard Method D 3176-84, p. 1 (Anon., 1989), when tabulated along with a proximate analysis, provides the data for a cursory valuation of coal for use as a fuel and coke for metallurgical purposes. An ultimate analysis includes the determination of carbon and hydrogen as well as sulfur, nitrogen, ash, and the calculation of oxygen by difference. Typically, moisture is reported as well. The procedures for an ultimate analysis are also specified by ASTM (Anon., 1989).

In addition to the analytical procedures described previously, data on the major, minor, and trace elements in coal and coke ash often are of use in the evaluation of coal quality. Accordingly, methods for these determinations are presented in ASTM Standard Test Method D 3682-87, "Major and Minor Elements in Coal and Coke Ash by Atomic Absorption," ASTM Standard Test Method D 4326-84, "Major and Minor Elements in Coal and Coke Ash by X-Ray Fluorescence," and ASTM Standard Test Method D 3683-78, "Trace Elements in Coal and Coke Ash by Atomic Absorption." The atomic absorption measurement of the major and minor elements is accomplished after a lithium tetraborate fusion of the sample followed by hydrochloric acid dissolution of the fusion product, whereas the trace elements are determined following a mineral acid dissolution process.

5.4.4 QUALITY CONTROL

Most laboratories have an adequate quality control program covering their analytical work. Some commercial laboratories actually provide results of check assays with their reports of analysis. It would appear, however, that few laboratories include sample preparation in their quality control system; yet, as Royle (1989) has commented, "Wait until you see the numbers that show all the horrible things that happen in sample preparation of gold samples!"

During sample preparation, maximum particle size readily can be monitored by screening at various stages as the material is crushed and pulverized. Other parameters are more easily checked by actually analyzing the material.

Analysis of several pulps prepared from different splits of the crushed bulk sample will provide data on reproducibility of splitting. Analogously, the homogeneity of a pulp can be checked by taking a number of replicate portions for analysis from the same pulp and calculating the precision of replication. A simple procedure to evaluate the effectiveness of sampling drill cuttings is presented by Schwarz (1989).

Analytical precision and accuracy are best established and maintained through the use of reference standard samples and analytical control samples (Hill, 1975). Certified standard samples of mineral materials are available from some governmental agencies and professional or trade groups in several countries (Abbey, 1983; Flanagan, 1986). Such standard materials are expensive and limited in quantity. The elements present and concentration ranges in certified standards may not adequately cover the character of materials that the laboratory is engaged with; nevertheless, such standard materials may help to provide initial calibration. Matrix-matched control samples to provide batch-to-batch and day-to-day calibration and quality control in the laboratory can be prepared and blended from the reject samples from the project. The analytical development of these in-house control samples can be calibrated to the certified standards. Ideally, every set of analyses produced by the laboratory should have one or more control samples and duplicates included for quality control and assurance. Some governmental agencies that contract out a large quantity of sample preparation and analytical work arrange for 3 out of each 20 samples to be controls or replicates. Those more mathematically inclined can find much of value regarding analytical quality control in the laboratory in the *Quality Assurance Handbook* compiled by the Center for Analytical Chemistry of the National Bureau of Standards (Anon., 1987). ASTM gives guidelines for evaluating laboratories performing analysis of coal and coke (Anon., 1989, p. 357).

When the results of analysis of the controls do not agree with the established values within acceptable limits, the entire group of assays should be rejected, the problem identified and resolved, and the group of samples rerun. The timely realization and resolving of sample preparation and analytical problems is the essence of quality control.

Chapter 5.5
GEOLOGIC INTERPRETATION, MODELING, AND REPRESENTATION

A. J. ERICKSON JR

Chapter 5.2 provides a discussion of the importance of clear, complete, accurate, detailed, systematic collection of varied geologic data and suggests methodologies to accomplish this goal. Narrative guidelines and narrative-graphical formats are provided to assure the desired standardization in the acquisition of geologic information. The area of activity in the chapter is referred to as the data collection step in the three-step geologic information processing effort required in resource evaluation.

This chapter builds on Chapter 5.2 in discussing the purpose and recommending methodology in carrying out the remaining two steps, data analysis and interpretation. All three steps are required to discharge the critical responsibility of resource characterization for quantification, evaluation, mine planning, and extraction. *Resource characterization* is defined as the determination of the shape, size, quality, quantity, and variability of the geologic entity and, as importantly, determining the limits of variable geologic features. Proper characterization has both operational and exploration implications as it provides the information for synthesis of commonly subtle features into an accurate, predictive description of the resource environment. This description can then be used either in support of mining operations or in the ongoing search for additional reserves.

5.5.1 GEOLOGIC MODELING: GENERAL

Current terminology refers to resource characterization as the geologic model, or perhaps the three-dimensional geologic model, whereas earlier studies used the nearly synonymous term, zoning patterns. This model consists of a compilation of all geologic data, observations, and studies available at the time, assembled in such a way as to display and explain the observations from both an empirical and genetic point of view. The model may be extremely simple or highly complex depending on the nature of the resource, the data available, or the degree of sophistication in studies of the resource. The empirical model represents the compilation and integration of numerous types of chemical, mineralogical, structural, and not uncommonly numerically quantifiable zoning studies, whereas the conceptual or genetic model attempts to explain the distribution and origin of these features in a useful and meaningful way. The geologic model is commonly incomplete (Barton, 1986, p. iii), and as discussed by Peters (1987, pp. 214-217), the model will probably change or be revised as additional geologic data are acquired.

Erickson (1982), Eckstrand (1984), Cox and Singer (1986), and particularly Roberts and Sheahan (1988), together with reviews of these volumes by Barton (1985, p. 1758) and Skinner (1989, p. 725), present up-to-date synthesis of geologic data from a broad spectrum of mineral deposits into a number of both empirical and genetic models. Work by Dapples and Hopkins (1969), Horne and Fern (1978), Donaldson et al. (1979), Kaiser et al. (1980), Ayers and Kaiser (1984), Rahmani and Flores (1984), Walker (1984), Ward (1984), Reineck and Singh (1986), and Ayers (1986) provide excellent descriptions of coal deposits and associated geologic environments and processes associated with this resource. Models described in all these references provide a state-of-the-art picture of the products and of geologic processes and events and are extremely useful in guiding broad-scale exploration activity or more tightly controlled resource evaluation and operational support work. They are excellent and useful volumes as they are compilations from and syntheses of numerous, varied, studies of long-established mining districts or regions. Typically, these are areas where extensive exploration, development, and operational geologic programs have provided large factual geologic databases and extensive material for laboratory studies. Although each district or region may exhibit specific variations, the volumes summarize observations and studies from many deposits of a similar nature and hence provide a guide to the commonly observed typical features to be expected in a particular deposit type—the geologic model. They are extremely important and useful guides for interpreting geologic observations while work is being conducted on projects, when new district specific models are being constructed, and as aids during ongoing exploration or development programs.

Models should attempt to explain all observable facts. Geologic data should not be ignored or discarded if they do not fit the perceived model. The lack of agreement between facts and theory may indicate incorrect data, incorrect models, or insufficient data or all three, and thus point the way for further investigation.

The fundamental problem associated with resource characterization for evaluation and estimation is taking a very limited amount of geologic data, correctly analyzing and interpreting the data, extending these interpretations into unknown areas, and then making summary quality, quantity, and limit statements about the area. In simplest terms, where is the resource (ore), what are its limits (shape), what is the quality (grade), and what is the nature of the associated environment. Unfortunately, this implies sharp boundaries, which are seen in only a few specific types of deposits. More often, we are dealing with an irregular, poorly constrained distribution of values of a commodity as discussed and illustrated by Gentry and O'Neil (1984, pp. 59-61). Their illustration, here reproduced with minor modification as Fig. 5.5.1, is a lucid, simple illustration that clearly explains the resource estimation, external and internal dilution, and limit or edge problems that plague many operations.

Sound, careful geologic data analysis during model construction, frequently with much checking and rechecking as pointed out by Worthington and Brown (1984, p. 209), goes a long way towards solving the afore-described fundamental geologic problems in resource characterization. As discussed by Ranta et al. (1984, pp. 1-2), the geologic data and interpretation (the model), are the foundation of the evaluation process and are essential for the resource estimation and extraction. As Call (1979, p. 31) indicates in his discussion of statistical data handling in development drilling programs, "the validity of any analytical model must ultimately be determined by geologic interpretation." Sound geologic judgment, discipline, and hard work are needed to deduce the detailed geologic setting from drillholes, mapping, and sampling programs, which lead to the construction and understanding of the geologic model and its variations. The model is based on numerous, varied geologic studies, and assuming that all other factors (sampling, hole or data locations, analysis, etc.) are correct, ensures a reliable, best possible resource estimate, together with an understanding of

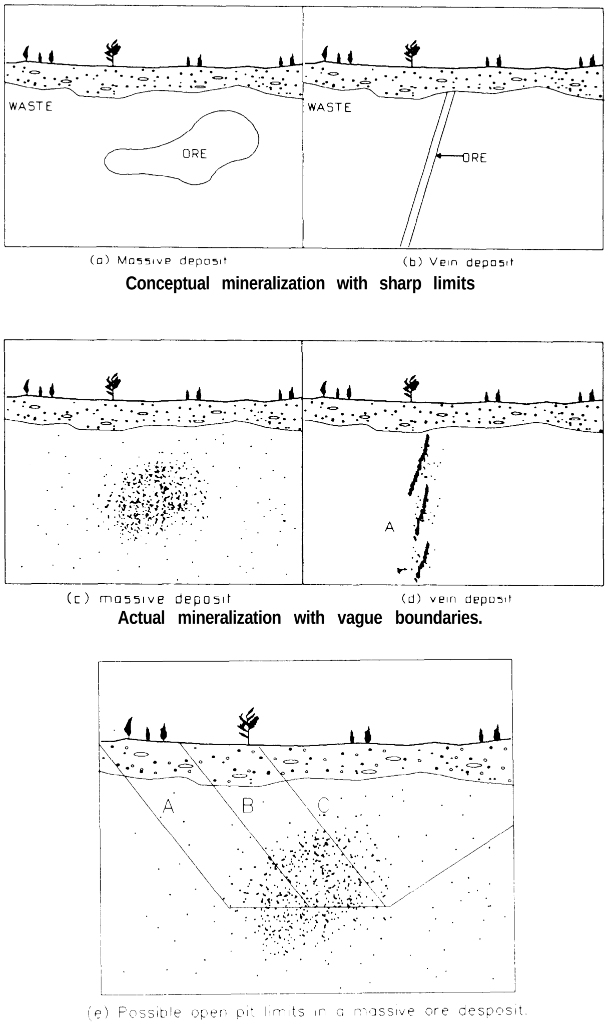

Fig. 5.5.1. Ore body representation. (a,b) Common conceptualization of ore bodies with clear, well-defined boundaries. (c,d) Actual typical distribution of a valuable commodity within an ore body with vague irregular boundaries. (e) Illustrates how an open pit mine may extract waste and the valuable commodity. Modified after Gentry and O'Neil, 1984.

ground conditions. "Without correct interpretation, drillhole data" (or any other data) can be misleading (Ranta et al., 1984, p. 2) and manual, computer-assisted, or the more sophisticated geostatistical estimates may be incorrect. The simple line on a map or cross section depicting the limit of a geologic feature to be estimated is an extremely powerful decision-influencing item, and only proper geologic interpretation assures its correctness. Sound interpretation is the only way a geologist can fulfill the challenge issued by Barnes (1980, p. 62) to "accept the responsibility of recognizing and recording boundaries" that characterize the deposit or distributions within the deposit.

In summary, "Good geology based on well-understood data is still the only recipe for good reservoir/site/deposit characterization" (Journel, 1988, p. ii). The geologist must thoroughly understand the total geologic environment and distributions to reliably estimate resources, delineate areas for mine planning, and support day-to-day operations.

5.5.2 GEOLOGIC MODELING: METHODOLOGY

With the foregoing serving as a somewhat detailed discussion of geologic characterization—the interpretative model—and the importance of developing a good model—for accurate resource evaluation—the remaining provides guidelines on how best to construct a geologic model of a resource. Emphasis is on an empirical model, one that accurately records the factual geologic observations.

The geologist normally starts with surface outcrop data and drillhole logs that, as reviewed in Chapter 5.2, are of high quality and have been collected using a rigorous standardized methodology providing unbiased factual data for compilation and analysis. The geologist builds a geologic outcrop map from surface work that contains all geologic observations. This map must clearly differentiate factual outcrop data from geologic interpretation and inference between outcrops. A common graphic methodology uses bold solid lines and patterns or dark colors for outcrop and dashed or dotted lines with similar colors, but applied in a pale or lighter fashion, for interpretations. As indicated by Herness (1977, p. 529), "there must be no screening of data to eliminate 'unimportant' facts" . . . as "often the importance of insignificant data is realized 20 or 50 years later" when mine workings or core unfortunately may not be available for remapping.

As an aside, with respect to core availability, the deliberate disposal of core from known ore deposits or established mining districts is unconscionable. Stored core is simply one of a number of the geologist's files that will be constantly reviewed as new ideas or data become available. "Core is our record; we must always go back to it" (Klohn, 1989). Numerous ore discoveries have been made because core was available for reexamination, resampling, and reinterpretation. A recent talk and abstract (Braun, 1991, p. 146, and personal communication) clearly demonstrate the importance of the availability of old drill core for relogging and resampling in the discovery of a new gold ore body. Future discoveries will be made because old core was available for examination in the light of new data, new ideas, other commodities, or, unfortunately, simply because a better or more conscientious geologist was involved. Geology is a continually evolving discipline, and new knowledge and understanding are accumulating at an astonishing rate. Discarding core because it has been logged is the equivalent of destroying survey or production records or a computer database after a set of maps or financial algorithms have been completed. It should not be done!

Gustafson (1989, pp. 987-993) in an important applied geology lecture and paper, clearly reviews the importance of good mapping to both exploration and operational geology and laments that in the modern era of specialized theoretical studies "perhaps . . . we no longer know how" to map.

After, or in conjunction with, the development of a surface geologic map, it is essential that a detailed set of geologic cross sections (and subsequently plan maps) be constructed, preferably at right angles to each other. This is easier if the critical aspect of a resource can be satisfactorily approximated by a set of N-S and E-W sections tied to a coordinate system. Other orientations are possible, although this can introduce measuring and posting problems in relationship to grid coordinates. Coordinates may also be rotated to provide local grids, but this practice may cause serious survey correction problems and difficulties in tying locations to the US Land System or various state plane coordinates. A reference line to aid in registration and data posting should be drawn on sets of sections, particularly those that do not parallel the coordinate grid system. All data from surface mapping and careful systematic core logging should be posted on appropriate sections and, as indicated by Call (1979, p. 31), "plotted, without interpretation on reproducible sheets. From these, copies can be made for use in interpretation. This process will maintain the distinction between observed facts and interpreted geology." These sections can be constructed manually as the project or drilling proceeds. If an appropriate computer-assisted package is available, data can be entered into an expandable database for rapid factual data posting to provide base maps for interpretation.

As new data are acquired, they are posted on the factual sheets, prints are produced, and new revised interpretations are developed. Additionally, completed interpretations can be transferred to a second set of reproducible bases (copies of the factual data) so multiple interpretative sets of maps can be reproduced for varied users. Drillhole traces and associated data should be plotted on the sections at a scale sufficient to allow for posting of multiple variables along the trace of the hole. Parameters normally of importance are lithology, structure, alteration (if present), grade (as a pattern, a color bar, histograms, or numerical values), and perhaps total sulfide or sulfur content. The particular parameters posted depends upon the resource being evaluated. This posting of several parameters allows for the determination of critical relationships that normally are of use in guiding interpretation and projections. An extremely risky interpretation is the simple correlation of assays (grade) from hole to hole with no consideration of associated geologic features. The process, which should be avoided, commonly leads to incorrect interpretation, overestimation of resources, and incorrect, usually overly optimistic, evaluation.

Clear cross-sectional construction allows one to determine hole-to-hole relationships and continuity of numerous key geologic features such as lithology, alteration, mineralogy, grade, structure, or perhaps features that may influence either mining, such as RQD (rock quality designation), or metallurgical treatment, such as hardness, of the resource. The construction of two sets, commonly at right angles, allows for both determination of hole-to-hole relationships in two directions, and hence section-to-section relationships in three dimensions. The development of a third set of illustrations, plan or level maps (sometimes referred to as slice maps), from the two sets of cross sections, and drillhole pierce points in the planes of the level maps is commonly the final step. This allows one to conform the sections and plans so all common points have similar x, y, and z coordinates in the now completed three-dimensional resource characterization. As indicated, multiple sets showing the important relationships of variables—the geologic model—is the product. The construction of this set of illustrations allows one to develop the fundamental geologic understanding of the resource needed for mine planning and financial evaluation. In the case of coal or uranium, the sets of plans and sections are commonly supplemented or replaced by isopach, isograde, and structure contour maps of varied features of importance. Of particular importance in this understanding is the determination of ore/resource controls such as lithology, primary structural features, secondary structures, structural intersections, or combinations of features that are directly responsible for the specific localization of the resource. Sufficient understanding, particularly of limiting features, should be developed in the process to allow the input of proper geologic controls in either conventional or computer-assisted resources estimation methodologies, such as block modeling or the gridded seam technique.

Fig. 5.5.2, modified from Herness (1951, p. 1008), illustrates the relationships of an orthogonal set of plan maps and cross sections, including the smaller field note-sheet subdivisions, used to collect and compile data and support interpretations in the development of a geologic model. This article provides an ex-

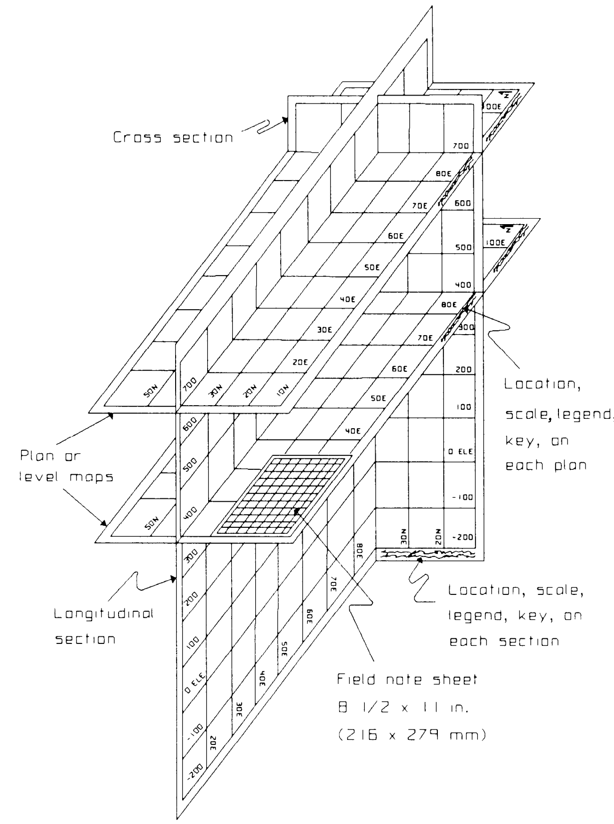

Fig. 5.5.2. Three-dimensional plan, section, and field note sheet relationship. Coordinates and elevations annotated. Scale and explanation omitted. Modified after Herness, 1951.

tremely detailed discussion, illustrations, and recommendations (some dated and others still current) on the essentials of setting up a unified geologic data recording and representation system. Figs. 5.5.3 through 5.5.6 depict the development of factual data and interpretative plans and sections needed to build the geologic model characterizing a particular resource. Combination of features such as mineralization and lithology, not shown here, is common. These types of illustrations ultimately form the basis for models illustrated in Figs. 5.5.7a and 5.5.7b. These latter two illustrations, modified after Roberts and Sheahan (1988, p. 147), illustrate an idealized volcanogenic massive sulfide model characteristics developed from studies of numerous deposits. Fig. 5.5.7b from the same reference illustrates various genetic models that account for the features and suggests processes responsible for formation of the varied deposit types of this class of deposits.

5.5.3 GEOLOGIC MODELING: PURPOSE

The geologic model is constructed to provide a clear picture of the three-dimensional geologic relationship of numerous features that limit varied distribution in the geologic resource. The plans and sections used to develop the model form the total basis for resource estimation in conventional reserve calculation schemes. They provide the input for limiting controls, generally as digitized polygons, in computer-assisted methodologies and are the primary standard of comparison between conventional

(a) Alteration interpretation at the elevation of the plan map developed from factual data in the drillholes and interpreted contacts transferred from cross section 400E in Fig. 5.5.5b. (b) Mineralization and ore body interpretation developed from data in Fig. 5.5.5a in a similar manner to lithologic and alteration interpretations shown in Figs. 5.5.5b and 5.5.6a.

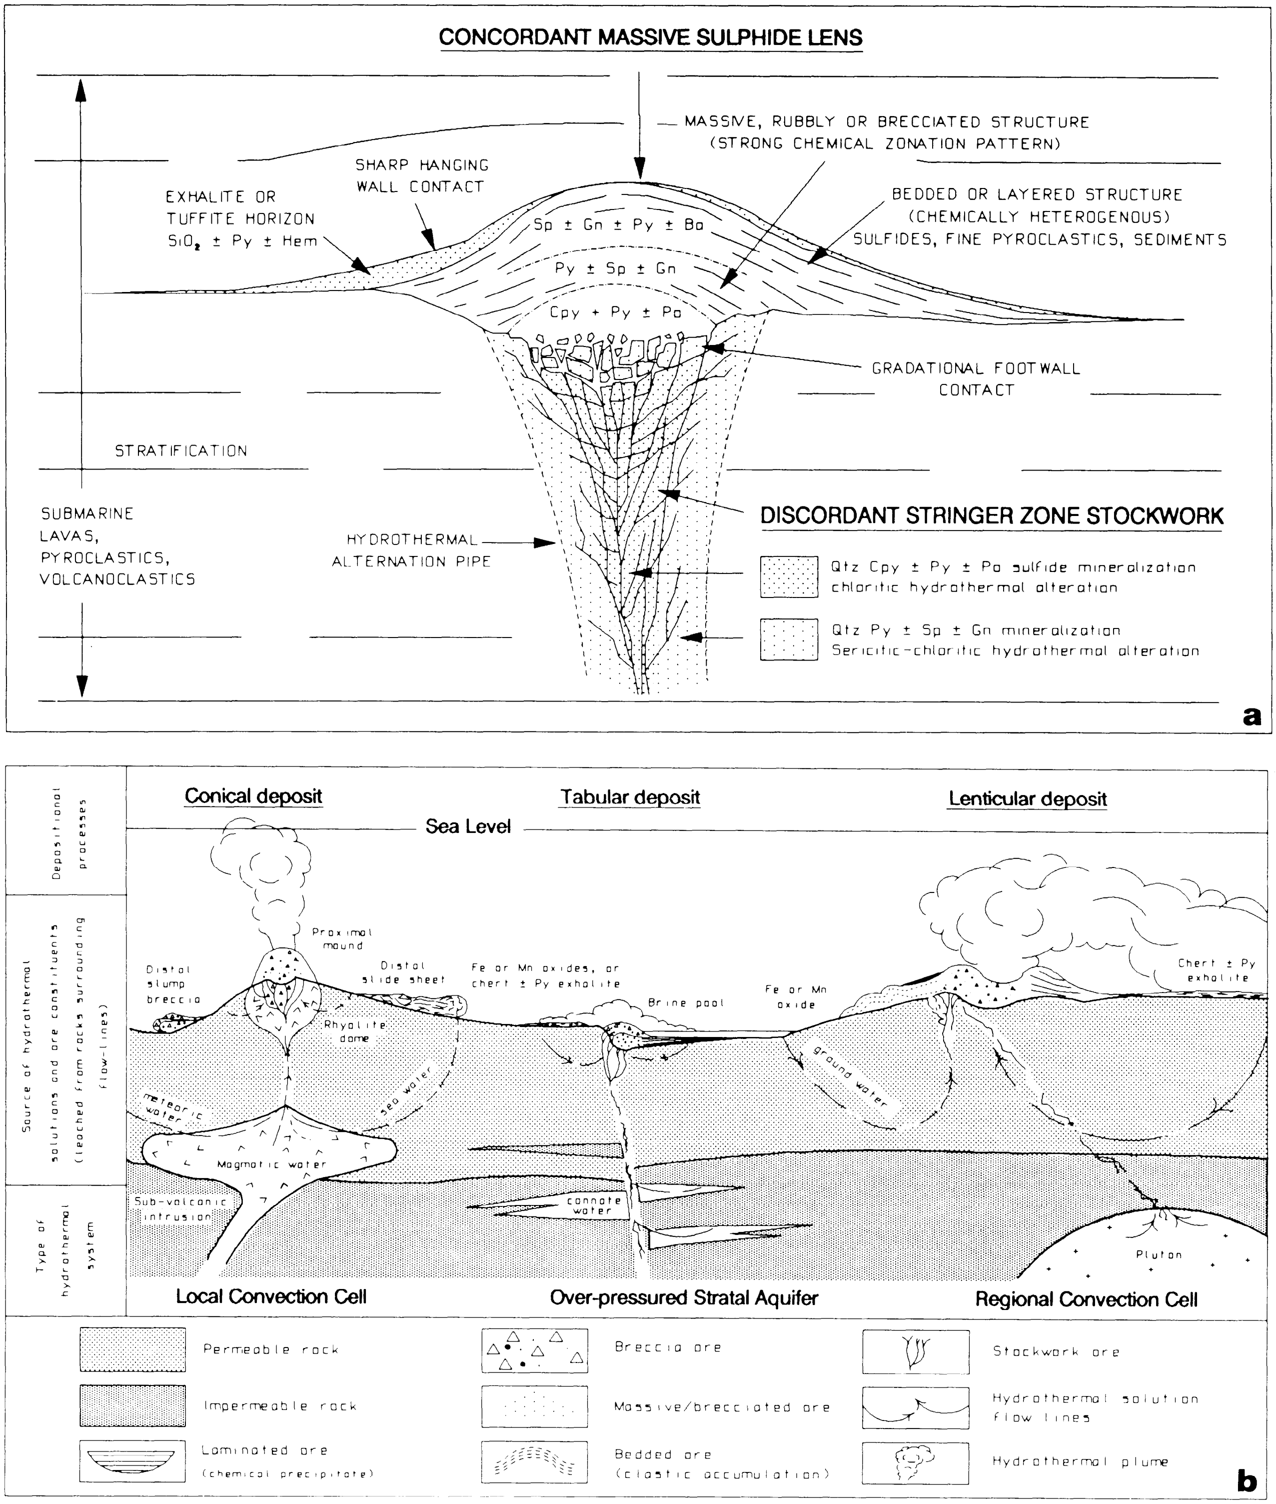

Fig. 5.5.7. Geologic models. (a) Empirical model of a volcanogenic massive sulfide (VMS) deposit showing mineral and metal distributions and features to be expected in the deposits. (b) Genetic model showing the varied geologic environments where VMS deposits are formed. Models of these types are extremely useful in interpreting observation, predicting varied geologic changes to be anticipated, and pointing the way to additional resources. Modified after Roberts and Sheahan, 1988. Not to scale.

and computer-generated resource estimates. The model provides the limits needed to prevent algorithms from estimating resources in unmineralized areas. A well-constructed model assures that the algorithms are being used on correlatable units or features. Not uncommonly, the varied relationships shown on the numerous plans and sections are combined into a few illustrative displays, cartoons, which depict the model and explain the observed geologic relationships as illustrated in Figs. 5.5.7a and Figs. 5.5.7b.

It is becoming increasingly apparent as more sophisticated computer-modeling techniques are developed that, given that correct analytical data and posting are available, the fundamental control of sound geologic interpretation is the most important factor in resource evaluation. Superior models require superior data collection and interpretative work to provide superior resource calculations.

Considering the risk associated with the heavy financial commitments in the resource industries, unquestionably, in the evaluation of all but the smallest resource, the best way to handle the massive amounts of data and to test sensitivities as parameters are varied is though computer modeling of the resource. These models, whether block or gridded seam or others, take a considerable amount of manpower to construct and control and require sound geologic judgment and experience. Once constructed, the parameters in the computer model can be rapidly varied and analyzed to determine sensitivities. It is imperative to have a correct resource determination in support of evaluation and risk assessment to assure the profitable outcome of the heavy financial commitment required for a new mine. The only way to effectively discharge the important geologic responsibility is through construction of an accurate geologic model.

5.5.4 GEOLOGIC DATA: REPRESENTATION

Geologic features of mineral resources are highly variable. A nearly constant change in three-dimensional shapes and relationships is the rule rather than the exception. Many parameters of varying significance must be considered in order to understand the resource and its normally complex geometrical shapes. It is essential that presentations or illustrations used in describing these complex relationships present sufficient, but not excessive, detail to provide accurate, clear, qualitative, and where possible quantitative, or at least semi-quantitative, representations of the important features. The illustrations must be systematic, consistent, preferably simple, and standardized, as professionals of varied disciplines, frequently nontechnical, will commonly be using them. Relationships depicted or documented by the illustration should be instantly obvious with a minimal chance for confusion or misinterpretation. The user must be able to quickly grasp the significance of relationships. Additionally, illustrations should be easy to update to assure that new data can be rapidly assimilated and available to support the decision-making process.

The basic illustrations commonly used to depict important geologic relationships should consist of an integrated set of plan maps and sections showing distributions of lithologies, alteration, and the resource under study. Structural features are commonly shown on all sets. Combinations of various parameters such as mineralization with lithology or perhaps isogrades reflecting sulfur distribution within minable areas of a specific coal seam are common. Almost any feature (parameter) showing variability can be mapped and, if of importance to resource characterization, can be illustrated in such a way as to depict the importance of the relationship. Sets of illustrations should have common coordinates and points of origins so they include identical areas. Sheet size should be standardized and neither too small to prevent adequate coverage of important areas nor so large as to be unwieldy if frequently used. Sheets 30 × 42 in. (760 × 1070 mm), a standard size readily available, are a good choice for most geologic work. Sheets should have coordinate grid lines with full numerical values of the coordinates identified, not coordinates with some digits removed for ease in posting, as this leads to questions concerning the actual location of data under discussion. (For example, 2,550,000 N should be stated as such and not abridged to 50,000 N). Similarly, elevations on cross sections should not be abridged or modified to reflect anything other than true elevation as related to sea level. Schemes which add or subtract constants to elevations tend to confuse and should be avoided.

Legends or explanations should be complete and on each illustration. The legend should include all symbology, have the scale shown as both a bar and ratio or representative fraction, and include location name, date, topic and/or subtopic, and a north arrow. Magnetic declination on plan maps may or may not be needed.

As indicated previously and shown in Figs. 5.5.3 through 5.5.6, illustrations should be clear and reproducible with sufficient detail included to provide appropriate understanding and with fact clearly discernible from inference. A base reproducible set showing all factual data should be maintained in order to provide easy copies for interpretative work. The interpretative sets, constructed from the base set, are the result of the data analysis process and form the basis for geologic predictions and projections into unsampled areas. Key simplified sets such as mineralization outlines, perhaps isograded, or coal thickness with sulfur content contours will typically be made available to operating personnel for mine planning and operational support. Fig. 5.5.8 is a highly detailed legend, or explanation, commonly found on cross sections illustrating the type of data required in the typical geologic evaluation of a porphyry copper deposit.

Scales of illustration vary as follows: extremely detailed and seldom used 1 in. = 10 ft (1:120) or the more common 1 in. = 20 ft (1:240) or 1 in. = 50 ft (1:600) for initial data compilation in a base metal deposit; the 1 in. = 100 ft (1:1200) or 1 in. = 200 ft (1:2400) for interpretative compilations and mine planning; the 1 in. = 400 ft (1:4800), 1 in. = 500 ft (1:6000), 1 in. = 1000 ft (1:12,000), 1 in. =2000 ft (1:24,000), or an inch equals a mile scale used for summary presentations or district or regional overviews.

Numerous other types of maps and illustrations can be constructed on an as-needed basis to depict or clarify important geologic relationships. Most useful among these are the following: structure contours or isopachs of geologic units or parameters, isogrades of metal values or perhaps dilutents as sulfur or ash content of coals, and ratio maps or combinations of parameters such as grade and thickness, common in uranium work, or total sulfide content. Any geologic parameter that can be quantified can be mapped or illustrated and may provide extremely useful data on trends, distributions, or variability; hence it contributes to interpretation and a better understanding of the geologic conditions associated with a resource. The key points on the use of any of these are accuracy, clarity, simplicity, and reproducibility.

Herness (1977, pp. 529-531) discusses subsurface geologic representation and provides a 19-point list of essentials for effective field and office representation of geologic data that is here abridged and summarized into 10 points as follows:

1. Techniques should be easy to master and rapid to use.
2. All megascopically recognizable features should be capable of being represented.
3. Representation legends should be logical, systematic, chromatic, or geometric sequences, clearly depicting trends.

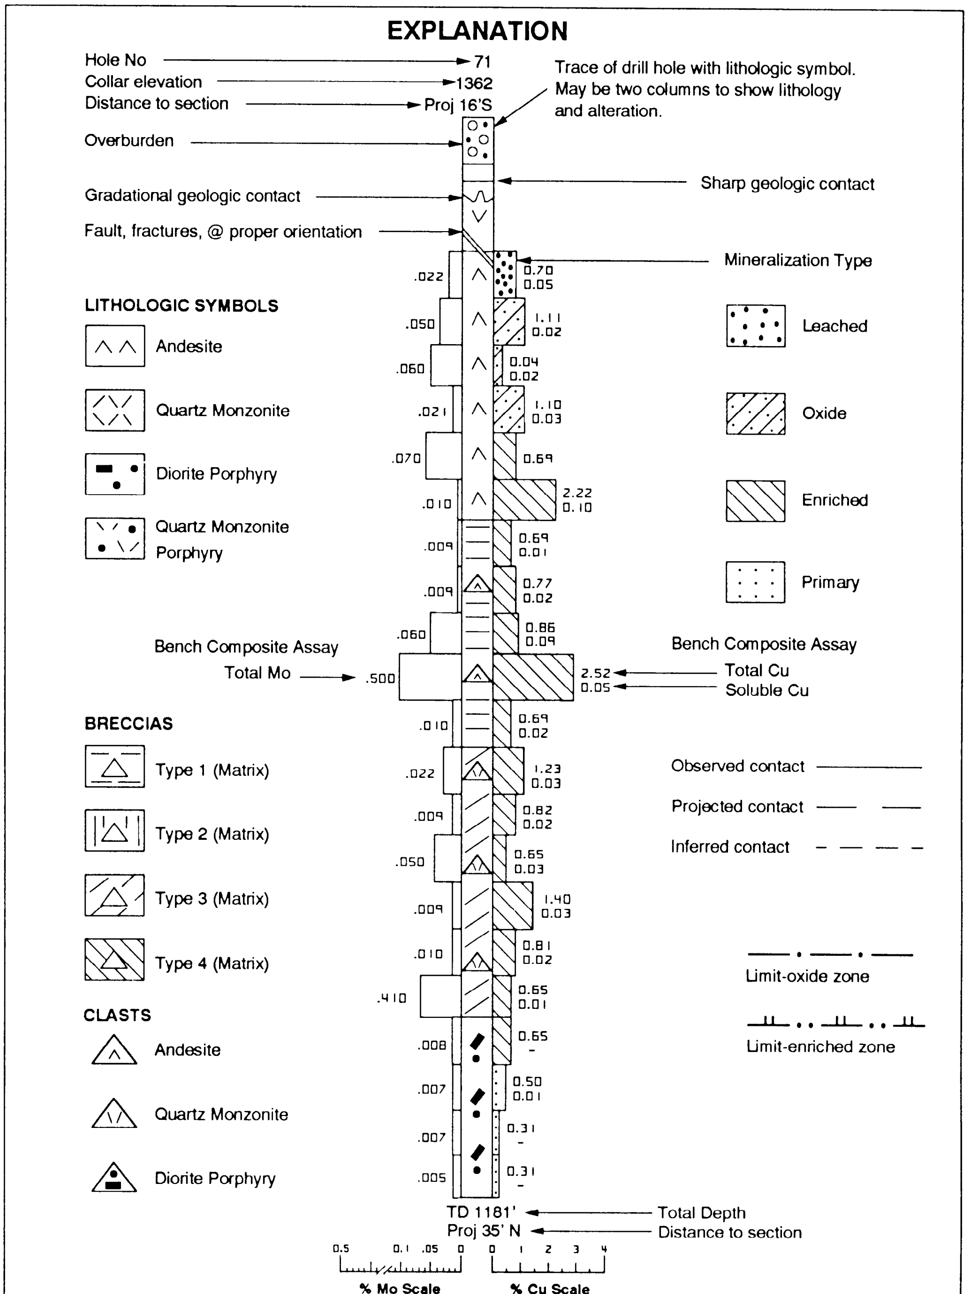

Fig. 5.5.8. Typical legend, or explanation, showing the varied data posted adjacent to each drillhole on cross sections constructed during evaluation of a porphyry copper deposit with associated breccia pipes. Modified and company name removed to ensure confidentiality.

4. Systems should be planned to prevent duplication, unnecessary maps, and map overlap.

5. Ongoing work maps should be easy to revise.

6. Sections and plan maps should be integrated to allow for efficient utilization and prevent data loss in files.

7. Note sheets should be uniform in size, kept in a logical available file, and never discarded.

8. Office maps should not be excessively large to assure ease of handling and prevent damage. (However, a good set of large, highly generalized, attractive display maps should be available for presentations.)

9. Coordinate grids should be parallel to the edges of note and map sheets, and maps should conform to a district-wide grid and not overlap.

10. Maps and note sheets should be clear, neat, and pleasing in appearance. They must have sales appeal because difficult concepts are being portrayed and a project's funding is commonly dependent on clarity of presentation. Impressive, well-executed note sheets and maps generally attest to the quality of the geologic work and of the geologist doing the work.

The variety, types, styles, and purposes of geologic illustration are too varied to allow an example of each. Any of the professional technical geologic journals can be reviewed for style and content. In addition, the following references are particularly good in their content of illustrations: LeRoy et al. (1977), Titley (1982, particularly the included papers by M. T. Einaudi); Dixon (1979), Hutchinson (1983, some are quite complex yet good), Rahmani and Flores (1984), Roberts and Sheahan (1988, very clear and simple, sometimes small), and Barnes (1981).

In summary, there is no substitute for high-quality resource characterization and evaluation based on sound geologic understanding and judgment and presented in an accurate, clear, and lucid manner.

Chapter 5.6
ORE RESERVE/RESOURCE ESTIMATION

ALAN C. NOBLE

Ore reserve estimates are assessments of the quantity and tenor of a mineral that may be profitably and legally extracted from a mineral deposit through mining and/or mineral beneficiation. Estimation of ore reserves involves not only evaluation of the tonnage and grade of a deposit but also consideration of the technical and legal aspects of mining the deposit, of beneficiating the ores, and of selling the product. Thus a number of professional disciplines may be involved in ore reserve estimation including geology, geostatistics, mining engineering, mineral process engineering, mineral economics, land and legal issues, and environmental engineering.

This chapter, however, addresses only the aspects of ore reserve estimation that include determination of the tonnage, grade, size, shape, and location of mineral deposits. Although these are often referred to as ore reserve estimates, the term resource estimation is used rather than ore reserve estimation to emphasize that all aspects of the ore reserve estimate are not being considered.

5.6.1 RESOURCE ESTIMATION METHODOLOGY

A *resource estimate* is based on prediction of the physical characteristics of a mineral deposit through collection of data, analysis of the data, and modeling the size, shape, and grade of the deposit. Important physical characteristics of the ore body that must be predicted include (1) the size, shape, and continuity of ore zones, (2) the frequency distribution of mineral grade, and (3) the spatial variability of mineral grade. These physical characteristics of the mineral deposit are never completely known, but are inferred from sample data. The sample data consist of one or more of the following:

1. Physical samples taken by drilling, trenching, test pitting, and channel sampling.
2. Measurement of the quantity of mineral in the samples through assaying or other procedures.
3. Direct observations such as geologic mapping and drill core logging.

Estimation of the resource requires analysis and synthesis of these data to develop a resource model. Methods used to develop the resource model may include

1. Compilation of the geologic and assay data into maps, reports, and computer databases.
2. Delineation of the physical limits of the deposit based on geologic interpretation of the mineralization controls at a reasonable range of mining cutoff grades.
3. Compositing of samples into larger units such as mining bench height, seam thickness, or minable vein width.
4. Modeling of the grade distribution based on histograms and cumulative frequency plots of grades.
5. Evaluation of the spatial variability of grade using experimental variograms.
6. Selection of a resource estimation method and estimation of quantity and grade of the mineral resource.

The estimation procedure must be made with at least minimal knowledge of the proposed mining method since different mining methods may affect the size, shape, and/or grade of the potentially minable ore reserve. The most important mining factors for consideration in evaluation of the ore reserve from the resource are

1. The range of likely cutoff grades.
2. The degree of selectivity and the size of the selective mining unit for likely mining methods.
3. Variations in the deposit that affect the ability to mine and/or process the ore.

These mining factors often determine the degree of detail that is required for the resource model and thus the degree of difficulty to develop a resource model for estimating ore reserves. For example, a disseminated gold deposit may be continuous and regular in shape, if mined by bulk, open pit methods. The same deposit may be discontinuous and difficult to estimate, however, if mined by more selective underground methods at a higher cutoff grade. Such large differences in deposit shape due to variations in cutoff grade and mining method may require different ore reserve estimation methods for different mining methods.

5.6.2 DATA COLLECTION AND GEOLOGIC INTERPRETATION

Data that must be collected and compiled for the resource estimate are as follows:

1. Reliable assays from an adequate number of representative samples.
2. Coordinate locations for the sample data.
3. Consistently recorded geologic data that describe the mineralization controls.
4. Cross sections or plan maps with the geologic interpretation of the mineralization controls.
5. Tonnage factors or specific gravities for the various ore and waste rock categories.
6. Surface topographic map, especially for deposits to be surface mined.

Although small deposits may be evaluated manually using data on maps and in reports, the amount of data required for a resource estimate is often large, and data may be more efficiently evaluated if they are entered into a computer database. Computer programs can then be used to retrieve the data for printing reports, plotting on digital plotters, statistical analysis, and resource estimation. Minimum information that should be included in a drillhole database are

1. Drillhole number or other identification.
2. Hole length, collar coordinates, and down-hole surveys.
3. Sample intervals and assay data.
4. Geologic data such as lithology, alteration, oxidation, etc.
5. Geotechnical data such as RQD (rock quality designation).

Entry of data into a computer database is a process that is subject to a high error rate if not carefully controlled and checked. Some procedures that may be used to ensure that the data have been entered correctly are

1. Verification of the data using independent entry by two

persons. This is a standard procedure at many commercial data-entry shops that may dramatically reduce data-entry errors.

2. Manual comparison of a random sample of the original data sheets to a print-out of the database.

3. Scanning the data for outlier values. For example: drill locations outside the project limits, high and low assays, and sample intervals that overlap or are not continuous.

4. Comparison of computer-plotted data with manually plotted maps of the same data. Collar location maps and cross sections are especially useful to rapidly locate inconsistent collar locations and down-hole surveys.

Additional care and attention to detail and accuracy during data entry are essential. A database with a large number of errors may result in a resource estimate that is inaccurate and requires a complete revision to provide defendable results.

5.6.3 GEOLOGIC INTERPRETATION

The sample database represents a large three-dimensional array of point locations in a deposit. The sample data are quantitative and have been subjected to minimal reinterpretation after the original measurements. There is another body of geologic knowledge, however, that does not fit this description. This is the interpretation resulting from the geologist's assimilation of the large quantity of geologic data. These interpretative data are often represented on plan maps or cross sections that show outlines of the extent of geologic features or iso-grade contours that define ore zones. These interpretations combine to provide an interpretative geologic model that is one of the most critical factors in the resource estimation. Failure to develop an appropriate geologic ore body model is the most common reason for large errors in the resource estimates. As shown in Fig. 5.6.1, an inappropriate geologic model may lead to errors greater than an order of magnitude.

The geologist's interpretation of the ore body should be used as much as possible in developing the resource estimate. There are, however, practical limits to the amount of complexity that can be included in the resource model, and the geologic interpretation will be limited to critical inputs that define the shape and trends of the mineral zones at different cutoff grades and the character of the mineral zone contacts.

Examples of geologic features that are often modeled include

1. Receptive vs. nonreceptive host rocks.

2. Alteration types that accompany mineralization or create problems in beneficiation.

3. Faulting, folding, and other structural modifications.

4. Multiple phases of mineralization.

5. Post-mineral features such as oxidation and leaching.

Changes in lithology are often important variables in resource estimation because mineralization can vary due to physical or chemical attributes of the rocks. The differences may be distinct, such as the sharp contact between a skarn ore body and an unmineralized hornfels country rock. They also may be gradational, such as the gradual decrease in grade that is often observed between a favorable and slightly less favorable host in a porphyry copper deposit. Other important lithologic controls include barren post-mineral intrusive rocks, nonreceptive shale beds, and other unmineralized materials that are contained within the mineralized zone.

The effects of faulting will vary according to whether the faulting occurred before or after the mineralization, and to what processes accompanied the faulting. A simple post-ore displacement may create a discontinuity in the ore trends, preventing simple interpolation across the fault. The same type of fault occurring prior to mineralization may have little or no effect on the mineralization or may localize high-grade, vein-type mineralization that must be modeled independently of a more uniform disseminated ore body. It is also important to determine whether the fault is a thin, well-defined structure or many smaller structures in a complex, wide shear zone. In the first case, the fault is modeled as a simple surface with no thickness; in the second, the fault zone must be defined and modeled apart from the adjoining rock units.

Folding is particularly significant in sedimentary and stratabound deposits. Modeling of folding depends on whether folding happened before or after ore deposition, on the tendency of the ore zoning to follow the stratigraphy, on any remobilization that occurred with the folding, and on the creation of traps or other favorable structures. In addition to defining the shape of the folds, it is important to determine whether the mineralization follows the contours of the folds or is independent of the fold geometry.

Multiple phases of mineralization must be defined, particularly where they complicate the ore zoning pattern through overlapping, discordant trends, and through post-mineral oxidation or leaching. Secondary enrichment and oxidation will almost always require delineation of the modified ore zones.

The character of the ore zone contact must be determined and input into the resource model. A sharp contact will be handled as a discontinuity and the data used strictly independently on either side of the contact. A transitional contact, however, is a broad, gradational boundary that may require data selection from zones of tens of feet (meters) to over 100 ft (30 m) to achieve true differentiation between the different grade zones. As a transitional zone becomes thinner, it will eventually approach a sharp contact. For practical purposes, any transitional boundary thinner than the smallest selective mining unit will be modeled as a discontinuity.

In addition to definition of these physical ore controls and post-mineral modifications, a clear understanding of ore genesis will always be beneficial in creating a resource model. In the simplest case, the ore genesis will give clues to the behavior of the grade distributions and variograms; in other cases, the genetic structure is so dominant that it can be used as a direct control in the estimation of mineral resources.

5.6.4 COMPOSITING

Compositing is a procedure in which sample assay data are combined by computing a weighted average over longer intervals to provide a smaller number of data with greater length for use in developing the resource estimate. Compositing is usually a length-weighted average. If density is extremely variable (e.g., massive sulfides), however, compositing must be weighted by length times density (or specific gravity).

Some of the reasons for and benefits of compositing include

1. Irregular length assay samples must be composited to provide equal-sized data for geostatistical analysis.

2. Compositing reduces the number of data and may significantly reduce computational time, which is often proportional to the square of the number of data.

3. Compositing incorporates dilution such as that from mining constant height benches in an open-pit mine or from mining a minimum height/width in an underground mine.

4. Compositing reduces erratic variation due to a high nugget effect caused by erratic high-grade values.

There are several different methods for compositing that may be used depending on the nature of the mineralization and

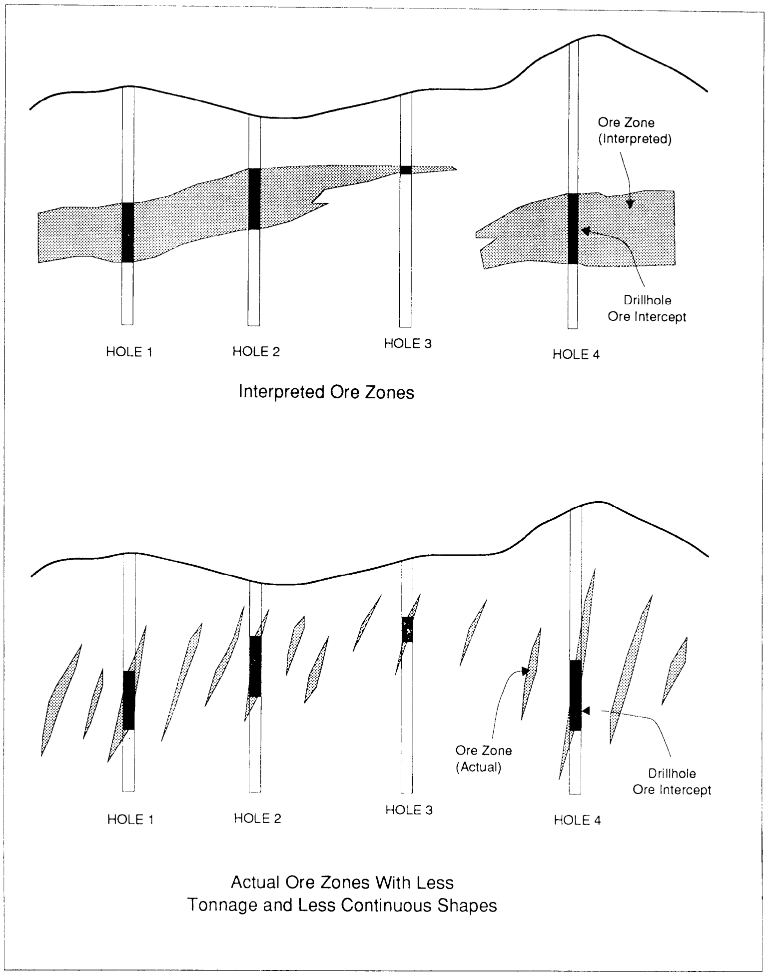

Fig. 5.6.1. Overestimation of ore reserves based on a geologic model that is less continuous than the actual ore zones.

the type of mining. Common compositing methods are (1) bench compositing, (2) constant length compositing, and (3) ore zone compositing.

Bench compositing is a method often used for resource modeling for open pit mining and is most useful for large, uniform deposits. Composite intervals for bench compositing are chosen at the crest and toe of the mining benches. Bench compositing has the advantage of providing constant elevation data that are simple to plot and interpret on plan maps. In addition, the dilution from mining a constant-height, constant-elevation bench is approximated by the bench composite.

Down-hole composites are computed using constant length intervals starting from the collar of the drillhole or the top of the first assayed interval. Down-hole composites are used when the holes are drilled at oblique angles (45° or less) to the mining benches, and bench composites would be excessively long. Down-hole composites should also be used when the length of the sample interval is greater than one-third the length of the composite interval to prevent overdilution when the sum of the lengths of the samples is much greater than the length of the composite.

Ore-zone compositing is a method of compositing that is used to prevent dilution of the composite when the width of the contact between waste and ore (or low grade and high grade) is less than the length of a composite. Use of bench compositing or down-hole compositing in this case may distort the grade distributions by adding low grade to the ore population and high grade to the waste population, resulting in underestimation of ore grade and overestimation of waste grades.

Ore-zone composites are computed by first identifying the interval containing each ore zone in the drillhole. Each ore zone is then composited individually as follows: (1) the length of the ore zone is divided by the desired length of the composite; (2) this ratio is rounded up and down to determine the number of composites that provide a length nearest the desired length when divided into the length of the ore zone; and (3) the ore zone is composited using length composites starting at the beginning of the ore zone and length as determined in the previous step.

A special case of ore-zone compositing is encountered in a vein or bedded deposit in that the width of the ore zone is determined by a combination of minimum mining thickness (height) and assay limits. In these situations, composites must be recomputed for each combination of assay cutoff grade and minimum mining thickness.

Geologic codes are usually assigned to composites according to the rock type, ore zone, or other geologic feature. This is often a simple procedure, since most composites will be computed from samples taken from a single geologic unit. Assignment of geologic codes to composites that cross geologic contacts is more complex, since the composite will be computed using data from multiple geologic units.

If the geologic contact is transitional and does not separate contrasting grade distributions, it is appropriate to assign the geologic codes according to the majority rule. If the composite crosses a sharp boundary between contrasting grade distributions, it is best to use geologic unit compositing or to assign the composite to the geologic unit with the most similar grade.

If some sample intervals in the data are missing assays, it is important to determine the reason for the missing data and account for it appropriately. Typical examples are

1. The missing zone was not assayed because it was low grade or barren by visual inspection, or the sample was missing because of poor core recovery in a barren zone.

Action: Composite using the average of the barren unit or zero grade for the grade of the missing assay.

2. The sample was missing because of poor core recovery in a narrow post-mineral fault.

Action: Ignore the missing interval when computing composites. The volume of the fault zone is small and the grade will be similar to the grades in the country rock.

3. The sample was missing because of poor core recovery in a vein that is higher grade and less competent than the surrounding country rock.

Action: Ignore the missing interval when computing composites, but retain the length of the interval for use in estimating the grade of the vein.

5.6.5 BASIC STATISTICS AND GRADE DISTRIBUTION

Computation of basic statistics and evaluation of grade distributions are the first quantitative analyses of the grade data and are basic tools to provide both feedback to the geologic analysis and input to the resource modeling. Important factors in these basic studies include

1. Detection of high-grade or low-grade outlier values.
2. Evaluation of the favorability of different lithologies as host rocks.
3. Differentiation of complex grade distributions into simple populations for resource modeling.
4. Identification of highly skewed and/or highly variable grade distributions that will be difficult to estimate.

Basic statistics should be computed for sample and/or composite grades in each geologic domain that is suspected to have different characteristics. This may include different lithologies, alteration types, structural domains, grade zones, or other grouping of data that has been recognized (or suspected) to have different grade distributions. Statistics that should be compiled include

1. Number of data (samples or composites).
2. Average grade, thickness, etc. (mean)
3. Standard deviation (std. dev.) and/or variance.
4. Coefficient of variation (COV), the standard deviation divided by average grade.
5. Histogram of grades.
6. Cumulative frequency distribution (probability plot).

The first item reviewed is the number of data; generally, at least 25 data are required to make comparisons between different geologic domains. If sufficient data are available, average grades and coefficients of variation will be compared among the various geologic domains. General rules for evaluating differences in average grade are as follows

Grade Difference	Interpretation
0% to 25%	Grade populations that do not usually require differentiation for resource modeling.
25% to 100%	Grade populations that require differentiation for resource modeling if divided by a discontinuity such as a fault, or if variograms or grade trends are dissimilar.
Above 100%	Grade distributions must be separated for modeling. Differences of 1000% or more may be observed when barren, mineralized, and/or high-grade populations are present.

Rules for analyzing coefficient of variation are as follows

COV	Interpretation
0% to 25%	Simple, symmetrical grade distribution. Resource estimation is easy, many methods will work.
25% to 100%	Skewed distributions with moderate difficulty in resource estimation. Distributions are typically lognormal.
100% to 200%	Highly skewed distributions with a large grade range. Difficulty in estimating local resources is indicated.
Above 200%	Highly erratic, skewed data or multiple populations. Local grades are difficult or impossible to estimate.

Distributions with COV greater than 25% often have a lognormal grade distribution, and the basic statistics will also be compiled for the natural logarithms of grades. For a perfectly lognormal distribution, the lognormal statistics are related to the normal statistics as follows:

$$\text{mean} = e^{(\alpha + \beta^2/2)} \tag{5.6.1}$$

$$\text{COV} = (e^{\beta^2} - 1)^{0.5} \tag{5.6.2}$$

$$\text{std. dev.} = \text{mean} \times \text{COV} = e^{(\alpha + \beta^2/2)} \times (e^{\beta^2} - 1)^{0.5} \tag{5.6.3}$$

where a is the average of the natural logarithms of grades; and b is the standard deviation of the natural logarithms of grades.

Close agreement between the mean, standard deviation, and coefficient of variation when estimated using both normal and lognormal statistics is indicative of a lognormal population and is required to use lognormal statistics.

5.6.6 GRADE DISTRIBUTION

The grade histogram and cumulative frequency distribution are used to study the relationship between the statistical grade distribution and geologic parameters. The analysis is usually begun with a histogram of sample or composite grades. If the histogram is bell-shaped and symmetrical, a normal distribution is indicated, and the cumulative frequency will be plotted on normal probability paper. Normal distributions are not usually found in mineral deposits except those with sedimentary origins.

If the histogram is skewed to the right, a lognormal distribution is indicated and the cumulative frequency distribution will be plotted on lognormal probability paper. Lognormal distributions are frequently observed in most hydrothermal precious and base metal deposits.

Normal probability paper is a special graph paper in that the y-axis is a cutoff grade and the x-axis is the percentage of samples above (or below) the cutoff grade. The x-axis is scaled such that a normal distribution will plot as a straight line, the

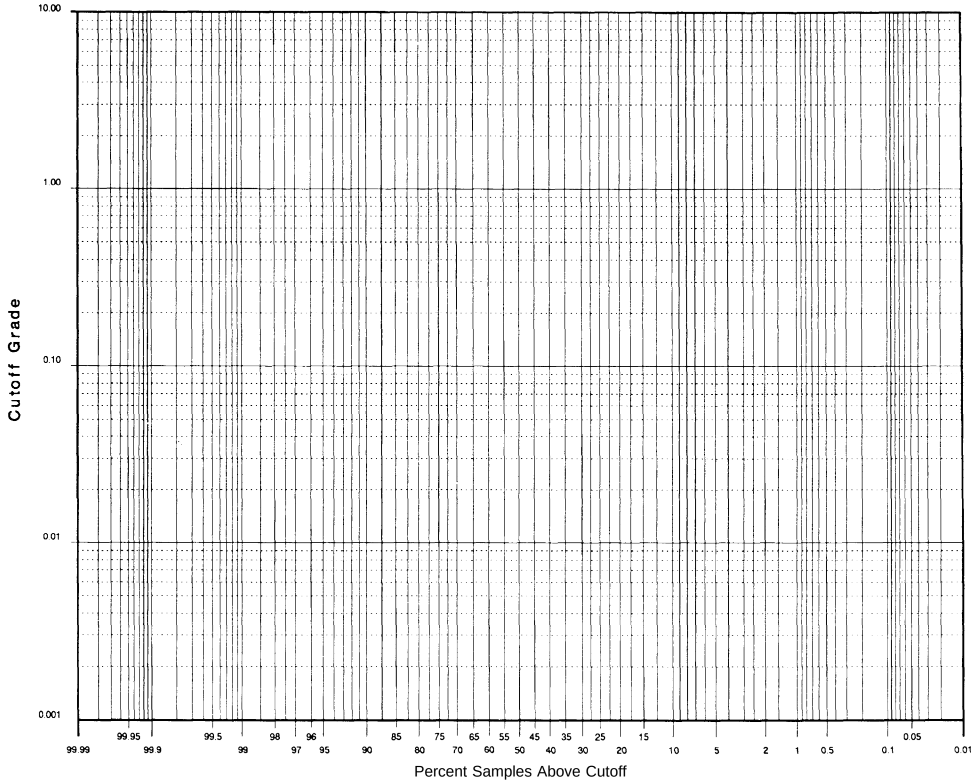

Fig. 5.6.2. Lognormal probability plotting paper.

slope of the line is proportional to the standard deviation of the distribution, and the 50th percentile is the average grade.

Lognormal probability paper is similar to normal probability paper except that the y-axis is scaled according to the logarithm of cutoff grade. The slope of the line is proportional to the standard deviation of logarithms of grade *b*, and the 50th percentile is the average of the logs of grades *a*. An example of lognorma1 probability paper is shown in Fig. 5.6.2.

The probability graph may be used to estimate the standard deviation based on probabilities from the normal probability distribution as follows:

$$\beta = [\ln(g_{97.7\%}) - \ln(g_{2.3\%})] \div 4 \qquad (5.6.4)$$

which is based on 2 standard deviations, or

$$\beta = [\ln(g_{98.0\%}) - \ln(g_{2.0\%})] \div 4.1 \qquad (5.6.5)$$

which is based on ± 2.05 standard deviations.

Often the probability graph is not a straight line, but will be composed of multiple straight lines or curves. A typical deviation from a straight line is a downward curve at the low end of the graph as shown in Fig. 5.6.3. This curve represents excess low-grade samples, and in porphyry systems is often attributed to weakly mineralized late intrusions or to post-mineral, barren dikes. On low coefficient of variation deposits, this type of graph may also represent a normal distribution that has been plotted on lognormal probability paper. The data should be examined to determine the source of the low-grade material and to determine whether that population has been or can be mapped geologically and estimated separately.

Another common deviation from a straight line on the probability plot is a steeper slope at the upper end of the curve as shown in Fig. 5.6.4. This represents excess material in the high-grade population and may be caused by two superimposed populations, such as high-grade veins within lower-grade disseminated or stockwork mineralization. Other causes of excess high-grade assays include small zones that are highly favorable to mineralization because of higher permeability, favorable chemical properties, secondary enrichment, or metamorphic remobilization. Since the high-grade mineralization usually has less continuity than the lower-grade mineralization, the source of the high grade must usually be identified and estimated separately from the remaining mineralization.

5.6.7 VARIOGRAM MODELING

The *variogram* is the fundamental tool used by the geostatistician and geologist to measure spatial continuity of grade data. The variogram is a graph of the average variability between samples vs. the distance between samples. A variogram is computed by averaging the squared differences between pairs of samples that are a given distance apart as follows

$$\gamma(h) = \text{variogram for distance } h$$

$$= \frac{1}{2N} \sum (g_i - g_{i+h})^2 i = 1,2,3 \ldots N \qquad (5.6.6)$$

where N is the number of pairs at distance *h*, and *h* is the distance between the samples.

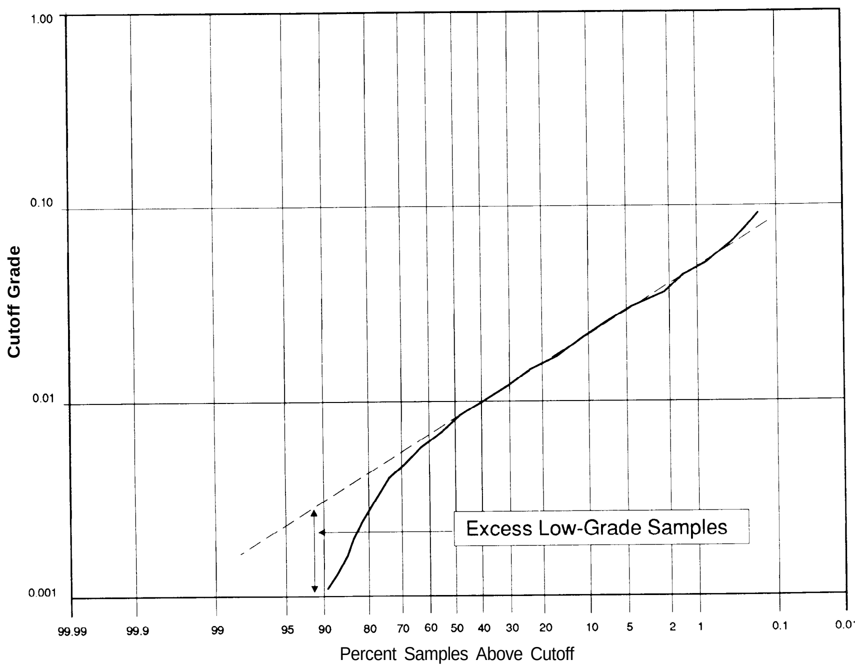

Fig. 5.6.3. Deviation from a lognormal distribution that is caused by excess low-grade samples.

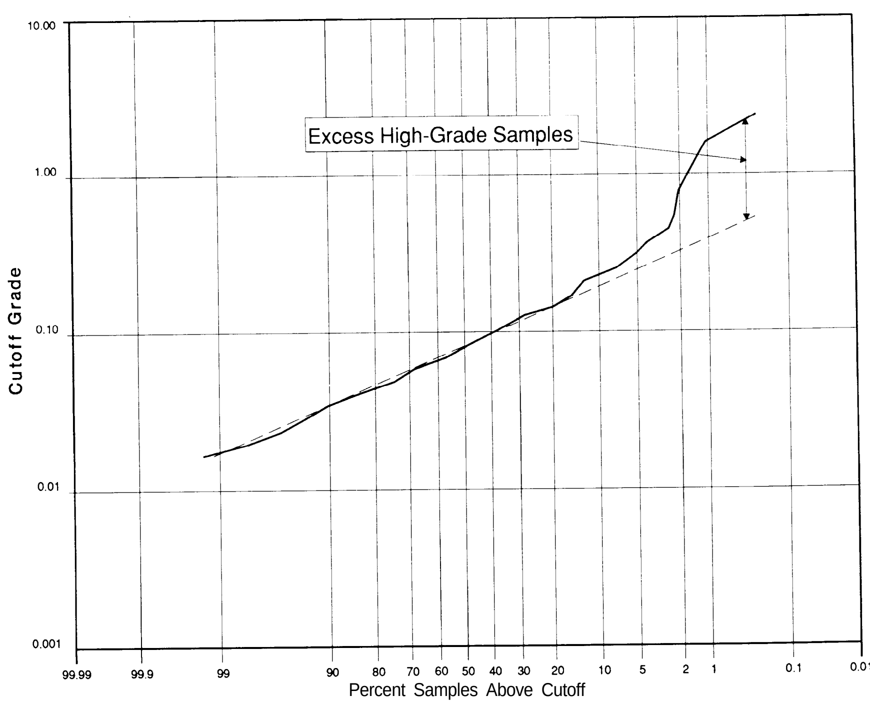

Fig. 5.6.4. Deviation from a lognormal distribution that is caused by excess high-grade samples.

The variogram function $\gamma(h)$ is computed for a number of different sample distances, to provide an experimental variogram that typically looks like the graph in Fig. 5.6.5. The most important features of the variogram are the nugget, range, and sill. The nugget value is identified as the y-intercept of the variogram curve and represents random and short-distance variability factors such as sampling error, assaying error, and erratic mineralization. High nugget values are commonly found in ore bodies where short distance variability is extremely high, where accurate sampling and assaying of ore is difficult, or where poor sampling and assaying techniques are employed. High nugget effects are found in many gold deposits because of random gold nuggets that cause large grade changes over small distances. Similar high nugget values are often found in molybdenum deposits; these are caused by small pockets of pure molybdenite in a disseminated or stockwork mineralization.

Small nugget values indicate an ideal situation reflecting good sampling techniques and locally continuous mineralization.

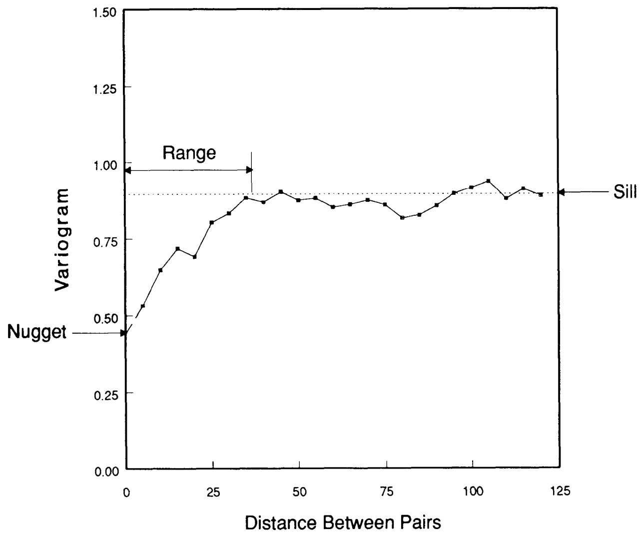

Fig. 5.6.5. Typical experimental variogram plot.

A small nugget value on a variogram confirms that the assays can be reliably used for geologic interpretation and resource estimation. Low nugget values are typically found in many types of deposits, including hypogene porphyry copper, iron ore, and coal. High nugget values have also been found for each of these types of deposits so each deposit must be analyzed individually.

Most variograms increase in value from the nugget for some distance and then level off to a constant value. This distance is called the range of the variogram, and the variogram value is called the sill. The range is equivalent to the geologist's concept of range of influence, that is, the distance beyond which samples are not correlated with other samples and beyond which grade trends should not be projected. The sill value is usually equal to the sample variance. If the sill is higher or lower than the variance, zonal effects or multiple grade distributions are usually indicated.

The slope and shape of the variogram often vary in different directions, with the range increasing in the direction of greatest continuity of the mineralization. This behavior is referred to as a geometric anisotropy.

5.6.7.1 Computing an Experimental Variogram

Computing an experimental variogram from a set of randomly spaced data involves finding pairs of data that are oriented in the required direction, determining the distance between the samples, then summing the squared differences of the grades. Since the data are usually sparse, it is necessary to use a tolerance when locating samples in the desired direction and to use a distance increment to classify samples by distance. The directional tolerance is usually achieved with a window angle, or a fixed distance, as shown in Fig. 5.6.6. These methods may be combined and/or generalized into three dimensions as shown in Fig. 5.6.7. The distance tolerance is a fixed distance increment (cell size), selected so a reasonable number of samples fall in each cell. Some guidelines to aid in computing experimental variograms are

1. Variograms must be computed within continuous zones of mineralization. Do not cross contacts between different geologic domains.

2. The maximum distance used should be less than one-half the length of the mineralized zone in the direction of the variogram.

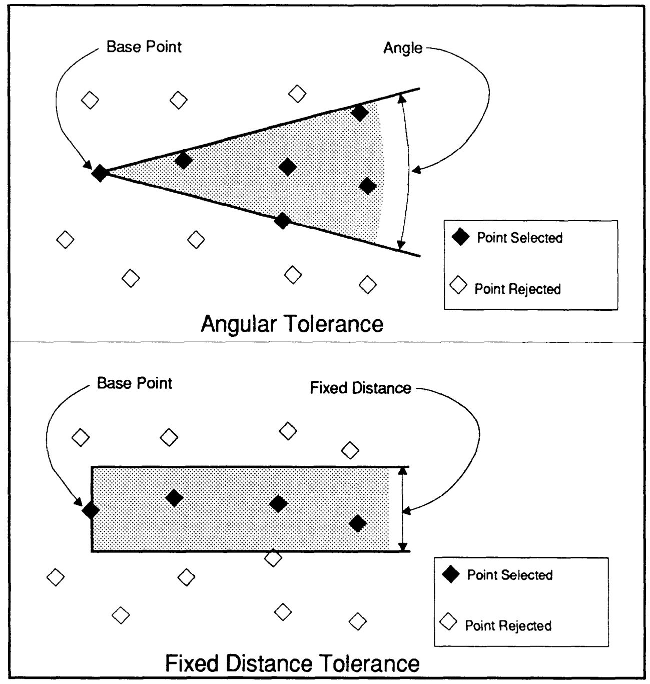

Fig. 5.6.6. Angular and fixed-distance tolerance methods for selecting variogram pairs.

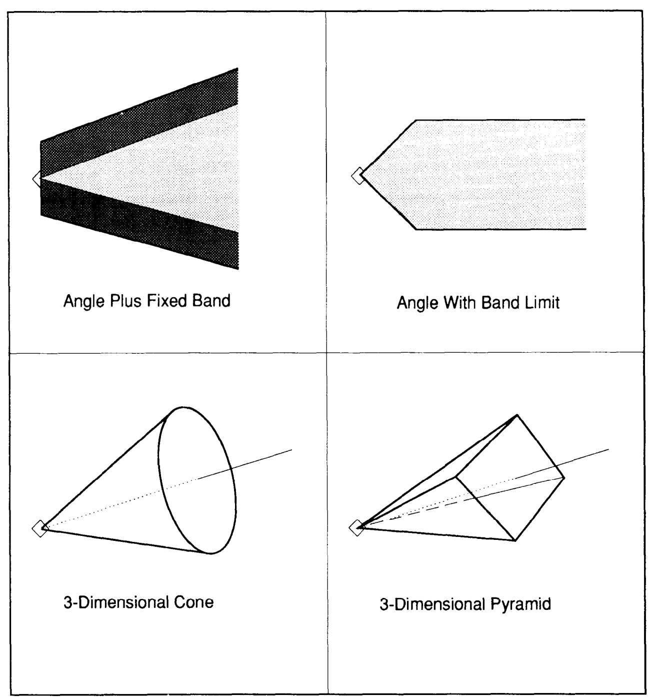

Fig. 5.6.7. Composite and three-dimensional methods for selecting variogram pairs.

3. The maximum search distance perpendicular to the direction of the variogram must be less than one-half the range of the variogram in the perpendicular direction.

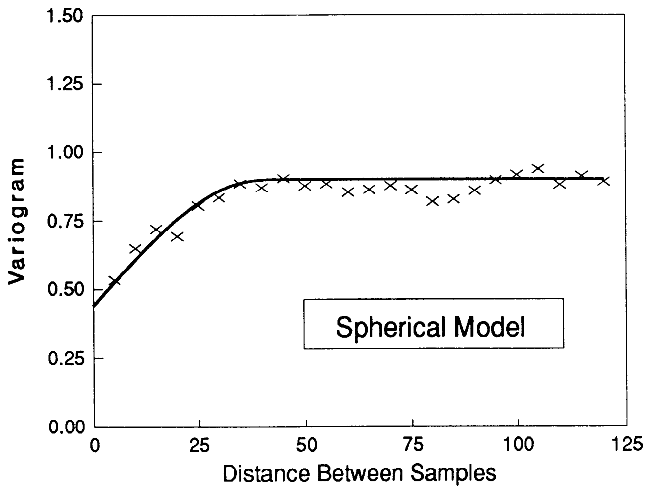

Fig. 5.6.8. Experimental variogram modeled with a spherical variogram model.

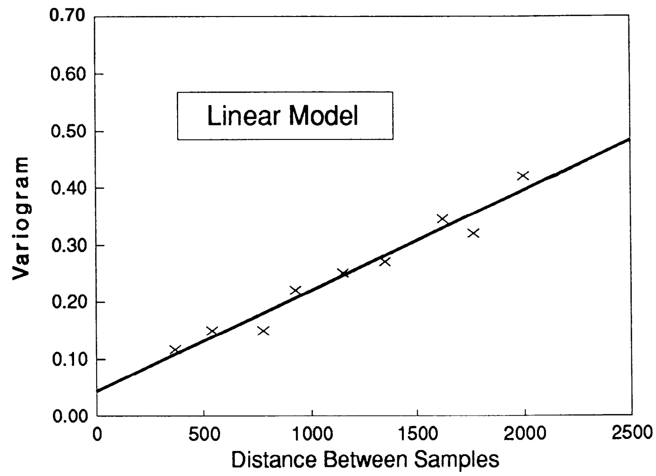

Fig. 5.6.9. Experimental variogram modeled with a linear variogram model.

4. The distance increment should be approximately equal to the average spacing between samples in the direction of the variogram.

5. At least 30 pairs of samples are required to compute a valid variogram. More pairs produce a more stable variogram.

6. All samples must be the same size and should be obtained by the same or similar sampling methods.

7. Data should be declustered before computing the variogram. In particular, a few twin holes may give a misleading impression of the nugget effect.

A model, or equation, is fitted to the experimental variogram for further geostatistical evaluations such as kriging. The most common variogram model is the spherical model shown in Fig. 5.6.8. This model has the equation

$$\gamma(h) = C_0 + C\left[\frac{3}{2}\cdot\frac{h}{a} - \frac{1}{2}\left(\frac{h^3}{a}\right)\right] \quad \text{for } h \le a \qquad (5.6.7)$$

$$\gamma(h) = C_0 + C \quad \text{for } h \ge a \qquad (5.6.8)$$

where C_0 is the nugget, C is the sill, and a is the range.

A spherical variogram model may be constructed graphically by drawing a horizontal line at the variogram value equal to the variance of the samples. This value is equal to nugget plus the sill C_0 + C. A line is drawn through the points at the short-distance end of the curve. The nugget C_0 is estimated where the line intersects the Y-axis, and the range a is estimated as 1.5 times the distance where the line intersects the variance.

Other variogram models used in resource estimation include the exponential, linear, hole effect, and various combinations of "nested" structures. Examples of some of these variograms are shown in Figs. 5.6.9 to 5.6.11.

5.6.7.2 Relative Variograms

Lognormally distributed data often exhibit a proportional effect where the standard deviation of grades increases with grade. This results in variograms with higher values in high-grade areas than in low-grade areas. This may be corrected by dividing each cell in the experimental variogram by the square of the mean of the samples that were used in the variogram

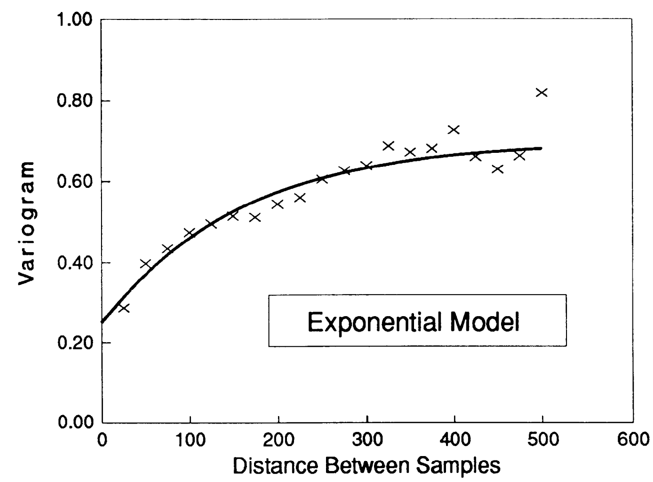

Fig. 5.6.10. Experimental variogram modeled with an exponential variogram model.

for that cell. The resulting variogram is known as a *relative variogram.*

5.6.7.3 Lognormal Variograms

If data are clearly lognormal, a variogram may be computed using the logarithms of sample grades. The resulting *lognormal variogram* is often less erratic and more easily interpreted than the variogram of untransformed values. This variogram may be used directly for lognormal geostatistics or may be transformed to a relative variogram as follows:

$$\sigma_R^2 = (e^{\beta^2} - 1) \qquad (5.6.9)$$

$$\gamma_R\,(\mathrm{h}) = \sigma_R^2 - e^{(\beta^2 - \gamma_{\ln}(h))} + 1 \qquad (5.6.10)$$

Caution must be exercised when using the lognormal variogram since small deviations from lognormality may have large effects on the transformation to a relative variogram.

5.6.8 RESOURCE ESTIMATION (MODELING)

Methods for resource estimation or modeling are generally divided into (1) traditional, geometric methods that are done manually on plans or sections and (2) interpolation methods such as inverse-distance-weighting and kriging that require the use of a computer.

5.6.8.1 Geometric Methods

Manual resource estimations are usually done on plan maps or cross-section maps that cut the deposit into sets of parallel slices. Data plotted on the maps include drillhole locations, assay values, and the geologic interpretation of the mineralization controls. The *geometric methods* used are based on geometric weighting of assays and include area averaging, polygonal, cross sectional, and triangular.

Area Averaging: The *area-averaging method* is among the simplest of all reserve estimation methods, involving only a geologic interpretation of the shape of the ore and averaging of the grades within that shape as follows:

1. Draw the outline of the ore body on each map; these are the ore blocks and may be regular or irregular shapes. If several ore zones or ore types are present, each is drawn individually.
2. Measure the area of each ore block (usually by planimetering). Multiply the area times the thickness of the ore and divide the resulting volume (cubic feet) by the tonnage factor (cubic feet per ton) to compute tons of ore; in SI units, multiply the volume (cubic meters) by the density (tonnes per cubic meter) to compute the tonnes of ore.
3. Compute the average grade of samples within each block.
4. Calculate the sum of the tonnage in the individual blocks. Average grade is the tonnage-weighted average grade of the individual blocks.

Despite its simplicity, the area-averaging method provides excellent estimates where the drilling pattern is uniform, grades are continuous, and ore boundaries are distinct and sharp. Problems may arise, however, when the drill pattern is nonuniform. With a nonuniform drill pattern, a cluster of holes in a high-grade zone will cause overestimation of grade. Area-averaging methods also may be difficult to implement on deposits with discontinuous or spotty ore zones, especially if the ore contacts are gradational, and multiple cutoff grades are desired.

Polygonal and Cross-sectional Methods: *Polygonal* and *cross-sectional methods* are related methods in that each ore interval is assigned its own polygon of influence. Tonnage and grade is then computed using the same procedure as was used for the area-average method, except that the areas used to compute tonnage are the area of each individual polygon. Polygons are drawn on plan maps based on the perpendicular bisectors of the line between each drillhole as shown in Fig. 5.6.12. The size and shape of the polygons may be limited, if desired, by a maximum distance from each hole. On cross sections, the polygons are usually drawn one-half the distance from each drillhole as shown in Fig. 5.6.13. The distance from a drillhole may also be limited to a maximum distance in the cross-sectional method.

A computer approximation of the polygonal method is the nearest neighbor estimation. This method requires superposition of a rectangular grid of blocks over the drilled area as shown in Fig. 5.6.14. The grade of the nearest sample is then assigned to each block. This method will closely approximate the polygonal method if the block size is no more than 25% of the average drillhole spacing.

Triangular Method: The *triangular method* is similar to the polygonal method except that areas of triangles are estimated, and the grade of each triangle is based on the average of the grades at each of the corners of the triangles as shown in Fig. 5.6.15.

The geometric methods all have the advantage of simplicity and ease of implementation. In addition, they will provide an unbiased estimate of the average grade of a deposit at a zero cutoff grade. A resource estimate using a geometric method provides a quick, inexpensive check to verify nonbias of a more complicated, computer-generated resource model.

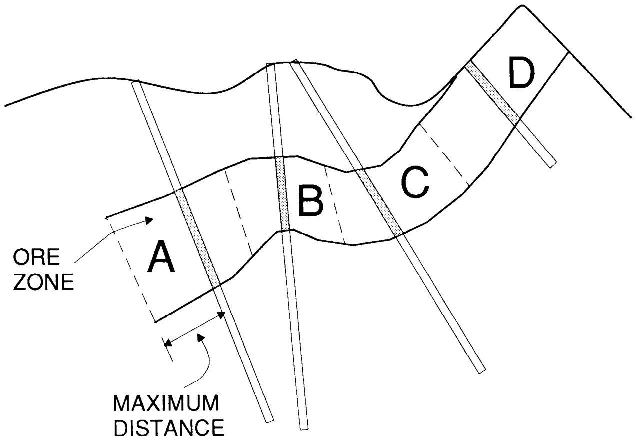

Fig. 5.6.13. Computation of an estimate using the cross-sectional method.

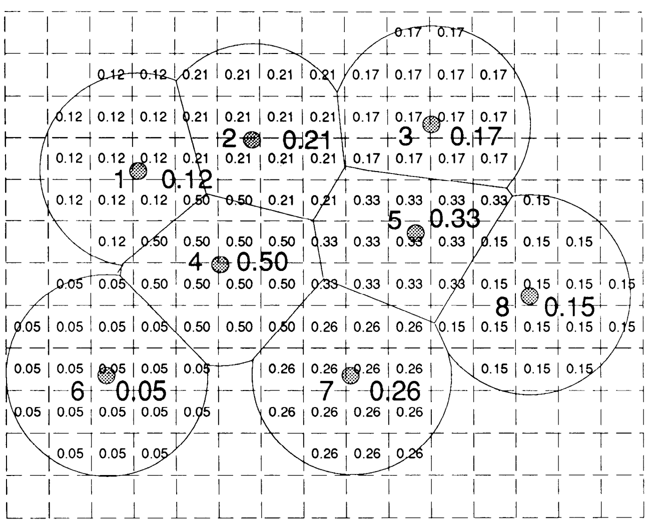


Hole	Grade	# Blocks
1	0.12	12
2	0.21	14
3	0.17	14
4	0.50	13
5	0.33	12
6	0.05	19
7	0.26	14
8	0.15	16

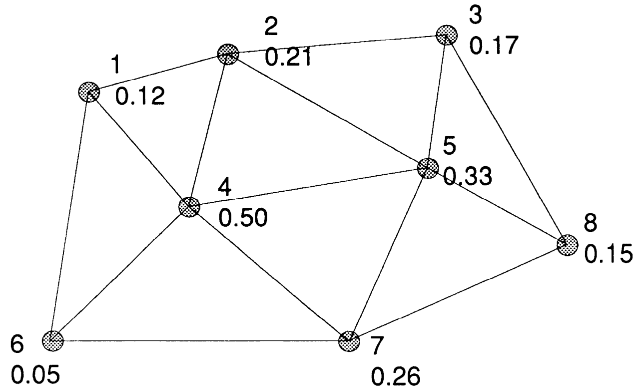
Total Blocks = 114

Sum Blocks × Grade = 24.21

Average Grade = 0.2124

Fig. 5.6.14. Computation of an estimate using the nearest-neighbor method.

The most common problem with geometric methods is that they may imply more selective mining than may be achieved by the mining method. This results from estimating the resource from samples the size of a drillhole but mining larger, less selective volumes. High-grade blocks usually include lower-grade material when they are mined, and low-grade blocks usually include



Triangle	Grade	Area
124	.277	14.5
146	.223	21.6
235	.237	21.1
245	.346	26.2

Total Area x Grade = 49.9

Average Grade = 0.280

Fig. 5.6.15. Computation of an estimate using the triangular method.

some higher-grade material. The resulting mined grades are different from the predicted distribution; for cutoff grades below the average grade of the deposit, the mined grade will be lower and the tons will be higher. If the cutoff grade is significantly higher than the average grade of the deposit, however, both the mined grade and tons can be lower, resulting in a severe overestimation of contained metal.

5.6.8.2 Moving Average Methods

The *moving average methods,* inverse-distance weighting and kriging, are the most widely used procedures for computer-assisted resource estimation. The basic procedure for both of these methods is as follows

1. Divide the ore body into a matrix of rectangular blocks as shown in Fig. 5.6.16.
2. If geologic controls are present and will be used to control or modify grade assignment, a geologic code must be assigned to each block.
3. Estimate the grade of each block by searching the database for the samples surrounding each block and computing the weighted average of those samples. The weighted average is computed using the following equation:

$$g^* = \Sigma w_i g_i \qquad i = 1,2,3,...n \tag{5.6.11}$$

where g* is the estimated grade, g_i is the grade of sample i, w_i is the weight given to sample i, and n is the number of samples selected.

5.6.8.3 Practical Considerations for Moving Average Methods

The determination of the block size, anisotropies, and the sample selection criteria are common considerations for either

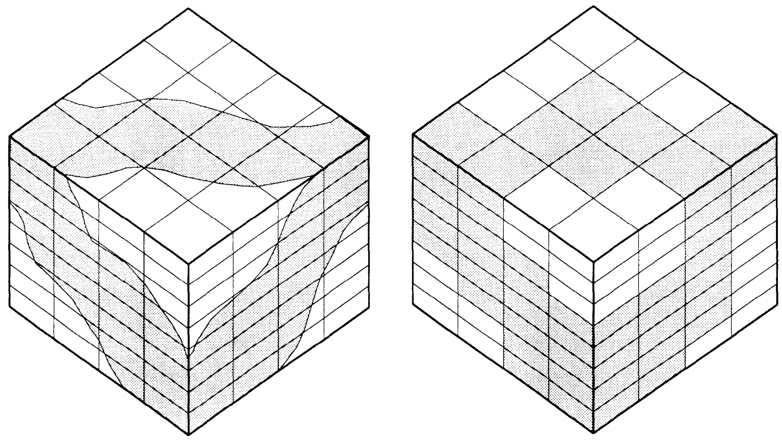

Fig. 5.6.16. Example of a geologic unit coded into a block model.

kriging or inverse distance estimation. These factors are often the most critical factors in developing a satisfactory resource model since the geologic controls are introduced via these mechanisms. Poor selection of these parameters commonly results in an unsatisfactory resource model with significant overestimation or underestimation of ore tonnage or grade.

Block Size: Factors that must be considered in determining block size include the size of the resulting model, drillhole spacing, mining method, and geologic controls. General rules for block size determination are

1. The largest block size possible should be used to minimize the size of the block model and reduce computational time and disk storage requirements.

2. The block is normally one-half to one-fourth the average drillhole spacing. A bigger block may be used if the drilling is extremely dense. Smaller block sizes provide minimal improvement in the estimation unless strong geologic controls are present.

3. The block size must be at least one-half the size of the smallest geologic feature that will be modeled. Larger blocks will destroy the location and/or size of small features.

4. Block size may be related to a proposed mining method. The block height is usually the same as bench height in a deposit that will be mined by open pit methods.

5. Most commercial software packages for resource estimation allow each dimension of the block to be a different size and may allow rotation of the entire model to an orientation other than north-south.

6. These rules are often contradictory, and the best solution will be a compromise that will vary on a case-by-case basis.

Anisotropies: Strong anisotropies, or trends, are often observed in mineral deposits that have ore zones with greater continuity in favorable orientations, commonly shown by variograms with longer ranges in certain directions.

Sample Selection: The purpose of the sample selection step is to provide a subset of the data that is representative of the region around the block. Weighted moving average methods may be very sensitive to sample selection and time spent in analyzing the sample search pattern and how it relates to the data is essential. Some rules to assist in defining a sample selection search are

1. Samples must be selected from geologic domains similar to that of the block.

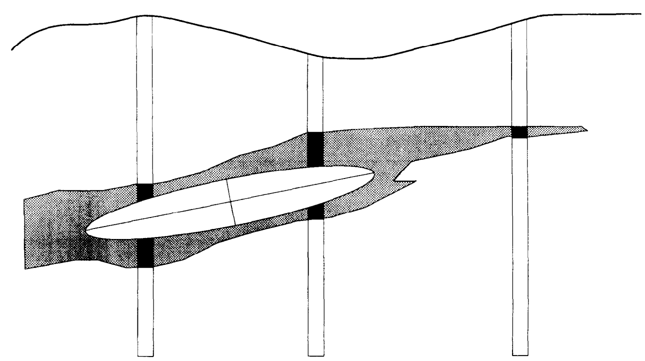

Fig. 5.6.17. Use of an oriented search ellipse to approximate the structure of an ore zone.

2. The maximum radius should be at least equal to the distance between samples to prevent discontinuities in the weighted average as samples drop in and out. (For a square grid, the maximum radius is the diagonal.)

3. The maximum number of samples is usually on the order of 10 to 20. More than 20 samples rarely improves the estimate; fewer than 10 samples may cause discontinuities in the estimated grades.

4. A minimum distance to the nearest sample may be used to prevent excessive extrapolation.

5. A search ellipse or other anisotropic pattern may be used to align the search with trends in the ore as shown in Fig. 5.6.17. The axes of the search ellipse should be oriented parallel to grade trends. The length of the ellipse axes should be proportional to the range of continuity in the respective directions. The variogram ranges and visual appraisal of the grade zones on plans and sections are both used as guides to determining the orientation and length of the search axes.

6. Three composites are usually the maximum required from a single drillhole. More than three provides redundant data and may cause strange kriging weights.

7. Search patterns may be modified to select data with quadrants or other geometric limit as shown in Fig. 5.6.18. Use of a quadrant search will improve estimations if data are clustered.

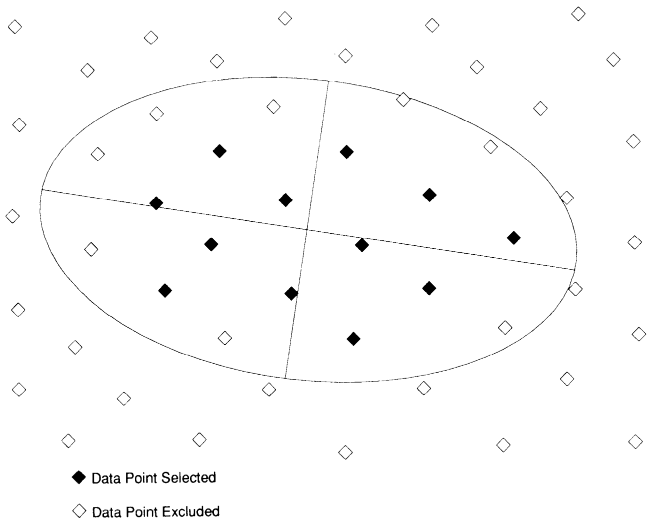

Fig. 5.6.18. Selection of data using a quadrant search and an elliptical search pattern.

8. Sketch the search pattern on plan maps and/or cross-sectional maps in both well-drilled and sparsely drilled areas. This will aid in visualization and assure that the search pattern is appropriate.

5.6.8.4 Inverse Distance Estimation

Inverse distance weighting, one of the earliest used interpolation methods, is based on an empirical observation that the weight of each sample in Eq. 5.6.11 is proportional to an inverse power of the distance from the location of the estimate to the sample. The inverse distance estimate is thus a weighted average with the individual weights computed as an inverse power of distance as follows:

$$w_i = \frac{d_i^{-\text{power}}}{\Sigma d_i^{-\text{power}}} \quad i = 1 \ldots \text{number of samples} \qquad (5.6.12)$$

where w_i is the weight computed for each sample i, each d_i is the distance between the location being estimated and sample i, and power is the inverse distance weighting power. Care must be taken with an inverse distance estimate to ensure that none of the distances d_i are very small or equal to zero, resulting in division by zero, or floating point overflow. This problem may be alleviated either by adding a small constant to each distance or by assigning the value of the closest point to the estimate if the distance is less than some threshold.

The degree of smoothing, or variance reduction, in the inverse distance estimates may be controlled by changing the weighting power and search parameters. A lower power, large search radius, and/or greater number of points used in the estimation result in more continuous estimations and a greater reduction in the variance of the estimated values. Higher weighting powers, smaller search radius, and/or fewer points result in less reduction in the variance of the estimated values and more erratic appearance of the estimated values. The appropriate parameters may only be found through trial and error and experience to achieve the desired distribution of the estimated values and trends, or contours, to match with production results, or to produce trends in the estimated values that visually match with the empirical expectations of the geologist.

5.6.8.5 Kriging

Kriging is the geostatistical estimation method developed to provide the "best linear, unbiased estimate" for grade based on a least squares minimization of the error of estimation, or kriging error. Kriging and its variants have had much theoretical development and are well described in the geostatistical literature. For a more detailed discussion of kriging, the reader may refer to David (1977, 1988) or Journel and Huijbregts (1978). Important factors in the kriging estimate are

1. The average of the estimates should not be systematically higher or lower than the true value; this is established mathematically by setting the sum of weights equal to zero, that is,

$$\Sigma w_i = 1 \qquad (5.6.13)$$

2. The error of estimation s_K^2, which is expressed as variance $(G - G^*)$, or

$$\sigma_K^2 = \sigma_{B,D}^2 - 2\,\Sigma w_i \sigma_{B,Xi} + \Sigma\Sigma w_i w_j \sigma_{Xi,Xj} \qquad (5.6.14)$$

is minimized, where G is the actual grade, G^* is the estimated grade, $s_{B,D}^2$ is the variance of blocks the size being estimated in the deposit, the $s_{B,Xi}$ are the covariances between each sample and the block being estimated, and the $s_{Xi,Xj}$ are the covariances between the individual samples.

The kriging variance in Eq. 5.6.14 is minimized using the Lagrange principle to create a modified equation that satisfies the nonbias constraint in Eq. 5.6.13 as follows:

$$\sigma_K^2 = \sigma_{B,D}^2 - 2\,\Sigma w_i \sigma_{B,Xi} + \Sigma\Sigma w_i w_j \sigma_{Xi,Xj} + \mu\,(\Sigma w_i - 1) \qquad (5.6.15)$$

where μ is the Lagrange multiplier. This equation is differentiated with respect to each of the w_i and μ, resulting in a set of simultaneous equations that may be solved for w_i and μ as follows:

$$\begin{aligned}
w_1\sigma_{X1,X1} + w_2\sigma_{X1,X2} + \ldots + w_n\sigma_{X1,Xn} + \mu &= \sigma_{B,X1} \\
w_1\sigma_{X2,X1} + w_2\sigma_{X2,X2} + \ldots + w_n\sigma_{X2,Xn} + \mu &= \sigma_{B,X2} \\
w_3\sigma_{X3,X1} + w_2\sigma_{X3,X2} + \ldots + w_n\sigma_{X3,Xn} + \mu &= \sigma_{B,X3} \\
&\vdots \\
w_1\sigma_{Xn,X1} + w_2\sigma_{Xn,X2} + \ldots + w_n\sigma_{Xn,Xn} + \mu &= \sigma_{B,Xn} \\
w_1 + w_2 + \ldots + w_n + 0 &= 1 \qquad (5.6.16)
\end{aligned}$$

The foregoing system of equations (5.6.16) is usually solved using simple gaussian elimination to determine the weights and the Lagrange multiplier μ. The kriging error of estimation is then computed based on the following relation:

$$\sigma_K^2 = \sigma_{B,D}^2 - \Sigma w_i \sigma_{B,Xi} + \mu \qquad (5.6.17)$$

which is based on the equation for error of estimation (5.6.14) and the relationship between μ and the kriging equations (5.6.16),

$$\mu = -\,\Sigma w_i \sigma_{B,Xi} + \Sigma\Sigma w_i w_j \sigma_{Xi,Xj} \qquad (5.6.18)$$

The individual covariances and block variances are computed from the experimental variogram as follows:

$$\sigma_{Xi,Xj} = \sigma_{S,D}{}^2 - \gamma(Xi,Xj) \qquad (5.6.19)$$

$$\sigma_{B,Xi} = \sigma_{S,D}{}^2 - AVE(\gamma(B,Xi)) \qquad (5.6.20)$$

$$\sigma_{B,D} = \sigma_{S,D}{}^2 - AVE(\gamma(B,B)) \qquad (5.6.21)$$

where $s_{S,D}{}^2$ is the variance of samples in the deposit, $g(Xi,Xj)$ is the value of the variogram function between samples Xi and Xj, $AVE(g(B,Xi))$ is the average value of the variogram between the block and sample Xi, and $AVE(g(B,B))$ is the average value of the variogram between all points within the block.

Lognormal Kriging: *Lognormal kriging* is a method of nonlinear kriging that was developed to improve estimation when the underlying data are distributed according to a lognormal probability distribution. The basics of lognormal kriging include: (1) the variogram is computed using the natural logs of the data, (2) the kriging system is solved to provide a weighted average of the natural logs of the data, and (3) the kriged log average is then transformed back to normal values using lognormal transformation similar to that shown earlier in Eq. 5.6.1. The mathematics of lognormal kriging are complex and are discussed in Rendu (1978) and Journel (1978, 1980).

Complications in the practical application of lognormal kriging are many, including a strict requirement for a lognormal distribution and a variogram which is stationary over the field of estimation. Serious local and global biases may occur if either of these conditions are not met. In addition, there is a tendency for lognormal kriging to overestimate the high-grade end of the population when the coefficient of variation is greater than 2.0. Lognormal kriging is recommended only for special purposes where the results can be monitored closely and adjusted to prevent biases.

Indicator/Probability Kriging: *Indicator kriging and probability kriging* are related methods that are used to improve estimation when ore zones are erratic and grade distributions are highly variable and complex. Advantages of indicator kriging include less smoothing of estimated grades than ordinary kriging and robustness in handling nonstandard grade distributions.

The first step in indicator kriging is to set one or more cutoffs with which to define indicator variables. Given a cutoff g_c, the indicator variable is set to 1 if the grade is above g_c or 0 if the grade is below g_c (the order of the { 1,0 } coding may be reversed); indicator variables are coded similarly for each desired cutoff. Variograms are modeled for each indicator variable and an expected value for each indicator is estimated using ordinary kriging and the appropriate indicator variogram.

The resulting indicator estimates, which may be interpreted as either the probability that the block will be above the cutoff or the percentage of the block that is above cutoff, are used to estimate the grade of the block as follows

$$g^* = \Sigma(I^*_j - I^*_{j+1}) \times g_j \, j = 0,1,2...n \qquad (5.6.22)$$

where each I^*_j is the estimate for the indicator for cutoff j, g_j is the estimated grade for the interval j to j+1, and n is the number of indicator cutoffs. The interval grades g_j are usually estimated as the average of the cutoff grades for the interval, or, if the interval is large, may be estimated from the kriged grade of those data in the interval j to j+1. The prior method is more precise when a large number of indicator cutoffs are defined; the latter is most often used for a single cutoff.

Other Types of Kriging: Other types of kriging that are not widely used include universal kriging, cokriging, disjunctive kriging, and soft kriging. *Universal kriging* is a method to incorporate trends into the kriging equations. If the trends are defined according to a secondary variable, it is known as universal kriging with exogenic drift. A method of universal kriging that uses the geologists' interpretation of grade-zone trends as the exogenic drift is zoned kriging. *Cokriging* is the method of kriging that accounts for the correlation of a primary variable with a secondary variable, for example, gold with silver or molybdenum with copper, etc. When cokriging is used with qualitative secondary variables such as alteration, rock type, or other geologic features, it is known as *soft kriging*. *Disjunctive kriging* is a method used which attempts to estimate not only the local block grade but also the shape of the tonnage-grade distribution within the block.

5.6.8.6 Volume-variance Effects and Recovery Functions

The volume-variance effect refers to the inverse relationship between the distribution variance and the volume of blocks. The volume-variance effect is characterized by Krige's relationship as follows

$$\sigma^2{}_{B,D} = \sigma^2{}_{S,D} - \sigma^2{}_{S,B} \qquad (5.6.23)$$

where $s^2_{B,D}$ is the variance of blocks in the deposit, $S^2_{S,D}$ is the variance of samples in the deposit, and $S^2_{S,B}$ is the variance of samples in the block. The variance of samples in the block may be estimated from the variogram as follows

$$\sigma^2{}_{S,B} = \overline{\gamma}(_{S,B}) \qquad (5.6.24)$$

where $\overline{\gamma}_{(S,B)}$ is the average of the variogram for samples within a block with the size and orientation of the mining block.

The volume-variance relationship is unimportant where the entire deposit is above the cutoff grade or where the ore is mined nonselectively. Generally, however, the cutoff grade is higher, and only a portion of the mineralized grade distribution is selectively mined as ore. The shape of the grade-tonnage distribution, as defined by the distribution variance, is then a critical factor in determining the grade and tonnage above cutoff.

For practical resource estimation purposes, the variance of mining blocks is generally larger than the variance of kriged resource estimation blocks. The variance of mining blocks is generally smaller than the variance of resource estimation blocks for polygonal estimation.

Polygonal estimation underestimates tons and overestimates grade for low cutoffs. At higher cutoffs, tonnage and grade are both overestimated. Kriging tends to overestimate tons and underestimate grade for low cutoffs. At higher cutoffs, tonnage and grade are both underestimated.

For polygonal estimation, the difference between estimated and mined reserves is usually handled with dilution factors where a fixed tonnage is added with a grade that is less than the cutoff. These dilution factors are adequate for correction of overall reserves but are not accurate for smaller areas if local grades vary significantly from the average grade. Caution must also be observed since dilution factors will vary according to the cutoff grade, the population variance, and the amount of variance reduction between the polygonal and mine block distributions. It should be noted that polygonal reserve estimates may require dilution factors for both volume-variance effects and contact-mining geometric effects.

Kriging reserves are corrected for volume-variance effects according to the distribution of mining blocks within the reserve block as (1) the variance and distribution of mining blocks within the reserve block is estimated, and (2) the tonnage and grade above cutoff is estimated for the block. The mining block distribution parameters are most effectively determined by compiling

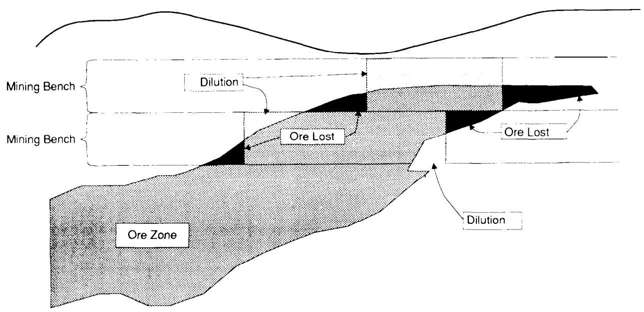

Fig. 5.6.19. Ore dilution and losses caused by mismatch between the mining geometry and the ore geometry.

production statistics of the grade-tonnage curves, or recovery curves, for several grade ranges of estimated blocks. Alternatively, a lognormal distribution may be assumed for mining blocks within reserve blocks. The variance of the distribution of mining blocks within reserve blocks may be estimated from production data. If production data are not available, the variance of mining block may be approximated by

$$\sigma^2_{b,B} = \sigma^2_{B,D} - \sigma^2_{S,B} + \sigma^2_{k,B} - \sigma^2_{k,b} \qquad (5.6.25)$$

where $\sigma^2_{b,B}$ is the variance of mining blocks in the estimated reserve block, $\sigma^2_{B,D}$ is the variance of reserve blocks in the deposit, $\sigma^2_{S,B}$ is the variance Of samples in the reserve block, $\sigma^2_{k,B}$ is the estimation (kriging) variance of reserve blocks, and $\sigma^2_{k,b}$ is the estimation variance of mining blocks (based on grade-control samples).

5.6.8.7 Dilution and Mining Losses

The estimated tonnage and grade must be adjusted for dilution of grade and losses of tonnage that occur in the course of mining. Dilution is waste that is not segregated from ore during mining, thus decreasing the grade of the ore and increasing the tons. Ore losses are due to the inability of the mining method to follow accurately and to segregate small isolated pods and small irregular offshoots from the main ore body. Dilution is most significant in deposits with sharp contacts between high-grade ore and barren waste and least significant in deposits with gradational contacts between ore and waste.

Dilution tonnage is estimated according to the quantity of waste mined with the ore based on the mismatch between ore body and mining geometry, overbreak in blasting, or lack of accurate location of the ore/waste contact as shown in Fig. 5.6.19. Care must be taken in estimating dilution that the actual ore/waste contact is not more irregular than the model since dilution will be underestimated as shown in Fig. 5.6.20. Dilution grade is estimated as the grade of the waste at the ore/waste contact. Mining losses and grades are estimated according to similar procedures.

5.6.8.8 Selection of Resource Estimation Methods

Selection of an appropriate resource estimation method depends on the geometry of the deposit, the variability of the grade distribution, the character of the ore boundaries, and the amount of time and money available to make the estimate. Deposit geometry determines the amount of detail that must be interpreted and input to the reserve estimation; the variability of the grade distribution determines the amount of smoothing that is required to estimate minable blocks; the character of the ore boundaries determines how grade will be estimated at the borders between different grade zones; and the available time and money determine the detail and effort that will be expended on the estimate. Considerations for selection of a resource estimation method are summarized in Table 5.6.1.

Cost: Simple, manual methods such as polygonal and cross-sectional estimations are the cheapest and quickest methods for estimation of resources when the quantity of data is small. This is usually the case for preliminary evaluations in exploration stages. As the number of data increase and a more detailed estimate is desired, computer-assisted methods should be used in order to save time and money. The least expensive computer-assisted methods are automated polygonal or nearest-neighbor methods and the most expensive methods involve extensive definition of geologic controls in conjunction with the more complex geostatistical methods. For further discussion of computer applications to ore estimation, see Chapter 8.4.

Ore Boundaries: The appropriate reserve and dilution estimation method is determined by the character of the ore/waste contacts. Sharp, simple boundaries are modeled with linear outlines defining discrete mineral zones. Individual estimations are made for each mineral zone; dilution is estimated based on the intersection between the shape of the mineral zones and the shape defined by the geometry of a mining method. A sharp, irregular boundary is also described with linear boundaries defining mineral zones; the actual ore-waste contact is much more irregular than the interpreted boundary, and dilution must be increased accordingly. Geometric methods are usually appropriate for ore bodies with sharp contacts, although kriging or inverse-distance methods may be used within the zones if supported by sufficient data.

Gradational boundaries are handled as transitional between different mineral zones; kriging or inverse-distance methods are most appropriate to model ore bodies with gradational contacts. Sufficient dilution for a gradational contact is usually incorporated in the modeling method.

Extremely erratic, irregular boundaries are difficult to define accurately and are most appropriately estimated using methods such as indicator kriging.

Deposit Geometry: *Simple geometry* is often found in tabular, stratabound deposits, veins, and structural zones. The geometry of these deposits is easily described using two-dimensional methods such as contouring of thickness and elevation. Few additional controls are required other than boundaries to limit the lateral extent of the mineral zones.

Deposits with *moderately complex geometry* include both deposits with simple geometry that have been moderately folded or faulted and deposits with large, simple, massive shapes such as porphyry copper and molybdenum. Definition of deposit geometry includes definition of fold axes, fault boundaries, and zoning of trends within the deposit. While these controls are not usually difficult to define, their definition is necessary to provide accurate resource estimates.

Deposits with *very complex geometry* are usually associated with structural deformation and are folded, faulted, stretched, and twisted to form extremely discontinuous shapes that are difficult to describe and model. Multiple ore controls such as a combination of stratigraphic and structural controls or multiple, overlapping pulses of mineralization also commonly form very complex shapes. Definition of deposit geometry requires detailed examination of structural geology and ore controls to provide cross sections or plan maps which define the shape and location of mineral zones. These sections or maps may then be used directly for manual resource estimation or may be digitized to provide control for a computer block model or three-dimensional

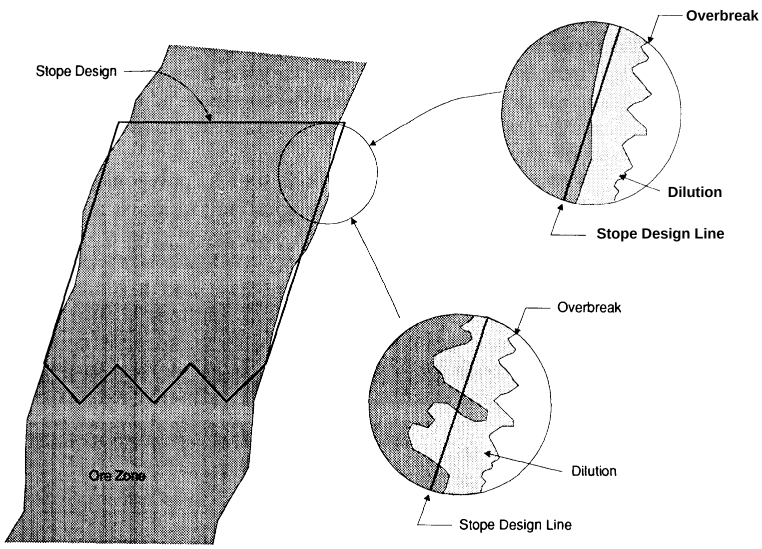

Fig. 5.6.20. Underestimation of dilution because of an irregular ore-waste contact.

wire frame model. *Deposits with complex geometry are prone to large estimation errors due to misinterpretation of deposit geometry and ore controls; order of magnitude errors are common.*

Grade Variability: Deposits with low variability may be estimated with many methods. Common methods include automatic contouring and polygonal methods with cross-sectional estimation or area-averaging techniques for more complex geometry.

Weighted averaging methods (kriging and inverse distance) are most commonly used for estimation of deposits with moderate variability although polygonal or cross-sectional methods are also used. Weighted averaging methods may require recovery functions and polygonal methods may require dilution to compensate for volume-variance effects, although in most cases the adjustments are small, on the order of 5 to 15%.

Weighted averaging methods are most commonly used for estimation of deposits with high variability. Other appropriate methods may include indicator kriging, polygonal, and cross-sectional methods. Volume-variance effects are often large with these deposits and must be compensated for with recovery functions for weighted averaging methods and large dilution of polygonal and cross-sectional reserves. For coefficients of variation above 2.0 or 3.0, local grade estimates are extremely difficult and must be tempered with judgment and caution.

Table 5.6.1. Selection of Estimation Method Based on Deposit Geometry and Variability

	Low Variability, COV < 0.25	Moderate Variability, COV > 0.25 < 0.75	High Variability, COV > 0.75
Simple Geometry			
Deposit description	Tabular, continuous grade and thickness Flat or constant dip	Tabular, large ore pods Moderately variable grade	Tabular, small ore pods Highly variable grade
Example deposits	Evaporite Sedimentary Iron Limestone Coal	Stratiform copper Mississippi Valley lead Simple porphyry copper, molybdenum	Gold veins Gold placers New Mexico uranium Alluvial diamond
Estimation methods	Grade and thickness using any 2-dimensional method: polygonal, contouring, inverse distance, kriging. Geometric controls for boundaries of ore zone, faults, and fold axes	2-dimensional methods. Inverse distance or kriging. Polygonal or cross section with 5 to 15% dilution	2-dimensional methods. Inverse distance or kriging with recovery functions. Polygonal with 15 to 35% dilution
Moderately Complex Geometry			
Deposit description	Simple, bedded. Uniform grade but erratic thickness, gentle folding, or simple faulting	Simple three-dimensional geometry. Moderately variable grade	Simple three-dimensional geometry. Two-dimensional with smaller, more erratic ore pods. Simple folding, faulting
Example deposits	Bauxite (variable thickness) Lateritic Nickel (variable thickness) Salt Dome	Porphyry copper Porphyry molybdenum	Stockwork and Carlin-type gold Volcanogenic base metals
Estimation methods	Estimate grade, thickness and elevation using any 2-dimensional method Must define structural geology (faults, fold axes) Variability of thickness may be difficult to predict	Inverse distance or kriging with external controls to define the shape and grade trends. Polygonal and cross-sectional methods may be used but will require dilution/volume variance correction	Inverse distance of kriging with recovery functions. Polygonal or cross section with 15 to 35% dilution
Complex Geometry			
Deposit description	Otherwise simple deposits that have been severely folded and faulted	Complex geometry due to faulting, folding, or multiple mineralization controls. Moderately variable grade	Deposits with extremely variable grade and highly contorted, complex ore shapes. Typically little continuity between individual ore zones. General mineral envelope definable but with 50% or less ore
Example deposits	Talc Gypsum (deformed)	Tungsten skarns (folding/faulting). Base metal skarns (erratic shape). Copper porphyry combined with local skarns or replacements (multiple controls)	Archean gold deposits Roll front uranium
Estimation methods	Cross-section methods with detailed definition of structural geology. Difficult to define geometry for 3-dimensional block models and geostatistical methods	Cross-sectional methods with detailed input to describe structural geology and or zones. Geostatistical methods may be appropriate but difficult to implement because of geometric complexity	Estimation very difficult. Size, shape, and grade not locally predictable. Cross-section, area-outline methods, indicator kriging applicable. Errors of 50 to 100% typical. Tonnage often overestimated because of incorrect geologic model

Chapter 5.7
EVALUATION AND PRODUCTION SUPPORT

DONALD E. RANTA

The value of geologic data gathered at mineral projects or mines lies in their effective use by other evaluation or production specialists. Little benefit is gained from accurate geologic information and sound geologic ideas if data are not properly organized and presented and if reports documenting the results are poorly written. Thus written and oral communications of geologic information are essential to guide the evaluation process and to achieve production goals.

Geologic data and interpretations form the foundation for both mine evaluation and mine production by providing essential information for estimating ore reserves and for mine planning and process design. Proper geologic work requires a keen awareness of and an ability to anticipate the technical requirements of geotechnical engineers, hydrologists, mining engineers, metallurgists, and other technical specialists who all rely on the geologic data and samples. Presentation of pertinent data in a usable format and frequent communication of new geologic knowledge to the other technical specialists are integral parts of the geologic program.

Geologic support for other specialists involved in mine evaluation and production includes the following (Ranta et al., 1984):

1. Gathering and assessing geologic data and samples for geotechnical analysis.
2. Collecting groundwater data for hydrological investigations.
3. Defining the ore body and high-grade areas for mine planning; exploring for additional ore bodies and other materials in the district.
4. Identifying ore types and collecting samples for metallurgical testing.
5. Evaluating geologic characteristics and ore potential of sites designated for waste dumps, a mill, leach pads, shops, offices, and associated facilities.
6. Assisting with land, legal, environmental, and permitting studies.

5.7.1 GEOTECHNICAL SUPPORT

Geotechnical engineers assist in mine planning and operations by collecting, interpreting, and applying geologic data to the solution of mine engineering problems. Geologists support this effort by collecting additional geologic data specifically useful to the engineer as well as standard geologic information. Geotechnical engineers use the data in helping to select a mining method, to design the mine, and to define and mitigate potential ground stability problems.

Geologic data most useful for initial geotechnical analysis consist of descriptions and map and section representations of rock types, structures, and alteration, which could be considered the "geologic model" of an ore deposit. First, ore types, wall rock, and overburden are separated on maps into structural domains and then physical characteristics are used to define rock strengths and rock mass fabric within each domain. Separate structural domains occur between major faults, which are the zones of greatest weakness, and are partly dependent on lithology and alteration. Structural domains are initially determined by the geotechnical engineer through review and analysis of the basic geologic data, including geologic maps, drillhole logs, and interpretive geologic sections and plans.

Rock strengths are determined by rock substance between structural discontinuities and by fracture strength. Rock mass fabric elements include faults, joints, bedding, veins, and foliation (Stewart and Sacrison, 1984). These types of data are used to establish classification systems in predicting and mitigating potential ground stability problems.

Additional geologic data collected specifically to support the geotechnical programs include estimates of rock competency and hardness, photographs of unsplit core that has natural fractures marked, representative rock or whole core samples for laboratory testing of physical strength, measurements of fracture characteristics in core and bedrock, and records of various water levels and flow rates. Engineering logs of fracture characteristics per unit interval of drill core often include the following: core recovery percentage, maximum length of unbroken core, fracture frequency, rock quality designation (RQD), and rock competency estimate. Noting the fracture orientation, fracture-filling material, and vein-filling material is also important. Monitoring of geotechnical equipment for evidence of ground movement in a mine is often the responsibility of the geology department. These data are collected by the geologic staff for use by the geotechnical engineer. According to Pillar and Drummond (1975), "the best information on the strength characteristics is obtained when the geologist logging the core can see the interrelationships of the various physical features and can make the appropriate notations."

5.7.2 HYDROLOGIC SUPPORT

Hydrologists have the responsibility of locating sources of both process and potable water for the mine operation. Several superior mineral deposits in desert regions are not "ore" bodies because of a lack in the quantity or quality of local water. Other deposits are not viable because local rainfall or groundwater inflow exceeds economic pumping capacity. Either too little or too much water is a hydrological problem that often is a function of the local geologic setting.

Geology is helpful, and often essential, in locating available sources of water. Water encountered during exploration drilling or in underground workings should be noted for location and measured for flow rate, pH, various dissolved solids, and temperature. Water courses should be correlated with known geologic features, especially structures or aquifers, to predict potential water source or problem areas. Surface water flow, springs, and seeps should be noted and plotted on maps, and measured, if possible, as a part of routine geologic mapping.

The mine planning department must have a reasonably accurate estimate of groundwater flow that will be encountered in open pit or underground mine development. Dewatering by a series of wells may be required in advance of the development. An accurate estimate of the time and costs of dewatering or of water development is necessary for proper planning.

5.7.3 MINE PLANNING SUPPORT

Mine planning engineers require definition of the location, size, shape, attitude, boundaries, and internal grade distribution of a mineral deposit for mining method selection, mine layout and design, and production scheduling. Tonnage and average grade above various cutoff grades of the geologic resource must be accurately estimated with a high degree of confidence. Through a detailed mine plan, a large portion of the geologic resource is designated as the minable "ore" reserve. Delineation and reserve estimation of high-grade zones as the most valuable portion of the ore deposit is especially important in selection of an initial mining area. Any changes in ore body configuration resulting from new drilling and sampling results must be quickly reported to mine planning engineers. Geologic resource data can be transmitted by sets of grade zone sections and plan maps that should be at the same scale as mine planning maps. A complete computer database of sample, assay, and pertinent geologic data in a format compatible for mine planning also must be transmitted. A reliable inventory of all mineralization should be estimated, also noting inferred resources and additional exploration potential. Ore types, such as oxide, sulfide, mixed oxide and sulfide, strong argillization, strong silicification, etc., should be identified to ensure proper production scheduling and blending, if needed. Chemical analyses for a variety of elements should be carried out on representative samples of ore and waste to identify potential byproducts and contaminants.

Potential byproducts should be considered in an equivalent grade model if their value could have significant economic impact on the mining operation. Unusual groundwater flow, faults, alteration, or rock types that may affect ground stability and mine design also should be located and described. Types and thickness of overburden, sharp assay boundaries, and post-mineral dikes and faults are identified to provide information on grade discontinuities that may limit mining recovery of ore or cause dilution. This detailed information is used by the mine geologist for grade control on benches or in stopes. Selective mining is largely dependent on a thorough geological understanding of a deposit. Specific gravity measurements of the various ore and waste types are made to determine their tonnage factors for converting volumes to short tons (tonnes). Specific gravity measurements are also needed for deposits having highly variable rock densities, for the selection of haulage equipment, and in planning production schedules.

Long-term planning can benefit from knowledge of additional ore bodies and potential ore bodies in the district. Discovery of new deposits could change the following: sequence of development and mining, optimum production rate, economies of scale, and mine life. If a significantly better deposit were found, the overall operation could be substantially improved. Also transmittance of the ore deposit data to an associated exploration group could benefit the entire company. Continuing exploration in and near the existing deposit is a vital function of the geological department.

5.7.4 METALLURGICAL SUPPORT

Ore types, which may behave differently in ore processing, must be identified and defined for the deposit according to their geologic characteristics. The various ore types should be plotted on sections and plan maps to show their spatial distribution throughout a deposit and transmitted to the metallurgist as the data become available for his/her short-term planning. An initial indication of the proportions of various ore types in a deposit can be determined by summing the cumulative drillhole footage of each ore type and calculating their percentages in the deposit. Composite samples of the various ore types are first identified and then assembled by a geologist, in close coordination with a metallurgist, to ensure that the samples are representative of the entire deposit (or selected portions of the deposit) and are adequate for bench-scale metallurgical testing. Samples of ore are usually collected from coarse rejects or cuttings resulting from drillhole samples that have been prepared for assaying. Other samples for testing can be collected from surface trenches, outcrops, mine benches, or underground workings. All coarse rejects of drillhole samples from a mineral deposit should be retained for possible metallurgical testing. If larger bulk samples are required for pilot plant-scale metallurgical testing, then large-diameter drillholes, test pits, or underground exploration/development workings into geologically specified areas may be necessary. The bulk samples should be representative of all the deposit or, at least, of the most important ore types.

Geologic characteristics that define various ore types include lithologic type, alteration type and intensity (e.g., argillization vs. silicification), mineralization type and intensity, sulfide vs. oxide, etc. Detailed mineralogic investigation of a deposit is necessary to define the ore types. Of the various ore types, unusually hard or soft rocks and deleterious trace elements, minerals, or rock types should be identified to help alleviate potential processing problems. Detailed information on the ore and gangue minerals, such as mineral assemblages, grain sizes and shapes, and textural relationships (e.g., interlocking or coating) should be described for the metallurgist. Potential byproducts should be considered and evaluated. Routine spectrographic analyses of representative samples will help identify potential byproducts and deleterious trace elements. Mineralogic examination of the intermediate materials resulting at different stages of the processing is often beneficial in determining how to improve metallurgical recovery.

5.7.5 LAND AND LEGAL SUPPORT

Initial support for land and legal aspects of a project in the United States can be provided by establishing mineral "discoveries" (valuable minerals in place) on all claims within the mineralized area, thereby validating the claims in accordance with the mining law. In addition, an evaluation of the mineral potential and "mineral-in-character" of areas designated for plant sites, waste dumps, tailing ponds, leach dumps, and ancillary facilities is necessary from both the engineering and permitting aspects of a project or expansion of a mine. The project or mine geologist should make recommendations for acquisition or disposition of property and evaluate nearby property submittals. Patenting of claims requires significant geologic input.

5.7.6 ENVIRONMENTAL SUPPORT

Identification of environmental geology hazards, such as potential landslides, flood plains, avalanche chutes, and active faults, can help avoid risk-prone areas in siting surface facilities. Environmental baseline studies and permitting often require geologic input. Environmental engineers require data on deleterious trace elements that may be naturally leached from waste dumps, tailings, or mine workings. Final reclamation of the entire mine site may be partly controlled by geologic conditions, such as acid leachate from the mine or dumps, or the future preservation of a low-grade resource. Because the exploration or project geologist is often the first company employee to reside at a property, he may be aware of valuable historical, political, sociological, and geographical information to pass on to the environmental and permitting specialist.

More generalized discussion of several of these topics is found in Sections 3 and 7.

Chapter 5.8
CASE STUDIES

PETER G. DUNN, DONALD J. BIRAK, THOMAS C. DOE, DAVID L. STEVENS, R.G. MATEER, AND J.M. MERCIER

5.8.1 DEVELOPMENT GEOLOGY OF THE COPPER FLAT PORPHYRY COPPER DEPOSIT

PETER G. DUNN

5.8.1.1 Introduction

The scope of geologic work expands significantly as a result of a successful exploration program. Geologists involved in subsequent development work obviously continue to be concerned with the control and distribution of the mineralization, but must also address such factors as:

1. Careful checks on the sampling and assaying.
2. Examination of underground workings driven to provide samples for both metallurgical testing and assay comparisons.
3. Selection of representative samples used to establish recoverable amounts of precious metals in base metal ores.
4. Location of an adequate water supply.
5. Determination of plant site and waste dump areas as nonmineral.

These investigations are necessary for engineering design, for acquiring environmental permits, and for financial analysis.

Development of the Copper Flat porphyry copper deposit in south-central New Mexico provides a case history of such studies. The mining district had produced gold from placer workings and both precious and base metals from vein deposits surrounding a porphyry stock. The porphyry deposit was recognized early (Harley, 1934), and had been evaluated in the period 1956 to 1972; the major development effort took place in 1975 and 1976. Plant construction began in 1980, and production began in 1982. The Copper Flat mine, however, had a short operating life due to depressed copper prices in 1982.

One aspect of this work that needs to be stressed is the careful recording and checking of the data. It is important not only for the mining company to know what it really has, but also for any possible joint venture partners and engineering firms to have access to the necessary data. It is particularly important, if the project is to be financed, that the lending institution is satisfied that the various studies have been well carried out and meticulously recorded.

5.8.1.2 Geology

The Copper Flat porphyry deposit is approximately 1500 by 2000 ft (450 by 600 m) in plan and occurs in the center of a small quartz monzonite stock that had intruded a circular block of andesite about 4 mi (7 km) in diameter. Latite dikes, 5 to 20 ft (2 to 6 m) thick, cut the quartz monzonite and extend across the andesite terrane. Most of the vein deposits in the district occur along the dike contacts.

The porphyry deposit includes a large hydrothermal breccia pipe about 1400 ft (425 m) long and 500 ft (150 m) wide, immediately below the alluvium. It extends to a depth of at least 1000 ft (300 m) and increases in size with depth. The breccia consists principally of quartz monzonite fragments within a matrix of quartz, biotite, and potash feldspar, with pyrite, chalcopyrite, and minor molybdenite (Dunn, 1982).

Copper occurs almost exclusively as chalcopyrite with minor amounts of chalcocite and copper oxide minerals. Molybdenum occurs as molybdenite. The sulfide mineralization first formed in narrow veinlets and as disseminations in the quartz monzonite with weakly developed sericite alteration. This stage of mineralization was followed by the formation of the breccia pipe with the introduction of abundant pyrite, chalcopyrite, and molybdenite with strong potassic alteration.

5.8.1.3 Diamond Drilling

Drillholes completed prior to 1975 had been spaced about 400 ft (120 m) apart, and breccia mineralization had been intersected in about eight holes. After the recognition of the mineralized breccia in the center of the deposit, the initial phase of the 1975 development drilling was undertaken to confirm that the eight breccia intersections represented a single breccia pipe.

Grade changes within the quartz monzonite are generally gradual, and by the completion of the development drilling program in early 1976, drillholes outside the pipe were spaced about 200 ft (60 m) apart. Grade changes within the breccia pipe, however, are commonly abrupt, so the drillholes in and immediately around the breccia pipe were spaced about 100 ft (30 m) apart. All told, 175 vertical holes with a total length of 125,300 ft (38.2 km) were drilled in the mine area; 135 of these holes, 96,500 ft (29.4 km), were drilled in 1975 and 1976. Almost all the core was NX, approximately 2 in. (50 mm) in diameter.

The principal purpose of the diamond drilling was to provide the best possible sample for assay. Because of the overall low grade of the Copper Flat deposit and because of the erratic nature of the mineralization within the breccia pipe, core recovery was important to the evaluation. For this reason, a core recovery incentive bonus, payable to both the contractor and the drill crews, was included in the drilling contract. Core recovery was calculated on a weight basis for the entire hole, and the bonus was paid on those holes with recovery above 88%, with a corresponding penalty (to the contractor only) for those below 88%. The overall core recovery on the project during the time the bonus provision was in effect was over 96%, and only three of the holes failed to gain the bonus. This figure can be compared with 89% recovery in holes drilled without the incentive bonus. The bonus increased the direct drilling cost about 10% ($1.60/ft or $5.25/m), but the amount was considered to have been well spent.

In drilling prior to 1975, the core had been split and one-half used for assay. The other half from selected intervals was later assayed, and the two results commonly did not correspond well—particularly for samples of coarse-grained breccia mineralization. It was therefore decided to use the entire drill core as the assay sample; each box of core was photographed, and the slides were kept as a visual record of structural features in the core. Short specimens were collected every 10 to 20 ft (3 to 6 m) and retained for a permanent core record. These specimens provided thin sections for later petrographic work and samples for rock strength tests. The coarse rejects from the sample preparation were also retained and were used for later metallurgical work.

5.8.1.4 Sample Preparation and Assaying

The importance of proper sample preparation and assaying cannot be emphasized too strongly. It is essential that a program of assay checks be undertaken throughout the drilling program, and that the results of these checks are available early so that any necessary changes in the procedures can be made before too much of the work has been completed. Two aspects of this procedure need to be checked: reduction of the core down to the assay sample and the analytical work itself.

At Copper Flat, sample preparation was checked by preparing a second pulp from the coarse reject and comparing the assay results from the two samples. The assaying was checked by having the original pulp reassayed by the original lab and by separate labs.

At the beginning of the drilling program in 1975, the core was brought to Tucson, and the pulps were prepared by a commercial assayer. Results from the first 78 reject checks indicated the sample preparation procedure was not acceptable. The differences between original and check copper assays averaged 0.04% copper, but with a standard deviation of 0.23. The *differences* between two pulps from the same sample interval ranged as high as 1.14% copper—nearly three times the average grade of the deposit. The differences between molybdenum assays from the same samples averaged 0.003% but with a standard deviation of 0.022. The highest difference was 0.12% molybdenum—10 times the average grade.

The problem in sample preparation was due to the splitting of samples, which averaged about 36 lb (16 kg), before they were crushed fine enough. The procedure was revised, and a sample preparation laboratory was built on the site. Under the new procedure, each entire sample was crushed to — 1/2 in. (12 mm) before being split, using a Jones splitter, down to one-eighth of the original weight; this one-eighth fraction was crushed down to — 10 mesh before being split again. The resulting split, approximately 2 lb (1 kg), was pulverized to — 100 mesh, and 0.5 lb (0.25 kg) of pulp was selected for assay.

Under the revised procedures, the reject checks were judged acceptable. Over 500 sample pairs were compared, with an average difference of 0.004% copper with a standard deviation of 0.07; the average difference in the molybdenum checks was nil with a standard deviation of 0.009.

Because of logistical problems, the results of the original reject checks were not available until nearly 30 holes had been completed. It was necessary to re-prepare nearly 2000 samples from these holes and reassay them at a substantial cost. It clearly would have been preferable to do it correctly from the onset.

The samples were assayed for total copper and molybdenum; the upper portion of each drillhole was also assayed for nonsulfide copper. The assay checks indicated that the precision was within acceptable limits. Although the range of differences between two assay values from the same pulp was slightly wider in the higher grade samples, there was no significant bias. A set of standards, prepared from Copper Flat ore, was included with each shipment of pulps, and the assays of these standards were also within acceptable limits.

Both gold and silver were known to occur in the ore body, but their concentrations in drill core were generally too low for accurate analysis. Because only the gold and silver recovered in the copper concentrate are paid for, the precious metal contents determined through bench flotation tests were the values used in the financial evaluation. Rougher flotation concentrates were prepared from 330 drillhole composites using the coarse assay rejects. Each composite represented about 80 ft (24 m) of core and weighed about 40 lb (18 kg). Each of these concentrates was assayed for gold and silver to provide data concerning the spatial distribution of precious metals in the deposit.

These rougher composites were subsequently combined into three samples that corresponded to the ore that would be mined during various stages of the planned production. Test work was carried on to the second cleaner concentrate on these three major composites before they were assayed. These results indicated the range of precious metals expected from the copper concentrates: a minimum of 50% of the gold and over 90% of the silver. Although little mineralogical work was done on the concentrates, these high recoveries suggested that most of the precious metals occur with the chalcopyrite.

It is important to remember that assay samples represent a minute portion of an ore body—even in the case of Copper Flat where the drillholes are close-spaced. The core drilled within the minable deposit amounted to about 200 tons—only slightly more than 0.0003% of the minable reserve. Assay pulps from that amount of core totaled about 3 tons (2.7 t). That may seem like a great deal of assay pulp, but it represented only about 0.000005% of the ore body. The time and money spent to provide confidence in precision of the sample data are clearly justified; engineers evaluating a mining property, particularly those representing lending institutions, are interested in more than just tonnage and grade. They are also interested in the precision of the assay data and in the efforts made to determine that precision.

5.8.1.5 Ore Reserve Estimates

Manual reserve estimates were made, using both cross sections and polygons, at various stages of the project. The reserve estimate made for the feasibility study, however, was computer-based using an ore body model of 50 × 50 × 40-ft (15 × 15 × 12-m) blocks. The copper and molybdenum grades assigned to each block were the grades of the nearest drillhole over the same elevation interval—the computer equivalent of a drillhole-centered polygon reserve. It was believed that this method most correctly characterized this particular ore body—that the marked grade changes in the breccia pipe would be offset by the close-spaced drilling, and that the gradual grade changes in the surrounding quartz monzonite would allow the more widely spaced drilling.

The minable reserve was estimated at 60 million tons (54 Mt) with an overall grade of 0.42% copper and 0.012% molybdenum plus credits in both gold and silver. The high-grade breccia pipe was estimated to contain nearly one-half of the recoverable metal but to comprise only one-third of the minable tonnage. Because much of the breccia ore was available for mining early in the project life, its existence had a positive effect on the predicted financial outcome. For that reason, the early development drilling had been directed at defining the grades within the breccia pipe.

To develop confidence in the computer-calculated reserve estimate, a final manual polygon estimate was made using over 100 polygons. The two reserve estimates had the same copper grade and a difference in the molybdenum grade of only 0.001%; the computer reserve indicated about 2% more ore. The differences were not considered to be significant.

This manual reserve estimate took about two employee-months, but it turned out to be well worth the time spent. The work included a calculation of the total tonnage in the pit using vertical cross sections. Although the two ore tonnages matched well, the two estimated waste tonnages did not. On checking, it was found that the computer tonnage had been calculated using a pit model with a severe overhang in part of the pit wall. With that error corrected, the two stripping ratios matched within 1%.

Assay data from the underground metallurgical sampling program, described in the following, provided additional checks on both the drillhole assays and the estimated block grades. Nearly 1600 ft (490 m) of drift were driven to obtain bulk samples. They were designed to intersect five drillholes in the breccia pipe and five in the quartz monzonite.

Each round was assayed for copper and molybdenum, and these results were compared both with the drillhole assays and with the block estimates. In the first case, assays along the drifts from the midpoint between drillholes were compared with assays for the same distance along the drillhole above and below the drift. The second comparison was made using the estimated block grades from the computer block model and the average grade of that segment of the drift that intersected the block. Thirty-eight of the blocks were intersected by drifts, with an average length in each block of about 40 ft (12 m).

The results from the two comparisons were similar and provided some confidence in the typical practice of estimating the ore reserve for porphyry copper deposits on the basis of vertical drillholes. In the first case, the drift samples averaged 0.02% lower copper and 0.007% higher molybdenum than the drillhole samples. In the second case, the drift samples had a lower copper grade in high-grade blocks but a higher copper grade in average and low-grade blocks. The molybdenum results showed the same 0.007% increase in the drift samples as in the first case.

No geostatistical treatment of the assay data was undertaken. Although it seems unlikely that a reserve estimate using geostatistics would have been appreciably different, it would have established confidence limits on the reserve figures. With a geostatistical program in place it also would have been possible to determine whether the close-spaced drilling in the breccia pipe had been necessary. A considerable saving might have resulted.

5.8.1.6 Metallurgical Samples

Preliminary flotation tests on Copper Flat ore were done using the coarse sample rejects from selected intervals of drill core. After it was determined that the high-grade intervals represented a single continuous breccia pipe, underground mining was initiated to collect bulk samples for metallurgical test work. The drifts were planned to intersect roughly equal amounts of breccia and quartz monzonite ore, and the two ore types were kept separate throughout the metallurgical testing. The workings were about 165 ft (50 m) below the surface in order to assure that the samples were free from both oxidation and enrichment; access was through a 15º decline about 625 ft (190 m) long.

A sample tower was built on the site to crush and split the muck; each round was treated separately. The entire round was first crushed to — 1/2 in. (12 mm), and split using a Vezin splitter. Through successive crushing and splitting, the plant produced one sample of 1/4-in. (6-mm) material, representing about 2.5% of the original weight of sample, and a smaller sample of 10-mesh material, about 0.25% of the original. The larger sample was used for pilot plant flotation test work, and the smaller sample was used for assay. Each reject was stacked as a separately marked pile; some of these later had to be used for additional metallurgical work. Several test samples were run through the sample tower to test that assays of each split of the sample corresponded well.

The sample plant crushed and split about 3200 tons (2900 t) of breccia ore and 2800 tons (2500 t) of quartz monzonite, providing roughly 80 and 70 tons (73 and 64 t) of metallurgical samples for the two types. The head grades of the samples were 0.50% copper and 0.017% molybdenum for the breccia and 0.47% copper and 0.021% molybdenum for the quartz monzonite. These grades corresponded well with the estimated head grades for the first few years of production.

Underground development also provided an opportunity to collect large run-of-mine samples; slab rounds from several places in the drifts were collected. These samples were representative of both ore types and were used for crushing and grinding tests.

Unfortunately, in 1975, no consideration was made of semi-autogenous grinding (SAG) in the Copper Flat mill, and no sample was collected to test the amenability of the ore to such a circuit. After the underground sampling was completed, the portal was closed and the drifts were allowed to cave. When it was later decided that a SAG mill might be preferable to conventional crushing, it was necessary to drill 6-in. (15-cm) diameter core holes to provide the test sample. Two holes, one in each ore type, were drilled in 1979 with a total length of 380 ft (115 m). The test work indicated that the ore was suitable for semi-autogenous grinding, and a SAG mill was installed.

It is worth remembering that large-diameter drill core is expensive and is not as suitable as a run-of-mine sample for grinding tests. It is also difficult to get a representative sample from a few isolated drillholes. It would have been simpler and much cheaper to provide a better sample four years earlier.

5.8.1.7 Water Supply

An adequate water resource is critical to the development of any new mine. At Copper Flat, this phase of the development work was actually initiated before the major diamond drilling program got underway in 1975. Discovery of a suitable water supply turned out to be a more difficult task than was anticipated.

Eight-inch (200-mm) rotary drillholes were drilled in the Tertiary Santa Fe Formation east of the proposed tailings area. These holes had a maximum depth of 2000 ft (600 m) and bottomed in the Santa Fe Formation. Pump tests indicated that, although there was adequate water, a sufficient amount could not be produced because of low permeability.

Rotary holes were drilled successively farther to the east until a zone of adequate permeability was discovered about 7.5 mi (12 km) east of the plant site. The water table was approximately 350 ft (105 m) below the surface and 1200 ft (365 m) below the plant site. Because of apprehension that the New Mexico State Engineer might close the water basin to development, three production wells were drilled immediately in early 1976 to assure the water rights. These production wells were 26 in. (660 mm) in diameter, gravel-packed, and cased. They were pump-tested but not equipped with pumps at that time. Pump tests indicated that the individual wells would be capable of producing from 1000 to 2000 gpm (65 to 130 L/s), that maximum pumping from the wells was not expected to lower the water table more than 100 ft (30 m), and that the water supply in the field would have been adequate for the life of the mine.

Eventual design changes to the concentrator meant that the three wells would not have had sufficient capacity for start-up, during which time no water would be returning from the tailings thickener. A fourth well was drilled in the same field during 1980 to cover that shortfall.

5.8.1.8 Nonmineral Exploration

Soon after it was determined that a viable ore body existed at Copper Flat, it was necessary to start a definite drilling and sampling program to locate barren areas suitable for the mill, the waste dumps, and the tailings disposal area. Such an effort is required not only to prevent building the mill over part of the ore body, but also to satisfy the Bureau of Land Management (BLM) that the mill site locations are actually on nonmineral ground. This nonmineral exploration program had three phases.

The first phase was diamond drilling within three potential plant sites. One of these sites was found to be underlain by ore-grade mineralization just outside the perimeter of the proposed pit. The other two sites were underlain by barren andesite, and the selection between the two was based on the haulage distance.

The second phase consisted of surface sampling along the dikes and veins that crossed the plant site and part of the waste dump. Sampling was concentrated along the andesite-dike contacts. Surface samples were supplemented by assays of drill core in the same areas. The samples were assayed for copper, molybdenum, gold, and silver, with consistently low values.

The third phase was the most extensive aspect of the nonminera1 program, and involved a placer evaluation of the tailings area. BLM was particularly interested in this phase because the area coincided with a pre-World War II gold operation that had been the most productive placer in the state during this century (Johnson, 1972). The examination was directed by a consultant recommended by BLM.

Backhoe trenches, up to 30 ft (9 m) deep, were dug throughout the area, and close-spaced large samples were cut vertically down the walls of each trench. Because placer samples should not be assayed, the in-place volume of each sample was measured, run through a mechanical gravity separator, and then run through a sluice. The heavy fraction was then panned, and the free gold was collected and weighed.

The evaluation indicated that little placer gold remained, and it was restricted to recent alluvium within the present drainages. The tailings area was underlain by well-cemented alluvium with no significant placer gold. BLM allowed the site to be used for the tailings disposal area.

5.8.1.9 Costs and Staff

The total cost of the development program described previously was approximately $2.75 million, as detailed in the following:

Development Costs

Drilling (including bonus)		$1,400,000
Six-in. (152-mm) coring		60,000
Sample preparation—assaying		115,000
Underground development		400,000
Adit	$160,000	
Drifts	240,000	
Bulk sample plant		100,000
Construction	75,000	
Operation	25,000	
Water development		525,000
8-in. (203-mm) holes	150,000	
26-in. (660-mm) holes	375,000	
Nonmineral exploration		100,000
Consulting, computer time		50,000
Total		$2,750,000

These figures do not include the costs of metallurgical test work, environmental studies, land acquisition, or the cost of the feasibility studies that were based on the results obtained from this development work. The costs also do not include salaries of the professional staff who worked on the development program. For most of the period from January 1975 to April 1976, the staff consisted of four geologists, one of whom was the project manager, and a drilling supervisor, a surveyor, and a rodman.

Management is commonly not aware of the scope of the geological work necessary in the development of a new mine; the staff at Copper Flat was stretched fairly thin to cover all the various tasks that were required.

5.8.2. NORTH GENERATOR HILL GOLD DEPOSIT, JERRITT CANYON DISTRICT, NEVADA

DONALD J. BIRAK, THOMAS C. DOE, AND DAVID L. STEVENS

The North Generator Hill gold ore body is the largest of a number of discrete bodies of gold mineralization that are collectively mined as part of the Enfield Bell mine and mill complex, located within the Jerritt Canyon Mining District in the Independence Mountains of northern Elko County, NV (Fig. 5.8.2.1). The North Generator Hill gold deposit is typical of other gold deposits within the Jerritt Canyon mining district and is also similar to other bulk-minable open pit gold deposits located in northeastern Nevada in that it contains micron- to submicron-sized gold particles disseminated in altered and highly fractured Paleozoic carbonaceous sedimentary host rocks.

Mineral exploration, originally directed towards antimony, commenced in the Jerritt Canyon area in 1971. By 1973, FMC Gold Corp. (then operating as FMC Corp.) discovered gold mineralization and turned its activities to that commodity. FMC was joined by Freeport Exploration Co. (manager prior to Independence Mining Co.) in 1976, following the signing of a joint venture agreement conveying to Freeport 70% of the interest in, and management of, its holdings within the Jerritt Canyon area. An area of interest was also created by the joint venture such that lands and leases acquired in an area peripheral to the existing holdings would become part of the joint venture agreement. An accelerated exploration program commenced in the summer of 1976, and by the fall of that year, high-grade economic gold mineralization was discovered in the fifth drillhole in the Marlboro Canyon area. Continued drilling discovered ore-grade mineralization in the southern portion of the North Generator Hill area during 1978. By the middle of 1979, encouraging results had been received from both the metallurgical work and ore reserve delineation in the Marlboro Canyon and North Generator Hill areas, and Freeport commenced preparation of a feasibility study and environmental impact study for the Jerritt Canyon area. Mining in the Jerritt Canyon area began in the middle of 1980 in the North Generator Hill and Marlboro Canyon regions. The North Generator Hill ore deposit was not explored aggressively until 1979, and exploration and development drilling along with mining, which began in 1980, has continued to the present.

As of Jan. 1, 1989, the North Generator Hill ore body contains a proven and probable ore reserve of 7,432,329 tons (6.74 Mt) at an average grade of 0.129 oz Au/ton (4.42 g Au/t) at an average waste-to-ore ratio of 2.5:1. The North Generator Hill ore body has produced over 901,000 oz (25 t) of gold, giving an

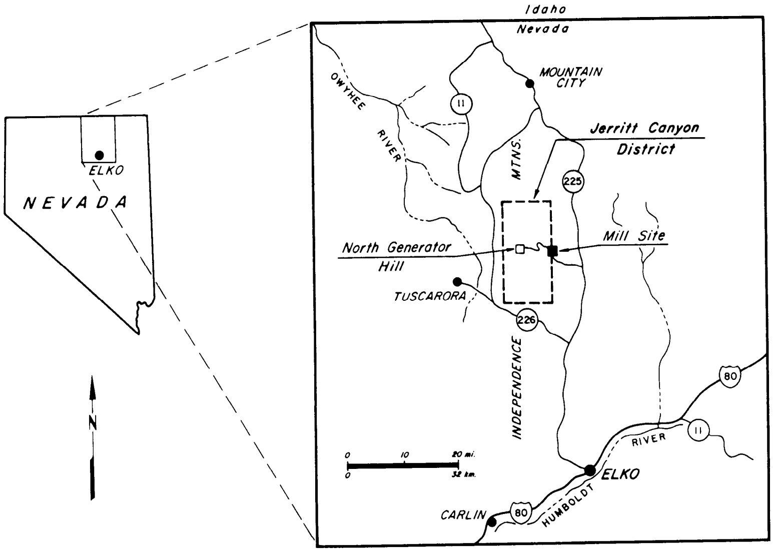

Fig. 5.8.2.1. Index map showing the Jerritt Canyon district, North Generator Hill deposit and Enfield Bell mill site.

overall recoverable reserve in excess of 1,950,650 oz (55 t) of gold. The deposit is currently being mined by open pit methods, and the gold is recovered by standard carbon-in-leach technology, which is preceded by a chlorine oxidation step. Commencing in 1989, a portion of the ore from the North Generator Hill ore body will be oxidized by passing the finely ground ore through a fluid bed roaster. This expanded capacity will give the overall Jerritt Canyon operation a capacity of 2.45 million tpy (2.22 Mt/a) of ore, which will produce between 388,000 and 423,000 oz (11 and 12 t) of gold per year for the joint venture.

This paper describes the discovery and geology of the North Generator Hill gold ore body and discusses the evolution of a geological resource to an ore reserve, with the development of evaluation techniques that led to the current ore reserve calculation practices at the Enfield Bell mine at Jerritt Canyon.

5.8.2.1 Discovery

FMC initially explored in the Independence Mountains for antimony in the summer of 1971. During 1973, FMC geologists recognized the potential for gold in the region and carried out wide-spaced soil sampling that covered, in addition to other areas, a portion of the North Generator Hill gold deposit. The soil samples were analyzed for gold by conventional fire assay techniques, and a gold anomaly was detected in the North Generator Hill area. During the 1974 field season, six NX 1.8-in. (45-mm) diameter core holes totaling 695 ft (212 m) tested the soil anomaly. Because of the difficulties in core drilling the massive jasperoidal silicification so prevalent over the deposit area, the holes did not penetrate the Hanson Creek Formation, which later proved to be the host for most of the gold mineralization in the Jerritt Canyon district. This initial six-hole drilling program encountered only sporadic low-grade intercepts of gold mineralization in the Roberts Mountains Formation. Exploration drilling did not resume on North Generator Hill until 1978.

Following geologic mapping and a comprehensive soil and rock geochemical survey carried out in 1977, several low-level geochemical anomalies and geologic targets were discovered in North Generator Hill. Drilling began in 1978, and by the summer of 1980, a minable ore reserve of 4.1 million tons (3.73 Mt) grading 0.212 oz Au/ton (7.26 g Au/t) had been defined. This initial reserve of 955,924 oz (27 t) of gold has yielded over 901,000 oz (25 t) of gold production with remaining reserves of nearly 1,057,920 oz (30 t) of gold. This increase has been achieved through a continued program of exploration drilling and engineering optimization.

Geology, Alteration, and Mineralization: The North Generator Hill gold deposit is hosted within faulted, folded, and altered sedimentary carbonate and clastic rocks of the upper and lower plates of the Roberts Mountains thrust sequence (Fig. 5.8.2.2, Hawkins, 1982). The (Ordovician/Silurian) Hanson Creek and (Silurian/Devonian) Roberts Mountains Formations form the lower plate of the thrust fault. These shelf and marginal-basinal facies carbonate rocks are truncated by the Roberts Mountains thrust fault, the hanging wall of which contains a thick sequence of deep-water, eugeosynclinal sedimentary, and volcanic facies assigned to the Ordovician Valmy Group. Displacement of these units along the Roberts Mountains thrust fault is believed to have taken place during the Antler Orogeny (Roberts et al., 1958). Subsequently, in the North Generator Hill area, these lithologies have been subjected to several pulses of folding accompanied by both high- and low-angle faulting, igneous intrusion, and, culminating with extensional tectonism, forming the Basin and Range physiography during the Miocene.

The detailed stratigraphic column of the North Generator Hill area is shown in Fig. 5.8.2.3, which has been adapted from Birak and Hawkins (1985).

The relative abundance of gold, organic carbon, and pyrite in the different rock types in North Generator Hill is shown by the bar charts in Fig. 5.8.2.3. The lengths of the bars are qualitative representations of the three components relative to the different rock types. Organic carbon and pyrite are important constituents of the North Generator Hill ore in terms of alteration and ore processing characterization.

Structure: Several tectonic events affected the rocks of the North Generator Hill area. Compressional tectonics dominated the early geologic history of the area. During the Devonian/Mississippian Antler Orogeny, eugeosynclinal, Ordovician rocks were thrust eastward over miogeosynclinal, Devonian and Silurian rocks along the Roberts Mountains thrust fault. This was followed by Permo-Triassic compression related to the Sonoma Orogeny, which resulted in the numerous east-west trending folds in the district and North Generator Hill area. Finally, Cretaceous compression, related to the Sevier Orogeny, produced major east-west faults, such as the Ridge Fault (Fig. 5.8.2.2), and broad north-south folds.

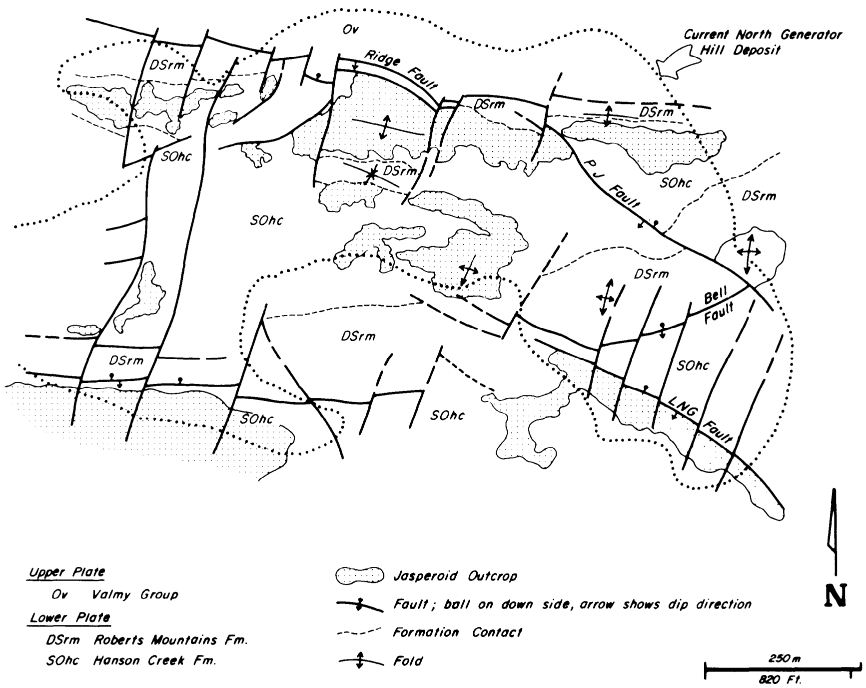

Fig. 5.8.2.2. Generalized geologic map of the North Generator Hill area.

Extensional tectonics became pronounced in the Tertiary, beginning perhaps as early as Oligocene time. The complex pattern of high-angle northeast- and northwest-trending faults, recognized in the area, are related to several episodes of Tertiary extension, culminating with Late Miocene, Basin-and-Range extension.

Alteration of the carbonate and clastic host rocks in the North Generator Hill deposit consists of extensive silicification, carbonization, decalcification, oxidation, and argillization (Birak and Hawkins, 1985). The jasperoid outcrops in the North Generator Hill area are the result of silicification and replacement of the carbonate minerals in the host rocks by quartz (Birak et al., 1987). Three stages of silicification have been documented in jasperoids from the Jerritt Canyon district and the North Generator area (Hofstra and Rowe, 1987; Northrop et al., 1987). The initial stage of silicification is believed to be the result of thermally and/or diagenetically driven connate fluids that were in chemical equilibrium with the host rocks. The second stage of silicification was structurally localized and in part coeval with gold mineralization. Isotopic evidence indicates that the second stage of silicification resulted from the mixing of deep-seated, isotopically exchanged connate fluids with meteoric waters. The final stage of silica deposition post-dates gold mineralization and may represent a continued and enhanced dilution of the second-stage, deeper-seated fluids with meteoric water. Gangue minerals, which may occur in varying abundances with all three stage of silicification, are barite, stibnite, calcite, gypsum/anhydrite, pyrite, variscite, or realgar.

In addition to silicification, carbonization and decalcification are important alteration features at North Generator Hill. Areas of carbonization and decalcification host some of the highest-grade gold mineralization observed at Jerritt Canyon. These alteration types frequently occur together and appear as black, sooty, carbon-enriched sheared zones in calcite- and dolomite-depleted limestone and siltstone host rocks. The carbon in this type of alteration consists of micron-sized discrete grains and aggregates of poorly crystalline graphite (Leventhal et al., 1987). Realgar, orpiment, and cinnabar are common gangue minerals. Carbonate veining occurs peripheral to the carbonized zones and may be remobilized from decalcified areas. Carbonization, based on paragenetic information and carbon crystallinity measurements, occurred early in the hydrothermal history of the rocks of the North Generator Hill area and may have preceded gold mineralization. Some of the carbon may have played a role in precipitating gold from subsequent hydrothermal solutions, although evidence to support this unequivocally has not been found.

Oxidation is characterized by the conversion of pyrite to iron oxides and destruction of organic carbon. The term argillization is used to describe rock that is variably enriched in clay minerals and/or sericite and nearly devoid of pyrite, organic carbon, and primary carbonate minerals. Argillization may destroy primary sedimentary textures, while oxidation alone often preserves even the most delicate of these features. Oxidation and argillization appear to be largely supergene as both are well developed at the present topographic surface, decreasing downward along favorable structures, and are the deepest along contacts, faults, and in the highly fractured cores of tight anticlinal folds. Oxidation and argillization post-date all other alteration types.

Gold occurs as discrete micron- and submicron-sized grains and grain clusters disseminated throughout the host rocks. It has been observed adhering to pyrite and organic carbon, interstitial to terrigenous grains, and included within hydrothermal barite and jasperoidal silica. The North Generator Hill area does not contain intrusive igneous rocks. As such, dating of gold mineralization by direct crosscutting relationships and igneous age-dating is not possible. However, age dating of a granodiorite stock south of the North Generator Hill deposit, coupled with structural paragenesis, suggests that gold mineralization occurred no earlier than 39.2 m.y. ago, and probably no later than mid-Miocene.

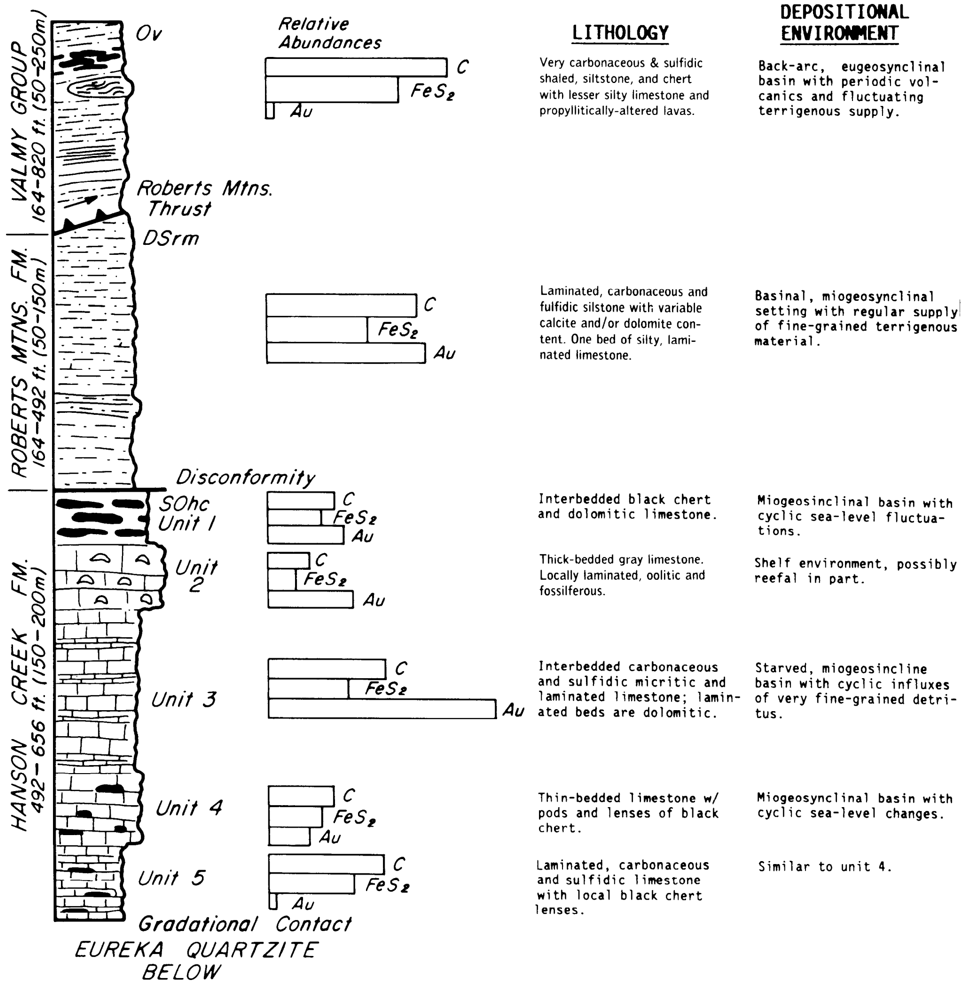

Fig. 5.8.2.3. Stratigraphic section of the North Generator Hill area.

Surface Geochemistry: Several surface geochemical sampling surveys have covered the North Generator Hill area. The earliest, in 1973, was part of a district-wide sampling program during which 135 soil samples were collected on ridges and spurs and random locations across the area that overlays the North Generator Hill gold deposit. Samples, collected with a shovel from holes dug approximately 8 to 12 in. (200 to 300 mm) deep and below the humic layer, were sieved to 80-mesh (0.18 mm) to remove organic material contamination and assayed with standard fire assay techniques. Fig. 5.8.2.4 shows the location of the 1973 soil sampling program, the resulting gold anomaly, and the outline of the North Generator Hill gold deposit. Concentrations of soil gold values greater than or equal to 0.003 oz/ton (0.09 g/t) are outlined on the map. This program was successful in defining a single multiple-sample gold anomaly in the extreme south-southeast portion that covered an area roughly 400 × 1200 ft (122 × 366 m). Several single-sample anomalies were also detected by this initial sampling program.

This initial geochemical sampling program was not an effective exploration tool for several reasons. First, the samples were assayed utilizing conventional fire assay techniques. The resulting range of detection limits was between 0.001 and 0.005 oz Au/ton (0.03 and 0.17 g Au/t). Later sampling programs determined that this detection limit and precision were inadequate. Second, at the time of the survey, sporadic Pleistocene glacial debris partially covered the subcrop of underlying mineralization. This formed a geochemically impermeable layer that covered 20% of the underlying mineralization. A third factor related to prioritization of the anomalies. In 1973, the Roberts Mountains Formation was the favored target for gold exploration in Nevada and accordingly received most of the attention in the Jerritt Canyon district. In the northern portion of the North Generator Hill area, the single-sample soil anomalies were developed over the subcrop of the Hanson Creek Formation, and these anomalies were downgraded.

Drilling: The initial exploration drilling for gold in the Generator Hill area was carried out by FMC in 1974. Six short 1.8-in. (45-mm) diameter core holes were drilled to test the gold soil anomaly over the subcrop of the Roberts Mountains Formation. Holes were not drilled deeper than the Roberts Mountains/Hanson Creek contact for the following reasons: (1) intense silicification and fracturing at the Hanson Creek/Roberts Mountains contact precluded effective core drilling, and (2) lack of knowledge of the potential of the Hanson Creek Formation to act as a host to gold mineralization. Fig. 5.8.2.4 shows the location of the initial six core holes with respect to the original gold soil anomaly and outline of the surface projection of the current ore reserves.

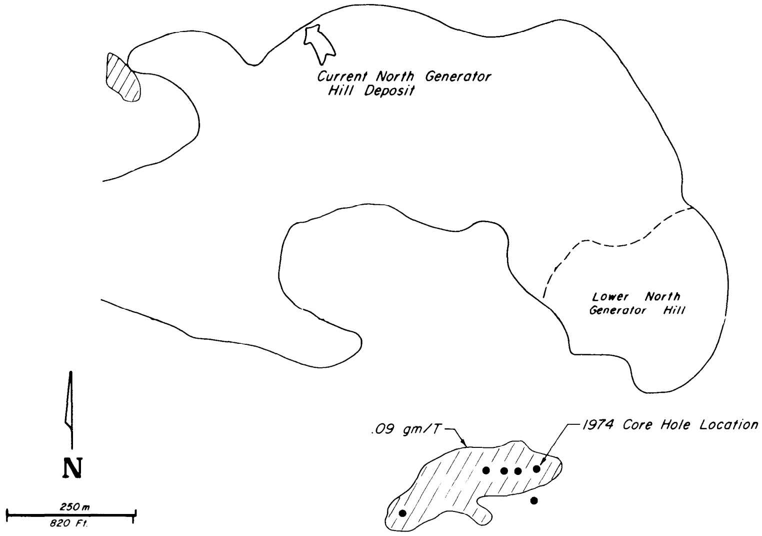

Fig. 5.8.2.4. Location of 1973 anonalous soil samples (cross-hatched areas) and first six holes drilled in North Generator Hill. Conversion factor: 1 oz/ton = 31.25 g/t.

Assay difficulties were encountered in analyzing the 1974 core drilling from Generator Hill. The initial gold assay, performed by standard sodium cyanide extraction and analysis by atomic absorption (AA), yielded accurate results only on the oxidized portions of the core. A considerable amount of the core was unoxidized, containing organic carbon and pyrite that did not allow the gold to be solubilized by sodium cyanide. It was later discovered that fire assaying or a roasting step prior to cyanidization was required to determine the gold content of the carbonaceous and sulfidic host rock. With this knowledge, all subsequent analyses were performed using either fire assaying or cyanide extraction preceded by roasting or heating the sample pulp in air at approximately 1000°F (550°C), which oxidized the carbonaceous material and sulfide minerals.

Drilling commenced in North Generator Hill in early 1978 following the identification of geochemical and geologic targets developed during the 1977 field season. In early 1978, seven widely spaced holes were drilled using rotary-percussion drilling. Six of these holes detected encouraging gold mineralization and three encountered ore-grade mineralization; > 5 ft grading 0.05 oz Au/ton (> 1.5 m grading 1.7 g Au/t). The location of these seven holes, as well as the six core holes drilled in 1974, is shown on Fig. 5.8.2.5. The most important aspect of the 1978 drilling was the discovery of gold hosted within the Hanson Creek Formation. This opened up a much larger area to exploration throughout the Jerritt Canyon district and indicated that North Generator Hill could host a significant tonnage of bulk-minable gold mineralization.

5.8.2.2 Cost of Discovery

Prior to 1977, FMC had spent approximately $1.5 million in exploration in the Jerritt Canyon district. Of that amount, it is estimated that less than $50,000 had been spent in the area of the North Generator Hill ore deposit.

Between 1978 and 1980, a total of over 95,000 ft (29 km) of drilling in approximately 200 holes had been completed in the North Generator Hill area. The total cost of this program was approximately $1.4 million.

The procedures established in the development drilling of the North Generator Hill deposit are largely followed today in our exploration and reserve definition practices throughout the Jerritt Canyon district.

5.8.2.3 Delineation Drilling and Sampling

Drilling: Three types of exploration and delineation drilling were carried out at North Generator Hill: rotary-percussion drilling with conventional circulation, rotary-percussion drilling utilizing dual wall pipe and reverse circulation, and core drilling. Core drilling was not extensively used due to the high costs associated with drilling in intensely silicified and fractured zones. Conventional circulation was used in areas yielding good sample recovery (solid ground conditions and minimal voids), and reverse circulation was used in cavernous areas or areas of broken ground. To check the quality of samples returned from rotary drilling, a series of drill twinning tests were made. These consisted of drilling proximal to several rotary drill sites with either reverse circulation rotary methods or with core. The holes were usually between 5 and 15 ft (1.5 and 4.5 m) apart. Closer spacings were not possible due to the probability of lost sample circulation from the twin hole into fractures adjoining the original hole. Overall, the comparison between the twin and original hole sample assays was acceptable. However, it was discovered that a low-grade "assay tail" of contamination that occurred in several of the conventional circulation rotary holes was not present in the reverse circulation or core twin holes. This finding resulted in a switch from conventional circulation to reverse circulation drilling in all further exploration holes at Jerritt Canyon. It was also necessary to determine if the reverse and conventional circulation drilling sampling methods were obtaining a representative sample. This was verified by collecting blow-by dust and comparing the assays with the coarse cuttings samples. The dust samples yielded gold assays that were slightly higher in grade than the coarse fraction sample assays. The overall correlation coefficient between the coarse and dust sample assays was 0.89 with the worst correlation in the < 0.02 oz/ton (< 0.69 g/t) assay range. Since the poorest comparison between dust and coarse sample assays was in the lowest grades, and since the remainder of the samples compared well, it was determined that air-circulation drill samples were acceptable.

The initial grid of exploration drilling at North Generator Hill was carried out in the spring of 1978 and consisted of 20 drillholes totaling approximately 6890 ft (2100 m), scattered across the eastern portion of the area (Fig. 5.8.2.5). These initial holes were established on a staggered 400-ft (122-m) grid to cover as much of the primary target area as possible during the

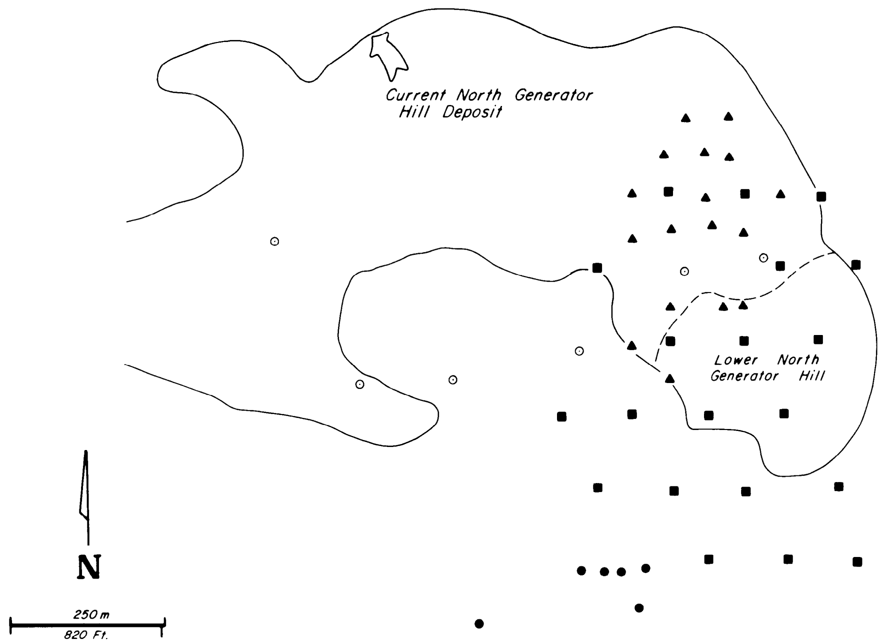

Fig. 5.8.2.5. Location of all holes drilled in North Generator Hill by the end of 1978. Denoted are 1974 exploration (solid dot), early 1978 exploration (open dot), 1978 400-ft (122-m) grid (solid square) and 1978 200-ft (61-m) grid (triangles) holes.

early portion of the field season. Seven of the 20 holes encountered encouraging thicknesses and grades of gold mineralization, with the best single intercept being 85 ft (26 m) averaging 0.264 oz Au/ton (9.05 g Au/t).

Because of the wide-spaced nature of the gold mineralization discovered in this first-pass drilling and the significance of some of the grades encountered, fill-in drilling on a 200-ft (61-m) grid was initiated. Seventeen holes totaling 4626 ft (1410 m) were completed (Fig. 5.8.2.5), seven of which intersected ore-grade gold mineralization. Although the percentage of ore-grade holes marginally increased from the first to the second drilling phase, the area of gold mineralization increased significantly, and the decision was made to accelerate the program and continue drilling through the winter of 1978-1979. The drill grid was modified in this accelerated program so that holes would form a five-spot pattern with a hole at each of the corners of a 200-ft (61-m) (east-west) and 400-ft (122-m) (north-south) rectangle and one hole in the center. Drilling continued throughout the spring and summer of 1979, and by the end of that year, a total of 226 holes had been completed totaling over 68,898 ft (21 km) of drilling. Additional delineation drilling continued on a five-spot grid during the summer seasons of 1980, 1981, and 1982.

During 1983, the drill grid was closed to 100-ft (30.5-m) hole spacings, and this tighter control resulted in the addition of approximately 820,120 tons (744 kt) of reserves containing an average grade of 0.244 oz/ton (8.36 g/t). The tighter grid was deemed necessary because of abrupt variations in the continuity and grade of mineralization and the need to determine more accurately grade boundaries for mine planning purposes. Reserve development drilling today continues on a 100-ft (30.5-m) grid, as this has been determined to be the optimum spacing for mine design requirements and ore-zone definition.

Sampling: In 1978, drill sampling was standardized to a regular 5-ft (1.5-m) interval. Previously, sampling intervals were established subjectively and based on logged geologic intervals of nonuniform lengths.

The 5-ft (1.5-m) interval for a rotary-percussion drillhole 5 in. (127 mm) in diameter would theoretically generate 99 lb (45 kg) of sample. However, fractured and open ground in addition to unrecovered dust resulted in considerably less sample being collected for each interval. At the drill site, the sample was reduced by passing it over a single tier riffle-type splitter with adjustable splitting bars. A technician at the drill site was responsible for the collection, splitting, and labeling of the samples. Three samples were collected from each interval: an 8-lb (3.6-kg) assay sample; an 8-lb (3.6-kg) duplicate assay/metallurgical sample; and a 10.6-oz (300-g) geologic sample. The geologic sample was collected in a clear plastic bottle and stored in a conventional cardboard core box. In this manner, the sample was readily retrievable for geologic logging.

All samples were initially analyzed for gold using AA preceded by an oxidative roasting. Samples returning > 0.02 oz Au/ton (> 0.68 g Au/t) were additionally analyzed with a dilute cyanide extraction not preceded by roasting to determine the amount of readily “leachable” gold as a metallurgical control. Assays returning ≥ 0.02 oz Au/ton (≥ 0.68 g Au/t) were also fire assayed as an additional check on the roasted AA assay. Using commercial laboratories, assay turn-around time varied between two and four weeks for all three assays.

5.8.2.4 Calculation of Reserves/Resources

A variety of methods, including cross sections, plan and block-model polygons, and geostatistics, have been used to estimate the reserves in the North Generator Hill deposit.

Initially, the geologic resource was determined utilizing cross-sectional polygons as follows:

Table 5.8.2.1. North Generator Hill Reserve Calculations, March 1979

Method	Tons (Tonnes)	Grade, oz/ton (g/t)	Total oz (kg) Au	Cutoff grade,[a] oz/ton (g/t)	
Cross sections	1,308,113	0.25	357,114	0.04	(O)
	(1,186,700)	(8.53)	(10,124)	(1.37)	(O)
				0.09	(C)
				(3.11)	(C)
Plan polygons	1,159,521	0.28	352,140	0.04	(O)
	(1,051,900)	9.49	(9,983)	(1.37)	(O)
				0.10	(C)
				(3.43)	(C)
Block model polygons	901,360	0.25	246,071	0.05	(O)
	(817,700)	(8.53)	(6,976)	(1.61)	(O)
				0.12	(C)
				(4.01)	(C)

[a](O) = oxide ore; (C) = carbonaceous ore.

1. North-south oriented cross sections were compiled at a scale of 1 in. = 50 ft (10 mm = 6.0 m) and spaced 100 ft (30.5 m) apart. Vertical drillholes were plotted on the sections.
2. Drillhole gold assays were subdivided into oxidized and carbonaceous metallurgical types.
3. Cutoff grades were estimated to be 0.04 and 0.10 oz Au/ton (1.37 and 3.43 g Au/t) for oxidized and carbonaceous ores, respectively.
4. A 10-ft (3-m) minimal drill intercept thickness (anticipated bench height) was used for grade averaging.
5. Gold grades were projected halfway to sections on either side of the reserve section.
6. Cross-sectional areas were determined by manual planimetering.
7. The areas were multiplied by 100 ft (30.5 m) to derive volumes.
8. A tonnage factor of 14 ft^3/ton (0.40 m^3/t) was applied.

In addition to the cross-sectional calculation method discussed previously, both plan-view polygons and block model polygons were used to prepare tonnage and grade estimates as a check to the cross-sectional method. These results are tabulated on Table 5.8.2.1.

Both cross-sectional and plan-view polygon ore reserve calculations indicated the same relative amount of contained ounces of gold; however, tonnage calculations varied by 13% and grade by 11%. These estimates were not conditioned by mining and processing costs, ore recoveries, stripping ratio, or pit design and were only used to model the overall picture of the in-situ gold resource.

The third reserve calculation method, block-model polygons, was derived from regularly shaped and sized computer-generated blocks throughout the deposit. The block model was created by compositing drillhole assays into 15-ft (4.6-m) lengths corresponding to the planned mining bench elevations. The deposit was then subdivided into a three-dimensional grid of 50 × 50 × 15 ft (15.2 × 15.2 × 4.6 m). The composited assay data was merged with the block file so that grades could be assigned using horizontal polygonal-extensional methods. Grades were assigned from the composited grade of the closest exploration drillhole to the block. In assigning grades, a search radius of 100 ft (30.5 m) was used except at the periphery of the deposit where a search radius of 50 ft (15.2 m) was applied. This minimized the overextension of reserves at the periphery of the reserve.

In summary, the tonnage and grade differences expressed on Table 5.8.2.1 by the various ore reserve calculation methods are attributable to

1. Varying cutoff grades assigned to the oxide and carbonaceous ores.
2. Vertical compositing to uniform bench thickness of 15 ft (4.6 m) in the block model reserve.
3. Mine design limitations which exclude some low-grade intercepts or isolated high-grades as uneconomically minable.
4. Search radius of 50 ft (15.2 m) on the edges of the ore zone.
5. Data from eight additional drillholes were included in the cross-sectional and plan-view polygonal estimates and not included in the computer-generated block model.

None of the reserve estimations were final at this point as the zone was open to further drilling in a number of directions and production cost estimates were preliminary. However, the minable reserve analysis generated from the block-model polygons indicated an economically exploitable body of gold mineralization and justified initiation of a feasibility study and continued exploration. The discrepancy between the reserve and resource estimates by the various calculation methods was anticipated and did not alter the decision to proceed with plans for development.

Until late 1979, the polygonal block-model reserve estimates were believed to be representative of future mine production. As only a few disseminated gold deposits were being mined at that time, potential ore estimation problems were not well understood. However, several other operations were experiencing unanticipated dilution, and this potential problem was addressed by the project staff at Jerritt Canyon.

To better assess the potential for grade dilution during mining at North Generator Hill, three additional ore-reserve calculation procedures were made: (1) insertion of an arbitrary dilution factor, (2) a kriged geostatistical approach, and (3) a modified polygonal block reserve utilizing a capped maximum assay value.

The dilution model involved inflating the tonnage factor by 15% and keeping the contained ounces constant. Subsequent production experience proved that a uniform dilution factor provided insufficient correction for the mining dilution and the method was abandoned. In 1980, Fluor Mining and Metals was contracted to make a kriged geostatistical study of the Lower North Generator Hill portion of the deposit. This is the same area that was previously evaluated with cross-sectional, plan-view, and block-model polygons in 1979. The objectives of this study were to determine (1) how much error could be expected in the polygonal block model, and (2) if the error could be minimized by grade-control procedures. A series of variograms was compiled in an attempt to model the entire ore zone, grade selective portions, and geologically selective portions. Using a

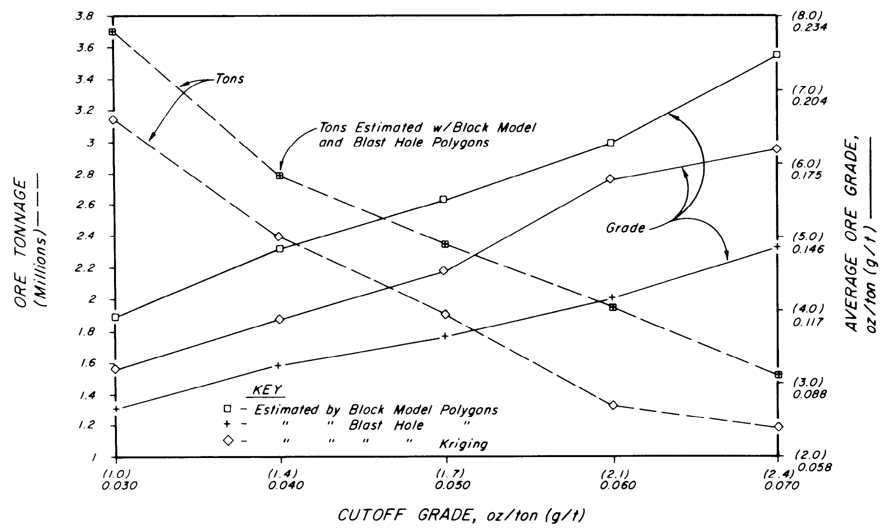

Fig. 5.8.2.6. 1980 North Generator Hill geostatistical evaluation, grade and tons, with different estimation methods.

volume-variance relationship, it was possible to estimate the amount of ore above any given cutoff grade that would be recovered with blasthole sampling and mining. Metallurgical and mining cost parameters were not considered in this exercise.

Resource estimates of tonnage and grade using block-model polygons were compared to estimated minable tonnage and grade using blasthole polygons and blasthole kriging techniques. The data in Fig. 5.8.2.6 show that the block-model polygons overestimated grade when compared to the grade selected using blasthole polygons and overestimated both tonnage and grade compared to kriged blasthole estimations. Kriging yielded grades between those of the block model polygons and the blasthole polygons. Based on these findings, additional series of geostatistical evaluations were designed to address the impact of selective mining unit (SMU) sizes and the geometry of these units.

In an effort to determine the best reserve calculation method, a second modification to the polygon block reserves was made that consisted of capping the block grades to a maximum value. As was later determined, each deposit in the district would have its own maximum capped grade. In North Generator Hill, the capped grade was determined to be 0.45 oz Au/ton (15.42 g Au/t). Capping has been effective in reducing the overestimation of the spatial extent of high compositive drillhole grades while not affecting the lower grades. The method for determining this value was as follows:

1. All composited exploration drillhole assays were sequentially ranked by decreasing grade.
2. Anomalously high-grade samples were eliminated from the sample population. In the case of North Generator Hill, values in excess of 0.75 oz Au/ton (25.7 g Au/t) were eliminated.
3. Subsets were established of the remaining rank-ordered composite data into groups of different numbers of composites (i.e., 4, 5, or 6 composites in a group).
4. The composited gold grades were averaged for each of the different group sizes.
5. The average composited gold grade was plotted against the sequential group number.
6. The major inflection point of the curve was visually established and the capped grade determined.

Cumulative frequency plots have also been used in the mining industry to determine capped grades. However, unlike cumulative frequency, the rank-order method is not as strongly affected by the range of the data set. The rank-order cap grade calculation was determined to be the most accurate grade control and is the method currently practiced at Jerritt Canyon.

All the mine plans and reserve estimates for the deposits in the Jerritt Canyon District are made using a US$450/oz gold price, current or forecasted operating and capital costs, recovery parameters, and open pit slope angles determined by geotechnical studies. The average pit slope angle is approximately 42º. Ore reserves are calculated at the end of each year following completion of the year's exploration and delineation drilling program and the deduction of the tons (t) of ore and ounces (kg) of gold produced.

Table 5.8.2.2 lists North Generator Hill ore reserves as tabulated at the end of each year since 1979. The overall increase has been accomplished by continued exploration and development drilling, ore processing revisions allowing a reduction of cutoff grade, and a bench height increase. Heap leaching became a viable process for North Generator Hill ores in 1985, thus adding to the ore reserve inventory.

Reserve estimates are only as good as production experience will allow. North Generator Hill production has been tracked against local reserve estimates since 1981. Since conversion from 15- to 20-ft (4.6- to 6.1-m) bench heights, block model polygons in North Generator Hill have been found to underestimate mined tonnage by 14.9% and overestimate grade by 9.4%. Obviously, the variance is affected by both the amount of low-grade ore mined vs. predicted and the accuracy of the grade estimate on high-grade exploration composites. Because of the impracticality of drilling a regular grid of delineation holes tighter than 100 ft (30.5 m) apart, low-grade ore will often be more abundant than predicted. In addition, low-grade ore often occurs blanketing high-grade and in separate ore zones without a high-grade core. Usually the latter case is the most difficult to define with delineation drilling. Fig. 5.8.2.7 shows the geology of a typical mining level of North Generator Hill superimposed with blasthole sample grade contours for comparison. Exploration drillhole locations are also denoted in Fig. 5.8.2.7. Note that the mineralization consists of several separate ore zones. Ore is frequently controlled by high- and low-angle structures as well as in the cores of anticlinal folds. The individual ore zones are much more

continuous horizontally than vertically. Frequently, the mine geologist will drill holes to fill in geologically critical ore zones for grade and volume definition. These holes will be located to yield the most geologic information on ore zone size and shape rather than on a predetermined grid.

Grade Control: Calculation of the grade of a selective mine unit is the fundamental role of a mine grade control program; the SMU being a function of production requirements balanced against dilution. Production requirements include milling rate, relative cost savings between different mine bench heights, rock fragmentation characteristics, and ore to waste ratios. At North Generator Hill, dilution consists of both mining and estimation types.

Mining dilution refers to the intermingling of ore and waste by raveling at ore and waste boundaries, drill sampling errors, shovel or loader operator error, or truck driver misclassification. It is a relatively fixed problem that must be addressed with proper training and supervision. As such, Independence Mining Co. does not apply a mining dilution correction factor into grade control.

Estimation dilution is a bigger problem than mining dilution and one that can be modeled and mitigated by use of geostatistics.

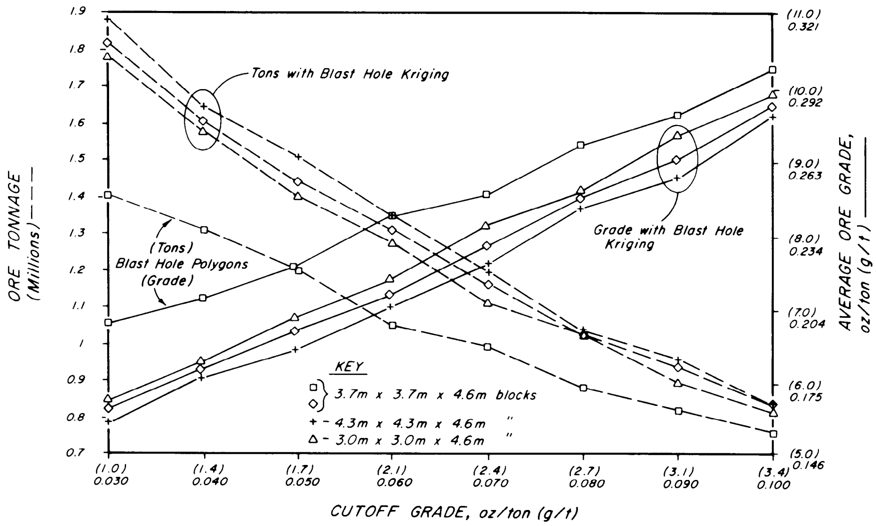

Fig. 5.8.2.8. 1980 North Generator Hill: recoverable grade and tons with different selection methods and selective mining unit sizes.

Estimation dilution refers to the variance inherent in the selection method, such as kriging or polygons, when compared to the actual grade mined for the same volume. These errors are usually normally distributed and their effects can be quantified by normal probability laws. Of the two selection methods, only kriging will minimize the estimation variance and thereby reduce the effects of estimation dilution.

The effect on recoverable reserves by both SMU size and selection method was examined in detail during preproduction and early production phases of North Generator Hill development. Fig. 5.8.2.8 graphically displays how recoverable tons and grades are affected by decreasing the horizontal dimension of the SMU. These curves were modeled using kriging and the volume-variance relationship taken from the deposit variogram. The volume-variance relationship relates the estimation variance to block volume: large blocks will be less variable than small blocks, but will result in a lower average grade. After considering the three curves and the estimated mining costs for each horizontal SMU size, the 12 × 12 × 15-ft (3.7 × 3.7 × 4.6-m) SMU size was chosen (Fig. 5.8.2.8, bold lines). As a comparison, the recovered tons and grade with central blasthole polygon of 12 × 12-ft (3.7 × 3.7-m) dimension are also displayed. Blasthole polygons would estimate less recovered ore tons but at significantly higher grade. This follows one of the basic axioms of geostatistics applied to mining: polygons tend to underestimate the spatial influence of low-grade samples and overestimate the spatial influence of the high-grade ones.

Metallurgical Evaluation: North Generator Hill ores were part of a district-wide metallurgical evaluation of all the ores in the Jerritt Canyon district. This decision ensured the timely completion of the mine and mill feasibility study for the entire Jerritt Canyon project. However, implementation of standard sampling and analytical procedures occurred much earlier and formed the foundation for later metallurgical tests.

Pre-metallurgical work began in early 1977 with a change in the assay procedure of exploration drill samples. The first change involved utilization of either a roast AA or fire assay for total gold determination. Both methods produced more accurate measures of the total in situ gold grades than the no-roast AA method used previously. Later, fire assaying replaced the roast AA assay for total gold analysis, the accuracy of which was dependent upon amount of sulfide-sulfur, organic carbon, and carbonate minerals in the ore samples (constituents that do not hinder accurate fire assaying). The no-roast AA assay, performed on samples with fire assay values 0.02 oz Au/ton (0.68 g Au/t), was used only to give an indication of the "leachability" of the total in situ gold. This measure, expressed by the ratio of the no-roast AA assay to fire assay, is referred to as the "leach ratio." Samples with leach ratios ≥ 0.60 were classified as oxidized and those < 0.60 were carbonaceous. Thus the total inventory of mineralized rock could be metallurgically categorized.

Based upon leach ratios, it was clear that the North Generator Hill carbonaceous and oxidized ores were quite intermixed. A limited program of core drilling was conducted in 1978 and 1979 to (1) provide pristine samples of different ores for metallurgy and grinding tests and (2) enable a more detailed geologic examination of the ore zones. All of the core, roughly 1.8 in. (45 mm) in diameter, was photographed, weighed, and split in half. Photographs provided a record of the core, while weight measurements facilitated bulk density calculations. After splitting and assaying, the geologist logged and selectively sampled the core for specimens of typical and unusual ore, waste, and gangue mineralogy. In addition, measurements of rock quality (RQD) provided information for future geotechnical studies pertinent to mine designing. Last, mineralized sections of the remaining core became the stock from which grinding and more accurate leachability tests were performed.

Because of the high costs, relative to rotary drilling, core drilling for metallurgical testing was site- and goal-specific. To decrease the costs of metallurgical sampling, a program of rotary drill bulk-sampling was begun in 1978. In addition to the three assay and geologic samples collected from every 5 ft (1.5 m) of rotary drilling, a large sample weighing approximately 40 lb (18.2 kg) was also collected. Bulk samples that contained ore-grade gold mineralization were retained for metallurgy. Bench-scale tests performed with the drill bulk samples of varying leach ratios yielded a relationship to leachability that was used in subsequent mill designs and mine planning. The tests involved pulverizing the drill sample to approximately 98% passing 0.008 in. (0.208 mm), followed by rolling agitation of 1.3 lb (600 g) of ore for 20 hr in the presence of 0.2 oz/a (0.6 g/a) NaCN solution and 7 oz (20 g) of activated charcoal. The gold recovery was

Table 5.8.2.3. Mined vs. Milled Ore; Total Jerritt Canyon (1981 through 1988)

	Mined	Milled and stockpiled	% Difference
Tons of ore (tonnes of ore)	10,042,497 (9,110,440)	10,231,874 (9,282,200)	+3.6
Grade, oz Au/ton (g Au/t)	0.23 (7.74)	0.21 (7.35)	-5.2
Oz Au (kg Au)	2,491,646 (70,637)	2,444,803 (69,309)	-1.9

determined by comparing the total gold in the feed sample to that remaining in the pulp after leaching. The degree of leachability, a function of several geologic characteristics of the ore, was affected most by the amount of organic carbon in the ore. Tests indicated that at leach ratios of 0.60, mill-modeled recoveries would be at least 75%. The ratio of oxidized ore to carbonaceous ore was roughly 50:50, and the mill feed rate and recovery circuit was designed accordingly.

A significant portion of the ore in the Jerritt Canyon district and North Generator Hill was not only unamenable to straight cyanide leaching but would scavange gold from gold-bearing cyanide solutions. This phenomenon, termed "preg-robbing," was known to exist in other disseminated gold deposits in Nevada. However, neither the strength nor extent of the preg-robbing Jerritt Canyon ores was known. A simple analytical test helped put the problem into perspective. The test was similar to a standard no-roast AA assay with the exception that a gold-bearing cyanide solution was used as the lixiviant instead of pure cyanide. The gold concentration of the pregnant solution was 0.29 oz/ton (10 g/t). Atomic absorption analysis of the final leach liquor, after contact with the drill sample, yielded a gold value that was a percentage of the total gold content of the sample plus the known standard. This was expressed as the percentage of gold robbed by organic carbon constituents of the ore. Leach ratios could not provide this information alone due to inherent inaccuracies in the no-roast AA assay. The work revealed that below leach ratios of 0.10, carbonaceous ore samples would rob between 97 and 100% of the total available gold; the actual limits of the preg-robbing were not measured, but are finite. Consequently, research began to find a method to beneficiate the carbonaceous ores in Jerritt Canyon. The result was a precursor to the chemical oxidation step, using chlorine, that is used on selected ores from the Enfield Bell mill today.

Metallurgical Balance: An accurate comparison of ore tons mined from North Generator Hill vs. milled is difficult because the Jerritt Canyon mill simultaneously processes ore from several deposits. All of the deposits in the Jerritt Canyon district have different ore-to-waste ratios. This, coupled with the fact that the mining operation is located approximately 7 mi (11.3 km) from the mill site, precludes direct feed of ore into the primary crusher. Mill-site ore stockpiles and several mine-site stockpiles must be used to maintain a balanced feed to the mill while keeping pace with waste stripping requirements. A comparison of mined to milled ore tons is performed on a year-to-year basis as a check of the grade-control program.

The comparison of tons mined to tons milled for the entire Jerritt Canyon project, from the beginning of production to the end of 1988, is depicted in Table 5.8.2.3.

This analysis shows that the mill at Jerritt Canyon receives a greater tonnage and lower-grade material than is produced by the mining operations. This variance reflects the total cumulative project dilution incurred since the commencement of production. These errors resulting in the dilution are a function of inaccuracies in mill throughput calculation, stockpile volume calculation errors, ore misclassification, assay variability, bulk-density variations, bank-volume calculation errors, and estimation variances inherent to the grade-control program. These overall variations are considered to be within the tolerance of anticipated project economics and in general reflect a high level of precision in the accuracy of grade determination and control in the North Generator Hill ore deposit. As each ore deposit will have its own characteristics, it is important that procedures for ore grade determination and mining control be developed in a flexible manner that is responsive to the geological and metallurgical characteristics of the individual deposit.

5.8.2.5 Conclusions and Current Practice

The North Generator Hill gold deposit is a typical "Carlin-type" disseminated gold deposit hosted in Paleozoic sedimentary rocks. The deposit was discovered by a combination of geological mapping, surface soil geochemistry, and rotary-percussion drilling. The first prospecting work in the area, based on a model that assumed the Roberts Mountains Formation to be the sole host to ore-grade gold mineralization, failed to test the potential of the deposit as it is currently known. Later review and reassessment of this initial exploration philosophy, as well as refinements in low-level gold analyses and rotary drilling methods, were successful in the discovery of the deposit. Yearly exploration and development costs reflect the changing priorities of the deposit spurred by these reviews and reassessments. Table 5.8.2.4 lists the yearly costs incurred in the North Generator Hill area and yearly footage of exploratory and development drilling.

The yearly costs include those typically incurred in an exploration program such as drilling, road and drill-pad construction, geochemical sampling and analysis, salaries, land payments, materials, and miscellaneous items. Costs after 1980 are not included in Table 5.8.2.4, even though delineation drilling is on-going, since the deposit was put into full production in 1981.

The North Generator Hill ore deposit is mined by open pit methods utilizing 20-ft (6.1-m) benches. Benches, drilled using rotary, down-hole hammer drills, are blasted with ANFO and excavated by hydraulic shovels and mechanical-drive trucks. Samples from blasthole drilling are assayed for total gold content and cyanide soluable gold content. The blastholes, drilled on 14 $\times$ 14-ft (4.3 $\times$ 4.3-m) square grids, define the current minimum selective mining unit size; the corners of the SMU are defined by blastholes. The blasthole gold values are used to calculate the grade of the SMUs by averaging the sample assay values of the four holes in a single SMU. This system was designed using geostatistics to determine the effect that different blasthole geometries and spacings would have on recoverable reserves. Compared to actual milled production, this grade-control system works quite well with less than 2% error on tonnage and not more than 4% error on grade.

5.8.3 EXPLORATION AND DEVELOPMENT GEOLOGY OF THE TWENTYMILE PARK UNDERGROUND COAL DEPOSITS, NORTHWEST COLORADO

R.G. MATEER AND J.M. MERCIER

This case study focuses on the development of a coal resource and covers the exploration effort required to identify and evaluate an underground coal reserve in northwest Colorado. It further describes the key geologic factors and considerations for successful underground mine design and production planning.

The area of interest, Twentymile Park, is located in Routt County in northwest Colorado. Cyprus Coal Co., a wholly owned subsidiary of Cyprus Minerals Co., controls 20,400 acres (82.6 Mm^2) of coal lands in the area. Cyprus acquired the property through its acquisition of Getty Coal Co. in 1985. When acquired, the property assets included an operating surface mine with attendant surface facilities and a small pilot mine (Foidel Creek mine) with federal, state, and private coal leases comprising the Twentymile Park underground reserve. In early 1981, studies indicated the Twentymile area contained a potential for over 300 million tons (272 Mt) of in-place, underground minable coal of excellent quality. An earlier 1979 test mine in the underground reserve, however, encountered adverse geologic conditions including multiple small faults, poor roof and floor rock, and high water inflow rates. Because of the apparent size and high quality of the underground reserve, a concerted effort, the Twentymile Park Project, was put forth to address the complex subsurface geology and to outline, as expeditiously as possible, an economically minable reserve. A primary focus of the Twentymile Park Project was to enhance confidence levels on various aspects of resource minability and provide accurate information for subsequent mine planning and development.

Cyprus Yampa Valley Coal Corp. (subsidiary of Cyprus Coal Co.), is in the final stages of surface reclamation due to surface coal reserve depletion. After several years of exploration, planning, and development, the Twentymile underground reserve successfully produced moderate development tonnages, which were marketed to regional utility companies. A longwall face was installed in the mine during 1989. Average raw tons per longwall shift for the first six months of 1991 averaged over 6300.

5.8.3.1 Introduction

Twentymile Park is located approximately 150 mi (240 km) northwest of Denver, CO. Access is from Steamboat Springs, 20 mi (32 km) by US Highway 40 and Colorado State Highway 131 to Oak Creek, CO, thence by paved county roads to the facilities of Cyprus Colorado Yampa Coal Co. A spur of the Denver and Rio Grande Western Railroad, present along the eastern margin of the area, ends at the Cyprus Colorado Yampa loadout facilities at the southern end of the Twentymile Park area (Fig. 5.8.3.1) shows the location of the Twentymile Park area and Cyprus' coal operations).

Twentymile Park is located within the Yampa Coalfield, which is approximately 600 mi^2 (1554 km^2) in area and is bounded on the east by the crystalline core of the Park Range and on the west by volcanic rocks of the White River Plateau. Topography in the area consists of "parks" (semi-enclosed basins), rolling and sloping plains, resistant bounding cliffs, and incised gulches developed above gentle folds. Surrounding the area are the rugged Elkhorn Mountains to the north and the Park Range to the east. Rough rolling hills to the west comprise the Williams Fork Mountains. Major drainage is supplied by meandering tributaries of the Yampa River. Elevations range from 6600 to 7600 ft (2012 to 2316 m) above sea level.

The climate of the Twentymile Park area is semi-arid with an annual precipitation of approximately 16 in. (401 mm) per year. A significant amount of this precipitation is in the form of snow.

Exposed slopes and rolling plains are vegetated with scrub grasses, brush, or are dry-farmed. Soil cover in the project area is generally thick (10 to 30 in. or 250 to 760 mm) and yields crops of winter wheat and barley.

Cyprus' Twentymile Park property has been subdivided into three generalized blocks (Fig. 5.8.3.1). The Tow Creek area encompasses the northern portion of the project area and consists of 11,000 acres (44.5 Mm^2) of private and state leases. The Middle Creek area includes the old Middle Creek test mine and adjacent past surface mine operations on the eastern border of Twentymile Park. Approximately 3200 acres (13 Mm^2) are

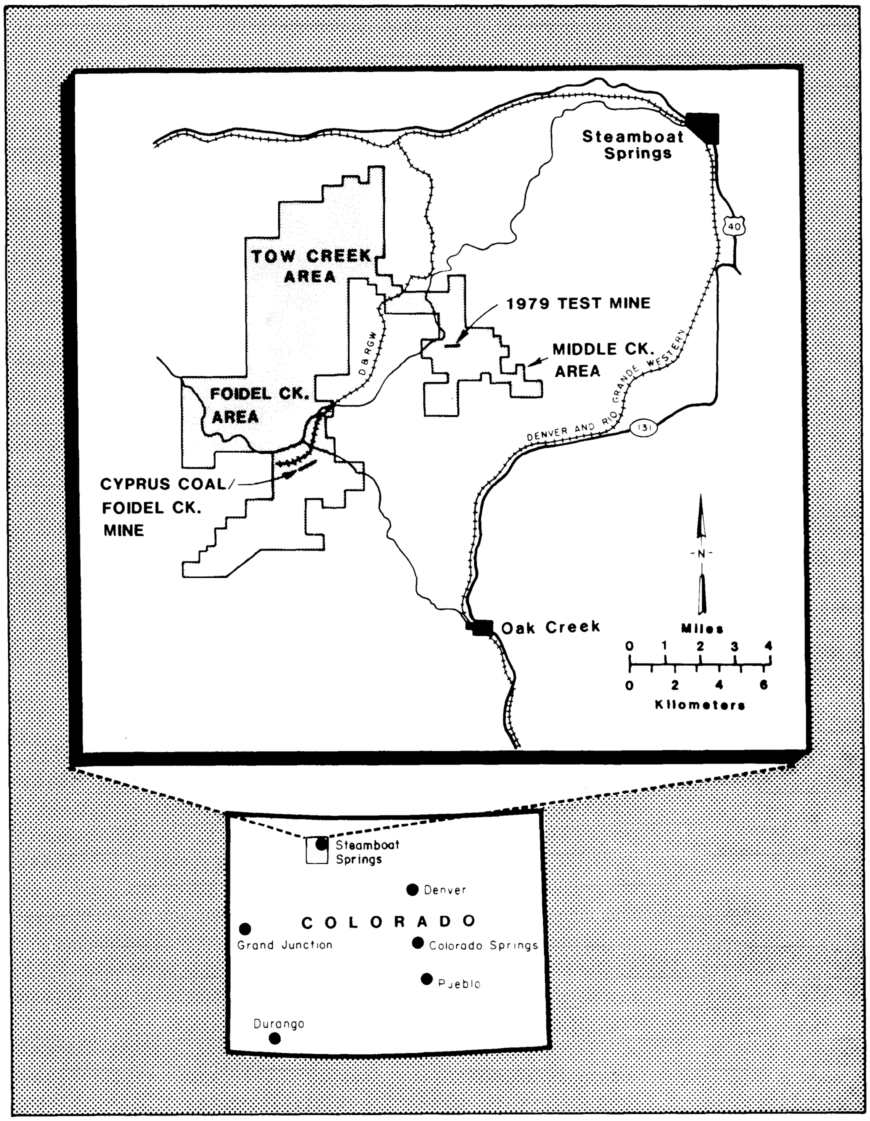

Fig. 5.8.3.1. Location map of the Twentymile Park area, Routt County, CO.

controlled through federal, state, and private leases in the Middle Creek area. The Foidel Creek area is located in the southern portion of Twentymile Park and contains approximately 8300 acres (33.6 Mm^2) of federal, state, and private leases. The entries for Cyprus' Foidel Creek mine are located in this area, with access to the north through a strip pit highwall left open for such purpose. This case study addresses the exploration effort and the resultant geologic considerations for the development of this deep mine. Numerous company reports summarize in detail the various geological and engineering aspects of this study especially Getty and Cyprus internal reports (Anon., 1983; Anon., 1985-1988) and Norwest Resource Consultants reports (Anon., 1982).

5.8.3.2 Geologic Overview

Stratigraphy: Coal-bearing strata within the project area include the Illes and Williams Fork Formations. The major coal seams are found within the lower portion of the Williams Fork Formation. These coal-bearing strata are enclosed within a stratigraphic sequence that is bounded by the massive Trout Creek and the Twentymile Sandstones (Fig. 5.8.3.2). These sandstones form massive cliffs along the margins of the Twentymile Park Basin. Intervening strata between the massive sandstones erode to form gentle slopes, which are characterized by poorly exposed outcrops. Overlying the Twentymile sandstone is the Holderness Member, a shoreline sequence that, in turn, is capped by the marine Lewis Shale.

The Wadge seam and the Upper and Lower Wolf Creek seams are the seams of economic interest (Fig. 5.8.3.2). The Wadge seam, the focus of this exploration and mine development effort, is extremely consistent in both thickness and lateral continuity. Across the main part of the Twentymile Park Basin, the Wadge seam ranges in thickness from 8 ft (2.4 m) to over 13 ft (4.0 m), averaging almost 10 ft (3.1 m). The seam crops out along the margins of the basin and reaches a maximum depth of 1800 ft (549 m) in the basinal center. The Wadge has been extensively mined in the past by surface methods.

The Wolf Creek seams are located 140 to 190 ft (43 to 58 m) below the Wadge seam and vary in thickness from less than 1 to over 13 ft (0.3 to 4 m). Drill data indicate a depositional

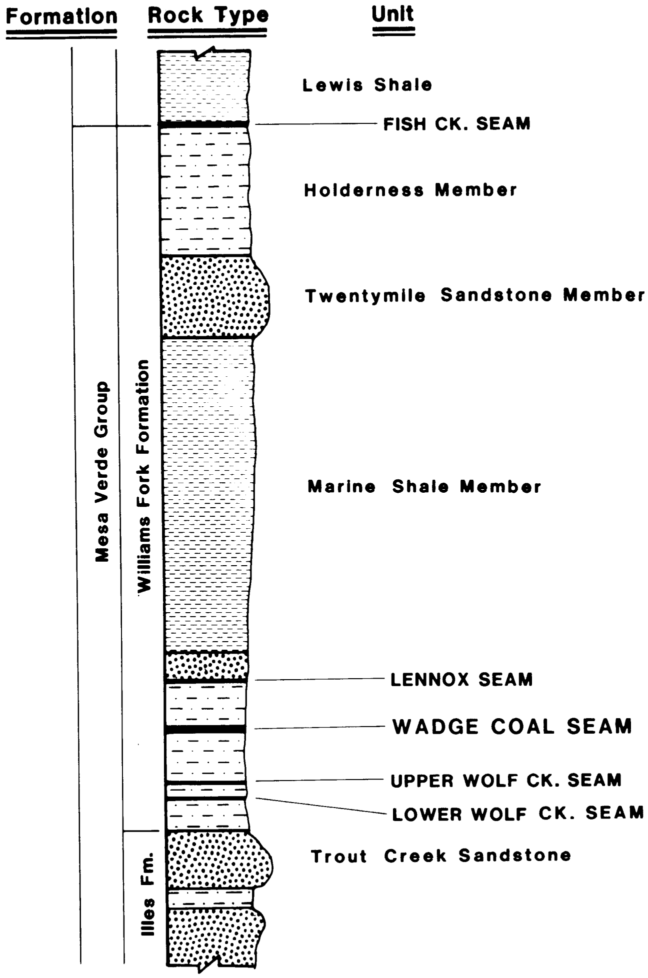

Fig. 5.8.3.2. Generalized stratigraphic column of the Upper Cretaceous strata of interest, Twentymile Park area, Northwest CO.

sequence containing several thin coal seams and two seams of economic interest. The two main seams, named the Upper and Lower Wolf Creek, contain rock bands and are locally split into subseams. Because seam quality is generally lower than the Wadge coal, the Wolf Creek seams were not rigorously studied during the project.

In general, the strata overlying the Wadge seam are found to be very predictable units (in terms of lateral continuity) of deltaic and marine origins. The strata below the Wadge seam, including the Wolf Creek seams, are highly variable and are comprised of interbedded coastal plain deposits with a high degree of fluvial influence.

Structure: Strata in the Twentymile Park area have undergone a long history of structural deformation that is predominantly compressional. Large folds and reverse faults formed early in the history while oblique normal faults apparently formed later. Three large, north-trending asymmetrical folds are the most prominent structural features that form the Twentymile Park basin. They cause the strata to dip in excess of 15% near the periphery of the basin and form the outer boundaries of the mine area. The reverse fault located in the west central part of the basin, with a displacement ranging from 20 to 80 ft (6.1 to 24.3 m), follows an arcuate line northward through the center of the basin (Fig. 5.8.3.3). The strata including the coal measures are also disturbed by northwest-striking normal fault zones, with displacements ranging from 0 to 35 ft (0 to 10.6 m), which occur in broad zones. These zones are 1 to 3 mi (1.6 to 4.8 km) wide and contain a number of faults that have similar characteristics to each other. The zones correlate to faults in the crystalline basement (Kucera, 1962) that were apparently reactivated during deformation of the sedimentary section.

Two major joint systems displaying consistent orientations occur throughout the basin. A shear system oriented northwest is very planar and terminates at lithologic boundaries. An extension system, oriented northeast, is sub-planar, open with mineral filling, and cuts indiscriminately across lithologic boundaries. Cleats in the Wadge seam share orientations with the joint sets and range in density from 6/ft (20/m) to spacings of one every 2 ft (0.6 m).

Hydrology: The Twentymile Park study area is an enclosed groundwater basin. Within the coal sequence strata, there are three significant groundwater aquifers: the Twentymile Sandstone, the overburden immediately above and including the Wadge seam, and the underlying Trout Creek Sandstone (Fig. 5.8.3.2). These aquifers are confined by shale layers above and below, and display artesian pressure levels in the center of the Twentymile Park basin. All three aquifers are recharged at the west and south flanks of Twentymile Park. Groundwater flows through the aquifers toward the east flanks, where it discharges into a perennial tributary to the Yampa River. During the study, joints and faults were recognized as conduits between lithologic units.

5.8.3.3 Twentymile Park Exploration Program

Pre-Exploration Data: Pre-exploration information was comprised almost entirely of drillhole data. These data consisted primarily of widely spaced holes completed into the Wadge seam from which geophysical logs were available. The quality of these logs ranged from unacceptable to excellent, with most in the good to acceptable range. If available, lithologic and core descriptions were usually too generalized to be of significant value. Drillholes were completed on ½- to ¾-mi (0.8- to 1.2-km) centers in the Foidel Creek area, except in the previously surface mined areas where drilling was shallow and of limited use. Drilling to the north in the Tow Creek area was particularly wide spaced, with no data available throughout the southern half of the area; holes were drilled on l- or 1 1½-mi (1.6- or 2.4-km) centers in the northern half of the area. Holes were somewhat more closely spaced in areas between old surface pits and the Middle Creek test mine. Drillhole data obtained on adjacent lands were generally spaced on ¾-mi (1.2-km) centers.

In addition to drillhole information, published reports of outcrop mapping were available. The US Geological Survey prepared a report (Bass et al., 1955) describing the general geology of the region, while two PhD dissertations concerning the stratigraphy, structure, and depositional environments of Cretaceous strata of much of the region were completed in the 1960s (Kucera, 1962; Masters, 1966).

Numerous mine pit exposures at nearby surface mines to the south were available to study seam character and continuity and structure.

In May 1979, Energy Fuels Corp., which controlled the property at that time, opened up an underground test mine in the Middle Creek area. This test mine experienced difficult mining conditions almost from startup, and ceased production in June 1980. Information on this failed project profoundly influenced the direction and goals of the Twentymile Park exploration program and subsequent mine planning.

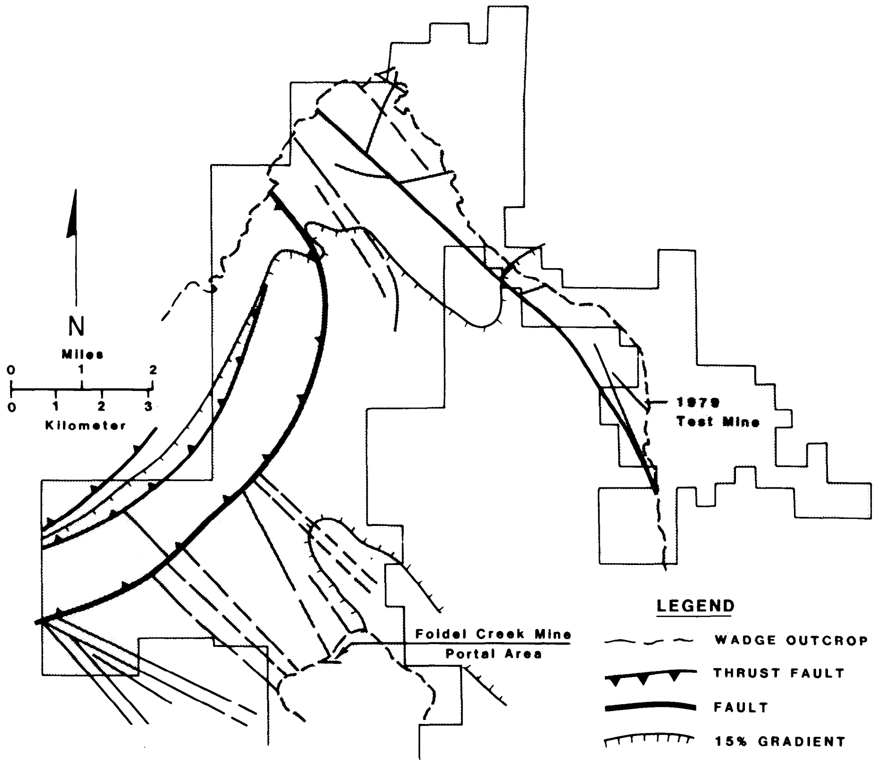

Fig. 5.8.3.3. Data of structure in the Twentymile Park area, Northwest CO.

Ongoing hydrologic and environmental studies in the Twentymile Park Basin were available at the beginning of the program along with a number of government and industry reports on the adjacent surface mine that were useful in the permitting process.

Scaling of the Exploration Effort: For three years, a multifaceted exploration program was conducted on the Twentymile Park area to address a variety of requirements and concerns. The phased program was comprised of conventional drilling and coring, field mapping, quality analyses, geotechnical testing of core, geophysical surveys, hydrologic data collection, overburden geochemical assaying, and preliminary wildlife, vegetative, and soil data collection. Steps in the program were designed to (1) achieve a broad database on the property, (2) focus efforts on a potential pilot mine(s) area, and (3) finalize mine planning details to support mine start-up efforts.

Project Specifics: Prior to the exploration effort, the underground coal resources were attached to the permit for the adjacent active surface mine. That existing permit allowed for the development of underground reserves from final pit exposures as a technical revision. It was decided that a pilot mine would be developed under the premise that the conditions encountered in the pilot mine would be found to be surmountable prior to the company application for a stand-alone mine permit.

Despite relatively harsh winter weather, field activities were conducted almost year around to achieve project goals. Actual drilling/coring was accomplished utilizing truck-mounted rotary drilling rigs (Gardner-Denver 2000, Gardner-Denver 15W, and a Midway 15M-2). Drilling was done with mud circulation systems. Holes averaged about 1500 ft (458 m) in depth. Completed holes were generally filled with an abandonment gel and the coal zone and upper portion of the hole cemented. A significant number of holes were completed as water monitor wells. Support equipment for the drills included a dozer and road grader (road and site work), backhoe (site work and reclamation), water truck, and a utility trailer. Four-wheel-drive vehicles were necessary because of the frequent muddy conditions.

Core was conventionally recovered at almost every site. Generally, $8\frac{5}{8}$-in. (219-mm) OD casing was set through surface alluvium, while rotary intervals were drilled $5\frac{5}{8}$ to 6 in. (143 to 152 mm) in diameter. As 3-in. (76-mm) core was desired for sampling, $4\frac{7}{8}$-in. (124-mm) OD chrisbit-variety core bits and/or conventional diamond bits were utilized. Cored zones were reamed if deeper seams were to be sampled. Six-in. (152-mm) diameter core was recovered from four sites to collect a reasonable bulk sample in anticipation of washability and certain geotechnical tests. Three drillholes yielded oriented core samples for geotechnical and structural studies. All holes were geophysically logged recording natural gamma, density, resistance, deviation, caliper, occasional neutron curves, temperature, sonic, dip meter, spontaneous potential (SP), and focused electric. Detailed seam thicknesses, ash analysis, and strength index interpretations were also computed. All logging information was stored on magnetic tape.

Cuttings were collected and logged on 5-ft (1.5-m) intervals. Core was logged for geotechnical properties including rock type, bedding, induration/competency, hardness, discontinuity characteristics, groundwater indicators, and effects. Core was photographed on l-ft (0.3-m) intervals and logged in detail prior to sealing in plastic and boxing. Core description included location, recovery, RQD (rock quality designation), discontinuity graphics and descriptions, three-digit lithology codes, lithologic and geotechnical descriptions, and sample designations. Samples of coal-bearing strata and coal were subjected to a wide range of ASTM standard quality tests. Quality analysis tests for seam composites included full proximate, ultimate, ash fusion, mineral analysis of ash, sulfur forms, hardgrove grindability, free swelling index, specific gravity, equilibrium moisture, and trace elements.

Short proximate analyses were also performed on selected immediate roof and floor samples and incremental seam samples. Although the property was anticipated to produce a run-of-mine (ROM) product, selected cores were subjected to washability studies. Specific gravity separations ranged from 1.30 to 1.80.

A geotechnical program was conducted to define rock mass parameters by measuring material properties, in situ horizontal stresses, and the geochemical nature of the confining strata. Stress relief overcoring and strain relief techniques were used to define in situ stresses. Geotechnical testing and analysis involved samples from across the property, but focused in the proposed Foidel Creek mine area. Rock properties testing was conducted by rock type and included Brazilian, uniaxial compressive, triaxial compressive, bulk density, moisture, slake durability, indirect tensile, and swelling index.

In general, the Wadge and Wolf Creek seams were cored in every hole and sent to the laboratory for qualitative testing. Along with each coal seam, 40 ft (12.2 m) of roof and 20 ft (6.1 m) of floor material was cored for geotechnical testing and engineering purposes. The Wolf Creek seam in nearly all the holes was paired, and a complete series of screen analyses and gravity separation tests were conducted to determine the preliminary washability characteristics of the coal.

Samples of the Wadge seam and immediate roof, obtained during drilling operations, were monitored for methane desorption from four drillholes. No significant amounts of methane were found associated with the coal seams. Petrographic analyses were also performed on the Wadge and Wolf Creek seams and included maceral composition and vitrinite reflectance.
