The advantages of Kimberley skips are (1) there is less shaft spillage when handling fine or wet material, and (2) they handle larger pieces for a fixed cross-sectional area. The disadvantages are (1) the capacity is limited due to the height-to-width ratio, (2) the payload ratio is usually lower particularly with sticky material that tends to build up in the bottom, (3) they generally impose higher stresses on the headframe and bins, and (4) they require more headframe height to dump.

SWING-OUT BODY. The *swing-out body skip* also consists of a bail frame, a shaft, and the skip body. In this case, the skip body is suspended from the shaft and the skip dumped by means of rollers mounted on each side (at the bottom) of the body, engaging a scroll and causing the body to pivot away from the bail into the dump. At the same time, a discharge door, which forms the bottom of the skip, opens and the material is discharged (Fig. 17.5.8).

There are three common types of swing-out body skips. These are the Jeto, Saunders, and Rollamatic. The differences among these three types is the mechanism involved with the opening and closing of the door and the location of the door hinge. Safety latches have been used on all three types. This is to prevent the skip from opening in mid-shaft, particularly when traveling empty.

For bottom-dumping skips in general, the cross-sectional area is partially determined by the size of material to be handled.

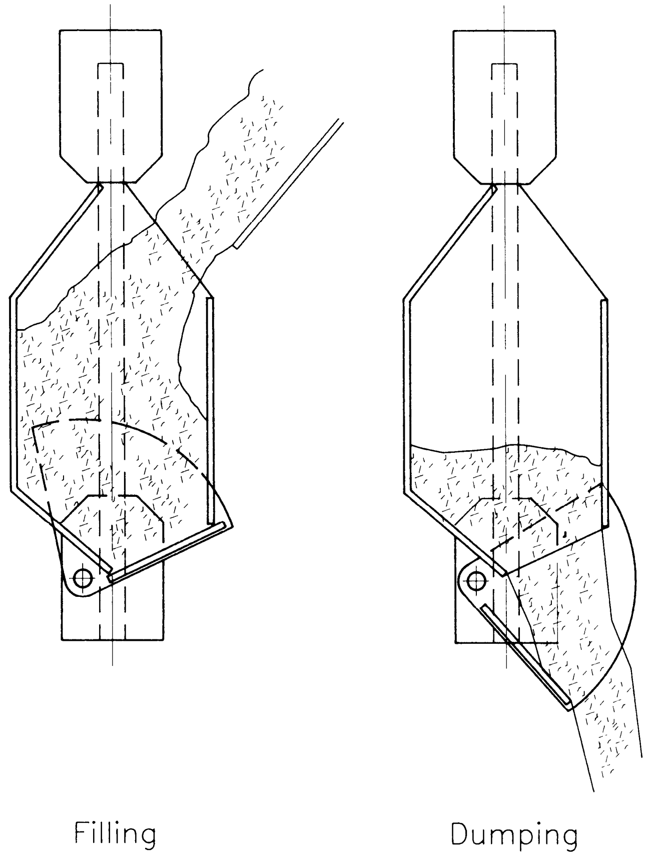

Fig. 17.5.9. Bottom dump skip, fixed body (Penning et al., 1977).

The door opening is sized to be at least three times the dimensions of the largest piece to be handled. This is to prevent possible bridging. Other factors to be considered are the length of the skip, the available space, and the hoist rope center-to-center distance.

The advantages of swing-out body skips are (1) they have more favorable payload ratio than the overturning type, (2) the tipping path is less complex than for overturning skips, and (3) the dumping distance in the headframe is less than for overturning type. The disadvantages are (1) muck build up at the hinge point in the door can prevent the door from closing and could place large forces on the headframe scroll or skip body during the closing cycle, (2) with wet material, there could be spillage or dribble from the door lip, and (3) the bottom door mechanism is more complex than the fixed body type.

FIXED-BODY. In *fixed-body skips*, the body of the skip remains fixed and does not move out of the confines of the skip compartment during dumping. Instead, a door at the bottom of the body swings open to form a chute and allows the material to discharge into the dump bin. This type of skip may or may not have a bail (Fig. 17.5.9).

There are several types of fixed-body skips. The most common are the Rolla-Chute, the Arc-Door, and Sala-type skip. The difference among these types is the mechanism involved with the opening and closing of the door. In the Rolla-Chute skip, the door is held closed by means of a door latch. When the skip enters the headframe, a latch track releases the latch, allowing the door to open and the material to discharge. With the Arc-Door chute, a roller is mounted on each side of the door. When the skip enters the skip dump, the roller engages a scroll, causing the door to swing open. In the Sala skip, the door is operated by means of air cylinders mounted on the skip body. Compressed air to operate the cylinders is provided through a yoke which is permanently mounted in the headframe and picked up by the skip as it enters the dump.

The cross-sectional area of fixed-body skips is determined by the size of the material to be handled. Since fixed-body skips can be built without a bail, the cross-sectional area of the skip can be increased by 10 to 15% when compared to skips with a bail for the same sized compartment.

The advantage of fixed-body skips are (1) the skip can load and dump through the guides, (2) the skip has no bail, thus allowing a larger cross-sectional area to be used for the skip body (this can reduce the overall length of the skip for a given capacity), (3) the only moving part is the door that forms its own dump chute, (4) they are suitable for fixed or rope guides, (5) a hinged floor at the top can convert the skip to a personnel and materials cage, (6) the skip requires less travel distance to open the door, (7) this type of skip places less stress on the headframe, skip body, and ropes during the dumping operation, and (8) there is less spillage at the door. The disadvantage of this type of skip is that its bailess construction requires adequate design and inspection during operation.

17.5.4.3 Skip Design Considerations

The process of skip design has been well documented by Penning (1977). When selecting a particular skip, the components to be considered during the evaluation process include (1) design methods, (2) factors of safety, (3) body, (4) door, (5) crosshead, (6) bail, (7) guide rollers, and (8) guide shoes.

DESIGN METHODS. Skip components may be designed on the basis of experience and practice or through analytical methods that define the loading being placed on the various components of the skip. The types of loading to be considered are (1) dynamic loading, caused by filling, hoisting, and dumping the skip, and (2) static loading. Factors of safety are usually specified by legislation.

BODY. The skip body is designed as a rectangular box with stiffeners. The type of material, its thickness, and the stiffener size and spacing are the variables to be examined. Particular attention must be given to the area on the back side of the skip that receives impact and abrasion from loading.

Skip bodies are usually lined with abrasion resistant (AR) material to increase its overall life. Two types of steel or elastometers have been used for skip liners. AR steels are members of the high-strength, low-alloy family of steels. Manganese steels are used because they have the ability to work-harden during service. Elastometers have the advantage of reduced weight, less ore sticking and buildup, corrosion resistance and ease of handling during replacement.

The use of aluminum is also increasing, particularly in drum hoist applications. Such skips have a lower mass and allow a higher payload to be hoisted.

DOORS. Both swing-out body and fixed-body skips have doors at the bottom of the skip. Doors must be designed to withstand the impact of large pieces falling on the floor during loading and the static loading of a full skip as well as abrasion during unloading.

With swing-out body skips, the door is hinged at the back, and there are several problems associated with leakage paths between the door and the body. These door leakage problems may be solved through the use of rubber sheets, flexible materials, or special modification of plates at the door. Fixed-body skips generally have fewer problems with leakage or door closure. One situation that may cause problems to both types exists when the skip is loaded on the side opposite the dump site. In this case, a vertical stop may be placed for the dump roller to react against. Doors are made and lined with the same material as used in the body.

CROSSHEAD. The *crosshead* fastens the bail to the rope. It must be designed to take all the skip loads, including acceleration, impact and service factors. The location of the crosshead above the skip is particularly important during loading. It should not interfere with the flow of muck from the loading pocket. The rope stretch in deep mines can be several feet and must be considered. It can be calculated from the following relation:

$$\text{rope stretch (ft or m)} = \frac{\text{muck load (lb or kg)} \times \text{rope length (ft or m)}}{\text{rope area (in.}^2\text{ or mm}^2\text{)} \times \text{rope modulus of elasticity (psi or Pa)}} \tag{17.5.37}$$

BAIL. During hoisting, the *bail* supports the body pivot, prevents the body from moving, and supports the door. At the dump, the bail is subjected to horizontal loading and supports the door and is thus subjected to both bending and axial loading.

GUIDE ROLLERS. The purpose of *guide rollers* is to keep the guide shoe off the guides. This in turn results in a smoother ride, reducing dynamic loading between the skip, guide, and buntons during travelling.

When selecting guide rollers, there is usually a conflict between a large-diameter tire, adequate shaft clearance, and the cross section of the skip. Left unresolved, the final design usually results in a small-diameter tire. Such tires need frequent replacement. The range of tire sizes used are from 6 in. (152 mm) to 14 in. (356 mm) in diameter. Tires are rated on a load-mile per hour basis.

GUIDE SHOES. *Guide shoes* are used on vertical conveyances to keep the main structure from being worn away by the guides. They are considered as expendable items to be replaced when they are too worn for further use. Clearance between the guide and guide shoe varies from ¼ to ½ in. (6.4 to 12.7 mm). Guide shoes can be made from many materials, such as cast iron, mild steel, hardened steel, AR steel, brass, or bronze. The amount of wear to be expected is directly proportional to the load on the guide shoe and inversely proportional to the hardness of the softer material.

17.5.4.4 Loading Pockets

At the *loading pocket,* ore and waste are transferred from the mine to the skip. The equipment and systems installed can vary from simple manually operated to complex and automated. There are two basic types of loading systems available. These involve measurement by weight or by volume.

The criteria to be considered in the design of all systems include (1) response time, (2) loading time, (3) accuracy of measuring devices, (4) operating and maintenance costs, and (5) amount of spillage.

Although details can vary, each system has certain common elements: (1) pocket chute with control gates, (2) measuring pocket, and (3) skip feed chute with control gate.

POCKET CHUTES. Pocket chutes are generally fabricated from steel with liners. They have an angle of inclination of 45 to 55°. Chute gates can be pneumatically or hydraulically controlled and may be guillotine, ball and chain, or radial type.

MEASURING POCKET. The measuring pocket construction is similar to that of the skip body. There are two types of fabricated pockets available, the swing-out body and the fixed-body. The fixed-body is preferred because it is faster operating, there are no large masses to be moved, and it can be easily automated.

The loading pocket is furnished with pneumatically or hydraulically controlled gates. The bottom of the loading pocket is usually inclined at an angle of 60° or greater to ensure rapid loading and complete clean out.

With balanced skip hoisting, two loading pockets are provided, one for each skip.

SKIP FEED CHUTE. A feed chute is required to direct the material from the measuring pocket to the skip. The angle of inclination of the feed chute is usually 60° or greater.

The clearance between the chute and the skip is approximately 3 in. (75 mm). It has been suggested that the ratio of the chute discharge width to the skip width should not exceed 0.7 for skips up to 4.25 ft (1.3 m) wide and 0.8 for skips up to 6 ft (1.8 m) wide. To reduce spillage, the sides of the chute should be slightly converged at the lip.

AUTOMATIC LOADING. Automatic loading of skips is used to improve the efficiency of hoisting systems and to reduce labor requirements. Efficiency is improved by ensuring that each skip receives the required load without overloading or underfilling. Manpower is reduced when automatic loading is used in conjunction with automatic hoisting. In order that automatic loading can be accomplished, a minimum of three control systems must be included (1) a means of measuring the weight and/or volume of material in the measuring pocket, (2) a means of opening and closing feed chutes to fill and empty the measuring pocket, and (3) a logic system to ensure that the above operations are carried out in the correct sequence to prevent such systems failures as double loading and dumping into an empty shaft. With automatic hoisting, the logic system extends to the operation of the hoist.

17.5.4.5 Spill Pockets

Despite the precautions taken to prevent spillage during the loading and dumping of the skips, a certain amount is inevitable below the loading pocket. This spillage may be confined to the hoisting compartment by lining these compartments down to a *spill pocket.* According to data collected by Souter (1973) from a number of mines in South Africa, the amount of spillage, expressed as a percentage of tons hoisted, varied from 1.5 to 5 %. The larger amounts of spillage were associated with manually operated systems handling uncrushed material.

There are two commonly used methods of handling spillage in modem hoisting systems. One method consists of installing deflectors in the shaft below the underwind position of the skip. These deflectors direct spillage into a pocket similar to the loading pocket. The spillage pockets are then cleaned as required. With drum hoisting, this system can be used at any elevation in the shaft. With a friction hoist, the spillage pocket must be located below the tail rope loops, and a second conveyance such as the cage must be used to handle spill. The second method of handling spillage consists of developing a ramp from the lowest elevation to the shaft bottom. In this system, any spillage falls directly to the shaft bottom, where it can be mucked out. Regardless of the system used, particular care is required with friction hoist systems to ensure that the tail ropes do not become entangled or affected by the build-up of spill in the shaft.

17.5.4.6 Cages

Cages are used primarily to handle personnel and materials entering and exiting from the mine. In some instances, cages are used to hoist cars loaded with ore and waste. The design and construction of cages are similar to those used for skips.

A cage is merely an enclosed box, opened by door(s), and suspended from a hoisting rope. The dimensions and capacity of the cage are determined by the quantity, volume, weight, and dimensions of the materials and/or items to be handled.

17.5.4.7 Counterweights

In some balanced hoisting systems, a *counterweight* may be used with either a cage or skip. Since counterweights serve no functional purpose other than to provide for balanced hoisting, their dimensions are quite variable. They are usually designed to fit the space available.

17.5.4.8 Safety Devices

In North America, different types of safety devices are used for drum hoists and friction hoists.

DRUM HOIST. With drum hoists, both excessive overwind and rope breakage can occur. Of these two types of accidents, rope breakage is considered the most serious, and provisions to bring the conveyance to a safe stop in the event of a rope break is required by legislation.

The most common safety device used is the *safety dog.* A pair of dogs is installed at the top of the conveyance at each guide. During travel, the tension in the hoisting rope keeps the dogs open. Should the rope break, or become slack, a large spring and series of levers cause the dogs to penetrate the guide and stop the conveyance.

FRICTION HOIST. In multiple rope friction hoist installations, the probability of all hoisting ropes breaking is small. Therefore, overtravel is considered to be more serious, and provisions to bring the conveyance to a safe stop in the event of overtravel are required.

The most common device used is *arrestor gear,* consisting of steel frames supported in the hoisting compartment and transported by the conveyance as it travels through the arrestor zone. these devices are located in the headframe and at the shaft bottom. They rely on friction between the device and the guides to decrease momentum.

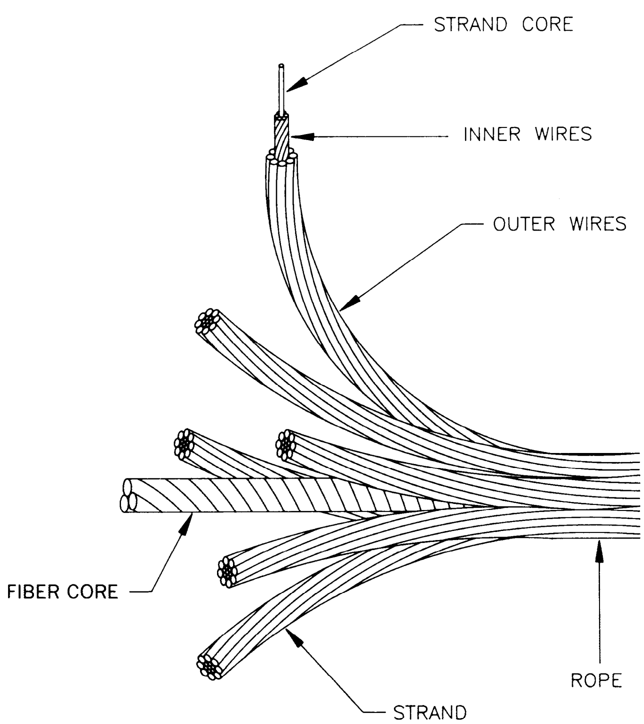

Fig. 17.5.10. Rope components (Anon., 1980a).

17.5.5 ROPES

The basic purpose of the *hoisting rope* is to connect the conveyance to the hoist. It is selected primarily on the basis of safety, compatibility, life, and costs. Safety requirements when hoisting personnel, or where persons may be endangered by hoists and their appurtenances, are usually determined by legislation. The life of a rope is usually expressed as the number of trips it will make; it is affected by rope construction, hoist and sheave dimensions, type of loading, shaft atmosphere, and maintenance. Costs of initial purchase, maintenance, and costs of rope changing including lost production are normally considered. In addition to hoisting ropes, the hoisting systems designer must be concerned with balance ropes (for friction hoist application), guide ropes, rubbing ropes, and rope attachments.

The type of rope construction commonly used for various hoisting applications are as follows:

Rope Use	Typical Rope Construction
drum hoist ropes	round strand—Lang lay flattened
	flattened strand 6 × 27 FC
	full locked coil
friction hoist rope	locked coil
	flattened strand
balance ropes	non-rotating 18 × 7 nylon core
	non-rotating 34 × 7 nylon core
guide and rubbing ropes	half locked coil
shaft sinking	non-rotating 18 × 7 IWRC
	full locked coil
slings	round strand 6 × 25 IWRC

In this segment, a general description of the various types of ropes, plus the factors to be considered to ensure correct application and selection, is presented.

17.5.5.1 Rope Construction

In the construction of most wire ropes, a number of individual wires are wound around a core to form a strand. The strands are then wound around a core to form the rope. Fig. 17.5.10 is an exploded view of a rope showing the components.

Some ropes are constructed without strands by winding consecutive layers of wire around the inner layers.

The factors to be considered in rope construction are (1) the wire, (2) strands, (3) cores, and (4) lay. By varying these factors, ropes with different characteristics can be constructed.

WIRE STRENGTHS AND PROPERTIES. Wire for manufacturing wire rope is available with varying strengths up to 360,000 psi (2480 MPa). It is thus possible to manufacture ropes of different strengths for the same diameter and the same construction. Generally speaking, as the wire strength increases, fatigue life and rope life tend to decrease.

The most common wire used in mining is improved plow grade 110/120. Wire is also available in different shapes with round, full-lock and half-lock being the most common. Galvanized wire is available for wire ropes and should be considered if ropes are being replaced due to corrosion.

STRANDS. Individual wires are twisted together to form *strands.* There are four common types of strands: (1) round strands, (2) triangular strands, (3) oval strands, and (4) flat strands.

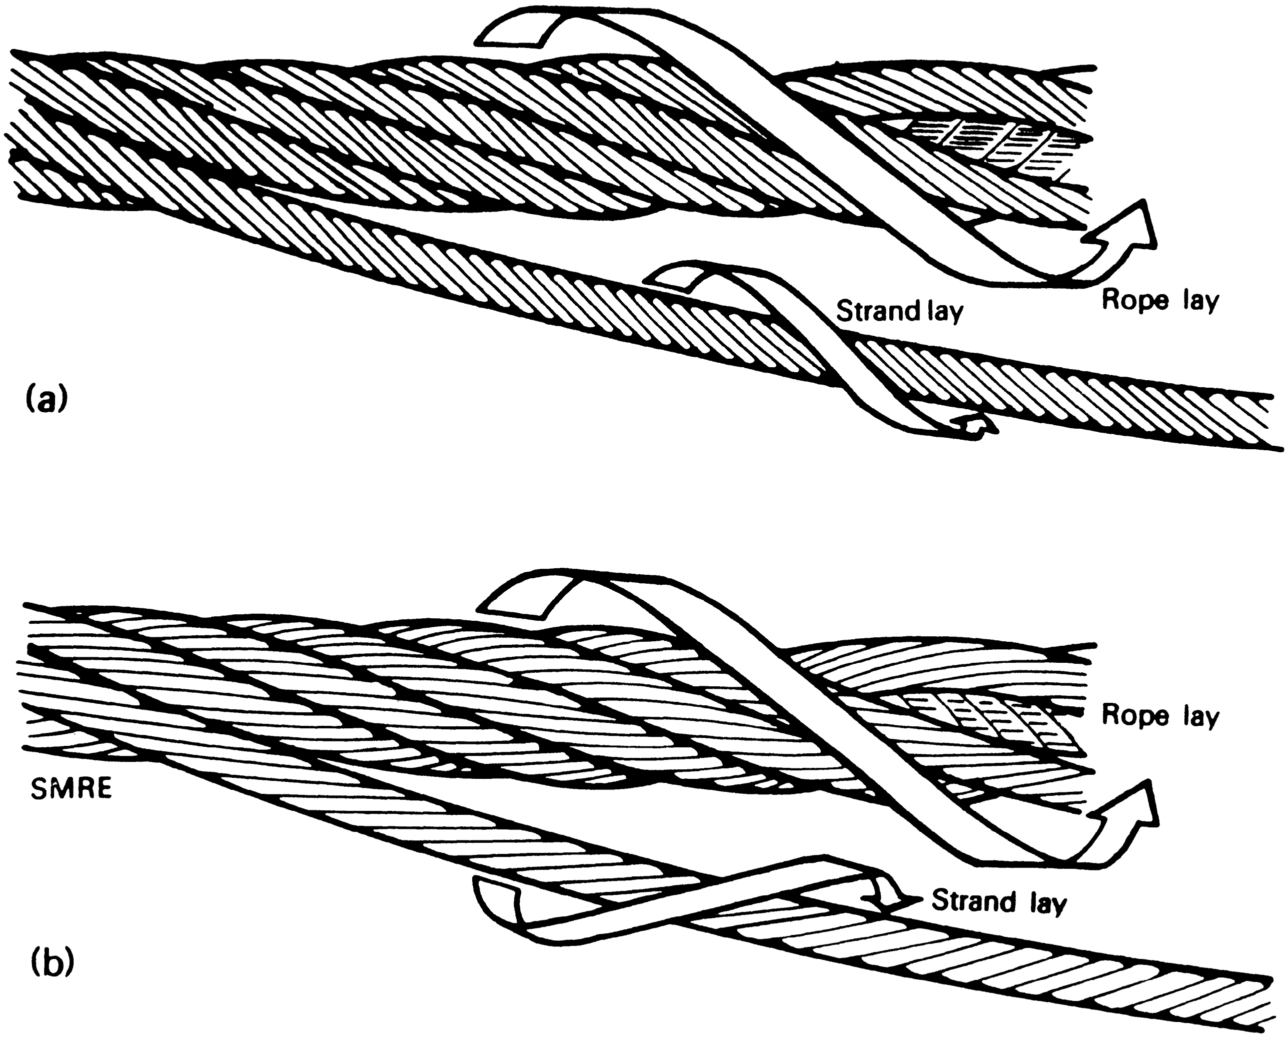

Fig. 17.5.11. Rope lay (Anon., 1980a). (a) Lang lay: wires and strands laid in same direction; (b) ordinary lay: wires and strands laid in opposite directions.

CORES. The purpose of the *core* is to take the internal compressive stresses. The largest of these stresses is due to the tendency of the rope to flatten when bent around a sheave or thimble.

Natural fiber cores (FC) such as sisal and hemp are suitable for most applications. Synthetic fiber cores such as nylon and polypropylene are used in conjunction with high-strength wires and in corrosive applications.

Independent wire rope cores (IWRC) are stronger than fiber cores. They add to the strength of the rope and reduce the stretch; fatigue life is reduced, however.

LAY. The *lay* of a rope is the manner in which the wires are twisted into the strand and the strands are twisted into ropes. There are three properties used to describe lay: (1) length (or pitch), (2) direction (right or left), and (3) type (regular or Lang).

Fig. 17.5.11 illustrates the direction of lay for regular lay and Lang lay, which are the usual lays used in mining ropes. The lay length is the distance from one crown to the next of a particular wire.

Right lay is usually used unless special circumstances require the use of left lay. Some drums are designed to take left-hand lay ropes and should be checked prior to purchasing. Fig. 17.5.12 shows how to select the lay of the rope required for a drum.

Regular lay ropes have the wires in the strands laid in such a manner that the wire crowns run approximately parallel to the rope direction. Such ropes have good resistance to kinking and twisting and are able to withstand considerable crushing and distortion. Regular lay should be used for slings and balance ropes.

With Lang lay, the wires are on the diagonal of the strand and are exposed for a greater length. This arrangement gives greater abrasion resistance and a more flexible rope. Lang lay is commonly used for hoisting ropes on drum hoists. Ropes with this lay slide into position on a drum better than regular lay ropes. Because of the tendency to untwist, these ropes should not be used with swivels or single-part hoisting without guides.

17.5.5.2 Hoist Ropes

The three types of ropes generally considered for hoisting ropes are round strand, flattened strand, and locked coil. Typical properties for these types of rope are given in Table 17.5.3.

ROUND STRAND ROPES. *Round strand ropes* consist of a number of strands, each consisting of wires, wound around a core. The rope designation (e.g., 6×27 FC) indicates the number of strands (6) and the number of wires (27) per strand; FC

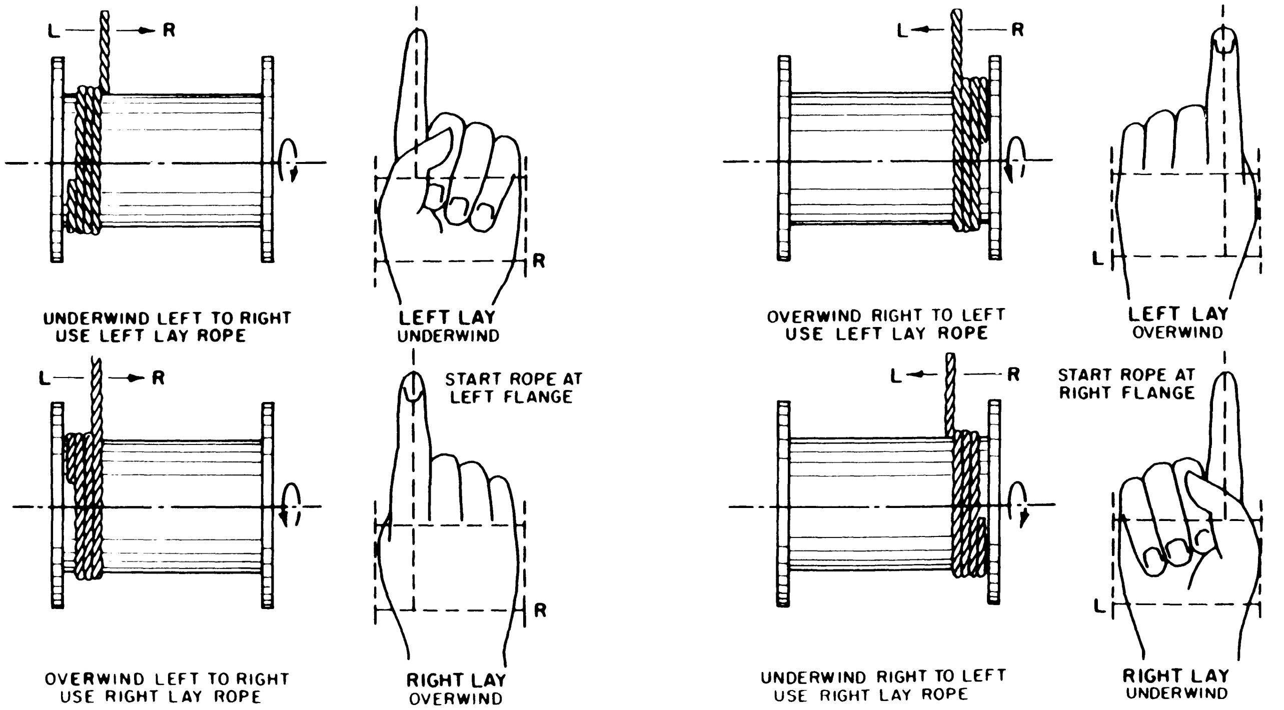

Fig. 17.5.12. Selection of correct direction of lay for a drum hoist ("Wire Rope Users Manual," 2nd ed., Committee of Wire Rope Producers, American Iron and Steel Institute, undated).

Table 17.5.3. General Wire Rope Data for Standard Tensile Wire, Nominal Breaking Load of 120 Long Tons/In.²

Rope	18 × 7 L.C. I.W.R.C. Spin-Resistant and Sinking Rope		6 × 27 F.C. Flattened Strand (Triangular)		Locked Coil	
Diameter (in.)	Weight (lb/ft)	Breaking Strength (1000 lb)	Weight (lb/ft)	Breaking Strength (1000 lb)	Weight (lb/ft)	Breaking Strength (1000 lb)
3/4	1.11	55.23	.97	57	1.31	69.4
7/8	1.42	74.04	1.33	78	1.85	94.0
1	1.84	95.85	1.74	103	2.45	123.2
1 1/8	2.33	121.21	2.22	132	3.08	156.8
1 1/4	2.80	148.65	2.74	163	3.75	192.6
1 3/8	3.38	179.44	3.32	197	4.53	233.0
1 1/2	4.02	212.53	3.95	235	5.25	277.8
1 5/8	4.69	249.00	4.66	276	6.24	324.8
1 3/4	5.62	298.47	5.37	319	7.29	376.4
1 7/8	6.18	331.19			8.46	432.4
2	7.08	375.79			9.67	492.8
2 1/8	8.19	434.85				
2 1/4	9.15	485.54				

Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 lb = 0.4536 kg, 1 long ton = 1.016 t.
Source: Wire Rope Industries Ltd.

stands for fiber core. The greater the number of wires in a strand, the greater the flexibility of the rope, but the smaller wires wear faster and are more easily damaged.

FLATTENED STRAND. The properties of round strand rope have been improved in *flattened strand rope* by making the strands triangular instead of round. The benefits of this are

1. An increase in the number of wires in contact with the sheaves and drums increases the contact area, thereby reducing the pressure and lessening wear on ropes, sheaves, and drums.

2. The rope has a greater crushing strength and can be used in multilayer winding.

3. The wire density in the rope is higher. Thus for the same diameter, more steel area is available, and the rope has a higher strength.

FULL LOCKED COIL. This type of rope is completely different from both round and flattened strand rope. The center or core of the *locked coil rope* consists of a concentrically laid strand of round wires. Around this core lies one or more layers of shaped wires, the outer layer always being interlocking. The shape of all shaped wires in a locked coil rope depends on the rope diameter and its end use.

Locked coil rope construction has some very definite advantages. In a locked coil rope, there is no initial twist in the rope so the wires do not tend to untwist under load. Locked coil ropes have a higher breaking strength than stranded rope for equal diameter and for the same nominal strength grade. Because of their smooth external surface, reduction in strength caused by frictional wear on drums or pulleys is much lower. Also, because of their design, locked coil ropes are less subject to rotation and stretch than stranded ropes.

17.5.5.3 Rope Selection

For the initial selection, four requirements should be considered: (1) strength, (2) resistance to being fatigued, (3) abrasion resistance, and (4) resistance to crushing or distortion. The choice should be made after correctly estimating the relative importance of each of the above requirements. Naturally, strength is the overriding concern.

Design considerations should provide economical and efficient rope service while maintaining the necessary degree of safety to both personnel and equipment. These objectives are best met by accepting the following guidelines:

1. Design the hoisting system with good rope life as an objective.
2. Specify ropes to be compatible with the required factor of safety to match the design of hoist, shaft, headframe, and sheave.
3. Design rope storage and handling procedures.
4. Design correct rope installation procedures.
5. Design correct and adequate maintenance procedures.
6. Design and institute an inspection procedure.

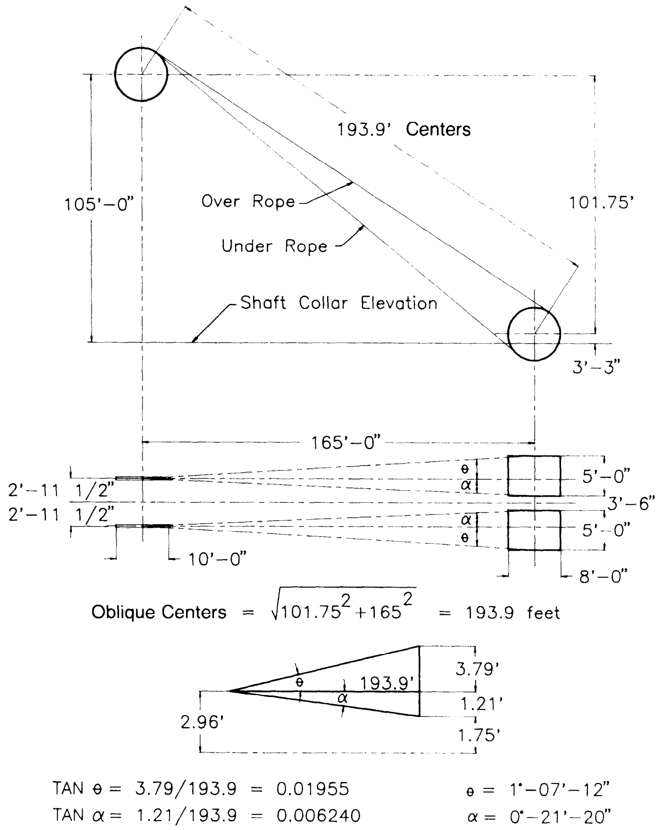
ROPE SELECTION FOR DRUM HOIST. This segment discusses the selection of the size of rope to meet operating conditions for drum hoists for vertical and slope applications. In the United States, the *Code of Federal Regulations* (CFR) (Anon., 1989) specifies minimum requirements for the following items that are relevant to drum hoisting: (1) factor of safety, (2) ratio of drum/sheave diameter to rope diameter, and (3) fleet angles. An example calculation of hoist rope selection concludes this discussion.

Factor of Safety—Mandatory requirements by the Mine Safety and Health Administration (MSHA) are covered in CFR. Sections 55/56/57.19-21 and 75/77.1431 for metal and nonmetal open pit mines, sand, gravel and crushed stone operations, metal and nonmetal underground mines, and underground coal mines, respectively, require the following minimum rope strengths, where L is maximum suspended rope length in ft:

winding drum ropes less than 3000 ft long: minimum rope strength = static load × (7.0 − 0.001L). (17.5.38)

winding drum ropes 3000 ft long or greater: minimum rope strength = static load × 4.0. (17.5.39)

Drum/Sheave Diameter—Mandatory requirements for drum and sheave diameters have now been removed from the regulations, but insofar as the old regulations are still common practice in the United States as well as Canada and Europe, they are repeated here.



Conversion factor:
1 ft = 0.3048 m

Fig. 17.5.13. Fleet angle calculation.

Drum and sheave tread diameters should be (1) not less than 60 times the hoist rope diameter for slope or inclined shaft applications, (2) not less than 80 times the hoist rope diameter if the hoist ropes are 1 in. (25 mm) in diameter or greater, or not less than 60 times the hoist rope diameter if the hoist ropes are less than 1 in. (25 mm) in diameter for vertical shaft applications, and (3) not less than 100 times the hoist rope diameter for locked coil ropes.

Fleet Angles—The mandatory regulation (Anon., 1989) states, "Fleet angles on hoists installed after Nov. 15, 1979, shall not be greater than ½° for smooth drums or 2° for grooved drums." (CFR 56.19-37). However, to increase rope life manufacturers of hoist ropes commonly recommend a maximum fleet angle of 1°20' and a minimum fleet angle of 0°30' to insure rope will crossback and start a new layer without piling. Computations of optimum total fleet angle are given in ANSI M 11.1 (Fig. 17.5.13).

Size Calculation—The procedure for sizing a rope for a drum hoist consists of the following steps:

Step 1. Tabulate operating conditions.

Step 2. Calculate personnel load.

Step 3. Calculate load with conveyance at collar. (Note: US practice only requires check of lowest level.)

Step 4. Calculate load with conveyance at lowest level.

Step 5. Select rope and check safety factor using ANSI M11.1 or CFR Title 30.

Step 6. Check other hoisting components.

Example 17.5.3. Given the following drum hoisting system:

Step 1. Assumed operating conditions.

Height, collar to head sheave	130 ft	(39.6 m)
Depth of lowest level	5000 ft	(1524 m)
Cage capacity	60 persons	
Cage capacity materials	20,000 lb	(9072 kg)
Cage weight	8000 lb	(3629 kg)
Weight of rope attachment	300 lb	(136 kg)

Select the proper hoisting rope and determine factors of safety SF.

Solution.

Step 2. Calculate man load.

60 persons @ 200 lb = 12,000 lb

Step 3. Calculate load with conveyance at collar.

(Not required in US practice.)

Assume 1-1/2 in., 6 × 27 flattened strand rope. Table 17.5.3 shows the properties of this rope.

Assume owner elects to employ factors of safety from 57.19a-21 of the *CFR* when hoisting materials.

Thus suspended load is

cage weight	8,000 lb
pay load	20,000 lb
rope attachments	300 lb
130 ft rope @ 3.95 lb/ft	514 lb
Total:	28,814 lb

Thus minimum breaking strength required = suspended load × SF = 28,814 lb × (7 − 0.001 × 130) = 197,953 lb.

Step 4. Calculate load with conveyance at lowest level.

suspended loads	
cage weight	8,000 lb
payload	20,000 lb
rope attachments	300 lb
5130 ft of rope @ 3.95 lb/ft	20,264 lb
Total:	48,564 lb

Thus minimum breaking strength = 48,564 × 4 = 194,256 lb

Step 5. Select rope and check safety factor.

From steps 3 and 4 above, it can be seen that the loading condition at the lowest level is critical, and that the minimum rope breaking strength required is 194,256 lb.

Referring to Table 17.5.3, it can be seen that 1½-in. diameter 6 × 27 flattened strand rope manufactured from 120 long tons/in.^{2} wire has an ultimate breaking strength of 235,000 lb.

For this rope the factors of safety are

		Actual	Required
@ collar	$SF = \frac{235{,}000}{28{,}814} =$	8.15	5.7 (not mandatory in US)
@ loading pocket	$SF = \frac{235{,}000}{48{,}564} =$	4.83	4.0

Rope is therefore deemed satisfactory.

Step 6. Check with other hoisting components.

The designer would normally check hoist drum storage capacity and fleet angles at this stage as well as rope projected pressure on the drum grooving. After considering the other components of the hoisting system, the designer may decide to reduce the weight or payload of the cage in order to use a smaller-diameter rope with higher tensile-strength wire. Alternatively, a decision may be made to use a larger-diameter rope and thus increase rope life.

Rope Selection for Friction Hoist. A friction hoist differs from a drum hoist in that the rope is not wound on and off the drum but passes around the drum, with the drum friction providing the force necessary to move the rope. Friction hoists may be mounted in the headframe tower directly over the shaft, or they may be mounted in a hoist house at ground level. The friction hoist drum is often referred to as a wheel.

A specific friction hoist application can have a number of acceptable hoist rope/tail rope alternatives. As the selected number of hoist ropes increases, their diameter can become smaller. This also means the hoist drum can have a smaller diameter, which affects the center-to-center distance of the compartments. Because of this, it is important that the hoisting system designer ensure compatibility with the other components of the hoisting system (i.e., shaft, headframe, conveyance).

Regulations and other calculations and considerations involved in rope selection for friction hoists are discussed here. An example that considers factors of safety and other criteria is then presented. When an overall hoisting system is designed by a hoist manufacturer, it is in the owner's best interest to carefully check the proposal as there have been instances where undue emphasis has been placed on the capital cost of the hoist at the expense of higher operating costs of the overall system. These trade-offs in system selection must be carefully weighed.

When determining a factor of safety for friction hoist ropes in North America, it is common practice to follow the Ontario (Canada) regulations:

$$\text{factor of safety} = 8.0 - 0.0005\,d, \text{ but not less than } 5.5 \quad (17.5.40)$$

where d is maximum length of rope in feet

Ontario (Canada) regulations require the following factors of safety that may be used as guidance for other ropes in a friction hoist installation:

1. Balance or Tail Ropes — 7.0 on weight of rope (static load)
2. Guide or Rubbing Ropes — 5.0 on weight of rope (static load)
3. Bending Ratio. The required bending ratios are the same as for drum hoists. The bending ratio may exceed the regulatory minimum but for locked coil construction does not normally exceed 140.

Wire Rope Industries of Canada recommends the following minimum bending ratios for locked coil ropes, although all such specifications have been removed from US CFR requirements:

Rope Size	Bending Ratio (Locked Coil Rope)
Less than 1 in. (25 mm)	100:1
1 to 1¼ in. (25 to 32 mm)	100:1
1½ in. (38 mm)	110:1
2 in. (51 mm)	120:1
Greater than 2 in. (> 51 mm)	130:1

In addition to the regulatory requirements for factor of safety, the following items should also be considered when selecting ropes for friction hoists: (1) T_1/T_2 ratio, (2) drum tread, (3) deflection sheaves, (4) differential rope loads, and (5) tail ropes.

T_1/T_2 Ratio—T_1/T_2 ratio is the ratio of the static rope tensions on each side of the drum, where T_1 is the weight of loaded conveyance plus weight of ropes, and T_2 is the weight of unloaded conveyance plus weight of ropes. The maximum recommended value for a particularinstallation is a function of the coefficient of friction of the tread material, of the acceleration and deceleration required, and of the angle of lap of the rope on the drum. A typical maximum value of T_1/T_2 is 1.5. This is also a concern for brake torque application. Should T_1/T_2 become too high, the rope will slip on the drum; when this happens, the coefficient of friction drops and control is lost. There will also be tread damage due to friction temperature rise and abrasion.

Drum Treads—Selection of an appropriate tread material for the drum rope grooves and tread pressure are important. As the rope passes over the drum, the load, and thus the strain in the rope changes. This change in strain tends to cause the rope to creep (as opposed to slip) on the drum. A resilient tread material such as polyurethane tends to flow with the change in strain and reduce creep.

Typically, the average tread pressure (i.e., the sum of the rope tensions/projected rope area on the drum) of 300 psi (2069 kPa) with lock coil, 250 psi (1724 kPa) with flattened strand, and 200 psi (1379 kPa) with round strand ropes on plastic treads will give good life.

Deflection Sheaves—Deflection sheaves are used when the pitch circle diameter of the friction hoist pulley wheel (sitting above the shaft) is greater than the center-to-center distance of the compartments. In addition to positioning the hoisting ropes, the use of deflection sheaves has the advantage of increasing the angle of contact of the ropes on the wheel, permitting a higher T_1/T_2 ratio before slippage will occur.

However, deflection sheaves have the disadvantage of requiring additional torque during the hoisting cycle, increasing the height of the headframe, and putting reverse bending into the ropes, which can reduce their life. One rule of thumb used to position the deflection sheaves is that the ropes traveling at full speed should take a minimum of 0.5 seconds to travel from the drum to the deflection sheave. This rule, it has been claimed, alleviates the fatigue problem due to reverse bending since it provides the requisite time for the rope strands and wires to adjust their position.

Differential Rope Loads—A great concern with multirope friction hoists is the equalization of loads between the ropes. The two most common causes of differential loading are a difference in rope length or in circumferential lengths of each rope groove on the wheel.

Analysis of this problem and procedures to identify and correct the effects have been well covered in the technical literature. In the initial design stage, it is important that steps be taken to reduce its effects. Since there are no hard and fast rules, the following rules of thumb have been developed in the industry:

1. The ratio of rope lengths (skip in dump to hoist drum)/(skip at loading pocket to hoist drum) should be greater than 0.015.

2. The total number of revolutions of the drum on a trip should be less than 100.

3. The number of ropes should be kept to a minimum. There will be less difficulty maintaining equal tension on a four-rope hoist than on a six-rope hoist. In addition, a larger wheel will be required for a four-rope drum having fewer revolutions per trip, lower rope bending stresses, and lower sensitivity to tension variations. This requirement may conflict with rope size choice, however.

4. Rope attachments should have both fine and coarse length adjustment.

Hoisting Speed—There are no relationships attributable to the effect of speed. However, as the speed of hoisting increases, any inadequacies in the hoisting system are magnified.

Tail Ropes—In friction hoisting, the use of tail ropes makes it possible to balance the head rope weight and achieve a lower peak horsepower than for drum hoisting. However, the use of tail ropes presents some additional problems that must be recognized.

1. *Tail Rope Orientation*

Any object falling down a mine shaft is affected by the angular velocity of the earth and will move toward the east wall. A tail rope behaves in a similar way. If the shaft compartments are arranged east—west, the tail rope loops will open and close freely. However, if the compartments are north and south, the ropes could foul the separators at the shaft bottom. Thus, if tail ropes are used, then the orientation of compartments should be considered. The above described action results from a physical principle known as the Corioli effect and is a function of the hoist speed.

2. *Tail Rope Loop Diameter*

A natural loop diameter exists for each type of tail rope depending upon its construction. This should coincide as closely as possible to the center-to-center distance of the conveyance. The bending ratio is defined as the natural bending diameter divided by the rope size. It is possible to specify different rope construction and number of tail ropes to satisfy the loop diameter requirements.

Rope Construction	Natural Bending Ratio
34 × 7 Non-Rotating	46:l
18 × 7 Non-Rotating	60:1
6 × 7 Round Strand—Reg. Lay	90:1

3. *Tail Rope Loop Dividers*

According to Delorme (1977), to avoid mishap and possible mechanical damage through entanglement, the balance rope loop area should be well controlled in the sump. One method is by constructing a loop divider. The balance ropes should be restricted quite closely in the direction of their lateral movement.

Early contact with the dividers between individual ropes will provide good control in the sump area and also assist in ensuring that adequate stability through the shaft is maintained. Longitudinal movement, on the other hand, should not overly be restricted. The dividers should be designed to avoid trapping any material from spillage. Some operators have found that wire rope covered with rubber hose and placed in the same configuration (as shown in Fig. 17.5.14) has proved most successful in this connection. The elevation of the loop divider for good results is one loop diameter plus approximately 3 ft (0.9 m) above the bottom of the loop. Some operators have placed such dividers at several elevations in the sump area to ensure good control.

Calculation—The design of a friction hoisting system, including the selection of ropes, involves a knowledge of costs, shaft design, headframe design, and other factors beyond the scope of this chapter. However, an example of rope selection is presented based on previously mentioned technical considerations. The procedure involved in the analysis is as follows:

Step 1. Tabulate data.
Step 2. Calculate rope tensions.
Step 3. Check factor of safety of head ropes.
Step 4. Check factor of safety of tail ropes.
Step 5. Check bending ratio.
Step 6. Check T_1/T_2 ratio.
Step 7. Check tread bearing pressure.
Step 8. Check loop diameter of tail rope.

Example 17.5.4. Given the following friction hoist system:

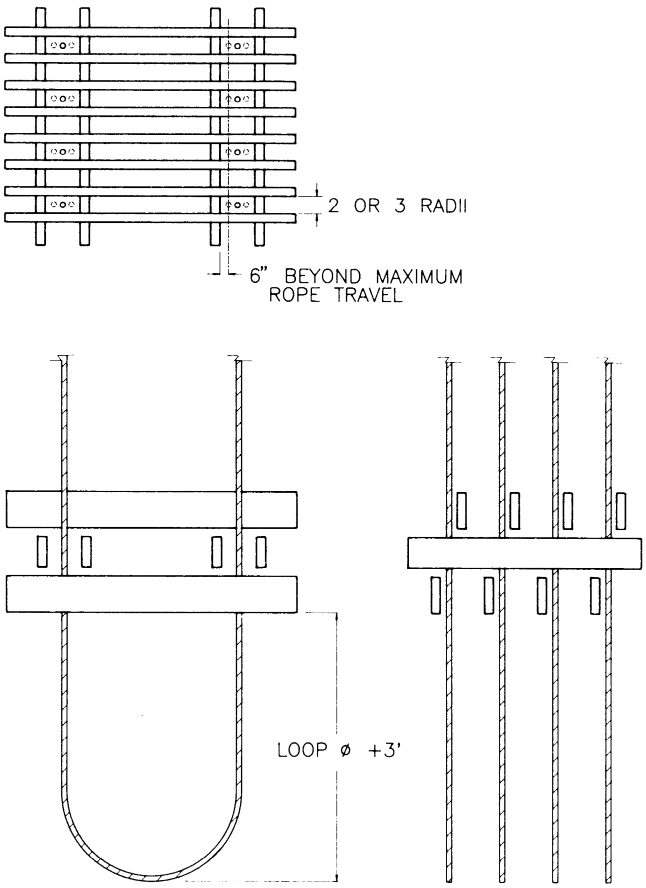


Fig. 17.5.14. Rope loop divider (Delorme, 1977).

Step 1. Assumed operating conditions.

a) Hoist wheel diameter	170 in. nominal	(4318 mm)
	172 in. new	(4369 mm)
	168 in. worn	(4267 mm)
b) Suspended loads		
Hoisting distance	1921 ft	(585.5 m)
Suspended ropes	2122 ft	(646.8 m)
Skip payload	105,000 lb	(47,628 kg)
Skip and rope attachments	136,000 lb	(61,690 kg)
c) Head ropes		
Type	6 × 27 flattened strand	
Number	6	
Diameter	2.125 in	(54 mm)
Ultimate strength	463,000 lb	(210,017 kg)
Weight/ft	7.8 lb	(3.53 kg)
d) Tail ropes		
Type	18 × 7 strand, non-rotating	
Number	4	
Diameter	2.625 in.	(67 mm)
Ultimate strength	493,000 lb	(223,625 kg)
Weight/ft	11.7 lb	(5.3 kg)

e) The difference between the hoisting distance (1921 ft) and the suspended rope length (2122 ft) is 201 ft. We will assume 100 ft of this is in the headframe and 101 ft is in the shaft bottom.

Select the proper hoisting rope and determine factors of safety.

Solution.

Step 2. Calculate rope tensions.

Wt/ft of 6 head ropes = 6 × 7.8 = 46.8 lb/ft
Wt/ft of 4 tail ropes = 4 × 11.7 = 46.8 lb/ft

Note: It is rare that a perfect balance is achieved, but a close match is desired.

The maximum rope tension T_1 occurs with the loaded skip at the dump.

T_1 = Rope from dump to drum 100 × 46.8	=	4680 lb
+ Skip weight		136,000 lb
+ Payload		105,000 lb
+ Tail ropes (1921 + 101) × 46.8	=	94,630 lb
		340,310 lb

T_2 = Rope from loading pocket to drum (1921 + 100) × 46.8	=	94,583 lb
+ Skip weight		136,000 lb
+ Tail ropes		4727 lb
		235,310 lb

Step 3. Check factor of safety of head ropes.

$$\text{SF} = \frac{\text{rope strength}}{T_1}$$

$$= \frac{6 \times 463{,}000}{340{,}310} = 8.16$$

This exceeds the requirement of 6.0 (according to CFR 57.19-21 and ANSI M11.1 standard for friction hoists at a depth of approximately 2000 ft).

Step 4. Check factor of safety of tail ropes.

From the calculation of T_1 the maximum weight of suspended tail rope is 94,630 lb.

$$\text{SF} = \frac{\text{rope strength}}{\text{suspended weight}}$$

$$= \frac{4 \times 493{,}000}{94{,}630} = 20.1$$

This significantly exceeds any regulations. This can be expected because the rope was selected on the basis of weight and not strength.

Step 5. Check bending ratio.

$$\text{Ratio} = \frac{\text{drum diameter (nominal)}}{\text{head rope diameter}}$$

$$= \frac{170}{2.125} = 80$$

This meets the requirements for good practice according to rope manufacturers and some codes that apply.

Step 6. Check T_1/T_2 ratio.

$$T_1/T_2 = \frac{340{,}310}{235{,}310} = 1.446$$

This is less than the 1.5 noted earlier as a typical maximum. The following should be borne in mind:

1. There is no code requirement for T_1/T_2.

2. A workable T_1/T_2 ratio is dependent on the coefficient of friction of the actual drum tread material and head ropes used, as well as angle of contact. The latter considerations enter with ground-mounted hoists that do not have as much contact as tower-mounted usually do.

3. Manufacturers apply a factor of safety to actual coefficients of friction to determine the T_1/T_2 for a particular application.

Step 7. Check tread bearing pressure.

$$\begin{aligned}\text{Average tread pressure} &= \frac{T_1 + T_2}{\text{projected area of ropes on drum}} \\ &= \frac{T_1 + T_2}{\text{no. ropes} \times \text{rope dia.} \times \text{drum dia.}} \\ &= \frac{342{,}736 + 235{,}431}{6 \times 2.125 \times 170} \\ &= 267 \text{ psi}\end{aligned}$$

Again there is no code requirement for tread bearing pressure, and acceptable pressures depend on tread material and rope construction. Varying the tread pressure changes the maintenance costs but not the safety of the installation.

Step 8. Check loop diameter of the tailrope.

Tailrope size	2.625 in.
Tailrope construction	18 × 7 NR
Bending ratio	60:1
Diameter of natural loop	= 2.625 × 60 = 157.4

This is marginally less than the drum diameter and is therefore satisfactory.

GUIDE AND RUBBING ROPES. Ropes used as guides and rubbing ropes may be of locked coil or half locked coil construction. These ropes are manufactured with a core of concentrically laid round wires covered with one or two layers of shaped wires. The outer layer of locked coil construction is always composed of interlocking wires of Z shape.

Some of the advantages of locked coil ropes as guides and rubbing ropes are as follows: (1) their smooth surface reduces friction, (2) they have a greater degree of rigidity, and (3) they have a higher breaking strength in relation to their diameter.

ADDITIONAL ROPE SELECTION CONSIDERATIONS. In addition to those factors covered in the previous sections, the following four items of importance should be considered in order to ensure that a particular hoisting rope will meet all of its hoisting requirements: (1) rope stretch, (2) rope torque, (3) rope harmonics and vibrations, and (4) rope sag. These are discussed in the following subsections.

Rope Stretch—When a skip is loaded at the loading pocket, the rope stretches. The amount of stretch, which has a static and dynamic component, has a number of significant consequences that must be considered in the design of the hoisting system. These are as follows:

1. The rope acts as a spring and helps absorb impact loads. The longer the rope, the greater the stretch, and the greater the amount of energy that can be absorbed. This is the reason why the codes permit reduction in the factor of safety with longer ropes.

2. When a hoisting system is being designed for balance hoisting using two skips, the amount of stretch must be considered when designing the overtravel allowance in the headframe. Under normal loading conditions, one skip will be positioned at the loading pocket after the skip in the headframe has completed dumping. If, however, a skip is not loaded, the stretch due to the payload will not take place. Should the empty skip be hoisted to the surface, it will be above the headframe dump (by the amount of rope stretch that did not take place) when the lower skip is at the loading pocket. For example, a 10-ton (9-t) payload on a 4000-ft (1219-m) long 1-in. (38-mm) rope would cause a stretch of about 4 to 6 ft (1.2 to 1.8 m).

3. Due to both the static and dynamic forces, the skip moves down during loading. Unless this movement is considered in the design of the loading pocket and the skip, considerable spillage could occur.

4. The static and dynamic rope stretch at the loading pocket must be considered in establishing the skip undertravel in the shaft bottom.

The formula for rope stretch or elongation in ft (m) is

$$\text{stretch} = \frac{PL}{AE} \tag{17.5.41}$$

where P is load in lb (kg), L is length of rope from the hoist to the loading point in ft (m), A is nominal rope cross-sectional area in in.^{2} (mm^2), and E is a constant for a given rope construction in lb/in.^{2} (Pa). E is analogous to Young's modulus. It is determined experimentally by rope manufacturers and takes into consideration the voids between the wires in the rope and the geometric change in the rope under load.

Values of E change as the rope stretches with use. Typical values are tabulated below:

Rope Construction	E, psi (kPa)
Full lock coil	14.3×10^6 (98.6×10^6)
Half lock coil	15.7×10^6 (108.3×10^6)
6 × 27 flattened strand	9.0×10^6 (62.1×10^6)
18 × 7 IWRC sinking	10.1×10^6 (69.6×10^6)
34 × 7 IWRC sinking	7.8×10^6 (53.8×10^6)
6 × 19 round strand, FC	9.0×10^6 (62.1×10^6)
6 × 19 round strand, WRC	9.9×10^6 (68.3×10^6)

The amount of dynamic stretch that takes place is proportional to the mass and velocity impact of rock feeding into the skip. These factors may be controlled (to reduce stretch) through loading pocket design. Dynamic stretch is commonly taken as equal to the static stretch produced by the load weight.

Rope Torque—Stranded ropes have a tendency to untwist. In drum hoisting, the rope is fixed at the drum, and at the conveyance the tendency to untwist is restrained by the guides and shoes. Consequently torque is developed in the rope. The counter torque exerted by the conveyance tends to produce wear on one side of the guides. When disconnecting the rope from the conveyance, the torque is released, and a dangerous situation develops if the end of the rope is not restrained and spins out of control.

Some mining companies are deliberately letting the torque out of the rope when they take rope end samples for testing. However, some experimental work, as reported by Dolan (1961), has shown that by allowing a rope to rotate, ultimate strength is lost.

One formula used for calculating the approximate amount of torque in a rope is

$$T = kPd \tag{17.5.42}$$

where T is torque in ft-lb, P is load in lb, d is nominal diameter of rope in in., and $k = 11 \times 10^{-3}$ ft/in. for Lang lay and $= 7 \times 10^{-3}$ ft/in. for regular lay.

Rope Harmonics and Vibrations—Vibrations in hoist ropes can be observed as "yo-yo-ing" at the collar, and in the case of drum hoists as ropes whip between the hoist and the head sheave. The causes of these vibrations are (1) jerking operations such as uneven braking, (2) the horizontal movement of the rope at the crossover points on the drum, and (3) the vertical movement of the rope at crossover points on the drum.

These vibrations cannot be avoided and normally do not cause problems. However, there have been cases where the frequency of the vibrations is a harmonic of the natural frequency of the hoist rope and severe and dangerous whipping has occurred. Such a situation is most likely with a long, flat span of rope between the hoist and head sheave. The following rules of thumb have been developed to assist designers to set up a good hoist and head sheave arrangement.

1. Keep the vertical rope angle as close to 45° as possible.
2. The slope distance along the rope, between the tangent points at the drum and the sheave, should not be an even multiple of the drum circumference.

The hoist designer should analyze the harmonic behaviors of the ropes and select the type of drum grooving which will avoid harmonic vibrations. This has been reviewed by Dimitriov and Whillier (1973). When unacceptable rope movements do occur, it is necessary to reduce hoisting speed or payload, or to install an intermediate tower with idler sheaves between the hoist and headframe.

Rope Sag—A rope between a ground-mounted hoist and a head sheave sags and takes the form of a catenary. With a heavy rope and a light load, the sag can be significant and cause problems at the sheave deck and the hoisthouse wall if not considered. Such a situation could occur during sinking a deep shaft when there is an empty bucket at the dump.

INCLINED (SLOPE) HAULAGE. The selection of ropes for an inclined shaft differs little from selection for a vertical shaft. The three major differences are (1) calculation of rope tensions, (2) sizing of sheaves, and (3) abrasive wear.

Calculation of Rope Tension—The tension in the rope is the sum of the gravitational, frictional, and accelerational forces. The gravitational force is the sum of the weights of the car(s), payload, and the rope multiplied by the sine of the angle of the incline. The friction force is commonly taken as 2.5% of the weight of the car and payload plus 10% of the rope load. To allow for acceleration, 10% is added to the gravitational and friction forces.

Sizing of Sheaves—Because of the space restrictions underground and the need for portability, deflection sheaves are commonly smaller than used elsewhere for hoisting ropes. Minimum *D/d* ratios are presented in Table 17.5.4.

Abrasive Wear—Abrasive wear is more likely to be a problem in a slope than in a vertical shaft and this potential problem should be addressed in rope selection. One approach is to select ropes with thicker wires such as 6 × 7. Some designers increase the factor of safety to allow more wear on the rope before it needs to be replaced.

Table 17.5.4. Minimum Ratio of Drum/Sheave Diameter to Rope Diameter

Rope Construction	Minimum Tread Diameter of Sheave or Drum
6 × 7 classification	72 × rope diameter
6 × 19 classification	45 × rope diameter
6 × 37 classification	27 × rope diameter
6 × 25 (Type B); 6 × 27 (Type H) 6 × 30 (Type G) flattened strand	45 × rope diameter
Rotation resistant	51 × rope diameter

Note: Conditions may exist where further reduction may be necessary. Under such conditions, service life would be affected and due precautions should be exercised. If possible, the hoist/sheave manufacturer should be consulted for guidance. Note that the Jan. 24, 1984, MSHA Standards do not define necessary *D/d* ratios.

17.5.5.4 Rope Testing Certification and Acceptance

It is common practice for the purchaser to require the manufacturer to certify that the rope will meet the nominal breaking strength. Certification usually includes a test report providing full particulars on the wires used to manufacture the rope as well as breaking strength in a failure load test to ultimate load. A test to destruction by an independent laboratory can be specified. However, such a test involves additional costs and is not normally specified in the United States.

17.5.5.5 Rope Operating Practices

The correct wire rope properly installed on well-designed equipment maintained in good working condition provides the foundation for satisfactory rope performance. In order to attain and sustain the required rope performance, it will be necessary that the rope be properly operated and adequately maintained. Well-developed rope operating practices should consider the following: (1) rope storage, (2) rope installation, (3) rope changing procedures, (4) rope operating practices, (5) equipment maintenance, (6) lubrication, and (7) inspection procedures.

ROPE STORAGE. Whether the rope must be stored temporarily or indefinitely, it should be indoors where it can be shielded from weather, corrosive fumes, and excessive heat that might dry the lubricant or fiber core.

ROPE INSTALLATION AND HANDLING. Ropes should be wound onto the drum under load. The direction of coiling should be determined by the accepted rule of thumb method, as shown in any rope handbook, and the individual turns should be tamped together using a copper hammer to avoid gaps between coils. Before cutting, the rope supplier or a technical handbook detailing correct cutting procedures should be consulted (Anon., 1980).

DRUM HOIST ROPE-CHANGING PROCEDURE. Rope changing procedures for drum hoists are relatively easy and are described in rope handbooks. Precautions must be taken, however, to ensure that adequate tensions are applied to provide correct spooling during installation.

FRICTION HOIST ROPE-CHANGING PROCEDURE. Rope-changing on friction hoists can be carried out using one of four methods.

1. *Method 1.* A rope-changing station is located midway in the shaft. Headropes are changed by chairing the conveyances at mid-shaft, where reels of new cable have also been positioned,

disconnecting both ends of the headropes and connecting one end of the old rope to one end of the new rope. The opposite end of the old ropes is connected to empty reels. All headropes are changed at one time by rotating the friction wheel and thus lifting the new ropes. The old ropes are wound on the empty reels. After the new rope has been hoisted into position and the old ropes wound on the spare reels, both ends of the new ropes are connected to the conveyance. Tail ropes are changed from the bottom of the shaft (see method 4).

2. *Method 2.* A portable rope winch located on the surface removes all head ropes one at a time, winding them on empty reels. New head ropes are lowered by this winch and installed on the conveyances. During this procedure, one conveyance is located at the top of the shaft, and one conveyance is located at the bottom of the shaft. Tail ropes are changed from the bottom of the shaft (see method 4).

3. *Method 3.* Both head ropes and tailropes are changed from the bottom of the shaft, using the hoist to raise the new ropes into position.

4. *Method 4.* In this method, the tail ropes are installed from the bottom of the shaft, following a five-step procedure: (1) locate no. 1 conveyance at the bottom of the shaft, (2) locate no.2 conveyance at the top of the shaft, (3) release the rope clamp on the bottom of no. 1 conveyance and start reeling the rope to be removed on a spare reel, (4) lower no.2 conveyance and remove rope clamp on the bottom of no.2 conveyance and complete winding up the end of the rope removed, and (5) install the new tail rope with the reverse procedure. The new tail rope will be hoisted into position.

The head ropes could also be installed by the use of an auxiliary rope-changing winch located at the collar elevation in line with the bending rotation of the hoisting ropes. The final method selected depends upon the amount of room available on the surface, orientation of hoist ropes, available space in the headframe, and personal preference.

ROPE OPERATING PRACTICES. Mine ropes are operated and maintained correctly when the following conditions are met:

1. Drum and sheave groove contours are correct.
2. Filler, starter, and riser strips are used on the drums where necessary.
3. Rope crossovers on the drum are prevented.
4. Shock loadings and overloads are avoided.
5. Vibration stresses are kept to a minimum.
6. Peening and abrasive actions are minimized.
7. Rope cutbacks are appropriately completed.
8. Cage-end attachments are refastened at regular intervals.
9. The rope is lubricated at regular intervals with the correct lubricant.

EQUIPMENT MAINTENANCE. Maintenance of equipment that comes in contact with the rope is important and should not be overlooked during the design or operating phase. Some items to be considered are the following:

1. Tight sheave and drum grooves will pinch the rope, restricting wire and strand movement.

2. Incorrectly designed rope crossovers on drum hoists will crush or flatten the rope, induce the core to pop, and severely scrub wires. This can be prevented through the correct design of filler, starter, and riser strips on the drum flange.

3. Faulty bearings can cause vibration stresses, which in turn cause fatigue fractures that are most likely to concentrate at the end attachment.

4. Corrugated deflection sheaves, drums and rollers can cause high unit pressures, aggravated wear, excessive rope vibration, and early wire fatigue. Correct measuring and trimming of tread diameters will prevent this problem.

LUBRICATION. Atmospheric moisture, shaft water, and chemical fumes are a few of the agents that will cause corrosion. This frequently leads to wire breakage and premature removal of mine hoist ropes. In mines with very wet and corrosive shafts, it is distinctly advantageous to apply a lubricant that will penetrate the interior of the rope and that contains a corrosion inhibitor. Lubricants with water-displacing properties are also available and are useful at end attachments.

INSPECTION PROCEDURES. In order to achieve optimum rope performance, an inspection procedure that requires findings to be recorded, fully diagnosed, and translated into appropriate action should be instituted.

The presence of the foregoing not only allows the operator to estimate the remaining safe working life of the rope but can also pinpoint the source causing such damage to the rope. For example:

1. Marked reduction in diameter may be due to a loss of rope's elasticity, excessive abrasion, or corrosion.

2. Broken wires may be due to worn out sheave, or drum grooves, tight oversized sheaves or gappy coiling.

3. "Kinking" and "birdcaging" of working ropes generally result from a sudden release of load.

The term "kinking" in rope use describes the snarling back of a rope on itself in the form of a loop resulting in a bend in the rope when straightened out, while "birdcaging" is applied to the springing of strands away from the core or inner strands.

A thorough evaluation of all facts obtained through routine inspections, examinations and tests, and compliance with statutory mining acts is needed to decide how early a rope should be discarded for the sake of safety, and how late can it be removed for the sake of economy.

17.5.5.6 Rope Attachments

Wire rope end attachments are as important as the rope to which they are fastened. Therefore, the selection of the correct type of attachments should be based on an understanding of how they affect ultimate rope serviceability and efficiency.

There are only two ways to attach something to a wire rope: (1) forming a loop in the rope, and (2) attaching a fitting to the rope. Loops are made either by splicing the rope to itself, or by use of clamps or wedges. Fittings secured directly to wire rope can be applied by cold forming (snagging) of the metal in the fittings, by pouring a liquid material such as molten zinc, or by a wedging arrangement. In this section, some of the most commonly used attachments are described.

FACTOR OF SAFETY. The factor of safety for rope attachments is not specifically covered in CFR *Title 30* (Anon., 1989). However, it is considered good engineering practice to design the rope attachments to be stronger than the rope, that is, the rope will fail before the attachments. British codes require a factor of safety of 10 based on static loads.

When an attachment is made to a rope, the attachment commonly weakens the rope locally. The efficiency of an attachment is expressed as the percentage of strength left in the rope after installation of the attachment. The efficiencies to be expected from the various types of attachments when correctly installed are presented in Table 17.55

CAPPELS. Cappels are rope fittings attached directly to the rope. These types of fittings consist of a pair of wedges grooved to suit the particular rope diameter and interlocked to ensure complementary movement. A number of bands driven over the diverging exterior surfaces of the cappel limbs provides the initial compressive force to ensure that the wedges grip the rope. The limbs' internal surfaces have been machined to fit the external surfaces of the wedges. A safety block is fastened on the end of

Table 17.5.5. Rope Attachment Efficiencies

Attachment	Size, in.	Efficiency, %
1. Thimble and clips	all	90–100
2. Thimble and clamps	all	90
3. Thimble and mechanical splice	less than 1	92–95
	$1\frac{1}{8}$–$1\frac{7}{8}$	90–92
	larger than 2	90–98
4. Thimble and hand splice	$\frac{7}{8}$–$2\frac{1}{2}$	75–85
5. Spelter or resin socket	all	100
6. Wedge socket	all	90

the rope, protruding beyond the bottom of the wedges. Several types of cappels are used for hoist ropes including the wedge and loop.

THIMBLES. In North America, most mine hoist ropes on drum hoists are terminated with a wire rope thimble and U-bolt cable clamps. With this type of attachment, a loop is formed in the rope and the thimble placed within this loop. The free end of rope is then clamped to the long end to secure the thimble.

Thimbles are made of cast steel, whereas the clamps, shackles, and pins are made of 1.5% manganese steel.

SWIVELS. When winding with balance ropes, the lay length tends to shorten as each conveyance in turn approaches the bottom landing. It is for this reason that swivels are provided in order to allow the ropes to spin and regain their normal length. Shaft conditions and loadings influence the type of swivel used.

ATTACHMENT MAINTENANCE AND INSPECTION. It is desirable that all types of attachments be installed as recommended by the manufacturer. If thimbles and clips are to be used, then the manufacturers' recommendation for the correct number of clips, amount of turn back, clip positions, and correct torques should be followed closely. If a wedge-type connection is being applied, then care should be taken to properly clean the rope surface. Frequent applications of cement dust and subsequent steel brushing will remove all the surface lubricant.

In some jurisdictions, statutory mining regulations requires that all types of attachments be inspected both visually and nondestructively on a regular basis. In other parts of the world, removal criteria for attachments have been established.

17.5.6 SHAFTS

A *shaft* is a vertical or inclined primary opening in rock that provides access to and serves various levels of a mine. Primary openings are those which are considered to be permanent and require a high degree of safety. Chapter 17.4 discusses design and construction details.

17.5.6.1 Shaft Design Procedure

A suggested procedure for the design of shafts follows. It is important that the steps be followed in the given sequence. It should be noted that the process is iterative and involves working through the process several times before an optimum design is achieved. The shaft design procedure involves the following steps: (1) define purpose of the shaft, (2) identify location and determine inclination, (3) determine the number of hoists required, (4) determine the size of conveyances and compartments, (5) determine the arrangement of compartments, (6) determine the exterior shape, (7) design interior members (guides, buntons, etc.), (8) design shaft lining, (9) check ventilation characteristics, (10) determine ground stabilization and temporary ground support, (11) determine shaft collaring method, (12) determine shaft sinking method, and (13) evaluate and modify starting at item 1.

17.5.6.2 Purpose of Shaft

One of the first items to be examined when designing a shaft is to identify its intended purpose. Shafts usually fall into one of the following categories: (1) production (ore and waste handling), (2) service (personnel and materials handling), (3) ventilation (upcast or downcast), (4) exploration (for defining mineral deposits), and (5) combination of the above.

17.5.6.3 Location and Inclination

LOCATION. Generally, the location of a new shaft at the mine site is determined after establishing the following: (1) mine surface layout, (2) location, dip, and extent of the ore body, (3) number of working levels to be considered, (4) location of ore and waste handling facilities, (5) water collection sump requirements, (6) safety and stability of the shaft pillar, and (7) the future planned expansion of the shaft. The bottom of the shaft, where possible, must also be in a stable formation and should be able to facilitate any planned, future redeepening. The location of the shaft must also avoid adverse surface features and should satisfy surface layout plus logistics of surface and underground ore and waste handling facilities.

INCLINATION. The dip of the ore body is the main factor involved in deciding to sink either a vertical or inclined shaft. A secondary factor is the relative ground strength and geologic formations to be encountered by the proposed shaft.

The main advantages associated with vertical shafts are (1) hoisting speeds are greater, (2) shaft maintenance costs are lower, (3) sinking can be carried out faster, and (4) sinking can be achieved in almost any type of ground.

Inclined shafts (slopes) are generally associated with inclined (dipping) ore bodies where the length of crosscutting to reach the ore body from a vertical shaft becomes longer with the increase in depth of the shaft. They have the advantage of minimizing development to reach the ore from the shaft and are used frequently in coal mines.

17.5.6.4 Number of Hoists

The number of hoists (and conveyances) required to meet hoisting demands has a major impact in the design of a shaft (see procedure, 17.5.3.5).

17.5.6.5 Compartment Size

The cross-sectional area of a particular compartment (horizontal area) is dependent upon its use. In order to determine the most appropriate size, it is necessary to list the items to be transported in the compartment, determine their approximate dimensions and weight, indicate their direction of flow and their approximate quantities. Another important factor to be considered is the size of the shaft sinking bucket. After having determined the size of compartments for cage, counterweight, and skips, the remaining area is then divided to accommodate ventilation, manway, and pipe facilities.

SIZE OF SKIP COMPARTMENT. The skip capacity is determined by such variables as the hoisting capacity, material density, lump size, and vertical height available in the headframe. Generally speaking, the skip dimensions and cross-sectional area are determined by the skip supplier. Good design practice allows the following clearances:

Skip compartment size:

face to face on guides = outside dimension of skip guide shoes + 1 in. (25 mm)

front to back = outside dimension of skip + 3 in. (75 mm)

SIZE OF CAGE COMPARTMENT. Cages are generally used to transport personnel and materials. The following clause of CFR *Title 30* (57.19-66 Mandatory) applies in the United States:

> "In shafts inclined over 45°. . . . Each person shall be provided a minimum of 1.5 ft^2 (0.14 m^2) of floor space."

The cage capacity is determined by the cage supplier based on a knowledge of the following factors (1) the amounts of material to be transported, (2) the dimensions and weights of the major pieces of equipment to be lowered and raised, (3) the number of personnel to be lowered and raised per shift, and (4) type of conveyance preferred (i.e, single deck, double deck, combination skip/cage, etc.)

After establishing the cross-sectional area for the cage, the cage compartment is sized the same way as the skip compartment to provide similar clearances.

SIZE OF MANWAY COMPARTMENT. From CFR *Title 30* (57.11-37 Mandatory): Ladderways constructed after November 15, 1979 shall have a minimum unobstructed cross-sectional opening of 24 by 24-in. (610 by 610 m) measured from the face of the ladder.

(57/11-41 Mandatory): Fixed ladders with an inclination of more than 70° from the horizontal shall be offset with substantial landings at least every 30 ft (9.1 m) or have landing gates at least every 30 ft (9.1 m).

In addition to the above, it is necessary to provide adequate clearance at the landing platform to allow a person to move from one ladder to the next offset ladder. Generally, an additional floor area of 36 by 24 in. (914 by 610 mm) is provided.

SIZE OF COUNTERWEIGHT COMPARTMENT. The counterweight compartment can be of any size or shape as long as it provides sufficient space and clearance for the safe passage of the counterweight with the same clearances as for skips and cages.

SIZE OF SERVICE COMPARTMENT. There are no hard and fast design rules for sizing the services compartment except that the cross-sectional area of the compartment should be adequate to provide the following: (1) separate locations for communications (signaling) and power lines, (2) space for locating air, water, pump, backfill lines, (3) clearance for pipe fittings, and (4) space for pipe column brackets.

17.5.6.6 Compartment Arrangement

The arrangement of the compartments in relationship to one another depends upon the surface layout, underground layout, and the type and size of hoist to be used. Because these design details are not known precisely during the initial design stages, one must first make a "best estimate" and be prepared to change the arrangement as the final design evolves.

On surface, the orientation of the compartments in relation to the hoist and headframe is of major importance. Good rope practice for drum hoists requires that the location of the hoist in relation to the shaft and headframe be in line to provide acceptable rope fleet angles.

For friction hoists, the center-to-center distance on the compartments is a major consideration for determining the size of the drum, the necessity for deflection sheaves, and the type of rope construction for the tail ropes.

17.5.6.7 Exterior Shape

The exterior shape of a shaft is established by considering ground stability factors. A circular shape provides better resistance to deformation by lateral pressure. In fair to competent formations, an opening excavated in this form is generally self-supporting. In weak formations, the circular shape is adaptable to a variety of lining materials, concrete, steel segments, or cast-in-place concrete. Competent formations can be excavated to a rectangular shape and be generally self-supporting. An elliptical shape offers better support than a rectangle but not as good as a circular one. The geotechnical considerations leading to the selection of an exterior shape are beyond the scope of this discussion, but their importance in the overall design process cannot be overstated (see Chapter 10.5). Also shafts may have different exterior shapes at different depths, reflecting the different strata encountered.

17.5.6.8 Interior Members

Guides and buntons are the main vertical and horizontal structural elements in a mine shaft conveyance system. The primary function of these members is to facilitate running of the shaft's conveyances. Their characteristics influence not only speed of operation and amount of maintenance required, but also production and ventilation costs. Therefore, the choice of sets and guides is of great importance to achieving operational cost savings.

SHAFT GUIDES DESCRIPTION. Shaft guides are used in vertical shafts to keep the skips, cages, and counterweights in proper shaft position. The two types of guides in use are (1) fixed guides (wood, rail, and steel), and (2) rope guides.

Wooden Guides—Wooden guides are supported by the horizontal sets installed in the shaft. They are favored where conveyances require safety devices. This is due to the fact that the decelerating characteristics of safety dogs on wood are more reliable than on steel or rail. When hoisting on wooden guides, a speed of 2200 fpm (11.2 m/s) with a medium-sized skip is the practical upper limit. Wooden guides are subject to changes in dimensions due to changes in moisture content. They are also subject to wear to a greater extent than steel guides. Wooden guides generally are not used in shafts where fire hazards exist, such as in coal mines.

Rail Guides—Rail guides are common in inclined shafts. These guides vary in size, with the larger rails giving a wider bearing surface for the wheel. The steel rail provides a harder surface but presents a smaller wear area; this creates more wear and maintenance on conveyance guide shoes and wheels.

Steel Guides—Structural steel tubes (SST) sections are becoming more popular as guides for production shafts where higher speeds and heavy loads require a fairly rigid and stable section. With steel guides, the conveyances are usually equipped with adequately sized guide roller assemblies to minimize wear between the guides and shoes on the conveyance. When hoisting on steel guides, a speed of 3000 fpm (15.2 m/s) is a practical upper limit.

Rope Guides—Rope guides are also used for guiding conveyances in vertical shafts. These are generally used with multirope hoisting systems where the effect of hoist-rope torque is minimal or nonexistent. Half locked coil ropes are used for this service. Rope guides do not require any intermediate support, thereby eliminating the steel sets required for fixed guides. Since rope guides are not able to withstand the horizontal forces of loading and unloading, the conveyance must be supported by other means in these areas. Fixed guides are used at the extremes of travel, and a retractable guiding system should be considered at intermediate levels. There are several schemes by which rope guides are suspended and tensioned, and the selection of any one of these will depend on the particular installation.

Because rope guides eliminate the need for horizontal buntons, the ability of the shaft to handle airflow is enhanced. In a large shaft, with multiple conveyances traveling at the same time, the aerodynamic effects can cause unexpected rope deflections. These effects should be studied during the design stage. Since rope guides are the smoothest of all guides, hoisting speeds up to 4000 ft/min (20 m/s) are feasible.

SHAFT BUNTON DESCRIPTION. Shaft buntons are horizontal members used to divide the shaft into compartments. They also support and carry the shaft guides, pipes and cables. Buntons can be of any cross-sectional shape and can be installed in a shaft at any spacing. However, the correct design and layout of buntons and their installation at a suitable spacing minimizes the air resistance of shafts and hence reduces ventilation operating costs.

GUIDE AND BUNTON STRUCTURAL DESIGN. Although there are no universally accepted loading parameters for the design of the shaft members, buntons and guides may be designed using empirical static loadings, generally accepted in the industry, and discussed in the next segments.

Bunton Loading—The static loads considered acting on set members are

1. The known weight of steel to be supported.
2. The vertical friction load on the guides transferred to the set members. The friction load is assumed equal to 3% of rope end load, where rope end load is calculated by adding the weight of conveyance, the attachments, and the payload in the conveyance.
3. A horizontal load transferred from guide members to set members assumed equal to 10% of rope end load.

Guide Loading—The static loads considered acting on the guide members are as for buntons. As mentioned earlier, there is no general consensus on these loading parameters and they have been challenged by several authors with diverging opinions (Bently, 1973; Backerberg, 1970; Van Wyk, 1961).

17.5.6.9 Shaft Lining

Shaft lining may be comprised of shotcrete, cast-in-place concrete, or steel and cast iron tubbing. When a lining is required, the selection depends on a number of design considerations that relate to the strata being excavated. For further discussion, see Chapter 17.4.

SHOTCRETE. Sprayed concrete, 5 in. (125 mm) or more in thickness, may be used to control immediate raveling and weathering of the shaft walls. To date, shotcrete has not been used extensively to provide long term support, nor as the only means of lining in shafts.

CONCRETE. The use of concrete for permanent support is becoming more common. Shafts may be fully lined or partially lined with "concrete rings" with areas of open ground between the rings. Common spacing used for ringed shafts is 4-ft (1.2-m) high concrete rings with a 4-ft (1.2-m) open area between, resulting in an 8-ft (2.4-m) set interval. Concrete is generally placed 12 in. (305 mm) in thickness, with a minimum of 10 in. (254 mm).

STEEL OR CAST IRON TUBBING. Although the use of concrete as a lining material is becoming more common, there are certain geologic conditions where steel or cast iron tubbing is a more appropriate material. Concrete is suitable when water pressures are less than 250 psi (1724 kPa) and when the stress field is uniform and compressive in nature. Steel is more suitable for a completely water-tight lining and is capable of withstanding tensile stresses. These stresses could arise if the shaft is subjected to bending loads caused by subsidence or buckling loads caused by a non-uniform horizontal stress field.

Steel lining can be butt-welded to give permanent watertightness and has a higher buckling safety factor than tubbing. Steel is particularly useful as a lining for shafts sunk by drilling methods. Cast iron tubbing consists of several segments bolted to form a ring and requires a lead gasket to be placed between segments.

DESIGN CONSIDERATIONS FOR SHAFT LINING. The design requirements for lining a structure is governed by the required duty of the shaft and environmental conditions in which it is constructed. Careful consideration of the following points should be made in the design of structural lining: (1) precise behaviour of the rock mass in situ, (2) self-supporting action of the rock itself, (3) effect of separation of the lining due to certain vertical and horizontal movements of the surrounding rock formation, (4) construction of watertight linings, and (5) economics of the lining structure.

The design of steel or cast iron linings is a much more complex process, since the buckling characteristics of an elastically embedded hollow cylinder with external pressure must be evaluated. Although the details of such a design are not discussed here, several reports on the subject are available in the technical literatures (Ostrowski, 1972; de la Vergne and Cooper, 1983; DeHart, 1983).

17.5.6.10 Ventilation Characteristics

The shaft is generally the largest single contributor to total mine air resistance when it is equipped with rigid guides for hoisting purposes. The resistance consists of two components: (1) frictional resistance, caused by viscous drag in the thin air layer at the shaft walls and the periphery of the vertical elements (guides, pipes, cables, ropes, etc.) of the shaft; and (2) shock resistance, due to the transverse sets (buntons and dividers), completely immersed in the airstream, thereby obstructing the flow, and recurring at intervals throughout the shaft.

These transverse elements create turbulence in the airstream with corresponding loss of flow energy. The turbulent waves below buntons and conveyances often contribute very much more to the total shaft resistance than the skin friction of the shaft walls. The forces caused by the buntons are parallel to the airstream, and proportional to velocity pressure, frontal area, surface texture, and shape. Because the frontal area of all the buntons in a shaft is likely to be more than the frontal area of the cages and skips, the aerodynamic design of the bunton is of importance in the design of a mine shaft.

A reduction in the shaft resistance can be achieved through (1) improving the aerodynamic effect of horizontal obstructions such as buntons, (2) minimizing the frontal area of the set members, and (3) increasing the spacing between the horizontal obstructions. Practical experience has indicated that there is little ventilation advantage to be gained from spacing greater than 15 ft (4.6 m).

General treatment of mine ventilation theory and practice is offered in Chapters 11.6 and 11.7.

17.5.6.11 Ground Stabilization and Temporary Support

Table 17.5.6 identifies three types of ground support problem encountered in shaft sinking and their corresponding solutions. For a detailed discussion of ground control, see Chapter 10.5.

Table 17.5.6. Ground Support Problems Encountered in Shaft Sinking

Problem	Solution
Ground is too weak or wet to allow any type of excavation	Pre-grout, freeze, drill and pump water wells.
Ground requires support during excavation	Rock bolts, screen, shotcrete, limit amount of unsupported ground.
Shaft requires permanent protection to allow hoisting	Install timber sets, steel sets, pour concrete lining either partial or rings, install steel or cast iron liner.

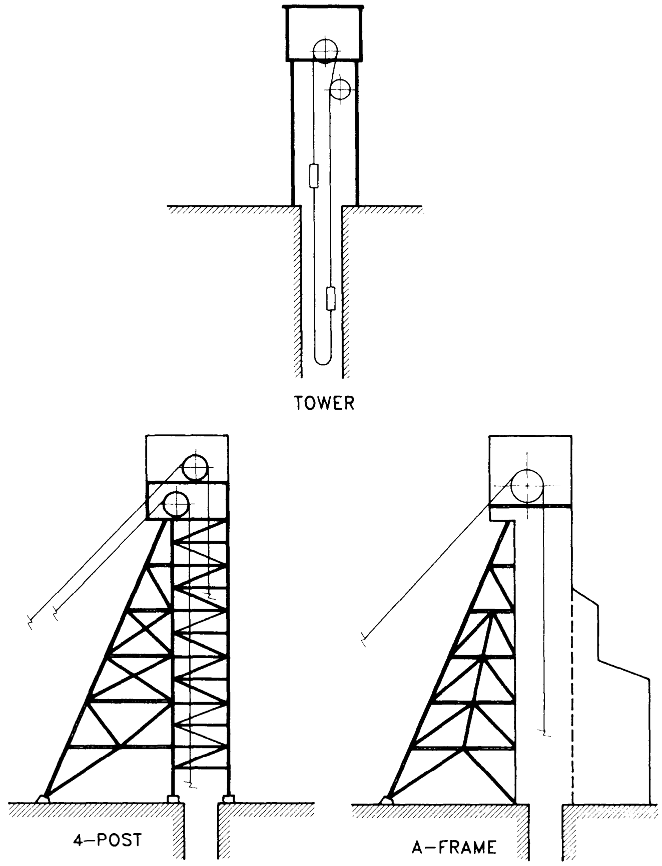

Fig. 17.5.15. Types of headframe structures.

17.5.6.12 Shaft Collar

Shaft construction begins with the excavation and forming of the shaft collar. The collar assists in forming the desired shape for the initial length of the shaft and provides the necessary stability and alignment for the remaining length of shaft to be excavated. Completion of the collar also allows erection of the headframe, sheave deck, and hoisting facilities for the sinking operation. The collar acts as a barrier to prevent water and soil from entering the shaft.

Collar construction methods are beyond the scope of this chapter but include steel sheet piling cofferdam, drilled interlocking concrete piles, steel walings with sheeting, drop caisson, drilling, pregrouting and sinking, open cut and dewater with well points, and deep well pumping.

17.5.6.13 Shaft Sinking

Following completion of shaft collaring, the actual shaft sinking is carried out usually by one of the following methods: (1) conventional methods of drill-and-blast or pilot raising and slashing, or (2) mechanized methods of raise boring or blind shaft boring. These are discussed in Chapter 17.4.

17.5.7 HEADFRAMES

The basic purpose of a headframe installed over a shaft is to support the sheave wheel over which a hoisting rope passes for raising or lowering conveyances. The construction of a headframe is also necessary to allow dumping of hoisted materials aboveground. Structurally, there are two types of headframes: (1) headframe structures with backlegs such as an A-frame, and (2) four-post and six-post and headframe structures of tower form (Fig. 17.5.15).

17.5.7.1 Construction Materials

Headframes may be constructed of timber, steel, or concrete. Modern trends to high-capacity hoisting have necessitated the construction of very large headframes, which effectively preclude the use of timber as a construction material.

COMPARISON—STEEL VS. CONCRETE. Butler and Schneyderberg (1981) outlined the principal criteria that should be used as a basis for a realistic evaluation of the merits of concrete and steel for a headframe. A summary of their arguments is given in Table 17.5.7.

Although the arguments given appear to favor concrete headframes, it should be noted that both concrete and steel can produce economically viable, structurally compatible, and visually appealing headframes for any new development.

Advantages of concrete structures include (1) effective use can be made of space within the structure for tower-mounted friction hoists, (2) when used in conjunction with ground-mounted drum hoists, the hoist may be located at any position around the headframe, (3) maintenance costs are low, (4) high damping effect of the massive concrete structure on shock and vibration, (5) simplicity of collar layout and interconnection with service buildings, (6) provision for future expansion, and (7) durability and resistance to corrosion. Disadvantages of concrete include (1) lengthy construction period, (2) higher capital cost in comparison with a steel headframe, and (3) no salvage value.

For steel structures, advantages include (1) lighter foundation loads, (2) adaptability to minor changes, (3) salvage value, (4) capital cost saving in remote areas, (5) can be pre-fabricated into transportable lengths for on site assembly, and (6) speedy construction. The main disadvantage of steel is that it is prone to corrosion, and thus not suitable as a production headframe for corrosive ore (e.g., salt and sulfides) unless the steel is treated.

17.5.7.2 Headframe Design Considerations

A successful design must be based on an overall integrated hoisting system design, which involves a critical examination of the impact of at least the following list of items: (1) loads, (2) foundations, (3) mine services, (4) sinking provisions, (5) equipment monitoring facilities, (6) conveyance handling and rope handling, (7) heating and ventilation, and (8) others, such as local mining regulations.

Table 17.5.7. Design Considerations for Concrete and Steel Headframes

Consideration Criterion	For Concrete Structures	For Steel Structures
Foundation	Requires sound bedrock	Lighter steel headframe can be erected on non-corrosive weak ground formations.
Construction	Slipformed concrete tower can (in favorable weather) cut construction time.	Can be erected in all weather.
Accommodation of shaft sinker	Can accommodate temporary sheave deck to facilitate shaft sinking.	Cannot facilitate installation of temporary head gear without extensive modification to the permanent structure.
Additional facilities	Provides sufficient enclosed space to house hoist's electrics, control room, and ventilation equipment.	Steel structure usually not capable of carrying extra loads.
Stiffness and damping effect	Concrete structure is stiffer to resist vibration during high speed.	Steel structure is more prone to vibration unless design is based on sophisticated dynamic studies.
Plant layout damping effect	Flexible to logistics, stiffer to resist vibration during high speed hoisting and in strong wind environment.	Steel structure is more prone to vibration unless design is based on sophisticated dynamic studies.
Adaptability to changes and future additions	Due to high load-bearing capability, concrete towers tend to be more flexible for future planned expansion.	Steel headframe, although amenable to minor changes, requires costly modification for major expansion.
Reclamation	Concrete headframe has no salvage value.	Steel headframe can be relocated and reused and has good salvage value.
Corrosion, durability and maintenance	Virtually immune to corrosion; can be made air-tight to isolate sensitive equipment from outside corrosive atmosphere.	Susceptible to corrosion, thus incurs higher maintenance cost; requires periodic repainting and cladding replacement.
Aesthetics	Visually more appealing to most people.	On unbroken flat horizons, large structure is often an aesthetic problem.
Cost	Depending on location and availability of the material, concrete headframe can be less costly.	In remote locations a steel headframe construction is usually cheaper.

Source: Butler and Schneyderberg, 1981.

LOADINGS. All headframes should be designed to withstand a combination of loads, comprised of the following: (1) dead load consisting of the weight of the headframe, sheave wheels, ore bins, and contents; (2) live load from hoisting at maximum capacity; (3) breaking loads of the ropes when the conveyance is stopped by the crash beams or if it is jammed in the shaft (breaking stresses introduced by an overwind are usually transferred to the structural system, often through an arrestor gear, and thus the supporting structure must be critically analyzed with a thorough understanding of the arrestor mechanism); (4) wind load, the intensity of which depends on the location, height, and shape of the structure; (5) snow load; and (6) temperature and seismic stresses, taken from published data relating to the geographic area of the shaft location.

FOUNDATION. Simply stated, the foundation should be capable of withstanding and absorbing stresses imposed by the structure and associated loads.

MINE SERVICES. The design of the headframe must suit surface layouts for providing the essential mine services. When possible, it should be located close to the shaft collar house, waiting area, lamproom, first-aid room, hoist house, maintenance shop, changing house, and administrative offices. The type and design of headframe must also take into account the shaft internal arrangement, position of the hoist with respect to the shaft, and the position of the sheave steel. Facilities for several key concerns listed must be considered and adequately developed during the conceptual design stage: (1) arrangement of skip dumping area in relation to ore and waste storage and handling facilities, (2) clearance required for installation, maintenance, and removal of conveyances, (3) lifting equipment required for maintenance of conveyances, and (4) access required for maintenance of conveyances, dump areas, etc.

In the case of headframes for drum hoists, provision must be made for (1) lifting equipment and access for maintenance of sheaves, (2) access and anchorage facility to support the ends of hoist ropes, when doubling down for pretensioning drum end coils, and (3) sub-collar loading access for double deck cages.

According to Cook and Werner (1966), the design of headframes for friction hoists should address the following: (1) supporting facility at predetermined elevations for hoist or balance ropes and conveyances or counterweights during installation and changes; (2) clearance for installation of conveyance arrestor gear; (3) provisions for handling shaft ventilation air and for sealing machinery rooms; (4) arrangement of MG sets close to hoist motors to minimize runs of heavy bus bars; (5) lifting equipment access during head and tail rope changing; (6) support, accommodation, inspection, removal, and replacement facilities for rope guides where used; (7) ventilation to specific machines and areas, controlling moisture, dust, and temperature where required; (8) accommodation of sinking arrangements; (9) accommodation of all services for air, water, communications, and power lines to the shaft and to the headframe-mounted equipment; (10) the accommodation of stairwells and elevators; and (11) lighting and lightning protection.

SINKING PROVISIONS. After the decision has been made to sink a shaft, considerations should be given to the type of surface sinking plant (such as headframe and hoist) that is to be used for shaft sinking. In particular, it should be determined whether the sinking plant is to be temporary or is to make use of the permanent headframe and/or hoist.

Temporary Headframe—Generally, a temporary headframe is used during shaft sinking by the contractor. These headframes may be a wood or steel structure in modular form. Some steel headframes may be fabricated from hollow structural steel, which combines strength with light weight, and facilitates easy erection and dismantling. Headframes of this type are portable and have a high resale potential.

Design criteria for a temporary sinking headframe are the same as for a permanent headframe. Its height depends upon the method of rock disposal and size of bucket. The sinking headframe should embody features for dumping buckets or skips, for protecting personnel on the surface and in the shaft from falling pieces of rock while dumping, and minimizing work of top men in dumping buckets and removing broken rock. The design of temporary headframe structures should accommodate an adequate-sized storage bin and sufficient clearance for a rock disposal vehicle.

Permanent Headframe—Current trends favor installation of a permanent headframe for the sinking operation, as it tends to be more economical and time saving. The permanent main skeleton can be designed to facilitate erection and installation of the sinking sheaves at a suitable elevation. The structure can then be finished and equipped during the shaft sinking operation. The use of the permanent structure as a sinking headframe can make the permanent hoisting facilities available at an earlier date following completion of the shaft sinking program.

EQUIPMENT MONITORING FACILITIES. Two main hoisting incidents, which can be detrimental to personnel and equipment and require monitoring, are (1) overtravel at the shaft extremities (i.e., sump, headframe), and (2) overspeed during the duty cycle. In order to protect against these incidents, it is mandatory that monitoring and safety devices be installed in the headframe.

Operation of all hoists are monitored mechanically by controllers, such as the Lilly hoist controller. These are powered off the hoist drums and check hoisting speed, overtravel at each end of the wind, and deceleration in the end zones. Additionally, track limit switches and conveyance arrestors must be incorporated. The function of track limit switches is to provide independent overtravel protection in the headframe.

Ultimate protection against overwind is provided for all friction hoists by conveyance arrestors. These are installed at the ends of travel in each hoisting compartment. The headframe arrestors are designed to retard an ascending conveyance from 70% of full speed at an acceleration of 0.9*g*. Shaft arrestors are designed to retard an empty descending conveyance from full speed at 2*g*.

Where applicable, the headframe should accommodate installations of a crash beam and catch gear. With drum winders, the crash beam is located below the sheaves in the headframe. In the event of an excessive overwind, it stops the conveyance from traveling beyond this point. Should a conveyance be involved in an overwind situation in which the hoist ropes breaks, the conveyance and tail ropes will fall down the shaft, causing damage. To prevent this, catch gear should be provided in the headframe to "catch" the conveyance.

CONVEYANCE AND ROPE HANDLING. In the design and layout of a headframe, provisions must be made for the handling and changing of conveyances, hoisting ropes, and rope guides (if applicable). Friction hoisting often requires the use of very large skips and cages. Because of their size, the service and handling of these conveyances, and the tying off the head and tail ropes associated with them, considerable problems can arise. In the friction hoist headframe, these can be facilitated through the installation of an adequately sized overhead traveling crane. In the drum hoist headframe, handling and changing of conveyances and ropes are relatively easy and are usually achieved through the use of mobile cranes, rope blocks, and tugger hoists.

HEATING AND VENTILATION. In warm climates, the headframe may be left open. However, in colder climates, it is necessary to design the headframe as an enclosed structure with adequate provisions for a heating system. In tower-mounted friction hoisting systems, with all of the hoists, motors, and controls, etc., enclosed in the headframe, it is necessary to provide a space ventilation system, supplying filtered air for both cooling and heating.

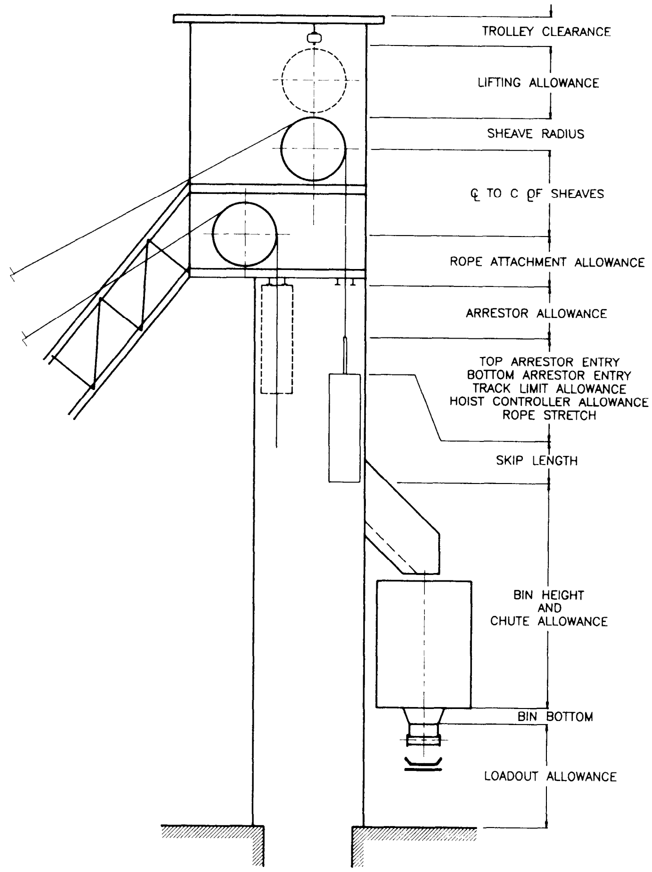

Fig. 17.5.16. Vertical general arrangement of headframe.

MINING REGULATIONS. Mining operations, including the design and construction of the headframe and shaft facilities, are subject to local, state, and federal regulations that relate to, among other things, safety of permanent structures and environmental protection. These regulations affect the design and construction of mine facilities.

HEIGHT. Due to today's increasing public awareness of the aesthetic impact of industrial development, the height of the headframe should be considered. This is especially true for locations in flat terrain where any large structure can be seen for long distances. The height of a headframe is generally based on (1) storage bin capacity requirements for ore and waste, (2) clearance for loading facility under the storage bin, (3) arranging that the resultant force from headframe loadings falls within the backleg post, and (4) providing minimum clearance for conveyance overtravel beyond its normal travel to the headsheaves. Of the above, the determination of the minimum clearance for overrun distance is the principal design consideration. This minimum clearance is obtained after establishing the value of three separate allowances (1) operating allowance, (2) rope stretch allowance, and (3) stopping allowance (Fig 17.5.16).

Operating Allowance—An operating allowance is required to allow for variations in repeatability of the final stop position of the conveyance in the headframe. In multilevel hoisting with drum hoists, this tolerance compensates for differences in coiling and rope stretch. In the case of friction hoists, the allowance compensates for creep during resynchronization and also allows a reasonable gap for rope adjustment due to permanent rope stretch.

Rope Stretch Allowance— This is included to avoid contact with the track limit switch when empty conveyances are hoisted. The rope stretch allowance generally includes an additional l-ft (0.3-m) margin as well as the extra travel length during brake deadtime and because of the effect of deceleration.

Stopping Allowance—A stopping allowance is to ensure that clearance remains between the top of the conveyance and the first obstruction in the headframe.

Calculations for Minimum Clearance—In an article describing hoisting plants at International Nickel Co., calculations for minimum headframe clearances were presented for both drum hoists and friction hoists (Albert, Cameron, and Gullick, 1975). These calculations are summarized in the following.

In computations for minimum clearances, two assumptions on hoist speed are made: (1) for rope stretch allowance, the hoist speed is 30 fpm (0.15 m/s); and (2) for the stopping allowance, it is assumed that the speed has been reduced to 300 fpm (1.5 m/s).

For drum hoists, the minimum clearance from the top of the hoist rope capping, in its lowest fully dumped position, to the rim of the headsheave is given by (in English units):

$$\begin{aligned}\text{clearance} &= \text{operating allowance} + \text{overtravel to Lilly limit}\\ &\quad + \text{rope stretch allowance} + \text{stopping allowance}\\ &= 5 + 1 + \frac{PL}{AE} + \frac{V_1^2}{2a} + V_1 t + 1 + \frac{V_2^2}{2a} + V_2 + 10 \end{aligned} \tag{17.5.43}$$

where P is maximum rated payload in lb, L is maximum hoisting distance in ft, A is equivalent area of rope in in^2., E is rope elastic modulus in psi, $V_1 = 0.5$ fps, $V_2 = 0.5$ fps, a is hoist deceleration rate in fps^2, and t is brake deadtime in sec.

For friction hoists, the minimum clearance from the top of the skip in its lowest position to the underside of the arrestor gear is given by (in English units):

$$\text{clearance} = 5 + 1 + \frac{PL}{AE} + \frac{V_1^2}{2a} + 0.5 + \frac{V_2^2}{2a} + V_2 + 7.5 \tag{17.5.44}$$

The required arrestor travel distance must be added to the above clearance in order to calculate the total clearance to the headframe crash beam. The arrestor travel length is given by (English units):

$$L = \frac{V^2}{2a} + H + \text{safety margin} \tag{17.5.45}$$

where L is arrestor travel length in ft, V is conveyance speed at time of entry in fps, a is maximum declaration rate of 0.9g (= 28.98 fps^2), H is height of arrestor gear (assume 4 ft), and the safety margin is 5 ft.

Section 18 Underground Mining: Self-Supported Methods

MICHAEL KARMIS, ASSOCIATE EDITOR
CHRISTOPHER HAYCOCKS, SECTION COORDINATOR

Chapter 18.0
INTRODUCTION

CHRISTOPHER HAYCOCKS

Self-supporting, open stoping underground mining methods are some of the earliest, starting with the prehistoric flint mines of Europe and the Egyptian gold mines of Nubia in the time of the pharaohs. When the early miner created an opening, it had to be inherently stable and self-supporting to enable him to continue. Therefore, as mining progressed beyond simple gophering, self-supported open stoping methods were devised to meet the needs of individual ore bodies. Timber for support appears in mines as early as 1000 BC, but this was for no more than local ground control. The ingenuity of mining engineers through history has so refined open stoping methods that today they produce more tonnage than any other mining system.

Self-supported open stoping finds its application in moderate to strong rocks that exhibit little jointing or fragmentation. Good back, hanging wall, and footwall conditions that require no more than incidental support are an essential part of these mining methods. Open stoping methods find applications in all inclinations of ore body from flat to vertical, and where ore movement may be either mechanical or under the influence of gravity. Table 18.0.1 demonstrates the range of ore bodies suitable for open stoping, with particular reference to their dip and the deposit thickness.

Most of the flat-dipping applications use ore pillars for overall support and ground control that may be recovered under some conditions after completion of normal stoping practices. In steeper ore bodies, rib, crown, and sill pillars used to block out the ore may be recovered subsequent to the completion of stoping. Open stopes are frequently filled to facilitate pillar recovery. Two of the methods, vertical crater retreat (VCR) and shrinkage stoping, utilize fragmented ore for temporary support in the stopes. In these two cases, the stope is not strictly open until after drawdown.

Table 18.0.1. Applications of Self-supporting Methods

Stoping Method	Ore Body Dip	Primary Support	Ore Body Thickness	Stoping Efficiency (TMS)*
Stope and Pillar, Room and Pillar	$<35°$	Ore Pillars	<300 ft (90 m)	30–70
Breast Stoping	$<35°$	Artificial Pillars	<12 ft (3.6 m)	1–5
Under/Overhand	$>45°$	None	<8 ft (2.4 m)	1–3
Shrinkage	$>45°$	(Broken ore)	>4 ft (1.2 m)	3–10
Sublevel	$>45°$	None	>20 ft (6 m)	50–70
Vertical Crater Retreat	$>45°$	None (Broken ore)	>40 ft (12 m)	>35

* TMS = tons/miner (employee)-shift

Self-supported stopes in ore bodies over 20 ft (6 m) thick are primarily high production and are amenable to mechanization, which makes them very efficient. The development of large-diameter (6- to 8-in., or 150- to 200-mm) down-hole drills has had a major impact on some open stoping because of their extreme accuracy over distances up to 400 ft (120 m). Innovative applications of these down-hole drills has significantly changed the layouts of the classical sublevel stope, making it much more productive while reducing costs. VCR stoping has also been a major beneficiary of this equipment. Most open stoping has also been a major beneficiary of trackless mining, particularly load-haul-dump units.

Chapter 18.1
ROOM AND PILLAR MINING

IAN FARMER

18.1.1 INTRODUCTION

Bullock (1982a), quoting previous data, showed that room and pillar mining together with stope and pillar mining accounted for most of the underground mining in the United States. He estimated that 60% of noncoal minerals (about 80 million tons or 70 Mt) and 90% of coal (about 290 million tons or 260 Mt) were obtained by room and pillar methods, and it is unlikely that things are radically different today. The method is cheap, highly productive, easily mechanized, and relatively simple to design. Ultimately, and particularly with increasing depths, mechanized longwall methods will make greater inroads into both coal and noncoal mining. But longwall requires major capital investment and development costs, and even now design is difficult, and success not always certain. In particular, longwall is inflexible. The rapid advance rates required to provide an adequate return on capital mean that all except very minor geologic faults must be avoided. Thus quite large areas of reserve are not minable using longwall methods, and they often give much lower overall recovery than retreat room and pillar mining, which is highly flexible.

The *room and pillar mining* method is a type of open stoping used in near horizontal deposits in reasonably competent rock, where the roof is supported primarily by pillars. Ore—or more commonly, coal—is extracted from rectangular shaped rooms or entries in the ore body or coal seam, leaving parts of the ore or coal between the entries as pillars to support the hanging wall or roof. The pillars are arranged in a regular pattern, or grid, to simplify planning and operation. They can be any shape but are usually square or rectangular. The dimensions of the rooms and pillars depend on many design factors, which will be considered later. These include the stability of the hanging wall and the strength of the ore in the pillars, the thickness of the deposit, and the depth of mining. The objective of design is to extract the maximum amount of ore that is compatible with safe working conditions. The ore left in the pillars is usually regarded as irrecoverable or recoverable only with backfill in noncoal mines. In this case backfill costs or the potential loss of valuable resource may be a limiting factor in room and pillar mining at greater depths. In coal mining, pillars are, ideally, recovered by retreat mining, allowing the roof to cave, thus relieving stress and reducing the likelihood of bumps.

The applications of pillar mining have been discussed by Hamrin (1982) and Hittman Associates (Anon., 1976) among others. Suitable conditions include ore bodies that are horizontal or have a dip of less than 30°. A major requirement is that the hanging wall is relatively competent over a short period of time, or is capable of support by rock bolts that are used extensively in room and pillar mining. The method is particularly suited to bedded deposits of moderate thickness (6 to 20 ft, or 2 to 6 m) such as coal—the main application—salt, potash, and limestone.

18.1.2 DESIGN OF PILLARS

18.1.2.1 Pillar Stress

Much of the following discussion is based on geomechanics theory presented in Chapter 10.5 and other chapters of Section 10.

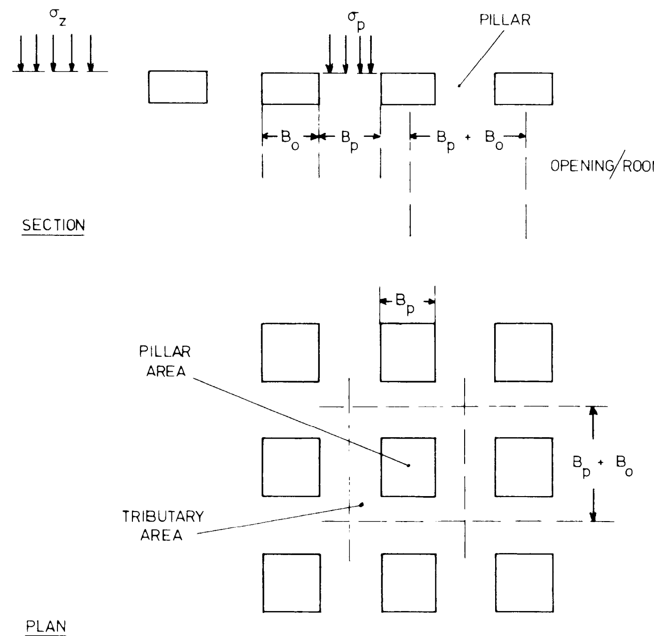

Fig. 18.1.1. Section and plans of rooms and pillars with widths and dimensions for simple analysis.

Despite the simplicity of the structure, and the detailed knowledge of rock behavior obtained over the past few years, pillar design has changed very little during the present century. It is based on the assumption that the stress in a pillar is evenly distributed and equal to the original vertical geostatic stress divided by the pillar area/original area ratio; and that pillar failure occurs when this stress exceeds the compressive strength of the pillar rock. It would be a naive assumption for any engineering structure in any material. It is particularly so in the case of pillars with high width/height ratios in a jointed, brittle material such as rock.

The major recent work on stresses acting on pillars has been carried out by Coates (1981). He started with the simplest and traditional statement of average pillar stress, known as the tributary area method. This assumes that each of the pillars left during excavation supports all the overlying strata that are "tributary" to their location. Then the average pillar stress σ_{pa} for square pillars with rooms of consistent width is

$$\sigma_{pa} = \sigma_z \frac{(B_p + B_o)}{B_p} \qquad (18.1.1)$$

where B_p and B_o are width of the pillar and room, respectively (Fig. 18.1.1), and σ_z is the geostatic or premining stress acting normal to the plane of excavation. If this is horizontal, then

$$\sigma_z = \gamma z \qquad (18.1.2)$$

where γ is rock average unit weight and z is depth to the mining horizon. This can be stated more simply for the common case of rectangular or irregular shaped pillars in terms of the extraction ratio R, where $R = \dfrac{B_o}{B_o + B_p}$ is the ratio of the area extracted to the total area of the orebody mined. Since $1 - R = \dfrac{B_p}{B_o + B_p}$, Eq. 18.1.1 can be more generally stated,

$$\sigma_{pa} = \sigma_z \left(\frac{1}{1 - R}\right) \tag{18.1.3}$$

This approach assumes that the mined area is extensive and shallow, that the mined rock is horizontally stratified, and that the pillars are equidimensional. It specifically ignores the relative extent and depth of the mined area, the stress component parallel to the plane of mining, the relative deformation properties of pillar, roof, and floor rocks, and the positions of the pillars in the mining zone. Taking some of these into account, Coates (1981) obtained a more general solution, principally for deep, long, mine pillars but applicable generally, by solving the statically indeterminate net deflection of the roof and floor rocks resulting from mining. Then the solution for average pillar stress becomes

$$\sigma_{pa} = \sigma_z \left\{ \frac{\left[2R - K_o \dfrac{H}{L}\dfrac{(1 - 2\nu_w)}{(1 - \nu_w)} - \dfrac{\nu_p}{(1 - \nu_p)} K_o \dfrac{H}{L}\dfrac{E_w}{E_p}\right]}{\left[\dfrac{H}{L}\dfrac{E_w}{E_p} + 2(1 - R)\left(1 + \dfrac{1}{N}\right) + 2\dfrac{RB}{L}\dfrac{(1 - 2\nu_w)}{(1 - \nu_w)}\right]} \right\} \tag{18.1.4}$$

where H is seam height; L is the extent of the mined area; K_o is the ratio between σ_h and σ_z or the coefficient of geostatic stress; and E_w, E_p, ν_w, and ν_p are the elastic constants of the wall (roof and floor) and pillar materials.

This is a two-dimensional elastic solution in plane strain and requires, strictly speaking, a length/width ratio of about 3 or more to be applicable. An analytical three-dimensional approach is not feasible, although finite element and boundary element methods (see for instance Tang and Peng, 1988) can be used to give a numerical solution.

Coates' (1981) approach is helpful in that it can be used to illustrate simply several of the fundamental characteristics of strata and geometry that affect pillar stresses. Some of these are illustrated in Fig. 18.1.2. For instance, as the E_w/E_p ratio rises (Fig. 18.1.2a), so the pillar stress is reduced from a magnitude close to $4\sigma_z$ (the extraction ratio has been chosen as 80%) to a level of $0.5\sigma_z$ for $H/L = B/L = 0.1$. This illustrates the bridging effect of the stiffer roof and floor layers and the tendency to transfer stress to the side abutment. Similarly, as L is decreased (Fig. 18.1.2b), the pillar stress is reduced from a maximum magnitude of $4\sigma_z$ to zero and $H/L = 0.4$ for a E_w/E_p, ratio of 6. Again this can be attributed to bridging at low spans. As a further illustration (Fig. 18.1.2c), using fixed values for E_w/E_p, H/L, B/L, there is considerable variation between the tributary area calculation (Eqs. 18.1.1 and 18.1.4) for stress at increasing extraction ratios.

It should be emphasized that this is used as an illustration, and that measurements of *average* pillar stresses are very infrequent. In fact, a review of the literature shows virtually no reliable measurements of average stress, principally because such measurements are difficult to obtain. One of the more interesting sets of data is by Orawecz (1977) from work in South African

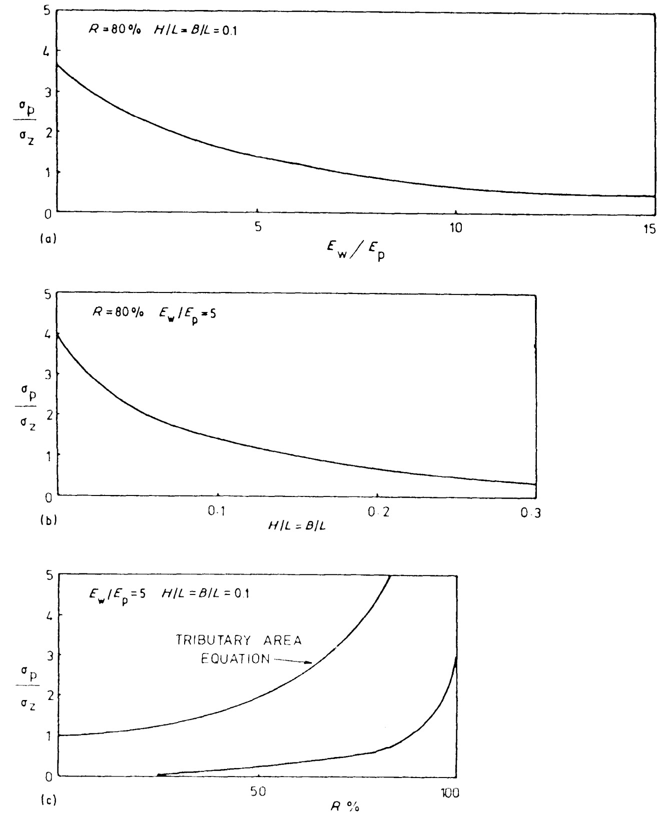

Fig. 18.1.2. Estimates of pillar stress σ_p as a proportion of vertical stress σ_z based on the variables in Eq. 18.1.4, putting $K_0 = 1$, $\nu_p = \nu_w = 0.33$, and N large, so that

$$\frac{\sigma_p}{\sigma_z} = \frac{(2R - 0.5H/L) - (0.5H/L \times E_\omega/E_p)}{H/L \times E_w/E_p + 2(1 - R) + RB/L}$$

coal mines. He describes two case histories in which surface settlements and underground displacements were measured using leveling and anchors in boreholes drilled from the surface to the seam level and below. The seams were at average depths of 131 ft (40 m) and 223 ft (68 m). The purpose of the measurements was to test an analog model, and satisfactory simulation allowed computation of pillar stresses from observed seam deformations.

The pillar geometries and data on the mining and instrumentation layouts are illustrated in Figs. 18.1.3 and 18.1.4 together with the pillar stresses σ_{pa}, computed from seam deformations in Figs. 18.1.3c and 18.1.4c. These are quite close to the pillar stresses σ_{pa} computed from the tributary area equation (Eq. 18.1.1). In these cases, the E_w/E_p and H/L ratios were, respectively, 3 and 0.01 and 2 and 0.05, and it can be seen from Fig. 18.1.2 that such a result would be expected. It is interesting to note the reduced pressure on the pillars adjacent to the ribside, and also the relatively low level of the abutment stress. The former would be expected; the latter is rather surprising and implies some weakening of the abutment.

The concept of average pillar stress is not a good one, since pillar stresses are not evenly distributed. This can be illustrated simply by stress analysis. A simple two-dimensional boundary element program, developed by Bray and Hocking among others, is included in Hoek and Brown (1981). This can be used, after modification, to calculate stresses around an opening or openings in a homogeneous, isotropic, linearly elastic material, under con-

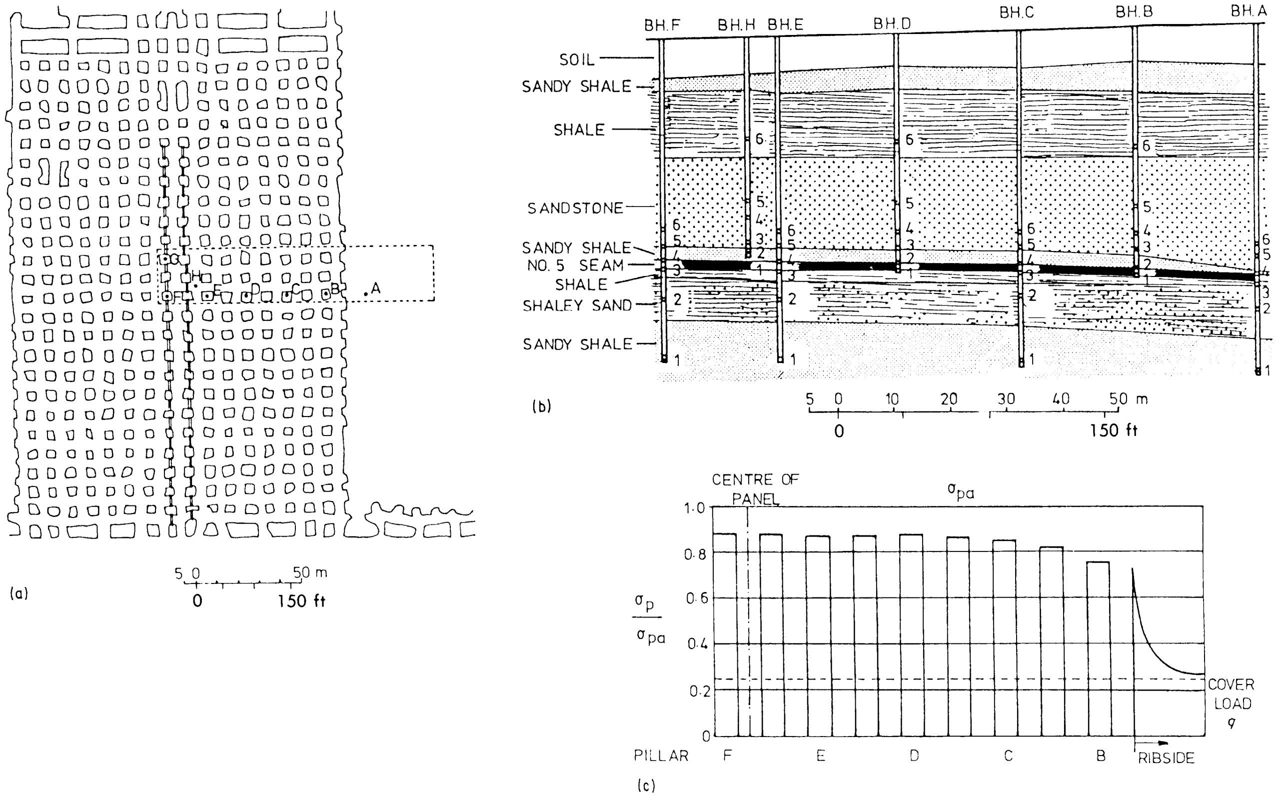

Fig. 18.1.3. Estimation of pillar stress σ_p as a proportion of pillar stress σ_{pa} computed from tributary area theory from experiments by Oravecz (1977) in No. 5 seam at Colliery A., South Africa. Data: average depth to mid-seam 40.3m; seam height 1.5m; pillar width 5.2m; room width 5.5m; percentage extraction 76.4%; panel width 176.2m (est.); deformation modulus, seam (est.) 1.54 GNm^{-2}; deformation modulus strata (est.) 4.43 GNm^{-2}; Poisson's ratio (est.) 0.15. Conversion factors: 1 ft = 0.3048 m, 10^6 psi = 6.894 GNm^{-2}.

ditions of plane strain in an infinite medium subjected to various combinations of uniform field stresses or external loadings. Typical solutions are given in Hoek and Brown, and the solutions for square and rectangular openings in a uniform stress field are reproduced in Fig. 18.1.5. Although the boundary conditions may be a little extreme for room and pillar mining, a simple example of how these computed stress distributions can be used in pillar design is given in Fig. 18.1.6. This takes the stress distribution in Fig. 18.1.5b and assumes initially two square rooms of dimension a at a distance 4a apart. Then the minor principal stress or confining stress in the pillar between the two can be projected on to a graph of minor principal stress against pillar width, to give the minor principal stress distribution and the average minor principal stress. This can be computed for pillars of any width (see Fig. 18.1.6c), and the resultant distribution can be used to compute the ultimate pillar strength using the strength envelope of the rock or coal in the form,

$$\sigma_{1f} = \sigma_{cf} + K_p\sigma_3 \tag{18.1.5}$$

Then σ_{1f} can be compared with the pillar stress σ_{pa} computed from the tributary area Eq. 18.1.1 to obtain an estimate of safety factor.

18.1.2.2 Pillar Strength

There is a large literature on pillar strength, much of it empirical. The most complete work is by Salamon and Monro (1967), and the best summaries by Bieniawski (1981) and Tsur-Lavie and Denekamp (1982). For detailed coverage of pillar strength theory, see Chapter 10.5.

The basic problem with pillar strength is that in a brittle rock, strength is dependent upon the size, and to a lesser extent, the shape of a test specimen. This means that the conventional method of pillar design, relating rock strength to pillar stress through a factor of safety $(FOS = \sigma_{cf}/\sigma_p)$, is unacceptable in brittle rocks, although it may be acceptable in more ductile rocks. The reason for this is evident: if failure occurs in a brittle manner, the strain energy stored in a pillar will be released from a volume onto a shear or tensile failure plane, where it will be distributed as surface energy per unit area of fracture surface; a constant for a particular rock. This is the basis of the Griffith failure criterion and is explained in Farmer (1985). Since energy is proportional to the square of stress, this means that strength will be inversely proportional to the square root of the dimension of the rock specimen, an observation confirmed experimentally by Bieniawski (1981) and Singh (1981) for various rocks including coal. In terms of pillar σ_{pf} and rock σ_{cf} strength, this can be expressed

$$\frac{\sigma_{pf}}{\sigma_{cf}} = \left(\frac{L_s}{L_p}\right)^{1/2} = \left(\frac{V_s}{V_p}\right)^{1/6} = \left(\frac{V_s}{V_p}\right)^{0.17} \tag{18.1.6}$$

where L and V represent dimension and volume, respectively, and the subscripts s and p refer to the laboratory specimen for strength testing and the pillar, respectively. In the ductile case, the energy is not transferred onto fracture surfaces but evenly distributed in the specimen or pillar. Then the exponent ap-

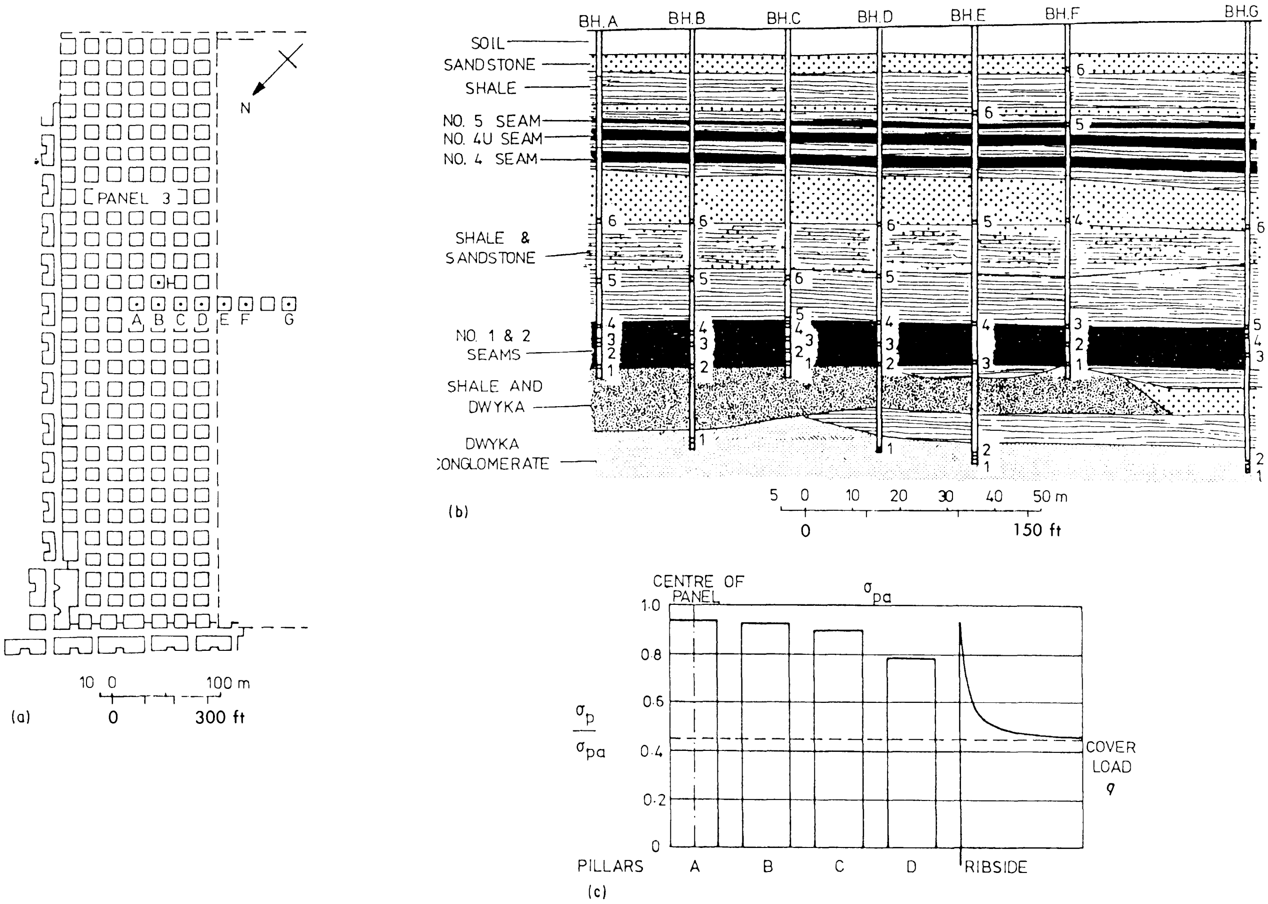

Fig. 18.1.4. Estimation of pillar stress σ_p as a proportion of pillar stress σ_{pa} computed from tributary area theory, from experiments by Oravecz (1977) in No. 2 seam at Colliery B., S. Africa. Data: average depth to mid-seam 66.7m; seam height 5.5m; pillar width 13.7m; room width 6.1 m; percentage extraction 52.1%; panel width 144.8m; deformation modulus, seam (est.) 3.92 GNm^{-2}; deformation modulus, strata (est.) 6.27 GNm^{-2}; Poisson's ratio (est.) 0.15. Conversion factors: 1 ft = 0.3048 m, 10^6 psi = 6.894 GNm^{-2}.

proaches unity. Thus, in the case of wide pillars, and pillars in pseudo-ductile rocks such as rock salt, Eq. 18.1.6 can be modified.

The relevance of Eq. 18.1.6 can, however, be confirmed by the empirical work of Hardy and Agapito (1977) on oil shale pillars in western Colorado. They proposed a general pillar formula which is recommended for all brittle rocks—that is, where the pillars fail in tension or shear—in the form,

$$\frac{\sigma_{pf}}{\sigma_{cf}} = \left(\frac{V_s}{V_p}\right)^{0.118} \left[\left(\frac{B_p}{H_p}\right) \Big/ \left(\frac{B_s}{H_s}\right) \right]^{0.833} \tag{18.1.7}$$

where B and H are pillar and specimen width and height, respectively. There are, of course, limitations for this approach, one of which would probably be the pillar width/height ratio. If this is less than 1, and particularly if the rock is ductile, the volume exponent will increase.

For the record, although the above method is strongly recommended, it is useful also to include the conventional representations of pillar design equations, often called the Holland-Gaddy (Holland, 1964) equation in the United States, which take the form,

$$\sigma_{pf} = \sigma_{cf}\left(a + b\,\frac{B}{H}\right) \tag{18.1.8}$$

$$\sigma_{pf} = K\,\frac{B^{\alpha}}{H^{\beta}} \tag{18.1.9}$$

In this case, σ_{cf} is uniaxial compressive strength of a cube of specified dimension; a and b are dimensionless constants, usually chosen so that $a + b = 1$ and $\sigma_{pf} = \sigma_{cf}$ when $B/H = 1$; α and b are dimensionless constants; and $K = f(\sigma_{cf})$ is a constant so that $K = \sigma_{cf}$ when $\alpha = \beta$ and $B = H$. There is a reasonable agreement about constants a, b, α, and β in Eqs. 18.1.8 and 18.1.9. Some representative values from early times to more recent are quoted in Table 18.1.1, principally for coal mines. All of the constants are effectively shape factors. The basic problem is that σ_{cf} in either equation is essentially the laboratory value, and a factor of safety, usually not included in the equation, is needed to allow for size effects and ensure safe design. Quoted values of this "safety factor" are difficult to find. Wilson (1983) suggests 5 for coal, but incorrectly recommends 1 for strong massive unjointed rock and 6 to 7 for weak rock—quite the reverse of the probable actual values. Where the economic success or failure of an operation depends on correct estimation of extraction ratio, a more accurate approach is required and Eq. 18.1.7 is recommended as a starting point. This represents a safety factor of 4 to 5 for most rocks and pillar shapes.

18.1.2.3 Barrier Pillar Design

Room and pillar mines are usually developed in a series of rectangular panels separated by barrier pillars. There is no specific design method for these pillars, but where the roof is not caved or where pillars are left in place, design of barrier pillars assumes greater importance. Fig. 18.1.2 shows that pillar stress is not necessarily evenly distributed, and where the roof and floor rocks are stiffer than the pillar rocks, stress with be transferred to an abutment. There is also the probability that deterioration—or overmining—of highly stressed pillars may lead to a reduction in load capacity of individual (or groups of) pillars, and transfer of load to other pillars that may lead to progressive failure. This is one of the most common causes of extensive pillar collapse (Mottahed and Szeki, 1982, describe a total mine collapse), and barrier pillars can control this.

Wilson (1983) analyzed this problem and suggested, for coal mines, barrier pillar widths of 1/10th of the working depth, but his approach, although applied to room and pillar workings, was designed principally to reduce entry damage in longwall entry chain pillars. A more satisfactory approach may be to consider pillar yield. Hudson, Brown, and Fairhurst (1971) in a series of tests on marble, which can be repeated on coal, showed that a pillar behaved in a yielding rather than a brittle manner if its height/width ratio was less than 1/3. The implication is that below this ratio, a pillar will deform rather than fracture, resisting rapid collapse. A yielding, barrier pillar of 3 to 4 times the excavation height can, therefore, be recommended, particularly at greater mining depths.

18.1.3 SUPPORT OF ROOMS

18.1.3.1 Rock Bolts

The key to design of rooms is support. This invariably means the use of rock bolts in room and pillar mining. At present, over 100 million bolts per year are installed in US mines. There are various types of rock bolt, and the type and method of installation can have a significant effect on performance. Classification of rock bolts into types is difficult. Conventionally, there are two methods, either as (1) grouted (usually fully grouted) or (2) mechanically anchored (usually point-anchored) bolts. A list of available bolt types from Peng and Tang (1984) is given in Table 18.1.2. A point-anchored bolt is usually tensioned; a fully grouted bolt is usually untensioned. A mechanical anchor can be installed easily, but is unreliable over a period of time; a resin bolt requires precision in installation-whether point or fully grouted-and usually has better long-term characteristics. The theory of rock bolting is developed fully in Chapter 10.5.

Conventional rock bolts are made from ⅝-in. (16-mm), ¾-in. (19-mm), l-in. (25mm), or l¼-in. (32-mm) steel rebar with an approximate yield force, respectively, of 7 (6), 9 (7.5), 17 (15), and 26 tons (23 tonnes). Normally, the installed bolt tension is 50% of this load. Steel bearing plates at the hole collar are usually 6 in. (150 mm) square and ¼ in. (6 mm) to ⅜ in. (9.5 mm) thick and are flat or bell-shaped with a center hole. The main function is to distribute stress to the rock at the collar through a nut threaded on to the top of the bolt, and tensioned through a drill chuck. Angle or spherical washers are used to create a uniform bearing surface. To prevent falls of rock between bolts-an important factor in weaker rocks-mesh or bench bars are placed behind the anchor bearing plates. For long-term installations, shotcreting is essential.

Bolts are usually considered temporary supports. At bolt forces close to working load, they are, like all rock stress systems, prone to deterioration with time. At differential roof deformations, greater than 1 to 1½%, they usually cease to function, although performance can be improved with shotcreting. The reduction or change in capacity with time is not well documented and relies to a great extent on ground conditions. A particularly useful recent paper by Signer and Jones (1990) illustrates the changing reinforcement loads on fully grouted bolts during roof deformation and illustrates their very flexible response to deformation.

In the case of mechanical bolts, installation is invariably accompanied by reduction in tension with time. This was investi-

Table 18.1.2. Types of Roof Bolt

Types of bolt	Types of anchor	Suitable strata type	Comments
Point-anchored bolt (tensioned)	Slot-and-wedge	Hard rock	Used in early stages
	Expansion shell	Medium-strength to soft rock	Most commonly used in US
	Resin grout	All strata especially for weak rock	Increased usage recently. Resin length less than 24 in. (0.6 m)
	Combination shell and resin anchor	Most strata	Resin lengths greater than 24 in. (0.6 m)
Full-length-anchored bolt (nontensioned)	Cement grout	Most strata	Disadvantage: (1) shrinkage of cement (2) longer setting time
	Resin grout	All strata	Increased use recently, especially for weak strata
Special bolts: Yieldable bolt	Expansion	Medium-strength rock	An expansion-shell bolt with a yield device
Pumpable bolt	Resin	Weak strata	Complex in installation
Helical bolt	Expansion shell	Most strata	In experimental stage
Split set	Full-length friction	Weak strata	Cheap but needs special installation equipment
Roof truss	Expansion shell	Adverse roof	Recommended for use at intersections and/or heavy pressure areas
Cable sling	Cement anchor and full-length friction	Weak strata	Substitute for timber, steel, or truss support
Lateral force system	Full-length 2-piece steel	Soft strata	Applying full-length lateral force (compression) to the strata
Swellex bolt	Full-length holding	Water-bearing strata	Using high-pressure water to swell the steel tube thus holding the rock

Source: Peng and Tang, 1984.

gated by de la Cruz (1964) and Parson and Osen (1969) among others and was attributed principally to slippage of serrations on the anchor shell, rock deformation and rock breakage at the anchorage and collar, and ground movement following excavation. In addition, dynamic vibration due to blasting is a major cause of tension loss. This means that constant monitoring and retensioning of bolts is needed if long-term installation is required. Conversely excessive bed separations can lead to bolt head failure, which is not found in grouted bolts.

It has been claimed that fully or point-grouted resin or cement anchors give improved performance, both long and short term, and there is some evidence for this. Franklin and Woodfield (1971), in a series of experiments, showed that reliance on bond rather than friction means that the force take-up is much quicker, and by extrapolation, the possibility of slippage is much less. There remain dangers associated with faulty installation, excessive annulus thickness, and poor bonding in wet holes, which in practice can make resin grouting less attractive.

The action of bolts is best described through the typical theoretical stress distributions around the openings illustrated in Fig. 18.1.5. In both cases, the surface of the opening is subjected to compressive tangential stress and zero radial stress. Further away from the surface, both the radial and tangential stresses approach the primitive stress levels in the rock mass undisturbed by excavation. The tangential compression stresses are high at the corners and in the sidewalls, but low in the roof and floor. This condition is exacerbated as the height/width ratio of the rectangular room is reduced further. This will have two effects: there will be crush at the corners and possibly squeeze in the sidewalls, and the reduced radial compression will allow sag of the roof and uplift of the floor. The most important of these is the reduced roof compression—particularly if combined with bedded and jointed strata—which will create conditions for bed separation or release of blocks from the roof strata.

Rock bolts are the cheapest and most obvious way of maintaining stability in such circumstances. Provided that the rocks are suitable for an anchorage location, are not subject to swelling or slaking, and there are no high pore pressures or water flows, then bolts have two main functions acting either singly or as a pattern. These are to maintain the stability of sagging roofs, particularly in weaker stratified rocks, and to restrain blocks in well-jointed or blocky rocks where release surfaces daylight in the exposed roof. The former application is principally for roof support in room and pillar mining in stratified rocks. This is the most common use of rock bolts, and it can be improved by variations such as trusses or slings (see, for instance, Seegmiller, 1990). The latter application is principally in civil engineering works, such as tunnel and cavern construction, and occasionally in slopes, where quite-large-capacity anchors are often used.

18.1.3.2 Support Design

Where a bolt is used to restrain a single block in the roof of an entry, the volume and hence the weight of the block and where necessary its direction of sliding can be determined by stereographic analysis of the kinetics of sliding. This method is outlined in Farmer and Shelton (1980) and in Farmer (1985). Methods of support based on the common requirement that bolt spacing should be half the bolt length are discussed in the same sources.

In coal mining, the design of bolts is usually based on Panek's (1962a, b) analysis. The most simple assumption for design purposes is to consider a sagging roof plate or beam of thickness L, span B, and length X, supported by rows of bolts with separation a between rows and spacing S. Then the bolt tension force P to support the roof will be given by:

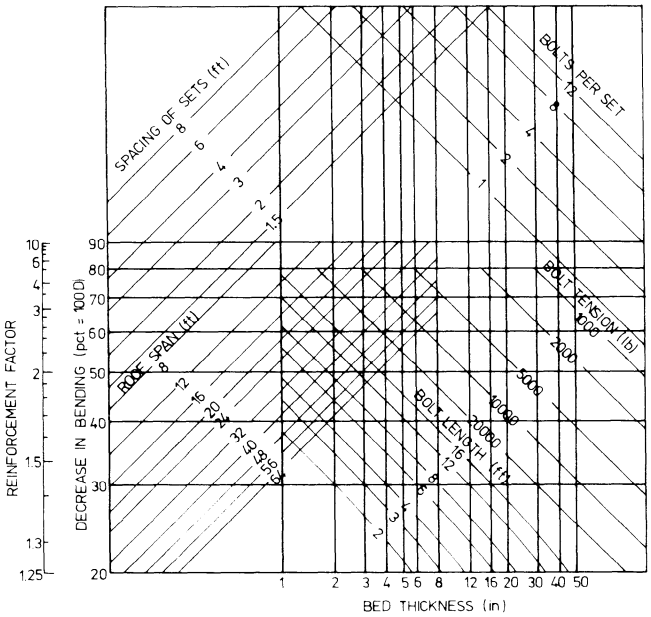

Fig. 18.1.7. Nomograph to determine the friction effect for bolting in mine roofs. $\mu = 0.7$, $\sigma = 24.6 kN/m^3$. Conversion factors: 1 in = 25.4 mm, 1 ft = 0.3048 m, 1000 lbf = 4.448 kN. (After Panek, 1962b.)

$$P = \frac{\gamma BXL}{\left(\dfrac{x}{\alpha} + 1\right)\left(\dfrac{B}{S} + 1\right)} \tag{18.1.10}$$

where γ is unit weight of the roof rock.

This equation, suggested by Obert and Duvall (1967), is valid if the roof above the excavation is completely suspended by bolts. For an assumed bolt load, it can also be used to estimate spacing and the number of rows. It represents the upper limit of bolt force since it ignores the important supporting effect of the abutments. It also ignores the interaction of a series of roof beds.

A more accurate approximation can be obtained by considering the effects of friction between beds and also by considering the roof span as a series of thin beams, fixed at each side of the opening. Panek (1962a,b; 1964) in a series of seminal papers considered this condition both experimentally by centrifugal testing and analytically, and developed the nomograph illustrated in Fig. 18.1.7, which has been used extensively in mine design. It is explained in detail by Panek and McCormick (1973) in the *SME Mining Engineering Handbook.* The basic variable is a reinforcement factor RF that is used to evaluate the interbed friction effect due to bolting. The roof is considered as a series of beds of equal thickness, of the same material, and without bonding between them. The bolts are assumed normal to the beds and tensioned to give normal compressive loading across the beds. Then

$$RF = \left(1 + \frac{\Delta\sigma_f}{\sigma_{fs}}\right)^{-1} \tag{18.1.11}$$

where $\dfrac{\Delta\sigma_f}{\sigma_{fs}}$ is the *decrease* in bending stress from frictional resistance induced by bolting, expressed as a ratio of the maximum bending stress in the unbolted strata, and is given by the empirical equation:

$$\frac{\Delta\sigma_f}{\sigma_{fs}} = \frac{3}{8}\,\mu(aB)^{-0.5}\left[\frac{B}{S}\,P\left(\frac{L}{t} - 1\right)\cdot\frac{1}{\gamma}\right]^{0.33} \tag{18.1.12}$$

where μ is the interbed coefficient of friction, a is spacing between rows, B is span, S is bolt spacing, t is average roof layer thickness, P is assumed bolt tension, and L is assumed equal to bolt length or supported thickness. For typical thin-bedded mine roof strata, *RF* should be greater than 2, and bolt spacing must by law be less than 5 ft (1.5 m). Spacings of 4 ft (1.2 m) are more common. Based on Eqs. 18.1.11 and 18.1.12, Panek's well-known nomogram (Fig. 18.1.7) allows rapid estimation of *RF* for a bolted roof, and forms a basis for rapid rock bolt pattern design.

18.1.3.3 Roof Caving

Although roof caving is not strictly speaking related to support, the mechanics are similar and it can be considered here. Caving is an important part of strata control in all mining operations. Correctly carried out, caving relieves stresses on abutments, barrier pillars, and chain pillars and improves overall mine stability. The need to cave the roof successfully determines the width of a room and pillar panel, as it does the width of a longwall face.

Cavability is a difficult concept. It is usually expressed in terms of a pressure arch, a circular, parabolic, or rectangular zone in the rock above an opening in two dimensions (see Fig. 18.1.5a) that has low radial compression stress, and where the rock sags and ultimately collapses under self weight at a critical unsupported span. This process is assisted by the presence of joints and weaknesses, which is why elastic analysis leaves a certain amount to be desired. The basics of computation of fracture onset in a roof span, analogous to the beam, plate, or "cracked arch," have been considered, with little success, by Obert and Duvall (1967) and Wright (1973). A better approach may be Terzaghi's (1946) arching theory, based on shear resistance in a frictional material above a bin hopper (the unsupported roof), and similar empirical methods that are summarized in Farmer (1985). An outline of this is given in Table 18.1.3. If a bulking factor of 1.1 is assumed for most layered rocks (Gorrie and Scott, 1970), then for caved strata to bulk sufficiently to support upper layers, the *span B* must be such that 1.1 $xB = xB + M$, where M is the excavated (or in the case of coal, seam) thickness, or

$$B = \frac{M}{0.1\,x} \tag{18.1.13}$$

where x = 0 *(good) to 2 (poor)* depending on the rock quality in Table 18.1.3. Obviously, a hard and intact rock is not cavable. For a massive, moderately jointed rock, a span in excess of 20 times the excavated thickness (i.e., 200 ft or 60 m, for a 10 ft or 3 m, thick excavation) would be required.

18.1.4 METHODS OF ROOM AND PILLAR MINING

18.1.4.1 Hard-rock Mining

Room and pillar mining takes place in sections or panels, which are usually rectangular and regular in plan. It is important

Table 18.1.3. Relation Between Cavability and Rock Classification Systems

Terzaghi classification	Rock behavior and possible causes of instability	Approximate stand-up time	Deere classification	Rock breakage height, m
1 Hard and intact	Stable excavation unless induced stress greater than rock strength	Many years	Excellent: RQD 90–100	0
2 Hard stratified and schistose	Bed separation with time; surface spalling	1 year		0.25 *B*
3 Massive, moderately jointed	Immediately stable. Detachment of blocks, progressively releasing further blocks	1 week	Good: RQD 75–90	0.5 *B*
4 Moderately blocky and seamy	Immediately stable. Detachment of blocks, progressively releasing further blocks	1 week	Fair: RQD 50–75	0.7 *B*
5 Very blocky and seamy and shattered	Immediately fairly stable. Surface dilation of rock due to rapid block detachment	1 day	Poor: RQD 25–50	1.5 *B*
6 Completely crushed	Local roof falls during excavation. Rapid peripheral dilation	1 hour	Very poor: RQD 0–25	2 *B*
7 Sand and gravel	Immediate collapse	0		
8 Squeezing: moderate depth	Rapid yielding and deformation		Squeezing and swelling ground	

Note: *B* is excavation span. RQD is rock quality designation.
Conversion factor: 1 ft = 0.3048 m.
Source: After Terzaghi, 1946; Deere, 1963.

here to differentiate between hard-rock and coal mining. In hard-rock mining of horizontal ore bodies, the method is very similar to open stoping (see Chap. 18.2). In many cases, ore grade control may be the primary requirement in mine design, and ground control and ventilation secondary considerations. This may lead to an ad hoc room and pillar design with irregular-shaped, nonrecoverable pillars of low-grade ore. In coal mining, ventilation and ground control are major factors, and this requires carefully designed room and pillar panels isolated from the rest of the mine and with a controlled ventilation system. It may also require plans for retreat pillar mining and caving.

Hard-rock room and pillar mining is effectively a method of open stoping (stope and pillar mining) at a low angle to the horizontal, excavating rooms and leaving supporting pillars. Where mineral values vary, the method is similar to the old "gophering" method of mining where random excavations followed highly mineralized zones. Where mineral values are consistent, the mine layout can be regular. The method differs from most hard-rock mining methods in that gravity flow is limited, and ore must be loaded in the excavation where it has been blasted and transported from that point. In large operations, this involves trucks and loaders or load-haul-dumps (LHDs), although slushers may also be used.

There are various methods of room and pillar stoping. The most common are full-face *slicing* or *breast stoping* and *multiple slicing or bench and breast stoping,* illustrated in Figs. 18.2.5 and 18.2.7 (see Chapter 18.2). In the former, the rooms are opened to their full vertical height with no mineral or economic value left in the roof or the floor. Probably the reasonable safe limit for full-face slicing is 25 to 35 ft (8 to 10 m) depending on drilling and support equipment, and beyond this, multiple slicing is used. In the United States, most coal, trona, and potash deposits are mined in one slice. Limestone, lead, and zinc mines use multiple slicing. In multiple slicing, the face is divided into a breast or brow, which is the top slice, and a bench (or benches), which is the bottom slice (or slices). It is quite common for mining to be organized so that there is simultaneous mining on the breast and one or two benches (Fig. 18.2.5). Multiple-slicing is usually done from the top down as illustrated (underhand stoping), but mining from the bottom up (overhand sloping) is equally feasible provided a layer of broken ore is left as a working platform. Overhand stoping is, however, more dangerous since new roof is continually exposed, whereas underhand stoping can be carried out under an undisturbed, supported roof.

18.1.4.2 Coal Mining

The basic unit in room and pillar coal mining is the panel that defines the area of the mine to be worked and ventilated. In the panel, there are two main phases in which the rooms are first developed, isolating the pillars, to the extent of the panel. Then the pillars may be extracted in a reverse direction. Conveyor belts, LHD transports, and services are extended with the room advance and are taken up during retreat pillar extraction. Room advance and pillar extraction can be carried out separately, or at the same time, or the pillars can be left in place. Kauffman, Hawkins, and Thompson (1981) describe four primary methods of production room and pillar mining—principally for coal mines—although they may be adopted for any mining operation. The methods are illustrated in Fig. 18.1.8 and may be summarized as follows.

1. *Panel advanced on entry set; rooms only extracted on retreat* (Fig. 18.1.8a). Here a group of entries, or an entry set, just large enough (usually three or four) to handle the necessary ventilation, haulage, and other support services, is developed, usually in the center of the panel, to the full panel length, connecting through to the return airway gas bleeder system in the case of a coal mine. Then production rooms in sets of four or five are driven in both directions as the equipment is retreated from the panel. No pillar extraction is carried out.

2. *Full panel advanced on rooms; pillars extracted on retreat* (Fig. 18.1.8b). Here a full width panel with 10 to 12 entries is developed off the panel neck to the full panel length, connecting through to the return airway entries and chain pillars to establish a bleeder system. Pillars are then extracted in retreat until the full panel in mined. It is essential, as will be shown, to maintain a pillar line for caving, and this is established either at an angle (conventional and continuous mining) or parallel to the line of retreat (continuous mining).

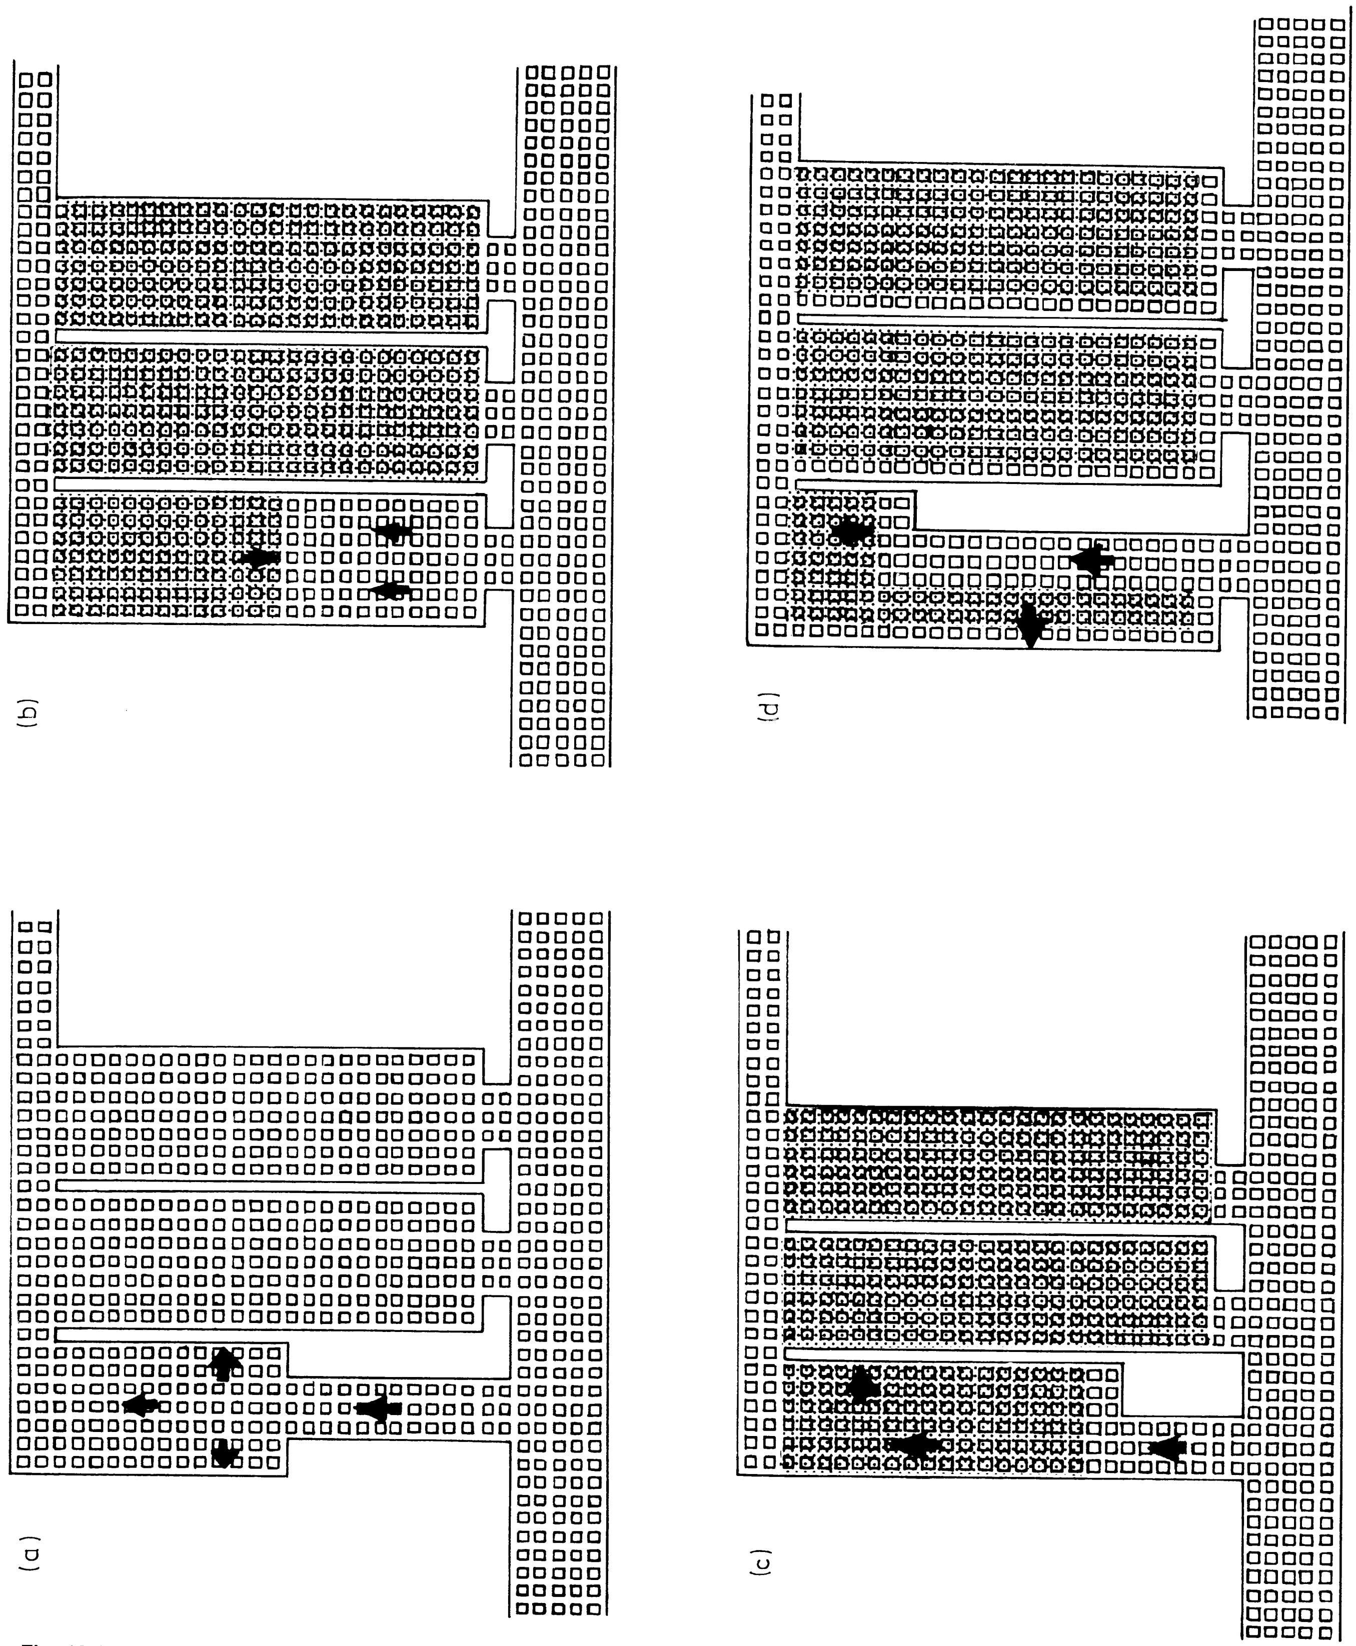

Fig. 18.1.8. Typical panel room and pillar coal mining methods. (a) Panel advanced on entry set; rooms only extracted on retreat. (b) Full panel advanced on rooms; pillars extracted on retreat. (c) Panel advanced on entry set; rooms developed and pillars extracted on retreat. (d) Panel developed on entry set; rooms developed and pillars extracted during advance and retreat. (After Kauffman, Hawkins, and Thompson, 1981.)

3. *Panel advanced on entry set: rooms developed and pillars extracted on retreat* (Fig. 18.1.8c). Here a panel entry set (three to five entries) large enough to handle ventilation, haulage, and support services is developed to the full panel length, usually on one side of the panel, although it can be in the center. After establishing a bleeder system, production rooms are developed to the side of the entry set in groups of three or four, then production and chain pillars are extracted using flat or angled pillar lines. Because of the limitation on the number of working faces, this method is only suitable for continuous mining.

4. *Panel developed on entry set; rooms developed and pillars extracted during advance and retreat* (Fig. 18.1.8d). In this method, rooms are developed and pillars extracted on one side of the panel entry set as the panel is advanced. When the entry set reaches the panel limit, and a ventilation bleeder system is established, the rooms on the other side of the entry set are developed, and the resultant pillars are extracted together with the entry set chain pillars in retreat. The pillar line can be flat or angled; the method is only suitable for continuous mining.

Kauffman, Hawkins, and Thompson (1981) consider the advantages and disadvantages of each of these methods related to the more desirable features of room and pillar mining, and these are worth repeating as they highlight the fundamental principle of this type of mining. Desirable features are listed below, and the methods not conforming are mentioned.

1. Active working places should not be near a caved area, since the increased pressures associated with caving increase the likelihood of roof falls. This is a drawback in the case of methods 3 and 4 above.

2. The length of time that openings are maintained should be a minimum. The loosening of roof bolts referred to above and exposure of roof and pillar sides to oxidation and moisture will cause deterioration. The exposure time is largest in the case of methods 1 and 2.

3. Ideally, solid coal should be retained on at least one side of the panel entry to reduce pressures on chain pillars during advance development. This is not the case in method 4.

4. Work places should be concentrated in a limited area. This reduces the area of direct supervision and improves management of the operation. This is not the case in method 2.

5. The tonnage produced between take-ups of belts and services should be maximized, and haul distances should be minimized to reduce nonproductive time. Arguably this is lowest in method 2, highest in 1, 3, and 4.

6. The ventilation system should operate with the minimum number of diversions during mining. The most difficult method to ventilate is method 4.

7. The bleeder system should be easy to establish and maintain in order to reduce ventilation. This is most difficult in the case of method 4.

8. The maximum amount of reserves should be recovered. Ore or coal left in the panel is lost and reduces the overall economics of mining. This is obviously a drawback with method 1.

18.1.4.3 Multiple Layer Room and Pillar Mines

A type of pillar mining that is common but not widely discussed is multiple-layer pillar mining where close vertical separation of pillars may lead to stability problems in roofs and floors. The applied mechanics approach to design is considered by Obert and Duvall (1967), and the main factors can also be identified from Figs. 18.1.5 and 18.1.6.

The main design approach must be to reduce stress concentrations in the roof. It is therefore logical to position pillars above pillars since the lower pillar will provide the better support for the upper pillar. Similarly the rock thickness between the mined layers must be sufficient to avoid excessive stress concentrations. This will depend on local conditions, but it can be seen from Fig. 18.1.5a that in the case of a rectangular excavation a roof thickness of twice the room height would be advisable.

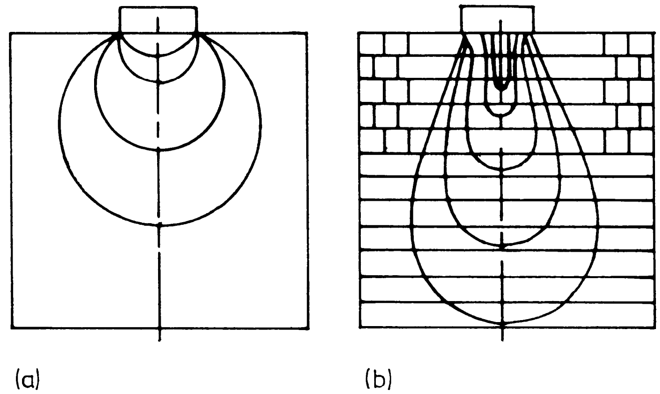

Fig. 18.1.9. Increase in major principal stress beneath a pillar in (a) homogeneous rock and (b) stratified rock. (After Gaziev and Erlikhman, 1971.)

Peng (1986) considers the particular problem in some detail, using the approach devised by Gaziev and Erlikman (1971) who demonstrated, using photoelastic models, the effect that layers of increasing or different modulus could have on the stress distribution beneath a foundation element (Fig. 18.1.9). The unavoidably high stress concentrations under pillars leads to Peng's particular recommendations for multiseam room and pillar mining:

1. *The upper seam is mined out prior to mining the lower seam.* High abutment pressure under upper seam pillars and abutments is the interaction problem most likely to be encountered in the lower seam. The design guidelines applicable to these conditions are (a) no pillars should be left unmined in the upper seam, (b) small pillars should be left in the upper seam if partial extraction is practiced, (c) pillars in the upper and lower seams should be columnized, (d) entries should not be driven under high stress zones such as abutment zones, and (e) longwalling might be the best alternative for the lower seam if pillaring is practiced in the upper seam with a few remnant pillars left.

2. *The lower seam is mined out prior to mining the upper seam.* Subsidence will be the most troublesome interaction effect. Caving induced by the lower seam mining might disrupt mining operations in the upper seam if seam separation is small. The design guidelines applicable to these conditions are (a) do not drive entries in the tensile zone of the subsidence trough, (b) reduce subsidence or arching effects by reducing opening width and extraction ratio, (c) columnize pillars, and (d) backfill the lower seam.

3. *Mining of the upper and lower seams is carried out simultaneously* with development and pillaring being kept in advance in the upper seam. Possible interaction problems are pillar stress concentrations. The design guidelines applicable to these conditions are (a) columnize pillars, and (b) keep the face of the upper seam ahead of the lower seam face by a minimum distance equal to the product of interburden thickness and the angle of draw.

18.1.4.4 Yielding Pillars

A major concept in pillar mining—although it has greater application in chain pillar design for longwall mining—is that

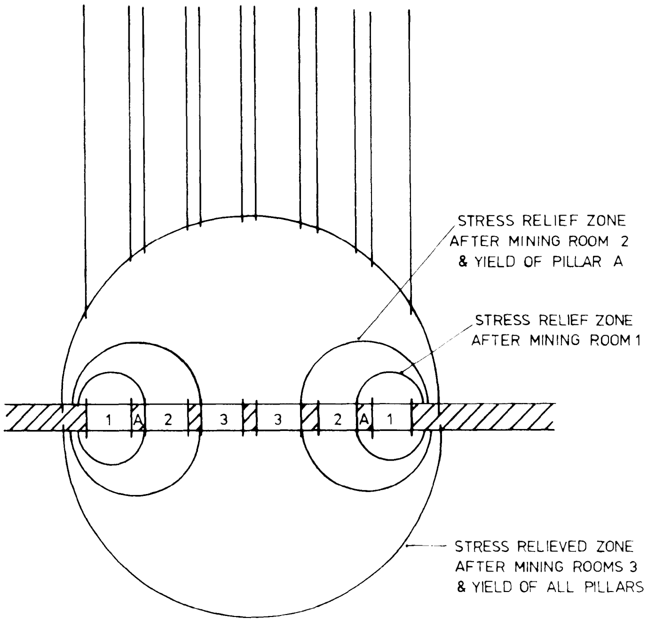

Fig. 18.1.10. A yield pillar layout for a six entry system, illustrating the development of a stress-relieved zone.

of yield pillars. A major application has been in deep potash mines, but it is important in any application where a combination of stress and rock conditions can leads to bumps, bursts or excessive deformation.

Yield pillars are pillars that are designed to yield as soon as they are isolated, so that they transfer most of their overburden pressure to the abutment pillars of the panel. This prevents the buildup of high roof and floor pressures at the edges of the pillars at the center of panel, and should ensure improved roof conditions in most rooms at the expense of the outer rooms. The detailed mechanics of yield pillar design are explained by Serata (1983), although the method has been used—often in an ad hoc way—for many years.

Fig. 18.1.10 illustrates a typical layout for a six-entry system. The outer entries are driven first, as rapidly as possible, and the adjacent entries immediately afterwards, leaving a yield pillar. Yielding of this pillar should concentrate stresses in the abutment pillar, creating a pressure arch that will lower the vertical stresses on the remainder of the panel while damaging the outer room and abutment edge. The inner entries can then be driven in stress-relieved ground. Pillar extraction, by outside lifting (see 18.1.6.2) from the four protected rooms can then be used to complete the mining process. With suitable ground conditions, this method can be adapted to a greater or lesser number of entries. Even where pillar extraction is not considered desirable or feasible, use of the yield pillar approach allows a much higher rate of extraction than conventional tributary area design, and reduces the likelihood of bumps, bursts, and other roof falls.

An alternative approach to high extraction, used in salt, potash, and trona deposits and sometimes called the time-control technique (Serata 1983), involves rapid single-, double-, or triple-entry extraction using a "Christmas tree" or chevron approach (Fig. 18.1.11). This is designed for use in weak ground, and the objective is to excavate as much ore as possible very rapidly in a controlled way, using secondary yielding pillars to protect the central access entry, and using as little support as possible over a short time period. This method is not feasible in coal mines

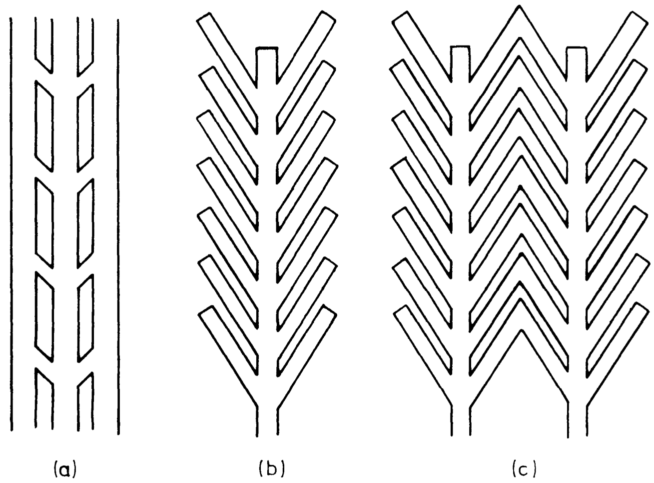

Fig. 18.1.11. Rapid development or time-control layouts used to obtain high productivity in weak deposits at depth: (a) 3-room yield pillar, (b) Christmas tree, and (c) chevron. (After Serata, 1984.)

but has been very successful in deep potash deposits where 50% extraction ratios are possible.

18.1.5 PRODUCTION METHODS—NONCOAL

18.1.5.1 Production Cycle

It is necessary to differentiate between coal and noncoal production methods. This has been done very ably by Bullock (1982 b,c,d), utilizing a US Bureau of Mines-commissioned report by Dravo Corporation (Anon., 1974) on noncoal mining and an EPRI report by Hittman Associates (Anon., 1976) on coal mining. The difference arises from three main factors:

1. *Strength*, which means that the weaker coal can usually be cut by continuous miners.
2. *Scale*, where US coal seams are generally thinner than noncoal deposits.
3. *Gas*, where coal mines are gassy and noncoal mines are usually gas free. Thus noncoal mines are usually mined by drilling and blasting off the solid in large working excavations; coal seams are undercut and blasted or continuously mined in relatively small excavations.

There are three basic types of room and pillar mining cycles, which are illustrated as flow diagrams and element interaction bar charts in Fig. 18.1.12. For *hard-rock ore bodies*, the basic cycle (Fig. 18.1.12a) is similar to hard-rock tunneling with four main elements: (1) mark out and drill blastholes, usually in a wedge pattern; (2) charge, blast, and ventilate to remove blast fumes; (3) introduce mucker and muck and load; and (4) scale the face and walls and bolt the roof where necessary. There is considerable complexity in the interaction among these elements that make up a basic critical path. In order to estimate the cycle time, it is necessary to determine unit loading and drilling rates and task times for these elements and also to estimate how subsidiary elements and tasks such as haulage and ventilation takeup may impinge upon the critical path in a badly organized mine.

18.1.5.2 Panel Development

A panel layout for a typical room and pillar mine in a noncoal mine is illustrated in Fig. 18.2.3 (see Chapter 18.2). The

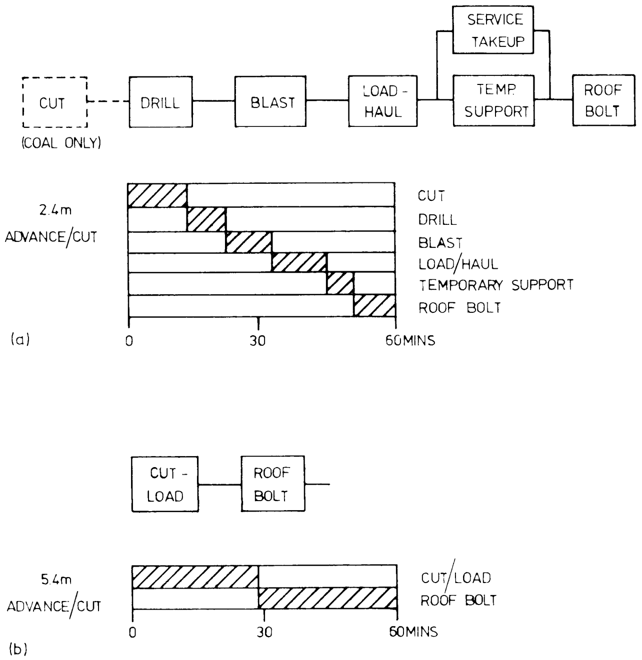

Fig. 18.1.12. Flow diagrams and element interaction bar chart for (a) conventional room and pillar and (b) continuous mining. Conversion factor: 1 ft = 0.3048 m.

excavation height is about 15 ft (4.5 m), and the normal stoping practice is to drive a single development drift about 35 ft (10.5 m) wide a distance of about four or five rooms into the ore body. This will serve as the main haulage drift. Pillars are then marked out on the drift walls and rooms driven between them.

To drill and blast the initial drive when the only exposed or free face is the drive face, some form of cut pattern is used. This is known as the “face round” or “swing” and in a 15- by 35-ft (4.5- by 10.5-m) face will comprise 60 to 70 holes (see Chapter 9.2) of about 1½ in. (38 mm) to a depth of 10 to 12 ft (3 to 3.6 m). If more than one face is exposed, a group of holes may be drilled at a low angle to the free face in what is known as a “slab round” or “slabbing” or “slashing”. This requires less explosive and less drilling than a single face. The most common form of face round is a wedge or V, cut although burn cuts can also be used.

Drilling is carried out with jumbo-mounted hydraulic drills; loading is usually by gathering arm loader, although in modern mines, trackless LHD vehicles are used to carry the load to a transfer raise where it is reloaded into trucks or conveyors. Some typical productivity figures for this type of operation are given in Table 18.1.4.

18.1.5.3 Cut and Fill Pillar Mining

Where the roof can be caved, as in coal mining, high levels of extraction can be obtained by retreat mining. Where the roof is stronger—as in most non-coal mining—the pillars are normally left as semi-permanent support. In high-grade ores at depth or where roof conditions are poor, loss of from 25 to 50% of the ore body may be unacceptable and, in this case, backfill may be considered. Placing of backfill can most easily be carried out using a form of slot and pillar, rather than room and pillar mining where parallel panels or drives are developed across the strike and then filled in an alternating sequence. A particular arrangement at a gold mine in Washington, designed to reduce subsidence in this case, is described by Tesaric, Seymour, and Vickery (1989) and Brechtel (1987). Slots or rooms (Fig. 18.1.13a) were excavated in 50-ft (15-m) vertical intervals by multiple benches 24 ft (7.3 m) wide and 24 ft (7.3 m) high. They were mined and filled in an alternating sequence from footwall drifts. The cemented fill was dumped from dumper trucks and allowed to settle at its angle of repose. At the top of the ore block, the backfill was rammed tight using a plate mounted on a LHD. It is a relatively simple system of mining that can be adapted for any room and pillar configuration. Completed stopes range in height from 30 to 130 ft (9 to 40 m), depending on their location in the ore zone. The fill comprised 55% minus 2-in. (50-m) river gravel, 40% alluvial sand, and 5% cement. A more useful mix might utilize tailings, which are often pozzolanic and require little or no cement.

A very radical approach to backfill pillar mining has been suggested by Dixon (1990). Called spiral slot and chamber mining, it is presented as a total extraction method for strata-bound deposits in a horizontal plane. The ore body is mined (Fig. 18.1.13b) in a continuous, flat, but not necessarily circular, concentric spiral pattern. There are three operations—top heading, benching, and backfilling from radial crosscuts with a chamber width of 30 ft (9 m)—the initial slot spiral being followed by a chamber spiral. The slot is backfilled with cemented fill the chamber with mine tailings or sand. Several potential benefits are claimed. The pattern should induce more even and favorable stress distributions than conventional layouts and should be more amenable to automation, leading to reductions in bursts, better strata control, and improved productivity.

One problem with backfilling, apart from the major logistical one, is the cost of cement, and in some cases its availability. Mitchell (1989) suggests using geogrid reinforcements as an alternative, and this is probably feasible. However, most silicates have some pozzolanic properties and it may be that added cementing agents, particularly in bulk fills, are unnecessary.

18.1.6 PRODUCTION METHODS—COAL

18.1.6.1 Panel Development

In coal mining, blasting off the solid is illegal, principally because of the danger associated with blown-out shots in an environment where explosive gases may be present. Where blasting is used, a horizontal cut is formed, generally in the face. This is usually a bottom cut in thin seams, a center cut in thicker seams. A vertical center cut may also be used. A similar approach may be used in rock salt and potash mining. The presence of the cut creates a free face for blasting and reduces both the amount of explosive needed and the possibility of blow-outs. A typical cutter jib is 9 to 12 ft (2.7 to 3.6 m) long, and the picks are arranged to cut a 6-in. (150-mm) slot or kerf. The cutter jib is sumped into the center of the face and moved to each side to complete the undercut. The basic cycle of operations (Fig. 18.1.12a) thus requires one more element before drilling.

Cyclic systems are usually referred to as *conventional room and pillar mining.* Much more productive and much commoner in mechanized mines is *continuous mining.* This is particularly important because, as the name implies, it reduces the number of unit operations and hence the cyclic element (Fig. 18.1.12c). There are several types of continuous miner, but they all combine the same basic elements—a cutting head above, or combined with a gathering arm loader, and attached to a short armored conveyor—so that the only delays on the critical path are for

Table 18.1.4. Typical Productivity of Noncoal Room and Pillar Mines (1970s Data)

Type of Rock	Location	No. of Mines in Sample	Range of Production 1000 tonnes/day	Range of Productivity tonnes/employee-shift	Average Productivity tonnes/employee-shift
Dolomite (Lead/Zinc)	New Lead Belt, MO	8	1.6–4.5	19.2–59.0	32.6
Cherty Limestone (Zinc)	E. Tennessee	5	1.4–3.1	12.5–26.6	17.8

ventilation and roof support. The reduction in the number of unit operations means that for efficient operations, a much smaller number of faces can be worked continuously. This is illustrated in Fig. 18.1.14, which shows typical plans for (a) conventional development of a six-pillar, seven-entry room and pillar panel, developed as in Fig. 18.1.8b as full panel, and (b) continuous miner development of a four-pillar, five-entry set for rapid development of a panel (see Fig. 18.1.17c or d).

In Fig. 18.1.14a, the conventional method, initial development is on 20-ft (6-m) rooms with 60- by 50-ft (18- by 15-m) pillars. Twenty feet (6 m) is the maximum room width under the Federal Coal Mine Health and Safety Act. The advance per cut is planned to be 10 ft (3 m). Unit operations have been described in detail by both Stefanko (1983) and Bullock (1982). The basic elements of the plan can be seen and can be described in terms of the working cycle in Fig. 18.2.3. Cut 1 (entry 7) is being loaded; entry 1 has just been loaded, and the loader, typically a gathering arm loader with integral armored flight conveyor on caterpillar tracks, has moved from this entry to cut 1. The blasted material is loaded into a rubber-tired shuttle car, which transports it to the feeder belt where it is dumped. There are usually two shuttle cars, and, depending on whether they are cable reel electric or diesel, they follow the same or separate paths. Cut 2 (entry 6) is being charged and prepared for blasting. Cut 4 (entry 4) is being drilled, and cut 5 (entry 3) is being undercut. Cut 6 (entry 2), after loading is being bolted, and cut 7 (entry 1) is being prepared for bolting and other service move-ups. The continuing sequence following this cycle can be seen in the numbered cuts in Fig. 18.1.14a.

The efficiency of the operation and the overall productivities and advance per shift depend on the time taken for each of the elements in the cycle, the way in which they interact, and the speed with which equipment can be moved from one entry to the next. Typical times, from the same sources as Fig. 18.1.14a, are:

Cutting cycle	11–16 min	2 employees
Drilling cycle	8–12 min	1 employee
Blasting cycle (6–8 holes)	8–12 min	1 employee
Load/haul cycle	12–20 min	3 employees
Temporary support cycle	5–10 min	1 employee
Roof bolt cycle	8–15 min	2 employees

Since these cycles are concurrent, the overall cycle time will be the longest part of the cycle, probably the load/haul cycle, which is discussed later. Ideally, it should be possible to complete a cycle in 12 to 20 minutes and to complete 24 to 40 cycles in each 8-hour shift. This may be compared with Table 18.1.5, which includes actual data. Bearing in mind the time lost in shift changes, traveling, and breakdowns, the actual achievement is remarkably good.

Continuous mining is noncyclic and utilizes a smaller crew, and the results (Table 18.1.5) are better in comparable situations. The major advantage is that the reduction in cycle time reduces the number of entries that need to be driven in order to maintain output to 3 or 4, since the only separate operations needed are cutting and roof support. Where these can be combined, and shuttle cars eliminated by extensible conveyors, then 100 ft (30 m) of continuous driving can be obtained to isolate a pillar side before moving the machine. The method then becomes very productive.

18.1.6.2 Methods of Pillar Extraction

Four basic pillaring methods are described in detail by Kauffman, Hawkins, and Thompson (1981). These are split and fender, pocket and wing, outside lift, and open ending. Each of these methods is illustrated in Fig. 18.1.15, and their basic characteristics are summarized in the following.

1. *Split and fender* (Fig. 18.1.15a) is the most commonly used pillar extraction method in the United States. The basis of

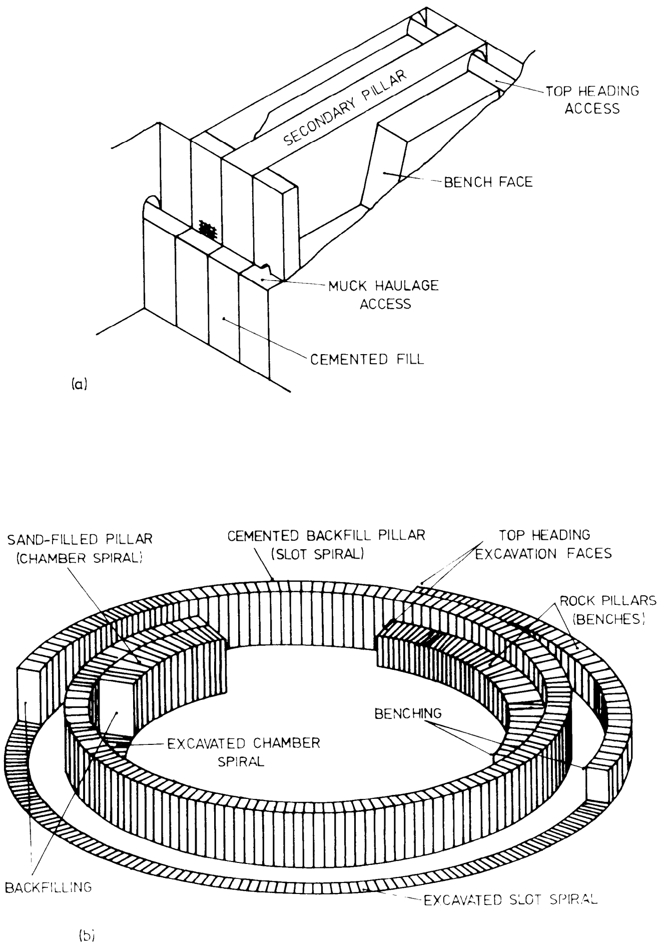

Fig. 18.1.13. (a) Slot and fill mine layout (after Brechtel, 1987). (b) Spiral slot and fill mine layout (after Dixon, 1990).

the method is to mine through the pillar center parallel to the longer side, creating a split and a fender of coal on each side of the split. Before mining, breaker posts are placed at all openings to the gob, and roadway posts are placed to reduce roadway widths to 16 ft (4.8 m). Turn posts and breaker posts are used in the split for additional support, and roof bolts are installed, as in room development, to support exposed roofs. The split is the same dimension as the rooms in the original panel, and the width of the fenders is usually fixed so they can be wholly extracted by the continuous miners without additional support. This effectively determines the maximum pillar width. Under most conditions, the minimum fender width is 8 ft (2.4 m), and the maximum about 13 ft (3.9 m). The split width can range from 10 ft (3 m) to 20 ft (6 m), giving a range of pillar widths from 26 ft (7.9 m) to 46 ft (14 m). Wider pillars can be extracted using multiple splits, but this reduces the simplicity, and the pocket and wing technique is more suitable. There is no limit on pillar length. The method usually involves mining two or more pillars simultaneously. Fig. 18.1.15a illustrates a double pillar sequence with 1 to 7 and 16 being split operations, the remainder fender operations. Support comprises roof bolts in the split. Breaker posts are installed after extraction of splits 7 and 16; turn posts are set across the split before the cut to extract each fender segment. Each fender sequence is therefore extracted from beneath supported roof. Ventilation is difficult, involving quite complex brattice curtain erections at critical points. The process is, however, simple and can be adapted to all thicknesses from 40 in. (1 m) to 25 ft (7.5 m) and to all equipment from simple loaders to continuous miners. The method is generally not suitable for large pillars and fragile roofs.

2. *Pocket and wing* (or pocket and fender, Fig. 18.1.15b) is a single pillar extraction method used mainly in northern West Virginia. Two working places are extended in the pillar leaving wings or fenders to support the roof. It can be easily adapted to large pillars and allows concentration of working places in a pillar, and hence, rapid extraction. Ventilation and haulage are also easier. It is not as efficient as the split and fender method and is used primarily where mining at depth requires large pillars for roof control. The method is not suitable in bump conditions.

3. *Open ending* (Fig. 18.1.15c) is a method similar to pocket and wing, but the mining sequence is taken along the sides of the pillars, breaker posts being extended at the pillar edge. It has limited use; ideally, the roof should be competent enough to span the opening, but brittle enough to break off or cave beyond the breaker posts.

4. *Outside lifts* (Fig. 18.1.15d) are rarely used except to extract narrow pillars rather like the fenders of the split and fender method. The method is used in shallow mines that allow the safe use of small pillars. A variation is in deep pillar extraction, particularly in bump prone areas where residual small yielding pillars are desired. Such a plan permits rapid extraction. The method can also be used for ad hoc partial extraction of pillars where bolting is not needed.

18.1.6.3 Mobile Roof Support (MRS)

Retreat pillar mining is highly productive. Supply, power, haulage, and ventilation systems are established during panel development and knowledge of roof and water conditions obtained. It is also dangerous, particularly where the roof does not cave in a predictable manner, and where the seam is prone to bursts, floor heave, and crushed pillars. The prime factor in improving safety is successful roof control through correct design of pillars, including yield pillars and supports such as posts, cribs, and roof bolts. These supports have the disadvantage that they act in a passive way. Technology from longwall mining, where active waste edge shields give an added dimension to roof control, was urgently needed, and this has been supplied through mobile roof supports (Thompson, 1983) developed initially by the US Bureau of Mines and improved by Fletcher (1990).

These are approximately 14 ft (4.2 m) by 6 ft (1.9 m) wide. Specific design features (Fig. 18.1.16) include continuous miner-type crawler drives with variable speed motors, hydraulically operated plows, 600-ton (540-t) total load capacity (through four cylinders each with 150-ton, or 135-t, yield load capacity), lemmiscate-linked canopy with free-floating support cylinders, and a heavy-duty rear shield. The supports are self contained apart from a cable reel electric power source, and are operated through a hand-held radio remote controller.

The mobile roof supports are typically used in two-pair configurations (Fig. 18.1.17), each pair being located between a solid pillar and the pillar being extracted. After each miner cut, they are advanced one unit at a time until there is just enough space remaining for the miner at the last cut.

18.1.7 VENTILATION

18.1.7.1 Bleeder Systems

Ventilation is particularly important in coal mining, and provisions of the 1969 Coal Mine Health and Safety Act affect

ventilation of room and pillar mines. A major provision is the requirement for bleeder entries and systems. *Bleeders* (Kauffman, Hawkins and Thompson, 1981) are entries surrounding an area being mined or which has been mined out. The purpose of bleeder entries is to bleed methane and other explosive gases from the gob area and into the main mine return airways, using a controlled filter of intake air. Bleeder entries should be maintained for access and examination. Only in areas liable to spontaneous combustion is sealing of caved areas permitted.

The practice of bleeding requires that a differential air pressure be maintained between the intake and return airways across a gob so that gases flow into the return airway. Where there

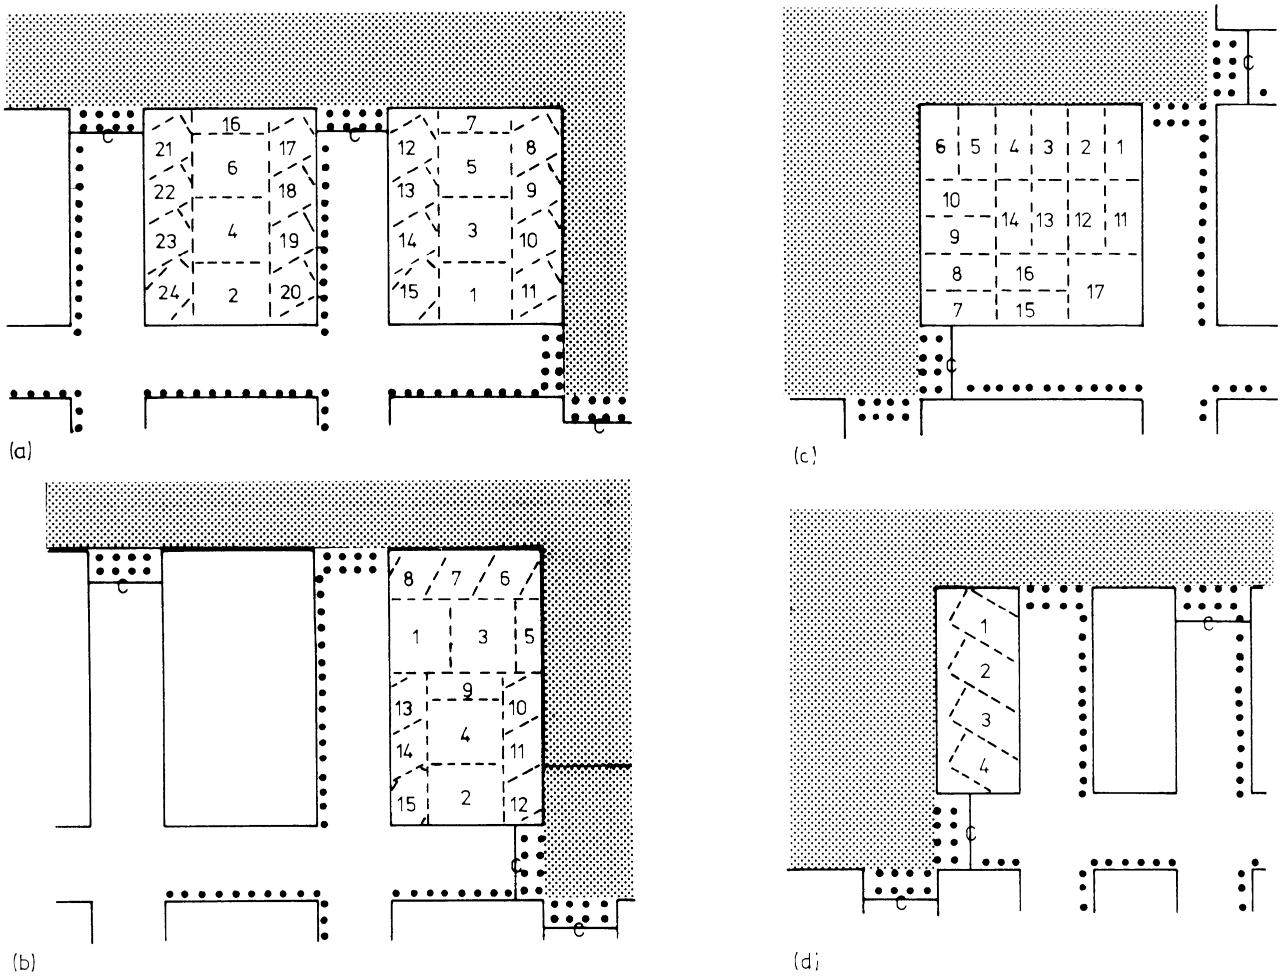

Fig. 18.1.15. Overall cut sequence for pillar extraction during retreat mining: (a) split-and-fender method, (b) pocket-and-wing or pocket-and-fender method, (c) open ending method, and (d) outside lift method (after Kauffman, Hawkins, and Thompson, 1981).

has been pillar extraction beneath a blocky roof, there will be sufficient flow through the caved area to bleed. A laminated roof may seal the caved area and an entry through the gob may be needed.

In order to simplify bleeding, it is sometimes desirable to remove barrier pillars during retreating to connect panels and to allow bleeding of an extended area of the mine. During development, it is better practice to bleed individual panels.

For details of mine ventilation theory and practice, see Chapters 11.6 and 11.7.

18.1.7.2 Section Ventilation

As discussed in Chapter 11.7.2, each working section of a coal mine should be ventilated with a minimum of 9000 cfm (4.25 m^3/s) of air to the last open crosscut. At least 3000 cfm (1.42 m^3/s) must reach each working face where coal is being mined. The air must contain more than 19.5% oxygen and less than 0.5% carbon dioxide.

During development, air going into the section is directed to the face by means of curtains across entries, line curtains, or auxiliary fans. This air is then directed to the main return. While rooms are being driven and pillars extracted, air going to the section is usually split at the working place with some going to the section return and some to bleed the gob.

Blower or exhaust fans in coal mines must be capable of delivering or exhausting 3000 cfm to or from the working face. Exhaust fans have the advantage that they can remove dust, fumes, and gas from the working area more efficiently than blower fans, particularly if the tubing is close to the continuous miner head.

A typical exhaust ventilation layout for a coal room and pillar system is illustrated in Fig. 18.1.18. This is a system employing line brattice curtains and is described by Stefanko (1983). The line brattice is essentially a space divider or temporary partition made of an impervious material that is installed and maintained carefully and kept as close to the face as possible. Its purpose is to guide the airflow through the face area and last open crosscut and into the return. Brattices were formerly (and to some extent still are) made of untreated jute, but nylon-reinforced plastics and similar materials are more commonly used today.

The line brattice is installed so as to split the heading longitudinally and thus provide an inlet as well as a return from the face to the last open crosscut. Since the mining machine must have room to maneuver on one side of the brattice, it is not practical to split the entry evenly, so a wide side is provided for the machine. The air may be brought up the narrow side and, after it sweeps by the face, returned on the wide side. Arrange-

ments may be made to blow or force the air into the heading or to exhaust it. The exhaust system illustrated in Fig. 18.1.18 is more commonly used since the operators work in fresher dust-free air. Exhaust fans can be used to replace line brattices at the face, and these are effective in controlling dust.

18.1.8 SYSTEMS ANALYSIS

The room and pillar method is particularly suitable for simulation modeling and systems analysis. Particular approaches are recommended by Bullock (1982c) and Stefanko (1983), but the most sophisticated model is that of Manula and Suboleski (1982). In this *Handbook*, there is coverage of systems analysis in Chapters 8.3 and 9.4.

Simulation modeling to optimize productivity requires a detailed analysis of the mining process and the way in which the mining variables interact with and affect the selection of mining methods and equipment. Mining variables include seam height, floor quality, roof quality, methane quantities, coal hardness, depth, and presence of water. Functional relations between these and unit operations are the basis—together with observations from underground studies—of planning and simulation. For instance, in a typical cycle, *cutting* and *continuous miner* operation will be affected by the seam thickness, floor quality, water presence, and particularly the strength of the coal. *Drilling* will be affected by coal hardness, because more holes will be required to break the coal, and *blasting* will similarly take longer if more holes are used. *Roof bolting* will be affected by roof quality, and *ventilation* by methane quantities. Layout and pillar size will be determined by depth, and this will affect loading and hauling.

Loading and hauling are unique in that they are affected by layout and design and are to a large extent independent of mining variables apart from weak or wet floors. They are also the major factor affecting conventional and continuous miner cycle times. Manula and Suboleski (1982) and Bullock (1982c) illustrate how *total cycle times* may be predicted through a simple mathematical model. Thus loader cycle time LCT for a cut is given by:

$$\mathrm{LCT} = \mathrm{LT} + \mathrm{COT} + \mathrm{WSC} + \mathrm{MISC} \qquad (18.1.14)$$

where $\mathrm{LT} = \mathrm{T}/(\mathrm{LR})$
$\mathrm{COT} = (\mathrm{N} - 1)\ (2 \times \mathrm{COD}/\mathrm{SPD})$
$\mathrm{WSC} = [(\mathrm{N} - 1)/2]\ (2 \times \mathrm{HD}/\mathrm{SPD} + \mathrm{DT}) - (\mathrm{NO} - 1) \times (\mathrm{CAP}/\mathrm{LR}) + (2 \times \mathrm{COD}/\mathrm{SPD}) - (\mathrm{NO} - 1) \times (\mathrm{CAP}/\mathrm{LR}) + (2 \times \mathrm{COD}/\mathrm{SPD}) - (\mathrm{NO} - 1) \times (\mathrm{CAP}/\mathrm{LR}) + (2 \times \mathrm{COD}/\mathrm{SPD})$
$(\mathrm{N} = \mathrm{T}/\mathrm{CAP})$

and where LT is the time loader spends loading, COT is the time the loader spends waiting for cars to travel, WCS is the time the loader spends waiting for the car to arrive at the change point after the other car has cleared the change point, MISC is the time to check for connect and disconnect water hose, hand curtain, tram, etc., T is the weight of coal in the cut, LR is the mean loading rate, N is the number of shuttle car loads in the cut, COD is the change out distance one-way, SPD is the mean shuttle car speed, CAP is the mean shuttle car payload, HD is the distance from dump to change point, DT is the mean dump time of the shuttle car, NO is the number of shuttle cars in use (normally equals two), [ ] indicates truncation of the number to the next lowest integer, and { } indicates raising of number to next highest integer.

Analysis of Eq. 18.1.14 can give several indications about production improvement methods. They are relatively insensitive to loading rate increases alone since a decrease in LT is partially offset by an increase in WSC, all other factors remaining equal. Increasing the number of cars in use at one time will decrease WSC but will have no effect on COT (in practice, COT is often increased in the case of three cars, since one of the cars may be forced to change out farther from the face than the other two); and the greatest sensitivity is experienced with a change in shuttle car payload, since this affects N, which in turn affects the value of COT and WSC. The payload also affects WSC directly.

Time studies and simulations of room and pillar mining systems indicate that *change-out time* can represent from 15 to 25% of the available time for production. (This is defined as the shift time less travel, face preparation, scheduled meetings, breakdowns, lunch, servicing, etc.; that is, the time in which the units and men otherwise are actually capable of coal production.) In general, available time for production will range from 175 to 300 min/shift with an "average" value at 225 min. Thus, 30 to 60 min could be saved if suitable continuous haulage units were available. It must be recognized, however, that not all of this time will be additional loading time. In general, this time will be distributed proportionally among the remaining loading and hauling activities.

Additional time is lost in those cuts where the car cannot go back to the change point at or prior to the time it is cleared by the previous car. The maximum distance from the dump to the change point at which an additional wait will not be encountered can be calculated by balancing the load and change-out time with the haul and dump times:

$$\mathrm{WAIT} = \mathrm{O} = (\mathrm{TTD} + \mathrm{D} + \mathrm{TFD}) - (\mathrm{N} - 1)\ (\mathrm{L} + \mathrm{T1} + \mathrm{TO}) \qquad (18.1.15)$$

where $TI = SE \times COD$
$TO = SL \times COD$

$TTD = SL \times HD$
$TFD = SE \times HD$

Then

$$(SL + SE) \times HD + D = (N - 1)\ (L + (SL + SE) \times COD)$$

or

$$HD_{max} = (N - 1)\ L - D + (N - 1)\ (COD)\ SL + SE$$

where L is loading time, TTD is the time to travel from the change point to the dump, TFD is the time to travel from the dump to the change point, D is mean dump time, N is number of haulage units in service, SE is mean travel time unloaded, SL is mean travel time loaded, TI is the changes out time unloaded, TO is the change-out time loaded, COD is change-out distance, and HD is the distance from dump to change point.

These are examples of simple approaches to planning. A fuller listing is given in Manula and Suboleski (1982), and elsewhere in this *Handbook.*

Chapter 18.2
STOPE AND PILLAR MINING

CHRISTOPHER HAYCOCKS

Stope and pillar is probably the oldest underground mining method, having been developed by flint miners in Europe some 6000 to 8000 years ago (Temple, 1972). Remains of many of these workings are still visible today in the great chalk beds. They show that these ancient underground miners had learned the fundamental rules of stope and pillar mining: (1) to leave sufficiently large ore pillars for roof support, and (2) to limit the width of openings to minimize the possibility of roof falls. The occasional skeletons of miners crushed by falling roof prove that these lessons were not learned without cost. In its modern form, stope and pillar mining remains essentially unchanged except for the effects of mechanization and vertical expansion to accommodate more massive deposits. Stope and pillar differs from room and pillar mining in that room and pillar is a term commonly reserved for coal mining, which has regular pillars normally developed in panels, and thin deposits of usually less than 8 ft (2.4 m). Stope and pillar is also known as breast stoping, breast and bench stoping, board and pillar, stall and pillar, and panel and pillar (Hartman, 1987).

18.2.1 GENERAL FEATURES

Stope and pillar mining is characterized by

1. Irregularly shaped and sized pillars left for support (Fig. 18.2.1), which may require little or no planning. In the extremes, the method is often little more than a variation of gophering (Peele, 1941) or breast stoping, where only artificial pillars are used for roof control. Most mines, however, specify minimum pillar dimensions to meet overburden support requirements, and the dimensions must take into account the ultimate pillar height, which is a major factor in pillar strength.

2. Typically flat ore bodies of large horizontal extent dipping less than the angle of repose. Below this angle of about 30 to 35°, the ore will not flow under the influence of gravity; this is the major difference between stope and pillar and the higher-angle stoping methods such as cut and fill, shrinkage, and sublevel. Cascade stoping developed for the Zambian Copperbelt mine of Mufulira was designed as an intermediate stoping method for ore bodies dipping at the angle of repose or in the range of 25 to 45° (Kelly, 1969). Massive ore bodies can be mined by the stope and pillar method by mining in a series of horizontal slices or passes from or near the top down, such as at the lead-zinc deposits at Austinville, VA, and the Bonne Terre Mine, MO, where pillars up to 300 ft (90 m) high were left (Wykoff, 1950).

3. Competent rock masses. These are very desirable as this is an open method where the stopes or rooms normally stay open during the life of the mine. Strengths may vary from 50,000 psi (345 MPa) to 4000 psi (25 MPa), and structural integrity of the roof, pillar, and floor components should ideally be excellent, unless increasing quantities of secondary support are to be used. There are numerous examples of successful stope and pillar mining in less than competent rock, such as some areas of the new lead belt in Missouri and the uranium mines of New Mexico and Wyoming (Bullock, 1982). Under these conditions, roof stability is of primary importance, secondary support is frequently used, and continual barring down or scaling may be essential. Uncontrolled pillar failure is to be avoided at all costs, as the failure can be progressive to surrounding pillars and jeopardize the entire mine. Occasionally, pillar recovery is possible under good ground conditions and where mine stability can be carefully controlled.

4. Definite depth limitations due to the load capacity of the pillars. Increasing pillar size to combat increasing vertical load is counterproductive as extraction decreases and can range from 25% in deep salt mines to a maximum of 95% in selected lead mines (Bullock, 1982; Prugger, 1984). Absolute depths to which the method can be taken depend on site-specific conditions, principally rock mass strengths, but typically 3000 ft (600 m) is a normal limit. In the deeper operations pillar sizes become so large that extraction falls to uneconomic limits and alternative methods must be considered. The exception to the depth limitation is the special case of breast stoping, which permits total stope closure and is used successfully at depths over 12,000 ft (3600 m).

5. Absence of surface subsidence, except in the very long term when massive roof or pillar failure has occurred, or in the case of breast stoping. Considering the fact that the oldest underground mines in existence are stope and pillar, it is possible to design successfully for long-term stability.

6. Stope and pillar mining is normally classified as a large-scale method in terms of total production, and is quite versatile and flexible enough to meet a wide range of production requirements.

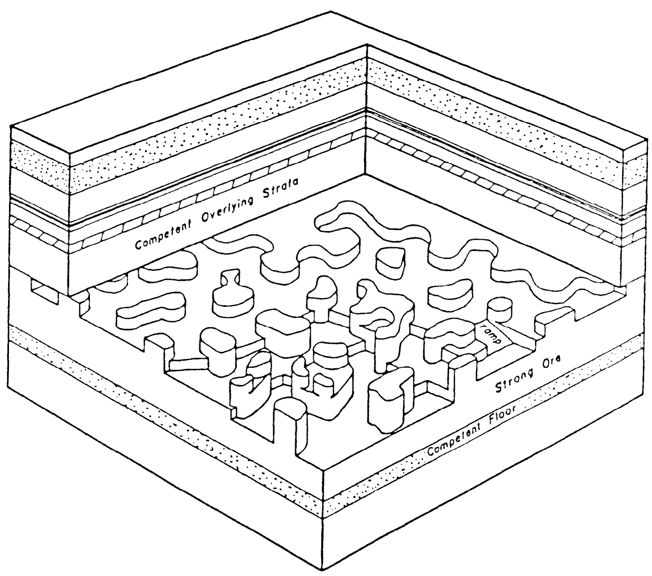

Fig. 18.2.1. Stope and pillar mining with random pillars (Clark and Caudle, 1961).

18.2.2 CONVENTIONAL STOPE AND PILLAR

18.2.2.1 Development

The basis of the stoping system is straightforward since, in most forms, the method requires no specific stope development unless the ore body is very irregular and a separate haulage level is driven. Under these conditions connecting orepasses, ventilation ways, and access raises will be necessary. Most mines hoist from a single level, and many utilize declines to facilitate movement of rubber-tired equipment underground.

18.2.2.2 Stoping

Stope and pillar mining is typically cyclic, consisting of the following unit operations (Hartman, 1987):

$$\text{DRILL} \rightarrow \text{BLAST} \rightarrow \text{SUPPORT} \rightarrow \text{LOAD} \rightarrow \text{HAUL} \rightarrow \text{DUMP}$$

In softer materials such as trona or halite, mining machines may be used to replace the drill-blast cycles. Drilling is usually carried out by self-contained, diesel-powered, trackless jumbos, but in smaller operations, hand-held jacklegs may be used. Under very soft-rock conditions, electrical-powered auger drills may be utilized. Holes are drilled horizontally using wedge or V cut rounds, although burn cuts may be used under some conditions such as in the harder limestones and dolomites (Fig. 18.2.2). Slabbing or sliping rounds are then typically used to expand the initial face cut around the proposed pillar (Fig. 18.2.3). Faces, or breasts, may be carried up to 30 ft (9 m) in height with the majority of conventional equipment, and hole depths of 16 ft (4.8 m) are suitable for most conditions. The predominant explosive is ANFO under dry conditions, with slurries, water gels, and dynamites as alternatives. Blasting may be carried out during the shift or at shift change times, depending on the size of the mine. Good fragmentation plus limiting the throw of the round are important in stope and pillar mining. Cleaning a large area and secondary blasting can seriously disrupt the production cycle. Barring down or scaling the back using cherry pickers is done immediately following blasting.

Mining takes place on the advance with ground control factors rarely, if ever, allowing for complete extraction of pillars, although substitution of artificial pillars has been tried under some situations (Reed and Mann, 1961). The use of artificial pillars was technically successful, provided the pillar could be prestressed; otherwise, roof deformation to load the pillar caused significant roof failures (Chellson, 1941). Unfortunately artificial pillar systems have all proved uneconomical to date in conventional stope and pillar systems, although they are an essential part of breast stoping.

Depending on the shape and thickness of the ore body, there are three mining options available: single pass, multiple pass, and advancing multiple bench.

SINGLE PASS. In thinner, less than 25 to 30 ft (7.5 to 9 m), regular ore bodies mining can take place in a single first pass. In the oil shales, attempts were made to single-pass mine, carrying benches up to 60 ft (27m) high, but were abandoned due to the high cost of the specialized equipment required (Hustrulid, Holmberg, and Pesce, 1984).

MULTIPLE PASS SYSTEM. The multiple-pass system is suitable for irregular ore bodies over 30 ft (9m) thick, such as some of the lead-zinc deposits of Missouri and some underground limestone mines where the face would be too high to be mined in a single full-face slice. In the multiple-pass system, the first pass is also used in part for definition of the ore body. Mining typically starts near the top of the ore body at a convenient mining height. By starting near the top of an irregular ore body, the first pass can be driven on a regular upgrade. The top of the ore body can then be mined out by upwards, or overhand, stoping by operating the drilling and support equipment on a shrinkage pile (Fig. 18.2.4). Under these conditions, holes are drilled horizontally into the brow or overhand bench either by hand or using a jumbo. When mining is complete, the shrinkage piles provide excellent stockpiles, although considerable capital can be tied up in a pile until it is available for processing. Another major advantage to starting at the top is that the back can be scaled and secured with secondary support where necessary while it is within easy reach. The underlying ore is then mined in a series of subsequent slices using either vertical or front benching. Vertical benching requires wagon type drills in addition to drill jumbos. This process is also known as multiple slicing (Fig. 18.2.5). Under these conditions, ore handling and equipment movement can become complex, and some mines resort to underlying haulage levels to simplify haulage and reduce costs.

ADVANCING MULTIPLE BENCH. This system is ideal for thick regular ore bodies such as oil shales, salt mines, and some limestones where the upper and lower boundaries of the ore body are regular and well defined. In these ore bodies, mining commences at the upper ore body contact with the lead pass and is then followed by a succession of benches in echelon (Fig. 18.2.5). Equipment moves between the benches via a series of ramps, and vertical bench blasting can be used in all passes except for the uppermost.

SLABBING AND PILLAR RECOVERY. To improve or optimize extraction, limited pillar robbing, or slabbing, may be permissible in some operations, provided ground control considerations are met. Slabbing is normally performed toward the end of the life of the mine and indeed may be the only option available when total pillar removal is not possible. Slabbing in the Old Lead Belt, under ideal conditions, permitted total extraction to increase from the first pass 85 to 95% (Bullock, 1982). The ore body was sufficiently narrow to permit arching to occur, and the slabbed pillars carried little load. The earliest recorded case of mining litigation involved illegal pillar robbing in the Athenian stope and pillar silver mines at Laurion in Greece. In 383 BC, a mine owner named Diphilios was sentenced to death and his fortune confiscated for directing his slaves to illegally rob pillars for quick profit (Rickard, 1974).

Pillar removal generally requires exceptionally good ground conditions. With low mining heights, caving that follows pillar removal will normally swell and support the main roof. With higher mining heights this is not possible; therefore either the roof must be self-supporting during pillar removal, or fill must be placed to support the roof. Whatever the situation, a number of ingenious systems have been developed for pillar removal, which can be particularly difficult in the case of very high pillars. Pillars are typically shot from the top down, although there are cases on record of mining commencing at the bottom when it was thought the pillar would separate cleanly from the back (Bullock, 1982; Reed, 1959).

18.2.2.3 Loading and Haulage

Trackless front-end loaders (FELs) and load-haul-dumps (LHDs) are normally selected for loading the sizes and capacities of which depend upon truck capacity, stope height, and size of the largest ore fragments. These units are used in 75% of hard-rock mines (Bullock, 1982). Slushers and gathering arm loaders are also used in soft rock. Boom-type shovels are used in some operations but require a large amount of clearance and are rarely the first choice of modern operators. To facilitate loading, sec-

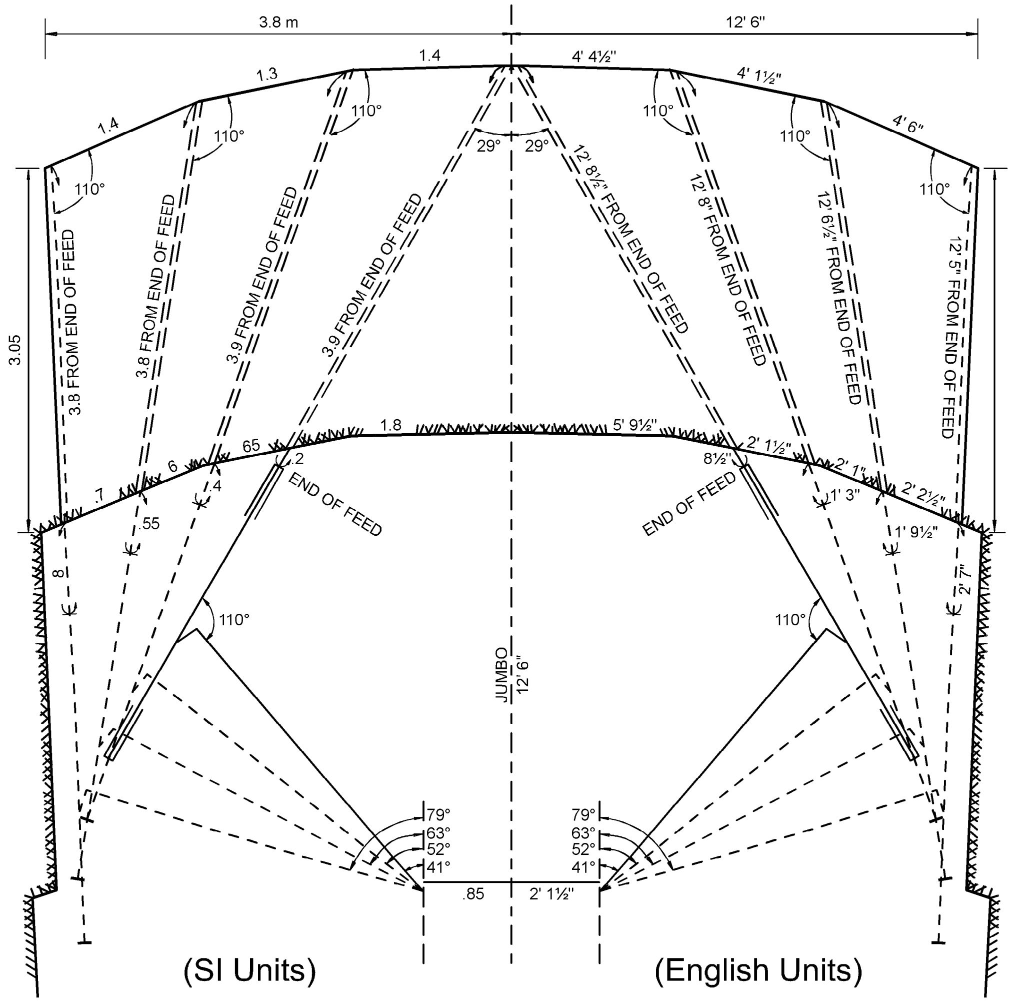

Fig. 18.2.2. Typical V cut as used in dolomites or limestones (Bullock, 1982).

ondary breakage is carried out where essential by blasting, impact hammer, or drop ball.

Since most stope and pillar mines are of large horizontal extent, ore must be transported considerable distances to the adit or shaft. Conventional diesel-powered trucks up to 100 ton (90 t) in capacity are used, the precise size depending on mining height and clearances. Truck haulage is used more often than rail haulage due to its flexibility and versatility. Rail haulage can be used where gradients can be guaranteed suitable. Belt haulage is also used under some conditions, particularly in soft ore bodies such as halite or trona where small fragments are produced, otherwise primary crushers must be installed near the faces. Part of the haulage cycle can be carried out using LHDs or slushers, but these are generally auxiliary to truck or rail haulage.

Selection of equipment combinations for a particular mine is necessarily site specific. Numerous computer programs now exist to facilitate such selection (Klemme and Mousset-Jones, 1984; Zambas and Yegulalp, 1973).

18.2.2.4 Ground Control

Specific design criteria for roof spans, pillar dimensions, support requirements, and floor stability are covered elsewhere in this *Handbook* (see Chapter 10.5). Support is typically installed outside of the normal production cycle as needed. Secondary ground control normally consists of roof bolts for both back and pillar control. Bolt lengths and types depend on local ground conditions and many operations have no artificial support except in the area of portals. Cherry pickers are used for scaling and barring down, which is done immediately after blasting and is an integral part of the production cycle. Less routine scaling may be performed periodically along roadways if ground conditions require. Under multiple-horizon mining conditions, columnization of the pillars is the most widely accepted ground control practice. This involves careful control of pillar sizing and location and is another practice that dates back to the silver miners at Laurium about 400 BC.

Where pillars have been excessively robbed, are inherently weak, or weakened by blasting, stabilization has been facilitated by pillar wrapping using wire ropes or encasing the pillar in shotcrete (Wykoff, 1950). These systems are designed to increase horizontal stresses in the pillar and thereby increase their resistance to shear failure. Horizontal bolting, sometimes with wire mesh, has also proved beneficial. Unless the panel width is small enough to permit arching, failure of under-designed pillars can throw additional load on surrounding pillars. This can in turn cause these pillars to fail, producing a domino effect, sometimes with disastrous results for the entire mine.

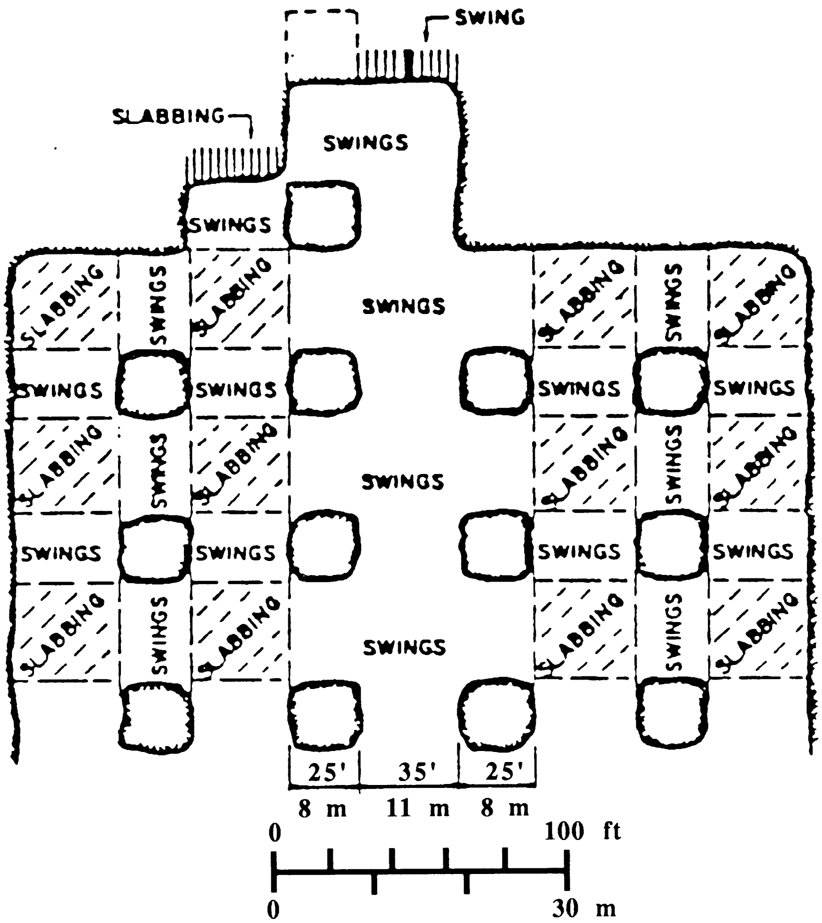

Fig. 18.2.3. Slabbing rounds driven off burn cut heading rounds (Bullock, 1982).

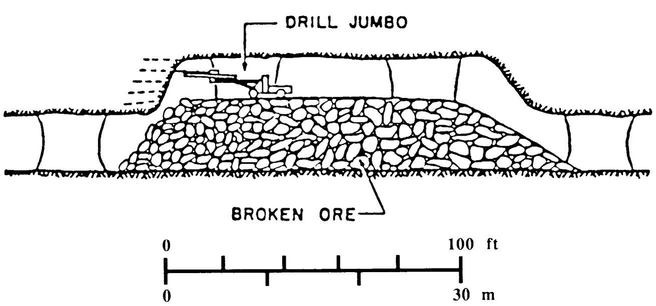

Fig. 18.2.4. Overhand stope and pillar mining (Bullock, 1982).

18.2.2.5 Ventilation

Ventilation is generally fair to good in this stoping method as the mines rely on their large volume to dilute exhaust gases and dust. If methane or toxic gases are present, the mine is subject to strict coal mine regulations that guarantee adequate airflow. Mines typically have dedicated exhaust and intake airways, but control of airflow underground is usually difficult due to large areas between pillars. Stoppings are rarely used, although brattice curtains and ventilation doors are employed only under exceptional conditions. Airflow near the face is normally effected using booster fans or air ejectors (Hartman, 1987).

18.2.2.6 Water

Water problems can be troublesome in some tabular operations as mining follows the ore body and openings cannot always be driven upgrade. Even small or shallow synclines or dips in the ore can serve to collect water, which then must be continually pumped away from the face. Portable compressed air or electritally powered pumps are used, and low points in the mine are selected to function as sumps with more permanent pumping arrangements. These pumps are frequently floating to combat significant variations in water level as water flow cannot readily be controlled in this stoping system.

18.2.3 DIPPING ORE BODIES

Conventional stope and pillar mining becomes impossible as the dip of an ore body increases beyond about 20% grade since equipment cannot travel updip. Numerous variations of stope and pillar have been developed to meet the needs of dipping ore bodies; for instance, the bar pillar system (Christiansen and Scott, 1975), and Elliot Lake stope and pillar (Hedley and Grant, 1972). After review of the numerous variations, two basic versions of stope and pillar can be identified for ore bodies dipping up to 30°, one suitable for rail haulage and the other for conventional trackless mining (Hamrin, 1980).

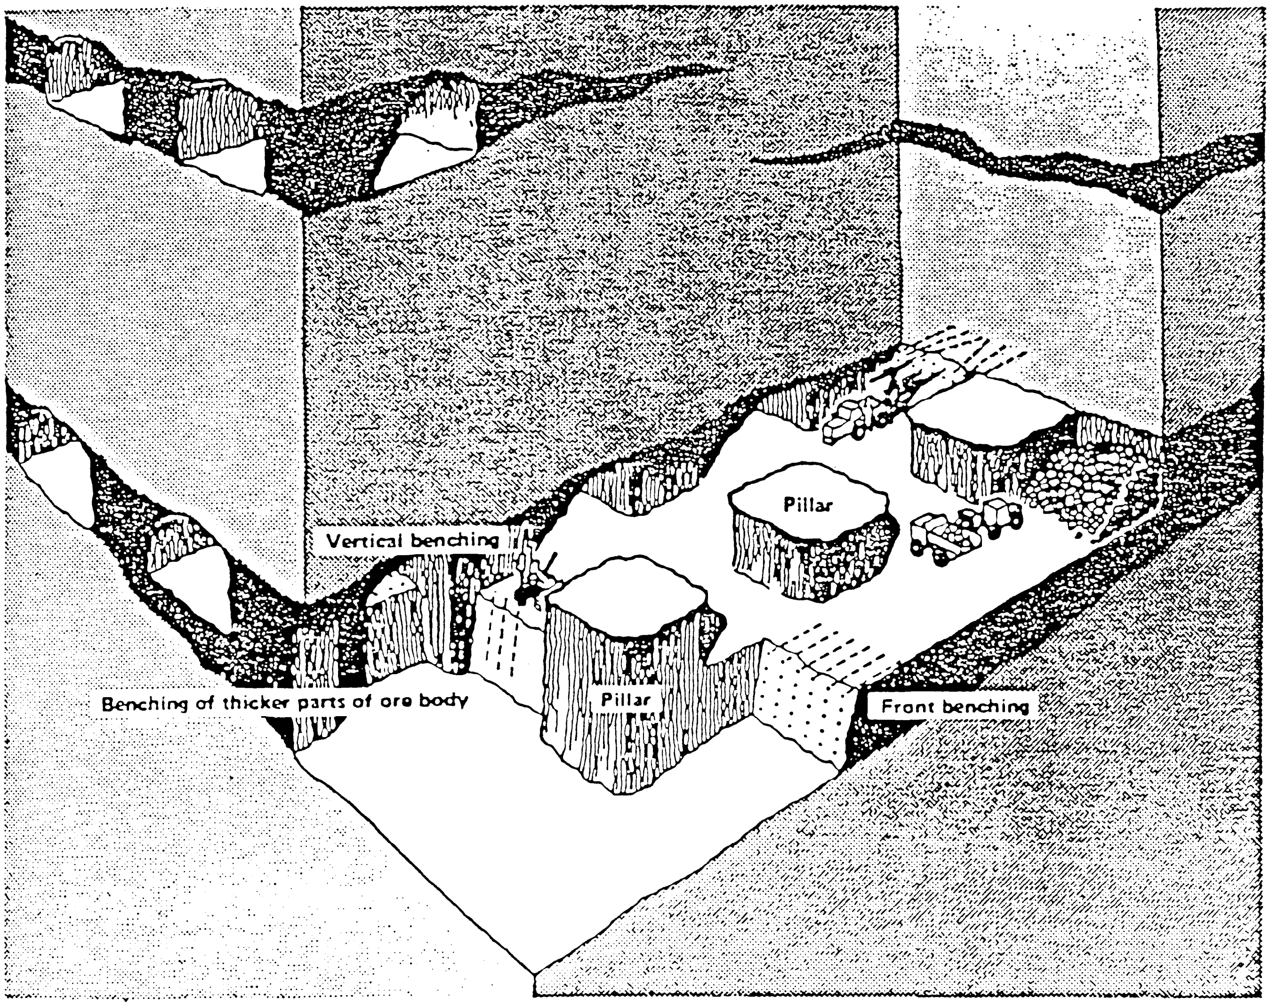

Fig. 18.2.5. Stope and pillar mining using vertical and front benching. (Hamrin, 1980. By permission: Atlas Copco.)

18.2.3.1 Step Stope and Pillar

Step stope and pillar mining utilizes trackless haulage with access drifts running transversely across the dip at an angle suitable for the equipment (Fig. 18.2.6). Ore extraction is made from a series of stope drifts that run horizontally following the strike of the ore body working from the top down. Pillars are sufficiently narrow updip to allow drilling and loading equipment to operate and extract broken ore. Stopes are cut successively downdip, each stope slice having an approximately horizontal floor and being stepped in the middle to the second half of the stope. Crosscuts are also mined with horizontal floors for passage of equipment. This results in the footwall being stepped downdip except where it is cut by equipment roadways.

18.2.3.2 Inclined Stope and Pillar

Inclined stope and pillar can operate efficiently at angles up to 30°. This method can utilize rail haulage, which is limited to near-horizontal grades. Development starts by driving a series of haulage drifts along the footwall following the strike of the ore body. Spacing of the haulage drifts is selected to allow operation of a single slusher to pull all the ore from immediately below the upper haulage level to the level below. In practice, this is typically up to 500 ft (150 m), although production is severely curtailed with longer scrapes. Stoping commences by mining updip from a haulage level using hand drills or jumbos where possible and then scraping the ore down dip into mine cars (Fig. 18.2.7). Scraper cutouts are made on the downdip side of the haulage drifts to accommodate slusher winches. At higher dips, the method is particularly labor intensive and therefore has low stope efficiency.

18.2.4 BREAST STOPING

Breast stoping is a unique variation in stope and pillar mining in that 100% of the ore in the stope is extracted, and no natural pillars are left for support. Instead, artificial pillars are left for roof control with the understanding that stope closure will ultimately approach 100%. While numerous variations of this method exist, it probably finds its most classic usage in the South African gold mines. Other mines, such as the Consolidated Denison, Canada (McCutcheon and Gutterer, 1960), the Conglomerate Mine, Michigan (Vivian, 1931), and the Radon mine in Utah (Love and Knoerr, 1956) have used the method. Breast stoping is confined to flat tabular ore bodies, dipping less than the angle of repose. Typically, the mining height is less than 8 ft

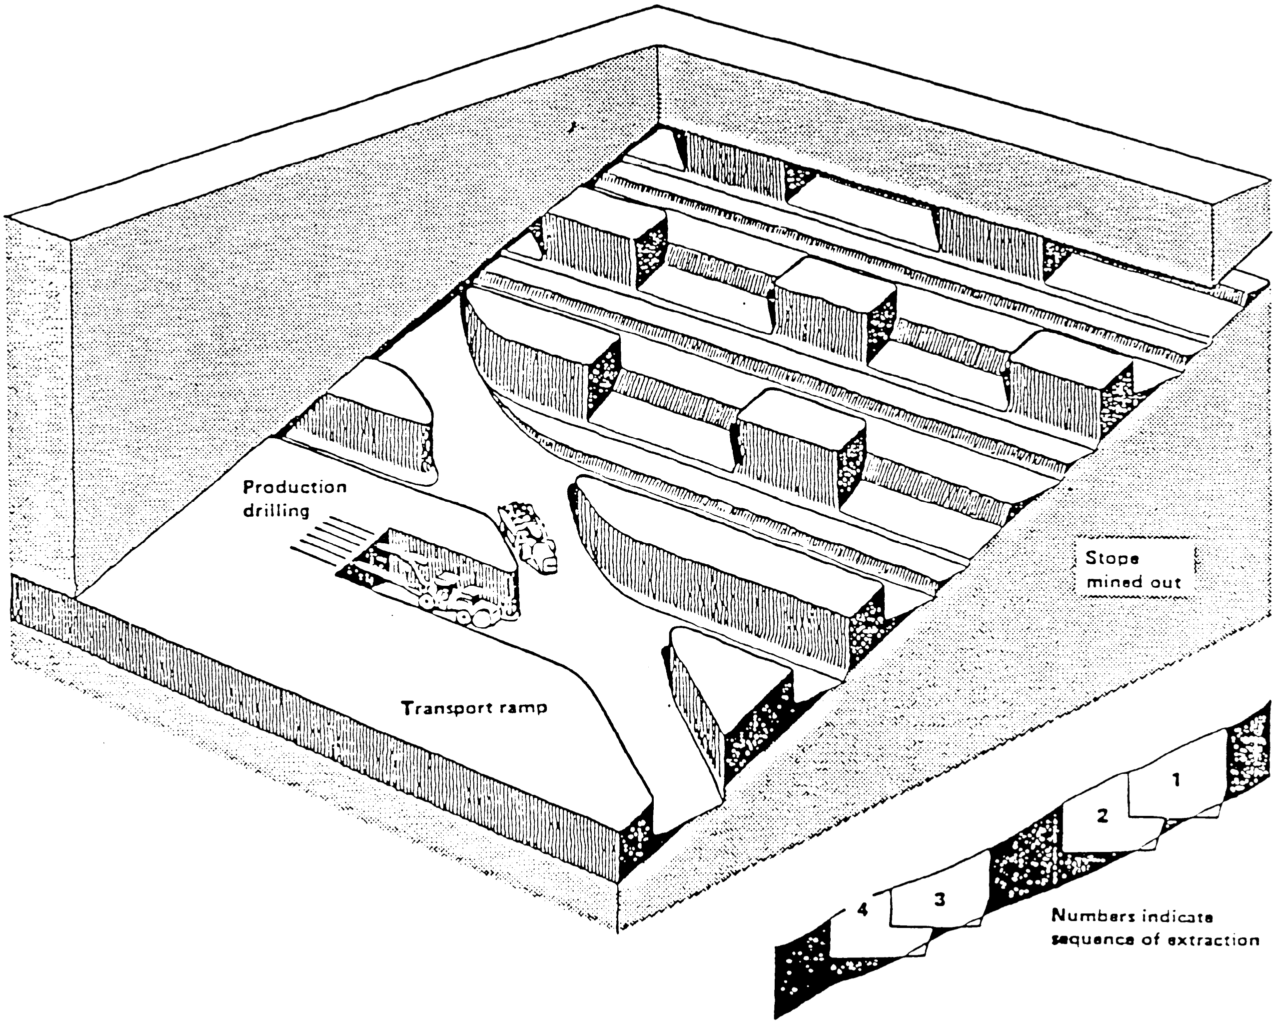

Fig. 18.2.6. Step stope and pillar in an inclined ore body. (Hamrin, 1980. By permission: Atlas Copco.)

(2.4 m) to permit controlled stope closure without caving of the back.

The choice of breast stoping vs. conventional stope and and pillar mining depends on (Haycocks, 1973):

1. The depth of the ore body in relation to the strength of the ore. Under very deep conditions, extraction ratios would be so low with stope and pillar systems as to be uneconomical.

2. Ground conditions sufficiently poor so as to make stope and pillar mining exceptionally hazardous due to back failures and rock bursts.

3. High cost of ground control under deep and poor ground conditions.

4. The deposit is not amenable to longwall mining as practiced in coal mines.

These conditions are all met in the South African gold mines where high stresses due to the great depth and the strong rock burst-prone ore make leaving conventional pillars impractical.

Ore is generally drilled using hand-held jackhammers. Four-ft (1.2-m) holes are placed perpendicular to the face and blasted electrically. The muck is then cross-scraped down the face to stope drifts where it may either be cross-scraped again to ore passes or deposited directly into rail cars. In soft nonabrasive ores, flight conveyors may be used at the face. Immediate face support is achieved using friction or hydraulic props that also support lagging boards placed to control fly rock. A variety of layouts has been devised to meet the needs of individual mines, such as the dip-gully method, the track-and-gully method, and the herringbone system (Fig. 18.2.8). Faces are carried as straight as possible where bursting occurs to reduce the incidence and may be up to 4000 ft (1200 m) long (Fig. 18.2.9). Packs are made of a variety of materials, but timber cribs filled with waste rock are typical. No effort is made to support the overburden, but rather to control closure and minimize stress buildup at the face. As with all stope and pillar methods, ventilation can present serious problems. Unless lagging or pack walls are built behind the face, booster fans are the only real way to provide air movement along the face.

Stope efficiencies in breast stoping are very low, as the method is invariably labor intensive. Average figures for the South African gold mines run 1 to 5 tons (0.9 to 4.5 t)/underground employee-shift (Anon., 1963). The Radon mine in Utah achieved 7.6 tons (6.8 t)/underground employee-shift, which is excellent for this stoping system.

The method is seriously disrupted by faults in the ore; but under many conditions, roof control is excellent, and almost 100% of the ore is extracted. Resuing is also possible with breast

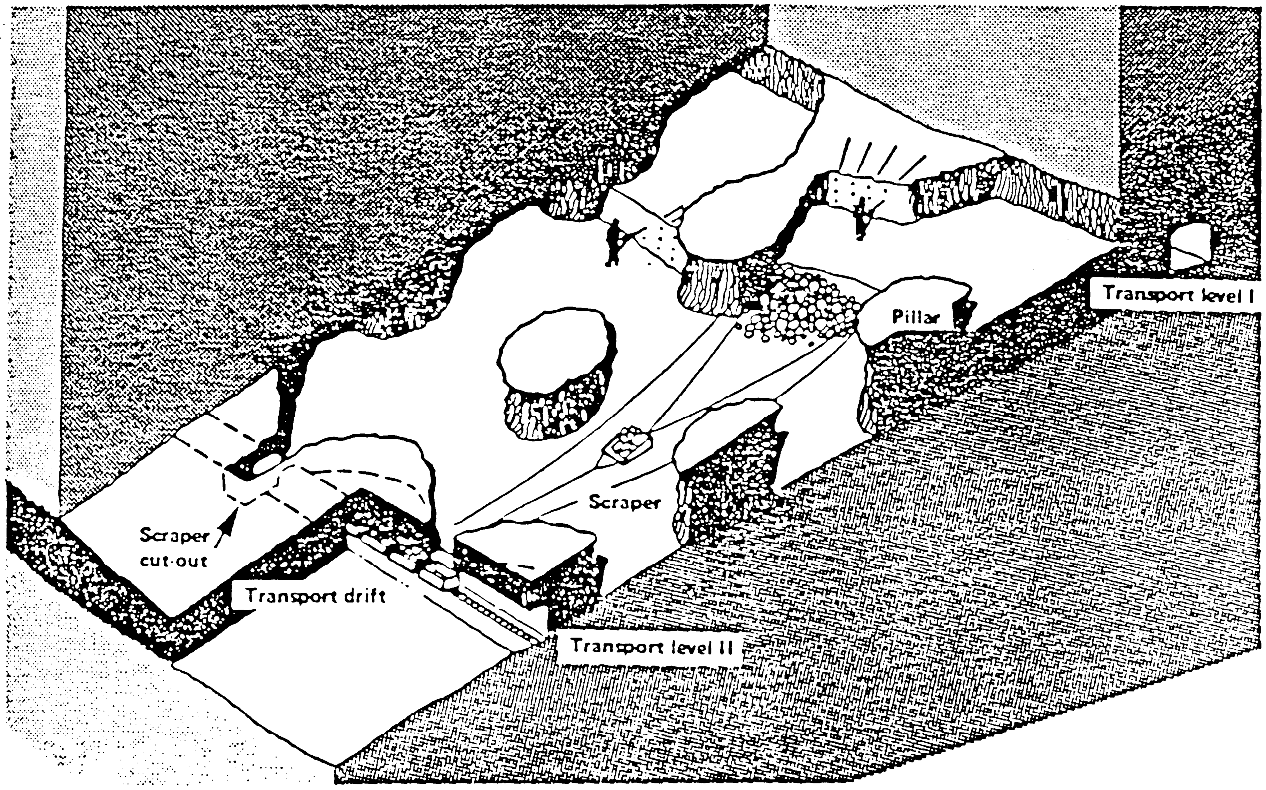

Fig. 18.2.7. Inclined stope and pillar operation in inclined ore using slushers and hand-held drills. (Hamrin, 1980. By permission: Atlas Copco.)

stoping, which can significantly improve the economics of some ore bodies.

18.2.5 ADVANTAGES AND DISADVANTAGES

18.2.5.1 Advantages

1. Most systems can be equipment intensive and are available for computerized optimization in the selection and utilization of equipment and therefore exhibit fairly high stoping efficiencies.
2. The method is somewhat selective. Lean ore can be left in pillars, or the area worked around.
3. Since no development is required with most applications of the method, production can start virtually immediately.
4. Multiple working places can be operated, and therefore production rates can be high if desired.
5. Most applications of the method lend themselves to mobile, self-contained trackless haulage and equipment with its high productivity potential.
6. The method is not labor intensive but may require extensive skills in equipment operation and maintenance.
7. Production rates vary from 50 to 70 tons (45 to 63 t)/employee-shift.
8. Dilution is low under most mining conditions, unless it is necessary to take a parting or roof or floor material for ground control reasons.
9. Surface subsidence should not be a factor in this method, if the mine is adequately designed.

18.2.5.2 Disadvantages

1. Up to 30% or more of the ore may be left in the form of pillars, which are usually not recoverable.
2. Stope ventilation is frequently difficult.
3. The openings can require continual maintenance when ground control conditions are minimal.
4. Water problems can create major difficulties when mining down dip, particularly in undulating deposits.

18.2.6 CASE STUDY: BUICK MINE

The Buick mine is an underground stope and pillar operation located in the Missouri Lead Belt in Iron County, some 120 miles (200 km) southwest of St. Louis (Anon., 1990; Osborne, 1990). The ore body was discovered in 1960, and the mine has been in operation since 1969. Production is approximately 5100 tons (4640 t)/day, from two shifts, with an overall efficiency of 75 tons (68 t)/employee-shift (includes underground mine and maintenance crews). The ore body has remaining reserves of some 17.8 million tons (16.2 M t) containing 5.7% lead, 1.3% zinc, and 0.08% copper; and it averages 14 ft (4.3 m) in thickness with an area of 14.5 million ft^2 (1.34 M m^2) and dips 2° to the north.

18.2.6.1 Geology

The ore body lies in the 42-mile (68-km) long Viburnum trend of the southeast Missouri lead-zinc belt. Mines along this belt account for over 90% of US lead production. Actual miner-

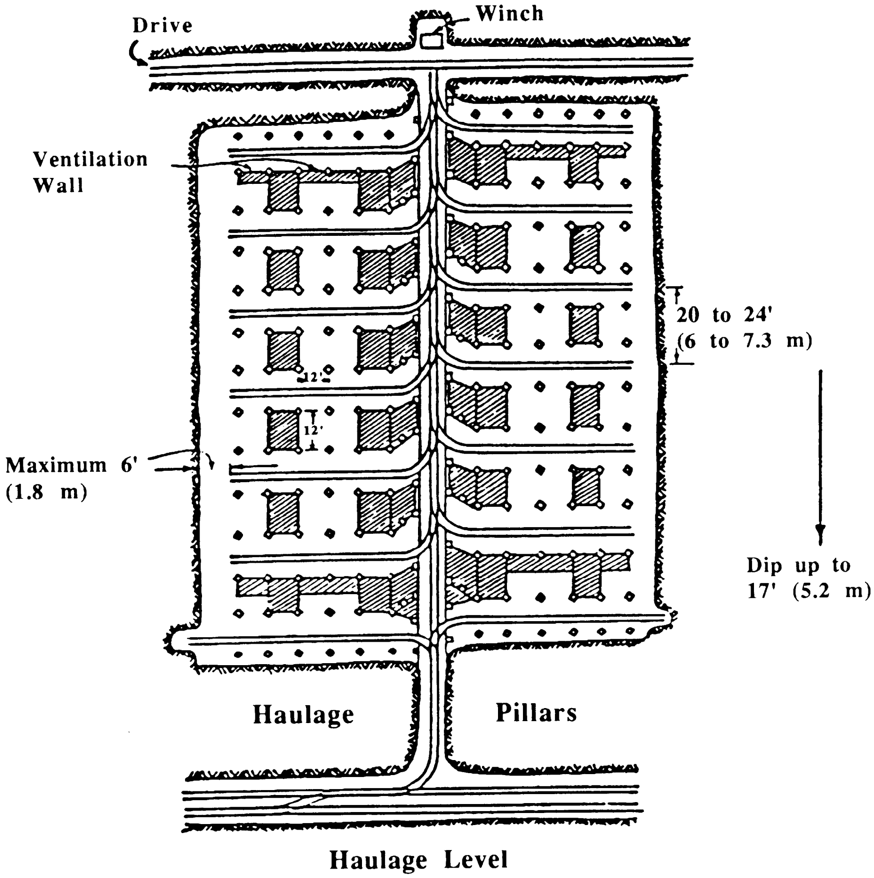

Fig. 18.2.8. Herringbone stope. Beck et al., 1961. (By permission: South African Institute of Mining and Metallurgy.)

alization is located in the upper 100 ft (30 m) of the Bon Terre formation, consisting of dolimitized sandstones and mudstones overlain by shales. Two distinct types of ore bodies are mined in the Buick mine, the breccia and the blanket. The breccia ore zones are up to 100 ft (30 m) in thickness, 250 ft (75 m) wide, and contain three mineralized zones. The blanket ore body is in the same stratigraphic position as the breccia but is only 8 to 22 ft (2.4 to 6.7 m) thick; it is, however, up to 1500 ft (455 m) wide and 5000 ft (1525 m) long (Fig. 18.2.10).

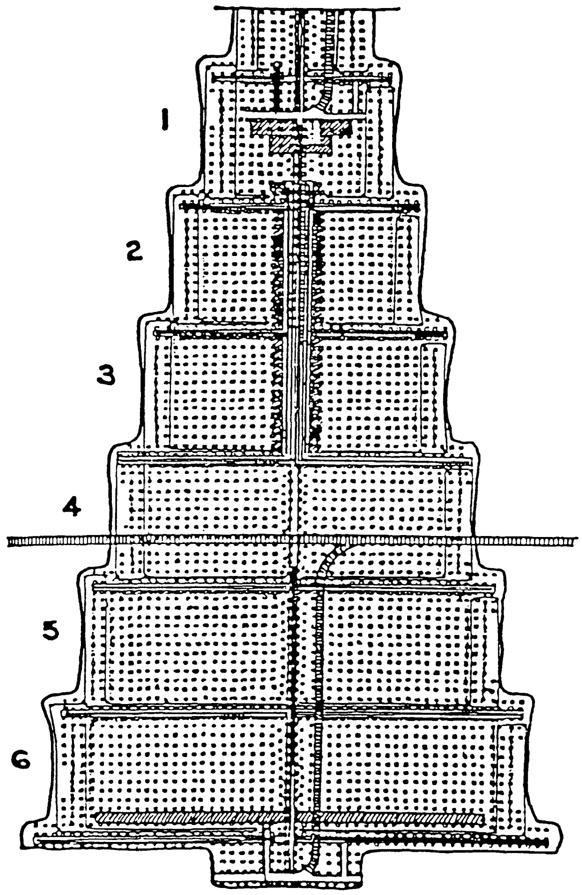
18.2.6.2 Mining Methods

The ore is mined in a series of passes, depending on the thickness of the ore body. The blanket ore body varies from 10 to 22 ft (3 to 6.7 m) in thickness and can be mined in a single or "first pass." First-pass mining accounts for 80% of the mine's production and enables the ore bodies to be fully defined. Openings and crosscuts are 32 ft (10 m) wide, and all pillars are a minimum of 28 by 28 ft (8.5 by 8.5 m). Stoping is carried out using 75-hole breast rounds, with 12-ft (3.6-m) 1-3/4-in. (41.3-mm) diameter holes. These are drilled with either Joy or Atlas Copco two-boom hydraulic jumbos equipped with electric motors and diesel tramming. Blasting is conducted using either an ammonium nitrate-fuel oil mix (ANFO) primed with Trojan stingers and 60% gelatin dynamite in the burn, bottom, and wet holes. Initiation is carried out using non-electric L-P series caps, 15-grain primacord, and one electric cap. Each blast produces 500 to 550 tons (455 to 500 t) and is shot at the end of each shift. Secondary blasting is usually not a problem, but a portable rock pick is available. The primary crusher is located underground and is a 60-in. (1.5-m) gyratory.

The thicker breccia ore body, which varies from 8 to 100 ft (2.4 to 30 m) in thickness, is mined in a series of passes (Fig. 18.2.11). A first pass driven near the top defines the ore body and, when complete, preparation can then be made to remove the remainder of the ore. Since the first pass is normally driven below the top of the ore body to ensure it stays in ore, the back is mined first. An up-hole cut is drilled and blasted with the broken ore providing footing for subsequent mining. Subsequent mining is done by drilling and blasting the breast. As many passes as needed are carried out until the top of the ore body is reached. After removal of the blasted ore, the third pass is carried out by blasting benches which have been drilled horizontally with 1-3/4-in. (44.5-mm) holes. In various parts of the mine, horizontal thicknesses of no less than 15 ft (4.6 m) are left between pillars to give added strength to the pillars. Benching using vertical holes was abandoned as the blasts caused excessive pillar damage. At the Buick mine, approximately 10% of production comes from third-pass mining, while all three passes extract 78% of the ore. When projected plans to recover high-grade pillars are carried out, total recovery is expected to be about 90%.

18.2.6.3. Loading and Hauling

Loading is carried out using two Caterpillar (Cat) 980C and Wagner ST8 8-yd^3 (6-m^3) FELs. The 980C loaders do most of the truck loading, with the ST8s used in headings less than 14 ft (4.3 m) in height. The truck fleet consists of two 50-ton (45.5-t) Kiruna beds or two 50-ton (45.5-t) CTC Lo-Pro wagons powered by Cat 631-E diesel tractors, or a 40-ton (36.4-t) Athey wagon powered by a Cat 631D diesel tractor. All rubber-tired vehicles are serviced and repaired underground in a shop facility,



Dip 25°; Length of longwall 900 ft (275 m); Stoping width 39 in. (1 m)

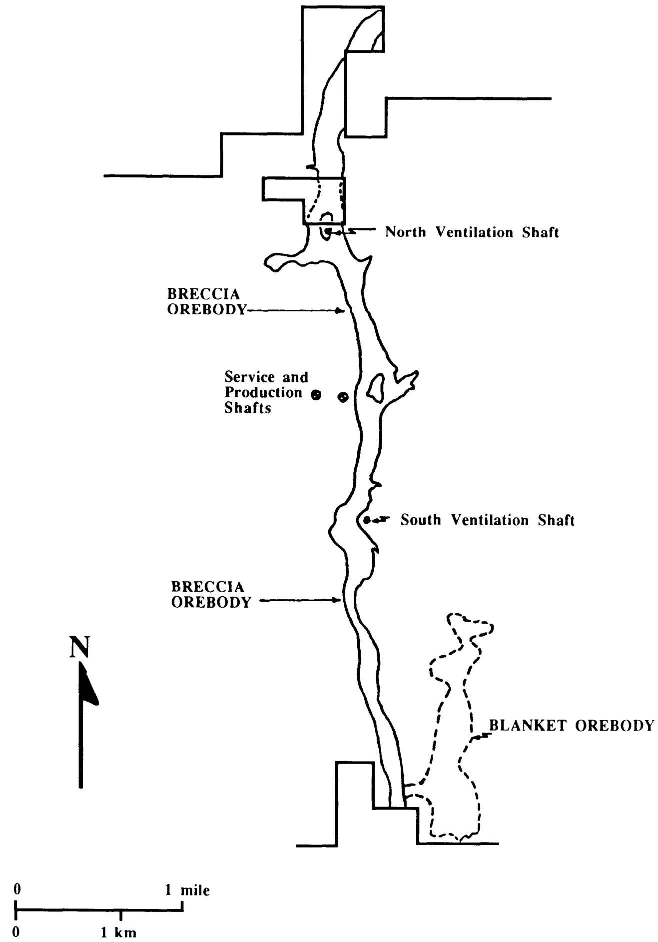

Fig. 18.2.10. Buick mine ore body (Anon., 1990).

with full spares available. The truck fleet averages 13,000 mi (21,000 km)/month. Trucks travel on specific haul roads and feed a 3000-ton (2700-t) central orepass. The orepass feeds the primary crusher, which reduces the ore to –6 in. (150 mm). The ore is then carried by conveyor to one of three 1000-ton (910-t) ore storage bins that feed the 12-ton (11-t) automatic skips. Shaft capacity is 400 tph (365 t/h) from high-speed friction hoists.

18.2.6.4 Drainage and Ventilation

Water flows by gravity through 6-in. (150-mm) drainage holes to the bottom level and then to the service shaft where it is pumped to the surface. The mine has six 500-hp (375-kW) centrifugal pumps, and the water is either used by the mill or directed to the tailings pond.

Ventilation needs are met by pulling 800,000 cfm (283 m^3/s) through centrally placed production and service shafts, then through the production level, down raises to the haulage level, and out through two ventilation shafts located to the north and south. The 12-ft (3.6-m) diameter south shaft has an 800-hp (597-kW) surface fan and the 8-ft (2.4-m) north fan a 500-hp (375-kW) surface fan. To facilitate airflow underground, eight 50-hp (38-kW) and 75-hp (58-kW) booster fans are used.

Chapter 18.3
SHRINKAGE STOPING

JACK HAPTONSTALL

18.3.1 INTRODUCTION

Shrinkage stoping is a vertical, overhand mining method whereby most of the broken ore remains in the stope to form a working floor for the miners. Another reason for leaving the broken ore in the stope is to provide additional wall support until the stope is completed and ready for drawdown.

Stopes are mined upward in horizontal slices. Normally, about 35% of the ore derived from the stope cuts (the swell) can be drawn off ("shrunk") as mining progresses. As a consequence, no revenues can be obtained from the ore remaining in the stope until it is finally extracted and processed for its mineral values.

The method is labor intensive and cannot be readily mechanized. It is usually applied to ore bodies on narrow veins or ore bodies where other methods cannot be used or might be impractical or uneconomical. The method can be easily applied to ore zones as narrow as 4 ft (1.2 m), but can also be successfully used in ore widths up to 100 ft (30 m).

Logically, the broken ore should be free flowing and not pack in the stope. Neither the ore nor adjacent country rock should contain undue amounts of clay or other sticky material to cause the ore to hang together in the stope and either be difficult or impossible to draw. Additionally, the ore should not readily oxidize, which may cause the broken pile to re-cement itself, and consequently "hang up." Oxidation can also have an adverse effect on ore dressing. Ore should be fairly continuous along the strike of the vein or ore body in order to avoid mining extensive amounts of waste as dilution from the stope back. However, small waste areas may be mined around and left as random pillars.

Consideration must also be given to the plunge or rake of the ore body, especially where the entire ore body may be mined as a single stope (Fig. 18.3.1 rather than as pre-established stope panels with defined vertical end lines. A stope with a shallow plunge or rake (< 50") may be very difficult to mine by shrinkage methods because the ore moves away too quickly from the pre-developed extraction system (Fig. 18.3.2). Additionally, stopes where ore abruptly extends for great distances beyond stope end lines are also difficult to mine because they often require much additional development work to the stope extraction system (Fig. 18.3.3), especially raising.

18.3.2 DEVELOPMENT AND PREPARATION

Sites for shrinkage stoping are generally developed by drifting in the vein or ore zone on two levels, spaced vertically 100 to 600 ft (30 to 180 m) apart. After a viable ore body has been established, the next phase consists of driving one or more raises to establish vertical ore continuity and also to provide ventilation and access to the stope (Fig. 18.3.1)

Raises may be driven conventionally, with Alimak-type raise climbers, or by raise boring machines. Drifting for shrinkage development is normally done by conventional drill-and-blast, track or trackless methods.

Stopes may be prepared with extraction raises on 25- to 30-ft (7.5- to 9-m) centers over the length of the ore shoot; each raise is fitted with a chute, normally of timber construction. Extraction raises are belled out and "hogged over" as the undercut for the start of the first stope cut. This type of preparation is still used but on a very limited basis.

Another method of preparing a stope is to blast down at least two backs of the ore zone, clean up the broken ore, and install stull timbers or timber sets in the drift below the stope. Timber chutes, or even "chinaman" chutes, are installed at approximately 25-ft (7.5-m) intervals as part of the timbering.

A more common method of preparing stopes in modern operations is to drive an extraction drift parallel to the ore body development drift, about 25 to 50 ft (7.5 to 15 m) in the footwall of the ore body. Subsequently, drawhole extraction crosscuts are driven from the footwall drift into the ore drift on 25- to 50-ft (7.5- to 15-m) centers. The back of the ore body is then blasted

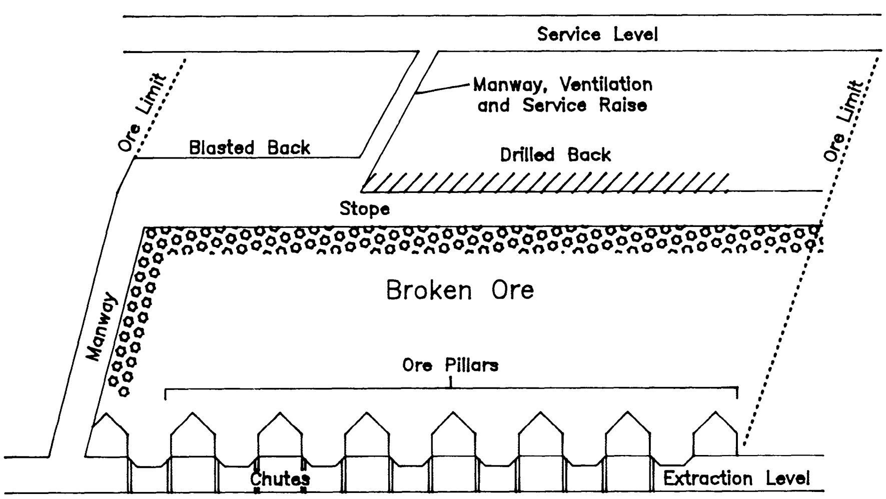

Fig. 18.3.1. Longitudinal section–typical shrinkage stope.

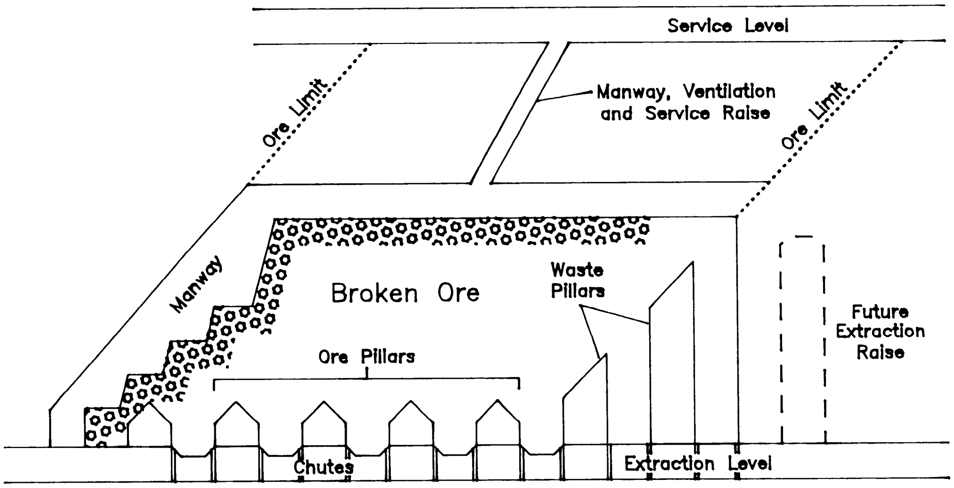

Fig. 18.3.2. Longitudinal section—shrinkage on shallow-raking ore body.

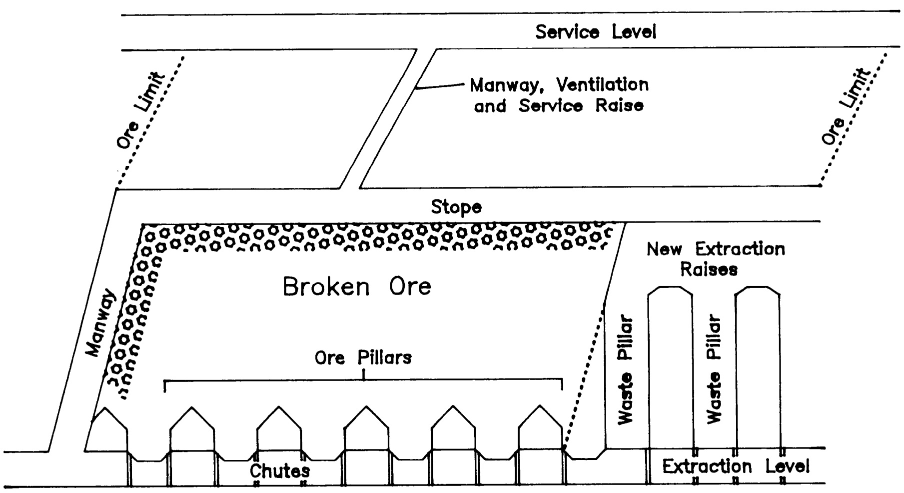

Fig. 18.3.3. Longitudinal section—shrinkage on irregular ore body.

down, and the swell is extracted through the drawholes, either with rail-mounted mucking machines or load-haul-dumps (LHDs) (Fig. 18.3.4).

18.3.3 STOPING OPERATIONS

Once a shrinkage stope has been established, manways are usually installed in the raise from the next level. A manway and service way is normally constructed on one or both end-panels of the stope. Often a timber slide is installed in one of the manways for hoisting and lowering materials into and out of the stope; hoisting is often accomplished with a single-drum air hoist installed in the level below the manway. Once the manways, ventilation raises, and service ways have been established for a stope, mining can commence.

Drilling of a shrinkage stope back is accomplished with hand-held stopers or jacklegs, although mechanized drill wagons or stope jumbos may be used in wider stopes. Back stoping is the normal mode of operation, but breasting down is also common. Up-holes are generally 1.8 to 2.4 m (6 to 8 ft) in length. In most cases, all holes are loaded and a complete back is blasted at a time. Breasts are drilled with a 8- to 10-ft (2.4- to 3-m) horizontal holes and normally blasted once per shift.

Holes are loaded with ANFO products or water gels and even with slurry blasting agents. Initiation is commonly with non-electric methods, but electric blasting is also practiced.

After a cut has been blasted in a stope, drawdown of the 35% swell is necessary, after which the muck pile must be leveled to facilitate drilling of the next cut. Leveling of the pile can be done by hand shovels in the case of small stope, with 2- or 3-drum slushers in larger or longer stopes, and even with LHDs in large stopes. After leveling, drilling of the next stope cut, raising of the manways, and so forth are done to continue the mining cycle.

Variations for the establishment of openings for manways, ventilation raises, or service ways may include installation of strategically placed timber cribbed openings, steel culverts or rings, or timber sets within the broken ore area. These installations may be very desirable during the mining phase, but may create safety problems and nuisances with the collapse of the materials used to construct these openings. Pinning, stulling, or wedging these installations to the stope walls may prevent their destruction during drawdown; materials from a destroyed manway may be drawn down with the broken ore into the chutes or drawholes and cause hangups.

A stope should have strong, self-supporting walls to permit the application of shrinkage stoping. Dilution through scaling of

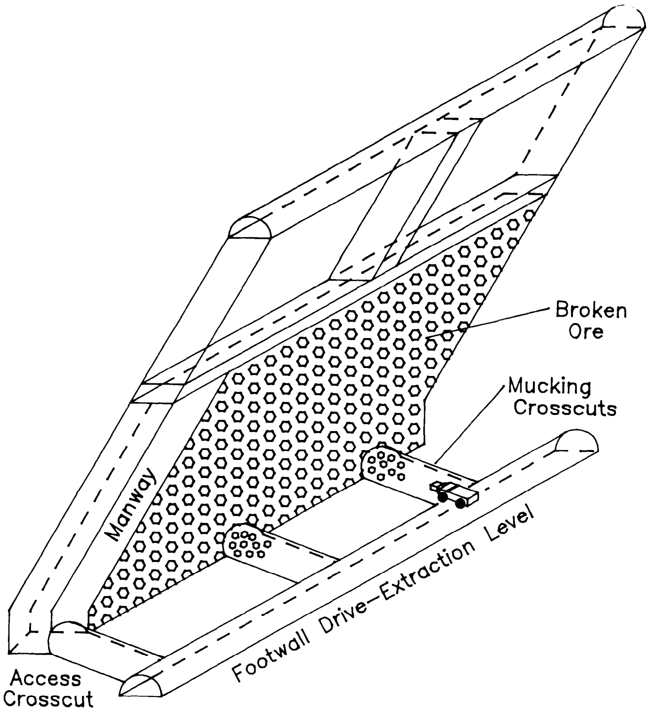

Fig. 18.3.4. Typical shrinkage stope with LHD extraction.

walls can preclude use of the method. Good mining practice coupled with state and federal regulations may dictate a least a minimum ground support program.

Wall and back support may be accomplished by leaving random or even systematic pillars. Pillars left in ore zones may be drilled off and blasted upon drawdown of the stope. Traditionally, timber stulls fitted with plank headboards have been installed to support suspicious slabs or areas of bad ground of stope walls. Horizontal stulls and cribbing are also used to support loose areas of stope backs; however, the timbers may be subsequently buried in the muck pile upon shooting the next stope back, and may become a hazard or, at the very least, a nuisance, upon drawdown of the stope. Rock bolting has evolved into the preferred mode of wall and back support. Mechanical as well as grouted types of bolts are used. Correct installation of bolts in the walls of narrow shrinkage stopes may be difficult because of the lack of room to drill the bolt hole perpendicular to the stope wall as well as to install the required length of rock bolt.

Sampling of narrow shrinkage stope backs is usually done by either taking a channel or chip sample by hand or through mechanical means. Sampling is usually done at a systematic interval (say, 5 ft or 1.5 m) along the entire back, ends, and in some cases, the ribs of the stope after every stope cut. In wider stopes, drill sampling of the back and ribs can be done. The drill sample may criss-cross the stope back on a predetermined pattern. Drill cutting samples are collected in a sample bag through a hose and funnel or other device.

18.3.4 STOPE DRAWDOWN

One of the most dangerous jobs in a mine is the drawdown of shrinkage stopes, especially where the ore contains sticky material to hang up between the stope walls. Hung-up stopes must either be washed down with water, bombed down with explosives, picked down by miners (a practice not recommended), abandoned, or re-mined. In any case, a hung-up stope is a costly and dangerous problem, and shrinkage stoping should not generally be used where the ore has a tendency to hang up.

Stopes should usually be drawn down systematically, drawing the pile evenly so if the stope walls do peel or slough, the waste remains atop the pile and does not trap broken ore rilled above the pile. Once a stope drawdown is started, the operator's control over the walls, pillar recovery, etc., is minimal and in most cases, the re-entry of miners into a stope under active drawdown would be considered too great a safety hazard to risk.

Stopes can be drawn down from strategically placed chutes or from drawpoint crosscuts. Haulage from the stope extraction points may be done with rail equipment or LHDs and/or trucks. Chutes should be robustly designed and constructed to avoid destroying them through blasting of large slabs in them. Stopes may also be extracted through slusher trenches developed below the stope.

18.3.5 VARIATIONS AND APPLICATIONS

Variations of shrinkage stoping include inclined shrinkage and longhole shrinkage. Recovery of large pillars may be done by shrinkage methods.

One example of mines that employed shrinkage as a primary stoping method is the Homestake mine at Lead, SD. Fifty-foot (15-m) wide "bull pen" shrinkage stopes were developed transversely across the full width of the great Main Ledge ore body. Stopes were mined over a timbered sill where strategic china chutes were constructed for ore extraction. Stopes were mined over the sill for about 70 vertical ft (20 m) to within 30 ft (9 m) of the next level. Twenty-five-ft (7.6-m) wide pillars were left between stopes, which along with the crown pillars, were subsequently extracted with square-set stopes. Homestake abandoned this type of shrinkage stoping just before World War II.

A second example is the Idarado mine located near Ouray and Telluride, CO. Stopes were mined along the veins and the full width of the veins, which varied from 5 to 25 ft (1.5 to 7.6 m). Stope panels were generally 400 ft (122 m) long and were prepared over a slusher trench developed about 20 ft (6 m) over the back of the main level drifts. A series of pockets and raises on 25-ft (7.6-m) centers were developed from the slusher trench and the pockets "hogged over" to form pillars between the trench and the first cut of the stope. Ore was extracted from the stope, slushing from the pockets to a chute in the center of the stope. Stopes were normally mined from level to level or about 200 ft (60 m) along the dip.

A variation of the above was practiced at the Morococha and Casapalca mines of the Cerro de Pasco Corp. located in the central Andes mountains of Peru, South America. Stopes in these mines were prepared over the main development level driving 25-ft (7.6-m) raises on 25-ft (7.6-m) centers and "hogging" out from the raises to form the first stope cut at about 16 ft (5 m) over the level. Each raise was then fitted with a timbered chute for ore extraction.

In all cases, a raise was first developed through each ore block or stope panel for ventilation and service. Manways were either carried as cribbed raises in the stope or, in the case of Idarado, as boreholes 10 ft (3 m) in the footwall of the vein. In the vein mines, drilling was accomplished with either stopers or jacklegs, while at the Homestake, drilling was done with bar-and-column mounted Leyner-type drills.

Some variations of shrinkage stoping include inclined shrinkage, longhole shrinkage, and construction shrinkage.

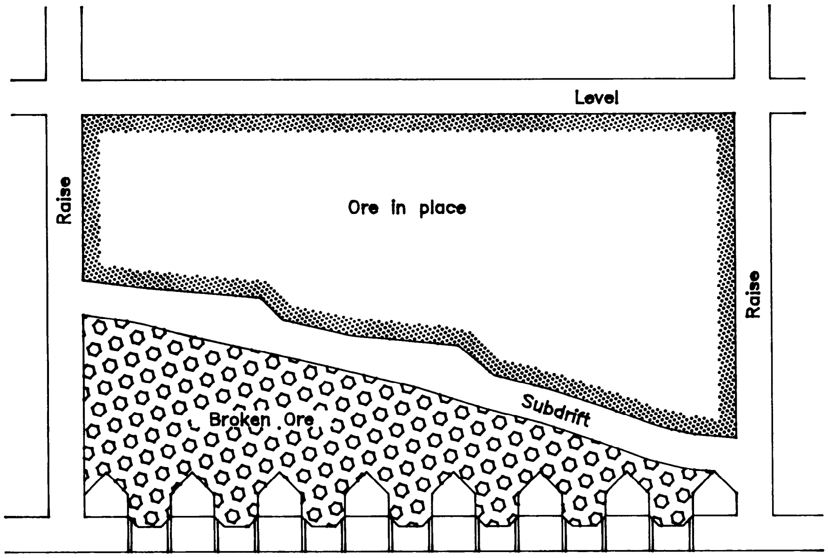

Fig. 18.3.5. Shrinkage stope, Rosiclare, IL.

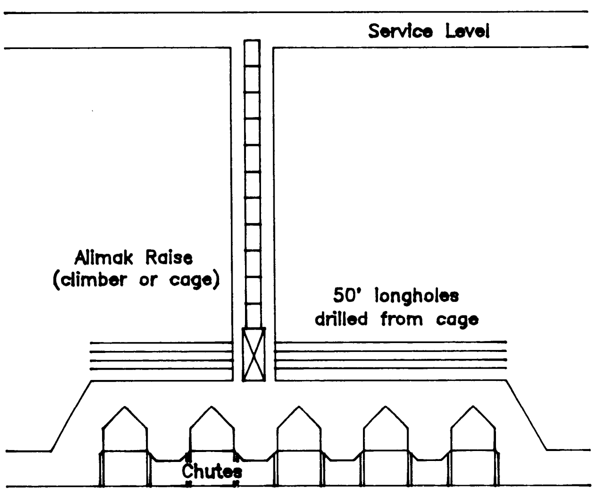

Fig. 18.3.6. Longhole shrinkage stoping.

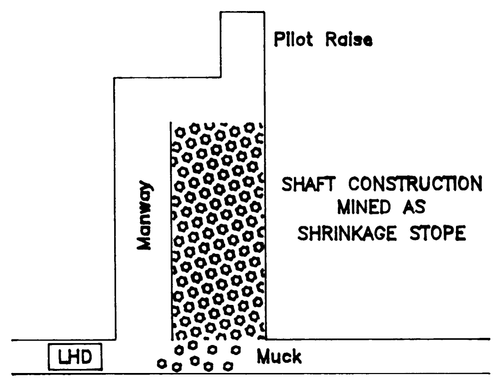

Fig. 18.3.7. Construction shrinkage stoping by conventional method.

Inclined shrinkage refers to a rill stoping adaptation where multiple faces or benches for drilling are carried along the back of the stope as it is mined upward (Fig. 18.3.5). Stopes are developed conventionally over pillars and chutes or over timber sets fitted with chutes on centers of about 25 ft (7.6 m). The advantage of carrying the stope in benches is that multiple faces can be drilled in a given shift where it is desirable to drill the stope with airleg-type drills rather than stopers.

Longhole shrinkage (Fig 18.3.6) is developed conventionally as described previously. The exception is that drilling of the stope is done from vertical raises driven through the ore zone on 50- to 100-ft (15- to 30-m) centers. Raises can be developed with raise climbers or through cage raising techniques. The raise climber or the cage becomes the entry and exit vehicle as well as the platform for drilling and loading. Parallel longholes are drilled along the strike of the ore body and loaded from the raises. Initiation normally is done from a safe area on the service level above the stope.

Shafts, winzes, or large break raises for blasthole or sublevel caving stopes may be developed through shrinkage methods (Fig. 18.3.7). In many cases, this is done as described in the longhole variation. Given a large enough opening, conventional shrinkage stoping of a shaft or raise may be justified.

18.3.6 CASE STUDY: LA LIBERTAD MINE, PUEBLO NUEVO, DURANGO, MEXICO

The small La Libertad mine was brought on-stream in July 1977 by Minas de San Luis, S.A., a 51% Mexican-owned company (Haptonstall, 1980). The mine was developed entirely for shrinkage stoping.

GENERAL. La Libertad was essentially a virgin silver-gold deposit in a very rugged location in the Mexican Sierra Madre mountains. The only previous mining done in the area was a small tonnage extracted from the outcrop of the principal Santa Rosa vein in the 1930s. Production ceased in the mine in 1985 due to political strife in the area. The total investment to bring La Libertad on stream was about $3.5 million (in 1975 dollars).

GEOLOGY. The ore deposit occurred in quartz veins hosted in tertiary rhyolite intrusives and tuffs. The principal oreshoot on the Santa Rosa vein is 1150 ft (350 m) long, 450 ft (145 m) high, and on average 20 ft (6 m) wide. Dip of the vein is 70°W.

ORE RESERVE. Mine commenced with 193,800 tons (176,200 t) averaging 11.5 oz/ton (400 g/t).

MINING METHOD. Shrinkage stoping.

EQUIPMENT. 1-yd^3 (0.8-m^3) LHDs, 2-drum air slushers, stopes and jacklegs, on-highway trucks.

PRODUCTIVITY. 7.7 tons (7.0 t)/employee-shift in stope.

18.3.7 SUMMARY

Under most economic evaluations, the labor intensity of shrinkage stoping precludes its widespread application in modern mining situations. However, it may be the only possible method applicable in the case of a mine in which the ore bodies occur in very narrow veins and cannot be stoped by other methods. Shrinkage may also be used in special situations where small ore blocks cannot be extracted economically any other way or in conjunction with other stoping methods.

18.3.7.1 Parameters

The following is based on Boshkov and Wright (1973), Lucas and Haycocks (1973), Morrison and Russell (1973), and Lyman (1982):

1. Ore characteristics: requires strong ore, non-oxidizing ore, ore that does not pack or stick together, and ore that does not spontaneously combust.
2. Host rock characteristics: requires strong to moderately strong walls.
3. Deposit shape: almost any shape but should have uniform dip and boundaries.
4. Deposit dip: greater than angle of repose (> 45°), and preferably steeper than 60°.
5. Deposit size: narrow to moderate width (3 to 100 ft, or 1 to 30 m); length minimum of 50 ft (15 m) to unlimited panel stopes on long strike lengths.
6. Ore grade: moderate to high.

18.3.7.2 Features

The following is based on Morrison and Russell (1973), Hamrin (1982), and Lyman (1982):

Advantages.

1. Small to moderate production rates.
2. Gravity drawdown of stope.
3. Simple method, especially for small mines.
4. Low capital investment, some mechanization possible.
5. Ground support of ore and walls minimal.
6. Stope development moderate.
7. Good ore recovery (75 to 100%) low dilution (10 to 25%).
8. Reasonable selectivity possible.

Disadvantages.

1. Productivity low to moderate, 3 to 10 tons (2.7 to 9 t)/ employee-shift in stopes.
2. Mining costs moderate to high.
3. Labor intensive, mechanization limited.
4. Difficult working conditions, especially in narrow and/ or short stopes.
5. About 60% of ore tied up in stope until completed.
6. Ore can pack, oxidize, or spontaneously combust in stopes.
7. Risk of loss of stope during drawdown if not properly controlled.

Chapter 18.4
SUBLEVEL STOPING

CHRISTOPHER HAYCOCKS AND R.C. AELICK

Sublevel stoping, also known as blasthole or longhole stoping, is an open stoping, high-production, bulk mining method applicable to large, steeply dipping, regular ore bodies having competent ore and rock that require little or no support. The method is reported to have originated in the Michigan iron mines in 1902 (Peele, 1941) and was originally devised as a shorthole bench and trail system. Production ranges from 15 to 40 tons (14 to 36 t)/employee-shift, and individual stopes may produce in excess of 25,000 tons (22,700 t)/month. Sublevel stoping currently accounts for some 9% of US and 3% of world noncoal production (Lawrence, 1982). The method is often selected as an alternative to sublevel caving when dilution levels must be kept to a minimum. In the Zambian Copperbelt, dilution was reduced from 30 to 20% by changing from sublevel caving to sublevel stoping, although recovery dropped from 90 to 80% because of difficulties in pillar recovery (Misra, 1983).

Sublevel stoping is very development intensive, although the cost of development is compensated by the fact that much of it is done in ore. It is currently limited to steeply inclined ore bodies where both ore and country rock are competent and broken ore flows under the influence of gravity. In the 1930s, it was used at the Roan Antelope Mine at dips as low as 12 to 30° with slushers to move the ore (Peele, 1941). More recently, the Cascade method, which is a direct modification of sublevel stoping, has been used at dips as low as 25°, also by utilizing scrapers to move the ore (Kelly, 1969). Ore bodies should be regular, because the method is not selective.

Production drilling is accomplished using longhole equipment. New developments in sublevel stoping involve the utilization of large-diameter DTH (down-the-hole) drills that, because of their directional accuracy, are revolutionizing the mining method (Pandey, 1984). The large, highly mechanized drilling equipment used restricts the minimum-width ore body that can be mined, while high development costs associated with sublevel stoping require that a high production rate be maintained. Efficient use of large-scale blasting makes sublevel stoping one of the lowest-cost underground mining methods available. Sublevel stoping also finds widespread application for pillar recovery in cut and fill and other types of mining methods (Irvine, 1982; Bharti, Lebl, and Cornett 1983). A variation of sublevel involves blasting the ore in horizontal instead of vertical slices with long stope holes drilled from raise climbers (Robertson, Vehkala, and Kerr, 1989).

18.4.1 ORE BODY TYPE

The typical ore body required for successful sublevel stoping must be regular, large, strong to fairly strong, and competent, and the wall rock must be self-supporting. Rock strengths vary widely and can be compensated for in the design, but typically range from a minimum of 8000 psi (55 MPa) with no upper limit. The dip of the ore body footwall must be such that it exceeds the angle of repose of the broken ore, which permits gravity flow of blasted ore through to drawpoints and chutes.

Ore bodies are typically a minimum of 20 ft (6 m) wide to afford efficient application of longhole blasting. Ore bodies less than 20 ft (6 m) wide realize a higher cost per ton of ore because of lowered production per blast, and as widths go less than 5 ft (1.5 m), hand drilling and overhand and underhand methods must be resorted to. In wider weaker ore bodies, transverse stoping may be practiced to afford additional stope support (Matikainen, 1981). No upper size limit exists for ore bodies mined using this method. However, in large ore bodies, support pillars must often be left in place during the entire mining cycle on that level. These pillars are usually recovered after adjacent completed stopes have been backfilled (Boshkov and Wright, 1973; Hamrin, 1982).

Longhole drilling and large-volume production blasting require ore bodies that are even and fairly well defined. Stope boundaries must be regular, because irregular ore bodies and those containing large waste inclusions cannot easily be avoided. Waste from irregular ore bodies and inclusions dilutes the ultimate grade of mined ore and thus increases the cost per ton of ore produced. A smooth ore-to-footwall contact allows for easier flow of blasted ore to drawpoints and chutes. Rock must be structurally competent and self-supporting as large openings may be left unfilled for extended periods of time. Additionally, repeated shocks from large blasts require an ore of high compressive strength and minimal structural weaknesses such as joints, faults, and bedding planes.

Failures resulting from collapse of incompetent ground cause excessive dilution, loss of sublevels, and large chunks blocking drawpoints, and necessitate reconditioning of stopes. Small, localized ground failures result in ground movement and displacement, and cracking of blastholes. This in turn makes loading of blastholes difficult and in some cases necessitates extensive redrilling of a block (Morrison and Russell, 1973; Mitchell, 1981; Lawrence, 1982). Sublevel stoping is used to depths of 3000 ft (900 m) (Misra, 1983).

18.4.2 STOPE DEVELOPMENT

18.4.2.1 Stope Layouts

Mine development normally starts from a shaft sunk in the footwall to avoid any subsequent caving effects from the stopes. The ore body is divided vertically by driving crosscuts and haulage levels every 150 to 400 ft (45 to 120 m). Access raises driven in the ore body are used to further subdivide the ore body into blocks for stoping. A collection system is constructed, during which time the stope block is all or partially undercut. Sublevels are driven through the proposed stope block every 30 to 180 ft (10 to 55 m) (Fig. 18.4.1), and more than one sublevel may be used on each level, depending on the width of the ore body. Some typical dimensions for a wide variety of ore bodies are shown in Table 18.4.1.

Stoping is carried out by blasting vertical slices into an expansion slot (Fig. 18.4.2) the height and width of the proposed stope, usually by enlarging a slotting raise with longhole drilling and blasting. Shrinkage stoping has also been used to form the starting slot that may be developed at the end or middle of the stope. Slotting has been shown to be a very expensive part of the stoping operation, accounting for 20 to 30% of total stoping costs (Matikainen, 1981).

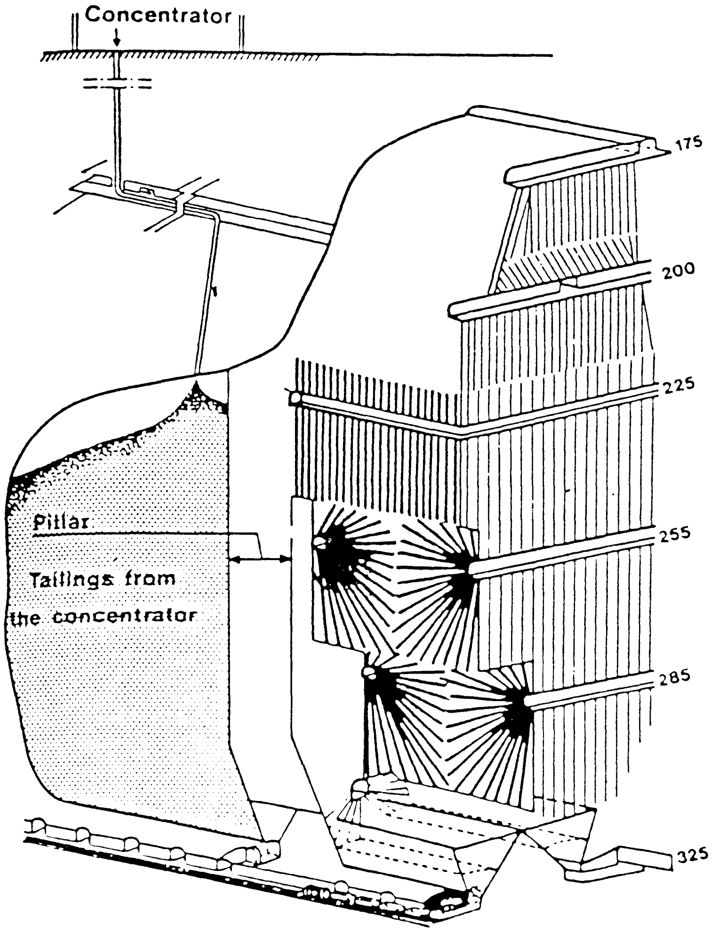

Fig. 18.4.1. Sublevel stoping at Outokumpu Oy Vihanti mine showing the relationship between development and production drilling (Matikainen, 1981).

Table 18.4.1. Sublevel Stoping Basic Dimensions

Mine	Ore Body	Stope Dimensions, ft				Pillars, ft	Haulage, Interval, ft
		Width	Length	Height	Sublevel		
Kidd Creek (Belford, 1981)	Massive base metal sulfide	79	98	299	98	70–98	397
Torman (Matikainen, 1981)	Massive limestone	148–164	328–492	328	49–164	148–164	—
Rio Tinto (Botin and Singh, 1981)	Massive sulfide	66	66–164	131–236	131–236	41	174–276
Mt. Isa (Goddard, 1981)	Bedded sulfide	82–164	98	410–820	66	82	574–984
Burra Burra (McNaughton, 1929)	Massive sulfide	39	328	164	43	43	197
Luanshya (Mabson and Russell, 1981)	Bedded sulfide	39	39	115	36	16–32	164–230

Conversion factor: 1 ft = 0.3048 m.

Stopes are typically contained by a crown pillar, which protects the level above, rib pillars, and a sill pillar through which the ore collection system is cut (Fig. 18.4.3). Substituting filled stopes for rib pillars has been achieved successfully under some conditions (Fig. 18.4.4) (Belford, 1981). Pillars are typically removed through large-scale blasting when stoping is exhausted, and up to 100% of the ore can be recovered under ideal conditions. Stopes can be filled where caving is unacceptable or must be controlled to reduce surface effects or minimize underground stress effects. Filling of stopes also facilitates pillar removal under some conditions.

18.4.2.2 Stope Extraction Systems

The base of the stope may be slotted horizontally prior to production blasting with the base of the slot being a collection trough or series of 45° cones. These are cut through the sill pillar to collect the ore. Alternative to this, no separate slot may be used, and stope blasting will expose the collection system as the stope face retreats. Excavation of the troughs or cones is typically carried out by drilling from the proposed drawpoint and mining upwards using small (2.16 to 3.70 in., or 55 to 94 mm) longholes (Fig. 18.4.5).

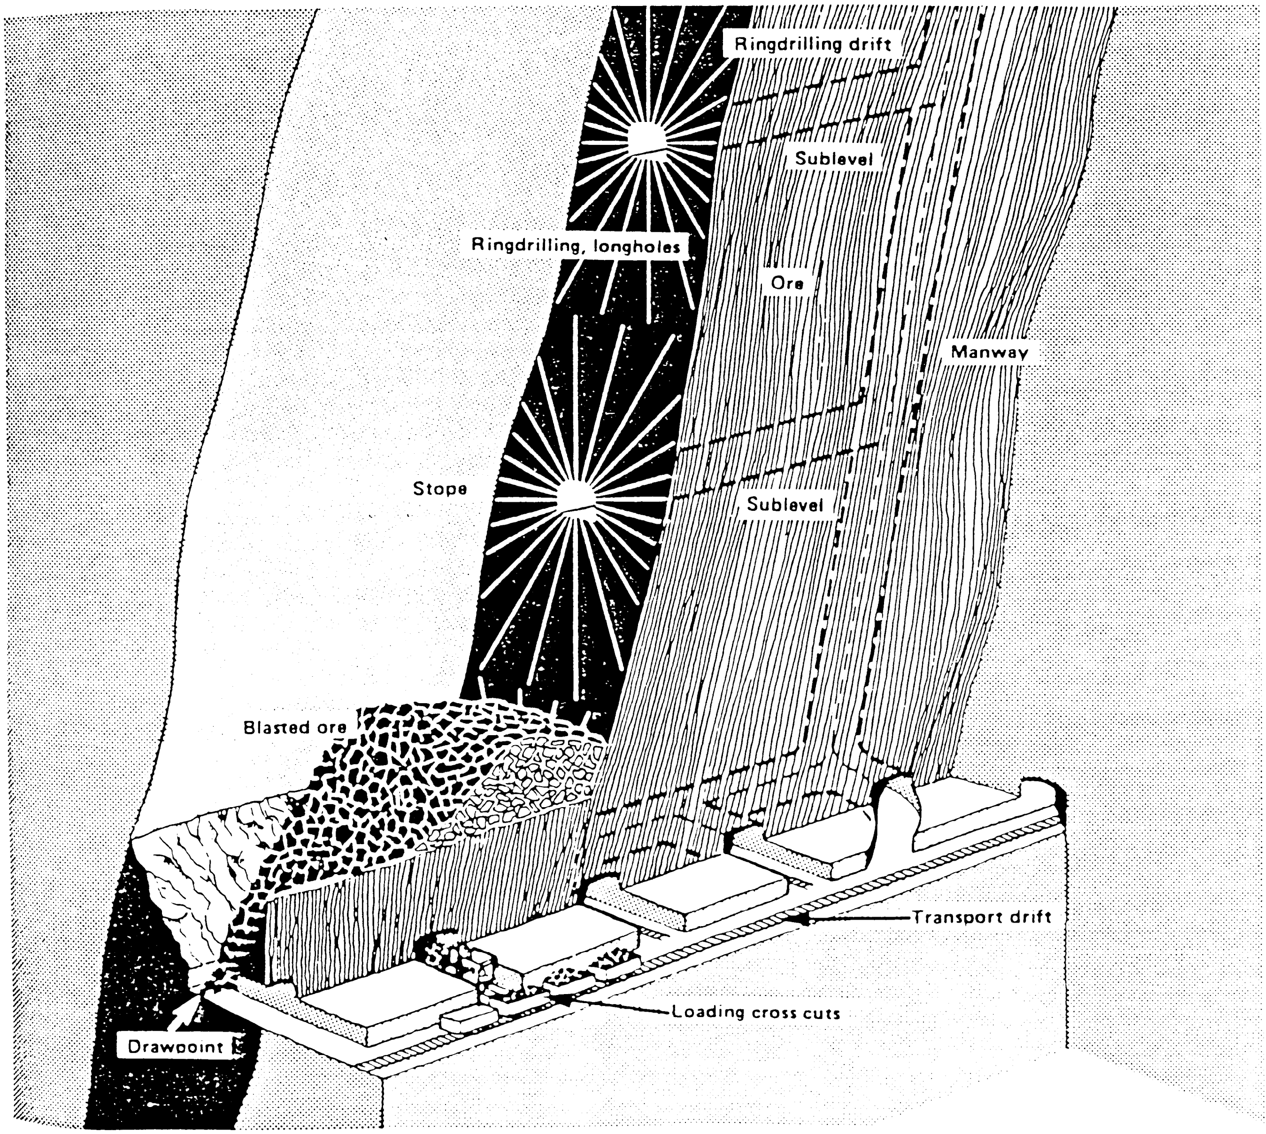

Fig. 18.4.2. Production blasting in a sublevel stope showing ring drilling patterns and loading system (Hamrin, 1982).

Seven ore handling systems are available to remove broken ore from the stope, depending on the needs of the various mining operations (Haycocks, 1973a):

1. Ore may be directed from the cones through finger raises to a grizzly level and then directly into mine cars (Fig. 18.4.6). In this case, secondary blasting is confined to the grizzly itself. This is a system usually selected for very large stopes where the high cost of development is offset by its longevity.

2. Ore can be drawn directly into the finger raises or chutes in cases where it breaks very fine, and then loaded directly through the boxhole to mine cars.

3. In order to minimize the number of boxholes, a single boxhole and chute feeding into a scram or slusher drift may be used. Up to ten drawpoints feed into the slusher drift that will pull ore to a grizzly.

4. This method is similar to (3) above but utilizes a chinaman and drops ore directly into the mine cars (Fig. 18.4.7). The method does not have as much storage capacity as the previous system.

5. The more modern system utilizes trackless rubber-tired load-haul-dump units (LHDs) loading directly out of drawpoints that lie below the cones (Fig. 18.4.8). The machines then transport the ore directly to orepasses. Remote-controlled LHDs have proved most successful for loading out drawpoints under exposed conditions, particularly near the end of the stope life (Bharti, Lebl, and Cornett, 1983).

6. This method utilizes a track-mounted system loading into a rail haulage system (Fig. 18.4.9).

7. Ore is loaded directly from drawpoints onto pan feeders (Lawrence, 1982).

Sill pillar thickness, which is usually the distance between the base of the stope and the haulage level, depends on the ore handling system selected but generally varies between 30 and 70 ft (9 and 21 m).

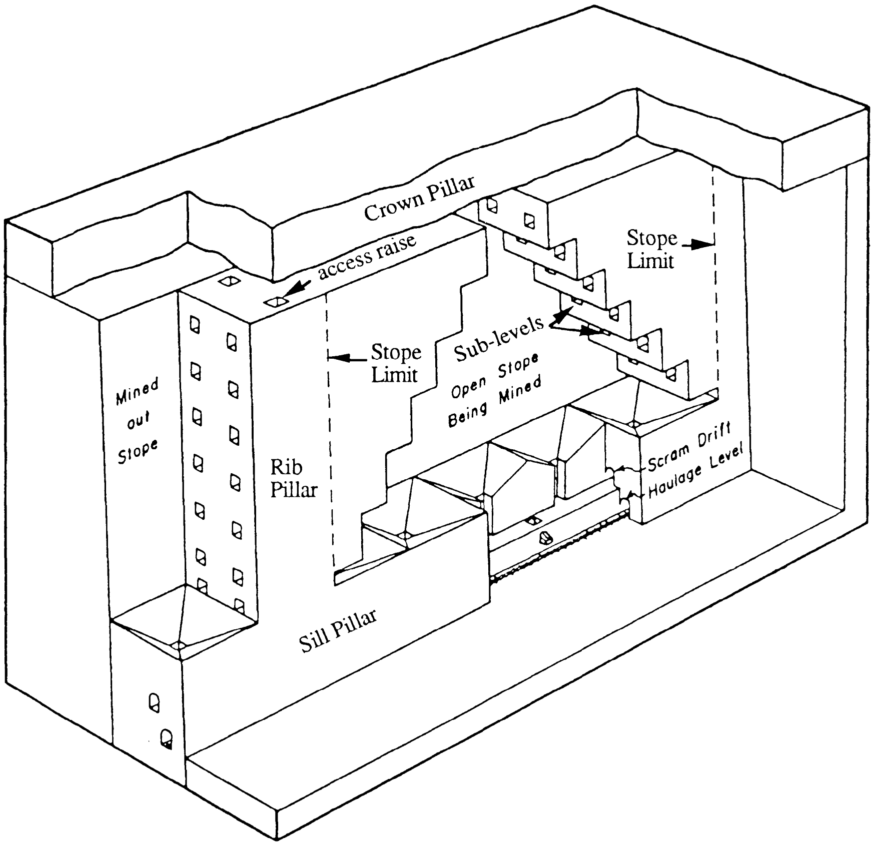

Fig. 18.4.3. Pillar system around a sublevel overhand stope (Clark and Caudle, 1961).

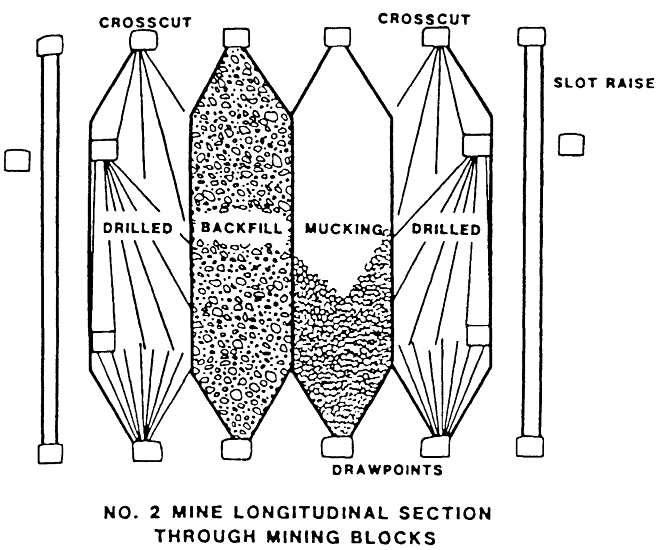

Fig. 18.4.4. Cemented backfill used as alternative to pillars (Belford, 1981).

18.4.2.3 Stoping Action

Stoping typically commences by blasting the lowermost faces first, then moves progressively upwards from the overlying sublevels (Fig. 18.4.3). The overall stope face is carried overhand to facilitate ore flow in the stope. The faces may be carried vertically where the ground is very weak. An alternative to this was implemented at the Burlington mine where the overall stope face was carried out underhand to improve stability (Fig. 18.4.10). Significant ore loading problems resulted (Fletcher and Evans, 1973).

18.4.3 PRODUCTION DRILLING

Consideration must be given to a number of factors before production drilling can commence. Drillability of the ore, required fragmentation size, hole size, hole length, orientation and spacing of drillholes, and desired drilling accuracy must be established. The above factors contribute to the selection of drilling equipment and design of production drilling patterns. Typically, production drilling is accomplished using mechanized longhole drilling. Recent developments in drilling technology include high-efficiency column-and-arm longhole drills, and DTH drill rigs have revolutionized sublevel stoping. These units incorporate electric over hydraulic drive and feed systems, high-pressure pneumatic DTH hammers, or rotary-percussion drilling systems. This type equipment is capable of drilling holes up to 9 in. (229 mm) indiameter to depths of 400 ft (120 m). Alignment errors of holes exceeding 400 ft (120 m) is generally less than 2%. Drilling accuracy can have important economic implications for any proposed mining operation (Almgren and Klippmark, 1981).

Many drill rigs have the capability of drilling a 360° ring of holes. This capability allows for up-hole and down-hole drilling, which in turn results in lower development times and costs. The best drilling efficiency, however, results when a pattern of vertical parallel holes can be drilled from a drill sill developed in the stope (Fig. 18.4.11).

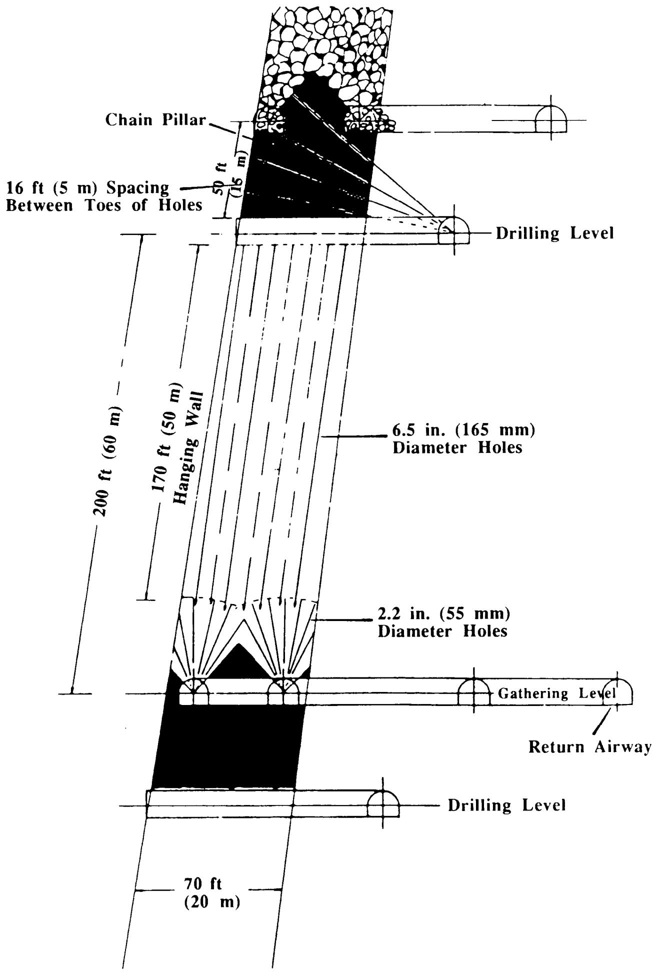

Fig. 18.4.5. Use of small-diameter holes for cutting collection cones (Mabson and Russell, 1981).

Holes patterns, whether parallel or in rings, are drilled from sublevels that are 60 to 400 ft (18 to 120 m) apart (see Fig. 18.4.1). Generally, steeply dipping deposits are drilled with parallel holes, whereas ring drilling is usually adaptable to massive ore bodies. With the introduction of up-hole and down-hole rigs, the drilling sill no longer has to be developed to the full width of the ore contact. A fan-shaped array of holes drilled from a narrow drill sill can effectively delineate the required width of the ore body. This is probably the oldest method, predated only by the now obsolete overhand and underhand shorthole bench and trail (Hamrin, 1982).

The second parallel hole system evolved from the old shorthole bench and trail method and utilizes 6 3/4-in. (170-mm), large-diameter, accurate DTH drills (Fig. 18.4.11). This method is much more efficient than ring or fan drilling and results in consistently acceptable fragmentation. The distance between sublevels can be extended to 150 to 180 ft (45 to 55 m) (Hamrin, 1982). This system also uses a starting slot cut to the full height of the stope for expansion of the initial blast. The problems with this system are the necessity of carrying the bench and trail, which must be continually developed as the stope advances, and the possibility that large charges could cause stope wall deterioration.

Drill patterns and hole sizes are frequently established by applying a preselected powder factor to the size of the ore block to be mined. Hole spacings vary from 20 by 20 ft (6 by 6 m) at Kidd Creek with 7 7/8-in. (200-mm) blastholes (Belford, 1981), to a burden of 5 to 7.5 ft (1.5 to 2.3 m) and a spacing of 7 to 8 ft (2.2 to 2.5 m) at Finnish operations using 2-in. (51-mm) blastholes (Matikainen, 1981).

18.4.4 PRODUCTION BLASTING

Selection of appropriate explosives is related to factors such as required fragmentation, hole size, spacing and burden, hole condition, water inflows, allowable blast sizes, and hardness of the ore. ANFO, water-gels, emulsions, and heavy ANFOS in bulk or packaged form can all be used for blasting sublevel stoping holes. The selection of explosive type is largely related to economics. Presently, ANFO is the least expensive form of explosives. ANFO can be free- poured in down-holes or pneumatically loaded in up-holes. The technology exists today to load upholes up to 6-in. (150-mm) diameter with ANFO. This situation requires the use of specially constructed collar plugs and cascading techniques.

In areas where water inflow is a problem, ANFO cannot be allowed to remain in the hole for periods of more than a few hours. In this type situation, watergel, emulsion, or a blend of the two is used. These products are waterproof, high-density, and typically high-velocity explosives. Again, these products can be loaded in either down-holes or up-holes.

A number of techniques can be used to load holes with explosives. In ring blasting, a slot or raise is developed in the footwall of the stope. This allows for either column loading of a hole or decking of a hole. A column-loaded hole is simply loaded from toe to collar with explosive, while a decked hole is loaded with alternating decks of explosive and an inert stemming material. The decision to load a hole with either a column charge or decked charge is based on considerations such as allowable powder factors, hardness of the ore, uphole or downhole condition, fragmentation requirement, and in some cases blast vibration considerations (Fig. 18.4.12). In the last 15 years, some mine operators have begun using spherical charges to blast large-diameter down-holes. This method requires that a charge height equal to six borehole diameters be maintained within the hole. An inverted crater is created when the charge is detonated. Craters from each hole are designed to overlap each other, effectively allowing for the blasting of a slice across the entire horizontal extent of the stope. Timing and sequencing of blasting is achieved by either electric or non-electric delay detonators. These detonators can be placed either in the hole or at the collar of each hole. Recently, electrical sequential blasting machines have been used in underground stope blasting to achieve greater timing flexibility and detonation accuracy.

The timing sequence of a blast is critical to the success of the blast and resultant fragmentation. Typically, a blast is sequenced so that one ring of holes is fired at a time. Rings are blasted in succession into the opening created by the blasting of the previous ring. Proper blast timing is also critical in minimizing the effect of excessive blast vibration and concussion effects underground.

Secondary blasting is necessary if primary blasting has failed to sufficiently fragment the ore to a size that can be dealt with by ore removal and handling equipment. Secondary blasting can take two forms. The first is called blockholing and involves drilling holes into oversize boulders and loading these holes with explosive. The second method requires that a small shaped charge be placed on top of the site to be blasted. The shaped charge is detonated, shattering the boulder.

Secondary blasting is an expensive, time-consuming exercise. Close engineering control on primary drilling and blasting will

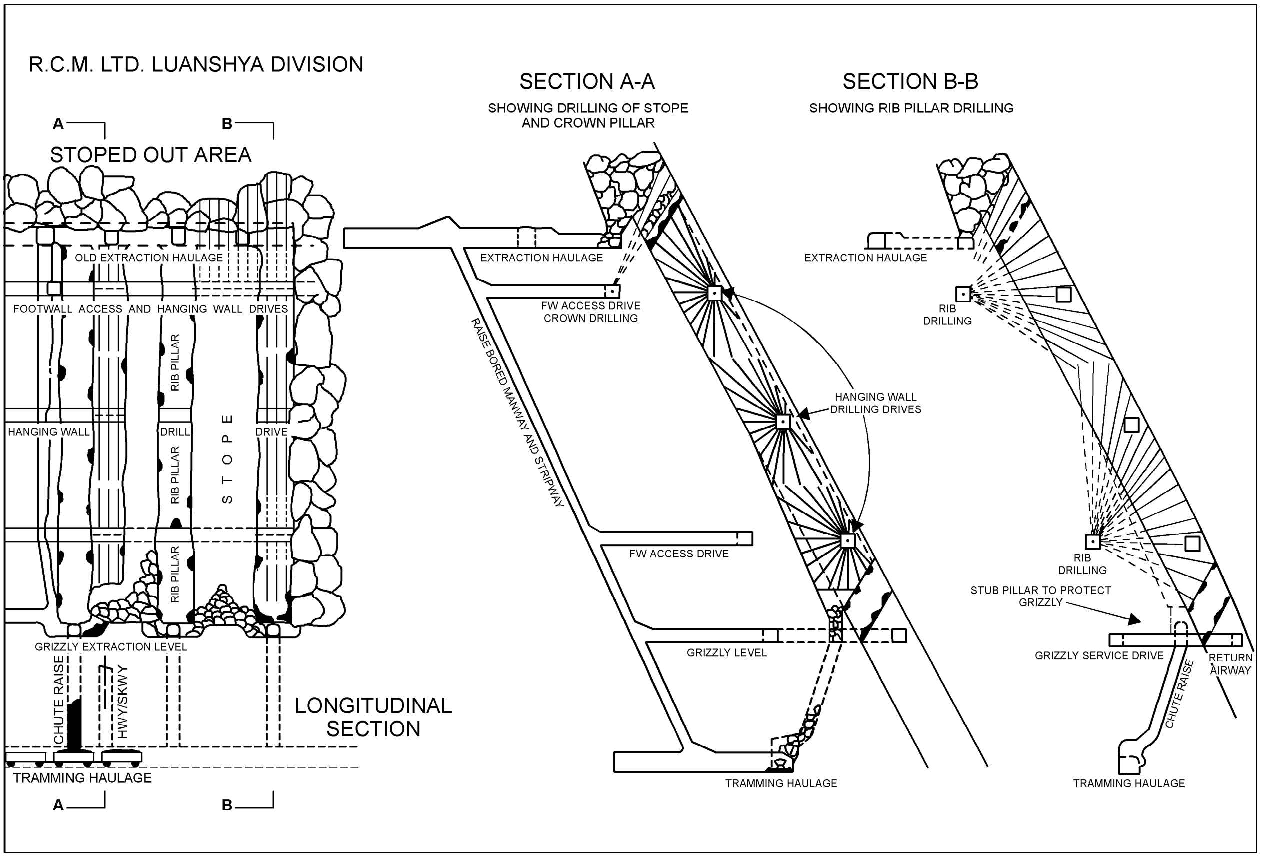

Fig. 18.4.6. Grizzly and orepass collection system (Mabson and Russell, 1981).

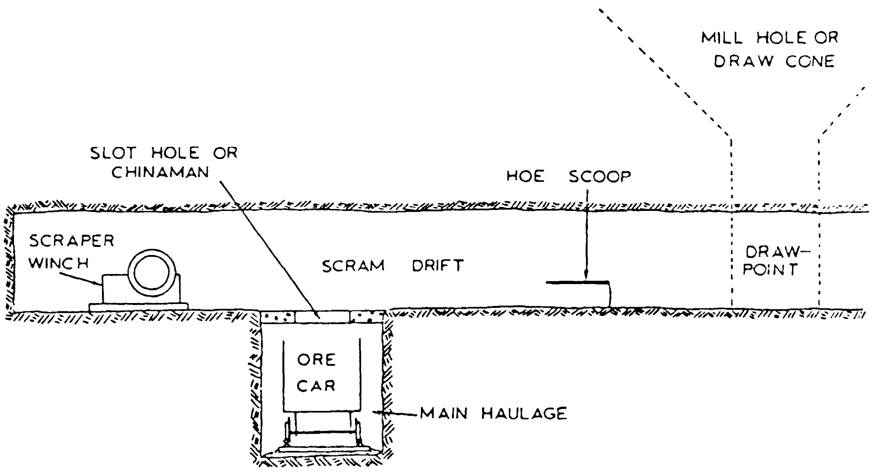

Fig. 18.4.7. Slot hole method of ore handling (Haycocks, 1973a).

minimize the frequency of secondary blasting. Analysis of a large sublevel operation has shown that blasting costs were less than 10% and drilling costs more than 30% of total costs. Optimization of the stoping layout is now possible using computer simulation (Chatterjee and Just, 1981). Dynamic programming methods have also been applied successfully to grade control and scheduling for sublevel stoping (Dowd and Elvan, 1987).

18.4.5 WASTE FILLING

The large openings created by sublevel stoping typically require that some sort of backfilling program be practiced. Backfill includes uncemented rock and sandfill, cemented rock fill, cement hydraulic tailings fill, and a high density tailings or alluvial fill. Backfilling allows for future recovery of support pillars.

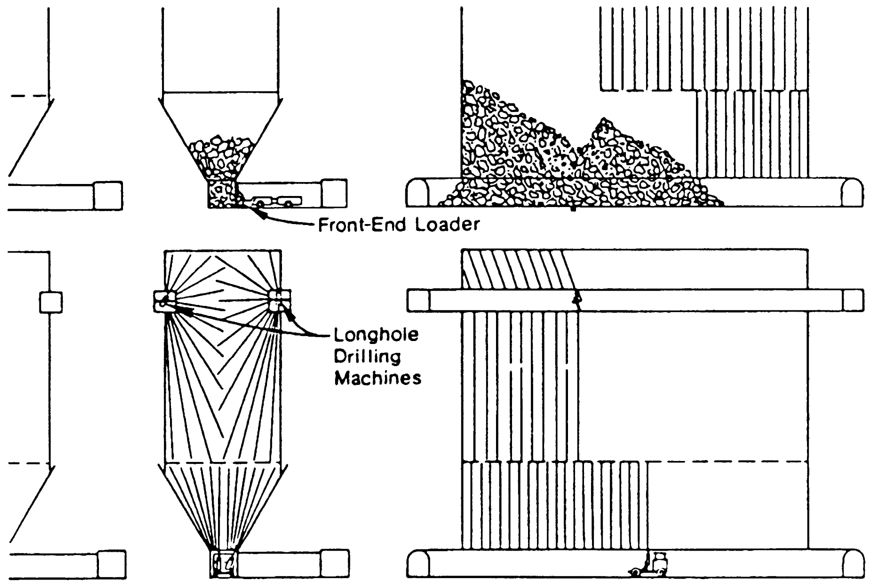

Fig. 18.4.8. LHD drawpoint system of ore extraction (Irvine, 1982).

Recovery of pillars permits up to 90% recovery of ore (Fig. 18.4.13). Backfilling also minimizes the occurrence of subsidence and allows for redistribution of stresses created by the mining cycle. This in turn minimizes the frequency of rock bursting. Backfilling has also been used successfully to eliminate rib pillars between the stopes. In this case the backfill contains sufficient cement to form a self-supporting unit (see Fig. 18.4.4). Cementing the backfill is not always economical, in which cases pillar recovery may not be practical, and the fill is used to control surface movement (Matikainen, 1981).

18.4.6 GROUND CONTROL

Ground control is typically minimal with this system because the rock must be inherently strong, although different types of bolts are used for local support, which may or may not include mesh (Fig. 18.4.14). Regional stresses have been shown to affect stope design and dimensions and are an important consideration. The large open stopes can serve to concentrate high horizontal stresses and cause severe deterioration in development openings in close proximity to the stopes (Goel and Page, 1981).

Cable bolting has proved very successful for full stope wall support, using cables up to 150 ft (45 m) long (Fig. 18.4.15). Cables are normally installed from the blasting sublevels during blasthole development, and resin anchored bolts have proven most successful although cement grout is also used (Goddard, 1981). A variety of cables have been used, including old hoisting cable and low-relaxation strand cable (Matikainen, 1981).

18.4.7 SAFETY CHARACTERISTICS

The sublevel stoping method is a very safe mining method by virtue of design. Typically, miners work only under conditioned ground that has been secured by means of rock bolts, cable bolts, and artificial supports. Miners are not required to work on top of broken ground. In addition, the method is such that mining is scheduled to retreat from unsupported or previously mined areas. The introduction of mechanized equipment has also yielded significant gains in safety. LHD units can be operated remotely by means of radio controls in areas where ground is unsupported. Much of the modern, sophisticated drilling equipment allows the operator to operate the equipment remotely from the collar location of the hole.

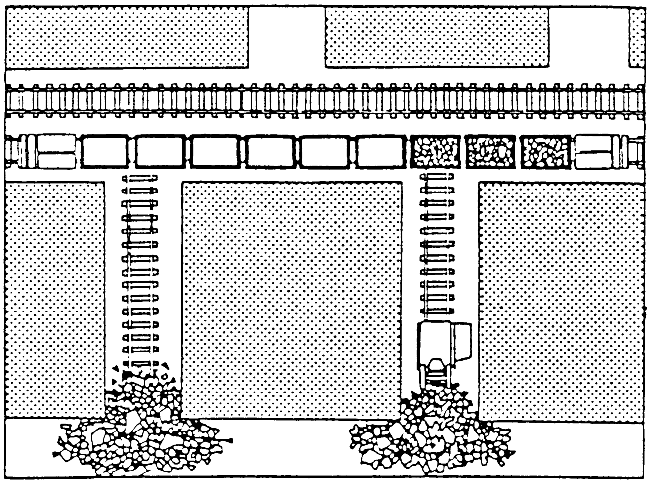
Being a bulk mining method, sublevel stoping requires that large-volume blasts be taken to maintain productivity levels. Such large-volume blasts are usually initiated remotely from a refuge station or surface location. This procedure ensures that no operating personnel are exposed during blasting. Additionally, it ensures that detonation gases have had time to be exhausted by the ventilation system before workers are reintroduced underground.

The large drifts, multiple accesses, and internal raise and winze system allow for a very efficient ventilation system that keep air clean and working conditions comfortable.

18.4.8. ECONOMICS

Sublevel stoping is an inherently high-production, low-cost method and is frequently selected as a primary underground method when surface mining of a deposit is no longer economical (Hedberg, 1981). The key to minimizing costs is mechanization, using as large-capacity machines as the ore body will permit in terms of production capacity and opening size. The utilization of large-diameter DTH machines can reduce total development compared to smaller-diameter longhole drills that are limited to hole lengths less than 90 ft (30 m) by accuracy restrictions.

A breakdown in mining costs for a typical operation is shown in Fig. 18.4.16. This figure clearly shows the development-intensive nature of sublevel stoping, with development accounting for one-third of total mining costs (Lawrence, 1982). Labor cost typically average 40 to 50% of total stoping costs (Matikainen, 1981). Cost analyses are now possible for sublevel systems, involving such factors as stope sizes, drilling and blasting parameters, number of drill points, and loading machines (Chatterjee and Just, 1981). Detailed analyses of stope potential and mining costs can be handled in a sophisticated and precise manner (Pugh and Rasmussen, 1982).



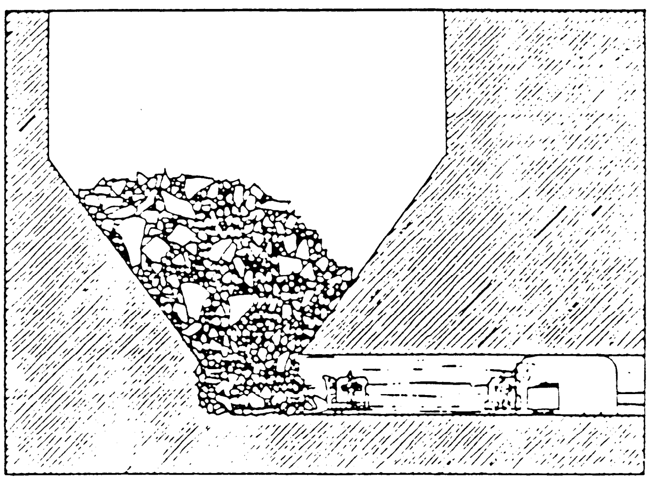


Fig. 18.4.9. Track-mounted loading system for sublevel stope (Bjorkstedt, 1981).

18.4.9 ADVANTAGES AND DISADVANTAGES

18.4.9.1 Advantages

1. Sublevel stoping is very amenable to mechanization, and therefore stoping efficiencies are high, running up to 110 tons (100 t)/employee-shift in larger stopes (Takata, Nanko and Izawa, 1981).

2. The method has a moderate- to very high-production rate, with individual stope outputs running as high as 25,000 tons (22,700 t)/month.

3. The method is safe and, apart from driving the sublevels, easy to ventilate, particularly where weekly blasts are used.

4. Ore recovery can be high, in excess of 90%, when good pillar recovery is possible. Dilution is generally low and can be contained below 20% for most operations.

5. Stopes can be drilled in advance of blasting as equipment is available.

6. In big operations, blasts can be carried out periodically, such as once a week, by very efficient highly trained crews, thus improving blasting efficiency.

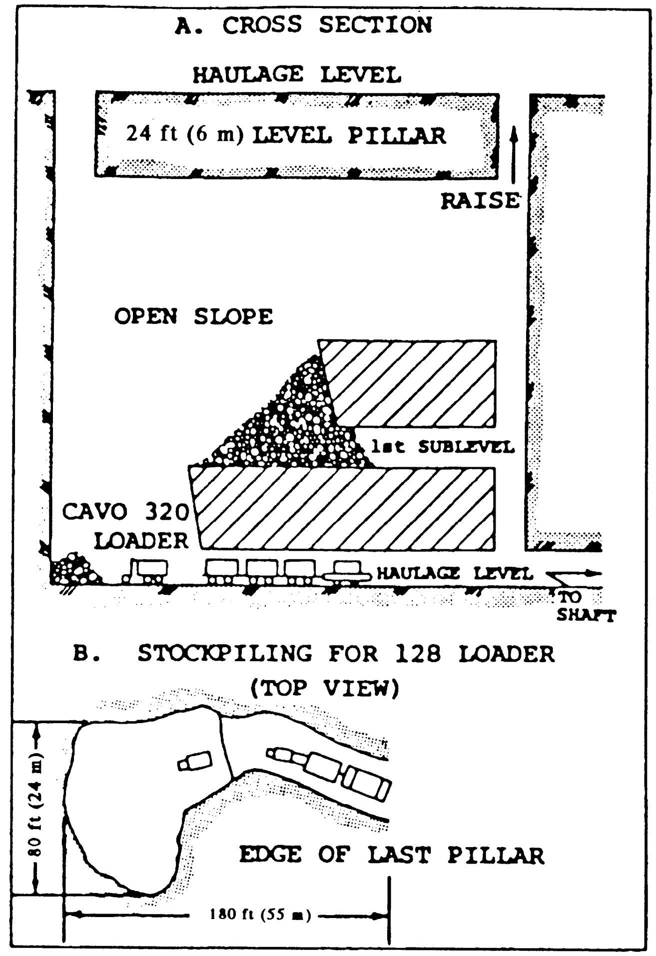

Fig. 18.4.10. Sublevel faces carried underhand (Lawrence, 1982)

7. Ore can be drawn off immediately once primary stope blasting commences.

18.4.9.2 Disadvantages

1. The method is very capital intensive, requiring a large amount of development before production can begin.

2. The method is nonselective and requires most of the ore body to be taken. Variations in footwall or hanging wall are difficult to accommodate.

3. The method becomes very inefficient at lower dips where dilution may be expected to increase.

4. Secondary blasting fumes may leak back into the stope if excessive secondary blasting is necessary.

18.4.10. CASE STUDY: SUBLEVEL STOPING AT KIDD CREEK MINES

The Kidd Creek (Belford, 1982) ore body is a massive base-metal sulfide with horizontal dimensions at the surface of 525 by 2075 ft (168 by 670 m). Initial mining was by open pit, which supplied ore until 1977 when it reached a depth of 680 ft (219 m). At this point, a second phase of underground mining was initiated. Careful planning was essential to ensure sending an even grade of ore to the concentrator. Two mines were commenced with the No. 2 mine below the No. 1 (Fig. 18.4.17).

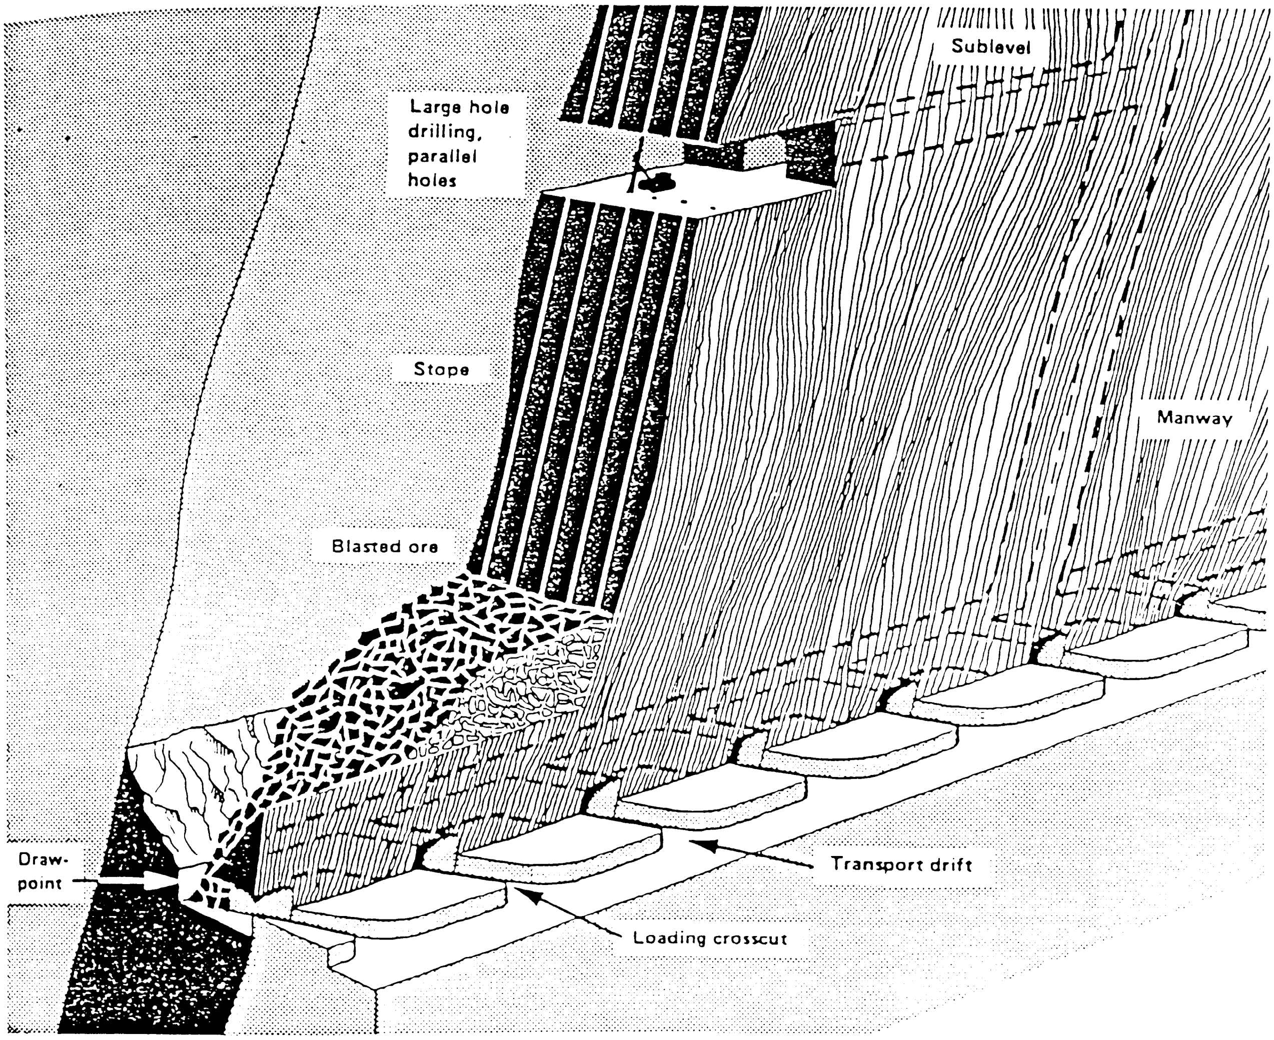

Fig. 18.4.11. Parallel hole system of stope drilling from a drill sill (Hamrin, 1982).

18.4.10.1 Mining Method Design: No. 1 Mine

Sublevel stoping was selected as the mining method, with stopes averaging 55 to 75 ft (18 to 24 m) wide, 95 ft (30 m) long, and 280 ft (91 m) high. Precise stope dimensions depend on local conditions. Rib pillars are 75 ft (24 m) wide and sill pillars approximately 95 ft (30 m) thick. The main footwall haulageways are being developed at 375-ft (121-m) intervals with crosscuts being driven through the ore body to a hanging wall drive. The ore extraction system from the stope consists of a series of drawpoints on 22-ft (7-m) centers driven from the haulage to crosscuts. Ore and waste passes are developed in the footwall.

Sublevels are driven on 95-ft (30-m) vertical intervals and are tied to the footwall ramp system. The sublevels are designed primarily to give access for longhole drilling in the stopes, but have also been used for production to facilitate draw control and ore blending.

Ventilation poses serious problems because of low winter temperatures. Air must be preheated prior to moving it underground, or the broken ore can freeze causing major hangups. Water sprays are used to control dust at drawpoints.

18.4.10.2 Stoping

Stoping commences by boring a raise from the uppermost sublevel to the undercut drill drift (Fig. 18.4.18). The base of the stope is undercut in the shape of a trough using Gardner-Denver DH123 2 1/8-in. (54-mm) diameter drills. The starting raise is enlarged using longhole drilling, and the fan stoping holes are drilled using Robbins 11D rotary drills drilling 7-7/8 in. (200-mm) diameter holes on a 20- by 20-ft (6- by 6-m) pattern. Blasting is done using water gels and ANFO with nonelectric methods of initiation. Initial results show damage to surrounding excavations from blasting the large-diameter charges. The method was resolved by breaking the charge down to a maximum of 350 lb (160 kg) per delay. Secondary breakage is achieved primarily through drill-blast. Hydraulic rock breakers have obvious advantages in that they do not interrupt the loading cycle, but they are bulky and have difficulty operating in the extraction drifts.

18.4.10.3 Equipment

Primary mucking equipment is Wagner ST8 scoop trams powered by GMC V8 diesels. The fleet is designed to work at

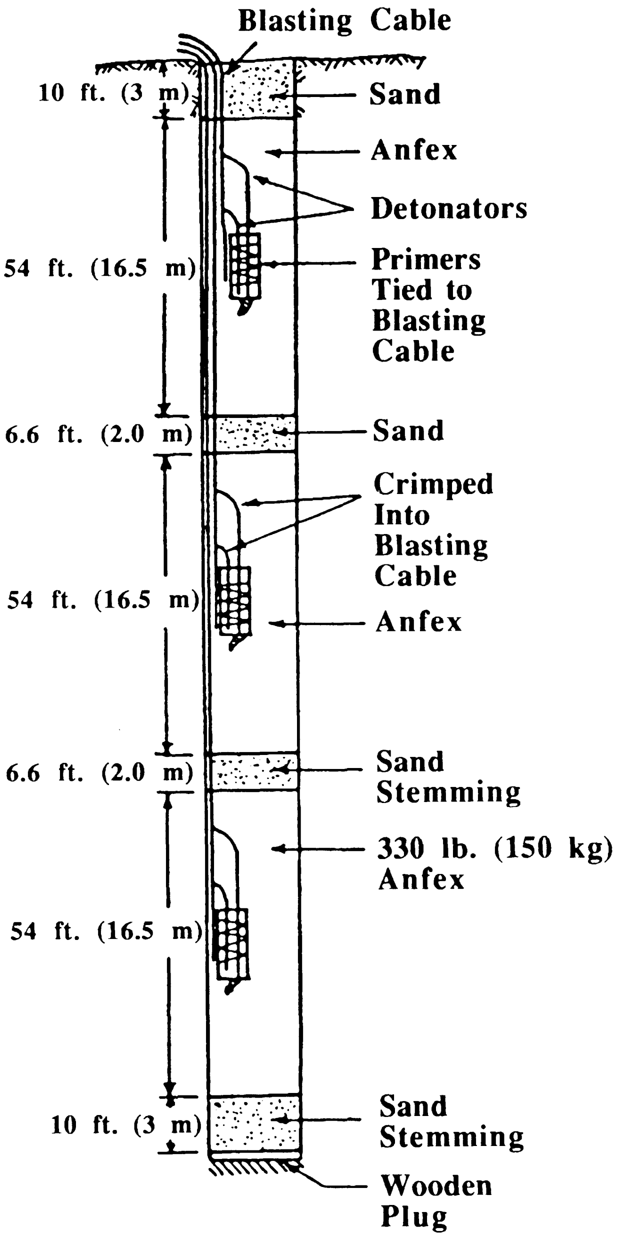

Fig. 18.4.12. Explosives layout in a large-diameter hole showing spacers (Pandey, 1984).

67% capacity with two out of three units being operated. To facilitate equipment utilization, roadway floors are concreted to an average depth of 10 in. (250 mm). This results in significant benefits in the life of the equipment, although roadways themselves must also be maintained and cleaned periodically.

18.4.10.4 Backfill and Ground Control

Stopes are backfilled upon completion primarily using cemented rock fill, but also occasionally sand fills. Design strengths of 1000 psi (7 MPa) are achieved, and fills are carried to the stopes using a fleet of haulage trucks. Both aggregate and cement slurries are delivered by conveyors and boreholes to the mixing stations, and success of the system is based on the efficient mixing achieved.

Ground conditions at Kidd Creek are normally very stable; however, permanent long-life excavations such as haulageways and ramps are supported primarily by grouted rebar bolts. Shotcreting is done in some special areas, such as underground shops and shaft stations. Cable bolting has been carried out in some geologically weak shear zones.

18.4.11. UNDERHAND AND OVERHAND STOPING

Sublevel stoping is ideal for ore bodies or stopes that are over 20 ft (6 m) in thickness. Widths below this create major problems for longhole blasting, and when widths approach 6 ft (2 m) or less, only shorthole methods of stope blasting are practical. At this point, underhand or overhand onto stulls are possible methods if shrinkage stoping is undesirable. Historically, such methods have been widely used in such areas as the Cornish tin and copper mines, Kolar gold field, and gold mines of Colorado. Today the methods are last-resort type because of the inherent limitations in mechanization, which result in low productivity and high cost. At the Geevor Mine in West Cornwall, England, a combination of underhand and overhand methods was used in the same stope (Haycocks, 1973b).

18.4.11.1 Major Development

The ore is typically blocked out by driving haulage levels in the ore 100 to 200 ft (30 to 60 m) apart vertically, the closest spacing serving to allow more detailed sampling of the ore body. Raise/winze connections are driven, again in ore, typically 200 to 250 ft (60 to 80 m) apart horizontally. Both underhand and overhand stoping typically use crown, rib, and sill pillars for protection of the stope, although stulls may be used under some conditions as an alternative to both crown and sill pillars. Box holes are cut in the sill pillar every 15 to 30 ft (5 to 10 m).

18.4.11.2 Underhand Stoping

Underhand stoping typically starts from a raise driven through the center of the projected stope (Fig. 18.4.19). Ideally a stope drive is carried below the crown pillar, and the face is benched underhand for shorthole blasting. A second stope drive is carried some 10 to 15 ft (3 to 5 m) above the haulage level, and cones are cut into the floor of this drift. The face is benched in a series of benches 6 ft (1.8 m) high and 4 ft (1.2 m) wide, with the overall face dipping approximately 60°. After blasting, the ore falls down the starting raise to a box hole. As the face moves backwards, new box holes are exposed. Stoping requires a considerable amount of physical effort on the part of the miners, as benches must be cleaned by hand prior to drilling, and drills and explosives must be hauled into the stope. Good hanging wall and footwall are essential in the method to prevent scaling, and thereby prevent material falling onto miners working below. Scaffolding could be used to bar down the base of the crown pillar. Stulls are occasionally left for support in underhand stopes and roof bolts are also used where necessary. In the Kolar gold field, cut granite blocks have also been used.

18.4.11.3 Overhand Stoping

In the overhand stope (Fig. 18.4.20) development is the same as for underhand, but stoping now commences from the base of the proposed stope, and the face is carried overhand at a dip of about 45°. Once the initial blasts have been carried out, stulls are installed that collect shrinkage material as stoping progresses. The miners use ladders to move between the stulls and work up the shrinkage piles to gain access to the face for

drilling and blasting. Again the method requires considerable physical effort on the part of the miners to haul drills into the stope, although ventilation and maintenance of the back is much easier with this method than with overhand.

18.4.11.4 Advantages

1. Both underhand and overhand stoping require very little timber for support, and major development is driven in the ore.
2. Neither method ties up significant quantities of ore in the stope as does shrinkage.
3. Ventilation is good with overhand stoping because air can be directed across the stope face.
4. Maintenance of the back is very good with overhand stoping because the miners work in close proximity to the stope face.
5. The methods are very viable for narrow steeply inclined ore bodies where shrinkage stoping is undesirable.

18.4.11.5 Disadvantages

1. Both underhand and overhand are high-cost low-productivity methods with production rates running 1 to 3 tons (0.9 to 2.8 t)/employee-shift.
2. Underhand stoping has poor ventilation, and leaves the miner exposed to falls of rock from the stope walls or crown pillar.

Chapter 18.5
VERTICAL CRATER RETREAT MINING

KELLY OSBORNE AND VERN BAKER

VCR (vertical crater retreat) mining is a horizontal, flat-back variation of sublevel stoping using spherical crater charges to break the ore. It is the only patented stoping method (Livingston, 1973). Blasting is carried out at the base of vertical holes, making horizontal cuts and advancing upward (Mitchell, 1981). Shrinkage can be utilized in the stopes for wall support. Because the method requires less development than sublevel stoping, it has the potential for lower costs and is finding increasing application not only for pillar recovery but also for primary stoping (Lang, Roach, and Osoko, 1982).

18.5.1 GENERAL METHODOLOGY

The first step in VCR mining is to define a block (stope, panel, section, pillar) of ore that is amenable to this type of mining. The initial criteria are dip and plunge, as the ore must be able to flow down to drawpoints under the influence of gravity. The second factor assessed is ore block shape and consistency. The ore block must have a shape that can be basically defined from two sills spaced a significant vertical distance apart. Once an ore block is defined, the blasting characteristics of the rock can be assessed. The assessment can be done theoretically or tests on similar ore blocks can be done for empirically developing the data (see 18.5.2). Selection of hole size and drilling system can be made once blasting characteristics are defined. The extraction system is often predefined by existing extraction techniques in use at the mine; if not, then ground control, block size, production needs, and availability of equipment will determine the size and layout of the mucking scrams and haulage system (VCR is a bulk method, and high rates of production are common).

Once the design is completed, the top sill and bottom sill are cut. The vertical separation between the sills is dependent upon ore consistency, drilling accuracy, accessibility, and hanging wall competency. After the sills are cut, any secondary ground control measures (such as cable bolts) necessary are installed, and the stope is drilled. The holes are drilled from the top sill down to the bottom sill, usually with a down-hole hammer to minimize deviation. With the drilling complete, the stope should be ready to blast. Blasting is done to take off vertical slices of ore progressing from the bottom sill to the top sill. During blasting, only enough broken ore is mucked from the stope to open up the volume necessary for successive blasts. This keeps the open stope full of broken rock to support the walls until blasting is completed (basically, a form of shrinkage stoping without miners having to crawl in on top of the pile of broken rock each cut). Many variations of the blasting sequence have been used successfully at different operations.

Once blasting is complete, the ore block is a large inventory of broken rock that can be extracted as fast as the extraction system will allow. After the ore is extracted, the bottom sill accesses can be closed off, and the stope can be backfilled from the top sill to maintain rock stability in the area.

18.5.2 VCR THEORY

C. W. Livingston (1973) derived equations modeling rock breakage from crater blasting. The basic theory is that a spherical charge placed at an optimal distance from the back of a stope will break a maximum volume of rock in the shape of an inverted crater. The theory correlates placement of a given charge weight in varying blasthole depths (height above back) to the volume of rock broken by its detonation. The actual charge size and placement is dependent upon the size of the hole and the density of the explosive as well as the characteristics of the rock. Charge geometry can alter blasting results—as the length of the charge increases relative to the diameter (defined by hole diameter), the blasting results adhere less rigorously to the theoretical results. Testing determined that a ratio of explosive column length L to hole diameter D of 6 or less ($L/D \leq 6$) will work similar to a spherical charge. Thus either higher-density explosives or larger-diameter holes will reduce the ratio for the same charge weight. Practice has shown that in most rock types, high-density/high-energy slurry explosives provide superior results. A good explanation of the mathematical equations and a description of a practical test is provided by Orr (1983).

18.5.3 ADAPTIVITY

Originally used to take out large pillars where only limited access was practical, VCR is now being applied to many situations. Some very large blocks have been mined in successive stages with VCR where adjacent ore blocks are filled with cemented backfill once mined out to provide an adequate wall for the next stope to mine against. Some very small blocks that would not support extensive development have been mined with VCR.

Effectively using VCR means adapting it to the specific situation. Many variations on the basic blasting sequence are also being used, the most common being multiple-face crater blasting where the early shots in a round are used to open up a vertical free face for successive shots to utilize. Another common blasting variation is to utilize a mass blast that may break up to 50% of the ore block's tonnage in a single round. Mucking methods have varied from slusher extraction to mechanical continuous muckers, although extraction by load-haul-dump (LHD) is most common.

18.5.4 ADVANTAGES AND DISADVANTAGES

VCR stoping possesses many of the best features of sublevel and shrinkage stoping, with which it shares some parentage. Advantages include:

1. Bulk, high-capacity mining method with good recoveries.
2. Efficient stoping method that is very susceptible to mechanization and can have productivities in excess of 35 tons (32 t)/employee-shift.
3. Offers good wall support during the stoping phase using shrinkage.

4. Safe method with miners working under fully supported roof that can be adequately ventilated.

There are also disadvantages:

1. Requires extensive diamond drilling, pre-stope planning, and development lead-time for maximum effectiveness.

2. Ore is tied up in the stope until final drawdown, which represents lost income and can tie up significant funds.

3. Some ores that are mineralogically unstable may be subject to break-down, causing subsequent difficulties in mineral dressing.

18.5.5 CASE STUDY: VCR MINING AT HOMESTAKE MINING COMPANY

The Homestake gold mine is a deep, underground gold property with a production of approximately 1.9 million tons (1.7 Mt)/year at 0.175 oz/ton (5.5 g/t). The mine has 41 active levels ranging from the 800 level (feet below collar) to the 8000 level. Levels are spaced 150 ft (45 m) vertically. Two main shafts serve for access and ore skipping from the 5000 level and up. Two major winzes provide access and skipping from the 7400 level and 8000 level to the 4850 level. Ramp systems have been developed in major ore zones; however, no ramps access the surface. The mine has been in continuous production (except for World War II) since 1877.

Declining grade and productivity in the 1970s led Homestake's management to investigate bulk mining methods. Some success was achieved with blasthole stoping; however, it was limited to areas of highly competent rock. Investigations led to testing of vertical crater retreat mining. VCR showed promise for several reasons: (1) minimum development was required, (2) broken ore can be retained to support the hanging wall until final draw down, (3) reduced safety concerns, and (4) high productivity. VCR mining was tested in 1978 and by 1983 was providing approximately 50% of the mine's production.

18.5.5.1 Geology

The Homestake mine is located in the Northern Black Hills of South Dakota. The predominant rock structures are three Precambrian metasediment formations, the Poorman formation (pf), the Homestake formation (hf), and the Ellison formation (ef), going from oldest to youngest. All formations have been highly folded into a series of synclines and anticlines, plunging 10 to 80° southeast and dipping 50 to 80° northeast. Major folds within the mine's structure are known as "ledges." Specific ledges contain the eight major ore trends now defined. Ore zones exist in many sizes and shapes within the ore trends. Ore bodies range from 10 to 100 ft (3 to 30 m) wide, 30 to 500 ft (9 to 150 m) in length, with vertical extension of 300 ft (90 m) or more common. Ore bodies are located within the Homestake formation, and gold is erratically associated with quartz, arsenophyrite, and phyrhotite. The Homestake formation ranges in strength from 30,000 psi in upper levels to 19,000 psi in lower levels.

18.5.5.2 Cratering Theory Applied to the Homestake Mine

In 1977, crater testing began at the Homestake mine. Original testing was done with 4-in. (100-mm) diameter holes drilled into the back at various lengths. Based on research, crater tests comparing water gel slurries to ammonium nitrate and fuel oil (ANFO) found high-energy metallized slurries gave superior results (Grant, 1964). Therefore, a high-density (1.36) aluminized slurry was used for initial testing. Results from these initial tests were tabulated, and empirical values for the rock at Homestake were given to many of Livingston's constants.

In applying test results to the basic mathematical relationships, the explosive length-to-charge diameter ratio (L/D) became a factor. Homestake found an L/D ratio of 6:1 to give the best fragmentation and still provide data comparable to true spherical charges. Testing and refinement produced a charge depth of 6.75 ft (2.0 m). Analysis of Canadian operations successfully applying VCR showed that 6 1/2-in. (166-mm) diameter holes were effective. This was a fairly standard bit size. Down-hole drills were available on the market for drilling the large 6-1/2-in. (166-mm) holes. Down-hole tests made in 1978 were successful.

18.5.5.3 Defining and Evaluating an Ore Body

Ore bodies at the Homestake gold mine are defined by diamond core drilling from main levels, spaced 150 ft (45.7 m) vertically. Drill setups are spaced on 50-ft (15.2-m) intervals along strike (Fig. 18.5.1). An array of angled holes is drilled in a vertical plane to define the ore in each section. All core is visually logged and defined by assay value. Sections are drafted of the vertical planes encompassing holes from each setup, and from these sections, estimates are made of the grade and tonnage of an ore body.

Each ore body is evaluated or reevaluated every six months and then assessed to see how it best fits into the overall mining sequence. The ore body is evaluated for its adaptability to VCR mining (Fig. 18.5.2). This is the cheapest and most productive mining method and is applied whenever possible. Once the mining method for an ore body has been selected, a rough schedule for mining is developed.

Several physical constraints determine the practicality of using VCR mining for an ore body. Hanging wall and footwall dips are a primary concern as are ore body consistency, thickness, plunge, and rock competency. Flat hanging walls tend to increase dilution. Footwalls of less than 55° dip tend to have large amounts of broken ore hanging-up on them. This not only hinders ore recovery, but may also build up, causing blasting problems by allowing little or no relief for sequential blasting. Ore consistency and thickness usually cause problems with blasting and dilution if not considered. Ore widths less than 16 ft (5 m) do not crater blast well, but they may be slab blasted if an area can be cratered nearby for relief. Waste horses in an ore body either complicate blasting or vastly increase dilution (sometimes both). Thickness is important as narrow stopes tend to have higher dilution factors because more hanging wall is exposed per ton of ore. Flat plunges can result in excessive waste mining during the development stage. The need to get the drilling sill (top sill) over the down-plunge ore necessitates waste mining. Also increased drilling is required per ton of ore due to the amount of waste material that is drilled to get to the flat-plunging ore. Almost every physical constraint can be and has been overcome; however, forcing the VCR method on an ore block not suited to VCR will be counter-productive.

18.5.5.4 Stope Development

PRELIMINARY DESIGN OF A STOPE. This segment is called "preliminary design" because all the components of a stope as discussed are constantly modified as new information becomes apparent during actual mining of the sills and necessary drifts.

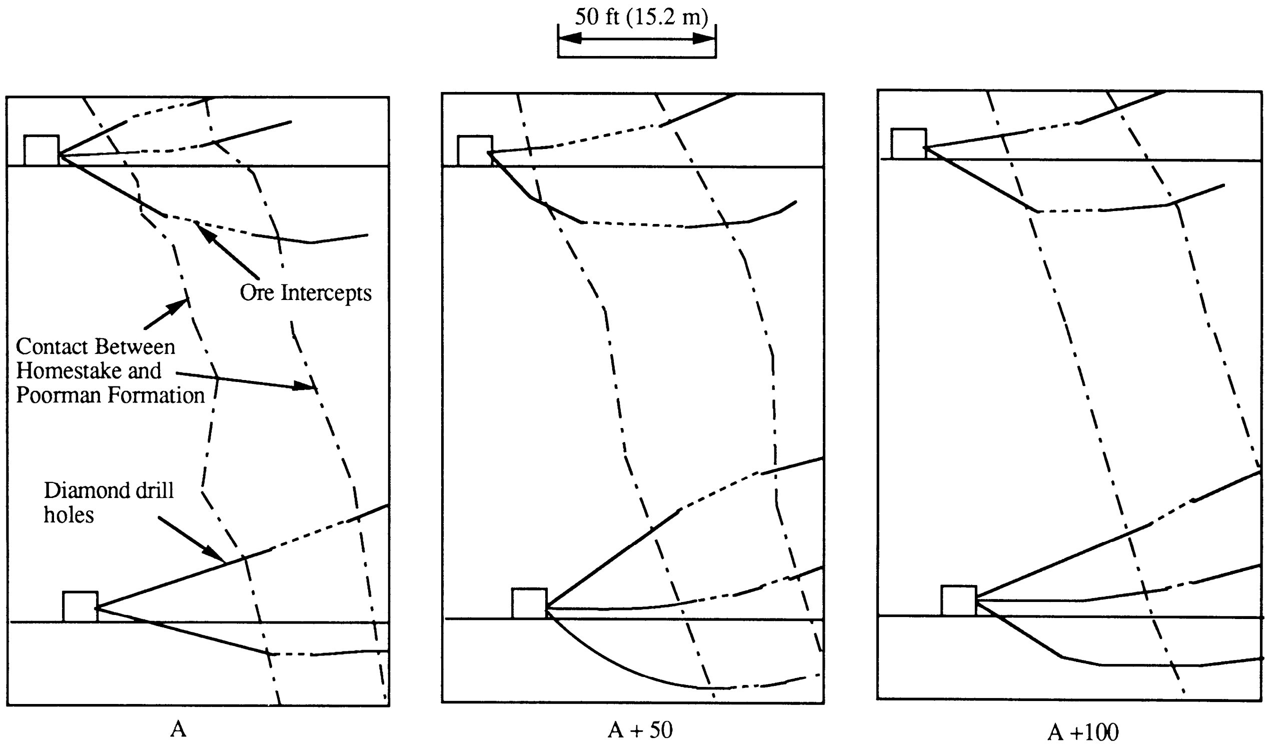

Fig. 18.5.1. Vertical cross sections with diamond drillholes and ore intercepts.

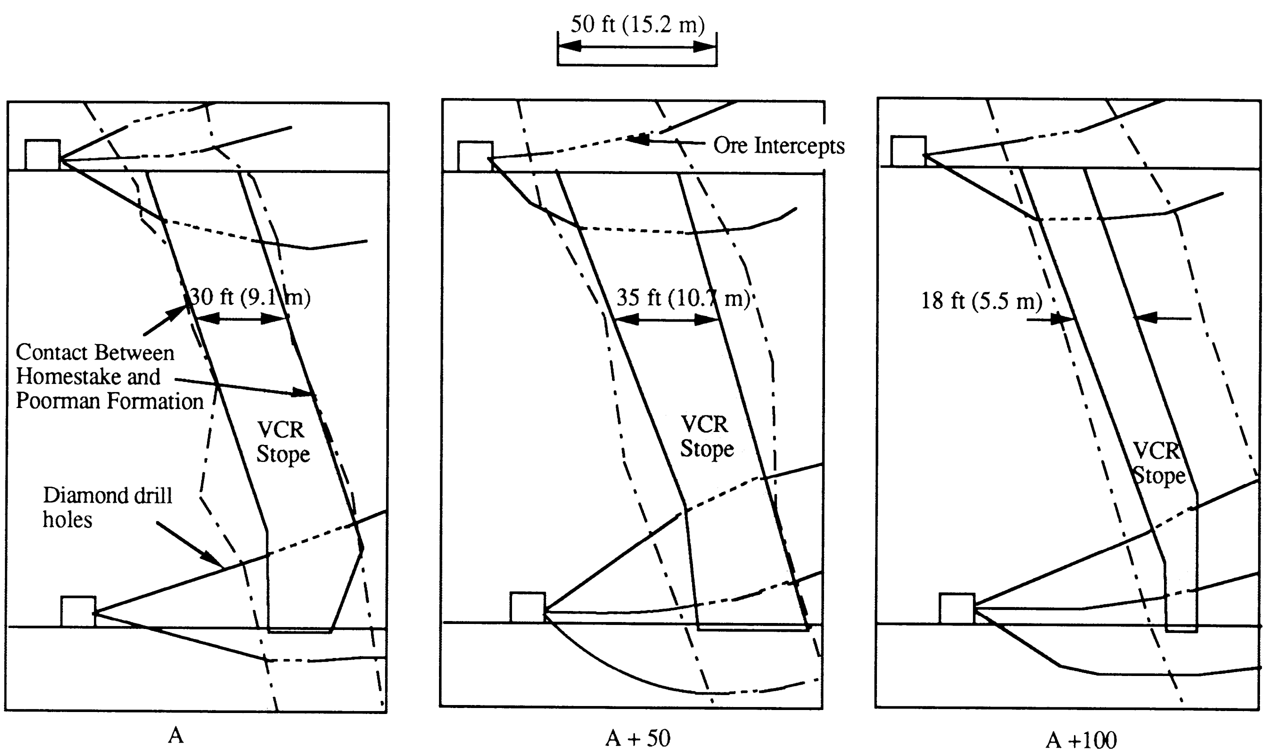

Fig. 18.5.2. Expected VCR stope outlines from plotted diamond drill intercepts.

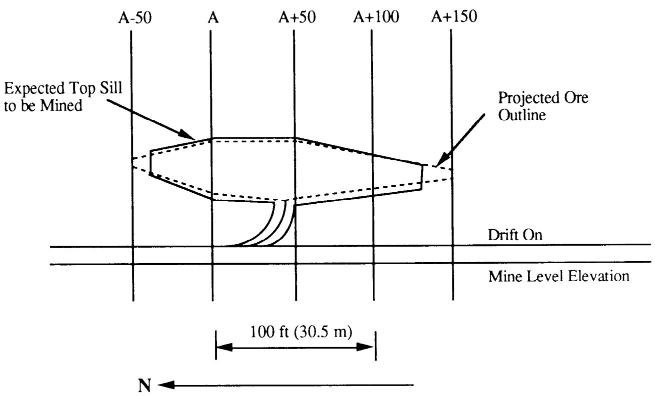

Fig. 18.5.3. Top sill layout of projected ore from vertical sections and expected sill to be mined.

to 50 ft (9 to 15 m) along strike. Ground conditions determine scram spacing (smaller spacing allows higher extraction without remote mucking, but leaves smaller pillars). Extraction boreholes are usually planned in conjunction with LHD mucking. A borehole is designed to access a haulage level 150 or 300 ft (45 or 90 m) lower. A power chute is built at the bottom of the borehole to regulate rock flow into granby rail haulage cars. Car loading by LHDs is sometimes used but is much less productive than a borehole system (Fig. 18.5.5).

CAVO muckers are usually used on smaller stopes in remote and/or hard-to-ventilate areas. The extraction system is designed for side-loading granby cars. The main haulage is track and driven 30 to 40 ft (9 to 12 m) from the bottom sill along strike. Scrams are driven as closely spaced as possible to maximize extraction because remote mucking is usually not feasible. Drifts and scams are driven 9 by 9 ft (2.7 by 2.7 m) arched. Scrams should be as perpendicular as possible to the main haulageways to facilitate side loading.

Some large ore bodies have necessitated panel mining systems. The basic difference is that adjacent stopes (panels) must

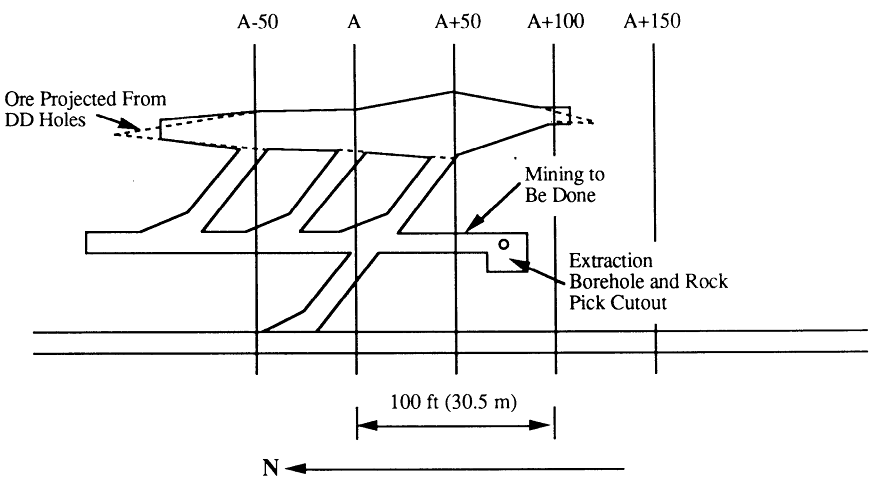

Fig. 18.5.4. Bottom sill layout on projected ore with mining to be done for scrams and borehole dump.

This is a big key in making VCR mining work, particularly with irregular ore bodies.

Once it is decided that an ore body will be mined by VCR, geologic data are used to develop and lay out the plan views and projections at the top and bottom sill elevations (Figs. 18.5.3 and 18.5.4). The layouts are designed to minimize development and optimize the drilling and blasting of the stope. If ground conditions or stope size dictate it, pillars of unmined ore may be left in the top sill. Once the expected sills are laid out, top sill access is usually designed as the minimum drifting necessary to reach the ore zone and planned as a 9- by 9-ft (2.7- by 2.7-m) or 10- by 10-ft (3- by 3-m) arched drift depending upon the LHD size used by the development crew. Sometimes ore bodies are stacked, and the top sill for one stope becomes the bottom sill for another stope. In this case, top sill access is usually designed to be integrated into the extraction system of the next stope. The bottom sill mucking system is very important as it determines the productivity of the stope. Mucking systems are designed in the footwall almost exclusively because of drawdown problems with hanging wall scrams. Whether a LHD unit or a CAVO mucker is used makes a large difference in mucking configuration.

LHD extraction is used predominantly. With LHDs (2 and 3 1/2 yd^3, or 1.5 and 2.7 m^3), accesses and drifts are usually driven 10 by 10 ft (3 by 3 m) arched. The main haulageway is usually driven along strike with 40 to 50 ft (12 to 15 m) separating it from the bottom sill. Scrams are driven into the sill every 30

be sequenced and backfilling must contain cement to provide strength. Low hanging wall competency has forced reduced stope heights in certain areas of the mine. One hundred vertical feet (30 m) between top sill and bottom sill is becoming almost as common as 150 ft (45 m). This has greatly reduced hanging wall failure.

DEVELOPMENT SEQUENCE. Top sill development consists of driving an access to the ore body and then cutting out the ore on that horizon, together with any waste mining necessary to form the drilling sill. The sill is now ready for ground control or down-hole drilling. The drilling sill must be cut at least 11 ft (3.4 m) high and 15 ft (4.5 m) wide for drill mast clearance and drill maneuvering.

The extraction system is developed with the bottom sill, which is accessed via the designed mucking system. The ore zone is accessed as soon as possible so that it can be cut out and compared to original estimates and design modification made as necessary. If the ore extends below the sill, but only by a small amount, the development crew may mine a 12-ft (3.6-m) cut out of the bottom of the sill. Once done, the crew will drive the extraction system and place the waste into the area just mined. As the crew mines the drifts, any major slips or ground control problems are noted and plans are changed when necessary. The development crew usually mines the bottom sill cut 10 ft (3 m) high. Often another cut is made above the sill cut. This helps

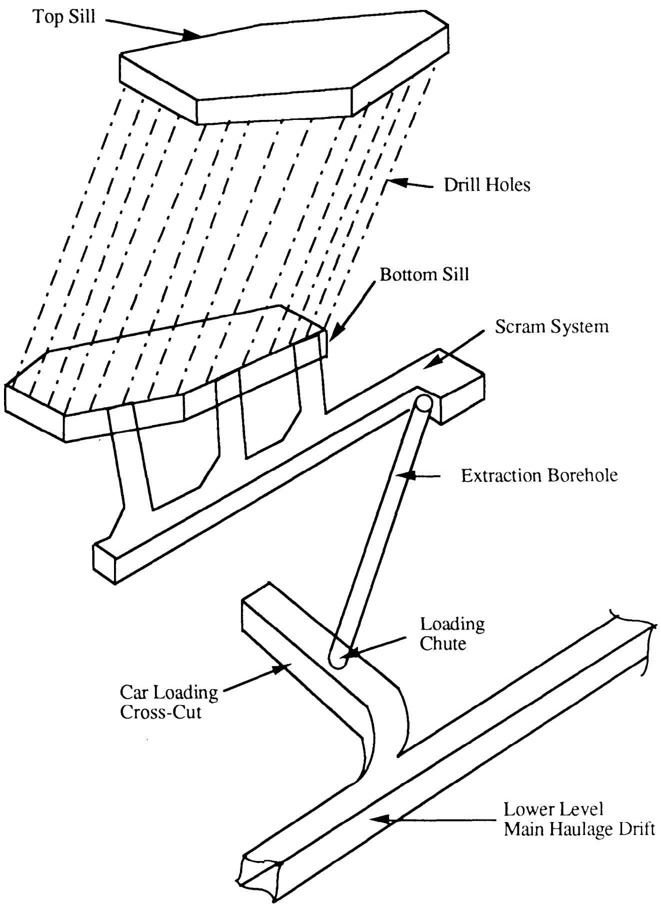

Fig. 18.5.5 Generalized schematic of VCR mining method.

minimize blast damage to scrams and also reduces the length of the down-holes to be drilled, thereby improving accuracy.

During the development stage, the preferred equipment is a 3.5-yd (2.7-m) Wagner diesel LHD and a two-boom, pneumatic hammer, diesel jumbo (MJM20B or GD Minibore). When a crew so equipped is not available, a crew outfitted with jacklegs and a Wagner ST2D (or JC220E) will do the development. When necessary, l-yd^3 (0.75 m^3) LHDs are used, or even slushers and track muckers. The extraction borehole is an important part of many stopes. This is usually drilled and reamed by a Dresser Super 480 or Dresser 500 machine to 6 or 7 ft (1.8 or 2.1 m) diameter.

Mining the cutout for a borehole machine that will drill and ream an extraction borehole is usually necessary and often a priority. Borehole drilling and then the installation of the power chute on the bottom of the borehole often cause delays to production, and close attention must be paid to these steps.

18.5.5.5 Exploitation

GROUND CONTROL. There are several stages of ground control in the development and extraction of a VCR stope. First, pillars may be designed into the sill cut to keep widths minimized and the back stable. Second, is the immediate ground control of each round blasted by the development crew. Here 5- and 8-ft (1.5- and 2.4-m) long bolts are installed (often in conjunction with mats) to secure the immediate back and walls. Cable bolts are the most common form of secondary reinforcement. Cable bolts are used to stabilize the back and hanging wall of the top sill during the blasting and mucking cycle. This helps to maximize the safety of blasters and to minimize dilution. Bolt length varies from 30 to 60 ft (9 to 18 m). Bolt length is determined from sill size, ground conditions, and additional mining plans for ore above the top sill. Bolts are twin 5/8-in. (16-mm) wire rope cables installed parallel in a 2 1/4-in. (57-mm) diameter hole and grouted with a type 2 cement. The standard pattern of cables is 10 by 10, with 10 ft (3 m) between rows and 10 ft (3 m) between bolt points.

Sequencing of mining by paneling a large stope is done to minimize the amount of open hanging wall at any given time. This has been effective in minimizing hanging wall slough. It does necessitate delays in stope production for backfilling of panels. Research into the rock mechanics of VCR stopes at Homestake by the US Bureau of Mines led to a rule of maintaining a 4:1 length-to-width ratio as the maximum amount of hanging wall to be opened by any single panel or stope.

During the mining cycle, several things can be done for ground control. The use of controlled blasting techniques along the hanging wall helps to minimize hanging wall fractures. Also keeping the stope as full of rock as possible to support the hanging wall during blasting seems to be effective.

Specialized equipment for ground control is limited to cable bolting equipment: a ringdrill and grout pump. Ringdrills are equipped with full rings and BBC 120 drills. Grout pumps are small auger-style pumps used to pump grout (Portland cement) into cablebolt holes.

DRILLING. The drill crew is provided with a map of the sill with the grid overlaid on it. Surveyors mark the location of each row (numbered) and reference strike lines (lettered). The drill crew will then drill plug holes at each location indicated by survey. (Plugs are wooden hole plugs, driven into drilled holes, and spads inserted.) Strings are pulled across rows to line up the drill mast and along strike lines to locate holes.

Ore bodies and sill configurations vary widely, and patterns are adapted to each stope. General guidelines are to utilize an 8- by 8-ft (2.4- by 2.4-m) pattern (Fig. 18.5.6), to minimize breaking into the hanging wall, and to minimize drill footage. Situations often force (or allow) departures from standard such as employing 10- by 10-ft (3- by 3-m) patterns, the need to splay holes into the hanging wall to recover ore, or utilizing a high density of drill footage near the top sill due to the changing geometry of the ore body between the sills. Holes that are drilled from the top sill and drilled through to the bottom sill cut are called "breakout" holes. Three breakout holes per row to start the blasting is the accepted minimum. Accuracy is a necessary part of the drilling. The grid developed in the top sill provides the basis for accurate drilling. Once a drill is lined up on the collar location of a hole, the inclination indicator mounted on the mast is used. The inclination indicator is set for the specified angle of the hole, a green light then indicates when the mast is correctly aligned, and a red light indicates improper alignment.

When the drilling is nearing completion, the location of holes in the bottom sill is checked. If there appears to be a problem, surveyors may be asked to check actual vs. planned hole breakthrough locations. If major deviation has occurred, then additional holes may be needed to cover the stope correctly.

Once set up, drilling proceeds fairly rapidly. Many crews can average 200 ft (60 m)/shift. Tons blasted per foot of hole drilled (total drilling) runs about 3.5 (11.5 t/m). Stope drilling is done with down-hole hammer drills and 6 1/2-in. (165-mm) diameter bits. The Homestake mine has four Gardner Denver ATD 3100 crawler carriers and two Mission Megadrill 6200 units, each equipped with TRW Mission masts and rotating head

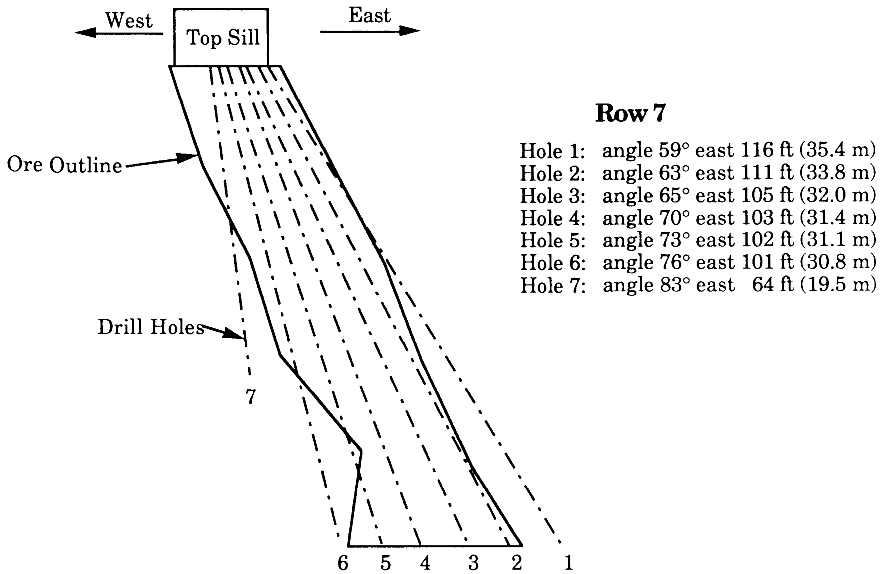

Fig. 18.5.6. Cross section of standard row of VCR pattern layout.

assemblies. The GD carriers utilize air-powered hydraulics and air tramming motors, while the Mission carriers have diesel- and electric-powered tramming motors and hydraulics. Compressors are necessary to boost mine air 100 psi (690 kPa) to provide 250-psi (1720-kPa) air to the down-hole drill. Each compressor unit consists of two model AOL 100 booster compressors driven by two 460-volt, 40-hp (30-kW) electric motors. A carrier combined with a compressor comprises one down-hole drill unit.

BLASTING. Blasting of VCR stopes is performed by a two-man crew monitored by an engineering technician. These technicians order necessary blasting supplies and do the design work for the blast. Blasting crews are on a production bonus system that rewards them according to tonnages broken. Supplies are usually delivered to the top sill by a LHD and then distributed by hand. Sometimes a Bobcat can be provided to the blasters for handling powder and sand within the top sill.

Prior to blasting, each hole is measured and recorded. Holes are measured by attaching a 1 1/2-in. by 1 1/2-in. by 3-ft (38- by 38- by 914-mm) piece of mahogany to the end of plastic coated 1/4-in. (6.4-mm) cable. The cable is approximately 150 ft (45 m) in length. The cable is stamped every 5 ft (1.5 m) from the end with the corresponding distance on the stamp. Each hole is measured by lowering this device down the hole until it reaches the floor or rock pile on the bottom sill. Next the cable is pulled up until the mahogany stick hits the bottom of the blasthole. In the case of nonbreakout holes, a steel weight may be substituted for the mahogany if the hole is wet.

Once all holes have been measured, it is necessary to estimate the volume of void available to determine if there is sufficient room for expansion of the rock from the blast. An area of the stope is selected which is equivalent to a volume of at least one-third the volume of the stope. This is called the slot and is the first section of the stope to be blasted. When cratering the slot, a 7-ft (2.1-m) average distance from rock pile to back of stope is the accepted minimum open space to allow successful blasting.

The next step is determining where to block the blasthole. Blocking is the process of securing two wedges at the desired location near the bottom of the blast- hole. The explosives are placed on top of the blocking. Angles of the blasthole determine where the hole is to be blocked. Generally accepted values for blocking heights are as follows (Andrews, 1988):

Hole Angle	Blocking Height (above hole bottom)
80–90°	4 ft (1.2 m)
57–79°	5 (1.5)
50–56°	6 (1.8)
Less than 50°	7 (2.1)

Loading the hole can begin now that blocking height and hole distance are available. A 12-grain primacord is measured according to desired blocking location, and a wooden wedge is tied to the primacord. The primacord is marked to correspond to the blocking location. Once the mark on the primacord reaches the hole collar, a second wedge is dropped down the hole and forms a friction lock with the first wedge at the desired blocking location. Next small rocks and drill cuttings are dropped down the hole to seal the space around the wedges. The end of the primacord is tied to a rock on the top sill until needed.

Holes in the slot are loaded with two 30-lb (13.6-kg) cartridges of water gel. The cartridges are cut lengthwise and one dropped down the hole. Next a sliding primer with the appropriate delay is assembled. The primacord is fed through the cord well of the booster, which is slid down the hole on the top of the explosives. The final 30 lb (13.6 kg) of explosives is placed in the hole on top of the booster. The completed powder column is approximately 4 ft (1.2 m) in height (Fig. 18.5.7).

Top stemming consists of a sand column of 7 ft (2.1 m). The sand stemming is topped off with 15 ft (4.5 m) of water. The break holes are shot first, and the remaining holes are capped in a concentric pattern. The slot will continue to be shot in this fashion until within 25 to 30 ft (7.5 to 9 m) of the top sill. This crown pillar will require double-decking two explosive charges in each hole. Delay time between the double decks is 25 to 50 ms.

MASS BLASTING. Typically, the initial slot in a VCR stope is one-third of the stope's volume. Once the initial slot has been blasted, the next step in the stope sequence is to prepare for the

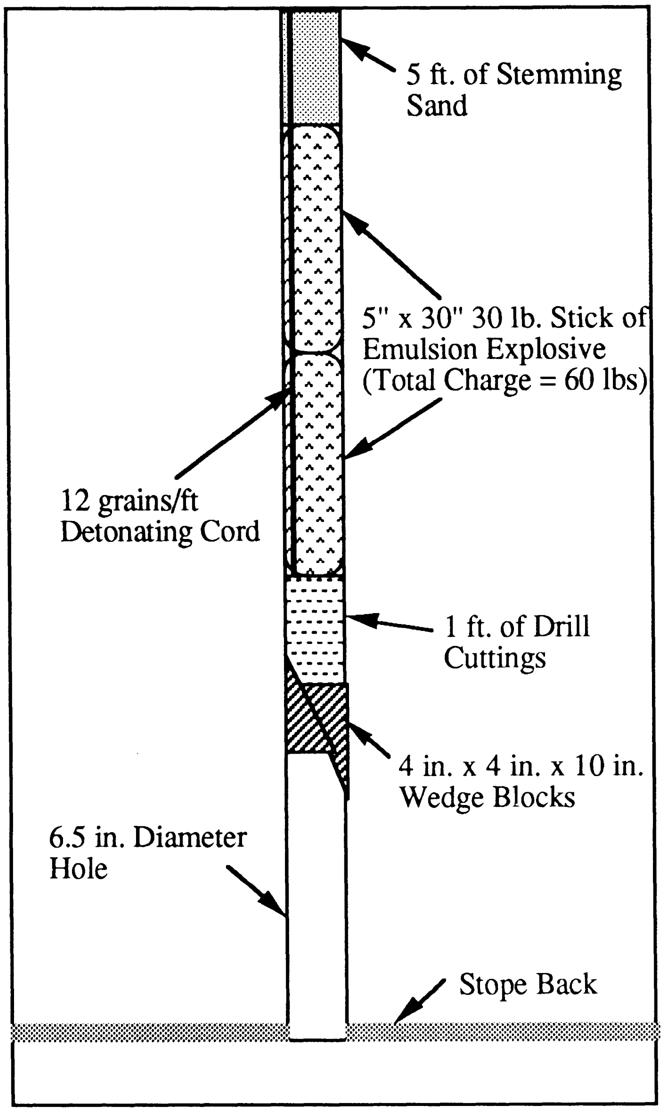

Fig. 18.5.7. Typical VCR cross section of a charged hole. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 lb = 0.4536 kg.

mass blast. The mass blast consists of shooting all the remaining holes in the VCR stope.

All holes available for the mass blast should first be measured. This will aid the blasting technician in determining the number of decks to shoot per hole. The following is a guideline at the Homestake mine (Andrews, 1988):

Number of Decks	Length of Hole
1	30 ft (9 m) or less
2	31 to 55 ft (9.3 to 16.5 m)
3	56 to 130 ft (16.8 to 39 m)
4	131 ft (39.3 m) or more

To stay within the maximum per delay requirement of 500 lb (226 kg), a column height of ANFO cannot exceed 40 ft (12 m). Explosives with higher densities are adjusted accordingly. All holes in the mass blast are loaded with ANFO unless water is a problem in nonbreakout holes. To keep the powder factor minimized, some upper decks may be eliminated from the design due to closer spacing of holes at the collar. Some holes may be 2 ft (0.6 m) to 4 ft (1.2 m) apart at the collar. Powder factors are ideally less than 1.1 lb/ton (0.5 kg/t). Seven to ten feet (2.1 to 3 m) of sand are used to stem between the decks and at the collar of the hole.

After determining the number of decks and column height of explosive, proper down-hole delays must be designed. All surface and down-hole delays are nonelectric initiators. In holes where multiple decks are used, a delay of 50 ms is used between decks. On double-deck holes, the bottom deck is a 450-ms delay and the top deck is a 500-ms delay. Triple-deck holes have a 400-ms delay on the bottom deck progressing to a 500-ms delay on the upper deck. Single-deck holes are delayed using a 500-ms nonelectric initiator. This type of delay pattern ensures a free face for each hole to break to. All holes in the shot will be delayed down-hole with this pattern.

Proper selection of delay intervals between rows is important to minimize duplication of firing times and reduce vibration. Ideally, all surface delays should be activated (hot) prior to detonation of the blastholes. To minimize the risk of cutoffs, the surface trunkline is covered with sand.

MUCKING. Mucking of VCR rock is usually done with Wagner 2- and 3.5-yd^3 (1.5- and 2.7-m^3) diesel LHDs, Jarvis-Clark 2-yd^3 (1.5-m^3) electric LHDs, and one Wagner 3.5-yd^3 (2.7-m^3) electric LHD; all are used in scram mucking at various places in the mine. In isolated areas, stopes may be mucked with rubber-tired CAVO 320 overshot muckers. The LHDs dump their rock into an orepass. Installed at this location is a steel grizzly on a 22- by 36-in. (0.56- by 0.91-m) pattern. Any oversize rock that cannot pass through the grizzly is broken by rockpicks where available, or otherwise slanted grizzlies are developed on a 22-in. (559-mm) pattern to handle the oversize.

In conjunction with the LHD mucking the stope, a grizzly and a rockpick are used to eliminate oversize rocks before they reach the skipping system. Two types of rockpicks are in use, Kent Pneumatic hammers, and Allied Hydraulic hammers. Both are pedestal mounted adjacent to a grizzly at a LHD dump point. When a LHD unit is not available, CAVO 320s have been used to direct load haulage cars. CAVOs are effective in remote and/or poorly ventilated areas. However, LHD production is significantly better and used most often.

During initial blasting, selective mucking is done to draw down the broken ore and provide enough relief for continued blasting. Oftentimes, various scrams may be mucked to provide the proper relief for the next blast. This is another reason why measuring drillholes prior to a blast is important: it provides the production foreman a profile of the existing muck pile.

Sampling the scrams is done twice a shift by the LHD operator. The information obtained from these samples is used to determine if a stope is above cutoff grade. If not, especially near final clean down, management can decide if a stope has reached its economic limit. Sample information is also used in determining the unit cost of the stope.

To keep VCR stope productivities high during the mucking cycle, two areas are focused upon: equipment availability and scheduling mucking as often as possible. In major mining areas, equipment availability increases with the accessibility of stopes via the extensive ramp systems.

Extra care and precautions must be taken when the VCR stope reaches its final stages of mucking. As the stope is mucked out, more and more of the hanging wall is exposed (this is where high productivities can pay off by minimizing exposure time), thus increasing the potential for hanging wall failure. As scrams are opened up, the chance of large boulders rolling into scrams increases, which increases the danger to the LHD operator.

BACKFILLING. When ore drawdown from a stope is completed, the backfilling process begins. Several factors affect this process: availability of waste material, the need to dispose of mill tailings, time available for backfilling, and the availability of a crew to wall off the bottom sill and scrams.

Walls are constructed in bottom sill scrams or accesses to keep backfill material from intervening with any level or stoping operations in the area. Walls are usually built by forming an 18- or 24-in. (457- or 610-mm) thick concrete wall. The concrete is placed into the forms by pumps. Drain pipes with "weeping tiles" (devices that allow water to pass but not sand) are installed in each wall to allow the stope to drain.

Sand is usually run into the empty stope once the walls are built to bed the walls and protect the drain lines. Unless an empty stope is very inaccessible, waste rock will be dumped into it. If sufficient time and waste are available, the stope will be completely filled with waste rock, and then sand will be placed to fill the voids. If time is short, sand will be placed concurrently with waste dumping until the stope is full. When a stope is a panel of a larger stoping area, it may be necessary to add cement (20 : 1) to the sand to provide a more competent backfill to mine against. In panel sequencing, six months is usually scheduled for water to drain off and fill material to solidify.

Backfilling is done with both mine waste and mill trailings. A sand system is in place that delivers the sand portion of mill tailings to the mine for backfilling purposes, via 5-in. (127-mm) rubber-lined pipe. Waste is usually placed back into a stope by a LHD or by dumping cars into a borehole that feeds into the top of the mined out stope.

18.5.5.6 Productivity and Costs

VCR mining has evolved into the most productive stoping method employed at the Homestake mine. Direct mine labor for VCR mining had a productivity of 35.1 tons (31.8 t)/employee-shift in 1988. By comparison, this shows a 30.5% higher productivity than the next best alternative, mechanized cut and fill (MCF) mining, which has a productivity of 26.9 tons (24.4 t)/employee-shift. Currently, 55% of total mine production is from VCR stopes.

Productivity of a VCR stope is directly related to the stope size. Large stopes have the tonnages to support the high mucking rates for extended time and therefore tend to have higher productivity rates. A small-block VCR program is being utilized for stopes from 10,000 to 50,000 tons (9000 to 45,000 t) in size. These smaller VCR stopes have been marginally successful; however, very tight control of each phase is necessary.

The Homestake mine as a whole has been improving productivity since the 1970s. VCR mining has been a major part of the effort (Fig. 18.5.8). Overall Mine Department productivity has risen from 5.94 tons (5.39 t)/employee-shift in 1979 to 10.38 tons (9.42 t)/employee-shift in 1988. Remarkably, this productivity increase has coincided with a greater average depth of mining. VCR mining has a 48% cost advantage over MCF in direct mining costs. This is attributable to higher productivity and less ground control.

For a discussion of the cut and fill method, see Chapter 19.1.

18.5.5.7 Safety

A major advantage of VCR mining is safety, based on minimizing the exposure of miners to ground that has not been secured by rock bolting (Fig. 18.5.9). Most VCR stopes are extracted with only two areas needing to be rock bolted, the top and bottom sills. In any type of overhand cut and fill, 13 to 16 lifts would have to be rock bolted. The bolting cycle is reduced by as much as 88%, comparing VCR to conventional cut and fill operations. Properly designed VCR stopes have good drainage, good visibility, stable ground, smooth corners, and are well ventilated. This leads to higher productivities and safer operations.

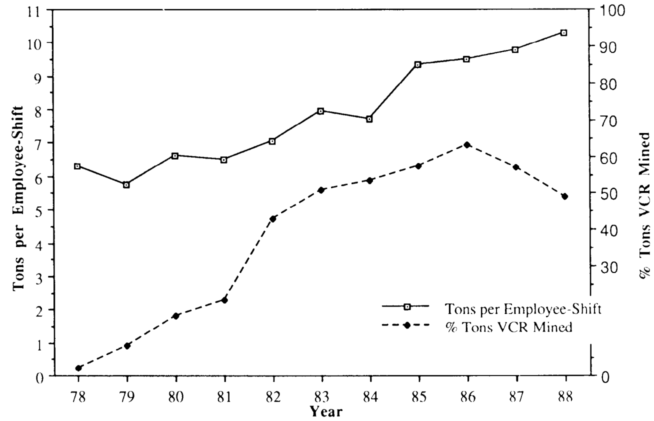

Fig. 18.5.8. Productivity per year compared to percentage of tons mined by VCR mining method at Homestake (1986 corresponds with replacement of remaining labor-intensive methods with mechanized cut and fill).

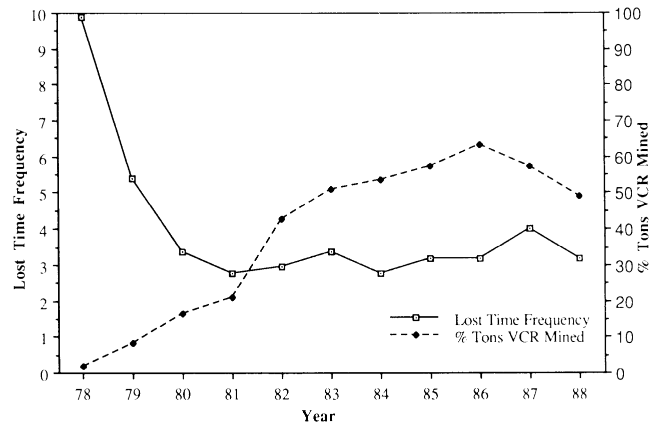

Fig. 18.5.9. Frequency of lost-time accidents compared to percentage of tons mined by VCR mining method at Homestake.

18.5.5.8 VCR Refinements

To adapt to a variety of different ore bodies, VCR mining at the Homestake mine is continually modified to accommodate each situation. Stopes have been successfully mined with VCR ranging from 15,000 to > 150,000 tons (14,000 to > 140,000 t).

Ongoing at the Homestake mine is research into improved drilling patterns, blasting techniques, etc. Tests are frequently done on different types of explosives. Stemming material has progressed from bagged sand carried in the top sill by hand to bulk sand that is delivered by LHDs or bobcats. Sampling programs on the drillhole cuttings (samples taken from cuttings of each 6 ft or 1.8 m of hole as rods are changed) were implemented to further delineate the ore bodies and in some instances, increase the actual tonnage of the VCR block. Drilling accuracy has improved along with refinement of top sill grid layout and locating of breakout holes on the bottom sill.

The VCR process at the Homestake mine has continually evolved with advances in technology and better understanding of crater blasting. Refinements have been made in stope design, equipment selection, blasting products, extraction systems, stope sequencing, and even in the backfilling process. Maintaining a cost-effective mining system demands continuing technical evolution.

Several imperatives of VCR mining can be generalized: 1) use as big and efficient equipment as possible to increase productivity; 2) adapt the mining plan according to the actual physical geometry of the ore body as it is accessed; 3) do not force VCR mining onto an ore body that has physical restraints limiting VCR applicability; and 4) integrate geology, engineering, supervision, and miners in planning and replanning of the stope.

Section 19 Underground Mining: Supported Methods

MICHAEL KARMIS, ASSOCIATE EDITOR
FRED BRACKEBUSCH, SECTION COORDINATOR

Chapter 19.0
INTRODUCTION

FRED W. BRACKEBUSCH

19.0.1.1 Section Organization

In underground stopes that require more than minimal support, backfill is almost universally used. The term *cut and fill stoping* is used in a broad sense in this section, which describes underground mining methods requiring support. Support in stopes can be classified as local or short-term and general or long-term. Local support for the back of a stope, for example, can be accomplished with rock bolts or timber stulls. General support for the walls of the stope is provided by backfill. Local support provides a safe working place for the stope miners. General support, provided by backfill, preserves the access way to the stope and prevents large scale dilution of ore.

Supported methods are a set of cut and fill stoping methods using backfill for general support and various local support methods.

This section is subdivided into three chapters:

19.1 Cut and Fill Mining
19.2 Excavation Techniques
19.3 Backfilling Methods

19.0.1.2 Definitions

In order to assist the user of the *Handbook* to understand the terminology used in this section, definitions of certain key words follow. Terminology varies in different parts of the world, but the definitions presented will aid the reader who may be unfamiliar with the terminology or who has a different terminology.

Back—The roof or overhead rock surface of an underground opening.

Breast—The vertical end or face of a horizontal cut. The breast is a mining face that is generally as wide as the ore body and as high as the cut height.

Caps—Round or square timbers generally greater than 8 in. (203 mm) in diameter, placed perpendicular to the vein for wall and back support. Caps are part of a timber set.

Chute—The loading arrangement that utilizes gravity flow in moving broken rock from a higher level to a lower level. A gate is used to control flow. Chute often refers to the wooden tube extending upward into the stope.

Concrete Admixture—An additive to concrete or backfill that modifies the setting time or handling characteristics of the mix.

Crosscut—A nominally horizontal tunnel, generally driven at right angles to the strike of a vein.

Culm—Waste from coal cleaning operations.

Cut (and Fill)—That part of the cut and fill mining cycle that includes drilling, blasting, slushing, mucking, and ground support. A rapid excavation technique may be substituted for drilling and blasting.

Cut—The volume of the ore body that is mined and filled in one cut and fill mining cycle.

Cyclone—A conical-cylindrical device with no moving parts, used to size or dewater mill tailings (or other slurries). The slurry is fed peripherally near the top end. Coarse material moves downward on the outside to the apex, and fine material moves up the center to the vortex.

Drift—A nominally horizontal tunnel, generally driven parallel to or coincident with a vein.

Dwidag bolts—A German-made, coarsely threaded rock bolt. The threads are present the full length of the bolt.

Girts—A timber, as part of a timber set, that braces caps or posts. Girts are placed parallel to the vein.

Heading—The working face of a drift, crosscut, or ramp. In timber sets, a heading is a bundle of wooden boards placed between a cap and the wall rock.

Grizzly—A grating, usually made of steel bars or rails, with square or rectangular openings for sizing coarse ore and waste.

Load-Haul-Dump (LHD) units—Rubber-tired, front-end loader-transports designed for efficient tramming of broken rock.

Manway—The compartment of a raise or shaft that is equipped with ladders and landings.

Mucking—The process of loading and transporting broken ore from the point where it is excavated to an orepass or haulage vehicle. Mucking generally involves the use of a wheel or track-mounted digging vehicle such as an LHD or an air-powered overshot loader.

Posts—Timbers that are placed vertically. When used individually for roof support in a flatly dipping ore body, they serve the same functions as stulls. When part of a timber set, posts support caps vertically.

Pugmill—A horizontal bed mixer with a pair of counter-rotating axles that carry multiple paddles; also called a paddle-mixer or twin-screw mixer.

Raise—An opening driven upward generally on the vein. A raise is an accessway to a stope. A raise consists of one or two chutes, a manway, and a timberslide.

Ramp—An inclined underground tunnel generally driven downward with LHD equipment.

Slushing—The process of moving broken ore from the point where it is excavated to an orepass, using a winch-driven, rope-drawn scraper bucket.

Sparging—Clearing a pipeline or other container by blowing with air and water.

Square Set—A prismatic set of timber comprising a cap, a girt, and a post.

Stope—An opening in which excavation of ore takes place. A stope may be any shape.

Stulls—Generally round timbers less than 8 in. (203 mm) in diameter, placed perpendicular to the vein for wall support. In a flat-dipping deposit, the same members are called posts.

Timberslide—A compartment in a raise used for hoisting materials. The hoisting bucket used generally slides on the footwall.

Tramming—The haulage of broken ore with a train, truck, or LHD from a working place to an orepass.

Uppers—In stope mining, the method of drilling blastholes in the back to excavate the ore.

Chapter 19.1
CUT AND FILL STOPING

FRED W. BRACKEBUSCH

19.1.1 GENERAL

19.1.1.1 Description of Cut and Fill Cycle

A description of cut and fill mining is necessary to avoid confusion with similar practices that are part of other mining methods.

Cut and fill stoping is an underground mining method. Open cast (strip) mining actually uses a cut and fill cycle, but surface mining is not discussed in this section. In the narrowest terms, *cut and fill stoping* includes methods in which a single excavation pass (cut) is completed and backfilled before another cut is made. Open stoping methods often use backfill, but these are not considered as cut and fill mining methods. For example, vertical crater retreat (VCR) stopes are routinely backfilled at the Homestake mine in Lead, SD, after completion of mining the entire stope block.

Cut and fill mining is primarily utilized for steeply dipping vein deposits and large, irregularly-shaped deposits. However, backfill is being used to a certain extent in the flatly dipping South African gold reefs.

A listing of the work elements involved in completing one cut and fill mining cycle is useful in describing the method. The cycle begins with the first round after backfilling on the previous cycle. The drill-blast-mucking-ground support cycle is a subcycle of the cut and fill cycle. Table 19.1.1 lists typical major work elements for a cut and fill mining cycle.

A much more detailed list of work elements in the cut and fill mining cycle is presented in Table 19.1.2. One must consider the entire daily or shift cycle, including travel time, lunch, and the blasting schedule.

19.1.1.2 Variations of Cut and Fill Methods

Following is a short list and description of various methods that are considered to be variations of cut and fill methods.

OVERHAND CUT AND FILL STOPING

General—Horizontal cuts, 6 to 15 ft (1.8 to 4.6 m) in height, are mined advancing away from an access point. The excavated ore falls and rests on the backfill placed during the previous cut and fill cycle. As cut and fill cycles are completed, the stope is advanced upward. This means that an ore block must be developed from the bottom.

Unsupported Backs—In competent ore, the stope back may require little or no support. An occasional rock bolt or stull may be required to support a loosened slab.

Rock-bolted Backs—The most common method of back support in overhand stopes is the installation of rock bolts on a pattern after each blast. This minimizes the extent of unsupported back that men must work near or under. Rock bolts prove to be a nuisance when mining the next cut, however, because blastholes may be drilled into an installed rock bolt, and rock bolts have to be manually removed from the broken ore.

Timber Stull Back and Rib Support—If backs and ribs are in poor condition, and breasting must be used, installing timber sets after each blast provides support for the back and ribs, preventing dilution and increasing safety for the stope miners. Generally, the advance in a blast is the span of one timber set, or about 6 ft (1.8 m). Before mucking out, a timber set is installed

Table 19.1.1. Major Work Elements of the Cut and Fill Mining Cycle

1. Drilling
2. Blasting
3. Mucking/Slushing
4. Ground Support
5. Cleanout
6. Raising Up
7. Preparation for Backfill
8. Backfilling

Note: Work elements 1–4 are cycled until the cut excavation is completed.

Make primers
Charge blastholes
Fire round
Place timber sets
Raise crib chutes
Raise equipment to next floor
Backfilling

by first heading in a cap from wall to wall at the proper location. The headings allow the cap to be tightly installed. Another function of the headings is to absorb wall closure without causing the cap to be crushed in compression. Because wood fibers in the heading are at right angles to the pressure, and because wood is compressible when confined at right angles to the fibers, the cap is protected until wall closure has compressed the headings to the fullest extent. A bulkhead is built from cap to cap to support the back. The bulkhead should contact the back tightly to prevent caving. Posts are placed under the cap near each heading and supported from a cap from the previous cut and fill cycle. Girts are placed from cap to cap and post to post along the walls to provide longitudinal support. Space between posts, at right angles to the vein, must be allowed for clearance of mucking equipment. Often when scrapers are used for mucking, boards are nailed on the lower part of posts along the walls to prevent broken ore from getting lodged in the spaces between posts along the walls, thus reducing the cleanout effort. The bulkhead from the previous cut becomes the floor for the current cut.

Square Set Timber Support—The square set stoping method is used for wide stopes where caps cannot reach from wall to wall. Square sets are prismatic timber sets, generally made from sawn timbers with mortise and tenon joints.

POST-PILLAR STOPING. The post-pillar method is used for wide ore bodies with a greater vertical extent than can be mined with the room and pillar method. As each horizontal cut is mined and backfilled, pillars are maintained to support the back. Pillars become tall and slender, but the backfill prevents buckling. Ore competency should be good to prevent pillar and back failure. Post-pillar can be classified as an overhand stoping method.

UNDERCUT AND FILL STOPING. Undercut and fill, or underhand cut and fill, mining consists of mining horizontal cuts as is done in overhand mining, but the direction of the stoping is downward rather than upward. As each horizontal cut is mined, it is backfilled with cemented backfill. Mining of the next cut proceeds beneath the cemented backfill.

DRIFT AND FILL STOPING. Drift and fill is a modern replacement for square set stoping. For wide ore bodies with moderate or poor ore competency, a horizontal cut is mined as a series of drifts. When a drift is mined, it is backfilled with cemented backfill, and another drift can be excavated beside the backfilled drift. The cemented backfill provides the back support adjacent to drifts.

19.1.1.3 Excavation Methods

BACK STOPING (UPPERS). When back stoping, enough open space is allowed between the backfill surface and the stope back to drill vertical or steeply inclined blastholes into the stope back in an upward direction. Back stoping can be done only with overhand or post-pillar stoping, with rock-bolted or unsupported backs. Ribs should be competent to avoid dilution and safety problems.

BREASTING-DOWN (UP). This excavation method employs a vertical working face and horizontal or slightly inclined blastholes. Backfill must be placed to nearly fill the void of the preceding cut, allowing only enough space (1 to 3 ft, or 0.3 to 1 m) for expansion space for effective blasting. After each round is blasted, mucking and ground support activities are completed. Breasting is generally used in poor rock conditions often with timber support. In undercut and fill stoping, rounds are breasted upward instead of downward.

DRIFTING. On the first cut or on any cut where breaking room is not provided, drift rounds are blasted using a burn cut or other type of drifting cut.

BENCHING. Benching or the drilling of vertical holes from the top down can be done in undercut and fill stoping.

MECHANICAL. Mechanical excavation methods could be utilized with any of the stoping methods. At this time, the use of mechanical stoping technology is not well developed.

19.1.1.4 Environmental Regulations

In the United States, mine backfilling operations are regulated as Class V Injection Wells under the Safe Drinking Water Act, *CFR* Title 40, parts 124, 144–146 (Anon., 1989). Mine backfilling is subject to inventory, assessment, and reporting requirements. The US Environmental Protection Agency was required to report to Congress on backfilling practices and environmental effects, which was done in September 1987. At present (1988), Underground Injection Control (UIC) regulations are in a confused state and subject to change.

19.1.2 HISTORY

The cut and fill mining method evolved from open stoping with occasional stulls for support (*stull stoping*), to fully timbered square set stopes with backfill (*square set stoping*), and finally to the general abandonment of timber with the use of rock-bolt systems and consolidated backfill.

Gardner and Vandenburg (1933) describe the reasons for development of square set stoping:

"Prior to 1860, open stope methods with stulls for casual support accounted for most of the mineral production from underground mines. Attempts to mine large ore bodies that required artificial support resulted in disastrous cave-ins and loss of life. The art of mining received a tremendous impetus following the introduction of methods for mining the bonanza ore body which was discovered in 1860 in the Ophir mine on the Comstock lode, Virginia City, NV. The ore body was phenomenally rich and eventually proved to be 122 m (400 ft) high, 27 m (90 ft) wide, and 98 m (320 ft) long. The mining of this large high-grade ore body taxed the best engineering talent of the time; the problem was finally solved by Philip Deidesheimer.

"According to Eliot Lord in 1882:

'At the 50-foot level the vein of black sulphurets was only 3 or 4 feet thick, and could be readily extracted through a drift along its line, propping up the walls and roof when necessary by simple uprights and cap-posts. As the ledge descended the sulphuret vein grew broader until, at the depth of 175 feet, it was 65 feet in width, and the miners were at a loss how to proceed, for the ore was so soft and crumbling that pillars could not be used to support the roof as in coal mines. They spliced timbers together to hold up the caving ground; but these jointed props were too weak and ill-supported to withstand the pressure upon them, and were constantly broken and thrown out of place. The dilemma was a curious one. Surrounded by riches, they were yet unable to carry them off and their mass of black sulphurets bade fair to become a white elephant on their hands. The Ophir Company began to wish themselves less fortunate, as their miners narrowly escaped burial day after day in their attempts to stope out the ore.

'A young mining engineer, Philip Deidesheimer, was in charge of a quartz mine in Georgetown, El Dorado County, Calif., in the autumn of 1860, when this serious check to the development of the lode occurred. At the request of William F. Babcock, a trustee of the Ophir Company, Mr. Deidesheimer left his California mine and crossed the mountains with a letter from the directors of the Ophir Company, authorizing him to inspect the workings of their mines and make such changes in the method of timbering as should seem to him expedient. After examining the vein he designed, in the course of a few weeks, a system of timbering which proved to be exactly adapted to the requirements of the work. Experiments which he had previously made in California gravel and quartz mines furnished the outline of his plan. This was to frame timbers together in rectangular sets, each set being composed of a square base, placed horizontally, formed of four timbers, sills, and crosspieces from 4 to 6 feet long, surmounted at the corners by four posts from 6 to 7 feet high, and capped by a framework similar to the base. The cap pieces forming the top of any set were at the same time the sills or base of the next set above. These sets could readily be extended to any required height and over any given area, forming a series of horizontal floors, built up from the bottom sets like the successive stories of a house. The spaces between the timbers were filled with waste rock or with wooden braces, forming a solid cube whenever the maximum degree of firmness was desired. By adjustments of these sets the ore bodies along the line of the lode were extracted with comparative ease and security.' "

Note that waste backfilling had already been introduced in the Ophir mine. Gardner and Vandenburg (1933) go on to describe the general adoption of waste backfill in square set stoping.

"In the earlier years of square set mining the erroneous idea was held that timber in heavy ground could support the mass of rock between the back of the opening and the surface. Round timbers 457 to 914 mm (18 to 36 in.) diameter and square timbers of 457 x 457 to 610 x 610-mm (18 x 18 to 24 x 24 in.) size were employed in square set stopes. Cave-ins were frequent occurrences on the Comstock, in Butte mines, on the Mother lode, and on the Homestake belt, in stopes where filling was not used. As it was recognized that any timbering short of solid cribbing could not withstand the slow movements of heavy ground, the sizes of square set stopes were restricted, and the timbering was followed closely by waste filling. This practice made possible the use of smaller timbers."

Waste to be used for backfill in stopes could originate in mine development headings. Often this source was not adequate, or timing of development waste availability did not coincide with the time of need of backfill in stopes. Thus it was common practice to drive headings into the walls of the stope simply to generate waste that could be easily moved into the stope for backfill.

In the 1940s and 1950s, hydraulic sandfilling was introduced largely to replace waste backfilling in stopes. Sand backfill was less labor intensive, and a reliable supply of sand could be produced by the milling operation. The use of timber declined from the 1950s to the present because of the adoption of rock-bolting systems and consolidated backfill.

In the late 1980s, square set stoping was not practiced at any major mine in the United States. Timber support is still used for access raises and for ore passes within backfilled stopes.

The mechanization of overhand cut and fill stopes with load-haul-dump (LHD) equipment has made it convenient to dispose of mine development waste as backfill in stopes. When broken waste is used as backfill, it is generally topped with hydraulic sandfill to fill the voids and provide a flat working surface for the succeeding cut.

19.1.3 REASONS FOR SELECTING CUT AND FILL METHODS

19.1.3.1 Ore Body Geometry

The shape of an ore body is important to the selection of a mining method. Cut and fill methods are almost always considered for steeply dipping veins. Most cut and fill stoping and development methods rely to some extent on gravity flow of broken rock, and thus veins with dips less than the angle of repose (< 45°) of broken rock must be mined using footwall or hanging wall development.

Irregular ore bodies, such as replacement ore bodies, are often candidates for cut and fill mining.

Whenever mining requires manned stopes with potentially high backs and walls, cut and fill mining is used to improve safety and wall support by limiting the working height of a stope. Backfill provides a working floor at a convenient elevation for mining activities.

19.1.3.2 Mining Selectivity/Grade Control

Because of the limited open volume of cut and fill stopes and the wall supporting function of backfill, very irregular surfaces can be followed precisely. Greater selectivity results in a higher-grade ore product, which is important to the economics of a mining operation.

19.1.3.3 Prevention of Caving and Dilution

The wall-supporting function of backfill aids in the prevention of massive wall failures in stopes. Limited open spans help prevent caving failure in the stope back. Dilution in overhand cut and fill mining frequently occurs when ore gets mixed with backfill during the mining process. In timbered stopes, ore can be lost in the nooks and crannies and beneath the timber floor. In waste-filled stopes, fine particles of ore become lost in the voids between waste fragments. Backfill can be cemented to minimize loss of ore values in the backfill. In undercut and fill mining, ore loss in backfill generally does not occur, but backfill can fall out of the back, diluting the ore.

19.1.3.4 Rock Quality Designation

The lower the rock quality designation of the ore and the quality of the enclosing wall rock, the more likely it is that cut and fill mining will be the favored method.

19.1.3.5 Prevention of Subsidence

Subsidence from caving methods and long-term failure of pillars in abandoned mines has grown to be a very expensive problem because of damage to surface structures. The use of backfill minimizes the amount of subsidence.

19.1.3.6 Waste Disposal

Where surface waste disposal is limited due to environmental factors or space limitations, backfilling can be utilized. Note that backfilling can serve this purpose not only for cut and fill mining but also for open stoping methods.

19.1.3.7 Stress Control in Bursting Mines

The stress near a longwall face or in pillars is reduced by tightly backfilling mined-out areas. Backfilling as soon as practicable after excavation is desirable. Backfill is compressed by the walls or roof until significant resisting forces develop. The strength of backfill is not necessarily as important to resist closure as is backfill density. The incompressibility of solids becomes the dominant factor in confined situations.

19.1.3.8 Ventilation

Ventilation can be effectively routed to the working face in cut and fill mining operations. The reduction of open space tends to reduce ventilation (quantity) requirements. Methane or radon gas emissions from mined-out areas can be minimized by backfilling. The disposal of combustible materials, such as wood, can be safely done when backfilling. The amount of wood exposed to air, and thus the risk of fire, is reduced when using cut and fill mining.

19.1.3.9 Cost

Cost is a primary consideration in the choice of a mining method (see 19.1.5). Cut and fill mining will generally be more expensive than open stoping. However, the previous criteria may rule out all methods except cut and fill, or the reduction in dilution may be financially attractive and justifiable.

19.1.4 CASE STUDIES

19.1.4.1 Overhand Cut and Fill Stoping

1. Sunshine mine—Kellogg, ID

The Sunshine mine uses a variety of overhand cut and fill mining methods, depending on ground conditions. Located in the Coeur d'Alene mining district of northern Idaho, the Sunshine mine contains narrow, steeply dipping veins containing copper-silver ore that cut Proterozoic quartzites and argillites. Mining width averages 5 ft (1.5 m), and the dips of the veins average about 70°. Ore shoots have short strike lengths, with most stopes being 100 ft (30 m) or less in total length. Mining is conducted from about 3000 to 5000 ft (900 to 1500 m) below the surface. The mine production rate is about 1000 tons (900 t) per day.

Where vein and wallrock are competent, mostly in the upper part of the mine, back stoping is conducted. Six-foot (1.8-m) high horizontal cuts are drilled with hand-held stoper drills using 1 1/2-in. (38-mm) bits. When back stoping, two or more raises in a stope are desirable because it is necessary to blast over the raises, thus blocking them temporarily. Back support consists of occasional rock bolts. About 7 ft (2.1 m) of vertical open space is required between the backfill and the stope back in order to operate the stoper drills. Most access raises are blind, that is, they do not extend above the elevation of the stope and are advanced concurrently with the stope. Access raises have three compartments: two orepasses and one timber slide/manway. Raises require an opening 9 ft wide by 20 ft long (2.7 m by 6.1 m), thus causing dilution because of the narrow vein width. Four round timber caps are used in sets 6 ft (1.8 m) on centers for raise support. Secondary access raises for a stope do not need orepasses, thus allowing a smaller raise to be used for access only.

In the deeper parts of the mine or where ground is poor, breasting-down stoping is practiced. Horizontal cuts are 9 ft high (2.7 m). Breast rounds are usually 6 or 8 ft (1.8 or 2.4 m) in length. Rock bolts and some stulls are used for back and wall support. Raises are similar to back stopes, but only one raise per stope is needed.

Average stoping productivity is about 10 tons (9 t) per employee-shift.

2. Homestake mine—Lead, SD

Located in the Black Hills of western South Dakota, the Homestake mine contains fairly wide, steeply dipping bodies of gold ore enclosed in metamorphic rocks. Mechanized overhand cut and fill stoping is one of the mining methods in use at the Homestake mine, where stoping is done at depths greater than 7000 ft (2100 m) beneath the surface (Smith, 1987). Cut and fill stoping is used in preference to VCR when (1) the dip is flat or variable, (2) the ore body is narrow or irregular, or (3) ground conditions are relatively poor for open stoping. (For a discussion of VCR mining, see Chapter 18.5.) Access to cut and fill stopes is by footwall ramps driven parallel to ore-body strike. Orepass boreholes are located in the footwall. Ventilation and waste transfer boreholes are located in the ore body. Horizontal cuts 13.5 ft (4.1 m) in height are excavated by breasting using pneumatic drill jumbos. Mine development waste is used for backfill to reduce waste hoisting. The mine waste is topped with hydraulic sandfill to provide a flat surface for mucking. Mucking is done with diesel-powered LHD equipment. Back support consists of cable bolts 60 ft (18 m) in length, installed on 10-ft (3.0-m) centers and short split-set and point-anchor bolts, 5 to 8 ft (1.5 to 2.4 m) in length, installed in a standard fixed pattern. Cable bolts need only be installed every three or four cuts, but the short rock bolts are installed every cut.

Average stoping productivity is about 29 tons (26.3 t) per employee-shift.

3. Galena mine—Wallace, ID

The Galena mine, located in the Coeur d'Alene mining district of northern Idaho, also uses overhand cut and fill methods. Narrow, steeply dipping (65 to 90°) veins containing copper-silver ore cut Proterozoic quartzites. Mining width is 5 to 6 ft (1.5 to 1.8 m) with some exceptions where vein width is as much as 12 ft (3.7 m). Ore shoots generally have short strike lengths, and most stopes are less than 150 ft (46 m) in length. Stoping is conducted from 3400 to 4900 ft (1030 to 1500 m) beneath the surface. The level interval is 300 feet (90 m). The mine production is 800 tons (725 t) per day.

Breasting down is the predominant excavation method at the Galena mine. Cuts are 9 ft (2.7 m) in height. The mining equipment most commonly used includes jackleg drills and slushers. In the occasional wide stope, an air-powered Cavo mucker may be used. Hydraulically placed mill tailings sand is used for backfill.

Average stoping productivity is 18 tons (16.3 t) per employee-shift.

19.1.4.2 Post-pillar Stoping

1. Blackcloud mine—Leadville, CO

The Blackcloud mine, located in the Leadville district, uses the post-pillar method or, as termed by the mine operators, random room and pillar/cut and fill stoping. The ore bodies are irregular replacement bodies of pyrite, sphalerite, and galena in dolomite near an igneous stock. A shale member forms the top limit of the ore bodies. Ore-body height ranges from 150 to 200 ft (46 to 61 m). The access shaft is 1500 ft (460 m) in depth. The mine production rate is 800 tons (725 t) per day.

Stoping is done using the breast-down excavation method with jackleg drills. Rock bolts are used for back support. Mucking is done with small electric LHD equipment and air-powered Cavo muckers. Pillars are left on a random basis, maximizing the use of waste or low-grade ore for supporting pillars. Pillars of ore are 10 to 12 ft (3.0 to 3.7 m) square. Hydraulically placed mill tailings support the slender pillars. The backfill has a high concentration of pyrite, which makes a dense fill.

Average stoping productivity is over 40 tons (36 t) per employee-shift.

19.1.4.3 Undercut and Fill Stoping

1. Lucky Friday mine—Mullan, ID

The Lucky Friday mine, also located in Idaho's Coeur d'Alene district, uses an undercut and fill method with longwall geometry. A steeply dipping vein containing lead-silver ore cuts Proterozoic quartzites. The mining width averages 7 ft (2.1 m), and the vein dips about 80°. A single vein with only minor branching has a strike length of about 2000 ft (600 m). Mining operations are being conducted about 5000 ft (1500 m) beneath the surface. Because of rock-burst problems, longwall geometry was adopted to eliminate mining of remnants.

A longwall geometry is used in laying out the mine, in that four or five stopes, all more or less at the same elevation, encompass the strike length of the ore body. All mine production, about 700 tons (635 t) per day, comes from these stopes, except for some remaining remnants in upper portions of the mine where overhand cut and fill stoping is used. Access to the underhand stopes is via ramps and sublevels located in the footwall quartzites. LHD equipment is used for mucking to rock passes that are also located in the footwall. Stoping is conducted beneath cemented backfill. Because wall closure tends to compress and fracture the backfill as mining progresses, a safety net of wire fabric is used to retain broken fragments of backfill. The stopes are about 500 ft (150 m) in length. Hand-held jackleg drills are used for drilling 1.5-in. (38-mm) diameter blastholes. The ore is breasted up because the backfill-ore interface acts as a free face for blasting. When a horizontal cut, which is 10 ft (3.1 m) in height, is completely mined, the stope is filled as completely as possible with a stiff, paste-like backfill consisting of mill tailings and cement.

19.1.4.4 Drift and Fill Stoping

1. Cannon mine—Wenatchee, WA

The mining method used for the B-North ore body at the Cannon mine does not fit exactly into the classifications used in this *Handbook.* The method, however, best matches overhand drift and fill stoping. Excavation methods include drifting, bench drilling or end slicing, and VCR raising. These methods are more commonly used in unsupported stopes. The B-North ore body is an epithermal gold deposit in Eocene volcanic rocks. Its approximate size is 400 ft (122 m) wide by 800 ft (244 m) long by 200 ft (61 m) high. The ore body is overlain by about 200 ft (61 m) of unconsolidated rocks. The mine has a circular shaft 620 ft (189 m) deep and a ramp for access. The production rate is 1500 tons (1360 t) per day.

Level development is done within the ore body because of poor wall rock competency. Drifts are driven on strike at vertical intervals of about 65 ft (20 m). Crosscuts 24 ft (7 m) wide are driven from the drifts on approximately 48-ft (15-m) centers to the footwall and hanging wall. Crosscuts from an upper level are directly above crosscuts of lower levels. Raises are driven between the ends of corresponding crosscuts. The raises serve as free faces for end slice blasting, as backfill conduits, and as ventilation ways.

Mining commences on the lowest developed blocks and proceeds upward in a generally overhand direction. Blastholes are drilled downward between corresponding crosscuts. Mucking is done with LHD equipment operating from the lower level. A cut is actually a slot about 24 ft (7 m) wide by 65 ft (20 m) high, driven transversely to the strike and extending from the footwall to the hanging wall. The slot or cut is backfilled with a cemented mixture of crushed rock and natural sands and silts. After backfilling of the slot, mining of the next higher slot can commence. Other slots on the same level are separated by slot pillars as defined by the crosscut development pattern. Of course, many slots can be mined concurrently on the same level.

As the mining proceeds on a level, alternating slots of backfill and ore result. The remaining slot pillars of ore are then mined in much the same fashion as the primary slots, but are backfilled with uncemented material including mine development waste.

Productivity for the entire mine department of 84 workers plus mine staff is 28 tons (25.4 t) per employee-shift.

2. Kristineberg mine—Sweden

The Kristineberg metal mine located in north-central Sweden uses overhand drift and fill and overhand cut and fill stoping methods. The deposits are enclosed in altered Precambrian volcanic and sedimentary rocks. Rock types are sericite/chlorite schists and quartzites with talc-rich rocks in the hanging wall of the stopes. The ore zones dip 45 to 70° and are as wide as 65 ft (20 m).

Overhand drift and fill stoping is used where the ore zone is wider than 16 to 20 ft (5 to 6 m), and overhand cut and fill is used in narrower parts of the ore zone or in good ground conditions. Backs are supported with cement-grouted rock bolts 9 ft (2.7 m) in length. Horizontal cuts are 13 ft (4 m) high. Cemented sandfill is used for drift and fill mining, and uncemented sandfill is used for cut and fill. Fill is transported hydraulically.

Footwall ramps provide access to the stopes for LHD equipment.

Stoping productivity exceeds 20 tons (18 t) per employee-shift.

3. Fukasawa mine—Japan

The Fukasawa mine in the Hanaoka area of northern Japan is an operation using the underhand drift and fill mining method. The base metal deposit being mined is a Kuroko complex sulfide volcanogenic ore body. The ore body is a flat-lying tabular-shaped deposit. The country rocks are clayey, soft, and fragile. Even though the depth is only 1300 ft (400 m), pressure is high because of the incompetent rock.

An inclined drift is first driven within the ore body. Horizontal gate drifts are driven from the inclined drift on 10-ft (3.1-m) vertical centers, thus dividing the ore body into stoping blocks or horizontal slices. From the gate drift, crosscuts are driven to the limit of the ore body in the footwall or hanging wall. As each crosscut is completed, it is backfilled before the adjacent crosscut is driven. Backfill is cemented to provide an artificial roof for the next horizontal slice to be mined beneath the backfill.

LHDs are used for mining, and the average stoping productivity is 25 tons (23 t) per employee-shift.

4. Hanaoka mine—Japan

The Hanaoka mine in northern Japan produces 2200 tons (2000 t) per day from the Matsumine Kuroko-type ore body. The stratabound deposit is 650 to 1300 ft (200 to 400 m) deep enclosed in volcanic pyroclastic rocks, which have been altered to clay. Ground pressure is heavy, and the ore body is irregular with zoning of economic minerals. The ore is relatively high grade (values of Au, Ag, Pb, Zn, and Cu).

A gate drift is driven between two chutes to define a horizontal slice 10 ft (3.1 m) high. Crosscuts are driven at right angles to the gate drift to the extremity of the ore body. A crosscut is backfilled with cemented fill before commencing an adjacent crosscut. When a horizontal slice is completely mined, the next lower slice is mined but with crosscuts at right angles to those in the previous slice. Only a few posts are required to support the backfill of the previous cut.

A stoping crew of three men can complete two rounds per shift during the excavation cycle, or a productivity of about 80 tons (73 t) per employee-shift.

19.1.5 MINING COSTS

19.1.5.1 Development

Development can be subdivided into primary development and secondary development. Secondary development is also known as *stope preparation.* Primary development includes:

1. Main access shaft or ramp
2. Secondary/escape shaft or ramp

3. Level development
4. Pumprooms, hoistrooms, and miscellaneous excavations

Secondary development includes:

1. Sublevels
2. Raises on vein
3. Footwall ramps
4. Raise preparations
5. Access crosscuts
6. Orepasses
7. All excavations in ore body prior to stoping

Development costs must be estimated for a given mine because each mine has unique characteristics. Also there are several development alternatives for each mine that should be evaluated and compared. The US Bureau of Mines *Cost Estimating System Handbook* (Anon., 1987), is a useful estimating guide for mine development. Cost case studies are provided in *Mineral Industry Costs* (Hoskins, 1982).

Generally, when a new mine is being developed, mine development is considered as a capital cost and is included in the return on investment calculations. The point to remember is that both primary and secondary development are investments and should be treated that way from an engineering point of view, no matter what accounting practices are actually used by the company. Primary development is usually concentrated during the initial development phase of a mine. Secondary development tends to occur uniformly throughout the operating life of a mine. Hence there is a tendency to consider secondary development as an operating cost, and benefits are not matched against investments to determine if investment criteria are met.

As an example of the capital nature of secondary development, consider the case of raise preparation. The purpose of raise preparation in vein mining is to support the wooden structure of a raise that provides access to a stope. However, raise preparation is made complex by the provision for chute lips and gates to control gravity flow of broken ore from the stope to train or truck haulage. In heavy ground, the raise preparation structure requires special timbering techniques in order to survive the duration of stoping operations, and repair costs usually mount with time. Since the primary reason that complex raise preparation is needed is to allow gravity flow of ore into train cars or trucks, one should consider much of the cost of raise preparation as an investment to make haulage efficient. Is that a worthwhile investment? Would it be better to use a simpler drawpoint technique with LHD mucking and loading of trucks or train cars?

Primary development, such as shaft sinking, requires special equipment and expertise. It is often advisable to contract the shaft sinking rather than acquire the equipment and expertise to do it in-house. In support of this point is the fact that most shaft sinking is done early in the life of a project when mine management has not been fully tested as an operating organization. After the initial shaft sinking activity, further sinking operations are often not needed for many years.

19.1.5.2 Exploitation

The individual mining methods that are included in the category of cut and fill mining are diverse, and so are the costs. Labor productivity is the most important independent variable affecting mining costs. The *Cost Estimating System Handbook* (Anon., 1987) is also a useful guide in preliminary studies for estimating exploitation costs for cut and fill methods.

Labor productivity for cut and fill stoping varies from 10 to 30 tons (9 to 27 t) per employee-shift in the case studies listed in the previous discussion (19.1.4). Naturally, mechanized stoping has a higher productivity than less mechanized methods. Underhand cut and fill and underhand drift and fill methods have high productivity if the mechanization is extensive.

The recommended method to estimate exploitation costs for a specific cut and fill mining operation is to build a spreadsheet model. The reader is referred to the various pertinent sections in this *Handbook* for aid in estimating costs.

Chapter 19.2
EXCAVATION TECHNIQUES

WALTER A. PARONI

19.2.1 OVERHAND CUT AND FILL MINING

19.2.1.1 Description of Methods

BREAST STOPING. *Breast stoping* is a method of extracting a block of ore by mining successive horizontal slices (cuts) 5 to 15 ft (1.5 to 4.6 m) thick from the back of the stope. Mining progresses upwards from a lower level to an upper level. Horizontal holes 5 to 15 ft (1.5 to 4.6 m) deep are drilled in the breast. After the ore has been blasted the walls and back are scaled, and temporarily supported by timber and/or rock bolts. The broken ore is then removed by use of slushers, or load-haul-dump (LHD) equipment in mechanized stopes, through orepasses to the level below (Fig. 19.2.1) (Rausch and Stitzer, 1973; White, 1984). Orepasses are usually spaced 50 to 150 ft (15 to 46 m) apart, and mining from one orepass to another constitutes a cut. When the cut is completed, the orepasses are extended upward the height of the ore removed, the stope is backfilled, and another cut is mined.

POST-PILLAR STOPING. *Post-pillar stoping* is used to mine wide ore bodies that have a great vertical extent. Horizontal cuts are made by breasting-down with jackleg drills. Sill pillars are left on a random basis, and where possible, low-grade and waste areas are used for the pillars. Each cut is backfilled, and the pillars support the back. As the mining progresses upward, the backfill prevents the tall slender pillars from buckling (Fig. 19.2.2).

DRIFT AND FILL STOPING. *Drift and fill stoping* is used to mine wide ore bodies, exceeding 16 to 20 ft (5 to 6 m) in width, where the competency of the ore is moderate to poor. The mining block is divided into series of parallel drifts with vertical walls. A heading is driven along the hanging wall contact for access to the stopes. The mining starts by stoping a drift with a 12 ft (3.7 m) high cut. The stoped area is then filled with cemented sand fill, which provides the back support for the next drift. Then another drift is excavated adjacent to the backfilled drift. This sequence is repeated until the entire block is mined out on that level (Fig. 19.2.3).

A variation of this method is the *transverse stope and pillars* method (Waterland et al., 1982). The ore body is mined by dividing it into transverse stopes and intervening rib pillars. During the mining of the stopes, the rib pillars serve as abutments for the stope back and provide some overall support to the hanging wall. The stopes are filled with cemented sand fill, and the rib pillars provide partial support, or resistance, to closure between the hanging wall and footwall. Extraction of the rib pillars is usually done by undercut and fill methods.

Another variation is called *concrete pillar stoping*. This method was developed by the Outokumpu Company of Finland, and it has been the main stoping method at their Keretti mine since 1954 (Murray et al., 1982). The mining block is divided alternately into 20-ft (6-m) and 26-ft (7-m) wide parallel rooms with vertical walls. The 20-ft (6-m) rooms are stoped first, and they are backfilled with concrete. Then the 26-ft (7-m) wide ore pillars are stoped, and they are filled with classified tailings and natural gravel.

BACK STOPING. *Back stoping* is very similar to breast stoping in that a horizontal slice of ore 3 to 10 ft (0.9 to 3.1 m) thick is removed from the back of the stope. The major difference is that the blastholes are drilled vertically, or at a steep angle (50 to 70°), instead of horizontally. Usually many holes are drilled, for example, from one orepass to another, and the entire series of holes are loaded and blasted at the same time.

After the ore has been blasted, the walls and back are scaled and temporarily supported by stulls and/or rock bolts. The broken ore is then removed by use of slushers, or LHD equipment in mechanized stopes, through orepasses to the level below (Fig. 19.2.4).

The orepasses are usually spaced farther apart in back stoping, 100 to 200 ft (30 to 61 m) spacing, depending upon how straight the vein is. The orepasses can be either in the backfill or in the walls of the stope.

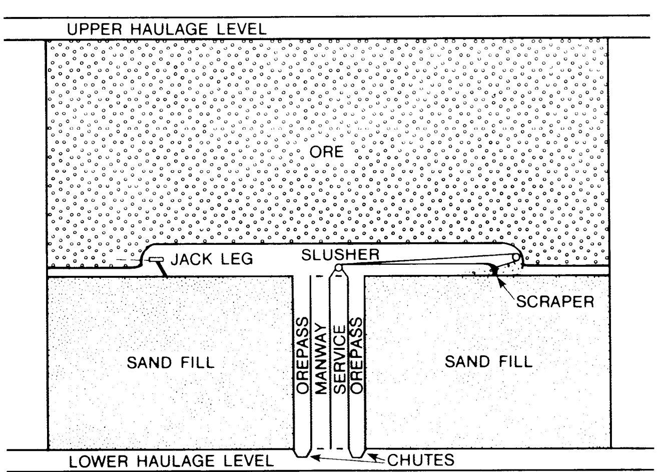

Fig. 19.2.1. Longitudinal section of a typical non-mechanized breast stope.

19.2.1.2 Application to Various Geometries

Overhand cut and fill mining is applicable to ore bodies that have considerable vertical extent and dip 50 to 90°. The method is suitable to ore bodies that meet one or more of the following conditions:

1. Require selective mining
2. Have weak walls
3. Have poor continuity
4. Other mining methods would produce excessive dilution

Post-pillar stoping is applicable to wide ore bodies that have a greater vertical extent than can be mined using the room and pillar method. The competency of the ore should be good in order to prevent failure of the pillar and the back.

Drift and fill stoping is applicable to ore bodies that exceed 16 to 20 ft (5 to 6 m) in width, and where the competency of the ore is moderate to poor.

Back stoping is particularly suited to steeply dipping, narrow-vein ore bodies.

Extensive sampling during each mining cycle permits the operator to change the size and shape of the stope as conditions

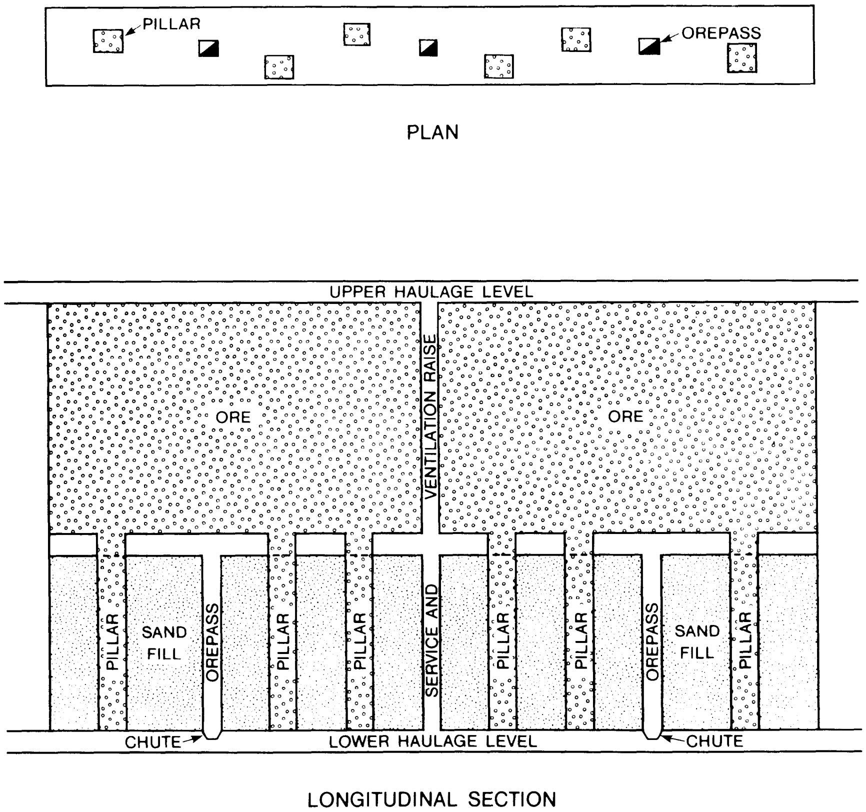

Fig. 19.2.2. Post-pillar stoping.

change. The major limitation is that the ore value must be high enough to support the high cost of overhand cut and fill mining.

19.2.1.3 Development

One common method of developing narrow veins is to drive crosscuts from a lateral in the wall rock when poor ground conditions exist, or when the vein is crooked or has poor continuity. The crosscuts are driven through the vein, and the raises are driven on the vein from the crosscuts. An initial drift is driven in the ore for the length of the stope, and it may be driven on the level or 20 to 25 ft (6 to 8 m) above the level. This serves as the undercut.

Another common method is to drift on vein and not drive laterals. This method is used by the Galena and Sunshine mines in the Coeur d'Alene district of Idaho.

19.2.1.4 Access

Access to the stopes is via raises or ramps in mines using LHD equipment.

Some mines drive raises from the lower level to the level above, or drill a borehole from the upper level to the lower level. In the Coeur d'Alene district, it is common to run the raises up to the initial drift, and then continue them upward as mining progresses.

Another method is to drive a three-cap raise in which one compartment serves as the manway and the other as the rock chute. Other mines maintain four, separate, closely spaced crib raises, surrounded by backfill: two for rock chutes, one for the manway, and one for the timberslide. These raises are usually constructed of square or hexagonal wood crib, or of round steel liner plate. The manway and timberslide also serve as ventilation conduits.

In mechanized stopes, ramps are driven in either the hanging wall or the footwall so that extraction raises may be installed. The inclination of the ramps varies from 1 : 5 to 1 : 10, depending on the mine. Short access inclines or declines are also driven into the stopes at regular intervals as the mining progresses.

19.2.1.5 Drilling

BREAST. Jacklegs are used for drilling in non-mechanized breast stopes. Normally, a 2-ft (0.6-m) starter steel is used to collar the hole, changing to 4-ft (1.2-m) and 6-ft (1.8-m) lengths to finish the hole. The drill steel may be either integral or tapered with a knock-off bit.

Rubber-tired or crawler-mounted, two-boom jumbos are used for breasting down in mechanized stopes. Either integral drill steel, or tapered drill steel with a knock-off bit, is used.

The number of holes drilled varies from eight for a narrow stope (42 in. or 1.07 m or less, in width) to 12 or more holes for wide stopes. It is important that all holes be drilled parallel to the walls in the vertical plane. In the horizontal plane, all except the top row of holes should be drilled parallel to the floor of the stope. The top row of holes should be inclined upward 2 to 3°.

UPPERS. Drilling upper holes is done with either stopers, jumbos, or crawler-mounted drifters.

In nonmechanized stopes, the drilling is normally done with stopers, using integral or tapered drill steel equipped with $1\frac{5}{8}$-in. (41-mm) bits. The holes are drilled vertical to a depth of 3 to 10 ft (0.9 to 3.1 m). The complete back of the stope is drilled out before blasting.

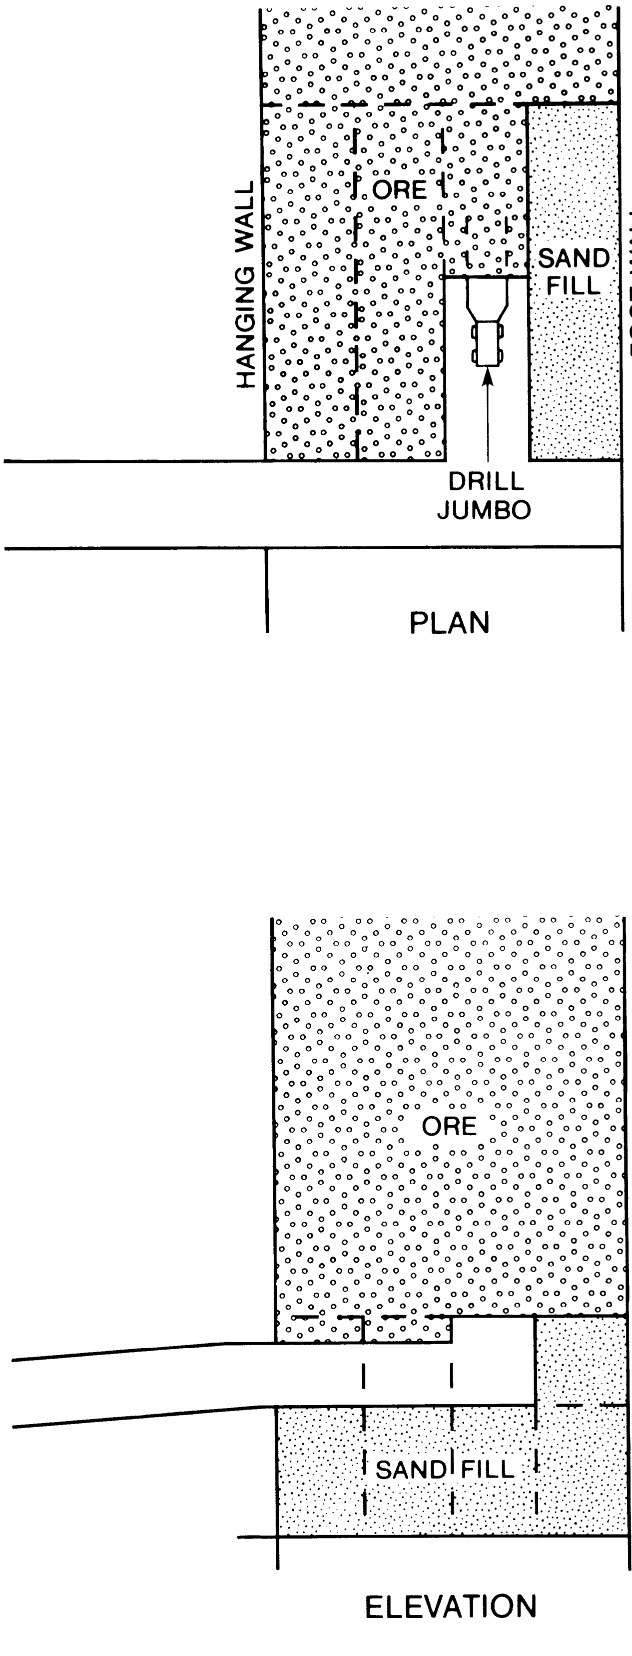

Fig. 19.2.3. Drift and fill stoping.

Homestake in Lead, SD, uses stope jumbos (Waterland et al., 1982). The jumbo is in the form of a tripod with the front of the feed shell mounted on a frame attached to two wheels, with the third leg of the tripod being formed by the end of the feed shell. The angle of the feed shell is preset to 55 to 60° from the horizontal. Presetting the angle ensures that all the holes will be drilled parallel and to the same height above the cemented sand fill floor. A 3-in. (76-mm) bore drill machine is mounted on the feed shell, and 3/4-in. (19-mm) hex drill steel with a 1-1/4-in. (32-mm) bit is used to drill the blastholes to a depth of 10 ft (3.1 m).

Two- or three-boom rubber-tired-mounted jumbos or crawler-mounted drifters are used for drilling upper holes in mechanized stopes. The holes may all be drilled vertical or at preset angle, and be 10 to 15 ft (3.1 to 4.6 m) in length.

The important thing is to drill all of the holes parallel to each other, and to have them all end at the same height above the floor of the stope.

If any ore is left on the periphery of the stope from the last cut mined, it is slabbed before the round is blasted.

19.2.1.6 Temporary Ground Support

Temporary ground support is provided by square sets, stull sets, stulls, and/or rock bolts.

SQUARE SETS. The use of square sets has declined in recent years due to the increasing cost of labor and material. This method is primarily used where the walls of the stope are weak, or where the ore body is too wide for stull timbering. The ore is excavated in blocks of approximately the same size, ranging from 5 to 5- by 7-ft (1.5- by 1.5- by 2.1-m) high to 6- by 6- by 8-ft (1.8- by 1.8- by 2.4-m) high. As soon as a block is removed, a square set is erected in the open space (Bishop, 1945; Haffner and Hoskins, 1973; Wilhelm et al., 1982; Young, 1946).

A square set is composed of a vertical post and two horizontal members, cap and girt, that meet to form a right angle. The ends of the three members are framed to give each a bearing against the other two at the corners, and they join with three other similar sets to form a complete timber support unit.

The cap is laid in the direction of the maximum lateral pressure, and it is the main load-bearing member. The girt acts as a stabilizer. The size of the timber is determined by prior experience in that ore body or in that district.

Sills are initially laid in trenches cut in the floor of the stope, and the posts are set directly on them. If no stoping is to be done from below, and if the ground is hard, the sills may be omitted, and the posts set directly in hitches in the floor or set on floorboards.

Through the years, many methods of framing square sets have been developed by various mining companies. A good reference is Peele (1941) in which 26 different methods are illustrated.

STULL SETS. Stull sets are applicable to ore bodies that dip 70° or more, have very heavy walls, and are not more than 20 ft (6.1 m) in width. The stull sets prevent movement of the walls on the mining floor until sand fill can be poured.

Stull sets were used at Hecla's Star mine in Burke, ID (Murray et al., 1982). The veins were 5- to 20-ft (1.5- to 6.1-m) wide and mining these veins caused plastic flow of the vein walls into the stope. The stull set consisted of two posts, a cap, and two squeeze headings. The caps were round timber, 12 to 24 in. (305 to 610 mm) in diameter, depending upon the span. The cap was supported by two posts extending to the footwall or the cap below. The posts provided rigidity rather than support, and were round timbers 8 to 12 in. (203 to 305 mm) in diameter. Girts were placed between the caps and between the posts to provide longitudinal support.

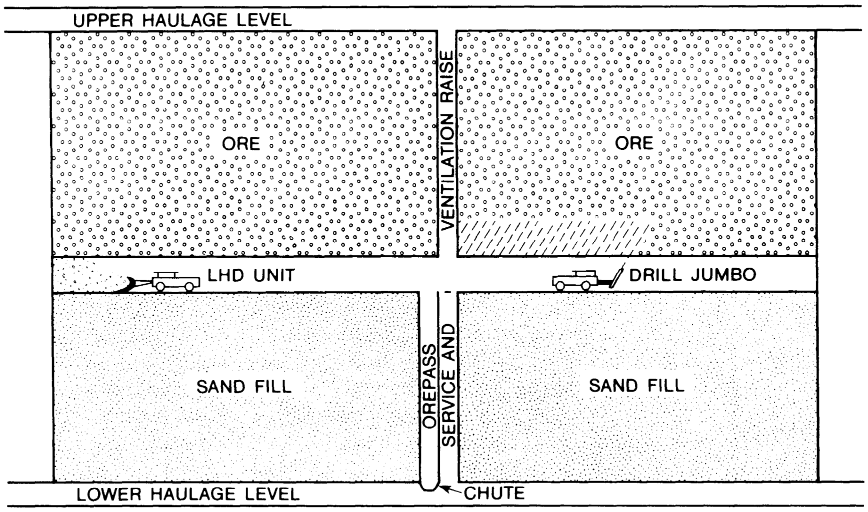

Fig. 19.2.4. Longitudinal section of a mechanized back stope.

The key to the system was the squeeze headboards composed of 3- by 12-in. (76- by 305-mm) lagging 24- to 36-in. (610- to 914-mm) in length. Two to four of the headboards were placed on each end of the cap and wedged tightly with wooden wedges. As the wall pressure increased, the squeeze headboards gradually collapsed but maintained maximum pressure.

Double lagging was placed on top of the caps, and where the back was high, cribbing was placed above the lagging.

STULLS. Stulls are used in narrow vein stopes where the span can be covered by a single timber. Stulls are applicable to stopes with weak walls or to stopes where the ore is irregular, which permits the removal of high-grade sections leaving the low-grade and barren sections behind. Stulls are usually the main means of temporary support in back stopes. Stulls do not carry the entire stress in the rock, so they are used only for temporary support until the stope can be backfilled.

Stulls are usually round timber, 6 to 8-in. (152 to 203-mm) in diameter, and with round timber 12 in. (305 mm) or more in diameter occasionally being used. Squeeze blocks are installed at one or both ends to prevent breakage of the stull in mines where continuous closure occurs (Young, 1946).

ROCK BOLTS. Rock bolts may be mechanically point-anchored (expansion-shell type), friction stabilizers (Split Set, Swellex), and grouted (resin or cement-grouted). Rock bolts are popular because they are inexpensive, relatively easy to install, efficient, do not reduce the cross-sectional area, and can be combined with other methods of ground support.

Expansion-shell type rock bolts tend to loosen shortly after installation so they have to be checked, and, if necessary, retorqued. This checking and retorquing procedure may have to be done daily for a week or more, depending upon the ground conditions and proximity of blasting. The use of expansion shell rock bolts has declined in recent years because MSHA requires that the torque of point-anchor bolts be checked when installed, and also periodically, which is time consuming and costly.

Friction stabilizers are easy and very fast to install. Their main advantages are that (1) the holding force acts over the full contact length of the bolt, (2) they have the ability to yield while retaining a full holding force, (3) anchorage increases with time, (4) plate loads are maintained, and (5) full contact around the circumference of the hole provides a greater resistance to displacement of the rock along the shear and bedding planes. The disadvantages are that they do not have the holding power of a resin-grouted rock bolt, and they do not hold as well as a resin-bonded bolt in hard, fractured ground.

The use of resin-grouted rock bolts is becoming more widespread because they provide instant support, the grouting length may be varied, and the resin cartridges are clean and easy to handle. The bolts may be plain rebar, threaded rebar, or cable. The disadvantages are the high cost, poor mixing of the resin and hardening agent under certain conditions, and the relatively short storage life of the resin cartridges.

Bolts grouted with bulk cement have good reinforcement properties, are protected well against corrosion, and the cement is inexpensive and readily available. The disadvantages are the long setting time, a mixer/grout pump is required, and it is not practical when only a few bolts are to be grouted.

19.2.2 UNDERCUT AND FILL MINING

19.2.2.1 Description of Method

Undercut and fill mining is a method of extracting a block of ore by mining successive slices (cuts) 6 to 15 ft (1.8 to 4.6 m) in height from the top down, and filling each successive cut with cemented sand fill. This method was developed in the late 1950s by Inco, Ltd., in the Sudbury district of Ontario, Canada, to deal with abnormal ground conditions encountered in pillar recovery. Many mines now use the undercut and fill method as their primary mining method (Murray, 1973; Murray et al., 1982; Rausch and Stitzer, 1973; Young, 1946). A vertical or steeply dipping vein is developed on levels 150 to 200 ft (46 to 61 m) apart with a system of lateral drifts on each level. Extraction crosscuts are driven through the vein on 100- to 300-ft (30- to 91-m) intervals. Orepass raises are driven or bored, in the ore body or wall rock, between the upper and lower crosscuts. In mechanized mines, ramps are driven for access to the stopes and orepasses.

The initial floor is established on the upper level. It is mined by driving a conventional drift round, and the opening is supported by square sets or by rock bolts and mats. The ore is removed by use of slushers, or LHD equipment in mechanized stopes, through orepasses to the level below. When the initial cut is completed, a timber and/or wire fabric mat is placed on the floor of the cut, and the opening is filled tightly with cemented sand fill; this method appears in Fig. 19.2.5

Access to the mining area on the next cut is achieved by carrying the manway and timber slide openings, or the access ramps, downward. Mining is then resumed on the next cut below

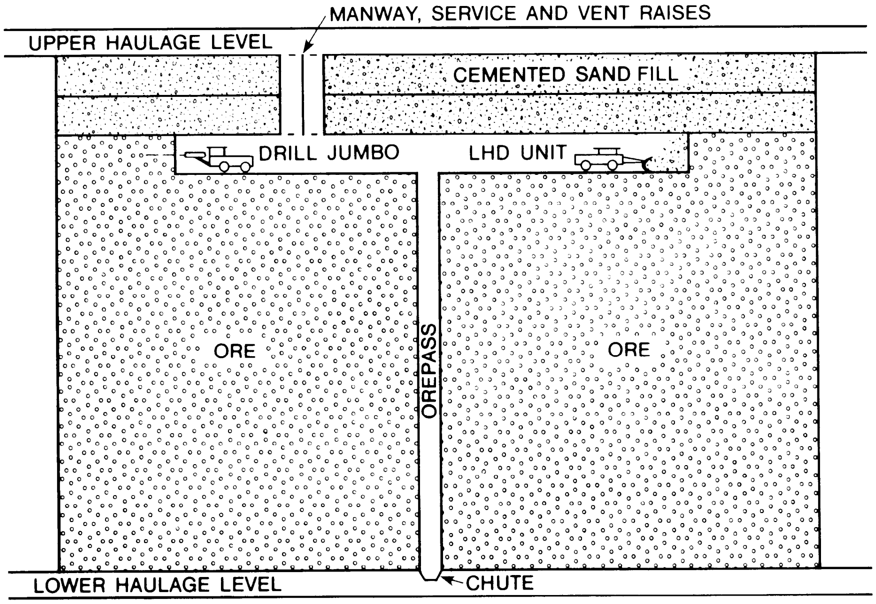

Fig. 19.2.5. Longitudinal section of an undercut and fill stope.

the mat. As the cut is advanced, the mat/sand fill covering is supported, if necessary, by round timber posts. Hecla's Lucky Friday mine in Mullan, ID, uses a net of wire fabric in lieu of posts. The net spans the two ribs and the floor, and it is held in place by rock bolts in the ribs.

The fill placed in each of the successive cuts must be competent in order for this method to be successful. There must be adequate cemented sand fill material available at the stope by having a dependable sand plant and distribution system.

19.2.2.2 Application to Various Geometries

Undercut and fill stoping can be used where either the wall rock or vein is too unconsolidated to permit safe mining by overhand cut and fill methods.

This method can be applied to ore bodies that vary in width and to those that dip from vertical to flat lying.

The method can be used to recover pillars in lieu of the labor-intensive and expensive square set method.

One advantage is that it eliminates the removing of a pillar of decreasing area, which supports horizontal stress, that is encountered in overhand cut and fill mining when advancing from a lower level to a mined-out upper level. In the deep mines of Idaho's Coeur d'Alene district, this method reduces rock-burst problems.

19.2.2.3 Development

In non-mechanized stopes, the laterals are driven in the wall rock parallel to the vein structure. Extraction crosscuts are then driven through the vein on 100- to 300-ft (30- to 91-m) intervals, depending upon the length of the vein, and the most efficient slushing distance for the mine.

Raises for orepasses are driven in the vein up to the upper level, or are bored in the vein from the level above. In mines where the ore is not competent, the raises are located in the wall rock. Loading chutes are then installed at the bottom of the orepass raises.

In a mechanized stope, a main ramp decline is driven in the wall rock from the upper level. These declines are driven at some predetermined distance in the wall rock, commonly 30 to 50 ft (9 to 15 m). Crosscut access ramps are then driven from the main ramp into the ore body.

19.2.2.4 Access

Access to the stopes is via winzes that are carried down as the mining progresses or via ramp declines in mechanized stopes. Access may also be provided via conventionally driven or bored raises that were completed during the development stage.

Some mines drive three-cap raises in which one compartment serves as the manway and the other as the rock chute.

19.2.2.5 Drilling

Drilling is done with either jacklegs or jumbos. Before the drilling commences, the face and walls are barred down, and the underside of the mat is checked to remove any loose sand fill.

The top row of holes is drilled flat and at a minimum distance of 2 to 3 ft (0.6 to 0.9 m) below the mat in order to prevent damage to the mat when the round is blasted. Also care is taken in drilling the lifter holes in order to avoid the necessity of popping (blasting) the bottom to set the posts and stringers. This also ensures a relatively smooth bottom for mucking.

Normally, a 6-ft (1.8-m) round is drilled, and in tight ground a burn cut is used.

19.2.2.6 Temporary Ground Support

Temporary ground support is provided by posts and/or rock bolts. As mining progresses, round wood posts are placed under the stringers of the previous cut. Rock bolts may also be used to supplement the posts.

In narrow veins, posts may not be required, and rock bolts are used to provide temporary support until the mat is constructed and the cemented sand fill is poured.

Another method is to span the two ribs and the floor with wire fabric, which is held in place with rock bolts.

The cemented sand fill supports the major portion of the load. The posts and mat have a double function as they carry the weight not supported by the sand fill, and also prevent any pronounced settling of the fill mass.

Table 19.2.1. Equipment Requirements

Type of Stope	Drilling Equipment	Mucking Equipment
Breast (Narrow Vein)	Jackleg	Slusher 1/2 yr^3 (0.4 m^3) LHD
Breast (Wide Vein)	Jackleg 2-boom Jumbo	Slusher 1–5 yd^3 LHD (0.8–3.8 m^3 LHD) Rubber tired Overshot Mucker
Post-Pillar	Jackleg	1–5 yd^3 LHD (0.8–3.8 m^3 LHD)
Drift and Fill	2-boom Jumbo	1–5 yd^3 LHD (0.8–3.8 m^3 LHD)
Back	Stoper Stope Jumbo 2- or 3-boom Jumbo Crawler mounted Drifter	Slusher 1–5 yd^3 LHD (0.8–3.8 m^3 LHD)
Undercut	Jackleg 2-boom Jumbo	Slusher 1–5 yd^3 LHD (0.8–3.8 m^3 LHD)

A detailed description of the permanent support system is given in Chapter 19.3.

19.2.3 ELEMENTS COMMON TO OVERHAND AND UNDERCUT METHODS

A comparison of equipment requirements for drilling and mucking with different stoping methods appears in Table 19.2.1.

19.2.3.1 Blasting

Each drillhole is first loaded with an initiating device such as an electric blasting cap or a nonelectric blasting cap, either of which may be a standard delay or a millisecond delay, along with a booster or a stick of powder. Then each hole is loaded with gelatin cartridges or ANFO.

19.2.3.2 Ore Removal

The ore is removed from a nonmechanized stope by means of a double- or triple-drum slusher. The slusher may be either electric or pneumatic powered. The ore is scraped to the stope orepass where it drops to the level below.

In mechanized stopes, the ore is removed from the stope by a diesel- or electric-powered LHD unit. The ore is dumped at the stope orepass for handling on the lower level, or the ore is transported directly to a main orepass.

As soon as a stope is mined out, all of the ore must be removed from the stope. This is called the clean-out cycle.

In stopes using slushers, the scraper should be played back and forth across the muckpile to keep it fairly level. Trenching or winrowing should be avoided. The clean out should progress from the back end of the stope towards the orepass. A minimum of sand should be taken in those stopes not using cemented sand fill.

The clean out usually progresses much faster in stopes using LHD equipment for mucking, as one area of the stope can be cleaned out entirely before progressing to the next area. The LHD operator should be careful not to dig too far into the sand if cemented fill is not used.

Whenever possible, any remaining slabbing should be done early in the clean-out cycle, and the walls should be trimmed down as the muck level is lowered. Where necessary for safety, and to prevent dilution, the walls should be supported by stulls or rock bolts in nontimbered stopes.

19.2.3.3 Orepasses

Orepasses can be unlined when they are located in the country rock. When they are located in the backfill, they are constructed of square or hexagonal wood crib reinforced with angle-iron wear plates, or constructed of round steel liner plate. Some mines are now lining orepasses with steel-fiber-reinforced shotcrete, and they are holding up very well. The choice of which lining to use depends upon the type of rock, the length of the orepass, and the estimated tonnage that will flow through the orepass.

Short unlined orepasses, 100 ft (30 m) or less in length, in hard tough country rock will probably stand up under the constant passage of ore or waste rock. Longer orepasses in country rock or those located in the ore should be constructed of wood crib, steel liner plate, or fiber-reinforced shotcrete.

The bottom of the orepass at the haulage level usually contains a loading chute that is lined with steel plate and equipped with a pneumatically operated gate. The ore is loaded into trucks or into trains containing 3 to 12 ore cars. The trucks or ore cars are then dumped at the main orepass, which is usually located at a haulage shaft.

Instead of using a loading chute, the ore may be dropped to an enlarged area beneath the orepass. The ore is then loaded into ore cars or trucks using either a LHD unit or an overshot loader, or the ore may be hauled directly to the main orepass by a LHD unit.

19.2.3.4 Ventilation

Fresh air normally enters the mine through a downcast shaft, and it is split to flow through the active work areas. The air is then exhausted through raises, laterals, and an upcast shaft. About 30 cfm (0.014 m^3/s) per person is required for normal ventilation, and where diesel equipment is used, the requirement is approximately 100 cfm (0.047 m^3/s)/hp. Hot mines will require more than the above-stated flows and possibly refrigeration equipment as well, depending upon the ambient temperature of the working place, which should be kept below 85°F (47°C) wet-bulb temperature.

Auxiliary ventilation for individual work places is usually provided by 10- to 20-hp (74.5 to 149-W) axial flow fans, and the air is conveyed to the area via 16- to 20-in. (410- to 510-mm) vent tubing, or 20- to 24-in. (510- to 610-mm) vent pipe. The Lucky Friday mine, Mullan, ID, uses 21- and 22-in. (530- and 560-mm) corrugated steel pipe that is buried in the sand fill. In the stope, a vent tube connected to the end of the corrugated pipe conveys the ventilation air to the work area.

Some mines drive ventilation raises at the extremities of each stope to exhaust the air, and these raises are equipped with ladders as well as compressed air and water lines. The raises can also be used for stope access and escape routes. Other mines do not drive raises all the way through from the sill level to the level above. These mines space their manways, timberslides, and rock raises 50 to 100 ft (15 to 30 m) apart, and the open manways and timberslides provide a conduit for the exhaust air.

In mechanized stopes, vent tubing is strung in the access ramp to convey the fresh air. The exhaust air is routed up a vent raise or out through an access ramp.

19.2.3.5 Crews

Non-mechanized stopes usually have a crew of two miners per shift. Back stopes may have three or four miners per shift, because normally a series of holes are drilled before blasting the round. The additional personnel speed up the drilling cycle and also decreases the time required for the mucking and raise up cycles.

Mechanized stopes usually have two miners per shift. Mt. Isa uses three miners plus a diesel operator in their large, wide stopes.

Stoping operations are usually conducted on a two-shift basis, but a few mines carry on operations on a three shift-basis.

Support crews consist of one or two nippers per level, depending upon the number of stopes. The nippers deliver supplies and haul ore and waste in small mines. In larger mines, the nippers only service the miners, and two-person crews load and haul the ore and waste.

Chapter 19.3
BACKFILLING METHODS

WALLACE E. CRANDALL

19.3.1 WASTE FILL

19.3.1.1 General

The use of waste fill is probably as old as mining since it has always been valuable to a mine operator to dispose of development rock in mined-out stopes to avoid removing it from the mine. The primary purpose of waste fill or any type of fill, however, is to support mined-out openings so as to prevent caving, surface subsidence, pressure on the work place, or rock bursting. Another reason for using waste fill is simply that the waste material may be conveniently available to the mine and is the most economic method of filling mined-out openings that require support.

19.3.1.2 Sources

Sources of waste fill material include the following:

1. Surface quarries near the mine.
2. Underground development rock.
3. River gravel.
4. Glacial till.
5. Talus.
6. Dune sand.
7. Mine dumps.
8. Sink-float plant reject.
9. Coal preparation plant reject.
10. Smelter slag, fly ash.
11. Naturally broken fault material from an underground source far enough from the workings to be caved and drawn safely. Source materials may include such variations as:

a. Completely ungraded waste rock with little or no fines.

b. Graded and sized material containing cement and appropriate water content for greater strength.

c. Raw material containing sulfides (e.g., pyrite, pyrrhotite) or other minerals that help consolidate the fill.

d. Mixtures of waste rock or gravel and mill tailings to provide a better size gradation that will fill most of the voids in the mixture. Part of the slime fraction may be removed by cycloning for better handling and placement.

e. Mixtures of waste rock and smelter slag or fly ash that may have cementing or pozzolanic properties resulting in consolidation of the fill.

19.3.1.3 Preparation and Delivery Methods

In general, the waste material has to be sized according to the handling and placement method used. If the waste fill is excavated in a surface quarry, dropped by gravity through waste raises, trammed by rail to a stope raise, and slushed from the raise into the stope, then –12-in. (305mm) material is satisfactory. This method was in common use for many years in the mines of the Coeur d'Alene District, near Wallace, ID. A typical example is the Star mine in Burke. During the period from 1950 to 1960, –12-in. (305mm) waste fill was quarried from a surface pit and fed to the upper workings via a system of waste passes to the working levels. Development waste was also used where possible. In some stoping areas, waste fill was broken by driving crosscuts in the walls. A hydraulic sandfill system replaced waste fill in 1959.

If development waste from underground is used for stope fill, material –12 in. (305 mm) in size is convenient. If the material is handled by conveyor belt, width and particle size must be compatible.

Pneumatically placed waste fill is usually –1 in. (25 mm) in size, although particles up to 4 in. (102 mm) can be handled, depending on pipe size (Powell and Ruby, 1981).

Any waste fill can be improved and made stronger by sizing the fines and coarse material so more of the voids will be filled and a more compact fill achieved. Crushing and screening are necessary, and the increased cost must be balanced against the need for a stronger fill; that is, can adequate wall support be attained without the expense of sizing the fill? Most waste fill can be placed without special sizing gradation and still provide adequate wall support or protection from pressure on the workings. However, some excellent consolidated waste fills have been made by the addition of cement to a graded sand and crushed rock mixture to produce concrete of the desired strength. A detailed study of the strength of fill that can be achieved using coal mine washery refuse is provided by Knissel and Helms (1983). The material studied was sandy shale and sandstone in particles from 0.0039 to 3.94 in. (0.1 to 100 mm) in size. Uniaxial compression strength up to 580 psi (4 MPa) was achieved in 28 days with 10% cement.

A mine that is developed by rail haulage via a long tunnel might find it necessary to haul waste into the mine in the returning ore cars. Similarly, waste fill may be hauled into the mine by returning trucks in a trackless mine. Conveyor belts can be used to deliver waste fill to the stoping areas, and waste rock, gravel, and sand can be passed through boreholes or raises of various diameters from surface to the mining area. As a rule of thumb, however, the hole or pipeline diameter should be at least three times the largest particle to prevent plugging. Pneumatic delivery of waste fill is a field in itself and discussed later.

19.3.1.4 Placement Methods

Actual placement of the waste fill material in the stope may be accomplished in the following ways:

1. *Slushing* (see definitions, Chapter 19.1, part 19.0.1.2). The waste fill may be slushed directly from a waste raise to the stope area to be filled. Usually, the waste raise leading to the stope is supplied by rail car, front-end loader, or load-haul-dump (LHD) from a waste pass or transfer raise, which is the material source for the entire mining area.

2. *Slinger belt placement.* This system may use a high-speed belt and hopper supplied by truck or LHD. The material may also be placed by a slinger belt mounted under a hopper. Slinger belt systems provide good compaction and relatively strong fill if gradation of the material is proper.

3. *Stower placement.* Dry waste fill in the 3-in. (76-mm) range may be placed by pneumatic stower. The system utilizes a low-pressure blower and a rotary feeder that delivers the mate-

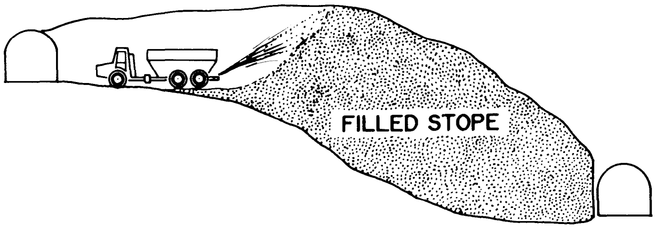

Fig. 19.3.1. Truck-mounted slinger belt at Keretti mine, Outokumpu Oy, Finland.

rial to the area to be filled via pipeline. See 19.3.2 on pneumatic filling methods for further details.

19.3.1.5 Advantages

Many times, an inexpensive source of waste fill available near the mine improves the economics of the mine. The preparation of waste fill is usually less expensive than other types of fill due in part to a simpler plant facility.

1. The use of underground development rock reduces the cost of disposal by removing it from the mine and also helps eliminate environmental problems on the surface.
2. The addition of cement or other binding agent can make a strong consolidated fill if necessary.

19.3.1.6 Disadvantages

Waste fill may result in a relatively loose, uncompacted fill that does not resist closure well if the material is not sized so that fines occupy most of the voids. Unconsolidated waste fill can result in unsafe caving or sloughing conditions if too much fill face is exposed. Overly wet fill in transfer raises can become hydraulic, resulting in dangerous surge problems.

19.3.1.7 Applications

Outokumpu Oy's Keretti mine in Finland uses a specially designed truck-mounted slinger unit to place a waste fill composed of 86% crushed rock, 5% cement, and 9% water (Fig. 19.3.1).

Asamera's Cannon mine in Wenatchee, WA., uses a concrete fill made of Columbia River sand and gravel and 5% cement in a very thick mixture (Argall, 1988). The sand, aggregate, and cement are transferred dry, by gravity, through boreholes to an underground mixing plant. Small bulldozers are used to level the low-strength concrete, providing flat working floors for successive cuts. Pillars are removed later and filled with 3% concrete fill or dry fill.

The Cannon mine is backfilling its overhand sublevel bench stopes at a rate of up to 480 tpd (435 t/day) with truck-placed cemented and uncemented backfill (Figs. 19.3.2 through 19.3.4). The high-strength, cemented backfill, consisting of sand, aggregate, and cement, is mixed underground by an automatic batching system operated by a programmable controller (Fig. 19.3.5). Batching is initiated by truck-mounted radio. Uncemented fill is delivered by the same system.

The need for a cemented fill strength of 1200 psi (8.3 MPa) was indicated by safety considerations and the expectations of full overburden loading of some cemented fill pillars during removal of the intervening secondary stopes. Because of this loading and in order to limit subsidence, both the cemented fill

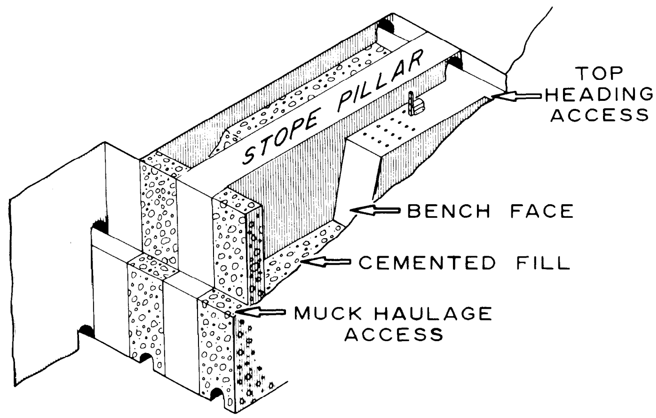

Fig. 19.3.2. Isometric drawing illustrating sublevel benching, cut and fill mining method, Cannon mine

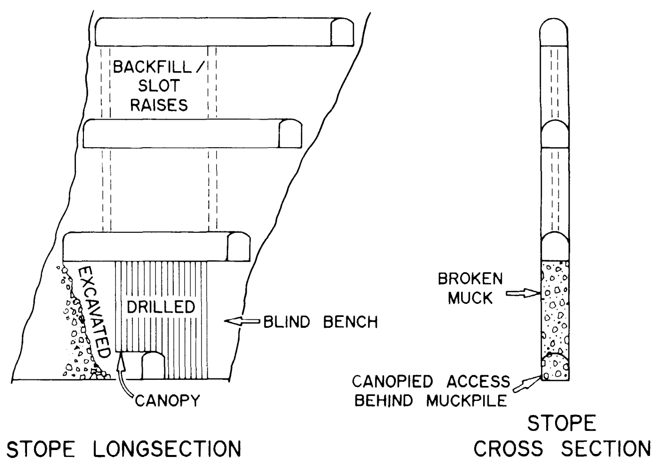

Fig. 19.3.3. Overhand/underhand bench, general arrangement, Cannon mine.

in the primary stopes and the uncemented backfill in the secondary is placed tight against the back at the top of the ore body. A mechanical jamming device has been developed in conjunction with a 5-yd^3 (3.8-m^3) LHD to drive the fill tight against the back.

Fill material is delivered from surface sources to the grizzlies, over the boreholes, leading to the underground mixing plant (Fig. 19.3.5). Initially, fill material was a mixture of 55% 3-in. (76-mm) aggregate, sand, and 5% Portland cement, but this resulted in segregation when dumped over a berm in the stope (Fig. 19.3.6). Subsequent use of aggregate with a maximum size of 2 in. (51 mm) has adequately relieved the problem.

Surface subsidence is minimized by the support offered either by in place pillars or the pillars created by high-strength fill. The voids (e.g., robbed pillars) that do not require cement fill are available as dump points for mine waste, eliminating the costly handling of waste both underground and on the surface.

Cemented backfill is the support means that allows complete pillar recovery with no perceptible surface subsidence. The cemented fill is designed to be strong enough to support full overburden load and provide stable exposed stope walls during extraction of secondary stope benches.

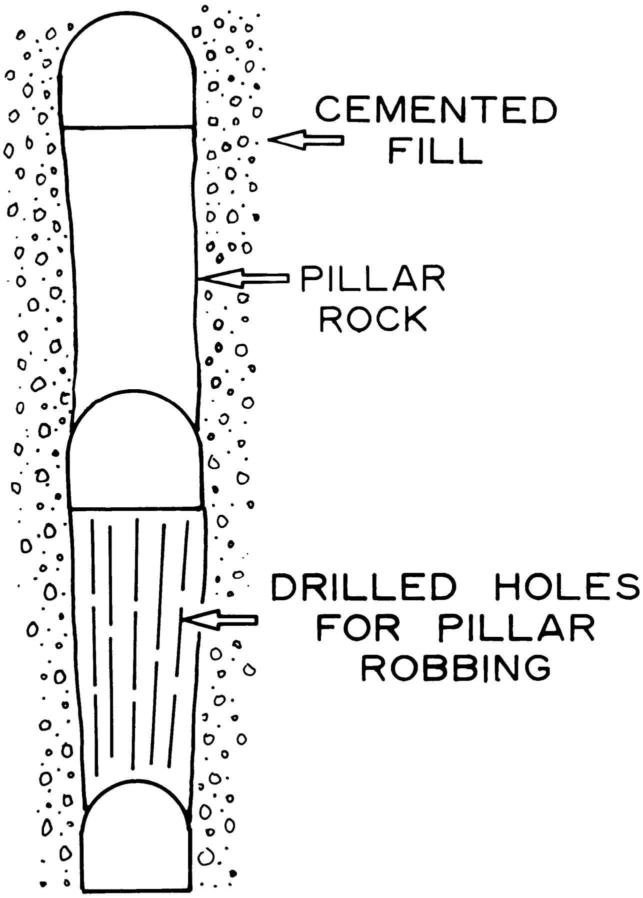

Fig. 19.3.4. Pillar robbing cross section general arrangement, Cannon mine.

The backfill mix is as follows:

Aggregate (2 in. to #4 mesh, or 51 to 4.7 mm)	55%
Sand	40%
Type I, II Cement	5%
Water : cement ratio	1 : 1
Water reducing admixture 6 oz/100 lb (3.8 g/kg) cement.	

The backfill mix provides an unconfined compressive strength of 1200 psi (8.3 MPa).

Cemented fill is batched by a pugmill underground. Sand and aggregate are dumped down boreholes into underground silos of approximately 3000 tons (2700 t) each. The sand and aggregate are fed into the pugmill by vibrating feeders. Cement is stored in a 350-ton (318-t) capacity surface silo and fed to the pugmill by a pipeline in a borehole from the surface. The cement flow is regulated by two vane feeders, one on the surface and one near the pugmill. The water-reducing admix is prepared on the surface and metered to the pugmill by a pump. All material feeders are controlled by a process controller. The ingredients are mixed and fed into a fill bin by a double-screw pugmill. The batch is fed into a truck by a clam gate. The pugmill batch cycle is initiated by the truck driver after his truck is loaded. The batch cycle requires approximately 4 minutes to process 10 yd^3 (7.65 m^3), equivalent to 18 tons (16 t). The trucks dump the cemented fill down a backfill slope with a 38° angle of repose. The low water content of the fill allows the trucks to drive on freshly placed fill (Guenther, 1988).

B.P. Minerals, Ltd. operates the Greens Creek mine on Admiralty Island west of Juneau, AK. They use a drift and fill mining method in ore bodies averaging 8 to 15 ft (2.4 to 4.6 m) in thickness (Steffen, Robertson, and Kirsten, 1984). Since the grind in the mill is 95% –200 mesh (0.074 mm), the tailings are too fine to make a satisfactory fill. Less than 15% of backfill requirements could be met with appropriate material recovered by cycloning. Wall rocks are friable argillite and tuffite, which would result in 25% of development waste rock being discarded as fines, aggravating the disposal problem. Further degradation would occur in pumping, all of which makes a conventional hydraulic fill unattractive. Pneumatic delivery has also been discarded due to high cost and inflexibility. There will be an accumulated stockpile of development waste available, which will be sufficient for 5 years of backfilling. The system planned will use this available waste with 3% (30 : 1) cement and slinger belt placement, utilizing either slinger belts loaded with an LHD unit or with a truck-mounted slinger belt loaded directly from the truck body. This system is expected to give adequate-strength fill for a 15-ft (4.6-m) high free-standing face.

The Meggen mine in western Germany has a total extraction drift-and-fill system that uses a clean 2-in. (51-mm) maximum size aggregate from a heavy media separation plant together with 3 to 5% cement to produce an effective backfill. The cleaned aggregate at Meggen is deficient in fines but reaches an adequate strength (Steffen, Robertson, and Kirsten, 1984; Rohlfing, 1983).

Fill is placed with a skid-mounted or truck-mounted stowing machine (Figs. 19.3.7 and 19.3.8). Only dry placement methods are in use with rockfill out of development drifts (5%) and slinger belt stowing with cleaned rockfill (95%). Slinger belt stowing replaces pneumatic stowing, which results in rather high overall backfill costs.

The compaction of fill material by the slinger belt system is comparative to pneumatic stowing and provides a surplus of compressive strength compared, for example, with rockfill placed by LHD units. The complete filling of a mined-out room in a flat-lying deposit can only be achieved with pneumatic or slinger belt stowing.

The use of slinger belt stowing superseded the earlier use of pneumatic placement because of higher performance and lower overall costs of this method (Rohlfing, 1983).

An example of the use of dry sand fill in Canadian mines is described by Twidale (1962). Two of the oldest gold mines have used dry sandfill in the past. These mines are deep, and fill is required in a multitude of small vein-mining operations. The practice of sand filling existed before hydraulic systems came into use, and it is not considered economical to change the material and methods. The pit-run sand is mined by mechanical shovel and transported some 3½ miles (5.6 km) to the mine site by aerial tramway. The fill is stored in near-surface stopes and fed to a sand pass that connects the mining horizons to a total depth of nearly 6000 ft (1800 m). Sand and gravel fill is placed in similar fashion to fill empty shrinkage stopes less than 1000 ft (300 m) below the surface that have been emptied of ore and where stability is consequently necessary to prevent ground movement. A near-surface stope is used as a storage bin and connected to the sand pass through control gates.

19.3.2 PNEUMATIC FILL

19.3.2.1 General

The disposal of mine tailings, development rock, and other unwanted refuse material underground in mines by using pneu-

matic conveying techniques has been practiced in the coal industry for many years. Similar equipment has been utilized for backfilling hard-rock mines and is currently being applied in a South African gold mine where the development rock is being stowed in mined-out stopes to reduce the incidence of rockbursts. On a limited scale, pneumatic conveying has been applied for backfilling uranium mines, and one mine in New Mexico has used this technique for eight years (Powell, 1980). The method was also used at the Billie mine in Death Valley, CA, and at the Apex mine near St. George, UT.

Pneumatic conveying can overcome many of the problems that result from hydraulic filling of flat-lying stopes, in that voids can be completely filled with a high degree of compaction, heavy bulkheads are not necessary, and development rock can be added to the pneumatic system for disposal underground, thus eliminating the hoisting cost to the surface. Cement can be added to the wetted material to form a high-strength concrete (Powell, 1980).

Although pneumatic conveying has several advantages over hydraulic fill, there are two major disadvantages: (1) the excessive power required for long horizontal distances; and (2) as a result of the high air and material velocity in the long pipeline, a wear problem that necessitates frequent rotation of the pipelines and eventual replacement.

Where long pneumatic pipelines require high horsepower and high velocity with resultant wear, a combination hydraulic-pneumatic system has been proposed by Leon Gregory but not yet used (Powell, 1980). The hydraulic fill material would be delivered to the mining area by pipeline or borehole using pumps or gravity, as required. Then the slurry would be dewatered, development waste added as well as cement, if desired, and the mixture delivered pneumatically to the stope to be filled. Main pipelines and fittings would be manufactured from abrasion-resistant steels with a hardness of up to 700 Bn (Brinnell). Elbows would be made with replaceable liners. (Such high-quality steel would be required only in the more permanent installations.) In the stopes themselves, mild-steel pipelines could be utilized and, when worn, patched and finally rejected. Rubber hose could also be used for elbows and for the final placement section in the stope. A properly graded fill could result in a relative density of 79 to 83% due to the high impact of larger particles driving the fines into the voids.

19.3.2.2 Sources and Materials

Sources of materials for pneumatic filling are much the same as those used for waste fill. Again, a low-cost, convenient, and accessible source with a simple preparation plant may make a mine requiring fill economic while other more sophisticated systems would not be commercial. Typical sources may include the following:

1. Deposits of overburden such as talus, sand and gravel, glacial till, dune sand, or river gravel.
2. Mine dumps.
3. Mine development waste.
4. Sink-float reject.
5. Coal preparation plant refuse.
6. Smelter slag.
7. Mill tailings or mixtures of mill tailings and waste rock.

Cement can be added with appropriate moisture to any of the above for greater strength and stability. The primary difference from ordinary waste fill is in the methods of preparation and delivery.

19.3.2.3 Preparation, Delivery Methods, and Equipment.

Dense-phase pneumatic handling techniques are used for such fine-grained materials as cement, rock dust, pulverized coal, and chemicals that are readily flushed. Air at high pressure is usually provided by a reciprocating compressor. Pneumatic conveyors of the dilute-phase type are used to handle the materials used in mine backfilling. Air supplied by a fan or positive-displacement blower is used to transport the material at relatively low pressures, usually ranging from 5 to 20 psi (34 to 138 kPa)

(Powell, 1982). The particles are suspended and carried in the airstream.

Dilute-phase pneumatic conveying has been applied in coal mines since the 1920s to convey rock or mine refuse into underground workings. Its use is mainly for roof support in those areas where coal has been extracted. It has a secondary application in that it does reduce or eliminate the disposal of rock waste on the surface of mines. In more recent years, the same technique has been applied for hoisting coal out of mines through vertical shafts. Similarly, pneumatic conveying has been used to hoist shaft or raise-boring cuttings vertically up a bored shaft (Powell, 1982).

It is recommended that the pipeline diameter should not be less than three times the largest particle size, though in practice in the mining industry, 8-in. (203-mm) I.D. pipes are commonly used even though there is an occasional lump of 3 in. (76 mm). Rubber-lined pipes are not recommended for pneumatic conveying systems due to the high friction factor and sharp particles of rock slicing the rubber. As the material is abrasive, and rapid wear can take place in the pipeline, consideration is given to abrasion-resistant steel pipes where the inner face is hardened to 500 Bn in order to reduce the wear. There is an increase in cost compared to mild steel pipe, but it is justifiable from an economic point of view, providing that the wall thickness does not have to be increased. This, of course, makes the pipes much heavier, increasing the labor cost for laying and recovering the pipelines. When handling sand, plastic and fiberglass pipes have been used, although these wear more rapidly than steel pipes and are used for the last sections in the pipeline only where they are to be constantly coupled and uncoupled. The detrimental costs in high wear rates is offset by the savings in labor, with one man able to carry a 10-ft (3-m) length of plastic pipe compared with the requirement of two men for an equivalent length of steel pipe (Powell, 1982).

The use of early-bearing compact stowing is considered particularly appropriate for support beneath objects or areas that are subject to mining damage. The most compact possible stowing pack with the lowest possible pore volume can only be obtained in the presence of a grain-size distribution curve of the stowing material that largely coincides with the Fuller curve for concrete aggregates. It is of particular importance that the stowing material contains a sufficient amount of fine and finest grains to allow the formation of the most densely compressed spherical packing. Flotation slurries with their particularly high clay content are suited to this purpose. Electrostatic filter ash from power stations with its long-term hydraulic binding effect can also be used for admixture (Voss, 1983).

In order to keep dust levels at a minimum at the delivery point, it is essential that neither too little nor too much moisture be present in the feed. Too much moisture can result in fog carrying dust, just as too little moisture results in airborne dust. A moisture content averaging 8 to 10% for material with a good size distribution range will usually result in the highest density of fill. Water is generally injected through a wetting ring near the discharge nozzle, especially if cement is used. Too much moisture in the delivery line may result in build-up. Water added at the head end of the system helps to lubricate the pipeline but must be controlled carefully.

A pneumatic conveying system consists essentially of an air supply, an in-feed arrangement, a pipeline with necessary elbows, and a discharge. A heavy-duty pneumatic conveying system also consists of these essentials but with several important differences that are necessary to accommodate the large abrasive material. Component parts are described below.

The air requirement for a heavy-duty pneumatic system, say, for example, conveying 200 tph (181 t/h) of refuse into a coal mine, will require from 3000 to 5000 cfm (85 to 142 m^3/ min) of air. With a pipeline diameter of 8 or 10 in. (200 or 250 mm), pressure requirements for the air supply will be in the region of 15 psi (104 kPa) and, allowing for some reserve, should have a maximum pressure available of 18 psi (124 kPa). Such an air supply is most economically provided by a positive-displacement blower, of which there are several types and makes available.

This method of producing pressurized air is probably the most economical, and in most instances, blowers of this size can be direct coupled to an electric motor operating at 1750 rpm. Blowers of this type are simple in construction and easy to maintain. Provided they are selected to operate at a known height above sea level, so that there is always sufficient quantity of air flowing through the blower to dissipate the heat of compression, they will have a long life. They have one inherent disadvantage, in that the air produced is pulsating, and, close to the blower itself, the noise is objectionable. To overcome this problem in the confined space of a mine, the blower and electric motor are enclosed in an acoustically insulated enclosure provided with the necessary access doors. The components are mounted on a substantial fabricated steel base with sufficient rigidity to prevent strain on either the motor, blower, or coupling when located underground in the mine on an uneven floor. The mine air is often polluted with dust, which could in time affect blower operation by wearing the rotors. This increases the air gaps and lowers the efficiency. The air is carefully filtered before being drawn into the blower by means of a panel filter that can be readily changed when necessary. The starter for the motor is mounted on the same skid-base, which reduces the amount of electrical connection work the mine electricians have to undertake when these units are frequently relocated.

Being a positive-displacement machine, the blower supplies air at a pressure that increases according to the demands on it, and if the pipeline becomes choked with material or becomes crushed from a roof fall, the pressure continues to increase until the electric motor is switched off by the overcurrent relays. To ensure that physical damage does not take place, there are several protection devices built into the blower units, including the following:

1. Pressure relief valve set at 18 psi (124 kPa).
2. Rupture disc.
3. Series of pressure-sensing switches:
   a. To reduce infeed.
   b. To shut down the motor if pressure continues to increase.
   c. To shut down the motor if air temperatures become too high.
   d. To provide electrical overload tripouts on the motor.

Reciprocating compressors can be used as an air supply and were used for many years in Europe to supply air to pneumatic backfill systems in coal mines. However, mine compressed air is usually supplied at a pressure of 90 to 100 psi (621 to 690 kPa), which is much higher than that required in a pneumatic conveying system of the dilute-phase type. Pressure has to be reduced to approximately 20 psi (138 kPa) through an orifice plate or pressure-reducing valve. In European coal mines, these compressors were already available for powering, by compressed air, other machinery in the mine, such as coal cutting machines and drills. They were, therefore, readily available for operating the backfill equipment, which was most often done on a nonproduction shift when the other machinery would not be in use in the mine. The positive-displacement blower has, however, proven to be the most economic source of pressurized air for pneumatic conveying of coal or rock in the mining industry.

There are several methods of introducing material into the pressurized airstream from atmosphere, namely, lock gates, pressure vessels, and rotary valve feeders. The rotary valve feeder has proven to be the best infeed device for handling large-sized abrasive materials. Occasionally, this type of feeder becomes jammed by foreign material that cannot be sheared. Provision of a fluid coupling or a shear pin prevents damage. It is often found that a piece of rock, especially shale or the weaker sandstones, will break after being subjected to two or three blows. Arrangements are made so that when the feed wheel is stopped suddenly, it immediately reverses for a short distance and then turns forward again. Several repetitions will often shear the rock or move it to the end pocket, allowing the feeder to continue turning.

These feeders are made of Ni-hard castings of 700 Bn hardness for wear and abrasion resistance. The stator halves are also adjustable so as to compensate for wear. Wear on end housings is reduced by pressurizing them with clean air. The feeder unit is assembled on a skid base that also accommodates the pipeline inducer where the material is accelerated into the airstream. A rotary valve feeder capable of handling 200 tph (181 t/h) weighs 6000 lb (2720 kg). A skid-mounted power center contains a hydraulic oil supply for the drive motor of the rotary feeder, auxiliary air for the end housings, backup controls for the system, a variable volume hydraulic pump that allows the operator to adjust the speed of the rotary feeder, a hydraulic relief valve, oil tank, filters, forward/reverse valve, and pressure sensing devices for providing optimum load conditions.

A control panel is attached to the unit by a 50-ft (15-m) umbilical cord, allowing the operator access to all functions of the pneumatic system.

Pipelines generally are made of specially hardened steel, but also can be of mild steel, plastic, or fiberglass depending on the specific application required. They should be kept as straight as possible and also should be turned regularly to even out the wear that occurs primarily on the bottom of the pipeline. Elbows are designed with replaceable hardened steel bricks on the outer radius. These together with an impact section and an accelerator assure that the direction of flow is changed smoothly.

As the material flows along the pipeline, the larger particles tend to bounce along the bottom, with the fine particles being carried in the airstream and the intermediate particles in between. As the various sizes fall out of the airstream, saltation takes place. The material then forms slugs, which results in inefficient flow. To overcome this problem, devices called kickers are installed that direct the material back toward the center of the airstream, alleviating the problem.

For mine backfill systems, the material is ejected from the open pipe at high velocity and the air allowed to flow away freely. It is this property of a pneumatic conveying system that makes its application attractive for backfilling mine refuse in mine galleries, due to the compaction achieved when the particles impact on each other at the face of the placed material. This not only results in the maximum volume of material being confined in the minimum of space, but also helps to stabilize the support pillars and roof, which will reduce collapse and subsidence at the surface (Powell, 1982).

19.3.2.4 Advantages

Advantages of the method include the following:

1. Improvement of the face climate. The air delivered by a pneumatic system may be valuable for ventilation purposes.
2. In uranium mines, better control of radon gas emission is achieved. There is less air leakage through a tightly packed fill.
3. In coal mines, better control of methane gas may be achieved by better overall control of ventilation due to the high density fill.
4. Reduction of surface subsidence is possible, with as little as 13% convergence achieved in some European coal mines (Voss, 1963).
5. Reduction of internal mine damage, that is, damage to the mine structure. Bumps or bounces in coal mines and rock bursting or excess pressure on the workings can be controlled by high-density, early-bearing, pneumatically placed fills.
6. Use of underground development waste saves the cost of delivery to the surface and reduces the environmental problems of surface storage.
7. Problems of excess water in hydraulic fills are eliminated.
8. High-velocity impact yields high-density fill with good strength.

19.3.2.5 Disadvantages

1. If the pneumatic system is located underground (perhaps due to the great distance to surface), it will be necessary to provide a transportation system from surface for the fill material.
2. Dust from highly siliceous waste can be a problem in the stoping area being filled and may require additional ventilation.
3. Initial capital costs may be high due to the need for specially hardened steels in feeders, pipelines, elbows, fittings, and nozzles.
4. Operational costs are high due to the requirement for large volumes of compressed air and high wear on components.
5. Handling and placing of heavy pipeline and fittings can increase operational costs. However, it may be shown that the labor cost associated with the lighter pipelines may more than offset the added pipe cost (Soderberg and Corson, 1976).
6. High noise level at the blower requires special sound insulation.
7. Pneumatic filling is not well adapted to small crooked veins in cut and fill operations, for these reasons:
   a. The number of elbows causes increased wear, reduced velocity, and decreased density in place.
   b. Short time duration of filling compared to the cost of setting up and filling.
   c. Difficulty in producing a level working floor for clean-up purpose (Soderberg and Corson, 1976).
8. For an underground installation in a small mine, the equipment is large and difficult to move and set up. A semi-permanent installation is almost mandatory.
9. The system may be restricted to surface installations due to the size of equipment and accessibility of materials. This may result in excessive power use and high cost of delivery due to long lines.

19.3.3 HYDRAULIC FILL WITH DILUTE SLURRY

19.3.3.1 General

The first use of hydraulic fill is thought to have been in 1864 at Shenandoah, PA, when breaker waste and culm were slushed into old mine workings to protect the foundation of a church (Lightfoot, 1951). Shortly afterward, the method was applied to several eastern coal mines for area fill to control subsidence. In 1884, hydraulic backfilling was used to control a mine fire in the Schuylkill region of Pennsylvania.

The idea was taken to Europe by German engineers and developed, successfully, at the Myslovitz colliery in Upper Silesia in 1901. From there it was applied to several mines throughout Europe. The practice of area filling was taken to South Africa in 1909 to the Village Gold mine in the Transvaal.

At the start of World War I, mill tailings were being used for mine backfill on a limited scale in the Cripple Creek district of Colorado. By the end of the war, the method was introduced by the Anaconda Co. in Butte, MT, to fight mine fires. Since 1917, more than 7½ million tons (6.8 Mt) of mill tailings have been placed hydraulically in the Butte mines.

During the 1920s, many world mining districts used fill material placed as a slurry. The Matahambre mine in Cuba was one of the first to make extensive use of hydraulic backfilling as an integral part of their mining method. They also pioneered in the use of rubber-lined pipe as a transporting system.

Homestake Mining Co. was one of the first in the United States to exploit simultaneous hydraulic backfilling as a part of the mining cycle. In 1932, the company developed a method of handling its washed cyanide tailings in pipelines and introduced the sand portion for stope fill.

After World War II, many mines in the western United States and in Canada applied hydraulic backfilling methods, and developed mining cycles based on the use of classified mill tailings. This progress was due in part to the increased experience within the minerals industry in the handling of solids in liquid suspensions. The perfection of rubber-lined slurry pumps and the expanded technology of materials handling in pipelines, together with the application of wet cyclones for dewatering and desliming, led to economical applications in the mining field (Stewart, 1958).

Hydraulic fill may be described as a dilute slurry varying generally from 35 to 75% solids. There are, however, variations above and below these limits. The slurry may be pumped to the stoping area by various types of pumps or delivered by gravity flow.

A survey by the Fill Subcommittee of the Canadian Advisory Committee on Rock Mechanics (CACRM) indicated that hydraulic fill prepared from mill tailings is the most common material in current use. The 10,830,000 tons (9,824,976 t) of fill placed in reporting mines in 1971 consisted of 8,240,000 tons (7,475,328 t) of hydraulic mill tailings, 1,370,000 tons (1,242,630 t) of rock, 870,000 tons (789,264 t) of hydraulic alluvium and 350,000 tons (317,520 t) of miscellaneous material including dry sand, slag, float, etc. Some 228,000 tons (206,840 t) of cement was used for floors and fill stabilization. Ninety percent of the ore involved was produced by mining methods using concurrent filling, and 70% of this ore came from overhand cut-and-fill methods. No fill was used primarily for subsidence control, although this and fire control are important applications of hydraulic filling in various parts of the world.

Wall support was recognized by all mines as the most important function of fill. Use as a working floor followed, with void filling and tailings disposal, as the third major use.

All mines indicated stabilization of the operating stope and adjoining pillar as a prime function of fill within the wall support category. Stabilization of access openings and boundary pillars is the next important function in small and medium mines, while large mines identify the stabilization of peripheral stopes and ore zones as a primary requirement. Control of surface subsidence was listed as the least important (Dickhout, 1973).

19.3.3.2 Sources

Of the several possible sources for hydraulic fill sands, the simplest is mill tailings, when the mine and mill are integrated. Alluvial sand or gravel deposits can also be considered as a source of fill material, when the mill is located at a distance from the mine, or when mill tailings are unsuitable.

Conventional backfill materials also include crushed mine waste, rock, glacial till, smelter slags, mixtures of mill tailings and –l-in. (25-mm) gravel, crushed open pit material, dune sand, and consolidated mill tailings, using cement or other binding agents. Mill tailings may be classified or unclassified, depending on the grind in the mill. The greatest fill strength is achieved when the material size gradient results in the maximum filling of voids between particles.

19.3.3.3 Preparation and Materials

Table 19.3.1 reports on a survey of plant operating conditions and describes typical hydraulic fills from 6 different mines. Several of these are no longer in operation, but the table illustrates the spread of classified mine tailings that can be used.

Typical screen analyses, for classified mill tailings, as used for backfill in the mining industry are shown in Figs. 19.3.9 and 19.3.10.

The following comments on the basic characteristics of various hydraulic fills are adapted from a paper by Dickhout (1973).

Corson in 1966 showed that unconfined compressive strength increases with increased cement use (Fig. 19.3.11). He also found that inclusion of minor amounts of dispersant yielded a significant increase in bearing strength of the leaner sand-cement mixes. Although this seemed important, there is no known application of the use of dispersants for this purpose in industry.

McCreedy and Hall, in 1966, reported further that fill, to which Portland cement in ratios of 1 : 30 to 1 : 20 had been added, behaves as follows:

1. Strength increases with age.
2. Strength increases significantly with increase in pulp density.
3. The percolation of acid mine water through the fill does not seem to affect the strength.
4. Using acid mine water to transport the cemented fill does not seem to affect the ultimate strength.
5. The various special Portland cements do not seem to produce any substantial differences in strength, as compared to conventional type 1 cement.
6. A Proctor needle can be used for determining the in situ compressive strength of the cemented fill.

Rawlings, Toguri and Cerigo, in addition, reported in 1966 that:

1. Compressive strength of cemented fill decreases with increased moisture content.
2. Permeability decreases with increased cement content.
3. Permeability decreases as curing progresses.

The Canada Cement Co., in cooperation with International Nickel Co. and Falconbridge Nickel Mines, carried out monumental studies confirming much of the earlier work, and introducing some new findings. Luka and Weaver in 1970 reported that:

1. Varying the fineness of Portland cement does not produce great changes in the strength of the cemented fill.
2. The addition of fly ash, to economize on the amount of cement required, is not particularly attractive.
3. The grain-size distribution of the tailings is significant.
4. Flocculants have beneficial effects on strength and percolation rate, and in reducing losses in the drainage water.
5. Curing temperatures of between 50 and 85° F (10 and 29° C) do not have much influence on the ultimate strength.

Further findings reported by Corson in 1970 include:

1. Compressive strength increases with increased cement content, but varies according to the properties of sand used. In lean mixes, the uniformity of the tailings material is the most significant factor.
2. Compressive strength increases more rapidly when dry cured than wet cured, which is the usual condition in the mine.

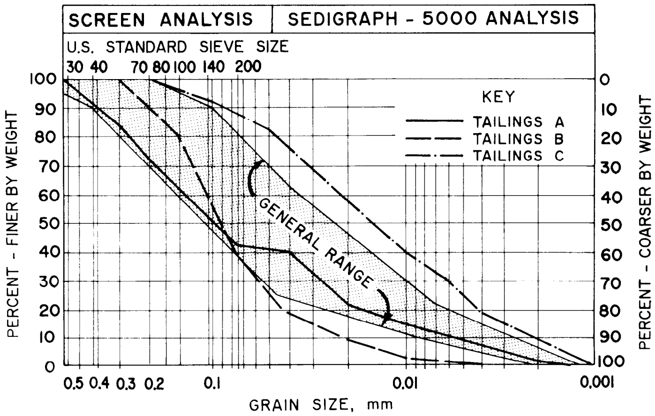

Fig. 19.3.9. General range of US metal mine tailings (adapted from Soderberg and Busch, 1977).

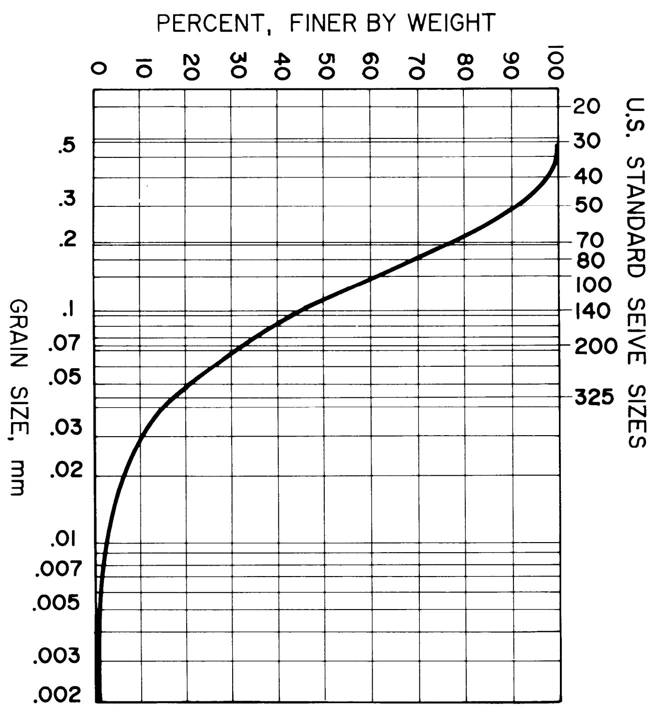

Fig. 19.3.10. Grain size distribution of a moderately well-graded fill (Dickhout, 1973).

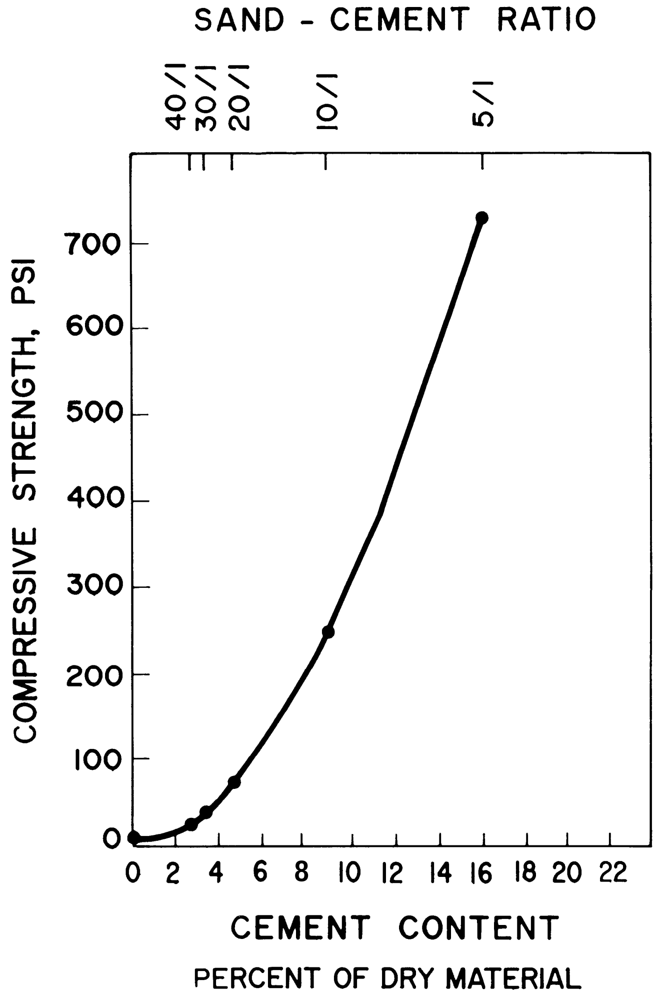

Fig. 19.3.11. Unconfined compressive strength vs. cement content (Dickhout, 1973). Conversion factor: 1 psi = 6.9 kPa.

3. Compressive strength is significantly higher in all sand-cement ratios, as density is increased by approximately 10 lb/ft^3 (160 kg/m^3).

4. Triaxial tests showed strengths increase with increases in either cement content or confining pressure. At a sand to cement ratio of 40 : 1, the finer material exhibited much higher cohesion than the well-graduated material, whereas the well-graded material had the larger angle of internal friction and was capable of supporting a higher normal stress.

Thomas, in 1971, published a comprehensive report on cemented-fill practice at Mount Isa, and again confirmed many previous findings as well as introducing new data, which included:

1. Moisture content decreases with increased cement content.
2. Void ratio decreases with increased cement content.
3. Compressive strength decreases with increased void ratio.
4. Compressive strength increases with increased fines addition.
5. At Mount Isa, ground copper reverberatory furnace slag, acting as a pozzolan, greatly increases the strength of cemented fill in proportion to the amount of slag added.

Nicholson and Wayment, in connection with vibratory compaction of mine hydraulic fill in 1967, reported that:

1. Probe-type concrete vibrators give effective compaction.
2. Density of fill increases with percentage solids by weight of fill poured.
3. Moisture of about 15% is optimum for vibratory compaction.
4. Fills with a uniformity coefficient of around 5 yield the lowest final void ratio after compaction.

Coates and Yu-in in 1969 further reported that the in-place density of most fills can be increased by modifying the grain-size distribution, and that by so doing, the following results were obtained:

1. The volume of stope tilled by 1 ton (0.9 t) is decreased, thereby increasing filling costs.

2. The stiffness of the fill is increased.

3. The percolation rate is decreased.

4. The amount of cement required for consolidation is decreased.

Corson, in 1971, reported on the field evaluation of hydraulic backfill compaction at the Lucky Friday mine. Measurements taken in adjacent stopes, one containing compacted fill and the other normal fill, showed the following:

1. The density was increased from 100 lb/ft^3 (1602 kg/m^3) to 104 lb/ft^3 (1666 kg/m^3) by compaction.

2. Pressures and closures, taken in both stopes, continue to increase with time.

3. Somewhat less strain was recorded on the 7th floor of the stope containing the compacted fill, than on the same floor of the stope containing the regular fill.

4. Pressure build-up was slower in the regular fill (Dickhout, 1973).

19.3.3.4 Applications

The hydraulic sandfill system at the Galena mine, near Wallace, ID, originally used unclassified mill tailings. Slimes were decanted from the top of the storage tanks, initially, but the method has been changed at present to cyclone classification.

The following comments are adapted from a paper by Suveg (1970).

The mill tailing was pumped at 20% solids from the mill by two 6-in. (152-mm), rubber-lined centrifugal pumps in series, driven by 25-hp (19-kW) motors through a 6-in. (152-mm) line, partly steel pipe and partly wood stave pipe, for a horizontal distance of about 850 ft (259 m) at a static head of 115 ft (35 m) into a surge tank. The tank had three conversion outlets and the tailings could be accumulated in either of the three 14- by 18-ft (4.27- by 5.49-m) steel tanks. Each tank initially had a 6-in. (152-mm) overflow pipe for decanting the slimes. The plant handled sand at a rate of 20 tph (18.2 t/h) at 70% solids.

Agitation was provided by both compressed air and by a 4-ft (1.22-m) diameter propeller-type agitator, driven at 110 RPM by a 30-hp (22-kW) reversible motor. Compressed air agitation was provided by eight peripheral nozzles and four bottom nozzles.

Compressed air at 100 psi (690 kPa) was introduced into the bottom nozzles and allowed to agitate for 10 minutes to free the propeller, then the agitator was started and the side nozzles turned on. After thorough agitation, the pour was started.

An independent telephone system was installed from the sandhouse to the stopes for communication. The sand was poured through a 3-in. (76-mm) standard pipeline. In the shaft, to minimize wear and maintenance, the 3-in. (76-mm) pipe was lined with ¼-in (635-mm) rubber. Sand presently flows by gravity, a vertical distance of up to 4900 ft (1494 m). Before a pour is started, the line has to be cleared. High-pressure water was injected for 30 seconds, followed by compressed air until the water reaches the stope. The sandman notifies the sand house operator and then bleeds back the line. After the line was cleared, water was introduced again into the line followed by sand. The pour was started at 70% solids and finished at 65%. One hour was required to pour one tank. Two tanks were poured in sequence. An average stope required 5 to 6 tanks of sand during each filling cycle. A sand pour had a percolation rate of 6 in./hr (152 mm/h), and this made it possible to blast the next cut on the following shift.

After the mining cycle was completed, the stope was cleaned out and a crib chute raised. Five-inch (127-mm) × 8-in. (203-mm) cribbing was used. The chute was burlapped and the stope filled (Suveg, 1970). Cement capping was used for several years, but was dropped about 10 years ago as being too expensive and ineffective due to loss of cement in the overflow from the stope.

In most flotation concentrators in the Coeur d'Alene mining district, the grind is fine enough to produce an excess of slimes in the sandfill. The slimes may be decanted but can also be removed by cycloning, as was practiced at the Star, Lucky Friday, Sunshine, and Bunker Hill mines. If too much slimes (– 325 mesh or 0.044 mm) are left in the fill, a layer of sticky clay will be left on the fill surface that is difficult to work on. An average 20 to 22% of –325 mesh (0.044 mm) material has been found to be satisfactory for a well-graded fill without excess slimes.

During the period from 1960 to 1985, the Lucky Friday mine near Mullan, ID. used the following system:

Tailings containing 71% solids were pumped from the mill with 4- × 4-in. (102- × 102-mm) rubber-lined centrifugal pump with a 20-hp (15-kW) motor through 902 ft (275 m) of 5-in. (127-mm) standard pipeline at 60-ft (18.3-m) static head. Two hundred forty gpm (15.2 L/s) was pumped at a velocity of 5.3 fps (1.62 m/s). This pump was started manually by mill personnel, but was shut down by remote control from the stope where sand was being poured.

Sand from the mill pump was delivered to a small constant-head receiving tank located over the main storage tank near the No. 2 shaft. A 3- × 3-in. (76- × 76-mm) rubber-lined centrifugal pump was fed by this tank and provided the pressure to operate two 10-in. (254-mm) diameter cyclones in parallel. The cyclone underflow containing 22% –325 mesh (0.044 mm) sand fed directly into the tank. Cyclone overflow was returned to the mill tailings line. The 18-ft (5.49-m) deep by 17½-ft (5.33-mm) diameter storage tank held 120 tons (109 t) and was excavated out of solid rock. It has a concrete bottom and a small raise connects to the manway compartment of the shaft. It is equipped with an agitator having a 48-in. (1.22-m) diameter, rubber-covered impeller, driven by a 30-hp (22-kW) motor at 95 rpm. Sand slurry was poured at 68 to 70% solids. The sand fill system was remotely operated. Four signals were transmitted each way over a single two-conductor, type 50, size 16 cable, utilizing 380 to 9900 cycle signals and transistor-operated relays. The receiver and transmitter units were developed to company specifications. The four signals from tank to control panel operate lights that indicate the following:

1. Storage tank full.
2. Storage tank empty.
3. Agitator operating.
4. Main slurry valve open.

The four-signal control panel to the tank was switch-operated and performed the following functions:

1. Close the solenoid valve controlling water pressure to the jacket of the main sand valve.

2. Operate the 2-in. (51-mm) solenoid valve controlling air to purge sand lines.

3. Operate the 2-in. (51-mm) solenoid valve controlling water to flush sand lines.

4. Close a system shutdown switch that operates a solenoid controlling pressure to an air cylinder on the slurry diversion funnel in the mill. This also initiates a timed automatic flushing cycle that clears the line from mill to storage tank.

The primary purpose for automation was to reduce the number of personnel required to operate the plant to one employee/shift and to give better control of pouring. This remote control system was in use from 1959 to about 1980 and has now been replaced by a high-density, consolidated-fill system (see 19.3.4.5).

A 2½-in. (62-mm) Victaulic standard-weight pipe with ¼-in. (6.35-mm) rubber lining to 2-in. (51-mm) I.D. was used for transporting the sand down the vertical shaft. Sand has been transported up to 5000 ft (1524 m) vertically and 2000 ft (610 m) horizontally with this system. Pouring rate was 40 to 50 tph (36 to 45 t/h), and the tank was filled at a rate of 16 tph (14.5 t/h). The stopes were untimbered and from 5 to 15 ft (1.5 to 4.6 m) wide.

The latest addition to hydraulic fill practice (1962 to 1970) was consolidation of the fill by cement addition. The first work involving cement addition was done by International Nickel Company followed by the Mayflower mine in Utah and the Homestake mine in South Dakota. Hecla Mining Company conducted experimental work at the Lucky Friday mine in 1962, but it was not until early 1964 that a decision was made to use cement-stabilized fill on a regular production basis in the mining system. The Lucky Friday operation was then equipped for developing a cement capping on top of the regular hydraulic sand fill. Pilot test work was successful and a system was installed. For many years, most operating companies in the Coeur d'Alene mining district used cement capping in their stopes. Cement capping provided substantial savings. Experience with hydraulic sand fill shows that 8 to 10 in. (200 to 250 mm) of sand are removed in conjunction with ore in the slushing cycle during the final clean out of the stopes. This indicated that the recycled sand amounted to 3.6% of the mill tonnage. Cement capping stopped this loss and increased the tonnage of ore put through the mill by an equal amount. Cement capping was placed at a ratio of 1 part type I Portland cement to 7 parts sand. The capping was placed at an average thickness of 6 in. (150 mm). This provided a good clean-up surface for the overhand mining method used. The first floor on each level was poled over with 6-in. (150-mm) diameter timber and filled to within 18 in. (0.46 m) of the back with 1 : 20 ratio sandfill for consolidation. This provided a strong back to mine under from the level below.

In actual practice, some additional, hidden savings that appear to be quite substantial, were encountered. They are

1. Speed-up of stope clean-out after each cut.
2. No ore is lost in sand.
3. No sand in chutes to cause hang-ups.
4. Miners and supervisors devote more effort to obtaining level stope backs.
5. Sandmen are more particular about leveling out the sand pours.

The bulk cement was stored in a 10-ft (3-m) diameter by 20-ft (6-m) high cement silo equipped with an 8-in. (203-mm) by 8-in. (203-mm) rotary feeder and variable speed drive controlling the feed. The cement was fed into a fluidizing cone where it was slurried and then pumped through a 2-in. (51-mm) line into the 3-in. (76-mm) sandfill line in the shaft.

At the Galena mine, near Wallace, ID, an 8 : 1 sand to cement ratio was used for capping. The cemented sand has been found to have several applications in addition to capping stopes:

1. Stabilization of backfill in underhand mining.
2. Consolidation of the fill material in the initial pour of the first stope cut, to permit pillar removal.
3. Consolidation of fill material in intermediate stope drifts, or in any areas that will eventually have the ore mined from underneath.

The mining of irregular ore bodies or paralleling vein splits has also been improved with the use of cemented sand.

To summarize, cement is used in hydraulic sand fill mainly for two specific applications: (1) floor capping and (2) consolidation of fill material. These applications have resulted in substantial savings, improved grade control, and increased flexibility of mining methods (Suveg, 1970).

At Homestake Mining Company's Bulldog Mountain mine in Creede, CO, an undercut and fill mining method using LHD units was developed to mine a section of vein lying 50 to 80 ft

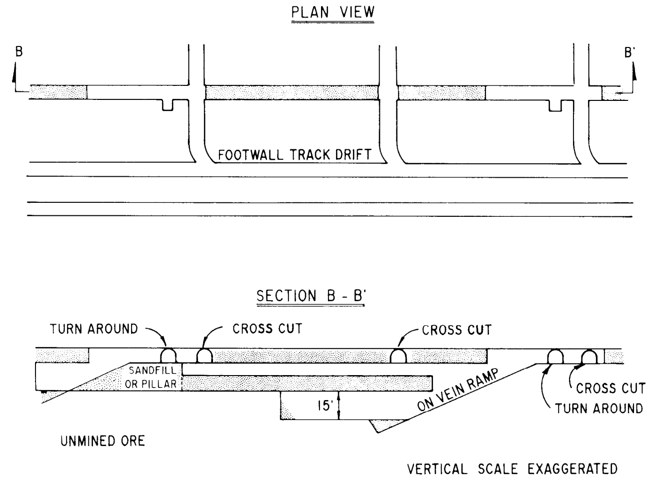

Fig. 19.3.12. Idealized on-vein LHD-UCF, no level below (Simonson and Logsdon, 1983).

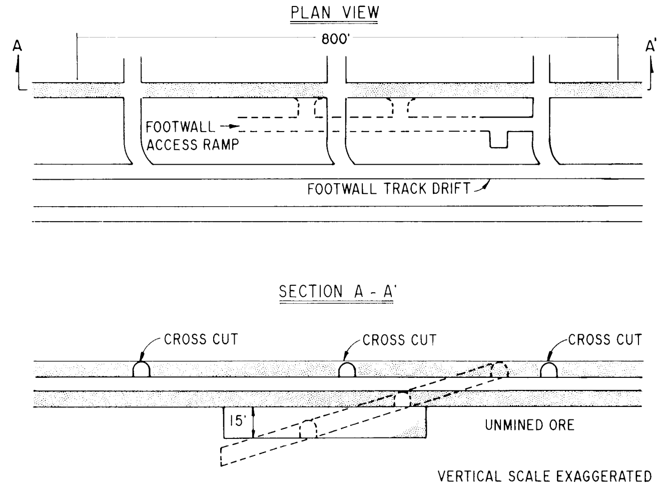

Fig. 19.3.13. Idealized off-vein LHD-UCF, no level below (Simonson and Logsdon, 1983).

(15 to 24 m) below the 9000 level. The underhand method was used because this block of ore did not justify driving a new level 150 ft (46 m) below the 9000 level. The original mining method at the Bulldog was ascending cut and fill but was changed to undercut and fill in the early 1970s due to the unconsolidated nature of the vein (Simonson and Logsden, 1983).

Both on- and off-the-vein ramping systems were developed, as shown in Figs. 19.3.12 and 19.3.13. Stoping cuts vary from 12 to 16 ft (3.7 to 4.9 m) in height, depending on the competency of the walls.

After a stope cut had been mined to its endline, it was prepared for sand backfilling. The stope floor was leveled with 6 to 12 in. (152 to 305 mm) of broken ore. This amount of ore was generally left as mining proceeded to maintain a smooth roadbed. In sandfill preparation, it was left to act as a cushion for the next lower stope cut. Round timbers 6 to 8 in. (150 to 200 mm) in diameter were then laid from wall to wall on 7-ft (2.1-m) centers. These timbers were set in hitches that had been installed in the walls and/or secured with $\frac{3}{8}$-in. (9.52-mm) cable

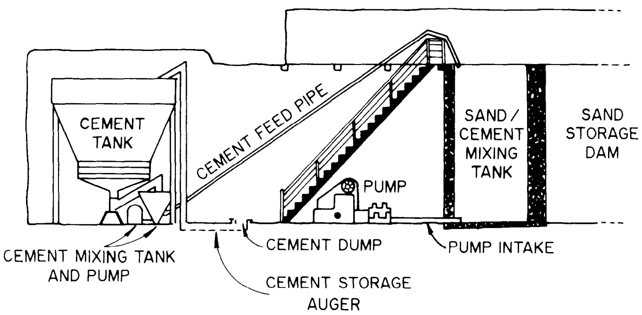

Fig. 19.3.14. 9700 sand plant. Bulldog Mountain mine (Simonson and Logsdon, 1983).

attached to an eye pin installed 4 ft (1.22 m) up the wall. (Often it is only necessary to hitch or cable tie the timber on the hanging wall and simply wedge the timber to the footwall.) Unmilled round timbers have recently replaced more expensive 8- by 8-in. (203- by 203-mm) milled timber in the sandfill preparation.

Chain-link wire was laid over the timber for the length of the stope. The wire was nailed to the timber and stretched along the floor between the timbers. Care was taken to get the timbers and wire on the floor. This allowed the cemented sand backfill to be poured with no danger of slabs hanging below the wire and timber on the next cut below. If the wire was stretched across the tops of the timber, as was previously the method, uncemented sand was poured first to fill this 8-in. (203-mm) gap. The sand then harmlessly fell out below the wire on the next lower cut. However, substantial ore dilution resulted from this layer of sand. The wire should be on the floor for improved grade control and safety.

A simple burlap covered bulkhead was constructed at the stope end. The bulkhead was designed to be as water tight as possible in order to avoid losing cement and sand through it. Clear water was decanted over the bulkhead and through the burlap. The hanging of 2-in. (51-mm) plastic pipe with distribution valves and hoses every 20 ft (6.1 m) completed the stope preparation. Backfilling began with a 3-ft (0.9-m) layer of cemented sand, followed by 4 to 5 ft (1.2 to 1.5 m) of sand. The desired cement-sand mix was 15% cement by weight. Through experience and testing, 15% cement was determined to safely provide enough strength to the mix. When the cement drops below about 10% by weight, its addition does not add appreciable strength to the sand. The strength is low due to low solids. The 4- to 5-ft (1.2- to 1.5-m) layer of sand was added to control wall movement, and add weight to the cemented sand layer, so as to eliminate lifting from blasting.

When the amount of cement in the backfill drops below the desired 15% by weight, failures in the stope backfill began to occur. Backfill failures cause safety problems, production losses, and grade dilution. The control and consistency of cement addition at the sand plant is most critical to the overall quality of the stope backfill. When failures began happening regularly, problems at the sand plant were apparent. The former auger system, conveying the dry cement to the mixing chambers was inadequate for mixing cement with the sand slurry. The system was inconsistent due to variabilities in the cement moisture and temperature, causing extreme variations of the feed rate. A steady, adequate flow of cement could not be maintained. To eliminate this problem, the auger was removed and replaced with a cement slurry pump. The dry cement is fed directly from the storage tank to the pump. A small amount of water is added to slurry the cement. This slurry is then pumped to the mixing chambers for addition to the sand slurry (Fig. 19.3.14). Cement flow control to the pump is from a variable speed auger in the bottom of the cement storage tank. The cement pump then maintains a steady, correct flow of cement to the sand mix.

The undercut and fill system at the Garpenberg Mine in Sweden is typical of Boliden's cut and fill mines. Ninety percent of the annual production is by undercut and fill. The ore body is irregular in shape with some areas that can be mined with drift and fill methods. The method of filling is as follows:

First about a 12-in. (0.3-m) layer of ore using the bucket on an LHD is leveled off. On top of this is placed ordinary building polyvinyl chloride (PVC) sheeting, which is followed by a layer of welded wire netting with about a 6- by 6-in. (15- by 15-mm) grid. The first pour is made 6 ft (1.8 m) high, and the area to be poured is bulkheaded off with a timber wall to retain the cemented fill. This wall is later extended to the roof for the completion of the pour, and the bulkhead is equipped with drainage water outlets. The drainage outlets are sealed with planks, as filling progresses, and the fill in progress has relatively clear decant water. The first 6-ft (1.8-m) pour is made with a ratio of 1 part cement to 4 parts sand, and is poured in one steady stage so as to achieve a uniform quality without stratified layers if possible. Then the remaining 8 ft (2.4 m) is sanded with a weaker cement ratio of 1 : 10 in the second stage. The pours are made as close to the roof as possible. This second pour can be interrupted if necessary. The lower 6 ft (1.8 m) is very strong, averaging 700 psi (4.83 MPa). The upper 8 ft (2.4 m) is softer, but the entire mass is a very strong beam. As the next floor is mined under this cemented fill, 5.2-ft (1.6-m) fully grouted rock bolts are placed in the lower 4.6 ft (1.4 m) of the fill to make sure it is bolted together to form a beam. The broken ore cushion serves to prevent damage to the sandfill, and the PVC sheeting serves to separate ore from sand. The wire netting strengthens the lower surface of the cemented fill in tension.

Ninety percent of the annual production at Garpenberg mine is through downward cut and fill mining.

The sandfill mixing plant is located on the surface in the mill, and mixing is a continuous process during the filling cycle (Fig. 19.3.15). It is automatically controlled and regulated. The capacity of the system is about 125 tph (113 t/h), and the water content is held at 30% plus or minus 1%. The fill is delivered hydraulically, and at 70% solids is about as thick as it is possible to handle. There are two 5-in. (127-mm) diameter feed lines, one of which is a reserve line with outlets at all of the mining levels. Cemented sand is delivered by means of a pump to the different stopes, and down to the current depth of 1641 ft (500 m) by way of horizontal transport drifts. The general sand plant is similar to that at other Boliden mine properties, with a bin for sand that has been filtered to about 15% moisture, a bin for cement, and a supply of water. These three items are mixed together in a paddle-type mixer, and delivered to the mine either by pump or gravity. Magnetic flow-meters control the mixture. Sand is fed from a bin by belt-feeder, and cement by an auger to the paddle-type mixing chamber. Weightometers on the belt control the amount of sand and cement, and the quantity of water supplied is measured with a water meter. The system is quite simple and easily automated. The slurry is pumped with a German-made concrete pump. There is little head against the pump, but an even flow rate is desired.

19.3.3.5 Advantages

When extensive use of hydraulic fill began in 1929 and 1930, the waste fill then in use was gradually replaced. Hence the advantages listed here compare hydraulic fill to waste fill in general. Advantages of hydraulic fill include the following:

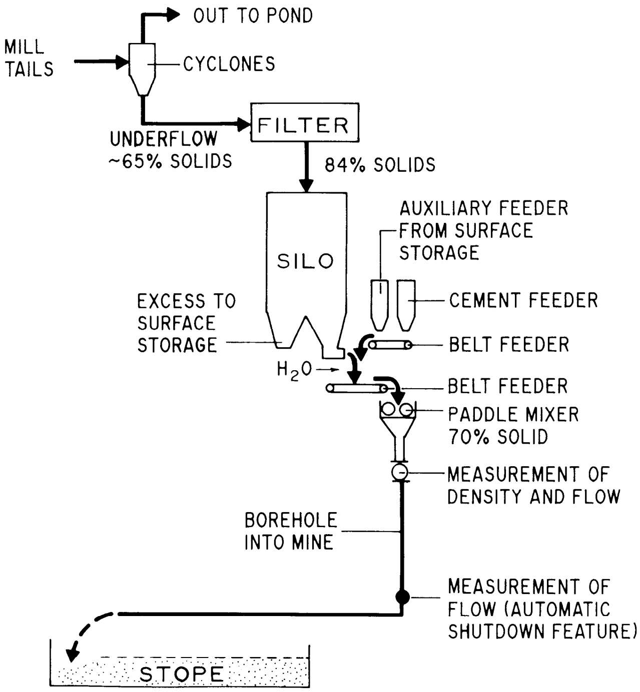

Fig. 19.3.15. Typical Boliden sand fill system (Brackebusch, 1984).

1. Better wall support is achieved as the hydraulic fill will flow tightly against irregularities in wall and back.
2. Overall pressure on the workings is reduced when the improved support reduces wall closure. This effect is enhanced when fill material is well graded so smaller particles fill voids. Addition of cement or other binder, of course, provides even greater strength.
3. Better ventilation control as much tighter seals are achieved.
4. When used with cement as a floor capping in overhand cut and fill stoping, a firm clean-up surface is provided. More fine ore is recovered, and little or no sand is recycled through the concentrator.
5. A good working surface is provided for mechanized mining equipment.
6. Surface storage and environmental problems are reduced.

19.3.3.6 Disadvantages

Hydraulic fill methods can have some disadvantages including the following:

1. If density is not maintained in the 65 to 70% range, excess water causes carry-over of slimes at the bulkheads, causing housekeeping problems, slime-filled sumps, wear on pumps, muddy haulage ways, equipment wear, and general disposal problems of slimes underground.
2. Excess water results in weak, stratified cemented sand fill and waste of cement when it washes over dams and bulkheads. If decant water containing cement gets into an ore-filled raise or pocket, plugging, hang-ups, or washouts will result.
3. There is a possibility of hydraulic failure if fill is not drained properly.
4. Slimes in sumps and shaft bottoms are difficult to remove.
5. Too dense a slurry can result in plugged pipelines.
6. High velocity in long, vertical pipelines can cause excessive wear. In deep mines, such as those in the Coeur d'Alene district of northern Idaho, ceramic-line-diameter reducers have been successfully used to overcome this problem.

19.3.4 HIGH-DENSITY BACKFILL

19.3.4.1 General

Development of high-density, consolidated backfills began in the 1970s and 1980s. Several considerations have led to the development of high-density backfills, consolidated or otherwise.

1. The excess water and slimes, associated with most hydraulic fills, cause wall deterioration in some mines with weak ground. Apart from this, there was a continual clean-up problem in ditches and sumps, as well as increased wear on pumps.
2. In deep mines with high wall pressures, a stronger, denser consolidated fill was advantageous to resist closure and reduce rock bursting.
3. In mines where high fill exposures were encountered in mining adjacent to the fill, a stronger consolidated fill was advantageous.
4. High-density, consolidated fill allows wider spans and a safer, stronger back in undercut-and-fill mining.
5. High-density fills allow the use of a greater proportion of slimes, thus reducing or eliminating the volume that must be impounded on the surface.
6. When cement is used, the low water content in high-density consolidated backfills results in maximum strength of fill, especially when the water content is just sufficient to hydrolize the cement. A water to cement ratio between 0.4 and 0.5 water to 1 part cement generally gives the greatest strength for the least cement.
7. Turbulent, high-speed transportation in pipelines may degrade a soft fill material and result in excess slimes in the fill. High-density pumped fills move at a much slower rate in the pipelines, reducing this problem and also reducing pipeline wear.

19.3.4.2 Sources of Material

It is entirely possible to "manufacture" a well-graded fill from numerous sources such as those described earlier for hydraulic or pneumatic fills. However, ordinary mill tailings are the most commonly used material today. This is primarily because the tailings are often readily available, fit the need for a graded fill, and also need to be disposed of underground to reduce environmental problems on the surface. Coarse rock, gravel, or development waste from surface sources, plus cement or other binders, may be added to prepare an even stronger fill than a straight tailings and slimes fill. The size range of coarser material will depend on whether the fill must be pumped with material of less than –1 in. (25 mm) or handled by gravity. In the latter case, particle size should be no larger than 1/3 the diameter of the pipeline used.

19.3.4.3 Preparation of Fill

The amount of fill preparation depends on the degree of support desired. If there is little or no wall pressure, and the requirement is simply to fill up the space, then total tailings with little attention paid to gradation might be used. If, in an overhand cut and fill system, a strong clean-up floor is desired, a graded fill with sufficient cement to provide a 600- to 700-psi (4.1 to 4.8 MPa) concrete may be necessary. In the case of the Lucky Friday mine, in the Coeur d'Alene mining district of northern Idaho, the wall pressure has been measured at 10,000 psi (69.0 MPa). The fill must be well graded, and 6% Portland cement is used.

Even solid concrete with a compressive strength of 3000 to 6000 psi (20.7 to 41.4 MPa) would not resist the wall closure until all voids are closed up. The mining method is being changed from overhand cut and fill to underhand longwall cut and fill. A system of 6- by 6-in. (152- by 152-mm) welded wire mesh and rock bolts, within the fill itself, is used to provide a strong, safe back as minor cracking of the 300- to 500-psi (2.1- to 3.5-MPa) cemented sandfill occurs.

It is apparent that sandfill must be designed to fit the requirements of the mine involved. Applications are presented in 19.3.4.5.

19.3.4.4 Delivery Methods

Because of the high density of the prepared fill, a positive displacement concrete or mud pump must be used to transport this fill material by pipeline. There are several existing systems at shaft-accessed mines, where the preparation plant and pump are located on the surface, with the pump and/or gravity supplying the pressure to place the fill in the stope. A secondary pump may be necessary underground if horizontal distances are too great.

The preparation plant can also be located underground with materials delivered separately to the site. Cement can be delivered pneumatically by pipeline or in bulk. Mill tailings with or without gravel can be delivered as a dilute slurry and dewatered prior to mixing. Although no instance is known, pneumatic delivery of tailings, sand, gravel, and cement should be possible.

Cement can be added either at a surface preparation plant, an underground preparation plant, or near the end of the delivery line in the stope. Adding the cement near the end of the line as a slurry prevents problems with line plugging and allows the line to be left full of high-density fill (82 to 87% solids) for hours or even days if desired. Only a slight increase in pumping pressure is required to start the material moving again after a shutdown. The high proportion of –325 mesh (0.044 mm) material in the fill makes the mixture thixotropic and provides a lubricating layer on the walls of the pipeline, reducing friction. Segregation of such material does not occur in the line or after placing in the stope.

19.3.4.5 Applications

Some of the earliest work on thickened backfill was begun in 1972 at Cambridge, Ontario, Canada. The following comments are adapted from a paper by Wayment (1978).

At this time, studies began toward the development of continuous or nonexplosive underground hard-rock mining systems. This led to the conclusion that a complementary technology had to be developed involving a support system that would fit the proposed mining system. Consequently, a new type of centrifuge or dewatering machine was developed that used either classified or unclassified mill tailings for feed at an optimum density of 60% solids by weight (Fig. 19.3.16). The centrifuge was found to operate most efficiently on unclassified tailings. Underflows from 76 to 85% solids, by weight, were achieved using various tailings. The centrifuge overflows contained from 5 to 15% of feed material that had to be either settled and stored underground or pumped out with the mine water. A second stage of centrifuging reduced the size of the overflow particles to –20 μm.

In the test process, 3% or more cement was added to the centrifuge underflow material. This lowered the water content by 1 to 2%, and consequently, the material exhibited considerable cohesion and behaved very much like a stiff mortar.

Fig. 19.3.17. Unconfined compressive strengths, 28-day (Wayment, 1978).

In the fall 1976, a semi-portable surface test plant was built at Anglo American's Western Holding, Ltd. mine in South Africa. Satisfactory underflow material was produced from these mill tailings. Two centrifuge units were then placed underground for initial trials. Cement was added to the underflows and used to fill an operating stope.

A wide range of unconfined compressive strengths for various cement mixtures, with centrifuge underflows from three different tailings, is shown in Fig. 19.3.17. Considerably higher strengths were achieved than are normally obtained, when equivalent amounts of cement were added to unthickened tailings with excess water. As in concrete technology, strength increases as the water-cement ratio decreases. In concrete work, a weight ratio of water to cement of 0.4 to 0.5 : 1 produces a strong concrete. With materials as fine as tailings with vastly increased surface area, the increase in strength is even more pronounced. A difference can even be detected between classified and unclassified tailings, with the latter producing the higher strength fill for a given amount of cement (Wayment, 1978).

The following comments are adapted from a paper by Patchet and Currie (1982), describing the Anglo American installation at Western Holdings, Ltd.

The system uses slurry transport, dewatering centrifuges, and positive-displacement placing pumps. The fill material ranges from 76 to 79% solids by mass and is placed tightly

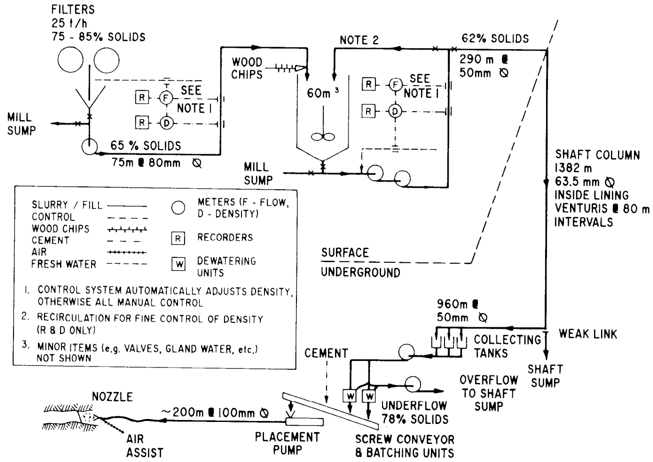

Fig. 19.3.18. Schematic flow chart of the prototype system (Patchett and Currie, 1982). Conversion factors: 1 ft = 0.3048 m, 1 gpm = 0.0631 L/s.

between hanging walls and footwalls, without shuttering or confinement, by use of air-assisted nozzles.

The system is cost-competitive with conventional support systems on a direct replacement basis. All the operation, basic repair, and maintenance are performed by typical mine labor. The system has an acceptable level of mechanical availability. The use of reduction plant tailings (RPT) and a slurry transport system using physical dewatering was chosen for the following reasons:

1. RPT are readily available on all mines.
2. RPT are produced as a matter of course, and do not incur any additional preparation costs.
3. RPT produce an excellent fill material provided the water content and density are controlled.
4. The transportation of RPT is proven, simple, low in cost, and entirely separate from all other transport and handling systems. It is readily suited to the placing of relatively small quantities of fill to a number of sites simultaneously.
5. The storage of slurry is relatively simple and cheap.
6. Dewatering centrifuges are fairly simple to operate, and provide a well-graded fill material of low water content. Positive dewatering eliminates decant or drain-water problems into stope faces, gullies, and boxholes.
7. Cement is added at the latest possible stage, which greatly reduces the possibility of setting in pipelines.
8. Pneumatic placement by means of hose and nozzle eliminates the need for shuttering on the face, ensures a uniform tight fill, allows placement at the earliest opportunity, and does not interfere with other operations on the face.

The trials and operation of the system lasted about 13 months, and during that period, some 1500 tons (1360 t) of fill was placed in old stopes. Sufficient data and operating experience were available to permit design and construction of pre-production equipment. A schematic flowchart of the system is shown in Fig. 19.3.18.

An examination of the fill some 12 months after its placement indicated that it does not slump, shrink, or crack, and a subjective assessment of conditions of old stopes in the area was that the fill area had closed slightly, but not nearly to the extent of the surrounding pack supported areas. Conclusions drawn from the prototype trials were

1. Slurry of controlled density can be prepared in a simple and easy manner.
2. The transportation of slurry is simple and effective.
3. Wear in slurry lines is negligible, even on sharp right-angle bends.
4. The ceramic venturis in the shaft column worked as designed and did not show any indications of wear.
5. The dewatering centrifuges worked acceptably well, but wear was a problem. A complete redesign of the centrifuge rig was indicated, both to simplify its construction and to improve its performance characteristics.
6. The placement pumps worked, but some fairly substantial changes were required to ease their repair and maintenance and improve their reliability.
7. Fill material could be placed without shuttering or other containment.

Preproduction trials followed in which four centrifuge and pump sets were installed on four stope panels with one common feed and waste system.

The system began operating in March 1980 with the installation of the first unit, and by June 1981 all four units were installed and 22,000 tons (19,960 t) of fill had been placed.

The existing shaft column was used, but the ceramic venturis have been removed. The column is rubber-lined, schedule 80, flanged pipe with a final internal diameter of 2.5 in. (63 mm.). It is run in a fully flooded condition, and the static head that develops at the bottom is used to drive the slurry approximately 1970 ft (600 m) to the storage facility.

The placement pump is an extensively modified positive-displacement concrete pump. The fill material is deposited in the hopper, and a small amount of cement is added by the use of a small belt conveyor. The hopper-agitator produced acceptable mixing. The material is then pumped to the desired placement location in the stope panel. Each site can serve several panels, and semi-permanent 4-in. (100-mm) lines are run to each. Relatively rapid changes can be made simply by changes between lines, at the dewatering site. The initial length of each line is high-pressure, lightweight, concrete placement pipe, but nearer the ends, as pressure permits, standard victaulic pipe is used. At the end of each line, a length of 2-in. (50-mm) hose is used with an air injection nozzle. Compressed air is added at the nozzle to break up and to impart momentum to the fill material, thus ensuring a dense backfill that fills all the irregularities, particularly in the hanging wall.

The slurry side of the system worked extremely well. The pipelines and shaft column presented no real problems. Initially, some difficulties were encountered with the glands of centrifugal pumps where little or no gland water can be used for reasons of density control. However, the selection of suitable packing materials, along with hard-coated shaft sleeves, has alleviated the problem. Agitation of the flat, low-slurry storage dams with compressed air has proved unsuccessful, and it appears that mechanical agitation is preferable. Air agitation does work, and would probably be successful in a vertical storage facility such as a bored raise.

The dewatering units have given a variety of problems but represent a significant advance over the prototype. Repair and maintenance have been eased, and the operation simplified. A considerable number of further design changes to both the centrifuge and the rig have been recognized. Most of the changes are in detail rather than in concept, but they should yield an improvement in mechanical performance equal to that achieved over the prototype when they are implemented on the next generation of equipment.

The placement pumps were completely redesigned after the prototype trials. As a result, repair and maintenance are much easier and faster. In both the dewatering rigs, the fill system is competitive with current support techniques on a direct replace-

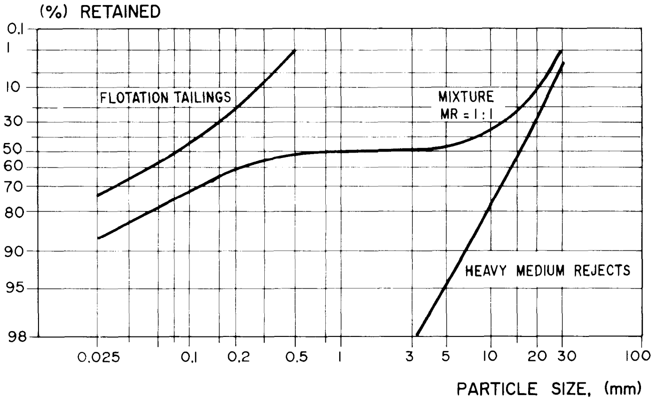

Fig. 19.3.19. Size distribution of pumped fill mixture (Lerche and Renetzeder, 1984). Conversion factor: 1 in. = 25.4 mm.

ment basis. The cost benefits would be greater at a lower stoping width, where a lower percentage filling by area is possible.

Trials of the production equipment result in these conclusions:

1. The use of slimes to produce a fill material of acceptable density and moisture content is possible.
2. The preproduction system described is capable of operating at acceptable placement rates in a production environment.
3. All the mechanical aspects of the preproduction system are acceptable. A variety of design improvements have been recognized, which should further increase the reliability by a significant amount.
4. The system can be operated and basically maintained using unskilled labor. The amount of supervision required is reasonable and acceptable.
5. The management of a fill system requires careful study if acceptable levels of capital expenditure and utilization are to be achieved.
6. The use of fill is cost-competitive with conventional support on a direct replacement basis (Patchet and Currie, 1982).

Preussag of West Germany published a paper in 1984 (Lerche and Renetzeder, 1984) describing the pumping of a high-density, concrete-like mixture of fine tailings and coarse rejects at the Grund mine. The system was developed between 1978 and 1983 to provide a satisfactory fill from available materials for cut and fill mining. Wall rocks are incompetent at the Grund mine, and sublevel caving methods in use during the seventies resulted in lower ore grades due to dilution.

Hydraulic filling was not considered due to degradation of shale particles from turbulent flow in the delivery lines. Excess slimes caused insufficient drainage, and desliming on the surface presented a storage problem.

Development then began on a high-density, low-turbulence, piped system similar to those used for conveying of concrete in the construction industry. The following decisive advantages of the pumped fill method were seen:

1. The fill materials available were fine and coarse mill tailings 0 to 0.012 in. (0 to 0.3 mm), and heavy media rejects from 0.12 to 1.18 in. (3 to 30 mm) in size (Fig. 19.3.19). The size range is almost complete so the packed fill material attains a density of 1.76 tons/yd^3 (2.1 t/m^3), resulting in excellent supporting properties.
2. The low moisture content of 12 to 15% means there is no excess water in the fill to weaken the natural rock bond, and there is no seepage of mud into the development workings and stopes.
3. Residual water is bound by cement. Owing to the low water content, addition of 3% cement (near the end of the pipeline) is sufficient to obtain a uniform compressive strength of 290 psi (2.0 mPa).
4. Because of these fill properties, mining methods can be better adapted to the conditions of the deposit (parallel slicing, underhand stoping, etc.), and the need for temporary ground support such as timbering is reduced or eliminated.
5. Stabilized rock conditions, owing to the high quality of the fill, leads to a reduction of ore dilution.
6. In conveying the fill material, a highly consistent mixture is formed that can be pumped uninterruptedly from the mill to the stope over a maximum of 6500 ft (2000 m) of pipeline, depending on pump pressure (294 to 1911 psi, or 2.0 to 13.2 MPa) and/or hydraulic profile, at rates of 26 to 40 yd^3/hr (20 to 31 m^3/h).
7. A flow velocity of up to 2.28 fps (0.7 m/s) is used, that results in minimal pipe wear.
8. The proportion of ultra-fine grains (< 0.001 in. or 0.025 mm), amounting to 10 to 15%, has a major influence on the pumpability of the mix. Under pressure, a lubricating film is formed at the wall of the pipe that reduces friction and saves energy.
9. The ultra-fine particles show thixotropic properties that provide a high degree of protection against settling out, so that the mixture may be left standing in the pipeline over several days and still remain pumpable.
10. The disposal of mill tailings in the workings, including slimes, clearly alleviates the problem of surface disposal of waste.
11. In favorable circumstances, the requirement for tailings disposal on the surface may be fully eliminated with concomitant cost and environmental benefits.

The pumped-fill process characteristically involves a high-density suspension of heterogeneous mixed solids that are conveyed in a pipeline. At the Grund mine, the fill materials available are substantially dewatered and mixed in the ratio in which they arise (approximately 1 : 1) to form a concrete-like mixture. To avoid blockages, the volume of fine material must always exceed the theoretical pore-volume of the coarse fraction. In addition, the consistency must be regulated so as to insure plug flow. A certain degree of segregation of the slime fraction occurs in the pipeline under pressure whereby the slimes tend to migrate to the low-flow region immediately adjacent to the side walls. This is clearly a welcome rheological effect.

Preparation of the fill on surface is shown in Fig. 19.3.20 and involves the dewatering of the heavy-media rejects to 2 to 3% moisture and filtration of the flotation tailings to 18 to 20% moisture.

The composition of the mix is controlled by belt-weighers (10 and 13), defined in 5-second cycles by the flotation tailings flow. The required quantity of coarse material is regulated by a variable feeder.

Final mixing is currently done by a twin-screw mixer (16). This mixture contains, basically, 12% moisture, but minor amounts of water may be subsequently added to achieve the best consistency for the particular requirements, dictated largely by conveying distances.

The surface pumping station (Fig. 19.3.21), houses a twin-piston concrete pump (3) with a power output of 215 hp (160 kW) and designed for delivery pressure of 1838 psi (12.7 MPa). Ahead of the pump is a mixer (1) and provision for measuring the pulp consistency (2).

The flexibility of a hydraulic transport system allows the fill to be brought directly to the working place, even in the confined

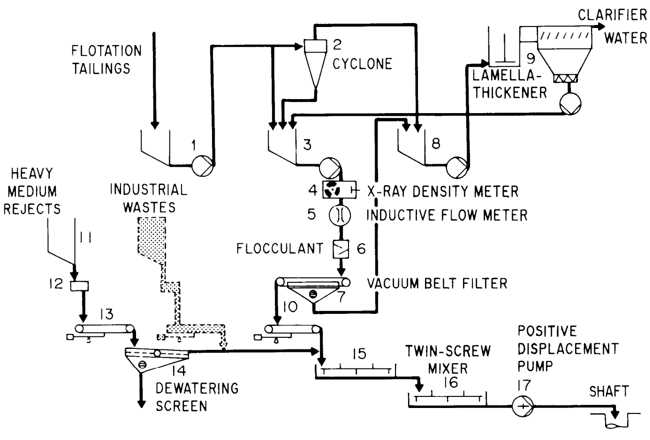

Fig. 19.3.20. Preparation of pumped fill (Lerche and Renetzeder, 1984).

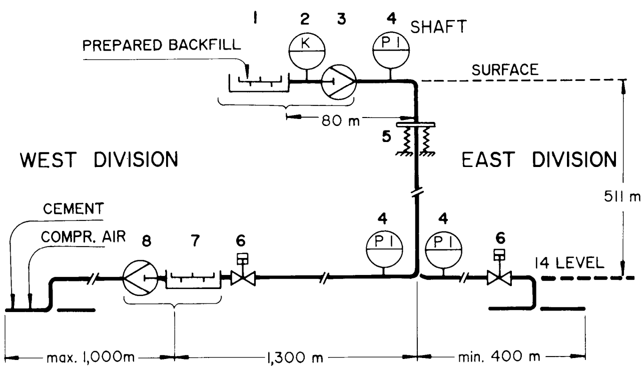

Fig. 19.3.21. Pumped-fill pipeline layout, surface and underground (Lerche and Renetzeder, 1984). Conversion factor: 1 ft = 0.3048 m.

conditions occurring in the cut and fill stoping of narrow veins. The cement to bind the fill and the contained water is injected immediately ahead of the pipe discharge as a slurry. The cement requirements are dictated by the moisture content and mining conditions. In general, 3 to 4% by weight is sufficient to yield a fill strength of 218 to 290 psi (1.5 to 2.0 MPa). The higher value is needed only when underhand stoping is in progress.

It is planned to replace the wet-dosing of cement by a pneumatic system. The dry method results in a stiffer mix that has a steeper angle of repose and facilitates the recovery of pipes and temporary supports.

To insure thorough mixing of the cement, a small injection of compressed air is made near the discharge point. This has the added function of increasing the throwing range and simplifying the task of packing the fill well up to the roof or backs.

A considerable amount of engineering, laboratory, and other test work was done by Preussag to determine the appropriate water content for mill tailings and coarse heavy media reject in order to arrive at the optimum of 12% moisture. This was determined to give maximum fill strength with a minimum cement use of 3%. It is apparent that similar test work must be done on fill material available at any mine in order to arrive at the lowest possible cement use for the fill strength desired.

Test work with pumped pipeline loops is also necessary to determine the pipeline sizes, pumping equipment, pumping rates, and fill density to design the optimum plant for a particular mine.

A high-density, consolidated fill system has also been developed at Lucky Friday mine near Mullan, ID. The following comments are adapted from papers by Brackebusch and Lautenschlauger (1988), and Noyes, Johnson, and Lautenschlauger (1988).

The Lucky Friday mine is developed by a 6200-ft (1890-m) deep primary shaft and a 5300-ft (1615-m) deep secondary shaft. The vein is near vertical, S-shaped, and has a strike length of approximately 2400 ft (732 m). Vein width averages 8 ft (2.4 m) with the maximum width less than 30 ft (9.1 m). Wall rocks are argillites, quartzites, and siltites of the Proterozoic age, Belt Supergroup. Within this group, the most productive horizon is the Revett-St. Regis stratigraphy. The Lucky Friday vein is a replacement vein containing the sulfide minerals galena, sphalerite, and tetrahedrite. The gangue minerals are quartz and siderite.

Historically, the mine has been developed on 200-ft (61-m) level intervals with drifting on the vein in early years, and by a lateral and crosscut system in recent years. Prior to 1958, waste fill was used and after that a hydraulic sandfill system with mill tailings. Mining was by overhand cut and fill stoping with horizontal slices of about 8 ft (2.4 m.). The Lucky Friday mine is currently in transition from the above system to an undercut and fill system using longwall geometry. During the period 1983 to 1986, a high-density, consolidated-fill system was developed to meet the requirements of this underhand method.

The Lucky Friday vein is enclosed in the brittle quartzites of the Revett formation. The vein strikes nearly parallel to the strata and dips steeply, ranging from 70° southerly to vertical.

The Coeur d'Alene District is located in a region of high horizontal stress, the maximum horizontal stress being about 1.5 times the vertical. This stress is nearly perpendicular to the plane of the vein at Lucky Friday. The high, horizontal stress field and the brittle quartzite rock together make the Lucky Friday a burst-prone mine. Bursting became common as the mine approached 3000 ft (914 m) in depth, and burst incidence has generally increased to the current stoping depth of about 5000 ft (1524 m). Failures are associated with stress concentrations caused by overhand stoping. The remnant of stope pillar between the stopes back and the mined-out area above has extremely high stress concentrations, due to magnification of the already high concentration of horizontal stress. Review of South African mining practice on the Witwatersrand indicated that the energy release rate associated with rock bursting could be reduced by the use of an undercut and fill system, using high-density, consolidated fill with a longwall configuration of stopes. It was apparent that the backfill system was the most important part of the undercut and fill mining system. Considering the weak wall rocks, rockbursting problems, the need for an underhand, longwall-type mining method with improved safety, and the many problems associated with dilute hydraulic sandfill in a deep mine, the selection of high-density consolidated fill for underhand mining was a logical conclusion.

In 1983, a formal research program was begun to test the new mining system called LFUL for Lucky Friday Underhand Longwall. A pilot stope was developed on the 5100 level using a footwall ramp and orepass with diesel LHD units for haulage. After testing and research on backfill system design, a new backfill plant was to be built.

A three-way cooperative agreement was made between Hecla Mining Co., the US Bureau of Mines Spokane Research Center and the University of Idaho College of Mines and Earth Resources. The latter two agencies performed much of the test work and assisted in many phases of the underground test stope.

Principal tests performed to aid in designing the backfill plant included the following:

1. Dewatering tests in a pilot scale dewatering plant using a thickener and disk filter. About 200 tons (188 t) of tailings containing 14% moisture were made. The size distribution was approximately:

Fraction	% Retained
50 mesh	1
70	3
100	8
140	13
200	18
325	22
−325	35

2. A surface pipeline test loop was set up. The line was 600 ft (183 m) long, using 4-in. (102-mm) standard pipe. A concrete pump such as is used in the construction industry pumped a tailings-cement mixture around the loop at rates from 30 to 60 yd^3 (23 to 46 m^3)/hour with slumps varying from 9 to 10 in. (22.9 to 25.4 mm) to 3 to 4 in. (7.6 to 10.1 mm). Pump pressures varied from 200 to 600 psi (1.4 to 4.1 MPa).

A model stope was set up on the surface and pumped full of cemented backfill. It was apparent that a hard, consolidated backfill could be produced from a tailings-cement with low-slump mixtures.

3. Flow of the high-slime tailings in bins and silos was tested and found to be a problem. Some compromise was, therefore, made with the amount of slimes included. Visual examination of different mixtures indicated those that would be a problem due to thixotropicity, the characteristic of converting from a solid when handled.

This work indicated that storage in a bunker rather than a silo was less risky. Also the decision was made to classify about 60% of the tailings slurry feed in order to facilitate the handling of dewatered tailings by conventional means.

4. Pneumatic conveying systems were reviewed for underground delivery but it was planned to use an existing 6-in. (152-mm) pipe column in the shaft in order to reduce costs. This line would not deliver the desired rate of 125 tph (113 t/h). In addition to the size limitation of the 6-in. (152-mm) shaft column, a pneumatic system was not tested because of the higher cost of conducting adequate tests, the concern due to higher energy costs, and because of abrasion due to high flow velocities.

Fig. 19.3.22 is a flowsheet of the consolidated fill plant. Two independent functions of the plant are:

1. Classifying and dewatering tailings.
2. Weighing, mixing, and pumping backfill.

Mill tailings are delivered to the dewatering section by centrifugal pump. About 40% by weight of the tailings go directly to the thickener where flocculent is added. The remaining 60% is cycloned with the overflow going to tailings disposal. Thickener feed and backfill have the following approximate size distribution since no further solids are removed:

Fraction	% Retained
70 mesh	15
100	17
140	15
200	13
325	13
−325	27

The thickener overflow is clear water, and the underflow is 60 to 65% solids, which is pumped to a vacuum drum filter. The filter produces fill material at 12% moisture that is then conveyed to a bin storage area. During the research stage, this bin was 20 ft (6 m) deep by 30 ft (9.1 m) wide by 40 ft (12.2 m) long with provision to increase the length for more storage as desired.

The dewatering section operates when the flotation concentrator is operating. The backfilling section of the plant is an intermittent process that is operated when stopes need to be backfilled.

During tests, the fill material from the bunker was fed to the mixing section by a front-end loader. Later, as the system became fully operational, a remotely operated multiple bucket reclaimer was installed, and the bunker capacity increased to 3000 tons (2123 t). Cement is conveyed from a silo to a separate weigh hopper, feeding into the mixer. A process control computer controls the conveyor to the weigh hopper, based on desired batch weights. The conveyors are automatically started and stopped during the preparation of batches.

The weighed portions of sand and cement are dropped into a high-intensity, paddle-type concrete mixer, where water is added under computer control. After a 2 yd^3 (1.5 m^3) batch is mixed, it drops into a pump hopper. The pump is a 125-tph (113-t/h) capacity concrete or sludge pump. The entire weighing-mixing-pumping process is controlled by the computer. Operating strategy is to produce a consistent, defined mix. The pump operating rate is controlled manually, and the computer provides mix to the pump as required by the pumping rate.

An 8-in. (203-mm) pipeline about 200 ft (61 m) in length connected the concrete pump to the 5100-ft (1554-m) long, 6-in. (152-mm) vertical line in the Silver Shaft. An 8-in. (203-mm) line about 2000 ft (610 m) in length, connected the shaft line on the 5100 level to a point near the pilot LUFL stope. The line used in the stope was 6 in. (152 mm) in diameter.

Mix design involved testing of a range of relatively liquid to stiff mixtures to obtain a given backfill strength of approximately 300 psi (2.1 MPa) unconfined compressive strength. A range of mixtures can be used; however, the stiffer the mix, the less cement content is required to yield the desired compressive strength. A more liquid mix requires a much higher cement content to yield the desired compressive strength. The liquid mix was termed the "Garpenberg" style after Boliden's Garpenberg mine in Sweden, which used a similar mix. Table 19.3.2 shows some of the specifications and properties for the different mixes.

A continuous range of mixtures between the stiff and Garpenberg styles can be produced using intermediate values of the specifications shown in the table, but all yield similar compressive strengths. As the mix becomes more liquid, there is a greater tendency for segregation of cement in the stope. Precisely controlled, high-density slurry avoids this problem.

After the completion of the new consolidated fill plant, initial pumping tests were conducted. The first testing involved calibration and observation of the equipment in operation. After the plant was checked out and problems corrected, loop pumping tests commenced. A pipe loop 463 ft (141m) in length consisting of 6- and 8-in. (152- and 203-mm) pipe was included with the new plant.

Besides the need for equipment operational data, two basic reasons for the loop tests were to determine friction factors and to determine the effects of time on fluid and pumping characteristics.

The results of the friction factor tests were particularly interesting:

1. Pressure loss due to pump hammer was greatest near the pump and decreased at greater distances from the pump. Pump hammer loss was greater with stiff mixtures, but effects were

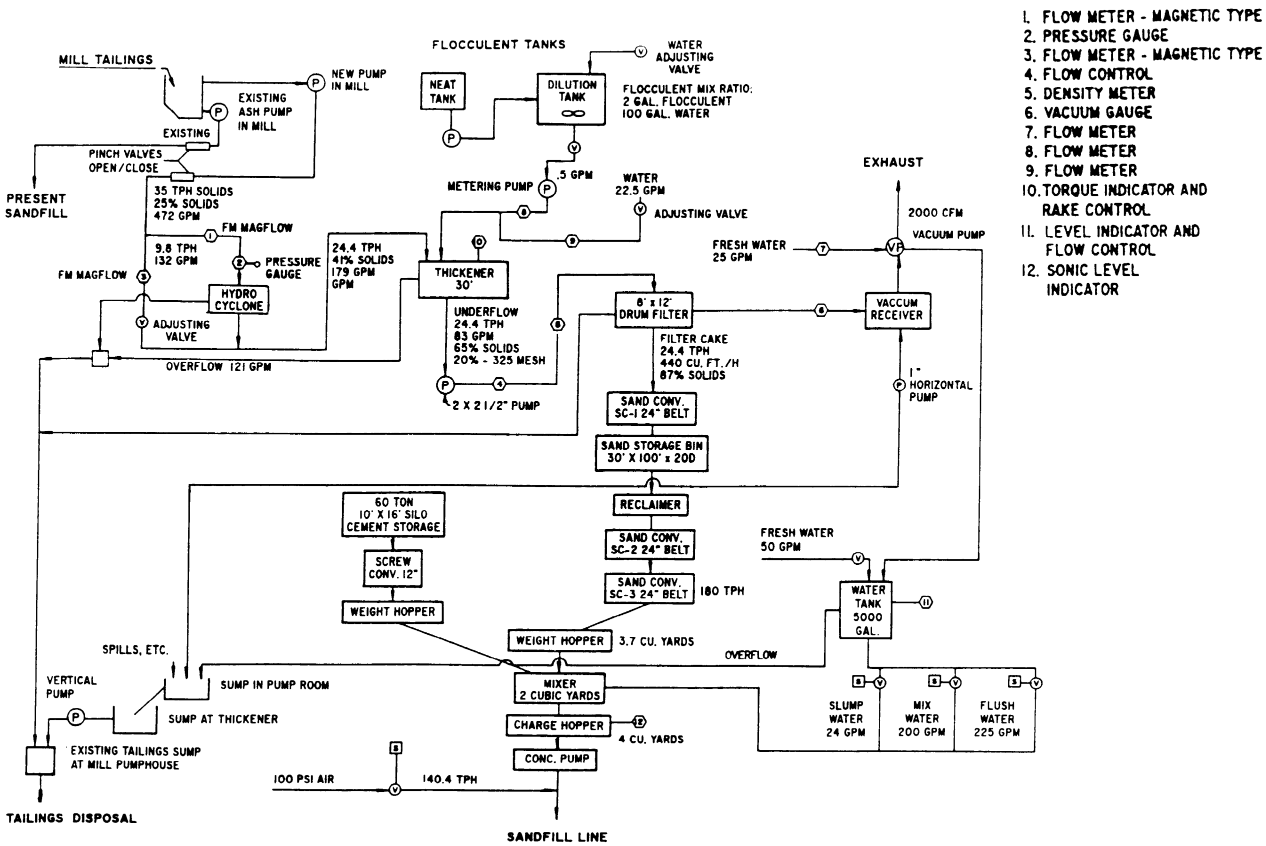

Fig. 19.3.22. Lucky Friday mine, underhand longwall consolidated-fill flowsheet (Brackebusch, 1988). Conversion factors: 1 ft = 0.3048 m, 1 ton = 0.9072 t, 1 yd^3 = 0.7646 m^3, 1 gpm = 0.0631 L/s, 1 psi = 6.895 kPa, 1 gal = 3.785 L.

Table 19.3.2. Mix Specifications and Properties

Specification/ Property	Very Stiff	Mod. Stiff	Garpenberg
Cement content	4%	5.7%	18%
Solids density	83%	82%	74%
Slump, in./mm	3/76	9/229	12/305
Minimum pipeline dia., in./mm	5/127	4/102	2/51
Cured strength, 28 day, psi/ MPa	300 to 440/ 2.07 to 3.03	300 to 500/ 2.07 to 3.45	300/2.07
Water-to-cement ratio	4.25	3.85	2.31

present for shorter distances away from the pump than with liquid mixtures.

2. With stiff mixtures, the pressure loss per foot in the 8-in. (203-mm) line was equal to or greater than the pressure drop in the 6-in. line (152-mm).

3. As pumping rate increased, using a stiff mixture, pressure drop increased in the 6-in. (152-mm) line, but was stable in the 8-in. (203-mm) line.

In the time duration test, a quantity of mix was pumped around the loop for two hours. The slump increased from 6 in. (152 mm) to 8.5 in. (216 mm), probably due to the time effects of wetting the surfaces of particles.

It was very evident from these initial loop tests that complex relationships exist when pumping thixotropic mixtures, but the loop testing showed that the desired mixes could be pumped at a reasonable pressure.

After the loop tests were completed, shaft pumping tests commenced. Backfill material was pumped down the 5100-ft (1554-m) vertical shaft pipeline and across the 5100 level to the LFUL stope. The total distance was about 7000 ft (2130 m), with about 2000 ft (610 m) being nearly horizontal.

A problem developed immediately, with mix falling at high velocities down the shaft pipeline and damaging the pipeline at the 90° curve on the 5100 level station. An impulse vessel was installed on 5100 level to absorb the energy of the falling mix, and at the same time, the shaft line was vented at the shaft collar. Problems with rapidly falling slugs of mix stopped with the venting of the shaft line, thus making the impulse vessel unnecessary. The presence of air in the line was cushioning the falling material, whereas before the pipeline was vented, the air was pushed out of the open pipeline in the stope, thus generating a vacuum in the shaft pipeline.

Pipeline failures in the 5100-level shaft station area were violent and caused considerable concern about the safety of the system. It was apparent that the pipeline had not been assembled and anchored properly. A test was conducted using a concrete pump on the 5100 station, which would be an inherently safer system because of the reduction in stored energy of a vertical pipeline containing a column of the backfill mix. The pipeline was opened up on the 5100 station and routed into the hopper of a portable construction-type concrete pump. Vertical flow with this setup was not a problem except that flow was intermittent and often overflowed the hopper of the concrete pump. However, the pump was unable to sustain the pressure needed to force the mix across the 2000-ft (610-m) horizontal distance of the 5100 level to the LFUL stope. The required pressure was about 500 psi (3.45 MPa) with 8-in. (203-mm) slump mix. This caused damage to the pump seals, which were then quickly eroded, disabling the pump. Line cleaning proved to be a problem for horizontal lines in the initial testing. Foam balls proved unsuccessful, as they tended to ride up over the material in the pipeline. Line cleaning worked best by pumping water immediately behind the mix. After the water emerges from the end of the pipeline, the line can be sparged with air and water to scour out any remaining mix in the pipeline. The sparging process consists of pumping water in slugs into the pipeline with the concrete pump while accelerating the water slugs through the pipeline with air pressure.

The results of these tests led to major modifications to the pipeline used for pumping stiff mixes which are described below. Meanwhile, the Garpenberg style backfill was being placed in the LFUL stope using the mine's existing 2- and 3-in. (51- and 76-mm) sand slurry pipeline, but supplied from the new consolidated backfill plant.

Because friction in pipes proved not to be as great as had been thought, smaller pipes could be used, thus simplifying pipe support and facilitating cleaning of the line. The pipeline in the 5100-station area was changed from 6-in. (152-mm) unlined steel to a 4-in. (102-mm), schedule 80, polyurethane-lined steel pipe for 150 ft (48 m), and the line was braced substantially. The impulse vessel was changed from 8-in. (203-mm) unlined steel to 5-in. (127-mm), schedule 80, unlined steel to the stope area. Four-inch (102-mm), schedule 40, unlined steel pipe was used for distribution to the stope. The stope distribution line has subsequently been changed to 4-in. (102-mm), schedule 40 steel. On the surface, the short pipeline between the backfill plant and the shaft was changed from 8-in. (203-mm) unlined steel to 4-in. (102-mm) unlined steel. The new pipeline configuration was designed to handle both stiff and Garpenberg styles of mix.

Certain plasticizers increase slump, at a given water content of a mix, and retard the initial set of the mix. Higher slump reduces pressure loss in pipelines. With the smaller pipelines to be used for both stiff and Garpenberg styles, it was decided to use an admixture with a resulting mix of 8 to 9 in. (204 to 229 mm) of slump for the stiff style.

The cement content of stiff style mix was set at 5% by weight of dry solids, with the goal of obtaining 300 psi (2.07 MPa) unconfined compressive strength in 28 days.

The Garpenberg style mix was not changed from that shown in Table 19.3.2.

After successful testing was completed for both stiff and Garpenberg styles of mix, the consolidated backfill plant was expanded to full-scale capabilities. This consisted primarily of enlarging the storage bunker and installing a reclaimer. The reclaimer drags buckets across the face of the sandpile and loads a conveyor that feeds the weigh hopper.

The backfill plant can produce up to 150 tons (136 t) per hour of operation. Typical results are shown in Table 19.3.3.

Flow in the shaft pipeline is smooth for Garpenberg style, but is intermittent for the stiff style. Thus flow rate into the stope with the stiff style also fluctuates. Apparently, slugs of fill build up in the vertical line in the presence of air "bubbles". Some of the air rises back up the vertical line to the vent, and some is entrapped and is emitted in the stope.

In placing of backfill in the stopes, the original objective was to fill the stope completely with consolidated backfill with no air space at all between the new lift of fill and the previous roof. While this may be a good objective, it has not been attained in practice. Actual practice leaves about an 18-in. (0.457-m) space that amounts to 15% of the mined-out void. With a stiffer backfill mix, the unfilled space can be reduced somewhat.

Table 19.3.3. Typical Operating Conditions

	Garpenberg Mix	Stiff Mix
Consistency, slump, in./mm	12/305	9/209
Pumping rate, strokes/min	12	10
Yd^3/hr (m^3/h)	110 (84.1)	92 (70.3)
Dry tons/hr (t/h)	118 (107)	122 (111)
Pump pressure, psi	150 to 200	175 to 225
Pump pressure, MPa	1.0 to 1.4	1.2 to 1.6
5100 station pressure, psi	300 to 400	700 to 800
5100 station pressure, MPa	2.1 to 2.8	4.8 to 5.5
Velocity, 4-in. line, fps	9.5	7.9
Velocity, 4-in. line, m/s	2.9	2.4
Velocity, 5-in. line, fps	6.1	5.1
Velocity, 5-in. line, m/s	1.9	1.6

Preparation for backfill consists of:

1. Spreading a layer of 12 to 18 in. (0.305 to 0.457 m) of broken ore evenly on the floor of the stope.

2. Laying 6- by 6-in. (152- by 152-mm) welded wire fabric along the long axis of the stope.

3. Driving 6- and 8-ft (1.8- and 2.4-m) Dywidag rock bolts into the broken pore to a minimum depth of 6 in. (152 mm). Bolts are installed on 3-ft (0.9-m) centers.

4. Attaching an 8- by 8-in. (203- by 203-mm) plate to the top of each "standing" bolt to serve as an anchor.

5. Installing a 4-in. (102-mm) steel fill delivery pipeline that extends to the face of the stope and connecting the stope line to the main fill delivery line. The same fill delivery pipeline can be reused by installing fittings that are buried in the layer of broken ore.

6. Building and sealing a wooden bulkhead at the entrance to the stope.

After backfilling the stope, a new underhand cut can be mined beneath the new layer of backfill starting as soon as 5 days after backfilling. As mining progresses, the vein walls close, and there is a tendency for the fill to fail in compression. Wire fencing is fastened to the protruding lengths of Dywidag bolts as they are exposed by blasting. The wire fencing and wire mesh serve to support loosened fragments of backfill.

Conclusions drawn from the design, testing, installation, and operation of this high-density, consolidated fill system are as follows:

The development of a high-capacity, consolidated backfill system at the Lucky Friday mine was successful and necessary as part of a new, underhand, longwall mining method for vein mining. While much remains to be learned about flow of thixotropic mixes (paste mixes), pipeline transportation of high-density backfill into a deep shaft and across long horizontal distances has proven completely workable.

The consolidated backfill, consisting only of fine mill tailings and cement, has proven to be an effective roof in stopes when lightly supported.

Precise control is required in the backfill preparation and pumping plant, with a process control computer being necessary. Pipelines must be engineered in detail, and good quality workmanship in connecting and fastening pipes is required. More highly skilled operators and better supervision are needed than with previous systems. These needs are all indicative of a higher level of technology.

Because of the many advantages of using a stiff backfill, more underground mines will probably develop similar systems and undoubtedly will improve the technology. The potential advantages include reduced cement usage, higher backfill strengths and densities, improved rockburst control (when used as a part of a mining system designed to reduce bursting), reduced mine dewatering requirements, fewer abrasive solids in the mine dewatering system, high solids flow rates, simpler sand bulkheads, reduced tailings impoundment requirements, and as a result of all of the above advantages, lower costs and higher productivity (Brackebusch, 1988).

19.3.4.6 Advantages

Obviously, there are many advantages to a high-density fill system compared to any of those discussed previously.

1. If desired, a high-density fill system can utilize all mill tailings including slimes. This eliminates or reduces surface impoundment requirements and associated environmental problems.
2. The system can also utilize waste rock or gravel up to 1 in. (25 mm) for a stronger fill. Underground waste removal can be reduced.
3. As described by Lerche and Renetzeder, (1984), a high-density pumped (or gravity) fill system can also be used to dispose of many other undesirable waste products.
4. A well-graded, high-density, consolidated fill produces a strong fill that allows underhand cut and fill, parallel slicing or drift and fill methods. Recovery of pillars against high fill faces, as in post and pillar mining, is also feasible. The method is useful in overhand cut and fill mining with cemented fill capping or no consolidation at all.
5. High-density fill (85% solids by weight) with a water-cement ratio that binds all or most of the available water, results in the strongest possible fill for the least cement.
6. Excess water (from a hydraulic fill) that increases wear on mine pumps and results in difficult clean-up problems is eliminated.
7. Using the slime fraction of the tails has marked benefit on pumping or gravity flow of the mixture. Slimes migrate to the pipe wall and act as a lubricant. However, sufficient water must be present to allow this flow between grains.
8. If cement is added near the end of the delivery line (approximately 30 ft or 10 m), the thickened slurry can be left in the pipeline for several days, with no start-up difficulty. This is due to the thixotropic nature of the sand-slime mixture.
9. Low pipeline velocity in a thickened fill system reduces pipe wear.
10. Use of timber or other support methods is reduced with a strong fill.
11. A stronger fill, used in conjunction with a longwall mining system, reduces rock bursting problems in deep mines that are prone to bursting.
12. Better wall support reduces dilution and improves grade control.

19.3.4.7 Disadvantages

Possible disadvantages of a high-density, consolidated fill system include the following:

1. The preparation plant is more expensive and more sophisticated than other methods. More precise control is required.
2. More highly skilled operators are required.
3. Depending on requirements of the individual mine, fill costs may be higher due to cement addition.

19.3.5 UNIQUE OR UNUSUAL FILL SYSTEMS

19.3.5.1 General

Several unusual fill systems are noted in the literature, which bear out the theory that in order for fill to be economic, the operator must utilize the material available at the least cost.

19.3.5.2 Frozen Fill (Archibald and Nantel, 1986)

Although no frozen tailings material has ever been used to backfill openings in Canadian mines (as of the date of this writing), this material may be required in the future to perform the support functions of underground mines located in zones of permafrost, notably in the high Arctic. At present, only one Canadian mine, the Polaris mine, situated on Little Cornwallis Island, is investigating the use of frozen backfill.

The potential for the use of this material may increase as future mines are discovered in permafrost areas.

19.3.5.3 Consolidating Fill with Non-cement Binders

Several mines have been using slag and rock fill for some years with an additive that cements the particles together in a solid mass (Twidale, 1982).

One mine uses granulated copper smelter slag with pyrrhotite concentrate as cementing agent. The slag is granulated by dumping it molten into a tank of water. The fine material is recovered with a clam-shell excavator. The granulated product is mixed with coarse slag (– 4 in. or 102 mm) and sent underground by a fill pass. At the first level, the slag is transported by a conveyor to the main fill pass where pyrrhotitic concentrate, in slurry form, is added. This pyrrhotite is a waste product from the flotation concentrator. The main fill pass delivers the fill, as required, at the working horizons as had been done previously with sand and gravel.

The reaction that consolidates the fill is by oxidation of the pyrrhotite to form a hydrous ferric oxide, which is the cementing agent. Heat and sulfur dioxide are given off. When a large mass is poured into an empty stope, the surface temperature reaches 100° F (38° C), the internal temperature being higher. When used in 6- to 8-ft (1.8- to 2.6-m) layers in a cut and fill stope, the heat effect of the reaction is dissipated in normal ventilation and is not felt. The sulfur dioxide is dissipated and is hardly noticeable.

Mineral admixtures are described by Plavsic (1984). Three specialty materials, (1) fly ash, (2) slag, and (3) silica fume, are classified as mineral admixtures. The first two materials exhibit many similarities in performance. The same characteristics that apply to slag also apply to fly ash. (One important exception concerns references to the pozzolanic behavior of fly ash; slag is not a pozzolan and does not exhibit those properties).

Fly ash is a finely divided residue resulting from the combustion of powdered coal in electrical power plants. Two types of fly ash are currently being produced, Class F and Class C.

When the coal is bituminous, the fly ash is a classic pozzolanit substance, that is, a siliceous or siliceous and aluminous material that in itself possesses little or no cementitious value, but when mixed with lime and water forms cementitious compounds. This fly ash is called Class F. Subituminous coal and lignite tend to produce a material containing appreciable amounts of lime as well as silica so that fly ash may be cementitious as well as pozzolanic. This type of fly ash is called Class C.

Blast furnace slag comes from the steel industry and may be used to replace cement as fly ash does. If the slag is granulated or quickly cooled in water, it may replace more cement than fly ash. If the slag is activated by sodium hydroxide, it may be used as the only cementitious material in concrete (or backfill).

Fly ash and slag should not be used in excessive amounts. When too much cement is replaced by these materials, the strength of the concrete or fill can be materially reduced. Because fly ash and slag can vary considerably in their effect on concrete mixtures, they should be tested before use in combination with the specific cement and aggregates being used.

Silica fume, also a pozzolan, is a byproduct of electric arc furnace production of metallic silicon and ferrosilicon alloys. It is an extremely fine material with an average particle size two orders of magnitude smaller than Portland cement. Chemically, it is nearly pure silica.

More water is required in the mixture when silica fume is used to replace cement. There are potential difficulties in handling silica fume because of its fineness, but these can be overcome by handling it in a slurry or in compacted form.

When used in quantities of 5 to 10% of Portland cement, it can easily produce concretes with compressive strength exceeding 15,000 psi (103 MPa).

It should, therefore, be possible to produce much stronger backfill, using less cement, by substituting such admixtures as those described above. However, little work appears to have been done in this field to date to determine the value of admixtures in backfilling materials.

Section 20 Underground Mining: Caving Methods

MICHAEL KARMIS, ASSOCIATE EDITOR
GEORGE A. MEALEY, SECTION COORDINATOR

Chapter 20.0
INTRODUCTION

GEORGE A. MEALEY

Caving mining methods that are based on a planned caving of rock above and/or at times surrounding the material being mined can be classified in three broad categories: longwall mining, sublevel caving, and block caving. Each of the three methods involves a distinct technology as well as art of operation. Each requires a relatively large, regular, and predictable ore body. As a rule, the effect of mining results in some form of impact or change on the surface.

Operationally, underground caving methods are characterized by high productivity as well as a high percentage of extraction of the mineral being mined. A key element for the productivity of this form of mining is the ability to standardize the various elements of work taking place underground. Therefore, workmen may perform a specialized role rather than function as all-around miners. Further, the nature of the mining methods lend them to a high level of mechanization. Operations and manpower can be centralized into a relatively small area where supervision can be concentrated and therefore be more effective. Productivity as well as safety benefits thereby.

The caving method is unique in that the exploitation openings are deliberately destroyed by the process of mining. Rock mechanics principles focus on the ensurance and the propagation of the cave as well as the continuance of the mine openings designed to extract the broken ore. As a rule, production operations are designed to maintain a steady, continuous flow of ore from the extraction areas. This steady flow rather than an intermittent flow tends to promote good caving action as well as reduce hangups.

As a class of mining, underground caving accounts for about 15% of US mineral production. Because of the relative advantages of the caving class vs. other classes, for example, low mining cost, high productivity, and high recovery, its use is growing.

Chapter 20.1
LONGWALL MINING

S.S. PENG AND H.S. CHIANG

20.1.1 INTRODUCTION

Modern longwall coal mining was introduced to the United States in the early 1960s. The *longwall mining* method has the simplest system layout and provides continuous production and full potential for automation, which can further improve productivity and personnel health and safety. The panel layout is simple and conducive to good ventilation, and crews always work under protective supported roof. Therefore, it is much safer than the room and pillar mining method and complies easily with current US laws. Since the longwall system with full caving leaves a lesser amount of residual pillars than other mining methods, coal recovery is higher and surface subsidence is relatively uniform and complete.

In the United States, longwall mining is mainly employed in the Appalachian coalfield, although more longwalls are expected to be installed in the Western and Illinois coalfields in the near future. Depth of overburden ranges from 200 to 2700 ft (60 to 820 m) with the majority between 400 and 1200 ft (120 to 370 m). Seam thickness ranges from 43 to 156 in. (1.1 to 4.0 m), but mostly between 48 and 120 in. (1.3 to 3.0 m). All coal seams are nearly horizontal and extracted in a single slice, although one inclined seam and one thick seam using multislicing longwall mining are being operated in the West.

Longwall panels are blocked out by the panel entries that are excavated in-seam on both sides of the main entries (Fig. 20.1.1). Longwall mining in the United States is of the retreating type. The immediate entries on both sides of the panel are called the head entry and tail entry. The *head entry* is used for the passage of intake air and the transportation of coal, personnel, and supplies, while the *tail entry* is used for the passage of the return air.

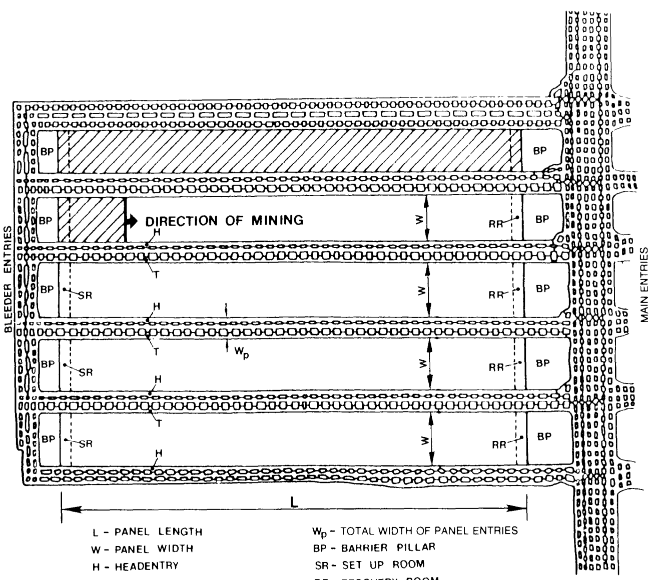

Fig. 20.1.1. Typical US longwall panel layout (Peng and Chiang, 1984. By permission from John Wiley & Sons, Inc., New York).

Fig. 20.1.2 is a cutaway view of a longwall face. Coal at the face cut by the shearer or plow is loaded onto the armored flexible conveyor (AFC) and transported to the head entry T-junction. Then coal is transferred from the AFC onto a stage loader, which in turn empties onto the entry belt conveyor. Powered supports are used to support the roof along the whole face. The AFC and powered supports are advanced hydraulically after each cutting cycle of the shearer, and the roof strata behind the supports are permitted to cave immediately after advance of the support. The extracted area between the rear edge of the supports and faceline is called the *face area* or working face, while that behind the roof supports is called *gob*. The method of roof control is classified as a roof caving method.

The panel entries are maintained by roof bolting as in room and pillar mining. But in the tail entry, one or two rows of cribs are erected to strengthen the entry support. At the head entry T-junction area, about 100 to 500 ft (30 to 150 m) outby the face, one or two rows of temporary supports are generally set to increase support density to cope with the moving front and side abutment pressures.

20.1.2 PANEL LAYOUT DESIGN

Panel layout design includes the determination of panel size, entry width, and the size and number of chain pillars (Fig. 20.1.1).

20.1.2.1 Panel Size

Panel width and panel length are usually determined by experience, based on the size and shape of the coal reserve, geologic conditions if known, location of surface structures, and the capacities of the transportation, ventilation, and power equipment that can be supplied. In the United States, the panel width *W* varies from 400 to 960 ft (120 to 293 m) center to center with an average of 666 ft (203 m). Most panels are wider than 600 ft (180 m), and a few are 900 ft (275 m) or larger. The panel length *L* varies from 3000 to 14,000 ft (610 to 4268 m) with the most common lengths from 4000 to 6000 ft (1220 to 1830 m).

If the panel width is substantially less than 400 ft (120 m) then the method is referred to as *shortwall mining* (Hartman, 1987). In application, it is intermediate between longwall and room and pillar mining (Chapter 18.1).

It is obvious that panel width is very important, because a wider longwall will increase the production of coal. A large number of factors influence the panel width, which can be divided into economic and technical.

ECONOMIC FACTORS. From an economic point of view, increasing panel width will reduce the number of panels in a mine reserve, resulting in (1) reduction of the development cost of panel entries, especially for a multiple entry layout; (2) an increase in the recovery rate of coal due to fewer chain pillars; (3)

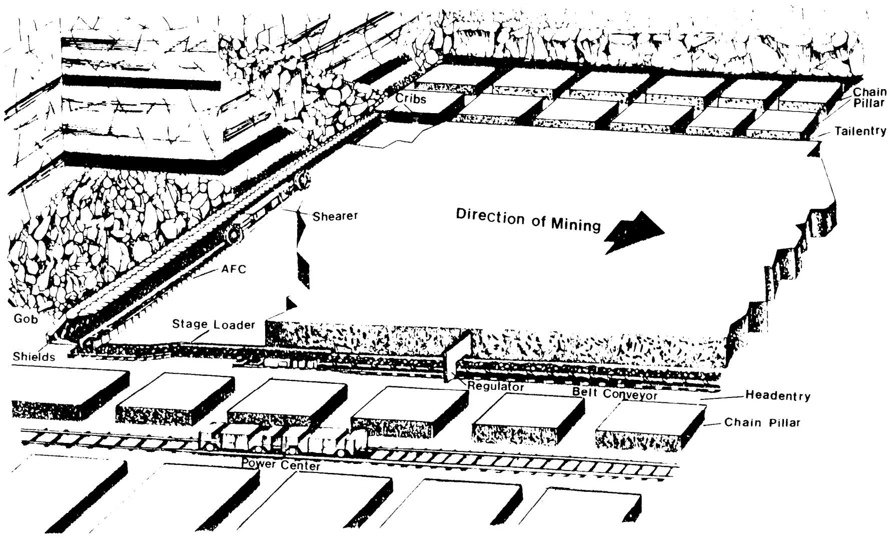

Fig. 20.1.2. Typical longwall face in cutaway view (Peng and Chiang, 1984. By permission from John Wiley & Sons, Inc., New York).

an increase in the production of coal, but, if the panel width exceeds a certain range (e.g., 1000 ft or 300 m), further increases in panel width have less influence on coal production; (4) reduction of the number of face moves and an increase in the minable coal per move, but with corresponding longer move times because more equipment has to be moved for longer distance; and (5) an increase in the total capital investment of the face equipment (i.e., more units of support, longer and stronger face conveyor, etc.).

TECHNICAL FACTORS. US longwall mining technology has proven that panel widths up to 1000 ft (300 m) are not only feasible but also achievable with high production. However, some important technical factors should be considered. (1) The panel width is primarily limited by the power required and structural strength of the face conveyor. (2) Roof control is now playing a less significant role in panel width. But, under unstable immediate roof and unidirectional cutting pattern conditions, increasing panel width increases the roof exposure time, resulting sometimes in local roof falls between the faceline and the tip of the canopy. It will reduce the support advance rate and, consequently, results in decreased overall shift production. (3) Operational and management considerations play a more important role in wider longwall faces. For example, in order to keep a normal shearer cutting, the faceline, powered supports, and the face conveyor should maintain three separate straight lines. If the panel is wider, more time is needed to adjust the faceline, supports, and conveyor, especially at both ends of the face.

20.1.2.2 Total Width of Panel Entries

The width of the panel entries W_p varies from 100 to 350 ft (30 to 110 m), depending on the number of panel entries. In the United States, three- and four-entry systems are commonly used in longwall panel layout, although a two-entry system is often used in the West. However, three entries is the minimum and thus the most common number of entries required by law for developing panel entries: one for the intake air escapeway, one for the return air escapeway, and one for the belt conveyor in neutral air. In a four-entry system, a neutral track entry is maintained, and two entries are served by intake air so that sufficient air quantity can be provided to the face from the main entries. In high-production retreating longwall mining, a fast entry development rate is required to support the continuous longwall production. Therefore, the number of panel entries is an important factor when the panel layout system is being designed.

20.1.2.3 Chain Pillar Size

In the three-entry system, two rows of equal-sized square chain pillars are commonly used. Under this condition, the following expression applies (Peng, 1986):

$$W_{pc} = \left\{ \frac{E_i}{E_c}, \frac{E_m}{E_c}, \frac{H_m}{H_c}, \frac{E_f}{E_c}, h, \sigma_c, d, W, \frac{H_i}{H_c}, W_o, \sigma_h \right\} \tag{20.1.1}$$

where W_{pc} is the width of square chain pillar; E_i, E_c, E_m, and E_f are the Young's modulus of the immediate roof, coal, main roof, and floor, respectively; H_i, H_c, and H_m are the thicknesses of the immediate roof, coal (mining height), and main roof, respectively; h is seam depth; σ_c is minimum uniaxial compressive strength required for a specifically sized coal pillar to remain stable under a certain roof condition; d is half-panel length; W and L are the panel width and panel length, respectively; W_o is width of the entry, and σ_h is in situ horizontal stress. Eq. 20.1.1 is for subcritical or semi-critical panels. If the panels are critical or supercritical in size, $L = (1.2 \sim 1.4)$ h.

Fig. 20.1.3 is a nomograph constructed by using a three-dimensional finite element technique in a series of parametric analyses to verify the quantitative relationship of Eq. 20.1.1.

Example 20.1.1. To demonstrate the use of this nomograph, follow the dotted line a-b-c-d-e-f-g-h to determine the pillar size W_{pc}, given the following conditions:

$\sigma_c = 1000$ psi (6.895 MPa); $E_m/E_c = 0$; $E_i/E_c = 0$; $L = 5000$ ft (1524 m); $h = 500$ ft (152 m); $E_f/E_c = 1$; $W = 400$ ft (122 m)

The value of W_{pc} read from Fig. 20.1.3 is 61 ft (18.6 m).

When designing a new panel without roof property information, it is recommended that the values of E_i/E_c, E_m/E_c, and

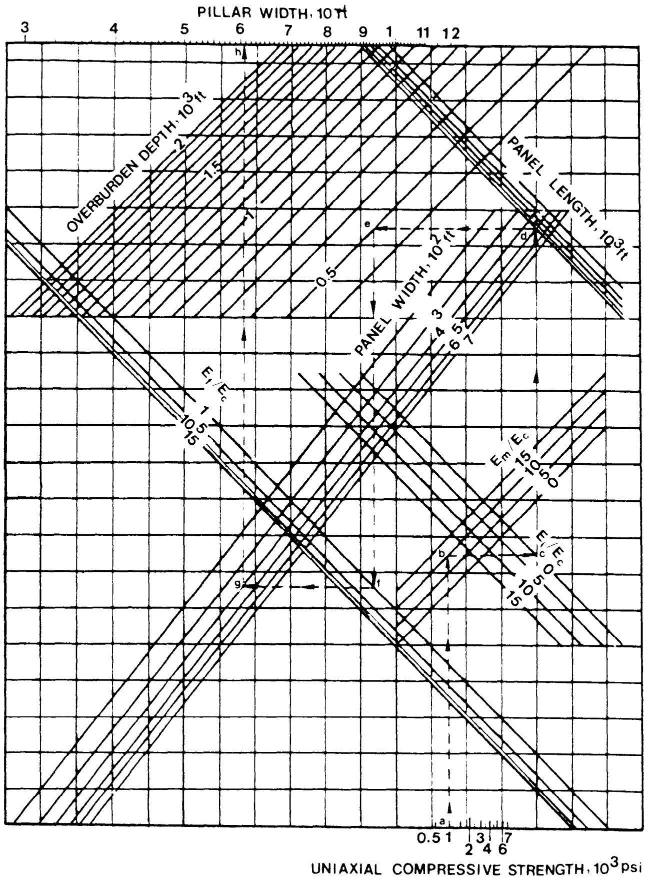

Fig. 20.1.3. Nomograph for determining chain pillar size (Peng, 1986: By permission from John Wiley & Sons, Inc., New York). Conversion factors: 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

E_f/E_c should be assigned as small as possible. For a safe design, E_i/E_c and E_m/E_c are assumed to be zero. Since the parameter E_f/E_c in the formula is in logarithmic form, it cannot be zero. Therefore, it is assumed to be 1.

20.1.2.4 Barrier Pillars

In order to protect the bleeder entries and the setup room, where all of the face equipment is located initially, a barrier pillar between the bleeder entries and the setup room, ranging in width from 200 to 500 ft (60 to 150 m), is developed depending on the seam depth. Sometimes, if the bleeder system contains a sufficient number of entries, no barrier pillar is developed, and the setup room is developed as part of the bleeder system. Also a barrier pillar from 300 to 500 ft (90 to 150 m) (sometimes less than 200 ft or 60 m) in width is left between the recovery room and the main entries for protection of the mains.

20.1.3 SELECTION OF MINING EQUIPMENT

20.1.3.1 Selection of Cutting Machine

The *shearer loader* and the *plow* are the two major types of cutting machines used on longwall faces. Major factors to be considered in selecting the cutting machine are the mining height, seam structure, roof bonding strength of the coal, and the cutting/plowing resistance. However, in US longwall mining, the shearer loader is almost exclusively used (95%). Only five plow systems (5%) are employed, and those where the seam thickness is below 50 in. (1.27 m). Major parameters for selecting the shearer are (1) type, (2) dimension, (3) haulage speed, and (4) power capacity.

TYPES OF SHEARER. Nowadays, three types of shearer loader are used on US longwall faces: *double-ended ranging-drum* (DERS), *single-ended ranging-drum* (SERS), and *single-ended fixed-drum* (SEFS) *shearers.* The vast majority of these are DERS, which are used to extract coal seams from 58 to 156 in. (1.47 to 3.96 m) in thickness. Only two SERS units are employed simultaneously on a longwall face with a 60-in. (1.52-m) mining height. Two SEFS units are used simultaneously to extract a thin seam of 48 in. (1.23 m) thick, while another two units of an older SEFS type with a rope haulage system have been employed since 1968 in two thin seams 50 and 54 in. (1.27 and 1.37 m) thick, respectively. However, DERS is used predominantly when the seam thickness exceeds 60 in. (1.52 m) because it can cut the whole seam height in one trip and in either direction of travel, thereby ensuring high production with rapid face advance and shortening of roof exposure time. Recently, the in-web shearer has gained some favor due to interest in extracting thin coal seams. It moves on the floor in front of and along the face conveyor. In this case, the leading drum cuts the coal and makes sufficient space for the passage of the shearer's body.

There are two cutting patterns for the shearer: unidirectional and bidirectional. A unidirectional cutting pattern is the most commonly used in US longwall mining in order to reduce the shearer operator's and shield mover's dust exposure. Nowadays, due to adoption of automation and remote control technologies, the shearer operators and shield movers can always stay on the fresh-air side of two major dust sources, the shearer and moving shields. Therefore, in order to increase coal production and reduce the unsupported roof exposure time, a bidirectional cutting pattern is favored for increasing longwall production.

In *unidirectional cutting,* the common practice is that when the shearer travels from tail entry to head entry, the leading (or the headend) drum is raised and cuts coal while the trailing (or tailside) drum is free or cuts the floor coal depending on seam height. On the return trip from head entry to tail entry only cleaning of loose coal is performed. In *bidirectional* (or bi-di) *cutting,* a web width of coal is cut in both directions of travel. It must be noted that in bi-di cutting, each cutting trip involves two face-end operations to turn the shearer around; whereas in unidirectional cutting, only a tailend turn-around operation is needed, and in some cases no turn around is required depending on the method selected.

DIMENSIONS OF SHEARER. The shearer comes in different models with varying dimensions and power available, depending on the manufacturer. In selecting the shearer, the mining height H_c should first be considered for properly selecting the dimensions of the shearer, which includes the diameter of the cutting drum D, body height H_b, ranging arm length L_a, body depth B, and swing angle (above the floor) a of the ranging arm (Fig. 20.1.4). The relationship among those parameters can be expressed by:

$$H_c = H_b - \frac{B}{2} + L_a \sin \alpha + \frac{D}{2} \qquad (20.1.2)$$

Fig. 20.1.5 is a nomograph to verify the quantitative relationship of Eq. 20.1.2. However, for the double-ended ranging-drum shearer, the maximum mining height should not exceed twice the diameter of the cutting drum D.

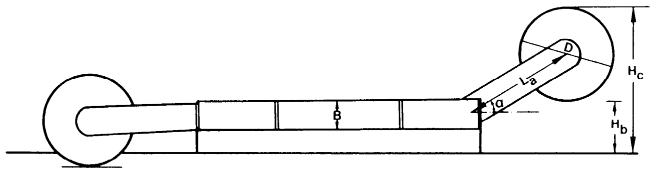

Fig. 20.1.4. Components for determining shearer dimensions and mining height.

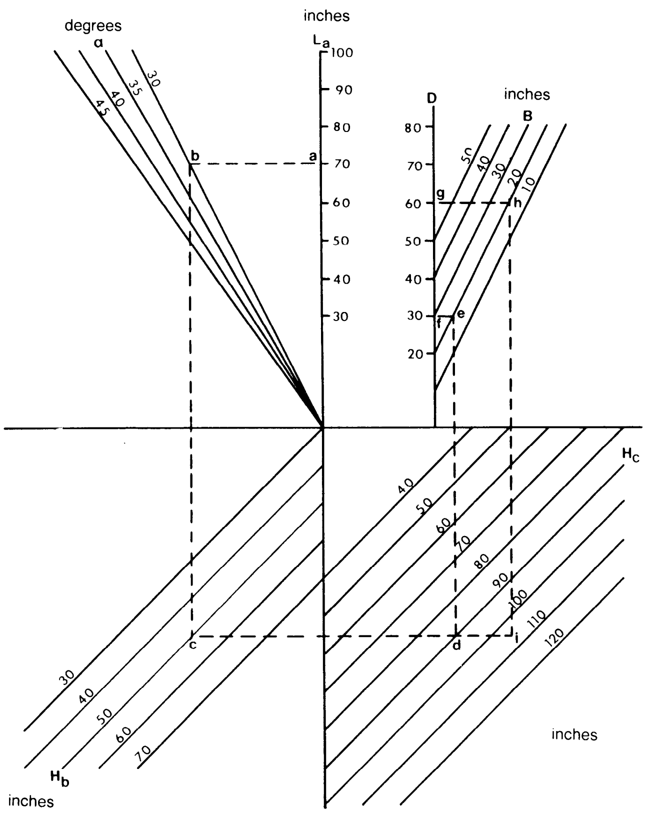

Fig. 20.1.5. Nomograph for determining shearer dimensions and mining height. Conversion factor: 1 in. = 25.4 mm.

Example 20.1.2. Use the nomograph shown in Fig. 20.1.5 to select the drum diameter *D*, given the mining height and major dimension of a shearer:

H_c = 90 in. (2.29 m); H_b = 50 in. (1270 mm); B = 20 in. (508 mm); L_a = 70 in. (1778 mm); α = 30°

Solution. Follow the dotted line a-b-c-d-e-f in Fig. 20.15. The minimum value of *D* required under the given conditions is 30 in. (762 mm). In practice, in order to reduce the loading resistance of the drum and to increase the loading efficiency, the drum diameter is selected larger than the minimum value. Usually, the drum diameter is 75 to 80% of the mining height; i.e., in this example, *D* = 60 in. Thus, following the dotted line g-h-i in Fig. 20.1.5, the cutting height of the shearer can attain 105 in.

Three web widths are currently in use: 30, 36, and 40 in. (762, 914, and 1016 mm) with the most common one being 32 in. (813 mm). Drum rotational speeds are 36, 44, 58, or 63 rpm, depending on the manufacturer, with the most common one being 44 rpm. Drums rotating less than 36 rpm have poor loading capacity. Conical bits account for 75% while radial bits cut 25%.

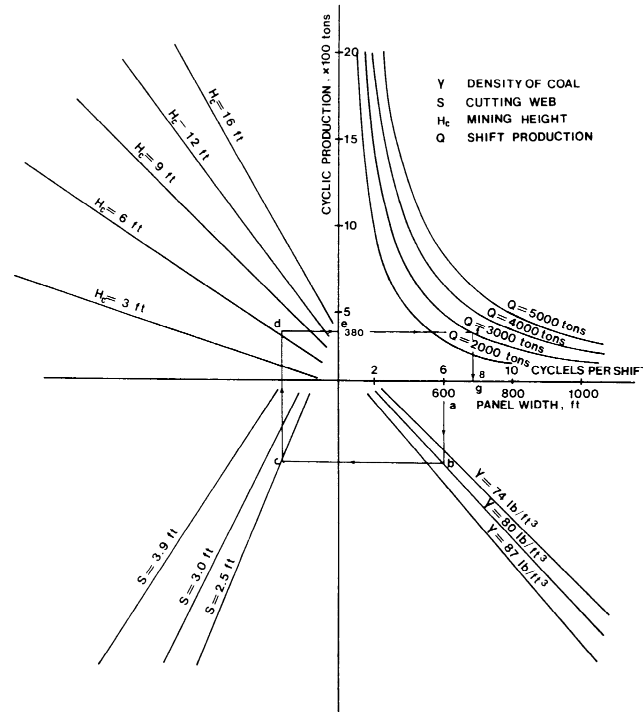

Fig. 20.1.6. Nomograph for determining longwall production. Conversion factors: 1 ft = 0.3048 m, 1 lb/ft^3 = 0.01602 t/m^3, 1 ton = 0.9072 t.

HAULAGE SPEED OF SHEARER. The haulage speed of the shearer ranges from 13 to 82 fpm (4 to 25 m/min). In order to increase coal production, higher haulage speeds (40 to 59 fpm, or 12 to 18 m/min) are now in common use.

The shearer hourly production Q_{she} in tons/hour, cycle production Q_c tons/cutting cycle, and its cutting cycle time T_{cut} in minutes can be determined, respectively, by:

$$Q_{she} = 60\ H_c\ s\ V_s\ \gamma\ C \tag{20.1.3}$$

$$Q_c = W\ H_c\ s\ \gamma\ C \tag{20.1.4}$$

$$T_{cut} = 60\ k\ Q_c/Q_{she} \tag{20.1.5}$$

where H_c is mining height in ft or m; *s* is cutting web in ft or m; V_s is haulage speed of the shearer in fpm or m/min, γ is weight per unit volume of coal (generally 74.8 to 87.3 lb/ft^3, or 1.20 to 1.40 t/m^3); *W* is panel width in ft or m; *C* is the loading coefficient of the shearer (generally 0.90 to 0.95); and *k* is the coefficient of time utilization, generally 1.1 to 1.4, depending on the amount of time required for shearer stopping/reversing at both ends of the face and some stoppages occuring along the panel. Fig. 20.1.6 shows a nomograph to determine longwall production.

Example 20.1.3. Use the nomograph shown in Fig. 20.1.6 to determine the cycle production and the required number of cutting cycles per shift. If the panel width *W* is 600 ft (180 m), the weight per unit volume of coal γ is 80 lb/ft^3 (1.28 t/m^3), the cutting web of the shearer *s* is 2.5 ft (0.76 m), and the mining height H_c is 6.5 ft (2.0 m), then follow the arrow to determine

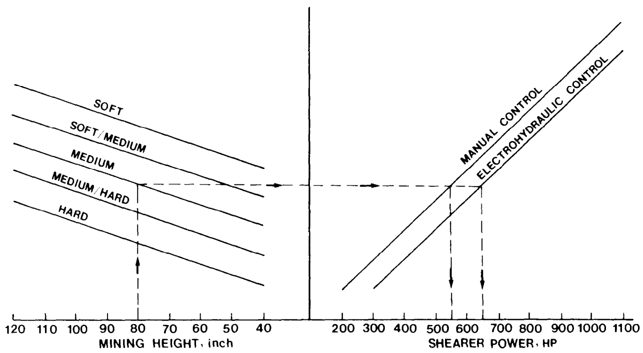

Fig. 20.1.7. Nomograph for selecting shearer power. Conversion factors: 1 in. = 25.4 mm, 1 hp = 0.7457 kW.

the cycle production, Q_c = 380 tons (340 t). Thus, if the planned shift production of coal is 3000 tons (2700 t), 7 to 8 cutting cycles should be completed.

POWER CAPACITY. Power consumption of the shearer reflects the total electrical load during shearer operation, which is affected by a series of operation-related factor, such as haulage speed, drum diameter, width and rotational speed, cutting depth and bit conditions, mining height, and seam hardness. Under normal conditions, mining height, seam hardness, and haulage speed are major factors in selecting the power capacity of the shearer. Based on a recent survey of the shearers employed in US longwall mining, a reference chart is constructed for selecting shearer power under different conditions (Fig. 20.1.7).

Example 20.1.4. Use the chart shown in Fig. 20.1.7 to determine the power required of the shearer under the following conditions: mining height is 80 in. (2 m), and seam hardness is medium. Follow the arrow to select the power required: N = 550 hp for manual control, or N = 650 hp for electrohydraulic control.

20.1.3.2 Selection of Armored Face Conveyor

TYPES OF CONVEYOR. There are four types of chain strands for longwall armored face conveyors: *single center* (SCS), *double center* (DCCS), *double outboard* (DOCS), and *triple-chain strand* (TCS). In US longwall mining, the double chain strand DCCS, with chain size of 1.18 and 1.34 in. (30 and 34 mm) and the single center strand with chain size of 1.50 and 1.65 in. (38 and 42 mm) are most often employed. In comparison with DOCS, the double center strand provides a larger loaded cross section, more flexibility, less chain wear, and easier maintenance. Lately, chain strength has been improved considerably, and the single center strand is gaining more acceptance. As production increases in longwall faces, a chain size of 102 in. (2.6 m) or less becomes insufficient.

Recently, in order to meet the demand of high-production longwalls, wider pans are being used. More than 40% of them are in the range of 37 to 39 in. (945 to 1000 mm).

CAPACITY OF AFC. The carrying capacity of the AFC, Q_{afc} in tph (t/h) can be determined by the relations:

$$Q_{afc} = q_c\, V_c = 60\, A_{max}\, \psi\, \gamma_c\, V_c \tag{20.1.6}$$

$$q_c = A_{max}\, \psi\, \gamma_c \tag{20.1.7}$$

where q_c is the weight of coal loaded per unit length of AFC; A_{max} is the largest loaded crosssection of the pans line, which depends on the construction and width of the pan, type of chain strand, angle of repose of the broken coal, and height of spill plate; ψ is a loading coefficient, with ψ = 1 when it is fully loaded but generally 0.65 to 0.90, depending on the seam inclination, hardness and size of the broken coal, and the structural features of the pans and spill plates; γ_c is weight per unit volume of the loaded coal, generally γ_c = 55 to 76 lb/ft^3 (0.88 to 1.22 t/m^3); and V_c is chain speed, usually 250 fpm (76.2 m/min) or less but recently some designs of 300 fpm (91.5 m/min) have become available to meet the demand of a wider face and higher production of coal.

Table 20.1.1. Coefficients of Moving Resistance for Chains

Chain Strand Type	f_c	f_n
SCS	0.40–0.60	0.25–0.40
DOCS	0.60–0.80	0.20–0.35

* f_n is positive when the chain is moving upslope while f_n is negative when the chain is moving downslope.
** when the floor and subsequently the AFC are undulating, f_c and f_n may be increased accordingly.

POWER REQUIREMENTS OF AFC. In determining the power requirements of the AFC, the moving resistances R_L and R_E for loaded (upper) and empty (under) sides of the AFC, respectively, and haulage force at drive sprockets F_S should be determined first by:

$$R_L = (q_c f_c + q_n f_n)\, L_{afc} \cos\alpha \pm (q_c + q_n)\, L_{afc} \sin\alpha \tag{20.1.8}$$

$$R_E = q_n\, L_{afc}\, (f_n \cos\alpha \pm \sin\alpha) \tag{20.1.9}$$

$$F_S = K_b\, K_S\, (R_L + R_E) \tag{20.1.10}$$

where L_{afc} is length of AFC in ft or m; q_c and q_n are weights of loaded coal and chain, respectively, per unit length of L_{afc} in lb/ft (kg/m); f_c and f_n are coefficients of moving resistance for loaded coal and chain unit, respectively (reference values of f_c and f_n are listed in Table 20.1.1); a is angle of face slope in degrees; K_b = 1.1 is a resistance factor considering the additional resistances due to curvature and bearings at the sprockets; and K_S = 1.1 is another resistance factor for the snaked portion of the AFC.

Finally, the maximum power required for the AFC can be determined by:

$$N_{max} = \frac{1.15\, F_S\, V_C}{C_{ele}\, \Phi} \tag{20.1.11}$$

where F_S is haulage force in lb or kg, V_c is chain speed in fps (m/s), Φ = 0.80 to 0.83 is transmission efficiency of the gearbox and fluid coupling, C_{ele} is a conversion coefficient = 550 hp units and = 102 kW units, and 1.15 is a safety factor.

The minimum power required for the AFC when the shearer just starts is

$$N_{min} = \frac{1.15\, q_n\, f_n\, L_{afc} \cos\alpha\, V_c}{C_{ele}\, \Phi} \tag{20.1.12}$$

Thus the AFC power required for longwalls with shearer can be determined by:

$$N = 0.58\, K_{afc} \sqrt{N^2_{max} + N_{max}\, N_{min} + N^2_{min}} \qquad (20.1.13)$$

where K_{afc} = 1.15 to 1.20 is a safety factor. Thus the total power required for the AFC can be determined. However, if the floor is soft and/or floor heave occurs, additional power, up to 35% of the total, should be added according to the site conditions.

Example 20.1.5. Use Eqs. 20.1.3 to 20.1.13 to select an AFC. The carrying capacity of the face conveyor Q_{afc} should be compatible with that of the shearer, that is,

$$Q_{she} = Q_{afc} \qquad (20.1.14)$$

Given the panel conditions as follows:
- Panel width W = 600 ft
- Mining height H_c = 6.5 ft
- Coal seam is approximately horizontal, $\alpha \cong 0°$
- Weight per unit volume of coal γ = 80 lb/ft^3

Major specifications of the shearer are given as follows:
- Cutting web s = 2.5 ft
- Loading coefficient C = 0.92
- Haulage speed V_s is 30 fpm on average; this is compatible with the electrohydraulic controlled advance rate of the shield supports (if the advance cycle time for each support is 10 seconds, the advance rate will be 6 shields/min or 30 fpm).

Solution. Using Eq. 20.1.3, the production of coal by the shearer is

$$Q_{she} = 1076 \text{ tph}$$

Major parameters of SCS type AFC are known as follows:
- Chain size is 30 × 108 mm
- Weight per unit length of chain q_n = 12.9 lb/ft
- Pan width B_P = 32.76 in.
- Maximum loaded cross section A_{max} = 3.0 ft
- Loading coefficient ψ = 0.85
- Weight per unit volume of loaded coal γ_c = 63 lb/ft^3
- Coefficient of moving resistance of loaded coal f_c = 0.5
- Coefficient of moving resistance of chain, f_n = 0.3

Using Eq. 20.1.6, the weight per unit length of loaded coal is determined,

$$q_c = 161 \text{ lb/ft}$$

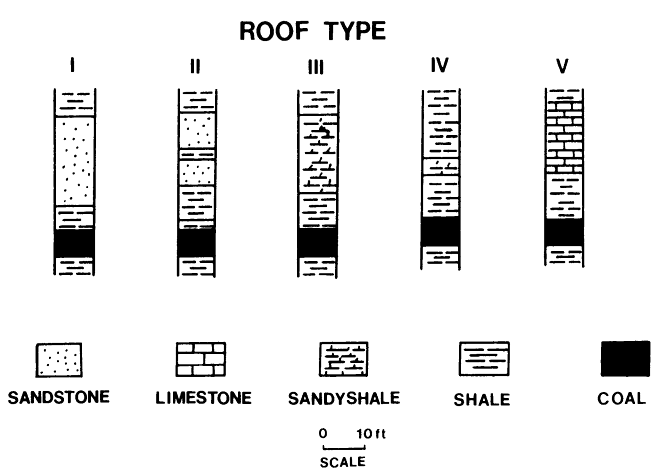

Fig. 20.1.8. Classification of roof strata (Peng, Hsiung, and Jiang, 1987). Conversion factor: 1 ft = 0.3048 m.

Use Eqs. 20.1.7 and 20.1.14 to determine the chain speed of AFC:

$$V_c = 3.74 \text{ fps}$$

Major factors selected for the AFC drive unit:
- Resistance factors K_b = 1.1 and K_S = 1.1
- Transmission efficiency Φ = 0.81
- Conversion coefficient C_{ele} = 550
- Safety factor K_{afc} = 1.2

Use Eqs. 20.1.8 to 20.1.12 to determine the maximum and minimum power capacities required for the AFC:

$$N_{max} = 618 \text{ hp}$$

$$N_{min} = 23 \text{ hp}$$

Finally, the total power for the AFC operated under the conditions as given above can be determined by Eq. 20.1.13:

$$N = 438 \text{ hp}$$

20.1.4 ROOF CONTROL

In US longwall mining, *shield supports* are predominantly used for roof control, accounting for 98% while four-leg *chock supports* are responsible for only 2%. Among shields, the majority (67%) are the two-leg type, while four-leg shields and chock-shields account for 32% with only one panel employing six-leg shields. The most important element in successful longwall mining is good roof control, which requires complete understanding of the behavior of the overburden strata for proper selection and application of powered supports.

20.1.4.1 Classification of Roof Strata

According to the thickness and uniaxial compressive strength of the immediate roof, the ratio of the thickness of the immediate roof to the mining height, and the thickness and tensile strength of the main roof, roof conditions can be classified into five types under US coal seam conditions (Fig. 20.1.8) (Peng et al., 1987):

Type I. The main roof consists of a thicker and stronger sandstone, and the immediate roof is very thin. Normally, the main roof can overhang a large distance in the gob, causing severe periodic weighting.

Type II. Features for Type II are similar to those of Type I, except that the main roof of sandstone in Type II is thinner, or that it can cave separately if multiple-layered.

Type III. The thickness of the immediate roof is one to two times the mining height, and the main roof consists of a thicker sandy shale.

Type IV. There is no main roof, or the thickness of the immediate roof is larger than four to six times the mining height. Under these conditions, there is no or only a small effect of periodic weighting; consequently, the support load requirement is small.

Type V. The main roof is a thick jointed limestone that can sag gradually and form an equilibrated semiarch. Thus, as a main roof, the effect of the limestone is very small, and the required support capacity is smaller.

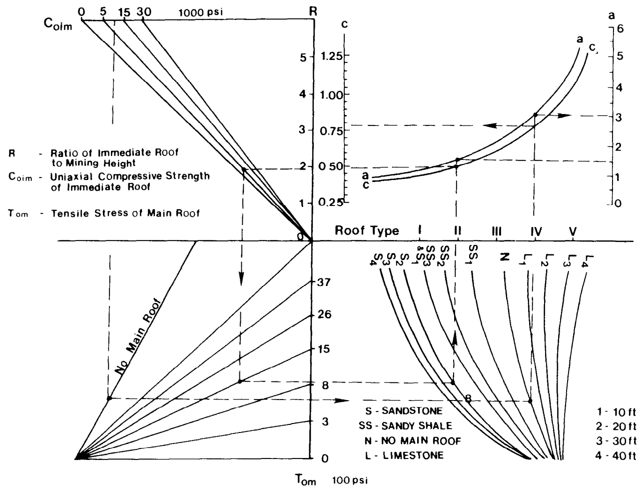

Fig. 20.1.9. Nomograph for determining constants a and c (Peng, Hsiung, and Jiang, 1987). Conversion factors: 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

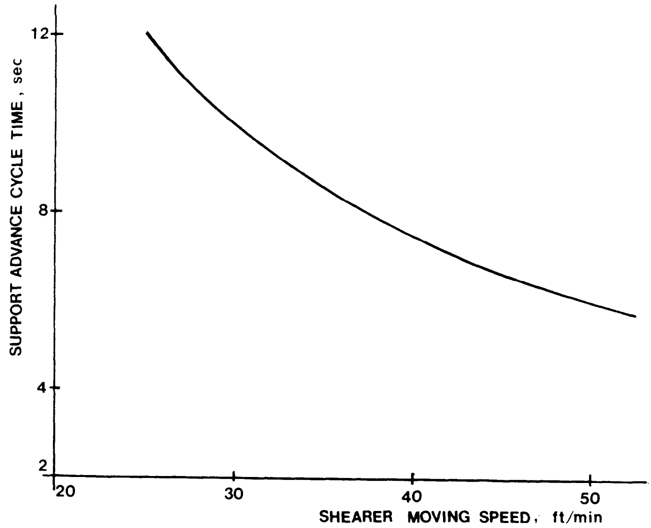

Fig. 20.1.10. Support advance cycle time required to achieve a given shearer moving speed. Conversion factor: 1 fpm = 0.3048 m/min.

20.1.4.2 Determination of Support Capacity

Based on the characteristics of the roof, a statistical model for describing the interaction between the roof strata and support has been developed (Peng et al., 1987):

$$\Delta q = 2q_s^2 \, e^{-2q_s} \tag{20.1.15}$$

where Δq is the effective increment of load density in tons/ft^2 (i.e., $\Delta q = \Delta P \eta / A$; $q_s = P_s \eta / A$); P_s is the setting load in tons; ΔP is the load increment from support setting to final load immediately before the support is released for advance in tons; η is the support efficiency; A is the canopy area of the support in ft^2; and a and c are constants related to roof conditions.

Based on this model, the following formulas can be used for calculating the setting load, load increment, and the yield load P_y:

$$P_s = 3.2 \; A / c \; \eta \tag{20.1.16}$$

$$\Delta P = 0.417 A \; a / c^2 \; \eta \tag{20.1.17}$$

$$P_y = P_s + \Delta P \tag{20.1.18}$$

Values of the constants a and c can be determined using the nomograph shown in Fig. 20.1.9. Thus the required support setting and yield capacity can be calculated using Eqs. 20.1.16, 20.1.17, and 20.1.18.

20.1.4.3 Selection of Support Type

Two-leg shields are most suitable for weak immediate roof while four-leg shields and chock shields are excellent for medium and strong roofs. A weak immediate roof refers to roof that caves immediately behind the shields, while in medium roofs the immediate roof is relatively thin and overhangs slightly. A strong roof refers to a massive immediate roof that overhangs considerably into the gob.

20.1.5 LONGWALL AUTOMATION AND REMOTE CONTROL

Since 1984, automation and remote control technology have been rapidly adopted in US longwall mining (Chapter 22.2). Now there are 72% of all longwalls equipped with electrohydraulic control, most of which are equipped with the option to expand to a shearer-initiated control system (Broussard and Palowitch, 1979; Wood, 1982; Nelson and Bessinger, 1989).

20.1.5.1 Automation and Remote Control of Support Advance

High-production longwall mining requires faster support advance. This is achieved via the electrohydraulic control system, which also provides uniform and consistent support and conveyor advance, reduces the size of the face crew, and reduces the exposure of shield men to respirable dust. The systems employ two basic modes of operation: floating batch control and shearer initiation. The floating batch control is most commonly used in US longwall panels (Peng, 1987). The adjustable size of the batch ranges from two units to full face. Usually, 8 to 30 units are recommended, because within this range a shield man can keep sight of the shearer. In a floating batch control system, several modes can be operated simultaneously, depending on the area of the face and cutting pattern adopted (e.g., bidirectional electric adjacent autosequence control, bidirectional electric adjacent manual control, and in-support hydraulic manual control). Generally, the cycle time for support advance of the latest models ranges from 6 to 10 seconds. However, the advance cycle time should be compatible with the shearer's moving speed, which ranges from 35 to 82 fpm (10 to 25 m/min). For example, a shearer speed of 35 fpm (10 m/min) requires a cycle time of less than 8.6 seconds (Fig. 20.1.10). Consequently, the shearer speed is always limited by the support advance rate, especially under bad roof conditions.

Shearer initiation is an electronic control system that issues commands for the automatic operation of support cycling and AFC advance at fixed distances from the shearer. In this system, a microprocessor console located in the head entry controls all of the support functions and another electronic unit monitors and indicates the shearer's position along the face. The initiation system controls the supports and AFC to be advanced at a predetermined distance behind the shearer. Using this system, the number of shield men can further be reduced to one for the whole face, but the shearer speed is very much limited by the support cycling time because the supports are advanced conventionally one by one.

In order to solve the problem of constraints on shearer speed, the softwares of the electrohydraulic control and shearer initiation systems have been improved so that:

1. Two adjacent supports can be advanced simultaneously, if the immediate roof is stable, or
2. Two odd supports advance first behind the shearer and then the even number of two adjacent supports, if the immediate roof is unstable, or vice versa. In this case, the snaked portion of the AFC will be longer.

In this manner, the shearer speed can be doubled, and coal production can also be increased proportionately.

20.1.5.2 Automation and Remote Control of the Shearer

The latest technology of automation and remote control for the shearer consists of remote control by the operators, cutting horizon control of the drums, face alignment control with support advance and AFC advance, and roll control of the shearer body.

Remote Control by the Operators. The main purpose of this technology is to protect the operator's safety from falls of coal and rock fragments and health from exposure to airborne dust. Using a shortwave radio system, the operator can be sited in a safe position on the intake side of the shearer about 10 to 40 ft (3 to 12 m) or farther from the face to control all shearer functions and observe the operation of the shearer. Remote control of the shearer is now commonly employed in US longwall faces.

Cutting Horizon Control. The function of horizon control is to maintain the cutting drums of the shearer to cut the seam at a predetermined distance from the coal-roof and/or coal-floor interface, so that only the coal is extracted or a fixed thickness of roof coal is left unmined. Numerous sensors have been developed and applied for horizon control system; they are divided into three groups: (1) coal thickness indicators that measures the thickness of the coal left on the roof and/or floor after a cut, (2) surface recognition sensors that differentiate between coal and rock and also indicate the coal-rock interface, and (3) roof height followers that indicate the position of the existing roof.

Data obtained by the sensors have to be transmitted to the control system for evaluation and processing, and then the commands from the control system are issued to the hydraulic system to adjust the positions of the drums.

Face Alignment Control. The irregular shape of the coal face generally is caused by irregular shearer cutting, while irregular shearer cutting is usually caused by unequal advance of both AFC and supports. In order to maintain a straight faceline, an optical instrument called the coalface surveyor has been developed for monitoring face alignment. The surveyor unit is mounted on the shearer and emits a pulse of low-intensity infrared light after every 4 in. (100 mm) of travel of the shearer. The light beam is reflected back along its initial direction by the retroreflectors, which are mounted on every fifth shield, and focused onto a linear photodiode array. The angle at the shearer subtended by adjacent two retroreflectors is continuously measured and transmitted, along with the distance traveled by the shearer, to the main processor located at the head entry. The main processor computes the face profile and displays it, interfacing with the AFC advance control system.

Roll Control. Roll of the shearer is a common event in longwall operation, which is usually caused by undulating floor, soft bottom coal and floor, and the inherent instability caused by the offset of the drum from the supporting shoes, especially with longer ranging arms. Two kinds of instruments have been developed for monitoring shearer roll, the tilt transducer and inclinometer.

1. *Tilt transducer.* It measures the inclination of the shearer based on the desired orientation of the AFC, which may not be horizontal. The measured data are transmitted to an automatic adjustment control system, and the shearer angle necessary to reach the desired orientation is computed by the control unit. Then the shearer position is reoriented by adjusting the underframe steering jacks.
2. *Inclinometer.* It is an integrated part of the roll control system and detects the angles of shearer roll by gravitational acceleration. The vibrational accelerations along the sensitive axis will be transferred into roll signals, and the control system rotates the shearer about its longitudinal axis by using the hydraulic actuators to adjust the shearer position to the desired orientation.

20.1.5.3 Status of Implementation of Longwall Automation and Remote Control

Control of shields using the electrohydraulic control system is a routine operation. In this system, no more than two shield operators are required for a longwall face up to 900 ft (270 m) in width, and in some faces only one operator is sufficient.

Shearer initiation has been successfully demonstrated in operational faces, but the practice of advancing shields one by one slows down the shearer's cutting speed. Therefore, if shearer initiation is to be widely used, some techniques of improving the shield advance time such as those mentioned earlier must be perfected.

All shearers are equipped with remote control either by radio or umbilical cord. The first level of automation is the use of nucleonic sensors to detect the roof coal thickness and then direct the drum to cut and leave a predetermined roof coal thickness. In more advanced levels, the drum cutting height at all locations along the face for one cutting cycle is stored in a computer. These data are used to direct the second cutting cycle during which the roof sensors continue to collect a new set of data. If there is any discrepancy between the 2nd and the 1st cycle, the 2nd cycle data will replace the 1st cycle ones and be used for the 3rd cycle setting. This process repeats for all subsequent cutting cycles.

It must be noted that current automation technology is not universally applicable. The roof must be fairly good without large roof falls or steps in unsupported areas, and the floor must not be too soft and sharply undulating.

20.1.6 LONGWALL FACE MOVE

A longwall face move is a major job when one panel has been completed and all the longwall equipment is transferred to the next panel for setup. During a longwall face move, production is interrupted, resulting in a decrease in overall longwall output and productivity and in an increase in the operating cost per ton, in addition to an interest increases due to the large capital investment. For example, with an $8 million investment and a 20% return on investment, a longwall move of 4 weeks causes a loss of $135,000, in addition to labor expense of $200,000 for the move, and the interest and depreciation costs of the equipment (Adam et al., 1982). The key to reducing the loss from a longwall move is to shorten the move time, which ranges from four days to four weeks. The major factors in reducing longwall move time are good planning and coordination, proper tools and equipment, and effective and efficient operations (Peng and Chiang, 1984; Adam et al., 1982).

A longwall face move includes the following steps: pre-move preparation, move preparation, move and transportation, and installation and completion.

20.1.6.1 Pre-move Preparation

At least one month before the last panel is completed, a number of tasks for preparing for the move should be started and performed. The major ones include (1) preplanning, (2) arrangement of supplies, tools, and equipment, (3) preparation of the transportation route and communication system, (4) location of transfer points, storage areas, and repair shops, (5) provision of communication system, and (6) manpower organization and training.

20.1.6.2 Move Preparation

Move preparation includes preparation of the recovery room and inspection and maintenance of face equipment.

PREPARATION OF RECOVERY ROOM. Usually, the last 5 to 10 cuts from the termination point of a longwall are used to prepare a safe and efficient *recovery room.* This consists of determination of the roof control method, room size, and room installation.

Roof Control Methods—Methods of roof control in the recovery room depend on the immediate roof conditions. Generally, steel wire meshes over canopies by bolting are commonly used under either weak roof or stable roof conditions. However, under weaker roof conditions, in order to strengthen the supporting capacity of the wire meshes, wire rope and/or steel I-beams are laid parallel to the faceline on top of the wire meshes at regular intervals, comparable to the center-to-center distance of the supports. Sometimes, cribs and single posts are also used as temporary supports.

Room Size—Usually, the height of the recovery room remains the same as the normal mining height. Sometimes, the room height at the panel end may be increased to facilitate equipment recovery. The effective width of the recovery room is the lineal distance between the faceline and the front of the base plate of the support. It must be sufficient for shield removal.

Room Installation—For example, crib blocks needed during the support withdrawal operation must be delivered and placed in the recovery room or close to the room. Rails and winches must be installed, if rail transportation is selected.

INSPECTION AND MAINTENANCE OF FACE EQUIPMENT. A careful and comprehensive inspection of all face equipment must be planned and performed before the longwall face reaches the termination point. Based on the inspection, usually some maintenance and repair work can be performed at the face and completed prior to terminating the face during downtime and maintenance shifts, and some maintenance and repair work should be scheduled for completion during the face move at the underground repair shops. Any equipment that is to be employed for the next panel but can only be overhauled on the surface requires a special schedule with the highest priority.

20.1.6.3 Face Move

Face-move procedures depend on the transportation route and methods, available spare equipment, and maintenance requirements. The detailed move procedures vary from mine to mine and time to time. As an example, the sequence of removing and transporting the major equipment for a shearer face consists of (1) entry belt conveyor, (2) power center, (3) stage loader, (4) face conveyor chain units, spill plate, head drive, and cable handler, (5) shearer loader, (6) communication system, cables, and water lines, (7) face conveyor linepans and tail drive, (8) face lighting system, and (9) shield supports.

The setup room should be well prepared: the face side rib must be straight, the floor smooth and the roof well supported.

The installation sequence of the face equipment in the setup room depends on the withdrawal and transporting sequence from the recovery room and the amount of spare equipment available. Generally, the installation sequence at the new face is approximately in reverse order as the old face is removed, but some installation operations can be performed simultaneously because the equipment can be entered from both head and tail entries. However, all installation should follow a critical path flowchart and/or Gantt chart, according to the face move plan.

Chapter 20.2
SUBLEVEL CAVING

RUDOLF KVAPIL

20.2.1 INTRODUCTION

Sublevel caving is a mass mining method based upon the utilization of gravity flow of the blasted ore and the caved waste rock. As with any other mining method, sublevel caving has advantages and disadvantages that must be carefully considered and evaluated for mine design and planning.

Major advantages of sublevel caving are the following.

1. Safety. Because all the mining activities are executed in or from relatively small openings, sublevel caving is one of the safest mining methods. Drifts are the primary working places. They are distributed in a uniform pattern on all levels. Normally, the maximum dimensions of the sublevel drifts are about 17 to 20 ft (5 to 6 m) wide and 12 to 13 ft (3.7 to 4.0 m) high. Transportation drifts can have the same cross section, or the height may be increased to about 15 ft (4.5 m) when trucks are loaded in the transport drifts. The stability and safety of such drifts in competent rock can be easily controlled by smooth blasting alone or by a combination of both smooth blasting and shotcreting. In less competent rock masses, stability can be achieved by a combination of smooth blasting, shotcreting, and rockbolting.

2. Mechanization. As shown in Fig. 20.2.1, when using the sublevel caving method, major mining activities can be broken down into four groups of unit operations: (1) drifting and reinforcing, (2) fan drilling, (3) production blasting (i.e., fragmentation), and (4) ore drawing, loading, and transportation. Because of the repetitive nature of the mining system, almost all mining activities can be standardized. This means that a high degree of mechanization is possible. In modern sublevel caving, cross sections of the drifts and tunnels are sufficiently large to allow the introduction of large trackless mining equipment. The advantages of a trackless system can then be broadly utilized not only for direct mining but also for all services.

3. Flexibility. Standardization and specialization of mining activities and equipment on separate levels (lower level or levels in development, upper level or levels in production mining) together with a trackless haulage system creates a high degree of flexibility. This allows a rapid start-up of mining and flexibility when making production rate changes.

4. Work Organization. This method lends itself to good work concentration, organization, and working conditions. Normally, on the lower levels, various phases of development are underway. Upper levels are in various stages of extraction. Therefore, the work can be easily organized into a system which excludes interference between mining activities.

In summary, safety of mining (in small-dimension openings), good flexibility, work organization, and high mechanization using large modern mining equipment provide very good working conditions. The method also facilitates a high work concentration and rationalization of separate specialized mining activities. Therefore, mining by sublevel caving can be effective and relatively inexpensive.

Major disadvantages of sublevel caving are

1. There is a relatively high dilution of the ore by caved waste, especially when higher recovery is requested.

2. All ore must be drilled and blasted in order to obtain a coarse material suitable for extraction by gravity flow.

3. Various types of ore loss can occur. When the extraction limit (that point yielding the maximum acceptable amount of dilution) is reached, the remaining highly diluted ore represents an ore loss. Some ore is lost in passive zones located on the level of extraction between the active zones of the gravity flow. A small part of the ore forming these passive zones can be recovered together with ore extraction on the lower sublevel, but some undiluted ore located in passive zones above the plane of the footwall is lost. In general, these losses are larger as the inclination of the ore body and the footwall is reduced.

4. A relatively large amount of development is required. This includes transport drifts, usually located in the footwall waste rock on each sublevel, and sublevel drifts, which connect the active mining areas in the ore body to the transport drifts. The sublevel drifts are partially in ore and partially in the waste rock. The waste rock length increases as the inclination of the ore body and footwall decreases. The system also needs orepasses, used to transport the ore or waste from the separate sublevels downward to the main haulage level, and these openings are located in waste.

5. Mining generates progressive caving in overlying rock and results in subsidence and damage to the surface.

6. To maximize ore recovery, minimize dilution, and achieve a high efficiency of mining by sublevel caving, good data regarding the gravity flow parameters for the blasted ore and the caved waste are of utmost importance. The exact type and amount of data required depend upon the purpose and needs of the mine design. For the first feasibility study, it may be sufficient to utilize the data from other sublevel caving operations with similar conditions and circumstances. For any higher level of mine design and planning, it is clear that more exact data, including analytical and experimental analyses up to full-scale in situ testing, are necessary.

Gravity flow principles and design guidelines for the application of the sublevel caving mining method are presented in the segments that follow. Although somewhat simplified, they should provide a basis for mine planning and operation. The gravity flow principles described can be effectively applied to other mining situations, with some modification. Also steeply dipping formations such as coal seams can be effectively mined by modified sublevel caving.

In sublevel caving, all ore must be drilled and blasted in order to utilize the gravity flow of fragmented ore, which after blasting forms so-called “coarse material”. The objective is to obtain by minimum drilling and blasting a coarse material with a fragmentation that will permit gravity flow and undisturbed ore extraction.

The coarse material is characterized by different size distribution and shape. The size distribution and shape of fragments depends on the density of the drillholes and on “blasting/tectonics” of the ore. Coarse materials can be very heterogeneous. With certain simplification, we could distinguish (with respect to their behavior) four basic types (Fig. 20.2.2). Type I shows coarse material with large “spherical” pieces of more or less the same size and shape. Type II represents a material almost of the same size but different shape. Type III indicates a coarse material composed of large fragments, chippings, and sand. Type IV

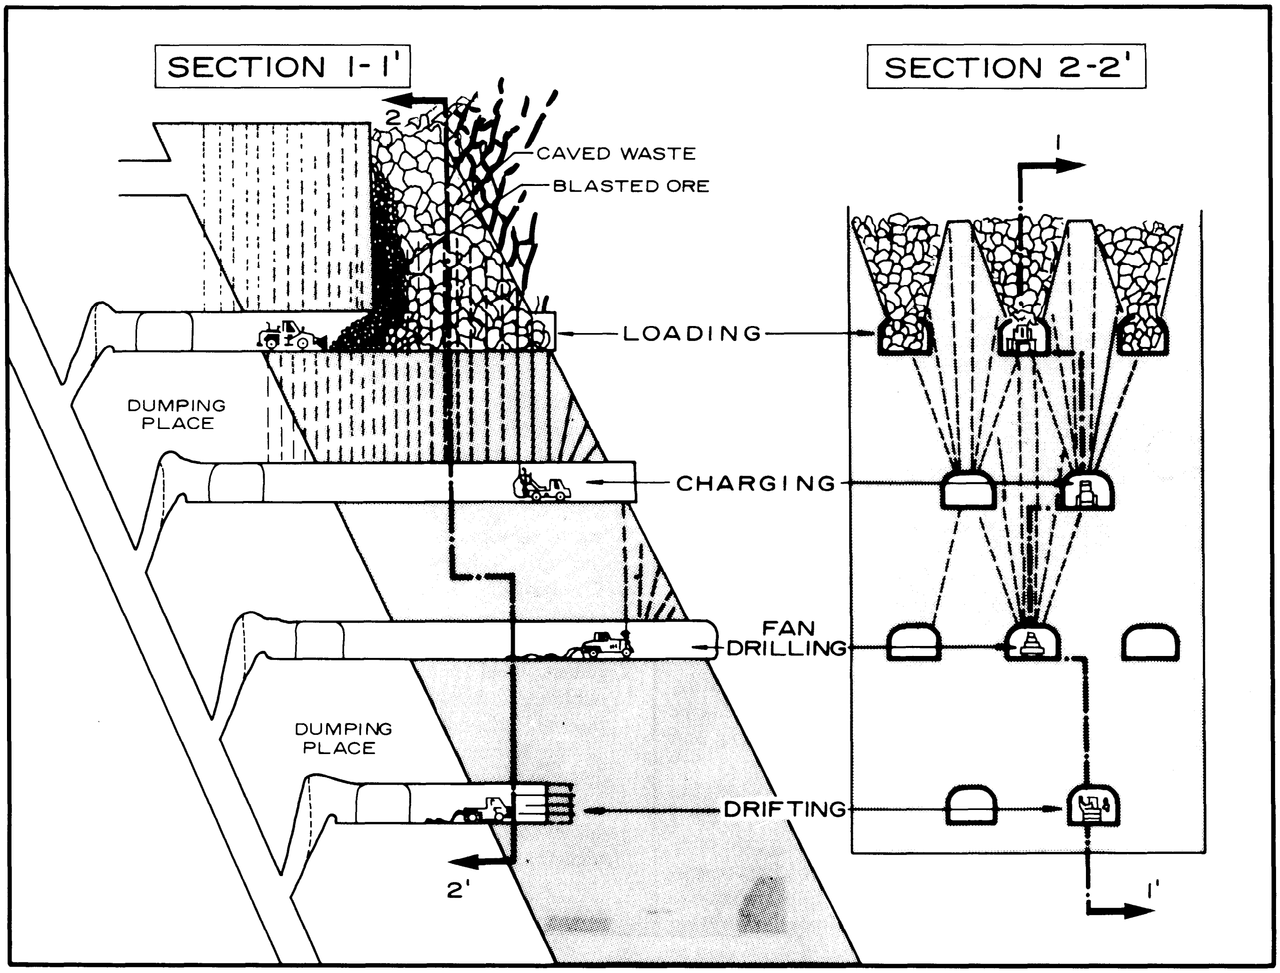

Fig. 20.2.1. Typical schematic of sublevel caving visualized on a simplified transverse section 1-1′ and longitudinal section 2-2′ (after LKAB information brochure, 1989).

represents a coarse material that is characterized as a mixture of large blocks, medium-sized fragments, chippings, sand and/or rock powder, earth or clay components, etc. The coarse material, Type III, and especially Type IV, could change considerably the mechanical properties and behavior depending on the percentage of fine particles (sand, clay, etc.) and on the presence of water. If water is present, then especially in coarse material, Type IV, the fine particles could create plastic and sticking components. This could change very unfavorably its properties and behavior.

Naturally, the coarse materials could have very different properties. The most simple characterization is shown in Fig. 20.2.2, indicating the angles for gravity transportation of coarse material. Up to about 40° the coarse material requires mechanical transportation. With larger angles of inclination, gravity transportation could be used in open chutes or in orepasses. In Fig. 20.2.2, GF represents the range of gravity transportation applicability, where the range A is for open chutes for transportation of Types I and II only, while the Types III and IV (in inclination range B) must be transported in steep passes. Type III requires inclination BI, and Type IV, especially when wet, needs very steep passes in the inclination range BII (Fig. 20.2.2). Almost all blasted ores (and waste) are similar to Types III and IV. The composition, properties, behavior, etc., of these materials could be very different because they could consist of very large boulders down to the finest particles.

20.2.2 PRINCIPLES OF GRAVITY FLOW

In order to construct efficient bins or silos, it is necessary to know the principles of *gravity flow* the stored materials. Undisturbed operation of a bin is a function of the gravity flow, of the material.

Gravity flow of blasted ore and caved waste in sublevel caving is a process much more complicated than flow in bins. The geometry, dimensions, and even operational constraints of sublevel caving cannot be selected at random, but must be planned respecting the laws that govern the gravity flow of coarse materials (i.e., the gravity flow of blasted ore and caved waste rock). Because of the heterogeneity of coarse materials and a great number of other factors and conditions, the gravity flow of these materials is a very complex process.

It must be emphasized that although flow as used in gravity flow means an uninterrupted movement of coarse material, it is a completely different process from the flow of liquids. Hence knowledge of the flow of liquids cannot be applied to gravity flow of coarse materials. The basic laws and principles of gravity flow are independent of fragment size; they are the same for coarse material as for small granular material (i.e., small gravel or sand). Geometrical parameters are different in some materials and under varying conditions.

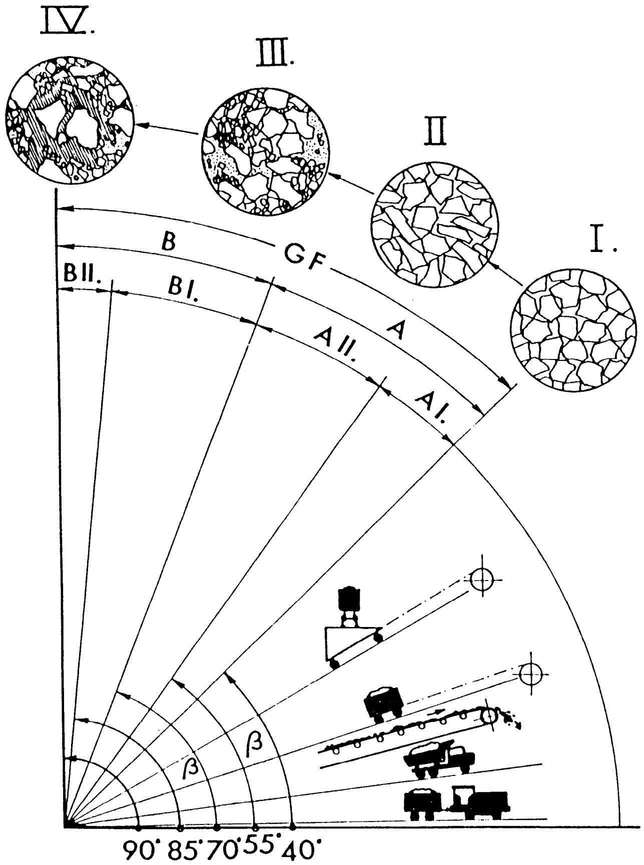

Fig. 20.2.2. Four basic types I through IV of coarse material and their mobility as a function of inclination of chute or orepasses.

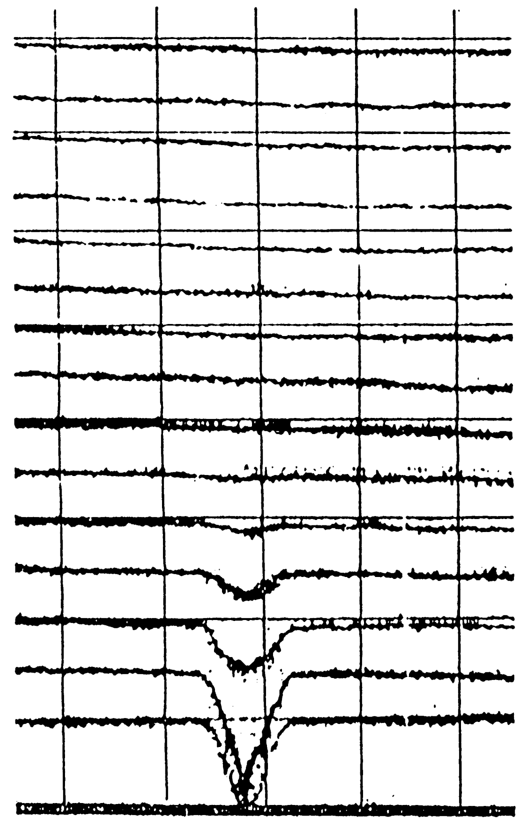

Fig. 20.2.3. Model of gravity flow; beginning of material extraction initiates the gravity motion of sand filling, visible by curvature of originally horizontal black line.

20.2.2.1 Factors That Control Gravity Flow

Gravity flow is usually demonstrated with a very simple vertical glass model with horizontally layered white and black sand filling, as shown in Fig. 20.2.3. For model research, we can use more sophisticated models, such as having the fill materials arranged like a black and white checkerboard (Fig. 20.2.4).

It has been found that gravity flow in a bin has a rather complex form, as is shown in Figs. 20.2.5 and 20.2.6 (especially when the involved height of the granular or coarse material is small). This form is even more evident from the model of a bin shown in Fig. 20.2.7, where the apparently low cohesion of sand is caused by a small percentage of water. (Note: As is evident from Figs. 20.2.5 and 20.2.6, the inclination of the bin bottom has no influence on the gravity flow of its fill materials in the short term. The bottom must be much steeper in order to influence the flow in the bin or silo.)

For simulation of the gravity flow principle used by sublevel caving (or block caving), the most simple model was used. This model represents a vertical section of a bin or a sublevel through the axis of its extraction opening (or sublevel drift) on the bottom. The extraction opening in the model bottom has minimum dimensions, but it is sufficiently large for a fluent and uninterrupted flow of material. (For simulation of certain sublevel caving conditions, the model is continuously refilled during extraction). Figs. 20.2.8 through 20.2.10 represent successive phases of material extraction.

The deflection of the originally horizontal thin black layers indicates the *active zone,* that is, the zone with gravity motion of the material. Because the motion is caused by the gravity, the axis of the active zone is vertical. The material with an intact white and black pattern is stationary and forms the so-called *passive zone.*

As simply shown on Fig. 20.2.8, when the individual black lines at the boundary of gravity motion are connected, one obtains a form similar to an ellipse. The real shape, as has been demonstrated on the models in Figs. 20.2.5 through 20.2.7 is not elliptical, but the elliptical shape is introduced for simplification and also, because at greater heights, the active zone is very similar to an ellipse. In reality, this ellipse is a vertical and axial section of an axisymmetric body, namely, that of an elongated ellipsoid of revolution whose geometry can be explicitly defined by eccentricity. This simplification enables application of simple numerical analysis.

It should be emphasized that the demonstration of gravity flow depicted in Figs. 20.2.3 through 20.2.10 is incomplete and can lead to erroneous conclusions because gravity flow is even more complex.

To avoid errors, it must be understood that what is being demonstrated by these successive phases is only the consequence of the extraction of a certain material volume from the model. The elliptical zones of the gravity motion can now be seen, but only the gravity motion of that material still remains in the model.

After the extraction of a certain volume, the remaining material replaces this loss by its loosening. Although it is evident that a certain relation exists between the extracted material and the loosening, only the visible zone of the *ellipsoid of loosening* can

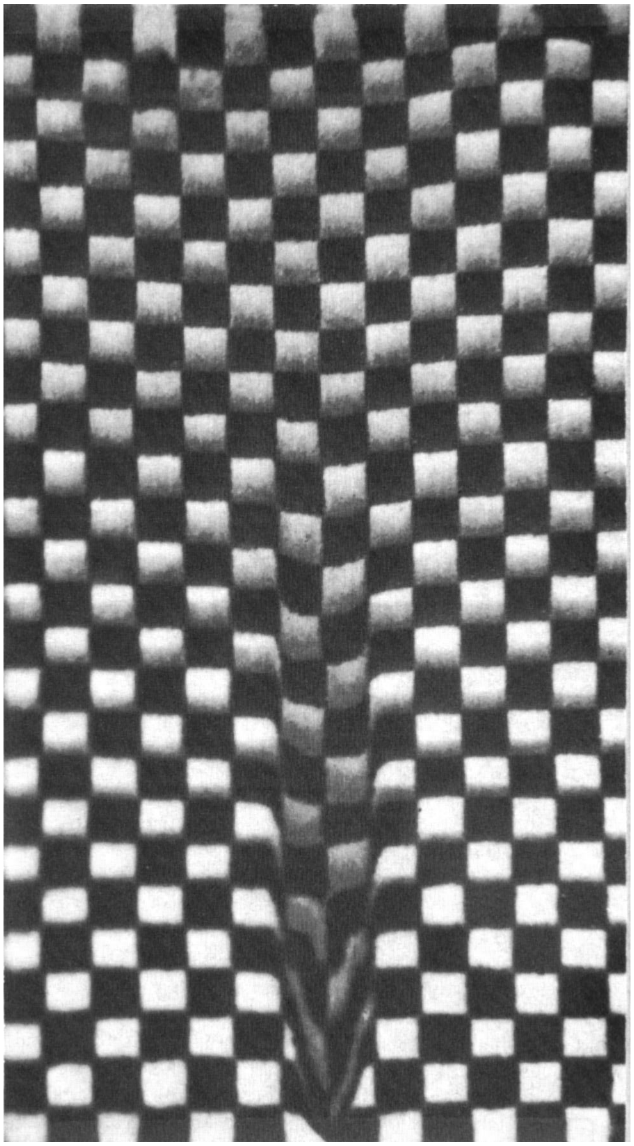

Fig. 20.2.4. Beginning of gravity motion in a model with checkered (black and white) sand (Kvapil, 1955).

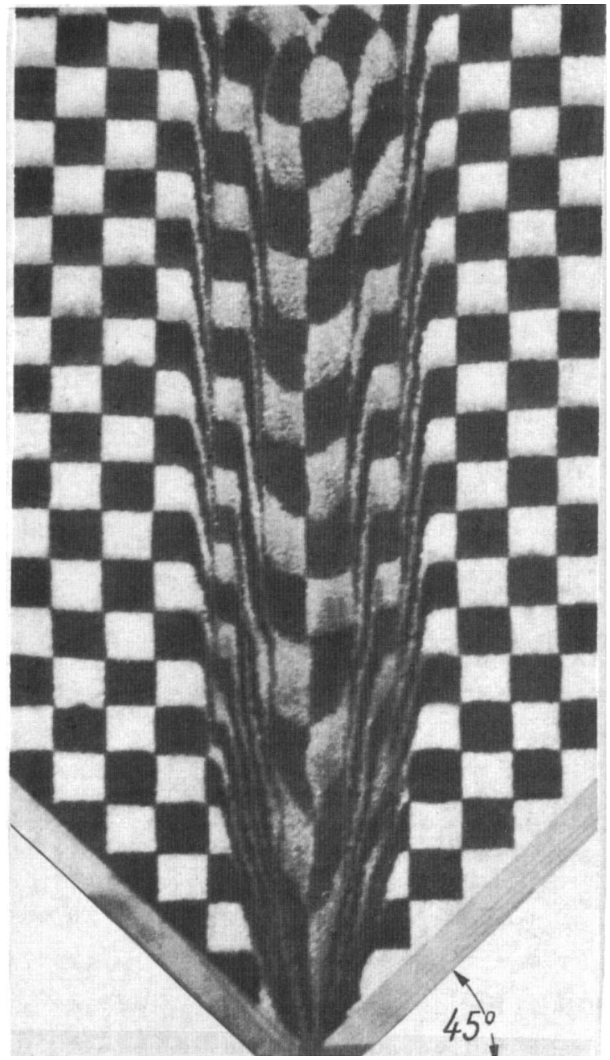

Fig. 20.2.5. Model of gravity flow shape in a bin with 45° bottom inclination (Kvapil, 1955).

be defined by the models shown above. The size of the ellipsoid (and its eccentricity) increases as more material is extracted. Depending upon material properties and the acting conditions, the volume of the ellipsoid of loosening can be about 14 to 16 times larger than the volume of extracted material.

From observing the pattern of deflected black lines (or checkered pattern in different phases of extraction), it is not possible to define either the location, shape, dimensions, or volume of the zone from which the material, now lying below the discharge opening, has been extracted. Extraction of a certain volume of material results in the development of a certain ellipsoid of loosening. Under these conditions, there is momentarily no motion at the boundary of the ellipsoid of loosening, and the greatest particle velocity is in the center of the discharge opening. The result of an analysis to determine the velocity distribution on levels E-E′ down to A-A′ is shown in Fig. 20.2.11. This provides an axonometric representation of the envelope surface of velocity vectors from $V = 0$ to $V_1 > V_2 \ldots > V_5$ For better visualization, the velocity vectors are not constructed in a true direction, but perpendicular to the axial section of the ellipsoid, with zero velocity on the boundary.

From Fig. 20.2.11, one can easily derive the zones of the same particle velocity V_1 defined on the boundary. This is shown in Fig. 20.2.12. The line which connects the particles of the same velocity forms an elliptical figure in a vertical section, and in space an ellipsoid of the same velocity. Evidently, the shape of the gravity flow zones is controlled by a specific distribution of the velocity of motion, resulting in ellipsoids of the same velocity. Therefore, not only does the zone of loosening have the shape of an ellipsoid (boundary of the ellipsoid of loosening has the momentary velocity = 0), but so also does the zone from which the discharged material was extracted. This zone, similar to the elongated ellipsoid of revolution, is called the *ellipsoid of extraction.*

20.2.2.2 Simplified Theory

The existence of the extraction ellipsoid can be demonstrated by using several different methods. One possibility is a three-

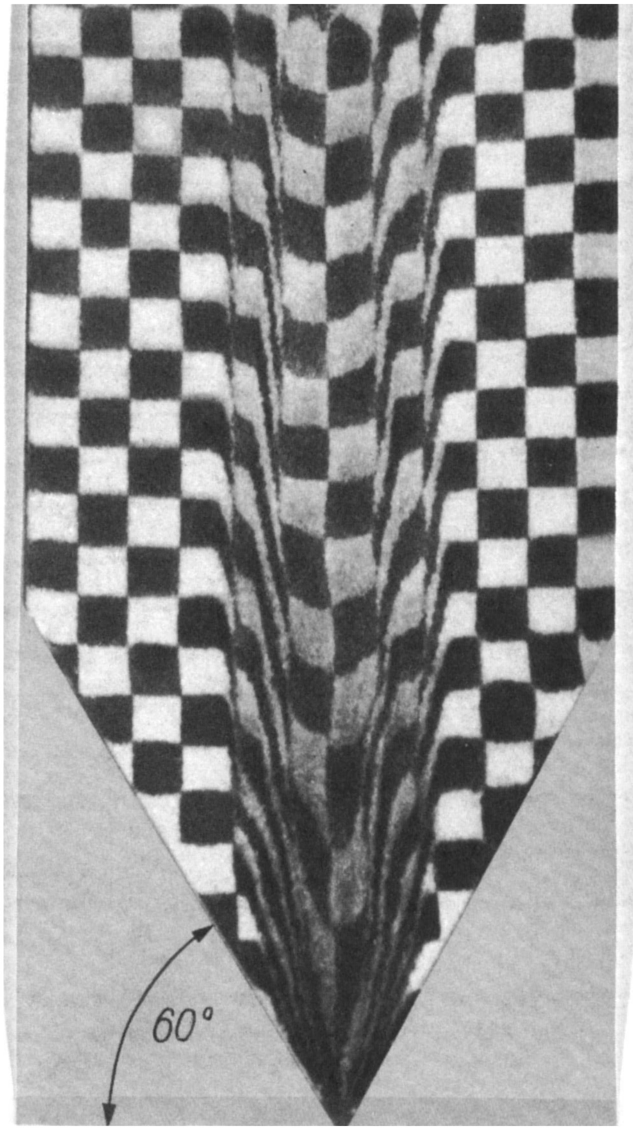

Fig. 20.2.6. Same case as in Fig. 20.2.5, but bottom of bin is inclined by 60° (Kvapil, 1955).

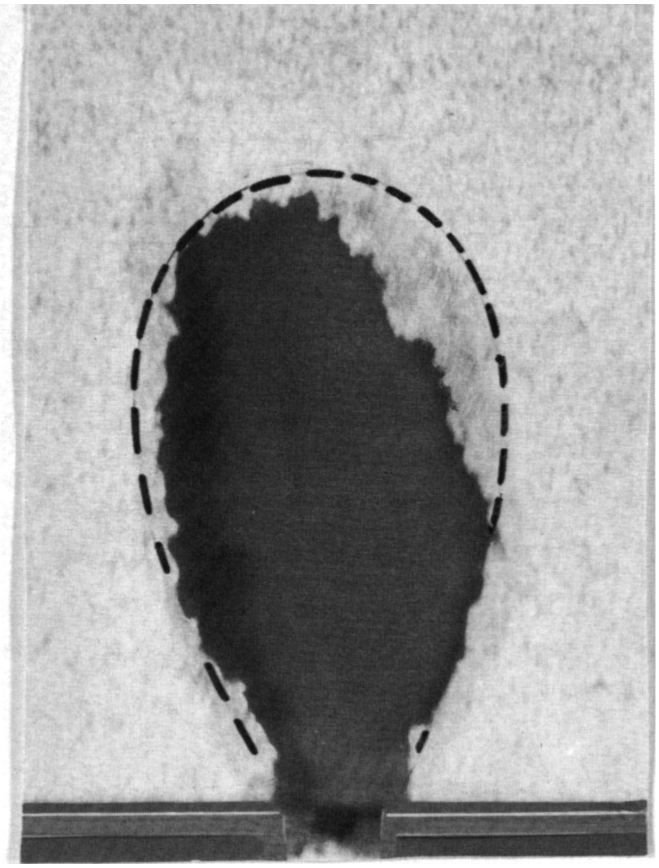

Fig. 20.2.7. Exaggerated shape of gravity flow visualized by a cavity in sand model with apparent cohesion (Kvapil, 1955).

dimensional model in which markers are located in a certain pattern in the granular material. When the original location of the marks is known (defined by space coordinates) before the extraction, the extracted markers together with the extracted material will define the extraction ellipsoid.

This method of using markers has been applied to determine the extraction ellipsoid (and also the entire active zone) in bins and silos. In order to ensure that the markers will correctly follow the gravity flow of stored material, they were constructed from rubber rings and picked out on a screen below the outlet. In sublevel and block caving tests, the markers were made of pieces of compressed air hoses (rubber), longitudinally cut and marked inside with a short-half-life radioactive color in order to determine their coordinates. These markers were fixed in the drillholes by cement grouting, and then detected in the muck using a Geiger-Müller radioactivity counter (Kapil, 1954). This system was also used to project and realize full-scale tests of sublevel caving in Grängesberg, results of which were later published (Janelid, 1975).

Probably the most instructive evidence of an extraction ellipsoid is obvious from Fig. 20.2.13. Phase a represents the model with a clearly marked ellipsoid of extraction. The eccentricity of the extraction ellipsoid was determined on a separate model with the same granular material. Apex point N is at a distance h_n above the discharge opening. Note that h_n represents the height of the extraction ellipsoid. As evident from phases b, c, and d (Fig. 20.2.13), increased extraction results in a successive decrease in the volume of the extraction ellipsoid and an increase in the volume of the loosening ellipsoid. When the apex point N arrives at the outlet, the entire volume of the extraction ellipsoid has been discharged and forms a cone below the discharge opening.

The gravity flow mechanism is shown diagrammatically in Fig. 20.2.14a, b, c, and d, which is identical to the model test of Fig. 20.2.13.

From Fig. 20.2.14d, it is evident that, with complete extraction of the extraction ellipsoid, the original horizontal plane n passing through the apex point N is deflected downward forming the outflow funnel 1, N, 2. Points 1 and 2 intersect the ellipsoid of loosening at the height h_n, which is equal to the height of the extraction ellipsoid. It means that the outflow funnel diameter 1, 2 is equal to the horizontal section of the ellipsoid of loosening measured at the height of the apex point (N) of the extraction ellipsoid. The volume of the outflow funnel is the same as the volume of the extraction ellipsoid.

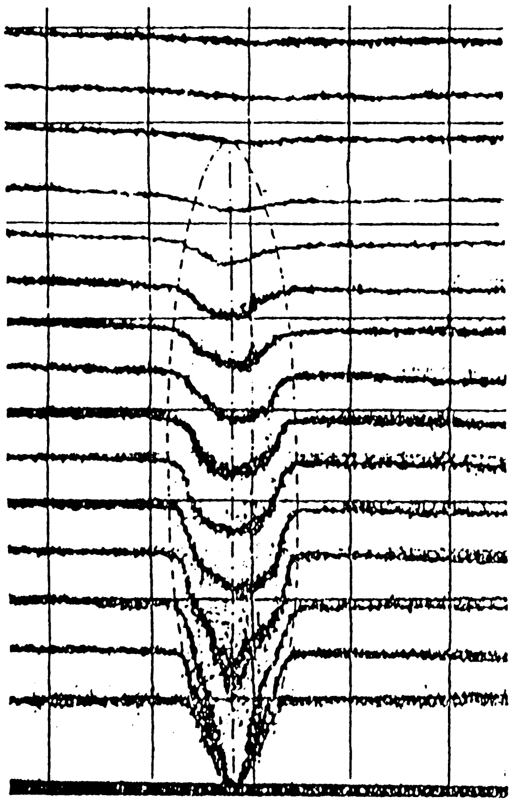

Fig. 20.2.8. Successive phase of material extraction from model shown in Fig. 20.2.3. Boundary of gravity motion forms a zone similar to an ellipsoid. It is an ellipsoid of loosening that is shown in the model by an ellipse.

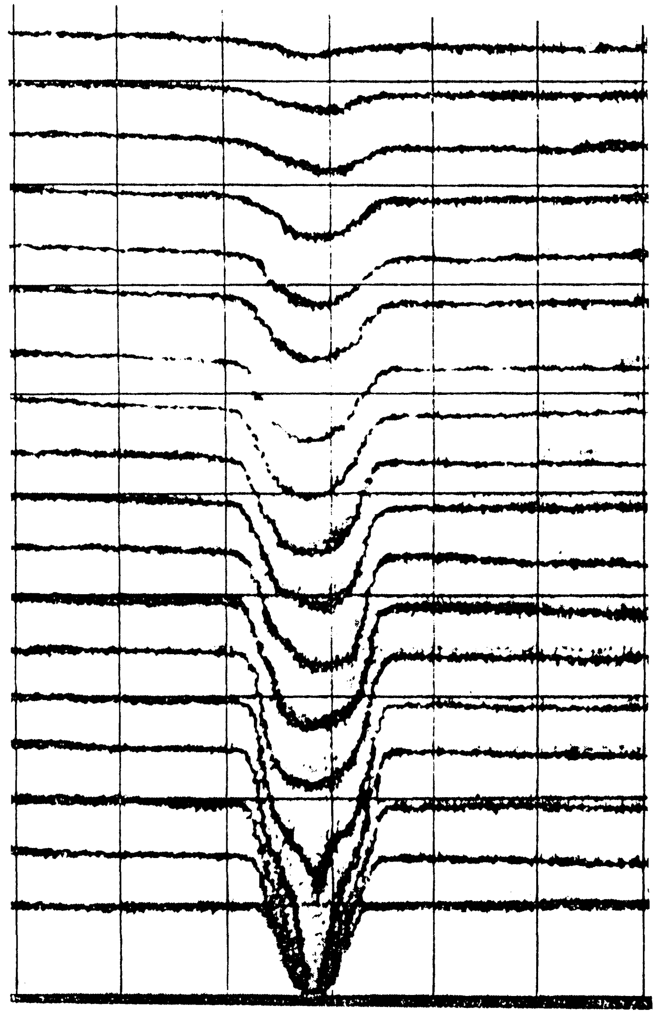

Fig. 20.2.9. Gravity motion created by successive phase of extraction.

As shown in Fig. 20.2.15, for a certain extraction height h_n, the mechanism of gravity flow is defined by explicit relationships between the discharged material, the ellipsoid of extraction, the outflow funnel, and the ellipsoid of loosening.

Using the designated nomenclature (V_c is volume of discharged material, E_E is the extraction ellipsoid, V_{EE} is volume of the extraction ellipsoid, h_n is height of the extraction ellipsoid, E_L is ellipsoid of loosening, V_{EL} is volume of the ellipsoid of loosening, h_L is height of the ellipsoid of loosening, F is outflow funnel, and V_F is volume of the outflow funnel), the characteristic relations for gravity flow can, by introducing certain simplifications, be expressed by the following formulas:

$$V_{EE} \approx V_C \tag{20.2.1}$$

that is, the volume of the extraction ellipsoid is the same as the volume of discharged material,

$$V_{EE} \approx V_C \approx V_F \tag{20.2.2}$$

that is, the volumes of extraction ellipsoid, discharged material, and outflow funnel are the same,

$$E_{EL} \approx 15\ V_{EE} \approx 15\ V_C \approx 15\ V_F \tag{20.2.3}$$

that is, the volume of the ellipsoid of loosening is about 15 times larger than the volume of the extraction ellipsoid, the volume of discharged material, or the volume of the funnel.

Assuming approximately the same eccentricity of the ellipsoid of loosening and the extraction ellipsoid, and knowing that $V_{EL} \approx 15\ V_{EE}$, then

$$h_L \approx 2.5 h_n \tag{20.2.4}$$

Hence the height h_L of the ellipsoid of loosening is about 2½-times greater than the height h_n of the extraction ellipsoid.

These relationships, which are generally valid, form the basis for understanding, explaining, and justifying the different phenomena involved in gravity flow.

Consider, for example, the situation in which the lower part of the material with height h_n is the ore, denoted by R in Fig. 20.2.15, and the upper part is the waste rock W. As is evident from Fig. 20.2.15, the maximum volume of pure ore that can be discharged without any waste rock (i.e., without any dilution) is only that from the extraction ellipsoid with height h_n. Any additional material discharge will result inevitably in a rapid increase in dilution because the outflow funnel, equal to the discharged extraction ellipsoid of height h_n, is now filled by waste rock.

For the same extraction height h_n, the extraction ellipsoid can have a different volume in different materials because the

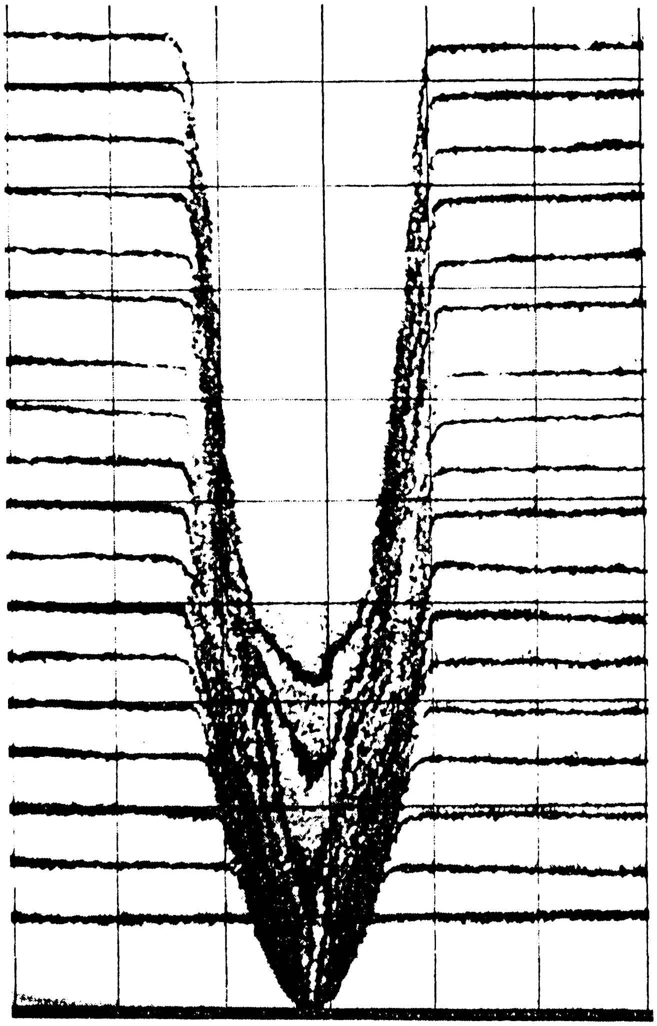

Fig. 20.2.10. Gravity motion created by much later successive phase of extraction in Fig. 20.2.9. Because the model is filled simultaneously while undergoing extraction, this figure shows the flow of white sand into the active zone.

eccentricity ϵ of the ellipsoid of extraction (and loosening) depends upon the material.

The formula for eccentricity of the ellipsoid is

$$\epsilon = \frac{1}{a}\sqrt{(a^2 - b^2)} \tag{20.2.5}$$

where a is the semimajor axis and b the semiminor axis of the ellipsoid (see also Fig. 20.2.15). Naturally, the greater the eccentricity, the slimmer the ellipsoid of extraction (or loosening) and the smaller the volume.

It is well known that in fine material (cement, fine sand, etc.), the active zone is very slender, and in coarse material, the active zone is broad. This is shown in Fig. 20.2.16a for very fine material, in Fig. 20.2.16b for granular material, and in Fig. 20.2.16c for coarse material. The eccentricity of the ellipsoid of extraction and loosening also increases with the height of the ellipsoids. This effect, which is relatively small in sublevel caving, has a much greater importance in block caving because of the very large block heights.

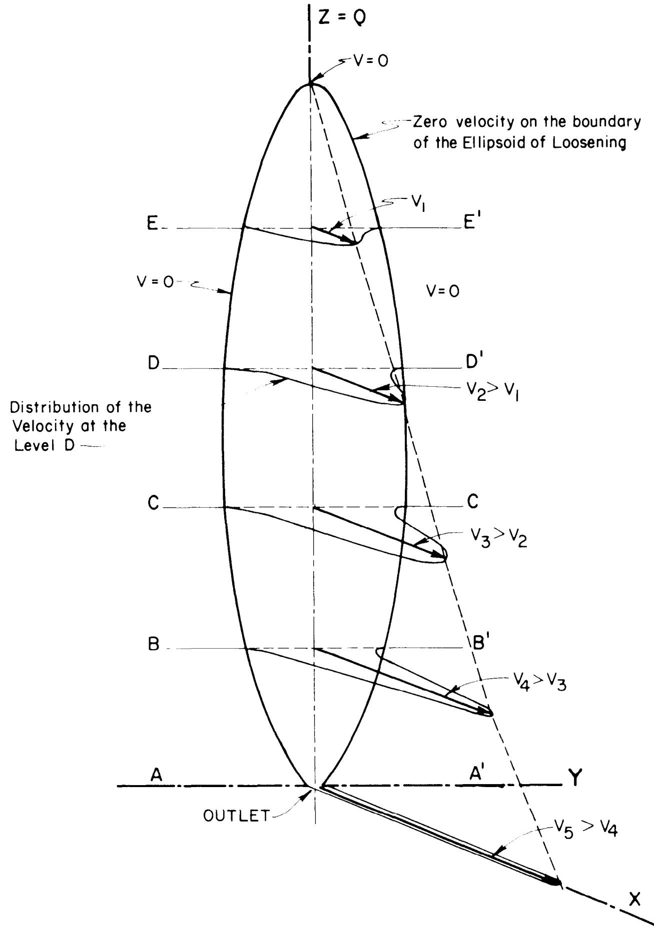

Fig. 20.2.11. Distribution of velocity in an ellipsoid of loosening (or extraction).

The eccentricity depends not only upon the size of the particles (and the gravity flow height) but also on many other factors, such as shape or form of the particles (spherical, irregular, etc.), surface roughness of the particles (smooth, rough), angle of friction (small, large), density (high, low), percentage of components with a lubricating effect (high, low), extraction or discharge rate (fast, slow), and material properties of the particles (strength, moisture, etc.).

All of these factors result in a certain behavior which can be expressed in terms of the mobility of granular or coarse materials. Greater material mobility results in smoother gravity flow and higher eccentricity of the ellipsoids. This means that in materials with high mobility, the ellipsoids are slender and in materials with low mobility, the ellipsoids are broad and contain large volumes.

Although an absolute scale is not yet available, the mobility of materials [classified between the limits of high (= very good) to low (= poor mobility)] can be used as a qualitative comparison of the flow behavior. From this indication of the flow behavior, one can deduct the approximate geometry of the ellipsoids. Fig. 20.2.17 shows the shape and eccentricity of the ellipsoid of extraction and loosening as a function of material mobility.

20.2.2.3 Specific Application to Sublevel Caving

For a vertical sublevel front, the sublevel drift forms a vertical opening, located in the plane of the sublevel front. Therefore,

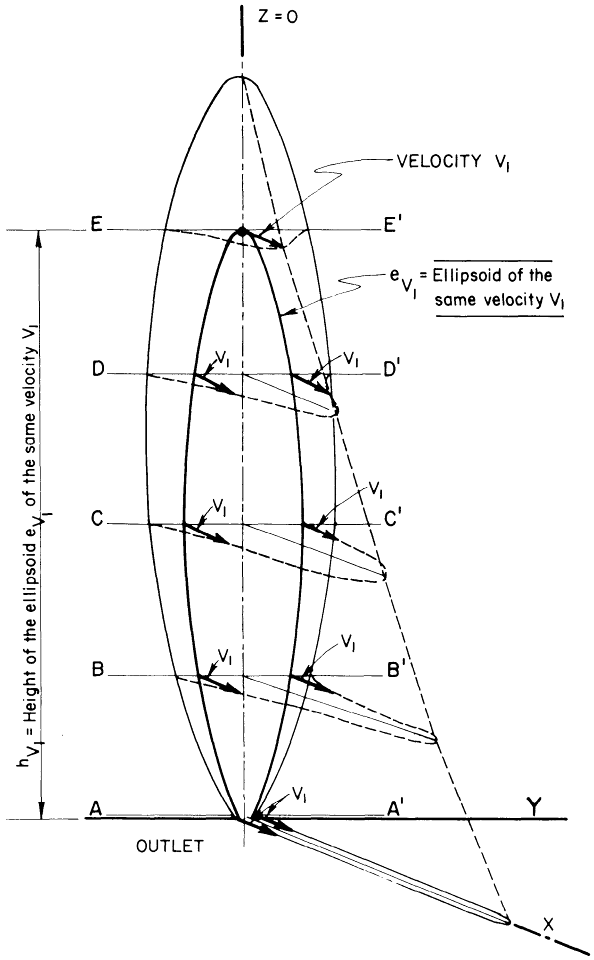

Fig. 20.2.12. Ellipsoid of same velocity.

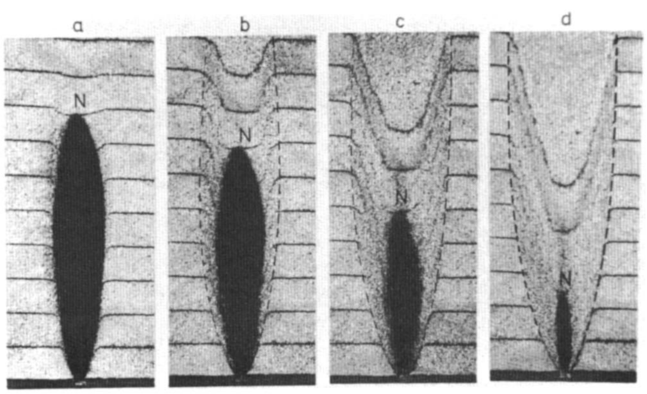

Fig. 20.2.13. Ellipsoid of extraction: (a) represents the model prepared for extraction; (b), (c), and (d) depict successive phases showing the flow of (black) material from the extraction ellipsoid and simultaneous development of the ellipsoid of loosening.

on a vertical section A-A′ as shown in Fig. 20.2.18, the geometry of sublevel caving is similar to a bin with discharge openings located not on the bottom but in the vertical wall of the bin. As is evident from the model in Fig. 20.2.19, the gravity flow zone is cut off by the vertical bin wall but is otherwise unchanged. It means that the vertical wall cuts off the ellipsoid of extraction and loosening as shown in Fig. 20.2.20.

The axis of gravity flow on this section deviates from vertical by a certain angle Δ. This angle increases as the friction along the vertical wall increases. Neglecting this deviation, one can assume that the vertical wall with vertical discharge opening cuts off half of the ellipsoid of extraction and loosening. Naturally, when this half of the ellipsoid is inscribed in a prism, then its volume is 50% of this prism. Therefore, in sublevel caving, if half of the extraction ellipsoid is inscribed in the body of blasted ore as shown in Fig. 20.2.18, then a maximum of 50% of the blasted ore volume can be extracted without dilution.

For the foregoing description of the gravity flow to be representative, the material must be discharged through a minimum size opening sufficiently large for the mass of solids to flow through the opening. In sublevel caving, the width of vertical discharge is formed by the width of the sublevel drift, which is greater than the width of a minimum size opening.

A greater opening width produces certain changes in the gravity flow that can be utilized for better ore extraction. These changes in the gravity flow pattern are clearly visible in the model shown in Fig. 20.2.21. To better demonstrate this effect, the model was constructed with an exaggerated opening width (in relation to the size of granular material). The central part of the gravity flow zone above the discharge opening moves downward more or less as a column; therefore, the black and white checkered pattern of the model filling is almost unchanged. This kind of gravity movement is called *mass flow*.

In sublevel caving, the opening at the level of the sublevel drift roof has the shape of a slot. Its theoretical length is equal to the roof width of the horizontal drift. In such a situation, the extraction zone (which has the same function as the extraction ellipsoid in a minimum size opening) no longer has the shape of an elongated ellipsoid of revolution, but forms an ellipsoid approximately similar to that shown in Fig. 20.2.22a. Simply, one can assume that this extraction ellipsoid consists of three parts as shown in Fig. 20.2.22b. Gravity flow consists of a partial mass flow (B) that only occurs on contact with the vertical plane of the sublevel front, while the remaining zones of the ellipsoid (A) undergo normal gravity flow. It means that mass flow occurs only in the zone that is marked as B in Fig. 20.2.22a and b.

It is clear that as the width of extraction opening increases, the width, and therefore the volume of the extraction zone, will increase. At the same time, a wide extraction opening will also result in an increase in the volume of undiluted extracted ore, because the outflow funnel will reach the extraction opening after the extraction of more undiluted ore than with a minimum size opening. This effect is shown in vertical section along the plane of the vertical front of the sublevel in Fig. 20.2.23. Here Fig. 20.2.23a represents the situation for a minimum size opening and Fig. 20.2.23b, the situation with a large width extraction opening.

It must be emphasized that the effective width of the extraction opening depends not only upon the width of the sublevel drift, but also upon the shape of the sublevel drift roof. When the roof is arched as shown in Fig. 20.2.24a, the slope of blasted ore will form a cone in the drift. Ore extraction from any place on the periphery of the cone toe will induce the flow of ore, which will follow the surface lines of the cone. Therefore, the cone will form a very narrow width outflow opening in the zone of the apex of the arched roof. Such a situation is unfavorable for sublevel caving because the effective extraction opening width will be very small. The gravity flow of blasted ore in the slice and flow of waste will have the pattern shown in Fig. 20.2.23a.

When the roof is horizontal (or slightly arched, see Fig. 20.2.24b), then the blasted ore will form a prism in the sublevel

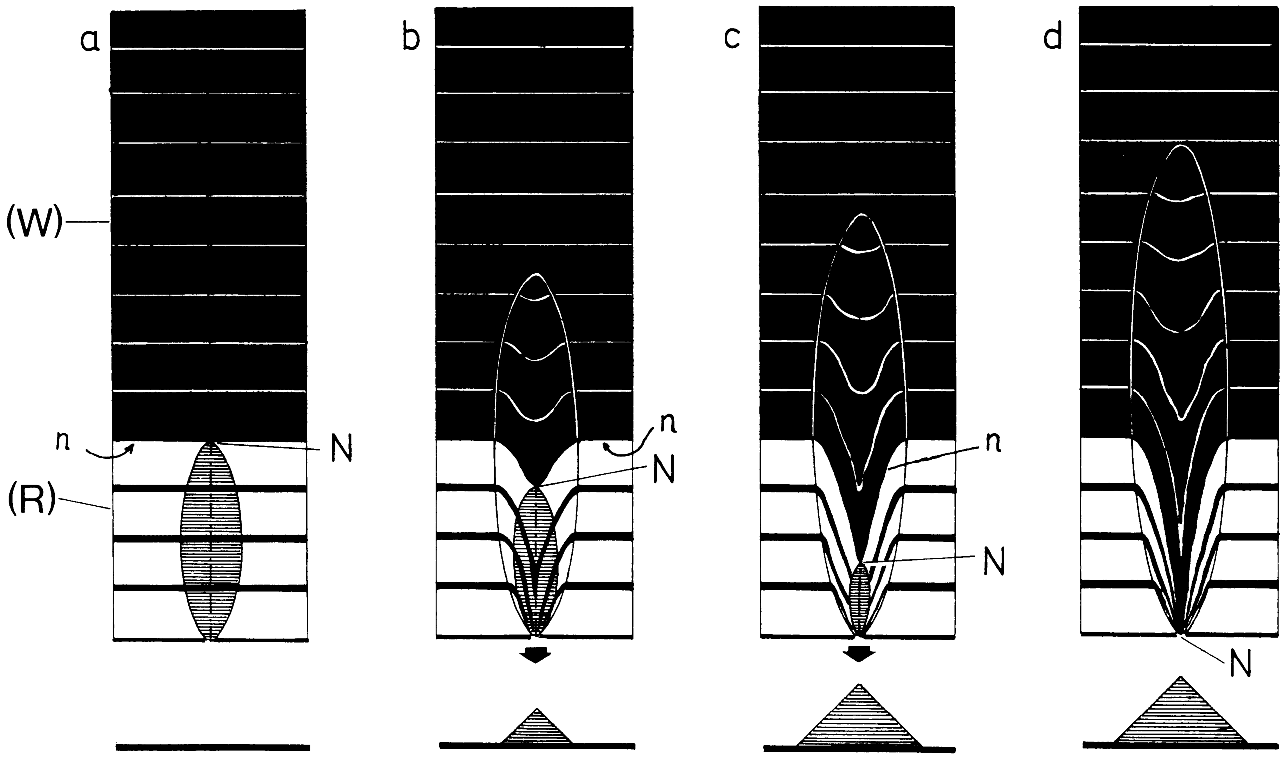

Fig. 20.2.14. Principle of gravity flow in an ellipsoid of extraction and loosening, identical to Fig. 20.2.13.

drift. Extraction from the slope toe of this prism will have a parallel flow on the slope, and therefore almost the total width of the sublevel drift can be utilized as an effective width of the extraction opening. Naturally, such a situation is favorable for sublevel caving because the effective width of extraction will be large and the gravity flow of ore (and waste) will have the pattern similar to Fig. 20.2.24b. Fig. 20.2.25 indicates the approximate effective extraction width as a percentage of the width of the sublevel drift w_d as a function of the roof shape.

Correct ore extraction demands not only a large extraction width, but also a satisfactory thickness or depth of the outflow zone. This depth depends upon how deep the loader can dig into the stope. Naturally, when the digging depth is small, the depth of the outflow zone is also small, and only a small part of the sublevel drift height is utilized for extraction.

According to Rankin's theory, the maximum stress trajectories in the slope of the bulk material are neither vertical nor perpendicular nor parallel to the slope inclination, but are inclined away from the vertical by $\beta = (90° - \phi)/2$ (see Fig. 20.2.26). In this figure, ϕ is the natural angle of repose, h_D is height of the sublevel drift, point 1 represents the theoretical slope toe, point 3 is the point at the edge that is formed by the intersection of the drift roof and sublevel front, point 2 represents the intersection of trajectories from point 3 with the floor of the sublevel drift, and X is the distance between points 1 and 2. With material extraction from the toe, the slope angle will approach the theoretical stable limit defined by the trajectory 3-2. This is the theoretical situation in which the slope 3-2 will have a stability coefficient equal to 1.0, which means that such a slope is just ready to fail.

Logically, in order to utilize the complete height h_D of sublevel drift for extraction, the digging depth must be

$$X = h_D \cot\phi - h_D \tan \frac{90° - \phi}{2} \tag{20.2.6}$$

The digging depth of a loading machine, usually about 3 to 4 ft (1 to 1.3 m), is much smaller than the theoretical depth X. This means that only a certain upper part (e) of the sublevel drift height will be utilized for normal extraction (Fig. 20.2.27). The remaining lower part, although not utilized for a normal extraction, also has a function: allowing the extraction of blocks with dimensions larger than the depth of the outflow zone on the level of the sublevel drift floor.

Even in normal extraction, the slope in the sublevel drift does not have a constant angle. The slope can vary between the limits, defined in Fig. 20.2.26 as points 1 and 2. It means the slope toe (point 1) can be close to point 2. In some cases, point 1 will be identical with point 2, and the slope will be very steep. The closer the slope is to the plane 3-2 (see Fig. 20.2.26) the more dangerous is its abrupt failure. Therefore, for safety reasons, it is useful to define the limiting angle of plane 3-2 and to induce the slope failure before this limiting condition occurs.

Extraction can be stopped by arching the material over the extraction zone. Most of the time, arching occurs over the outflow depth of the extraction zone (see Fig. 20.2.27) because this is the smallest dimension of the extraction opening. Although arching can have many variations, one can distinguish the following three basic types: (1) arching caused by a group of blocks that forms an arch structure, (2) arching caused by a compacted material (including the effect of apparent cohesion and/or plasticity), and (3) arching by a combination of these two.

When ore extraction is interrupted, the blasted ore (and caved waste) starts a process of settlement that can result in some compaction of the material. This occurs primarily when

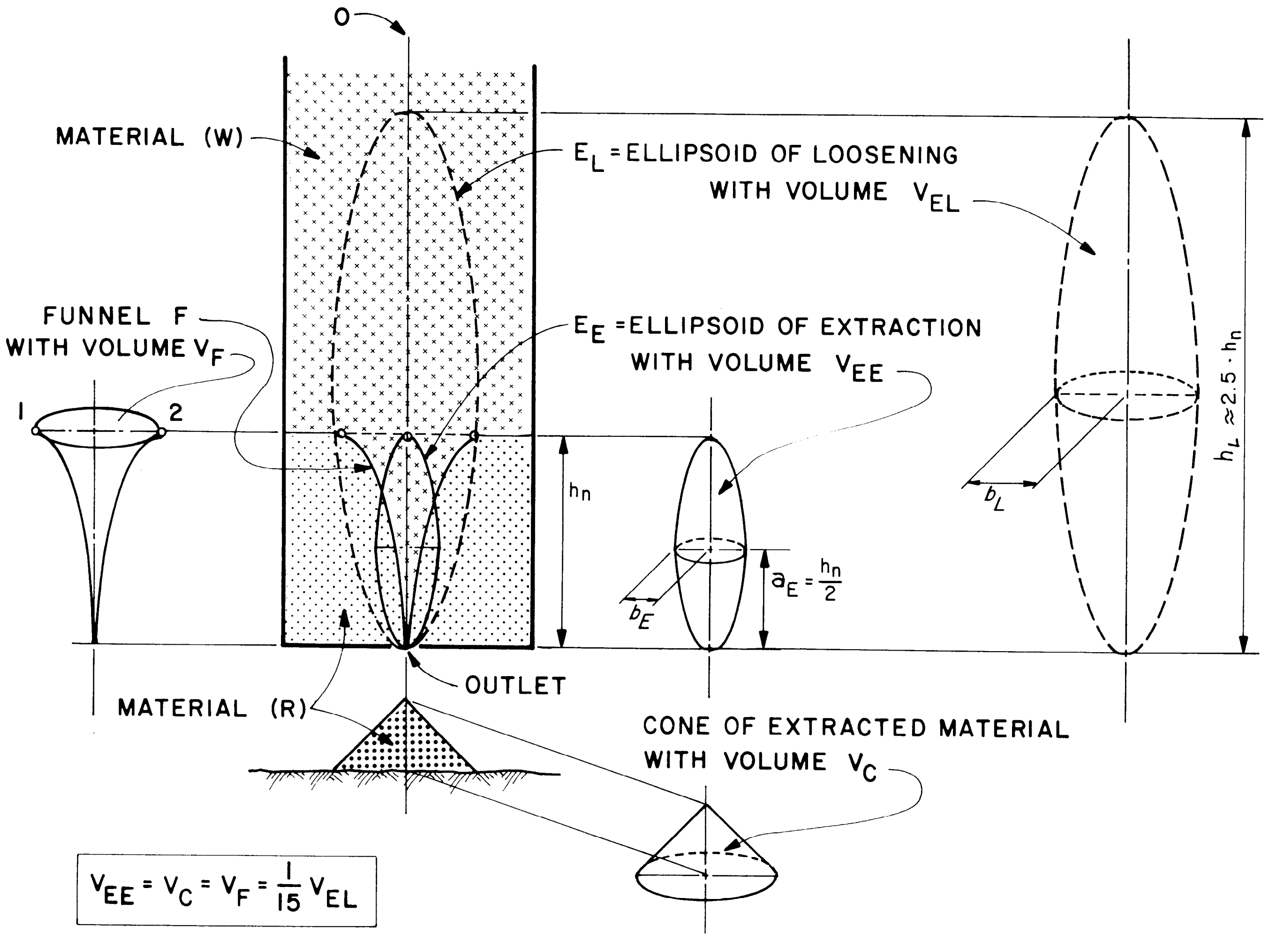

Fig. 20.2.15. Relationships in gravity flow mechanism.

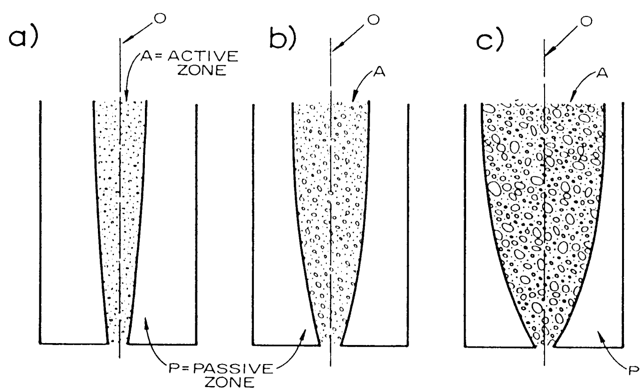

Fig. 20.2.16. Principle of particle or fragment size influence on shape of active (gravity flow) zone: a = fine material, b = granular material, c = coarse material.

plastic components and/or fine particles and water are present (see coarse material Type IV in Fig. 20.2.2). Arching (mainly of the second type) is more frequent after holidays or after any longer interruption of the flow of extraction muck. In materials with a relatively high rate of settlement and compaction, it is best to prevent this interruption. In practice, this means that total ore extraction from blasted slices of a sublevel should be completed before any long interruption.

The best method to avoid or minimize arching caused by large blocks is through controlled drilling and blasting, that is, to control the fragmentation.

Another question is the safe and efficient removal of the different types of arches. It is impossible to define a universal method that will satisfy all types of arching under varying conditions and circumstances. It can only be recommended that before any removal work commences, it is very important to understand the type, structure, and probable behavior of the arch and to define the critical zone or spot whose displacement (or excavation) will induce the failure of the arch. Otherwise, the work can be unsuccessful and even very dangerous.

As has been mentioned, the extraction ellipsoid (for a minimum-sized opening) does not have the shape of an elongated ellipsoid of revolution whose upper half is exactly identical to its lower half. Rather, the real shape has an upper half wider than the lower half (Fig. 20.2.28). For fine materials, the difference between the real and simplified shape is very small and can be considered negligible. The difference starts to be more pronounced in coarse materials and for extraction openings with widths greater than the minimum size. Lower mobility of coarse material, an apparent interlocking of the large fragments, together with partial mass flow in the central zone, results in a steepening of the lower part. Here the loosening and gravity

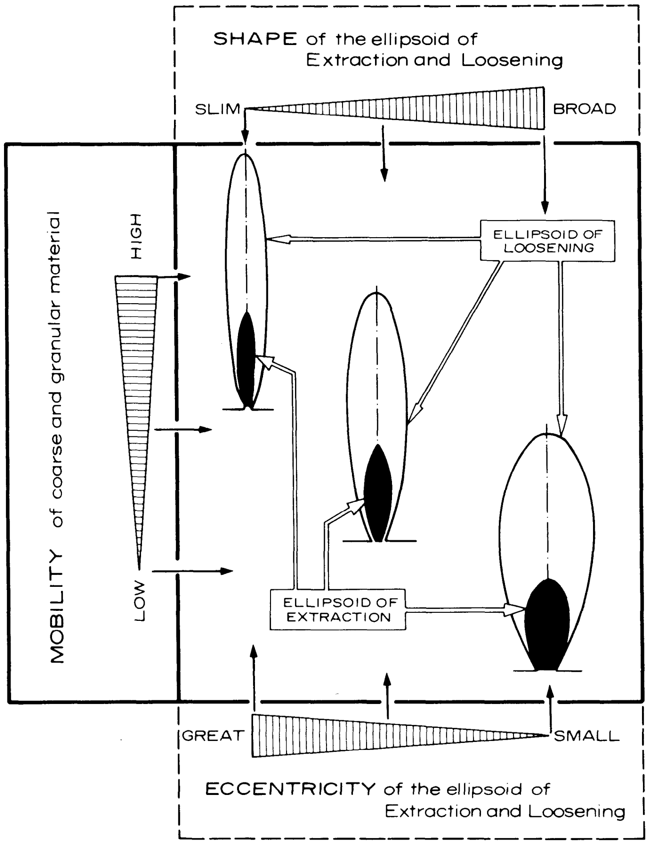

Fig. 20.2.17. Shape (and eccentricity) of ellipsoid of extraction and loosening as a function of material mobility.

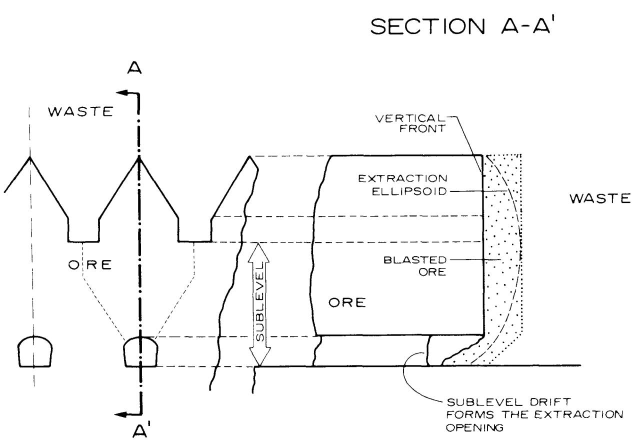

Fig. 20.2.18. Simplified geometry of traditional sublevel caving.

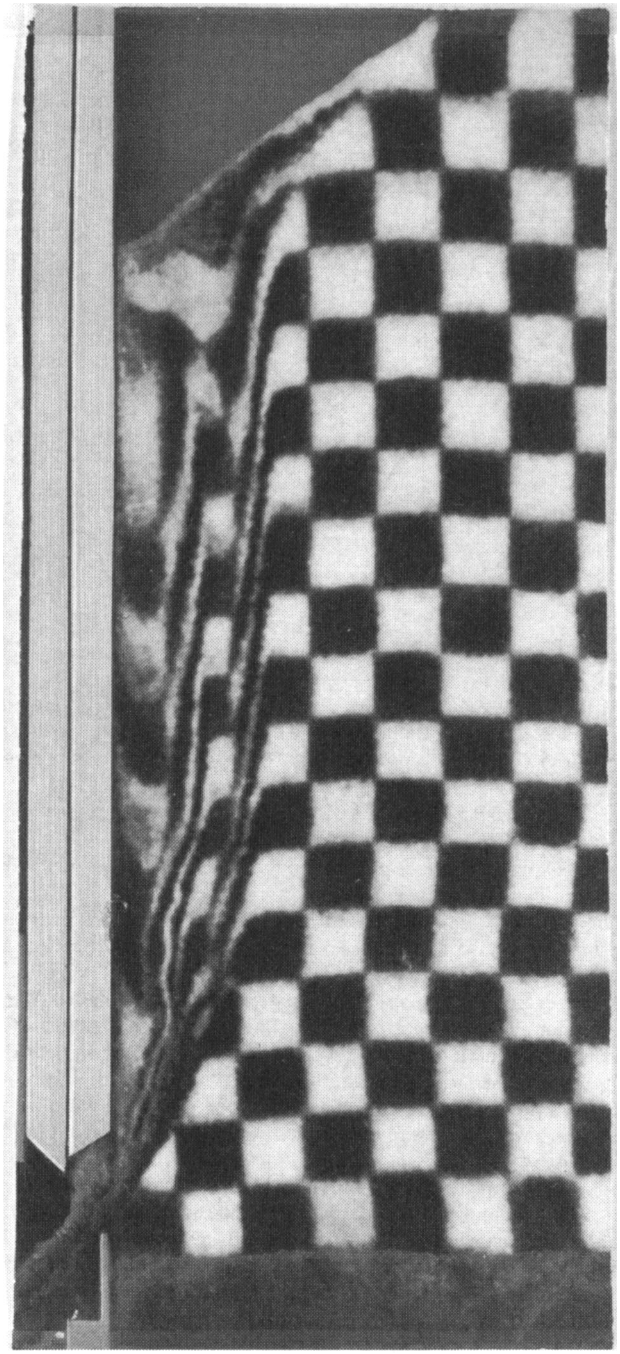

Fig. 20.2.19. Model of gravity flow when discharge opening is vertical, characteristic of sublevel caving (see vertical section A-A′ in Fig. 20.2.18).

motion is smoother because it is directed toward the extraction opening. The material in the upper part is remote from the opening, has lower loosening and lower mobility, and therefore needs a wider zone for gravity flow (see Fig. 20.2.29).

The change of shape is even more evident in sublevel caving because, in addition to the coarse and blocky material and greater width of the extraction opening, there are some additional factors due to ore blasting. In sublevel caving, the vertical slice of the ore is blasted against the caved waste. The final swell of the blasted ore varies over the height of the slice. Naturally, the greatest swell and loosening is in the lower part because a certain volume of the blasted ore falls and flows into the sublevel drift. This lower portion of the slice also has finer fragmentation due to the closer spacing of the drillholes in the fan drilling pattern. (Even with a parallel drilling pattern, the lower part of the blasted slice contains a higher percentage of small fragments and

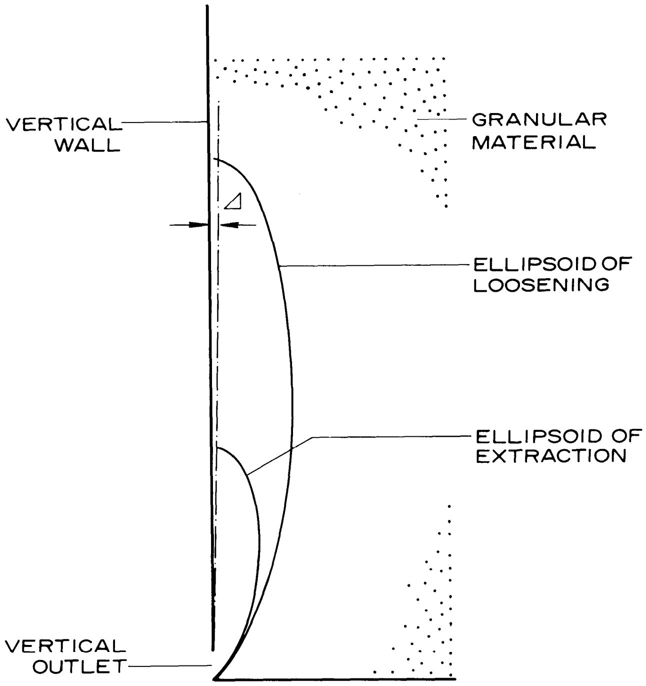

Fig. 20.2.20. Schema of ellipsoid of extraction and loosening when material is extracted through vertical outlet (sublevel drift) located in bottom of vertical wall. The vertical wall cuts off approximately half of both ellipsoids.

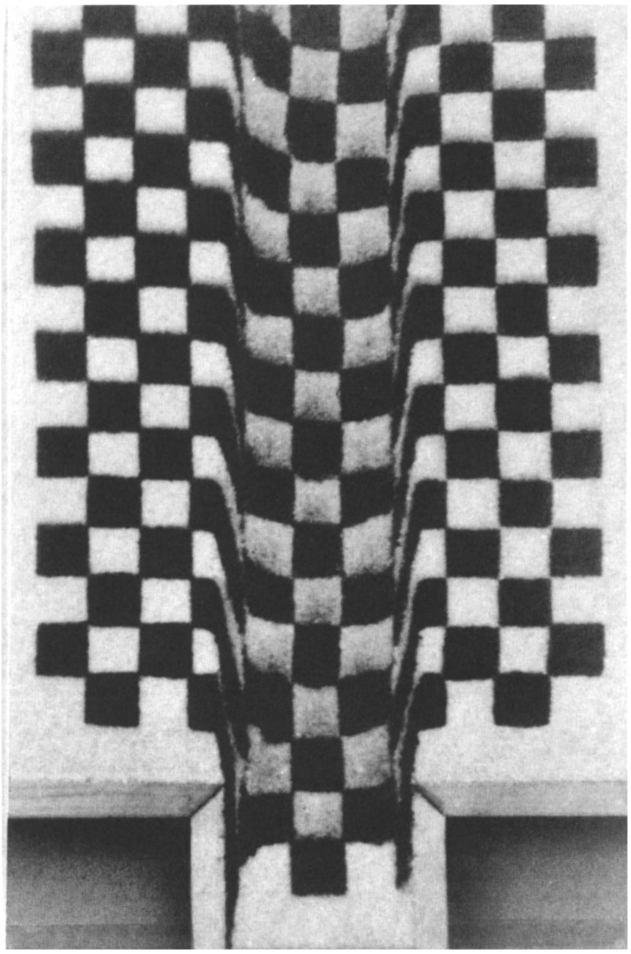

Fig. 20.2.21. Model of mass flow of material caused by exaggerated width of the extraction opening.

particles than the upper part, since they can penetrate downward into the cavities between the larger fragments.)

The swell and mobility of blasted ore in the slice decrease upward (away from the sublevel drift), and the fragments (and blocks) are bigger because of the larger spacing of drillholes in the upper part of the fan drilling pattern. In the upper parts, the confinement of the blasted ore in the slice is higher than in the lower part, which certainly results in a lateral prestressing of the blasted ore. An additional factor that can decrease the mobility of the upper parts is the penetration of a certain volume of overlying waste between the blasted slice and the ore front at the moment of blasting when, for a short while, the blasted slice is separated from the sublevel ore front. This can also be combined with a certain back break in the remaining ore front of the sublevel. It can be said that the blasted ore in the slice has the highest mobility in the lower part and the mobility decreases in the upward direction. The smaller the mobility, the greater the width necessary for gravity flow.

The extraction ellipsoid will be slimmer in the lower section with its maximum width being realized somewhat above half of its height, as is shown in Fig. 20.2.30a.

The shape of the extraction zone (in vertical section A-A′, perpendicular to the sublevel front) is constructed in Fig. 20.2.30b. Because the surface of the sublevel ore front is very rough, the friction along this plane is high, and the ellipsoid axis will deviate from vertical. The deviation *e* increases with increasing friction. Determination of this deviation is difficult, but it can be assumed that at a sublevel height of about 37 ft (11 m), the horizontal distance between the apex of the extraction ellipsoid and the vertical plane representing the sublevel front can be about 3 ft (1 m) or even more, depending on sublevel height.

Blasted ore in the slice usually represents a very heterogeneous material. Even with perfect drilling and blasting, the variations induced by so-called blasting tectonics can result in the creation of zones with large fragments or zones with fine material. Big blocks of ore (or waste) occur at random, mainly in the upper part of the slice. The migration of these large blocks or even pockets of fine ore (or waste) will cause disturbances in the gravity flow. Many other disturbing factors can also enter, for example, interruption of ore extraction from the slice, that can result in settlement and compaction of the blasted ore; discontinuous failure and caving of waste rock masses that can change the stresses acting on the slice of blasted ore; progressive failure and caving of other kinds of rock types at depth that can produce another type of fragmentation of caved waste than experienced in the upper zones; and increased size of the progressive failure zone and increased area of subsidence leading to the collection of water, that can cause undesirable changes in the properties and behavior of the blasted ore and therefore difficulties in ore extraction, etc. It is evident that because of these factors, the extraction ellipsoid in sublevel caving is not regular as might be expected with a homogeneous coarse material extracted without these disturbing influences.

20.2.2.4 Laboratory Studies and In Situ Testing

Research directed toward understanding the shape of the extraction ellipsoid in sublevel caving has been executed both on

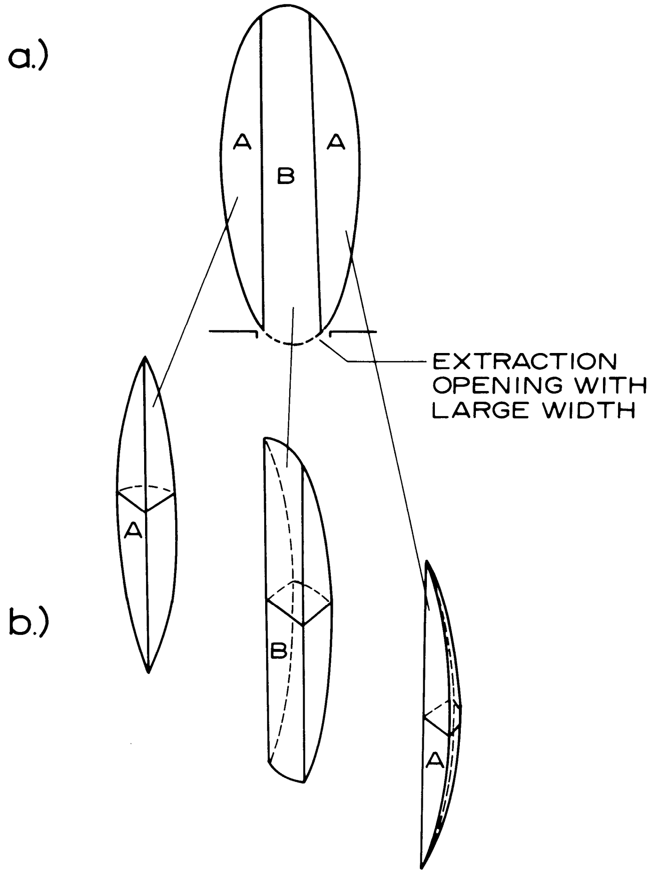

Fig. 20.2.22. Simplified shape of extraction zone created by sublevel caving and caused by large extraction width of the sublevel drift.

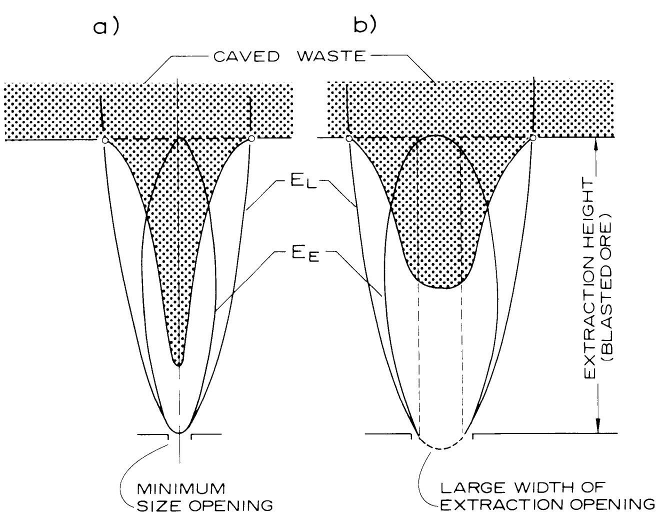

Fig. 20.2.23. Influence of extraction width on gravity flow pattern: a = small opening width, and b = large opening width.

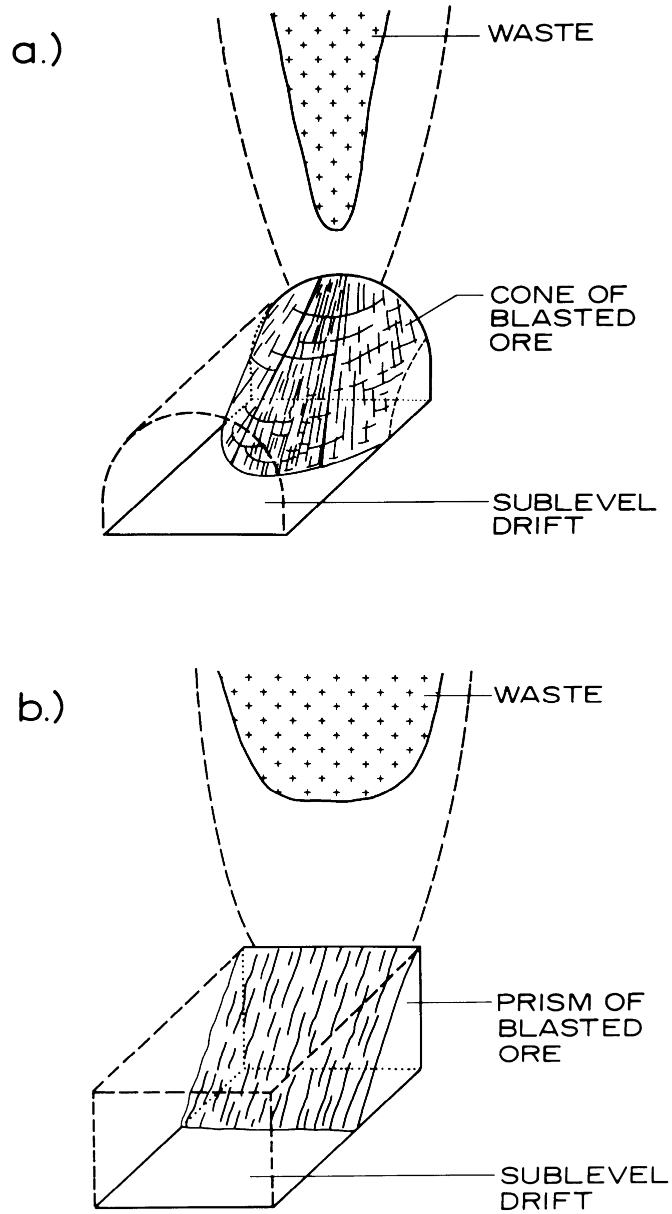

Fig. 20.2.24. Gravity flow pattern as a function of the shape of sublevel drift roof: a = arched roof, and b = flat roof.

models in the laboratory and full-scale in situ testing. Each of these approaches has certain advantages and disadvantages. In the laboratory, even very sophisticated models cannot simulate natural conditions correctly. In the field, two types of testing may be necessary.

The first type of in situ testing is based on the utilization of a large number of radioactive markers, located in drillholes in the ore slice before blasting and fixed into position by cement grouting. After blasting, the markers are dispersed in the rubble, and their exact location is not known. The second type is based upon the location of markers in the fragmented ore, that is, in the blasted ore of the slice. This method is difficult, laborious, and very expensive, and therefore only a few markers can be safely installed in blasted ore.

Analysis of laboratory experiments and of in situ tests suggests two shapes for the extraction ellipsoids in sublevel caving. The generalized geometry of both shape types is shown in Fig.

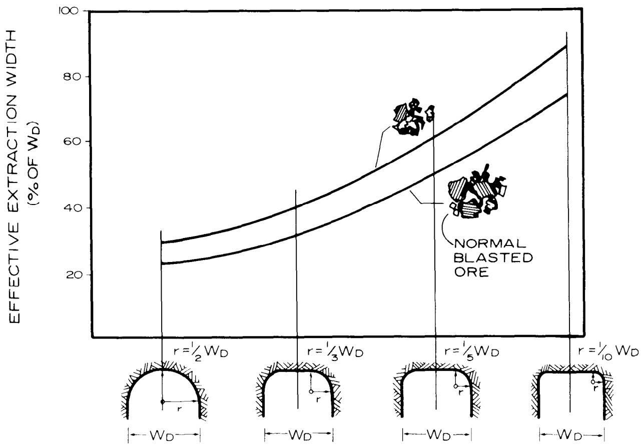

Fig. 20.2.25. Approximate effective extraction width as a function of the sublevel drift roof shape, expressed in a percentage of the sublevel drift width.

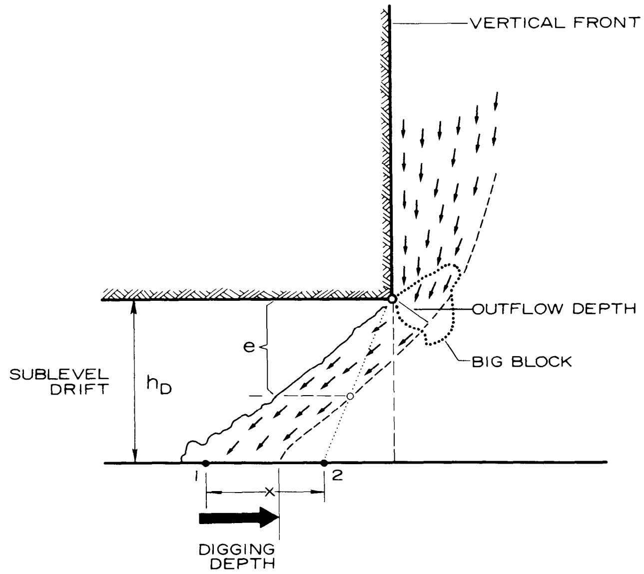

Fig. 20.2.27. Approximate outflow depth into the sublevel drift as a function of digging depth.

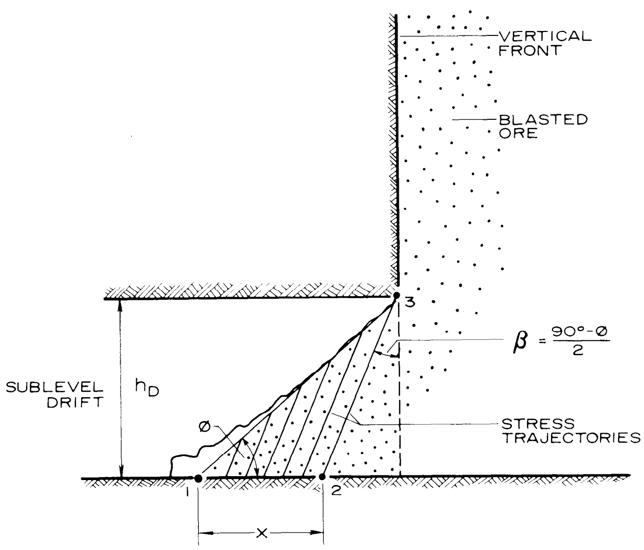

Fig. 20.2.26. Mechanics of the slope from fragmented material in the sublevel drift.

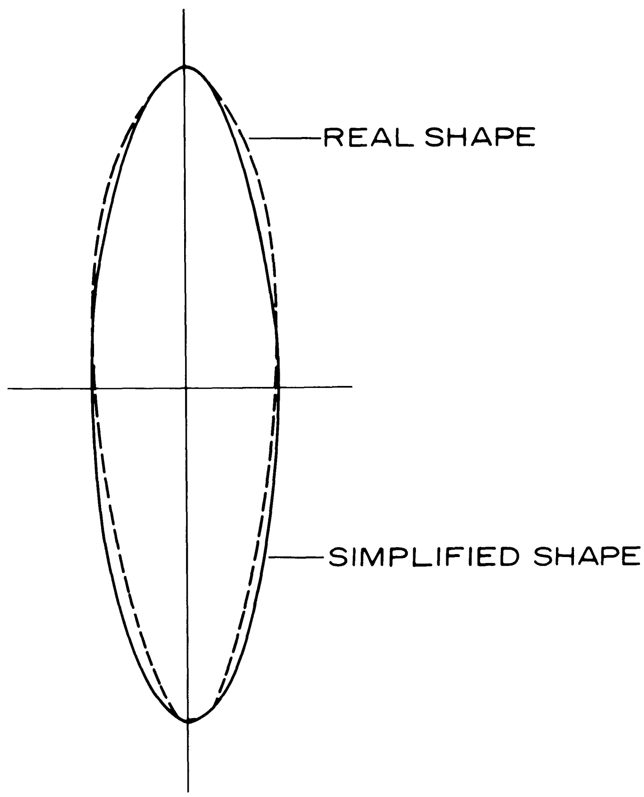

Fig. 20.2.28. Principle of the difference between simplified (idealized) and actual shapes of ellipsoid of extraction in a uniform granular material having a minimum size extraction opening.

20.2.31. Although the differences are relatively small, it is possible to distinguish that type A has a more rounded shape while type B is more angular. The cause of a type-A or a type-B shape is still questionable since the data from models (with limited precision) and from in situ tests (small number of tests) are still insufficient for explicit solution.

In both shapes, the maximum width W_T of the extraction ellipsoid is about 2/3h above the floor of the sublevel drift, where h is extraction height (see Fig. 20.2.31). The maximum depth d_T (ore thickness) of the extraction ellipsoid perpendicular to the sublevel front also occurs at the same height. Because of the large width of the extraction opening, the structure of the extraction ellipsoid is analogous in principle to that shown in Fig. 20.2.22.

For these reasons (disturbance factors and difficulties in testing), the exact shape of the extraction ellipsoid in sublevel caving is still not explicitly defined. As shown in Fig. 20.2.32, which represents the full-scale in situ test at Grängesberg, the shape of the extraction ellipsoids is very irregular depending on acting disturbances. This shape changes with the extraction height, that is, with a volume of extracted material. Even so, the contour shape is very similar to the type A shown in Fig. 20.2.31. Although knowledge of the shape is sufficient for engineering

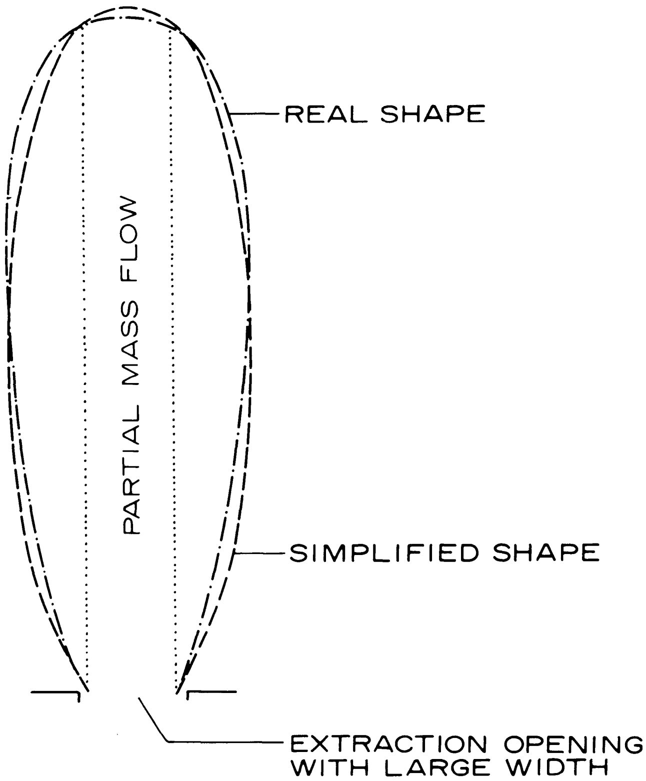

Fig. 20.2.29. Simplified and actual shape of an ellipsoid in granular material having a large-width extraction opening.

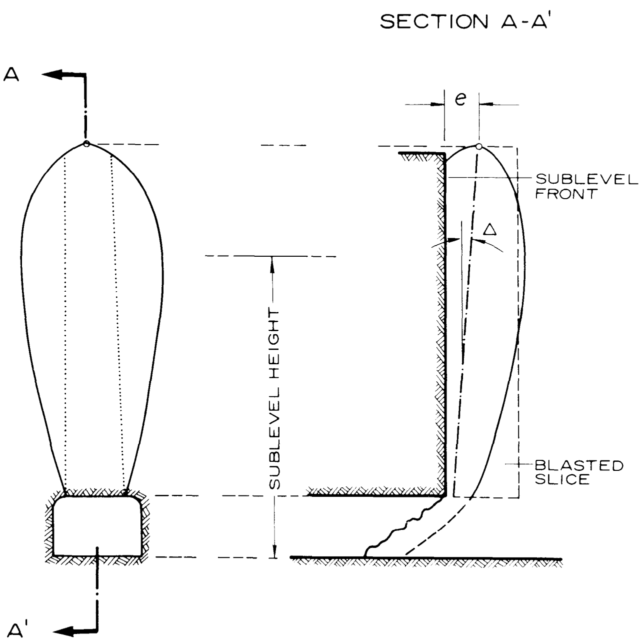

Fig. 20.2.30. Principle of actual shape of extraction zone in sublevel caving.

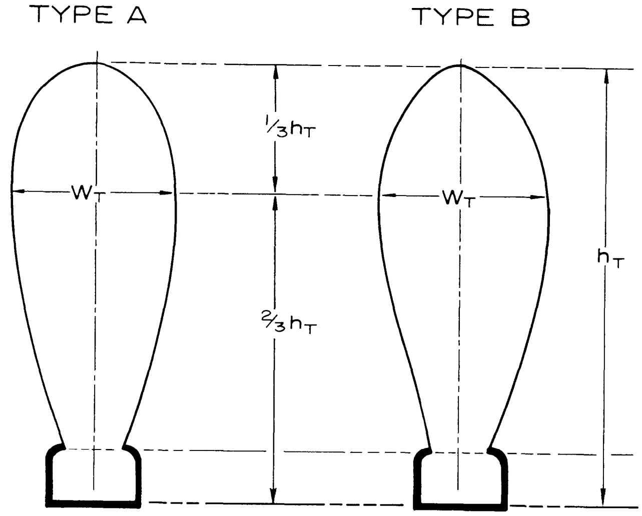

Fig. 20.2.31. Generalized geometry (type A and B) of extraction zone.

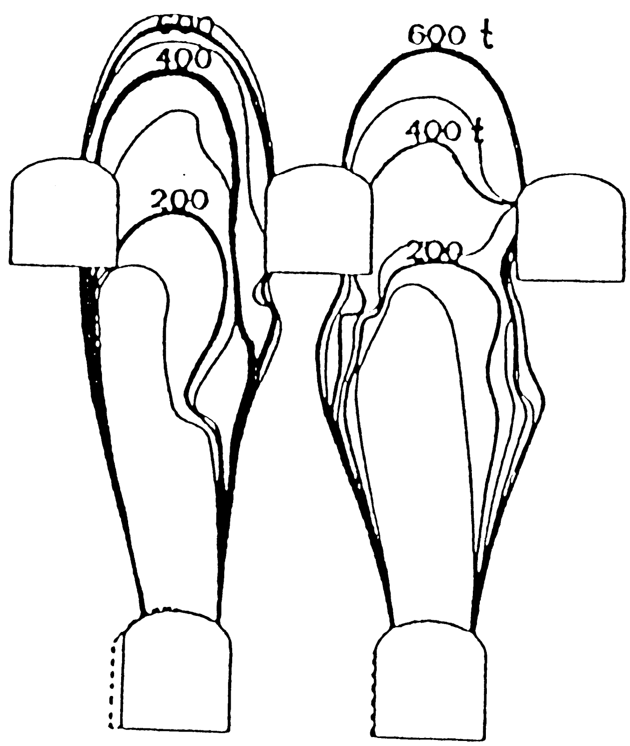

Fig. 20.2.32. Full-scale test of sublevel caving at Grängesberg mine (Janelid, 1973). Conversion factor: 1 ton = 0.9072 t.

practice, it is still insufficiently precise for the development of an explicit theory.

20.2.3 PRACTICAL DESIGN GUIDANCE

The main question in the design of a sublevel caving mining method is the determination of a mining geometry that will satisfy as much as possible the parameters of gravity flow. This means that one needs first to determine the width and thickness of the extraction ellipsoid for a certain extraction height.

These parameters can be determined by in situ tests, but usually test data are not available in time for the mine design.

Presently, no explicit method for making engineering calculations of these parameters is available. Because of the heterogeneity of coarse materials and the complexity of factors involved in gravity flow, certain empirical formulas will be introduced here that can serve as guidelines for the approximate determination of gravity flow parameters and for the geometry of the method.

20.2.2.1 Dimensions of the Extraction Ellipsoid

Coarse material is actually a mixture of different-sized particles. A small proportion of fine particles and fragments decreases, often markedly, the effect of the coarse fragments. As a result, the gravity flow zone in coarse material is sometimes surprisingly narrow.

Since the eccentricity of the ellipsoid increases with its height, the greater the height, the slimmer the flow. (This is very well known in block caving. With large block heights, the gravity flow above a single drawpoint can form a chimney with vertical walls.) With the same fragmentation, the gravity flow of a high-density material (i.e., blasted iron ore) will be slimmer than the flow of a low-density material (i.e., blasted copper ore). The width of the gravity flow depends also upon the size of the extraction opening. (See also Figs. 20.2.22 through 20.2.25 and 20.2.29.)

To exclude the variable factor of different extraction opening sizes, the data from analytical and model research, in situ tests, and observations in sublevel caving operations were used to determine an approximate theoretical width W' of the extraction ellipsoid, assuming extraction of material through a minimum size opening. Assuming a normal fragmentation of the blasted ore, the theoretical minimum size opening is about 6 ft (1.8 m). For high-density blasted ore (iron ore), the approximate theoretical width W' of the extraction ellipsoid is shown in Fig. 20.2.33 as a function of the extraction height h_T. In traditional sublevel caving, the total extraction height h_T in the ore is normally between 70 ft (20 m) and about 100 ft (30 m). The theoretical width W' of the extraction ellipsoid, corresponding to the different total extraction heights h_T within these limits, is shown in Fig. 20.2.24 for low- and high-density blasted ore. The effective extraction width a (see also Fig. 20.2.25) is usually larger than the width of a minimum size opening (6 ft or 1.8 m), and therefore, the total width W_T of the extraction ellipsoid in a sublevel caving operation will be bigger than that shown in Fig. 20.2.34.

A very approximate value of the total width W_T and total depth d_T of the extraction ellipsoid for a given height h_T can be calculated (in meters) using the following empirical formulas:

$$W_T \approx W' + a - 1.8 \tag{20.2.7}$$

$$d_T \leq W_T/2 \tag{20.2.8}$$

where W' is total extraction height h_T (see Fig. 20.2.34), and a is the effective width of the extraction opening dependent upon the shape of the sublevel drift roof (see Fig. 20.2.29, expressed as a percentage of W_D.

20.2.3.2 Vertical Spacing of Sublevel Drifts

The sublevel caving extraction drifts should be located in a checkered pattern conforming to the pattern of gravity flow.

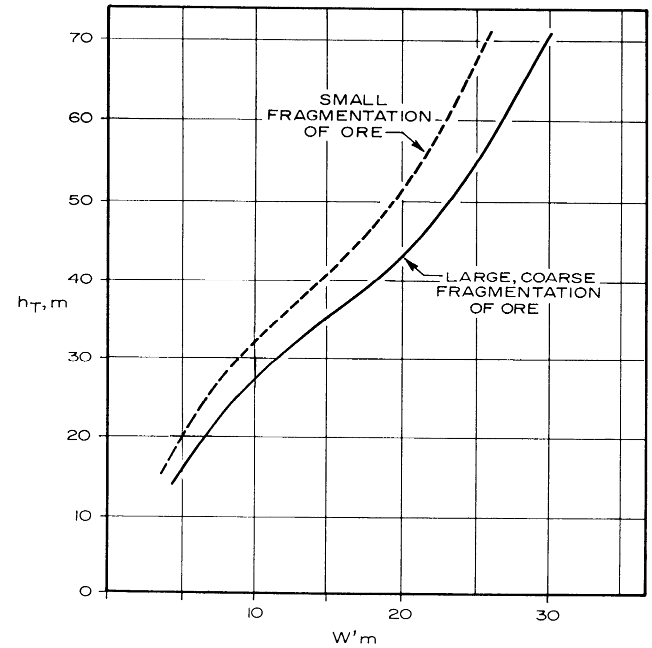

Fig. 20.2.33. Theoretical approximate width W' of a very large extraction ellipsoid for high density ore as a function of its height.

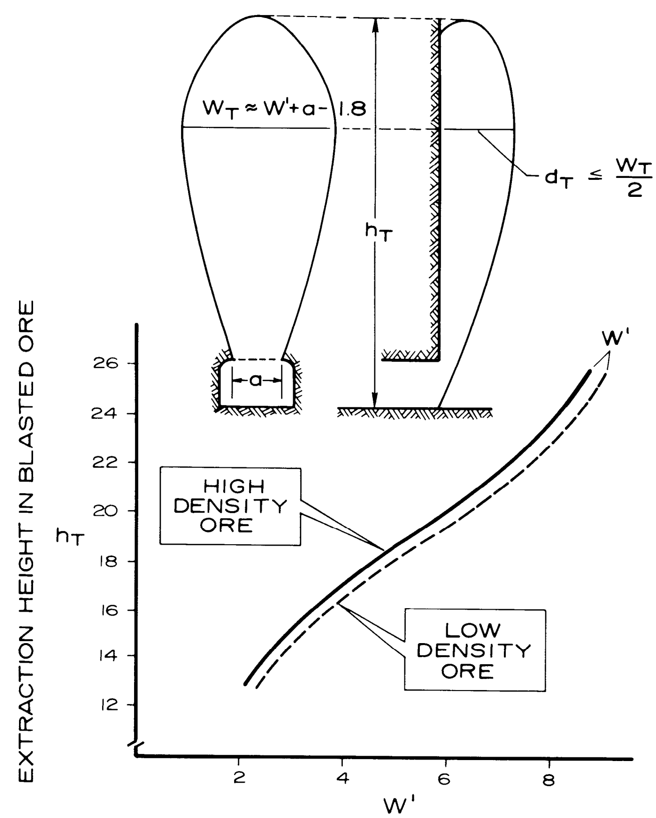

Fig. 20.2.34. Approximate width of the extraction ellipsoid (in traditional sublevel caving) in high- and low-density ore.

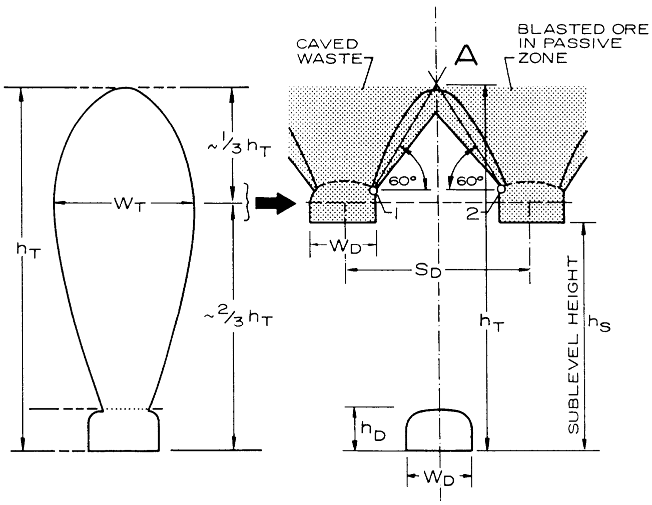

Fig. 20.2.35. Vertical location of sublevel drifts conforming to pattern of gravity flow.

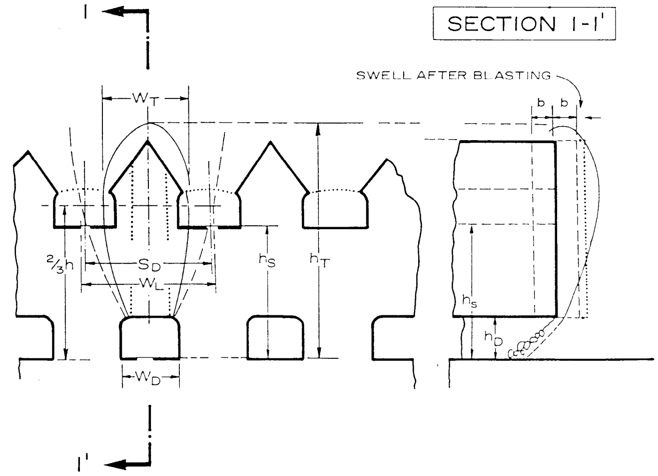

Fig. 20.2.36. Simplified sublevel caving geometry.

Using traditional sublevel caving methods, in vertical locations (see Fig. 20.2.35), sublevel drifts should be located in the zone where the extraction ellipsoid has a maximum width W_T. This occurs at about $2/3h_T$. In principle, this location indicates approximately the height h_S of the sublevel (see Fig. 20.2.35).

After ore extraction, an intact (not blasted) ore pillar having a triangular shape (transverse section) formed by the limiting inclined drillholes of the fan drilling pattern remains between the sublevel drifts on the upper level. This pillar is usually covered by blasted ore remaining in a passive zone above the pillar after ore extraction. The thickness of this passive zone of blasted ore can be large or small depending upon the inclination of the limiting drillholes in the fan drilling, the width W_D of sublevel drifts, the spacing S_D of sublevel drifts (see Fig. 20.2.35), and the properties and gravity flow parameters of the coarse material that control the shape of the passive zone.

The blasted ore in the passive zone can be partially recovered by extraction on the lower sublevel. Therefore, the total extraction height h_T is the distance between the floor of the lower sublevel drift and the apex A, formed by the remaining blasted ore in the passive zone (see Fig. 20.2.35). Because it is difficult to define the shape and dimensions of this passive zone, one must usually estimate the total extraction height h_T using experience from sublevel caving operations with similar conditions. As a rule of thumb, the lowest location of the apex A can be very approximately defined as the intersection of 1.05 rad (60°) inclined planes from points 1 and 2, as shown in Fig. 20.2.35. The minimum inclination of these planes is 60°. The highest location of this apex is defined by the floor of the upper sublevel drifts. The height depends greatly on the drilling design.

20.2.3.3 Horizontal Spacing of Sublevel Drifts

An approximate horizontal spacing S_D of the sublevel drift axes can be determined knowing H_T and W_T. This determination is based upon utilizing the idealized relations between the ellipsoids of extraction and loosening described in Fig. 20.2.15. Assuming similarity of eccentricity of ellipsoids and that the loosening ellipsoid is 2.5 times bigger than the ellipsoid of extraction, the width of the extraction ellipsoid is 40% of the width of the appropriate ellipsoid of loosening. (For these idealized conditions, one can calculate the width of the ellipsoid of loosening on any horizontal section of extraction ellipsoid.)

In sublevel caving, one needs to determine the width W_L of the loosening ellipsoid on a horizontal section just at the level where the extraction ellipsoid has its maximum width W_T (Fig. 20.2.36). The width of the loosening ellipsoid on this level indicates the approximate horizontal spacing S_P of the sublevel drifts.

Assuming that the relations and principles of idealized gravity flow (depicted in Fig. 20.2.15) can be applied to sublevel caving, the total width W_T of the extraction ellipsoid in sublevel caving is about 60 to 65% of the width of the loosening ellipsoid on the level where the extraction ellipsoid has its maximum width W_T. The width is about 60% for heights up to about h_T = 60 ft (18 m). Above that the width W_T is about 65%. Hence the approximate horizontal spacing S_D of sublevel drifts is

(1) For extraction heights $h_S \leq 60$ ft (18 m):

$$S_D < \frac{W_T}{0.6} \tag{20.2.10a}$$

(2) For extraction heights $h_S > 60$ ft (18 m):

$$S_D < \frac{W_T}{0.65} \tag{20.2.10b}$$

The basic geometric unit of sublevel caving is in principle defined by the relation between the horizontal spacing S_D of sublevel drifts and vertical height of the sublevel h_S. In conventional sublevel caving (see Fig. 20.2.36), this relation is

$$S_D \leq h_S \tag{20.2.11}$$

which means that the basic geometric unit has a square shape, or deviates only slightly from square.

Improved precision of longhole drilling in recent years has resulted in a tendency to increase the height of the sublevels with the goal of decreasing the volume of development. Ore draw can continue over heights greater than the extraction height h_T in the ore, but the dilution then rapidly increases. Large-dimension sublevel caving is discussed later in this chapter.

20.2.3.4 Thickness of the Blasted Slice

An approximate guide for the thickness of the blasted slice b (burden spacing) on the front of the sublevel is usually

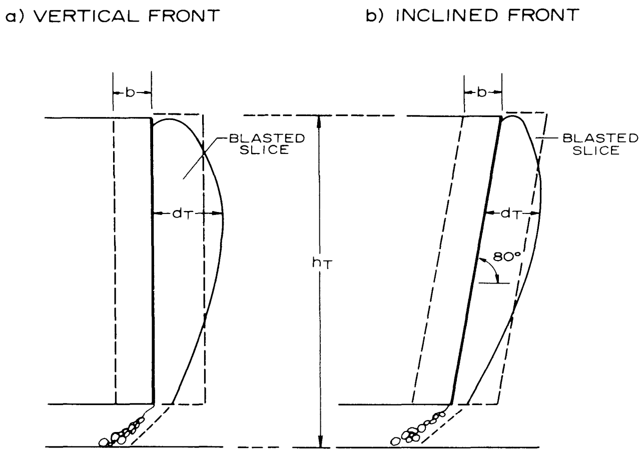

Fig. 20.2.37. Vertical (a) and inclined (b) front of sublevel caving. Inclined front decreases dilution.

$$b \leq \frac{d_T}{2} \qquad (20.2.12)$$

where d_T is found from Eq. 20.28. This relationship can be used as an estimate for traditional sublevel caving. For large-dimension sublevel caving, made possible by new drilling equipment having the capability to drill very long drillholes (13 to 20 ft, or 40 to 60 m) with satisfactory precision, different relationships are valid, because the eccentricity of the flow ellipsoid rapidly increases with its height.

20.2.3.5 Inclination of the Front

The sublevel front is usually vertical or inclined at 1.4 rad (80°). This inclination is favorable not only for drilling and charging of drillholes but also for minimizing the dilution. The effect of the sublevel front inclination is evident as shown in Fig. 20.2.37, where Fig. 20.2.37a has a vertical front and Fig. 20.2.37b has an inclined front. The extraction height h_T is the same in both cases.

With a vertical front (Fig. 20.2.37a), the extraction ellipsoid intrudes deeper into the caved waste rock. This is particularly true when the sublevel is high.

The inclination 1.4 rad (80°) of the front shown in Fig. 20.2.37b will cause a change of the gravity flow shape, and the extraction ellipsoid will be much slimmer than with a vertical front. It can be simply said that in this case, the extraction ellipsoid has a tendency to be inscribed within the blasted ore slice. The intrusion of the extraction ellipsoid into the caved waste is smaller, and therefore, the dilution, with ore extraction over the same extraction height h_T, will be smaller than with a vertical front.

20.2.3.6 Extraction and Dilution

The dilution process in sublevel caving can take many different anomalous and unexpected forms; for example, the outflow of a certain quantity of caved waste-rock almost at the beginning of ore extraction that is then followed by normal ore flow; or the random occurrence of waste rock pockets at different stages of the ore extraction, etc. The cause of such phenomena is still not defined satisfactorily, although big blocks are surely of great importance. In ore which tends to arch over the extraction opening, one can expect a higher probability of anomalous dilution.

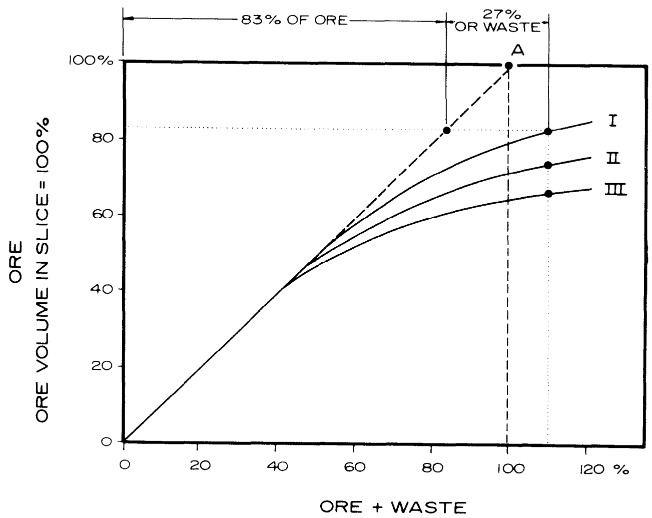

Fig. 20.2.38. Simplified process of dilution development in sublevel caving. Curve I represents good extraction, and Curve III represents bad extraction with high dilution.

The ideal process of normal dilution development in sublevel caving is illustrated in Fig. 20.2.38 as a function of the volume of the ore and the volume of extracted material (consisting both of ore and caved waste). It is expressed as a percentage of the volume of ore slice where the total volume of the ore slice is 100%. Theoretically, the best extraction will be defined by the line OA. This means one will extract 100% of the ore without any waste. Such a situation is not possible in practice.

Fig. 20.2.38 shows three different cases of ore extraction with different dilutions, that is, with different volumes of waste extracted together with the ore. The optimum total extraction (ore and waste) can have different values depending upon the value of the ore and the overall economics. In Fig. 20.2.38, it is assumed that extraction will stop after drawing 110% of the slice volume.

Curve I in Fig. 20.2.38 represents good extraction because ore recovery is 83% with only 27% waste.

Curve II demonstrates a case in which the distribution is about 75% ore and 37% waste for a total extraction of 110%. Of course, this is not as good as the previous example, but in certain conditions, primarily in cases when a simple and cheap process of waste separation is applicable, it can be acceptable.

Curve III characterizes a bad extraction. In this case, for a draw of 110% total material, only 65% of ore with waste as high as 45% is extracted.

As a guide for evaluating the extraction (assuming 110% of material [ore and waste] extraction), the following classification can be used:

1. Class I: Extraction is good as the ore is at least 80% and the waste is less than 30%.
2. Class II: Extraction is acceptable in certain cases as the ore is at least 75% and the waste is no more than about 35%.
3. Class III: Extraction is poor as the ore constitutes about 65% and the waste 45% or more.

Total dilution development is already defined at the beginning of the dilution process. Approximate relations are evident from the chart in Fig. 20.2.39. For example, if after a material extraction of 71%, the ratio is 60% ore and 11% waste (see point A in Fig. 20.2.33), one can expect that with 120% material extraction (see point B in Fig. 20.2.39), the ratio will be about

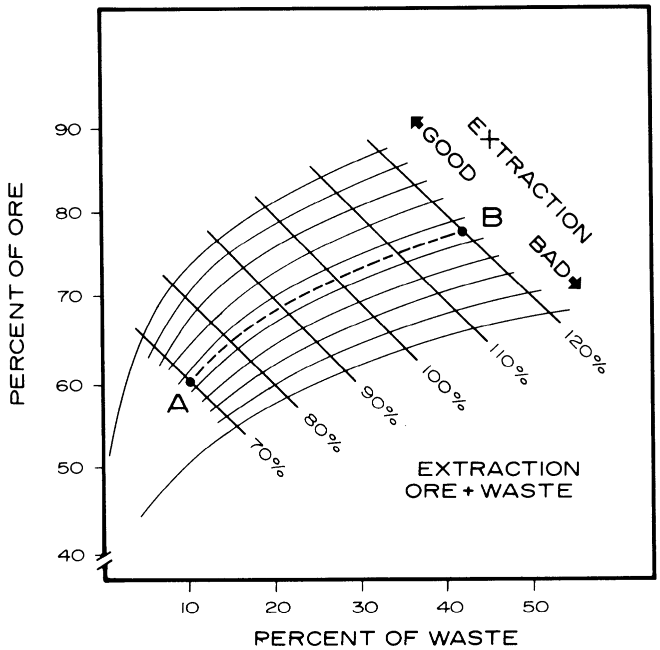

Fig. 20.2.39. Simplified chart of dilution development.

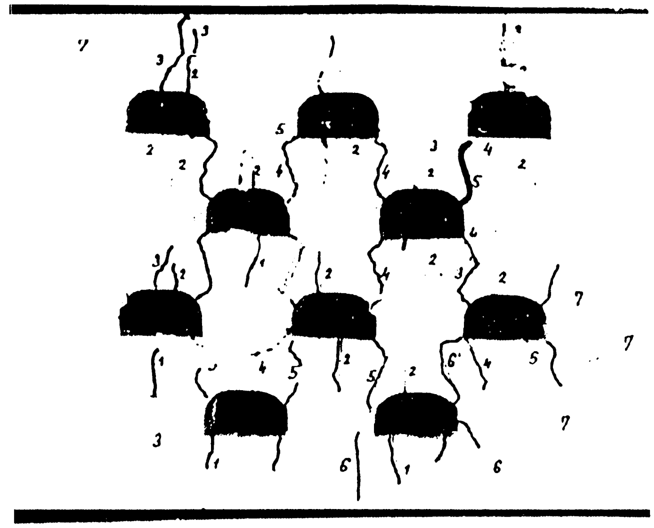

Fig. 20.2.40. Plaster model showing characteristic failure of a "checkered" sublevel drift structure. Failure is caused by shear cracks between the closest corners of overlying sublevel drifts.

77% ore and at least 43% waste. The limit between good and bad extraction can be different in different ores with different ore grades. The approximate boundary between good and bad extraction is indicated in Fig. 20.2.39 by the line A-B.

20.2.3.7 Opening Stability

The stability of the opening of the sublevel caving structure is usually very good, and so this method can be safely utilized even in relatively soft ores and rock masses. Nevertheless, it is necessary to understand that the checkered pattern of sublevel drifts generates a special stress distribution that determines the stability limits of the structure. This checkered pattern of drifts results in high shear stress concentrations in the rock lying between the closest corners of drifts on the upper and lower levels.

Under the same loading conditions, the stress concentration increases with decreasing sublevel height h_S and drift spacing S_P and with increasing sublevel drift width W_P and height h_P (see Fig. 20.2.36). Under critical loading, the failure of the sublevel structure is characterized by shear cracks between the closest corners of sublevel drifts on upper and lower levels. This characteristic pattern of cracks is shown on a plaster model in Fig. 20.2.40. Detailed stress analysis can be provided using finite element or other methods of analysis.

The location and direction of failure shear cracks follow the zones of maximum shear stress concentration. This is shown in Fig. 20.2.41 in which the dotted lines represent the isochromatic lines obtained on a photoelastic model with the same geometry and with the same kind of loading as the plaster model in Fig. 20.2.40. The higher the order of the isochromatic line (marked in Fig. 20.2.41 with numbers 1, 2, 3, etc.), the higher is the maximum shear stress. Therefore, from Fig. 20.2.41, it is evident that the shear cracks correspond to the maximum shear stress concentration. It is necessary to emphasize that the introduction of sublevel caving at depth requires a careful stress and stability analysis for definition of a safe geometry.

With regard to the checkered location and relatively short distance between sublevel drifts, damage to the rock mass re-

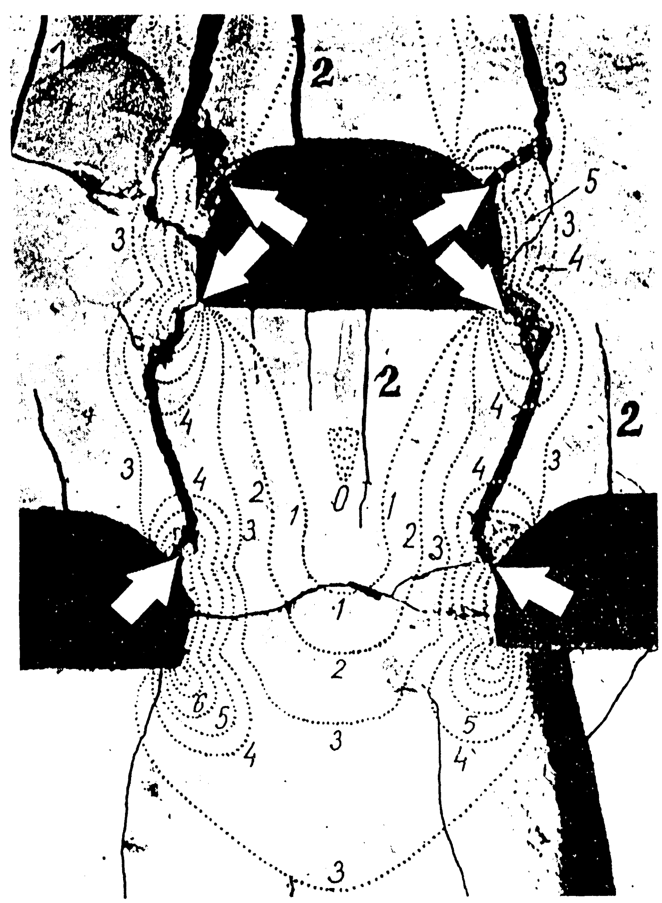

Fig. 20.2.41. Detail of plaster model shown in Fig. 20.2.40, completed by dotted isochromatic lines obtained on a photoelastic model. Main shear cracks on the plaster model correspond with the zones of maximum shear concentration visualized by the highest density (and order) of isochromatic lines.

sulting from poor drifting practice (drilling and blasting precision of drift geometry and location) is very undesirable for good stability. Therefore, correct geometry and relative location of drifts and good smooth blasting is very necessary, particularly in soft ores and rocks and at greater mining depths. The precision of the correct geometry, smooth contour of drifts and exact location of drifts is extremely important when using large-dimension sublevel caving.

Example 20.2.1. This involves the determination of an approximate geometry for traditional sublevel caving, given the following information:

Width of the sublevel drift W_D = 5 m (17 ft)
Height of the sublevel drift h_D = 3.5 m (12 ft)
Blasted ore has a high density
Shape of the drifts: flat roof

Solution. To determine the parameters and geometry: Total extraction height is estimated to be h_T = 21 m. Shape of the sublevel drift with flat roof is favorable for ore extraction, and the effective extraction width of the sublevel drift (according to Fig. 20.2.25) is about 70% of W_D, i.e., $a = W_D \times 0.7 = 5 \times 0.7 = 3.5$ m.

With respect to the location of sublevel drifts in the vertical direction (see Figs. 20.2.35 and 20.2.42), the approximate sublevel height is h_s = 12.5 m. In accordance with Fig. 20.2.35, the sublevel drift is located at about ⅔ of h_T, i.e., $\frac{2}{3} \times 21 = 14$ m. Because the drift section is not exactly rectangular and its height is 3.5 m, its floor is about 1.5 m below the $\frac{2}{3}h_T$. Therefore, h_S *is* about $14 - 1.5 = 12.5$ m.

Theoretical width W' of the extraction ellipsoid for a total extraction height h_T = 21 m is determined from Fig. 20.2.33 to be about W = 6.8 m.

Approximate total width and depth of the extraction ellipsoid, using formulas 5 and 6, is

$$W \leq 6.8 + 3.5 - 1.8 = 8.5 \text{ m}$$

$$d_T \leq \frac{8.5}{2};\ d_T \leq 4.25 \text{ m}$$

Spacing of the burden b after Eq. 20.2.8 is

$$b \leq \frac{4.25}{2};\ b \leq 2.12 \text{ m}$$

Because the total extraction height h_T = 21 m > 18 m, the horizontal spacing of sublevel drifts is calculated using Eq. 20.2.7:

$$S_D < \frac{W_T}{0.65} = \frac{8.5}{0.65} = 13.07 \text{ m};\ S_D \leq 13.07 \text{ m}$$

For good ore extraction, it is favorable when the adjacent zones of loosening at the elevation of the maximum width W_T of the extraction ellipsoid intersect. Therefore, the spacing becomes:

$$S_D = 12 \text{ m} < 13.07 \text{ m}.$$

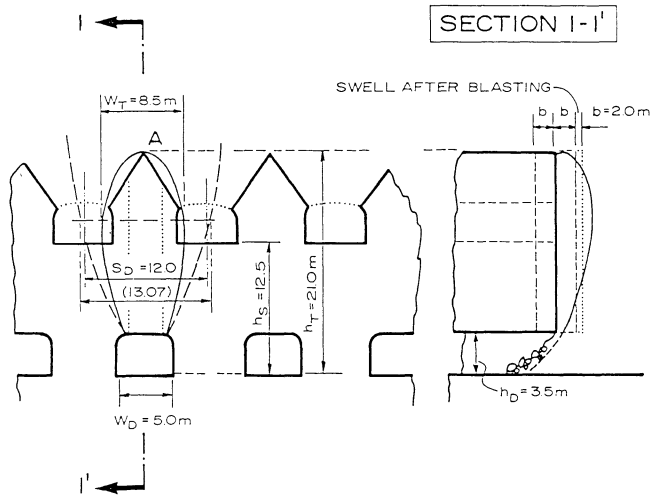

Fig. 20.2.42. Sublevel geometry in 20.2.1. Conversion factor: 1 ft = 0.3048 m

As shown in Fig. 20.2.42, the complete geometry of the sublevel caving layout in the example is:

Sublevel height h_S = 12.5 m (42 ft).
Horizontal spacing of sublevel drifts S_P = 12 m (40 ft).
Total width of the extraction ellipsoid W_T, assuming a total extraction height h_T = 21 m (70 ft), is W_T = 8.5 m (28 ft).
Spacing of the burden b = 2 m < 2.12 m (7 ft < 7.1 ft).

It must be emphasized that the system for the determination of sublevel caving geometry presented in this section is over simplified and should serve as a guide only. It can be used for developing a preliminary concept of the mining method geometry, especially in cases where no other data are available.

20.2.3.8 Large-dimension Sublevel Caving

The development of more modern, powerful, and efficient mining equipment, and especially the development of high-performance drilling machines permitting long, precision holes, has led to the introduction of new drilling designs in sublevel caving.

The tendency to replace classic fan drilling with a design using a majority of parallel drillholes began, more or less, simultaneously in different places of the world. At a sublevel caving symposium held in Stockholm, a new drilling design used at LKAB-Kiruna and as shown in Fig. 20.2.43 was presented (Anon., 1972). On the left side is the traditional pattern; on the right is the new "silo" pattern. Very similar geometry was presented at the same symposium using the layout utilized at Pea Ridge Mine, Sullivan, MO, by Meramec Mining Company. A design similar to the "silo" method was also developed by Kirov's Apatite Combine (apatite/nepheline ore on the Kola Peninsula, USSR), including the interesting combination of design and blasting sequence shown in Fig. 20.2.44:

Fig. 20.2.44a Mining in layers, consisting of 11-ft (3.2-m) slices (before blasting).
Fig. 20.2.44b Mining in layers with an advance arrangement (*t* is thickness of blasted ore and *l* is length of the sill pillar).

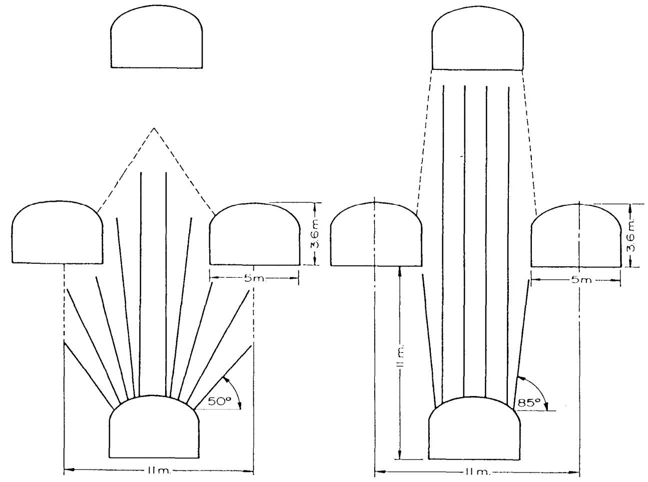

Fig. 20.2.43. Drilling design at LKAB-Kiruna: old design on the left; new "silo" design on the right, (after LKAB information brochure, 1989). Conversion factor: 1 ft = 0.3048 m.

Fig. 20.2.44c Mass advance blasting above the sill pillar using 4.2-in. (105-mm) blastholes and extraction of ore swell in the first phase; and in the second phase, blasting and extraction of sill pillars and overlying fragmented ore.

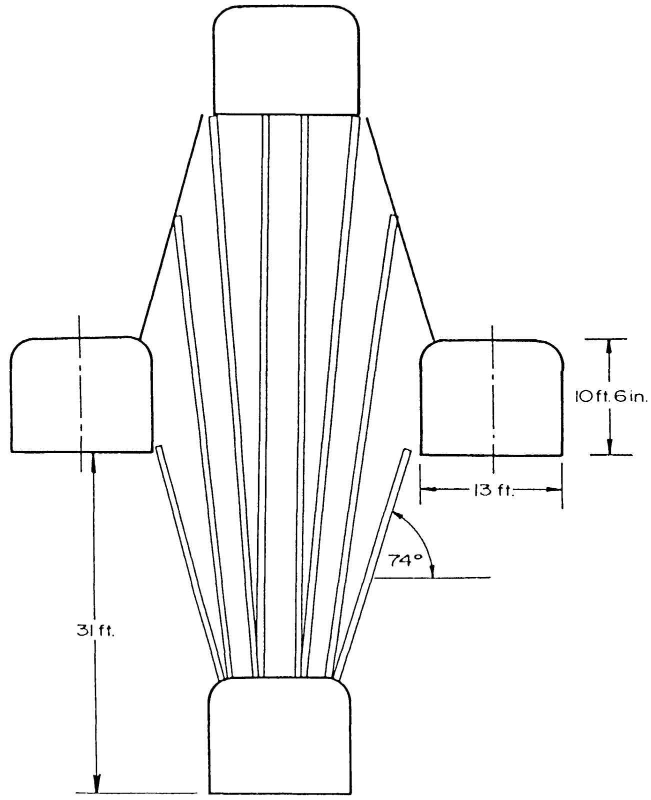

Fig. 20.2.45. Drilling pattern at Craigmont Mines. Conversion factor: 1 ft = 0.3048 m.

Fig. 20.2.45 shows another example of the same principle of drilling pattern as used at Craigmont Mines in Canada. The pattern discussed in Figs. 20.2.43 through 20.2.45 introduces longer drillholes than normally used in traditional sublevel caving. More or less parallel holes enable better and more uniform fragmentation. Steeper drillholes on both sides of the fan are better for gravity flow, not causing any changes in the principles of gravity Fig. 20.2.46. flow. As it is evident from Fig. 20.2.46, even a bin bottom inclination of 60° does not influence the parameters of the gravity flow area. Gravity flow in sublevel caving can be favorably influenced when the outside drillholes of the fan are very steep, that is, having an angle from horizontal of at least 65, 70, or 75° depending on the coarseness of the material. With such a steep angle, a much bigger part of the blasted ore will flow to the extraction opening (drift) in a mass flow, thus decreasing dilution. Such steep angle generates the gravity flow shape, by which the intermediate sublevel drifts are located in the middle of the extraction ellipsoid height.

In order to minimize expensive development works (sublevel drifts and haulage drifts), the LKAB-Malmberget Mine introduced large-dimension sublevel caving, the geometry of which is shown in Fig. 20.2.46. Sublevel height is 67 ft (20 m), horizontal distance between the axes of sublevel drifts is 75 ft (22.5 m), and sublevel drift width is 20 ft (6.0 m). Outside drillholes of the fan have an angle from horizontal of about 70°; drillhole diameter is 4 in. (100 mm).

Even this large-dimension geometry of the extraction ellipsoid (see Fig. 20.2.31) corresponds to the principle of gravity

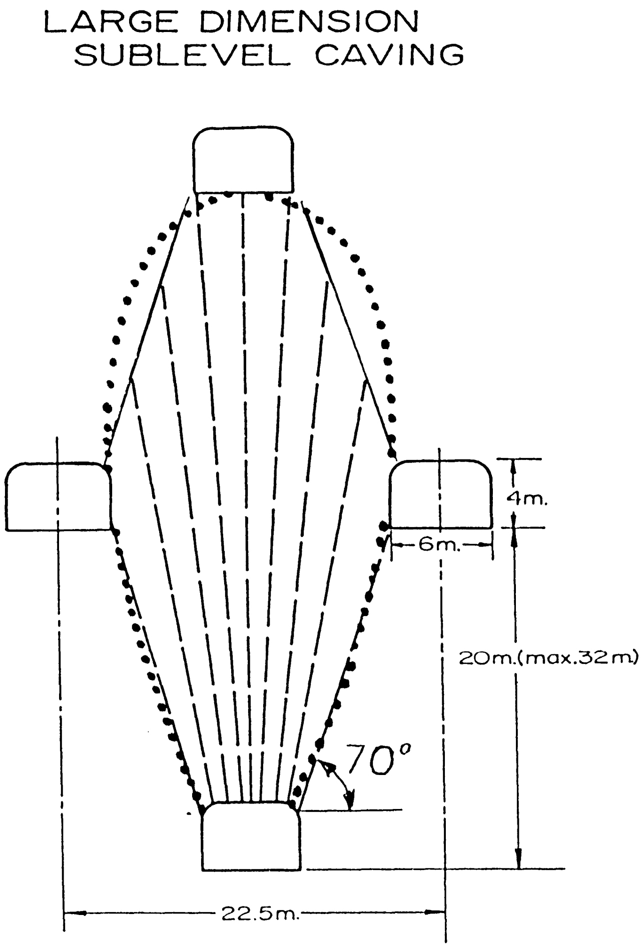

Fig. 20.2.46. Drilling pattern of large-dimension sublevel caving at LKAB-Malmberget. Conversion factor: 1 ft = 0.3048 m.

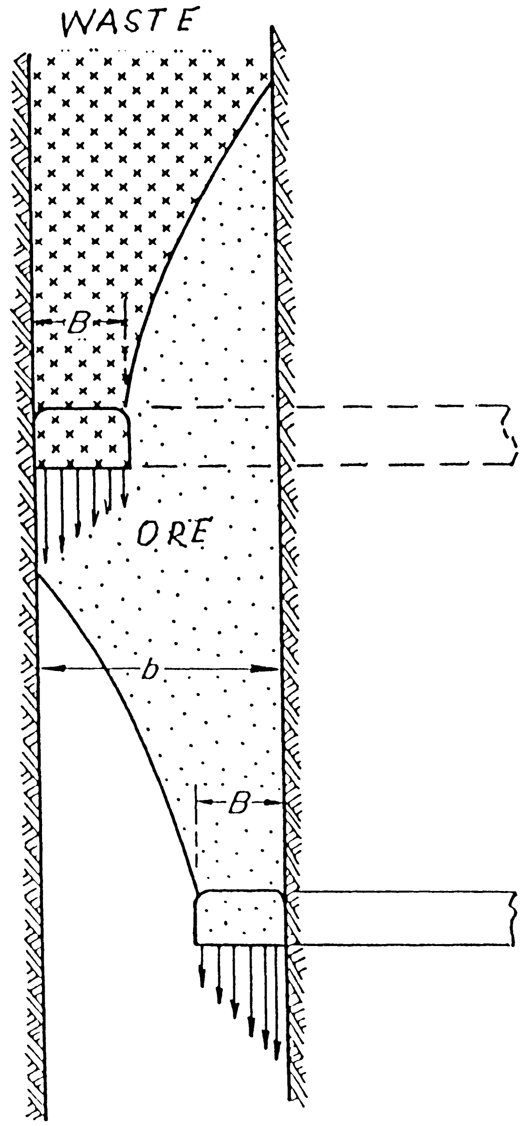

Fig. 20.2.47. Most favorable location of sublevel drifts in a narrow and more or less vertical ore body exploited by longitudinal sublevel caving.

flow as specified above. For better visualization, the typical form of an extraction ellipsoid is circumscribed (see dotted line) on the drilling fan. The same is valid for even larger dimensions that are introduced in parentheses in Fig. 20.2.46.

In order to satisfy the parameters of gravity flow, such large-dimension sublevel caving can give good results, especially when two (or more) burdens (slices) are blasted to ensure sufficient thickness of the fragmented ore. Naturally, sublevel caving with large-dimension geometry is especially favorable for application in magnetite ore where the increased dilution is easily balanced by very simple and inexpensive magnetic separation.

20.2.3.9 Longitudinal Sublevel Caving

In certain cases, sublevel caving can be successfully utilized for exploitation of narrow ore bodies. In such conditions, a transverse location of sublevel drifts is expensive, and therefore, sublevel drifts should be located in a longitudinal direction.

When the ore body is more or less vertical and wider than the sublevel drifts, the sublevel drifts should be located in the ore body as shown in Fig. 20.2.47. Such arrangement enables minimizing ore losses and dilution. A vertical or very steeply dipping ore body is the most favorable for longitudinal sublevel caving.

When the ore body layer is inclined, then we must be aware that gravity flow is influenced mainly by inclination of the ore body (hanging wall and footwall), but also by the width of the ore body layer. Probably the clearest and most simple explanation of the influence on the inclination and width of an ore body on the gravity flow is evident from the models a and b in Fig. 20.2.48. In longitudinal sublevel caving, gravity flow characteristics, a function of the ore body inclination and width, are defined in the figures by the different size and shape of the black passive zones. Fig. 20.2.48a shows the occurrence of passive (black) zones in ore layers of three different thickness with little inclination. This figure also shows three ore bodies (layers) as in case a, but in case b, the ore body inclination is steep. A direct comparison of three different thicknesses using the same inclination as well as different inclinations, defines the characteristics of the gravity flow by its passive zones.

This question is additionally explained in Fig. 20.2.49a, b, c, and d. These four cases show also the occurrence of passive zones P as a function of the inclination of the ore body and the location of the drift.

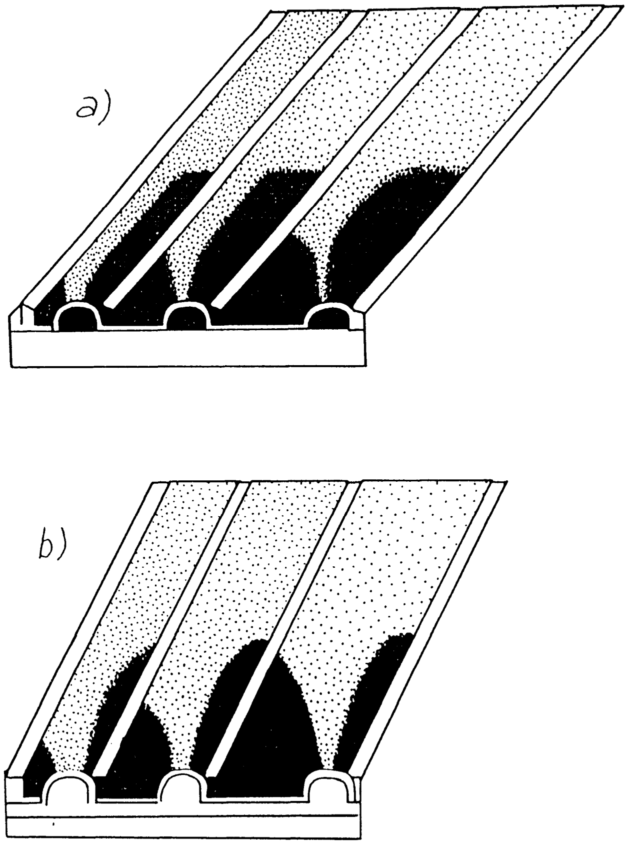

Fig. 20.2.48. Models of longitudinal sublevel caving.

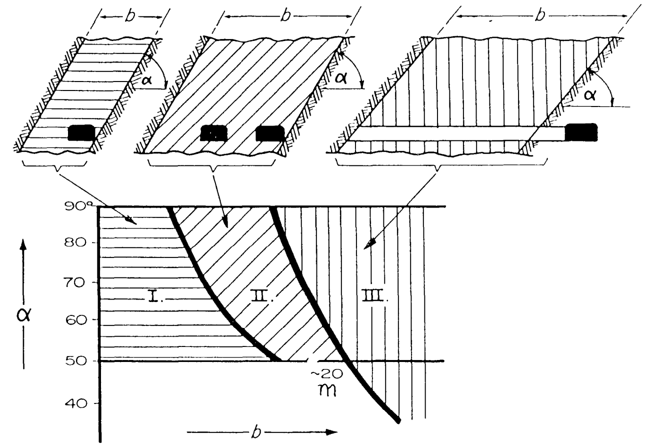

Fig. 20.2.50. Longitudinal (or transverse) sublevel caving as a function of ore body inclination and width.

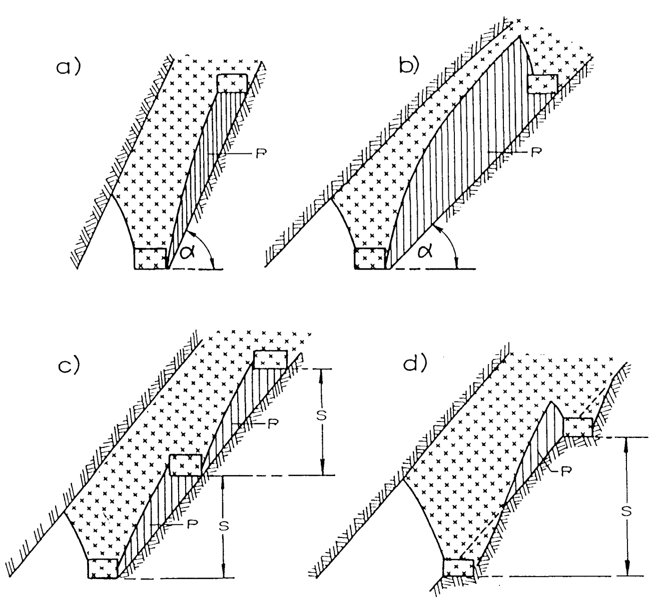

Fig. 20.2.49. Passive zone P as function of ore body inclination, ore body thickness, and location of the sublevel drifts.

Longitudinal sublevel caving is practical mainly for steep ore layers and for relatively narrow ore bodies. Maximum width of the ore layer is around 70 ft (20 m). For this thickness, it is then useful (in order to increase recovery) to utilize two sublevel drifts on each sublevel. A very approximate relation between ore body inclination, its thickness, and arrangement of sublevel drifts (longitudinal or transverse sublevel caving) is shown in Fig. 20.2.50.

20.2.4 SUBLEVEL CAVING IN COMBINATION WITH OTHER MINING METHODS

Sublevel caving can be used in many cases as a method for second-phase exploitation especially when the ore value is sufficiently high. Sublevel caving also can be used in all cases of room (stope) and pillar mining in flat ore deposits under economically favorable conditions. The necessary conditions are that the rooms are backfilled and that the rib pillars are accessible and remain sufficiently stable when perforated by the sublevel drift. The sublevel drift is located on the longitudinal axis of the pillar and follows the floor (or is below the floor) of adjacent rooms.

This method can be used to recover the remaining pillars (and sill pillars) of stopes that were backfilled. In this case, it is advantageous to have an ore body that is steep or very steep, after having been exploited primarily in backfilled stopes.

Sublevel caving was also successfully used to recover the pillars (about 33 to 37 ft, or 10 to 11 m thick) between the backfilled stopes at Kamoto Mine, operated by GECAMINES/ EXPLOITATION in Zaire in two parallel ore layers 50 ft (15 m) thick and only inclined 30 to 35°. Ore layers 50 ft (15 m) thick were separated by 50 ft (15 m) of waste. The combination of backfilled stopes (with overhand mining direction) and sublevel caving (with underhand mining direction) enabled the mining out of about 72% of the ore without dilution, attaining a total recovery of 82 to 85%.

It is possible to introduce a number of cases where sublevel caving can be successfully used to recover ore reserves remaining in situ after the main phase of exploitation.

Sublevel caving can be very successful in the recovery of remnant sill pillars and the passive zone of fragmented ore above the sill pillars, overlying the haulage drifts in a continuous caving area (Chapter 20.3). When extraction of the ore by continuous

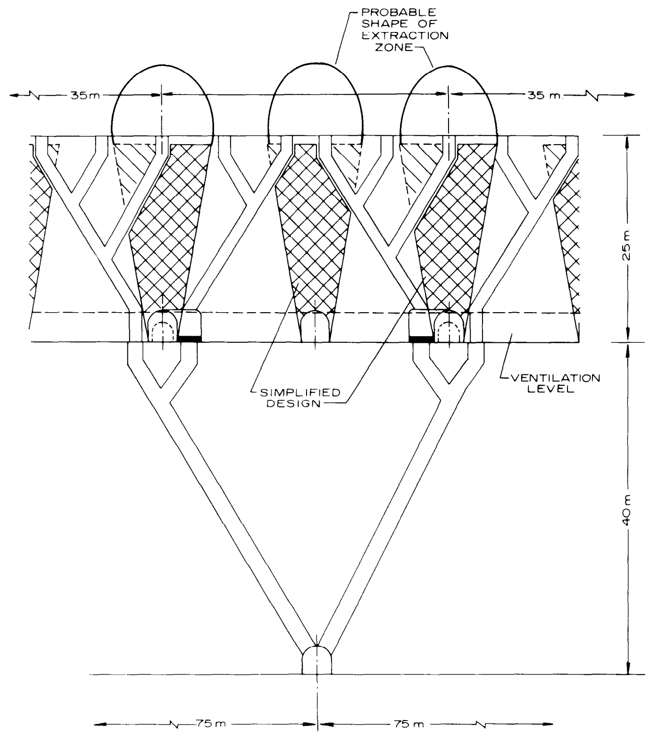

Fig. 20.2.51. Original recovery of remaining ore in sublevel caving after traditional (gravity) block caving at El Teniente mine. Conversion factor: 1 ft = 0.3048 m.

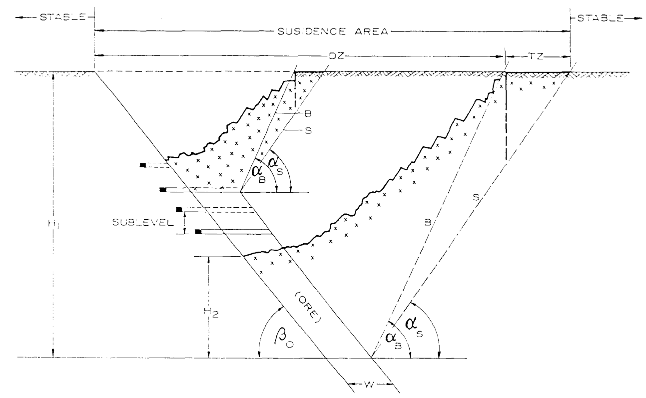

Fig. 20.2.52. Progressive caving and subsidence of hanging wall overburden, induced by sublevel caving.

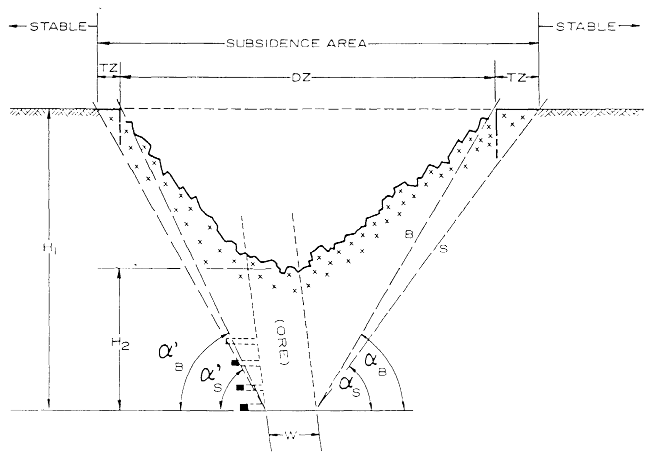

Fig. 20.2.53. Progressive caving and subsidence caused by sublevel caving, both in hanging wall and footwall.

caving is completed, then waste rock remains in the drawpoint drifts. The assumption that the relatively high passive zone of fragmented ore and the sill pillar above the production level will be recovered by the following, lower extraction level is very questionable, especially with regard to the very large height of modern block caving. The conditions for recovery are especially good when the production (extraction) level of continuous (block) caving has been constructed for load-haul-dumps. This enables very easy and inexpensive recovery of a big part of the remaining ore, because the most expensive part (large dimension drift) is there and was already paid for by block caving exploitation.

An original solution was developed by the engineering team in the mine planning and engineering department of El Teniente Mine, operated by CODELCO in Chile, for ore recovery after traditional gravity block caving. In this case, the underlying level 83 ft (25 m) below the new extraction level (see Fig. 20.2.51) was slightly modified and used as a sublevel drift level. Even this arrangement, although it does not recover all remaining ore reserves, was very efficient and inexpensive, because it required only fan drilling and mucking. All other necessary infrastructure for sublevel caving was there, because it was realized by the development of the block.

20.2.5 SURFACE EFFECTS FROM SUBLEVEL CAVING

Concerning environmental constraints, the basic condition for utilizing sublevel caving is that an inevitable deformation of the surface (subsidence) is permissible. Sublevel caving will induce progressive failure, caving, and subsidence of the overlying waste rock masses, undercut by mining. In the following section, the extent of the damage zone will be considered.

20.2.5.1 Shape, Size, and Extent of Disturbance

The shape, size, and course of the progressive failure and caving depend on many factors. Probably the most important are the inclination of the ore body β_0, ore body width W, depth H_1 of the bottom level of future underground mining, height H_2 of the caved waste rock zone which generates the arching forces that resist failure, shear strength of the rock masses involved in progressive failure, defined by effective cohesive strength c and friction angle ϕ, and density of the waste rock masses γ.

When the ore body inclination creates a stable footwall slope, the progressive failure and caving will occur only in the hanging wall as shown in Fig. 20.2.52. Mining of a vertical or very steeply dipping ore body will induce progressive failure both in the hanging wall and the footwall (Fig. 20.2.53). A simplified mechanism of progressive failure is characterized by the break plane B at angle α_B and the sliding plane S with angle α_S. The magnitude of these angles is a function of certain configurations of H_1, W, H_2, C, ϕ, γ, and α.

As is evident from Figs. 20.2.52 and 20.2.53, the deformation zone DZ is limited by the intersection of the break plane B with

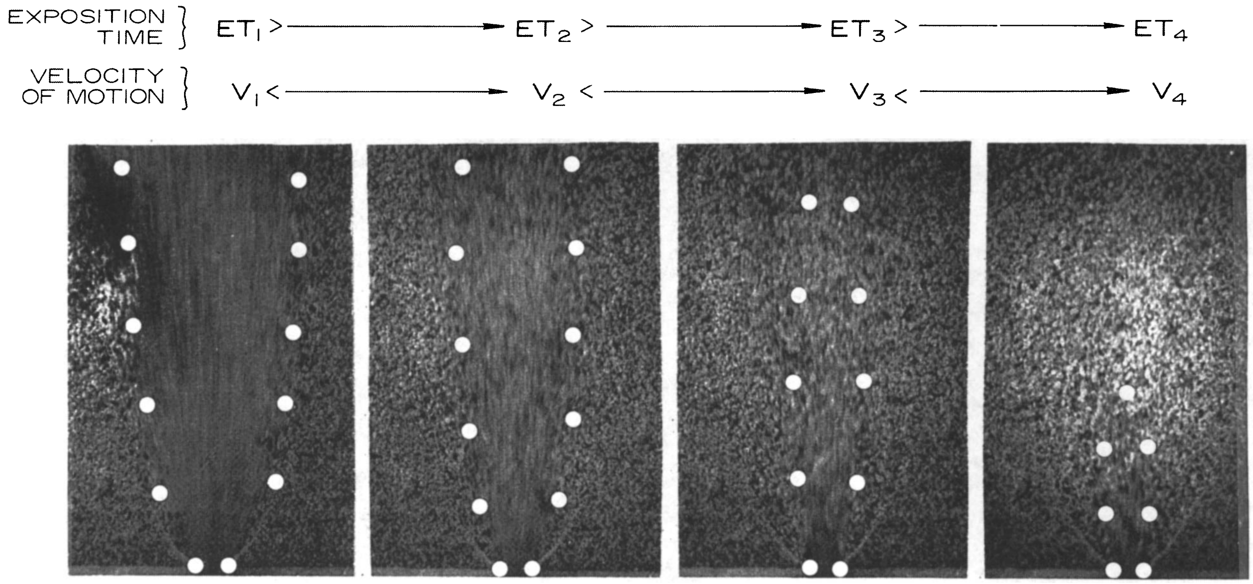

Fig. 20.2.54. Various velocities of motion zones $V_1 < V_2 < V_3 < V_4$ for granular material above the bin outlet. Material flows out continuously through the outlet and the bin is continuously refilled. Velocity of motion zones is visible on photographs, using various exposure times $ET_1 > ET_2 > ET_3 > ET_4$.

surface. Between the intersection of break plane *B* and sliding plane *S* with the surface is a so-called transition zone *TZ*. Even this zone is not sufficiently stable for the location of any permanent construction. The intersection of the sliding plane *S* with the surface represents the boundary of subsidence area. Naturally, the stable surface is outside the subsidence area.

For the safe location of permanent structures on the surface (shafts, concentrator, buildings, tailings, dams, etc.) and underground (crushing plant, pumping station, main orepasses and waste-rock passes, permanent tunnels and drifts, etc.), it is necessary to define the consequence of sublevel caving; that is, it is necessary to determine the unstable zones of progressive failure (limited by sliding planes) and the subsidence area. All important construction must be located outside of these zones.

20.2.6 OTHER CONSIDERATIONS

20.2.6.1 Distribution of Motion in Gravity Flow

Figs. 20.2.11 through 20.2.14 illustrate the principles of gravity flow for granular and coarse materials flowing freely from an extraction opening. Figs. 20.2.11 and 20.2.12 demonstrate the principles of velocity distribution of a particle's motion in the gravity flow. The velocity of this motion is greater at shorter distances from the extraction opening and from the vertical axis of the gravity flow. Inversely, the movement velocity of a particle decreases at greater distances from the extraction opening and from the centerline (vertical axis) of the gravity flow. The particles of a granular material are motionless outside of the contour of the ellipsoid of loosening or outside of an active zone.

For completeness and a better visualization and understanding of the distribution of particle motion in the gravity flow, the approximate elliptical shape of the flow zones at various velocities can be demonstrated in a single model (Fig. 20.2.54). On this model, which has a constant gravity flow (outlet is open and the model is continuously refilled from the top), the zones with various velocities of material movement can be identified using photographs with different exposure times. The relation between the velocity of particle movement and exposure time makes the moving particles in the model appear on the film (and photograph) as lines. An increased time of exposure allows smaller velocities of particle movement to be traced and recorded on the film. By shortening exposure time, all particles having a velocity of movement below that which corresponds to the ratio between exposure time and movement velocity, are “shut out”, appearing on the photograph as being motionless. Fig. 20.2.54 shows four subsequent cases of decreasing exposure time ET. The zones of particle movement velocity $V_1 < V_2 < V_3 < V_4$ were obtained at exposure times $ET_1 > ET_2 > ET_3 > ET_4$. The borders of these velocity zones are marked with white dots on each of the photographs.

20.2.6.2 Sublevel Caving with Large Vertical Intervals Between the Sublevels

As was explained in the discussion of Figs. 20.2.5 and 20.2.6, the slope of a bin bottom inclined 45 or 60° (from horizontal) does not influence gravity flow parameters or the occurrence of passive zones. Very steep bin bottoms are necessary in order to eliminate or minimize passive zones in bins of granular materials. For example, in order to obtain a satisfactory flow (without passive zones) of iron pellets (spherical-shaped) in a shaft furnace, it was necessary to increase the slopes of the furnace bottom to at least 77° (Kvapil, 1967). The same principle is valid for a basic geometry concept of sublevel caving with large vertical intervals between the sublevels.

The main unit of sublevel caving is determined by the geometry of a sublevel front on its vertical, transverse section. Fig. 20.2.55 shows that the geometry is determined by points 0, 1, 2, 3, 4 and (4), (3), (2), (l), (0), by inclination α of the peripheral drillholes of the fan (forming the slopes on intact ore), and by width *w* and height *h* of the sublevel drift. Naturally, the most

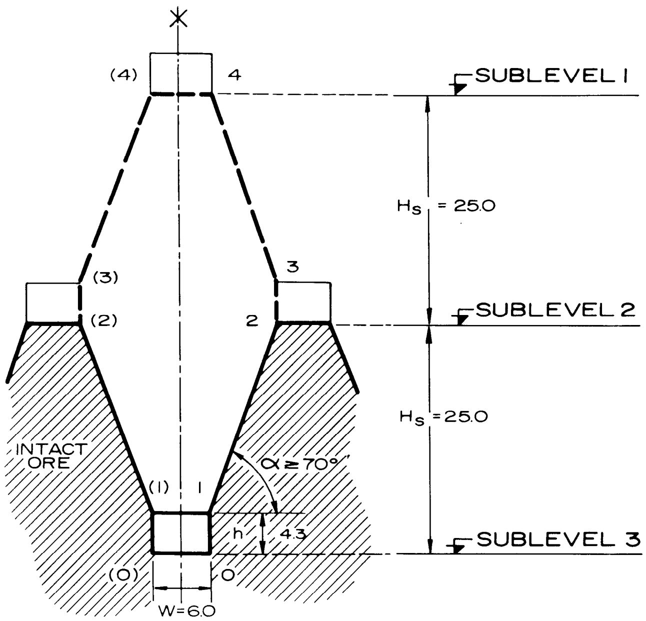

Fig. 20.2.55. Principal unit of sublevel caving geometry having large vertical distances between sublevels. Conversion factor: 1 ft = 0.3048 m.

important factor is the angle α. With an increased content of small fragments and fine particles in coarse material, the angle α should be increased to about 75°. With respect to the different types of coarse material (see Fig. 20.2.2), for material types I and II, an angle of 70° or even less could be used: and for material IV, the angle used could be about α = 75°. Such determination of sublevel caving geometry is meant only as a first approximation. Any higher stages of design require further study, using the principles specified in the foregoing text.

20.2.6.3 Importance of Precise Sublevel Caving Geometry

The importance of precise sublevel caving geometry on mining efficiency needs to be emphasized. Any deviation from the regular pattern of sublevel caving geometry (the relative position of sublevel drifts, as well as the precision, regularity, and axisymmetric shape of the sublevel drift sections) can cause disturbances in fragmentation, gravity flow, and stability. This deviation could result in decreased ore recovery, increased dilution, and increased costs for drift reinforcement and maintenance.

Chapter 20.3
BLOCK CAVING

DOUGLAS E. JULIN

20.3.1 GENERAL DESCRIPTION

Block caving is a general term that refers to a mass mining system where the extraction of the ore depends largely on the action of gravity. By removing a thin horizontal layer at the mining level of the ore column, using standard mining methods, the vertical support of the ore column above is removed and the ore then caves by gravity. As broken ore is removed from the mining level of the ore column, the ore above continues to break and cave by gravity. The term block caving probably originated in the porphyry copper mines where the area to be mined was divided into rectangular blocks that were mined in a checkerboard sequence with all the ore in a block being removed before an adjacent block was mined. This sequence of mining is no longer widely used. Today most mines use a panel system, mining the panels sequentially, or by establishing a large production area and gradually moving it forward as the first area caved becomes exhausted. The term block caving is used for all types of gravity caving methods.

There are three major systems of block caving and they are differentiated by the type of production equipment used. (1) The first system based on the original block cave system is the *grizzly* or *gravity system* and is a full gravity system wherein the ore from the drawpoints flows directly to the transfer raises after sizing at the grizzly and then is gravity loaded into ore cars. (2) The second system is the *slusher system* which uses slusher scrapers for the main production unit. (3) The last system is the *rubber-tired system* which uses load-haul-dump (LHD) units for the main production unit. Each of these systems is described in some detail later.

Block caving is the lowest cost of all mine exploitation systems with the exception of open pit mining or in situ recovery.

20.3.2 SUITABLE ORE BODIES

20.3.2.1 Ore Body Characteristics

A typical ore body suitable for block caving is a porphyry-type deposit with well-disseminated mineralization and of fairly large lateral and vertical extent such as a copper porphyry deposit. It has also been used in molybdenum porphyries, hematite, asbestos, and diamondiferous deposits. It can be applied to steeply dipping vein deposits of sufficient width and in thick, flat-lying deposits. The rock strength can be fairly weak or fairly strong, but the total mass must have sufficient fractures in different orientations to allow the rock mass to break up under gravity into pieces small enough to pass through the drawholes into the production drifts. The lateral extent of the ore body must be large enough to insure that a cave can be established. The horizontal area required to establish a cave will depend on the strength of the rock mass, but generally the minimum horizontal dimension of the mining area should be about 300 ft (90 m). The height of the ore column should be sufficient to allow a reasonable productive life to the individual drawpoints and also to insure a reasonable rate of return on the development and production costs. The rate of return will also depend on the value of the mineral in the ore.

20.3.2.2 Determining Cavability

After determining that the size of the ore body is large enough to justify consideration for block caving, then the *cavability* must be determined. The frequency and orientation of the various fracture sets must be evaluated. The first look at the ore is usually through diamond drillholes. Some of the fracture sets can be identified by looking at the drill core; however, trying to determine the orientation of the fractures can be difficult unless the drill cores have been oriented. Determining the *rock quality designation* (RQD) of the drill core has become rather standard practice when block caving is being considered. RQD is determined by measuring the length of drill core pieces over 4 in. (100 mm) in length and dividing the accumulated length by the actual length of the drillhole section. Usually, the increments used are 10 ft (3 m). RQD can certainly be a first indicator for determining cavability, but it does not give the fracture orientation, it does not adequately identify the fracture intensity, nor does it give a complete picture of all the fracture sets. Access to the ore body by exploratory drifting is almost essential before a final determination of cavability can be made.

At least three sets of major fractures are necessary to justify the use of block caving. Two vertical sets at approximately 90° orientation to each other and a third set lying approximately horizontal will form rectangular blocks when the fractures separate. The spacing of the fractures is also important since the spacing will determine the size of blocks that will appear at the drawpoints. The fracture and joint fill material must also be identified since the composition of that material will help determine how easily the fractures will separate or if the fracture fill material is actually stronger than the host rock. The same analysis must be made of the waste capping to be sure that it will also cave as the ore is removed. If it appears that the capping will break more coarsely than the ore, then dilution of the ore will be minimized. If the capping will break more finely than the ore, then dilution will be a greater problem with a greater amount infiltrating into the ore. Major faults and dikes must also be identified since they may have an effect on the caving action and on the mine layout. Heslop and Laubscher (1981), White (1979b), and others have initiated systems for determining rock mass classifications. These classifications incorporate such information as joint spacing, joint conditions, intact rock strength, joint filling, and other factors. Based on the rock mass classification, the ease or difficulty of caving is determined.

As can be seen from the above discussion, a thorough geologic and rock mechanics study should be made before a decision to use block caving is made. There are numerous computer programs available to help in the evaluation.

20.3.2.3 Productive Capacity

Block caving is best suited for high daily production. The system has been used at mines with production rates ranging from 2000 tpd (1800 t/d) to more than 80,000 tpd (72,000 t/d). The productive capacity of a mine will be determined by the rate of vertical draw that can be made and the horizontal area that can be undercut at any given time without producing unusual ground control problems. Draw rates at various mines vary from

6 in. (150 mm) to 2 ft (0.6 m) per day. The daily rate of draw will be determined by the rate at which the ore will cave. Strong, less-fractured rock may cave very slowly whereas weak, highly fractured rock may cave very rapidly. There is no method to predetermine how rapidly a given ore body will cave. Experience at other mines with similar type rock will be the best guideline, and after that, experience at the new mine will be the final criterion.

20.3.3 SELECTING THE MINING SYSTEM

Once the cavability of the ore body has been determined and the approximate size of material that will arrive at the drawpoint evaluated, a mining system must be selected. The size of broken material will probably dictate which system is suitable. Mine site location, availability of labor, and economics will also be determining factors.

Drawpoint spacing is dependent on material size. If the ore breaks very fine, then close drawpoint spacing will be required. If the ore breaks fairly coarse, then wider drawpoint spacing can be used. It has been demonstrated at operating mines and by "sand-box" studies that the area of influence by one drawpoint is determined by the size of material in the cave. For fine ore, the area of influence is rather small and for coarser material, the area of influence increases. In summary: (1) For fine material, the full gravity system is most suitable. (2) For somewhat coarser material, the slusher system should be considered. (3) For quite coarse material, the LHD system may be best. Of course, other factors must be considered such as the sophistication of the work force, the cost of labor, the availability and capital cost of equipment, and the technical requirement for maintaining the equipment plus any other factors that may be unique to the particular mine being evaluated.

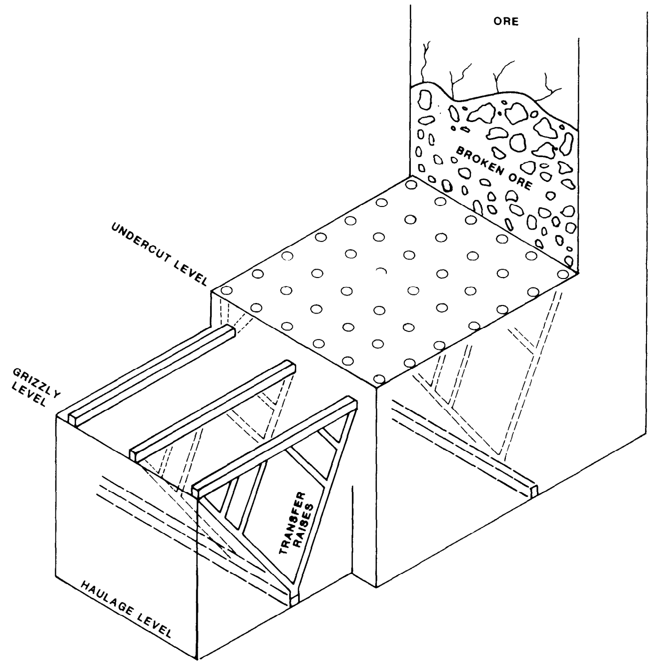

Fig. 20.3.1. Grizzly system—typical layout.

20.3.3.1 Choice of Various Forms of Block Caving

Full Gravity (Grizzly) System. The grizzly system consists of the haulage level, transfer raises, grizzly level, finger raises, and undercut level (see Fig. 20.3.1 for a typical grizzly layout). The haulage and grizzly levels are driven across the ore block to be mined. This work can be done simultaneously since they are on different levels. Finger raises are driven from the grizzly level to the undercut elevation, and then short horizontal connections are driven between the tops of the finger raises to form pillars that will later be longholed and blasted to initiate the caving action. Transfer raises are driven between the haulage and the grizzly level with a loading chute at the haulage level and grizzly rails for sizing at the grizzly level. After undercut blasting, broken ore flows down the finger raises and is sized by the grizzly rail spacing, passes into the transfer chutes, and thence is loaded into rail cars. Sledge hammers are used to break up oversized pieces at the grizzly, although some mines have tried using mechanical breakers. Some large pieces may hang up in the finger raises, and these are usually broken up by secondary blasting using packaged dynamite placed strategically against the oversized rocks.

The San Manuel copper mine in Arizona and the Andina copper mine in Chile are excellent examples of the grizzly system.

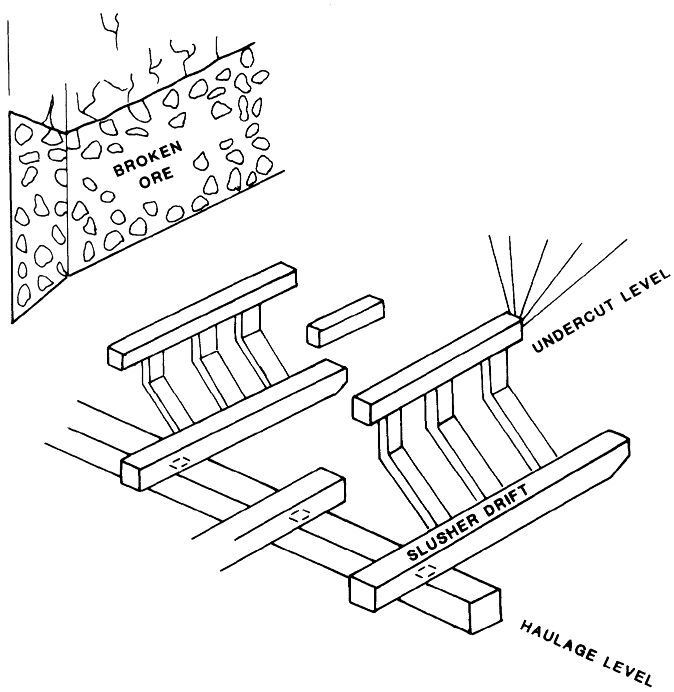

Fig. 20.3.2. Slusher system—typical layout.

SLUSHER DRIFT SYSTEM. The slusher system is used for rock that will break into moderate-sized pieces. Fig. 20.3.2 shows a typical slusher system. The system consists of the haulage level, slusher drifts immediately above the haulage, finger raises, and the undercut level. Haulage drifts are driven on even centers across the block to be mined. Ventilation drifts are then driven at the haulage elevation half-way between the haulage drifts. The slusher drifts are driven at right angles to the haulage at even intervals, usually with every other slusher drift driven at 180° to the previous drift. After placing concrete support in the slusher drift, finger raises are driven to the undercut elevation and concreted. The undercut drifts can be driven from the finger raises or can be developed from a separate access simultaneously

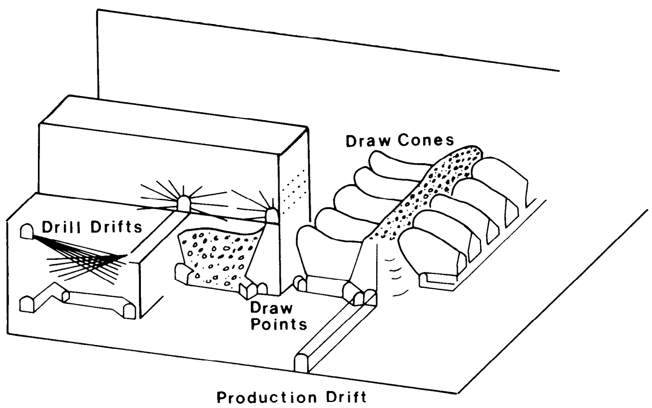

Fig. 20.3.3. LHD system—typical layout.

with the lower level development. Longhole drilling is done from the undercut drifts and then blasted to complete the undercut and initiate caving.

The Climax molybdenum mine in Colorado is a good example of the slusher system.

LHD (RUBBER-TIRED) SYSTEM. If geologic studies show that ore will break into relatively large pieces, rubber-tired equipment should be considered. Fig. 20.3.3 shows a typical LHD system. LHD units are much better suited to handling the larger pieces. LHD equipment usually requires that the drawpoints be spaced at greater intervals to allow room for the equipment to operate. The wider spacing is suitable for the coarser rock. This system consists of the haulage level, ore transfer raises, the production level, drawpoint entries, draw cones to the undercut level, and undercut drifts. Longholing and blasting is used to form the undercut that promotes caving. The large draw cone will allow larger pieces of ore to move down near the drawpoint where small drills and explosives can be used to break up the larger pieces. Experience at operating mines has shown that high hangups practically never occur with this system. With this system, using separate accesses, the haulage, production, and undercut levels can be developed simultaneously. The haulage and production levels should be separated by a substantial distance to provide adequate storage in the transfer raises so that the loading of the trains is not delayed waiting for the LHDs. When the haulage and production drifts are complete, then the transfer raises and drawpoint entries can be driven. Drilling of the draw cones can be done from the drawpoint entries or from the undercut level. It is much safer to do the blasting of the draw cones from the undercut level; therefore, the drilling should also be done from the undercut level. Longholing from the undercut is the final step before the undercut blasting is done. The Henderson molybdenum mine in Colorado, the Ertsberg copper mine in Indonesia, and the El Teniente copper mine in Chile are examples of mines that use the LHD system.

20.3.4 DEVELOPMENT

The sequence and type of development opening will vary somewhat depending on which of the three systems is used and perhaps on the configuration of the ore body. Two of the main components, the haulage and the undercut levels, are fairly standard. The third main component, the production level, will be substantially different.

20.3.4.1 Haulage Level

The haulage level is located under the production level, the distance depending to some extent on which system is used. With the grizzly system, short transfer raises are usually driven between the production (grizzly) level and haulage level to allow for some storage of production rock for loading the haulage units. There is no reason why the length of raises cannot be extended to allow for greater storage if it seems desirable. With the slusher system, the haulage level is usually directly beneath the slusher loading hole so the ore can be loaded directly into the haulage cars although long transfer raises have been used at some mines. Using transfer raises with a slusher system may require an unusual amount of raising since each slusher drift will require an orepass or at least an orepass branch to transfer the ore to a gathering level. With the LHD system, the haulage and production levels should be separated by a substantial distance to provide adequate storage of production rock and to be able to reduce the number of raises required to meet production goals. Raises should be inclined at + 60 to 70° from the horizontal. This will insure good flow of the rock and provide additional breaking of the larger rock fragments as they drop down the orepass.

The Ertsberg mine in Indonesia has eliminated the need for large separation of production and haulage levels through the use of central storage bins and a distance of 33 to 49 ft (10 to 15 m) between production and transfer levels. The production ore is fed through grizzlies into central bins that discharge onto a 5-ft (1.5-m) belt that in turn discharges to a central crusher-conveyor-orepass system.

20.3.4.2 Production Level

In the grizzly system, the grizzly level becomes the production level. These drifts are usually driven at a fairly small cross section and are used for access to the finger raises and grizzlies for sizing the ore before it is sent down the transfer raises. The drifts may or may not be concrete lined although concrete lining is recommended. With the slusher system, the slusher drifts may be considered the production level. The drifts must be driven at a cross section adequate to fit the slusher scraper size. Scrapers used are usually 5 to 6 ft (1.5 to 1.8 m) wide. The drifts are generally concrete lined. The production level for the LHD system is the LHD drifts that provide access to the drawpoints.

20.3.4.3 Undercut Level

The quality of work on the undercut level is very important. The undercut drifts are driven a suitable distance over the tops of the drawpoints. They are to be used for the longhole drilling that will effect the final undercut blast to produce caving. The undercut drifts must be driven with great accuracy to be sure they are in proper alignment with the workings below. Crosscuts between the undercut drifts may be driven from time to time to facilitate access between the drifts and to delimit areas to be blasted during some specified time period.

20.3.4.4 Longhole Drilling

Longhole drilling is the last step before undercut blasting. Its purpose is to remove the pillars between the undercut drifts and to form the horizontal slot that will allow the ore above to commence caving. The longholes may be drilled horizontally through the pillars or at some angle above the undercut level in order to form an apex between the drawholes (the flattest angle is usually about 45°). The drill pattern must be spaced evenly

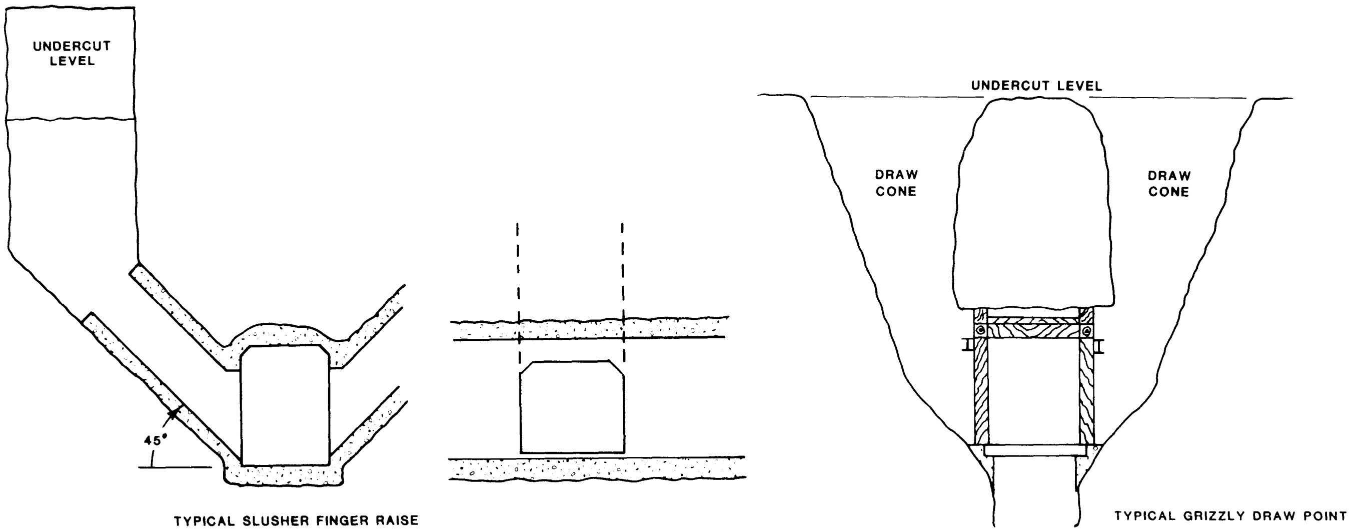

Fig. 20.3.4. Drawpoint design–slusher and grizzly.

along the undercut drifts with the spacing between drill patterns determined by the hole size and powder load to be used. The height or thickness of the undercut formed varies substantially between various mines. The height of the blasted zone can vary from as little as 8 ft (2.4 m) to 50 ft (15 m). There is some question as to how much benefit is derived from a very high undercut. If the ore is very blocky and caving may be difficult to initiate, then the higher undercut may be justified.

20.3.4.5 Drawpoints

The drawpoints for the grizzly and slusher systems are driven at right angles to the grizzly or slusher drift. They are also inclined to the horizontal. The angle varies from nearly vertical down to 45°. The cross section should be large enough to allow most of the rock fragments to pass through the opening without requiring secondary breakage. After driving the inclined section of the drawpoint out to the drawpoint center, a vertical section may be driven upwards to the elevation of the undercut level. This will allow the undercut level to be raised further above the production level to insure an adequate pillar between the cave area and the production level. See Fig. 20.3.4 for a typical drawpoint design. Drawpoints may or may not be lined with concrete. A concrete lining will allow a better flow of the broken rock and will retain its size better than unlined rock. If repair is required because of excessive erosion, then repair can be more easily accomplished if the drawpoint was concreted originally. It is important to maintain the size of the drawpoints to prevent flooding of the production drift with broken rock.

With the LHD system, the drawpoint entry must be nearly horizontal to allow entry of the production unit. The connection between the production level and the undercut level is usually a fairly large draw cone formed by drilling and blasting. The draw cone is sized to allow larger pieces of rock to move down near the brow of the drawpoint where they can be drilled and blasted if they are too large for the LHD bucket. The brow of the drawpoint should be high enough to allow the LHD bucket to lift a load, but not so high as to allow broken rock to flood out into the production drift passageway where it will hinder free travel of the LHD.

20.3.4.6 Boundary Weakening

Boundary weakening has two purposes. One is to minimize side flow of the waste material into the broken ore column and the second and more important is to facilitate the caving. This is especially important during the initial caving period. All rock has a tendency to arch, and this arching will often hinder attainment of a fully active cave. Boundary weakening should be placed on two adjacent sides of the initial caving area. The extent of the weakening will depend on the strength of the ore. For a very weak, highly fractured ore body, some corner raises and drilling along the two boundaries may be sufficient. For a stronger, less-fractured ore body, a completely fractured zone about 8 to 10 ft (2.4 to 3 m) may be required. This type of boundary weakening is formed by driving sublevel drifts along the boundaries at vertical intervals about 60 ft (18 m). The number of sublevels required will be determined by the height of the ore column and the strength of the rock. Two or three lines of vertical drillholes are then drilled between the sublevels. When these drillholes are loaded and blasted, they will produce a completely fractured zone that will weaken two legs of a potential arch and greatly facilitate the initial caving action. Fig. 20.3.5 shows this type of boundary weakening. Once an active cave has been established, pre-splitting may be all that is required, or it may be possible to eliminate all boundary weakening.

20.3.4.7 Undercut Blasting

Undercut blasting is the last step to initiate the caving. This should be done with great care and the cave area constantly checked for pillars of unblasted ore. It is advisable to blast only a few longhole patterns at a time so that the task of checking for pillars is not too difficult. All pillars should be removed before the next blasting sequence. If pillars are left in the cave area, they will hinder proper caving action and can transmit damaging weight into the workings below. The end result is either excessive expenditures for repair or, even worse, the loss of ore.

20.3.4.8 Support

Support of the rock is very important in block caving. As the cave area is enlarged, the weight that was supported by the

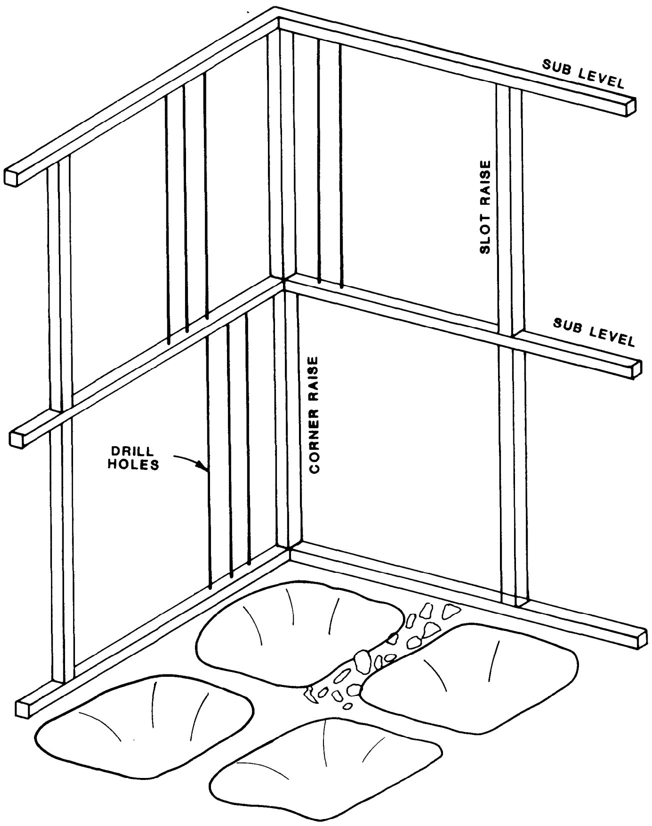

Fig. 20.3.5. Boundary weakening.

undercut area will be transferred to the area around the undercut area. This will place added stress on the rock and workings immediately adjacent to the cave area. It is important to maintain as much of the initial integrity of the rock as possible. Rock bolts and concrete are the most common method of support used in block cave mines. Rock bolts should be installed as soon after the openings are made as possible. It is preferable to have rock bolting as an integral part of the normal drill-blast-muck cycle. Timber and steel sets have been used for support of the main haulage ways although concrete is being used more often. The most common support in grizzly drifts, slusher drifts, and LHD drawpoints is concrete. Reinforcing steel is not recommended where blasting concussion will be present. It has been found that the concussion will often separate the concrete from the reinforcing steel, exposing it and causing substantial problems with loose rebars hanging out into the working area. The concrete should have high strength, no segregation, and minimal cold joints.

20.3.4.9 Ventilation

A good ventilation system and frequent monitoring of the air quality is essential with a block caving system. The production phase for all three systems will generate a substantial amount of dust, especially if the ore is very dry. Contaminated air should be removed from the fresh airstream soon as possible. Intake and exhaust laterals that are separated from the main mine workings are the most desirable. The intake lateral should be so positioned that controlled amounts of air can be introduced into the main haulage or production drifts and then to the individual working places. Contaminated air should be captured as close to the working place as practical and sent to exhaust vent drifts and thence to a main exhaust lateral where it is discharged from the mine. The amount of air required will depend on the number of working places being utilized at any given time and on the type of equipment being used. Air requirements for diesel equipment is substantially greater than for compressed-air or electrically operated equipment.

Table 20.3.1. Drawpoint Spacing and Block Height

Mine	Median Fragment Size ft (m)	Drawpoint Spacing ft^2 (m^2)
Ertsberg	2.3 (0.7)	2540 (236)
El Teniente	2.3 (0.7)	2410 (224)
Grace	2.6 (0.8)	1776 (165)
Henderson	1.6 (0.5)	1600 (148)
Creighton	1.6 (0.5)	1184 (110)
Climax	3.0 (0.9)	1141 (106)
Urad	2.0 (0.6)	900 (80)
Thetford	1.6 (0.5)	624 (58)
Mather	0.6 (0.2)	344 (32)
San Manuel	1.3 (0.4)	258 (24)
Lakeshore	0.6 (0.2)	280 (26)

20.3.5 PRINCIPLES AND PRACTICES

20.3.5.1 Drawpoint Spacing

Drawpoint spacing is important to insure good recovery of the ore. If the drawpoint spacing is too far apart, then good ore will be lost or dilution may become so great that the ore becomes uneconomical. If the drawpoint spacing is too close together, then the mining costs are greater than they should be. There are no set formulas to accurately determine what drawpoint spacing should be. Comparing the ore to other block caving mines is the best guideline. Each drawpoint has a certain area of influence on the broken ore above. The drawpoint spacing should be so spaced that these areas of influence will overlap slightly to insure that the total ore column is moving downward as the draw progresses. Table 20.3.1 shows drawpoint spacing at several mines.

White (1979a) has constructed a regression curve based on the information from Table 20.3.1 that can be used to approximate the draw area based on median fragment size. For example, if the medium fragment size is 0.8 m (2.6 ft), then the draw area would equal 131 m^2 ($y = 152 \times 0.8 + 9.8 = 131.4$ m^2, or 1414 ft^2).

A fragment size estimate based on a fracture frequency study does not account for attrition of the fragments as they are drawn down through the ore column. A conservative approach in selecting drawpoint spacing based on the foregoing formula should be used.

20.3.5.2 Height of Blocks

The height of ore column mined can vary a great deal from mine to mine or even in the same mine. The critical height of ore is such that the mineral content will pay for the development, production, milling, and overhead costs, and still provide some profit. The grade of the ore and selling price of the product will have a substantial effect on critical height. The productive life of each working place should also be considered. If the tonnage is exhausted too rapidly, it may be difficult to develop new working places rapidly enough to maintain the desired daily production. It is obvious that the higher the ore column, the cheaper the development cost per ton will be; however, there are other considerations that will affect the final decision. The configuration of the ore body may determine where the mining level or levels should be established. It is usually not very practical to mine waste material to recover the ore above so that a horizontal horizon in the ore body may set a mining level. The number of tons that can be drawn through a drawpoint before repairs are required may also have some effect on the height of ore drawn per drawpoint. If several repairs will be required before all the ore is exhausted, it may be advisable to chose a lower height of ore. The height of ore drawn will also have an effect on the amount of dilution drawn with the ore. The higher the column of draw, the more potential there is for greater dilution. If the thickness of the dilution zone is small compared to the ore column, or if the dilution will break coarser than the ore, then higher columns of ore can be drawn. If the dilution zone is very thick in comparison to the ore column, or if the dilution material will break much finer than the ore, then shorter ore columns are more desirable. Ore columns varying from 100 to 820 ft (30 to 250 m) have been drawn successfully.

20.3.5.3 Dilution Control

It is not possible to predetermine the exact dilution factor, but some estimate can be made based on experience at other similar mines. The dilution factor typically can vary from 10 to 25% of the total ore drawn. The amount of dilution that can be accepted often is a function of ore grades, grade of the dilution material, costs, and metal prices. Regardless of these factors, the more dilution tonnage that is drawn, the higher the cost will be per pound of mineral recovered.

One of the greatest dangers of block caving is the potential for excessive dilution that could significantly reduce the grade of the ore or result in a significant loss of ore. The only method to insure good ore recovery with minimal dilution is through carefully monitored draw control. The draw must be distributed evenly over the entire caved area, being sure that the rate of draw does not vary substantially between drawpoints. The ore adjacent to an uncaved block should not be completely drawn down before the adjacent ore has been caved. Dilution can easily migrate from the sides into the newly caved area, cutting off the ore above and preventing it from caving. The purpose of good draw control is to maintain a minimum area of contact between the ore and the dilution (waste) zone above. An uneven draw line will increase the area of contact between the ore and dilution, creating more opportunity for the ore and dilution to mix. Concentrating production in a small area of the caved ore will create a funnel for the dilution to flow down into the ore zone to become intimately mixed with the surrounding ore. The more dilution that is mixed with the ore, the lower the grade of ore drawn and the more tons will have to be drawn to recover the mineral, or a greater amount of ore may be lost. There are various methods of draw control. One that has been used successfully at the Climax and Henderson mines is to limit the draw in the drawpoints against uncaved ore to a small percentage of the ore column. The draw is increased by equal percentage increments in each line of drawpoints as they progress away from the cave line. The principle is to maintain an ore-to-waste contact of 45 to 50° moving away from the uncaved ore. Fig. 20.3.6 demonstrates this method. Other methods are used at the different mining properties, but the main parameter is to maintain an even draw among the drawpoints.

20.3.5.4 Mining Limits

Mining limits are usually determined by economic limits in porphyry-type deposits. In this type deposit, there may be no definite separation between mineralized and waste rock; rather the grade of ore gradually diminishes until it becomes too low to recover economically. In this case, the mining limit is set by the minimum height of economic-grade ore that will still contribute to the profitability of the mine. Where there is a sharp differentiation between the ore and the waste rock, the setting of mining limits is somewhat simpler. If the lateral extent of the ore body is very large, it may not be practical to mine the full width of the ore body as one block. In that case, it will be necessary to divide the mining level into several blocks and mine them sequentially. If there are to be more than two mining blocks, then the new mining block should be immediately adjacent to the first mining block. If mining is done on two sides of an unmined block, the potential for excessive rock pressures in the unmined block becomes much greater.

20.3.5.5 Observation of Cave Action

When new caving is initiated, it is natural to wonder how the caving action is progressing. Unfortunately, it is not possible to see into the cave area at least until the first surface subsidence occurs. Various methods have been tried to monitor the caving action with varying degrees of success. The method used depends on how much money and effort the owner is willing to invest. One method is to drive an observation drift along one or two sides of the initial cave area at some distance above the undercut level and outside the cave line. Crosscuts are driven over to the cave limits. If an open arch is forming over the cave, the arch can be observed from the crosscuts. It is also possible to hear the caving action if the cave is active. If the arch should become stable and caving action has stopped, the observation drifts can be used to drill and blast longholes out over the arch to help restart the caving action. Obviously, this method is rather expensive. Once the cave is fully active, the observation points are covered with broken rock and are no longer useful.

Another method is to use drillholes that are over the area of the initial cave to survey the top of the arch. These drillholes can be used to install co-axial cables that are cemented in the holes. As the caving progresses upward, the cables will bend or break. Using a galvanometer, the resistance of the cable can be measured to determine the location of the break. Kinks or breaks may occur anywhere in the cable where there is a displacement of the rock. The method does not locate the top of the broken ore, so the method is not the most accurate. Wooden or metal plugs attached to a cable can also be dropped down the drillholes to measure the top of the arch. When the plug reaches an obstacle (theoretically the broken ore) then the plug is pulled back up the hole until it reaches the arch back. By measuring the length of cable, the top of the arch can be measured fairly accurately, and the top of the broken ore is approximately located. Obviously, the more drillholes that are used, the more complete the survey. Fig. 20.3.7 shows how this plug is used.

20.3.5.6 Weight Problems

Weight problems are inherent to block caving. As rock is removed in one area, the support of the rock above that area must be transferred to the surrounding in-place rock. It follows that the pressures will increase due to the extra support require-

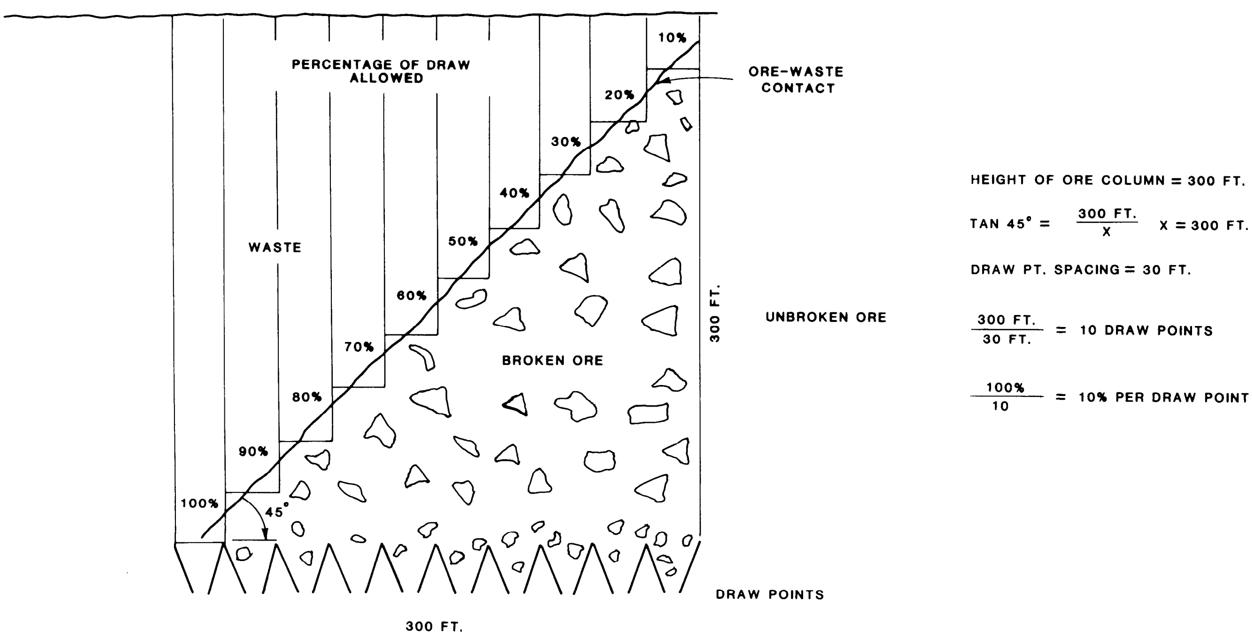

Fig. 20.3.6. Draw control section. Conversion factor: 1 ft = 0.3048 m.

ments. As the mine excavation for development progresses, the in-place rock will also take on additional weight (or pressure). The more rock that is removed for development, the greater the pressure on the remaining rock. This pressure is transferred to the workings in the production area. When the undercut is blasted, there is a momentary release of that pressure that can cause cracking of the concrete support due to relief of the compression. If the tension cracking that results from this relief is too severe, it may be necessary to place rock bolts in the concrete to prevent slabbing.

The advancing cave line is usually the area of greatest pressures that will cause damage during the development stage. The mine workings directly under and in front of the advancing undercut are most subject to weight damage. By advancing the undercut blasting as rapidly as possible, the length of time that the workings are exposed to this excess weight can be minimized. If the undercut cannot be advanced rapidly, then the final connections between the production level and undercut level should be delayed until just before the undercut is blasted. The general idea is to retain as much rock in place as possible until just before the undercut blast so that support of the rock can be retained.

Another source of weight damage is from unblasted pillars or stubs left in the undercut area. These result from incomplete blasts or poor mining practice. Pillars of ore in the cave area can interfere with the proper caving action and transfer unusual pressures to the workings below causing severe damage. It is important that the undercut area be checked after every undercut blast to be sure that no unblasted pillars remain. Any remaining pillars must be removed before the undercut blasting continues. Some weight will be transferred to the areas around the cave limits. If possible, no critical workings should be constructed immediately adjacent to the cave limits. Where it is necessary to have workings in the critical area, they should be well supported. Once caving reaches the surface, weight problems will become somewhat reduced, but the mining personnel should continue to be alert for possible areas of isolated weight problems. To minimize the effect of weight at the advancing undercut line, the line between caved and uncaved ore should be advanced at some angle to the main workings. The cave line should never be stopped for an extended period of time immediately over or adjacent to a main working. The longer the workings are exposed to the excess weight the greater the danger of major damage.

There are several methods of monitoring weight during the production period. The simplest is to install extensometer stations at various locations in the various working areas to measure the divergence between the back and floor. The rate or amount of divergence can signal where weight problems may be occurring.

20.3.5.7 Promoting an Active Cave

In caving, all rock has a natural tendency to form an arch. The dimensions required to produce an active cave will depend

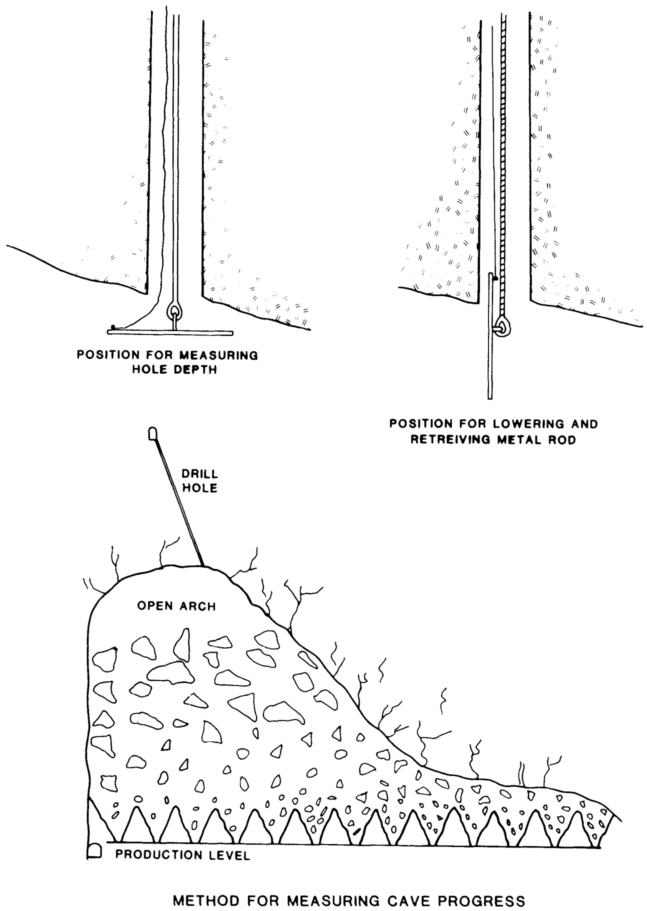

Fig. 20.3.7. Cable and plug for finding top of arch.

on the strength of the rock mass. If the rock mass is highly fractured and weak, a fully active cave will be started with a fairly small undercut area. The stronger the rock mass the greater the total undercut area that will be required to establish an active cave. The mine layout should provide for expanding the undercut area in two adjacent directions. The minimum dimensions of the cave area will determine when an active cave will start. That is, if an arch is formed over the short axis of the undercut area, then expanding the cave along the long axis will probably not produce a fully active cave. In order to break a stable arch over the undercut area, another line of undercut should be blasted, preferably along the short axis. This will cause additional caving action until another stable arch is formed. Then another line of undercut should be blasted. Eventually, the shear strength of the rock mass will be overcome and caving will be continuous. Boundary weakening can be a great aid in establishing an active cave especially during the initial caving sequence. Boundary weakening is discussed in 20.3.4.6.

A number of people have developed methods to determine rock competency classifications for rock support and cavability. Laubscher (1977) has used his classification to determine the undercut area required to establish an active cave. This method assigns a hydraulic radius required for caving based on the various rock classifications. The method can be used for planning the initial undercut area, but some care should be used in advancing the undercut blasting since the size of area required may vary for different types of ore bodies.

20.3.5.8 Induced Caving

Usually increasing the size of the undercut area will eventually produce a cave, but there may be occasions where the undercut area is becoming so large that it does not seem advisable to continue the undercutting until an active cave is established. There also may be occasions where the mining limit has been reached in one dimension and no further expansion is possible. It then becomes necessary to try some type of induced caving. If the new mine is in an area of previous mining, then some of the old drifts above the caving elevation can be used for access. If the original mine plan included some observation drifting, then these drifts can be used for access above the cave area. If neither of these options is available, then some auxiliary raising and drifting may be necessary. The usual methods for trying to promote caving are through longhole drilling or powder drifts. Longholes can be drilled around the perimeter of the undercut area and blasted as a presplit to try to induce further caving action. Longholes drilled over the top of the stable arch and blasted will usually promote some additional caving action. In the case of drilling out over the top of the arch, efforts should first be made to locate the top of the arch so that the longholes will be properly located and the powder load can be calculated with some confidence. Drifts over the top of the arch can be loaded with explosives and well stemmed to prevent a possible "gunbarreling" effect. This method has been effective in finally inducing a fully active cave. In this case, the top of the arch should be located so that the proper powder load can be calculated.

20.3.5.9 Development Rate

The rate of development must be balanced with the production rate. Generally, if the number of new tons caved during a year is equal to the number of tons drawn, then the productive capacity should remain constant. If the tonnage above the individual drawpoints varies significantly, then some adjustments must be made so that the number of available drawpoints is adequate to meet the production requirements. The amount of lead time required to prepare the drawpoints must be carefully calculated. The lead time required will depend on the available manpower and the efficiency of the manpower and equipment being used. Generally, about three years will be required to prepare a new production drift from the time the initial access is started until the undercut longholes are blasted. Undercut drifts should be completed about six months to one year before undercut blasting to allow adequate time to complete the longholing. Longholing should precede blasting by about six months.

20.3.5.10 Number of Active Drawpoints for Production

The number of drawpoints required for a given level of production will depend on the rate that the ore will cave, the amount of tonnage that will flow through the drawpoint per day, and the productive capacity of the equipment. The productive capacity of the equipment can be calculated from the tables supplied by the various manufacturers. These tables should be used with some discretion since there are always some delays not accounted for in the tables. The rate of draw will depend on how rapidly the ore will cave. Very weak ores may cave very rapidly while stronger ores may cave at a very slow rate. The rate of draw should be fast enough so that there is room for the in-place ore above to cave but not so rapidly that a large void is created between the in-place ore and the broken ore. Draw rates can vary anywhere from 6 in. to 2 ft (150 to 610 mm) per day. The amount of tonnage that can be expected from a given drawpoint also will depend on how many hangups occur during a given time period. Once the number of drawpoints required has been determined, a small percentage should be added to allow for hangups and for repair. Availability will probably range between 80 to 90% for new drawpoints. As the drawpoints become older and require repair, the availability may decrease. When calculating the capacity of the production equipment, be sure not to forget the haulage equipment and its accessibility to the loading points. If all the loading points are concentrated in one or two loading drifts, it may not be possible to reach the desired tonnage even though theoretically there are adequate drawpoints.

20.3.5.11 Secondary Blasting

The caving action will always produce some oversize boulders that will not pass through the drawpoints. This is especially true during the initial caving period when attrition has not had an opportunity to reduce the size of the rock fragments. The common method of breaking oversize rock is by use of concussion blasts. Five- to 8-lb (2.2- to 3.6-kg) bags of explosives ("bombs") are placed in strategic spots between rock fragments. In order to place the bombs, the bags are tied to sticks 10 to 20 ft (3 to 6 m) long. Primacord is laced through the bag for detonation, and using the stick, the bomb can be placed against the hangup. If hangups in several drawpoints are to be blasted simultaneously, then the primacord can all be tied together and ignited with one detonator. If hangups consist of clusters of smaller rocks, a high-pressure water hose can be used to loosen the hangup. With the LHD system, large rock fragments are usually close enough to the drawpoint brow that they can be drilled with a carrier-mounted jackleg or small single-boom jumbo and loaded with stick dynamite.

Shooting hangups, especially with the slusher system, is hazardous work, and employees require special training.

20.3.5.12 Subsidence

Surface subsidence will always occur with block caving. The time from initial production to the first surface disturbance will depend on several factors: depth of mining level below surface, strength of ore, and rate of draw are the major factors. The first sign of subsidence may be a circular hole or funnel appearing somewhere within the boundaries of the undercut area. Subsidence can also be a general settling of the surface within the boundaries of the undercut area. Eventually, the total area of caving will settle, and escarpments will form. Escarpments may be nearly vertical to as flat as 45° or less, depending on rock strength and topography. Tension cracks will form around the escarpments. If a 45° line is drawn from the undercut level to the surface, this is the area in which tension cracking may occur. No permanent structures should be placed inside this line since there is a high probability that they will be disturbed by the tension cracks.

20.3.6 MINE DESIGN

20.3.6.1 Grizzly Systems

The grizzly system is best suited for ores that break very finely and require closely spaced drawpoints. It is also favored where labor is plentiful and fairly cheap. The system is labor intensive and can be used where sophisticated mining equipment is not available. The system requires considerably more development than the other systems, and therefore development costs are comparatively high.

HAULAGE LEVEL. The haulage or gathering level is driven some distance below the grizzly level to allow room for storage for loading the trains. This distance should be about 60 ft (18 m) but may be much greater if orepasses are used to transfer the ore to a central gathering level. If long orepasses are used, there should be a short section just below the grizzly level so that the tons of ore drawn per drawpoint can be measured for draw control purposes. The haulage level may be subjected to extreme weight conditions, so often the haulage drifts are supported with concrete.

The cross-sectional size will be determined by the haulage equipment dimensions and safety requirements for manway clearances.

RAISES. Transfer raises are driven from the haulage level to the grizzly. Usually, each transfer raise will serve multiple grizzlies. The number of grizzlies that can be served by one transfer raise will depend on the distance between the two levels and the grizzly chamber spacing. The transfer raises are usually lined with timber or concrete. Since this system is used in weaker ores, lining the transfer raise is necessary to insure that the raise will last the life of the production from above. Chutes are usually installed at the bottom of the transfer raises although other loading mechanisms could be used. Grizzly rails are installed at the top of the transfer raise in order to size the material passing down the raise. The cross-sectional size will be determined by the amount of ore storage required within the constraints of the ground conditions.

GRIZZLY DRIFTS. Grizzly drifts are driven to connect the top of the transfer raises that lie in a given line. The drifts serve as manway access to the drawpoints and for distribution of fresh air to the grizzlies. The grizzly drifts are usually lined with concrete or timber for support against the weight that may occur during undercutting and production. The pillar above the grizzly drift may be supported with rock bolts. The grizzly drifts can be relatively small in size since no production equipment will be required to pass through. They are connected around the fringes of the ore block for ease of access between the drifts and for ventilation purposes.

DRAW (FINGER) RAISES. Draw raises are driven from the grizzly to the undercut level. Two raises are driven on opposite sides and at right angles to the grizzly drift and located at the top of the transfer raise. These raises are driven nearly vertical or inclined at an angle not less than 45° above the horizontal. The distance between the grizzly and undercut level depends on how much pillar is required between the two levels. A 15-ft (4.5-m) pillar is common.

The raises may or may not be lined with concrete. The brow at the intersection of the draw raise and the grizzly drift is supported with posts and beams to help maintain its size. During production, if the brow becomes too worn, the broken muck will flood the grizzly drift, making access to the grizzly difficult.

UNDERCUT DRIFTS. Undercut drifts are driven to connect the tops of the draw raises. The driving of the undercut drifts forms pillars that are later drilled and blasted to initiate the caving action. These drifts are driven large enough to accommodate the drilling equipment that will be used to drill the pillars and to provide expansion room for the blasted pillar rock. When the undercut drifts have been completed, the pillars are then drilled and blasted to initiate the caving. Great care must be taken to see that the blasted pillars have been completely removed before any additional pillars are blasted.

VENTILATION. The ventilation of a grizzly system is fairly simple. Fresh air is passed through the haulage drifts and then up to the grizzly levels. Fresh air is circulated through the drifts passing from one fringe drift to the other and then to a main exhaust vent drift and to the surface. With such a system, the working areas may not always be getting the best of air, especially where dry and dusty ore is encountered.

20.3.6.2 Slusher System

The slusher system can be used for fine-breaking ores but is better suited where the ore breaks into medium-coarse pieces. Since the system uses electric slushers for production, somewhat more mechanical expertise will be required, although slushers are not usually a high-maintenance item. Where a substantial amount of the production rock will be coarse, large slushers are most appropriate (125 to 150 hp, or 93 to 112 kw). The scrapers will be 5 to 6 ft (1.5 to 1.8 m) in width.

HAULAGE DRIFTS. Haulage drifts are driven on even centers across the block to be mined. The distance between haulages is determined by the slusher drift length and the drawpoint spacing. The size of drift is a function of the size of haulage equipment. The drifts can be supported by timber or steel, but concrete is the support most often used.

SLUSHER DRIFTS. Slusher drifts are usually driven directly above and at 90° to the haulage drifts. The slusher drift consists of a loading cutout directly above the haulage, a slusher cutout at the end opposite from the slusher drift, and the slusher drift. The size of opening depends on the size of scraper being used. The width of the finished slusher drift should be only 1 ft (0.3 m) greater than the width of the scraper. This will help prevent side spill as the loaded scraper is pulled to the drawhole and produce greater payloads for each scraper trip. The slusher cutout, loading cutout, and slusher drift are usually lined with concrete, although other support materials have been used. The floor of the slusher drift should have rails installed as this provides a better sliding surface for the scraper and prevents gouging of the floor concrete. The drift should also have an upward grade to 5%. This will allow for water drainage toward the haulage and also will favor the loaded scraper for somewhat easier loading. The slusher drifts are usually staggered along the haulage. That is, every other slusher drift is driven at 180° from the previous slusher drift.

VENTILATION DRIFTS. Ventilation drifts are driven one-half the distance between each pair of haulage drifts directly under the tail ends of the slusher drifts from two adjacent haulages. Small ventilation raises to the slusher drift above serve for exhausting contaminated air from the slusher drift. The ventilation drift is sized according to the amount of exhaust air that it will be required to handle. Ventilation drifts are not usually concreted but may require roof bolts and shotcrete.

FINGER (DRAW) RAISES. Finger raises are driven at right angles to the slusher drifts at an angle of approximately 45° above the horizontal. The raises are advanced to the centerline of the drawpoint spacing and then driven vertically to the undercut level. Finger raises are driven from both sides of the slusher drift, usually in opposite sets although they may be staggered from one side of the drift to the other. The size of the finger raise is determined by the size of material that the designer wishes to pass with ease through the finger raise. If the finger is too small, then the frequency of hangups is greater, increasing the need for secondary breakage. If the finger is too large, then the material reaching the slusher drift may be too large for the scraper to handle. Lining of the finger raise is desirable for two reasons. The height of the brow of the drawpoint must be controlled. If it becomes too high, then the broken rock can flood the slusher drifts, making it impossible to pull the scraper behind the muck pile for efficient loading. It has been found that rock rubbing against rock will wear faster than rock against concrete. When

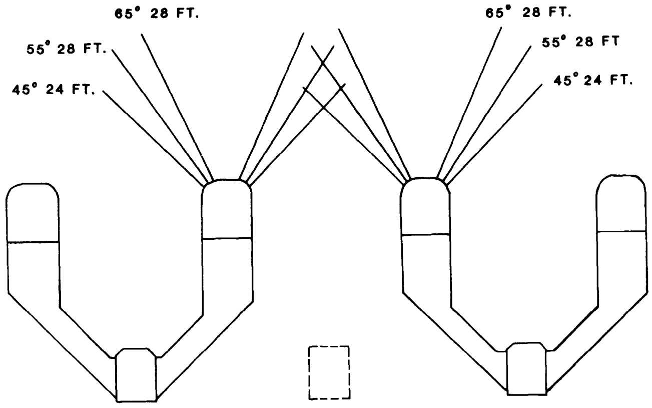

Fig. 20.3.8. Typical drill pattern for undercut blasting—slusher drift. Conversion factor: 1 ft = 0.3048 m.

repair of the drawpoint becomes necessary, it is much easier to repair concrete than to try to form new concrete against worn rock.

UNDERCUT DRIFTS. Undercut drifts are driven over the tops of the finger raises. The size of undercut drift is usually determined by the size of equipment used for the longhole drilling. Great care should be taken so that the drifts stay on the centerline of the drawholes to insure that the longhole drilling is properly spaced for an effective blast of the final undercut. The elevation of the undercut level is determined by the amount of pillar desired between the slusher drifts and the cave bottom. The pillar should be adequate to provide for wear during the production period and for protection of the slusher drift if weight should occur.

LONGHOLE DRILLING. Longhole drilling is usually done in the shape of a fan with the bottom holes being drilled at a minimum angle of 45°. The size of the longholes and the powder load required are dependent on the rock strength, and these two will determine the spacing between the fans. The drilling and blasting of the drill fans in two adjacent undercut drifts form an apex over the slusher drift that protects the slusher drift and also help the ore over the apex move to the finger raises. Care must be taken when blasting the drill rings to be sure that no unblasted pillars of ore are left. These pillars will interfere with good caving and could cause weight to be transferred to the workings below. No more than two or three drill fans in an undercut drift should be blasted at one time. Fig. 20.3.8 shows a typical drill pattern for undercut blasting.

VENTILATION. Ventilation with a slusher system is somewhat more positive than with the grizzly system. An intake ventilation lateral can be driven around the fringes of the mining area or underneath the haulage level. Fresh air flows through the loading drifts and into the slusher drift. The air then passes through the slusher drift to the vent connection and into the exhaust ventilation drifts where it flows to a main vent lateral and then is discharged. The volume of air feeding each slusher drift can also be controlled by placing a vent box at each vent connection. By changing the size of vent box opening, the amount of air in each slusher drift is controlled. This system does require constant monitoring to be sure that various controls are in proper position, especially in areas of high secondary blasting.

20.3.6.3 LHD (Rubber-tired) System

The LHD system has been gaining in popularity in recent years because of the high productivity and efficiency that can be obtained. The system requires less development per ton of ore and has a high production-output capability. The savings in mining manpower can quickly be negated, however, because of the greater mechanical manpower required. If the mechanical maintenance program is properly organized, executed, and monitored, then real savings can be realized. It should be emphasized that a well-trained mechanical crew is required. If skilled manpower is not available in the local labor market, then a good training program at the mine site will be required.

The system is best suited to ore bodies that are not intensely fractured and will cave in larger pieces that would not be practical to handle with the other two systems. Diesel equipment requires substantial room to maneuver and therefore will require wider drawpoint spacing. This is especially true of 5-yd^3 (3.8 m^3) equipment and larger.

HAULAGE LEVEL. The haulage level should be located well below the production level so that adequate storage is available in the centralized orepasses. This will provide sufficient loading capacity so that haulage trains are not directly dependent on LHDs for loading and larger-sized ore cars can be used. The size of the haulage drifts is dependent on the size of haulage equipment. Since the haulage level is located well below the caving level, the drifts are not usually subjected to unusual weight, and therefore standard support methods are adequate.

PRODUCTION LEVEL. Production drifts are driven on even centers across the ore body or production block. The spacing between production drifts is determined by drawpoint layout and spacing. The size of the drifts depends on the size of production units being used. The larger the production unit, the greater the cross section required. The length of the unit will also have some effect on the width of the drift since adequate room to maneuver the unit into the drawpoint is required. The production drifts can be subjected to future heavy weight; therefore, good support is required. These drifts should be roof bolted and concreted or at least shotcreted.

DRAWPOINTS. Drawpoints are driven horizontally from the production drifts. They are driven at some angle to the production drift, usually about 45° to facilitate entry of the LHD for production. The distance from the brow of the drawpoint to the opposite rib of the production drift must be sufficient for the LHD to be at nearly zero degrees articulation when entering the muck pile. The height of the brow of the drawpoint must be high enough to allow the bucket of the LHD to raise its load but not so high that the broken rock will flood out into the production drift. The drawpoint is usually lined with concrete in order to maintain the proper size and also for support against the weight from undercutting and blasting. Steel lintels in the brow have also proven beneficial.

Drawpoints from two adjacent production drifts may be connected by a crosscut. The crosscut is used later for forming the draw cone. One draw cone will feed broken ore to two drawpoints (Fig. 20.3.9).

UNDERCUT LEVEL. The undercut level is driven at some distance above the production level, usually in the range of 50 ft (15 m). This system has the advantage that more pillar can be left between the production and caving level, offering greater protection to the production level. The undercut drifts are usually driven directly above the production drifts. The size of the undercut drifts is determined by the size of equipment used. The drilling equipment may require more room than the LHDs used for driving the drift because of room required for drill rod changes. It is good practice to use the same type of LHD for development as is used for production. This helps reduce the number and types of equipment required. These drifts are not usually supported unless rock conditions require some temporary support.

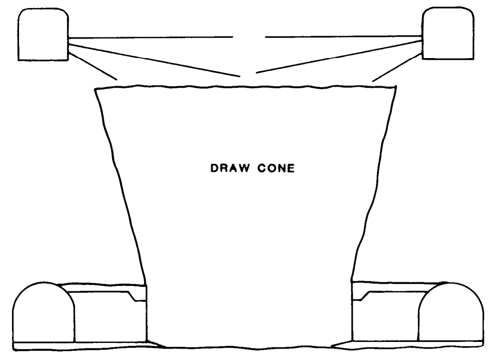

Fig. 20.3.9. LHD drawpoint and cone.

LONGHOLE DRILLING. Drilling of the undercut longholes and for the draw cones is done from the undercut level. Drilling the draw cones from the undercut level does require more drilling than if done from the production level, but the blasting sequence for the draw cones is much safer from this level. Blasting for the draw cones is usually done one or two rings at a time. When drilling is done from the bottom, once the first rings have been blasted, access to the remaining rings is difficult and hazardous. A typical drilling pattern for the undercut and draw cone is shown in Fig. 20.3.10.

Blasting of the draw cones immediately precedes blasting of the undercut. The cones should only precede the undercut blasting by one or two drawpoints. This way, the minimum amount of ground ahead of the cave line is opened and more support is offered to the weight that precedes the cave line. Blasting of the longholes is done two or three fans at a time. With this system, it is fairly easy to check for unblasted pillars. As with the other systems, the cave line should be advanced at some angle to the major workings to minimize the amount of weight transferred to the production level.

OREPASSES (STORAGE BINS). Orepasses are driven between the production and haulage levels for transferring production rock to the trains. The orepasses should be spaced intermittently along the production drifts so they can be serviced by several drawpoints. The distance between orepasses is determined by the most efficient haul distance for the LHDs and the amount of tonnage per orepass required per shift or per day to service the haulage trains below. By use of branch orepasses, several production drifts can be serviced by one loading point on the haulage level. Loading chutes are installed at the bottom of each orepass and a dump pocket installed at the production level. Orepasses are not lined because of their length, so care must be taken to place them in good-quality rock. If the rock is good, one orepass should be able to pass approximately 2 million tons (1.8 Mt) before it becomes too worn for further use. Raise boring machines can prove to be economical if the orepasses are fairly long. The use of these machines can greatly simplify the driving of long orepasses.

VENTILATION. Ventilation requirements for the LHD system are substantially higher than for the other systems because of the high ventilation requirements for diesel equipment. Mine Safety and Health Administration standards for diesel equipment are published (Chapter 11.5). A system of distribution drifts completely separate from the production level is almost obligatory in order to bring the proper amount of clean air to the various working areas.

Main ventilation laterals can be driven underneath the production level. Fresh air is introduced to the production level at

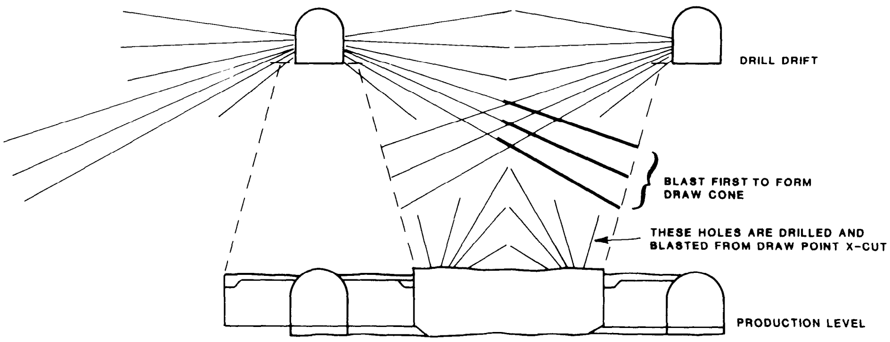

Fig. 20.3.10. Drilling pattern for drawcone and undercut.

strategic points throughout the mine by raises from the intake lateral to the production level. Small ventilation raises adjacent to each orepass dump point pick up the contaminated air and take it to small exhaust vent drifts below the production level, thence to the main exhaust lateral, and finally discharge it to the surface. The volume of air discharged at each exhaust raise has to be replaced with clean air immediately downwind from the exhaust raise in order to maintain the proper quantity of airflow in the mine.

20.3.7 ECONOMICS

Block caving is probably the least expensive underground mining system since the amount of drilling and blasting per ton of ore produced is much less than with any other system. The actual cost per ton for development is difficult to quantify since it depends so much on the height of ore column being developed on any given mining level, the type of block cave system being used, and the drawpoint spacing. The recent severe depression of the mining industry has caused most mining companies to aggressively seek cost-cutting measures and increased efficiencies. Costs that were applicable in the early 1980s are no longer applicable. The best approach for the engineer who is trying to develop a cost projection for a new mining property is to generate the costs for each item of work required to develop a mine, based on the use of modern equipment and high manpower efficiencies, and then to apply the total to the complete block of ore to be mined. Great care must be taken in using historical costs from other mines since the methods of stating costs per ton vary significantly from one mine to the next. Some mines carry development costs as an operating expense whereas other mines may capitalize development costs and amortize them over the life of the ore block or complete ore body. In the case where a mine treats development costs as an operating cost, if development is progressing at a rate higher than production, then costs per ton produced may appear high. If the development rate is slowed down, the costs per ton produced will appear low. Some mines use a mixture of operating cost and capital costs. Main entries, ventilation laterals, and equipment purchases are capitalized; and haulage drifts, drawpoints, and undercutting may be charged as operating expense. When using historical costs from another property, be sure that the method of costing is thoroughly understood.

A recent publication by the US Bureau of Mines (Anon., 1987) can be used to get a "ball-park" cost estimate of US mining costs.

20.3.8 CASE STUDIES

20.3.8.1 El Teniente Mine, CODELCO, Rancagua, Chile*

The El Teniente copper mine, a division of CODELCO Chile, is located 31 miles (50 km) northeast of Rancagua City. The first mining level is situated at an elevation of 6506 ft (1983 m).

Main access to the mine is through a 5-mile (8-km) tunnel on Teniente 8 level. Access to the mining levels above is through two main shafts. Shaft B services 5 to 1 levels. Shaft C services levels 8 to 5. Both shafts are equipped with friction-type hoists with double-deck cages having a capacity of 350 employees. Total hoisting capacity of shaft B is 37.5 tons (34.0 t) and of shaft C is 32 tons (29.0 t). Other shafts are available for various services.

Present daily production is 99,500 tons (90,273 t), coming from four separate mining areas:

North Mine (Teniente 4)	32,273 tons (29,272 t)
South Mine (Teniente 1)	13,219 tons (11,990 t)
Central Mine (Teniente 4)	43,922 tons (39,837 t)
Fortuna Mine (Teniente 4)	8,073 tons (7,322 t)

A total of 40,653 tons (36,873 t) is sent to the Sewell Concentrator and the balance to the concentrator at Colon. The mine operates three 8-hour shifts per day for 360 days/year. Total work force is 3198.

GEOLOGY. The El Teniente mine is one of the largest copper ore bodies in the world today. The ore body has a generally triangular shape in plan view, elongated to the north, where it is centered in the Teniente Porphyry and extends toward the southwest into the Sewell Diorite. The central area consists of a low-grade zone related with the Braden Pipe. The vertical development includes an oxidized-leached zone that averages 328 ft (100 m) thick, a supergene enrichment zone that reaches a depth of about 1640 ft (500 m) in the northern part of the ore body, and a hypogene or primary mineralization zone, proven to a depth of 5249 ft (1600 m).

Eighty percent of the copper and molybdenum mineralization occurs in andesites of the lower member of the Farellones formation. This formation (Miocene) was subdivided in the area of the ore body into three members separated by angular discon-

* Based on information from Gabriel Gutierrez C., El Teniente Division, CODELCO.

tinuities: the lower member consisting of massive andesitic flows, the middle member with epidotized andesitic flows with reddish lacustrine sedimentary intercalations, and the upper member, with basaltic intercalations.

The intrusions in the deposit are diorite, dacite porphyry, latite porphyry, and andesite and lamprophyre dikes. In the central part of the ore body, there is a complex megastructure designated as the Braden Breccia.

The main hydrothermal stage is superimposed on the late magmatic stage and it is characterized by quartz-sericite-chlorite and anhydrite bearing veinlets and alteration halos. It develops to the northeast and subordinately northwest in veinlets, which commonly do not affect the whole rock. The main sulfides associated with this stage are chalcopyrite and pyrite, which are disseminated in halos and as veinlet fillings.

METHOD OF EXPLOITATION. There are two basic types of ore at El Teniente, primary and secondary, that are characterized as hard (primary) ore and soft (secondary) ore. The primary ore that breaks into coarser fragments is mined by an LHD system. The secondary ore that breaks into smaller fragments is mined with the grizzly (full gravity) system.

Grizzly (Full Gravity) System—This system has been used in the secondary ore for many years at Teniente. It is currently being used in the South Mine (Teniente 1) and the North Mine (Teniente 4). Typical mining block dimensions are

width	197 to 262 ft (60 to 80 m)
length	295 to 394 ft (90 to 120 m)
height	394 to 590 ft (120 to 180 m)

Fig. 20.3.11 shows the arrangement of the full gravity system.

Production drifts are driven at 49-ft (15-m) centers across the block to be mined. Drift size is 6 by 7.5 ft (1.8 by 2.3 m). Grizzlies are spaced at 24.6 ft (7.5 m) along the production drift. Rail spacing for the grizzlies is 13.5 in. (343 mm). Vertical coned-out raises from both sides of the grizzly are driven to the undercut level. These cones have an opening or drawhole at the grizzly elevation of 5 by 6.6 ft (1.5 by 2.0 m) and widen at the top to a cone 11.5 ft (3.5 m) in diameter at the undercut level.

The undercut drifts are at an elevation 26 ft (8 m) above the production drifts and are driven parallel to the production drifts. A pattern of 2.5-in. (63-mm) diameter longholes are drilled at 5-ft (1.5-m) centers along the undercut drift. The total height of the undercut after blasting is designed for 26 ft (8 m). Blasting is done on a daily basis ranging from one to eight blasts per day.

The broken ore from the drawpoints passes through grizzlies for sizing and into orepasses of 5 by 5 ft (1.5 by 1.5 m) cross section to the transfer level. The transfer level is used to control the flow of ore to the main orepasses. From the transfer level, the ore is transferred to orepasses that have a cross section of 6.5 by 6.5 ft (2 by 2 m) to storage bins on the haulage level. The ore is then loaded to rail cars and transported to the concentrators.

The primary rock in Teniente 4 South and Teniente 4 Fortuna area has a much lower fracture frequency than the secondary ore in Teniente 1 South and Teniente 4 North. The full gravity system is not suitable for this harder rock and larger fragment size; therefore, a new system of mining was necessary.

Mechanized LHD System—This system requires four main levels (Fig. 20.3.12): undercutting level, production level, rock-breaker level, and haulage level. In Teniente 4 South, the distances between levels are

undercut to production	59 ft (18 m)
production to rock-breaker level	105 ft (32 m)
production to haulage	213 ft (65 m)

The effective draw area for each drawpoint is 2798 ft^2 (260 m^2). In the Fortuna mine, the distances are less:

undercut to production	52 ft (16 m)
production to rock-breaker level	98 ft (30 m)
production to haulage	141 ft (43 m)

The effective draw area per drawpoint is 2100 ft^2 (195 m^2).

Fig. 20.3.13 shows a typical production level layout for the LHD system. The drawpoint crosscuts are driven at an angle of 60° to the centerline of the production drifts. The distance between the production drifts is 98 ft (30 m), and the distance between drawpoint entries is 56.8 ft (17.3 m). The drawpoints are well supported with steel and concrete (Fig. 20.3.14).

Blasting of the undercut to initiate caving consists of three steps:

1. An initial separation slot is formed by drilling 3-in. (76-mm) diameter vertical holes 42.6 ft (13 m) long. This double row of holes, spaced 6.5 ft (2 m) apart, when blasted forms a line of weakness to assist caving action and as an expansion chamber when the undercut holes are blasted.

2. Drilling and blasting the drawbells through which the caved ore flows to the drawpoints. These 2.5-in. (63-mm) diameter holes are drilled in a series of fan-shaped patterns from the drawpoint crosscut on the production level. When blasted sequentially, a drawbell is formed approximately 39 by 49 ft (12 by 15 m) at its top and 49 ft (12 m) high. This insures that large rock fragments can move down near the drawpoints for easy access for secondary breakage.

3. From the undercut drifts, a fan-shaped pattern of drillholes 2.5-in. (63-mm) in diameter are drilled. In Teniente 4 South, these fans may have 25 holes, whereas in the Fortuna area, only 17 holes are drilled. The total number of holes is adjusted according to the rock mechanics of the area. Fig. 20.3.15 shows the drill pattern and explosives load for one area of Teniente 4. The blasting of these drillholes is the final step in initiating the cave. Fig. 20.3.16 shows the total LHD system.

Production units are 5- and 6-yd^3 (3.8- and 4.6-m^3) LHDs. The LHDs tram the ore to orepasses that are spaced at 197- to 328-ft (60- to 100-m) intervals along the production drift. The ore drops to the rock-breaker level where the fragments are reduced to – 30 in. (– 762 mm). Reduction of the oversize material is with mechanical rock breakers. From the rock-breaker level, the ore moves through orepasses to the haulage level where it is stored in bins for loading into haulage trains.

Although the primary ore is much more competent than the secondary ore, efficiency with the mechanized system has proven to be much better than the full gravity system. A comparison of mine efficiencies is shown in Table 20.3.2.

HAULAGE AND CRUSHING SYSTEM. There are five different train systems at Teniente:

Teniente 1 — 30-in. (762-mm) gage track,
15-car trains, 10-ton car capacity
Teniente 5 North — 30-in. (762-mm) gage track,
15-car trains, 20-ton car capacity
Teniente 5 Fortuna — 30-in. (762-mm) gage track,
15-car trains, 20-ton car capacity
Teniente 5 Central — 56.5-in. (1435-mm) gage track,
12-car trains, 28-ton car capacity
Teniente 8 — 56.6-in. (1435-mm) gage track,
18-car trains, 100-ton car capacity

The crusher for treating oversize ore, mainly from the LHD areas, is a 54- by 74-in. (1.37- by 1.88-m) gyratory crusher. Its capacity is 2866 tph (2600 t/h).

Conversion factor: 1 ft = 0.3048 m.

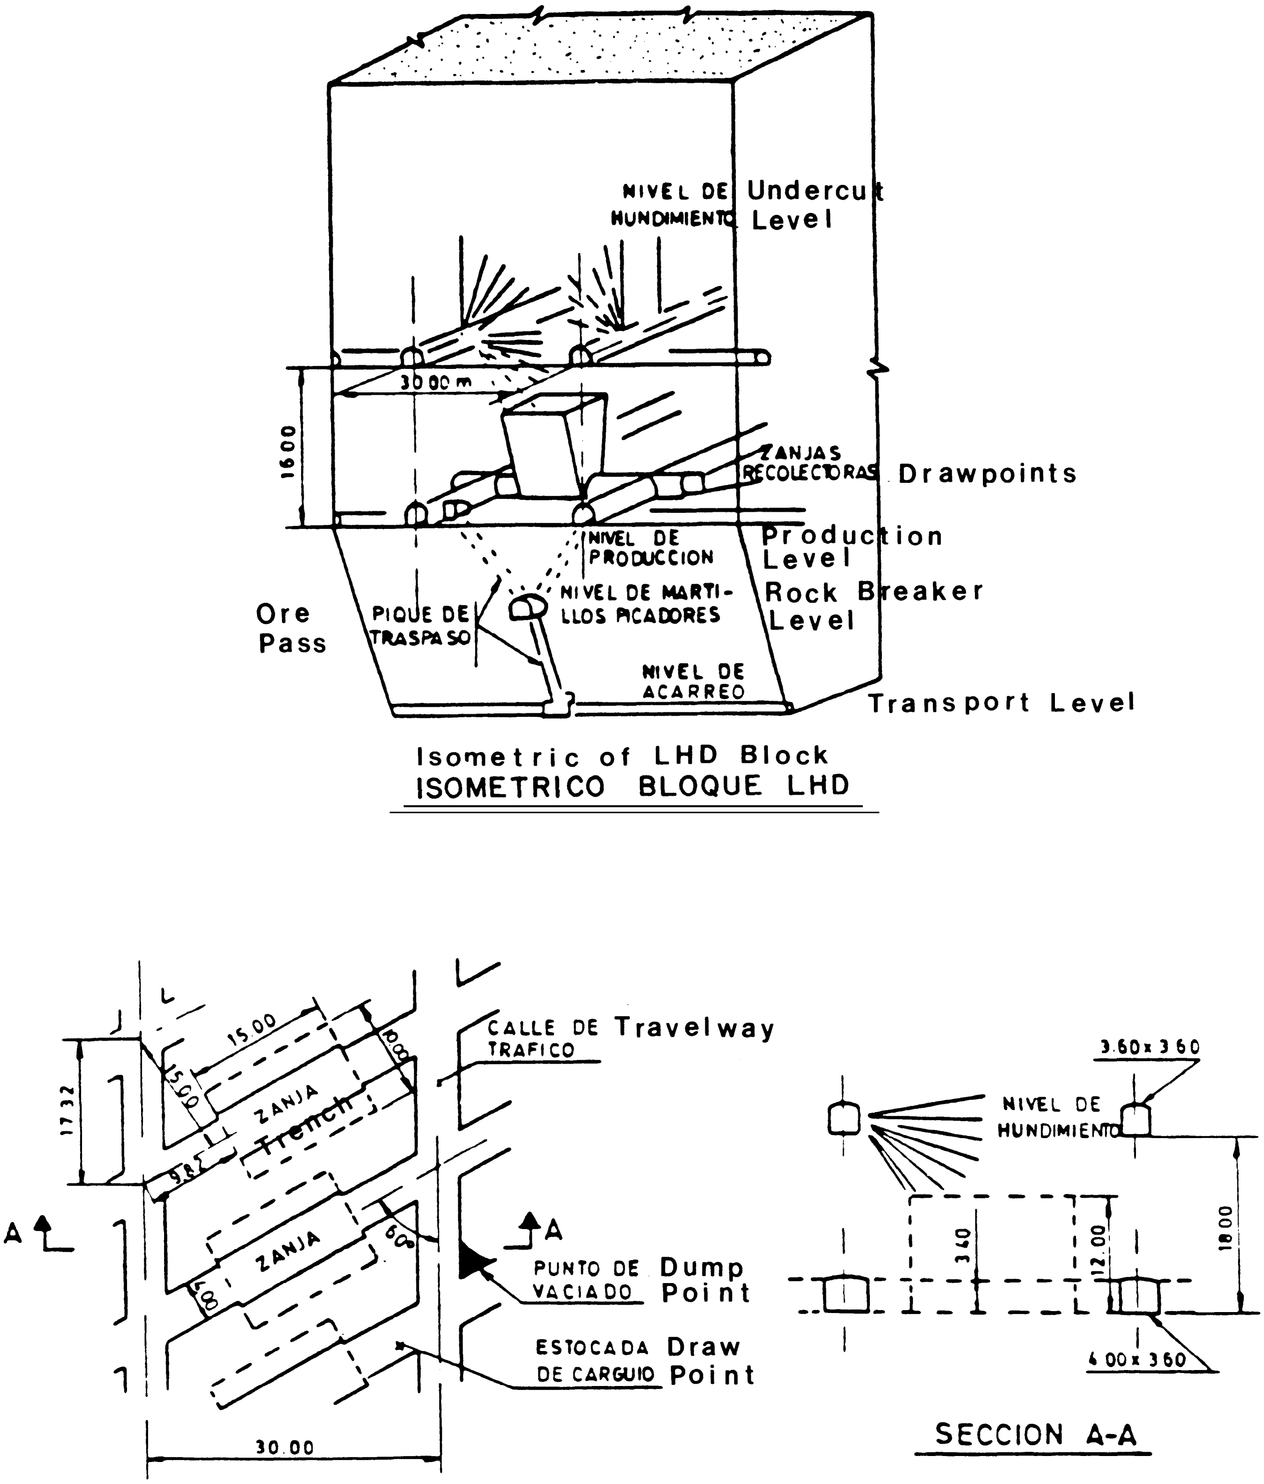

Fig. 20.3.12. Isometric of LHD block, plan of production block. Conversion factor: 1 ft = 0.3048 m.

VENTILATION. The main ventilation system of El Teniente mine is composed of several independent systems that supply the production and haulage areas. Distribution and air return is carried out through sublevels and overlevels developed exclusively for ventilation. There are 14 fans operating currently, six of which are used as intake fans and eight for exhaust air. Together, they move approximately 2,460,000 cfm (1160 m^3/s).

20.3.8.2. Ertsberg East Mine, Freeport Indonesia, Inc., Irian Jaya, Indonesia*

INTRODUCTION AND ORE BODY. The Ertsberg East underground mine is located in a remote area of the province of Irian Jaya (formerly Dutch New Guinea) in the Republic of Indonesia, approximately 75 miles (120 km) inland from the Arafura Sea. The mine is in rugged mountainous terrain, with the highest surrounding peaks exceeding 16,400 ft (5000 m) above sea level. The mine offices, shop buildings and mine portal are situated at an elevation of 11,800 ft (3600 m).

The Ertsberg East (GBT) ore body is a deposit of copper-rich garnet/monticellite skarns that occur along a major east west regional structure known locally as the hanging wall fault zone (HWFZ). This structure, which is the controlling feature of the ore body, is a high-angle (60 to 80°) normal fault interrupting a 3.2 m.y. quartz diorite intrusive. The quartz diorite intrusive served as the heat pump/source rock for the skarning event and is the southern boundary of the ore zone. The upper reaches of the deposit are exposed on the side of a high-relief, south-facing slope on an upthrown block of the Jayawijay mountain range.

The general geology of the deposit can best be described through a north-to-south cross section (Fig. 20.3.17). The HWFZ waste units on the north side of the fault consist of a sedimentary sequence of limestones interbedded with quartz-rich siltstone layers. These sedimentary units were metamorphosed by the skarning event to a series of interbedded marbles and quartz hornfels. The metamorphosed units dip steeply to the north. The ore-bearing portion of the HWFZ consists of two units: the first is a calcite-silica cemented breccia, and the second is a discontinuous highly altered clay.

The ore zone is divided into a skarn section on the footwall side of the HWFZ and a breccia within the hanging wall fault zone itself. In roughly descending order of overall abundance, the metallic minerals are bornite, digenite, chalcopyrite, chalcocite, idaite, covellite, marcasite, valleriite, and pyrite. The skarns additionally consist of a variable mix of garnet, monticellite, diopside, forsterite, calcite, and, in places, magnetite, while the HWFZ breccias are calcitic adjacent to the skarns and clay altered near the hanging wall (Fig. 20.3.18).

HISTORY

Original Discovery and Selection of Mining Method—An exploration program started in 1975 first located the Ertsberg East deposit. In 1977, an exploration adit was collared. Driving of drifts during the exploration phase revealed that most of the ore body would not stand unsupported over a broad span. By the end of 1978, data assembled indicated the ore body might be mined using caving techniques. Mineralization definition drilling indicated that minable widths could range from 197 to 394 ft (60 to 120 m) and more, depending on cutoff grade. The ore body is bounded by a sharp fault cutoff to the north. The southern boundary is an economic cutoff. Two methods of extraction were considered: block caving and sublevel caving. An analysis of the two methods was undertaken and minable reserves calculated for each, along with manpower and operating costs. Analysis of the two alternatives showed block caving to be the preferred method.

Review of the rock mechanics data supported the conclusion that the rock was cavable and further revealed that the broken ore would be composed of better than 50% fines. In the northern section of the ore body, in the breccia zone, the rock was projected to break easily producing the majority of the fines. The southern zone was expected to be more difficult to break but was predicted to follow the breccia. These conclusions led to the decision to use a conventional slusher scraper system.

Mine Development—Analysis of the geologic samples obtained (core samples) indicated the ore would break into very fine particles. This dictated closely spaced drawpoints with an area of influence of 17.1 by 17.1 ft (5.2 by 5.2 m) to insure maximum ore recovery. Drawpoint width was set at 4.9 ft (1.5 m). Slusher lines were spaced at 32.8-ft (10-m) intervals. Six lines made up one block (123 by 196.4 ft) (37.5 by 60 m) and four blocks made up the initial 246 by 393.7 ft (75 by 120 m) area of undercut. Primary development was with rail-mounted equipment. The slusher drifts, haulage drifts, and other areas needing ground support were supported by up to 1.6 feet (0.5 m) of monolithic concrete.

The undercut level 32.8 ft (10 m) above the slusher level was developed by driving a series of crosscuts in the block and then extracting pillars using jackleg drills. Ore was drawn from the cave area via finger raises and moved by slushers to grizzlies equipped with 14-in. (356-mm) spacings (Fig. 20.3.19). Transfer raises beneath the grizzlies held about 40 tons (36 t) each (Fig. 20.3.20). The ore was loaded into 8-yd^3 (6-m^3) side-dump cars through center-loading chutes spaced at 32.8-ft (10-m) intervals. Initially ore was hauled to the surface by trolley locomotives and later by diesel locomotives.

OPERATING EXPERIENCE

Start-up—The initial mining area of 246 by 394 ft (75 by 120 m) was subdivided into four 123- by 197-ft (37.5- by

60-m) blocks. This was determined to be the minimum block size necessary to induce caving action and facilitate the desired production draw of 4960 tpd (4494 t/d).

Boundary weakening was conducted on two sides of the block. Actual undercutting commenced in November 1980. By

April 1981, the first four sub-blocks were undercut (Fig. 20.3.21).

Problems—Almost from the beginning, the ore did not cave as planned. By the end of the first six months of production, it became obvious the system had serious problems. Although the production goals were being met, the cost was high. During the caving startup, numerous boulders were encountered, especially in the southern drawpoints, resulting in excessive secondary blasting.

The north side had its own set of problems:

1. The northern drawpoints were encountering boulder hangup problems.

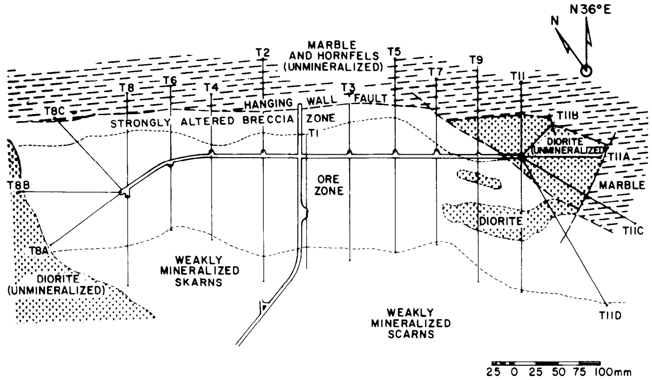

Fig. 20.2.18. Generalized 3600 level plan.

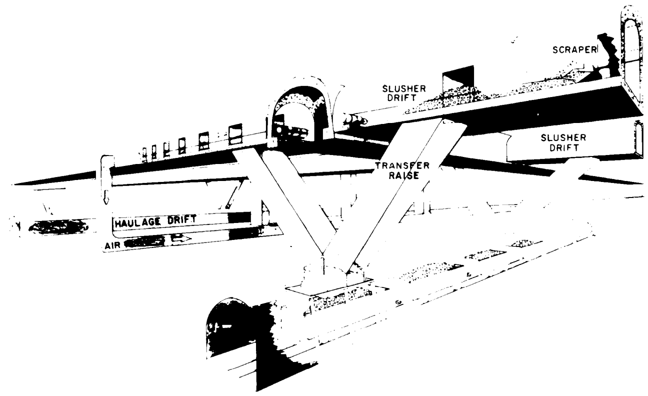

Fig. 20.3.20. Ore transfer raise system.

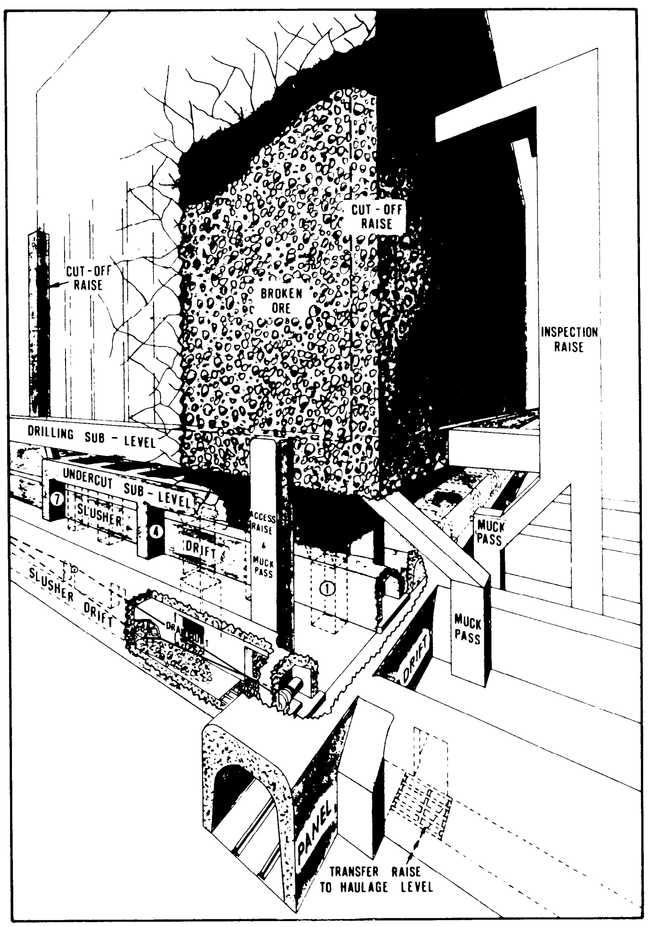

Fig. 20.3.19. Copper mining block caving.

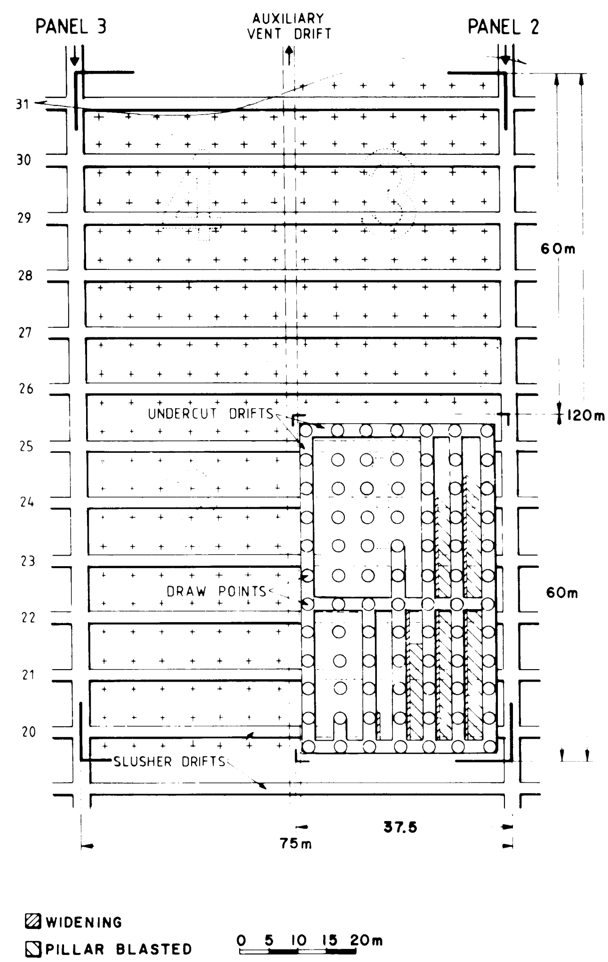

Fig. 20.3.21. Proposed stope plan at undercut level. Conversion factor: 1 ft = 0.3048 m.

2. The breccia was slow to cave, and if the drawpoints were not drawn continuously, the ore packed. The packing caused weight to be shifted on to the drawpoints. Even though the slusher drifts had up to 18 in. (460 mm) of reinforced concrete, weight on the drawpoints became so excessive that one slusher drift was lost for six months.

In November 1981, it was discovered the cave was not propagating as predicted and a void had developed above the cave area. Investigatory diamond core holes were drilled around the perimeter of the cave. Evaluation of the gathered data indicated:

1. The cave had arched, reaching an almost stable condition.
2. The cave back was highest on the south side.
3. The skarn area of the deposit was fragmenting into extremely large boulders, and without proper caving action to

assist breakage, the drawpoints were experiencing severe weight problems from these boulders.

Several problems had to be addressed at once:

1. Drawpoints were too small. Instead of encountering the fine muck predicted, they were being asked to handle numerous large boulders.

2. Close spacing of the drawpoints coupled with the minimum height between levels was allowing the uneven weight distribution from the massive boulders to cause ground failures around the drawpoints.

3. Repair costs due to weight problems and secondary blasting was excessive.

4. Excessive secondary blasting and the lack of cave propagation was severely limiting production.

5. The haulage system was experiencing problems of its own due to the type and number of chutes being in use below the slusher extraction levels.

6. The overall operating costs were running 50% above plan and were rising.

DESIGN CHANGES

Slusher Blocks—Several changes were implemented to solve these problems:

1. The next slusher block developed (block 5) incorporated a drawpoint that was 25% larger in an attempt to ease the boulder problem. The distance between drawpoints was enlarged to increase pillar size.

2. The undercut level was raised 7 ft (2.1 m) to a total of 40 ft (12.1 m) to protect the drawpoints during undercutting.

3. The lower 16 ft (4.9 m) of the drawpoints was concreted to better protect them during the undercutting and secondary blasting phases.

4. A cave inducement program was initiated. Initial efforts concentrated on the few areas that could be reached from the perimeter of the cave on the existing level.

5. A new adit on the 3780 level was collared to permit better access over the top of the cave for additional inducement.

LHD Block 6—Even as these steps were being implemented, it was recognized that major changes must be made to get a better fit between the ore characteristics and the extraction methods. The operating philosophy of Freeport Indonesia (FI) played an important role in the events that followed:

1. Key people within the organization came from a variety of mining backgrounds, including both caving and non-caving operations.

2. FI management was open to suggestion and changes. FI management demonstrated a continuing confidence in the operating staffs ability to overcome the caving problems and garner productivity improvements.

These two factors encouraged the staff to explore nontraditional ideas, often quite unfamiliar to many of the operators.

Time was a critical element at this point. If this project was going to survive, it was imperative that new methods of extraction be elected and implemented quickly. Only a minimum of time was available to perform evaluations.

In order to handle the large boulders with any efficiency, the drawpoint openings had to be at least doubled in size. Additional pillar support around each drawpoint and between the extraction and undercut levels was also needed. Drawpoints needed to be isolated individually for blasting or repair without shutting down an entire area. Transferring of the ore from the drawpoint to the haulage trains had to be simplified.

From these discussions, a concept evolved to develop a test block (block 6) using LHD equipment. A design was laid out that made best use of existing technology. Drawpoint dimensions were widened to 41- by 41-ft (12.5- by 12.5-m) spacing with 12-ft (3.66-m) width drawpoints. The undercut was raised 10 ft more (3 m) to a total of 49 ft (15 m). This permitted drawbells with 60° slopes (the minimum muck run angle), yet still provided sufficient pillar support between drawpoints. In addition,

1. 3-yd^3 (2.2-m^3) development loaders already on site were "borrowed," and two additional LHD units were ordered to complete the test.

2. Drawbells were formed using existing bar and column mounted drills.

3. The undercut pillar extraction was accomplished using jackleg drills.

4. Block 6 was located near to an existing rail haulage orepass to keep the loaders isolated from the slusher drifts.

RESULTS. Second generation results yielded the following:

Slusher Blocks—Block 5 slusher changes did little to improve productivity. Drift support was improved, but boulders were still a severe problem requiring substantial secondary blasting.

LHD Block 6—In contrast, completion of Block 6 (LHD test block) proved to be a success.

Virtually all the boulders passed through the drawpoints. Those that did not were easily accessible for drilling and blasting. Because of this accessibility and the more robust drawpoint size, blasting damage was reduced significantly.

Due to increased pillar size, boulder-weight damage to the drifts and drawpoints was minimal.

POST LHD INTRODUCTION. During the development of LHD block 6, it became apparent that this system had the flexibility necessary to handle the problems encountered to that point. Thus additional LHD development blocks were laid out. All caving blocks since the successful completion of block 6 have been developed as LHD blocks. Table 20.3.3 shows improvements to the underground operating efficiencies in the years since the change. Each succeeding block caving process has been additionally modified, incorporating new techniques that have been identified as increasing the productivity of the ore extraction process or providing easier development of the block (Fig.

Table 20.3.3. Productivity Data—Underground Mine Ertsberg East Mine

Tons Mixed per Full-time Underground Employee

Conversion factors: 1 lb = 0.4536 kg, 1 ton = 0.9072 t.

20.3.22). Ultimately, these changes have resulted in lower costs per ton produced. From 1982 to 1983, underground production costs per ton mined dropped 77%. Through 1984, the cost was lowered by 146% compared to 1982. The table shows the relationship to productivity on a per-ton basis during this period.

LHD SYSTEM. Present operations include two operating block caving areas within the Ertsberg East mine and a new block caving development called the DOM mine. While development and production systems in these three areas vary according to geologic conditions and rock mechanics requirements, they all have some common elements.

Undercutting—The original room and pillar undercutting system was slow and arduous and generally resulted in severe weight transfer that damaged the extraction drifts during the undercutting phase. A new method called the trench undercutting system has been developed to permit the undercutting to be accomplished using large down-hole hammer drills and permit development of undercutting and production drifts simultaneously.

In this system, trench drifts are driven on the extraction level between the planned extraction drifts. Simultaneously, 60 ft (18 m) above the extraction level, on the undercut level, drill drifts are driven directly over the extraction drift locations. Then using down-hole hammer rigs drilling 5- to 6-in. (130 to 150 mm) holes, a fan pattern is drilled that, when blasted, will open up a V slot. The trench drift forms the bottom of the V, and the drill drifts form the top edges of the V. Blasting starts at one end of the drill drift, the end where the V slot has been created. The swell muck from the blast is mucked out of the slot from the trench drift. All drilling and blasting take place on the undercut level leaving the trench drifts clear for mucking. Currently, face advances of 32.8 to 42.6 ft (10 to 13 m)/week per drill machine are obtained drilling 394 ft (120 m) per fan with 8.2-ft (2.5-m) spacing. Approximately 1000 tpd (900 t/d) of muck is produced from each fan during undercutting. Once the undercutting has been advanced there is a destressed inverted V pillar left over the extraction drift.

Draw—During the evolution of the LHD system, different draw configurations were tested. The initial draw pattern was a 41- by 41-ft (12.5 by 12.5-m) pattern with the drawpoints directly opposite each other. Staggered drawpoint alignment along with enlarged drawpoint areas of influence have been tested. It was found that behavior of the caving rock dictated the drawpoint area of influence. Enlargement of the drawpoints area of influence to 45.9- by 52.5 ft (14- by 16-m) allowed larger drifts and drawpoints. This in turn allowed larger loaders (5 yd^3 or 3.8 m^3 capacity), thus increasing productivity. Minimum drawpoint width is now 11.8 ft (3.6 m), with 13.1 ft (4 m) being used in the areas where 5 yd^3 (3.8 m^3) loaders are working.

Ground Support—Monolithic concrete is the primary ground support. Tests have been conducted using shotcrete but, due to the varying ground conditions, shotcrete has not proven practical. Future efforts focus on increasing the pillar size within the production area as well as between production drifts. Cable bolting of the production drifts is also being tested.

SUMMARY. Productivity improvements and cost reductions continue to play an important role in the operation at Freeport Indonesia. The Ertsberg East mine could not have achieved its success without the technological improvements that have been incorporated to achieve the productivity and cost reduction. The project now ranks as one of the lowest-cost operations in the world.

A critical factor in the success of this program was FI management support. Senior management's commitment to the operators involved, in giving them full management support and as the operators implemented the major revisions to the initial mining plans, helped ensure the final success of the changes.

Section 21 Underground Mining: Comparison of Methods

MICHAEL KARMIS, ASSOCIATE EDITOR
STEPHEN A. ORR, SECTION COORDINATOR

Chapter 21.0
INTRODUCTION

STEPHEN A. ORR

Underground mining is a dynamic art and science with a diverse set of design, production, and economic criteria that must be considered before selecting an optimal method to extract the ore. While all methods can be technically classified as either self-supported, supported, or caving, the multitude of subsystems and existing variations bear witness to the fact that each ore body is unique and, as such, justifies an individual approach to optimize mineral extraction. In this sense, underground mining is an art. The ability to evaluate the unique characteristics of each ore body and utilize sound engineering principles to design the optimal system constitutes effective method selection.

The task by no means ends at this juncture, however. Subsequent implementation requires an ability for modification. Very rarely are all the facts available to make a concrete decision prior to development of the resource. As a result, the risk of a wrong decision can never be eliminated. This requires a significant degree of flexibility with each method. Each unit of exploration, development, or exploitation work contributed to a deposit enhances knowledge of the ore body. The best mining methods are those that correctly account for the known parameters but provide an allowance for change at minimal cost and adapt to unanticipated conditions.

Section 21 provides a comparative discussion of underground mining methods and the basic tools for mining-method selection, evaluation, and implementation. The description of selection criteria along with the features of each commonly used method provide a basis for evaluation and design of the best means to mine a resource underground. Steps have also been addressed to define frequently encountered problems with various mining methods.

Due to the distinctive nature of coal mining, a unique group of problems not applicable to underground hard-rock mining can be anticipated. For this reason, Section 21 has been divided into separate hard-rock and coal segments, with the first three chapters (21.1, 21.2, and 21.3) devoted to method selection criteria, features, and a summary for hard-rock mining, and the final chapter (21.4) covering the similar topics for coal mining.

Chapter 21.1
HARD-ROCK MINING: METHOD SELECTION CRITERIA

STEPHEN A. ORR

The selection of a suitable underground mining method for an ore deposit involves consideration of a diverse set of criteria. A multitude of dynamic parameters exist, and their importance cannot be overstated. Mining is somewhat unique as it requires heavy initial capital expenditure in preproduction development prior to generating a positive cash flow. In this respect, there is a significant degree of risk, because the ability to change methods once mining has initiated is difficult and could augment capital expenditures to the point where the project is no longer viable.

All mining methods can be classified as either self-supported, supported, or caving, and the determination of which method is most applicable rests upon evaluation of parameters that can be grouped into seven basic categories (Table 21.1.1):

1. Geotechnical considerations.
2. Mineral occurrence.
3. Ore body configuration.
4. Safety/regulatory factors.
5. Environmental factors.
6. Economic considerations.
7. Labor/political considerations.

Each of these criteria can become the principal determining factor in method selection, but the obvious predominance of one consideration should not preclude careful evaluation of all parameters. Method selection is the fundamental decision made in a mine project, and a proper choice is critical as it impacts virtually all other major decisions. As has often been said, “mines are not discovered; they are made.” The degree of consideration given to complete evaluation of an ore deposit can make the difference between a geologic inventory and a mine.

Table 21.1.1. Underground Hard-Rock Mining Method Selection Criteria

Evaluation Parameter	Considerations
Geotechnical	- Lithology
	- Groundwater
	- Geophysics
	- Ore genesis
Mineral occurrence	- Continuity of ore zones within mineralized strata
	- Occurrence of mineral within ore zone (geologic grade)
	- Economic mineral occurrence within ore zone (mining grade)
Ore body configuration	- Dip
	- Plunge
	- Size
	- Shape
Safety/regulatory	- Labor intensity of method
	- Degree of mechanization
	- Ventilation requirements
	- Refrigeration requirements
	- Ground support requirements
	- Dust controls
	- Noise controls
	- Gas controls
Environmental	- Subsidence potential
	- Groundwater contamination
	- Noise controls
	- Air quality controls
Economic	- Minable ore tons
	- Ore body grade
	- Mineral value
	- Capital costs
	- Operating costs
Labor/political	- Costs, influences

21.1.1 GEOTECHNICAL EVALUATION

Geotechnical considerations in method selection include an evaluation of lithology, groundwater, geophysics, and ore genesis of the deposit. This analysis should occur concurrent with the exploration drilling phase and must include an evaluation of the ore zone hanging wall and footwall host formations and general surface topography. As a result, a percentage of the drilling must provide core. For a detailed discussion of geomechanics, see Section 10.

21.1.1.1 Lithology

Drill core structural mapping provides critical information on faulting, jointing, foliation, shears, and oxidation that could affect the integrity of both ore and host formation zones. As a three-dimensional model of the ore body is built, so must all structural features be included. These become the parameters by which future method selection and subsequent design is influenced. For example, a highly sheared hanging wall would certainly preclude open stoping as a viable option and, depending upon geophysical testing and ore body configuration, could favor sublevel caving as the optimal method. The degree of foliation and oxidation within an ore zone can have a significant impact on the amount of ground support required or whether the ore zone is cavable. Additionally, detailed evaluation of the surface topography from aerial photographs and magnetic surveys will reveal geologic structures, such as major faults or magnetic anomalies. These allow a broad overview of the area and can subsequently be tied to detailed lithologic core mapping.

21.1.1.2 Groundwater

Initial exploratory drilling will usually define the existence of groundwater. It is important to determine water levels within the formation, permeability of the formation, initial flows, and sustained flows. Initial quantification during drilling can be made of the water-bearing strata interval and a selected number of holes then designated for piezometer installation. This will monitor water pressure within the borehole and become an indicator of whether the system is recharging itself. Flows can be measured from drillholes with packers and flowmeters, and evaluation of flows over a period of time will provide data on the system’s recharge rate. Finally, formation permeability can most simply be analyzed by pumping through drillholes into the formation. Flows are monitored along with pumping pressures and rate of pressure discharge once pumping is terminated. Selected formations through which the drillhole has penetrated can be selectively isolated by setting packers in the hole at specified points above and below the strata. These hydrologic studies are imperative to proper design and can certainly influence the choice of mining method. Intersection of consistent flows may dictate a more selective method such as open cut and fill stoping to allow water influx control.

21.1.1.3 Geophysics

Once the drill core has been lithologically evaluated, samples from the ore zone and host formations should be subjected to geophysical testing. Basic data for evaluation includes tensile strength, compressive strength, modulus of elasticity, Poisson's ratio, angle of internal friction, and specific gravity. Additionally, a determination of in situ stress can be made by utilizing the borehole overcoring technique.

The Brazilian disc test is commonly used to determine tensile strength for drill core with the axial-load compression test providing compressive strength. Triaxial testing places a confining load perpendicular to the axial load and allows delineation of the modulus of elasticity and the angle of internal friction. Poisson's ratio can then be calculated from tangential and axial strain.

In situ stress measurements provide a quantification of existing stress within the rock. As a result, holes must be drilled in the formation specifically for this purpose. The data generated becomes a foundation for determining premining stress and modeling subsequent behavior during the mining cycle.

A series of measurements in multiple orientations should be made on laboratory and in situ tests to (1) account for planes of weakness such as jointing or foliation and (2) measure in situ stresses in all dimensions (see Chapter 10.2 for a detailed discussion of rock mechanics testing).

All generated data should be computer modeled using element analysis under a variety of mining scenarios to project areas of high stress concentration and possible rock displacement magnitude during the mining sequence. This will allow optimization of a mining method to the unique geophysical characteristics of the deposit. For example, a method which creates large voids such as open stoping (stope and pillar) or vertical crater retreat (VCR) mining would probably be a poor candidate if high stress concentrations exist or would be generated in the hanging wall. Subsequent failure would severely dilute ore and possibly threaten surrounding mine activity. Alternatively, specific design parameters can be customized to minimize projected stress. Using the preceding example, both open stoping or VCR mining might be feasible methods if the maximum vertical stope height were reduced, stope length along the strike shortened, or cablebolts added to the hanging wall (Figs. 21.1.1 and 21.1.2). Once valid base data are obtained, application of computer modeling allows generation of a multitude of mining scenarios.

Unfortunately, any initial model must make a significant number of assumptions that greatly increase the risk of error. As a result, an active rock mechanics monitoring program during development and subsequent mining is absolutely critical to provide an early warning of impending ground control problems and consistently refine the geomechanics model. Each new bit of absolute data increases the projection accuracy of future mine planning. Strategic installation of extensometers and borehole load cells in the ore body and host formations will provide constant monitoring to quickly delineate stress concentrations, avert potential failure, and collect data for subsequent modeling.

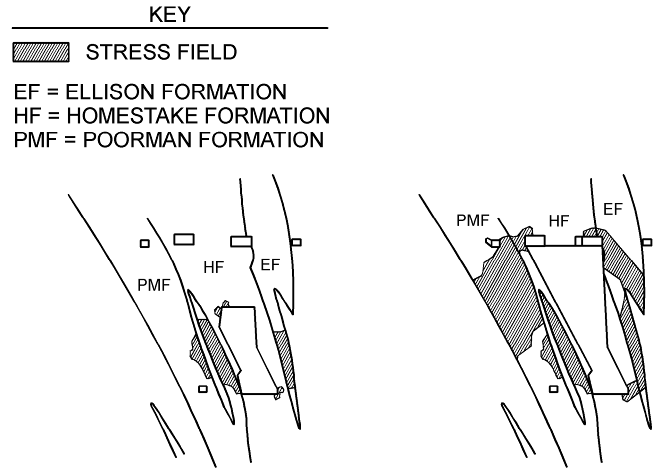

Fig. 21.1.1 Cross section effect of VCR stope height on stress distribution.

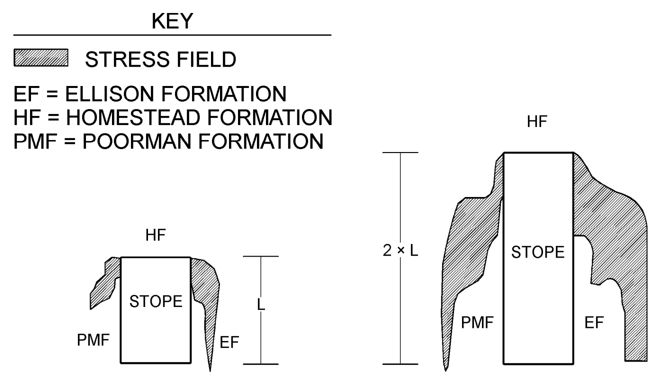

Fig. 21.1.2 Plan view. Effect of VCR stope length on stress distribution.

21.1.1.4 Ore Genesis

Ore genesis evaluation is predominantly applied to deposit exploration for generation of a new ore body or addition of reserves (Sections 4 and 5). In limited respects, however, genesis can become a preliminary mining method evaluation parameter. For example, an epigenetic vein deposit typically contains high-grade ore shoots. optimization of mining would require a selective method which minimizes dilution. Telethermal deposits, formed by hydrothermal fluid migration, usually occur in flat beds with uniform ore occurrence within a well-defined stratigraphic interval. These deposits, typified by the Missouri lead-zinc belt, are particularly amenable to room and pillar or stope and pillar mining. Sedimentary syngenetic deposits, unless they have undergone regional metamorphism, are usually structurally incompetent. This would require a method that minimizes active mine openings and utilizes permanent pillars within the ore zone. Additionally, genesis is an excellent preliminary means to project the mineral occurrence within a deposit.

21.1.2 MINERAL OCCURRENCE

The spatial distribution of a mineral within the deposit can significantly impact the choice of mining method. There is actually a two-fold consideration which constitutes continuity of ore zones within the mineralized strata and the occurrence of mineral within the ore zone. A large mesothermal copper porphyry deposit, in which the ore has permeated rocks as disseminated veinlets and spots, typically has higher-grade cores with a massive mineralized halo zone. Depending upon cutoff grade, this type of deposit is particularly amenable to non-selective bulk mining methods. The geophysical evaluation would determine if block caving, sublevel caving, VCR mining, room and pillar mining, or open stoping should be utilized.

Ore bodies that occur as concentrated chutes or loads, such as those within the Golden Mile of the Kalgoorlie District in Western Australia, require a very selective mining method. This provides significant grade control throughout the mining cycle to ensure that dilution is minimized. In this case, a method such as shrinkage or cut and fill stoping would be appropriate. While these methods are more labor intensive than their nonselective counterparts, they are amenable to mechanization. The hazard that must be avoided is improperly sized equipment for the ore body. Oversizing equipment for a small deposit does nothing more than burden mining with excessive dilution and diminish profits (see Chapter 21.3 for further discussion on common pitfalls in method selection).

The grade of a deposit is a reflection of mineral units entrained within the delineated tonnage. This will normally be termed as both a geologic grade and mining grade. Very rarely will the two correspond since mining grade is profit dependent and consequently always higher. This represents the concentration of mineral units within a given tonnage that can be mined at the desired profit. It will often influence the mining method because deposits with a high-grade core can often be mined at greatest profit by a selective method that ignores lower-grade reserves even though they are economic. Optionally, the method may be designed to allow initial mining of high-grade reserves for quick recovery of project capital then mine lower-grade ore for the duration of mining life (see 21.1.6, Economic Considerations).

21.1.3 ORE BODY CONFIGURATION

The physical parameter of an ore body will often preclude use of many mining methods. Orientation considerations such as dip, plunge, and strike along with the size and shape of the ore body are key evaluation factors. Many methods, such as shrinkage stoping, open stoping, VCR mining, and sublevel caving, depend upon gravity ore flow to extraction points. However, deposits with footwall dips less than the broken ore rill angle will not allow complete extraction with these methods. Generally, ore bodies with dips less than 55° are not amenable to gravity flow. Additionally, hanging-wall dip must be considered in any method with structurally incompetent host rock. The hanging wall will often begin caving during extraction of a gravity system, and as shown in Fig. 21.1.3, waste is soon pulled through the extraction cone, progressively diluting and finally displacing ore. Those deposits with flat footwall dips are best mined with cut and fill or panel longwall methods. Where applicable, room and pillar is certainly preferred for its high mechanization and productivity amenability.

Plunge is the vertical angle component along strike and it affects the number of mineral units per vertical and horizontal linear distance. In this respect, plunge has a significant impact on the amount of development required for each ton of ore. A flat-plunging ore body will ultimately require much more development than its steeper counterpart. Methods such as sublevel caving or undercut and fill stoping may be chosen in this

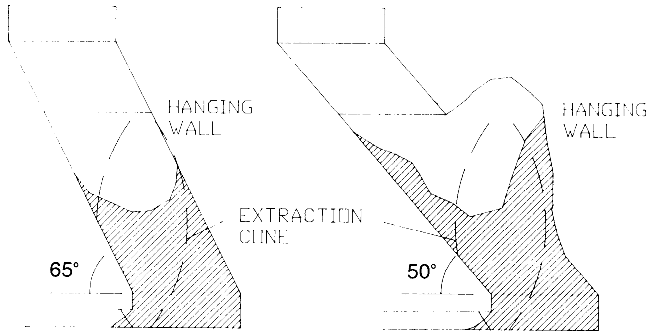

Fig. 21.1.3 Cross section showing dilution incurred in a VCR stope with flat hanging wall.

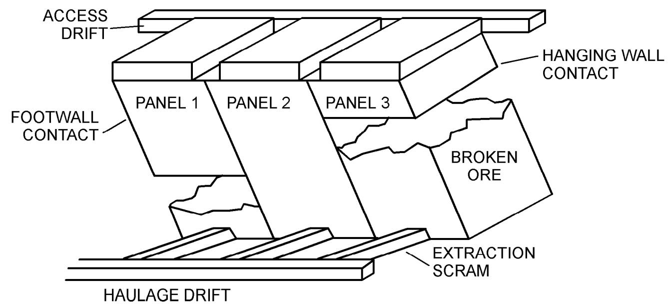

Fig. 21.1.4 VCR transverse panel mining along strike.

instance because mining can progress down-plunge and minimize preproduction development.

The strike or azimuth of an ore body in the long dimension can affect a mining method by its length. Open voids have a critical geophysical length-to-width parameter beyond which they are no longer stable. Open stoping, shrinkage stoping, or VCR mining that creates large openings are often designed in a series of smaller panels to avoid hanging wall failure in deposits with a long strike dimension (Fig. 21.1.4). These panels are then mined and backfilled in an alternating pattern along strike or complete extraction sacrificed and permanent ore-bearing pillars left as support.

21.1.4 SAFETY/REGULATORY FACTORS

The health and safety of personnel is of paramount importance in the selection of any mining method (Chapter 11.1). Irrespective of which commodity is extracted, a mine's most valuable asset is its people. Consequently, a number of safety considerations need to be included in any mining method evaluation. Primarily, those methods that are the least labor intensive offer an inherent safety advantage by minimizing the exposure of personnel to hazards. Replacement of shrinkage stoping with more recently developed VCR mining has been due, in part, to safety benefits derived by elimination of mining work on a broken ore pile in the active stope.

Maximizing mechanization not only increases efficiency and reduces labor requirements but also reduces the physical work effort and resultant occupational injuries. Many previously termed "labor-intensive" mining methods have been adapted to mechanization. Typical cut and fill stoping that utilized jacklegs and slushers has now incorporated rubber-tired jumbos and load-haul-dump (LHD) units. This has reduced instances of back injury, carpel tunnel syndrome, and a multitude of accidents.

Mechanized mining systems do contain unique inherent safety considerations. Increased use of diesel equipment requires special environmental controls such as adequate airflow to effectively sweep exhaust contaminants from the working face and evaluation of heat generation and effect on working-area temperature. Proper airflow is a function of diesel horsepower, and when the requirement cannot be achieved, consideration should be given to electric or pneumatically powered equipment. Additionally, a 100-hp (75-kW) diesel machine adds about 800,000 Btu (844,000 kJ)/operating hour while a comparably powered electric unit contributes only 250,000 Btu (264,000 kJ)/operating hour. Thus mines with a high geothermal gradient must weigh the cost of additional refrigeration against use of electric equipment.

In mines with radon gas emissions, adequate airflow is the best means to dilute gas concentrations to an acceptable level. Radon daughters attach themselves to diesel emission particles or dust. Water is the best and most common means for dust suppression. Exhaust scrubbers or most recently, ceramic filters, are effective controls for diesel emissions. In all cases, respirators are absolutely essential for personnel operating in these conditions.

Virtually all underground methods utilize noisy equipment. Manufacturers have only achieved limited success in reducing equipment decibel levels through engineering controls. To date, personal ear protection still provides the best means to prevent hearing loss from noise exposure.

The problems of elevated dust, gas and noise levels are compounded by the enclosed underground environment. If not properly mitigated, overexposure risks will be incurred with any underground method.

An improper selection of mining method can create serious ground-control-related safety hazards. For example, utilization of block caving in an ore body with poor natural cave characteristics will create bridging problems. Attempts to dislodge hangups expose personnel and equipment to unstable ground, and eventual failure can result in an air blast. Use of open stoping in a deposit with structurally weak host rock can promote massive hanging wall failure, which risks surrounding mine structures and personnel safety. Therefore, all possible safety risks which could be created as a result of a method's application must be anticipated in advance.

21.1.5 ENVIRONMENTAL FACTORS

Most underground mining, except the caving methods, have the distinct advantage of creating a minimal disturbance to the environment. Many underground operations exist below communities, and through proper choice of method and sound operating procedures, surface impact from mining is virtually nonexistent.

Where consideration must be given to minimizing impact on the surface environment, any mining method that could result in subsidence should be avoided (Chapter 10.6). Both block caving and sublevel caving are systems employed in ground where either the ore and/or the host rock will naturally cave once extraction is initiated. These methods usually result in significant surface subsidence. In cases where block or sublevel caving is applicable, geotechnical considerations may preclude use of any other unsupported method. Supported methods must then be evaluated, and depending upon ground competency, either cut and fill or timbered cut and fill stoping utilized. The resultant productivity of the operation will be reduced and operating cost increased. If economically viable however, these methods will allow mining of the resource with minimal environmental impact.

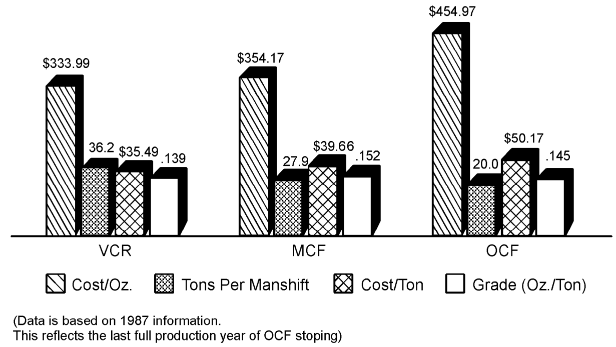

Fig. 21.1.5 Comparative unit cost, productivity, and grade of VCR, MCF, and OCF mining at the Homestake gold mine. Conversion factors: 1 ton = 0.9072 t, 1 oz/ton = 31.25 g/t.

Unlike surface mining, dust or gas emissions to surface air are limited to ventilation exhaust discharge locations (Chapter 11.7.2). Placement of discharge should be downwind from populated areas.

21.1.6 ECONOMIC CONSIDERATIONS

The economic feasibility of an ore deposit is dependent upon the following basic parameters:

1. Minable tons.
2. Ore body grade.
3. Mineral value.
4. Capital costs.
5. Operating costs.

Method selection plays an integral role in these considerations since it impacts all factors except mineral value. As a result, proper extraction method design dictates a project's profit margin, and in this sense, mineral value influences the mining method (Section 6).

An ore body's minable inventory is a reflection of the tons and grade that can be mined at a desired profit. The mining method will significantly influence this inventory by affecting selectivity. For example, open cut and fill (OCF) stoping offers a high degree of extraction control and will optimize the mineral content of every ton mined. Unfortunately, selective methods generate higher operating costs because they are more labor intensive and consequently less productive than bulk methods. This increased cost will often diminish the benefits of optimizing mined ore grade. Fig. 21.1.5 shows a comparison between VCR, mechanized cut and fill (MCF), and OCF mining at the Homestake gold mine. While OCF allowed a 4% increase in extracted grade over VCR, the 55% lower productivity translated to 36% higher operating costs and resulted in an uneconomic method. MCF was specifically introduced to replace OCF as a relatively selective method that employs higher mechanization to reduce operating costs and boost productivity. Table 21.1.2 shows a comparison of relative direct costs of various mining methods.

Normally, a method is chosen that generates a minable inventory to sustain consistent profitable cash flow for the longest period of time (Chapter 2.5). This allows for full project capital recovery and provides cash flow to use for exploration and development of additional reserves. A factor such as market price, however, can adversely affect this philosophy. Commodities such

Table 21.1.2. Hard-Rock Underground Mining Methods Relative Direct Cost Comparison

Method	Relative Cost
Block Caving	1.0
Room and Pillar Mining	1.2
Sublevel Stoping	1.3
Sublevel Caving	1.5
Vertical Crater Retreat Mining	4.3
Mechanized Cut & Fill (w/LHD)	4.5
Shrinkage Stoping	6.7
Conventional Cut & Fill (w/slusher & jackleg)	9.7

as strategic metals and precious metals that are subject to drastic price fluctuations, often dictate initial "high grading" of an ore body to reduce capital recovery time. This is a means to mitigate the risk of market volatility, and if the remaining mineral inventory can still be mined profitably, it may be the most profitable economic scenario. This is true particularly if loans are involved and discounted cash-flow considerations include service of a debt. This practice usually has the inherent disadvantages of sacrificing lower-grade reserves that could otherwise have been blended into a consistent economic grade resulting in the ultimate extraction of more mineral units. Essentially, the goal is to generate the optimal mix between quickest return on investment and highest return on investment.

Choice of a mining method has a significant impact on capital requirements and revenue-generation lead time (Chapter 23.3). Some mining methods, such as block caving, are particularly development intensive and, as a result, require more preproduction capital expenditure and a longer lead time prior to revenue generation. Once in the production phase, however, operating costs are lower since most ore body development is completed. Oftentimes, ore body grade does not allow much flexibility since low-grade deposits require high extraction rates to maintain low unit costs for profitability. This dictates a bulk method such as block caving, sublevel caving, open stoping, or VCR mining. So while shrinkage or OCF stoping requires significantly less lead time prior to production, either method generates lower productivity and higher unit costs since concurrent development is constantly required to maintain ore flow. Accordingly, the choice of OCF or shrinkage stoping to reduce preproduction leadtime could significantly diminish the operation's profitability.

Cutoff grade is a dynamic number affected by commodity value and cost to produce the product. In this respect, each mining method will generate a unique cutoff grade. Calculation of this cutoff when choosing a mining method should be based on all operating costs incurred to produce the commodity. This corresponds to the active cutoff grade utilized in a producing mine. Including capital costs in the calculation generates an unrealistically high number that is not a true reflection of the grade required to produce a sustained desired cash flow for given market conditions. Consideration of capital and operating costs could preclude use of a less-selective caving method and eliminate economic tons from the mining inventory.

21.1.7 LABOR AND POLITICAL CONSIDERATIONS

The choice of any mining method is influenced by the availability and cost of labor (Chapter 8.5). While the preceding discussion has assumed a relatively high labor cost, the economic situation in many countries results in an abundant work force, which is often unskilled. Depressed labor costs make mechanization a less economically attractive alternative in this case. Additionally, governments in these situations may be less profit motivated and more interested in maintaining maximum employment. Economic considerations take a diminished role in favor of providing consistent production. A mechanized method requiring trained personnel may not be a practical alternative since introduction of machinery will probably not reduce the work force.

The political climate in many countries can result in relatively unstable governments. Significant risk associated with these conditions favors a mining method that minimizes capital outlay and provides the quickest return on investment. For instance, sublevel caving may be rejected in favor of cut and fill stoping because of the latter method's ability to generate revenue in significantly less time with less capital investment. In these cases, mitigation of risk on investment becomes a predominant factor in the choice of a mining method.

Chapter 21.2

HARD-ROCK MINING: METHOD ADVANTAGES AND DISADVANTAGES

THOMAS G. WHITE

21.2.1 INTRODUCTION

Once an underground mineral deposit has been located, conventional wisdom dictates that certain criteria must apply as to whether the deposit is an ore body or just an interesting prospect. Ever since Georgius Agricola used the word *philosophy* to apply to underground mining in 1556, society and miners have had tugs-of-war, further complicating the relevant issues.

The purpose of this chapter is to describe why a certain underground hard-rock mining method may have distinct advantages or disadvantages as compared to an alternative method. Specific case studies are summarized, which is helpful when attempting to relate textbook mining methods to real-world scenarios. The continued rapid improvements and innovations in equipment for drilling, blasting, loading, hauling, crushing, and hoisting have resulted in the acceptance or rejection of specific mining methods and techniques. These equipment advances are discussed as well, with emphasis on how mining methods changed to better utilize the benefits of the newer equipment.

Today there are pressures on underground miners from a vast array of fronts to confuse the technical issues and complicate the selection of mining techniques and project ore body definition. The mining company that does not pay serious attention to environmental concerns, citizenry complaints and interests, land status, and a host of other criteria when making a mining method selection in the last decade of the 20th century is in for a rude awakening.

In 1988, there were an estimated 3000+ underground mines in the world each producing less than 150,000 tpy (135,000 t/a), and some 600 underground mines exceeding that rate. Of the larger tonnage mines, only 25% are in North America with another 25% in Africa. Obviously, method selection for the two continents would employ some non-geologic criteria. Considering as well, Asia, Europe, and Australia with their respective non-technical constraints, final method selection will most assuredly be more than a simple geologic and rock mechanics exercise.

To better understand the features, or advantages and disadvantages, of various mining methods from an overall socio-economic and technical basis, a basic understanding of the predominately used underground mining methods is required. When considering the basic principles employed, there are relatively few mining methods used today: caving methods, naturally supported stopes, and artificially supported stopes.

Since each ore body is unique, and with different environmental and location considerations, the variations of each mining method are limitless. The mining method employed must above all be flexible to deal with the various surprises Mother Nature and the elements spring on the unsuspecting.

Table 21.2.1 summarizes the principal features of the major hard-rock mining methods.

21.2.2 CAVING METHODS

21.2.2.1 Sublevel Caving

Sublevel caving is considered by some to be a variation of top slicing. In top slicing, the ore is removed by driving a series of timbered drifts and crosscuts at the top of the ore body, and when the timbers are removed or blasted, the caved ore is mucked out. Top slicing requires ground so weak that when the supports are removed, the ore readily will collapse. Sublevel caving has been adapted to ores in stronger ground that require drilling and blasting. Since the method does rely upon caving of the walls, the technique is termed a caving technique. Some of the more common advantages and disadvantages of sublevel caving are summarized in the two operational case studies cited below.

KIRUNA. Starting in the early 1950s, LKAB's very large Kiruna iron-ore mine in the arctic north of Sweden has been mined by sublevel caving. In Kiruna's case, there are several advantages to the method:

1. Because the ore body is huge and tabular, large-scale, standardized mechanization is possible.
2. Sublevel caving is well suited to selective mining, which is important because of the varying phosphorus content throughout the mine.
3. The method permits many drifts to remain open, which aids in overall flexibility.

A disadvantage is that planning is complicated, with three major work steps occurring: development, fan drilling and loading, and hauling.

Prior to the advent of sublevel caving at Kiruna, shrinkage stoping methods had been used, but greater tonnages and increased selectivity resulted in sublevel caving techniques being adopted. Rock mechanics techniques leaned toward sublevel caving since the Kiruna deposit is wide and steep with relatively weak hanging walls.

At Kiruna, some other disadvantages of sublevel caving include the high investment cost, relatively extensive development work, and the potential for rock mechanics problems at depth.

Kiruna is one of the outstanding examples of sublevel caving techniques in the world and is an interesting compromise of high-speed haulage, large work force, heavy development requirements, and imaginative engineering practices.

CRAIGMONT. The Craigmont mine in south-central British Columbia, Canada, although now depleted, is another good example of sublevel caving. In 1961, after life as an open pit mine, underground mining methods of blasthole stoping and cut and fill stoping were tried but with limited success. It was decided to adopt the sublevel caving method once the open pit ceased operations for the following reasons:

1. Knowledge of ground conditions was obtained from previous mining.
2. Ground adjacent to the ore was reasonably incompetent.
3. It was more cost effective than block or panel caving because of the irregular nature of the ore body.
4. Sublevel caving did not tie up ore in pillars.
5. A high degree of mechanization could be employed.

In most sublevel caving operations, dilution is the main drawback. Kiruna's large tabular ore body minimizes that problem, while the irregular ore zones at Craigmont accentuate the problem. In an ore body with a reasonably flat dip, sublevel caving yields poor recovery as compared to high recovery from an ore body with a vertical dip.

Table 21.2.1. Summary of Features of Major Mining Methods

Methods	Advantages	Disadvantages
Sublevel caving	• High degree of mechanization is possible • Good selectivity can aid in grade control if ore at near vertical dip • High tonnage and productivity are possible	• High initial investment • Potential for dilution if ore body thin or near horizontal
Block caving	• Can be very cost effective • High production levels can be achieved • Grade control through drawpoint monitoring an asset	• Surface subsidence • Big development effort • High capital costs
Room and pillar mining	• High degree of mechanization possible with excellent productivities • Flexible and safe • Good grade control	• Ground movements can become onerous • Capital intensive • Ore left in pillars
Sublevel stoping, blasthole stoping, and VCR mining	• Easily mechanized • High productivities • Large equipment can be utilized	• High capital investment • Grade control can be a problem • Strong engineering and technical support required
Shrinkage stoping	• Small stopes can be mined • Minimal development costs • Simple drilling and mucking equipment	• Broken ore required as fill material • Grade control can be difficult • Not a high-tonnage or productive method
Cut and fill stoping	• Ground movement minimized • Dilution can be controlled more easily • Compatible with nonfilling methods • Undercut and fill techniques can be utilized	• Labor intensive unless efficient support system possible • Ventilization can be difficult • Can be costly so requires a higher grade ore body • Mill required for tailings fill
Timbered stoping	• Excellent ground control • Maximum ore extraction possible • Applicable for a wide variety of mining problems	• Costly and requires special skills • Not suitable for deeper mines • Low productivities • Nearby source of timber required

21.2.2.2 Block Caving

Block caving methods require large massive ore bodies with a proper fracture pattern. The surface capping should be fairly competent to avoid plugging the cave. Once the ore is undercut, the settlement causes crushing and fracturing of the ore. As the broken ore is drawn off, additional settlement and crushing occur. Blocks can be 300 to 600 ft (91 to 183 m) high and may extend the full width of the ore body, although less than 200 ft (61 m) in width is generally preferable. Panel caving is a variation of block caving and geologic structure, and rock competency can determine whether or not blocks or panels should be mined.

The advantages of block caving are

1. It is a reasonably inexpensive underground method since drilling, blasting, ground support, and labor costs are reduced.
2. Ventilation is generally simplified.
3. Production levels can approach those of large open pits.
4. Low-grade ore bodies can be more economically mined.
5. Grade control through drawpoints aids mine planning.

Block caving has several disadvantages:

1. It is accompanied by major surface subsidence.
2. Development time and money can be excessive.
3. Drift and drawpoint maintenance is expensive.
4. Ground conditions due to weight can damage or shut down production drifts.
5. Draw control is a constant and rigorous endeavor.

Two outstanding examples from practice can again be cited. AMAX's Climax, CO, mine was one of the pioneer block caving operations. The nearby Henderson operation was able to draw upon the Climax experience and make several improvements, notably the LHD (load-haul-dump) vs. scram slusher drifts.

HENDERSON. The Henderson mine is a large-scale, rubber-tired, continuous panel caving system. The porphyry molybdenum deposit has horizontal dimensions of 2200 by 3000 ft (670 by 914 m) and is 600 ft (183 m) thick. The production levels are 55 ft (17 m) above the undercut levels. Drawpoint crosscuts are on 40-ft (12-m) centers. Longhole drills are used to bell out the ore in front of the advancing cave line. Ventilation drifts are required for dust control and diesel exhaust.

The LHD drawpoints are large enough to pass most oversize, which is a decided advantage over the Climax mine with its smaller drawpoints. Certainly Henderson, because of the combinations of geology, good engineering, and company experience should be viewed as one of the best examples of modern caving technology.

EL TENIENTE. The large El Teniente copper mine in Chile is a classic example of block caving technology, with continuous modernization since 1905. Recent earthquakes and ore of lower metallurgical recovery have resulted in setbacks, but at nearly 90,000 tpd (80,000 t/d) and reserves in excess of one billion tons, the El Teniente deposit will be a block caving operation to study for years.

Some of the El Teniente ores are wet and clayey in nature, and older orepass height design had to be restricted to 66 ft (20 m) with drifts set 98 ft (30 m) apart and an orepass spacing of 49 ft (15 m). Only a high-grade ore (+ 1% cu) such as El Teniente could absorb associated costs. Another major advantage is that no ore hoisting is required. Newer blocks in the mine are harder and of lower grade and could not be economically mined with the older methods. Increased mechanization through the use of larger LHDs, more productive drilling and blasting equipment, and newer underground crushing and haulage systems were required.

The disadvantages of the older El Teniente systems were obvious to the operators, and modernization of the equipment and caving techniques resulted in a highly competitive operation being developed. No underground mining methods can compare to the combination of high productivity and accompanying large initial capital investment of block caving operations.

21.2.3 OPEN STOPING METHODS

21.2.3.1 Room and Pillar Mining

Room and pillar mining is the most classic of unsupported or open stoping techniques and, in one form or another, is practiced in most mining methods, particularly in mine development. Room and pillar or stope and pillar mining is, at its classic best, utilized in mining Missouri lead, Wyoming trona, New Mexico potash and uranium, limestone and salt worldwide, Canadian lead-zinc and uranium, and a host of other commodities and locations. In these cases, the ore zones are reasonably flat lying and generally continuous so either a random or regular pillar-support pattern can be established.

By necessity, the method involves hauling the ore and mineral from the face to a central hauling, hoisting, or crushing station. Continuous mining techniques in place of drilling and blasting can be used with the less abrasive and softer ores. It is not uncommon to have underground productivity rival block caving operations. The deposit's size, shape, thickness, and rock structure are the primary criteria for evaluating the suitability of an ore body for room and pillar mining.

Large drills, loaders, trucks, and support equipment cause many room and pillar operations to rival an open pit in planning, maintenance, and operating cycle. Not recognizing the potential efficiencies of modern equipment can hamper room and pillar economics.

Room and pillar mining methods have several decided advantages:

1. The nature of the applicable ore bodies lends itself to a high degree of mechanization and labor efficiencies.
2. Extreme flexibility exists, and rapid changes can be made when required.
3. Grade control can be maximized by adjusting drift dimensions and leaving support pillars in low grade or waste.
4. Productivity can approach or exceed block caving systems if the ore horizons are wide and high.
5. Method can be made very safe and training due to repetition is facilitated.

Disadvantages of the method include:

1. Ground swelling and movement as large areas are opened creates difficulties.
2. Roof and back maintenance can become excessive if larger open areas are required.
3. To provide necessary roof support, high-grade pillars must at times be left.
4. Capital intensive due to mechanized equipment requirements.

BUICK. The New Lead Belt near Viburnum, MO, is made up of eight mines, including the Buick, utilizing room and pillar techniques in lead, zinc, and copper ore bodies. The host rock is dolomite and easily mined by the largest underground equipment available. Ground control is primarily roof bolting and proper pillar spacing, although overlying shale can be a problem if mining gets too close to the undulating shale layers. Rooms are generally 32 ft (10 m) wide and can exceed 100 ft (30 m) in height as successive levels are mined out.

As with all mines in the area, high-grade ore, up to 30% lead, must at times be left in the pillars. High-grade pillars are weaker, and overmining of high grade must be avoided to avoid major groundfalls. In the higher-grade areas, filling techniques may be possible for pillar removal, such as Cominco is doing at their Magmont mine.

The central shops, ventilation system, and high-speed haulage facilitate mining of the 6-mi (9.7-km)-long Buick ore body, which is part of a trend approaching 40 mi (64.4 km) in length. The wet nature of the area requires massive pumping systems, and mine development is hampered when wet ground is encountered. Ore grade at Buick in the earlier years of operation exceeded 13% lead and 4% zinc, with current grades about one-half of these earlier levels.

FMC. Trona (soda ash) mining in Wyoming continues to be a growing and quickly changing industry, with FMC being the pioneer, commencing operations shortly after World War II. Since then, a continuous series of expansions, including solution mining, has taken FMC to nearly 4 million tpy (3.6 Mt/a). Continuous boring (mining) machines are used for driving the development entries to the room and pillar areas. Various face-breaking techniques are used, including kerf cutters and drills with loaders and shuttle cars used for ore removal.

Because of the extent of the trona horizons, FMC designs some of their mine layouts for up to 50 years of safe access. Due to the unique nature of trona mining, FMC has had to design much of its specialized equipment. High wear rates on the continuous miners require more frequent rebuilds than a coal application requires. Setting the stopes up for high production panels during retreat mining is of utmost importance. Generally, the commercial beds are 8 to 10 ft (2.4 to 3.7 m) thick and of large areal extent. Low-height mining equipment, therefore, is required with continuous redesign occurring. Trona mines in Wyoming are considered gassy, so permissible equipment is generally used with elaborate mine ventilation systems required.

In FMC's earlier days, some caving systems were tried and then halted when rock mechanics studies and effects showed weight was not relieved but only transferred. FMC's mining plans, although centering on room and pillar, do embody solution mining. Trona mining in Wyoming requires significant labor training and safety education, which is an advantage when the work force is eventually trained, but is a tremendous disadvantage when turnover is high.

21.1.3.2 Sublevel Stoping and Vertical Crater Retreat Mining

The other predominant type of open stope mining is sublevel stoping, which can be employed when the ore zones or veins are reasonably wide, steeply dipping, and the wall rock is strong and competent. Crosscuts are driven in the ore body, with sublevel drifts used for drilling the ore, which then is blasted in successive vertical lifts. Recent developments in drilling and blasting technology have resulted in sublevel stoping becoming more versatile and widely accepted. Other terms for, or variations of, sublevel stoping are longhole and blasthole stoping and vertical crater retreat (VCR) mining, usually considered as a separate method.

Recently, VCR mining methods have become more successful and widely used, partially due to improved drilling, blasting, and rock mechanics techniques. Different terms are used to define some of the new blasting techniques, such as mass blasting and spherical charge.

Drawpoint design and slot placement are critical for sublevel stoping systems to ensure that expansion space is available for the blasted ore. Crew safety, oversize considerations, and equipment size also dictates that the sublevels be properly designed.

EL SOLDADO. Sitting on the western slopes of the Chilean Andes Coastal Range is Exxon's recently modernized and expanded El Soldado mining operation. The region has been a continuous copper producer for 150 years, with successful variations of sublevel open stoping being practiced from the district's earlier production era. It was recognized by the operators in the late 1970s that the excellent ground conditions and minimal support requirements, combined with ore body access through mountainside adits, could quickly lead to mine expansion and modernization.

By 1983, open stoping, using sublevel blasthole techniques and including large-diameter blastholes and fully mechanized equipment, provided virtually all of the mine production. The basic technique involves undercut fan drilling of a stope 328 ft (100 m) long by 115 ft (35 m) wide with 295 ft (90 m) between sublevels. Sublevels are developed for LHD drawpoints at the base of the stope. The 3-ft (75-mm) fan drillholes to form the slot and undercut the block are up to 82 ft (25 m) in length. The 6.5-in. (165-mm) diameter vertical blastholes on a 11.5- by 15-ft (3.5- by 4.5-m) pattern are 230 ft (70 m) in length and charged with ANFO and prills in a deck blasting arrangement.

The blasting success at El Soldado is partially attributable to the advancements that ring-drill, up-hole, and down-hole drilling equipment have made. Combined with LHDs up to 13 yd^3 (9.9 m^3) capacity and 60-ton (54.4-t) underground haul trucks, the 12,700 tpd (11,500 t/d)mining rate is very effectively and efficiently achieved.

The advantages of the sublevel stoping method as practiced at El Soldado are many:

1. Easily mechanized.
2. Large equipment utilized.
3. Productivity high.
4. Repetitive techniques aid training and safety.

Disadvantages of the system as compared to other methods are few. Capital equipment outlays and development costs were high but justifiable due to the grade and tonnage of reserves. If development schedules are rushed and blocks mined prematurely, the sublevel open stope technique can suffer. Planning and scheduling correctly are of paramount importance.

LEAD. Homestake's 100 + -year-old gold operation in South Dakota has undergone continual mining method upgrades. By the late 1970s, it was recognized that, due to increasing costs and a shortage of skilled miners, cut and fill, shrinkage, and square set methods were becoming outmoded. Highly mechanized bulk systems were studied and VCR techniques were adopted.

The VCR techniques as used at Lead have gone through many different stages of testing, evaluation, and equipment modification. As a deep and older operation, many compromises were required, which finally resulted in a cost-effective and productive mining system.

Like all sublevel stoping techniques, uniform and steeply dipping ore bodies are an asset if not a requirement. With VCR mining, as practiced at Lead, zones of erratic mineralization that lead to dilution are economic due to the high productivity. Topsill widths are a minimum of 24 ft (7.3 m) with the 6.5-in. (165-mm) diameter downholes drilled with a Mission DTH hammer on an 8 by 8 ft (2.4 by 2.4 m) pattern. Maximum stope height is 150 ft (45.7 m).

Blasting techniques when slabbing down the back into the open stope are critical. The broken ore must be mucked to provide void space for the next blast but not overmucked since support is provided by the broken ore. LHDs of 2-yd^3 (1.5-m^3) capacity are used to muck in the lower-level scram drifts.

As practiced at Lead, VCR mining requires strong technical support to insure that optimum hole spacing and alignment and proper blasting procedures are followed. It should also be noted that backfilling of many of the mined-out VCR stopes is essential. One could argue that VCR then is a supported system, but while mining activities are occurring, no additional support is required, so the VCR method is referred to as "unsupported."

Advantages of VCR mining as practiced at Lead are:

1. The method is easily mechanized and cost effective.
2. Development is simple.
3. Large-diameter downhole drilling is possible.
4. Good fragmentation.
5. Broken ore gives wall support.
6. Good safety can result.

Disadvantages of VCR techniques are

1. Quality engineering and technical expertise are a must.
2. Capital investment for equipment is high.
3. Drilling and blasting techniques must be precise.
4. Powder factor can be high.
5. Grade control can be a problem.

21.2.4 STOPING METHODS USING ADDITIONAL SUPPORT

When the predominant mining method requires artificial support techniques, there are numerous support choices available. Depth, rock type, ore continuity, geologic setting, economics, environmental concerns, and a host of other criteria must be understood when selecting the supporting methods. In the past, many near-surface operations have used timber alone for support. Stulls (posts) and caps are the simplest timber supports, with complicated square set timbering systems being used when depths increase.

Gravity alone contributes approximately 1 psi/vertical foot (22.6 kPa/m), which could translate to 72 tons/ft^2 at 1000 ft (690 t/m^2 at 300 m) if no load were transferred to the adjoining abutments. Even hydraulic supporting equipment cannot carry a heavy surface load at depth for a prolonged period, which leads to backfilling techniques that can support 100% of the overburden weight once subsidence occurs and compacts the fill material.

Since World War II, great advancements have been made in equipment and techniques to lessen the significance of timber supports and increase the use of cut and fill mining. Some of the reasons are

1. Rock and cable bolting techniques have become more widespread.
2. Unavailability of cost-effective timber and high labor costs associated with timber-set installation.
3. Improved filling technology and equipment when using mill tailings or appropriate fill material.
4. Advancements in underground drilling and hauling equipment.

The more common types of artificially supported mining methods include:

1. Shrinkage stoping.
2. Cut and fill stoping (overhead).
3. Undercut and fill mining.
4. Timber and prop support systems.
5. Top slicing and longwall and shortwall mining.

Obviously, various methods can be combined within a given mine as economics, geology, continuity, depth, and other factors change. Many cut and fill operations have embraced some form of sublevel stoping techniques such as VCR or blasthole stoping.

21.2.4.1 Shrinkage Stoping

Shrinkage stopes are a combination of open stoping and supported stoping (see Chapter 18.3). Either the ore zone must be very thick or exist as a steeply dipping vein where both the wall and ore can stand with minimal support. The ore swells in place as it is broken and in turn provides ground support and a working area for the miners. Once the ore is drawn off, the remaining open stope can remain empty or backfilled with sand-fill or waste to prevent caving. With increasing depth or adverse ground conditions, lateral stresses can cause the walls in a shrinkage stope to squeeze and compress the ore so it cannot easily be pulled from the stope. The basic criteria for shrinkage stoping to be effective are

1. When broken, the ore must not pack due to clay, fines, water, or chemical reaction.
2. Ore zones should not be too deep such that gravity-caused ground problems result.
3. The wall rock and ore must be strong enough to stand with minimal support.
4. Limit the size of stopes, maintain a rapid mining cycle, and promptly draw stope empty when mining is completed.

The advantages and disadvantages of shrinkage stoping become obvious when viewing the above criteria. Because sublevel open stoping or cut and fill stoping are viable alternatives, shrinkage stoping may be viewed as an adjunct technique in some cases. The disadvantages of shrinkage stoping also include:

1. Ore, at least two-thirds of the total, is tied up as fill material until the stope can be drawn empty.
2. Safety problems exist with loose rib and back material.
3. It is less easily mechanized.
4. Grade control can be troublesome if irregularities exist in wall rock.

21.2.4.2 Cut and Fill Stoping

For many years, the open cut and fill stoping method has been commonly used throughout the world. Many of the longer-lived deposits have become progressively deeper, making cut and fill techniques even more widely practiced. The method is best suited for vein or bedded deposits that dip fairly steeply and have surrounding rock, mainly the hanging wall, that will not stand for a long period without support.

Normally, a slice of ore 8 to 10 ft (2.4 to 3 m) thick is drilled, blasted, and partially mucked, and the back scaled and bolted as required. The remaining broken ore is removed through ore-passes, the orepasses extended to the next level, the stope back-filled, and another cycle begins. The individual mining steps are reasonably well defined, but what can become the biggest logistics problem of all in a cut and fill mine is the production, transportation, and placement of the fill material.

MOUNT ISA MINES. The Mount Isa operations in northwestern Queensland have utilized many different mining methods over the past 20 years, including sublevel open stoping with both slusher and LHDs for mucking, sublevel caving, mass firing of large pillar blocks, and cut and fill techniques. The older cut and fill methods employed at Mount Isa relied on vertical access, whereas more recent cut and fill techniques utilize footwall openings permitting easy access to the ore bodies by mobile equipment. Although both up-holes and horizontal drillholes are used, the flat-backing provides better ground conditions. The individual stopes are grouped into 13,000- to 20,000-ton (11,800- to 18,100-t) blocks, which provides an optimum mining cycle and minimizes orepass placement. Fill is added to the open stope to provide enough height for equipment movement and still provide easy access to the back for roof bolting, scaling, and other ground control methods.

Fill towers and drain pipes must be constructed prior to fill placement so that excess water can be removed as soon as possible. The normal fill is deslimed mill tailings with cemented fill used when additional strength or a better working area is required. As with most cut and fill operations, the availability of fill material is a constant juggling act. Hydraulic fill from milling is generally the cheapest material and fairly easy to distribute but is not available in sufficient quantity to meet all needs. Furnace slag has been used to reduce cemented fill costs. Fill material from the surface siltstone deposit is used in large quantities for backfilling as well.

Mass blasting adjacent to the cemented backfill areas has been done with great success, which speaks highly of the success achieved in fill technology by Mount Isa personnel.

CANNON MINE. Near Wenatchee, WA, the Cannon gold and silver mine is located. The operation is worth describing for several reasons. Open pit methods would have been possible, but environmental concerns and surface disturbance precluded this option. Initial high-grade mining was 200 to 400 ft (61 to 122 m) below the surface. More recent mining has stopes 50 to 100 ft (16 to 33 m) wide by 300 ft (98 m) long with stopes separated by 25-ft (8-m) pillars.

An underground, automated fill-mixing station permits combining river pebbles, sand, and cement. The concrete is dumped directly into the open stopes from haulage trucks. Coarse mill tailings is also used as fill material. The pillars between the backfilled stopes are recovered and backfilled with 3% concrete or dry fill.

The combination of large drilling and hauling equipment combined with the fill techniques makes Cannon one of the more mechanized and modern cut and fill operations.

ADVANTAGES AND DISADVANTAGES. Because the variety of ore bodies suitable for cut and fill methods is numerous, the advantages of the method are equally varied.

For instance, if pillar recovery only is the reason for filling, increased ore extraction would be a major advantage. Generally, however, the classic advantages can be cited as

1. Sampling of the ore block as it is being mined is facilitated.
2. Large-scale ground movement is kept to a minimum.
3. Steeply plunging ore bodies can safely and cost effectively be mined.
4. Dilution can be more easily controlled.
5. There can be compatibility with non-filling mining methods as geology or rock type changes.

Disadvantages of cut and fill mining also can be varied but generally are

1. Dependent upon degree of mechanization, it can become quite labor intensive and require more skills than alternate techniques.
2. Safety problems can be more rigorous, especially if open ground is not adequately scaled and bolted.
3. Ventilation is more difficult.
4. The method is more expensive per ton, therefore not readily applicable to lower-grade ore bodies.

21.2.4.3 Undercut and Fill Stoping

Some operators have chosen an undercut and fill stoping method. The method is generally chosen when compared to overhand cut and fill techniques when bad ground conditions exist, particularly in the back. The advent of more sophisticated roof bolting and ground control techniques has somewhat lessened the need for undercut and fill systems. In an undercut and fill operation, the ore is mined from the top down while carrying the fill line in the back. The overhand cut and fill method, or conventional cut and fill as some operators refer to it, carries the fill in the floor with the ore in the back being removed.

Successful underhand systems rely upon the theory of a voussoir arch forming within the cemented sandfill. The weight not supported by the arch is carried by timber posts and mats.

Undercut and fill stoping methods are used by Inco and Falconbridge in Canada, with great success. Fill technology by both operators has been developed to a high degree. Inco developed the method in the 1950s to facilitate transverse pillar mining. Many mining companies have used the method with the following advantages:

1. When fill in the back is properly consolidated, it is far safer than an ore back.
2. Pillar and rib mining is easier.
3. Grade control is precise.
4. Allows mining to proceed safely when ground conditions would preclude other methods.

Disadvantages of the undercut and fill method would include:

1. Quality of the fill material has to be very good, which adds to the expense.
2. Supporting the fill with timbers and mats adds to the cost.
3. Poor fill in the back can lead to major safety problems.
4. Blasting and drilling techniques must be very precise to maintain the integrity of the overhead sill.

21.2.4.4 Timber and Prop Support Systems

It is all too easy for the modern miner to categorize timber and prop-supported mining systems as archaic. Yes, they are in one fashion or another, a throwback. The earliest underground miners used some sort of wood support, and during the latter part of the 19th century, timbered mines were becoming sophisticated and commonplace. Prior to 1860, open stoping using stulls was the common underground mining method, and with sometimes disastrous consequences, throughout the world.

The Ophir mine in Virginia City, NV, was very high grade, and in 1860, the width of the ore body became too great for the current roof and rib support systems. Philip Deidesheimer, a young mining engineer, was assigned the task of designing an improved timbering system. What he devised at the Ophir was probably the most unique and elaborate timbering system ever used.

In the western United States at that time, many high-grade ore bodies were developed with similar exotic timbering systems. It became quickly apparent that some method of rapid backfilling in conjunction with timbered systems was required to further reduce ground movement. In the last 100 years, backfilling has reduced the complexity of timbering systems so that posts, caps, and girts (ties) comprised the only supports.

Timbering systems, in one fashion or another, are still commonly used. Most undercut and fill stoping methods rely upon timber supports to hold the overhead fill, particularly during placement. When driving development headings or haulageways, timber systems are still used to support bad ground where bolts and mats would otherwise not work. In very high-grade ore bodies, some form of timbering can yield greater ore recovery than more common filling systems. Some mine operators are far removed from an adequate supply of sandfill, which may lead to timbering systems.

The major advantages of timber supported systems are

1. Excellent ground control method.
2. Maximum ore extraction possible.
3. Trained crews can easily install the system.
4. Applicable for a wide variety of mining problems.
5. Does not require hydraulic fill, so mine can be separate from mill.

The disadvantages are

1. Requires adequate timber supply.
2. Training and education of crews different than with more common methods.
3. Costly as compared to bolting or other support systems.
4. Not as applicable to large tonnage operations.
5. Timbers alone cannot support heavy ground in deeper mines.

21.2.5 OTHER MINING METHODS

There are several mining methods that will not be discussed in detail but are worth mentioning because of their past or possible future application in noncoal underground mines.

21.2.5.1 Top Slicing

In the early part of the 20th century, top slicing techniques were somewhat common, particularly underground in the Lake Superior iron ore district of the Mesabi Range. Basically, top slicing consists of driving a series of heavily timbered drifts and crosscuts and blasting out the supporting timbers. The unsupported ore will then cave or subside onto the floor of the opening and permit slicing downward in successive lifts, using the broken timber mat to prevent further subsidence until the lower-level supports are again blasted.

In modern day mining, top slicing is considered expensive and very seldom used. For it to be a successful method, timber must be cheap and plentiful. Generally, high ore extraction with little dilution is possible. Subsidence will occur, and ventilation can prove difficult to control. A significant fire hazard exists, especially since the broken timbers are not accessible for normal inspection, and old timbers continue to break up and form kindling.

21.2.5.2 Longwall Mining

Although considered a coal mining technique, longwall mining has seen application in Wyoming trona, South African gold and potash, iron ore in Europe, and others. Many underground sedimentary deposits, including salt, uranium, and sulfide minerals, have potential future applications. Longwalling is considered a supported stoping method because of the massive props used to support the roof over the face, although controlled caving of the roof is also involved (Chapter 20.1).

The basic requirements for longwall mining to be considered as a method include deposit size and thickness, back and overburden strata, dip, face characteristics, abrasiveness and hardness, and gas conditions. The method has commonly been used in Europe, in fact, since the late 17th century.

Longwall mining today is characterized by some sophisticated equipment including cutters and shearers, hydraulic roof supports, and automated loading and conveying systems.

21.2.5.3 Shortwall Mining

The equipment and concepts used in shortwall mining closely match those in longwall, with but one important difference: the shortwall face is generally less than 200 ft (61 m), whereas in longwall mining the face can easily exceed 1000 ft (305 m).

21.2.6 MINING METHODS—ROCK MECHANICS AND PLANNING

21.2.6.1 Rock Mechanics

All too often, the initial information available on a new mining venture is inadequate to define all of the necessary ingredients required for making a successful operation right from the onset. Most competent engineers are aware that even the best information does not guarantee design tonnage and budgeted costs. Successful mines are more often than not a series of compromises, built around a broad yet definitive plan that must use flexibility as one of the prime design criteria.

Rock mechanics has been practiced for centuries in one form or another and today is an integral and significant part of all mining engineering curriculums. The science of rock mechanics has developed in a slow but steady fashion as mine successes and failures were analyzed, determining reasons for departures from theory. Sensor and monitoring devices such as load calls, earth pressure cells, extensometers, and sloughmeters are all part of the mining engineer's rock mechanics arsenal. Combine that with mathematical models, computer simulations, and case studies, and concepts quickly become applicable for prediction of mining method selection and parameters.

Rock mechanics can and has assisted caving operations in selecting equipment and drawpoint configurations. Being able to accurately predict the broken ore size in a caving operation is essential for designing haulage systems. Ideally, the best caving system has (1) the ore horizons in highly fractured ground with discontinuities and flows that form planes of weakness, and (2) the sublevels, haulageways, and drawpoints in competent and easily supported rock under the ore zone. Thorough rock mechanics studies and geologic interpretation are essential to establish a successful block caving operation. The ore-zone rock characteristics and nonore zone beneath the ore body rock and geologic criteria are important as well.

If studies indicate that block caving is not practical, then sublevel caving, sublevel open stope, or even mechanized cut and fill could be considered. In each case, rock mechanics studies along with geologic studies and ore body configuration are crucial.

The advent of large and productive mechanized equipment has caused some mine operators to design their mine around the equipment rather than the equipment around the mine. Both approaches are compatible but not exclusive. Most room and pillar operations have sufficient flexibility to design haulageways and pillar patterns to satisfy a broad range of equipment and productivity criteria. Several room and pillar operators, lacking an understanding of rock mechanics, have pushed too hard for productivity and mineral recovery and suffered disastrous consequences.

A more thorough understanding of rock mechanics allows planning engineers to schedule more proficiently drilling, blasting, mucking, supporting, and backfilling cycles. Success in minimizing rock bursts has primarily been a result of proper mining method selection and scheduling. There are several older mining operations that have used rock mechanics studies as part of the criteria for altering or fine tuning mining methods. The Mount Isa operation in Australia, Lead in South Dakota, Kiruna in Sweden, and most of the larger South African gold producers have dramatically changed their mining methods through improved knowledge of rock mechanics.

Rock mechanics and related topics are detailed in Section 10.

21.2.6.2 Subsidence

Surface subsidence is an issue that is gaining significant attention around the world, particularly in North America. Many hard-rock mining engineers would like to think that subsidence is a coal issue, but that is not the case.

The conflicts between miners and nonminers over land use will fan the discussion in future years. This does not bode well for the mining companies that are near populated areas and are employing caving techniques or near surface operations robbing pillars. Mining method selection should out of necessity use subsidence possibilities as one of the criteria for mine evaluation and design.

Planned subsidence questions should also involve near-surface aquifer loss or contamination. Unplanned subsidence is worse in that overlying tailings impoundments or surface facilities can be damaged with corresponding human tragedy.

Again rock mechanics and mine planning are significant tools in making a mining method selection. Add to that environmental concerns over groundwater contamination, ventilation releases, and subsidence problems and the modern day miner has a host of parameters to consider when making a mining method selection.

Chapter 21.3
HARD-ROCK MINING: METHOD SELECTION SUMMARY

DENNIS KRANTZ AND TIM SCOTT

21.3.1 IMPORTANCE OF PROPER METHOD SELECTION

21.3.1.1 Flexibility of Method

One of the most important outcomes of proper method selection is a solution that allows the maximum degree of flexibility. The ability to adapt to unexpected underground conditions or external considerations can go a long way in determining the immediate and long-term success of a mining operation.

There is no one mining method that allows the mine operator to be able to accommodate all the known and unexpected conditions, but the mining method chosen should be the one that best accommodates the known and expected parameters at the lowest possible cost per ton mined, and still allows the flexibility to handle the unexpected. During the initial phases of method selection, there are conditions that are clear cut and have little possibility of being different than expected. There are areas, however, where the information necessary to make an accurate determination of conditions is not available. It is in these areas that flexibility in the chosen mining method is most important.

Proper method selection incorporates the flexibility to respond to changes in both internal and external conditions. Internal conditions are those that are dictated by the deposit itself, whereas external conditions are determined by outside considerations such as business or market requirements.

The first main consideration is ore deposition. In some cases, the choice of mining methods is relatively clear cut. A flat-lying or vertically dipping deposit automatically eliminates certain mining methods from consideration. It is those deposits that occupy the middle ground that make the selection process more difficult. A deposit that lies near the angle of repose dictates that the method chosen has the flexibility to handle stopes where the broken ore moves freely to a drawpoint as well as those where it does not.

The other consideration of ore deposition is whether the mineralization is uniform throughout the deposit or is erratic. The mining method chosen should allow the flexibility to mine the higher-grade portions of the ore body where and as they occur. A mining method that does not allow pillaring of the low-grade sections or requires that they are broken and treated as ore greatly increases the overall costs.

The next major consideration where flexibility is important is the ground conditions of the deposit and surrounding host rock. Proper method selection allows for mining areas with varying ground conditions without major changes in the mining method. An example of this is vertical crater retreat mining, where the broken ore can be left in the stope for support much like a shrinkage stope or drawn empty like a sublevel stope.

A third major internal consideration should be the working environment. In this area, the mining method chosen should be able to accommodate changes in ventilation requirements, water inflows, etc. If the mining method is chosen assuming that only minor ventilation is necessary, there can be major problems if it becomes necessary to control airflows throughout a mine that has too many dead headings or interconnected workings.

External conditions involve changes that require a different but no less important type of flexibility from the chosen mining method. These considerations are usually of a more long-term nature. A mining method that allows for adjusting the mined grade to accommodate changes in the market will possibly allow the mine to continue to operate through low periods in a market cycle. The mining method should also allow for increases in the tonnage produced to take advantage of upward swings in the market cycle. A mining method that dictates that each stope be operated in a set sequence will more than likely not allow for changes in the tonnage and ore grade produced and therefore will not be readily adapted to swings in the market place.

In the final analysis, the mining method chosen should be the one that best suits the deposit being mined and the conditions most likely to occur. Consideration should be given when choosing the method to how well it can handle changes in conditions that are considered to be possible.

21.3.1.2 Capital Costs and Cash Flow

The selection of a mining method should consider the capital cost associated with bringing a mine into production and its continued operation. At the same time, it is necessary to consider the cash-flow requirements of the method chosen.

Ideally, the method chosen should not require that all necessary capital costs be incurred before any production. The full cost of mining a deposit can be greatly reduced if the capital costs are incurred as the mine is being brought up to full production. This has the result of producing a positive cash flow sooner, which allows the operator to reduce the amount of capital required to bring a mine into production.

Equipment and initial development costs are normally the two major components involved in bringing a mine into production. The mining method chosen should not require that the bulk of the initial development work be completed before any production commences. If instead the development coincides with some degree of production, the final costs are decreased to some extent. The earlier production can then be used for a gradual startup and break-in of the milling facilities. This ideally would allow both the mining and milling to reach full production in the same time frame that will improve the cash flow of the operation.

21.3.1.3 Matching Politics and Economics of the Area

Major consideration should be given in the initial phases of the mining method selection to the political and economic conditions in the area. Both can have a major impact on the success of the method chosen. Whether the mine is located in the US or abroad plays a major role in this.

Political concerns are probably not a major concern in an industrialized area, but if the mine is located in an area lacking any major employers, there may be restraints placed on the operation. These may require hiring a major portion of the work force from the native (local) population, or simply the desire to have as many people employed as possible.

Economic concerns normally are related directly to the skill level and cost to employ the people who will make up the mine work force and must be considered when choosing the mining method. Choosing a highly mechanized mining method for a deposit in an area that lacks a skilled labor pool increases costs by requiring a long lead time to train a crew or the necessity to bring in outside people. The same increase in costs holds true for choosing a labor-intensive method in an area of high employment or a small labor pool that would require higher labor rates to draw the necessary people.

The same basic considerations apply for the equipment required by the mining method. An area where parts and service are readily available would favor a highly mechanized method. Conversely, an area where parts and service are not readily available requires the maintenance of a large parts inventory and the ability of the operations to perform a much larger variety of specialized maintenance.

The final method selection should take into consideration the skill and size of the available labor pool and their effects on equipment selection and ultimately the overall mining costs.

21.3.1.4 Environmental and Safety Considerations

Both environmental restraints and safety have major impacts on mining costs and ultimately on method selection. While some of them are easy to quantify, others are harder to identify but still can have a major impact.

There are environmental restraints, such as mine waste disposal, water discharge, etc., that are readily apparent and the effects considered in the method selections. There are others that are just as important to the overall success that are easily overlooked or not given full consideration. One of these is the final disposition of the property after the operation has finished. This phase can result in major costs required for final closure that could be reduced if they are considered as an integral part of the method selection. For these reasons, the effects of long-term subsidence, drainage, etc., should be considered.

It is hard to place a final dollar figure on safety and the working environment, but they do have an effect on the success of the method chosen and must be considered. A method that requires a major effort to maintain a safe and comfortable working environment increases the mining costs. If the conditions are too severe, they will affect work performance, absenteeism, labor turnover, insurance premiums, etc., all of which have a direct effect on the final costs.

In summary, there are many things that are directly or indirectly influenced by mining method selection. All should be considered, and their impact on costs considered when making a selection. Once a method has been selected and the operation is underway, it is difficult and expensive to make changes.

21.3.2 COMMON PITFALLS IN METHOD SELECTION

The most common pitfalls in the selection of a mining method are the same basic considerations that, when properly considered, result in a successful operation. These areas may be considered, but due to lack of experience, poor or disregarded information, or simply the belief that they can be solved when the problem arises, lead to problems that could have been avoided.

21.3.2.1 Method vs. Tonnage and Grade Requirements

Probably the most common pitfall is choosing a method that is not suited to the tonnage and grade requirements that are necessary to meet milling and marketing requirements. Most mining methods can be scaled up or down to some extent, but have a general tonnage and grade flexibility range that makes them best suited for a particular size and type of deposit.

Block caving might be suitable for a deposit and material that have a large and relatively stable market. In most cases, it would not meet the needs of an operation that must adjust to relatively large swings in market demand or pricing.

Recognizing the final market for the material and its relative stability helps to choose the mining method that best allows the operation to respond in a cost effective manner.

Another common area for problems is the adaptability of the chosen methods. These are generally associated with the ability of the mining method to adapt to unexpected conditions within the deposit, or to changes dictated by market conditions involving the mining sequence and production scheduling.

It is a common failure when choosing a mining method to assume that ground conditions, grade distributions, etc., are reasonably constant throughout the deposit. Rarely is this the case, and a method chosen without consideration of how it will handle these variations will not always be able to accommodate them.

At the same time, the method chosen should have the ability to accommodate the swings in production scheduling and resulting changes in mining sequence that would normally be expected for the material being mined. If the method chosen requires mining in a rigid sequence, the operation may be required to shut down during low points in the market cycle. If instead it can accommodate ceasing operations in low-grade/high-cost areas, it may be possible for the operation to run during low points in the cycle, then resume mining in those areas at a later point when it is economically feasible to do so.

21.3.2.2 Environmental/Health/Safety Concerns

It is easy for those choosing the mining method to fail to realize or adequately consider the effect the method has on the environmental and health and safety phases of the operation. This failure can later be readily apparent in the case of external environmental constraints, but may not be as obvious in the areas of health and safety. The effects on both areas should be considered through the entire life of the operation and its final closure. Neither is the determining factor in the final method selection, but they can greatly affect mining costs.

21.3.2.3 Complexity of the Method

A common pitfall in the choosing of a mining method is to choose one that is not suitable to the availability and skill level of the labor pool, or whose equipment requirements are not easily met and serviced in the area. This is most commonly done when choosing a mining method for a locale where the engineer is not familiar with the cultural and economic conditions.

A mining method that requires a relatively high degree of literacy and mechanical ability on the part of the hourly operator may be the best choice for on operation in the United States, but is probably not the best choice for a third-world country. Conversely, choosing a labor-intensive method for an area with high labor costs may not be cost effective.

In the final analysis, the mining method chosen should be the best balance between (1) labor and equipment costs and (2) availability and skill levels of the local labor pool.

There are numerous other areas that, if not considered during the selection process, will most likely result in problems later in the operation. It is advisable to consider every aspect of the methods operation and how well it will adapt to any reasonably foreseeable problem. Even recognizing that the method does not easily handle a problem is of value in making the final selection and in implementing the chosen method.

21.3.3 STEPS FOR PRACTICAL APPLICATION

21.3.3.1 Research of Similar Deposits

Anticipation of problems before they occur is a key consideration in formulating a mine plan. Time spent on research and consideration of all possibilities during the planning stage is more than repaid later in the project life. Avoidance of common pitfalls in the selection of a mining method or methods begins with an examination of other deposits with similar features that have been successfully mined by other operators. Research of written material, direct interviews with personnel at other mining operations, and onsite visits will identify common aspects of the projects and the successful resolution of problems associated with these aspects. This background study of how others have handled problems similar to those the development engineer may reasonably expect to encounter is one of the best foundations for mine planning.

21.3.3.2 Establishment of Desired Goals

The background information gathered form the study of other similar deposits is the basis for establishing an aggressive set of goals that are achievable within constraints imposed by the nature of the deposit. These constraints include the tonnage and grade of the minable reserve base, the confidence level of the reserves, and the potential for expansion or contraction of the reserve base through changes in market conditions and ongoing exploration.

Project goals are also impacted by the magnitude of necessary development and the time delays between the beginning of development, the beginning of production, and the beginning of a positive cash flow. Consideration of production and marketing sequence requirements in light of qualitative estimates of cash flow and changes in market conditions will also put limits on reasonable goals. It is important to maintain a proper balance between a positive approach that will promote continuation of the project and a realism of the goals that the deposit will support.

21.3.3.3 Method Selection: Advantages vs. Disadvantages of Each

The selection of an appropriate mining method benefits from a method-by-method tabulation of advantages and disadvantages. This tabulation will examine the various features of the deposit such as tonnage, grade, homogeneity, geometry, and accessibility and how these features have been handled by other successful mining operations. The planner should always consider the possibility of using more than one method for different portions of a deposit or of modifying a method as a result of unique deposit characteristics or the experience of other operators.

21.3.3.4 Mine Life Plan

A basic plan for the life of a mine looks at the schedule and timing for the entire project from development through production to final reclamation. It applies the chosen mining method or methods to each portion of the deposit in appropriate sequence and evaluates the subsidiary needs of all phases of the project. During this process, it is valuable to reconsider the choice of mining method, how that choice was made, and whether modifications of the method are needed.

21.3.3.5 Scheduling Development/Production

A viable mine plan ultimately includes a detailed scheduling of all phases of the project. These include manpower requirements, both numbers and necessary skill levels, and equipment requirements including type, size, quantity, and cost.

A very important though sometimes overlooked aspect of this phase of the planning process is that of materials handling. This includes the obvious components of transport of supplies to the active areas and ore to the process facilities as well as other components such as waste-to-ore ratios, the handling of waste without sacrificing production, and the potential benefit of interaction within a plan. For example, shift scheduling can help simplify the movement of waste and supplies and development excavation can frequently be used as a source of fill for cut and fill mining operations.

21.3.3.6 Continuing Modification of the Plan

The steps in the planning process, although outlined in a logical sequence, are greatly dependent upon each other. This interdependence requires a continuing examination and possible modification of previously established components of the plan based on other evolving features as it develops from the beginning general framework. A periodic revisitation of earlier decisions results in detailed documentation that will ultimately be useful to evaluate and control the project. This continuing modification of the plan is a process that may continue through development and into the established production phase of the mine.

21.3.4 RECOGNITION OF PROBLEMS: IMPORTANCE OF MODIFICATIONS AND FLEXIBILITY

The ultimate level of profitability of a mining project is enhanced by flexibility in the mine plan and choice of mining methods.

21.3.4.1 Establishing a Mine Plan: Expectations vs. Actual

The procedure used to establish the parameters under which the project is to operate does not end when the project is being implemented but rather should be ongoing throughout the project. Just as the various elements of a mine plan and the information gained from the research of similar deposits are used in an interrelated manner to refine the details of mine planning and method selection, so the experience gained as the project proceeds and the comparison of the actual to what was expected or predicted by the mine plan is the best information with which to refine the mine plan. The extent to which the initial plan has the flexibility to allow the introduction of these data into the process may determine the level of success of the project.

21.3.4.2 Internal (Short-Term) Modifications

Internal conditions dictated by the deposit are again a major consideration and the first to be examined. The evaluation of ore deposition from exploration data only may be inaccurate due to unexpected changes in orientation or geometry between drill intercepts or points where information has been gathered. A deposit that may have seemed to mandate a particular mining method may in fact be of a marginal nature as revealed by the more extensive excavation that occurs during development. In such a situation, the mine plan must have sufficient flexibility to allow the mining method to be changed and still meet the other goals of the project as defined by production scheduling, economic analysis, and manpower and equipment availability.

In a similar manner, unexpected variations in ore grade encountered by mine development may require a change in the mining method to maximize the profitability of the ore block or may require redefinition of the boundaries of the mining blocks to allow low-grade uneconomic material to be left as pillars.

Another important impact of grade variation is on the scheduling of mining activity. The sequence of production from the various stope blocks may require some change to meet steady-state grade requirements of the processing plant. These changes affect the entire balance of material handling within the mine and must be accommodated by changes in material flow.

The final elements of an internal or short-term nature to be considered are the ground and working environment conditions. A mine plan must have the flexibility to modify mining methods in response to unexpected ground conditions. In addition, it must have the flexibility to carry changes in mining method through the other aspects of the plan, including production scheduling, ventilation, and material handling.

21.3.4.3 External (Long-Term) Modifications

External or long-term conditions provide a more fundamental basis for the mine plan and are usually more difficult to modify without major impact on the other aspects of the plan. In addition, external conditions interface with elements beyond the control of the mine operator such as market conditions and the cost and availability of capital, equipment, and manpower to support the mining activity.

Impacts on the capital and cash costs of a project may have internal sources from change in scope, method, or scheduling of the project that have already been discussed. Modification of cash-flow and capital requirements of a project from external sources are to a great extent beyond the control of the mine operator. They are a particular problem for projects with a long lead time between commitment to the project and actual production and positive cash flow. The mine plan must have enough flexibility built in at the start to accommodate a reasonable range of expected change.

On occasion, advanced metallurgical test work or actual mill operation in its early stages may show an optimum blend of ore that is somewhat different from what was planned. In addition, problems with achieving the projected grade control with the chosen mining method may result in an unfavorable grade of ore being delivered to the mill. In either case, modification will be necessary to bring mine output in line with the requirements of the processing facility. These modifications usually involve mining methods and production scheduling, which in turn affects the other aspects of a mine plan.

A third area of concern for the impact of external conditions is that of fluctuations in market conditions or requirements. As a result of these fluctuations, the quality of the mill product may be unacceptable in the market place. The fluctuations may be due to changes in the supply from other sources, the demand for the product, or in the technology of secondary processing operations.

Price fluctuations may also require adjustment of the quantity of product and perhaps the life of the project in order to meet overall economic goals. All other phases of a mining operation must have the flexibility to accommodate these changes if the mine is to be profitable.

21.3.5 SUMMARY

Underground mining offers a wide variety of methods that can be adapted to suit virtually any size and type of deposit. These methods allow for the exploitation of deep deposits that would otherwise be uneconomic, and in some cases, they are competitive with surface mining methods (Section 16).

Unlike surface mining, underground mining offers a wide variety of methods, several of which might be adaptable to a given deposit. It is deciding which methods are applicable, and then choosing from those the one that offers the most cost-effective method of extraction, that is the key to a successful operation.

The success of the mining method is to a great extent dependent on the thoroughness of the final selection. The main criteria for selection will always be generally the deposition and ground conditions of the ore body itself, but it is the determination of the likelihood and effect on mining of a host of other interrelated conditions that make the critical difference in the selection process. The degree to which these conditions are foreseen, their effects taken into consideration, and adaptions made yields benefits that far outweigh the efforts involved.

Chapter 21.4
COAL MINING: METHOD SELECTION

THOMAS C. BIBB, II and KEITH M. HARGROVE

The focus of this chapter is on generally accepted current industry practices, together with an emphasis on the methodology used to generate accurate decisions on the economic viability of a given mining method used on a given set of reserves.

It is worth noting that most of the subjects mentioned in this chapter— as in the previous three —are covered in greater detail elsewhere in this *Handbook,* and the reader is encouraged to supplement the information contained in this chapter with those additional resources, especially in Section 17 and Chapters 18.1 and 20.1.

21.4.1 GEOTECHNICAL CONSIDERATIONS

A thorough review of the geotechnical features associated with a given set of reserves is critical in selecting the optimal mining method for those reserves. The characteristics of the seam itself, the roof, and the floor must be thoroughly examined to assure the viability of the mining methods selected.

21.4.1.1 Seam Characteristics

THICKNESS. The thickness of the seam mined has a major impact on the mining method selected and the equipment required for that method.

For continuous miner units, the current effective range is between 36 and 120 in. (1 and 3 m). Machines for this height range are readily available from all current manufacturers. Heights in excess of 120 in. (3 m) call for specialized equipment, while thicknesses of less than 36 in. (1 m) are currently mined only in the Appalachian coal fields and with auger-type continuous miners.

Conventional drill and blast equipment is useful from 36 in. (1 m) to heights in excess of 120 in. (3 m), although current economics have substantially reduced its application in US coalfields. Some areas in East Kentucky are still shooting on the solid, without mechanical undercutting, in seam heights down to 28 in. (0.7 m), although the economics are extremely marginal at those heights.

Longwall mining is similar to room and pillaring with continuous miners, in that there are four distinct seam thickness ranges, each of which calls for different sets of equipment choices.

There are six basic conditions that any longwall system has to meet:

1. The armored face conveyor that (AFC) must have sufficient width and height to provide adequate capacity (typically a minimum of 1200 tph or 1100 t/h).

2. If a shearer is used, there must be adequate height between the top of the AFC and the underside of the shearer to allow the efficient passage of coal cut on the inby side of the shearer (8 in. or 200 mm).

3. The shearer itself must be thick enough to provide motors of reasonable power (300 hp or 220 kW plus).

4. There must be some clearance between the top of the cutting machine and the underside of the support canopies (typically, a minimum of 8 in. or 200 mm.).

5. The machine length must be minimized to enhance the ability of the system to negotiate seam undulations while staying within the seam.

6. The cutting machine must be able to effectively vary the cutting height to accommodate changes in seam thickness.

These six conditions effectively limit seam heights of 30 to 42 in. (0.8 to 1.1 m) to in-web shearers, where the bulk of the machine sits off the AFC and in between the cutting drums, or plows, which have no motors. (The plows also require hard bottom, soft-to-medium coal hardness, and uniform seam thickness).

The range between 42 and 54 in. (1.1 and 1.4 m) effectively opens the options to in-web double-ended ranging drum shearers (DERDS), single-ended ranging drum shearers (SERDS), or plows for the same six reasons. At the time of this writing, SERDS have been the system of choice in the United States for this range. The Europeans have had a substantial amount of success with the in-web DERDS at these heights, and it is anticipated that this technology will be adapted in US coal mining in the near future.

In the range of 54 to 120 in. (1.4 to 3.0 m), which covers the vast majority of current longwall installations, the DERDS is the machine of choice. Plows and SERDS can also be used at these heights, but current technology provides the maximum available power and flexibility in the DERDS.

At ranges above 120 in. (3.0 m), DERDS are also the machine of choice, but the power, size, and stability required at these heights dictates somewhat specialized machines.

Seam thicknesses above 16 ft (4.9 m) are mined by sublevel caving behind the shields, multiple-lift longwalling, hydraulic mining, or other very specialized mining techniques. As of this date, only one face with multiple-lift equipment has been tried in the United States, and the vast bulk of experience at these heights has been in Europe and Asia. Detailed information on these systems is available from European manufacturers.

RESERVES. The size and shape of the available reserves are critical from two standpoints:

1. A sufficient amount of reserves must be present to justify the capital cost of the mining system selected.

2. The shape of the reserves can place limits on the type of mining system employed.

Consider the two principal mining methods: (1) room and pillar with drill and blast or continuous miners and (2) longwall. In the case of continuous miners or drill and blast methods, reserves of as little as 100,000 recoverable tons (91,000 t) have been exploited, although 500,000 recoverable tons (450,000 t) is a much more realistic figure in market conditions prevalent at the time of writing.

The shape of the reserves can be highly irregular, provided the economically minable reserves are contiguous.

If the case of longwalls, reserves of 7 to 8 million recoverable tons (6 to 7 Mt) are typically the minimum, although use of previously purchased equipment and/or the existence of other reserves that are amenable to the same equipment can shift this number downwards. In any instance, a detailed economic evaluation is required to accurately match capital costs against available reserves.

The reserve shape for longwall mining is much more critical, because effective longwall operations require large rectangular blocks of coal, preferably situated side-by-side to minimize development and moving costs. Current United States longwall practice favors panel widths of 500 to 1000 ft (150 to 300 m), and lengths of 4000 to 10,000 ft (1200 to 3000 m) plus, with the trends favoring longer and wider. In general, panel lengths of 2000 ft (600 m) or less are not economical at the time of writing, although site-specific conditions may alter that minimum somewhat.

QUALITY PARAMETERS. Quality parameters of the salable product can be substantially impacted by the mining method selected. More importantly, the very marketability of a given reserve block may be a function of the mining method. In general, a high degree of variability in quality characteristics favors the smaller unit production systems (continuous miner, drill and blast) that provide flexible mining to produce a consistent product. One alternative to this is blending with other coals to produce a consistent product. The only other is to mine the reserve as efficiently as possible, and trust the sales group to find an acceptable market at an acceptable price.

The basic quality parameters that must be addressed in the review of any coal reserve are sulfur, moisture, fixed carbon, volatile matter, calorific value, and ash. Increasingly, markets are becoming more and more specialized, and additional quality parameters that are associated with the targeted market must be closely analyzed to assure reserve viability. Some other quality indicators are sodium ash fusion and rare earths.

In addition to the inherent qualities of the coal, some of these parameters will be changed by processing. Notable among these are sulfur, ash, moisture, calorific value, and size consist.

A very realistic view should be taken of the in-seam and out-of-seam extraneous material that will be taken or, more accurately, given with a particular mining method. In general, longwalls will produce higher reject levels than room and pillar with drill and blast or continuous miner methods, due to their lesser ability to deal with seam variations.

This may not be true in seams with competent immediate roof and floor consistent seam sections and limited and gentle grade changes, but such conditions are not always found.

In any event, considerations of reject material generated by the mining method chosen cannot be reviewed too carefully.

Higher-than-anticipated reject levels increase mining costs, increase coal preparation and attendant refuse disposal costs, and may imperil the actual sales contract itself. It has meant the demise of many a mine. In current conditions, non-longwall reserves that have associated reject levels higher than 30 to 40% are generally considered to be marginal to impossible, depending upon mine productivity, preparation costs, haulage costs, and contractual sales obligations.

STRUCTURAL CHARACTERISTICS. The structural characteristics of a coal seam can have a substantial impact on the mining method selected and the success of that method. It should be noted that a thorough exploration program of a property is the best initial investment that can be made, and one that will prevent many unwelcome surprises and/or expensive mistakes in the course of mining.

The structural characteristics to be discussed are those of regional and local dip, strike, cleats, and faults.

Regional dip and strike will control drainage, and may limit the options in mining methods, equipment, and haulage equipment. Severity of the grade can also affect weight transfer from gob areas. Localized changes in dip and strike (rolls) must be considered because of their adverse impact on track and belt installations, drainage, and the requirement to take additional rock from floor and/or roof in these areas. Additionally, these rolls will impede productivity. Finally, localized rolls will require higher equipment clearances than normal.

Current longwall equipment is limited to grades of 20% without special modification. Rubber-tired equipment can handle grades up to 15% in dry conditions, but equipment power must be adequate, and wet muddy conditions reduce that maximum rapidly. Rail equipment is limited to grades of 5% without special traction devices and/or hoist assist. Crawler-mounted equipment is limited to approximately 25%.

In general, grades below 10% can be mined without specialized equipment. Grades of 10 to 15% necessitate equipment review and a careful review of potential productivity. Grades of 15% or greater require specialized equipment and mine designs.

Cleats in the seam must be reviewed for stability and cutting/blasting directional preferences. The more prominent cleat, the face cleat, and the less prominent, the butt cleat, typically are positioned at 90° to one another. In general, a mining orientation of 45° to each is preferred, and is increasingly critical in thicker seams to avoid heavy rib sloughage.

Faulting is a critical problem in any block of reserves, and particularly those with displacements that exceed seam thickness. Again, if the presence of faulting is likely, the exploration program cannot be too thorough. In conjunction with drilling, new techniques such as radio imaging and cross-hole seismic surveys are useful in detecting faults (Chapter 10.3). In general, the presence of substantial faulting favors the use of room and pillar mining over longwall mining due to its increased flexibility and economic advantage in mining smaller blocks. In any event, the presence of faulting adversely impacts the economics of any property.

PHYSICAL PROPERTIES. Physical properties that affect the selection of mining methods are hardness, strength, cleat spacing, and chemical characteristics.

Hardness is usually measured by the standard ASTM Hargrove Grindability Index; it is one measure that predicts the difficulty and cost of cutting the coal, in conjunction with cleat orientation and spacing. It is a particularly important factor if longwall plows are considered, as they function best in soft cutting conditions. Coal strength is the determining factor in the design of effective pillars and barriers. In addition, some coal seams have separate layers of coal with unequal strength characteristics, which must be considered for design calculations. Cleat spacings have a major impact on cuttability and actual strength determinations used for pillar design. In general, closer cleat spacing favors cuttability and decreases strength. Finally, a review of chemical characteristics of the coal should be made to assess the likelihood of spontaneous combustion. Specialized mine planning, ventilation, and material handling schemes are required to deal effectively with this problem.

GEOLOGIC ANOMALIES. Included in this category are linear deposition, seam washouts, partings, and intrusions. Linear deposition occurs when the coal is laid down in a channel, and this can be very misleading without a thorough exploration program. Similarly, washouts of the seam by roof or floor can be very localized, sporadic, and difficult to predict without a good knowledge of the general geologic trends of the seam and its depositional environment. The presence of substantial seam thinning or washout is critical in longwalls and can force abandonment of panels. Radio-imaging and in-seam seismic techniques have proven most beneficial in detecting geologic as well as structural anomalies. Seam partings increase run-of-mine reject and can pose cutting or blasting difficulties when composed of harder material. They can also generate difficulties in geotechnical design and force changes in mine plans if thick and persistent. Another difficulty is posed by seam intrusions, typically found in coals subjected to volcanic and/or tectonic activity. They produce both obstacles to reserve continuity and chemical changes (metamorphosis) in the coal immediately adjacent to the intrusion.

21.4.1.2 Roof Characteristics

ROOF LITHOLOGY. Roof characteristics are a critical factor in the selection of coal mining methods and associated extraction rates. In general, the study of roof characteristics can be limited to 60 times seam thickness, since that is the maximum height at which disturbances generated by mining have occurred. In fact, the first 5 to 15 seam thicknesses of roof material are even more critical in high extraction mining methods that cave the roof, since all of the cave and most of the major fracturing will occur within this horizon.

In high-extraction mining methods (longwalls and retreat-mined room-and-pillar operations), cavable roof is a must. This requires either shales or weak sandstones within the first 5 to 15 seam thicknesses. Strong massive sandstones or limestones should be very carefully noted, since they both limit caving and transfer stress. The presence of aquifers within 60 seam thicknesses should be noted, since the fractures generated by high-extraction mining may reach that far, although 30 seam thicknesses are the more usual maximum. Pillar design, mining layouts, and extraction rates for retreat mining should consider the possibility of strong strata bridging across the panel and withholding true vertical stress from the pillars until a sufficiently large stress is generated to force failure of those strong strata, resulting in catastrophic pillar failure. During longwall mining, the same situation results in a complete lack of cave until additional mining and increased stress exceed support design limits, force massive caving and resultant airblast, or some unhappy combination of the above effects, with accompanying support difficulties in gateroads as an additional unpleasantry.

Based on this data, panel designs, extraction ratios, and support designs for longwalls can be developed.

GEOLOGIC ANOMALIES. All of the preceding data should be reviewed for the existence of anomalies, particularly within the defined caving zone for high extraction mining or alternatively, the support zone above mine openings. Bed thicknesses should be mapped and isopachs prepared. The existence of sandstone channels should be noted. Any data that indicate a change in immediate roof lithology should be noted and examined, especially the existence of thin (less than 5 ft or 1.5 m) and weak shale roof below more competent strata; this condition almost guarantees problems. In deltaic depositional environments, thick sandstones can disappear in very short lateral distances, and these changes can substantially modify stress fields generated by mining.

21.4.1.3 Floor Characteristics

FLOOR LITHOLOGY. Floor characteristics are usually not reviewed with the care that roof and seam characteristics receive, which is unfortunate. The first 10 ft (3 m) of floor should be reviewed as carefully as the roof and seam, because it can have an equally large impact on equipment selection, pillar design, and productivity. Soft and/or weak floor limits pillar sizes, forces compromise in powered roof supports for longwalls, and impedes movement and productivity of tracked and wheeled equipment. It will also increase run-of-mine reject.

Floor strata should be carefully studied for the following data within 10 ft (3 m) of the seam: lithology, fracture density and orientation, strength, brittleness, and the presence of clays. Additionally, tests should be run to determine the behavior of the strata when exposed to water. In general, the presence of thin, brittle, and/or highly fractured material immediately below the seam is suspect, particularly if coal leader seams are present. In the case of longwall supports, base lift should be fitted if there is even a possibility of soft floor.

In general, soft floor conditions are more easily dealt with by continuous miner/drill and blast techniques than by longwalls, at the expense of increased reject levels.

GEOLOGIC ANOMALIES. Geologic anomalies that affect floor conditions are the same that affect the roof. Murphy's law dictates that floor lithologies will be different where drilling was not done. The value of a thorough geologic exploration that established overall trends, possible anomalies, and an understanding of the depositional environment cannot be overstated in its relation to the optimal selection of equipment and mine design.

21.4.1.4 Stress Field Considerations

The stress field in which a mine is developed is one of the most important items to be considered in the selection of a mining scheme. It affects the stability and design of every hole in that stress field and, even more importantly, the stability, shape, and size of the coal and rock surrounding those holes. Those two items taken in aggregate define a mine. The stress field consists of the initial isotropic stress field generated by the overburden, and subsequent modifications made by tectonics, geologic anomalies, and other mining.

OVERBURDEN. Overburden or depth of cover in general defines both the vertical and horizontal stresses encountered in mining. In general, depending upon overburden lithologies and densities, sedimentary strata generate approximately 1 psi of vertical compressive stress per foot (22.6 kPa/m) of overburden. These resultant vertical stresses, coupled with typical sedimentary rock strengths, limit coal mining to overburden depths of less than 4000 ft (1200 m), with the vast majority of mines in the United States at depths of 2000 ft (600 m) or less. As regards mining methods, high-extraction (greater than 70%) mining with continuous miner/drill-and-blast methods has typically been limited to depths of 2000 ft (600 m) or less. Practice in the Eastern coalfields indicates that under current economic conditions, high-extraction mining with continuous miner/drill-and-blast methods is limited to 1200 to 1500 ft (370 to 460 m) in conjunction with mining conditions and specific economic factors. Conversely, longwall mining is routinely being utilized at depths of 2000 to 2500 ft (600 to 760 m). Mining at depths greater than 2500 ft (760 m) is a rarity, and is possible only where geologic and market conditions are exceptionally favorable.

GEOLOGIC ANOMALIES. As discussed previously, the original stress field is generated by overburden, and is theoretically isotropic. In practice, the horizontal components of this stress are always modified by geologic structures and anomalies. In principle, the maximum horizontal stress will parallel the major jointing pattern and/or major faulting in the area. It may also exceed the vertical stress by a substantial margin. An estimate of both the direction and magnitude of the horizontal stresses should be made, because high horizontal stresses will generate roof and/or floor failures that are substantially dependent on mine orientation and layout. Given higher-than-normal horizontal stress magnitudes, longwalls will cope with these conditions better than continuous miner/drill and blast techniques, due to the lesser amount of roof that must be maintained and the economics of production that usually allow more expensive roof control measures to be taken.

MINE WORKINGS. Mine workings above or below will modify the stress field associated with a given seam, sometimes quite substantially. The effects are dependent on the depth of overburden, the interseam thickness, the amount of extraction in the mine workings, the size and shape of the remaining coal pillars, the order of mining, the length of elapsed time since mining, and the strength of the interseam strata. Influences from existing mine workings have been reported at interseam thicknesses of 800 ft (240 m), although that appears to be a practical maximum, with the vast majority of cases at 500 ft (150 m) or less. In general, any pillars/barriers in the existing mine workings focus the vertical stress field, and the effects of the increased stress can be seen both above and below the old workings. Large barriers or pillars increase the probability of increased stresses. Then again, the presence of high vertical stress concentrations favors the use of longwalls, due to their enhanced ability to deal with difficult roof and the enhanced economics which allow for more expensive roof control measures.

21.4.2 SAFETY/ENVIRONMENTAL/REGULATORY CONSIDERATIONS

Coal mining is an inherently dangerous business. It also has a direct impact on the environment wherever it is practiced. As a result of these factors, it is also arguably the most regulated industry in the United States. As a result of this, safety and environmental issues must enter into the selection of any mining system.

21.4.2.1 Mine Environment

The mine environment is critical to the safety and productivity of the mines. Although regulatory agencies set standards for all critical mine environment issues, the operator should review his conditions against those regulatory requirements. In many instances, and particularly in the case of longwall mining, the minimum regulatory requirements may not be adequate.

VENTILATION. Mine ventilation is a subject of substantial weight and is more thoroughly addressed elsewhere in this *Handbook* (Chapters 11.6 and 11.7.2). However, it may be useful to review some general rules of thumb for underground coal mining.

Room and Pillar Mining—In general, 25,000 cfm (11.8 m^3/s) delivered to the last intake stopping of the section in mining heights of 4 to 8 ft (1.2 to 2.4 m) will prove adequate. Higher mining heights typically require more air to generate the minimum required velocity of 60 fpm (0.3 m/s) over the miner. Lower heights will conversely dictate a lower air quantity. A special precaution should be noted if diesel-powered face equipment is used. Required air quantities are also a function of the number and type of diesel engines used in that equipment. Double-split section ventilation effectively doubles the air quantities required. Double-split section ventilation is almost mandatory with diesel-powered face equipment. Auxiliary face fans are quite common in seam heights of 8 ft (2.4 m) and higher and are quite effective, but special attention should be paid to localized air recirculation that is typically generated by these systems. In general, ventilation systems that are initially overdesigned will subsequently prove to be most helpful as time-related deterioration of airways increases mine resistance. Any mine larger than two sections with a life of more than 10 years will benefit highly from life-of-mine computer simulation for selection of main fans, design of mains, and other critical decisions. With the advent of personal computers, it can be done rapidly and conveniently at the minesite at minimal cost. Blowing ventilation systems should be considered in instances where isolation from the atmosphere and/or old workings cannot be maintained.

Longwall Mining—The ventilation of longwalls is absolutely critical due to the high production rates and associated generation of dust and methane. In general, actual quantities delivered across the face range from 40,000 cfm (18.9 m^3/s) in seam heights of 4 ft (1.2 m) with minimal methane liberation, to 150,000 cfm (70.8 m^3/s) or greater in seam heights of 7 ft (2.1 m) or more with substantial methane liberation. It has been proven that face velocities above 500 fpm (2.5 m/s) can entrain increased quantities of dust, causing problems in compliance with the federal respirable dust standard of 2 mg/m^3. It should also be noted that the amount of quartz detected in respirable dust samples lowers the effective allowable respirable dust concentrations. Strong roof that caves in large pieces will adversely affect the ability to maintain adequate face velocities due to high leakage rates through the gob, and may be a particular problem during the first 500 to 1000 ft (150 to 300 m) of mining in a panel. Daily wash-down of face supports may be required to minimize entrainment of dust generated by caving of the roof. In some instances, water sprays have been installed on roof supports to minimize this dust, although maintenance can be a problem. Maintenance of bleeder systems around the perimeter is always a problem due to the high stress fields encountered, and high safety factors for pillar designs as well as supplemental roof support is required in these areas. Adequate ventilation of gob areas may require surface boreholes with high-head fans to assure adequate dilution and removal of methane. Seams with high methane quantities typically require degasification boreholes from the surface or in the longwall panel in advance of mining. Infusion of high-pressure water into the seam in advance of the longwall face has proven beneficial in reducing respirable dust generation in some coal seams, notably the Pocahontas and Pittsburgh seams.

GROUND CONTROL. Ground control is a complicated subject more thoroughly covered elsewhere in this *Handbook* (Chapter 10.5), but it may be useful to briefly discuss its implications on mining method selection. In principle, roof control difficulties increase as a function of increasing cover and percentage of extraction. Roof bolts are the principal means of roof control at present, ranging in order of cost from mechanical shell anchor bolts to fully grouted resin bolts to larger-diameter point-anchor bolts. Timber and concrete posts and cribs are also used quite commonly. More substantial support is available with roof trusses, steel arches or square sets, and polyurethane foam injection. In practice, ground conditions that require more than roof bolting, cribs, and the very occasional use of more substantial support will not be economically viable with continuous miner or drill and blast techniques. Because of their enhanced productivity, generation of high stress, and use in the deeper seams, longwalls both require and can afford more expensive and elaborate ground-control measures.

NOISE. Noise is increasingly a problem underground as machine power has increased (Chapter 11.8). Also the long chain conveyors associated with continuous haulage systems and longwalls can increase noise levels substantially while running empty. Although not typical in most coal mines, air-powered drills have always delivered noise levels well above allowable levels.

Substantial efforts have been made over the years by the manufacturers, users, and the US Bureau of Mines to reduce the noise levels produced by the machinery. However, in many instances, the operator's position is still exposed to noise levels in excess of the 8-hr weighted exposure requirement of 90 dB maximum. It is worth mentioning that noise levels in excess of 90 dB do permanent damage, and the damage is cumulative. The most effective preventative is personal hearing protection. The types of hearing protection available and approximate levels of noise reduction are listed below in order of effectiveness:

Soft foam ear plugs	30–35 dB
Rigid ear muffs	24–29 dB

The effectiveness of any improvised ear plugs, such as cotton, cigarette butts, or other expedients, is largely illusory and cannot be recommended.

Many companies are now requiring ear protection at all times, with required use in high-noise-level areas, and this effort is highly recommended; noise damage is insidious and cumulative.

STATE AND FEDERAL REGULATIONS. As noted earlier, the mining industry, and more particularly coal mining, is heavily regulated (Chapters 3.3 and 11.1). In that environment, state and federal regulations have an impact on mining method selection. Because of the wide variations in state regulations, these must be reviewed very carefully. Of possible interest is the total ban on blasting on the solid in many states.

There is little purpose here again in discussing specific issues in most states, or even at the federal level, since they are subject to revision. It is worth noting that longwall mining, which has heretofore been the focus of a limited amount of state and federal regulations, is being increasingly regulated by both.

21.4.2.2 Outside Environment

SUBSIDENCE. Subsidence is an increasing concern with all underground coal mining, and particularly with longwalls, although any mining method that provides high extraction ratios will induce subsidence (Chapter 10.6). Many states are now routinely requiring subsidence predictions as a part of the mine permitting process, and this trend will continue.

Technical issues in predicting subsidence accurately have effectively been solved on a regional basis during the last five years. Regional studies in the West and in the Appalachians have produced data that support accurate regional prediction models for longwall and high-extraction room and pillar mining.

Areas that require surface support are typically limited to 50% extraction, which means that room and pillar mining with continuous miners or drill-and-blast methods are the only choices. Extraction rates of 50 to 85% typically generate partial subsidences, and the actual extent and degree of subsidence associated with this level of extraction are difficult to predict.

Compensation for damage to surface structures is a given, and any plan that utilizes high-extraction mining should be reviewed for potential costs associated with surface structures, as well as areas of the surface under which high-extraction mining is prohibited.

HYDROLOGIC IMPACTS. The fracturing of roof strata associated with high-extraction mining has an impact on the subsurface hydrologic regime. Also the change in surface topography generated by subsidence can affect surface drainage, particularly in the case of flat land used for agriculture. The changes to the surface are obviously permanent, but the subsurface hydrologic regime is more variable. Typically, the increased fracturing increases permeability, with the usual affect of diminishing or effectively eliminating sources of water for wells, natural springs, and other sources of domestic water. In many instances, as the fractures fill with clayey material, these water sources have returned. In others, they have not. Many companies have adopted a policy of replacing these water sources for the surface owner if his/hers are damaged or destroyed. Therefore, the use of high-extraction mining systems should include a review of surface ownership and potential hydrologic damage consequences as a function of mine planning.

STATE/FEDERAL REGULATIONS. Increasingly, the mandate for the regulation and reclamation of surface mining and the surface activities of underground mines given to the federal Office of Surface Mining or its equivalent on a state level is being extended to underground operations and their associated surface effects. Regulations and interpretations thereof are quite dynamic, so the operator must familiarize himself or herself with the applicable regulatory agencies and regulations in his/her area. In general, operators of high-extraction underground mining methods can look for increasing constraints upon their operations.

21.4.3 OPERATIONS PLAN DEVELOPMENT

21.4.3.1 Introduction

It is necessary to develop a relatively detailed mine plan when comparing alternative mining systems or when considering the economics feasibility of a particular mining method in a given reserve area. Both underground and surface requirements should be addressed. An underground mine plan should be developed that integrates mine plan projections, production forecasts, mine ventilation system, mine water supply/dewater system, haulage system(s), power system, and mining equipment. These plans are all interrelated and therefore, they cannot be considered separately. A surface plan should be developed that considers (1) the surface construction and support facilities that will be required to facilitate mining, (2) the transportation system that will be used to transport run-of-mine coal to cleaning and/or load-out facilities, and (3) coal preparation requirements. Finally, the staffing requirements to support both the underground and surface operations should be developed.

21.4.3.2 Underground Mine Plan

MINE PLAN PROJECTIONS/PRODUCTION FORECAST. The overall mine design and layout (the location and orientation of all mains, submains, and panels) is often dependent on several of the geotechnical factors already discussed in this chapter, that is, faults, overlying mine workings, etc. These factors should be considered when laying out all mine projections. In general, mains and submains are costly to develop because of the high cost of purchasing, installing, and maintaining long-term sustaining items such as belt, track, pipe/pipe couplings, ventilation controls, outby power centers, and power cable. For this reason, development of mains and submains should be minimized to the extent possible. Similarly, mining costs associated with the development of longwall headgate and tailgate panels are relatively high. For this reason, the current trend in longwall mining is toward longer, wider faces that reduce both mains development and headgate/tailgate development while maximizing longwall tons.

The number of entries developed on each respective main, submain, or panel depends on the following factors:

1. Production considerations. For any given set of continuous miner or drill-and-blast equipment, there is an optimal number of entries and pillar sizes that will maximize productivity. “Super-sections” and drill-and-blast sections typically require 7 to 10 entries, while single continuous miner units require 4 to 7 entries.

2. Ventilation considerations. Sufficient cross-sectional areas must be provided to insure the availability of required air quantities. If CO monitoring systems are contemplated, the belt entry could be used as an additional intake.

3. Haulage considerations. If belt and track/roadways are placed in separate entries, an additional entry will be required.
4. Ground-control considerations. The number of entries and the pillar sizes selected must provide stable roof and floor conditions, particulary in mains or submains with long lives.

Typically, main headings are developed utilizing a 6- to 10-entry system, submains are developed utilizing a 4- to 8-entry system, continuous miner panels are developed utilizing a system of 5 entries or more, and longwall panels are developed utilizing a 2- to 5-entry system.

The production expected from a continuous miner or longwall unit can be estimated after carefully analyzing the following information: (1) prior mining experiences in the same seam, especially those in the same general locality, (2) mining experiences in seams with conditions very similar to those expected for the newly proposed mine, and (3) actual production rates achieved with the mining equipment selected. In order to develop a production estimate, the number of operating days per year and the number of production shifts per day will have to be factored in. The current trend is to operate two production shifts and one maintenance shift per day for approximately 240 days/yr. The production estimate can then be used to determine the linear advance rate for each unit (feet or meters of advance per day). The linear advance rate for each main, submain, or panel can be used to determine the length of time required to drive each set of entries. Mine development can easily be mapped showing monthly, quarterly, or yearly mine development.

In a longwall mining application, the number of continuous miner units that will be required to keep mains development and longwall panel development ahead of longwall mining should be determined. The total number of miner units used throughout the life of the mine should be minimized to the extent possible in order to keep equipment costs and manpower requirements down. The longwall start-up rooms should be developed a minimum of three months ahead of the longwall and, if possible, the longwall start-up rooms should be developed six to nine months ahead of the longwall to allow for unforeseen slowdowns in production. However, longwall panel development should not exceed the nine-month time frame by very much because conditions are likely to worsen in a panel after an extended period of time. Also the requirements for belt, track, and other sustaining items will increase if several headgate panels are developed far in advance of the longwall, only to be idled.

Mainline development in a new reserve block should coincide with the orderly retreat of units from a reserve block where mining is nearing completion. Here again, avoid developing mains or submains too early. Mains, submains, shafts, slopes, etc. should be developed as necessary to match mine development with production and ventilation requirements.

The annual tonnages from each active production unit should be tabulated to provide a production forecast for the projected mine. Downtime resulting from equipment moves (from panel to panel) should be factored in the production forecast, whether it involves longwall equipment or continuous miner equipment. If poor mining conditions are expected in localized areas due to geologic conditions such as severe dips or washouts, then the production rate should be reduced to reflect this information.

VENTILATION. It is essential to determine the ventilation requirements for a proposed reserve area and incorporate these requirements into the mine plan projections. The ventilation plan for a projected underground mine should include the following information: (1) the air quantities needed during all phases of mining; (2) the size, shape, and number of airways needed to achieve the desired air quantities; (3) the general location and timing for all shafts, slopes, drifts, mine fans, etc.; and (4) the capital costs associated with the ventilation system.

General guidelines for required quantities of air were discussed in 21.4.2.1. Design engineers are advised to use generous design quantities and conservative friction factors in planning the ventilation network.

The mine ventilation plan must be reviewed and approved by state and federal agencies. These agencies may have established certain requirements and/or guidelines that often have a direct bearing on the ventilation.

The mining equipment selected can also impact face ventilation requirements. For example, diesel mining equipment requires a minimum air quantity for each piece of diesel equipment utilized in the face (see Chapter 11.5).

It will be necessary to determine the size, shape, and number of airways needed in order to meet ventilation requirements throughout the mine. In most instances, the mining height is simply the seam height plus the thickness of any extraneous material that is expected to be mined with the seam, for example, soft fire-clay bottom. However, in thicker coal seams (more than 12 ft or 3.7 m), the entire seam may not be mined due to ground-control problems resulting from the increased height. In lower seam heights, it may be necessary to mine out-of-seam material in order to provide clearance along track haulageways. Here again, the selection of mining equipment can have a direct impact on the minimum entry height; that is, the height of the stage-loader on a longwall face will affect the minimum entry height that can be taken during development of each headgate entry in the mine. The width of the airway is determined by ground-control analysis. Maximum entry widths are usually preestablished by state and/or federal regulations.

The size, location, and number of openings (shafts, slopes, or drifts); the size, location, and number of mine fans; and the number of airways for each main, submain, or panel is a function of the size and shape of the reserve area, the size and shape of the airways (entries), the number of units, and the overall mine design/layout. Due to the complexity of mine ventilation networks, computer analysis and simulation of the mine ventilation system is used to develop and optimize the overall ventilation plan. Additional shafts, slopes, or drifts (with or without fan capabilities) are variables that can be used in lieu of developing a large number of airways, and these alternatives should be considered. In large reserve areas, it is usually not necessary to have all projected mine openings and/or mine fans established as part of the initial mine development. Instead, the need for additional intake/return capability usually becomes necessary due to mine expansion: as the mine development progresses into new reserve blocks and the size of the mine increases, the requirements of the mine ventilation system also increase.

Once the ventilation requirements for the reserve area have been detailed, the costs associated with the ventilation system can be estimated. (Particular attention should be paid to the date that each phase of the ventilation system needs to be in operation.) The capital cost estimate should include the costs to develop ventilation shafts, slopes, and/or drifts and also the cost to purchase, construct, and install each fan and fan housing. The yearly operating costs for the mine ventilation system should also be estimated (e.g. fan maintenance costs, power costs, airway maintenance costs, etc.).

EQUIPMENT SELECTION. It is not necessary to detail equipment specifications and select manufacturers at this early stage in mine planning. What is necessary is to determine what parameters the equipment will be required to work in and then determine the mining equipment that is best suited for this type of application.

When selecting equipment for either continuous miner applications or for longwall applications, the geotechnical considerations discussed earlier in this chapter define the working environment for the equipment. What is the height range that the equipment will be required to work in? What grades will the equipment routinely have to negotiate? What roof and floor conditions can be expected throughout the mine? Will out-of-seam material have to be taken? These are all important factors that can be answered by analyzing the roof, floor, and seam characteristics. Mining at lower heights requires low coal equipment that also translates to lower production rates.

Once the working parameters for the equipment are determined, the size, type, and amount of equipment best suited for the mine can be determined. For example, if out-of-seam floor and/or roof rock will periodically be mined, then the cutting equipment should be designed with the motor horsepower, frame/drum size, bit lacing, etc., necessary to cut the rock. Note that the equipment being considered must also meet safety, environmental, and regulatory considerations.

Once the general specifications for the mining equipment are known, relatively accurate cost estimates can be obtained from several equipment manufacturers.

HAULAGE. The haulage system(s) necessary to transport run-of-mine coal to the surface and to transport personnel and materials underground should be determined. Track systems, belt conveyor systems, and combination belt/track systems are all being used to meet haulage requirements in large underground applications. The method of choice in the United States in recent years has been to utilize belts to transport coal and utilize track or rubber-tired equipment to haul personnel and supplies. In shaft mines, an underground belt system can be utilized in conjunction with an underground storage bunker that provides surge capacity until the coal is hoisted to the surface.

The location of all mainline belts, submain belts, and panel belts should be determined. Since belt transfer points represent a high maintenance area for the life of the mine, they should be minimized to the extent possible. The current trend is toward longer belts of higher strength with bigger drives and bigger motors. A booster drive installation can also be considered for long belt applications; the main belt drive works in conjunction with a series of booster drives. In either case, transfer points are reduced.

The peak tonnage requirements for each belt line should be determined. The maximum number of units dumping on a particular belt line at any given time can be taken directly from the mine plan projections. The tons per hour from each unit depend on the equipment being utilized. Typically, a feeder is used in a continuous miner unit to load coal uniformly onto the belt; generally, the peak discharge rate from a feeder ranges from 5 to 10 tph (4.5 to 9 t/h) depending on equipment size, type, and specifications. The peak discharge rate from a longwall unit ranges from 10 to 30 tpm (9 to 27 t/min) depending on the size, type, and specifications of the equipment used on the longwall face.

The belt length, the difference in elevation, the peak loading rate, and the run-of-mine coal density are used to calculate the belt speed, belt width, belt loading (in pounds per inch, or grams per millimeter of width), and belt tensions. This information can then be used to aid in the development of specifications for drives, take-ups, and belt structure.

The mainline track system used to transport men and supplies is typically comprised of 60-to-100 lb (27-to-45 kg) track on wooden ties, ballasted, with sufficient vertical and horizontal clearance to permit mining equipment to be hauled in and out of the mine on a low-boy. If rubber-tired equipment is used, haulage roads should be graveled, graded, and maintained with a grader to minimize equipment downtime and travel time to the active areas.

MINE WATER SUPPLY/DEWATER SYSTEM. The mine water system necessary to supply water underground should be determined (Chapter 12.1). First of all, mine water usage should be estimated (designed for full production). To estimate the peak water usage for the mine (in gallons or liters per minute) and to establish the minimum water pressure required to operate effectively, the following information should be compiled: (1) the water volume/pressure required to operate all face equipment, including ancillary equipment such as water sprays, scrubbers, etc.; (2) the water volume/pressure necessary to operate water sprays and water deluge systems at belt drive installations; and (3) the water consumption expected from other miscellaneous activities such as equipment maintenance and washdown. Typically, continuous miner units require from 10 to 40 gpm (75 to 150 L/min) at a working pressure from 200 to 300 psi (1.38 to 2.07 MPa), and longwall units require from 60 to 120 gpm (227 to 454 L/min) at a working pressure from 200 to 300 psi (1.38 to 2.07 MPa). The actual water consumption at belt drives is relatively small, usually ranging from 5 to 10 gpm (19 to 38 L/min). However, the mine water supply system must be capable of supporting fire fighting activities at each drive and along each belt line. Booster pumps should be considered to maintain higher pressures when dust suppression is required.

Second, the best potential source of water for the projected mine and the supporting facilities should be determined. Several alternative water sources may be available and all of these options should be analyzed in order to determine the most cost-effective alternative. For example, there may be an existing water source from a nearby mine or other facility that can be utilized. Water may be available from overlying, underlying, or adjacent mine workings. There may be groundwater inflows expected into the proposed mine that can be used for the mine water supply. It may be relatively easy and inexpensive to develop a groundwater well to supply water for the mine and support facilities.

Once the water quantity and pressure requirements have been estimated and the water source has been determined, the mine water supply system can be developed to meet these requirements. It will be necessary to determine the pipe size, type, and pressure rating required for the water supply pipe to be used on each main, submain, and panel. An elevated water tank near the mine portal may be needed to achieve the working pressures required for mining and to provide surge capacity (it is desirable to be able to store a two-to-three-day supply of water in case of interruptions in the water supply). The need for elevated water tanks, pumps, and/or booster pumps depends on the location of the water source, the structural characteristics of the seam (strike, dip, and elevation changes along mains, submains, and panels), the size and shape of the reserve area, and the number of units. Here again, computer-aided analysis and simulation can be used to help develop and optimize the plan for the mine water supply system.

The water required to operate the mine bathhouse and other mine support facilities should be added to the underground water requirements in order to calculate the total water demand for the facility.

Similarly, a mine dewatering plan should be developed that addresses how water accumulations will be handled and removed from the mine. There are many potential sources for unwanted water inflow and accumulation in a mine. For example, groundwater flow into mine workings can be a problem, particularly when mining nears the seam outcrop. Also water from adjacent or overlying mine working can create a chronic dewatering problem as water continually seeps through fracture planes. This seepage may become much more prevalent during full-seam mining methods. Water accumulation can also result when the underground water-supply pipe breaks as the result of a roof fall or other reason. The volume of water that will have to be continually removed from the mine should be estimated after carefully analyzing the potential water sources and after reviewing prior mining experiences with respect to the seam being mined. Again, the system of pipes, sumps, pumps, etc., that will be needed to effectively dewater the entire mine workings should be designed.

21.4.3.3 Surface Plan

SURFACE FACILITIES. When analyzing a given reserve area, there may be several alternative sites that can be used as the main portal for the mine. It will be necessary to determine which location is best suited for the mine. Surface ownership and access/availability of water, electricity, roads, and railways must be considered. A primary consideration is the overall surface topography, particularly when the mining is in steep terrain. There may be a strip bench left from prior mining or there may be another relatively flat area available that can cut initial development costs considerably. Another primary consideration is to have the mine portal located as close to the preparation plant as possible, particularly when an existing preparation facility is going to be used. Also, as discussed earlier in this chapter, there are several underground considerations that may influence the location of the mine portal. For example, there may be an area in the reserves where faults, washouts, or lower seam heights are prevalent and as a result, this area would not be suitable for mainline development. Once all these factors have been considered, the most cost-effective location for the mine portal can be selected. In large underground mines, it may be cost effective to utilize several different portals in order to reduce the travel time required to transport men to and from the active workings.

The total surface area needed to support the proposed mine will not be fully known until the plans for the surface facilities, the materials handling system, and the coal preparation facilities are clearly defined. Mining in areas with steep terrain will require extensive excavation to establish bench area to work from with correspondingly high development cost. For this reason, it may be cost effective to locate some support facilities such as preparation or bathhouse facilities away from the mine portal. Similarly, it may be cost effective to locate some supporting facilities such as shops or manstation facilities underground. It may be more effective to locate shops underground in shaft and slope mines due solely to equipment haulage constraints. These factors should be considered when developing the mining plan.

The surface facilities necessary to support the mine should be determined. These plans should address the preliminary design, location, timing, and costs for the following requirements: (1) access and/or haulroads; (2) site preparation; (3) office facilities, warehouse facilities, shop facilities, bathhouse facilities, personnel facilities, parking facilities, etc.; (4) substation(s); (5) supply yard(s); (6) ventilation structures such as fans, fan housing, shafts, etc.; (7) environmental structures such as sediment ponds, diversion ditching, sumps, etc.; and (8) disposal areas for trash, breaker rock, etc.

Further discussion of the surface mine plant is contained in Chapters 7.2, 17.3, and 17.5.

MATERIALS HANDLING SYSTEM. The materials handling system located on the surface is used to handle, store, and transport the run-of-mine coal. It may also be necessary for this system to handle and segregate underground waste rock that is occasionally generated during mine development for overcasts, drive areas, belt trenches, etc.

There should be adequate storage capacity at the minesite to insure that underground coal production is not affected when unforeseen problems occur that stop the flow of coal from the minesite, for example, a major breakdown at the preparation plant. As a rule of thumb, there should be enough storage capacity at the minesite to store one week of mine production. Of course, the available surface area and the surface topography significantly impact the storage capabilities at the minesite and, as a result, it may be too cost intensive to develop a large storage area.

The trend today for large-scale operations is toward live storage where the run-of-mine coal stored at the minesite is automatically retrieved by the materials handling system without the need for men and machines to rehandle the material. Typically, either a reclaim tunnel system is used with open storage, or silo(s) are used, or a combination of both.

A rotary breaker is often located at the minesite for the purpose of removing large rock from the run-of-mine coal in the early stages of the material handling system. Transportation and handling costs can be significantly reduced if rock is removed before the run-of-mine coal is transported to the preparation plant.

If the preparation facilities are not located at the minesite, then the transportation method to get the run-of-mine coal to these facilities should be selected. The coal is routinely transported by either trucks, railroads, or overland conveyors but other methods are available such as slurry systems, aerial trams, or pneumatic systems that may be desirable in certain applications. Small-scale operations typically stockpile their run-of-mine coal on the ground and then periodically load and haul the coal in trucks to nearby cleaning facilities. Trucking offers a low initial cost; however, the operating costs to rehandle and truck the coal are generally high. Large-scale operations typically use either a loadout facility dumping into railcars or an overland conveyor to transport run-of-mine coal to nearby preparation plants. Although the initial capital costs for these systems are high, the operating costs are generally low in comparison with trucking and other systems.

COAL PREPARATION. In almost every instance, run-of-mine coal requires cleaning before it can be sold, and this constitutes a significant part of the overall mining cost. However, certain areas in a given reserve base or certain mining methods such as longwall mining may produce a run-of-mine product that is suitable to meet coal quality parameters or that may be blended raw with clean, processed coal to form a marketable product. If these conditions are likely to exist, a tremendous cost savings will be realized if the raw blend product can be segregated. Material handling systems are being utilized that have a nuclear analyzer to detect a raw blend product, which in turn triggers a flop gate and separates the raw blend coal.

In many instances, a company will have active coal preparation facilities located near the projected reserve area. It will be necessary to determine if these cleaning facilities can handle the run-of-mine feed. The quality parameters (percentage ash, sulfur, moisture), the percentage of fines in the run-of-mine coal, etc. will also be considerations when determining if the existing plant can continue to operate effectively and meet quality constraints. Plant modifications may be possible that will allow the facility to handle the increased tonnage and/or help the facility to better meet the coal quality parameters.

If existing preparation facilities are not available for the proposed reserve area, then the location and the detailed design/layout for the preparation plant will have to be developed so that it can process the run-of-mine coal output and meet all coal quality parameters. The capital cost to construct a coal preparation facility can be staggering, and careful planning is essential to develop accurate cost figures. The total capital cost required to construct the preparation plant should be determined. In addition, the costs required to operate the preparation facility should be determined (the operating cost is typically figured as a cost per ton of clean, or processed, coal).

21.4.3.4 Staffing

Labor costs represent a significant portion of the total mining cost and, for this reason, an accurate estimate of the manpower requirements should be determined for the proposed mine. The manpower needs for any given year of mining largely depend on the following factors: (1) the number and type of production units in operation, (2) the overall extent of the active underground workings, (3) the type of equipment, (4) the general mining conditions, and (5) the availability of regional support groups. All of these factors should be carefully considered when developing the staffing requirements for the proposed mine.

The number and type of production units utilized during each year are developed in the mine plan projections and production forecast. Typically, a continuous miner section employs from 7 to 12 persons while a longwall section employs from 5 to 10. The exact number of employees utilized on each production unit depends on the face production system and the type of equipment utilized. For example, in longwall mining, fewer shield operators are required to routinely advance shields with electrohydraulic controls as compared to a longwall face with manually operated hydraulics shield control.

The need for outby support personnel (i.e., motormen, beltmen, trackmen, etc.) increases as the number of active production units increases. The overall size of the mine also has a bearing on how many outby workers will be needed; additional personnel will be needed to maintain airways and maintain belt and/or track haulageways in large mines. Certain mining conditions can also dictate the need for additional mine personnel. For example, if wet mining conditions are expected throughout the life of the mine, then pumpers will be needed to maintain the mine dewatering system. Also, if poor roof conditions are expected throughout the mine, then additional personnel will be needed to construct cribs and timbers, spot bolt, and rehabilitate mine haulageways and airways.

In some instances, companies employ regional support staffs to perform functions such as accounting, engineering, payroll, etc., for several company mines and support facilities. If this situation does not apply, the mine will have to hire technical and administrative personnel to perform these services at the minesite or the work will have to be contracted out.

21.4.4 ECONOMIC CONSIDERATIONS

21.4.4.1 Capital and Operating Costs

In the real world, the selection of mining methods is inextricably tied to the costs associated with those methods. These costs are grouped into two areas: capital costs, and operating costs.

Capital costs are these associated with the purchase of equipment or facilities, and these costs have a substantial impact on both the initial financing of a mine and its subsequent operating performance. Capital costs to open a single-unit drift mine range from $200,000 to $500,000, and costs for a multiple-unit mine requiring shaft/slope access can easily total $30 to $50 million, excluding in-mine infrastructure and mining equipment. A complete longwall system currently costs $12 to $16 million, without regard to additional costs for mine infrastructure purchase or improvement costs. Similarly, a complete set of equipment for a continuous miner section costs $1.5 to $2 million.

In the case of continuous miner units, rebuilt/used equipment can usually be obtained at substantially lower prices, with the trade off of less than state-of-the-art performance and a probable increase in maintenance costs. Longwalls are always designed as a system for a specific set of mining conditions, and the purchase of any used longwall equipment should be very carefully reviewed for compatibility with existing mining conditions prior to purchase.

The cost of capital and the various methods for financing capital requirements are beyond the scope of this chapter (see Section 6), but limitations in the ability to obtain capital can by itself dictate the mining method selected.

Operating costs include all those variable expenses associated with mine operation. The principal items are labor, supplies, power, haulage, preparation, and administration. Cost calculations are discussed in the following.

21.4.4.2 Mine Budget Development

It is necessary to develop accurate mining costs when comparing alternative mining systems or when considering the economic feasibility of a particular mining method in a given reserve area. A mine budget spreadsheet appears in Table 21.4.1 for a hypothetical underground coal mine for a 15-year operating life.

Before accurate mining costs can be developed, it is first necessary to develop a relatively detailed mine plan when the operations plan is completed, a cost sheet or mine budget summarizing all of the costs required for mining should be developed that includes (1) the cost for labor and related benefits, (2) the supply costs necessary to support daily mining activity, (3) power costs, (4) contracted services/equipment rental, (5) coal transportation costs, (6) preparation and tipple costs, (7) the cost of utilities, travel, and civil penalties, (8) the cost for administrative expenses, (9) the costs to pay coal royalty, taxes, and insurances, and (10) the capital costs expensed over the life of mine. Most of the detailed cost information needed for the mine budget will be generated during the development of the mine operations plan.

Once the mine costs have been established for a proposed mining plan in a given reserve area, the economic viability of the plan can be determined by calculating the present worth of the investment. Alternative mining systems can be compared by reviewing the respective cost sheets and comparing the present worth figures. Other factors that influence the economic viability of a proposed mine plan are (1) the availability of markets to sell the coal and (2) the availability of capital to invest in the project.

LABOR COSTS. Staffing required to operate the mine will be determined during the development of the mine operations plan. This information should be used to determine the corresponding labor costs. The mining industry is labor intensive, and the cost of labor represents a significant portion of the total mining cost.

The salary structure and benefit earnings for the general workforce and the mine supervisory/technical personnel are often quite different, particularly when the general workforce is a signatory member of the United Mine Workers of America (UMWA) or other union. For this reason, labor costs are usually calculated separately for the general workforce (non-exempt) and the supervisory or salaried (exempt) personnel. These figures are then combined to give the total labor cost.

If unionized, wage rates for union employees are specified in the contract, and these rates can be used to compute wages. Development of an average daily wage rate can simplify the computation process. The overtime cost is usually given as a percentage of the regular labor costs. Typically, overtime costs range from 5 to 15% of the regular wage costs. An overtime rate of 10% is used in the example shown in Table 21.4.1. The costs to provide benefits such as paid vacation days, paid holidays, additional pay received for unused vacation days, annual retrain-

Assumptions: A typical mine budget spreadsheet is shown for a proposed union-affiliated (United Mine Workers of America) mine using continuous miner units and a longwall. Initial mine development is projected in 1990 with 2 continuous miner units. A longwall is added in 1994. See text for explanation (21.4.4.2). Costs in US dollars/ton (constant). Conversion factor: \$1/ton = \$1.10/t.

ing, and clothing allowances should be computed. The insurance costs to provide health insurance coverage and other company-paid insurances as well as the cost to pay taxes such as state and federal unemployment taxes, social security taxes, workers compensation, black-lung trust fund payments, and any other applicable taxes should be computed. The payments required to be made into the union health and welfare funds should be computed, if applicable. The total non-exempt labor cost is computed by combining the costs for wages, benefit earnings, taxes, insurance, health, and welfare.

The salaries projected for the supervisory/technical personnel can be combined to compute the labor costs for exempt personnel. The overtime percentage for salary personnel is usually smaller than it is for the non-exempt labor because not all supervisory personnel are eligible for overtime pay. An overtime rate of 5% is used in the example shown in Table 21.4.1. The additional labor expenses for taxes, insurance, pensions, etc. should be computed. In a well-established company, the related labor expenses are well known, and they are therefore often computed as a percentage of the salaries. In the example shown in Table 21.4.1, the related labor expenses are estimated to be 24% of the wages. The total labor cost for the supervisory/technical personnel is computed combining the costs for wages, overtime, and related expenses.

The total labor cost is easily computed by combining the non-exempt and the exempt labor costs.

SUPPLY COSTS. An accurate cost estimate of the supplies necessary to support routine mining activity is essential. Supply costs are usually separated into two main categories, operating supplies and maintenance and repair costs.

Operating supply costs include the costs of mine supplies used for roof control (roof bolts, straps, plates, timbers, cribs, etc.), ventilation (concrete block, motor mix, curtain, etc.), cutting (miner bits, roof drill bits, drill steel, etc.), and other miscellaneous items (rock dust, sand, etc.). Researching the operating supply costs at other mines in the same seam, and researching the operating supply cost at other mines in similar conditions, can help to develop an accurate operating supply cost.

Typically, the operating supply costs for continuous miner units ranges from $2.00 to $7.00/ton ($2.20 to $7.70/t). The average supply cost will depend largely on advance rates, seam height, and overall mining conditions. Operating supply costs tend to be more expensive when mainline headings are being developed as opposed to room and pillar panels. This is a result of the need to provide long-term roof control and to establish clearances in mainline belt and track entries, all of which work to increase costs. Operating supply costs required in areas outby the working face increase as the mine advances and the extent of the active workings increases.

The operating supply cost is much lower for longwall mining due to the increased tonnage rates coupled with the reduced demand for supplies (no roof bolts, straps, plates, curtains, etc.). Typically, the operating supply cost for longwall units ranges from $0.50 to $2.00/ton ($0.55 to $2.20/t).

Maintenance and repair supply costs include all parts and tools used to maintain, service, and repair all mine equipment located at the face and outby, including power centers, belt installations, belt drives, pumps, etc. The costs associated with equipment rebuilds or overhauls is generally capitalized and it therefore, is not included in the maintenance and repair supply costs.

Typically, the maintenance and repair supply costs for continuous miner units will range from $2.50 to $7.50/ton ($2.75 to $8.25/t). The average maintenance and repair supply cost will depend on the overall mining conditions and the type of mining equipment selected. The establishment of a good preventive maintenance program at the mine will help to reduce maintenance and repair supply costs as well as increase face availability.

Again, maintenance and repair supply costs are much lower for longwall mining. Typically, the maintenance and repair supply cost for a longwall unit ranges from $0.50 to $2.00/ton ($0.55 to $2.20/t). In some cases, it is desirable to collect or accrue maintenance and repair charges during mining of a longwall panel that will be used for repairs scheduled at the end of the panel. In this case, a fixed cost per ton is charged during longwall mining, and the money is set aside in a longwall accrual account. When the longwall panel is completed, the money is spent for pre-established maintenance and repair purposes such as refurnishing the longwall shearer, etc.

POWER COSTS. The annual power costs required to operate the mine will be determined during the development of the mine operations plan.

In the example shown in Table 21.4.1, the annual power cost estimate required to operate the proposed mine has been tabulated.

CONTRACTED SERVICES/EQUIPMENT RENTAL. Several mine services such as road maintenance, building maintenance, construction work, etc., may not be done within the company. Instead, these jobs may be contracted out to other companies when these services are required. Similarly, it may be advantageous to rent or lease certain equipment outright, particularly when the equipment will only be needed for short periods of time.

In the example shown in Table 21.4.1, road maintenance work, cleaning of sediment ponds, and other construction work needed periodically at the mining operation will be contracted out. Off-road haulers will be periodically used to haul wasterock away from the mine site and dozers will be periodically used to grade both the coal stockpile area and the wasterock disposal area. The cost estimates to provide these contracted services and to rent the equipment needed are combined.

TRANSPORTATION COSTS. The method of transporting coal to the preparation facilities and the corresponding costs are determined during the development of the mine operations plan. If the preparation facilities are located at the minesite, then there are no coal transportation charges.

In the example shown in Table 21.4.1, the run-of-mine coal initially is hauled by trucks to a nearby coal tipple where the coal is loaded into railroad cars and transported to the coal preparation facilities. Construction of the permanent materials handling system and loadout facility will be completed by the second year and, at this time, run-of-mine coal will be loaded directly into railroad cars, reducing the transportation costs.

COAL PREPARATION AND TIPPLE ALLOCATIONS. Coal preparation costs are determined during the development of the mine operations plan.

In the example shown in Table 21.4.1, the run-of-mine coal is being transported to a centralized coal preparation plant that processes run-of-mine coal from several mines located in the same general vicinity. The percentage of the total preparation costs attributed to each mine is charged back to the respective mines as well as any other applicable coal processing and/or tipple charges.

UTILITY, TRAVEL, CIVIL PENALTIES. The cost to provide utilities other than power, such as water, sewage, telephone, etc., should be estimated and included in the mine budget. Business travel for the purpose of continuing education, examining new equipment and mining methods, etc., should also be included. The cost of civil penalties resulting from state and/or federal citations should also be included in the budget. While no company wants to plan for civil penalties, they are a fact of life in mining, and they increase costs slightly.

If any other miscellaneous expenses are expected, they should also be included in the mine budget.

In the example shown in Table 21.4.1, the mine expenses pertaining to utilities, travel, and civil penalties are combined.

ADMINISTRATIVE EXPENSES. Several mine support services such as engineering, accounting, payroll, human relations, coal sales/marketing, etc., may be done at a local and/or a regional level for several different mining operations owned by a company, rather than at each individual minesite. In this case, a percentage of the total cost to provide these services is allocated to each mining operation.

In the example shown in Table 21.4.1, all of the services discussed above are being provided by a centralized or divisional support group that supports several mines located in the same general vicinity. The percentage of the total cost for this support group is charged to each respective mine.

COAL ROYALTY, TAXES, INSURANCE. It will be necessary to pay coal royalty charges (also in dollars per ton) if the mineral rights are not owned outright by the mine operator. Also the tax charges for coal severance tax, federal reclamation tax, property tax, state and federal income taxes, applicable state/county mineral depletion taxes, etc., should be estimated and included in the mine budget. The costs to provide coverage for fire insurance, accident insurance, property insurance, company vehicle insurance, etc., should also be estimated and included.

In the example shown in Table 21.4.1, the mine costs to pay coal royalties, taxes, and insurance are combined.

DEPRECIATION AND DEPLETION. Capital expenditures that are required over the life of the mine are determined during the development of the mine operations plan. Generally, the capital expenditures are broken down in four major categories.

1. Equipment purchases. New mining equipment that is purchased either to start the mining operation or new equipment that is purchased to replace old, outdated equipment.

2. Equipment rebuilds. Mining machinery is frequently overhauled or rebuilt on a regular schedule (2–3 years), and then put back into production. Equipment rebuilds costs typically average about 60% of the cost of a new piece of equipment, and this can represent a significant cost savings to the mine.

3. Sustaining items. The cost for items such as belt structure, belt, track, high voltage cable, and pipe is normally capitalized. The mine plan projections reflect the total feet of mine advancement during each year of mine development. This information should be used to determine the sustaining items required during each year of mine development.

4. Special projects. Capital expenditures to establish items such as mine offices/bathhouse facilities, site preparation, fan installations, substation installation, etc.

All capital costs should be tabulated by the year in which the expenditure is to be charged. This provides a summary of the annual capital costs required over the life of the mine. These expenditures will have to be financed in some fashion (either cash, loan, lease agreement, etc.) in the year in which they occur. However, if the large capital expenditures were all charged to the mine at one time, the mine cost sheet would reflect these large increases. For that reason, it is desirable to charge the cost of equipment back to the facility in a way that spreads the cost of the equipment over the life of the equipment (amortization). A convenient way to do this is to calculate the depreciation of the capital expenditures and then set the amortization schedule equal to the depreciation.

Depreciation is a tax deduction for the exhaustion, wear and tear, and obsolescence of property used in a business. Capital expenditures must be depreciated rather than expensed. The first step in computing depreciation is to determine the estimated useful life of the asset or its allowable depreciable life (refer to applicable tax codes). Once the depreciation has been calculated for all of the anticipated capital expenditures, the annual depreciation figures should be determined for each year of mine development. The annual depreciation figures are used in income tax computations in addition to producing the amortization schedule for the capital costs.

Depletion refers to the recovery of an owner's economic interest in mineral reserves through federal tax deductions related to the removal of the mineral over the economic life of the property. In the example shown in Table 21.4.1, there is no depletion credit because the reserves are not owned by the mine operator. In this example, a royalty is being paid to the owner of the mineral rights and the owner is entitled to the depletion credit.

Also, as shown, depreciation charges represent the cost of capital that is being charged to the mine.

21.4.4.3 Economic Viability

MARKET FORECASTING. Market forecasting is a subject in and of itself and is outside the scope of this chapter (see Chapter 2.3). However, it is important to note that the success of any mining scheme is subject to the market for the coal produced. Given the inherently cyclical nature of the coal market, the rapid and large impact of environmental regulation on its customers, the increasing globalization of the market, and its competition with other energy sources both domestically and abroad, market prices can change dramatically. That fact, when coupled with the large capital investments required and the long life of large reserve blocks, dictate that any economic decisions be based on the best market forecast available, and should include both best and worst case scenarios.

CASH FLOW. In order to compare alternative mining systems in a given reserve area or when considering the economic feasibility of a particular mining plan, the present worth of the investment is calculated (Section 6). Potential markets available must first be analyzed to determine the revenues expected from the sale of the coal. Annual expenditures (determined in the mine budget development) and annual coal revenues are computed over the life of the mine. The use of an after-tax discounted cash flow technique can then compare the present worth of the various alternatives. It is important to look at the analysis after taxes because of the impact taxes will have on a potential investment.

21.4.5 HUMAN RESOURCES

Human resources available can have a substantial impact on the viability of any mining method selected. As was stated earlier, mining is a labor-intensive business and will continue to be, despite the technological advances that constantly are being made. Furthermore, the best of technology is limited in effectiveness without the support of a motivated, well-trained, and dedicated work force.

Of the mining methods discussed, drill-and-blast mining is the most difficult to use in relation to the work force. This method has rarely been successful without the availability of a labor pool with substantial experience in these techniques, and that labor pool is shrinking rapidly or has effectively disappeared in most mining areas. For this reason, this technique is rapidly vanishing from the coal mining industry.

Continuous mining units are the industry standard, and all coal mining areas have a labor pool that is familiar with the operation and maintenance of this equipment.

Longwalls are relatively new to the United States coal industry, but most mining areas have at least one or two companies using this technology. Furthermore, there are many examples in the industry of companies with no prior longwall experience successfully implementing longwalls. This has been done by carefully selecting the personnel involved and mounting a strong training program prior to the arrival of the equipment, during installation, and continuing through startup activities.

Chapter 22.1
RAPID EXCAVATION

C.D. BREEDS AND J.J. CONWAY

22.1.1 INTRODUCTION

For the purposes of this section on innovative mining methods, *rapid excavation* is defined as underground excavation by means faster than conventional methods. However, many of the techniques and mining methods described below are well proven in civil construction and in a small number of US mines. A major innovation would be broader acceptance of these technologies by the mining industry.

Two major organizations in the United States promote the use of rapid excavation techniques for civil and mining applications. The Executive Board for Rapid Excavation and Tunneling Conferences (RETC) was established in 1971 to disseminate technical information in this rapidly advancing field of underground construction. The RETC and its proceedings provide a wealth of case study information related to site investigation, groundwater control, design and analysis, equipment, instrumentation, materials handling, and support for rapid excavation projects in soft ground and hard rock. The more recently established Institute of Shaft Drilling Technology (ISDT) provides a forum for discussing and reporting advances in shaft drilling. Short courses in mining techniques, shaft sinking, and boring techniques are provided through the ISDT and are highly recommended for engineers and owners planning major shaft projects.

This chapter draws extensively from publications of these organizations, field experience in rock cutting and excavation engineering, and input from equipment manufacturers and contractors. Each segment has been written to provide the reader with a description of the equipment used and an overall appreciation of selection methodology. Emphasis is placed on methods and equipment used for mine access construction and mine development. Rapid excavation methods associated with development and production mining (e.g., longwall mining, continuous mining, and stoping methods) are discussed elsewhere in the *Handbook* (see Chapters 17.4, 17.5, 18.1, 18.2, 19.1, and 20.1).

22.1.1.1 Rapid Excavation System Performance

A short section on system performance evaluation is provided for each rapid excavation method described. Simple empirical techniques, which utilize existing case study data and qualitative information, are used to estimate the probable range of system performance. This approach is considered to be applicable at a conceptual level of project planning. More detailed analyses, rock cutting experimentation, and equipment/system performance predictions are available from equipment manufacturers, but, due to space constraints cannot be adequately dealt with here.

22.1.1.2 Cost Estimating

Since the inception of mechanized mining, many papers have been published which enumerate the absolute cost advantage of mechanical vs. conventional construction. However, technical advancement in equipment design, owner experience, and increasing competition among contractors decreases the utility of absolute cost estimates especially when presented in a medium with an anticipated useful life of a decade or more. The approach in this chapter is, therefore, to present a list of the main components important to estimating project costs and to direct the reader to potential unit cost providers.

22.1.2 MECHANICAL ROCK CUTTING TECHNIQUES AND THEIR APPLICATION TO MECHANICAL MINING EQUIPMENT

The mechanics of mechanical rock breakage, and the parameters important to determining cuttability and production rates are presented in Chapter 9.2 of this *Handbook.* The objective of this chapter is to describe five basic cutting methods and their application to mechanical mining equipment.

These basic cutting methods, defined in terms of tool type, are illustrated in Fig. 22.1.1 and include:

1. Drag bit cutting.
2. Point-attack bit cutting.
3. Disk cutting.
4. Button cutting.
5. Roller cutting.

22.1.2.1 Drag Bit and Point-attack Bit Cutting

The application of both drag bits and point-attack bits is similar. The tools are inserted in tool holders (or boxes), which are integral parts of the cutting head, and may be held in place by a circlip or spring. Point-attack bits are commonly free to rotate in their holders. It has been claimed that this feature promotes more even tool wear (self sharpening) and better overall tool life, although research by Hurt and Evans (1981) disputes this. During cutting, the bits are pushed into the rock, developing cutting forces parallel to the direction of head rotation and normal forces parallel to the direction of head thrust. As these forces build up to critical values, a macroscopic failure surface develops ahead of the bit, and a piece of rock spalls away. The pick then moves ahead into the space left by the spalled chip until a new rock buttress is encountered, and tool forces again build up. The cutting process is thus a cyclical one with rapid fluctuations in tool forces. Adjacent bits produce parallel grooves, and interaction between these has an important influence on cutting efficiency.

Roadheaders use drag and point-attack bits almost exclusively. These tools also find application on tunnel boring machine (TBM) cutterheads, but in this role they are generally limited to machines operating in weaker formations.

22.1.2.2 Disk Cutting

Disk cutters (Fig. 22.1.1c) generally consist of solid steel alloy discs with a tapered cutting edge. The disk is mounted in a bearing and is free to roll in response to applied forces acting parallel to the rock surface. These rolling forces are analogous to the cutting forces applied in drag bit cutting.

Thrust and drag forces are applied to the disk through the bearing and act normal and parallel respectively to the rock surface. Disks used in practice may be of the simple type illus-

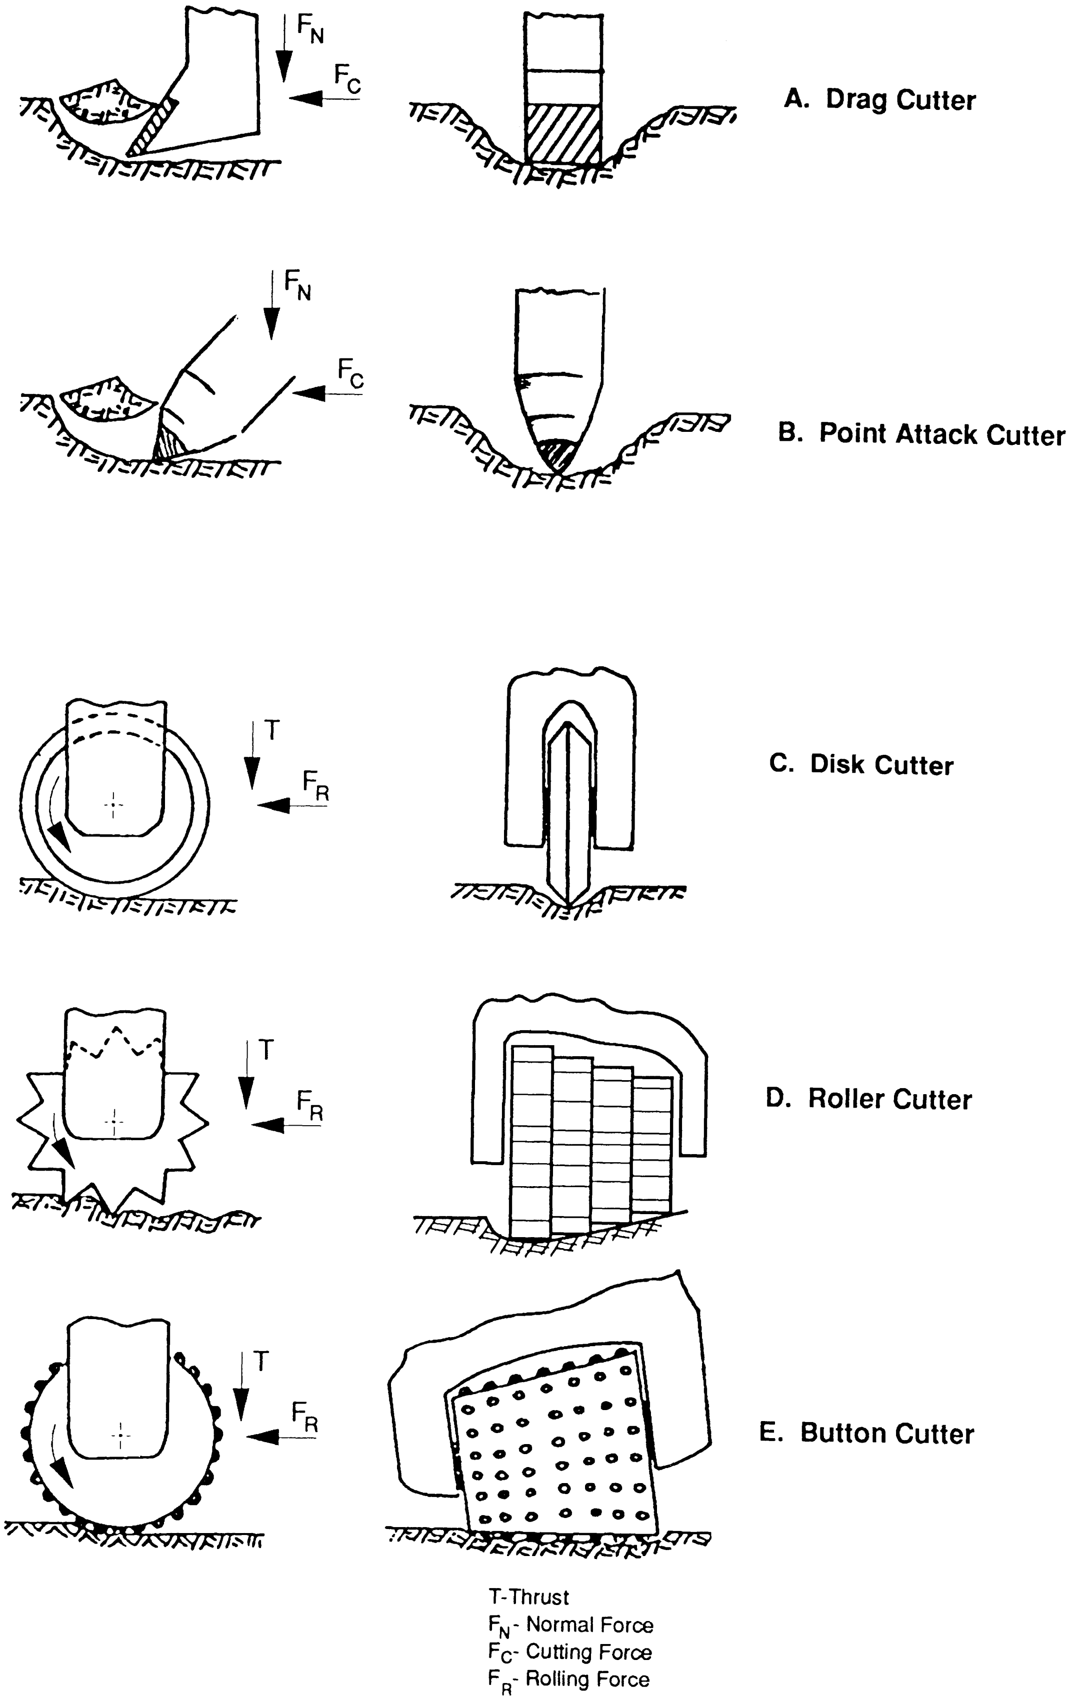

Fig. 22.1.1. Rock cutting techniques (after Roxborough and Rispin, 1973).

trated, or may consist of multi-edge varieties, including types with successively smaller disk diameters giving a tapered or conical arrangement. Frequently these multi-row disks employ carbide inserts with chisel points imbedded nearly flush with the circumference.

Simple disk cutters are used primarily on full face TBMs, and multi-row disks on raise boring machines (RBMs). Thrust forces acting on the cutting head push the cutter into the rock building up stresses which cause local rock failure. Because of the translatory motion of the cutting head, the disk rolls forward cutting a groove in the rock. As in the case of drag cutters, interaction between adjacent grooves has been shown to have an important influence on cutting efficiency.

22.1.2.3 Roller or Mill Tooth Cutting

Roller or mill-tooth cutting is similar to disk cutting except that instead of a tapered disc edge, the tool is equipped with circumferential teeth (Fig. 22.1.1d). As the cutter moves in response to rolling forces, each tooth in turn is pushed into the rock, acting like a wedge, and causing local failure.

22.1.2.4 Button Cutting

Button cutters consist of cylindrical or conical tool bodies inset with tungsten carbide buttons (Fig. 22.1.1e). The tool is mounted in a bearing in the same way as disk cutters or roller cutters and is free to roll in response to applied forces acting parallel to the rock surface. Thrust forces cause high stress concentrations beneath each button as they roll across the rock surface, resulting in local failure and pulverization of the rock. The area of influence of each button is small and results in a fine-grained product. Because the product size is small, specific energy requirements are high and button cutting is the least efficient of the rock cutting methods discussed. Button cutting is used in applications in which high rock strength and abrasivity preclude the use of other methods. These cutters also find application as reaming cutters used for final profiling on RBMs and TBMs.

22.1.3 BASIC METHODS OF PREDICTING INSTANTANEOUS CUTTING RATES

22.1.3.1 Introduction

When considering the feasibility or cost effectiveness of employing a mechanical excavation system, the central questions are (1) Can this machine cut this rock? (2) If so, how fast? and (3) What is the cost of maintaining this performance? Clearly there is a need for a reliable method of performance prediction. Two aspects of machine performance need to be assessed to answer the above questions. First, machine performance in terms of cutting rates or penetration rates must be assessed. Second, the overall system performance and reliability, with particular reference to those aspects that impact machine utilization, must be assessed. In the following discussion, methods of predicting or estimating cutting rates or penetration rates will be described, while methods of overall system assessment will be addressed in subsequent segments dealing with specific mechanical excavation methods.

Prediction of cutting rates requires information on rock material properties, rock mass properties, and machine characteristics. The link between these three groups of data is provided by what may be termed rock-tool or rock-machine interaction models, and the result of applying such a model is an estimate or prediction of performance. In the following discussion, prediction methods are placed into two broad categories depending on whether the interaction model is theoretical or empirical.

Before discussing performance prediction, the following terms must be defined:

Cutting rate (used in conjunction with roadheaders and boom-type tunneling machines) is the rate at which rock is excavated during cutting (volume excavated/cutting time), usually expressed in units of ft^3/hr (m^3/h). Care must always be taken to determine whether quoted "cutting rates" refer to what may be termed the *instantaneous cutting rate* (ICR) or the *operational cutting rate* (OCR). Cutting rates determined under highly controlled conditions, such as a research field test, in which cutting time is recorded as the actual time spent in cutting (determined from instrument measurements of power consumption against time) are instantaneous cutting rates. Under typical operational conditions, cutting time is generally taken as synonymous with utilization. Minor delays resulting, for example, from adjusting the boom position at the end of each cutting traverse, or reduced rates of production during final profiling, are neglected. Cutting rates determined using utilization as the cutting time are termed operational cutting rates. Clearly, performance predictions based on instantaneous cutting rates, without an appropriate cutting time correction, will be overly optimistic. Back analyses suggest that operational cutting rates commonly have values in the range of 0.45 to 0.60 times the instantaneous cutting rate. For final profiling, this figure may drop to 0.3, while during bulk production, an experienced operator may achieve a ratio as high as 0.85.

Specific energy is a commonly used measure of cuttability that is defined as the work done to excavate a unit volume of rock. In the context of rock cutting, specific energy should not be thought of as a fundamental property of the rock. Rather, it is a function of rock properties, cutting tool design, and cutting tool interaction, in the same way as compressive strength is a function of specimen size, shape, and test conditions. Measured specific energies are many times greater than theoretically determined values, the difference being accounted for in energy lost to frictional heating, vibration, and so on.

Penetration rate (used in conjunction with full-face shaft or tunnel boring machines) is the rate of advance measured during the cutting cycle, normally expressed in inches or feet (meters)/revolution or feet (meters)/hour. For practical purposes, instantaneous and operational penetration rates are considered equal.

Utilization is the time remaining for excavation when planned and unplanned machine stoppages have been accounted for. Stoppages are required for a variety of reasons including support installation, survey work, pick replacement, routine and non-routine maintenance, muck haulage delays, shift changes, and so on.

Advance rate is the rate of tunnel or drift advance, usually expressed in units of feet (meters)/day, feet (meters)/shift, etc., and is equal to

$$\text{OCR/face area} \times \text{utilization} \quad \text{or} \quad \text{penetration rate} \times \text{utilization} \tag{22.1.1}$$

22.1.3.2 Theoretical Models of Rock Cutting

Theoretical models have been proposed that attempt to analyze peak forces required, or work done, to excavate a unit volume of rock, and to relate these to fundamental rock properties such as shear and tensile strengths and internal friction angles. All these models have certain weaknesses that limit their usefulness for solving practical problems in machine design and performance. These weaknesses relate to a poor understanding of both the state of stress developed in the rock as a result of the applied forces and the mechanics of crack initiation and propagation. In addition, materials are generally considered to be homogeneous, and the important influence of pre-existing fractures is ignored.

Even with the simple case of a single cutting tool, a complex three-dimensional state of stress must exist in the rock around the tool tip. It is generally acknowledged that in the immediate contact area of the tool, intense crushing of the rock must occur, and that the properties of this crushed material differ markedly from those of the "intact" material. Theoretical approaches generally assume a simplified two-dimensional stress distribution, such as a point or line load, and neglect the properties of the crushed zone and the important role of this zone in transmitting stresses from the tool to the intact rock. Further, in practical cutting applications, multiple tools are arranged in a manner that promotes interaction between adjacent cuts, which has been shown to improve the overall efficiency of the system. This introduces a further level of complexity to the three-dimensional stress distribution that tends to be neglected in theoretical models.

Both brittle and plastic failure modes have been considered in theoretical rock cutting models, the appropriateness of each depending on the initial properties of the rock, and changes induced during cutting. Even in brittle rock, plastic deformation may occur in the intensely stressed zone adjacent to the tool tip. Failure criteria based on both tensile and shear stresses has been applied to rock cutting, although in practice, failure may be initiated in one mode and change to the other as the stress distribution changes during crack propagation. Thus a rigorous theoretical description of rock cutting must incorporate a sophisticated failure model, which accounts for both localized differences in material behavior and transient responses to a changing stress distribution. However, there can be little justification for developing or applying such a failure model until equally sophisticated three-dimensional stress distribution models are available.

APPLICATION OF THEORETICAL CUTTING MODELS TO ROADHEADERS. In the case of roadheaders, the limitations of theoretical models are compounded by the relatively large number of pick geometries available, the mode of roadheader operation (which involves continually varying normal forces), depths of cut and mode of cutting [i.e., sumping, traversing, etc. (Fowell and McFeat-Smith, 1976)], and a generally less-controlled cutting environment. Cutting theories applicable to roadheaders are not considered sufficiently developed at this time to be useful as prediction tools and are not discussed further here.

APPLICATION OF THEORETICAL CUTTING MODELS TO TUNNEL AND SHAFT BORING SYSTEMS. In the case of full-face excavation systems, theoretical modeling problems are less acute. Here, variations in cutter geometries are limited to variations in disk diameter and blade width. In addition, the cutting process is more controlled, involving relatively constant penetration rate and depth of cut, and only a single cutting mode. Because of this, some progress has been achieved in the application of theoretical cutting models, albeit oversimplified, to prediction of the performance of full-face TBMs. The better theoretical models of TBM performance are widely used as prediction tools, however, occasionally a significant deviation occurs. Whether the problem is in the model or in the ability of the sample or geotechnical data to represent the rock mass is not clear.

To be useful, such models must be able to predict thrust forces and rolling forces corresponding to specific depths of penetration in relieved cutting. Conversely, the models may predict achievable penetration given machine constraints governing available thrust and rolling forces. A model of this type will predict machine advance per revolution for a given machine power and tool spacing; a separate calculation of yield per revolution is not required.

Roxborough and Phillips (1975) have presented expressions for thrust force F_t and rolling force F_r, acting on a disk during unrelieved cutting:

$$F_t = 4\sigma_c \times \tan \theta/2 \times (Dp^3 - p^4)^{0.5} \tag{22.1.2}$$

$$F_r = 4\sigma_c \times p^2 \times \tan \theta/2 \tag{22.1.3}$$

where s_c, is unconfined compressive strength (UCS), q is disk edge angle, D is disk diameter, and p is depth of penetration. Based on breakage patterns observed during actual cutting tests, they concluded that the failure process is controlled by shear stresses acting on the plane connecting the apices of adjacent grooves.

Comparison of experimentally determined forces (for Bunter sandstone) with calculated values presented by these workers indicated good correlation. Farmer and Glossop (1980) have presented these equations (slightly modified in the case of F_t), and claim that expressions of this general form are in reasonable agreement with experimentally determined results.

Roxborough and Phillips (1975) also suggest that the optimum spacing/penetration ratio is given by

$$S/p = \sigma_c/\tau \tag{22.1.4}$$

where t is shear strength of the rock. Again, good correlation was demonstrated between calculated and observed *S/p* ratio for Bunter sandstone.

Eqs. 22.1.2 to 22.1.4, however, provide only a partial solution for prediction or head design. Using Eq. 22.1.4, the optimum spacing for a given penetration p can be calculated. Using this value of p, it should then be possible to calculate F_r and F_t for individual tools, using Eqs. 22.1.2 and 22.1.3. The total number of tools can be determined from the optimum spacing and head diameter, and hence the total torque and thrust requirements can be determined. However, these will be overestimated because Eqs. 22.1.2 and 22.1.3 apply to unrelieved cutting, whereas the actual spacing is selected to minimize tool forces.

Because of the current limitation of theoretical models, practical design approaches use empirical methods, as described in 22.1.3.3.

22.1.3.3 Empirical Methods of Predicting Instantaneous Cutting Rates for Roadheader and Boom-type Tunneling Machines

Because of the theoretical difficulties of modeling roadheader cutting performance, approaches to this problem are essentially empirical. It can be claimed that theoretical considerations have shed some light on which material and machine parameters have an important influence on performance, but while these parameters appear in many empirical performance equations, they are always associated with dimensionless constants derived from actual cutting trials or performance data.

The simplest empirical prediction methods are based on the extrapolation of performance records of specific roadheader models under specific geotechnical conditions that match those of the proposed site. While this approach has the advantage of simplicity, it also has a number of weaknesses. It is very difficult to collect high-quality roadheader performance data under other than the highly controlled conditions of a research project. Performance data collected under typical operational conditions,

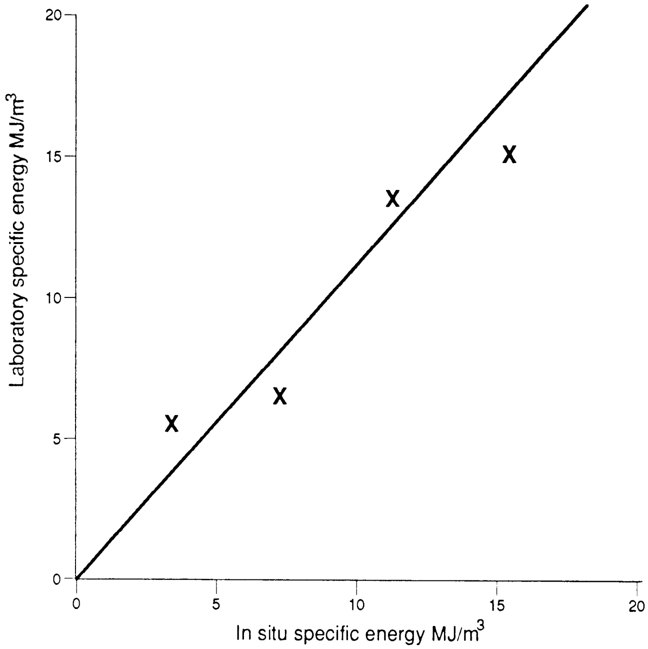

Fig. 22.1.2. Correlation of laboratory specific energy and in situ specific energy (after McFeat-Smith and Fowell, 1977). Conversion factor: 1 Btu/ft^3 = 0.0373 MJ/m^3.

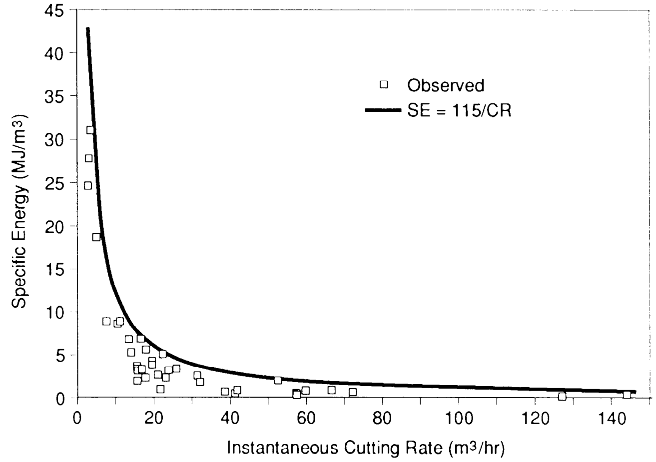

Fig. 22.1.3. Comparison of instantaneous cutting rates and specific energy requirements for a DOSCO MKIIA (after McFeat-Smith and Fowell, 1977). Conversion factors: 1 Btu/ft^3 = 0.0373 MJ/m^3, 1 ft^3/hr = 0.0283 m^3/h.

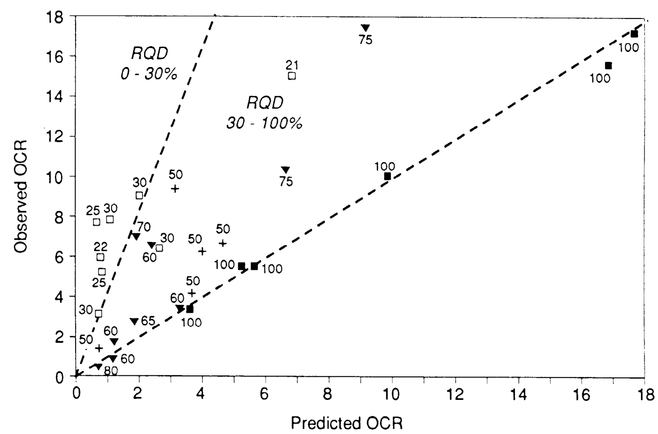

Fig. 22.1.4. Comparison of observed operational cutting rates and operational cutting rate predicted using data from McFeat-Smith and Fowell.

which constitutes the bulk of the data base, must be treated with caution. Furthermore, a good match between geotechnical conditions at the proposed site and a past site may not exist. In this case, the process becomes rather subjective, and there is no clear means of deciding what weight to attach to particular parameters.

In an effort to remove some of the subjectivity and identify important performance predictors, McFeat-Smith and Fowell (1977) investigated the relationships between rock index properties, laboratory specific energies (determined from small-scale cutting tests), in situ specific energies (determined from field-scale cutting tests), and instantaneous cutting rates for a variety of British Coal Measure rocks. Application of multivariate statistical methods to the results of laboratory tests enabled these workers to derive prediction equations that use a small number of index properties to predict specific energy requirements for rock cutting. These predictions were shown to correlate well with field specific energy measured during actual cutting trials (Fig. 22.1.2). Field specific energy was shown to be related to cutting rate using a very simple rock/machine interaction model. Fig. 22.1.3 shows a plot of measured in situ specific energy against cutting rates for Coal Measure strata reported by McFeat-Smith and Fowell (1977). Included on this plot is a theoretical curve developed from the rock/machine interaction model:

$$SE = HP/ICR \qquad (22.1.5)$$

where SE is specific energy, HP is head power, and ICR is instantaneous cutting rate. This curve provides a very good upper bound fit to the measured data, and in most cases shows that actual specific energy was less than predicted to achieve a given cutting rate. This may reflect the tendency of rock mass structural features to reduce specific energy requirements.

Fig. 22.1.4 shows a plot of observed OCRs from various sources, vs. predicted cutting rates using McFeat-Smith and Fowell's predictive equations and the simple rock/machine interaction model given by Eq. 22.1.5. Once again, in nearly all cases, actual performance was better than predicted. When *rock quality designation* (RQD) is considered, the data are seen to fall into two broad fields, although considerable scatter is still present. However, those data points for 100% RQD fall close to the lower bound (i.e., predicted = observed). Many of the points included in Fig. 22.1.4 are for roadheaders with up to twice the cutting-head power of the machine utilized in McFeat-Smith and Fowell's work, and cutting rates for this machine were predicted simply by inserting an appropriate value of HP in Eq. 22.1.5 It would appear, therefore, that these predictive equations may be applicable to a range of machines, provided that appropriate cutting time factor corrections are made. Also, direct determinations of specific energy using core grooving tests could be used in conjunction with Eq. 22.1.5 to predict instantaneous cutting rates.

The predictive equation approach has also been used by Aleman (1983) who has demonstrated good correlations be-

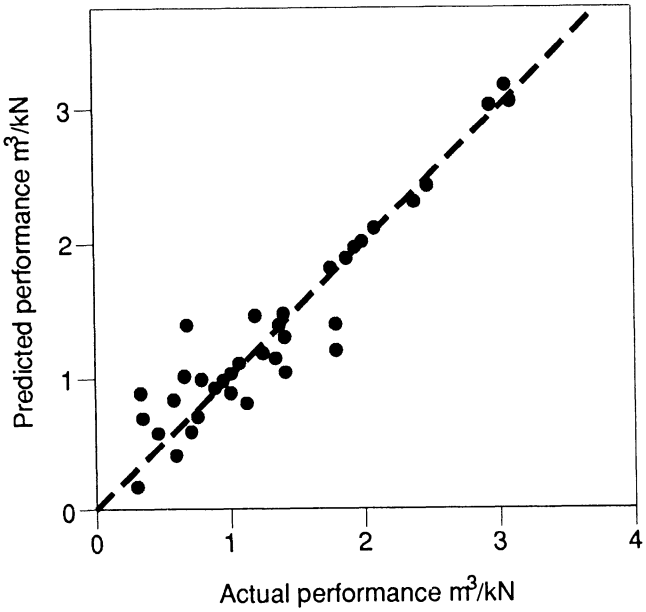

Fig. 22.1.5. Comparison of observed and predicted roadheader performance using Aleman's method (after Aleman, 1983). Conversion factor: 1 ft^3/lbf = 6.6367 m^3/kN.

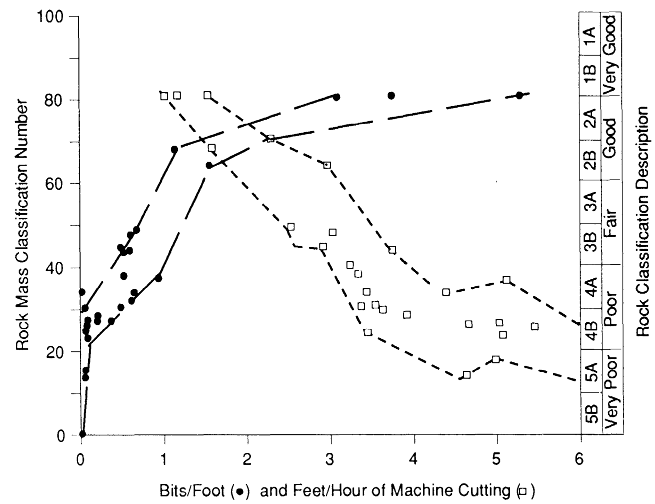

Fig. 22.1.6. Roadheader performance vs. rock class, P.21A Test, 2375 Level (after Sandbak, 1985). Conversion factor: 1 ft = 0.3048 m.

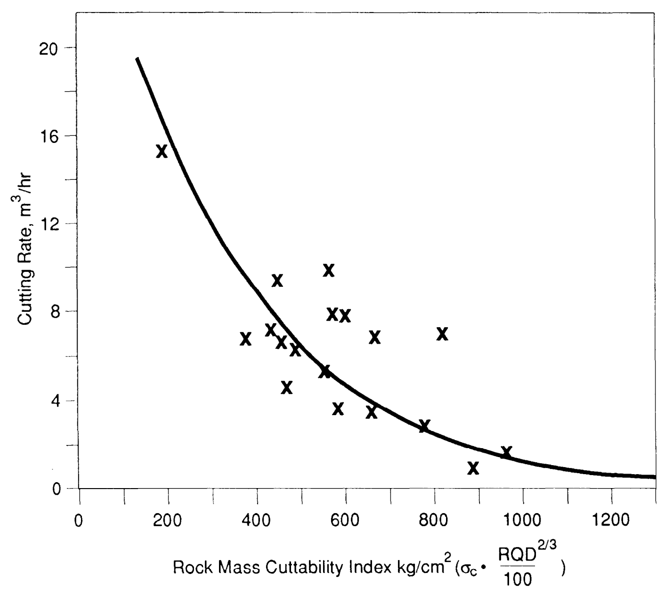

Fig. 22.1.7. Relationship between machine advance rate and rock mass cuttability index (after Bilgin et al., 1988). Conversion factors: 1 ft^3/hr = 0.02832 m^3/h, 1 psi = 0.0703 kg/cm^2.

tween predicted and observed performance for a variety of roadheaders (Fig. 22.1.5). Important aspects of Aleman's approach are the inclusion of RQD and an assessment of microfracturing in the predictive equations so that a secondary assessment of the influence of rock mass condition is not required. The predictive equations are used in conjunction with a more sophisticated machine model than that of Fowell and McFeat-Smith. This approach takes into account the limitations of available arcing force, and head rotation speeds, to derive instantaneous cutting rates.

It is worth noting at this point that many of the indices or parameters that appear in predictive equations, or are referred to in the literature as being significant predictors of roadheader performance, are often strongly correlated. Several parameters show strong correlation with unconfined compressive strength. Therefore it is not surprising that this parameter is shown to be significant in most of the studies undertaken. Where such correlations can be demonstrated, some predictive equations can be simplified to give expressions primarily in terms of unconfined compressive strength.

With good data collection, cutting rates can generally be correlated with rock mass and rock material properties at specific sites. The results of this type of study provide a useful means of predicting performance of a specific machine type under a variety of geological conditions. But since the results are not presented in terms of specific energy (McFeat-Smith and Fowell, 1977) or machine characteristics (Aleman, 1983), the results cannot, strictly, be extrapolated to machine types other than those for which they were derived. Two good examples of this type of study have been reported by Sandbak (1985) and Bilgin et al. (1988).

Sandbak demonstrated correlations between performance (operational cutting rate and bit consumption) and Bieniawski's *rock mass rating* (RMR) for a Dosco SL-120. Although the scatter in the results is rather large (Fig. 22.1.6), the overall trends are clear. Cutting rates are lowest in strong rock with few fractures, corresponding to high RMR values, and highest in low-strength, heavily fractured rocks corresponding to low RMR values.

Bilgin et al. (1988) collected detailed data on machine performance (for a Herrenknecht SM1), rock mass properties and rock material properties. Statistical analyses showed significant correlations between operational cutting rate and the product of UCS × $RQD^{2/3}/100$ (or *rock-mass cuttability index* RMCI, Fig. 22.1.7). These workers also investigated the applicability of the RMCI to prediction of cutting rates for a Dosco Mk 2A and a Pk 2r at other sites and found a reasonable correlation. These results suggest that the RMCI may be applicable to a variety of machines provided that an adequate allowance can be made for variations in head power. It should also be noted that the

Table 22.1.1. Summary of Empirical Roadheader Performance Prediction Methods

Reference	Rock Material Properties	Rock Mass Properties	Machine Characteristics	Rock-Machine Interaction Model	Comments of Applicability
Fowell and McFeat-Smith 1976, McFeat-Smith and Fowell, 1977	(1) Cone indentor hardness, shore hardness, Cementation coefficient, UCS (2) Cone Indenter hardness, 'plastic hardness.'	Not considered	Head power	Empirical—predicts specific energy and instantaneous cutting rate.	(i) Prediction equations can be expressed largely in terms of UCS. (ii) Needs CTF correction for OCR. (iii) Developed for DOSCO MK IIA, may be applicable to other light-medium-duty roadheaders.
Bilgin et al., 1988	Unconfined compressive strength (UCS)	Rock quality designation (RQD)	Not considered	Empirical and machine specific. Predicts OCR for lightweight-mediumweight roadheaders.	Developed for shield-mounted Herrenkneckt SMI. Needs correction for other machine powers and non-shielded or non-stelled machines.
Sandbak, 1985	UCS	Rock mass rating (RMR)	Not considered	Empirical and machine specific. Predicts OCR for lightweight-mediumweight roadheaders.	Developed for DOSCO SL 120. Would need correction for other machine powers/head configurations.
Aleman, 1983	UCS Cerchar abrasivity	RQD microfracturing	Torque, arcing force, head RPM	Empirical—uses machine specific constants linked to geotechnical properties in prediction equations for ICR.	Derivations of empirical constants not presented in cited references.
Farmer and Garritty, 1987	UCS	Deformation modulus	Head power, Energy transfer ratio.	Empirical—predicts cutting rate for selected energy transfer ratio.	
Hurt et al., 1981	Not considered	Not considered	Number & orientation of tools, radial distance, torque, and arcing forces.	Predicts ICR if tool forces are known.	Requires detailed knowledge of head design, machine characteristics.

Herrenknecht machine was shield mounted, a condition which generally results in a more rigid system and hence higher cutting rates than for a non-shielded machine.

The methods discussed above tend to be machine specific and/or utilize empirical constants that are machine specific. Other approaches to performance prediction, which are based on fundamental material properties, have been proposed. Farmer and Garritty (1987) make use of a strain energy approach to predict roadheader performance. Input data for this model includes UCS and deformation modulus of the rock mass. The machine model consists of head power coupled with an energy transfer ratio, which accounts for energy loss as a result of frictional heating, vibration and so on. Results indicate that as little as 1 to 2% of the available energy is actually used in rock breakage.

Table 22.1.1 summarizes the main features of the prediction methods discussed above, including limitations on applicability.

Currently, the best procedure for roadheader performance prediction may be the use of one or more of the empirical methods discussed above, provided that the limitations of these methods are understood. All of the approaches outlined above are deterministic in nature; however, actual case history data indicate considerable scatter even within a single rock type, which may approximate to normal or lognormal distributions. This is because of the inherent variability in rock material and rock mass properties and in operational conditions (including machine and pick condition, operator skill, etc.). A better approach to both the analysis of case history data and the prediction of machine performance is the use of probabilistic methods. Using this approach, geotechnical and operational variables are input to the analysis in the form of probability distributions, the output also being in the form of a probability distribution.

Empirical Methods of Predicting Instantaneous Cutting Rates for TBM and Shaft Boring Systems. Reliable empirical approaches to estimating penetration rates for full-face boring machines are generally far less complex than those previously described for roadheaders. Howarth (1986, 1987) reviewed seven published methods for the prediction of TBM advance rates and concluded that one simplified method (Farmer and Glossop, 1980), based on thrust per cutter and tensile rock strength, provided good correlation with actual penetration rates from 20 case histories. A complex model suggested by Lislerud et al. (1983) was considered to have the potential for more accurate penetration prediction but was discounted on the basis of cost. A brief review of these two methods is provided below.

METHOD DESCRIBED BY FARMER AND GLOSSOP (1980). Farmer and Glossop derived a relationship between the average cutter force F_L, the penetration per revolution P, and rock tensile strength s_{tf} equating the energy input per unit length of cut to the energy required to satisfy fracture surfaces in the rock:

$$P = K\, F_L/\sigma_{tf} \tag{22.1.6}$$

The value of K was obtained by least squares regression of eight cases where P, F_L, and s_{tf} were measured, so that in SI units:

$$P = 624\, F_L/\sigma_{tf} \tag{22.1.7a}$$

with P measured in mm/rev, F_L in kN, and s_{tf} in kPa. The equivalent equation using English units can be written:

$$\frac{P = 0.0158 \times F_L}{\sigma_{tf}} \tag{22.1.7b}$$

with P measured in in/rev, F_L in lbf and s_{tf} in psi.

A similar equation has been suggested by Graham (1976) based on use of the Robbins TBM in hard rock with unconfined compressive strengths ranging from 20,000 to 29,000 psi (140 to 200 MPa).

$$P = \frac{3940\, F_L}{\sigma_{cf}} \tag{22.1.8a}$$

where, s_{cf} is uniaxial compressive strength in kPa.
The equivalent equation written in English units becomes,

$$P = \frac{0.1\, F_L}{\sigma_{cf}} \tag{22.1.8b}$$

As simple ratios are typically used to relate tensile and uniaxial compressive strength (e.g., ranging from 1 : 10 to 1 : 20) either equation, possibly supplemented by additional performance data, may be used.

METHOD DESCRIBED BY LISLERUD (1983, 1988). Lislerud has developed a TBM performance prediction method based on rock mass factors (rock mass jointing, intact rock strength, brittleness, and abrasivity) and machine factors (thrust per cutter, cutter edge bluntness, cutter spacing, cutter diameter, torque capacity and RPM, and cutterhead curvature and diameter). Lislerud's equation for net penetration is written (in SI units):

$$P = i_b \times K_s \times K_d \text{ (mm/rev)} \tag{22.1.9}$$

where i_b is the basic penetration rate in mm/rev and is a function of the thrust per disk and the *drilling rate index* (DRI) as shown in Fig. 22.1.8 (DRI is based on testing described by the Norwegian Institute of Technology), K_d is a correction factor for cutter diameter; and K_s is a correction factor for joint rating and frequency (see Fig. 22.1.9).

As noted by Howarth (1986), this method requires a considerable amount of geotechnical and laboratory test data and is probably only suited to foliated, high-grade metamorphic rocks such as those found in Scandinavia. In less anisotopic rocks, use of the simpler relationships suggested by Farmer and Glossop (1980) and Graham (1976) is warranted.

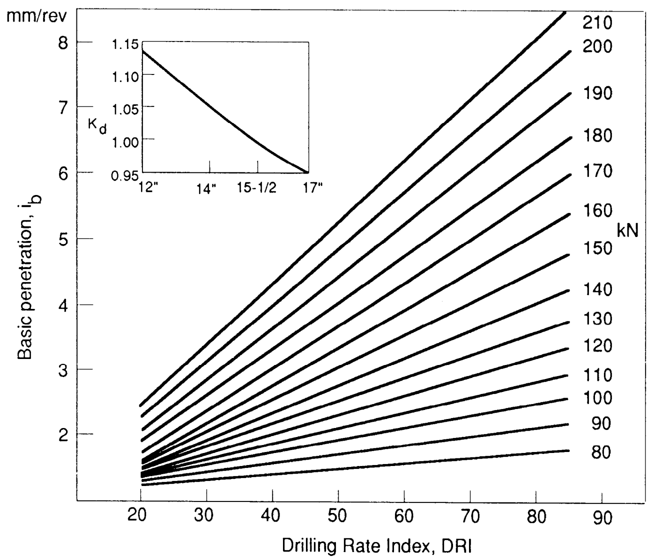

Fig. 22.1.8. Basic penetration as a function of drilling rate index (DRI), average thrust per disk, and cutter diameter (after Lislerud, 1988). Conversion factors: 1 in. = 25.4 mm, 1 lbf = 4.4482 N.

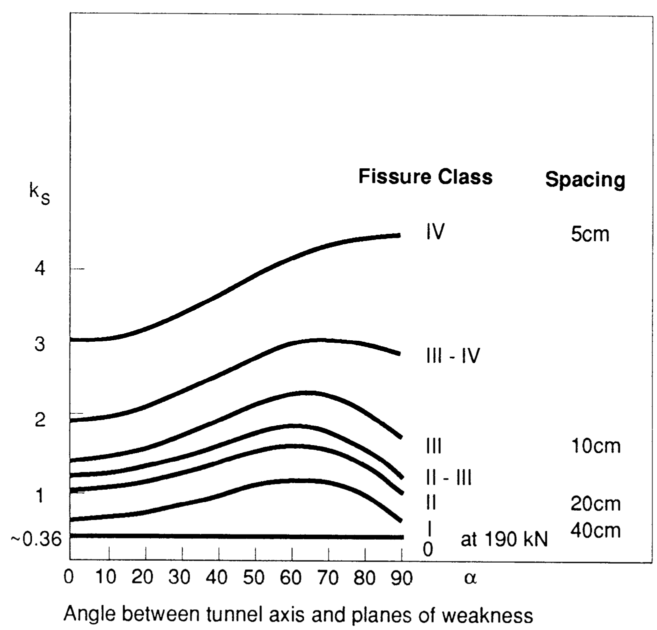

Fig. 22.1.9. Correction factor K_S as a function of fissure class and angle between tunnel axis and planes of weakness (after Lislerud, 1988). Conversion factors: 1 in. = 2.54 cm, 1 lbf = 4.4482 N.

22.1.3.4 Summary

Empirical methods currently provide the best means of estimating machine performance. Such estimates can be made directly based on previous experience in similar ground conditions or can utilize one of the predictive equations. In considering the results, the user should be aware of the limitations of each method. Input should also be sought from machine suppliers or

22.1.4 SHAFT CONSTRUCTION SYSTEMS AND EQUIPMENT

Three major rapid shaft excavation systems are described in this subsection, namely, blind shaft drilling, vertical tunneling mole or V-mole, and raise drilling. Data are included to provide the reader with a means of comparing the relative merits of each system and to assist with method selection.

22.1.4.1 Rotary Blind Drilling Systems

Large-diameter shaft drilling systems are an extension of conventional rotary drilling techniques used extensively for oil well boring. Extensive development work was pioneered by the Atomic Energy Commission (AEC) during the 1960s as part of the US nuclear testing program at the Nevada Test Site. Blind drilled shafts have since provided rapid access for underground mining projects throughout the world and are proven under a wide range of operational and site conditions (see Table 22.1.2 for summarized case study data). System components and operational considerations are described below. A generalized blind shaft drilling equipment set-up is shown in Fig. 22.1.10.

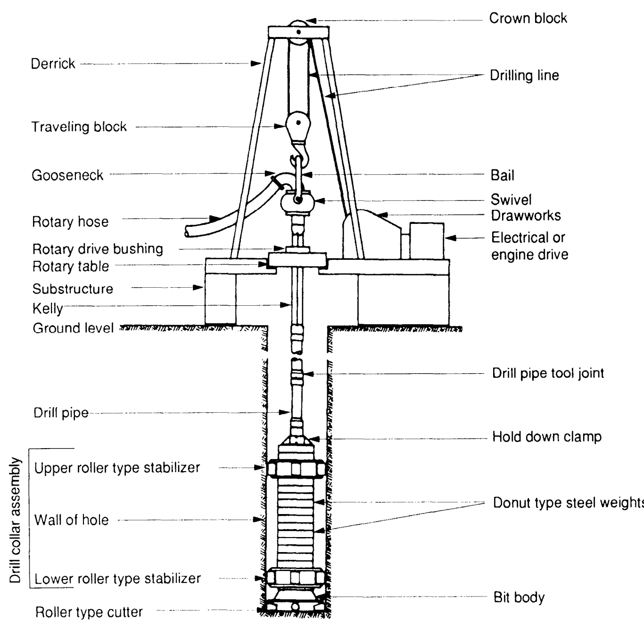

Fig. 22.1.10. Schematic blind shaft drilling equipment setup.

Shaft Collar and Foundation. A shaft collar is typically excavated using either an auger rig or conventional drill-and-blast mining during mobilization of the blind shaft drilling equipment. Collar depth depends on the overall length of the bottom-hole drilling assembly and is designed so that the assembly can be positioned below the drilling rig's rotary table. The collar may be lined with steel, shotcrete, or concrete, depending on ground conditions. A cast-in-place, reinforced concrete foundation will be designed to support the drill rig.

Drilling Rig. Major components of the drilling rig include a mast and substructure, drawworks and tugger hoists, rotary table, crown and traveling blocks, hook, swivel and kelly. The drill pipe and down-hole drill tools are supported by the mast through a conventional crown and traveling block/hook assembly. Static hook load capacities, for large-diameter blind-shaft drilling, may range from several hundred thousand pounds (kilograms) to more than a million pounds (half million kilogram) requiring more substantial masts than typically used for conventional rotary drilling. The rotary drilling motion is transferred from the rotary table to the drill pipe using a square section kelly bar. Mud is pumped to the down-hole system via a swivel located above the kelly.

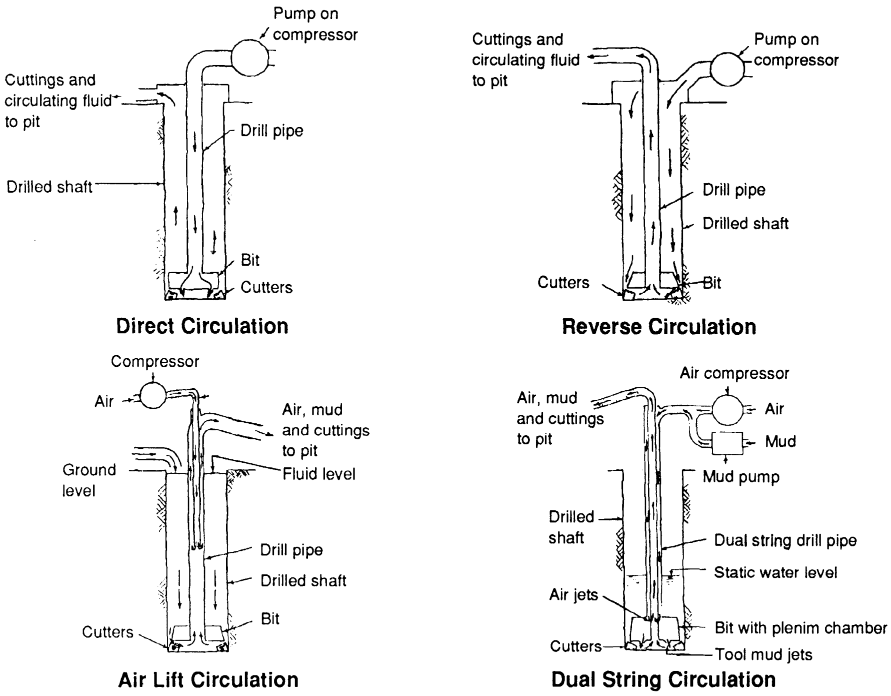

Fig. 22.1.11. Mud circulation systems for blind shaft drilling.

DOWNHOLE DRILLING TOOLS. These include the drill pipe and bottom-hole drilling assembly. Drill pipe is selected based on maximum tensile and torsional loading conditions and consideration of mud circulation requirements; data sheets are available from the pipe manufacturers. A common US drill pipe, used for large-diameter blind shaft drilling, has an outside diameter of 13 3/8 in. (340 mm), weighs 90 lb/ft (134 kg/m), and requires in excess of 100,000 ft-lb (136 kN-m) of makeup torque.

The *bottom hole drilling assembly* includes a drill bit, mandrel, stabilizers, and donut weights. Cutters are mounted in cutter mounts or saddles and bolted to the underside of the flat-bottomed drillbit. The drill bit is in turn bolted to the mandrel that serves as a base for locating donut weights. Donut weights are added to provide the required normal force at each cutter (typically from 10,000 to 20,000 lb (44.5 to 89 kN) per cutter), which is a function of the relative hardness of the formation to be drilled. Donut weights are secured to the drill pipe by a hold-down clamp which forms the top of the bottom-hole assembly. Stabilizers may be added directly above the mandrel and toward the top of the bottom-hole assembly to assist directional control.

OPERATIONS. An important element of blind shaft drilling is to maintain a straight, vertical alignment. The key to effective directional control involves minimizing the fraction of total effective bottom-hole assembly weight transferred to the bit while maintaining acceptable penetration rates. This maximizes the pendulum effect experienced by the bottom-hole assembly and, in conjunction with stabilizers, provides a straighter shaft.

Most large-diameter drilled shafts use air-assisted reverse circulation. Drilling mud is added to the hole at ground level and circulated through the cutters and up the inside of the drill pipe. Air is added inside the drill pipe causing a density imbalance that induces flow rates sufficient to remove the drill cuttings. Air-assisted reverse circulation and alternative mud circulation systems have been described by Lackey (1982) for blind-shaft drilling at the Nevada Test Site (Fig. 22.1.11). The "dual-string airlift reverse circulation" method incorporates a plenum chamber in the drillbit and dual string drill pipe. Mud and compressed air are pumped down the outer annulus of the drill pipe to the plenum chamber where the air separates from the mud. Mud flows through the plenum chamber and is forced through fluid jets located in the bit in order to clean the hole bottom. The air is routed through the top of the plenum chamber into the inside of the inner string and induces upward flow of mud and drill cuttings. Mud flows from the top of the drill pipe into the first mud pit where up to 90% of the cuttings drop out. Overflow from the first mud pit goes to the second and third where the remaining cuttings settle out.

GROUND SUPPORT. A cake of mud is deposited on the shaft walls during drilling. The thickness and strength of this cake may be optimized based on cuttings removal and ground support requirements to prevent mud loss during drilling. Control of mud density and head (i.e., height of mud column) acting against this impermeable surface permits shaft excavation in poor ground.

SHAFT LINING. The final lining for a blind drilled shaft typically consists of a ring-stiffened steel liner. This is equipped with external guides to facilitate grout line deployment and is outfitted internally.

Liner sections are fabricated offsite in lengths compatible with transportation and handling requirements; sections may be up to 60 ft (18 m) in length. The liner is lowered into the mud-filled hole using either casing jacks or the drill rig. Each liner section is aligned and welded to the one below to provide a completely water-tight membrane. Loads on the casing jacks may be limited, in the case of deeper shafts, by capping the bottom liner section so that the liner can be "floated" into place. Water is pumped into the casing to control buoyancy as the capped liner is lowered into the shaft. When liner installation is complete, the annulus between the steel liner and the shaft wall is filled with grout.

Other lining systems, compatible with the concept of rapid, remotely controlled placement, have been developed but are not

Table 22.1.3. Breakdown of Blind-drilling Project Costs

in common use. These include slip forming (both bottom-up and top-down), jump forming, precast concrete cylinders, and remotely placed shotcrete. Finally, if ground conditions permit, conventional lining placement techniques (e.g., involving slip forming, jump forming, or shotcrete, placed using a galloway) may be used.

BLIND-DRILLING SYSTEM PERFORMANCE PREDICTION. The performance of a blind shaft drilling system is simply defined as a function of the operational penetration rate and the system utilization. Penetration rate is, in turn, a function of the geology (rock strength, fracture frequency, hardness, abrasivity); drill assembly (cutter type, size, and spacing; cutter load; and available torque); and cuttings removal system. Moss et al. (1987) developed a *drillability index* to predict relative penetration rates in rock rated from exceptionally poor (Q = 0.001 [Barton et al., 1974]) to fair (Q = 10) with intact strengths ranging from 3000 to 43,000 psi (21 to 297 MPa). Variations in average penetration rates were smaller than expected and correlation with the index was poor. Several important observations were made as a result of this case study:

1. Lower than predicted rates of penetration in clay were thought to be due to plugging of the bit. Associated problems included reduced mud circulation rates and poor control of shaft verticality.

2. An increase in the rolling resistance when drilling in rock of lower rock mass quality was thought to result from fragments that were larger than those normally resulting from the cutting action.

The results of this study serve to illustrate the potential shortcomings in generic performance prediction systems. The operational penetration rate for a blind-shaft drilling project can be estimated using available equipment specifications and the simple relationships suggested by Farmer and Glossop (1980) and Graham (1976). Adjustments are required for available thrust, calculated as 30% of the sum of the weights of down-hole components corrected for buoyancy from the drilling mud and imperfect hole cleaning (Maurer, 1962).

High utilization factors are possible for well-planned operations; for example, Hunter (1982) reports utilization factors of 74, 80, and 79% for the three Crown Point Project shafts.

BLIND-DRILLING COSTS. Table 22.1.3 provides a breakdown of blind-drilling cost components and their relative contribution to total project costs. It can readily be seen that the project costs are dominated by the acquisition and installation cost of the steel casing used for final lining.

22.1.4.2 Other Blind Boring Systems

A manned blind-shaft boring (BSB) system, with operators located underground, was developed and demonstrated by the Robbins company in the late 1970s. A 24.5-ft (7.5-m) diameter shaft was sunk to a depth of 587 ft (179 m), proving the application of horizontal tunnel boring methods to vertical shaft boring. The BSB used a full-face rotary cutterhead equipped with 56, 13-in. (330-mm) disk cutters with a conveyor bucket elevator mucking system (Fig. 22.1.12). A second generation shaft boring machine (SBM) (Fig. 22.1.13) has subsequently been developed by a Redpath/Robbins team to mechanically excavate a 20- to 24-ft (6- to 7.3-m) diameter shaft. The second generation machine incorporates a 10-ft (3-m) diameter cutter wheel fitted with 28, 15.5-in. (394-mm) cutters for a 20-ft (6-m) shaft diameter and a boom-mounted clam-type mucking unit.

Hendricks (1985) presents a detailed prediction of the performance of the SBM in hard rock (18,000 to 30,000 psi or 124 to 207 MPa) shaft construction. Fig. 22.1.14 has been reproduced from this text to simply illustrate the predicted cost and schedule advantages of the SBM over conventional shaft mining methods.

22.1.4.3 Vertical or V-mole System

The V-mole is a horizontal tunnel boring machine modified for vertical deployment by the German firm Wirth. First introduced to construct large diameter (16 to 21.5 ft, or 4.88 to 6.55 m) shafts in Europe in the early 1970s, it has since been used to construct four 23-ft (7-m) diameter shafts for an Alabama coal mine. Summary data for these case studies are presented in Table 22.1.4. The equipment, shown in Fig. 22.1.15, consists of the cutterhead, drive assembly, thrust and directional control cylinders, kelly, gripper assembly, and work platforms.

The gripper assembly, consisting of 8 to 12 grippers, provides resistance to the thrust and torque required for rock boring. Rotary motion is transmitted from the gripper assembly to the cutterhead through a kelly and up to 6 thrust cylinders are controlled by the operator to provide the required penetration rate. Muck is removed into a pilot hole by scrapers located on the cutterhead. The shaft lining is placed from work platforms located above the gripper assembly providing a continuous excavation/lining cycle. Services and support equipment are deployed using techniques traditionally associated with conventional shaft sinking.

In addition to the obvious differences in down-hole tools, the V-mole requires a pilot hole for muck removal. However, offset reaming can be controlled by the operator, allowing some deviation from pilot hole direction to be accommodated during sinking.

22.1.4.4 Raise Boring Systems

Raise boring has been used to drill shafts ranging in inclination from horizontal to vertical with a majority of applications involving large-diameter holes steeper than 45° (see Table 22.1.5 for summarized case study data). System components and operational considerations are described below. A generalized raise boring equipment setup illustrating the available range of deployment methods is shown in Fig. 22.1.16.

CONVENTIONAL RAISE BORER.

Setup and Equipment—A *raise collar* is sometimes used to support the raise drill and provide sufficient vertical clearance for the reaming head during holing through. Conventional shaft collar excavation and lining techniques typically are used to construct the raise collar. The raise drill is positioned on a steel substructure anchored to the collar lining after completion of the pilot hole.

The *pilot hole* can be drilled during mobilization of the major plant using rotary drilling methods, however, more pilot holes are drilled with the raise drill after it is positioned. Since the

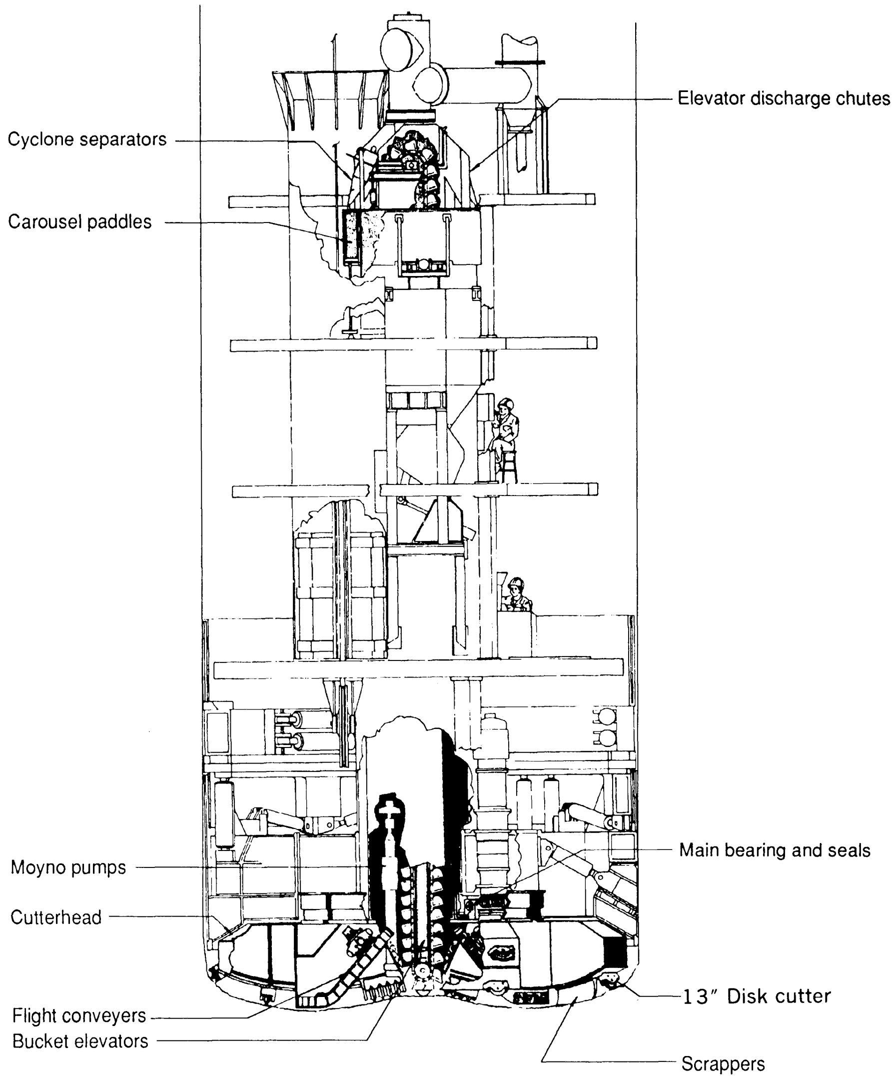

Fig. 22.1.12. Blind-shaft-borer down-hole equipment (*courtesy:* Robbins Co., Seattle, WA, Model 2418B-189).

accuracy of this borehole directly influences shaft verticality, great care is taken to ensure that the pilot hole is drilled within owner-specified tolerances. Directional surveys are routinely performed every 25 or 50 ft (7.5 to 15 m) using conventional oil well survey techniques.

A skid-mounted raise drill typically consists of a crosshead, positioned between two cylindrical guideposts, and hydraulic rams that lift the head and apply thrust, via the drill rods, to the reaming head. Rotary motion is provided through a ring gear and motor/reducer installed on the crosshead.

The raise borer reaming head is transported underground during drilling of the pilot hole. Underground set-up involves assembly and attachment of the reaming head to the raise drill rods and preparation of the underground mucking system.

Operations—Initial raise drilling is conducted at low thrust and RPM until all cutters on the reaming head are in contact with the rock. Thrust and rotation are varied by the raise operator to provide optimum penetration for each stratum encountered. Cuttings fall through the reaming head and are removed at the shaft bottom using the mine's mucking equipment; common practice involves maintaining the cutting pile flush with the mine roof to reduce airborne dust levels.

The reaming head is immobilized and suspended from steel fixtures cast into the shaft collar concrete following break-through. It can be removed from the shaft, after the raise drill and steel foundation are demobilized, using a small crane.

A comprehensive paper by Worden (1985) provides a detailed, pragmatic description of activities involved in the reaming cycle.

Ground Support—Raises are commonly unlined since raise boring is typically used in relatively competent formations. However, if ground conditions or use dictate the installation of a final lining, there are a few rapid lining systems to choose from.

DOWN-REAMING RAISE BORING. A small proportion of raise-bored shafts have been excavated using an upward-drilled pilot hole with downward reaming to full shaft diameter. The advantage of reduced pulling capacity, associated with down-reaming, is more than offset by problems associated with muck handling (muck must travel down the pilot hole alongside the drill pipe) and cutter replacement.

DOUBLE-PASS RAISE BORING. Shaft size limitations in conventional raise boring are primarily associated with exponentially increasing torque requirements and the cost/feasibility of machine and tooling upgrades. As noted earlier in this chapter, the required torque is a function of the sum of the individual cutter rolling resistances multiplied by the mount radius and the torque required to overcome friction between the drill pipe and pilot borehole. As both the number of cutter kerfs and the aver-

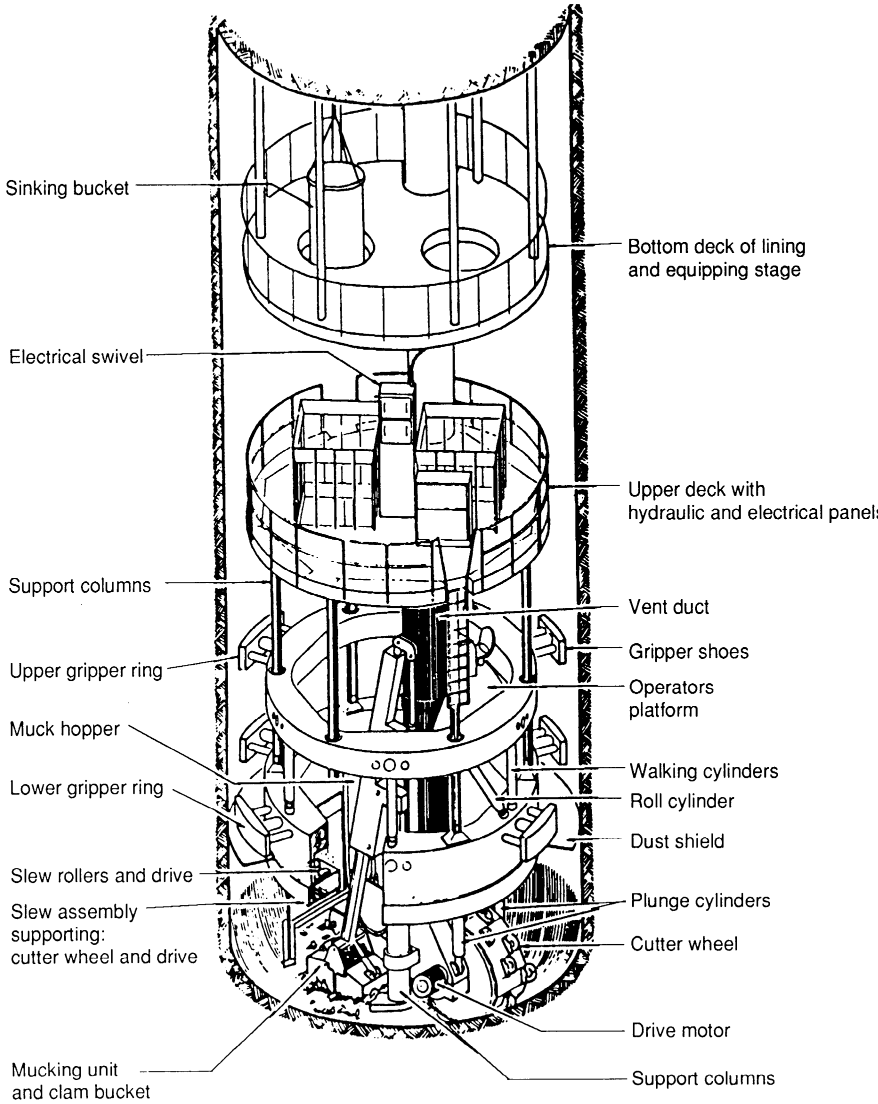

Fig. 22.1.13. Shaft boring machine, 20 to 24 ft (6 to 7.3 m) (*courtesy:* Robbins Co., Seattle, WA).

age mount radius are proportional to the shaft diameter, the required cutterhead torque is proportional to the square of the shaft diameter. Excavation of shaft diameters beyond the single-pass capability (machine and drill-pipe capacity) of onsite equipment can be accomplished by reaming a smaller shaft with second-pass reaming to full size. Reaming heads should be selected to optimize the torque distribution and drilling load. Stabilizers are essential when second-pass reaming in longholes to prevent drill string whip. Alternatively, the raise may be sequentially reamed in short sections.

TWO-STAGE SEQUENTIAL REAMING-HEAD RAISE BORER. The two-stage sequential reaming head was first introduced in South Africa in 1985 as an alternative method of reaming larger-diameter, deeper shafts in hardrock. In operation, the smaller head is sumped in and advanced about 3 ft (1 m) (Fig. 22.1.17). This head is then retracted, and the remaining shaft area is reamed by the larger head; this cycle is repeated until the raise is completed. The first sequential-head raise borer, using an 8-ft (2.44-m) primary and 12-ft (3.66-m) secondary reamer, was used to bore three, 300-ft (91-m) deep ventilation raises at the Western Areas Goldmine. Wirth, in conjunction with Rocbor Raise-boring and Mining Contractors, subsequently developed the HG330 raise borer 14-ft (4.3-m) primary and 20-ft (6-m) secondary reaming head) that has been used during construction of raises up to 3200-ft (975-m) deep (Schmidt and Fletcher, 1987). Many of the early problems, typically associated with a protypical method, have been resolved according to Schmidt and Fletcher (1987). Outstanding issues, traditionally associated with large-diameter shaft construction, include excavation in poor quality and blocky ground, presence of large groundwater influx, and the impact of pilot hole accuracy on final shaft verticality. This latter constraint currently restricts most large-diameter raise developments to shafts that will not be outfitted.

Blind Raise-boring—Blind raise boring, or boxhole drilling has been used in the South African goldfields to construct small-diameter (5 to 6 ft [1.52 to 1.83 m]) raises up to 500 ft (152 m) in length. Raise boring can be conducted with a predrilled pilot hole or blind (without pilot hole) at advance rates between 4 and 6 ft (1.22 to 1.83 m)/hr (Friant et al., 1985).

Raise-boring System Performance Estimation—System performance, at a conceptual level, can be estimated using the case study data in Table 22.1.5 or by using Eq. 22.1.7 or 22.1.10. For example, a mine requires construction of 400-ft (122-m) long, 10-ft (3-m) diameter ventilation shafts in granitic rock with uniaxial

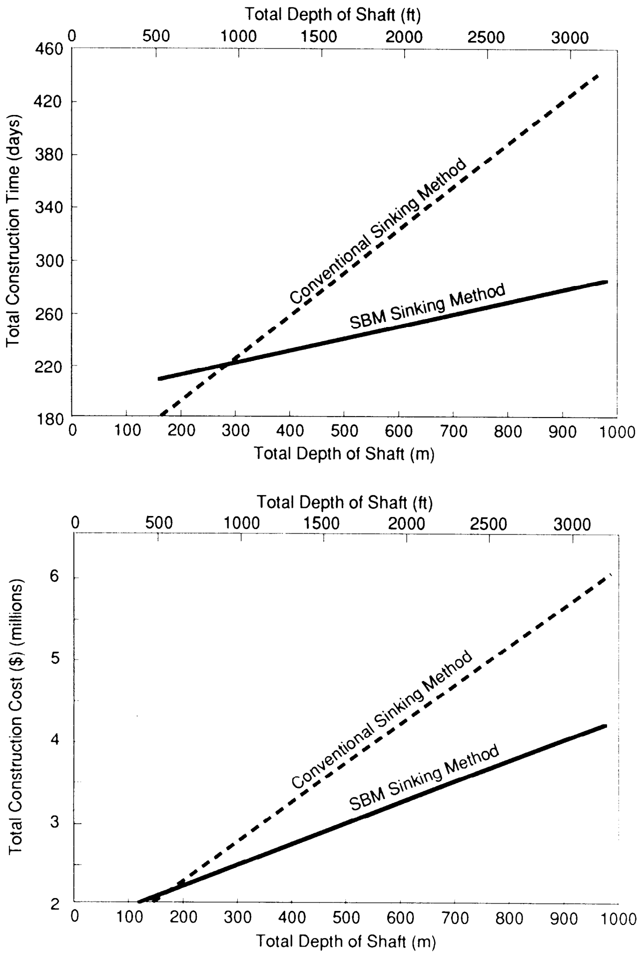

Fig. 22.1.14. Predicted performance of shaft boring machine (after Hendricks, 1985).

compressive strength ranging from 24,000 to 30,000 psi (165 to 207 MPa). Excavation is in good quality rock, and stress or structurally controlled failures of the rock mass are not considered to be a problem for this shaft diameter. From the case study data, pilot-hole drilling rates can be expected to range from 6 to 9 fph (1.83 to 2.74 m/h), with reaming rates from 2 to 3.7 fph (0.61 to 1.13 m/h). The project appears to be well within the range of a number of raise borers, including the RBM-7, and will require a nominal 12.25- or 13.75-in. (311- or 349-mm) pilot hole; pipe size and tooling requirements should be selected by the contractor.

Example 22.1.1. Estimate the penetration rate for a raise drill; using the following machine data available from the manufacturer,

Maximum available thrust	2,000,000 ft-lb	8,900 kN-m
Maximum torque	2,150,000 ft-lb	8,474 kN-m
Maximum recommended thrust/cutter	25,000 lbf	111 kN

Solution. Assume s_{tf}/s_{cf} for granite = 1 : 14.
From Eq. 22.1.8,

$$P = \frac{0.1 \times 25{,}000}{27{,}000} \qquad P = \frac{3940 \times 111}{186 \times 10^3}$$

$$= 0.093 \text{ in./rev.} \qquad = 2.35 \text{ mm/rev}$$

$$P_{HR} = \frac{0.093 \times 8 \times 60}{12} \qquad P_{HR} = \frac{2.35 \times 8 \times 60}{12}$$

$$= 3.7 \text{ fph, or} \qquad = 1.13 \text{ m/h.}$$

which must be derated for utilization

Raise-bore Costs—Economic factors of mechanical raise boring have been discussed by Norman and Dye (1978), and a detailed breakdown of a raise-bore contractor's bid is presented in Nash (1982). Table 22.1.6 details the essential elements of a raise boring project for which costs should be estimated, and

Fig. 22.1.18 provides a rough guide to project costs as a function of raise diameter and required torque.

22.1.4.5 Selection of Shaft Construction Method

Selection of the appropriate shaft construction technique for a given site involves an in-depth analysis of site geomechanical and geohydrological conditions, design criteria (e.g., diameter and depth, shape, use, life, etc), and availability and location of equipment, plus a determination of their relative impact on project cost and schedule. Cost is nominally the overriding consideration; however, timing may be critical, and higher shaft construction costs may be off-set by rapid access to the ore body.

SITE-SPECIFIC DATA REQUIREMENTS. The geotechnical data set required for shaft design and construction bid package preparation is essentially the same for all shaft construction methods. The site investigation program should incorporate a fully logged core hole located within one shaft diameter of the proposed shaft centerline. (Note: a borehole on shaft centerline is preferred; however, the verticality of this borehole may impact the construction method if a pilot hole is required.) This borehole should be geotechnically logged (e.g., recovery, RQD, discontinuity description, lithology, rock description) and core samples selected for testing (e.g., uniaxial compression, slake durability, swelling, hardness, petrographic analysis). Samples may also be required by cutter manufacturers for proprietary drillability testing. Hydrogeologic data should be obtained by profiling the borehole using a down-hole (in line with drilling) or straddle packer test tool. Data analysis will provide the location and magnitude of groundwater inflows, shaft wall stability and rock support requirements, shaft liner design loads, rock mass data for blast design, and estimates of drill penetration rates, bit wear, cuttability, and overall suitability for mechanical excavation. These services are available from mining geotechnical companies and have been described extensively in the literature (e.g., see Hoek and Brown, 1980; Goodman, 1980).

METHOD SELECTION GUIDELINES. As previously noted, the overall selection of an appropriate shaft construction method must be made on the basis of cost and schedule. This analysis may be supported initially by conceptual designs as described in this section. However, a final decision should be made in consultation with personnel experienced in the field application of each technique.

Factors influencing the selection of each shaft construction method have been assembled and are presented in Table 22.1.7. At a broad conceptual level, the blind-shaft drilling method is preferred for conditions where

1. Freezing would be required for groundwater control during conventional shaft excavation.
2. Shaft lining requirements dictate the use of a fully hydrostatic steel/concrete lining.
3. Rapid access outweighs added cost.
4. Disturbance of the surrounding rock is a prime criterion.
5. Access is not available for subsurface muck removal.

Use of the blind shaft borer (BSB) or V-mole may be preferable where

1. Adverse impacts of groundwater inflow can be economically mitigated prior to construction (e.g., through grouting) and/or are relatively easy to handle during excavation.

Conversion factors: 1 in. = 25.4 mm, 1 psi = 6.895 kPa, 1 ft = 0.3048 m.

2. Rock quality permits stand-up times compatible with the V-mole's mining cycle.

3. Rapid access outweighs added cost.

4. Minimum disturbance of the surrounding rock is a prime criterion.

5. Access is available for setup and underground muck removal.

6. Geologic structure permits pilot-hole drilling to the tolerances required by the shaft designer (V-mole only).

7. Immediate access to drilled strata for geologic logging, instrument installation, and testing is required.

8. There are no existing mine openings (BSB only).

Raise drilling may be preferred where

1. Site conditions (e.g., rock quality and absence of large groundwater inflows) provide for stable excavation conditions.

2. Access is available for setup and underground muck removal.

3. Geologic structure permits pilot-hole drilling to the tolerances required by the shaft designer.

4. Design requirements (e.g., diameter, depth) are compatible with available equipment capabilities.

Under these conditions, raise drilling may offer a less costly alternative to all other methods of shaft construction.

22.1.5 RAPID EXCAVATION SYSTEMS FOR HORIZONTAL AND SUBHORIZONTAL MINE DEVELOPMENT

Three rapid excavation systems are described in this segment, namely, full-face tunnel boring, mobile miners, and roadheaders or boom-type tunneling systems. Data are included to provide the reader with a means of comparing the relative merits of each system and to assist with method selection.

22.1.5.1 Full-face Tunnel Boring Systems

Full-face boring systems or TBMs have been in common use in civil tunneling for many years but are used less frequently in mining projects. Nevertheless, TBMs in European coal mines and the TBM at the Stillwater Mining Company's platinum/palladium mine near Nye, MT (Tilley, 1989) are proving the

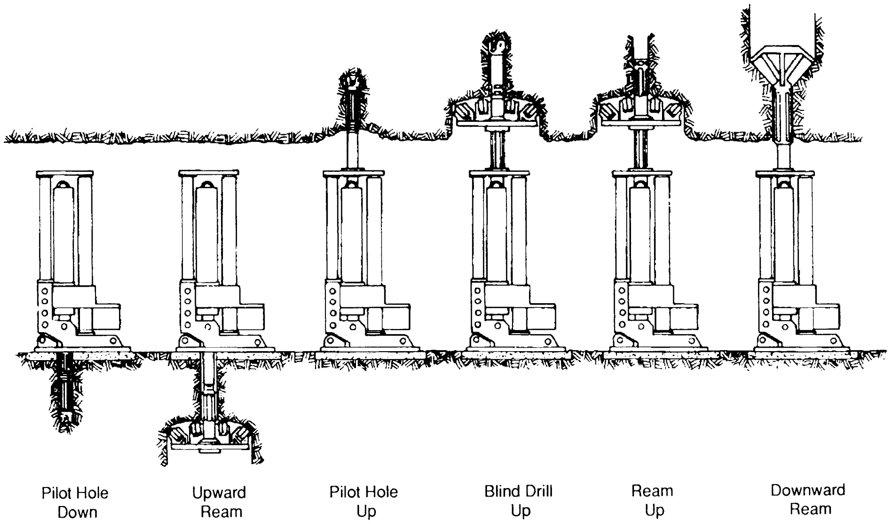

Fig. 22.1.16. Alternative raise boring methods (after Friant et al., 1985).

viabilty of TBMs in mine development. These experiences may spur more widespread acceptance and utilization of this method of mechanical drivage within the industry. Constant development and improved tooling have resulted in machines that are capable of advancing large-diameter openings in strong igneous and metamorphic formations at rates that compete favorably, and in many cases exceed, conventional drill and blast methods. Tilley has reported advance rates up to 165 fpd (50 m/day) and 700 ft/wk (213 m/wk) for operations at the Stillwater mine.

In addition to high advance rates, TBMs leave a smooth profile and minimize ground support requirements. A disadvantage of TBMs is their wide turning circle, although a range of mini-fullface machines are available that have smaller turning radii. The high initial cost of these machines is balanced by low running costs compared to drill and blast excavation systems. Fig. 22.1.19 shows the cutterhead, shields and operator console of a hard-rock double-shield machine designed for use in claystone, mudstone, sandstone and shale excavation. Fig. 22.1.20 shows a large-diameter hard-rock TBM equipped with a slotted shield to facilitate support installation. Breakthrough of a 20-ft (6-m) diameter drivage in limestone is also shown. System components and operational considerations are described below. A generalized TBM equipment setup is shown in Fig. 22.1.21.

SETUP AND EQUIPMENT. Full-face boring machines consist of a rotating cutting head fitted with disk cutters, drag bits, button bits, or various combinations of these. Advanced machines are available on which the tool type can be changed and tool spacing varied. These developments have arisen from the need for machines that can cope with a variety of poor ground conditions. The cutting head may be an open structure with spoke-like cutting arms, or it may completely conceal the face except for muck-removal openings and access ways for tool maintenance. The open-type head gives better access to the face and tools, and can be used with a forepoling arrangement.

Cutting forces are provided by the head rotation, while normal forces are provided by the thrust of the machine against the tunnel face. Reaction to this thrust is provided by grippers mounted on the TBM body, which in turn react against the tunnel sidewalls. Mucking is performed by buckets mounted on the periphery of the cutter head, and muck is removed via a central conveyor system.

OPERATIONS. Preparations for TBM excavation typically involve portal construction, placement of a concrete pad on which the TBM will be assembled, and installation of support services and equipment. Careful excavation, including the use of controlled blasting techniques, is usually required to mine the setup area to the tight tolerances required. Placement of a thin, 1- to 2-ft (0.3- to 0.6-m) concrete layer against the start-up face is recommended to reduce out-of-balance loads. TBM excavation is a continuous process, with cutting, mucking, and support installation proceeding concurrently. As the cutting head rotates, it moves forward, reacting against the grippers. The grippers are repositioned periodically when they reach the limit of their travel. On Wirth and Jarva TBMs, the grippers are also used to steer the machine. Robbins and Domag TBMs steer while boring using a floating main beam.

Mucking in the immediate vicinity of the face is done by buckets located on the head periphery, and a central conveyor system that moves the muck through the body of the machine to a bridge conveyor. The bridge conveyor allows access for track laying and service installation without disrupting the mucking operation. A variety of mucking systems can be used to haul muck to the surface, but typically conveyors or shuttle trains are used. Adequate muck removal rates are critical to optimum face advance rates.

The orientation of the TBM is controlled by the grippers, in conjunction with a laser beam and microprocessor-controlled guidance system. These allow precise positioning of the machine, but problems may still be encountered in weak or soft ground in which the effectiveness of the grippers is greatly reduced. In these situations, 3-dimensional orientation control is facilitated by TBMs, that steer while boring.

SUPPORT SERVICES AND EQUIPMENT. The trailing gear following the TBM provides an interface with the support utilities and equipment installed in the completed tunnel up to 650 ft (200 m) behind the machine. Components, and their configuration, are primarily a function of tunnel size and may include:

1. Bridge conveyor required to transport muck from the TBM to the muck cars.

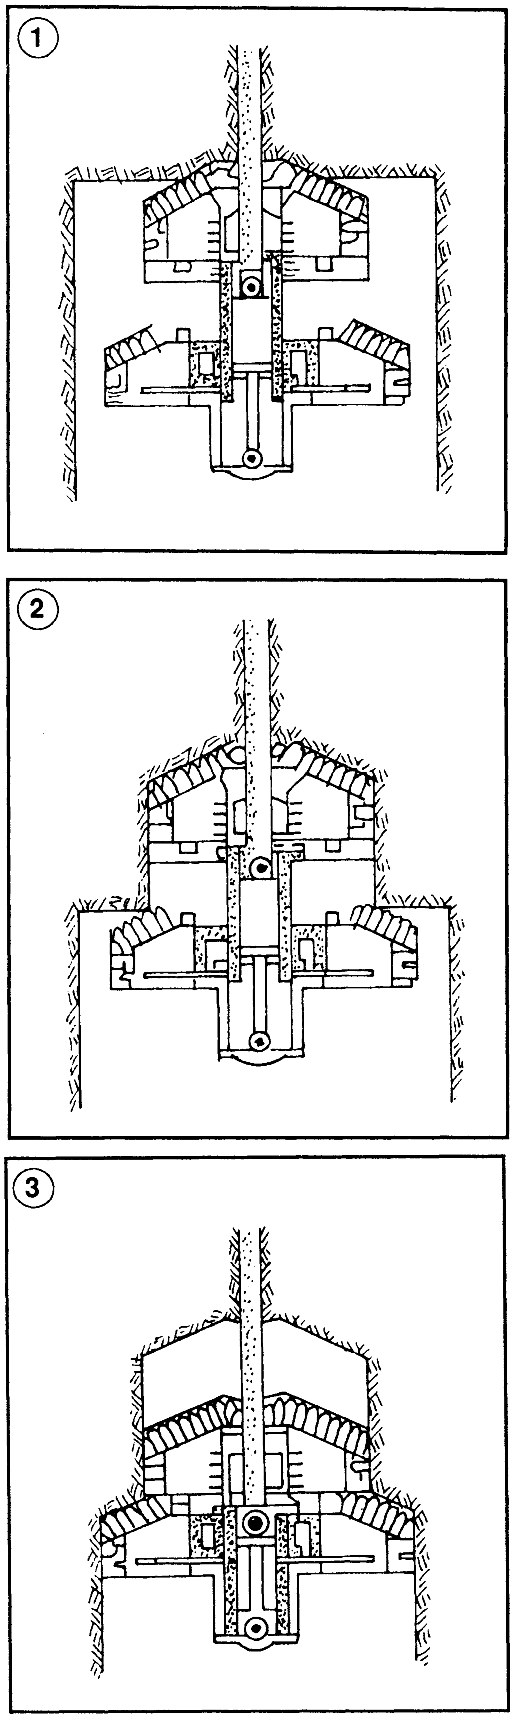

Fig. 22.1.17. Sequential reaming sequence (after Schmidt and Fletcher, 1987).

2. Dual-track rail system with remote muck car loading and handling (for larger diameter tunnels).

3. Telescopic ventilation line, auxiliary fan(s), and scrubber system.

4. Hydraulic power unit, transformer(s), and trailing cable.

5. Supply hoist for unloading and moving supplies.

6. Rock drill (for bolt installation), rock drill power unit, and rock bolt supplies storage.

7. Mechanical shop and cutter and supply storage area.

System components are briefly described below; more detailed descriptions and specifications are contained in the references cited at the end of this chapter.

Haulage System—Rail systems are commonly used to transport muck during TBM excavation. Various types of muck cars and trailing gear are available that facilitate continuous loading. Additional details, regarding conventional muck haulage systems, are presented in Chapter 9.3. Alternate muck removal systems, incorporating pneumatic or hydraulic transport of crushed muck, have been used in a small number of civil tunneling projects.

Ventilation System—The ventilation system typically consists of 24- to 36-in. (610- to 914-mm) ventilation pipe with in-line booster fans located several thousands of feet (meters) apart along the tunnel. The system is designed and deployed to maximize the cross-sectional area available for mucking equipment and is normally configured to exhaust air to the portal (Chapter 11.6).

Electrical System—The electrical system typically consists of a high-voltage feeder cable with stepdown transformers mounted on the trailing gear and at strategic locations along the tunnel to service ventilation fans, lighting, pumps, etc. (Chapter 12.4). Total installed power requirements can be roughly approximated at twice the predicted TBM consumption.

GROUND SUPPORT. Rock support requirements (Chapter 10.5) for hard-rock TBM drivages are generally minimal and estimates have suggested that the savings in rock support costs (compared to drill and blast) can offset the cost of the machine in as little as 4 miles (7 km) of tunnel drivage (McFeat-Smith, 1982). Hard-rock TBMs are commonly equipped with a partial or slotted shield, and when support is required, conventional rock support methods are used. Both soft-rock and hard-rock TBMs can be equipped with a full shield and segmental linings installed. This equipment enables hard-rock TBMs to cope with localized occurrences of soft ground.

TBM PERFORMANCE PREDICTION—SIMPLIFIED APPROACH. As noted in 22.1.3, simplified approaches to TBM performance prediction, such as those presented by Farmer and Glossop (1980) and Graham (1976), are preferred over methods that rely on detailed site data (e.g., as suggested by Lislerud, 1983) due to cost considerations. These simplified formulas are consistent with the conceptual level planning approach incorporated herein. However, the owner is well advised to maximize geotechnical data collection and interaction with the TBM manufacturer so that uncertainties in performance prediction are minimal.

Table 22.1.8 compares data available from one TBM manufacturer with cutting rates predicted using Eqs. 22.1.7b and 22.1.8b.

System Utilization—TBM utilization is defined as the ratio of the productive TBM operating time to the total time available for tunnel drivage. An estimate of the machine cutting rate, derated for downtime using the system utilization factor, can therefore be used to provide an estimate of the project schedule.

TBM system downtime has been analyzed extensively by Nelson et al. (1985); Tables 22.1.9 and 22.1.10 have been reproduced from this source to illustrate potential downtime sources,

Table 22.1.6. Raise-bore Project Cost Elements

Item	Estimated Quantity	Unit	Unit Price	Total Price	Approximate Percentage of Total
Mobilization	____	L.S.	____	____	2–10
Site preparation	____	L.S.	____	____	5–20
Underground setup	____	L.S.	____	____	2–8
Production					
• Pilot bit cost	____	ft	____	____	2–8
• Reamer cutter cost	____	ft	____	____	20–70
• Operating labor	____	ft	____	____	5–10
• Supplies/maint.	____	ft	____	____	5–10

Note: High cutter cost is a function of rock properties (e.g., strength, hardness, abrasivity, bedding, etc.). Risks can be offset by requiring manufacturers to bid cutter cost on a per foot (meter) basis.

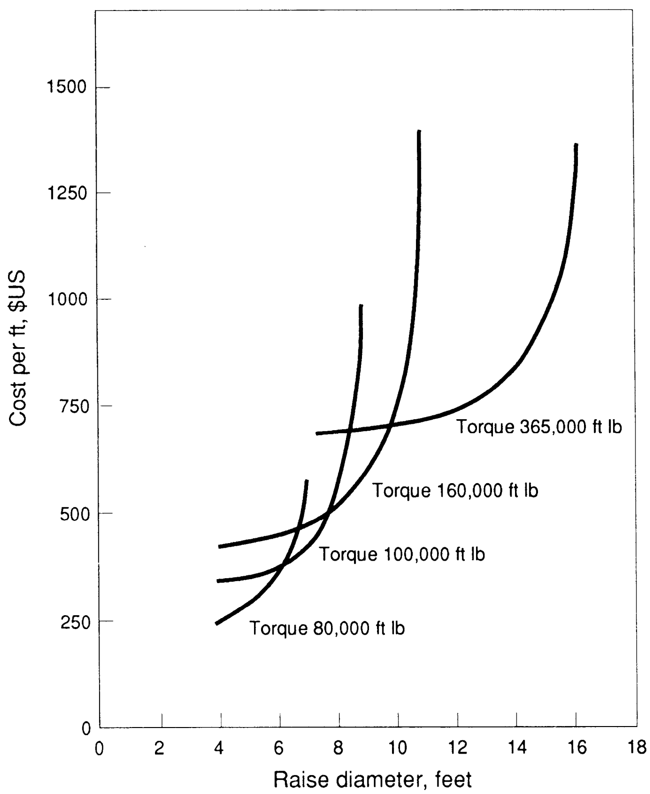

Fig. 22.1.18. Raise costs as a function of diameter and torque (modified from *Engineering and Mining Journal,* Anon., 1981). Conversion factors: 1 ft = 0.3048 m, 1000 ft-lb = 1.356 N-m.

average TBM utilization factors, and the relative impact of each major downtime component on utilization.

One other major cause of downtime, excluded from the utilization calculation in Table 22.1.10, involves remedial work required when mining through major faults and shear zones. Major collapses and large inrushes of mud and water, heavily squeezing ground, and gouge that clogs the mucking system are a few of the reasons for significant delays when mining through tectonically altered zones. Case studies involving TBM excavation under adverse ground conditions have been reported by McFeat-Smith (1987) and are reported in summary form in Table 22.1.11. The importance of a carefully executed geotechnical site investigation designed to evaluate potential impacts of these features and to provide data for remediation, and selection of an appropriately equipped TBM cannot be overstressed.

TBM PERFORMANCE PREDICTION.

Example 22.1.2. The following data apply to the construction of a 24-ft (7.32-m) diameter tunnel (Kerckhoff No. 2) in granitic rocks (s_{cf} = 20,250 psi or 140 MPa; s_{tf} = 1450 psi or 10 MPa), 25% quartz content.

TBM Data (Robbins 243-217)

Diameter	24 ft 1 in.	7.34 m
No. Cutters/Diameter	57 × 15.5 in.	57 × 394 mm
Thrust	2,280,000 lbf	10.14 MN
Torque	1,980,000 ft-lbf	2.68 MN-m
Cutterhead Horse-power	2200 hp	1640 kW
Cutterhead Speed	5.8 rpm	5.8 rpm

Determine the overall rate in advance.

Solution. Assuming operating thrust/cutter = 70% of machine capability,

$$F_c = \frac{2{,}280{,}000}{57} \times 0.7 = 28{,}000 \text{ lbf/cutter}$$
$$(124.5 \text{ kN/cutter})$$

1. Farmer and Glossup

$$P = \frac{F_c \times 0.0158}{1450} = 0.306 \text{ in./rev}$$
$$(7.77 \text{ mm/rev})$$
$$P_{HR} = \frac{0.306 \times 5.8 \times 60}{12} = 8.9 \text{ fph}$$
$$(2.71 \text{ m/h})$$

2. Graham method

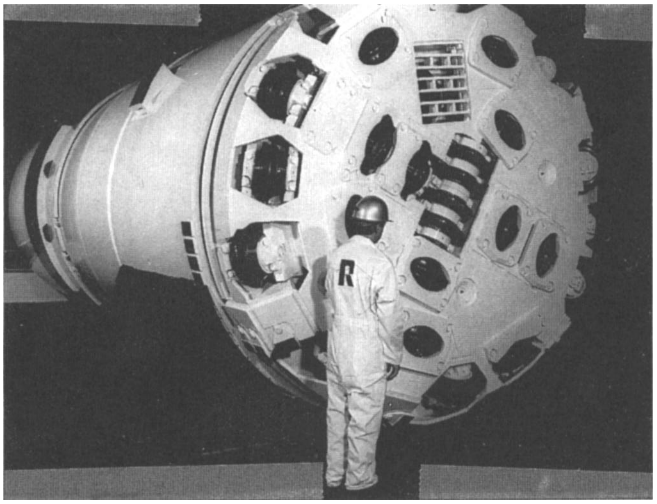
$$P = \frac{F_c \times 0.1}{20{,}250} = 0.138 \text{ in./rev}$$
$$(3.5 \text{ mm/rev})$$
$$P_{HR} = \frac{0.138 \times 5.8 \times 60}{12} = 4.0 \text{ fph}$$
$$(1.22 \text{ m/h})$$

Assume utilization = 40%.

P_{sys} = 1.6 to 3.6 fph (0.5 to 1.1 m/h),
or 38 to 86 ft/24hr-day (12 to 26.4 m/day)

Table 22.1.7. Comparison of Factors Influencing the Selection of Blind Drilling, Raise Drilling, and Conventional Shaft Construction Methods

Factor Influencing Selection	Blind Shaft Borer (BSB)	Blind Drilling	Raise Drilling	Vertical V-mole	Conventional Shaft Sinking
Design considerations					
Safety	Utilizes underground operators working under cover and behind shields. No operation of large moving equipment required.	Does not require miners to work underground.	Only requires underground labor set-up and mucking. No labor required in the shaft prior to shaft lining.	System utilizes underground operators working in a controlled environment. Considered safer than conventional shaft sinking as operators are located remote from the working face.	Requires equipment operation in confined environment. Considered to be the most dangerous of the five shaft construction methods.
Shaft size	Depth is limited by skip-hoist rope capacity.	Limited by required depth, available equipment, and cost. Drilled shaft diameters range from well size to 20+ ft.	Nominally limited by available machine torque. Short (300 ft) shafts have been raised at 20 ft diameter.	Limited by available equipment from 16 to 23 ft in diameter.	Required to be larger than 10–12 ft for most applications. Upper limit not controlled by method.
Shaft depth	Depth is limited by skip-hoist rope capacity.	Limited by required diameter, available equipment and cost. See Table 22.1.2 for case study data.	Raise depths up to 3200 ft have been reported.		
Shaft verticality	Verticality can be controlled within extremely tight tolerances. Equal to or better than conventional.	Deviation can be estimated from geological data. Difficult to maintain an absolutely vertical shaft in sub-vertical structure. Suggested tolerance for design purposes = 0.25–0.5°.	Shaft verticality is controlled by pilot borehole. Pilot hole accuracy controlled by directional survey and careful drilling practice. Design tolerance should be specified based on use requirements.	Shaft verticality is controlled by pilot hole. However, offset reaming can be controlled by the operator providing additional control when following a deviated pilot borehole.	Verticality can be controlled within extremely tight tolerances. The most accurate shaft construction method with regard to verticality.
Ground disturbance	Minimal mechanical disturbance of shaft wallrock.	Provides minimal mechanical disturbance of shaft wallrock.	Provides minimal mechanical disturbance of shaft wallrock.	Provides minimal mechanical disturbance of shaft wallrock.	Conventional (drill-and-blast) excavation can result in deep seated blast damage.
Timing/schedule	Setup time is 1 month or more. Advance rate should be between 20 and 40 ft/day. In general muck haulage and lining limit advance.	Typically much faster than conventional shaft construction methods. See Table 22.1.2 for case study excavation rates.	Reaming range from 15 fph (5 ft dia.), 3 fph (10 ft dia.), to 1 fph (15 ft dia.)	Reported rates between 30 fpd (16 ft dia.) and 60 fpd (23 ft dia.)	Generally restricted to one round per shift (e.g., 1 fph)
Operational considerations					
Groundwater	Same techniques as conventional sinking.	Method provides superior control of groundwater during excavation.	Groundwater controlled by pretreatment where necessary.	Large projected inflows require pretreatment (e.g., using grouting or freezing)	Large projected inflows require pretreatment (e.g., using grouting or freezing)
Support during excavation	Temporary or final support can be installed a short distance behind advancing face.	Support provided by hydraulic pressure and impermeable polymer skin permitting excavation in very poor ground conditions.	Not possible.	Temporary/final support can be installed a short distance behind advancing face.	Temporary/final support can be installed a short distance behind advancing face.
Final lining	Installed during excavation.	Steel/concrete composite lining typically used in weak ground. May incorporate bitumen layer for groundwater control and be designed for full hydrostatic, bituastatic or lithostatic loading conditions.	None usually required. Many rapid lining systems available—see text.	Final lining may be installed during excavation.	Final lining may be installed during excavation.
Miscellaneous			Requires existing underground access.	Requires existing underground access.	
Other considerations					
Shaft outfitting		If a final steel lining is installed, considerable time can be saved through surface installation of guides, brackets and pipes. All furnishings can be aligned prior to welding to the downhole liner assembly.	Pilot hole deviation usually prevents raises from being used for man or materials winding.	Outfitting in-line with excavation and final lining if required.	Outfitting in-line with excavation and final lining if required.
Costs					
—Initial		High	Medium	High	Low
—Operating		Medium	Medium	Medium	High



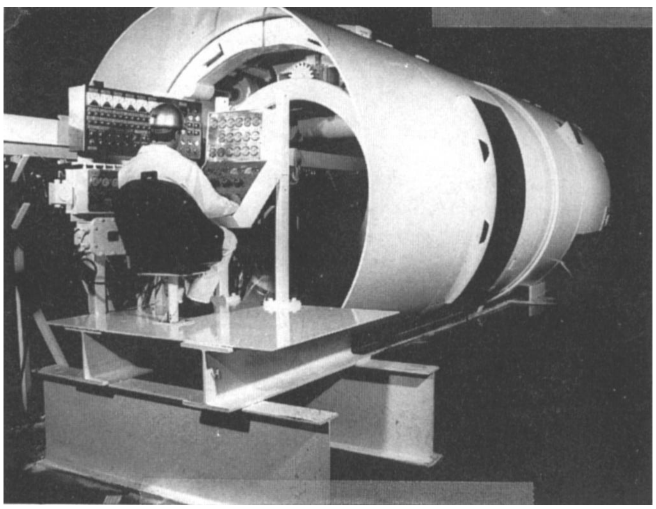


Fig. 22.1.19. Model IIII-234 Robbins hard-rock double shield (*courtesy:* Robbins Co., Seattle, WA).

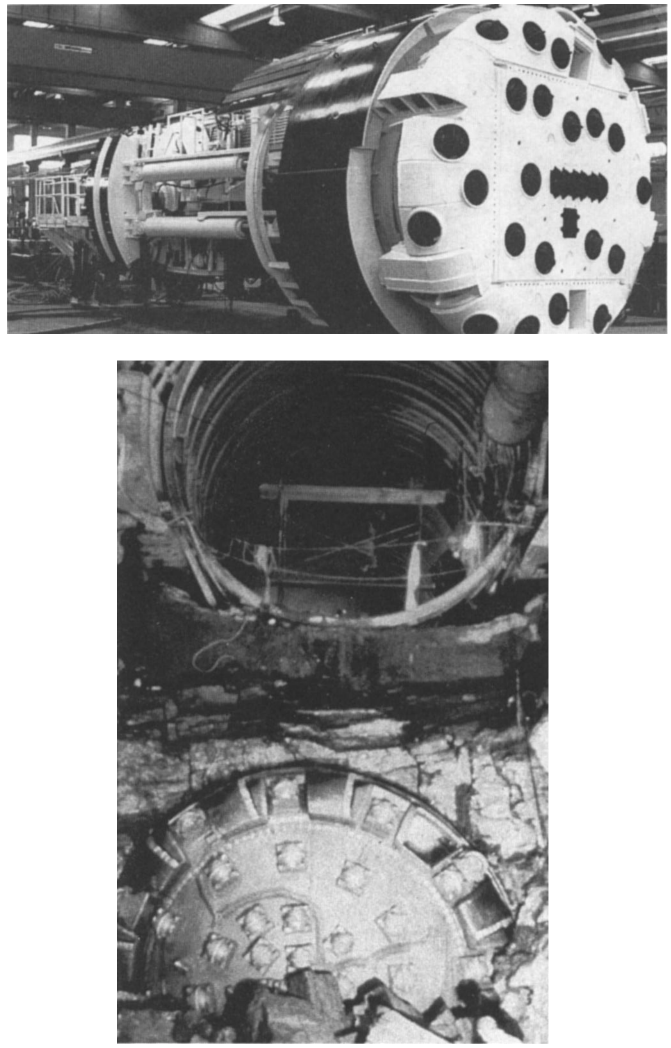

Fig. 22.1.20. Large-diameter TBM and breakthrough of a 20-ft (6-m) diameter TBM drivage in limestone/shale (*courtesy:* Robbins Co., Seattle, WA).

This compares to a forecast rate of 55 fpd (16.8 m/day) based on case study data analysis and an actual production rate of 60.5 fpd (18.4 m/day) (Woodward, 1983).

22.1.5.2 Mobile Miner

A prototype of the Robbins mobile miner (Fig. 22.1.22) was introduced in 1984 for development of a 3773-ft (1150-m) decline at Mt. Isa mine, Australia. Advances of up to 12 ft/shift (3.66 m/shift) were made while mining a 12-ft (3.66-m) high, 21-ft (6.4-m) wide section in high-strength quartzite (16,000 to 39,000 psi or 110 to 269 MPa) (Boyd, 1987). Upgrades in dust control and sealing systems improved the initial utilization rates from 17 to 34%, with the best single eight-hour shift resulting in 12 ft (3.66 m) of drivage for 5.3 hours cutting time. Redesign of the cutter wheel, to avoid high imbalanced loads and other upgrades resulting from the Mt. Isa experience are anticipated to provide 50% utilization. This compares favorably with the 36% utilization required for break-even with drill and blast (Robbins, 1986).

22.1.5.3 Roadheader Systems

Roadheaders have been in use in mining and tunneling for many years, and are known under a variety of names including boomheaders, boom-type tunneling machines and selective tunneling machines. Fig. 22.1.23 shows two of the many varieties of roadheader, and Fig. 22.1.24 illustrates commonly used terminology for the various machine components.

Roadheaders were originally developed as a means of advancing roadways in underground coal mines and early machines were limited to cutting relatively low-strength strata. Continuous development of these machines has greatly extended the range of applications, and they now are used in a wide variety of mining and civil tunneling work, including mine production (Sparks, 1980). Improvements in cutterhead design (Hurt et al., 1982) and the increasing use of water-jet-assisted cutting (Barkam and Buchanan, 1987; Timko et al., 1987; Hood, 1985) will result in a further extension of the range of roadheader applications in coming years.

Roadheaders offer a number of advantages over full-face tunneling machines, chiefly related to flexibility. Roadheaders can cut a variety of cross sections, limited only by the basic dimensions of the machine, and are able to cut tight curves or corners. They are thus usable, for example, in room and pillar operations. Roadheaders can selectively cut narrow bands or

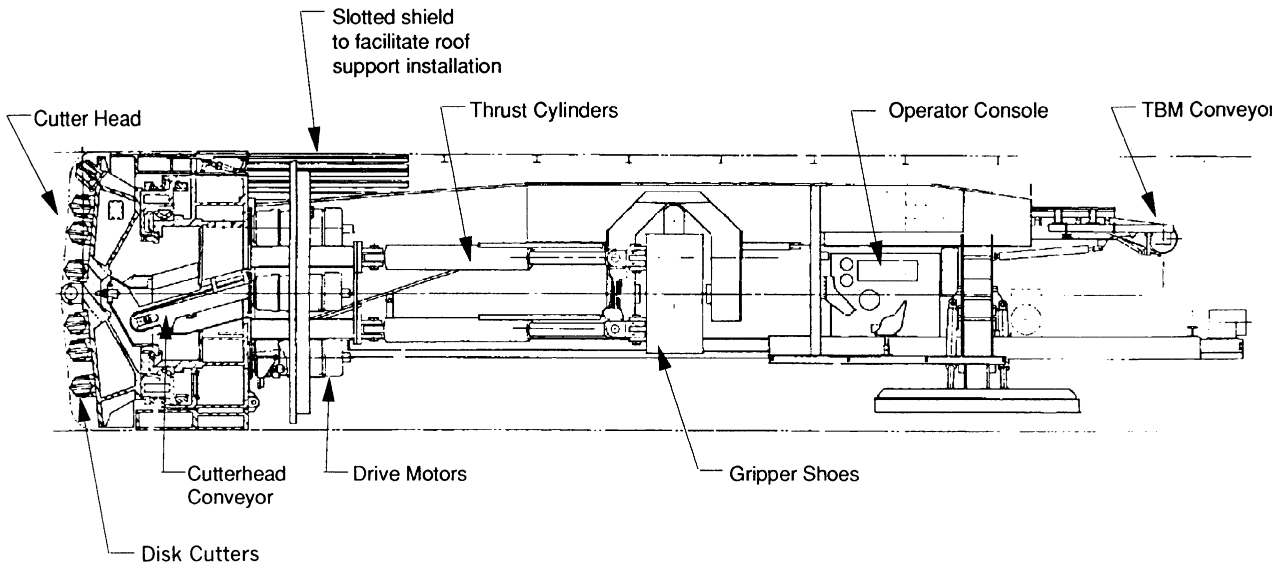

Fig. 22.1.21. Sectional view of tunnel boring machine.

beds and are thus suitable production mining tools if a careful sequence of mining and mucking is followed. Also they have lower initial costs than full-face machines.

Roadheaders also offer advantages over conventional drill and blast methods. One of the most important advantages of roadheaders is the avoidance of blast damage to the rock and the consequent savings in ground support costs. In addition, because mechanical excavation is a continuous process, shift time is more effectively utilized. Navin et al. (1985) estimated that support requirements in openings excavated by a roadheader were reduced by 40% compared to drill and blast excavations, and advance rates by roadheader were 1.5 times as rapid as drill and blast. McFeat-Smith (1982) reported average utilization of about 50% in roadheader excavation systems compared to 33% for drill and blast.

EQUIPMENT. The main components of roadheader excavation systems are discussed in some detail in this segment. However, because roadheader equipment is in a constant state of development, the reader is advised to consult manufacturers with regard to specific machines, detailed specifications, and applications.

Roadheader cutting assemblies consist of a cutting head on a movable, hydraulically powered boom, mounted on a rotatable turret attached to a track-driven chassis. In addition to the cutting head, the machine also incorporates either a gathering arm or chain conveyor mucking system to remove broken rock from the face. The machine may be controlled by an operator seated on the machine or located some distance away, perhaps inside a shield, or beneath a supported roof section. To improve machine stability during cutting, many machines are equipped with hydraulically powered stelling rams which are used to brace the machine off the excavation sidewall.

Pearse (1988) has studied the products of 13 roadheader manufacturers and tabulated basic specifications for about 60 machines, with total installed powers ranging from 70 to 600 kW, and weights ranging from 17 to 130 tons (15 to 120 t) (Table 22.1.12).

Two types of cutting heads are available from several manufactures and are interchangeable on specific machines. These heads are termed transverse and in-line heads (Pearse, 1988), or ripping and milling heads (Kogelmann and Schenck, 1982). In-line heads rotate co-axially with the boom, and arcing forces developed during transverse cutting may need to be resisted by stelling rams, particularly if the machine is of light weight. According to Pearse (1988), these heads are best suited to cutting rock with an unconfined compressive strength of 12,000 psi (80 MPa) or less. In-line heads require less thrust when sumping, and the head shape allows greater selectivity in cutting specific beds or bands, but stelling rams can be rendered ineffective if weak rock bands are present in the drift sidewalls. Transverse heads rotate at right angles to the boom axis, so arcing forces are resisted by the weight of the machine, and stelling is not usually required. An important advantage of this is that machines can be lighter than similarly powered machines with an in-line head.

Advances in cutter booms have resulted in machines equipped with telescopic booms, or booms with extended length for cutting high backs or crowns. Telescopic booms are useful for cutting on steep gradients or on weak floor materials where the thrust from the machine's travel system would not be adequate. In such cases, the machine can be stelled, and the thrust provided by the booms' telescoping hydraulics reacting against the machine. Kogelmann and Schenck (1982) have described soft-rock cutter booms (SRBs) and hard-rock cutter booms (HRBs), and report that the trend is toward the development of the latter. HRBs are reportedly more stable in cutting, producing less vibration and, consequently, less damage to bearings and picks. In low-strength formations, however, SRBs perform satisfactorily, and the increased cost of an HRB-equipped machine is not justified.

Better cutter head design and analysis methods (Hurt and MacAndrew, 1981; Hurt et al., 1982) can lead to improved pick utilization and pick life and reduced torque variation during cutting. These lead to reduced vibration and bearing damage. Cutterheads supplied with machines should be designed using sound engineering principles, and field modifications and repairs (e.g., replacing pick boxes) should be subject to the same controls and standards. Water-jet-assisted cutting heads are now available as standard or optional features on many roadheaders. Research in the application of low-, medium-, and high-pressure water jets

Table 22.1.9. Downtime Categories for TBM Operations

Major Category	Individual Downtime Sources
TBM maintenance and repair	Cutterhead check and routine maintenance
	Lube oil system
	Hydraulic system
	Cutterhead motors
	Electrical system
	TMB conveyor
Backup system	Tunnel power supply
	Utility lines (air, water, fanline)
	Laser guidance and surveying
	Trailing floor conveyor
	Tripper or car pass
	Train delay—muck bound at heading
	Shaft or portal equipment
	Installing rail and switches
	Derailments
Ground conditions	Water inflow rock support installation— bolts and straps, steel sets
	Gripper/sidewall support
	Equipment clearance
	Scaling loose material
	Muck jams in conveyor and hoppers
Cutter changes	
Other	Scheduled downtime
	Probe hole drilling
	Contractual downtime
	Moving TBM to new location
	Shift changes

Source: Nelson et al. (1985).

to assist cutting has indicated substantial improvements in pick life and dust suppression, and has reduced potential for frictional ignition of methane. In general, machines equipped with water jets can cut higher-strength formations than equivalent machines without water jets.

Roadheader face mucking systems generally consist of an apron with either a scraper chain or gathering arm system (Fig. 22.1.25). Scraper chains generally extend around the perimeter of the machine, while gathering arms load muck onto a short conveyor that passes through the body of the machine. In either case, the muck is generally discharged onto a bridge conveyor. From this point, the muck may be removed by a wide variety of methods including shuttle trains, conveyors, LHDs, trucks, and so on. This allows roadheaders to be used in conjunction with an existing mine haulage system, provided that adequate capacity exists. Without adequate capacity, the face will become muck bound and excavation will be delayed. In low-strength formations in which high cutting rates are possible, the mucking system may become the limiting factor in controlling advance rates.

Roadheader cutting booms are generally mounted on a custom chassis with track propulsion. Track dimensions control ground pressures and should be carefully assessed in conditions in which the invert rocks are weak or prone to slurrying. Increasingly, booms are being mounted on a variety of other machines, such as hydraulic breakers, trucks, traveling gantries, and inside shields.

Conventional manual/hydraulic control systems are being increasingly superceded by electronic/hydraulic control systems linked to microprocessor-based guidance and profile control systems. Guidance systems consist of fixed laser sources mounted some distance behind the roadheader and photoelectric targets mounted on the roadheader. Deviations of the roadheader from its desired position and orientation are detected by the targets, and corrections are automatically made. In addition to guidance control, automatic profile control is also available. These systems consist of a microprocessor programmed with the required excavation profile, and transducers that continually monitor the position of the cutting boom. The boom hydraulics are controlled electronically to ensure that the correct profile is cut. These developments enable very accurate alignment and profile control, which eliminates overbreak and ensures that the cutting sequence is optimum; work stoppages to allow time for survey work are also reduced. Electronic systems are also being used on roadheaders to monitor the condition of mechanical and hydraulic components, enabling preventative maintenance to be scheduled, reducing unplanned downtime.

OPERATIONS. The excavation cycle commences with sumping or forming a cavity in the rock face to the operating depth of the cutterhead. During this operation, the cutter boom is kept stationary while the cutting head rotates and the whole machine is gradually moved forward on the tracks. When the sump has been formed, it is enlarged by tracking the cutting head across the face to the outer perimeter of the excavation. At the end of this arcing cut, the head is moved up or down, and another arcing cut is made across the face in the opposite direction to the first cut. Proceeding in this way, the opening is gradually enlarged to the full dimensions of the face. When the full cross

Table 22.1.11. Case Histories of Tunnel Boring in Adverse Ground

Machine Type Tunnel Dia.	Geology	Geological Feature	Av. Rate Advance ft/week	Delay to Progress	Tunneling Problems in Adverse Zones	Design	Comments
TBM (medium weight) 11.5 ft	Moderately strong sandstones (Class 4)	75 ft length of intensely jointed mudstones and sandstone	465	76%	Generally minor—Arch supports used	Reliable mucking systems and easy access for support installation	TBM well designed for conditions
TBM (heavy weight) 11.5 ft	Dolerite sill intrusion into sedimentary sequence	1200 ft of competent, (Classes 2–3) 50,000 psi dolerite sill	295	60%	Slow cutting. Average progress reduced to 115 ft/week. Cutter costs very high.	Triple button disks used although single disks may have been better	Operating considered to be a success for such hard rock.
TBM (heavy weight) 11.5 ft	Pure mudstone at roof level (Class 3) overlying limestone (Class 1)	60 ft of soil infill zone in roof (Class 5) caused by dissolution of limestone	295	342 hours	Delays mainly for support and mucking due to collapse of roof.	Long roof shield prevented installation of heavy temporary support, conveyors chocked	Inadequate design features enhanced delays
TBM (medium weight) 11.5 ft	Sandstone, mudstones	660 ft throw fault giving 50 ft clay gouge zone with boulders (Class 5) and 33 ft shattered zone (Class 4)	390	67 hours	Generally minor—Arch supports used—timber packing required for gripper pads	Suitable access for installation of arches close behind face. Single gripper pads most appropriate	TBM very well designed for this severe condition

Conversion factor: 1 ft = 0.3048 m.

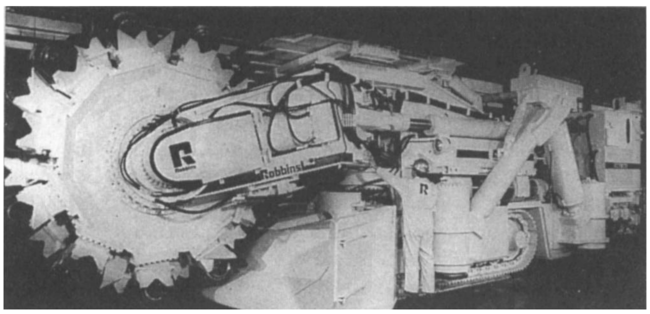

Fig. 22.1.22. Robbins mobile miner (*courtesy:* Robbins Co., Seattle, WA).

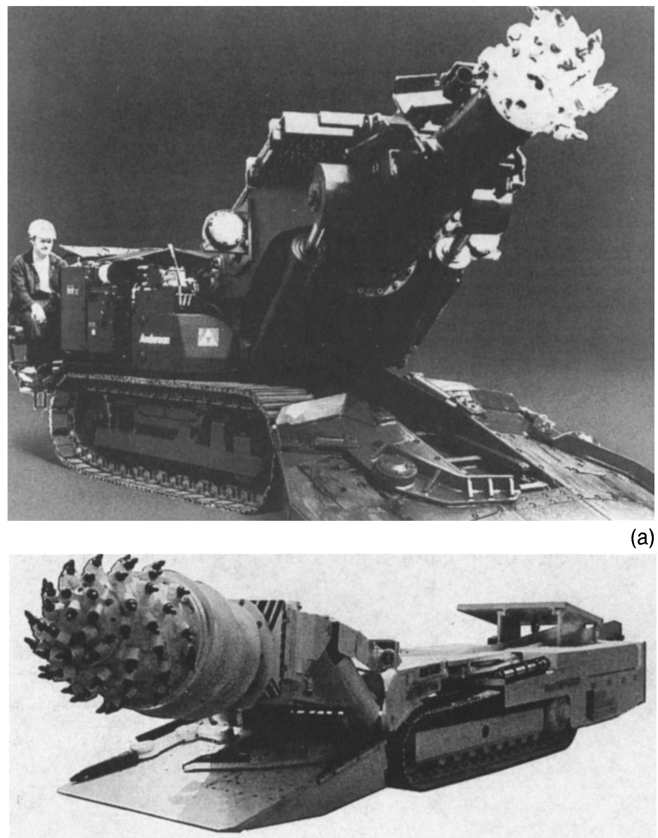
section has been excavated and the muck removed, a new sump is formed, and the entire process is repeated. The pattern of sumping and arcing cuts, relative to the direction of cutterhead rotation and geologic structure, influences the efficiency of roadheader excavation.

SUPPORT SERVICES. In the vicinity of working roadheaders, high concentrations of airborne dust, generated during both cutting and transport of the muck, and high ambient temperatures commonly occur. In addition to exceeding statutory respirable dust limits, excessive dust may completely obscure the face, resulting in inefficient excavation and increased overbreak. High temperatures and humidity result in labor inefficiency and overheating of electrical motors. The use of waterjet-assisted cutting leads to a reduction in dust levels, but does not entirely eliminate the problem, and may actually increase humidity at the face. Meyeroltmanns (1982) has described practical methods of using ventilation to control airborne dust in the vicinity of roadheader faces, methods that also assist in controlling heat and humidity.

GROUND SUPPORT. One of the primary advantages of selecting a roadheader excavation system over drill-and-blast methods is the elimination of blast damage and the consequent savings in rock support costs. McFeat-Smith (1982) estimates that in excavations requiring temporary support, the cost saving may be on the order of 10 to 15%, and in suitable ground, the need



(a)

(b)

Fig. 22.1.23. Roadheader-type tunneling machines. (a) Model RH 25 (*courtesy:* Anderson, Strathclyde) (b) Model ABM 330-1 (*courtesy:* Alpine Equipment Corp.).

for support may be eliminated entirely. All types of rock support can be adopted for use in conjunction with roadheaders. However, because it can be relatively difficult to reverse a roadheader away from the face, the machine must be covered prior to shotcrete application. When ground conditions require, roadheaders

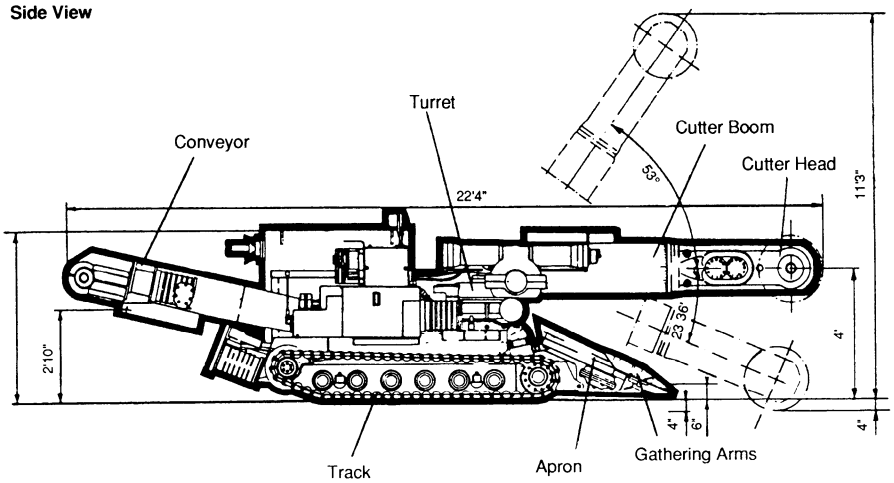


Fig. 22.1.24. Typical roadheader showing main components. Conversion factor: 1 ft = 0.3048 m.

can be mounted inside shields (Fig. 22.1.26) or advance within self-advancing powered supports (Fig. 22.1.27). The roadheader is supported on a slide mechanism and can move independently of the shield. Excavation, mucking, and erection of a segmental lining can proceed concurrently. The use of short shields allows tight turning circles to be maintained, although the system is less maneuverable than a non-shielded roadheader. Several cutter booms can be mounted in shields when large-diameter openings are required.

ROADHEADER SYSTEM PERFORMANCE PREDICTION. Methods of predicting instantaneous and operational cutting rates for roadheaders were presented in 22.1.3. Overall system performance, assessed in terms of advance rate, is a function of OCR, face area, and utilization:

$$\text{Advance rate} = \text{OCR/Face Area} \times \text{Utilization} \qquad (22.1.10)$$

Utilization is defined as the time available for advancing the face when all planned and unplanned machine stoppages have been accounted for. Machine stoppages generally fall into one of the following categories:

1. Planned maintenance of roadheader and backup equipment.
2. Unplanned maintenance of roadheader and backup equipment.
3. Mucking delays.
4. Ground control.
   a. Rock support installation.
   b. Control of water inflows.
5. Survey work.
6. Meal time/shift change time.

Guidance for typical roadheader utilization has been suggested by Kogelmann (1988) based on the type of ground support to be installed:

Support Type	% of Cutting Time per Available Face Time
None	60 – 80
Rock bolts	40 – 50
Shotcrete	40 – 50
Shotcrete and rock bolts	30 – 35
Steel sets	30– 35
Steel sets with full lagging	20 – 25

Examples of the application of cited performance prediction methods are presented below to further illustrate the process.

Example 22.1.3. This example is based on results reported by Sandbak (1985) for mine drift development in quartz monzonite and dacite porphyry. The roadheader is a Dosco SL-l-20 with an 82-kW cutter motor.

Table 22.1.13 summarizes key geotechnical properties for sections of drift over which cutting rates were recorded. Two prediction methods were used, and the results of these can be compared with observed OCR data given in the table.

Solution.

1. Prediction Based on Method of Bilgin et al. (1988)

The first step in the application of this method (see 22.1.3) is calculation of the rock mass cuttability index, RMCI (see Fig. 22.1.7). This is given as:

$$\text{RMCI} = \text{UCS (kN/cm}^2) \times \frac{\text{RQD}^{2/3}}{100} \qquad (22.1.11)$$

which is then used in the prediction equation to determine OCR:

$$\text{OCR} = 28.06 \times 0.997^{\text{RMCI}} \qquad (22.1.12)$$

Because the prediction equation given by Bilgin et al., is for a somewhat more powerful machine than the Dosco SL-120, a slight linear correction is applied to Eq. 22.1.12 as follows:

$$\text{OCR} = 28.06 \times 0.997^{\text{RCMI}} \times \text{HP}/95 \qquad (22.1.13)$$

where HP is the head power of the Dosco SL-120.

These results are in remarkably good agreement with observed OCR data.

2. Prediction Based on Method of Fowell and McFeat-Smith (1976, 1977)

The first step in this prediction is the calculation of specific energy SE required for cutting, given by:

$$\begin{aligned}\text{SE} = &-4.38 + 0.14(\text{CI})^2 + 3.3(\text{UCS})^{1/3} \\ &+ 0.000018(\text{SN})^3 + 0.0057(\text{CC})^3 \qquad (22.1.14)\end{aligned}$$

where CI is cone indenter hardness, UCS is unconfined compressive strength, SH is shore hardness, and CC is cementation coefficient.

BH = Backhoe, D = Disc, FC = Flight chain, GA = Gathering arm, SC = Scroll, SW = Star wheel.

Source: Pearse, 1988.
Conversion factors: 1 ft = 0.3048 m, 1 hp = 0.7457 kW, 1 ton = 0.9072 t.

Cone Indenter hardness and Shore hardness have been shown to be linear functions of unconfined compressive strength (Atkinson et al., 1986), so that Eq. 22.1.14 can be rewritten in terms of USC and CC:

$$\mathrm{SE} = -4.38 + 0.14\,(0.0377\ \mathrm{UCS} + 0.254)^2 + 3.30\ \mathrm{UCS}^{1/3} + 0.000018\,(0.441\ \mathrm{UCS} - 8.73)^3 + 0.0057\mathrm{CC}^3 \qquad (22.1.15)$$

Cementation coefficient is based on petrographic descriptions of the rock (McFeat-Smith, 1977).

When SE has been calculated, instantaneous cutting rate ICR can then be calculated from Eq. 22.1.5:

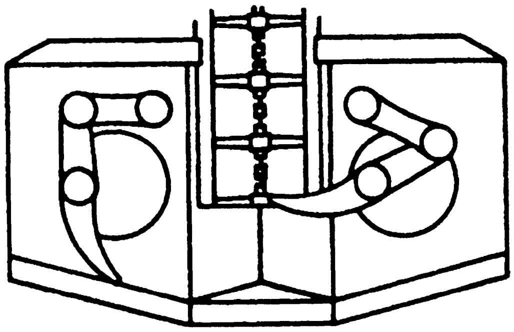
$$\mathrm{ICR} = \mathrm{HP/SE}$$

Because the prediction equations use SE based on actual cutting time, a *cutting time factor* (CTF) correction must be made to Eq. 22.1.5. CTFs for bulk excavations with an experienced operator are estimated to have values in the range 0.65 to 0.85, while for final trimming, it may drop to 0.3. Overall values for bulk excavation and final profiling of a face may be in the range of 0.45 to 0.65. In this example, 0.45 was assumed and applied as follows:

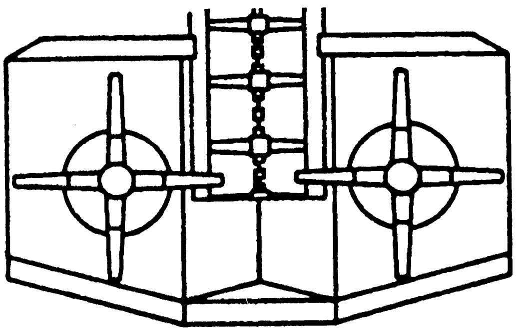
$$\mathrm{OCR} = \mathrm{HP/SE} \times \mathrm{CTF} \text{ or} \qquad (22.1.16)$$
$$= \mathrm{ICR} \times \mathrm{CTF}$$

In this example the predicted values are low compared to the observed cutting rates, and this may be attributable to rock mass factors.

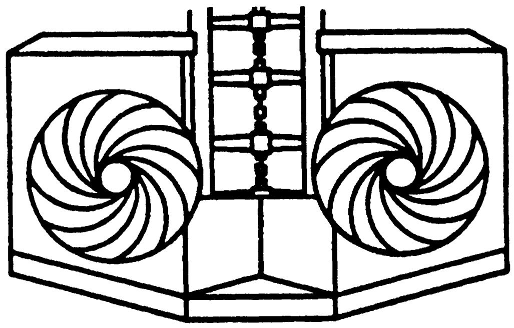
Example 22.1.4. This example is based on results reported by Bilgin et al. (1988) for drivage of sewer tunnels in Turkey using a Herrenknecktt SM1, and coal mine development drives using a Dosco MKIIA. Results are presented in Table 22.1.14.



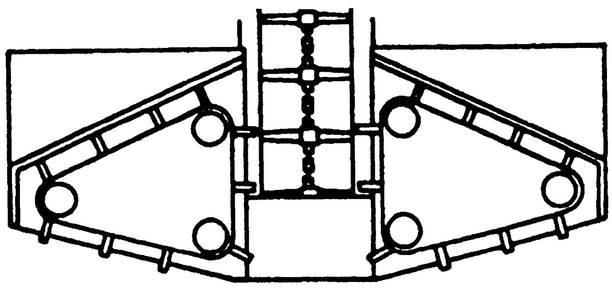
Gathering - Arm Loader
For blocky, interlocked, wet and sticky materials. Effective loading on steep slopes.



Star - Wheel Loader
For dry, non-interlocked and non-sticky materials.
High loading rates at continuous flow.
Low maintenance.



Spinner - Disk Loader
Same as Star-Wheel Loader



Scraper - Conveyer Loader
For non-blocky, non-abrasive materials

Fig. 22.1.25. Roadheader loading (gathering) systems (after Kogelmann, 1988).

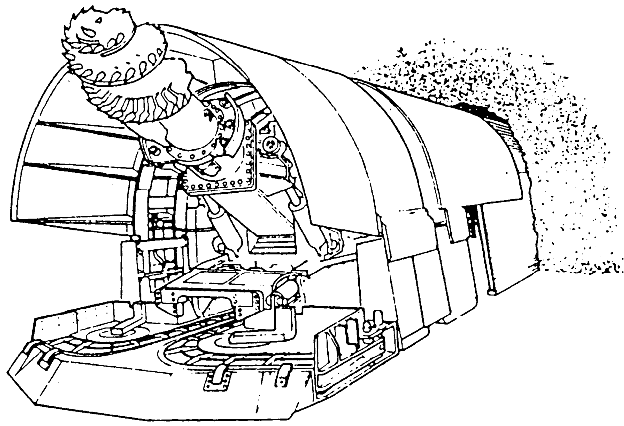


Fig. 22.1.26. Roadheader in horseshoe-shaped shield support system (after Kogelmann, 1988).

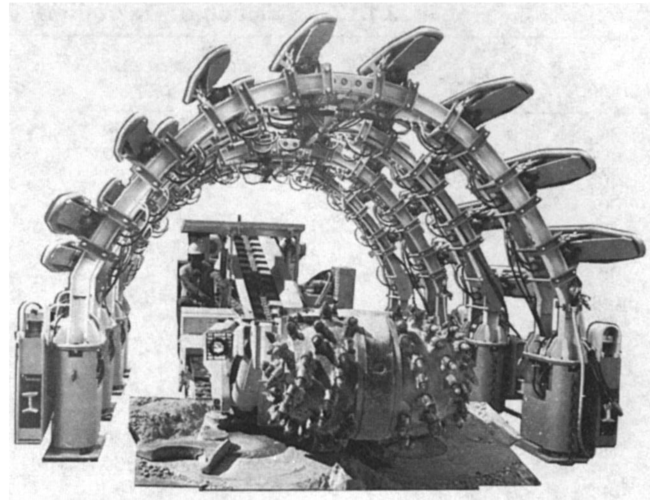

Fig. 22.1.27. Model ABM-T roadheader with waling, hydraulic roof support system (*courtesy:* Alpine Equipment Corp.).

Results for both of the methods used are in good agreement with the observed results. Again, a CTF of 0.45 was assumed.

Example 22.1.5. This example is based on cutting trials in British Coal Measures reported by Fowell and McFeat-Smith (1976) using a Dosco MKIIA. Although individual results (Table 22.1.15) show appreciable scatter, mean predicted values are in reasonably good agreement with the observed noncoal values. Again, a CTF of 0.45 was assumed. The correlation could be improved if suitable rock mass property corrections were made.

ROADHEADER PROJECT COSTS. Advance rates can be predicted based on the foregoing estimates of operational penetration rate and equipment utilization. Roadheader project costs are calculated based on these advance rates with loading of the following costs and resources:

Component	Costs Available in	Costs Calculated at
Capital/lease cost (1)	($/wk)	($/ft, $/m^3)
Labor (operating and support)	($/hr)	($/ft)
Cutters and maintenance (1)	($/yd^3, $/m^3)	($/ft)
Mucking - equipment (1)	($/mo)	($/ft)
- operators	($/hr)	($/ft)
Ventilation - equipment (1)		($/ft)
- installation and power		($/ft)
Support - shotcrete	($/yd^3, $/m^3)	($/ft)
- concrete	($/yd^3, $/m^3)	($/ft)
- rock bolts (1)	($ each)	($/ft)
- steel sets (1)	($ each)	($/ft)

Notes: (1) Available from manufacturer.

22.1.5.4 Selection of Tunnel Construction Method

Selection of the appropriate tunnel/drift construction technique will involve an in-depth analysis of site geomechanical and geohydrologic conditions, design criteria (e.g., diameter, length, shape, use, and life, etc.), availability and location of equipment and qualified labor, project schedule requirements and cost. The approach in this *Handbook* is considered to be applicable at a conceptual level of project planning. More detailed investigations and analysis should be undertaken using expert services available from geotechnical and design engineers, construction contractors, and equipment manufacturers prior to final method selection.

SITE-SPECIFIC DATA REQUIREMENTS. Field data required for design and construction bidding are essentially the same for all tunnel construction methods. The site investigation program should include geologic mapping and fully logged corehole along the tunnel alignment; in certain circumstances, horizontal boreholes are the most cost effective method of evaluating in situ conditions. Site investigation coreholes should be geologically and geotechnically logged (e.g., core recovery, RQD, discontinuity description, lithology, rock description, etc.) and core samples selected for testing (e.g., uniaxial and tensile strength, slake durability, swelling, hardness, etc.); samples will also be required by TBM manufacturers for proprietary drillability testing. Hydrogeologic data can be collected in-line with core drilling or after drilling has been completed.

Data analysis will provide estimates of groundwater inflows and parameter values that input to the design of grouting programs; rock quality, strength testing, and in situ stress will be used to evaluate stability, design rock support or lining systems, and for blast design; laboratory strength and index test data will be used to estimate drill penetration rates, bit wear, cuttability, and suitability for mechanical excavation.

METHOD SELECTION GUIDELINES. The choice of a tunneling method should be made using the approach outlined in 22.1.5 and the selection factors presented in Table 22.1.16. Mechanical mining systems are now available that can rapidly mine a broad range of rock types at gradients up to 25%, while negotiating relatively tight and variably curved alignments. Further innovations and developments in cutting technology, especially with regard to water and particle-assisted rock cutting; mucking systems (e.g., with regard to continuous mechanical conveying and hydraulic and pneumatic transport); and machine features (e.g., access to cutterhead for maintenance, guidance systems, gripper and steering systems, etc.) are underway. However, motivation for these developments must come from a receptive and innovative mining industry.

Table 22.1.16. Comparison of Factors Influencing the Selection of Horizontal Tunneling Method

Factor Influencing Selection	Tunnel Boring Machine	Roadheader	Mobile Miner	Conventional Mining
DESIGN CONSIDERATIONS				
• Safety	Miners work under supported ground. Special safety precautions may be required where access to the face of the machine is required for cutter changes.	Shields and hydraulic supports available for poor ground conditions. Equal safety potential to TBM, much safer than conventional mining.	Main application in hard, high strength rock requiring little-to-no support. Safety rated equivalent to TBM with improvement, to dust suppression system.	Inherently the least safe of all development mining alternatives.
• Tunnel line and shape	Method restricted to circular shape. Tunnels up to 35-ft diameter have been excavated in hard rock.	Multiple heading levels permit a wide range of opening sizes and shapes to be mined. Single heading range is from 6-20+ ft.	Flat-back, rectangular, minimum height controlled by size of cutter wheel (> 10 ft).	Can produce full range of sizes/shapes typically required.
• Tunnel length	Unsuited, due to capital equipment and mobilization costs to short drivages. TBM applications seldom economical for single drivages less than 7000 ft.	Non-circular tunnels up to about 2,000 ft (with sections larger than 200 sq. ft.) in softer sedimentary formation can be driven more economically using a roadheader.	No restriction.	No major physical restriction.
• Alignment	Clockwise rotation causes TBM to drift to left. Deviation is easily controlled, and alignment ensured through use of laser guidance system. Laser deviation may present problem in extremely long drivages.	Accurate alignment and profile control available using laser guidance systems and microprocessor cutting boom control.	Minimum operating radius is about 40 ft. Alignment controlled by continuous survey or laser.	Easily controlled, no major restrictions.
• Minimum radius	About 600 ft. Curves as tight as 300 ft are possible with modified equipment.	25 ft.	65 ft (horizontal) 260 ft (vertical)	No major restrictions.
• Normal maximum gradient	About 25% limitation associated with mucking and gripping systems. Larger gradients are possible but require equipment modifications (e.g., hydraulic and lubrication systems).	About 25% controlled by equipment stability and mucking.	About 25% controlled by equipment stability and mucking.	About 50% controlled by equipment ingress/egress and mucking.
• Ground disturbance	In good rock, TBM produces a smooth, hydraulically efficient bore. Overbreak and rockwall damage are practically eliminated.	Minimal rockwall damage due to mining. Special precautions and careful operation required to avoid overcutting profile.	Minimal ground disturbance associated with mechanical cutting (cutterwheel fitted with disc-cutters).	Care required to minimize rockwall damage and overbreak. Recent advances in high-speed digital seismography allow accurate analysis of blast related rockwall damage and subsequent re-design to minimize effects.
• Timing/schedule	Advance rates of 165 ft/day and 700 ft/week have been reported for mine-sized development drivages with moderate utilization (<35%).	Cutting rates in low strength rocks up to twice as fast as drill-and-blast (see 22.1.3.5). Typically restricted to cutting rock <15,000 psi.	Initial poor utilization (17%) improved to 31%, 50% utilization rates are achievable with advance rates (10′ × 21′ heading) on the order of 12 ft/shift.	Typically the slowest of the four methods compared here. Advance rates typically equal to the smallest tunnel dimension per 8-hr shift for mine development headings.

Table 22.1.16. Comparison of Factors Influencing the Selection of Horizontal Tunneling Method (cont.)

Factor Influencing Selection	Tunnel Boring Machine	Roadheader	Mobile Miner	Conventional Mining
OPERATIONAL CONSIDERATIONS				
• Groundwater	Large predicted inflows may require ground pretreatment (e.g., grouting). Groundwater control during excavation can result in significant reduction in utilization.	No major restrictions to groundwater handling as part of excavation cycle. Performance may be improved by pretreatment.	No restrictions to groundwater handling as part of excavation cycle.	No restrictions to groundwater handling as part of excavation cycle. However, inflows typically slow progress and result in difficult mucking conditions. Wet conditions may require more expensive explosive types.
• Ground support	Smooth, undamaged profile less likely to require ground support. Most conventional ground support systems can be installed in line with excavation.	Mechanical cutting provides smooth profile minimizing the need for ground support. Required ground support can be installed at the face.	Used in hard rock applications where ground support requirements are minimal. Ground support can be installed at face.	Uneven profile and overbreak typically requires more rock support than used in mechanical excavation. Project costs may increase by up to 15% unless careful blasting practices employed.
• Rock homogeneity	Cutting rate and cutter consumption are primarily a function of rock type and properties. Best performance is in good quality, homogeneous rock. Poor quality and mixed face conditions can require careful planning and execution, and proper machine selection.	Care must be taken to ensure that variations in rock properties along proposed alignment are within the capabilities of the equipment.	No major restrictions. Current use in high strength quartzite.	Conventional drill-and-blast can be used in practically all rock conditions. Preferred over TBM in mixed face conditions, where large variations in rock mass strength will be encountered, or when tunneling through rock masses containing faults and shear zones.
• Rock temperature	High rock temperatures coupled with machine heat may require special cooling systems (e.g., air and water spray).	No restrictions.	No major restrictions.	No major restrictions.
• Muck removal	Muck removal typically by rail, which usually limits advance rate. Continuous conveyors and pneumatic/hydraulic systems may ensure a continuous mucking cycle, at required mucking rates, in the future.	Muck discharge via conveyor at rear of machine. Rail and trackless haulage available. Moderately more versatile than TBM.	Same range of options as for roadheader.	Muck loaded from tunnel floor to truck or rail based haulage system, as part of excavation cycle. Scoop trams may be utilized for short haulage distances.
• Auxiliary services	Auxiliary services housed on trailing gear (power, compressed air, water, ventilation, etc.). Power consumption high relative to other methods.	Similar to those required by TBM. Although installed power typically considerably less than for TBM, efficiency of converting power to rock breakage is less favorable.	Similar to those required for TBM. Improvements in dust suppression required based on initial field trials.	Power requirements considerably less than for mechanical systems. Drilling requires compressed air or water cooling.

Table 22.1.16. Comparison of Factors Influencing the Selection of Horizontal Tunneling Method (cont.)

Factor Influencing Selection	Tunnel Boring Machine	Roadheader	Mobile Miner	Conventional Mining
• Auxiliary equipment	Muck cars and train, roof support (if required).	Auxiliary equipment typically suited to other mine duties.	Auxiliary equipment typically suited to other mine duties.	Auxiliary equipment includes drill jumbo, loader, scoop-tram, truck or shuttle car or rail based haulage. Auxiliary equipment typically suited to other mine duties.
OTHER CONSIDERATIONS				
• Costs	High	Low-Medium	Medium	Low
—Capital	Medium	Medium	Medium	High
—Operating	Low	Low	Low	Potentially High
—Support				
• Utilization	30–50%	30–80%	17–50%	N/A
• General		Capable of working in multi-face operations requiring cyclic excavation/support activities.	Improved utilization coupled with a relatively small turning radius suggest that boring machines of this type will gain favor for development in hard rock mining.	Versatile equipment can be easily allocated to other mine construction/ore mining operations.

Conversion factors: 1 ft = 0.3048 m, 1 psi = 6.895 kPa.

Chapter 22.2
AUTOMATION AND ROBOTICS

ROBERT H. KING

Mining automation and robotics are controversial topics. Some miners see automation as a threat to their jobs or as a change that will remove the art and romance from mining. Many believe robotics will never progress to the point of cost-effective application in the rough mining environment. Nevertheless, some predict it is the inevitable future of mining because of the possible health, safety, and productivity gains. Many of these different opinions stem from different perceptions of a robot. When thinking of a mining robot, people visualize a wide range of forms, from a human mimic like Asimov's R. Daneel Olivaw to the Star Wars' R2D2 (a metallic but somewhat humanoid form). However, machines that look like present mining equipment but are computer controlled represent the most likely short-term breakthroughs.

Other industries successfully have adopted automation to improve productivity, but early experiments in mining did not show similar results. The reason is that mining tasks are not a series of cyclic motions readily accomplished by factory-floor mechanisms. Mining takes place in the geologic environment where conditions are highly variable and unpredictable. As a result, mining systems must have substantial cognitive abilities to recognize and deal with these unpredictable variations. They should be "intelligent mining systems" rather than automated systems (King, 1988; also see Chapter 8.3).

The path to intelligent mining systems follows the progression of mechanization, remote control, teleoperation, and robotics. The mining industry has adopted *mechanized* equipment to a large extent. *Remote-controlled* equipment, where an operator is stationed some distance from the machine but within line-of-sight, is found on some continuous mining machines in underground coal mines and some load-haul-dumps (LHDs) in underground metal mines. *Teleoperated* equipment, where operators can be stationed further away, beyond line-of-sight, is currently in the experimental stage. Research projects currently focus on robotics, the last stage of the progression. *Robotics* has been described as the intelligent connection between perception (the ability to understand the world around the robot) and action. It may provide the greatest benefits in productivity and safety since it incorporates artificial-intelligence-based algorithms that show promise for adapting to the dynamic mining environment.

Mechanization in mining has reached the stage where, in an attempt to improve productivity, machines have become increasingly expensive and complex and pose excessive demands on already highly stressed operators. Often the potential capacity of a machine outstrips the manipulative skills of the person operating it. Also the efficient use of large complex machines calls for levels of precision that many times are beyond the capability of even highly trained miners. In addition, these expensive machines should not sit idle while miners do other tasks.

These problems occur in surface and underground mines, but underground mining is receiving more attention since it usually is less productive and more hazardous. In addition, maintaining an artificial environment in an underground mine that is conducive to optimal work performance is expensive. By its nature, underground mining can be hot or humid; in addition, the equipment produces dust, noise, fumes, and other hazards. Explosive or toxic gases and the constant danger of rock falls add to the increasing list of health and safety concerns that have initiated volumes of federal and state regulations for maintaining safe work places for humans in underground mines. These regulations cause tremendous capital and operating expenditures that prevent many mineral deposits from being mined profitably. For example, in both underground coal and metal mines, miners excavate many more entries or drifts than necessary to produce and remove the ore or coal in order to provide a safe environment for humans. These difficulties will increase as mines deplete near-surface reserves that have the best working conditions.

To solve these problems, mining engineers and researchers are applying some robotics technologies without waiting for researchers to produce completely autonomous (self-controlling) equipment. For example, they are providing aids for machine operators, information for managers, and mechanical failure prediction. Mines can gain great advantage by developing equipment and associated mining systems that ease the burden of the operators by removing them, as far as possible, from hazardous and stressful environments and providing the opportunity for greater productivity.

22.2.1 STATE OF THE ART IN OUTDOOR AUTONOMOUS VEHICLES

Most robotics texts primarily cover manipulator robots intended for manufacturing and have limited use for mining application. Fu, Gonzalez, and Lee (1987) is an exception because it is a recent text that covers control, sensing, and intelligence in a fashion that can be applied to mobile robots as well as factory-floor manipulators.

Another excellent reference is the survey of collision avoidance and ranging sensors by Everett (1987). It is especially useful, since it describes the sensors necessary for perception of complex dynamic environments.

Because there are few general reference texts on intelligent mobile robot applications in complex natural environments, individual reports of specific projects describe the current state of the art. Most of this work is for the military. Even though the military and mines share problems in dealing with complex natural environments, mining requires additional development. The following reviews the work done for military applications.

Hennessy and King (1989) describe development of the Autonomous Land Vehicle (ALV), sponsored by the Defense Advanced Research Projects Agency (DARPA) (part of the Strategic Computing Program) and contracted through the Army Engineer Topographic Laboratories. Martin Marietta Information and Communications Systems in Denver built the ALV and conducted experiments with it to advance autonomous navigation technologies. The ALV drove autonomously on a black-top surfaced road and cross country. Fig. 22.2.1 shows that the vehicle is an eight-wheeled, skid-steered vehicle designed for on and off road. It has all-wheel hydrostatic drive powered by a Caterpillar 3208 turbo-charged diesel engine. A foam-filled fiberglass enclosure covers the computers and 100,000-Btu/hr (29.3 kW) air conditioning system. The ALV weighs 18,000 lb (8165

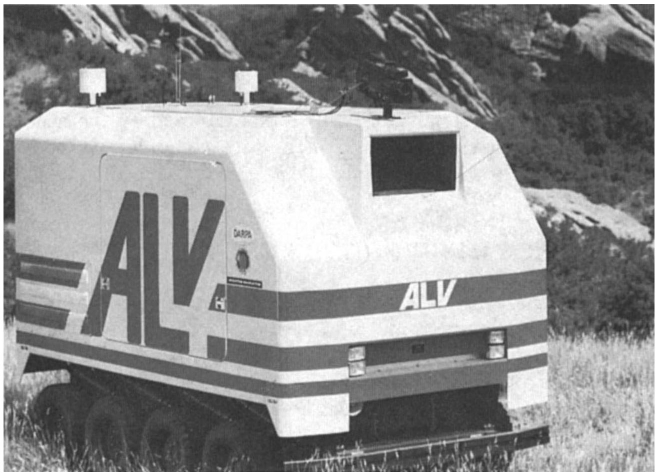

Fig. 22.2.1. Autonomous land vehicle, ALV (after Hennessy and King, 1989).

kg) and requires a 30-kW air-cooled generator for electrical power. Concerns about control system stability limit the vehicle's on-road top speed to 15 mph (25 km/h) and its weight and high center of gravity keep top speed to 6 mph (10 km/h) off road. Computers control the vehicle during autonomous experiments, and operators ferry it to and from the test track under radio remote control. It has a stereo vision teleoperation capability (including a work station in a remote laboratory).

The ALV perceives the environment and locates itself with three sensors: color video, a scanning laser ranger, and a gyrocompass. Data from the color, CCD (charge-coupled device), 512 × 480 pixel (picture element), 57.6° horizontal × 72.5° vertical field-of-view camera produce images for road-edge definition. The Environmental Research Institute of Michigan 256 × 64 pixel scanning laser ranger with 64-ft (20-m) ambiguity interval and 80° horizontal × 30° vertical field of view locates obstacles within the video field of view and characterizes off-road features. The Bendix land navigation system determines vehicle pointing, pitch, roll, and position with a north-seeking directional gyrocompass and two odometers. Researchers have investigated several additional sensors such as forward-looking infrared radar, low-light video, passive multi-spectral, millimeter wave radar, doppler ground speed radar, accelerometers, and ultrasonic rangers. The processing and communications architecture is shown in Fig. 22.2.2.

McTamaney (1987) described the FMC mobile robotic test bed developed for DARPA's advanced ground vehicle technology (AGVT) program. The FMC test bed transmitted data over a five-channel line-of-sight microwave using automatic tracking antennas and a 4.5-MHz band width carrier between the vehicle and a mobile command center to allow off-board processing over a 200-ft to 2.5-mi (60-m to 4-km) range. The command center receives data from robotic sensors, processes the information, and transmits control commands in real time to the vehicle (a modified M113 armored personnel carrier). On-board Intel microprocessors in a multi-processor configuration communicate with the control center, control the mobility actuators and monitor mobility sensors, and generate navigation reports that describe local attitude, position, and speed. Vehicle sensors include a 9600-Hz sonic transmitter and 16 microphones that produce a 16 × 24 range image every 200 ms for obstacle detection at 50 to 110 ft (15 to 33 m). Because of problems with engine and track noise interference and a blind spot, FMC also developed a 30-kHz sensor with 2- to 70-ft (0.6- to 21.3-m) range and 180° field of view.

The software perceives, plans, and controls navigation. The planning system uses a terrain map data base and a planning knowledge base to build a sequence of tasks and routes that will reach the goal. The perception system processes sensor data taken along the route to guide the vehicle along the planned routes by building a local map and fusing it with the planner's world map. The result is added to the vehicle mobility knowledge in the navigation system to create mobility commands.

Harmon (1987) describes the ground surveillance robot (GSR), a modified M114 armored personnel carrier. The program objective is to develop a second-generation autonomous vehicle test bed that can traverse unknown natural terrain between two given geographic locations. The GSR perceives the environment with 33-ft (10-m) acoustic rangers, a high-resolution gray-scale camera, a low-resolution color camera, and a laser range finder. Dead reckoning sensors (track speed, gyrocompass, and a doppler) define relative vehicle position and attitude. Since none of these provide accurate information in all circumstances, their data is fused to obtain the best relative position estimate. A satellite navigation system provides absolute position within 330 ft (100 m).

A world model is constructed with objects represented by triangles using a class tree with inheritance. The world map is used for long-range path and route planning. Route planning software relies on a minimum cost algorithm that considers energy requirements, estimated unknown hazards, estimated velocity, and distance to the goal. Intermediate goals are developed (trading off energy consumption, opportunity to gain valuable new information, and progress to the goal) in unknown terrain if the final goal is not within the sensor's field of view.

Carnegie-Mellon University's Navigation Laboratory (NAVLAB), based on earlier work with the Terregator, has a

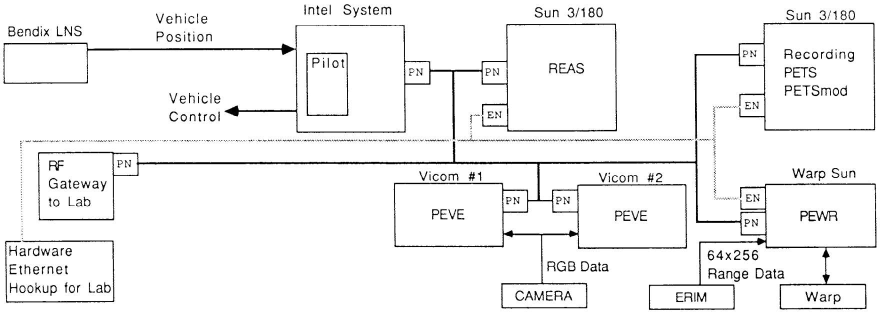

Fig. 22.2.2. Autonomous land vehicle processing and communications architecture (after Hennessy and King, 1989).

sensor suite similar to that of the ALV, but it does not have cross-country mobility capabilities (Goto and Stenz, 1987). It has successfully navigated sidewalks and a curved road using the CODGER (communications database with geometric reasoning) software system.

The robotic command center (RCC) is being designed to house workstations and communications to control multiple unmanned military machines (McTamaney et al., 1988). The current system assigns two vehicles to each of two drivers in the command center, which also houses a commander. The commander will plan wide-area operations and monitor them while the other workstations drive the vehicles with computer-aided remote driving or teleoperation. The system architecture is based on FMC's AGVT and extended to control multiple vehicles. Microwave and RF communications will link the vehicles to the RCC.

22.2.2 AUTONOMOUS VEHICLE ACCOMPLISHMENTS VS. MINING NEEDS

These autonomous vehicle projects demonstrated and developed considerable technology that can be borrowed and adapted to mining:

1. Closed-loop control systems utilizing sensor data to detect errors from planned or specified actions.
2. Pattern recognition algorithms.
3. Computing systems that permit real-time multi-tasking operations.
4. World modeling algorithms.
5. Path planning algorithms.
6. Work stations and intelligent user interfaces for supervising multiple semi-autonomous machines.
7. Ultrasonic ranging.
8. Laser ranging.
9. Land navigation systems.
10. Teleoperation.
11. Sensor fusion algorithms.

Mining engineers and researchers must adapt these advances to the mining environment and mining needs and develop additional technology for cost-effective application for the following reasons:

1. Some mining equipment (like mobile haulage vehicles) can navigate from a map. They do not need to explore.
2. Mining engineers can modify the layout to reduce the navigation and obstacle detection problems.
3. The mining environment is harsher in some respects than any that the autonomous vehicle research programs have encountered.
4. Mining equipment must operate faster and more precisely than most of the present autonomous vehicles.
5. Mining equipment must operate reliably over long periods of time and not just show success with a few demonstrations.
6. Mining machines must have better on-board machine health monitoring and diagnostics.
7. Excavation and drilling equipment require geo-sensing.
8. Some of the autonomous vehicle program technologies are not cost-effective for mining. For example, the software development and compute power for robotic image processing is not cost-effective in the dusty mine environment.

The comparison of autonomous vehicle development and mining needs shows that mining engineers and researchers must (1) develop computer representations of mining-specific knowledge in areas like layout and planning, machine capabilities, mine geometry, machine interactions, and machine conditions; (2) develop cost-effective sensors that will perceive and withstand the special mining environment; (3) analyze (e.g., using pattern recognition algorithms) and reason about mining specific sensor data to intelligently control machines; and (4) discover completely new mining methods or new approaches to traditional methods through removal of constraints imposed by the necessity of human operators. Some of this work is underway and is described under the next topic.

22.2.3 MINING ROBOTICS PROJECTS

Evans and Mayercheck (1988) and Frantz and King (1977) thoroughly reviewed mine automation, and Chapter 12.6 on mine monitoring and communications describes typical automated control strategies for stationary systems like conveyors. Therefore, this segment provides a reference and design source focus on research efforts that anticipate future intelligent mining systems. Cost-effective application requires real-time sensing and reasoning at the same level as a highly experienced human operator. This is a very difficult and expensive research and development task, considering the highly variable and dangerous mining environment. Therefore, mining researchers have not begun to develop equipment for all applications. They are focusing their efforts on the most promising. To achieve short-term results at the least cost, these projects borrow technology from the autonomous vehicle programs described in 22.2.1, allowing them to focus their limited resources on the specific mining problems listed in 22.2.2.

22.2.3.1 Autonomous Continuous Mining

Schnakenberg (1990) described the US Bureau of Mines efforts to develop enabling technology for computer-assisted control of mining equipment to improve worker safety and productivity. The work covers basic machine electrical, mechanical, and hydraulic components; sensors, algorithms, and languages for intelligent closed-loop control; obstacle detection and guidance sensors and algorithms; geosensing sensors and algorithms; machine health sensors and knowledge-based systems; and path planning algorithms. It is applicable to a wide range of mining equipment, but Bureau personnel are carrying out and demonstrating results on a modified underground coal continuous-mining machine fitted with electrically actuated controls in the Pittsburgh Research Center Mining Equipment Test Facility (METF).

Schiffbauer (1990) developed the Bureau of Mines Network (BOMNET) based on an Intel iSBC 286/12 central processing unit connected for multiprocessor networking through a Bitbus to several peripherals, sensor conditioner modules, communications devices, and a Solidrive magnetic bubble memory cartridge on the miner. The system hosts the iRMX86 operating system and PLM 86 software. Fig. 22.2.3 shows the Bitbus configuration that connects a single board computer for on-board attitude and location sensors, a Sun 3/60 workstation for the laser-based angular positioning system, a Sun 4/110 supervisory control workstation, and a Symbolics 3670 unit for machine health status.

Sammarco (1988a) developed closed-loop control for all machine functions except tramming using output from rotary variable differential transformers and hydraulic-pressure, temperature, and flow transducers (Fig. 22.2.4). He achieved closed-loop control for shearing, stab jack, and conveyor swing, based on the position of each component when operating in free space and cutting coalcrete. He controlled tram speed, direction, and pivot in an open loop (time clock limited) mode with the control safety relay, pump, gathering head/conveyor, and cutter motors

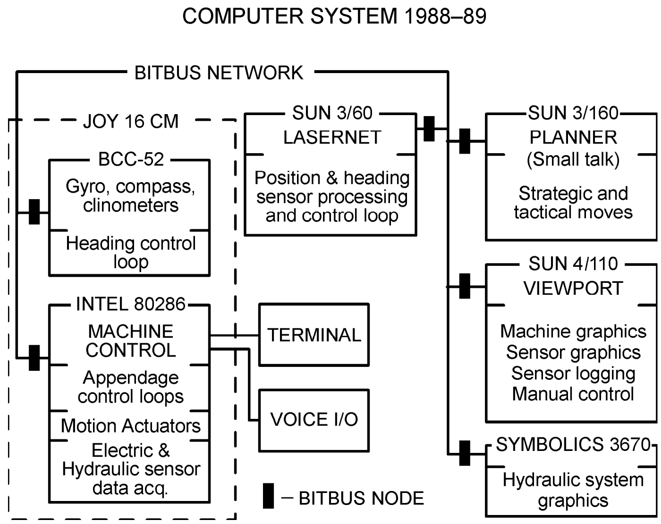

Fig. 22.2.3. US Bureau of Mines autonomous continuous miner computer network (after Schiffbauer, 1990).

latched. Sammarco established set points in degrees of movement reported by the resolvers and evaluated errors caused by lag times in both the hydraulic and electrical systems. The system operated accurately in free space and when subjected to the vibration and stress of cutting coalcrete. Sammarco described initial efforts to fail/safe the control with checks on microprocessor power and software execution, and recommended additional verification of sensors and machine during startup.

In an effort to extend closed-loop control to tramming, Sammarco (1988b) experimented with on-board machine attitude and location sensors including a gyroscope for entry centerline control (yaw), flux gate compasses for redundant heading data referenced to magnetic north, and clinometers for gravity referenced pitch and roll. The objective of the on-board system is to provide attitude and location within a cut. The on-board data will be fused with the laser-based angular positioning system for long-range guidance. Sammarco found that the gyro

1. Drifts 9.73 degrees/hr in Pittsburgh.
2. Has cumulative errors.
3. Has moving parts that will require maintenance.
4. Is very expensive.
5. Needs a 5- to 10-minute warm-up period.
6. Requires special power sources, signal conversion, and control.
7. Provides ±0.02° heading changes within milliseconds.

For comparison, Sammarco determined that local magnetic fields affect the flux gate compass which was not able to keep up with a machine pivoting at 3.3 °/sec, but it does not drift, its errors do not accumulate, it has no moving parts, it does not require warm-up, and it is inexpensive. The present flux gate requires the machine to be stopped for 2 sec to accommodate the present 2-sec averaging window; however, he believes modifications might be possible.

Anderson (1989) developed the laser-based angular positioning system shown in Fig. 22.2.5 for precise, longer-range navigation guidance of the continuous miner in the face area. The positioning system reference is a mobile control structure, patterned after a mobile roof support that will follow the continuous miner along an entry. Either surveyors or a long-range automatic total station will determine the precise coordinates of the mobile control structure after it is set at the face. During the excavation of each cut, the continuous miner will locate itself relative to the mobile control structure with a laser scanner mounted on the mobile control structure seeking retroreflective targets on the miner. Multiple scanners that sweep 90° each and multiple targets reduce obstruction problems and provide redundancy. Anderson's algorithms use two geometries (Fig. 22.2.5) to determine position and attitude, one where two or more laser photodetectors sense the angular position of two or more targets on the machine, and the other where one photodetector senses three or more targets. She is developing a fusion algorithm that assigns confidence (weights) to each angle measured based on the knowledge that certain orientations affect measurement reliability.

Mining machine control will ultimately become intelligent. That is, the miner will be able to alter its cutting plan if sensors report deviations from the conditions and events used to generate initial plans. Bureau of Mines researchers are developing three software modules for this objective. The navigational goal scheduler will plan the sequence of machine actions and positions necessary to complete a cut, and represent them as a series of goals. An action planner will plan the actions necessary to progress from one goal to another. The contingency goal scheduler will allow operations to continue when the miner can not reach a planned goal. It will attempt to discover the problem and plan an alternative goal. To speed the application of intelligent control to mining, the Bureau contracted with the National Bureau of Standards to transfer their standard architecture for intelligent control of manufacturing robotic work cells and the space station to the autonomous continuous miner program (Albus et al., 1987).

The control developed by Sammarco uses only position sensors for controlling cutting horizon; as a result, frequent contingencies may arise because seam height varies dramatically in some mines. Mowrey (1990a) studied waveforms generated by accelerometers mounted on the machine and on the coal to develop algorithms that will automatically discriminate between vibrations resulting from cutting coal and rock. Natural gamma radiation had also been used successfully for cutting horizon definition (Mowrey and Maksimovic, 1990; Nelson and Bessinger, 1990). Infrared imaging is another technique under investigation because it discriminates between coal cutting and rock cutting by producing images of the higher-temperature areas that result when cutting rock (Mowrey, 1990b). However, this technique requires compute-intensive video image processing.

The autonomous continuous miner will cost much more than present machines. Therefore, it must be very reliable to be cost effective. High reliability also reduces maintenance personnel exposure to face hazards. Consequently, Mitchell (1990) is developing an expert system prototype to interrogate the various hydraulic sensors and report on machine health. The system will diagnose hydraulic problems based on sensor and user input. It will explain how it reached conclusions, and provide recommendations for repair. Mitchell used a hierarchy of rules to represent the knowledge of hydraulic diagnostic experts and backward chaining to search through the knowledge base to diagnose the condition of the hydraulic system. She implemented the system with an expert system shell called Goldworks. Berzonsky (1988) covers the electrical system, and eventually, machine health systems will cover all continuous miner components. He developed a prototype expert system for interactive troubleshooting and training of personnel for electrical system fault diagnosis with the Level 5 expert system shell.

Carnegie-Mellon University (CMU) developed the locomotion emulator for the autonomous continuous miner research program at the US Bureau of Mines. It has general locomotion and can emulate the characteristics of different vehicles like a

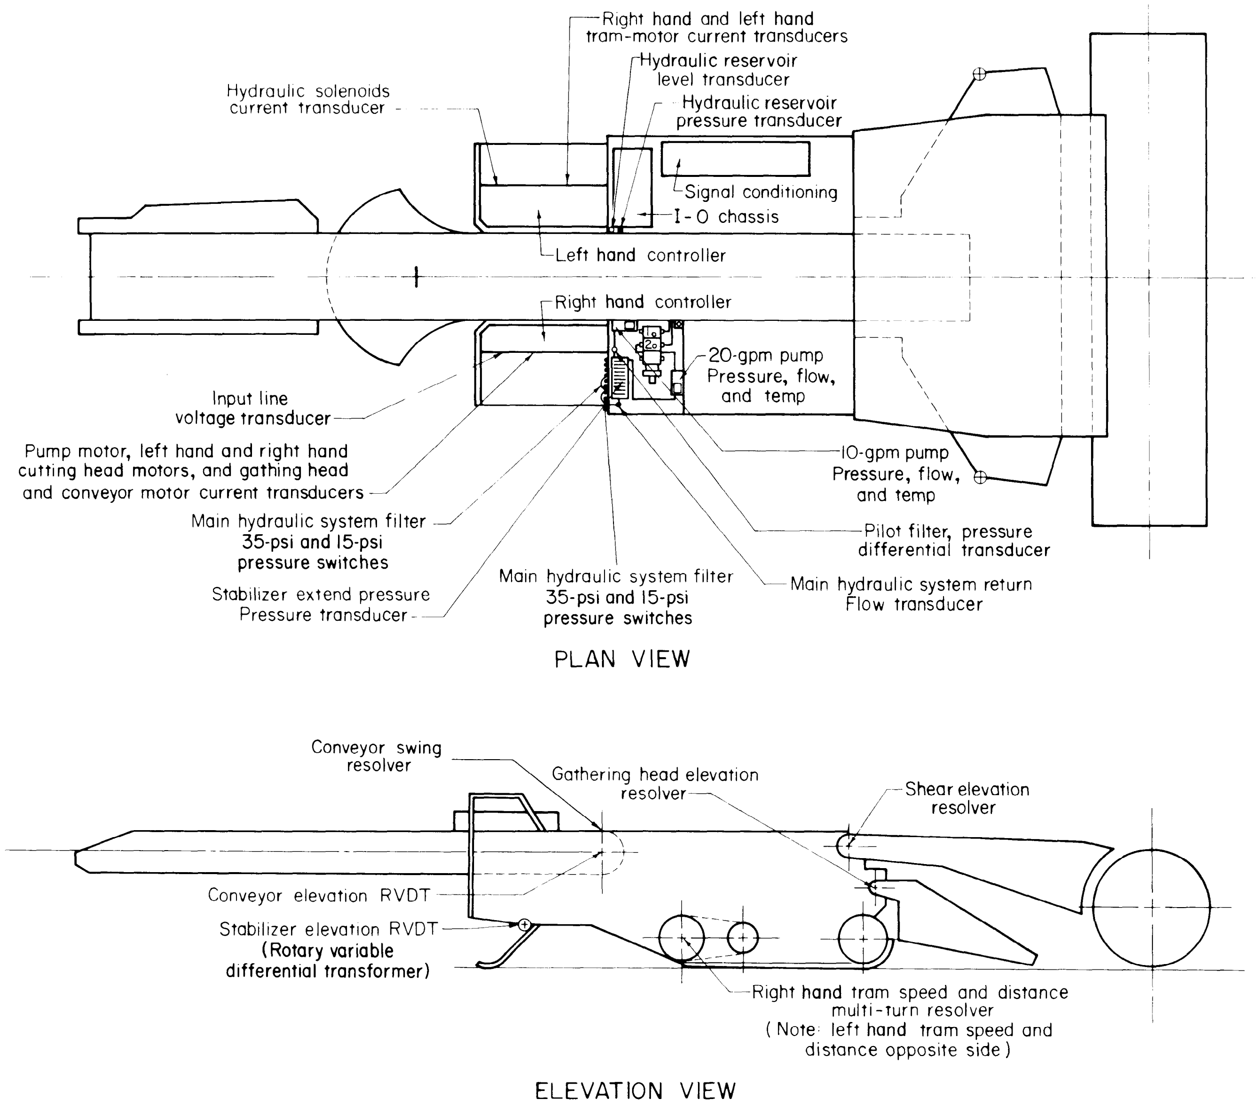

Fig. 22.2.4. US Bureau of Mines autonomous continuous miner sensors (after Sammarco, 1988a and b). Conversion factors: 1 psi = 6.895 kPa, 1 gpm = 3.785 L/min.

unicycle, Ackerman steered, and skid steered units (Schnakenberg, 1990).

22.2.3.2 Teleoperation for a Highwall Mining System

Kwitkowski et al. (1988) teleoperated a low-profile continuous miner and haulage system to extract coal from strip mine highwalls at the METF. The system will mine without exposing personnel, since the operator will remain in a supervisor's station on the highwall bench while the miner and haulage system (Fig. 22.2.6) extend up to 3300 ft (1000 m) into the untapped highwall reserves. The teleoperated miner will use a laser beam as a guidance reference. A tether carries operator commands, audio/video signals, and sensory data between two microcomputers (housed in the supervisory station) and the machine. Bureau researchers modified a low-profile machine (Fig. 22.2.7) that the manufacturer equipped with tethered remote control. They added two-color video systems, microcomputer and communications hardware, explosion-proof housings for the new electronics, and a suite of sensors to measure machine health, attitude, and position. The miner can load coal into a variety of haulage systems, but the researchers chose the multiple-unit continuous haulage system previously developed by a Bureau contractor (Evans and Mayercheck, 1988).

22.2.3.3 Computer-assisted Longwall Equipment

Fisher and Palowitch (1978) and Hartley (1982) described the extensive programs on longwall automation in the 1970s at the US Bureau of Mines, US Department of Energy, and the UK National Coal Board Laboratories. Recent work has focused on coal interface detection, automatic shield advancement (shearer initiation), and system monitoring. Nelson and Bessinger (1990) recently evaluated and applied results of the interface detection research to measure boundary, coal thickness.

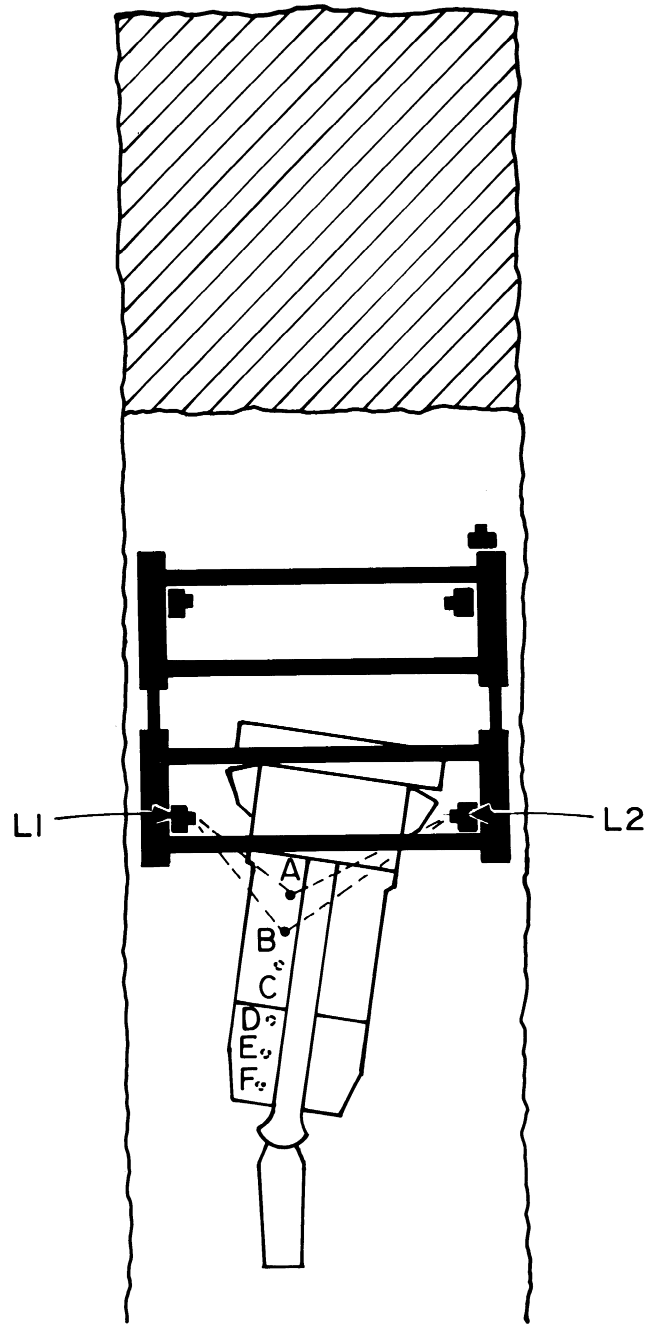

Fig. 22.2.5. US Bureau of Mines autonomous continuous miner laser and target positioning system (after Anderson, 1989).

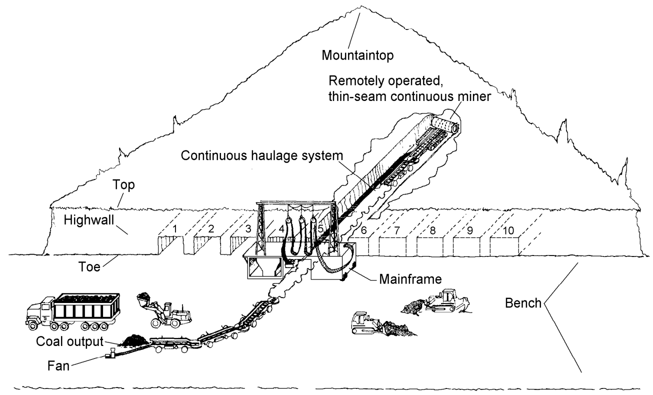

Fig. 22.2.6. Artists conception of the highwall mining system (after Kwitkowski et al., 1988).

Their evaluation revealed that a natural gamma background sensor was most appropriate, and they installed one with a single scintillation crystal, a photomultiplier tube, and a control panel with counts-to-thickness conversion, selectable sampling time, and digital thickness display on shearing machines in two mines. These instruments aided shearer operators to consistently leave 6 to 8 in. (150 to 200 mm) of roof coal in one mine. They successfully modified the sensor for more rugged mounting in shield toes for floor, coal thickness measurement.

Owen (1988) reviewed the development of the National Coal Board monitoring and information processing and reporting systems for longwall faces. The National Coal Board developed standard systems that collect data from in-mine transducers and transmit them to a surface computer for analysis and reporting. The software is divided into modules: a basic operating system, data transmission and interface with applications software, data files, applications software, and tables of colliery characteristics. The number of sensors for machine condition monitoring is growing rapidly and covers haulage and loading equipment and shearers and plows. The surface computer console operator gathers data about delay causes by calling the face whenever the display screen shows production interruptions. The system reports the resulting data at the end of shift and in longer-term management reports. Owen stresses that the information available made several improvements but causes considerable upheaval in traditional mine management structure and practice. Lever et al. (1990) are building similar information systems for continuous mining.

22.2.3.4 Semi-autonomous Load-Haul-Dump Machines

In underground mines, the lowest productivity and greatest hazards occur on mobile mining equipment operating in stopes and at the face. Mobile fragmentation machines are difficult to control autonomously because the level of sensing and intelligence necessary to handle exceptions in the highly variable geologic environment is sophisticated and underdeveloped. Controlling the direction of cutting or drilling and determining the proper levels of force to use in rock masses with variable properties are difficult. However, there are significant economic and safety gains associated with autonomous excavation equipment.

Primary transportation vehicles, which also may include loading, have some of these problems in distinguishing and handling oversize material, but not nearly to the extent of extraction equipment. In addition, they can apply the navigation perception, reasoning, planning, and control successes from the previously described autonomous vehicle programs. LHD vehicles are like many intermediate haulage vehicles such as shuttle cars and trucks. They follow a cyclic operating pattern over various well-defined paths and thus become good candidates for autonomous vehicle technology application. For example, at the AMAX Henderson mine, LHDs load molybdenum ore from drawpoints, tram to an orepass, dump, and return or switch to another drawpoint. King (1988) estimated a favorable return on investment from semi-autonomous operation of the Henderson LHD fleet. An autonomous LHD at Henderson must

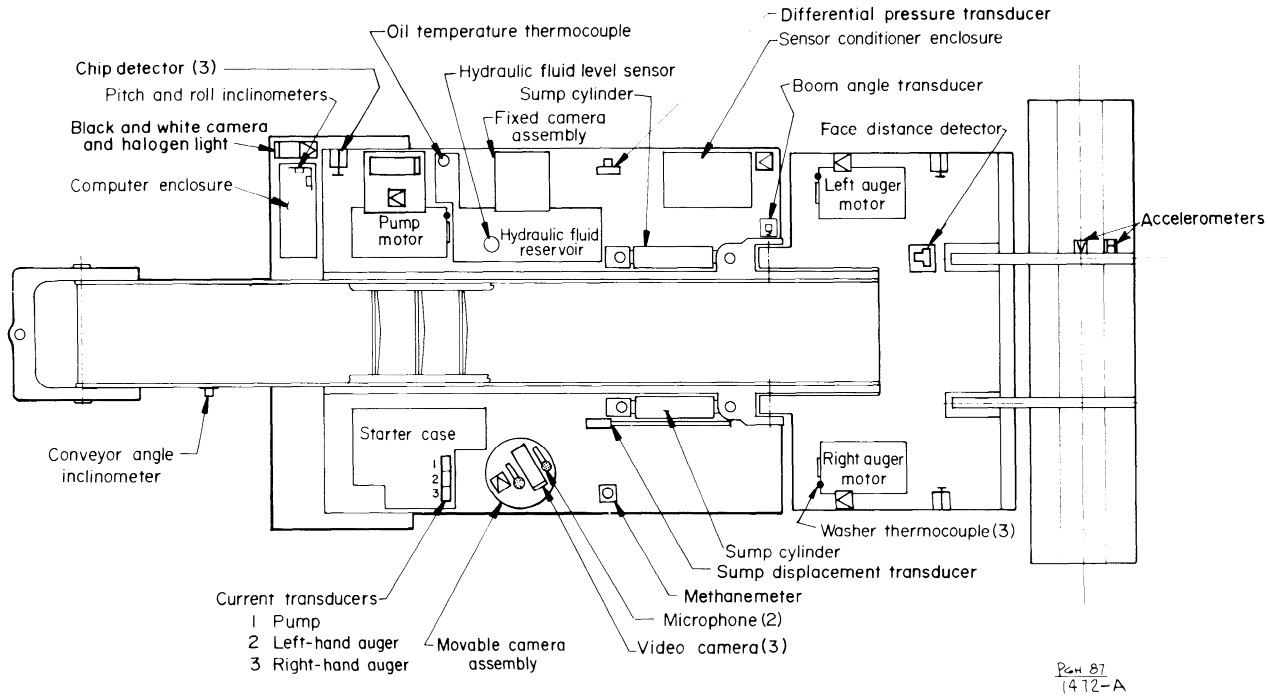

Fig. 22.2.7. Teleoperated highwall miner sensor locations (after Kwitkowski et al., 1988).

1. Sense vehicle position along the route.
2. Relate sensor data to stored map information to determine location.
3. Follow drift centerlines.
4. Plan paths between dump points and orepasses.
5. Compare sensed position with planned position and initiate appropriate control commands.
6. Sense vehicle operating status and vehicle health.
7. Key on features or targets for special tasks like high-speed turns.
8. Perform end-of-travel tasks (loading and dumping).
9. Detect and avoid obstacles.

These goals are similar to those for shuttle cars, trucks, and front-end loaders, and therefore much of the technology is transferable. Thus several researchers are focusing on intelligent control for LHDs. Supervised autonomy can reduce the number of operating units by increasing operating time per shift since computer-controlled machines can operate during lunch and between shifts and reduce operator errors. Inexpensive, robust sensors requiring minimal processing are a key to cost-effective implementation, so ultrasonic ranging is a good candidate. It is appropriate for underground mines because the equipment travels in well-known areas, and the ultrasonic ranger can locate the machine relative to features in an on-board map. For example, range readings to the ribs can help maintain a straight path along the entry centerline, or the LHD can cue on rib features for turning (Strickland and King, 1990).

The problem with ultrasonic ranging is that conventional sensors report the range to the first object in the sensor field of view in a multi-object environment, but the first object may not be the one of interest. Attempts to solve the problem with an array of sensors, fusing with other sensor types, horns to reduce the field of view, and building maps from multiple range readings from different robot locations are not appropriate for mining. For example, world modeling and reasoning software can build a model of an object when mobile robots take many readings from different view points. However, this solution requires the robot to roam around an area, plan paths to reveal occlusions, etc., reason about what it finds, and replan the discovery path. This technique is not appropriate for a vehicle trying to accomplish an industrial task where it has to reach an objective quickly. Therefore, current work is developing algorithms that recognize patterns in ultrasound return signals that distinguish between objects (Gordon and King, 1990).

Baiden (1988) is developing a monitoring system and expert system to report on LHD machine health. It will reduce downtime, lower consumption of components, and increase machine life. Baiden selected a radio link to transfer data from the 73 on-board sensors to a remote microcomputer. Over three months, the system collected 50 megabytes of data describing the conditions of seven machine subsystems: engine, brakes, hydraulics, drive train, electrics, fuel, and exhaust. Baiden is developing data reduction and pattern recognition algorithms and interfacing the monitoring system to a maintenance assistant expert system. The maintenance assistant uses rules to represent the knowledge of LHD maintenance experts in the M.l expert system shell. Because of the difficulty of representing such complex knowledge with rules, he has focused on the braking subsystem to date.

Granholm et al. (1988) studied and tested LHD guidance systems. In one of their tests, they teleoperated an LHD with a TV camera. In another test, the operator drove the LHD using a TV and monitor placed inside a cab with the windows covered. They are also experimenting with painted-line-following techniques similar to those used by automated guided vehicles in factories and warehouses. The researchers painted a 4-in. (100-mm) wide line on the back of a haulage drift and used CCD cameras to locate the line. They found the system could detect 0.4-in (10-mm) deviations from the path.

In a similar teleoperation effort, Nantel et al. (1988) installed a video camera on a LHD and transmitted the image 75 ft (23 m) to a remote operator in the Noranda Lyon Lake mine. The purpose was to help the operator load the bucket fully when operating by remote control in a production drawpoint below a bulk mining stope. This was an important study because for many years, the phases of robotic development in mining will require the use of supervision. Supervisors might need video images to properly control robotic equipment in contingency situations. Video transmission using radio waves (without tethers and leaky feeders) is difficult, as these researchers report. They could practically transmit only 330 ft (100 m). They transmitted digital video data from a camera with 510 $\times$ 492 pixel images with a transmitter providing 1W of video-modulated radio frequency at 439.25 Mhz powered by 12-V dc from the LHD circuit. The LHD operator used the 4-in. (100-mm) monitor provided with the system to successfully load the LHD bucket.

Kallio (1988) reported on similar teleoperation work with cameras mounted on the machine and on the rib. LHD operators expressed that teleoperation was easier than remote control. Kallio's paper also described a computerized equipment control and monitoring system (CECAM), that is a microcomputer-based production and condition data acquisiton and storage system. Kallio further reported that a wire guidance system, similar to that used on factory automated guided vehicles, was used to control an LHD tram path.

22.2.3.5 Computerized Drills

Recent advances have made mine drilling equipment partially automatic. If this trend continues, drills will become more autonomous, which will improve their output, reduce labor cost, but increase their purchase price. So far, the increased capital investment has not shown adequate savings to US mine operators, who use few automatic drills. However, robotic technology is appealing since drilling is an inherent element in most mines' production cycle. Underground and surface metal, nonmetal, and coal mines all employ drills to penetrate rock for exploration, blasting, and ground support. Although the machines' size, shape, and function vary, enough similarities exist for advanced robotic technology duplication. Furthermore, many other industries like tunneling, underground nuclear waste cavity excavation, underground missile site development, and civil construction use mobile heavy drilling equipment.

Bristow (1985), Kelly and England (1986), King (1987), Montan (1984), and Ulvelin and Puhakka (1988) describe the advance of drilling technology from hand drilling in the early 1900s to computer-controlled drilling today. These developments are driven by the fact that human operators are not capable of obtaining maximum equipment productivity. For example, they cannot reposition drills fast enough to keep up with the fast penetration-rate capability of hydraulic drills, and they cannot accurately position drills as quickly as computer control. In addition, when human operators leave for shift change, for example, expensive drills must be shut down unless they are computer controlled.

Bristow (1985) describes a basic computerized jumbo that contains a microprocessor; a control console; angle transducers at boom joints; linear transducers for extension, feed, and crowd; hydraulic sensors; and electro-hydraulic valves. The drill operates in either automatic, manipulator, or manual mode. In automatic mode, a drill pattern in the computer defines the position, direction, and depth of holes in relation to the tunnel axis. The operator can modify and store drill patterns with a portable computer to avoid collaring in holes left from the previous round. The sequence of events begins by inputting a reference into the computer such as the relation between the tunnel axis and a fixed laser beam. Then the drill is manually trammed to the face, and a drill rod is aligned with the laser. The operator presses the navigate button, and the jumbo drills the round if it is physically able to reach all the hole positions. A video display shows the entire pattern and shows which holes have been drilled. The video display graphs penetration rates for each drill to help the operator determine when to change bits and whether geological conditions have changed. The display also shows boom positions relative to the reference axis. In manipulator mode, the computer actuates the boom and drill movements that are manually commanded. The movements are therefore more efficient and accurate in response to "joy sticks" than in the manual mode. Display features are also active in manipulator mode.

Peck, Scoble, and Edwards (1988) described work on algorithms that will make computerized drills more intelligent. Their sensors monitored rotary speed, torque, thrust, air-flushing pressure, and instantaneous penetration rate with a microprocessor on a surface blasthole rig. Then they developed relationships between the changes in these data and rock mass properties. Their work will allow drills to characterize the rock mass. As a result, the control system can recognize and respond to geologic condition changes automatically and optimize penetration rates while minimizing wear and maintenance on drilling equipment.

Hay and Howie (1988) instrumented a roof bolting machine to study similar relationships, but for a different reason. They described work to determine the optimal type and installation of coal mine roof bolts. Furthermore, their research will ultimately provide intelligence for autonomous roof bolting machines. Their system will replace the feel and expertise of the expert roof bolter operator to adjust standard bolting patterns to achieve the best support when rock mass properties change. In cooperation with a private contractor, they built a real-time measurement and display system that calculates instantaneous specific energy at the current bit position in 1-in. (25-mm) intervals and logs each hole drilled on an experimental machine at the US Bureau of Mines Spokane Research Center. Sensors on this machine measure torque, thrust, penetration rate, and rotation rate. The system aids the roof bolter operator to locate voids, inclusions, and changes in strata. The sensors report data to an on-board computer in a permissible enclosure. Some data (specific energy vs. bit and void position) can be downloaded to a removable semiconductor memory device for additional processing on an off-board "fresh air" microcomputer that is also used for software development. Hay and Howie plan to extend the system to closed-loop automatic control by adding servo valves to the hydraulic control circuit. They will add the full-control bolting system that reports anchorage strength and installation torque of each bolt and matches the bolt installation procedure to the existing geologic conditions. Using this combination, the system will identify roof properties during drilling and select and carry out the appropriate roof bolt type and installation procedure to provide optimal support. Hay and Howie plan to add vibration sensors and processing algorithms with an expert system to assess machine health. They can also constantly update geological data for an intelligent mine-wide monitoring system.

22.2.4 SUMMARY

Most of the present work in mining robotics focuses on individual machines. Some researchers integrate them into systems and develop new systems. Some notable examples are Wolfenden and Shaw (1988), Kwitkowski et al. (1988) Schnakenberg (1990), and Frantz and King (1977). Integrated approaches are necessary to develop intelligent mining systems.

A compilation of the individual robot design studies and the synthesis works show that the major components for mining robots are:

1. Mobility.

2. Intelligence.
3. Robust components.
4. Supervised autonomy.
5. Navigation and guidance.
6. Geologic perception.
7. Environmental perception.
8. Location perception.
9. Machine health perception.
10. Obstacle detection and avoidance.
11. Path planning.
12. Closed-loop control.
13. Real-time multiple tasking computer architecture.
14. Intelligent user interfaces.
15. Teleoperation.

A summary of the tasks necessary to perfect a mining robot include the following:

1. Acquire and test candidate sensors
2. Specify and purchase sensors.
3. Mount sensors.
4. Specify and purchase computer processing, memory, data acquisition, control, and interfacing hardware.
5. Mount computer processing, memory, data acquisition, control, and interfacing hardware.
6. Interface sensors.
7. Establish teleoperation capability with communications link and workstation.
8. Develop, encode, test, and modify (a) data reduction algorithms, (b) fusion algorithms, (c) object recognition algorithms, (d) control algorithms, and (e) software architecture.
9. Test and modify computer processing, memory, data acquisition, control, and interfacing hardware.
10. Develop, encode, test, and modify object recognition algorithms.
11. Develop, encode, test, and modify control algorithms.
12. Develop, encode, test, and modify software architecture.
13. Test and modify computer processing, memory, data acquisition, control, and interfacing hardware.

Chapter 22.3
HYDRAULIC MINING: JET-ASSISTED CUTTING

DAVID A. SUMMERS

22.3.1 INTRODUCTION

Hydraulic mining, the use of water to break and remove rock, is not new. But within the last twenty years, as it has become commercially possible to generate fluid flows of higher pressures, the technology has found new applications. These new ways provide advantages for this method of excavation, which is therefore becoming more widespread. This chapter describes the development of the technology, some of the lessons learned, and some of the applications.

22.3.1.1 Terminology

Although high-pressure water jets were first investigated as a new mining tool, they have become more extensively used for cutting metal, glass, and other industrial materials. The terminology used by this industry is relatively common; only a few terms may need clarification.

22.3.1.2 Definitions

Gooseneck: The sequential combination of two articulated elbows to allow monitor flexibility.

Miners inch: The volume flow rate of water flowing through a l-in. (25mm) square hole under a head of 6 in. (150 mm). Forty miner inches are equal to 1 cfs. (The term is historic; a miners inch roughly translates into a flow of 0.03 m^3/s under a pressure of 1.75 kPa.)

Monitor: The accelerating nozzle, with its support and steering mechanism used in the large-volume excavation of alluvial deposits.

Nozzle: The shaped section at the end of the delivery pipe through which the fluid is accelerated to its final velocity.

Orifice: The smallest cross section within the nozzle area, normally at the downstream end, which controls (for a given volume flow) the velocity of the fluid.

Roadheader: A mechanical excavation machine fitted with a rotating head mounting picks that are dragged over the rock surface. The machine excavates the tunnel face a segment at a time.

Specific energy: The amount of input energy required to remove a unit volume of material.

Tunnel boring machine (TBM): A full-face, continuous mining machine, generally fitted with disk cutters that are compressed against the face of the tunnel as they rotate. The tunnel is excavated across its full cross section at one time.

22.3.2 HISTORICAL BACKGROUND

22.3.2.1 Hydraulic Mining Development

Water naturally erodes soil and rock, but at a speed that is normally too slow to be of interest. However, water can penetrate into the cracks and natural grain boundaries of material weakening it and helping remove softer deposits. Such erosion of soil occurs after a heavy rain. Only a small increase in pressure is required to obtain a water flow that will remove poorly consolidated material.

In the early days of the California gold rush, once the gold-bearing rock had been found, large mine workings were common. Working under a steep slope of relatively soft material was a slow and dangerous process when the material was removed manually. In February 1852, Chabot and Matteson first used a 40-ft (10-m) long, 4-in.(100-mm) diameter rawhide hose to direct a jet of water at the ore and remove the soft material (Kelley, 1954). The water was pressurized by the drop from the top of the bank, some 30 ft (9 m). Since the water also carried the ore to the sluices and cradles, where the gold could be removed, hydraulicking proved to have an overwhelming advantage and rapidly spread throughout the gold fields (Fig. 22.3.1)(Anon., 1853). A reliable supply of water was a perennial problem, and typically cost between $0.75 and $1.00/miners inch. However, this volume increased a miner's production by more than three-and-a-half times over that using a pan, with less physical strain (Wilson, 1912).

The hose was changed to canvas, and in 1855 the goose-neck joint was added (Egenhoff, 1931). This was followed by the addition of a deflector that improved the maneuverability of the monitors that had grown more than 10 ft (3m) in length (Kallenberger, 1970). By 1886, more than 2375 million yd^3 (1868 Mm^3 of dirt had been removed, creating an environmental problem (Egenhoff, 1931). Chapter 15.1 of the *Handbook* discusses hydraulicking as a current placer mining method.

Water jets remove material on a grain-by-grain basis. But the sandy rock containing the gold held a significant amount of fine material that was also liberated. These fines did not settle as the water passed down through the sluices, because of its relatively high speed. The particles only settled out when they reached the relatively slow-moving rivers that flowed from the mountains to the sea. This rapidly filled the rivers with silt, and when the weather produced rain, the rivers overflowed their banks, flooding the adjacent farms. In order to stop this silting of the rivers, the farmers took the mining companies to court, and in 1883 were successful in obtaining injunctions from Judge Sawyer (Kelley, 1959), which effectively closed many mines. This "anti-dumping" legislation marked the end of the boom period in the California hydraulic mines that had produced more than $150 million in gold. A contemporary comment stated, "At one blow, the Sawyer decision reduced the visible assets of the State of California by 100 million dollars" (Kallenberger, 1970).

The technology had spread through most of the west and abroad. In 1867 a device invented by Chausov was used in the area around Lake Baikal in Russia for gold mining (Yufin, 1965). By the turn of the century, water jets were used to mine peat in Prussia, and in 1935, Muchnik (1952) first used water jets underground for the mining of coal. Hydraulicking proved particularly useful in the thin, steeply dipping coal seams of the Don and Ural basins, but it was not until 1952 that a complete hydraulic operation was started at the Tyrganskii Uklony Mine (Muchnik, 1956).

Hydraulic mining expanded steadily in Russia because of the relatively low cost of the technology, the low levels of manpower

Fig. 22.3.1. Early water-jet monitor being used in Idaho (Idaho Historical Society).

required, and the relatively high volume of coal that could be produced from difficult-to-mine deposits. Trials were also performed in other countries. Because of the high volumes of water required, and the difficulty in adapting this technology to relatively flat seams, experiments in Germany (Gottwald, 1968) and the United Kingdom (Jenkins, 1961) were not successful. In Japan (Sato, 1988), China (Tian, Sun, and Zou, 1985), and, most effectively, in Canada (Grimley, 1972), successful mines were developed.

At the Sparwood mine in British Columbia, a monitor used 1200 gpm (4.7 m^3/min) of water at pressures up to 1800 psi (12.5 MPa), to successfully mine coal from a 40-ft (12-m) thick seam dipping at some 45°. The operation had an average productivity, over 10 years, of 3000 tons (2700 t)/shift from a machine that required only two men to operate. As a further advantage, the water used to mine the coal also carried the coal from the mine. Economic conditions and other problems, however, have recently caused both this mine and the one in Japan to close, so that at present the only extensive hydraulic mining operations are being practiced in China and Russia.

22.3.2.2 Water-jet Cutting of Rock

EUROPEAN BEGINNINGS. Hydraulic mining of coal and soft rock was sufficiently successful that trials were begun on cutting stronger rock. Because such rock was believed to be harder to break, Russian investigators built a single-shot water cannon to drive slugs of water at pressures of up to 100,000 psi (700 MPa) (Chermensky, 1976). Studies in the United Kingdom also used a water cannon to examine the ability of water jets to cut rock (Leach and Walker, 1966).

COOLEY THEORY. In the United States, Cooley (1975) extended the European work using a cannon capable of reaching 600,000 psi (4200 MPa). On the basis that the best system was the most efficient, Cooley analyzed his results (Fig. 22.3.2) to conclude that a jet pressure of 20 times the uniaxial compressive strength of the rock should be used. Thus 600,000 psi would be needed to effectively cut 30,000 psi (210-MPa) granite.

The same premise formed the basis of work carried out at Bendix Laboratories and at IIT Research Institute (IITRI) under Singh (Labus, 1976), who similarly sought a more effective method of cutting rock by building very high-pressure water-jet systems.

COOLEY THEORY REVISED. The experimental data that Cooley analyzed came from single-shot devices, with rock and nozzle fixed. Other work, in Russia and Leeds (Summers, 1968) had, however, shown that a water jet could cut granite at 9000 psi (63 MPa). This occurred when a continuous jet was traversed over the rock. Penetration of small fluid wedges into the cracks between the granite grains was followed by pressurization of the water, crack extension, and ultimate material removal. Although

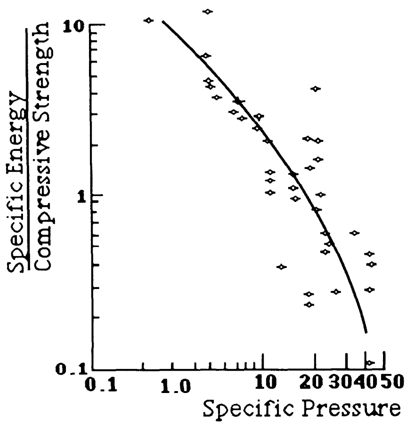

Fig. 22.3.2. Relationship between specific pressure and specific energy, proposed by Cooley.

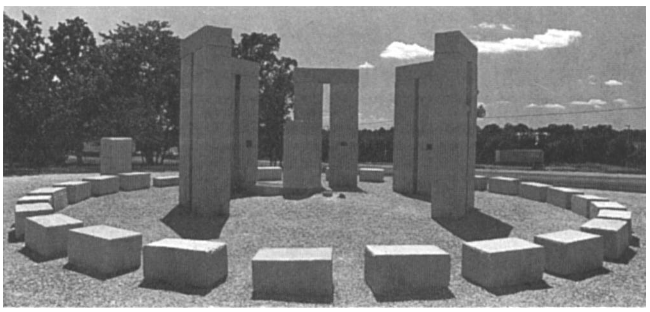

Fig. 22.3.3. Stonehenge, a UMR monument carved from 30,000-psi (207-MPa) granite at 15,000-psi (103-MPa) jet pressure.

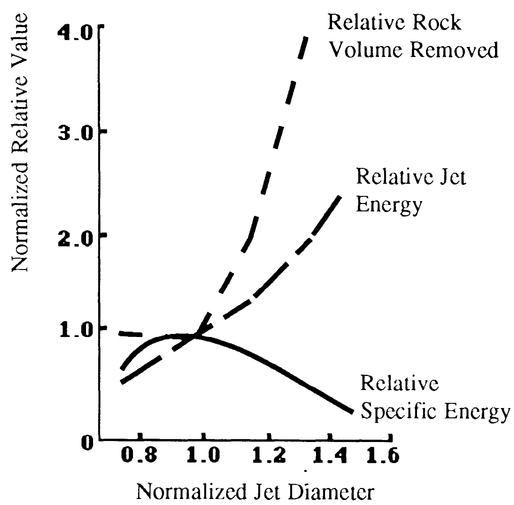

Fig. 22.3.5. Specific energy change with change in relative flow rate (nozzle diameter).

slow, such a jet drilled a hole 9 in. (230 mm) deep in a granite block. The jet pressure was less than 1.5% of that suggested in the earlier relationship.

Subsequent development has produced equipment for cutting soil and rock at commercially available pressures, as shown by the cutting of the UMR (University of Missouri—Rolla) Stonehenge (Fig. 22.3.3). Research has shown that the mechanism of crack growth can be more easily exploited by increasing the fluid flow at a given pressure rather than by increasing the pressure at a constant flow. This can be illustrated by data from a factorial experiment in which both flow rate and pressure were varied in cutting coal. As the pressure increased (Fig. 22.3.4), so the volume of coal removed increased, but the specific energy of cutting only decreased slightly. In contrast, where the power was increased by enlarging the jet (Fig. 22.3.5), the volume removed increased more than equivalently, with a larger drop in specific energy.

This mechanism can be usefully exploited in concrete cutting. Normal concrete has small microcracks around the aggregate boundaries. As the concrete weathers, these cracks extend and the concrete strength reduces. Deteriorated concrete is thus identified as material with significant crack lengths. The pressure of a water jet can be adjusted so that it will easily extend the larger cracks in weathered material, but has insufficient pressure to enlarge the much smaller cracks in "good" concrete. Thus one can develop a tool that can evaluate and remove only damaged material.

22.3.2.3 Limitations of Water Jets Alone

Because water jets penetrate material through crack extension, it is difficult for a water jet to easily penetrate fine-grained materials and those with a high intergranular strength. However, if the crack density under the attacking water jet could be increased, much more material could be removed. Three different

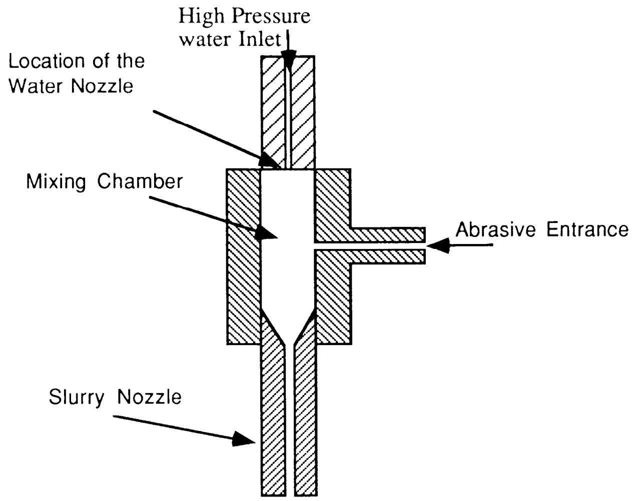

Fig. 22.3.6. Conventional abrasive injection into water.

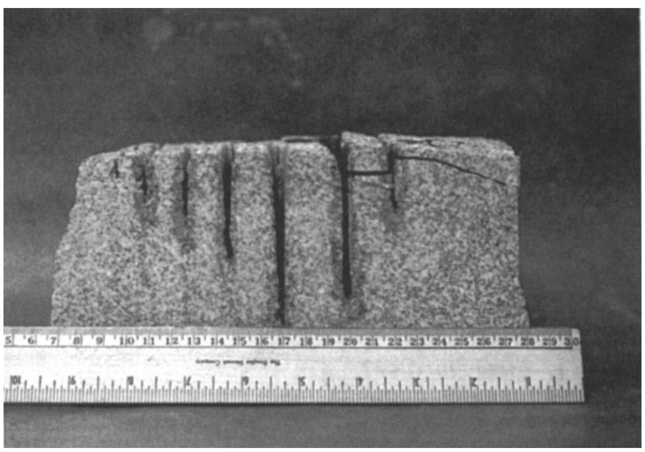

Fig. 22.3.7. Granite block cut by a 30,000-psi (207-MPa) water jet with increasing concentrations of abrasive. Cuts start at the left with no abrasive in the water.

basic mechanisms have been proposed to create these additional cracks.

The most widely used method in mining is to add a water jet to a mechanical cutting device. This method has proven to be the most successful to date. Two other approaches have been developed. The first is to add an abrasive to the water-jet stream (Fig. 22.3.6). By accelerating the abrasive to the fluid velocity, the two combine to cut slots up to ten times deeper than water alone (Fig. 22.3.7). First developed for industrial cleaning, it was modified for use at much higher jet pressures (Hashish, 1982). By adding 1 lb/min (0.4 kg/min) of a garnet abrasive to a water-jet flow of 1 gpm (4 L/min) at 35,000 psi (250 MPa), a virtually universal cutting tool was developed.

Although abrasive-laden water jets are making significant inroads into industry, particularly in the cutting of metals and ceramics (Posner and Kim, 1987), the high quality required for the water supply, and the relative delicacy of the equipment has limited its use in mining. Two solutions are currently being developed. At the US Bureau of Mines (USBM) in the Twin Cities, Savanick and Krawza (1987) have shown that the mixing of abrasive into a larger volume flow at 10,000 psi (70 MPa) (Fig. 22.3.8) will create a jet that can drill through quartzite at 6 in./min (150 mm/min). More recently, researchers at UMR have used equipment developed in England (Fairhurst, Heron, and Saunders, 1986) to drill quartzite at equivalent penetration rates but with a jet pressure of only 5000 psi (35 MPa). The jet is formed by mixing abrasive into the jet before the water is finally accelerated (Fig. 22.3.9). Although both tools have a potential in mining, neither has reached widespread use.

The third alternative is to induce cavitation bubbles into the water-jet stream (Johnson et al., 1972). The destructive nature of cavitation has been known for many years. The power available is illustrated by the damage to the Tarbela High Dam Project (Kenn, 1983). Due to an unfortunate geometry, water released into the main generator tunnel during the start-up process cavitated as it left the control gates. Within 24 hrs, the induced cavitation had demolished an 8-ft (2.4-m) concrete wall and chewed a hole 11 ft (3.4 m) deep into the tunnel wall. However, cavitating jets have limits in rock cutting, not the least of which is ensuring that cavitation does not destroy the cutting tool as fast as it erodes the rock. Cavitating jets, while promising, have been sidelined as an area of research recently, and their application in the near future is unlikely.

22.3.3 WATER-JET-ASSISTED CUTTING

22.3.3.1 Early American Research

In the early 1970s, there was considerable concern in the USBM over the dust and ignition hazards created when machines excavate hard rock. One way to suppress these hazards was to add water to the cutting head. Low-pressure jets were kept from the cutter tips by the cuttings, so higher pressures were proposed. Such a jet would reach the crushing zone around the tool, dampening the dust and cooling the bit. The jet would also drive water into weak planes in the coal, reducing its resistance to cutting.

Field trials were undertaken at the USBM Experimental Mine at Bruceton, PA (McNary et al., 1976). High-pressure water was fed to a small roadheading machine, where it was formed into a jet directed to cut into the coal between the drums of the roadheader. Lower cutting forces were measured, and dust was reduced by 70%. Although this program was discontinued, it provided an incentive for three subsequent programs.

22.3.3.2 Jet-assisted Tunnel Boring Machines

FIRST FIELD TRIAL. The slow pace of tunnel construction in the early 1970s led the National Science Foundation (NSF) to seek better methods of cutting rock. In a courageous and forthright approach, the agency made initial awards to a wide range of sources (Brown et al., 1976) to develop ideas of possible merit and assess their viability. At that time, tunnel boring machines were becoming popular, but they suffered from rapid cutter wear and the limited horsepower that could be transmitted through the gears and bearings to the rock surface. High-pressure water jets that transmit high levels of horsepower through very small erosion-resistant pipes and nozzles were thus a competitive candidate in the NSF program.

A water-jet-assisted TBM was built by a consortium consisting of the Robbins Co., Flow Industries, and Colorado School of Mines (CSM). Preliminary tests at the CSM Earth Mechanics Institute showed that water jets would improve the performance

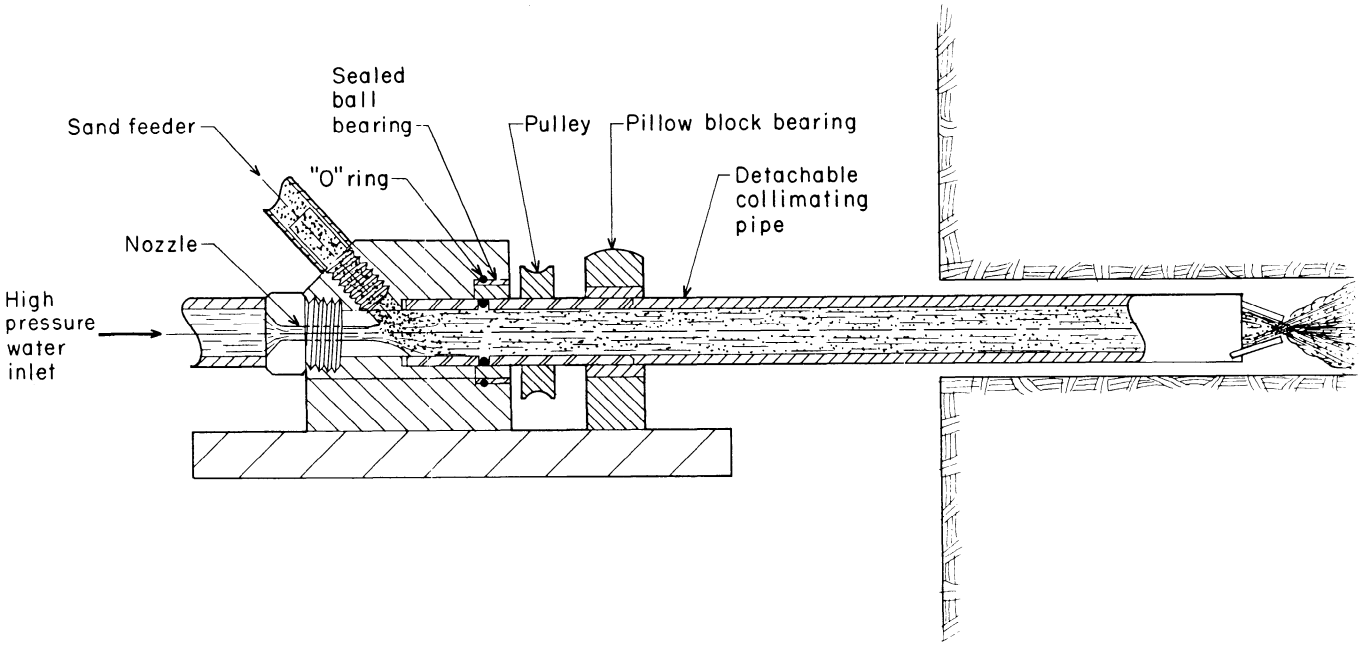

Fig. 22.3.8. An abrasive water-jet drill.

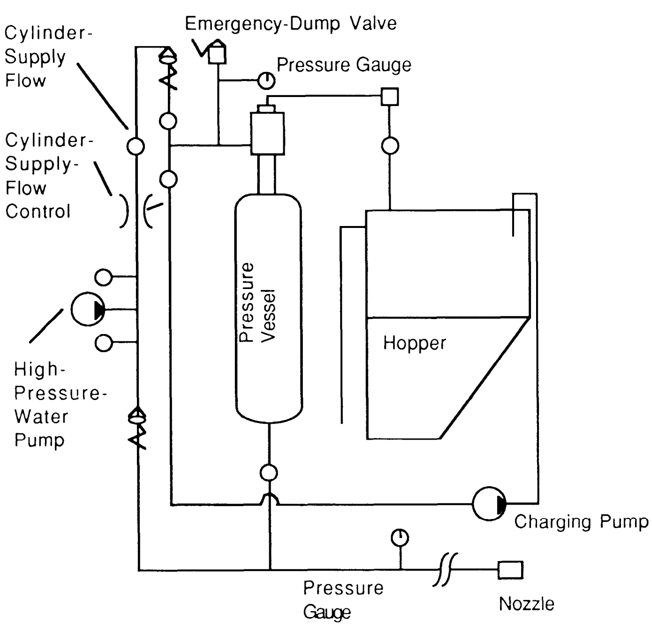

Fig. 22.3.9. Early schematic of DIAJET method of abrasive injection.

of the disk cutters of a TBM in two ways (Miller and Wang, 1976). Improvements were found both if the jets were directed to work in the same groove as the disk cutter and also if they cut an intermediate path between two adjacent cutters.

A field trial, funded by NSF and the USBM, was performed, in late 1976, at a granite quarry in Skykomish, WA. An 8-ft (2.4-m) diameter TBM was fitted with a number of nozzles fed from

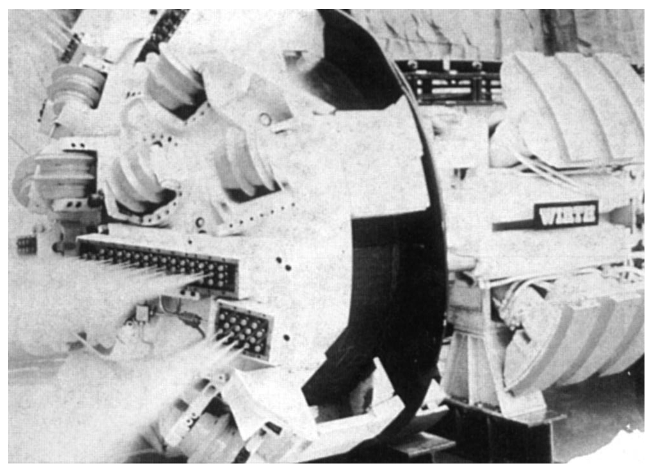

Fig. 22.3.10. Water-jet-assisted tunnel boring machine.

two 500-hp (350-kW) pumps (Fig. 22.3.10). After advancing the TBM without the jets, to generate a database and locate the machine in a consistent rock, the full power of the water jets was applied. The machine immediately began to advance at a faster rate. Unfortunately, the initial nozzle body assembly was located too close to the face of the machine and the unexpectedly rapid advance left large ribs of rock between the disk cutters. These ribs protruded into the path of the nozzles and caused significant damage to them and their supports.

Under normal circumstances, this relatively minor accident would not be worthy of comment. However, its impact on machine design philosophy had a great and often unappreciated effect on machine performance. To avoid problems the nozzles were set back from the face, out of the path of the rock between the cutters. This rock would then be chipped away by the cutters,

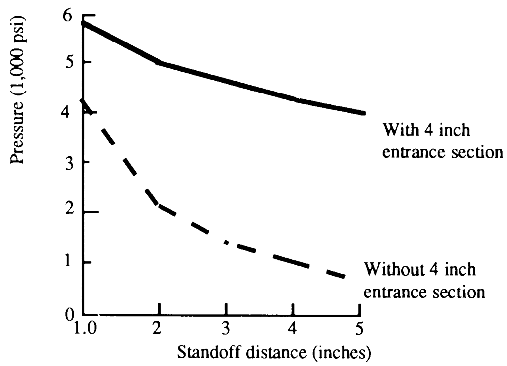

Fig. 22.3.11. Improvement in pressure where a 4-in. (100-mm) tube is used to lead into a water-jet nozzle.

before it reached the nozzles. To understand the unforeseen consequence, one must consider the fluid-flow path to the nozzle.

Water was supplied to the TBM through a fixed line at a pressure of 55,000 psi (380 MPa). In order to feed water to the nozzles in the rotating cutting head, it had to pass through a rotary coupling. Given the state of the art, a single, centrally located high-pressure swivel was mounted on the TBM. The high-pressure water was fed from this swivel into a rotating manifold on the face of the machine, where it divided to enter the nozzles.

Because of the low-volume flow in each jet, it was assumed that a simple orifice inserted into the manifold would provide an adequate jet. In retrospect, this has been found to be incorrect. Recent work at the USBM (Fig. 22.3.11) has shown the need for a short entrance section between the manifold and the nozzle (Kovscek, Taylor, and Thimons, 1988). This pipe stabilizes the jet flow before it leaves the orifice. Without the stabilizing section, the jets issuing from the nozzles were not of high quality.

The definition of *high quality* relates to the internal structure of the jet, which, in turn, controls jet effectiveness. The simplest illustration involves the range of the jet. As the jet leaves the nozzle, it is decelerated and disrupted by the air through which it passes. Thus each jet has an effective range. In an effective jet, this range is on the order of 200 nozzle diameters (Selberg and Barker, 1977). To achieve high pressures, at the low flow volumes used with a TBM, small orifice diameters about 0.01 in. (0.25 mm) are normally used. The effective range for such a jet would be 200 times 0.01 in, or 2 in. (50 mm). However, in order to protect the nozzles, they are frequently set back 4 in. (100 mm) from the rock. Thus the majority of the jet energy has been lost before it reaches the rock, severely restricting system performance. Nevertheless, the Skykomish trials showed that adding water jets to a TBM could improve performance by roughly 37% (Miller and Wang, 1976).

INITIAL PROBLEMS. The large horsepower apparently required for the water jet system suggested that these improvements would only be obtained at high cost. The move toward stronger disks which cut deeper into the rock, when taken with the high lateral traversing speeds of the cutters on the outer edges of the machine face, placed increasing demands upon the performance of the water jets. NSF commissioned Hustrulid (1976) to compare these power requirements with the potential gains from adding water jets to future TBMs. It was his conclusion, being unaware of the power loss problem, that, the gains would not be sufficient to justify the additional effort. As a result of that review, further research in the United States was halted.

EUROPEAN STUDIES. The potential gain from water-jet assistance still appeared attractive. Under an agreement with Bergbau-Forschung, a full-scale TBM was fitted with a modified array of jets and tested in Germany. At a fixed advance rate, force reductions above 50% were found when the jets were used (Knickmeyer and Baumann, 1987). This is an advantage since TBMs require considerable force to penetrate rocks. To achieve this force, large, heavy and expensive equipment is required. Adding water jets allows the TBM to drive at the same speed, but, with less force being needed, a smaller, lighter, and cheaper machine can be used. This advance has, however, been overtaken by another development, which has supplanted the interest in water-jet-assisted full-face tunneling machines.

22.3.3.3 Alternative Approaches

MOST EFFECTIVE PRESSURE. The use of 50,000-psi (350-MPa) pressure on the TBM arose, in part, from the Cooley study, and the assumption that high pressures were needed to cut granite. Although this is not the case, a similar discussion, on the most effective pressure for cutting coal, was taking place at the same time.

The benefits of hydraulic coal mining were clear by this time. However, most of the coal in the United States lies in horizontal seams where disposal of large volumes of water is difficult and where the underlying shale deteriorates when wet. Further, tests by Palowitch had not provided the optimistic levels of production suggested by work elsewhere (Frank, Fogelson, and Chester, 1972). Accordingly, the USBM sought better alternatives for using water jets to mine coal.

The most effective pressure to mine coal first had to be established. The Bureau funded three programs. The first used water jets at a pressure of 10,000 psi (70 MPa) (Summers, Barker, and Mazurkiewicz, 1977); the second suggested a pressure of 60,000 psi (420 MPa) (Singh, Labus, and Finlayson, 1974); while a third program designed a machine to work at 100,000 psi (700 MPa) (Read et al., 1974). After first-year funding, the programs at the higher pressures were terminated and the low-pressure program (at UMR) was continued.

COMPARISON OF RESULTS. It is important to explain this choice. It may be difficult to understand why, when a jet at a pressure of 60,000 psi (420 MPa) is not effective, that a 10,000-psi (70-MPa) system can work.

The reason for this apparent *non sequitur* lies partly in the volume of water in the cutting jet, and partly in the way in which jets penetrate coal at different pressures. Under normal circumstances, for equivalent power, the higher the pressure at which a jet is operated, the lower the volume which is available. This can be seen from the basic hydraulic power equation (in English units):

$$\text{horsepower} = \frac{\text{flow (gpm)} \times \text{pressure (psi)}}{1714} \tag{22.3.1}$$

However, the jet velocity increases as the pressure increases, initially in a form approximated by:

$$\text{velocity (fps)} = 12.5\sqrt{\text{pressure (psi)}} \tag{22.3.2}$$

The reason for the approximation is that the relationship holds only directly at the orifice, is controlled by the nozzle design, and neglects compressibility, which becomes a factor at pressures above 15,000 psi (100 MPa). As the water pressure increases, the volume available not only reduces, but must also flow faster. This means that the diameter of the jet must be significantly reduced in order to conserve volume. This causes two problems.

Initially, experiments show that, to a first approximation, the depth to which a water jet will cut is given by:

$$\text{depth of cut} = k\,\frac{\text{pressure}^{1.0}\ \text{diameter}^{1.5}}{\text{traverse velocity}^{0.33}} \qquad (22.3.3)$$

where k is a constant that varies with the material being cut and the units being used.

Therefore, the first problem is that under constant flow, increasing the pressure has less effect than decreasing the diameter, and performance may not increase as much as anticipated as pressure goes up (see Figs. 22.3.4 and 22.3.5). Under a constant horsepower restriction, an actual decrease in performance may result.

The second problem relates to the way a jet cuts. Lower-pressure water jets penetrate into and exploit pre-existing cracks in the coal. In this way a water jet at 10,000 psi (70 MPa) can cut a single slot in coal that may be 25 times the jet width. However, at a higher pressure, as the diameter is reduced, not only does the jet hit fewer cracks, but it is so powerful that it cuts right past the crack rather than taking advantage of it. The result is a very narrow slit cut into the material.

This narrow cut raises yet another problem in rock removal. Rock underground is under considerable vertical and horizontal stress. If a very narrow slot is cut into that material, then the volume of rock stress-relieved by the cut is often sufficient to swell and close the cut, reestablishing pressure on the cut material, and holding it in place. If a wider slot is cut, then this will allow total stress relief of the rock/coal column, which becomes easier to move. This behavior gave a major advantage to the development of the UMR machine.

Hydrominer and Its Development. Before introduction of the longwall shearer, one of the most successful mining machines in England was the Meco-Moore cutter loader. This used two horizontal cutting booms to slot a longwall face, while a third vertical cutter ran at the back of the cut, freeing the web from the solid. The resulting block of coal fell under its own weight and was transported to the face conveyor by a small cross conveyor. This machine produced large coal with relatively little dust.

In 1974, the USBM funded development of the Hydrominer, in which a similar concept was adapted to improve the performance of a coal plow (Summers, Barker, and Mazurkiewicz, 1977). Four oscillating water-jet pairs were placed around the perimeter of a plow blade so that the coal ahead of the blade would be undercut, cut at the back, and at the top of the machine (Fig. 22.3.12). Thus, as with the Meco-Moore machine, the coal would be de-stressed and easy to move.

Surface trials showed that the machine produced large coal, important when it costs \$1.50/ton (\$1.70/t) to clean 4-in. (100-mm) coal and \$6.00/ton (\$6.70/t) to clean –0.5in. (–1.25-mm) coal. The coal was mined without dust or the risk of spark ignition. Wide slots were ensured by dividing the water at each nozzle into two adjacent streams, thus cutting a slot 2 in. (50 mm) wide.

While two generations of cutting heads were built in the United States, the technology was not tested underground. The German manufacturer GHH worked with Bergbau-Forshung to develop and field test a different model based upon the same principle. Although the machine mined coal at 65 fpm (20 m/min) on a longwall face with a 1.5-ft (0.5-m) web in 5-ft (1.4-m) high coal (three times the production of an equivalent shearer), some difficulties were observed (Schwarting et al., 1981). These related in part to the use of single jets instead of twin jets. The single, narrow jet slot under the coal was closed by stress relief, and the design did not provide a continuous mechanical edge along the face of the plow to assist in the breakout of the coal.

The water jets only cut the perimeter of the web, while the central mass of coal was removed by the mechanical wedging action of the plow blade. The machine showed considerable promise despite the early problems with its use. However, the potential market size for this machine was not considered sufficient to justify the cost of development. The concept behind the machine has, however, been incorporated into the design of a new version being constructed under US Department of Energy funding.

22.3.4 FUNDAMENTALS OF JET-ASSISTED CUTTING

Although there are many situations in which high pressure water jets and water jets working with mechanical assistance have shown potential, as yet they have made relatively little impact on the industry. One area in which water jets have, however, already found an application is directly assisting in cutting by mechanical drag bits. Before discussing the development of the two major efforts in this area, it is pertinent to describe the underlying premise upon which this technology is based and to provide an insight into several of the critical points that are involved in the successful application of this new technology. The most cogent summary of this technology has been given by Geier, Hood, and Thimons (1987) and it is appropriate to review that here (also see Chapter 9.1 in this *Handbook*).

22.3.4.1 Drag-bit Cutting Fundamentals

When a cutting tool is dragged across a rock surface, it will crush the rock ahead of it and successively chip pieces of material from the surface until a single large chip breaks out ahead of the tool. This frees the tool from the high forces and confinement, allowing it to reinitiate the cycle (Fig. 22.3.13). The movement of the tool over the surface forces some of the crushed rock under the tool at relatively high pressure. As the tool drags over this material there is considerable friction that can develop very high temperatures and is a source for face ignitions of gas. Concurrently, the crushed material dissipates the force exerted on the uncut material since the force is evenly distributed around the envelope of this zone. The crushed material is thus a significant hindrance to the performance of the tool. The high pressures and temperatures that are exerted on the tool lead to premature tool failure.

22.3.4.2 Principles of Water-jet Assistance

The most obvious use of a water jet is to assist the cutting tool by removing the crushed rock from the vicinity of the tool. Thus the material causing premature tool failure is eliminated. At the same time the force applied by the pick is no longer distributed around the crushed zone, but is concentrated at those prominent points in the rock resisting pick advance. The force is higher, and the rock fails more rapidly and at lower overall levels of applied force. The removal of the crushed material in a stream of water naturally reduces the amount of dust that would otherwise be liberated into the air.

The water jets must, however, be applied in the right location and at the right flow rate and pressure. To act on the crushed zone, it has been found most effective if the jets are directed to within 0.07 in. (1.8 mm) of the leading edge of the cutting tool

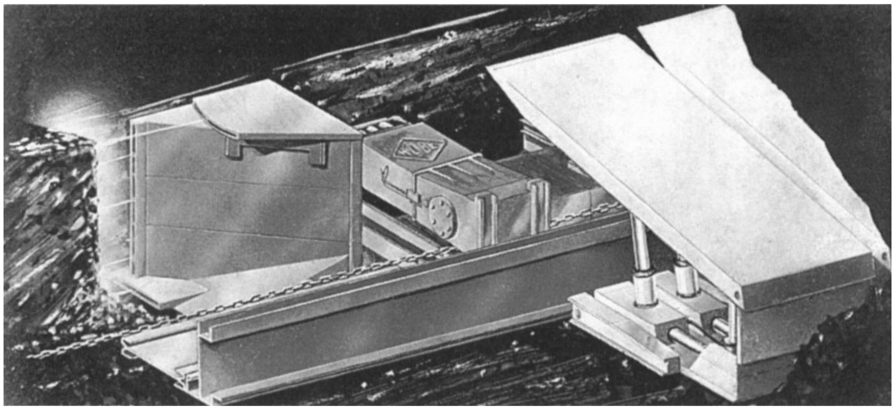

Fig. 22.3.12. Artist's sketch of Hydrominer.

(Fig. 22.3.14). This requires careful positioning of the jet nozzles, which must concurrently be placed as close to the leading edge of the tool as can safely be accomplished in order to get the most energy transfer to the material to be removed. It cannot be emphasized too strongly that, if the jet is not directed at the proper place within the zone of crushed rock right at the base of the tool, then its effectiveness is much reduced. In fact, poor positioning can result in no improvement in cutting conditions. Many tests that have reported poor results have suffered from this failure to accurately locate the point of jet application.

The gain in performance is much more obvious when water jets are added to radial picks rather than point-attack picks. In the latter case, as Hurt and Evans (1980) have pointed out, the removal of material at the tip of the tool merely shifts the force application to the shoulders of the tool, often with a reduction in tool effectiveness. Thus a different strategy must be sought for more effective application in this latter case.

22.3.4.3 Water-jet Cutting Parameters

In order for the jets to do the most good in removing the fine material around the pick, it is necessary that the jet reach that material with sufficient energy. Apart from ensuring that the jet is directed toward the correct location, it must be remembered that the nozzle supplying the jet is set back a considerable distance from the surface. Much discussion has been given to the question of raising the pressure of the jet in order to improve performance of water-jet-assisted machines. Preliminary experimentation has shown that increased pressure has not had any significant effect. This is really not surprising if the actual role of the water jets is as described previously. The need for pressure is to ensure that the jets reach that crushed material, through any fragments of uncut material that may pass between that surface and the nozzle. However, as was discussed earlier, jet effectiveness is better achieved in many documented cases where water flow rather than jet pressure is increased. Given the success that jets have had at lower flow rates for dust suppression on working faces, there is some room to increase the flow rate to the nozzles (by increasing the diameters) and to operate the jets at lower pressure. This would further reduce the cost of the additional water-jet components in the hybrid systems and may produce even greater gains than those catalogued to date.

22.3.5 JET-ASSISTED DRAG BITS

22.3.5.1 Preliminary Studies

In 1974, Hood began a program in South Africa to improve the performance of mechanical bits in cutting the quartzites of the gold reefs. The major problem with the bits was that they melted under the forces necessary to cut the rock (Hood, 1977). Hood calculated that a high jet pressure would be needed to get sufficient water into the cutting area to cool the bit and keep it intact. Experiments showed not only improved bit life, but also a greater depth of cut with lower cutting forces (Fig. 22.3.15). Where a drag bit without water would reach maximum available force with a cutting depth of 0.2 in. (5 mm), with two 10,000-psi (70-MPa) jets on the corners of the bit, it could cut 0.35 in. (9 mm) without stalling the machine.

This significant increase in performance was due to more than keeping the tool cool, and reflected a synergistic interaction between the water jet and the cutting bit in the zone of rock reaction. Underground trials of the equipment then showed that it was possible to achieve even greater relative performance in the field.

22.3.5.2 American Investigations

Report of Hood's work, when combined with the research at CSM, led to an investigation of water-jet-assisted pick and drag-bit cutting (Ropchan, Wang, and Wolgamott, 1980) in coal measure rocks. The benefits found were rock specific, but it was projected that the addition of water jets to a machine would reduce costs per foot (meter) drilled by up to 40%. However, the position of the water jet relative to the tip of the cutting bit was shown to be critical.

22.3.5.3 Cooperative Program

Following this work, the US Department of Energy collaborated with the National Coal Board (NCB), to develop a water-jet-assisted roadheader. Early in 1980, a Dosco MK2A machine was fitted with an intensifier delivering water at 10,000 psi (70 MPa) to 15 nozzles mounted on the cutterhead (Tomlin, 1981).

Rock at the test site, however, was too strong (average range: 17,500 to 20,000 psi, or 120 to 140 MPa) for the lightweight MK2A. A sandstone face was therefore constructed across the end of the tunnel. Few benefits, in terms of cutting performance, were obtained in cutting the sandstone, which the machine could cut adequately under its own power. These benefits were the elimination of frictional sparking and the virtual elimination of dust.

A more dramatic result was, however, achieved when the cutting head was turned onto the native rock. Without water jets, the pick head could not be kept in the cut, due to boom instability, and the head continuously stalled under overload. At the same time it was noted that the picks were rapidly worn and chipped during the cutting. When point-attack picks with water-

Where possible the standoff distance a should be less than 200 jet diameters
The distance b that the jet leads the bit tip should never be more than 1.5 mm.

Fig. 22.3.14. Geometry for maximum effect from a water jet assisting a drag bit. Action of a drag bit moving over rock.

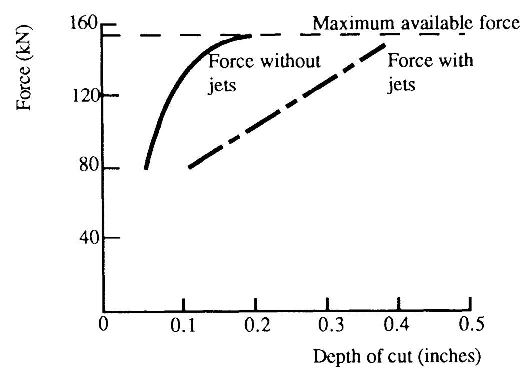

Fig. 22.3.15. Improvement achieved by Hood in adding water jets to a drag bit in cutting norite. Conversion factors: 1 in. = 25.4 mm, 1 lbf = 4.448 N.

jets were tried, the boom stabilized significantly and reduced pick wear was observed, but excessive vibration in the boom was still noted.

When water jets were tried with radial picks, the cutting performance of the machine was vastly improved. With a flow of 1 gpm (4 L/min) per nozzle, it was found that cutting rates were increased 2.0 to 2.5 times. The results were sufficiently promising that a short tunnel was driven with this combination of cutters and jets. Optimum cutting was found to occur where the leading nine picks of the head were assisted by a jet at 10,000 psi (70 MPa).

Under normal conditions, the Dosco machine would be restricted to operating in rocks with a compressive strength below 10,000 psi (70 MPa). A much heavier machine, costing about $650,000, would be needed to mechanically cut the test rock. Use of a lighter machine would bring the equipment cost down to around $250,000 for the roadheader and $150,000 for the water-jet modification. In addition, the removal of the spark and dust hazards and the smaller envelope of the machine make its use more universal.

22.3.5.4 Commercialization of Technology

Both British roadheader manufacturers, Anderson Strathclyde and Dosco, worked with the NCB to develop the new technology as improvements on their basic product lines (Barham and Buchanan, 1987). Machines were developed which showed significant increases in performance over existing equip-

Fig. 22.3.16. Water-jet-assisted roadheader (*courtesy:* Dosco).

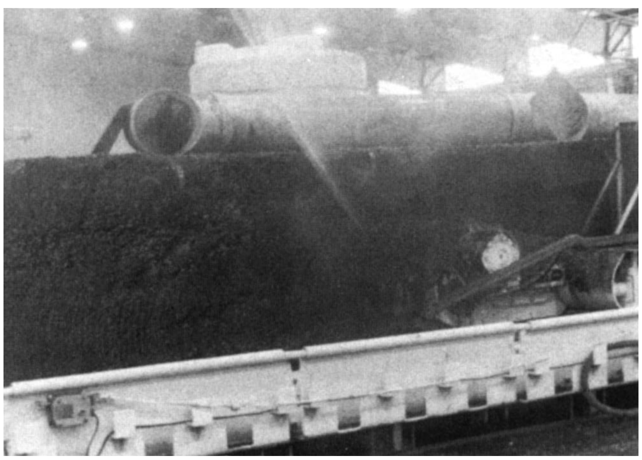

Fig. 22.3.17. Water-jet-assisted shearer.

ment (Fig. 22.3.16). At Sutton Manor Colliery water jets at 10,000 psi (70 MPa) helped drive a 1150-ft (350-m) entry in rock that had strengths ranging to 24,000 psi (165 MPa). The tunnel-driving rate was increased by 50% while dust generation was reduced by 70%. Bit wear was reduced to roughly 25% of that without water jets.

Over 70 water-jet machines had been sold by these two companies by mid-1987. The average cost of a retrofit package for Dosco machines had fallen to $75,000, and the technology has now been incorporated into equipment available from manufacturers in Germany, Austria, and Japan.

22.3.5.5 Development of a Water-jet-assisted Shearer

With the advantages of water-jet-assisted rock cutting established, a similar approach is being taken to coal excavators. Soviet scientists (Ekber and Kuzmich, 1980), were the first to apply water jets to assist plows and trepanners. Recent emphasis has been to add water jets to shearer picks (Fig. 22.3.17).

The USBM has contracted with Eickhoff, to develop a water-jet-assisted shearer (Neinhaus et al., 1986). In the United Kingdom, Minnovation has placed a small pump inside the shearer drum to overcome the problems associated with phasing the water jets on the picks (Tuke, 1988). This is required, since it would be unproductive and hazardous to have the jets operating when the picks are not in contact with the coal. A six-month trial of this system at Bolsover colliery, using water jets at a pressure of 22,800 psi (157 MPa), indicated the following advantages to the system:

1. 6.4% improvement in shearer efficiency.
2. 16% reduction in haulage force.
3. 18% improvement in mechanical efficiency and an improvement of more than 200% in operational lifetime of the cutting arm.
4. Pick life was extended by a factor of ten as a minimum, and significantly less wear was found in the transmission components between the shearer motor and the cutting drum.
5. 40% reduction in water consumption on the shearer for dust suppression.
6. Significantly smoother cutting characteristics.

An alternative system of water delivery was developed by British Coal using an Anderson Strathclyde machine and tested at Golborne colliery (Barham and Buchanan, 1987). When 9500-psi (65-MPa) water jets were added, the power required for a given performance was reduced by 40%. The use of the water-jet-assisted picks reduced the number of picks needed on the drum, lowering fines by some 20%. Dust was reduced by 33%, using one-third less water than conventionally used for dust suppression.

The joint USBM/Eickhoff machine underwent trials at the Auguste Victoria Colliery in West Germany. The shearer was supplied with a flow of 30 gpm (120 L/min) of water at 10,000 psi (70 MPa). The major difference from the British trials is that in the German machine, point-attack picks were used, in contrast to the radial picks used on the British machines.

22.3.6 Practical Application of Jet Assistance

There has been a significant amount of research on the use of water jets to assist mechanical cutters. There have also been enough demonstration projects that have provided favorable results to show that the technology can work. Unfortunately, as with many things, it is not quite as easy to make the system work as might appear. The technology suffers from the perception that it is simple to apply. In fact, there are certain small but critical factors that must be addressed if the application is to provide an advantage. Although these have been discussed in some detail above, it is perhaps pertinent to review them from the point of view of an applications engineer. These include the stages that must be gone through, potential costs involved, and some idea of the productivity that may be anticipated as a result.

The fundamental object of the mining tool is to break rock as cheaply and expeditiously as possible. The major tool for doing this is a series of drag bits fitted on a drum, which, when rotated cut a series of grooves in the rock. By the proper design of the pattern, these grooves overlap and allow extraction of the entire rock surface. The addition of water jets to the process will not, at this stage, change this basic approach to rock removal. What then are the potential gains that an engineer should look for?

When the water jets are properly applied to the cutting zones around the individual rock bits, they enhance the cutting performance of each bit. The improvement comes in three ways:

1. The bit can cut through harder rock and with the same amount of power.
2. The bit can cut to a greater depth in rock of the same strength with the same amount of power.
3. The bit will last longer.

Potential cost savings will arise only if the machine is used to take advantage of these possible gains. For example, rather than purchasing a larger machine to cope with a harder rock, the modification to a smaller machine would provide a significant cost savings. Because it is early in the development of equipment, there is still a significant amount of overhead cost associated with the addition of water jets to cutting drums. It should be noted, however, that pumps are available that deliver 75 gpm (20 L/min) at 5000 psi (35 MPa) for under $5000. Experimental evidence would appear to indicate that this pressure is sufficient to enhance the performance of cutting picks in most rock types. The relative cost benefit of using a smaller machine can be as high as $250,000, as discussed in 22.3.5.3 above. In most mines, however, the volume of rock encountered that the normal machine will have difficulty in cutting may be significantly less than 20%. In this circumstance, the volume of rock to be removed may not justify the equipment modification by itself.

However, if existing equipment is already cutting the rock adequately, then it may be difficult to see much direct gain from the use of water jets. This is because the jets enhance the ability of each individual pick to cut, but the pattern of the picks will probably need to be modified to take advantage of a deeper cutting distance. This has not been common practice. The increased life is not likely by itself to provide sufficient cost savings to justify the modification to the cutting head.

Simply adding a water-jet stream to the vicinity of the path of the rock bit will not provide much improvement in performance. The jet must carry its energy to within 0.06 in. (1.5 mm) of the leading edge of the cutting tool and must be directed along the plane of the tool edge. To get the jet to this point with most of its energy retained, is not always as simple as it sounds. For example, a 60-psi (400-MPa) water jet issuing from a 0.12-in. (0.3-mm) orifice will likely be totally dissipated within 4 in. (100 mm) of the nozzle. Unfortunately, because of the cutting head designs now in use, it may be difficult to place the jet nozzle much closer than this distance from the rock.

Jet performance can be improved in four ways:

1. The pressure can be lowered.
2. The diameter of the jet can be increased.
3. The flow conditions into the nozzle can be improved.
4. Additives might be added to the water.

Of these options, the first is unlikely to be desirable. A minimum pressure is required to help cut the rock, or improvement rapidly disappears. Increasing the nozzle diameter provides a number of benefits in terms of jet cohesion and enhanced cutting ability, but carries with it significant problems in terms of the resulting working condition (jet cohesion disappears rapidly when the machine has to work underwater). Phasing the water-jet system so that the water flows only when the pick is in contact with the rock can improve this situation significantly. Valves have now been developed so that this is a viable option. However, the pumps normally used with the water-jet assistance have not allowed much increase in flow volume. Working conditions in some mines also mitigate against the use of larger volumes of water.

Improving the flow path into the jet nozzle may require a redesign of the cutting head. Such a redesign may well be necessary to take full advantage of the changed cutting conditions for each bit. There should be a lead-in section of straight pipe, at least 3 in. (75 mm) long and preferably 4 in. (100 mm) long. Where this is not possible, then flow straighteners should be placed behind the nozzle to enhance jet cohesion. Manifold designs to distribute the water should be arranged to minimize turbulence and to ensure that the water is divided before it is accelerated. The flow path should be one of constantly decreasing cross sections, since significant energy losses can occur any time the flow path expands.

Maintenance costs for this system are likely to be a little higher than with conventional cutting heads. If individual picks wear too long, for example, then the jet would not cut close enough to the tip to provide any effective support for the cutting process. Nozzles can also wear, and visual evaluation of jet structure is usually not an adequate measure of performance. Running a wooden 2×4-in. plank across the pick head should show some penetration of the wood, as an example of a simple test to check on nozzle quality. Nozzles are relatively inexpensive (less than $30 each) and, with normal clean water, should have a long life. But, it should be remembered that, as with the picks themselves, nozzles are wear items and will need to be replaced. The cost may, however, be more than offset from the increased life of the bits. Further, the increased depth of cut achievable will allow an increase in the separation of the picks so that less will be required on the head. This change, however, needs to be made with some caution. Although the use of water jets will reduce the vibrations caused by individual picks, the increased spacing and change in pattern might, if improperly done, induce other waveforms into the drive train that will lead to premature equipment failure from fatigue.

Chapter 22.4
HYDRAULIC MINING: BOREHOLE SLURRYING

GEORGE A. SAVANICK

Borehole mining, also known as slurry mining, is a process in which a tool incorporating a water-jet cutting system and a down-hole slurry pumping system are used to mine minerals through a single borehole drilled from the surface to the buried mineralized rock. Water jets from the mining tool erode the ore to form a slurry. The slurry flows into the inlet of a pump at the base of the tool. The material is lifted to the surface in a form suitable for pipeline transfer to a mill or processing plant.

As defined by this paper, borehole mining appears to be a likely prospect for the near future. It offers a number of important advantages over conventional open pit and underground mining methods, and it can access mineral deposits that presently are not mined because of technical or economic difficulties. This method can achieve essentially immediate production because there is no need to drive openings to and in a proved ore body to prepare it for mining; in contrast, conventional mining methods require from three to five years before production and return on investment can be expected. The fragmentation and transportation systems are incorporated into a single machine that is remotely operated from the surface by a two- or three-person crew, thus eliminating health and safety problems inherent to underground mining. The equipment is amenable to automated operations.

The environmental disturbance is minimal and short term; no overburden is removed, and subsidence can be avoided.

22.4.1 BOREHOLE MINING TOOLS

The earliest patent for a tool that used a water jet to fragment rock adjacent to a borehole and a down-hole slurry pump to lift the broken ore to the surface was issued to Clayton in 1932.

Patents on similar borehole-mining tools were issued to Aston (1950), Quick (1955), Fly (1964), Pfefferle (1969), Wennenborg (1973), Archibald (1974), and Brunelle (1977). Fly's apparatus was built and used to excavate sandstones, limestones, and shales to a maximum depth of 350 ft (100 m). Mining rates of 1 yd^3/min (0.8 m^3/min) were achieved, and cavities were excavated to a lateral distance of 30 ft (9.1 m) from the borehole. The apparatus had two sidewall nozzles operated at 800 psi (5.52 MPa) and 200 gpm (12.6 L/s) each to form the water jets. The slurry was caused to flow into the intake of a down-hole jet pump, which hoisted it to the surface. The jet pump was operated at about 800 psi (5.52 MPa) and 500 gpm (31.6 L/s). Jets were also formed by forcing water through the water courses of a tricone rock bit attached to the base of the tool. These jets kept the slurry in suspension so that it could be taken into the down-hole slurry pump. This tool used a single, pressurized water supply to operate the sidewall jets, the pump, and the tricone jets.

The apparatus described in the Wennenborg patent was built by the FMC Corp. and tested in phosphate ore in eastern North Carolina. This device uses a high-volume, low-pressure water jet to slurrify the ore and an eductor to lift the slurry to the surface. Its most novel aspect is that it provides a method for drilling into, as well as mining, a deposit of granular ore. All previous mining tools required a predrilled, cased borehole. The Wennenborg device is designed for mining unconsolidated, easily drilled sediments, such as North Carolina phosphates.

The apparatus described in the Archibald patent was built by Marconaflo, Inc., and used to mine uraniferous sandstones and tar sands on an experimental basis. The jet-cutting unit consists of a single nozzle and high-pressure piping that rides on a vertical rail attached to the main body of the device. This rail allows the nozzle to move independently of the slurry pump; the nozzle could be slid up and down as well as rotated 180° about a vertical axis. The vertical motion allows cutting to occur at various horizons without lifting or dropping the entire device, and it lets the intake of the slurry pump to be cleared of blockages by the cutting jet. The cutting jet is operated at 400 to 500 psi (2.76 to 3.44 MPa) and 150 to 170 gpm (9.4 to 10.7 L/s).

The slurry pumping system contains a pump mechanically driven from the surface and 20-ft (6-m) long sections containing a drive shaft and slurry conduits. Both a Moyno pump and a centrifugal pump have been used to pump slurry in the Marconaflo apparatus. The device operated in a 30-in. (762-mm) diameter borehole and produced 30 to 45% solids in the slurry. It was tested successfully by mining a uraniferous sandstone from a roll-front deposit in the Gas Hills of Wyoming from a depth of 180 ft (54.9 m) and by mining tar sands from a depth of 350 ft (107 m) in the McKittrick oilfield near Bakersfield, CA.

In 1974, the US Bureau of Mines (USBM) contracted with Flow Industries, Inc., to design, fabricate, and test a borehole mining tool. The USBM equipment has an eductor for a down-hole slurry pump, whereas mechanically driven slurry pumps were used in the Marconaflo equipment. It contained separate conduits for the eductor driven water and the cutting-jet water, contrasted with the FMC and Fly systems that used a single conduit.

The Bureau's system, shown schematically in Fig. 22.4.1, is composed of the mining tool suspended from a crane in a 16-in. (406-mm) diameter cased borehole. The mining tool generates a high-velocity water jet that erodes and slurrifles ore. The slurry is drawn into the inlet of an eductor and lifted to the surface where it is metered and deposited into a slurry discharge tank (Fig. 22.4.2). The ore settles in the tank while the water overflows into a pond, which is the source of water for pumps that supply the cutting jet and the eductor.

The mining tool, which is operated while suspended from a crane (Fig. 22.4.3), is in the form of a 12-in. (305-mm) diameter cylinder capped with a three-passage swivel. The cylinder is composed of a kelly section, a series of standard sections, and a mining section.

The cutaway view of the three-passage swivel is shown in Fig. 22.4.4. The outer part is stationary and is supported by a crane. The swivel core rotates relative to the exterior while simultaneously passing the three pressurized streams: the water supply to the cutting nozzle, the drive water to the eductor pump, and the slurry output. The swivel is connected to a kelly section by eight bolts. The kelly section is a cylinder 22 ft (6.71 m) long and 12 in. (305 mm) in diameter with two 0.75-in. (19-mm) webs welded along its length. The webs key into a rotary turntable, thereby transmitting torque to the mining tool.

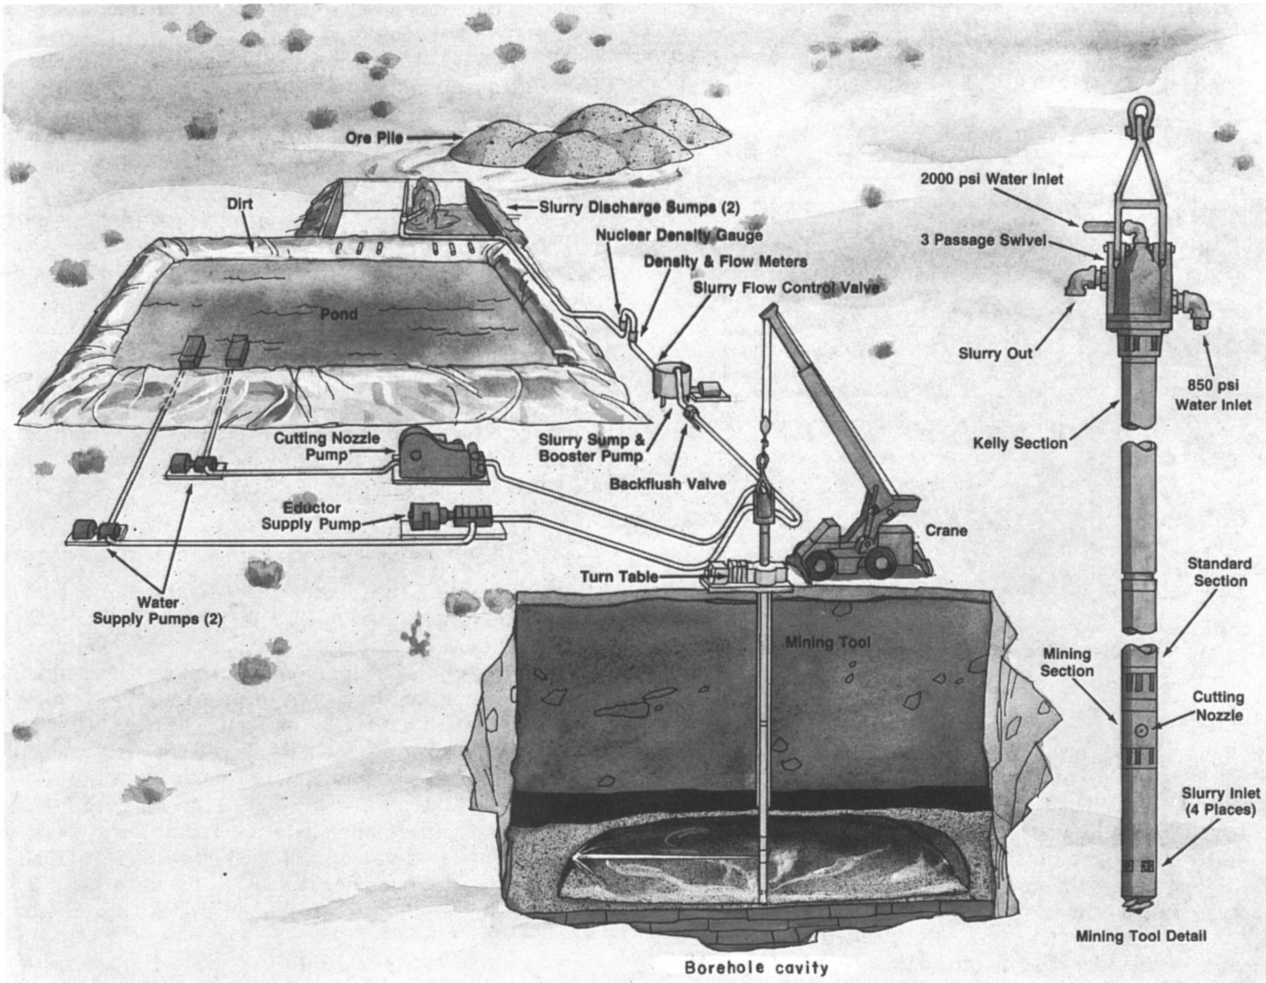

Fig. 22.4.1. US Bureau of Mines borehole-mining system. Conversion factor: 1 psi = 6.895 kPa.

Fig. 22.4.2. Slurry discharge.

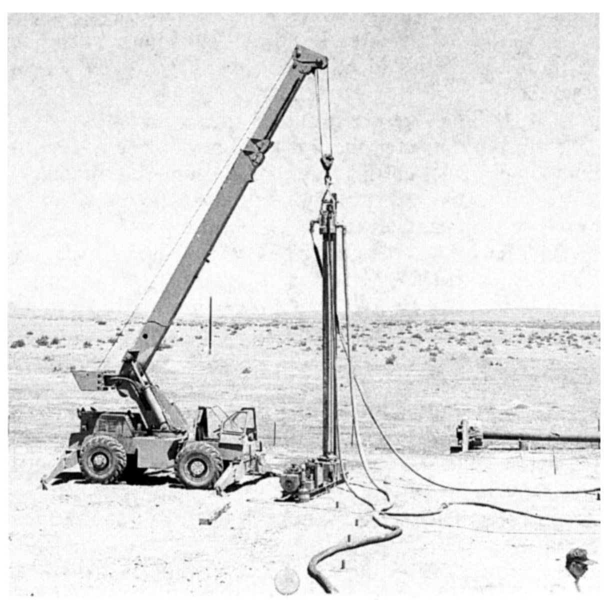

Fig. 22.4.3. Borehole-mining tool suspended from crane.

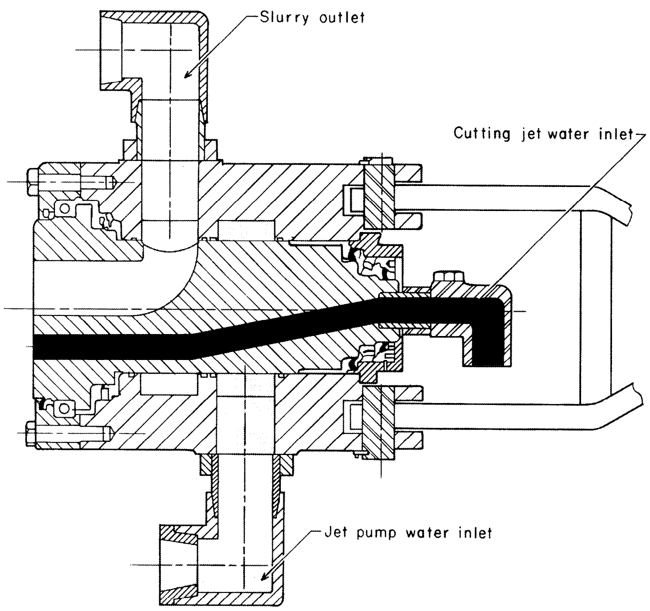

Fig. 22.4.4. Cutaway view of three-passage swivel.

This turntable is driven by an hydraulic motor and governed by hydraulic controls and limit switches, which allows for rotary speeds of 0 to 20 rpm and for automatic oscillation for any interval from 0 to 360°.

The internal configuration of the kelly section is shown in Fig. 22.4.5. The 12-in. (305mm) diameter cylinder houses a 4-in. (102-mm) diameter slurry discharge pipe and a 2-in. (51-mm) diameter supply pipe for the cutting jet. The space inside the cylinder not occupied by pipes is the conduit for the jet-pump drive water. The end of the kelly section is covered by a flange that provides for the interconnection of the conduits in adjacent sections: two circular spaces for the jet-cutting and slurry-output pipes, the two kidney-shaped spaces for the eductor drive water. The kelly section is connected to a string of standard sections, each 20 ft (6 m) long and 12 in. (305 mm) in diameter, that provides the length to reach the ore. The internal configuration of these sections is identical to that of the kelly section just described.

The mining tool is terminated with a mining section 12 in. (305 mm) in diameter and 6 ft (1.83 m) long (Fig. 22.4.6). It is composed of jet-cutting and slurry-pumping modules (Fig. 22.4.7). The jet-cutting module contains a flow-turn and nozzle device that maximizes the effective cutting length of the water jet. This device was designed by TRW Defense and Space System Group under a USBM contract. The nozzle profile consists of a smooth, transitory curve from nozzle entrance to the outlet orifice. Upstream of the nozzle is a short-turn elbow with flow-splitting plates to guide the flow around the elbow with reduced flow disturbances.

The slurry-pumping module contains the eductor (jet pump) and a conical tool. The jet pump has a nozzle that generates the high-velocity water jet. The venturi effect caused by the discharge of the jet draws slurry into the pump through screened intake ports. The slurry mixes with the drive water in the throat of the jet pump and enters a diffuser where it acquires the pressure to lift it to the surface. The intake ports are screened to prevent oversize material from blocking the pump. Should the material block the inlet, a fast-acting valve ("back-flush" valve) is closed in the slurry discharge line at the surface, forcing the jet-pump drive water to flow out of the pump intake and clear away the blockage. The conical tool, which is bolted to the base of the mining section, facilitates entry into cuttings that fill the void caused when the tool is raised. A 50-gpm (3-L/s) water jet issues downward from the center of the auger and agitates the cuttings below, thereby helping the mining section enter the muck pile.

Flow Industries, Inc., independently produced a borehole mining tool based on the USBM design, but with some notable design changes. The Bureau of Mines and Flow Industries, Inc. products are similar in that both are composed of 20-ft (6.1-m) lengths of cylinders connected by flanges, and the slurry pumps have the same design. They differ in that the cutting nozzle of the Flow product is controlled independently from the remainder of the tool, similar to the Marconaflo tool. This permits water-jet cutting to be performed anywhere along the length of the borehole while the pump is low in the sump, where the slurry density is highest.

22.4.2 COAL MINING

Flow Industries, Inc., under a USBM contract, conducted borehole mining operations in 1975-76 at a site 3 miles (4.8 km) south of Wilkeson, WA. This site contained a seam of bituminous coal 17.8 ft (5.4 m) thick, dipping at 42°. Three vertical boreholes (two shallow and one deep) were drilled through the dipping coal seam and cased to the hanging wall. The two shallow boreholes (25 and 35 ft, or 7.6 and 10.7 m) were used to conduct preliminary tests designed to optimize mining procedures to be followed during a 4-hour production test in the deep (88-ft, or 26.8-m) borehole. The preliminary test results were as follows:

1. The cutting jet was more efficient at cutting coal than the slurry system was at removing the coal from the borehole. Thus, the maximum mining rate was limited by the slurry-pumping rate.
2. A cutting radius of 10 ft (3 m) was attainable with the 4500-psi (31-MPa), 100-gpm (6-L/s) jets.
3. Shale tended to clog the jet pump because it breaks into acicular particles that lodge between the nozzle and the sidewall of the jet pump.

A production rate test was conducted in the deep borehole, which was lined with 16-in. (406-mm) steel casing. The parameters of the cutting jet were similar to those used in the preliminary test except that a single, high-discharge jet (4500 psi or 31 MPa, and 200 gpm or 12.6 L/s) was used to increase the effective cutting range to 15 ft (4.5 m).

This test yielded a production rate of 8 tph (7t/h). This rate, along with the fact that no mechanical failures of the mining tool occurred during the field program, indicates that it is technically feasible to mine coal remotely from the surface through a borehole. It was concluded, however, that the test production rate was too low for commercial feasibility.

Flow Industries, Inc., conducted a further study for the US Department of Energy on borehole mining of pitching coal seams. This study proposed an optimum borehole mining plan and system for mining coal seams less than 10 ft (3 m) thick that pitch more than 25°. This plan utilized a double-drill system. This method uses a larger vertical hole for the slurry pump and a smaller slant hole for the cutting tool. This slanted cutting hole is drilled down-dip on the footwall of the seam to intersect the vertical hole at maximum depth. The cuttings drain down the cutting hole to its intersection with the pumping hole, from which they are pumped to the surface.

According to Boyce, the borehole mining method is not economically competitive with other surface mining methods for

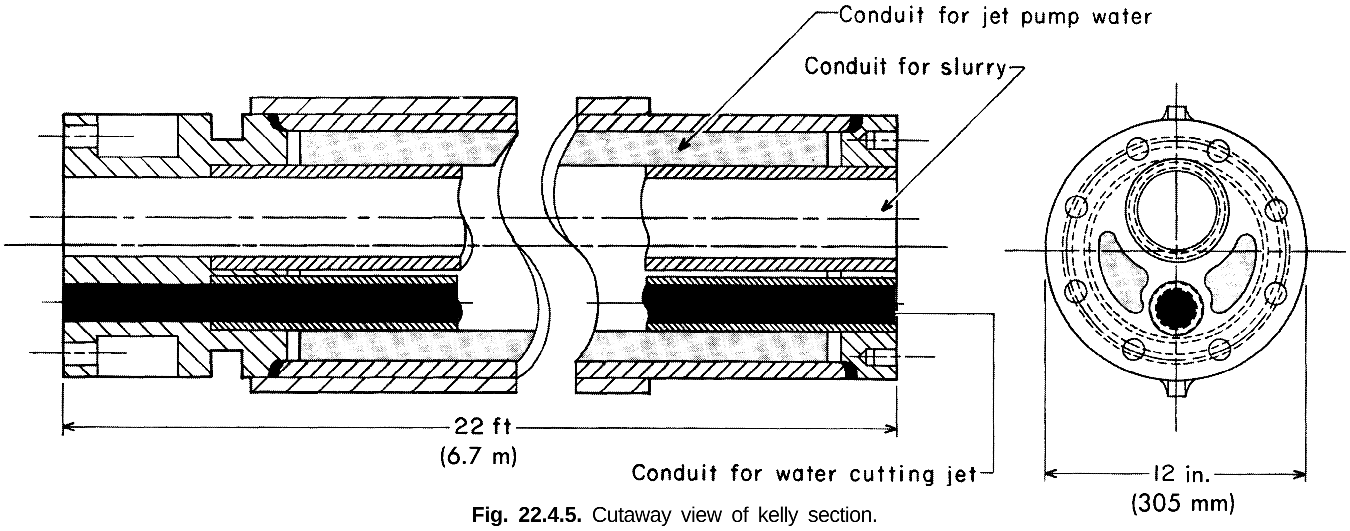

Fig. 22.4.5. Cutaway view of kelly section.

Fig. 22.4.6. Mining section.

horizontal coal seams with the same ratio of overburden to coal. It is generally agreed that borehole coal mining methods are applicable mainly to steeply dipping coal beds.

22.4.3 URANIUM MINING

Uranium sands are considered to be a likely prospect for borehole mining because (1) the ore has a high unit value, (2) the sandstones can be cut by low-pressure (1000- to 3000-psi or 6.90- to 20.69-MPa) water jets, and (3) many deposits are shallow, small, irregularly shaped, and isolated; these deposits cannot be mined by conventional methods, but are amenable to the selective capabilities of the borehole system.

Marconaflo, Inc. and Rocky Mountain Energy (RME) conducted tests from 1973 to 1975 in the Powder River Basin and the Gas Hills of Wyoming using the equipment described above. A total of about 700 tons (630 t) was mined, but problems were encountered with the sand plugging and severely wearing the down-hole Moyno slurry pump used in these tests.

The USBM cooperated with RME at its Nine-Mile Lake site, Natrona County, WY, in a borehole-mining test in 1977 and 1978. RME prepared the site, drilled a water supply well, constructed a pond and lined it with polyethylene, and drilled three 16-in.-ID (406-mm) cased boreholes to a depth of 100 ft (30.5 m) into the Teapot sandstone ore body. Flow Industries, Inc., under contract to the Bureau of Mines, modified the tool used for coal at the Wilkeson, WA, site and conducted the sandstone mining operations. A shallow deposit at Nine-Mile Lake was chosen for the test because the slurry pump is limited to differential lifts of 200 ft (61 m). The modifications included fitting of the mining tool with a turning-vane nozzle ensemble designed to pass 300 gpm (18.9 L/s) at 2000 psi (13.8 MPa), the flow conditions chosen for efficient erosion of the Teapot sandstone.

During mining operations, approximately 940 tons (850 t) of ore were mined from depths of 75 to 100 ft (22.9 to 30.5 m) at an average rate of 8 tph (7 t/h) from standoff distances as great as 25 ft (7.6 m). Slurry densities ranged from 0 to 46% by weight with an average of 700 determinations being 7.2%. The tests also showed the following:

1. The average jet-cutting rate was about 16 tph (14.5 t/h) at 520 hp (388 kW). The slurry pump normally works at a lower rate because the tool moves vertically as one piece, thereby lifting the pump out of the slurry sump during part of the mining cycle. The pumping rate could be made equal to the jet-cutting rate if the cutting jet could be moved independently from the slurry pump.
2. The optimum jet-cutting traverse rate across the sandstone was between 40 and 80 in./sec (1016 mm/s and 2032 mm/s).
3. The jet-cutting rate was proportional to the horsepower of the cutting jet.

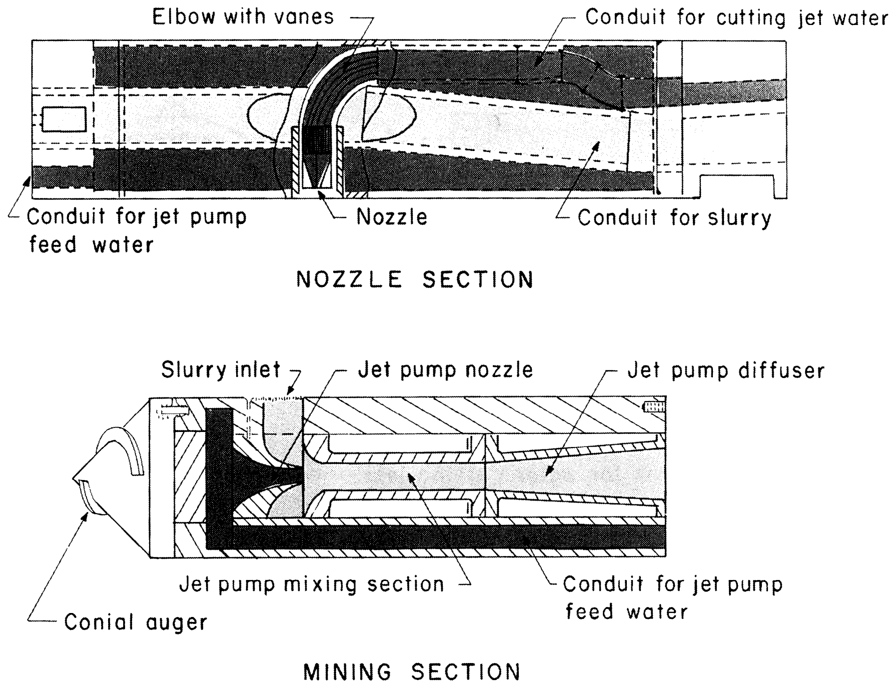

Fig. 22.4.7. Internal configuration of mining section.

Fig. 22.4.8. Cavity produced during borehole mining.

A photographic survey of the borehole cavities created in the Teapot sandstone ore body was taken using equipment developed for the purpose by the Bureau of Mines. Fig. 22.4.8 shows the cavity created in one of the boreholes at Nine-Mile Lake. The white, 2-in. (50.8-mm) diameter PVC pipes in the foreground are placed in monitor holes drilled 10 and 20 ft (3.05 and 6.10 m) from the center of the borehole. A 1-in. (25.4-mm) diameter steel pipe 26 ft (7.93 m) from the borehole is shown in the background. This photographic survey showed that roof failure was confined to a 7-ft (2.1-m) radius from the center of the borehole. Presumably, this indicates that rock within this radius was damaged during drilling.

22.4.4 OIL-SAND MINING

The possibility of mining oil in the 383 known shallow US oilfields has become a matter of interest because of the energy crisis of the 1970s. Oil could be produced from these shallow fields by surface mining methods. However, open pit mining of oil sands could be expected to meet with environmental objections including the following: (1) disruption of the surface, (2) increased air pollution from volatile hydrocarbons uncovered in the open pit, (3) accumulation of waste rock piles, (4) accumulation of tailings, and (5) surface water pollution. Clearly, added costs for restoration and reclamation would be incurred.

Borehole mining offers an alternative method of mining the oil sands with minimal disturbance to the environment because no overburden is removed, no waste rock piles are generated, tailings can be backfilled into the borehole cavity, no surface streams are polluted because a closed-loop water system is employed, and surface subsidence can be avoided by backfilling the mined cavities. Thus borehole mining appears to be more acceptable on an environmental basis than does surface mining. The greatest concern would be possible degradation of groundwater quality.

In 1975, Marconaflo, Inc. conducted borehole mining tests in 300- to 380-ft (91.4- to 115.8-m) deep oil sands at McKittrick, CA. The equipment was that used in uranium mining with the exception that a down-hole centrifugal slurry pump replaced the Moyno pump. During this program, approximately 2000 dry tons (1810 t) of oil sands were mined.

In 1979, the USBM and Flow Industries, Inc., performed borehole mining tests on a site in Kern County, near Taft, CA, in the Midway Sunset oil field. This test demonstrated that the borehole mining technique was an environmentally compatible method for mining oil sands. The experiment measured production rate along with the environmental impacts.

Mining was conducted from July 25 to Aug. 24, 1979. During the operation, 994 tons (902 t) of oil sands were extracted from two holes. The mining rate ranged from 0 to 45 tph (0 to 41 t/h). Typical operating parameters are listed in Table 22.4.1. A range of values is given when the parameter varied significantly.

One major complication was encountered during the operation. The borehole became filled with rocks that accumulated at the base of the mining tool because they were prevented from

Table 22.4.1. Operating Parameters for Oil-Sand Mining, Kern County, CA

		Typical Value	Range
Cutting jet:			
Pressure	psi	400 (2.75 MPa)	100–2500 (0.69–17.2 MPa)

Solids	wt %	15	0–35
Specific gravity		1.1	1.0–1.3
Slurry flow:			
Rate	gpm	800 (50.6 L/s)	600–1100 (37.9–69.5 L/s)
Line diameter	in.	3.75 (95.25 mm)	NA
Solids	wt %	7	0–18
Specific gravity		1.05	1.0–1.15
Mining rate	tph	15 (13.6 t/h)	0–45 (0–40.8 t/h)

entering the slurry pump by a screen over the inlet. The tool was unable to penetrate this pile of rocks. Mining had to be terminated in each borehole when the pile got so high that the jet could not be lowered below the casing (110 ft or 33.5 m). The addition of a crusher to the mining tool would prevent the rocks from obstructing the mining tool.

Ground subsidence is possible in borehole mining operations. To evaluate it, a series of surveys collected information on changes in ground elevation at the site. Surveys were performed to obtain baseline elevations before mining, weekly during the project, and 30 days after the mining stopped. No significant short-term subsidence was detected.

22.4.5 PHOSPHATE MINING

Magnet Cove Barium Co. used a waterjet borehole mining tool to extract 8000 tons (7260 t) of ore from four boreholes near the Pungo River in North Carolina in 1964. FMC Corp. conducted borehole phosphate mining tests in Beauford County, NC, in the mid-1970s. The FMC borehole mining tool, incorporating a drilling tool and a mining tool in a single unit, was used in four test holes. The borehole mining equipment operated from a barge.

The USBM and Flow Industries, Inc., in cooperation with Agrico Mining Co., conducted borehole phosphate mining tests in St. Johns County, near St. Augustine, FL, in 1980. The purpose of the test was to determine if phosphate ore could be mined economically in an environmentally compatible manner with the Bureau's borehole mining system.

Between Apr. and Aug. 1980, 1700 tons (1540 t) of phosphate ore were produced (Fig. 22.4.9) from three boreholes that ranged from 232 to 253 ft (70.7 to 77.1 m) deep. Mining in the first hole was conducted to determine the feasibility of mining with the borehole filled with water. This wave experiment yielded 860 tons (780 t) at an average rate of 36 tph (33 t/h) while cutting with a submerged jet (Fig. 22.4.10) in a 360° arc. The specifications for water-jet mining in borehole 1 are shown in Table 22.4.2.

When the water was pumped from the cavity, the immediate roof failed, indicating that the water pressure had supported the roof. Although the rock in the ceiling of the cavity failed, no surface subsidence was noted. However, no further mining could be performed in this hole. This experiment did indicate that borehole phosphate mining in a submerged mode is technically feasible.

Attempts to mine in an air-filled cavity were made in borehole 2 (Fig. 22.4.11) where mining was confined to a 30° arc and a 330° pillar supported the roof. However, a roof failure occurred after 300 tons (272 t) of ore had been produced. From this test, it was concluded that (1) the roof rock did not have sufficient strength to permit mining in an air environment, and (2) any future mining would require that the cavity be filled with water.

A third borehole tested an "air-shielding concept" designed to combine the need to have flooded conditions and the advantages of mining in air. Under this concept, the water jet was in a shroud of compressed air; this allowed cutting at longer standoff distances while retaining the roof support and increased pumping capability gained by working under a hydrostatic head of water. The air-shielded water jet issued from the usual borehole cutting

Fig. 22.4.9. Phosphate ore deposited at outlet of mining tool.

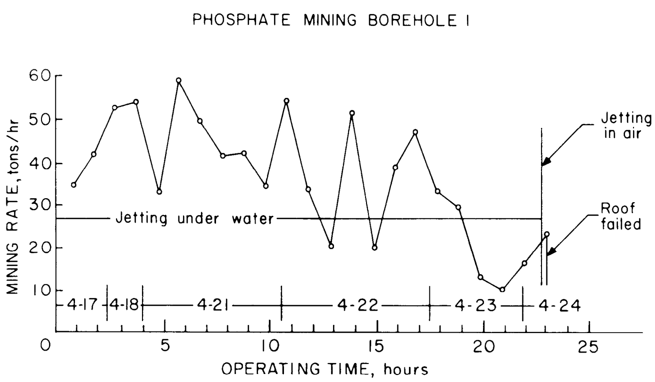

Fig. 22.4.10. Phosphate production in borehole 1. Conversion factor: 1 ton = 0.9072 t.

nozzle with an annulus for compressed air around it. Compressed air was supplied through conduits in the borehole mining tool connected to an air compressor at the surface. The water-jet specifications for mining in borehole 3 are shown in Table 22.4.3.

A total of 430 tons (390 t) was mined in this borehole without actuating the air shield in order to establish the baseline solids production (Fig. 22.4.12). After 23 hours of mining, the solids content of the slurry began to decrease, indicating that the submerged jet had reached its maximum effective radius. At this point, the air-shield was activated, and an additional 137 tons (124 t) was mined at the rate of 25 tph (23 t/h). The cavity radius was about 18 ft (5.5 m), and no roof failure had occurred when the mining stopped. This experiment indicated that phosphate can be mined effectively in a flooded cavity and that

Table 22.4.2. Parameters and Specifications for Mining in Wave Experiment Borehole 1

Parameter		Specifications

air shielding substantially increases water-jet effectiveness while operating underwater.

Further borehole mining in St. Johns County was performed in 1984 and 1985 by Agrico Chemical Co. and International Minerals and Chemical Co. The borehole mining tool used was built by Flow Industries based on the USBM design, but with the addition of a cutting nozzle that can be moved independently of the slurry pump. This test confirmed the findings of the Bureau of Mines tests and in addition demonstrated that well casings could be removed and reused.

Large deposits of phosphate ore occur on the Continental Shelf off the coasts of North Carolina, Georgia, and Florida. Serious consideration has been given to methods of mining these deposits. It appears that borehole mining may have potential as a method for offshore phosphate mining.

22.4.6 BACKFILLING OF BOREHOLE-MINED CAVITIES

Surface subsidence and the presence of tailings piles are the major potential adverse environmental impacts of borehole mining operations. Methods of mitigating these impacts have been investigated by the Bureau of Mines. Three methods were tested for backfilling cavities at the Nine-Mile Lake site with the sand produced during previous borehole uranium mining operations. The project consisted of intervals of backfilling followed by photographic surveys to determine the distribution of backfill in the hole. The backfilling methods investigated included bulk dumping down the borehole, slurry jetting in air, and slurry jetting under water. Slurry jetting underwater was found to be the most effective method. More than 90% of the sand removed from the cavity was returned by that technique.

A 1% by weight cement-sand mixture was introduced into a 4-in. (102-mm) ID pipe through a hopper, upstream of the centrifugal slurry pump (Fig. 22.4.13). The outlet pipe from the pump was connected via a loose victaulic coupling (which acted as a swivel) to a similar pipe terminated by a 4-in. (102-mm) ID elbow in the borehole. Slurry was injected at the rate of 350 gpm (22.1 L/s) through a 4-in. (102-mm) pipe rotating under water in the cavity. Sand was backfilled at the rate of 16 tph (14.5 t/h).

Analysis of cores taken from the backfilled cavity after 6 months indicated that adding 1% by weight of cement to the backfill did not increase the stability of the backfill material. It is estimated that a 5% mix would be required.

Backfilling experiments were conducted along with borehole phosphate mining experiments conducted by the USBM in cooperation with Agrico, Inc., in St. Johns County, FL. These tests, and follow-on tests, conducted by Agrico and International Minerals and Chemical Co. and described by Woolsey and Dibble (1987), demonstrated that waste clay, a major environmental and disposal storage problem in the phosphate mining industry, could be successfully thickened and injected into the cavities created by mining.

22.4.7 PRESENT STATUS

The technical feasibility of the remote extraction of coal, oil sands, uranium ore, and phosphates as a slurry through a borehole has been demonstrated. It has also shown that borehole mining can be performed so that the associated environmental impact is minimal.

No commercial borehole mines are in existence, but borehole mining has been the subject of several field trials. Borehole mining of phosphates was the most successful of the field trials. The productivity was higher than that of the other commodities because of the lack of induration of the phosphate ore, and because of the high-positive suction head of the slurry pump owing to the fact that mining took place with the borehole filled with water.

Borehole mining fulfills the need for a method to mine “incremental” uranium ore. Incremental ore refers to those small, irregular, high-grade uranium ore bodies that, although adjacent to working open pits, cannot be mined from these pits because of engineering limitations. The small size and the irregularity of these deposits make them ideal candidates for borehole mining because of the high areal selectivity of the borehole mining method.

The borehole mining field tests of oil sands and coal demonstrated the technical feasibility of the remote extraction of these commodities through boreholes, but the rates at which these fuels were produced under the conditions tested were too low for commercial viability. The tests demonstrated the need for developing borehole mining equipment that will allow higher productivity.

Backfilling of borehole-mined cavities by horizontal, underwater jetting of slurry into the cavities was proven to be feasible. Backfilling is likely to be an attractive method to prevent subsidence in those cases where a suitable supply of granular fill is available. Disruption to the environment would be minimal unless fill would have to be obtained from a borrow pit.

Environmental monitoring for groundwater pollution and subsidence conducted during these mining tests indicated the virtual absence of both phenomena. This indicates that borehole mining may be an attractive candidate for mining environmentally sensitive areas.

Chapter 22.5
METHANE DRAINAGE

GERALD L. FINFINGER AND MICHAEL A. TREVITS

22.5.1 INTRODUCTION

Methane is a gas that is slightly lighter than air and is colorless, odorless, and nonpoisonous. It occurs in the air of most coal mines, because when coal was formed from ancient peat swamps, methane also was formed. Air containing 5 to 15% methane and at least 12.1% oxygen concentration will explode if ignited.

All coalbeds contain methane, the amount of which can vary from 0.01 ft^3/ton (3.1 x 10^{-2} m^3/t) to more than 600 ft^3/ton (18.7 m^3/t) (Skow, Kim, and Deul, 1980). Usually, the amount of methane in coal increases with higher rank and greater depth. The gas is adsorbed on the micropore structure of the coal matrix and compressed in the fracture system of the coalbed. Wherever coal is uncovered by erosion or mining, the equilibrium that exists in the coalbed under confining pressure is disturbed, and methane is emitted.

The rate of methane emission underground is dependent upon the pressure gradient between the coalbed and the mine and also upon the permeability of the coalbed. Not all the gas is emitted at the working face where the coal is extracted; as much as 70 to 80% of the methane in the mine atmosphere enters from the exposed ribs and adjacent strata. But the emission rate per unit area of coal exposed is many times higher at the face than from the ribs. Thus, emission in the face area is frequently a major determinant of the quantity and delivery rate of fresh air required to ventilate the mine.

In the early years of coal mining, inadequate ventilation, failure to test for methane, use of open lights, smoking, failure to remove or control dust accumulations, and the improper use of black powder for blasting were the most frequently cited factors in explosions (Deul and Kim, 1988). Although both the number of explosions and the number of fatalities per million tons of coal produced have declined, approximately 10% of all underground coal mine fatalities are still due to explosions.

Ventilation is the only technique used universally in underground mines for the control of methane. To maintain operations within federally mandated requirements, the general approach has been to increase the quantity of ventilation air as methane emissions increase. However, there are times that even large quantities of air are not sufficient to dilute and remove the methane safely. Faces with high coal production rates, newly developing mines, and mines where development headings are being driven in virgin coal are all potential candidates for excess methane emissions.

The only alternative to decreasing the rate of coal production in order to stay within the statutory limits is to decrease the amount of methane emitted from the coalbed. To do this requires either removing the gas from the coal before it is mined or controlling the emission rate during mining. Toward this goal, a number of researchers have developed a basic understanding of the storage and migration characteristics of methane in coal, techniques to remove gas from coal before it is mined, and methodologies to control emissions into the working place during mining.

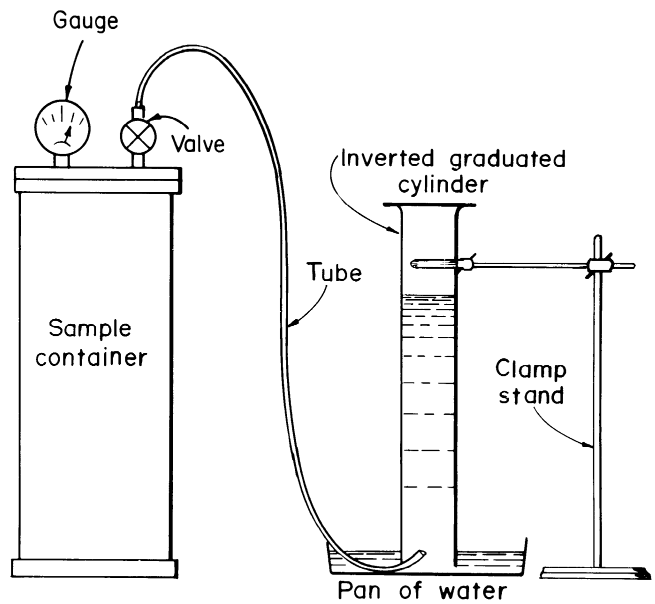

Fig. 22.5.1. Equipment for measuring gas content of coal cores.

22.5.2 DEFINING THE METHANE PROBLEM

Coal for gas-content testing is usually obtained from core samples recovered from vertical exploratory drillholes. Generally, it is possible to obtain only a limited amount of sample for gas content testing because of the coal-quality testing needs of the coal company. Therefore, it is important in all cases to obtain the cleanest section of coal, that is, coal without obvious extraneous shale, pyrite, or other noncoal inclusions. Collection of multiple samples or even testing of the entire coalbed is the preferable sampling procedure.

The equipment (Fig. 22.5.1) required to measure the actual volume of gas desorbing from the coal sample consists of a sample container, an inverted graduated cylinder sitting in a pan filled with water, and a ring stand and clamps to hold the graduated cylinder in place. The desorbed gas that collects in the sample container is periodically bled into the graduated cylinder and measured as the volume of water displaced. This procedure is performed at the drill site and subsequently in the laboratory.

22.5.2.1 Calculation of Gas Content

The gas content of a sample is composed of lost, desorbed, and residual gas, each of which is determined by slightly different techniques (Kissell, McCulloch, and Elder, 1973). Generally, coal begins to desorb gas when the pressure equilibrium in the coalbed is disturbed. Therefore, gas desorption takes place as the coal sample is recovered. The volume of gas desorbed is known as *lost gas,* primarily because it is gas that is lost from the sample during the recovery and collection process. The amount of lost gas depends on the drilling medium and the time required to retrieve, measure, and describe the core and seal the sample in the can. The shorter the time required to collect the sample and seal it in the can, the greater the confidence in the lost-gas calculation. In general, because of its speed, wireline retrieval of the core is preferable to conventional coring. If air or mist is used in drilling, it is assumed that desorption begins immediately upon penetration by the bit. With water, desorption is assumed to begin when the core is halfway out of the hole, that is, when the gas pressure in the sample is assumed to exceed that of hydrostatic head.

The volume of lost gas can be calculated by a graphical method based on the following relationship. For the first few hours of emission, the volume of gas desorbed is proportional to the square root of the desorption time. A plot of the cumulative volume desorbed after each measurement against the square root of the time that the sample has been desorbing ideally should produce a straight line.

Desorbed gas is simply the total volume of gas drained from the sample and measured in the graduated cylinder. Generally, a sample is allowed to desorb gas until a very low emission rate is obtained, usually an average of less than 4×10^{-4} ft^3/day (10 cm^3/day) for a one-week period. The time required to reach this low rate of emission varies depending on the size of the sample, the physical characteristics of the coal, and the amount of gas contained in the sample.

When the measurement of desorbed gas is discontinued, the coal sample will usually still contain gas. To complete the gas content determination, the amount of residual gas must be measured. Residual gas is released by crushing the coal sample to a fine powder in a sealed container. When crushing is complete, the container is allowed to cool to room temperature, and the volume of gas released is measured by the same water displacement method used for determining desorbed gas. The crushed powder and any uncrushed lumps are weighted separately. The volume of gas released is attributed only to the crushed powder. The total gas content of a particular sample is the volume of lost gas and desorbed gas divided by the total sample weight plus the residual gas content.

Theoretically, it is possible to crush a coal sample at any point after collection and to obtain the total gas content (excluding lost gas) of the sample. This procedure generally is not considered appropriate if maximum information from the sample is desired. By crushing the sample before the desorption process is complete, it is impossible to obtain the relative amounts of desorbed and residual gas. This distinction is important because the actual residual gas, which will not desorb from the sample while sealed in the canister, probably represents gas that will not flow to a methane drainage borehole, and possibly represents gas that will not be emitted into a mine atmosphere. During the process of mining coal, the coal is broken up into a variety of sized pieces; however, the majority of these pieces usually will not duplicate the very fine powder that crushing produces in the residual gas content procedure. Table 22.5.1 lists the highest measured gas contents in the United States (Diamond, LaScola, and Hyman, 1986).

22.5.2.2 Geologic Influences

Previous horizontal borehole methane drainage studies that utilized holes drilled in advance of mining found that geologic features (e.g., clay veins, sandstone channels, and the coal's natural fracture system) have a significant effect on borehole gas productivity (Prosser, Finfinger, and Cervik, 1981). Gas flow rates are generally found to be higher when drainage holes are drilled perpendicular to the direction of the face cleat (Fields, Cervik, and Goodman, 1976). However, coalbed discontinuities such as clay veins and sand channels tend to isolate blocks of coal and restrict gas flow.

CLEAT ORIENTATION IN COALBEDS. The natural vertical fracture system in bituminous coalbeds, *cleat,* is usually composed of two components (sets) separated by at least 30° (McCulloch, Deul, and Jeran, 1974). The more dominant fracture plane is the *face cleat;* the minor fracture plane is the *butt cleat.* The face cleat is more continuous, crosses bedding planes in the coal, and may extend for longer distances. The butt cleat is commonly short, may be curved, and is a discontinuous feature that frequently terminates against the face cleat.

The orientation of coal cleats is important to efficient gas drainage. The face and butt cleats provide a directional permeability; that is, the flow of gas is greater in the direction parallel to the face cleat. Experiments conducted underground in coal mines have shown that horizontal holes drilled perpendicular to, and therefore intersecting, the largest number of face cleats will yield larger amounts of gas in a given amount of time than holes drilled perpendicular to the butt cleats.

The cleat system of a coalbed also affects vertical gas drainage holes drilled from the surface into a coalbed. A vertical hole completed in a coalbed with a well-developed face and butt cleat will collect gas at a higher rate from fractures oriented in the face cleat directions than from fractures trending parallel to the butt cleat direction. Therefore, an elliptical drainage pattern (Fig. 22.5.2) will be developed, with the long axis parallel to the face cleat. Differences in face and butt cleat permeability are most pronounced in blocky coals. In friable coals, where the face and butt cleats are more nearly equal in prominence, coalbed permeability tends to be anisotropic.

COALBED DISCONTINUITIES. When rocks are subjected to stress, they usually respond by bending and breaking or fracturing. When measurable movement occurs after breaking, a fault is produced. Fracture zones are areas that contain a higher number of fractures than adjacent areas. Fractures and faults when open and extensive are highly permeable to methane and water migration.

Movement along a fault zone may cause localized compression of the coal, which results in decreased permeability. Faults and fractures are related to geologic forces. Study of local geology and particularly structure can indicate the existence of these features and the extent to which they may affect methane drainage.

CLAY VEINS. Clay veins are wedges of indurated clays and silts that penetrate the coalbed from either above or below (Fig. 22.5.3). They can be vertical (parallel to the cleat direction) or can form an angle of about 45° with the vertical (parallel to shear direction). Clay veins encountered in mines are usually crooked, are frequently angular, and interfinger with the coal rather than forming smooth contact surfaces. They may be hard enough to damage mining equipment. Thickness normally ranges from 1 in. to several feet (25 mm to a few meters), but may be as much as 15 ft (4.6 m). A total length of more than 1000 ft (300 m) has been observed underground (Hadden and Sainato, 1969).

Clay veins often form cells of coal that isolate large volumes of gas under high pressure. In one study, a test hole drilled into a cell measured an in situ gas pressure of 263 psi (1813 kPa) (Hadden and Sainato, 1969). When mining encounters such a cell, gas is released rapidly into the mine environment, creating a hazard. Furthermore, the chance of an explosion is increased by sparks that may be generated when mining into clay veins with both continuous miners and longwall systems.

Methane drainage rates from horizontal boreholes in the Pittsburgh coalbed generally averaged 250 ft^3/day (7.1 m^3/day) per ft (m) of hole. In an area of the Pittsburgh coalbed containing

Table 22.5.1. Highest Measured Gas Contents of US Coalbeds

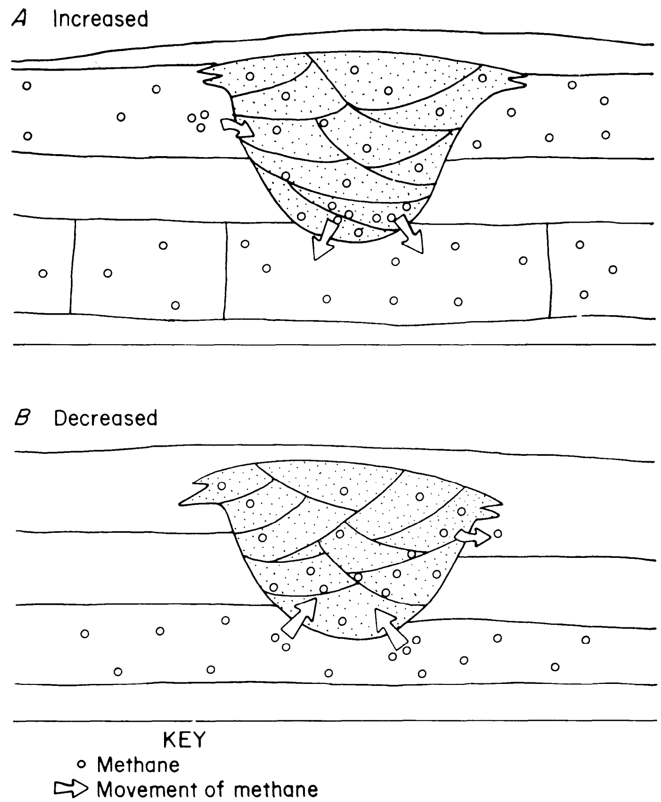

Fig. 22.5.4. Sandstone channels impacting methane migration.

clay veins, the methane emission rate was less than half of the average (Prosser, Finfinger, and Cervik, 1981). Since methane drainage is usually conducted in virgin areas, the geologic data to locate small discontinuities such as clay veins may not be available. In such cases, the degasified area may be limited to blocks of coal delineated by the clay veins and/or other discontinuities.

SAND CHANNELS. Sand channels are lenticular, sometimes sinuous bodies of sandstone extending into and sometimes completely through a coalbed (Fig. 22.5.4) (McCulloch et al., 1975). They are erosional depositional features formed by the cutting action of paleostreams that were eventually filled with sediment. As deposition of the sediment filled a particular channel, new channels formed. Thus a deltaic environment may contain a succession of sand-filled channels. These channels often impact coalbed permeability, thereby reducing the flow of gas through the cleat system and into methane drainage boreholes. Identifying the channels prior to initiating a methane drainage study can allow for a more effective drainage design. This is accomplished by locating drainage boreholes in areas where they are least impacted by the reduced permeability zones.

Many geologic factors affect methane emission rates in underground coal mines. The orientation of the cleat system with respect to methane drainage boreholes may have an effect on the competency of the hole and the rate at which methane gas is produced. Fault and fracture zones, clay veins, and sandstone channels can aggravate methane emission problems and complicate attempts to drain gas in advance of mining. Predicting cleat orientation and indicating the probable location and extent of other geologic features through geologic reconnaissance, computer-assisted mapping, and other techniques can improve the application of drilling technology and drainage systems to the control gas in underground bituminous coal mines.

22.5.2.3 Impact of Mine Design

ROOM-AND-PILLAR/LONGWALL DEVELOPMENT. Mine operators in the United States predominantly use continuous mining machines in room and pillar mines. The longwall (retreat) method of mining also requires the use of a continuous miner to develop the panel. These longwall development sections are essentially identical to room and pillar mining sections. Therefore, all the 200 mines identified as being significantly gassy (daily emissions of methane of at least 100,000 ft^3/day or 2830 m^3/day) utilize room and pillar mining techniques (Grau and LaScola, 1984). Methane problems on room and pillar or longwall development sections normally occur in one of two areas: the working place or returns.

Methane control standards established by the Mine Safety and Health Administration are defined within Title 30 of the *Code of Federal Regulations,* CFR, Part 75—Mandatory Safety Standards—Underground Coal Mines. The *working place* is defined in Paragraph 75.2 (g) (1) as the area of a coal mine inby (towards the face) of the last open crosscut. In this area, all electrical equipment must be permissible. The *returns* are the entries on the section through which the ventilating air is coursed after it has swept the face area and is contaminated with gas. Any electrical equipment used in the returns must also be permissible. The *fresh air entries* are those splits that course the air to the working face for ventilation purposes. During normal operations, the distribution of methane gas in the air at the face and in the returns must be kept below 1.0%. Methane gas concentration in the fresh-air entries is typically very low (< 0.2%).

RETREAT LONGWALLS. The retreating longwall is the predominant longwall mining method used in US underground coal mines. In fact, of the 92 operating faces in the United States in 1989, only one was an advancing face (Sprouls, 1989).

It is significant to note that 16 of these operating retreat longwalls are in the 10 mines identified as having the highest methane emissions in the United States. Methane problems on retreat longwall sections normally occur in one of five areas: working face, returns, fresh air entry, bleeder system, or gob. The definitions and allowable methane concentrations (working place, returns, fresh air entry) described for room and pillar sections are also applicable for retreat longwalls.

A gob area is associated with full-extraction mining (e.g., longwall) and is the area of the mine roof that collapses after the coal is fully removed. When the immediate roof collapses and falls into the space created by the removal of the coal, fractures propagate up into the overlying strata. If there are methane-bearing strata above the longwall panel, then the gas can migrate from the overlying areas into the collapsed material.

A *bleeder system* is a set of entries that carries methane-laden air from the mine after the air has been directed through abandoned areas that have been wholly or partially extracted. The concentration in the bleeder system cannot by law exceed 2%.

22.5.2.4 Regional Impacts: Geographic Variations

During 1985, 180 coal mines in the United States had methane emissions in excess of 100,000 ft^3/day (2831 m^3/day) (Grau, 1987). The total amount of methane gas produced by these mines equaled 304 million ft^3/day (8.6 Mm^3/day) and was emitted from mines located in 12 states.

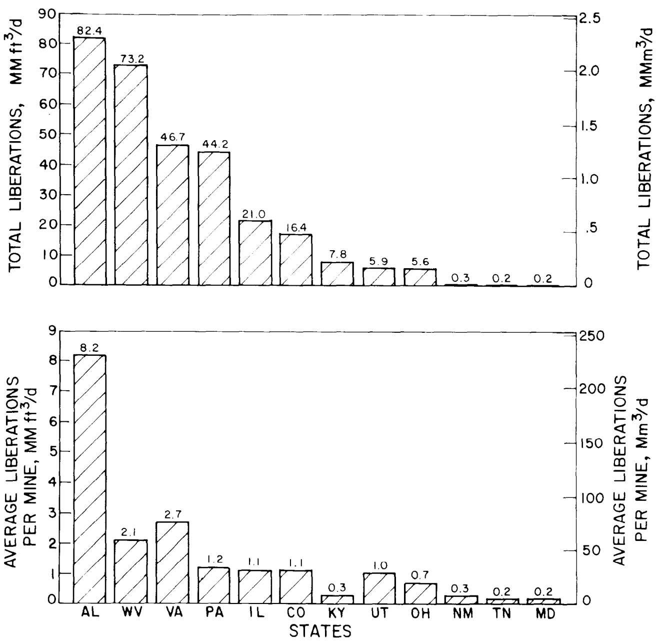

Fig. 22.5.5. Coal-mine methane emissions.

The relationship between coalbeds and methane emissions was analyzed, and the data are shown in Fig. 22.5.5. Most emissions came from the Pittsburgh Coalbed, which produced 80 million ft^3/day (2.3 Mm^3/day), or 26.5% of the total methane emitted. Mines operating in the Mary Lee and Pocahontas No. 3 Coalbeds emitted slightly less than mines in the Pittsburgh Coalbed. The highest average emission rate per mine came from the operations in the Mary Lee Coalbed at 8 million ft^3/day (227,000 m^3/day).

22.5.3 METHANE DRAINAGE TECHNOLOGY DURING MINING

Typically, as methane emissions increase on a section, more air is directed to the section to dilute the gas. However, as coalbeds with higher gas contents are exploited in conjunction with the demand for ever-increasing production rates, the mine ventilation engineer may find that it is not possible to direct a sufficient amount of air onto the section to ensure the safe extraction of the coal. To enable the mine to maintain production, various techniques were developed to remove gas from the coal. These techniques include drainage from horizontal, vertical, and directionally drilled boreholes.

22.5.3.1 Horizontal Borehole Drainage

The method of drilling a horizontal borehole into a coalbed to remove methane has been known since the early 1960s; however, much of the technology to effectively drill these holes was perfected in the 1980s (Spindler and Poundstone, 1961; Cervik, Fields, and Aul, 1975; Prosser, Finfinger, and Cervik, 1981). Fig. 22.5.6 illustrates the principle of methane drainage through horizontal boreholes. Basically, the horizontal borehole extends the low-pressure atmosphere within the mine to some distance within the coalbed.

There is a concomitant twofold effect on the coalbed gas reservoir that occurs as gas is removed. First, gas content is

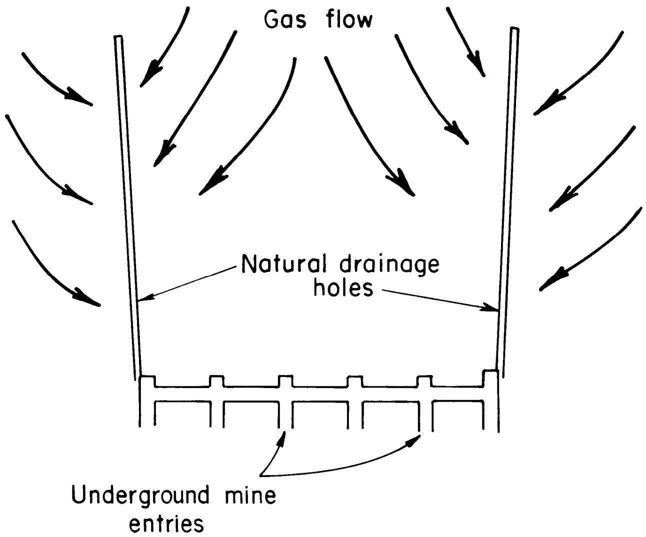

Fig. 22.5.6. Concept of methane drainage by horizontal boreholes.

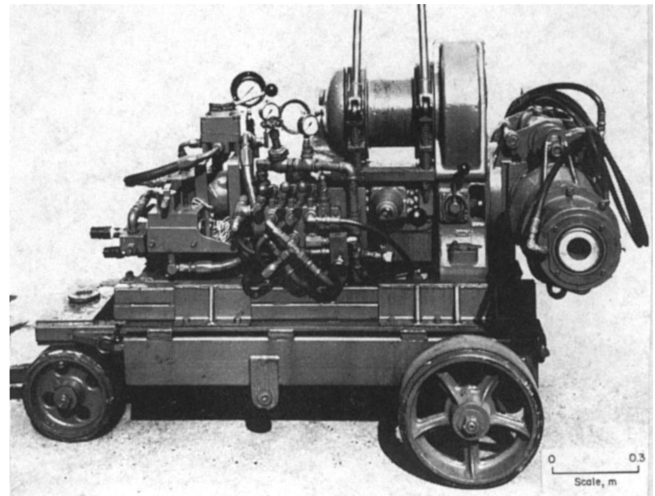

Fig. 22.5.7. Horizontal methane drainage drill.

lowered. This was shown in one study to be as great as 50% after four years of drainage. Second, the gas pressure is lowered.

For the mine ventilation engineer, the practical effects of horizontal methane drainage are a reduction in methane emissions during mining, an increase in mine safety, a potential for increased productivity, and a potential for selling the captured gas.

The use of horizontal boreholes has been shown to consistently reduce methane emissions by more than 50% thus improving the safety of the mining environment. Also, on a longwall development section in an Alabama mine, a 50% increase in productivity was achieved in addition to a 54% decrease in methane emissions. Finally, an economic analysis has shown that a 25% rate of return on investment can be realized from the sale of 3 billion ft^3 (85 Mm^3) of methane at a mine site price of \$2.25/1000 ft^3 (\$79.00/1000 m^3) (Baker, Grau, and Finfinger, 1986).

Horizontal methane drainage is a many-faceted technique for methane control. It can be used to drain large blocks of coal, prior to mining and to control both excess face emissions and methane problems in the returns. The earliest reported studies of this technology were conducted to determine the proper procedures for drilling short horizontal boreholes (Hadden and Sainato, 1969). During these studies, the electrohydraulic drills used were either hand-held or post-mounted. These drills were easy to transport underground but were not capable of drilling holes of lengths up to 1000 ft (300 m). Later studies which investigated factors that influenced bit trajectory led to the design and development of equipment for drilling horizontal boreholes in excess of 1000 ft (300 m) (Cervik, Fields, and Aul, 1975).

22.5.3.2 Horizontal Drilling Operations

Methane drainage from virgin coal can be incorporated into the mining cycle. In this process, long horizontal holes are drilled in outside entries, ahead of the advancing section. Methane gas that would normally flow toward the face areas of an advancing section is diverted away through the horizontal drainage holes. This process lowers gas pressure immediately ahead of the face.

The rate at which methane gas can be removed from the coalbed is proportional to the length of the drainage hole. Drilling long horizontal holes in a coalbed requires maintaining the drillbit on the proper trajectory within a relatively small target zone. There are two basic techniques that have been developed for guiding the path of a drillbit during horizontal drilling in coalbeds: rotary drilling and down-hole drilling (Cervik, Fields, and Aul, 1975; Kravits, Sainato, and Finfinger, 1985). Both techniques require the use of an underground drill unit that has been constructed to allow drilling in a horizontal orientation. There are a variety of units that can be used for this application (Fig. 22.5.7) (Finfinger and Cervik, 1980). The drills are normally either pneumatically or electrically powered. The primary function of the drill is to provide both rotation and thrust to the drillbit. Bit thrust and rotational speed are the two drilling parameters that affect the path of the bit in a vertical plane during rotary drilling. The applied thrust determines not only the penetration rate but also the path of the bit. Table 22.5.2 summarizes the effect of thrust and bit rotational speed on bit trajectory (Cervik, Fields, and Aul, 1975). Levels of thrust and rotational speed shown in Table 22.5.2 are meant as guidelines and may vary from one coalbed to another.

Table 22.5.2. Effect of Thrust and Bit Rotational Speed on Hole Trajectory

Thrust, lb	(kg)	Bit, rev/min	Effect on bit trajectory
800	(362)	700–900	Downward or dropping
1200	(544)	400–600	Holds angle
2000 or greater	(907)	200–300	Upward or lifting

The procedures for dropping the bit trajectory are to reduce thrust to about 800 lb (362 kg) and increase bit rotational speed to about 800 rpm. At the end of each 10-ft (3-m) segment of drilling, several slow reaming passes are made to wear the bottom of the hole. This procedure is repeated for each 10 ft (3 m) of penetration for distances of 50 to 100 ft (15 to 30 m).

Procedures for lifting the bit trajectory are easier and generally more effective. Thrust is increased to 2000 to 3000 lb (900 to 1360 kg), and bit rotational speed is about 200 rpm. A hole deviating by 1° is brought back on course within 30 ft (9 m) of horizontal drilling.

In order to determine the path of the drillbit, it is necessary to periodically survey the angle of the borehole (Cervik, Fields,

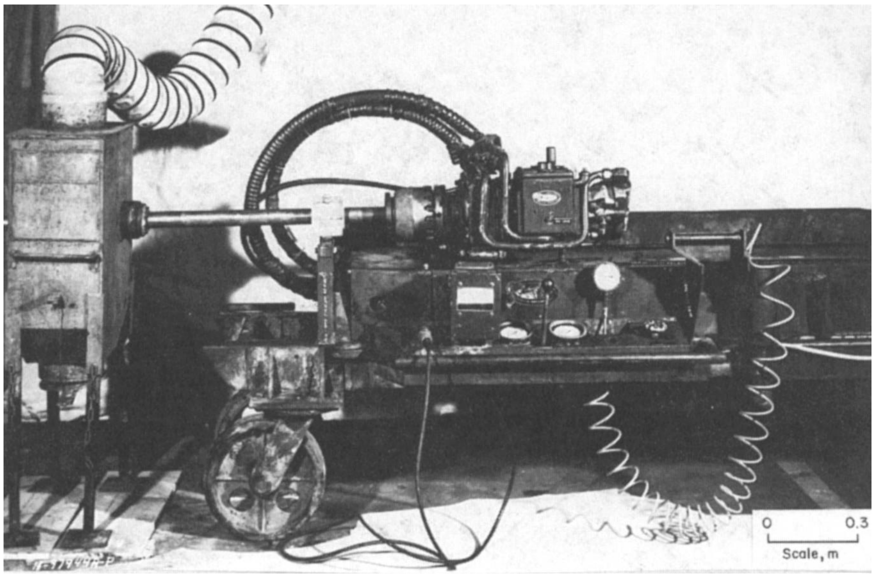

Fig. 22.5.8. Stuffing box attached to front of horizontal drill.

and Aul, 1975; Rommel and Rives, 1973). Surveying is conducted with instruments designed specifically for this purpose, such as photographic or electronic devices. Both instruments provide similar data on borehole inclination and compass heading. From successive surveys, it is possible to compute the path of the borehole trajectory and implement changes to the drilling operation to match the trajectory of the borehole to the dip of the coalbed.

A down-hole motor can be used for rotational power and borehole trajectory control in conjunction with the underground drill unit used to provide bit thrust. The down-hole motor hydraulically rotates the drillbit without rotating the drill rods connecting the drill unit to the motor. With an in-hole motor assembly, borehole trajectory control can be achieved by placing a slightly bent (2° or less) drill rod directly behind the motor and aiming the bend in the desired direction. The drillbit will directionally react based on the orientation of the bent drill rod. This type of drilling provides a more positive directional control system than rotary drilling (Kravits, Sainato, and Finfinger, 1985).

To control methane emissions during drilling, a pilot hole is drilled into the coalbed for a distance of 10 to 20 ft (3 to 6 m). The hole is then cased with 4-in. (102-mm) diameter steel pipe. The pipe is then grouted in place and connected to a stuffing box (Fields, Cervik, and Goodman, 1976). The stuffing box (Fig. 22.5.8) has a spring-loaded door on the bottom and a flexible hose at the top. Drill cuttings and water drop to the bottom of the stuffing box, and methane gas is drawn out through the top. The gas produced can be discharged in the returns, but this requires large volumes of air to quickly dilute the gas below the explosive limit. An alternative approach is to pipe the undiluted methane gas to the surface. The gas can then be captured in almost pure form and transported in pipelines as a form of natural gas. Methane from coal has properties similar to those of natural gas and can be used in many cases as a direct substitute. With the increased cost of natural gas, methane from coal can be a valuable asset.

Horizontal drainage holes are effective in any mine when the coalbed has relatively good permeability. In-mine drainage studies have been conducted in a variety of coalbeds, and the studies in the Pittsburgh and Pocahontas No. 3 Coalbeds are summarized as follows

CASE HISTORY 1: PITTSBURGH COALBED. In an initial study, three horizontal holes were drilled in a 500-ft (152-m) wide section of the Pittsburgh Coalbed, the hole in the center of the section being used to continuously monitor gas pressure within the coalbed (Deul and Kim, 1988). The holes on the right and left sides of the section were drilled about 5° off the projected development of the outside entries.

Initially, gas pressure within the coalbed was 33 psi (227 kPa). When the second hole was drilled, the gas pressure declined. When the third hole was completed, the measured gas pressure within the coalbed was reduced to 9 psi (62 kPa). The decline in gas pressure occurs when methane that would normally flow toward the face is drained from the coal through the horizontal holes.

In another study in the Pittsburgh Coalbed, two holes were drilled in Bethlehem Mines Corporation Marianna Mine (Prosser, Finfinger, and Cervik, 1981). One hole was 1066 ft (325 m) long, the other 2500 ft (762 m) long. The methane production rate was 180,000 ft^3/day (5097 m^3/day) from the first hole and 330,000 ft^3/day (9345 m^3/day) from the second hole. The gas drainage rate averaged 143 ft^3/day/ft (12 m^3/day/m) of drainage hole. Over a one-year period, methane emissions at the face were reduced by 90%.

CASE HISTORY 2: POCAHONTAS NO. 3 COALBED. A study conducted in the Pocahontas No. 3 Coalbed in an area known to have low permeability indicated that horizontal drainage holes were not effective at reducing face emission (Deul and Kim, 1988). The mine section was about 360 ft (110 m) wide. A gas-pressure monitoring hole was drilled near the left side of the section to a depth of 108 ft (33 m) and filled with packers to about 98 ft (30 m). Gas pressure in the 10 ft (3 m) of open hole at the inby end was monitored continuously. Hole 2 (left side) and hole 3 (right side) were drilled to 255 and 259 ft (78 and 79 m), respectively. Gas pressure in hole 1 stabilized at 650 psi (4481 kPa) and remained constant during drilling. After 14 days, pressure declined to 636 psi (4385 kPa). During this period, the total quantity of methane emitted through the face areas of the section, approximately 4 million ft^3 (113,000 m^3), showed little or no decrease. The small decline in gas pressure (2%) can be attributed to normal bleed-off through the face areas of the section during an idle period rather than to drainage through the horizontal holes.

The low permeability in this area of the Pocahontas No. 3 Coalbed was related to a large fault traversing the mine property. Subsequent tests have indicated that coalbed permeability improves as the distance from the fault increases. Therefore, horizontal drainage holes may be a feasible method of controlling methane in other mines in the Pocahontas No. 3 Coalbed.

22.5.3.3 Cross-measure Boreholes

Methane gas produced by longwall operations in the United States is controlled by dilution with ventilation air and by surface gob boreholes. Surface gob boreholes cannot always be drilled, however, because of a lack of available surface sites. Furthermore, topography may be too severe to develop adequate surface locations, or access to private property may be denied. Consequently, an alternative method of controlling gob gas is needed that is independent of the mine ventilation system and surface right-of-way problems.

The single-entry longwall is the predominant mining system in Europe where both retreating and advancing longwalls are used (Cervik, 1981). However, the proportion of faces utilizing advancing techniques dominates (82% in the United Kingdom and 75% in West Germany). Post-World War II mechanization and mining of deeper and gassier coalbeds forced the application of gob drainage systems on European longwalls. The most commonly used method of controlling gob gas during mining in Europe is the cross-measure borehole technique.

CROSS-MEASURE BOREHOLE SYSTEM DESIGN. The design of cross-measure boreholes in the United States is based on European experience (Schatzel, Finfinger, and Cervik, 1982; Campoli, Cervik, and Schatzel, 1983). Endpoints of the cross-measure boreholes are normally spaced 200 to 300 ft (61 to 391 m) apart. All boreholes are drilled over a support pillar to protect the borehole when the longwall face passes the collar of the hole. Borehole length, inclination, and horizontal direction should be chosen to accomplish the following:

1. Maintain the height of the borehole over the far end of the support pillar at least eight times the coalbed thickness. Estimates of the height of the rubblized zone in the gob range from four to eight times coalbed thickness.

2. Terminate the borehole about 100 ft (30 m) into the gob. Researchers have shown higher methane concentrations in the gob on the return side than the intake side because of the pressure differential in the mine's ventilation system.

3. Intercept all coalbeds within 100 ft (30 m) above the mined coalbed.

4. Angle the borehole at least 45° (0.79 rad) to the axis of the longwall.

Generally, gas production begins when the face is 75 to 100 ft (22 to 30 m) beyond the end of the borehole but before it passes the collar of the hole.

DRILLING EQUIPMENT AND PROCEDURES. An electrohydraulic or pneumatic drill is used to drill the cross-measure boreholes (Fig. 22.5.9). The first 25 to 30 ft (7 to 9 m) of each borehole are drilled with a 4-in. (101-mm) diameter drill, while the remainder of the hole is drilled with a 2-in. (50-mm) diameter bit. Plastic standpipes are cemented into each cross-measure borehole after the completion of the drilling phase. The cementing phase is important because, if not completed properly, mine air could short-circuit into the cross-measure borehole, reducing the borehole's ability to draw gas from the gob. Access to the surface is provided by a surface borehole. The borehole is lined with steel pipe and cemented the entire length. An underground pipeline is used to connect the surface borehole to the cross-measure boreholes.

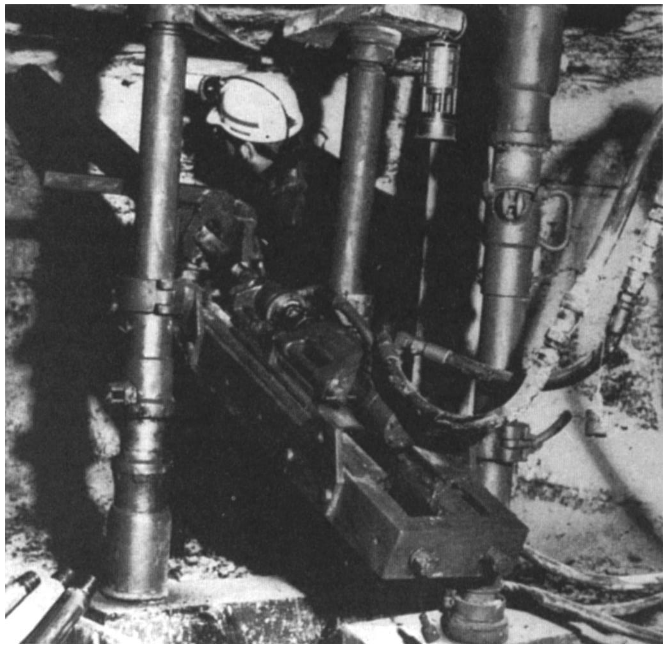

Fig. 22.5.9. Drill unit for cross-measure boreholes.

GOB GAS PRODUCTION. A cross-measure borehole study was conducted on a retreating longwall in Bethlehem Mines' Cambria 33 mine (Campoli, Cervik, and Schatzel, 1983). An enlarged view of the test panel is shown in Fig. 22.5.10. The underground pipeline was located in the center entry of the three-entry return-air gateroad. All cross-measure boreholes were drilled from the center entry, which was supported by a line of cribs. The center entry remained open and passable after the panels on both sides were removed.

Gob gas was extracted from 11 of the 12 cross-measure boreholes. Hole 1, the only borehole that failed to produce gob gas, was drilled with its endpoint only 27 ft (8 m) from the starting point of the panel. Apparently, the strata in this area did not fracture; thus no flow paths were created to permit gob gas movement toward the hole.

No free flow of methane gas occurred from any cross-measure borehole. Even with an applied partial vacuum, flow did not occur until the face passed 75 to 100 ft (30 m) beyond the end of the hole. Flow did occur however, before the face passed the collar of the hole.

Figs. 22.5.11 and 22.5.12 show methane and gob gas (methane plus air) flow rates, respectively, for each cross-measure borehole. Generally, the flow-rate curves for each cross-measure borehole follow the same pattern. The gob gas production life of the cross-measure boreholes ranged from 14 to 149 days. Borehole inclination and penetration into the gob were two important parameters that appear to affect gas production life of boreholes. Borehole life seemed to be greater for inclinations of about 25°. Boreholes with higher inclination angles also tended to produce higher average methane flow rates than lower inclination boreholes. Borehole penetration into the gob ranged from 90 to 136 ft (27 to 41 m), which is only 16 to 25%, respectively, of the width of the longwall panel. Optimum borehole inclination and penetration into the gob appeared to be at least 30° and 100 ft (30 m), respectively.

EFFECTS OF THE CROSS-MEASURE SYSTEM. Methane gas enters mine workings during longwall mining from fractured

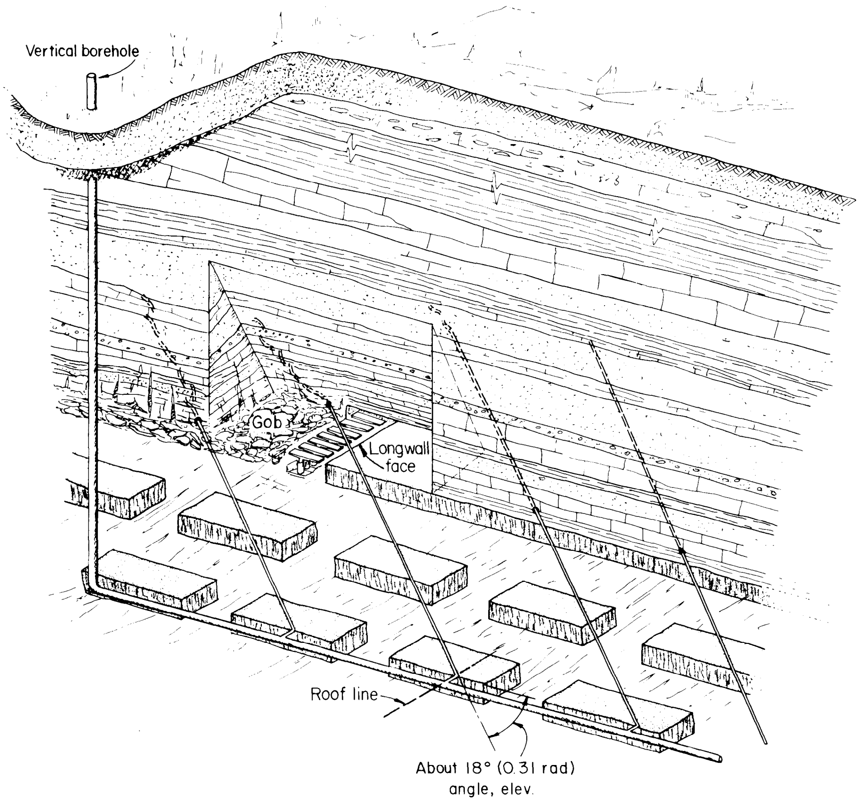

Fig. 22.5.10. Schematic of cross-measure borehole system for gob gas control.

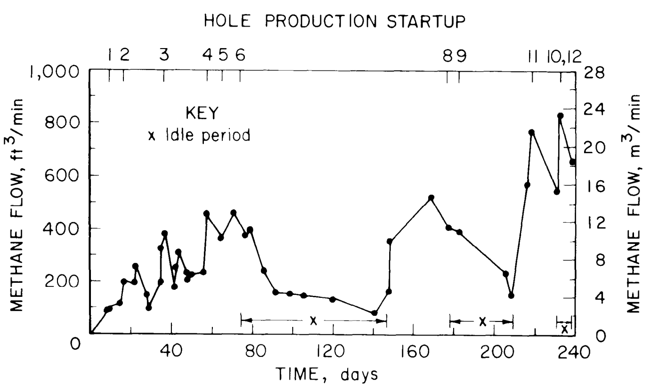

Fig. 22.5.11. Methane production history from cross-measure borehole system.

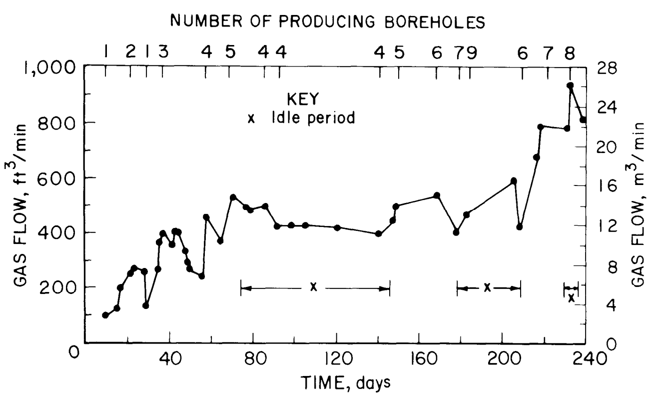

Fig. 22.5.12. Gob gas production history from cross-measure borehole system.

roof and floor strata and from the mined coalbed. Ventilation and methane surveys conducted at the tailgate of the longwall showed that the flow of methane gas from the mined coalbed during mining was about 20 ft^3/min (0.6 m^3/min). During nonmining periods, however, the flow of gas was negligible. The contribution of floor strata to methane emitted in the gob is unknown. Also coalbeds in the roof strata are known methane source beds.

The cross-measure borehole system captured about 50% of the methane produced by the mining operation. The other half was removed by the mine ventilation system. Methane flows in both systems declined during the life of the panel.

The effect of the cross-measure borehole system on methane in the mine ventilation system was dramatic. The methane flow in the return air from the longwall increased by a factor of > 2 when the cross-measure borehole system was not in operation. These data clearly demonstrate the effectiveness of the boreholes in controlling methane in the gob.

22.5.4 METHANE DRAINAGE TECHNOLOGY IN ADVANCE OF MINING OR WITHOUT MINING

22.5.4.1 Vertical Boreholes

The amount of gas contained within any given area of a coalbed depends on the coal's inherent storage capacity and the physical conditions of the coalbed. The storage capacity of coal is primarily a function of rank and, as such, cannot be affected by the presence of a methane drainage borehole. Certain physical characteristics of the coalbed can be changed which will affect the release and migration of gas in the coalbed. By removing accumulated water from a vertical borehole, two important changes occur in the coalbed: pressure is reduced, and water saturation level is lowered. Reducing pressure releases additional gas from the coal itself as the coalbed adjusts to the change. Increasingly larger amounts of gas are released for each incremental decrease in pressure. Lowering the water saturation level raises the permeability of the coalbed to gas and allows the gas to more readily migrate to the wellbore (Lambert and Trevits, 1978).

Vertical boreholes are normally rotary-drilled using portable drilling rigs. Air, mist, water, foam, and mud have been used to carry rock cuttings to the surface. To minimize the possibility of decreasing coalbed permeability by infiltration of drilling fluid, the use of drilling muds should be avoided except where considered absolutely essential. Air or light foam guards against permeability damage and increases drilling speed by reducing pore pressure at the bit-rock interface.

The depth and thickness of the coal units penetrated in boreholes must be known for stratigraphic correlation, well-completion plans, and stimulation design. Evaluation of rock cuttings and drilling time logs, though helpful, do not supply the precise information usually required. The most accurate data are obtained from cores, but these are quite expensive. Geophysical logging is less expensive and can be used to delineate coal zones less than 1 ft (0.3 m) thick. Density logs are typically used in coal identification. The relatively low bulk densities of coal cause distinctive log responses, which are easily recognized. Density logs are obtained for boreholes before they are cased.

If gas is to be drained from several coalbeds, casing is set along the full depth of the borehole, and openings are cut or pierced through the casing at each coalbed horizon. This type of completion allows any number of selected horizons to be produced simultaneously.

Two completion techniques have been used to expose coalbeds through casing: (1) perforating casing using shaped charges and (2) cutting vertical slots through the casing using jetting equipment (Lambert, Trevits, and Steidl, 1980). The perforating technique has been used in a number of different coalbeds. However, even in coals that have been hydraulically stimulated, production from perforated wells has been significantly less than production from wells with open-hole completions. Partial plugging of perforations may be a major cause of the comparatively low flows.

Hydraulic stimulation is a standard technique used to increase well productivity in the oil and gas industry. Modified versions of oil and gas industry hydraulic stimulation techniques have been applied to coalbeds in several areas of the United States. The basic mechanics of stimulation for gas drainage from coalbeds are quite simple (Fig. 22.5.13). Hydraulic pressure, generated at the surface by pumping fluid, is applied to a selected rock unit (coalbed) to widen or extend existing fractures. The fractures are extended into the coalbed by continued injection of fluid. During the treatment, sized particles (e.g., sieved sand) are added to the fluid as a propping agent to hold the fracture open after the hydraulic pressure is released, and the stimulation fluid is drained off. Stimulation creates conductive pathways from the wellbore to points several hundred feet (meters) within the coalbed.

Stimulation treatments are generally categorized according to the type of fluid used. Water, gelled water, and foam are the major types of treatment tested, each type having advantages as well as limitations. Gelled fluid is a water-based, natural guar gum mixture, which serves to carry sand proppant and retard leakoff. After stimulation, gelled fluids are designed to revert or break down to a fluid with a viscosity similar to water.

REQUIREMENTS OF FOAM-TYPE STIMULATION TREATMENTS

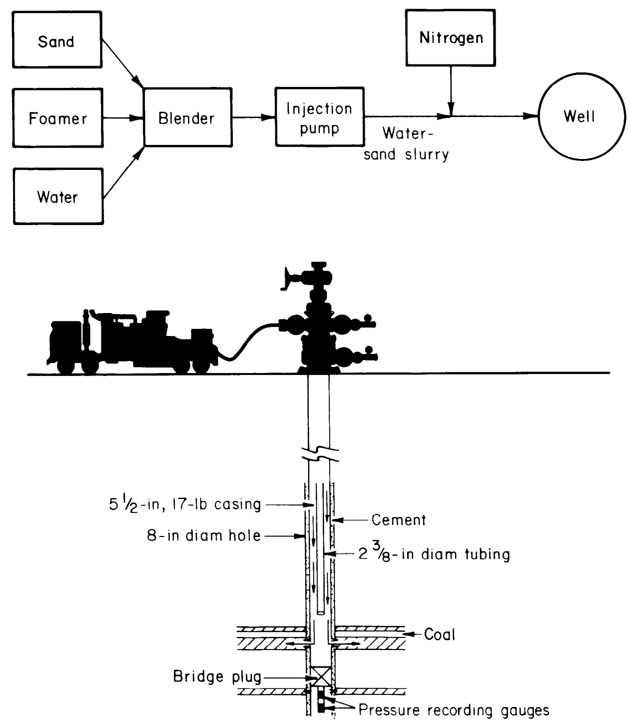

Fig. 22.5.13. Schematic of hydraulic stimulation system for vertical boreholes.

Gel treatments include some type of “breaker” ingredient, which reduces fluid viscosity. The time required after treatment for breakdown to occur depends primarily on the temperature of the coalbed. If adequate breakers are not used or if the in situ temperature of the coalbed is incorrectly estimated, stimulation fluid breakdown may not occur as desired. For example, stable gel or viscous gel residue was observed at well sites several months after stimulation treatment. The presence of gel within coalbed fractures retards fluid flow to the wellbore. Gas and water production have been low where gel has been found.

Foam, as used in coalbed stimulation, is a mixture of fresh water, nitrogen, foaming surfactant, and sand. Various types of surfactant have been used; nitrogen is nonreactive with coal and associated reservoir fluids. Using foam rather than gelled fluids has several advantages. Foam appears to decrease the amount of fluid leakoff to the coalbed. As a result, the occurrence of sandouts has been reduced by more than 50% (Lambert and Trevits, 1979). In foam treatments, problems associated with proper proportioning, mixing, injection, and breakdown of gel are avoided. Foam treatments are very clean; most stimulation fluids are removed from the coalbed in less than one day. This short exposure time limits the possibility of harmful reactions with the coalbed reservoir system, which could reduce fracture conductivity or cause formation damage. Also, site water requirements are about 60 to 80% less than for gel treatments of similar volume. The low liquid content of foam requires reduced hydraulic horsepower for injection, and smaller pumping units can be used for stimulation. Reduced onsite storage and equipment size minimize costs for site clearing operations. Injection rates for foam can be low, 10 bbl/min (1.6 m^3/min) or less. Wells have been stimulated with 50,000 gal (189 m^3) of foam using a single small pump truck normally used for borehole cementing work.

Another coalbed stimulation treatment, referred to as Kiel Frac, is a pressurization-depressurization technique (Kiel, 1976). In theory, this technique creates long fractures along two transverse directions, then props the fractures with reservoir rock material that sloughs off during the treatment. The intermittent pressurization/depressurization is said to produce small horizontal fractures perpendicular to the primary vertical fracture. Water and sand are used in Kiel Frac stimulations. No chemical mixing is required, and potential problems due to fluid formation damage or incomplete gel breakdown are avoided. The sand is supposed to filter-pack the natural joint system and/or the downward extent of vertical rock joints. This limits fracturing to the upper portion of the coalbed, and it is estimated that leakage is inhibited by the overburden.

Experience has shown that single methane drainage boreholes in virgin coalbed areas do not produce high sustained gas flow rates. This indicates that the boreholes cannot reduce coalbed pressure and decrease water saturation rapidly enough and/or to a great enough degree to maintain high flow rates. Given a water-saturated condition and an infinitely large reservoir, fluid drainage can only be effective in an area where permeability to the borehole is greater than the coalbed's natural permeability. At stimulated boreholes, this effective drainage area is directly related to the length and conductivity of the induced fractures. Outside these zones of induced permeability, significant pressure and saturation reductions must occur very slowly since water is supplied by the coalbed at nearly (very sightly below) the same rate as it can be removed (Lambert and Trevits, 1978).

Water production from a single borehole is typically high during the early phases of pumping since water originates primarily from the area of induced permeability around the borehole. Water flow, however, decreases sharply as drainage expands beyond this highly permeable zone. This lower level of water production then very slowly decreases through the remaining life of the borehole (Lambert and Trevits, 1978).

A more efficient method used to reduce pressure and decrease water saturation is to draw fluids from a more limited area of the coalbed. This can be accomplished by completing multiple-borehole patterns or by positioning boreholes close to mine workings. As coalbed fluids are removed from two or more of the boreholes, the drainage areas overlap, which allows the boreholes to remove more fluids from specific coalbed areas. By doing this, coalbed pressure is reduced to a greater degree within a shorter period of time, allowing much more gas to be released from the coal. Water saturation is also lowered to a greater degree which increases gas permeability and thereby enhances flow to the boreholes (Lambert and Trevits, 1978).

Experience with vertical boreholes for methane drainage has indicated that they can be effectively used to reduce methane emissions underground and to produce marketable quantities of gas (Lambert and Trevits, 1978). A number of studies have been conducted, and results of these tests ranged from wells producing 1000 ft^3/day (28 m^3/day) to wells producing more than 100,000 ft^3/day (2831 m^3/day) (Lambert, Trevits, and Steidl, 1980; Deul and Kim, 1988). The production rate was apparently dependent upon factors such as gas content, the efficiency of water removal, proximity of other drainage points, and coalbed characteristics. Cumulative production was related to the average production rate and the duration of the production period.

22.5.4.2 Gob Ventilation Boreholes

Methane gas can be recovered from gob by holes drilled well in advance of actual mining (Deul and Kim, 1988). A zone of tightly compacted rubble is created in areas where virtually all of the coal has been extracted and the roof strata are allowed to fall. Air does not flow easily through this rubble, and large quantities of methane gas may accumulate. On occasions when the barometer falls, the methane-laden air in the gob can expand and enter portions of the mine where a spark source is more likely to be found. Gobs may be sealed; however, these seals cannot be made completely airtight, and so they also can leak methane-laden air as the barometer drops.

Vertical boreholes into gob areas are a common methane drainage technique (Skow, Kim, and Deul, 1980). Usually, two or three holes are drilled into a longwall panel before mining, as close to the panel centerline as the surface terrain allows. The first hole is about 500 ft (152 m) from the point where mining begins; subsequent holes are spaced at 1000- to 1500-ft (304- to 457-m) intervals.

The holes are usually drilled to the coalbed, although recent research has shown that holes completed 100 ft (30 m) above the coalbed to be mined can also be effective. The borehole is cased and cemented through the lowermost water-producing zone, leaving as much open hole at the bottom as possible. The lower 200 to 300 ft (60 to 91 m) of the hole is left open. As the overburden fails, gas emitted from this area is diverted to the hole, rather than entering the mine gob. If casing is used in this part of the hole, it is cut with large slots to avoid restricting gas flow.

When the hole is intersected by the longwall panel, the overburden fractures and flow begins. Production is highest for the first few months; flows of 100 to 200 cfm (2.8 to 5.7 m^3/min) of methane gas are typical, although some holes have produced at twice this rate (Deul and Kim, 1988). Production from gob holes declines, and after a year or two, the flow may be one-tenth of the initial value. The methane concentration varies and may decline as the total airflow declines. Gob gas drainage holes, drilled on a regular basis, drain an average of 40% of the total gas from longwall panels. Drainage from room and pillar panels is less efficient, about 25%. More gas is drained from longwall panels because extraction of the coal is more complete, and the roof caves and fractures to a greater degree.

SURFACE GOB HOLE SYSTEMS. In the central Pennsylvania and northern West Virginia areas, three gob holes are normally drilled into each longwall panel. The first gob hole is drilled about 400 ft (120 m) from the start line of the panel, and the other two are equally spaced over the remaining length of the panel (Deul and Kim, 1988). In the deeper coalbeds where the overlying strata are gassier than at shallow depths, four gob holes are typically used in each panel. In southern Virginia, the first gob hole is located about 300 ft (90 m) from the start line of the panel and the other three holes are spaced at 1200 ft (365 m). In northern Alabama, gob holes are drilled about 500, 1000, 1800, and 2800 ft (150, 300, 540, 840 m) from the start line of the panel.

Gob hole completion differs in various areas because of hole size, size of casing, and depth of hole. In central Pennsylvania, the gob holes are typically 600 ft (182 m) deep. Initially, a 12-in. (304-mm) diameter hole is drilled to 500 ft (152 m). An 8-in. (203-mm) casing is set to the bottom of the hole with a bottom seal arrangement installed. The hole is then extended an additional 100 ft (30 m) with an 8-in. (203-mm) bit. This later section is not cased. The 8-in. (203-mm) diameter casing is sealed with grout at about the 500-ft (152-m) depth.

Gob holes in the northern West Virginia area are typically drilled to a depth of 900 ft (274 m) with an 8.75-in. (222-mm) diameter bit. The hole is then lined with 700 ft (213 m) of 7-in. (177-mm) diameter standard casing and 200 ft (60 m) of 7-in. (177-mm) diameter slotted casing. A formation packer, which is installed above the slotted casing, allows the 700-ft (213-m) length of casing to be grouted in place. The slotted casing that hangs below the formation packer extends to within 20 to 90 ft (6 to 27 m) of the coalbed.

In southern Virginia, average overburden is about 1800 ft (540 m). Gob holes are typically drilled to within 20 ft (6 m) of the coalbed with a 12.25-in. (311-mm) diameter bit. The hole is then lined with 1600 ft (487 m) of 9-in. (228-mm) diameter casing and 180 ft (54 m) of slotted casing. A formation packer, which is installed above the slotted casing, allows the 1600 ft (487 m) of casing to be grouted in place.

Gob holes are about 2050 ft (624 m) deep in northern Alabama. Initially, a 17.5-in. (444-mm) diameter hole is drilled to 150 ft (45 m) and a 13.5-in. (342-mm) diameter casing is grouted in place. Subsequently, the hole is extended about 1880 ft (573 m) to within 20 ft (6 m) of the coalbed using a 12.25-in. (311-mm) diameter bit. The hole is then lined with 1450 ft (441 m) of 9.5-in. (241-mm) diameter slotted casing. A formation packer is installed above the slotted casing, and the top 1450 ft (441 m) of casing is grouted in place.

All gob holes are equipped with exhausters to provide the partial vacuum to draw the gob gas to the surface. The size and capacity of the exhausters are dependent on the relative gassiness of the strata in the study area. The surface venting facilities are fenced and equipped with lightning protectors and flame arresters.

CASE HISTORY 3: POCAHONTAS No. 3 COALBED. The site chosen for this study was approximately 2260 ft (688 m) below the surface in the Pocahontas No. 3 Coalbed in Buchanan County, VA (Maksimovic and Kissell, 1980). The coalbed in this region is approximately 51 in. (1295 mm) thick and has a small shale parting approximately 15 in. (381 mm) below the top of the bed. The horizon above the coal is sandy shale with sandstone streaks and partings. Below the coal is a 10-in. (254-mm) zone of quartzite, and below this is a massive micaceous sandstone.

An 8-3/4-in. (222-mm) diameter gas drainage hole was drilled to a level 4 ft (1.2 m) below the coal. A 7-in. (177-mm) OD casing was placed in this hole and pressure grouted from the surface to within 139 ft (42 m) of the coal. This left an annular space between the lower slotted section of casing and the hole. The grout prevented the entry of water and gas from the upper horizons but permitted the passage of gas through the slots in the lower 120 ft (36 m) of casing and through the end of the pipe.

The gas drainage hole was completed in the spring; mining of the panel was initiated approximately 3-1/2 months later. No significant flow of methane was detected at the top of the casing until after the borehole was intersected by mining.

The longwall panel was 370 ft (112 m) wide and 3920 ft (1194 m) long. A bidirectional plow was used for extraction and the roof was supported by self-advancing, double-frame, heavy-duty hydraulic units; each unit consisted of four double-acting 140-ton (127-t) jacks. The face equipment required a minimum space of 11 ft (3 m) between the coal face and the gob. A single split of air was used to ventilate the longwall panel. The airflow rate past the head end of the face ranged from 77,000 to 82,000 cfm (2180 to 2321 m^3/min) during the study period. Approximately 20% of this air reached the tail end of the face, with the remainder flowing past the roof support units into the gob.

The effect of the borehole was quite evident. Not only was there a decrease in the methane flow rate found underground, but the short-term fluctuations in flow rate were diminished markedly. Presumably, much of the gas emitted by the overlying strata passed through the borehole and was thus prevented from being forced into the mine as the immediate roof and adjacent strata collapsed. Further, there was an associated marked decrease in the maximum measured underground methane concentration. The maximum value recorded before borehole intersection was 1.9% and the maximum value after intersection was 1.3% in approximately 100,000 cfm (2831 m^3/min) of air; this represents a decrease of slightly over 25%, approximately the proportion of methane carried away by the borehole under free-flow conditions. However, an ever larger portion of the gas was removed by the use of an exhaust fan.

The methane concentration of the gas discharged by the borehole during the study period ranged from 77 to 100%. Because the concentration tended to decrease when the exhaust fan (exhauster) was turned on, it was used only intermittently to keep the methane content of the gas flow from the borehole above about 30%. Although the exhauster increased the methane flow rate through the borehole from about 25 to 35% it also entrained some air.

Because gob gas boreholes divert methane from the mine returns, the mining rate can be increased with a particular ventilation system without exceeding the legal methane limit. Higher mining rates were measured after borehole intersection occurred.

22.5.4.3 Horizontal Boreholes from Shaft Bottoms

Construction of shafts for use in methane drainage requires no unusual equipment or techniques. The shaft is drilled to the coalbed and lined. A plate divides the shaft into intake and exhaust sides. Outside the lining, there are two 4-in. (101-mm) diameter pipelines to carry the gas to the surface and one 3-in. (76-mm) pipeline for a power drop. Hoisting facilities and an exhaust fan are located on the surface.

When the shaft is completed, the area within the coalbed is enlarged to provide working space and to accommodate drilling equipment, power supply, stuffing box, water trap, and gas collector. Long horizontal drainage holes are then drilled around the periphery of the shaft. After the holes are drilled, they are connected to a gas-water separator. Since water fills the fractures in the coalbed, it must be removed before gas can flow freely. Generally, as the coalbed is dewatered, the gas flow rate increases (Fields, Cervik, and Goodman, 1976). After the methane is piped to the surface, it can be vented or collected and used commercially. The surface installation depends on the end use. If the gas is to be vented, a stack with a check valve and flame arrester is needed. If the gas is to be added to a commercial gas line, a compressor must be typically used, but other cleanup equipment is usually not needed. The US Bureau of Mines has demonstrated the use of shafts for coalbed gas drainage at the Multipurpose Borehole and Honey Run shaft of the Federal No. 2 mine and at the Maple Meadow mine.

CASE HISTORY 4: FEDERAL No. 2 MINE. In the initial demonstration of the use of shafts for methane drainage in advance of mining, a 4-ft (1.2-m) diameter borehole (designated the “multipurpose borehole” because of its many potential uses) was drilled to virgin coal on Eastern Associated Coal Corporation’s Federal No. 2 mine property, Monongalia County, WV (Fig. 22.5.14) (Fields, Perry, and Deul, 1975). First, an 84-in. (2133-mm) diameter hole was drilled 50 ft (15 m) to bedrock using a rig set up especially for shaft drilling. The surface hole was cased with 74-in. (1879-mm) ID rolled-and-welded casing cemented in place. A 72-in. (1828-mm) diameter hole was then

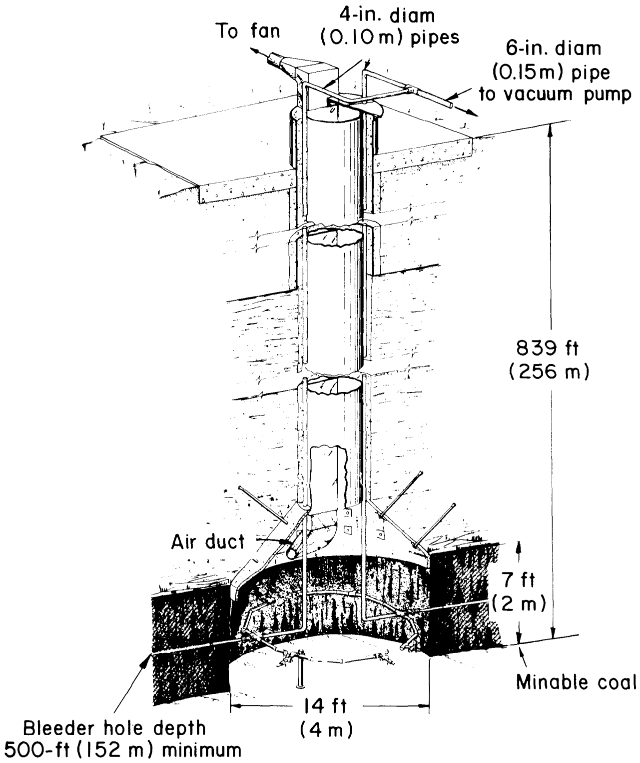

Fig. 22.5.14. Schematic of multipurpose borehole for methane drainage.

drilled to the bottom of the Pittsburgh Coalbed, a depth of 839 ft (255 m), using reverse mud- and air-assist circulation to remove cuttings. After the hole was drilled, a 48-in. (1219-mm) ID casing was grouted in place to a depth of 826 ft (251 m), 8 1/2 ft (2.6 m) above the top of the Pittsburgh Coalbed. The casing had a plate welded in it to divide it into intake and exhaust sides. Outside the casing, two 4-in. (101-mm) ID pipes were tack-welded to be used as gas exhaust lines along with two 3-in. (76-mm) pipes, one for water removal and the other as a power drop. An 8000-lb (3628-kg) capacity, 30-ft (9-m) high tripod headframe and a 5000-cfm (141-m^3/min) exhaust fan were then installed. Within the coalbed, the borehole was enlarged to a diameter of 14 ft (4 m). Seven gas drainage holes, ranging in length from 500 to 850 ft (152 to 259 m) and a 199-ft (60-m) in situ pressure-monitoring hole were drilled from the bottom of the shaft.

The in situ pressure, measured in the monitoring hole, was 203 psi (1399 kPa) just before all the holes went on production. Within 10 days of the initial gas and water production, the pressure had dropped to 18 psi (124 kPa). During the next 4 yrs, the pressure declined gradually to 5.5 psi (38 kPa).

Initial gas flow was 1.2 million ft^3/day (34,000 m^3/day). Within 90 days, total gas flow from all holes declined to 410,000 ft^3/day (11,600 m^3/day). The decline in gas flow paralleled the exponential decrease in waterflow rate. After the immediate area around the hole had been dewatered, gas flow gradually increased over the next year to a maximum of 700,000 ft^3/day (19,800 m^3/day). Gas flow averaged 600,000 ft^3/day (16,900 m^3/day) over the period of 3.5 yrs before the shaft was flooded. After the borehole was drained and gas production resumed, the initial flow rate was 600,000 ft^3/day (16,900 m^3/day), which gradually declined to a level of 370,000 ft^3/day (10,400 m^3/day). Total gas production for approximately 2500 days was 1.10 billion ft^3 (31 Mm^3).

22.5.4.4 Directionally Drilled Slant Holes

Directional drilling for coalbed gas drainage is an outgrowth of the techniques developed for methane drainage. This technique has been modified from horizontal holes drilled underground, either in mines or from the bottom of shafts, and surface vertical boreholes. Horizontal holes were found to have the advantages of relatively low drilling costs and the ability to intersect the coalbed cleat or fracture system, thus increasing permeability to gas flow. However, this method required underground access and facilities that often interfered with the mining cycle. The requirement of access to the coal occasionally limited the value of the horizontal holes because of the limited time and/or distance they could be drilled ahead of mining. Hydraulically stimulated vertical holes eliminated the latter problems but had the disadvantages of requiring large numbers of surface sites, higher costs, and production and maintenance problems.

The concept of directionally drilled degasification holes was originally considered by the US Bureau of Mines as a means of combining the best elements of the surface vertical borehole and underground horizontal drilling techniques (Diamond, Oyler, and Fields, 1977). From a single surface site, a vertical or near-vertical well could be progressively deviated to intersect a coalbed horizontally (Fig. 22.5.15). Several horizontal gas collection holes could then be sidetracked from the original well path in the coalbed. It would also be possible to orient the drill rig in several other directions on the same surface site and drill a succession of directional degasification holes. The cost of site preparation and production facilities would be significantly reduced by having the entire gas flow from a large coalbed area centralized at one surface location.

Thus directional drilling would eliminate the need for underground gas piping systems, would make entry into mines unnecessary, and could remove gas from large areas of coal far ahead of mining. The directional degasification hole could be used at sites where conventional horizontal or vertical holes are not feasible and at sites that are unsatisfactory for other types of methane drainage. Before this technique can be used routinely, problems in bit control, down-hole surveying, and removing water from the horizontal portion of the hole must be solved. The present high cost of the method and the need for a large number of exploratory coreholes may hamper widespread use of directional drilling for coalbed degasification.

CASE HISTORY 5: UPPER FREEPORT COALBED. A hydraulically operated, diesel-powered experimental rig, capable of working at a maximum angle of 10° from the vertical, was used to drill a directionally controlled hole to the Upper Freeport Coalbed horizon in Greene County, PA (Diamond, Oyler, and Fields, 1977). This capability is required in directional drilling to shallow seams (less than 1000 ft or 304 m of cover). At the Greene County site, the cover was 928 ft (282 m) and the rig was tilted to 5°. In the original plan, the hole was to be drilled in several stages. First, a 3-in. (76-mm) diameter pilot hole was to be drilled to the coalbed using BQ drill rod and a 2-3/8-in. (60-mm) diameter Dyna-Drill with a bent sub. Then the hole was to be reamed to 8-3/4-in. (222-mm) diameter, either by the use of a stringer bit or by overreaming the BQ drill string. A 5-1/2-in. (139-mm) diameter casing to the coalbed was then to be cemented in place. Finally, multiple horizontal holes were then drilled in the coalbed from the end of the casing using the Dyna-Drill and BQ drill rod. Owing to discontinuous coal, only the pilot hole was completed in this study.

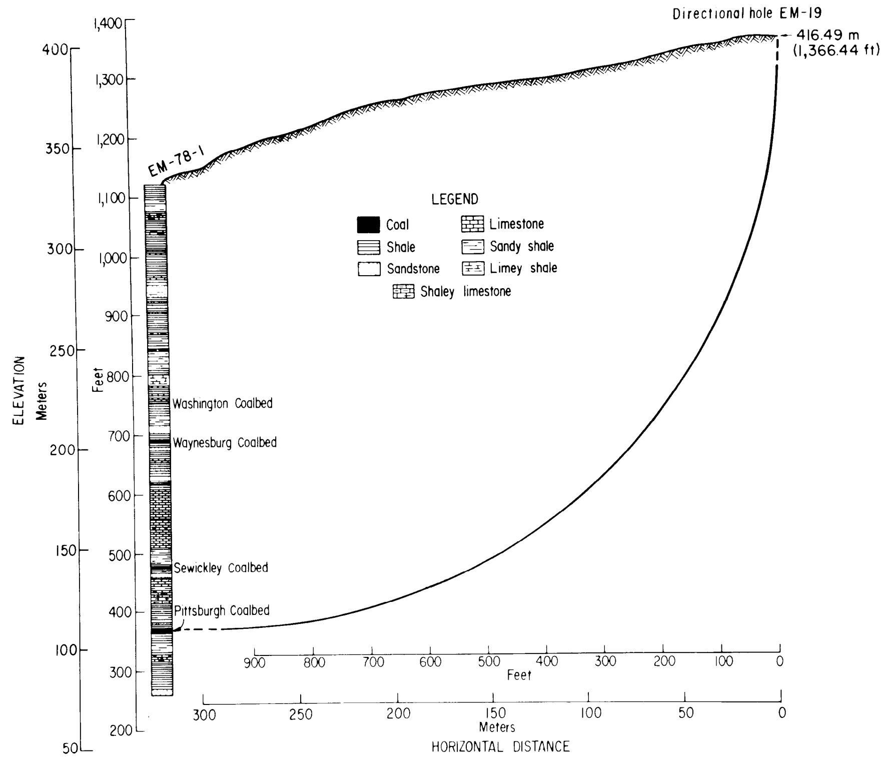

Fig. 22.5.15. Schematic of directionally drilled methane drainage borehole.

At the Greene County site, the 3-in. (76-mm) pilot hole was successfully drilled to a nearby horizontal position at the Upper Freeport Coalbed horizon. The first intercept of the target encountered less than 0.5 ft (0.15 m) of coal. This intercept was only 750 ft (228 m) from an exploratory corehole containing nearly 7 ft (2 m) of Upper Freeport coal. Five additional intercepts of the coalbed horizon encountered 0 to 4.3 ft (0 to 1.3 m) of coal. After approximately 1500 ft (457 m) of horizontal drilling in the target zone, it was decided that sufficient continuous coal thicknesses did not exist at the site to warrant further drilling.

CASE HISTORY 6: PITTSBURGH COALBED. In another test of directional drilling technology, three horizontal drainage holes were drilled in the Pittsburgh Coalbed from a directional surface borehole (Oyler and Diamond, 1982). A 3-in. (76-mm) diameter pilot hole was drilled from the surface to intercept the coalbed horizontally. The directional borehole was located at the top of a ridge to allow sufficient overburden above the coalbed for a circular arc of about 6° per 100 ft (30 m). The vertical distance to the coalbed was 1000 ft (304 m). Actual drilled distance of the directional pilot hole well path was 1652 ft (503 m). The directional drilling was accomplished with a 2-3/8-in. (60-mm) diameter Dyna-Drill down-hole motor and BQ wireline drill rod as the drill pipe. The rate and direction of angle were controlled by using various bent housings. Control of the well path was within specifications, and no remedial drilling was required to complete the pilot hole to the coalbed.

After the pilot hole was completed, a string of BCQ drill rod with a string of 1-in. (25-mm) diameter pipe inside for added stiffness was placed in the hole to be used as a guide string for overreaming bits. A gamma ray log was also run to confirm that the pilot hole had reached the top of the Pittsburgh Coalbed. Reaming operations used 3-1/2-in. (88-mm) diameter pipe with an 8-3/4-in. (222-mm) drillbit.

A vertical borehole was drilled near the coalbed intercept and equipped with a downhole plunger pump for dewatering. The vertical borehole was foam-stimulated to create a path for water to flow from the horizontal holes into the vertical dewatering borehole. Seven other vertical boreholes were planned in order to monitor the progress of gas drainage by observing the changes in hydrostatic pressure at each location. The horizontal portion of the directional hole was drilled to a measured depth of 1732 ft (527 m), slightly past the vertical dewatering hole.

In the initial horizontal drilling, it was necessary to drop through approximately 2 ft (0.6 m) of roof rock to enter the main bench of the Pittsburgh Coalbed. Apparently, the pilot hole had been drilled through the Pittsburgh rider coal into the roof shale above the Pittsburgh Coalbed, and instead of going into the Pittsburgh Coal, the hole had gone back into the rider coal. This error proved to be a major problem for two reasons. First, the vertical dewatering borehole and directional borehole had been placed so that fractures from the stimulation treatment would cross the horizontal hole just beyond the end of the casing. Since the horizontal hole was possibly in roof rock near the anticipated intercept of the stimulated fracture with the horizontal hole, direct communication may not have been achieved. Second, the initial portion of each horizontal hole was in rock that had a tendency to cave or slough, thus blocking the holes.

Continuous drilling of the first horizontal leg, hole 1, used clear water as the drilling fluid to prevent mud additives from plugging the coalbed fracture system. However, the removal of drill cuttings was more difficult because of the low viscosity of water. Fluid loss was also a problem, which could not be solved without the risk of damaging the coalbed's natural fracture permeability. Fluid losses as high as 15,000 gal/day (56 m^3/day) were experienced before hole 1 was completed. The first horizontal leg was completed at 3362-ft (1024-m) measured depth, when it was impossible to reenter the horizontal hole after a pipe trip. The hole had a total horizontal length of 1767 ft (538 m) beyond the end of the casing and was drilled in 26 working days, for an average rate of 67 ft/day (20 m/day).

Leg 2 was completed in 36 working days at a total measured depth of 4802 ft (1463 m). This was the longest horizontal hole drilled from the directional well, reaching 3207 ft (977 m) from the end of the casing. The average daily footage was 89 ft (27 m).

Leg 3 was drilled to a measured depth of 4588 ft (1398 m), a horizontal length of 2993 ft (912 m) from the end of the casing. Leg 3 was discontinued because it could not be reentered, owing to the apparent sloughing of the shale section at the bottom of the casing.

The final drilling operation performed on the slant hole was the underreaming of a horizontal sump 8-1/2 in. (215-mm) diameter from the bottom of the casing to a measured depth of 1742 ft (530 m) along the center leg, hole 1.

After drilling was completed, water production began at a pump capacity of 120 bbl/day (19 m^3/day), and intermittent gas flows were measured up to a rate of 1200 ft^3/day (33 m^3/day). After several days, water production declined drastically without any increase in gas production. It was believed that a barrier to waterflow between the slant hole and the dewatering hole was responsible. Several attempts were made to increase water production by flushing out both the slant and dewatering holes and to extend the dewatering hole's fractures.

Drilling the directional borehole to the Pittsburgh Coalbed demonstrated that it is possible to drill a directional pilot hole to a target coalbed. To determine that the hole actually was in the target coalbed required drilling an additional hole completely through the target coalbed. This was necessary because the accuracy of current directional well surveying is at best 2 to 3 ft (0.6 to 0.9 m) vertically.

The gas production from the directionally drilled borehole was insignificant due to the previously discussed problems. Technically, the drilling operation was successful, but the concept of this method as a methane drainage system remains unproven.

22.5.5 FUTURE TRENDS

Advancements in methane control techniques have been achieved to the extent that a number of different approaches exist for solving gas emission problems. However, additional studies are currently being conducted to address recent technological changes within the industry and within the scientific community. For example, short-radius directional drilling, which has been pioneered by the petroleum industry, is being proposed as a cost-effective method for methane recovery from vertically drilled boreholes. This system would permit a number of horizontal boreholes to be drilled within a coalbed from a single vertical borehole and would have the advantages of the slant hole drainage system without the disadvantages of dewatering problems and extended drilling lengths for the slant hole portion of the system. In addition, the short-radius system could easily be adapted to allow drainage from a number of different horizons such as multiple coalbed deposits.

One trend in the underground coal mining industry is the increased use of larger-dimension longwall panels, as the average panel currently exceeds 650 ft (195 m). This represents an increase of about 20% over the last five years. The implications of this trend on methane drainage systems primarily focus on the expansion of the gob area, Larger gob areas create additional disturbed ground surrounding the longwall panel, which increases the number of methane gas sources exposed to the mine environment and increases the total gas emissions associated with longwall mining. Gob gas drainage by vertical boreholes must become more scientific in nature as more gas must be handled by the drainage system. A basic understanding of the gob gas reservoir system is required to permit proper sizing and siting of the vertical boreholes.

An additional impact on methane control technology from increasing longwall panel dimensions is the importance of the time dimension on installing and operating the drainage systems. Larger longwall panels along with shorter time intervals between panel outline and retreat require methane drainage systems that operate at high efficiency. The drainage boreholes must recover large volumes of methane gas in relatively short periods of time. Drainage enhancement systems must be developed to achieve this goal.

Chapter 22.6
IN SITU GASIFICATION AND COMBUSTION OF COAL

ROBERT F. CHAIKEN AND JOSEPH W. MARTIN

22.6.1 INTRODUCTION

Underground coal gasification (UCG) and *in situ coal combustion* (ICC) are processes that can recover the energy of coal seams without the extensive use of traditional mining operations, either underground or surface. In UCG, the primary product brought from underground is a combustible fuel gas of low to intermediate heating (calorific) content, 100 to 300 Btu/standard cubic foot (scf) (3700 to 11,200 kJ/std m^3). In ICC, the primary product brought from underground is hot fully cornbusted flue gas, 1100 to 1800°F (600 to 1000°C), whose sensible heat contains most of the heating value of the coal, 5000 to 13,000 Btu/lb (11,600 to 30,200 kJ/kg).

Both UCG and ICC are particularly applicable to coal deposits that are not economically or technically feasible to mine by conventional methods because of seam quality or quantity, depth, dip, strata integrity, overburden thickness, etc. Actually, the two processes are corollary to each other in that those seam and site conditions that are favorable for UCG (e.g., thick, deep, partially wet seams) often will not promote in situ combustion, whereas conditions that are favorable for ICC (e.g., shallow, rubblized, dry seams) will not promote underground coal gasification.

UCG is the older of the two in situ coal conversion concepts, dating back over 130 years. It has received considerable attention worldwide during this century, particularly by the Soviet Union, and more recently by the United States.[1] Technical specifications and operational procedures for a number of UCG operations have been developed. They are generally site specific; however, the large background of technical data and experience that are available do indicate that the process is ready for commercial use in the United States, at least in the thick subbituminous and lignite seams located in the West.[2] The greater part of the chapter will focus on this aspect of in situ coal recovery.

ICC is a relatively new concept and was first proposed by the US Bureau of Mines (USBM) in 1974 (Chaiken, 1974). The subject of a much smaller development effort than UCG, it has been submitted to only one underground test as part of the development of burnout control, a USBM patented process for controlling fires on abandoned mined lands (Chaiken, 1980, 1983). Although further engineering and field trials will be required before burnout control can be commercialized as an ICC process, it is useful to describe the process here because of its potential application to the relatively thin, shallow bituminous seams (and abandoned mines) that are so prevalent in the eastern United States.

In the following segments, a description of some of the basic physics and chemistry of UCG is given that will allow the mining engineer more fully to understand the site assessment and engineering requirements for a UCG operation, and hopefully to enable him/her to extrapolate those requirements to various sites and coal conditions. This is followed by a discussion of applicable resources and utilization of the fuel gases that can be produced and a description of several types of UCG operations of potential commercial significance and their environmental problems.

Finally, a similar but much shortened approach is taken in describing burnout control as an in situ combustion process.

22.6.2 UNDERGROUND COAL GASIFICATION

22.6.2.1 Basic Processes in Underground Gasification

Gasification Reaction. Coal is gasified underground by injecting air or oxygen/steam through boreholes into a reaction zone formed in the coal seam. The hot gaseous reaction products are forced to migrate though the coal seam to an exit borehole where they are drawn from underground to the surface. Upon reaching the surface, the gases can be cleaned for direct use as a low-to-medium Btu gas, for upgrading to a substitute natural gas (SNG), or for some other chemical feedstock (SynGas). In essence, UCG involves achieving a spatially and thermally distributed reaction zone in the coal seam that consists of overlapping regions of coal oxidation, coal reduction and coal pyrolysis.

This is shown in Fig. 22.6.1, which depicts the basic chemical reactions and temperatures defining the distributed reaction zone. Entering air causes the coal to burn, an exothermic process releasing heat and consuming oxygen. The hot oxidized product gases migrate toward the exit borehole, passing in turn through a reducing region where, in the absence of oxygen, they are converted to combustible gases by a number of endothermic reactions which absorb heat. The somewhat cooler but still hot combustible gases continue to migrate toward the exit borehole, where they cool further as they pass through a coal pyrolysis region. In this region, the coal is heated to drive off its volatile matter, that is, tars, hydrocarbons, and other gases both combustible and noncombustible. The entire gas mixture then exits the seam through a production borehole.

Water plays an important role throughout the entire reaction zone. It is responsible for much of the hydrogen produced in the reduction region, being reduced by carbon in an endothermic reaction:

[1] The history of UCG prior to 1970 has been reviewed quite extensively in several references (Elder, 1963; Little, 1971; Wang et al., 1973). References Edgar and Gregg (1981) and Olness and Gregg (1977) are devoted to the extensive program carried out in the Soviet Union, and reference Gibb et al., 1964 is devoted to the UCG program (1949–1956) carried out in Great Britain. Since 1975, almost all work on UCG, worldwide, has been reported at openly attended annual symposia sponsored by the US Government; the proceedings of which (except for the first meeting in 1975) have been published by the Energy Research and Development Administration (ERDA) and its successor, the Department of Energy (DOE) (Anon., 1976–1988).

[2] It is useful to note that six UCG stations have been operated in the USSR. Starting in 1933, experiments were carried out in the brown coal of the Moscow Basin. Stations operated as research facilities, and some eventually developed into small industrial producers. However, the Angrenskaya station in the lignite fields near Tashkent was apparently established initially in 1952 as a commercial venture. There are currently two other commercial-scale UCG stations operating, one at Shatky (Moscow Basin lignite) and one at Yuzhno-Abinsk (steeply dipping bituminous seams) (Stephens, Hill, and Borg, 1984).

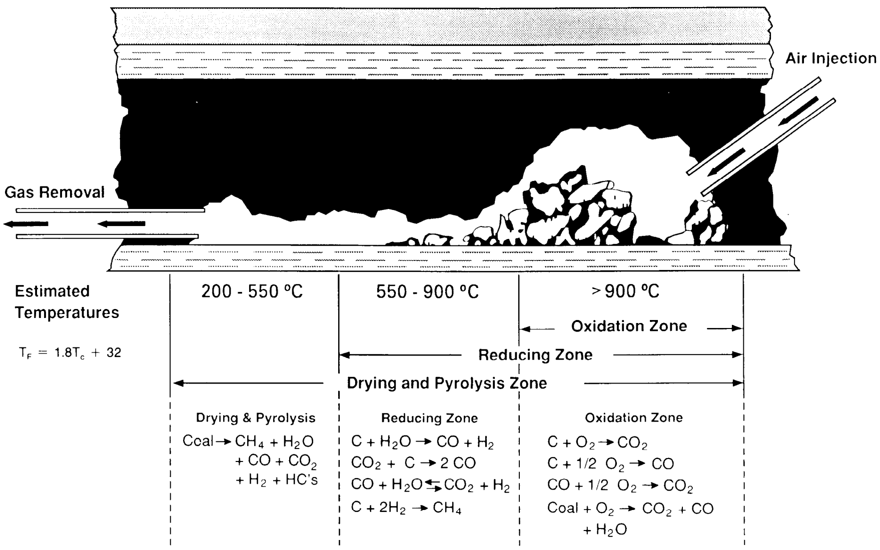

Fig. 22.6.1. Schematic representation of an underground coal gasification reaction zone (Anon., 1977).

$$C + H_2O \rightarrow CO + H_2 - 31.4 \text{ kcal/mol} \qquad (22.6.1)$$

This water reduction reaction enhances the heating value of the product gases. However, further reduction of water by CO in the water-gas shift reaction:

$$CO + H_2O \leftrightarrow CO_2 + H_2 + 9.4 \text{ kcal/mol} \qquad (22.6.2)$$

will detract somewhat from the heating value of the product gas. Here the hydrogen is formed at the expense of carbon monoxide, a somewhat more more energetic fuel gas, and also at the expense of forming additional CO_2 diluent in the product gas. Carbon dioxide is much more difficult to remove from the final product gas during cleanup than is H_2O.

While some water is an important reactant in the underground reaction zone, excess water will behave as an evaporating heat sink, moderating the temperature rates of the chemical reactions, particularly the char gasification reactions in the reducing zone (see Fig. 22.6.1). These reactions generally require temperatures in excess of 1100°F (600°C). With air injection, there will generally be an optimum water/air/coal ratio that yields a maximum heating value for the product gases (Edgar and Gregg, 1981). While some of the water for this ratio will be formed by oxidation of the hydrogen component of the coal, the optimum condition usually requires additional water supplied either by the moisture already in the seam itself or by intrusion from the surrounding strata. Control of this additional water is possible, in part, by varying the pressure of the injection air and in part by increasing the rate of air injection, and hence the gasification rate. However, increased injection pressure will tend to increase gas loss from the underground reaction zone to the surrounding strata.

An example of this is shown in Fig. 22.6.2, which contains data from an experimental Soviet underground gas generator. At constant air injection rate, a linear relationship was observed between gas loss V(loss) and the difference between the square of the absolute pressure P_{av} (averaged over the underground reaction zone) and the square of the atmospheric pressure P_{at}, that is,

$$V(\text{loss}) = C\,[(P_{av})^2 - (P_{at})^2] \qquad (22.6.3)$$

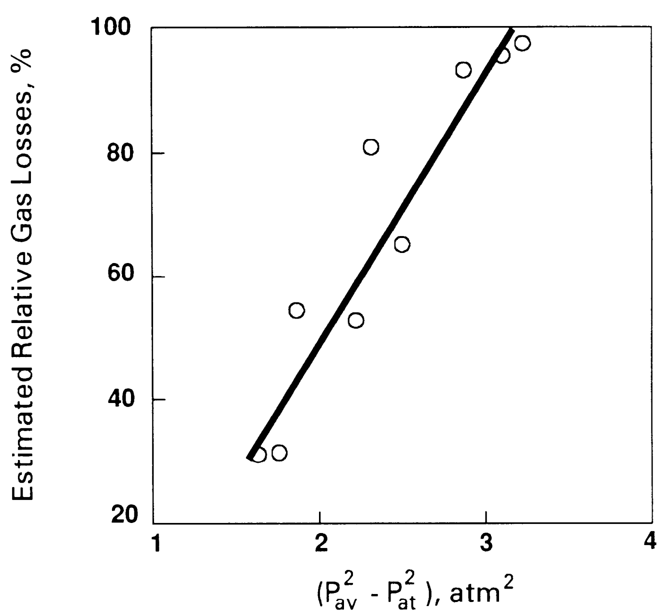

Fig. 22.6.2. Dependence of the relative value of the gas losses on the gas pressure in an underground gas generator (Pitkin, 1960).

The slope C of the straight line in Fig. 22.6.2 is undoubtedly site specific, depending on the permeability of the strata.

Fig. 22.6.3 shows the combined effect of gasification and water intrusion rates on the heating value of the product gases (again based on Soviet data). Here it is seen that excess water alters the heating value of the final product gases—most likely by decreasing the temperature and rate of the char reactions and hence altering the gas composition. This same effect of lower temperature leading to decreased heating values is also reflected in the data shown in Fig. 22.6.4, which show that thin seams, as well as increased water intrusion, decrease the heating value of the final product gas. Heat loss from an underground reaction zone to surrounding rock strata would be expected to vary inversely with seam thickness. Hence, in thin seams, UCG temper-

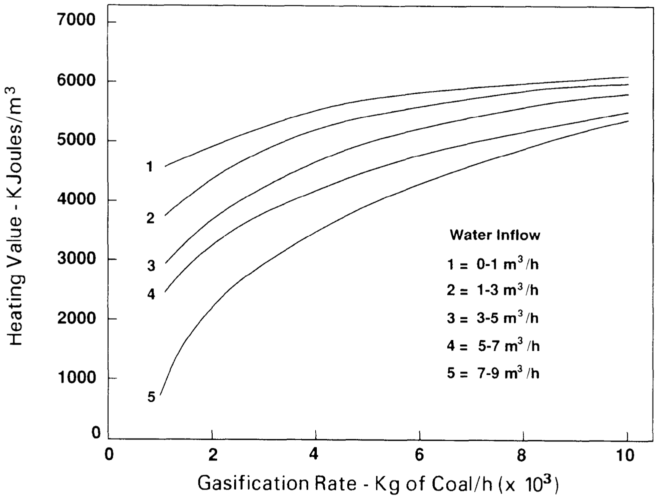

Fig. 22.6.3. Effect of gasification rate on heating value at various water injection rates (Edgar and Gregg, 1981). Conversion factors: 1 lb = 0.4536 kg, 1 Btu/ft^3 = 37.26 kJ/m^3, 1 ft^3 = 0.02832 m^3.

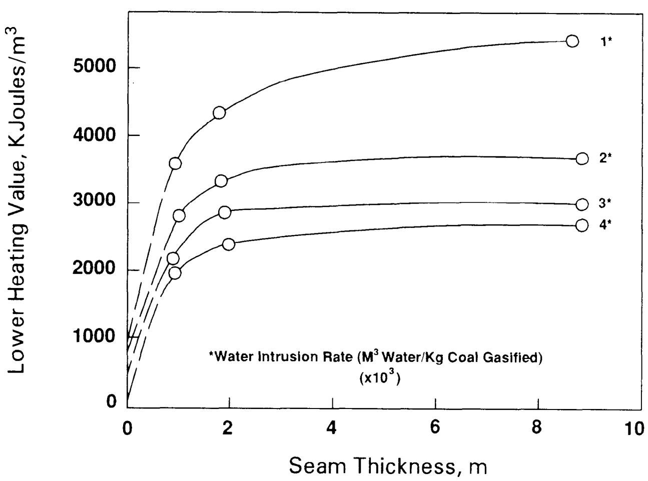

Fig. 22.6.4. Effect of seam thickness and water intrusion on UCG heating values (Anon., 1977). Conversion factors: 1 ft = 0.3048 m, 1 Btu/ft^3 = 37.26 kJ/m^3.

atures may be lower, and chemical reaction rates slower. In Fig. 22.6.4, taken from Soviet studies with brown coals, the heating value of the product gas deteriorates rapidly for those seams less than 6 ft (1.8 m) thick, and gasification can not be sustained for seams less than 3 ft (0.9 m) thick.

In practice, the migrating gases can be subject to high heat loss even in thick seams. Referring back to Fig. 22.6.1, it is easily visualized that the actual flow path of the UCG gases may be directed close to the top of the seam rather than through the main body of the seam. This would tend to enhance heat losses from the reaction zone and could lower product gas heating values. Avoidance of this type of heat loss requires locating the gasification channel(s) properly in the coal seam. This point is discussed below in some detail.

A related point, but one leading to a somewhat different problem, occurs when the path(s) of the underground gas flow enables oxygen from the injected air to reach and mix with the product gases directly in the vicinity of the exit borehole. This results in burning of the product gas prior to it being exhausted from underground, thereby decreasing the heating value of the final product gas, as well as increasing the temperature of production well. The "breakthrough" or bypass of air into the product gas stream often signifies the end of the useful life for a UCG reaction zone. This is seen in Fig. 22.6.5, which depicts heating values and exhaust temperature as a function of time for a UCG reaction zone formed between a single set of injection/production boreholes. The data come from the Hanna II experiment carried out by the USBM.[3]

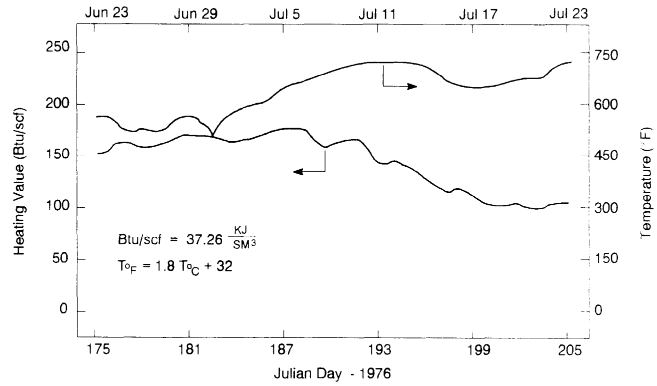

Fig. 22.6.5. Heating values and wellhead product gas temperature at Hanna II field trial (Schrider et al., 1976).

Table 22.6.1 shows some typical gas compositions and heating value data obtained in past UCG experiments (US Bureau of Mines at Gorgas, AL) as compared with results from surface gasifiers. The Gorgas data for UCG in a bituminous seam do not represent the best case for UCG (typically, 80 to 150 Btu/scf, or 3000 to 5600 kJ/std m^3, from subbituminous coal); however, it is seen that the UCG product is similar in composition to the surface gasifier product. The higher CO_2 values in the UCG product probably reflect the greater degree of "breakthrough" or bypass that was experienced in those field trials. More recent higher-quality UCG gases compare quite favorably with Lurgi producer gas (see 22.6.2.3).

Preparation of the Coal Seam. It was described above that proper reaction zone geometry and proper migration of the gas through the reaction zone play a very significant role in a successful underground gasification process. The permeability of the seam must be such that sufficient gas flow occurs, and along paths that ensure (1) minimum gas and heat loss from the seam, (2) a maximum functional life before oxygen breakthrough takes place, and (3) achievement of optimum chemical reactions and a consistent exiting gas composition. Even with an ideal thick seam having no faults, a low level of water influx, and a structurally sound roof strata, the achievement of a successful UCG requires careful seam preparations to obtain a suitable reaction zone.

Early UCG trials were carried out in roadways and drifts prepared by underground mining. The reaction zones established

[3] In 1972, the US Bureau of Mines/Laramie Energy Research Center (USBM/LERC) initiated a second major US developmental effort on UCG at a subbituminous site near Hanna, WY. These efforts followed more closely the Soviet approach than did the Bureau's first experiments in the 1950s at Gorgas, AL (Elder, 1963). In 1975, the UCG program along with all of the Bureau's Energy Research Centers were transferred to the newly formed Energy Research and Development Administration (ERDA), which subsequently (in 1977) was incorporated into the US Department of Energy (DOE).

Table 22.6.1. Data Comparing UCG and Surface Gasifier Products

	UCG			Gasifier		
	Air			Air		
Oxidant	Normal	N_2-free	Oxygen	Normal	N_2-free	Oxygen

in the relatively large cross-sectional-area roadways generally did not allow for sufficient interaction between the solid coal and the injected air, thereby leading to early breakthrough of the air. These designs were soon followed by the use of horizontal boreholes drilled from a mined gallery in the case of a horizontal seam (Fig. 22.6.6), or slant boreholes from the surface into a mined gallery in the case of a steeply dipping bed (Fig. 22.6.7). Gasification, fed by injected air and coal progressively spalling from the walls of the channel, would continue until breakthrough occurred. This is depicted schematically in Fig. 22.6.8 for a horizontal seam. The initial injection of air (or oxygen/steam) results in a reaction zone similar to that in Fig. 22.6.1. As coal spalls and is consumed, the oxidation region grows, extending to the roof and floor of the seam, and eventually expands as a reaction wave forward to the production hole, and to a lesser degree, laterally to the sides. The Newman-Spinney P-5 trial (Gibb et al., 1964) is a good example of this UCG process. Fig. 22.6.9 shows plan views of the 2.5-ft (0.8-m) seam before and after the 118 days of UCG. In this case, the final geometry of the reaction zone was verified by excavation.

Progressive UCG along a channel in a steeply dipping seam takes on a somewhat different form as depicted in Fig. 22.6.7. Coal along the horizontal gallery is gasified, leading to a continuing fall of ash and roof coal into the gallery. In this way, the linear reaction zone travels upward through the seam toward the surface outcrop.

The use of these preliminary underground mining methods in preparing a coal seam for UCG had varying degrees of success in several of the early experiments, but their development was discontinued in the late 1950s in favor of surface preparation methods only. This decision was prompted by the desire to have no personnel working underground, by advancements in directional drilling, and by efforts to enhance future application to very deep seams. However, as pointed out in a National Coal Board appraisal (Thompson, Mann, and Williams, 1976), preliminary mining methods can have some advantages, and interest in them will probably be renewed as additional commercial scale UCG plants are developed. Since the thrust of all current UCG projects is to use surface borehole methods exclusively, it is these methods that are emphasized in this segment.

A vertical or slant borehole from the surface is the quickest and simplest way of reaching a coal seam, so it is not difficult to establish an injection borehole and a production borehole by

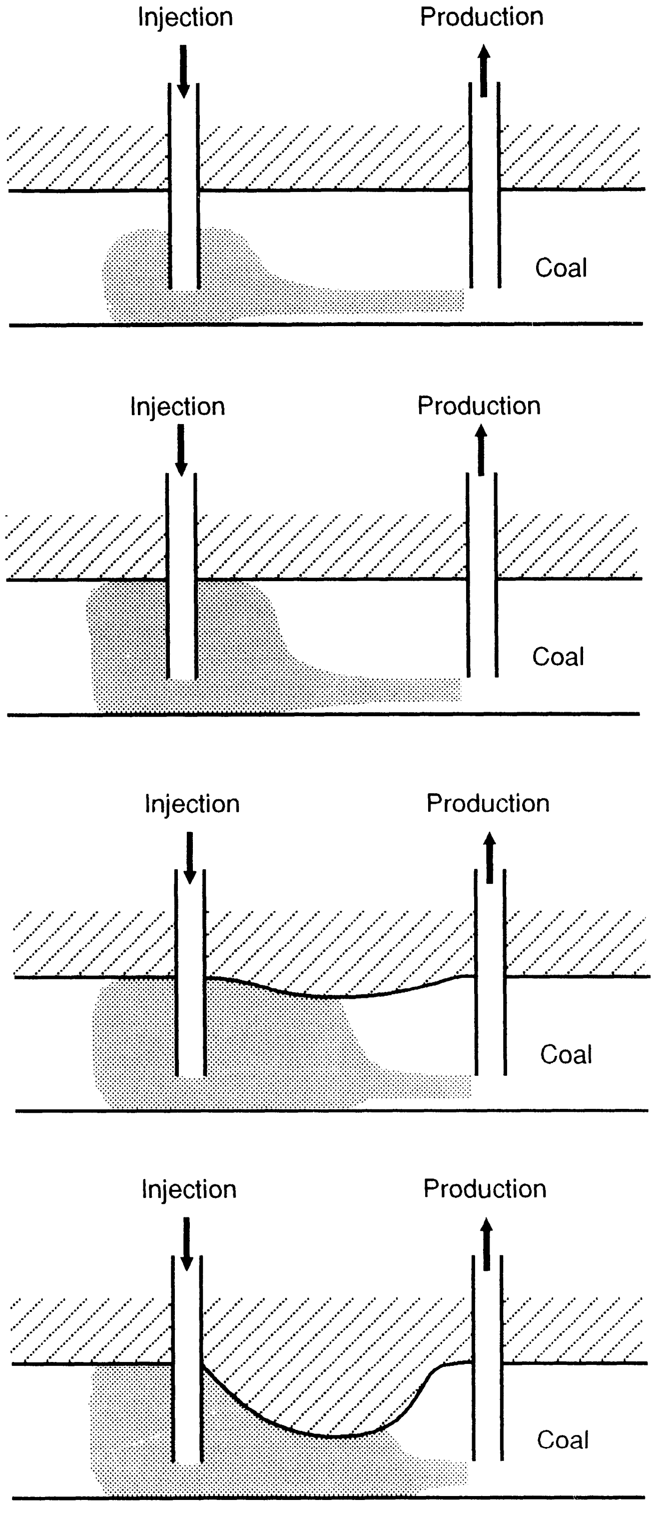

Fig. 22.6.8. Idealized progression of UCG in a horizontal seam (percolation or filtration method).

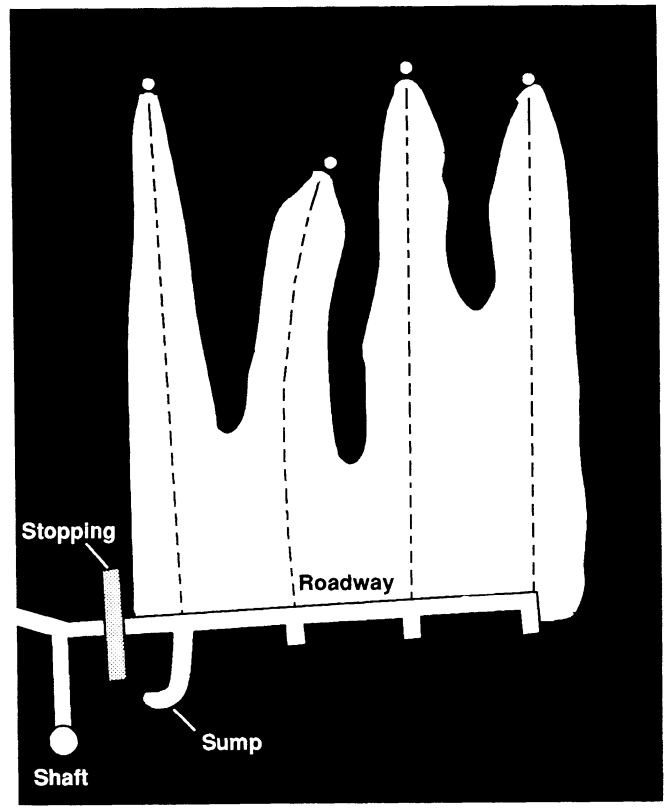

Fig. 22.6.9. Voids left at conclusion of P5 field trial at Newman-Spinney (Thompson, Mann, and Williams, 1976).

surface drilling methods. Fig. 22.6.10 depicts the construction of a typical process well. The problem is how to establish a proper initial underground gas flow link between the ends of the two boreholes, the natural permeability of the coal seam being too low to permit the required gas flows for UCG.[4] There are several methods available to link the injection hole to the production hole, each with their good and bad points. Two of the methods, directional drilling and counterflow or reverse combustion, are in current use and will be described below. The others—electrolinking, hydrofracking, and explosive linking—have been tested with varying degrees of success but are generally no longer of interest, although hydrofracking is still sometimes used in connection with reverse combustion to enhance the initial permeability of a seam.

DIRECTIONAL DRILLING. Adapted from oil well applications, the Soviets have employed *directional drilling* in the USSR since 1940 as a means of preparing the gasification link between injection and production boreholes. More recently, several UCG projects in the United States have also utilized the technique, which has the advantage of establishing a positive link at the base of the coal seam, relatively independent of the geology, dip, and fracture system in the seam. The hole in the coal provides the initial gasification channel, while that portion of the hole leading to the surface may or may not serve as the injection hole. Utilizing down-hole electrically or hydraulically driven cutting tools, curved holes with very small radii of curvature can be drilled. Fig. 22.6.11 shows a representation of a 3-in. (75-mm) directional (or deviated) borehole drilled to the 25-ft (7.6-m) Felix No. 2 subbituminous seam for the Hoe Creek III UCG trial. A $2\frac{3}{8}$-in. (60-mm) diameter Dyna-Drill with mud motor

[4] Permeability measurements on stress-relieved cores have indicated values of 1 to 10 millidarcies (md) for bituminous coal, 100 to 200 md for subbituminous non-shrinking coal, and 1000 to 2000 md for subbituminous shrinking coal (Lien et al., 1977).

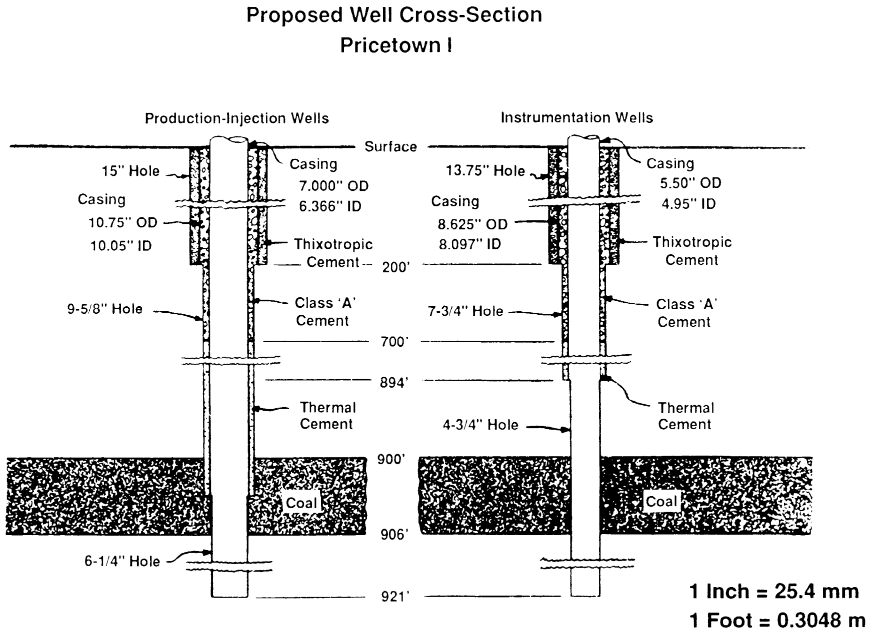

Fig. 22.6.10. Typical construction for UCG boreholes (Strickland, 1977).

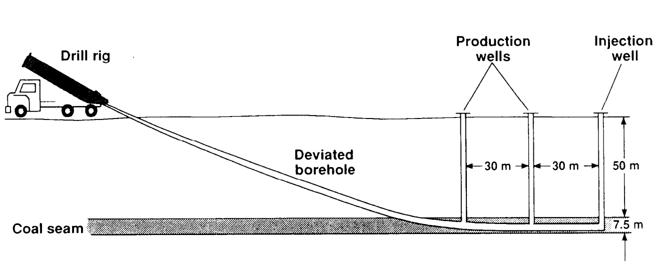

Fig. 22.6.11. Elevation of directional hole at Hoe Creek (Hill, Aiman, and Ganow, 1979). Conversion factor: 1 ft = 0.3048 m.

was used. The initial borehole angle of 30° to horizontal was deviated at a rate of 5°/100 ft (30 m) of travel. The total drilled distance was 705 ft (215 m) with the final horizontal 200 ft (61 m) in the coal about 10 ft (3 m) above the bottom of the seam. Deviated test holes into thinner coal seams have been drilled by experienced drillers; for example, up to 3000 ft (914 m) maintained in a 6-ft (1.8-m) coal seam at a 1000-ft (305-m) vertical depth (Siegel and Chambers, 1982).

REVERSE COMBUSTION. *Reverse combustion linking* (RCL) is a counter-current combustion process that is based on the simple fact that a propagating fire seeks oxygen. As depicted in Fig. 22.6.12, a fire started in the coal seam at the bottom of Well-1 will propagate towards Well-2, following the path of air flowing from Well-2 to Well-l. Unlike co-current burning where fire propagation and airflow are in the same direction, counter-current burning tends to follow a narrowly defined path of enhanced permeability within the coal seam rather than grow into a broad reaction front that expands outward to fill the entire seam (see Fig. 22.6.8). This difference between the two burning techniques is due in part to the direction of the hot gas flow. In co-current or forward burning, hot tarry gases are pushed into the coal ahead of the burn front where they can condense, causing a decrease in seam permeability. In counter-current or backward burning, the same gas products are swept back through the permeable channel of char behind the burn front, and away from

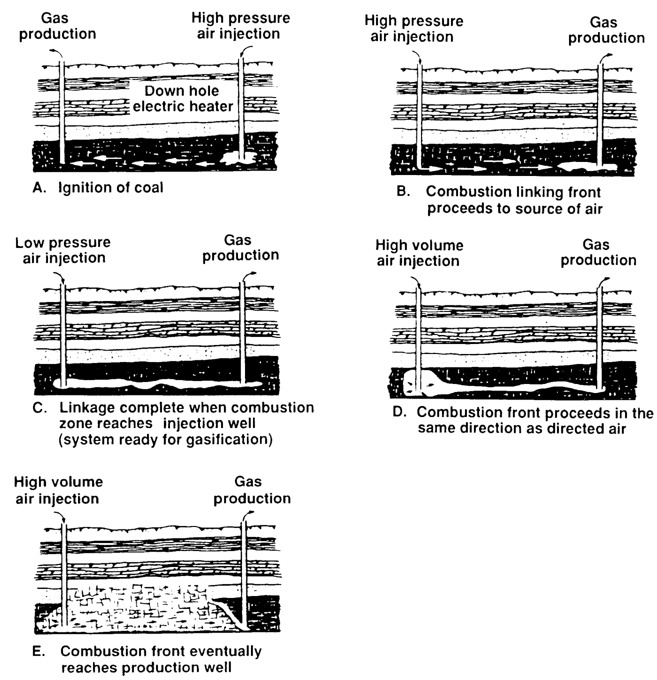

Fig. 22.6.12. Schematic representation of reverse combustion linking and UCG.

the unreacted seam. Thus the reaction front, propagating by thermal conduction from the char front into the seam, tends to grow unidirectionally toward the source of air.

In practice, air injection at high pressure is introduced into one hole until communication is achieved with the ignition hole. A fire is started in the ignition hole using an electrical heater or chemical igniter. Counter-current burning at the high injection pressure continues until linkage is achieved as signified by a

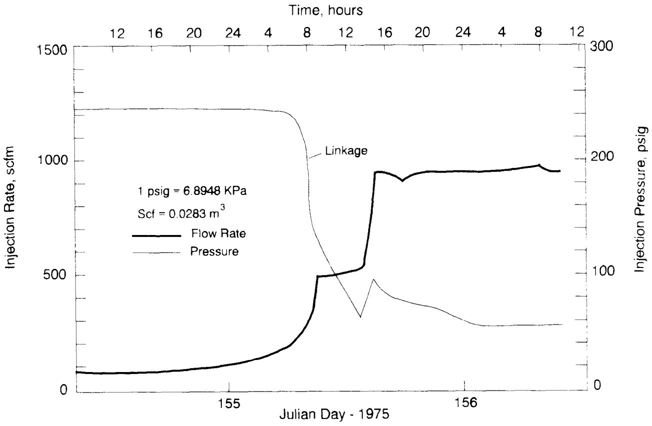

Fig. 22.6.13. Flow parameters as linkage was attained at the Hanna II field trial (Brandenburg et al., 1975).

sudden drop in line pressure (Fig. 22.6.13). In order to maintain the gasification channel on as straight a line as possible between the two boreholes, the holes are aligned with the maximum natural permeability of the seam.

An important use of RCL is in conjunction with directional drilling, namely, to link that part of the directional hole in the coal seam to vertical boreholes drilled from the surface. The vertical boreholes or extended linked wells (ELW) need only to intersect the seam near the horizontal hole, the final connection being made through RCL. The extended linked well would normally serve as the production well for UCG.

22.6.2.2 Resources and Utilization of UCG

COAL RESOURCES IN THE UNITED STATES. The available coal resources for UCG in the United States are tremendous, estimated to be almost 1.8 trillion tons (1.6 trillion t). Fig. 22.6.14 depicts the location of the coal fields on a map of the United States and the potential increase in coal resources through UCG over conventional mining. All regions of the country could benefit. The eastern and midwestern regions, with their large bituminous deposits, represent high concentrations of people and markets for energy, but also present more difficult technical challenges to UCG. The plastic and swelling characteristics of bituminous coal tend to lead to sealing of the gasification channels, and the thin seams of the eastern coal, many of them less than 6 ft (1.8 m), lead to higher heat loss from the seam and more difficult control of the UCG reaction zone.

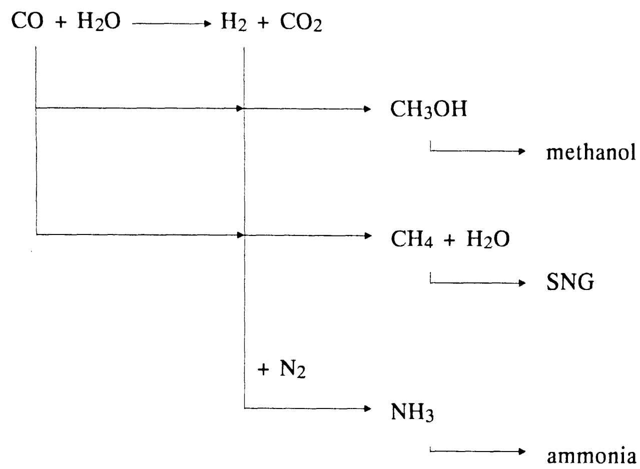
The Rocky Mountain region of the United States with its thick subbituminous seams, both horizontal and steeply dipping, has been the prime focus for UCG development by the US Department of Energy (DOE) and several private companies (e.g., ARCO, Texas Utility, Gulf R&D, Energy International, Gas Research Institute), despite the lower population density and lower market potential of this region. The resource more closely resembles those that the Soviets have exploited most successfully for UCG. Also, many of the thick, deep subbituminous deposits cannot be mined by conventional methods, and the possibility of utilizing this huge unminable resource with low water requirements and less surface disruption is very attractive.

Many of the coal reserves in the western regions of the United States (including Alaska and its 1.8 trillion tons or 1.6 trillion t) are not readily amenable to conventional mining, but a sizable amount may be suitable for recovery by UCG.

UTILIZATION OF UCG. The primary product of UCG with air as the oxidant is low-Btu gas (80 to 150 Btu/scf, or 3000 to 5600 kJ/std m^3), which is best suited for onsite or near-site use as a fuel for boilers, heaters, power generators, and kilns. As a low-heating-value fuel, it contains a sizable quantity of inert nitrogen, and hence is not cost effective for pipe transportation for any distance beyond about 1 mile (1.6 km). However, for onsite use, it is a good source of heat. While UCG fuel gas might have a heating value only 9% that of methane (the major constituent of natural gas), it will, when burned with air, lead to product gases (i.e., the high-temperature working fluid) whose heat content is a respectable 60% of the working fluid obtained when methane is burned with air (Chaiken, 1974).

UCG with oxygen/steam injection leads to a medium-heating-value gas (200 to 300 Btu/scf, or 7400 to 11,200 kJ/std m^3) that contains little N_2. It can be used in the same way as low-Btu gas, basically still onsite, except that the absence of N_2 makes the gas suitable for upgrade through chemical processing to a substitute natural gas (about 900 Btu/scf, or 33,500 kJ/std m^3) and/or to several synthesis gas compositions (see Table 22.6.2).

The synthesis gas would serve as chemical feedstock for making methanol or ammonia, that is,



(22.6.4)

The economics of processing UCG gas onsite in surface facilities appears promising, as shown in Table 22.6.3. However, chemical synthesis plants operated as part of the UCG surface facilities could add considerably to the water requirements at the site, and transportation costs to offsite chemical plants could alter the economics significantly (see Table 22.6.3).

22.6.2.3 Methods for UCG

GENERAL COMMENTS. The recent two decades of research and development in UCG by the US Department of Energy were directed to building a technology base from which one could adapt findings and developments to the development of a commercial UCG facility at any suitable site rather than to build and operate a pilot plant at one given site. A listing of all the appropriate UCG field tests in the Unites States has been compiled by the DOE (Anon., 1986). The recently concluded Rocky Mountain I test represents the latest (1986–1989) and largest of the field trials, and also the one most oriented to commercial interests. The available database on all these tests is well documented by the DOE, with a computerized bibliography stored in the CATAPULT Information DataBase at the Morgantown Energy Technology Center, Morgantown, WV. The UCG methods to be reviewed briefly in this section are described in detail in the documents available from the this center or from the US National Technical Information Center, Springfield, VA.

The extensive Soviet experience has involved numerous field trials, some of which have evolved into small commercial type UCG plants whose fuel gas output is used by onsite power plants (Olness and Gregg, 1977). These UCG (Podzemgaz) facilities include those sited in the flat beds of lignite near Moscow (Shatskaya) and near Tashkent (Angenskaya), and in the steeply dipping bituminous seams of the Donets basin (Lisichankaya) and Siberia (Yuzhno-Abinskaya). At their peak (in 1966), these plants had an annual production of 70 billion scf (2 G std m^3) of low heating value gas (80 to 100 Btu/scf, or 3000 to 3700 kJ/std m^3), equivalent to 860,000 tons (780,000 t) of coal consumed. This might be compared with the total of 34,000 tons (31,000 t) consumed in all the DOE field trials. UCG production in the Soviet Union has since declined (24 billion scf, or 0.68 G std m^3 in 1977), presumably due to the availability of other plentiful sources of fuel gas. Details on the Soviet experience can be found in the many reports translated into English which are included in the DOE database.

Additional trials, which have been carried out in most coal producing countries, have added to the available UCG database, including the Newman-Spinney P-5 trial in Great Britain where 900 tons (800 t) of a 2.5-ft (0.8-m) thick flat bituminous seam was gasified (Gibb, 1964). The resulting gas (average of 57 Btu/scf, or 2,100 kJ/std m^3) was of poor quality, but the efficiency of coal consumption, as determined by post-burn excavation, was high indicating that gasification and/or combustion reaction zones can be propagated through thin bituminous seams.

What can be assessed from these experiences is an organized way of approaching the development of a UCG facility at a specific coal site, which is the thrust of this segment.

SITE SUITABILITY. The importance of site selection and the subsequent characterization of the site cannot be over emphasized. Since the UCG reactor is bounded only by the surrounding coal and adjacent strata, the results of a UCG operation are subject, to a large degree, to the nature of the environment. For example, tests conducted in the United States have demonstrated that water-bearing strata immediately overlying the coal seam can collapse into the reaction zone, causing degradation of the product gas and even the extinguishment of the gasification front. Faulting in the coal seam and adjacent strata can also result in multiple flow paths, low product gas quality, and excessive gas losses. Even in the absence of faulting, weak and permeable strata above the coal seam have permitted significant gas losses with attendant groundwater environmental problems.

The US Department of Energy has completed an assessment of site selection and characterization needs. The basic requirements and procedures to determine site suitability are soon to appear in a handbook (Oliver and Covell, 1990). In general, cores are extracted and analyzed, well logging and other geophysical and geochemical measurements are performed, and geohydrology tests are conducted.

Geophysical data include seam thickness, seam dip, seam permeability, partings, faulting, depth, seam roof, water-bearing formations, rock strengths, aquifers, and topography.

Geochemical data include chemical composition, heating value, volatiles, ash and water content, shrinking or swelling tendency, agglomeration, sulfur content, and reactivity.

The data are then analyzed and interpreted with respect to the federal, state, and local permitting and environmental requirements/restrictions, and with respect to the planned gasification operations. The results are then used in the design of the plant, and to ensure that the operations are conducted in a manner consistent with the environmental and other permits required for plant construction, gasification, and shutdown of the UCG reactors.

PROCESS WELL LINKAGE. Tests conducted in the United States have established that the gasification reaction front does not progress below the elevation of the linkage path between process wells, and coal lying below the link is not recovered (Oliver, 1987). It is necessary to position the link as close as possible to the bottom of the coal seam to enhance the probability of attaining the highest resource recovery efficiency possible.

Reverse Combustion Linking—Initial experiments in the development of the technology successfully used reverse combustion linkage (RCL) to establish the required linkage paths over relatively short distances (60 ft or 18 m). Subsequent tests, however, met with a variety of problems including (1) loss of control due to faulting, (2) linking established at the coal seam/overburden interface because of the high pressures involved, and (3) plugging of the link due to swelling of the coal and condensation of high boiling point tars.

In the thick subbituminous seams of Wyoming, successful reverse combustion linkages have been achieved at up to 60-ft (18-m) separation between boreholes. The Soviets have reported reverse combustion linkages of up to 100 ft (30 m). However, the average linkage distance at the UCG station at Angren (USSR) was only 57 ft or 17 m (averaged over a total linkage distance of 53,000 ft or 16 km). Typical high-pressure air during linkage was 380 psi (2540 kPa), leading to a channel formation rate of about 2.5 ft/day (0.8 m/day). High-pressure air utilization was about 73,000 ft^3/ft (6800 m^3/m) of channel linked (Stephens, Hill, and Borg, 1984).

The cost of reverse combustion linking is very site selective but can run more than $200/ft ($650/m) of horizontal length in the seam, which is about half the cost of directional drilling (Stephens, 1979). However, the linkage could be seriously impaired by the geologic and chemical factors mentioned above.

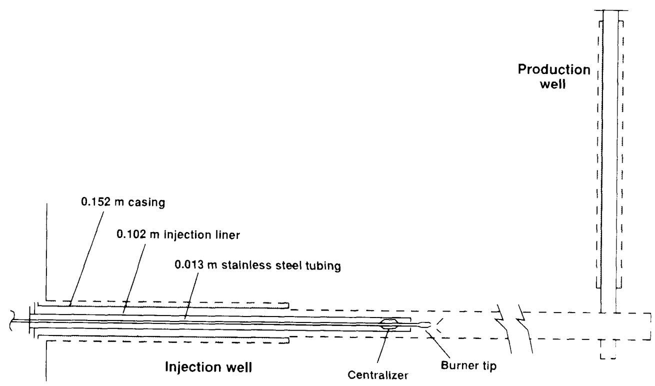

Fig. 22.6.15. Silane/propane igniter installation (Thompson and Skinner, 1982). Conversion factor: 1 ft = 0.3048 m.

Directional Drilling—Directional drilling, which was first advocated by the Soviets for a proposed UCG plant at Kohlmogorsk in the Soviet Union, offered the potential to alleviate the problems that had been experienced with RCL, and to provide a controlled, positive link between the process wells. Two tests, the first at the Hoe Creek site near Gillette, WY (Hill et. al., 1980), and the second at the TONO site near Centralia, WA (Martin and Davis, 1985), demonstrated that wells started at an angle at the surface could be deviated in a controlled manner to place the link parallel to, and at the bottom of the target coal seam. The gasification phase of the tests was subsequently completed with little or no problems related to the linkage path. Also, a directional well drilled earlier near Pricetown, WV, demonstrated that a well could be started at near vertical at the surface, turned nearly 90° over a depth of 900 ft (280 m), and be maintained in a flat-lying, 6-ft (2-m) thick coal seam for a distance of about 500 ft (150 m) (Martin and Liberatore, 1980).

Current directional drilling techniques should enable the proper emplacement of the intial UCG channel in almost any type coal seam. However, the cost of such drilling runs high (about $500/ft of horizontal seam, or $1640/m), and may inhibit its use depending on the specific resource being considered.

PROCESS CONTROL. It has been demonstrated repeatedly in over 21 tests conducted by both the government and industry in the United States that coal seam ignition and the shutdown of the UCG gasification reactor(s), with subsequent cooling of the coal seam to ambient temperatures, can be accomplished reliably. The proper selection of the site so that the reaction zone is below the water table ensures that the exothermic combustion reactions will terminate when oxidant injection is removed. The reducing gases produced from the devolatization of the coal inhibits the combustion process, and water will influx from the surrounding groundwater system to cool the reaction cavity.

Ignition—Reliable coal seam ignition was a problem until researchers advocated the use of a pyrophoric material in the gaseous phase, and devised the silane-methane igniter system (see Fig. 22.6.15). In this system, a small-diameter tube with a burner nozzle on the end is inserted into a larger-diameter tube in which there is flowing oxygen. An inert gas such as nitrogen is injected through the small-diameter tube to purge the line of oxygen. A slug of silane, a pyrophoric gas, is injected immediately behind the nitrogen, and a few seconds later, a combustible gas such as methane is injected. When the silane encounters oxygen, a flame is established which ignites the methane, forming

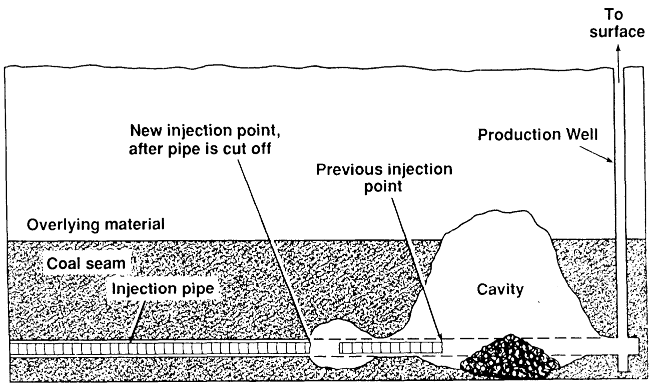

Fig. 22.6.16. Basic design of the controlled retracting injection point (CRIP) system (Hill and Shannon, 1981).

a high-temperature torch. Coal seam ignition has been accomplished in every case that this igniter system has been used.

Gasification—During the gasification phase of the operation, process control can be exercised by varying the gas flow rates and pressures, and by varying the composition of the injected oxidant, such as the steam to oxygen ratio. Test results have demonstrated repeatedly that gas quality degrades as the reactor matures (see Fig. 22.6.5). This has been attributed to the decline of turbulent flow as the reactor becomes larger in volume and to the decline in the cavity temperature when wet, inert overburden material collapses into the cavity.

Controlled Retracting Injection Paint—The controlled retracting injection point (CRIP) technique was conceived and advanced by researchers (Hill and Shannon, 1981) in an attempt to provide a more constant and desirable gas quality from the UCG process. In this technique, the silane-methane igniter is positioned at the point where the coal is to be first ignited (Fig. 22.6.16). The ignition sequence is performed, and when coal seam ignition is assured, the igniter is retracted and positioned within fresh coal at a point outside the predicted zone of influence of the developing gasification cavity. When the gasification reactor is mature and the gas quality declines to a predetermined value, the ignition sequence is repeated at the new igniter location, leading to a new UCG reaction zone (see Fig. 22.6.16). Application of this technique has been demonstrated to ensure the maintenance of the reaction zone at the bottom of the coal seam, and to enhance the production of a gas stream with an acceptable gas quality for the life of the module.

ENVIRONMENTAL RISKS. The environmental concerns associated with UCG processing are no worse than those associated with winning coal by underground or surface mining followed by gasification in a surface gasifier. In both cases, the winning of the coal from underground will result in some subsidence and its accompanying problems. Indeed, in situ processing of coal can be a significant improvement over some aspects of surface processing. For example, the steps usually followed for surface extraction and recovery include (1) mining of the coal, (2) cleaning the coal in a coal preparation plant, (3) transporting the coal to the point of use, (4) storing the coal, (5) preparing the coal for use, and finally, (6) cornbusting, gasifying, or liquefying the coal. Each of these steps produces a variety of solid, liquid, and/or gas residues that must be treated prior to disposal. In addition, a significant amount of potable water is consumed, and this water has to be treated before it can be returned to the environment. UCG, on the other hand, offers the potential to combine several steps such as mining, cleaning, preparation, and pro-

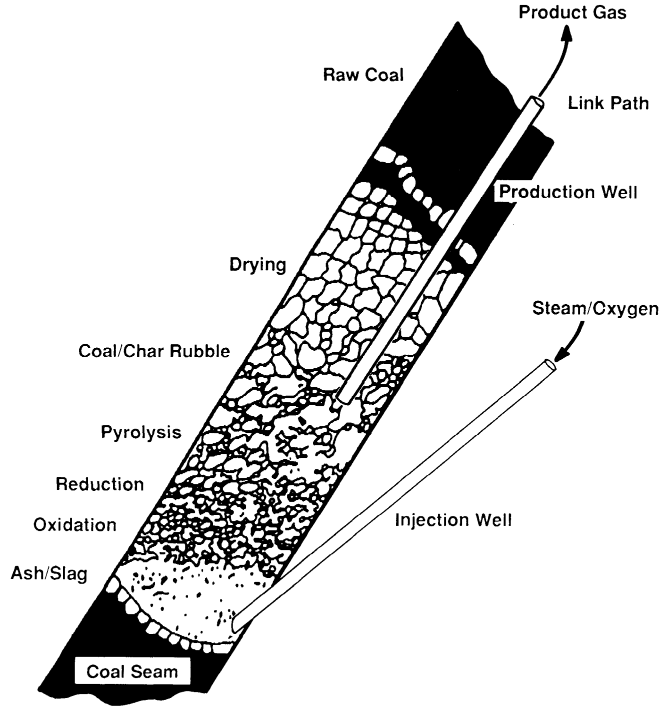

Fig. 22.6.17. Schematic representation of the steeply dipping bed gasification process.

cessing into a single operation—which may well be more acceptable environmentally—and in addition, offers the potential of reduced costs relative to the total costs associated with surface processing.

A possible additional environmental problem associated with UCG is the risk of contaminating the groundwater system. Early UCG tests, which resulted in contaminated groundwater in the unreacted coal as well as in adjacent water-bearing zones, were performed with high cavity pressures to inhibit excessive water influx into the gasification reactor. Subsequent laboratory tests led to the conclusion that high cavity pressures have little effect on the quantity of water that influxes into the reactor during gasification operations (Boysen et al. 1987). As a result of the laboratory studies and modeling of the generation and transport of ground water contaminants, a procedure was formulated (i.e., the "clean cavern concept") to minimize groundwater contamination during and immediately following UCG operations. In this concept, the subsurface reactor pressure is maintained below hydrostatic to minimize the loss of organic laden gases and to ensure a small but continuous influx of groundwater into the gasification cavity. When the gasification operations are complete, steam is then injected into the cavity to promote rapid cooling of the cavity walls and residues, and to "strip" the soluble and volatile organics from the cavity. The steam and contaminating gases are routed through an incinerator before being exhausted to the atmosphere. Operating in this fashion has confined the contaminants from UCG to the gasification cavity, and the contaminated cavity water can then be pumped to the surface for treatment before it spreads to the surrounding groundwater system.

22.6.2.4 Rawlins Steeply Dipping Bed Project

The application of UCG in a steeply dipping (> 45°) coal seam is depicted in Fig. 22.6.17. The oxidant injection well is drilled below the seam and out of the zone where any roof caving or subsidence may occur. The product gas well is drilled through the seam itself, near and parallel to the bottom wall. The oxidant injection well is slant drilled to intersect the coal seam at the prescribed depth. The coal is ignited, and a fire pit is developed at the level where the injection well enters the coal seam. Hot product gas flows upward to and through the unlined product gas well, causing the adjacent coal to dry and undergo devolitization. This process weakens the coal structure resulting in the collapse of a portion of the roof into the fire pit below. The fresh coal is then gasified, continuing the process that in effect becomes self-feeding.

UCG trials were successfully conducted with this configuration near Rawlins, WY, from 1979 to 1981 to demonstrate the viability of the steeply dipping bed technology. The second of two tests conducted at the site was performed about 600 ft (180 m) below the surface in a 23-ft (6.9-m) thick seam of subbituminous coal (Ahner, Bencini, and Bloomstran, 1982). Peak injection pressures in the 63° dipping seam were nearly 160 psi gage (1100 kPa) with oxygen and steam as the injection fluids. During one period of the operation, an average product gas heating value of 356 Btu/scf (13,300 kJ/std m^3) was achieved and maintained for nearly 20 days. Methane concentrations, which were attributed to the high in-seam pressures, of up to 24% were recorded which significantly enhanced the heating value of the gas.[5]

22.6.2.4 Rocky Mountain 1 (RM1) Test Results Summary

The results of the DOE's UCG program investigations were utilized by an industrial consortium (with government support) during the period 1986 to 1988 to design, construct, and operate the RM1 UCG test at a location near Hanna, WY.[6] The borehole linking experiences derived from the UCG program and other technology areas prompted a decision to use directional drilling for process well linking during the RM1 test. The technique known as medium-radius drilling was selected.[7] In this method, the process well was started in a vertical attitude at the surface, drilled to the "kickoff" point, and then turned at a rate of about 21°/100 ft (30 m) of hole drilled to achieve an approximate 300-ft (90-m) radius of curvature. This medium-radius hole was more expensive than a short-radius borehole; however, the short-radius hole would not have accommodated the installation of a casing that is required to isolate the product gas from any subsurface aquifers. Three such wells were successfully placed for the test (Fig. 22.6.18).

The placement of the horizontal and vertical boreholes did not make for physical intersection underground, but they were sufficiently close to enable the final necessary linkages to be accomplished with about four days of reverse combustion. No problems related to the linkages were encountered during the gasification phase of the test. A more complete description of the medium-radius wells completed for the RM1 test can be found elsewhere (Logan, 1987).

As shown in Fig. 22.6.18, two types of UCG modules were evaluated. The ELW module consisted of three process wells: two vertical injection wells (VIW-1 and VIW-2) and a horizontal production well (PW-1). In this module the operation was to inject oxidant initially via VIW-1. When needed, the UCG reaction zone would be extended to new coal by transferring the injection from VIW-1 to VIW-2 (100 ft or 30 m away).

The CRIP module also consisted of three wells: (1) a vertical startup well (CPW-2), (2) a horizontal injection well (CIW-l), and (3) an horizontal production well (CPW-1). CPW-1 was 5 ft (1.5 m) higher in the seam than CIW-1 to allow upward gasification to take place between the points of injection and production. When needed, a new reaction zone would be obtained by withdrawing the CRIP igniter about 100 ft (30 m) and burning off the stainless steel liner.

UCG operations were conducted for a period of 102 days, from Nov. 17, 1987, when the ELW module was ignited using the silane/methane igniter system, through Feb. 26, 1988, when the CRIP module was shut down. Both modules utilized steam-oxygen injection during the gasification phase of the test. A summary of the performance of each module during the gasification phase of the test is given in Table 22.6.4. The complete detailed description of the test can be found in the RM1 Final Operations Phase Report (Anon., 1989).

During the test, the clean cavern concept was followed closely considering the conditions encountered. Operating pressure during most of the gasification phase of the test was maintained between 65 and 90 psi (440 to 610 kPa), which was significantly below the hydrostatic pressure of 120 psi (820 kPa). When each module was ready to be shut down, steam injection was continued for about 10 days after oxygen injection was terminated. The product gas stream was incinerated during this period.

Samples of the cavity water collected after the cavities had refilled exhibited elevated levels of phenols and boron. All other aspects of the water were within the baseline values determined prior to ignition of the coal seam. In addition, three of the twelve groundwater monitoring wells surrounding the cavities showed elevated contaminant concentrations similar to those in the cavity water. These wells were located up dip, and the contaminants were the result of a gas bubble which formed in that area during the test.

Since the shutdown of the gasification phase of the test, cleanup of the cavity water has been completed. The treatment consisted of pumping the water from the cavities to the surface, treating the water in activated carbon adsorption units, and spray evaporating the water through atomizing nozzles. Water from the surrounding groundwater system was allowed to influx into the cavities to "wash" and confine any additional contaminants in the vicinity of the cavities. Water samples extracted from the refilled cavities indicated that the phenols were reduced to baseline levels, but the boron concentrations, although reduced, remained elevated. A second cavity water treatment was performed to insure that the groundwater at the site was returned to levels acceptable by state agencies.

The RM1 UCG test was designed to incorporate the advances developed under the DOE/UCG program, and to serve as the culmination of the technology developed for subbituminous coal seams. The test was conducted at a size scale, and for a time period appropriate for evaluation of the potential for commercializing underground coal gasification of this type of coal resource. At this point, it is believed that industry must decide whether UCG is a viable alternative energy option.

---

[5] As a result of the Rawlins test, a Department of Energy contract was awarded (1987) under the "Clean Coal" program to produce synthesis gas by UCG, and to use this gas onsite in the manufacture of anhydrous ammonia on a commercial scale (Davis, Singleton, and Penland, 1988).

[6] The industrial consortium was headed by Gas Research Institute and included Amoco Production Co., Electric Power Research Institute, and Union Pacific Resources Co.

[7] For convenience, directional drillholes can be categorized in terms of three ranges of deviation or curvature: short-radius [1.5 to 3.0°/ft (0.3 m), or 40 to 20 ft (12 to 6 m) radii]; medium-radius [8 to 50°/ 100 ft (30 m) or 700 to 125 ft (210 to 38 m) radii]; and long-radius [2 to 6°/100 ft (30 m) or 3000 to 1000 ft (900 to 300 m) radii].

22.6.3 IN SITU COMBUSTION OF COAL

22.6.3.1 Introductory Comments

In situ combustion of coal converts the spatially and thermally distributed reaction zone of Fig. 22.6.1 to complete oxidation, thus converting the underground coal seam cavity into a high-temperature (> 1000°C or 1800°F) furnace. The thermal energy release in the cavity furnace is recovered by bringing hot flue gases (mainly N_2, CO_2, and H_2O) to the surface for onsite conversion to steam, electricity, or simply process heat. The advantage of this approach over UCG is the ease of maintaining complete combustion (i.e., chemical equilibrium) as opposed to incomplete combustion (i.e., shifting equilibrium). This was exemplified in the UCG field trial at Gorgas, AL, where gasification was attempted in a double-entry channel, 600 ft (180 m) long, in an 8-ft (2.4-m) thick bituminous seam. Although this 900-hr test was for the purpose of producing combustible gas, it is evident (Fig. 22.6.19) that after 300 hr, the underground combustion reaction went to completion (probably due to "break through" of oxygen) and remained that way. It is also evident that steady burning was achieved where about 90% of the heating value of the coal appeared in the high temperature exhaust gas, at a thermal power level estimated to be 1.5 MW.

The ramification of the Gorgas UCG data in terms of a complete in situ combustion process was reported in a USBM Technical Report (Chaiken, 1974) and was pursued experimentally over the next decade primarily in connection with controlling and making use of the heat from abandoned coal mine fires. There are currently some 64 abandoned coal mine fires in the eastern coal producing states, representing a severe hazard to the environment as well as endangering some 116 million tons (105 Mt) of coal. It has also been estimated that some 500 million tons (450 Mt) of coal are contained in abandoned hilltop seams, mostly in the eastern US, many of which would be amenable to in situ combustion by the Bureau of Mines' burnout control process.

22.6.3.2 Burnout Control

General Description. *Burnout control* is a process that uses exhaust ventilation conditions to promote the complete burning of an underground mine fire while allowing total management of the hot gases produced (Chaiken, 1980). An artist's rendition of a burnout control system is shown in Fig. 22.6.20. An exhaust fan, connected to a ductwork system that leads to the underground mine, pulls a vacuum on the mine containing a

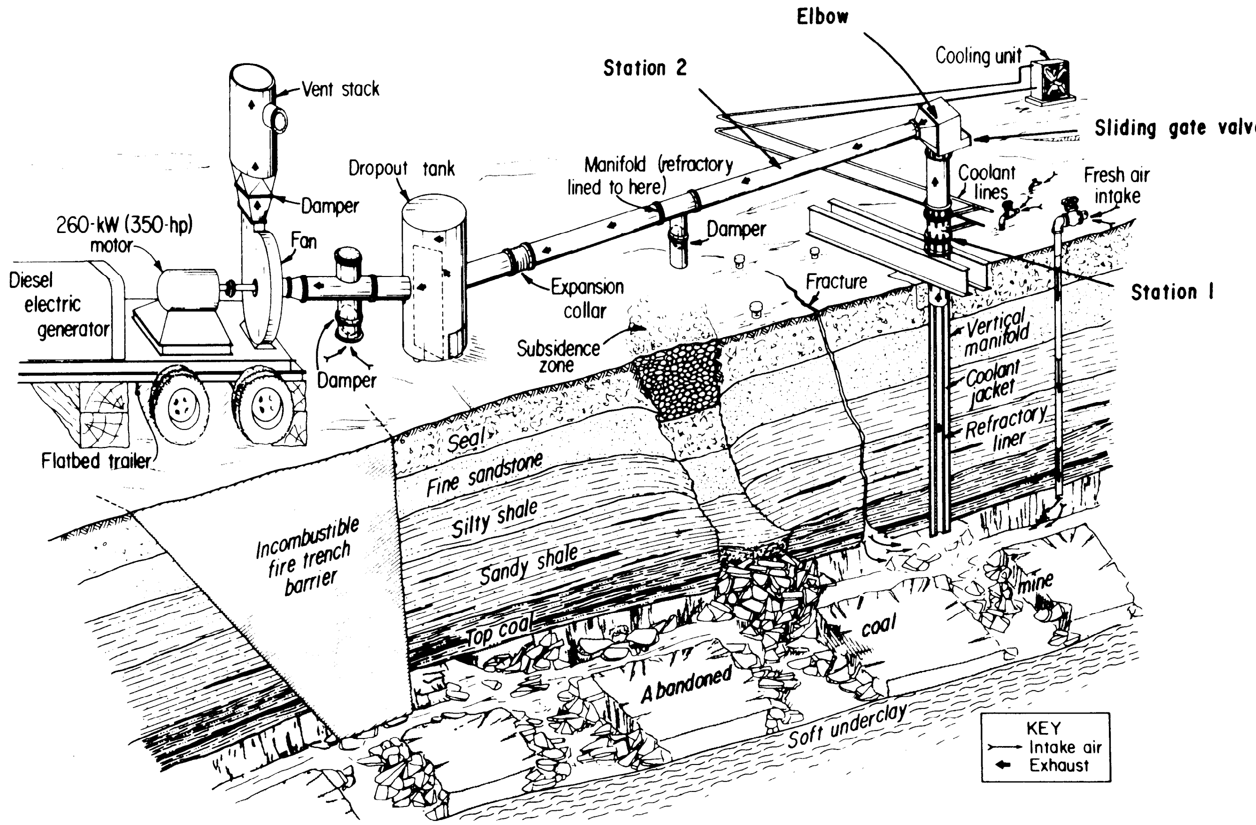

Fig. 22.6.20. Artist rendition of burnout control at Calamity Hollow (Irani et al., 1983).

smoldering fire. This results in air flowing into the mine through natural cracks and fissures and/or from air inlet boreholes set from the surface. The increased airflow intensifies the fire, and all heat and fumes (flue gas) are drawn to the single-fan exhaust point. Fig. 22.6.20 shows the flue gas being cooled by air dilution (via the damper at the end of the refractory lined portion of the manifold) and then simply exhausted to the air. However, instead of cooling by air dilution, the hot flue gas could pass through a waste-heat boiler to recover the sensible heat of the hot combustion products. If necessary, combustion of the hot flue gas can be completed with an afterburner, and air pollutants can be removed with conventional surface scrubbers.

There are several distinct advantages to utilizing the burnout control process for in situ combustion:

1. The affected coal channels are at negative pressure relative to ambient, and therefore all fumes produced will be drawn from underground at a single exhaust point. There will be no loss of gas to the surrounding strata, and conductive heat loss will be relatively small (less than 10%) (Chaiken, 1977).

2. Accumulation of heat and fumes at a single exhaust point enables (a) afterburning to insure complete combustion, (b) on-site utilization of the heat, and (c) the use of conventional or other air pollution scrubbers (mostly for SO_2).

3. The solid residues from high-temperature combustion are relatively inert ash and fused klinkers.

What may or may not be an advantage with burnout control is that the process is more amenable to dry seams with relatively open channels that contain coal rubble. In that sense, burnout control may not be suitable for the type of coal seam favored for UCG (i.e., thick and moist). On the other hand, as the UCG field trials at Gorgas and Newman-Spinney have indicated, burnout control should be applicable to the shallow, thin bituminous seams that are so prevalent in the high-energy demand areas of the eastern United States.

BASIC PROCESSES. The basic chemical process in in situ combustion is complete burning or oxidation of the coal. For stoichiometric burning of moisture free coal, the reaction (with ash taken as SiO_2) might be represented as

$$\underbrace{CH_{0.0856}O_{0.079}N_{0.018}S_{0.01}(Ash)_{0.053}}_{\text{1 mole coal (wt = 14.03 g)}} + \underbrace{1.219O_2 + 4.547N_2}_{\text{5.766 moles air}} \rightarrow$$

$$\underbrace{CO_2 + 0.428\,H_2O + 4.566\,N_2 + 0.005\,SO_2 + 0.053\,Ash}_{\text{5.989 mole gaseous products}} + \underbrace{97.34\text{ kcal}}_{\text{12,500 Btu/lb}} \qquad (22.6.5)$$

Ideally, 4.6 scf (0.13 std m^3) of air will combust 0.031 lb (0.014 kg) of coal to produce 4.79 scf (0.14 std m^3) of flue gas having a sensible heat content of 82.6 Btu/scf. In principle, a 1-MW thermal output can be obtained with a flue gas exhaust flow rate of 690 scfm (19.5 std m^3/min), representing the complete burning of 4.5 lb/min (2 kg/min) of coal.

The minimum fan air horsepower (ahp) to drive the exhaust flow is

$$\text{ahp} = (P)(Q)/6348 = 0.11\,P \text{ for 1-MW exhaust} \qquad (22.6.6)$$

where P is pressure drop across the fan in in. water, and Q is the exhaust gas flow rate evaluated at standard conditions in scfm.

The pressure drop requirements for the fan are site selective depending on the effective permeability of the underground burn zone to gas flow and the resistance of the duct system leading to the fan. The pressure drop due to the duct system alone can be readily estimated from pipe flow formulas; the effective permeability of the burn zone will require direct measurement of induced underground gas flows. However, it is readily seen that even with a fairly high vacuum of 100 in. water (25 kPa), and a fan/motor efficiency of 50% (both achievable with large conventional induction fans), it would require only 16.5 kW of electrical energy to produce 1000 kW of thermal energy. The effective electrical energy gain for operating a small electrical generation plant would then be a factor of 10 to 15, depending on the actual conversion efficiency of the plant. Large coal-burning utilities generally have an electrical energy gain of about 20.

When the underground flow follows Darcy's law, it is possible to develop size requirements for the fan in terms of the underground burning area and the thermal output. For steady radial Darcy flow toward the suction borehole, the exhaust flow rate is described by (Chaiken, 1989) as

$$Q(X) = [2(\pi)(k)(L)(X/\mu)]\ (dP/dX) \qquad (22.6.7)$$

where Q(X) is volumetric flow rate across a cylindrical surface of height L at radial distance X along the flow direction to the suction borehole; k is effective permeability of the mine strata; μ is viscosity of the flowing gas; and dP/dX is pressure gradient along the flow direction.

Integrating this expression with constant Q(X) between appropriate limits yields

$$DP = [(\mu)/2(\pi)(k)(L)]\ \ln(X_o/r)\ Q_{ex} \qquad (22.6.8)$$

where DP is vacuum level in the mine at the suction borehole; X_o is maximum radial distance from the borehole that is affected by the suction; r is inside radius of the suction borehole; and Q_{ex} = Q(X), the exhaust flow rate into the borehole.

Considering only the pressure drop through the underground burn zone, the fan power requirement is obtained by setting P = DP, or

$$ahp = (R)(Q_{ex})^2/6348 \qquad (22.6.9)$$

where $R = [(\mu)/2(\pi)(k)(L)]\ \ln(X_o/r)$ in in. water)/scfm.

The thermal output of the exhaust TP is given by

$$(TP) = (Q_{ex})(C_p)(\rho)(T_{ex} - T_o), \qquad (22.6.10)$$

where T_{ex} is temperature of the exhaust, T_o is reference air temperature (ambient), C_P is heat capacity of the exhaust gas at temperature T_{ex}, and ρ is density of the exhaust gas at the same temperature and pressure conditions as for Q_{ex} (as used here, Q_{ex} is in units of scfm). It is readily seen that the fan power requirement will increase as the square of the thermal output from the mine. Also, through the effective underground flow resistance R, the fan power requirement will increase as the logarithm of the underground area effectively being evacuated.

Some typical values for the parameters involved in the above relationships as determined during the USBM's Calamity Hollow Mine Fire Project (see next segment) are shown in Table 22.6.5. These parameters translate to a fan power requirement of 22 ahp (16.4 kW), which at a 50% motor/fan efficiency would result in an effective electrical gain of 20 to 30. However, this translation ignores the pressure drop requirements for the surface duct system, which were considerable for this particular field trial.

Table 22.6.5. Parameter Values Determined for Burnout Control at an Abandoned Mine Fire Site

Flow resistance, R	0.001 in. water/scfm (at DP = 4 to 16 in. water)
Suction Distance, X_o	160 ft (2 acre area)
Exhaust temperature, T_{ex}	600°C (average)
Exhaust gas flow rate, Q_{ex}	12,000 scfm (at DP = 16 in. water)
Exhaust thermal power, TP	5 MW (at DP = 16 in. water)

Source: Chaiken, 1989.
Conversion factors: 1 scfm = 0.0283 m^3/min, 1 in. water = 8.6 kPa, 1 ft = 0.3048 m, 1 acre = 4047 m^2.

22.6.3.3 Calamity Hollow Field Trial

The first field trial of burnout control was at the site of an abandoned shallow drift mine in the Pittsburgh seam whose outcrop had been stripped and then backfilled after a fire was discovered in the mine. A 1.8-acre (7300-m^2) isolated section of the mine adjacent to the covered outcrop continued to burn, smoldering under 35 ft (10 m) of cover (Fig. 22.6.21). Site evaluation included borehole corings to determine the stratigraphy and the residual coal values: 9000 tons (8000 t) of combustibles per acre with an average heating value of 12,000 Btu/lb (28,000 kJ/kg) (Irani et al., 1983).[8] Borehole temperatures were measured and air communication between boreholes verified utilizing a portable test suction fan (500 scfm capacity at 60 in. water, or 14 std m^3 at 15 kPa).

The burnout control ventilation control system was essentially that shown in Fig. 22.6.20. It was designed to withdraw 1800 °F (1000 °C) gases from the mine at thermal power levels up to 5 MW. At 5 MW output, it would take almost 3 years to completely burn out all the coal at the 1.8-acre (7300-m^2) site. No attempt was made to do this (the trial lasted four months), nor to utilize the thermal power generated. The gases were exhausted to the atmosphere through the fan after first being cooled with ambient air and water introduced directly into the duct system ahead of the drop-out tank (see Fig. 22.6.20).[9] This method of handling the hot exhaust required additional fan power beyond that needed to withdraw the hot gases from the mine, about 10 times the minimum value of 14 ahp estimated from Eq. 22.6.5 (assuming P = 25 in. water or 6.2 kPa). The burnout control suction fan (20,000 scfm capacity at 50 in. water, or 570 std m^3/min at 12.3 kPa) driven by a 350-hp (260-kW) electrical motor exceeded these requirements.

To channel the hot gases up from the mine, a water-jacketed, refractory lined pipe (26-in. or 660-mm ID) was suspended from the surface to the roof of the mine through a 4-ft (1.2-m) hole augered into the mine. This hole was sited at a position that did not reflect high underground temperatures, but was in good air communication with an underground region that did have elevated temperatures. The ground supports for all portions of the duct over the burn zone were floating in the sense that they rested on the ground with a wide footprint, and could be easily shored-up in the event of subsidence. The manifold was con-

[8] The main Pittsburgh seam at a nominal 6-ft (1.8-m) thickness would contain about 9000 tons (8000 t)/acre of minable coal. Conventional mining techniques would normally leave roof and floor coal, pillars, rider seams and carbonaceous shales, all of which would contribute to the total residual coal available through burnout control. Thus, with abandoned coal mines, as much coal (energywise) is left in place as has been mined.

[9] The thermal output of the exhaust could have been utilized if the section of the duct system where cooling air and water were introduced had been replaced with a waste heat boiler.

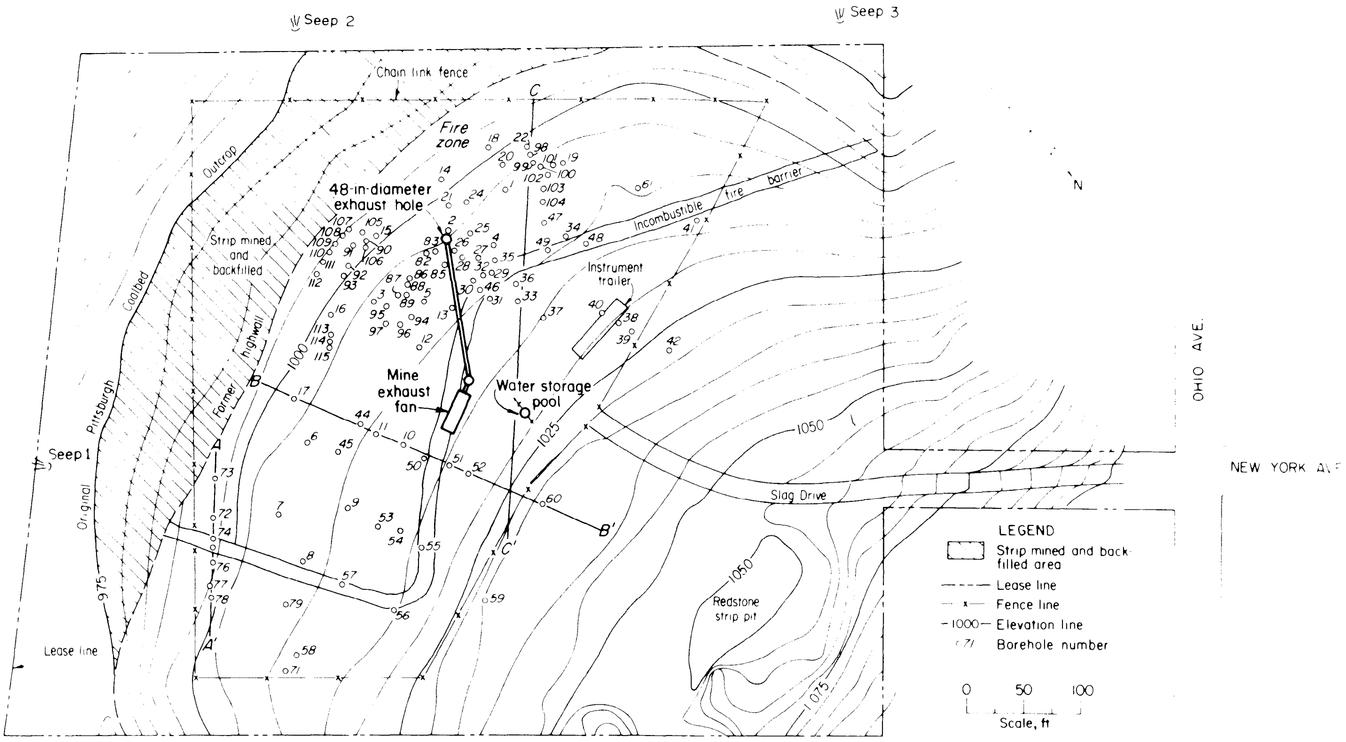

Fig. 22.6.21. Calamity Hollow site plan (Chaiken, Dalverny, and Kim, 1989). Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

nected to the fan through the steel duct system as depicted in Fig. 22.6.20. The refractory-lined portion of the duct system served as an afterburner where small amounts of ambient air could be introduced when necessary. A refractory gate valve (in the elbow section above the manifold) enabled the manifold to be sealed whenever the fan was shut down for any length of time.

Burnout control was carried out over a four-month time period in which the vacuum level in the mine was varied from 2 to 16 in. water (0.5 to 4.0 kPa). Both the gas flow (3000 to 12,000 scfm, or 85 to 340 std m^3/min) and thermal output (1 to 5 MW) from the mine correlated closely with the vacuum changes, while the exhaust temperatures changed only slowly with pressure, presumably due to the very large thermal inertia of the underground burn zone (Fig. 22.6.22).[10] This thermal inertia effect was beneficial for quickly resuming power output after fan shut-down, but made it difficult to alter the exhaust temperatures.

Gas analyses of the exhaust indicated a relatively oxygen-rich environment (13% excess O_2), with less than 0.1% fuel gas (i.e., unburnt CO and hydrocarbons) in the exhaust when its temperature exceeded 1100°F (600°C). When the exhaust temperature was less than 1100°F (600°C), the unburnt fuel content was about 1%. Fig. 22.6.23 depicts data accumulated on NO_X and SO_X produced during the latter part of the trial. The average *air-free* concentrations are 140 ppm for NO_X and 1660 ppm for SO_X. Comparing these observed values with the maximum possible concentration (i.e., 2600 ppm for NO_X and 1540 ppm for SO_X), calculated on the basis of the nitrogen and sulfur content in the residual coal it is seen that in situ coal combustion does bring out the SO_X from the coal, but produces far less NO_X than what might be expected. It can be anticipated that a commercial burnout control system would require air pollution controls for SO_X, but not for NO_X.

During the four-months' operational period of the field trial at Calamity Hollow, 1100 tons (1000 t) of residual coal were consumed to yield a flue gas with an average temperature of 1100°F (600°C) at an average thermal power level of 3.1 MW. A significant finding was that while subsidence occurred with numerous surface cracks and fissures appearing in the ground area above the burn zone, it was not sudden nor did it seriously effect the burnout control process—although it probably contributed to the excess oxygen observed in the exhaust.

22.6.3.4 Utilization of Burnout Control

The potential for burnout control is believed to be quite good, particularly for abandoned hilltop mine sites, which by their nature are isolated (or isolatable) from other coal seams and are not flooded. A number of current AML mine fires probably involve this type of site. In general, hilltop seams are dispersed and variable in size. In terms of utilizing burnout control, these factors call for the use of relatively small onsite power plants that can be relocated as required within a site or to different sites. Power plants up to 5 MW electrical could be mobile and should be suitable for firing by a single burnout control ventilation system.

Based on the Calamity Hollow findings, an abandoned mine in a 6-ft (1.8-m) seam of bituminous coal will contain about 4×10^{12} Btu/30-acre (4×10^{12} kJ/1.2×10^5-m^2) section of the mine, and a 30-acre (1.2×10-m^2) section of a mine could be placed under control from a single burnout control ventilation system. The system should be able to develop the necessary thermal power to operate a 5-MW electrical power plant for about seven years. Thus commercialization is envisioned as one

[10] The absence of data between days 11 to 29 in Fig. 22.6.22 is due to shut down of the fan to replace the diesel generator supplying electricity to operate the fan.

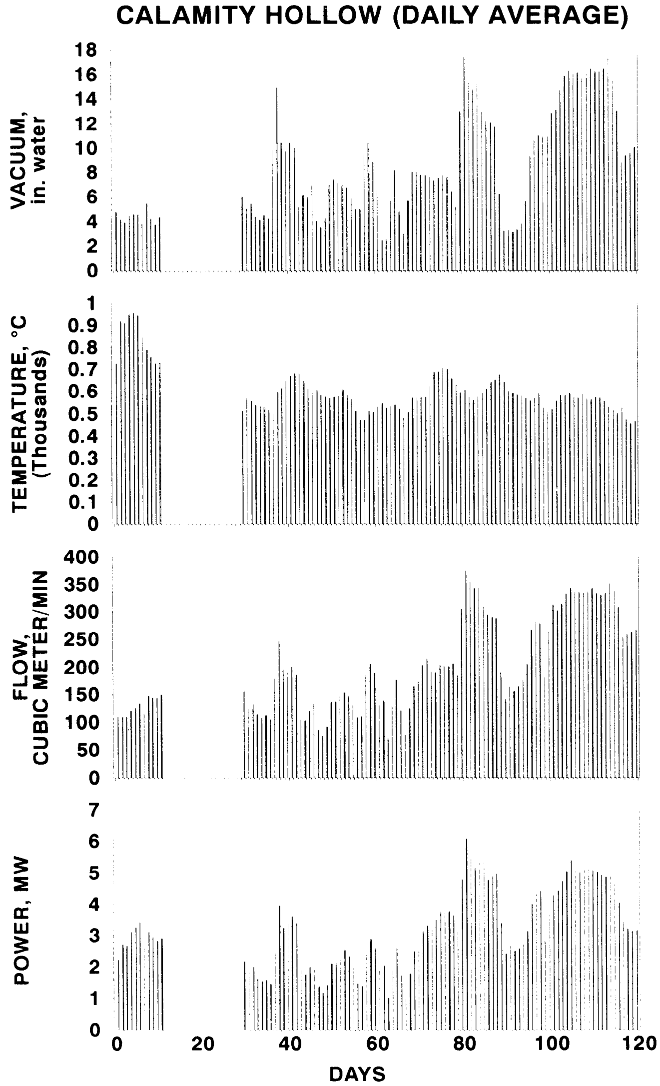

Fig. 22.6.22. Exhaust output, Calamity Hollow field trial (Chaiken, Dalverny, and Kim, 1989). Conversion factors: °F = 1.8°C + 32°, 1 cfm = 0.0283 m^3/min, 1 in. water = 0.249 kPa.

or more burnout control/power plant modules operating as a mobile surface facility, each connecting with the extensive electrical transmission network that covers the eastern United States. As each site or section is completely burned out, the module(s) is moved to a new location.

There are few detailed studies of the economics of burnout control as compared to other in situ combustion processes or even to UCG. However, it is significant that with in situ combustion, the underground burn zone takes the place of coal transportation and coal handling, air and fuel feed systems, fuel burners, and ash handling and cooling—processes which require 22 to 40% of the capital cost of the surface firing unit for a power plant (Maslan, 1980). Also the use of exhaust ventilation to supply air to the underground burning process vs. high-pressure injection (as with current UCG processes) leads to a low-energy expenditure to win the coal energy from the ground. The estimated energy gain from burnout control (10 to 15) at Calamity Hollow was comparable to that obtained with very large utility plants. Whether or not these aspects of a small mobile burnout

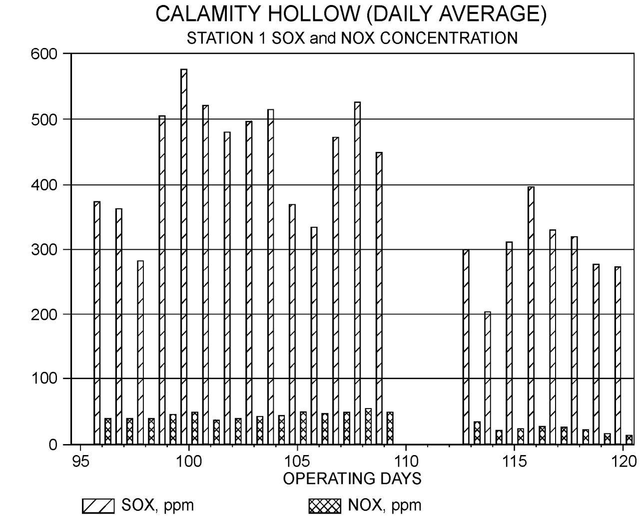

Fig. 22.6.23. Measured SO_X and NO_X in exhaust, Calamity Hollow field trial (Chaiken, Dalverny, and Kim, 1989).

control/power plant module would offset the economy of scale as represented by a 1000-MW (electrical) utility must await further trials of the small-scale in situ combustion process.

Chapter 22.7
UNDERGROUND RETORTING

THOMAS E. RICKETTS

22.7.1 INTRODUCTION

The oil crisis of the mid- 1970s provided a somber reminder of the dependence of the United States on foreign oil and thus was a very effective incentive for the nation to build a synthetic fuels industry. At the time, the federal government called the need for a synthetic fuels industry the “moral equivalent of war” and formed the Synthetic Fuels Corp., a quasi-government agency to administer a huge synthetic fuels program. A synthetic fuels program was proposed rather than expanding crude oil development since US crude oil reserves are very limited and represent only about 1% of the world’s known total reserves. However, overall US fossil fuel reserves including crude oil, coal, tar sands, and oil shale are a significant part of the world’s fossil fuel reserves and, in fact, at that time represented on the order of 40% of the world’s fossil fuel reserves. This was due largely to massive domestic coal reserves. But the United States also has immense oil shale resources that represent close to 75% of the world’s oil shale reserves; thus oil shale evolved as an important part of the proposed synfuels industry.

Both private industry and the government committed significant resources to the development of shale oil technology and to commercial feasibility and demonstration projects involving various shale oil processes. However, a dramatic drop in oil prices in the mid-1980s due to world overproduction of crude oil essentially ended any major government support for a synthetic fuels industry and resulted in the abolishment of the Synthetic Fuels Corp. This lack of government support along with private industry’s ensuing lack of commitment virtually eliminated all development work in oil shale as well as other synthetic fuel technologies. The major shale oil processes that emerged during this development period are briefly described here. Later segments present the state of the art of the most advanced underground retorting technology that existed at the end of the development period when most work was discontinued.

The two primary types of shale oil processes that evolved were the aboveground retorting process and the underground retorting process. The *aboveground retorting process* consists of a retorting module(s) located aboveground at a mine site. The shale fed to the retorts is mined underground using conventional mining methods. The mined shale has to be handled several times and crushed to a specific size distribution. Ultimately, after processing, the spent shale has to be handled and disposed of in an environmentally acceptable manner. The room and pillar mining method is typically used to produce the oil shale since it can be designed to provide high grade shale for retorting. Room and pillar mining thicknesses of 30 to 60 ft (9 to 18 m) nominally provide oil shale having a grade of about 30 to 40 gallons of shale oil/ton of shale (125 to 170 mL/kg). Other large-scale mining methods such as sublevel stoping can also be used, but are designed for thicker mining intervals and thus cannot provide high-grade shale. For example, 200- to 300-ft (60- to 90-m) thick intervals typically provide oil shale having a grade of about 15 to 20 gallons of shale oil/ton of shale (60 to 80 mL/kg).

The *underground retorting process* involves constructing a large-scale rubble bed underground, then isolating the bed from the mine workings, and finally processing the bed in place. For shallow deposits, the bed can be constructed and processed from the surface using drillholes with no mining required. Thick deep deposits, however, require mining to provide a void volume into which the surrounding shale can be blasted to produce a permeable rubble bed for processing. This latter process is called the *modified in situ* process. For this process, 20 to 30% of the shale within a retort volume is mined with the remaining shale subsequently blasted into this void volume. Typically, the void is in the form of several room and pillar openings 30 to 60 ft (9 to 18 m) high and distributed within the retort volume. Thus the mining is done using conventional room and pillar mining methods but the typical configurations do not provide the most efficient bulk-mining type operations. After blasting the rubble bed, the chamber is sealed off from the mine workings and the bed is processed in place.

The underground retorting process typically provides less yield than the aboveground retorting process, so the former was designed for thicker (on the order of several hundreds of feet, or about 100 m) leaner-grade shale deposits. These, in fact, represent most of the US shale oil reserves. The aboveground retorting process was envisioned for thinner (on the order of several tens of feet, or about 10 m) richer-grade shale operations to take advantage of the higher yield provided by this process. However, the high yields expected for the aboveground retorting process have not yet been demonstrated on a large scale in rich shale. Conversely, excellent yields relative to predicted values have been achieved for the modified in situ process in full-scale demonstrations in lean shale with low-void-fraction rubble beds (Stevens and Zahradnik, 1983). New modified in situ technology for constructing rubble beds has subsequently been developed that is expected to give even higher yields, with increases estimated at 30% or more (Ricketts, 1983; Bickel and Ricketts, 1986; Hommert and Bickel, 1987). A combination of aboveground and modified in situ retorting results in the best total oil recovery and thus resource utilization for a given site. For example, it has been estimated that nearly 5 billion barrels (795 GL) of shale oil can be recovered from a 5000-acre (20.2-Mm^2) government lease tract in Colorado (the C-b tract). This would utilize a combination of the aboveground retorting and modified in situ processes within the nominal 1500-ft (460-m) thick oil shale section that exists in this part of the Piceance Creek Basin.

Three main underground retorting processes have evolved during the synthetic fuels shale oil development program. All three processes were developed as proprietary processes, and thus full particulars are not available, although publications and patents provide some information. The first underground retorting process to be described involves shallow deposits on the order of 100 ft (30 m) deep. For this configuration, the rubble bed is prepared and processed using drillholes from the surface, with no underground mining required. The void into which the shale is blasted is created by initially blasting a wedge of shale upward. The surrounding shale is then blasted into the void that results from this vacated wedge. This process is considered to be more of a “true” in situ method rather than a “modified” in situ process (Tyner et al., 1982; Lekas, 1985). The process has been demonstrated using commercial-sized rubble beds.

The second underground retorting process to be described is for deep deposits and initially involves mining a void room at the bottom of the section to be processed and then blasting layers of oil shale down into the void. The drilling, explosives loading, blasting, haulage, and processing operations can be done from either a mining level within the mine for deep deposits or from the surface for shallow deposits. When necessary, rubble is drawn from the lower void room after a layer is blasted to make room for the blasting of successive layers until the final height of the rubble bed is achieved. This process involves continuous mining operations to construct the rubble bed and results in a high-void-fraction bed that involves a large amount of rock handling and removal. The bed is ultimately isolated from the mine workings and processed in place. This high-void-fraction modified in situ process has been demonstrated using intermediate-sized rubble beds (Anon., 1977; Berry et al., 1982).

The final underground retorting process to be described is for deep deposits and involves mining multiple-void levels within the section to be processed and then blasting the surrounding oil shale into the void levels in a single blasting round. The amount of void mined is designed to produce a low-void-fraction rubble bed to minimize the rock handling, removal, and continuous mining operations required to construct a single rubble bed. The bed is ultimately isolated from the mine workings and processed in place. This low-void-fraction, modified in situ process was developed by Occidental Oil Shale, Inc., a subsidiary of Occidental Petroleum Corp., and represents the most advanced large-scale underground retorting process to evolve during the synthetic fuels development program. It has been demonstrated numerous times using commercial-sized rubble beds (Ricketts, 1980, 1982) and has resulted in excellent oil yields compared to the maximum attainable predicted value. The large-scale rubblization technique for this process, which is the key to any modified in situ process, has been developed into a second-generation technology that has advanced far beyond typical blasting state-of-the-art technology. Consequently, this low-void, modified in situ technology will be the process described in detail in the remainder of this chapter.

It should be noted that this process represents an evolving, state-of-the-art development process and is not an ongoing, routine underground operation; thus there are no generic, handbook-type guidelines for engineers to use. Instead, this chapter presents the latest results of this state-of-the-art development program. This allows an engineer to start at the most advanced stage of this development program and either use the existing technology or know where to begin a new development program.

22.7.2 UNDERGROUND RETORTING DESIGN CONSIDERATIONS

The development of an improved underground retort design and a more advanced blasting technology that resulted from Occidental's modified in situ development program is presented first. These design concepts provide better economics due to less expensive mining and processing operations and higher processing yields than the concepts used in the final retorts constructed in Occidental's development program. The improved retort and blast designs are based on new technologies that have resulted from extensive underground testing and engineering analysis applied to these data. They have not been demonstrated full scale but are based on full-scale test data and have been demonstrated at quarter scale. As such, they represent the concepts that would have been demonstrated full scale if the development program had continued. Other technologies relating to seismic energy prediction and blast damage to underground workings have also been developed based on Occidental's development program, but these are not described here (Redpath and Ricketts, 1987; Ricketts, 1988). Modified in situ processing technology is then presented. This represents the retorting techniques that were used on the final two retorts, Retorts 7 and 8. These were constructed at Occidental's Logan Wash Mine where the modified in situ development program was conducted. The results of these two retorts are covered in more detail as a case history at the end of this chapter.

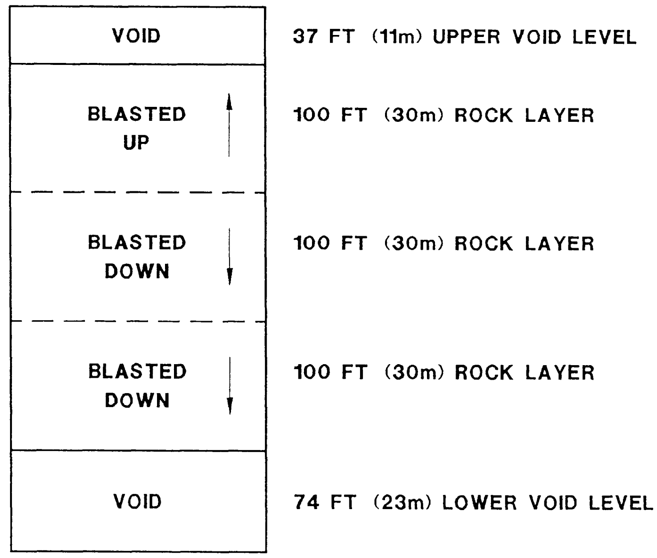

Fig. 22.7.1. Section view, two-void-level retort design (Ricketts, 1989).

22.7.2.1 Two-void-level Modified In Situ Retort Design

The final two retorts constructed in Occidental's modified in situ development program, Retorts 7 and 8, used a three-void-level design that allowed all the rock layers to be blasted into adjacent void levels at the same time (Ricketts, 1982, 1984); thus each rock layer was expanded into the same amount of void. At that time, it was not yet understood how rock bulked when blasted into a limited void volume. Thus a two-void-level retort design as shown in Fig. 22.7.1 was not attempted. This is because the first layer(s) uses up most of the void, if more than one layer is expanded into a single void room. Then, later layer(s) do not have sufficient void volume for expansion, resulting in poorly broken or unbroken sections in the retort. However, "limited void blasting" is now understood based on an analysis of extensive blasting data from Occidental's program. Such an approach can be used to design a two-void-level retort to provide a well-broken, vertically uniform rubble bed (Ricketts, 1989). This is important since the two-void-level design offers significant mining and blasting cost advantages as compared to the three-void-level design.

Limited void blasting refers to rock being blasted into a volume that is not sufficient to let it expand to its free-bulking value. Free bulking occurs when the rock particles have enough space to separate, tumble, and rotate to produce the maximum amount of voidage possible between the fragments when they finally come to rest. Although bulking value depends on particle size, distribution and shape, a typical free-bulking value for uniform, finely broken shale is about 1.67. The modified in situ development work has resulted in a limited void blasting curve,

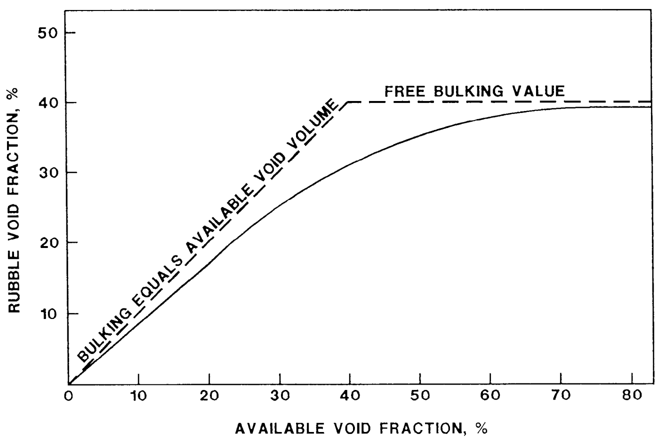

Fig. 22.7.2. Limited void volume blasting curve (Ricketts, 1989).

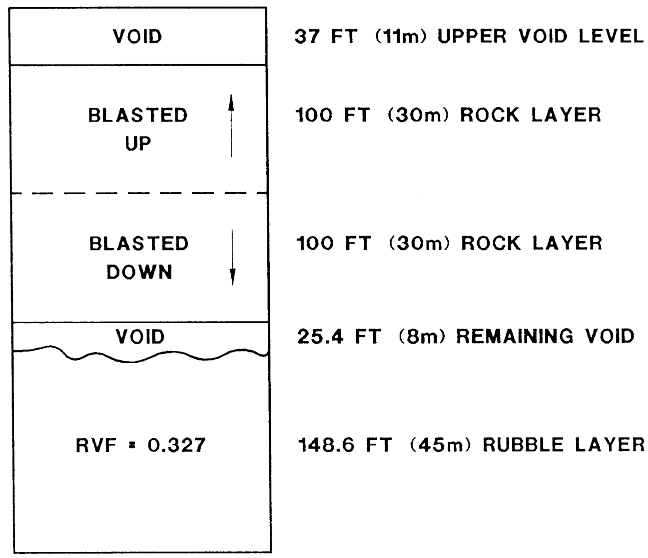

Fig. 22.7.3. Section view, two-void-level retort with bottom rock layer blasted (Ricketts, 1989).

as shown in Fig. 22.7.2. The *available void fraction* is defined as the ratio of the void volume into which a volume of rock is blasted divided by the sum of the void and rock volumes. The *rubble void fraction* is the actual fraction of void contained in a rubble bed and is given by the total rubble volume minus the original in-place rock volume (i.e., the actual void contained in the rubble bed) divided by the total rubble volume. A maximum free-bulking rubble void fraction value of 40% has been used in Fig. 22.7.2 as shown by the horizontal dotted line. *Bulking factor BF* is related to rubble void fraction *RVF* by the relation,

$$BF = 1/(1 - RVF) \qquad (22.7.1)$$

Thus a rubble void fraction value of 0.40 corresponds to a bulking factor of 1.67.

Also shown on Fig. 22.7.2 by a dotted line is the *intuitively expected bulking curve,* which is the bulking behavior that might be expected before actual data becomes available. For example, it might be expected that if rock is blasted into an available void volume that has less than the free-bulking volume, then the rubble would fill the void and have a void fraction value associated with the original volume. This is shown as the dotted line for available void fraction values below 0.40. For available void fraction values above 0.40, free-bulking values would occur that cannot be exceeded, and thus volumes in this range would not bulk full. However, it was found that volumes did not actually bulk full even for available void fraction values below 0.40, based on large retort blasts and extensive underground blasting programs (Ricketts, 1980, 1982). Thus blasting tests were specifically designed during later phases of Occidental's development program to resolve this limited void blasting issue.

The limited void blasting curve will be used in the following to design the most vertically uniform rubble bed possible for the two-void-level in situ retort design given in Fig. 22.7.1. This design consists of three 100-ft (30-m) thick layers of rock to be blasted into two void levels, a 37-ft (11-m) high upper void and a 74-ft (23-m) high lower void. The upper 100-ft (30-m) rock layer is designed to go up into the upper void and the lower 200-ft (61-m) rock layer down into the lower void. The rubble bed is constructed by first blasting the lowest 100-ft (30-m) layer downward, then waiting a sufficient time interval (on the order of 100 ms) before using explosive charges vertically centered in the upper 200-ft (61-m) layer to split this layer 100-ft (30-m) downward and 100-ft (30-m) upward. This splitting concept has been thoroughly tested and successfully demonstrated, and has been reported previously (Ricketts, 1980, 1982). This overall blasting method, however, causes a maldistribution in the vertical void fraction since the first down-layer uses more than its allotted proportion of void leaving less void for the second down-layer to expand into. This is the result of the first layer having an available void fraction value that is larger than the average value for the retort, thus allowing the first layer to bulk more than the average. The limited void blasting curve can be used to minimize the effects of this detrimental feature of the two-void-level retort design.

The overall available void fraction value for the design shown in Fig. 22.7.1 is 0.27. It will now be assumed that the minimum-void-fraction value that will be accepted in any section of the bed is 0.20, which is based on pressure drop and processing experience on previous large-scale retorts. (Note: Pressure drop results from the final two retorts constructed at the Logan Wash mine suggest that even a rubble void fraction of 0.18 is not totally unacceptable.)

This 20% minimum-void-fraction requirement leads to the overall available void fraction value of 0.27 for the two-void-level design. The available void fraction of the first 100-ft (30-m) thick layer blasted down in Fig. 22.7.1 is 0.425 (i.e., 74/174). The limited void blasting curve gives a rubble void fraction value of 0.327, which translates to a bulking factor of 1.486. Thus the 100-ft (30-m) layer expands to 148.6 ft (45.3 m), which results in the hypothetical configuration shown in Fig. 22.7.3. The second 100-ft (30-m) thick layer blasted down thus has 25.4 ft (7.7 m) of void to expand into, which is not symmetrical with the 37-ft (11-m) upper void room into which the upper 100-ft (30-m) thick layer is blasted. The second down layer has an available void fraction of 0.203 (i.e., 25.4/125.4), which results in a rubble void fraction value of 0.18 from the limited void blasting curve. This is below the 0.20 minimum desired rubble void fraction, and thus the chamber cannot be blasted using 100-ft (30-m) rock layers.

A more uniform vertical void fraction distribution is desirable in order to get the center section from a rubble void fraction value of 0.18 up to at least 0.20. This redistribution can be attempted by reducing the available void fraction for the first down-layer so it will bulk less and leave more void for the second

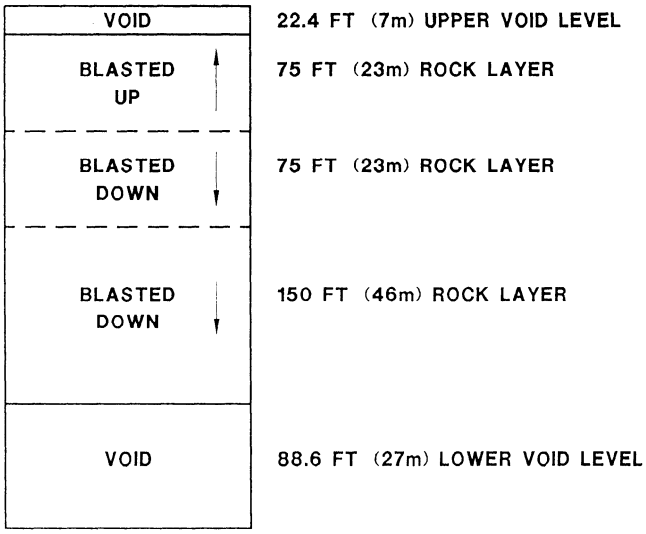

Fig. 22.7.4. Section view, improved two-void-level retort design (Ricketts, 1989).

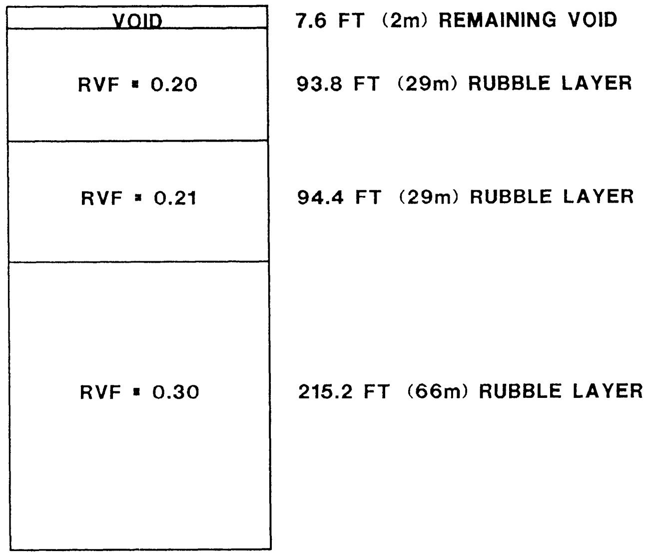

Fig. 22.7.5. Section view, improved two-void-level retort blasting results (Ricketts, 1989).

down-layer. The available void fraction of the first layer blasted down can be reduced by increasing the first layer thickness, say, to 150 ft (46 m). This would leave a 150-ft (46-m) thick upper rock layer to be split up and down into the upper void room and lower void that remains after the first layer is blasted down. This is less rock than that blasted originally, so the upper void room height should be reduced to give a rubble void fraction value at the minimum acceptable value for the upper rock layer. A rubble void fraction value of 0.20 for the uppermost rock layer that is blasted into the upper void level translates to an available void fraction value of 0.23 from the limited void blasting curve. For this value, the upper void room height can be reduced to 22.4 ft (6.8 m). The 14.6 ft (4.5 m) taken from this void level should be put into the lower void level to keep the overall available void fraction value for the retort fixed at 0.27. Thus the lower void room would be 88.6 ft (27 m) high, and the new two-void-level design is shown in Fig. 22.7.4.

The blasting of this improved design begins with a 150-ft (46-m) thick rock layer being expanded down into an 88.6-ft (27-m) lower void level. The available void fraction of this configuration is 0.371 (i.e., 88.6/238.6), which translates to a rubble void fraction of 0.303 using the limited void blasting curve. This corresponds to a bulking factor of 1.435, so the 150-ft (46-m) layer expands to 215.2 ft (66 m). This leaves 23.4 ft (7.1 m) of lower void for the expansion of the 75-ft (23-m) thick second down-layer. This 23.4 ft (7.1 m) of lower remaining void is fairly symmetric with the 22.4-ft (6.8-m) upper void, which gives a fairly uniform rubble bed for this case. The available void fraction for the second down-layer is 0.238 (i.e., 23.4/98.4), which gives a rubble void fraction of 0.205 and a bulking factor of 1.258. Thus this 75-ft (23-m) thick layer expands to 94.4 ft (29 m), which leaves 4.0 ft (1.2 m) of void for this layer. Recall that the upper 150-ft (46-m) thick layer for this design is split up and down at the same time using explosive charges vertically centered in the layer, so the remaining voids from the down layers will be translated to the top of the chamber. The available void fraction for the uppermost rock layer is 0.23, which gives a rubble void fraction value of 0.20 and a bulking factor of 1.25. Thus this 75-ft (23-m) thick layer expands to 93.8 ft (28.6 m), which leaves 3.6 ft (1.1 m) of void from this layer. This results in a total void of 7.6 ft (2.3 m) at the top of the chamber. The overall results of blasting this chamber using the improved blast design are shown in Fig. 22.7.5.

The lateral dimensions of the in situ chambers must now be discussed since it has been found that the lateral dimension actually controls the maximum layer thickness that can be blasted in the design. Extensive testing has shown that the maximum layer thickness that can be blasted using short-delay blasting is about one-half of the minimum lateral dimension of the chamber (Ricketts, 1979). Thus, for example, it would be possible to blast a 100-ft (30-m) thick rock layer for a 200-ft (61-m) square chamber. This maximum layer thickness that can be blasted is tied to lateral confinement of the layer just as in a heading round; that is, if too deep a heading round is attempted, it will not pull to the full depth and could freeze in place. The maximum heading-round depth is related to the drift cross-sectional size, and the larger the opening, the deeper the round that can be pulled. This concept becomes more restrictive as shorter delays are used in the round design. In the above example, a maximum layer thickness of 150 ft (46 m) resulted from the limited void blasting analysis, and thus the chamber should be at least 300 ft (91 m) square. The retort could also have a rectangular cross section, with the smaller dimension of at least 300 ft (91 m).

The use of pillars on the void levels must also be discussed since pillars must be used for large openings. No pillars were used in the above discussion to keep the analysis simple. These pillars support the roof while drilling and blasting operations are being done in the void rooms. However, to properly blast the main rock layers located between the void levels, all the void-level pillars must be removed before the main rock layers are blasted. Thus these pillars are considered temporary support pillars that must be blasted just before the main rock layers are blasted and still be in motion as the main layers expand into the void rooms. This sequence is well understood and has been described previously (Ricketts, 1980, 1982). When these pillars are present in the design, they must be included in the limited void blasting analysis. This is done by blasting them initially and letting them bulk to the free-bulking factor, then accounting for the void they will use up that will not be available for the main rock layers. The addition of pillars thus requires larger void-room heights to account for the expanded pillar rubble in order to keep the overall chamber void fraction at the desired value.

22.7.2.2 Blast Design for Uniform-flow Rubble Beds

The final two retorts constructed in Occidental's development program, Retorts 7 and 8, showed very good reproducibility between rubble beds. They also represented a definite improvement in rubble bed uniformity compared to previous retorts. However, based on thermocouple results during retorting, it was recognized that there was still room for improvement in rubble bed uniformity. One way to accomplish this was to attempt to produce uniform rubble properties across the bed. This had been the approach up to that time. An alternative was to produce a bed with a combination of nonuniform properties designed to provide a uniform flow distribution across the bed. This would result in a flat combustion front and greater oil recovery.

This new approach of constructing nonuniform rubble beds to provide uniform flow was developed using the results of the fragmentation testing and large-scale retort blasts in Occidental's development program (Ricketts, 1983). This concept has subsequently been modified to provide uniform retorting rubble beds rather than uniform flow beds and has been demonstrated on a small scale (Bickel and Ricketts, 1986). This modification causes only minor adjustments to the blast design; thus the remaining discussion follows the development of the uniform flow concept.

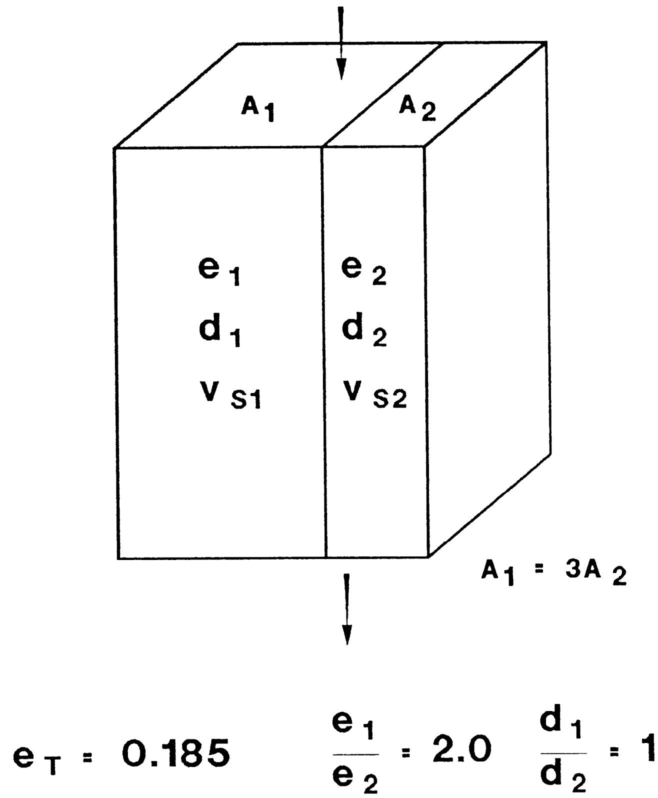
The uniform flow approach provides the design of a nonuniform rubble bed with the proper combinations of void fraction and particle size in different sections of the bed such that the mass flow rate per area during retorting is constant across the bed. This supplies equal oxygen flux to the combustion front all across the bed, which should result in a flat, uniform progression of the combustion front downward through the rubble bed.

The flow in a packed bed can be described by Ergun's equation that relates pressure drop through a bed to particle size and shape, rubble void fraction, and superficial flow velocity (Kunii and Levenspiel, 1977). The rubble beds in Retorts 7 and 8 constructed at the Logan Wash mine can basically be treated as beds with two regions of differing rubble properties, as shown in Fig. 22.7.6. Region A2 is of higher permeability and is found around the perimeter of the bed (Ricketts, 1983). If Ergun's equation is applied to both regions, the equations can be combined and rewritten in terms of particle size ratio. For equal superficial velocities in the two sections of the bed, that is, $Vs_1 = Vs_2$, this relation represents a uniform mass flow rate per area for a bed having two regions. The resulting expression gives the particle size ratio required for perfectly uniform flow in these regions as a function of rubble void fraction. This relation appears as

$$d_2/d_1 = (1 - e_2/1 - e_1)\,(e_1^3/e_2^3)^{1/2} \qquad (22.7.2)$$

where d is mean particle size and e is rubble void fraction.

The rubble void fraction and particle size values in the different sections of the rubble bed can be controlled using fragmentation data obtained in Occidental's modified in situ development program. These fragmentation data are given in Figs. 22.7.7 and 22.7.8. Fig. 22.7.7 shows rubble void fraction (which is related to bulking factor) as a function of powder factor and blasthole spacings. Fig. 22.7.8 gives mean particle size as a function of powder factor and blasthole spacing. Fig. 22.7.7 shows a trend of increasing void fraction for increasing powder factor for all blasthole spacings. The curves also show, for example, that for a fixed powder factor, the bulking can be increased by increasing spacing. Likewise, if a fixed void fraction is desired, a decrease in spacing would require an increase in powder factor. Fig. 22.7.8 shows a trend of decreasing particle size with increasing powder factor for all blasthole spacings. These curves also show, for example, that for a fixed powder factor, the particle size can be increased by increasing the spacing, and that if a fixed particle size is desired, an increase in spacing would require an increase in powder factor.



Fig, 22.7.6. Idealized rubble bed configuration for Retorts 7 and 8 (Ricketts, 1983).

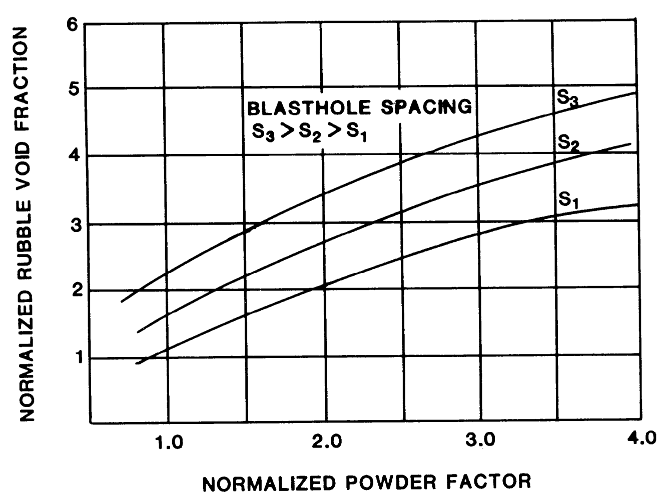


Fig. 22.7.7. Blasting curves relating rubble void fraction to powder factor and spacing (Ricketts, 1983).

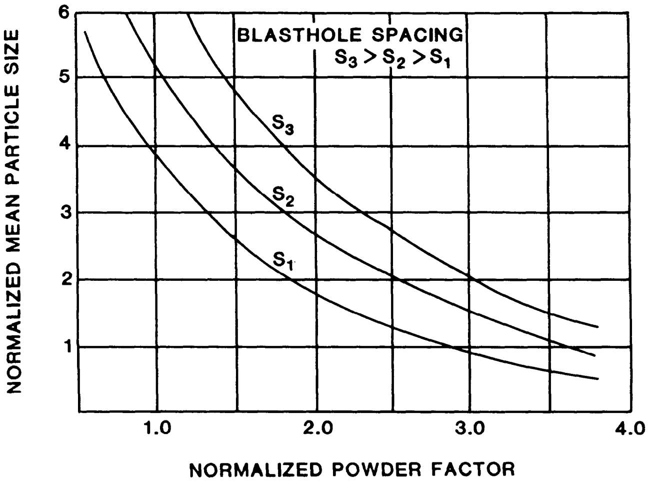

Fig. 22.7.8. Blasting curves relating particle size to powder factor and spacing (Ricketts, 1983).

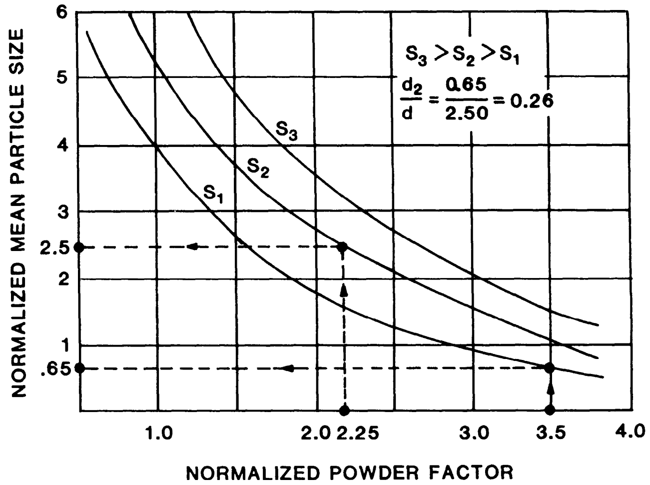

Fig. 22.7.10. Particle size curves for Retorts 7 and 8 uniform flow design (Ricketts, 1983).

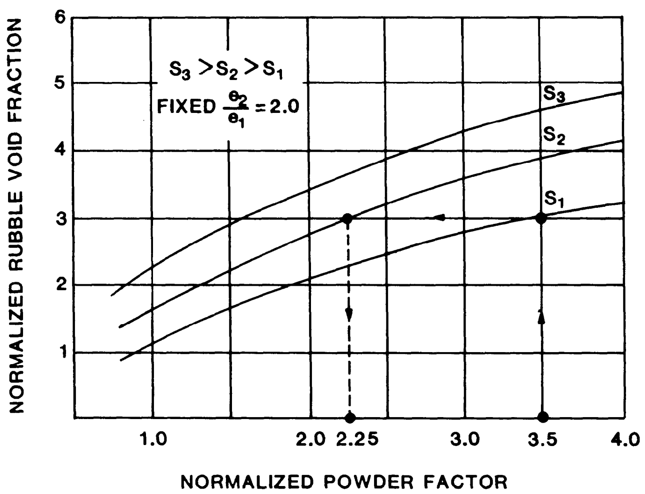

Fig. 22.7.9. Rubble void fraction curves for Retorts 7 and 8 uniform flow design (Ricketts, 1983).

The idealized rubble bed configuration representing Retorts 7 and 8 is shown schematically in Fig. 22.7.6 with rubble properties $e_T = 0.185$, $d_1 = d_2$ and $e_2/e_1 = 2.0$. This rubble bed was blasted using a spacing of 20 ft (6.1 m) and a normalized powder factor of 3.5, which is nominally 1.6 lb of ammonium nitrate-fuel oil (ANFO) explosive equivalent/ton of shale rubblized (0.80 kg/t). The design of Retorts 7 and 8 will be discussed in more detail in the case history, at the end of this chapter.

The two sections of differing rubble properties in Retorts 7 and 8 were divided such that the interior area $A_1 = 3A_2$. Based on 22.7.2, the required value of the particle size ratio d_2/d_1 is 0.29 for perfectly uniform flow conditions in the two sections of the bed, that is, for $Vs_1 = Vs_2$. The rubble void fraction curves in Fig. 22.7.9 show that increasing the spacing to 25 ft (7.6 m) in area A, requires a decrease in normalized powder factor to 2.25 to keep the rubble void fraction constant. This is nominally 1.0 lb ANFO equivalent/ton of shale rubblized (0.5 kg/t).

Keeping the rubble void fraction fixed in area A_1 is not necessary in this analysis. However, it results in the simplest case for designing a uniform flow distribution, since the rubble void fraction in area A_2 then also remains fixed. Fig. 22.7.10 then shows that the normalized particle size increases from 0.65 for the original blast design to 2.5 for the uniform flow design. This gives a ratio of $d_2/d_1 = 0.26$ compared to the desired value of 0.29 associated with perfectly uniform flow. A particle size ratio of 0.26 gives a flow velocity ratio of 0.80 for the two regions. This represents an acceptably uniform flow distribution, which, in fact, is very close to a uniform retorting design (Bickel and Ricketts, 1986). An iterative process could be used at this point to obtain a perfectly uniform flow design from the blasting curves in Figs. 22.7.9 and 22.7.10. However, in this case, construction of a rubble bed that exhibits a slightly nonuniform flow distribution is actually preferred. This is due to the higher density of rubble in the interior region, which requires more air flux per unit volume to retort compared to the perimeter region (Ricketts, 1983; Bickel and Ricketts, 1986).

In summary, the improved uniform flow design developed here involves increasing the blasthole spacing 25% in area A_1 and decreasing the powder factor 36% in this same area as compared to the blast design used in the final two retorts constructed in Occidental's development program. These two factors applied to three-fourths of the total retort cross section represent a significant blasting cost reduction. The flow results for a perfectly uniform flow design along with those of Retorts 7 and 8 are given in Table 22.7.1. These results show the calculated flow properties for the actual rubble beds in Retorts 7 and 8 and the redistribution of flow that occurs by using a uniform flow design. It can be seen that making $d_1 = 3.45\ d_2$ in area A_1, while keeping the void fraction fixed, causes a redistribution of flow such that the flow rate per area is uniform across the bed.

The most significant result of this flow redistribution is the three-fold reduction in pressure drop for the uniform flow design as compared to the Retorts 7 and 8 rubble beds. This translates to a sizable cost savings during commercial processing operations since blower pressure is required for about 300 days to completely retort a commercial rubble bed. Thus the total cost benefits gained by use of the uniform flow design will be significant for a commercial operation. Results include a reduction in rubblizing costs, a decrease in blower operating costs due to a substantially lower pressure drop in the bed, and an increase in the oil yield due to a more uniform retorting front.

Table 22.7.1. Flow Parameters for Retorts 7 and 8 and Uniform Flow Designs

Flow Parameter	Retorts 7 & 8 Design	Uniform Flow Design
Pressure drop per 100 ft (30 m), psi	1.94	0.61
(kPa)	(13.4)	(4.2)
Central region (A_1) flow rate, scfm	3,228	12,005
(scms)	(1.52)	(5.67)
Perimeter region (A_2) flow rate, scfm	12,750	4,001
(scms)	(6.02)	(1.89)
Central region (A_1) superficial velocity, fpm	0.24	0.90
(mm/s)	(1.2)	(4.6)
Perimeter region (A_2) superficial velocity, fpm	2.9	0.90
(mm/s)	(14.8)	(4.6)
Particle diameter ratio, d_1/d_2	1.00	3.45
Void fraction ratio, e_2/e_1	2.0	2.0

22.7.2.3 Processing of Modified In Situ Rubble Beds

The processing phase of the modified in situ operation represents an extensive part of the overall process and consists of numerous events that start after the retorts are mined and rubblized. The following processing considerations reflect the technology used on the final two retorts processed in Occidental's development program. A more detailed discussion of what was done on these retorts is given as a case history in 22.7.3.

CONSTRUCTION REQUIREMENTS. After the chambers are rubblized, it is necessary to construct bulkheads in the entry drifts into each void room to isolate the retorts both from the mine workings and from each other. A description of steel bulkheads used for this function, their construction, installation, and insulation, is given elsewhere (Nelson, 1982). To prevent leaks around the edges of the bulkheads, they are typically sealed in place with a blown-in ceramic-masonry grout. For drifts between retorts that are inaccessible after rubblization, it may be necessary to construct barriers to flow between the retorts prior to rubblization. A cost-effective technique of doing this consists of filling the drift with sand, protected at each end by mine-run rock.

Processing facilities typically include blowers and piping needed for supplying process air, and steam to the retorts. Other blowers, operating in the suction mode, can be used to pull the process gases through the retorts. Control valves at the product level bulkheads permit maintaining subatmospheric pressure within each retort, to prevent leakage of retorting gases into the mine ventilation air.

The off-gas from the retorts is transported to the surface processing plant using a cased raise. There, counter-flow direct-water-contact condensers can be used to condense water and C_5 + hydrocarbons from the off-gas.

A water-spray nozzle system can be installed in the collection drift on the product level of each retort. Late in the operation of the retorts, these spray systems are used to cool the high-temperature off-gas to temperatures acceptable to the bulkheads, downstream piping, and processing equipment.

PROCESSING INSTRUMENTATION. Direct periodic measurement of primary variables throughout the processing system and temperatures within and around the retorts should be collected and recorded preferably using a computerized data acquisition system (Kimball and Ogden, 1980). Frequency of measurement depends upon the anticipated rate of change of the variables. On-line analyses of off-gas compositions can be made continuously by specific-gas analyzers (oxygen in the off-gas, for example) and periodically by gas chromatographs. Operating conditions can then be computed and displayed on TV monitors for timely process evaluation and control.

A certain minimum number of key processing measurements are required on all retorts, especially in the inlet and off-gas streams, to safely control the process for maximum oil yield. The initial retorts in a commercial operation will require extensive instrumentation including measurements in the rubble bed so the retorting process can be understood and optimized for maximum oil yield. Thermocouples and gas sample taps are typically placed in the rubble beds after rubblization. Holes are drilled from access drifts through the intact shale surrounding the rubble beds and into the rubble to the desired location with the drill pipe left in place. Prior to installing the thermocouple and gas sample tap assemblies in the drill pipes, directional surveys should be made of the pipes. Survey results and thermocouple/tubing lengths then provide an accurate location of each thermocouple and gas sample tap for subsequent mapping of temperature, pressure, and gas composition distributions within the rubble beds during retorting.

PRE-IGNITION TESTING REQUIREMENTS. After completion of the gas-sample tap and thermocouple installation, and construction of the bulkheads and off-gas handling systems, tests should be run to determine the leak rates, pressure drops, and flow contours within the rubble beds. Results of these tests are used to establish safe and efficient operating conditions as well as any special processing strategy that needs to be used.

Leak tests are first conducted to locate and correct leaks and to minimize uncertainties in subsequent pressure drop tests. With blowers downstream from the retorts in the process gas stream, pressures in the retort chambers are kept subatmospheric during processing; thus any air leakage will be from the mine workings into the retorts. The maximum acceptable leakage rate can be established by the safe upper limit of 2% oxygen in the combustible off-gas during process operations. The pressure drop through the retort rubble is expected to increase with time through the retort like. Likewise, the mean pressure and leakage rate into the retorts is likewise expected to increase with time. Thus it is appropriate to determine cold-flow pressure drop values and from these predict hot-flow pressure drops in the retorts.

It is believed that during retorting, the increased pressure drop is partly due to an increase in gas flow generated from both combustion and pyrolysis, and partly to an increase in viscosity of process gases as the rubble bed temperature increases. The effective permeability also decreases as liquid products compete with process gases for void space, and effective void space also decreases slightly as the shale expands (exfoliates) during the retorting process. No evidence has been found to suggest that the rubble beds slump during retorting. Typical pressure drop values for rubble beds 240 ft (73.2 m) high having an average rubble void fraction of 0.185 are on the order of 15 in. water (3.7 kPa) for cold flow at a rate of 12,000 scfm (5.7 scms) and about 60 in. water (14.9 kPa) during retorting. Most of the pressure drop occurs at the bottom of the retort in the outlet region where turbulent flow conditions exist. For example, the pressure drop for a 200-ft (61-m) section of rubble bed away from any inlet and outlet effects is less than 1.0 in. water (249 Pa) for the void fraction and flow rate values specified above.

RUBBLE BED IGNITION PROCEDURE. The retort startup procedure was developed using a series of laboratory tests and laboratory pilot plant experiments, with the resulting procedure successfully tested underground on intermediate-sized rubble beds before it was used on full commercial-scale retorts. This startup procedure begins with the uniform heating of the top surface of the rubble bed to ignition temperature using an external heat source. The retort and blasting designs have been developed to provide a void room above the rubble bed after the retort has been rubblized. This is specifically for the start-up phase of the processing operation. Open access to the entire top of the rubble bed depends on the roof stability over the bed (which can represent a very large span) both before and during the ignition procedure. It has been found that ignition over the entire top of the bed can still be accomplished after a roof fall due to the large particle size of the roof-fall material and the large voids that exist between these particles. When ignition temperature is achieved, oxygen (air) is gradually supplied to the top of the bed to start combustion within the rubble. When sufficient combustion has been initiated on the rubble surface, the external heat source is turned off.

Typically, a hot inert-gas generator has been used, with shale oil as the fuel, to inject hot (inert) products of combustion (water quenched to 1600°F or 870°C) into the void above the bed. With proper design of the outlet nozzle from the generator, the void above the bed can act as a completely stirred tank that distributes the hot gas uniformly over the rubble. A slight excess of oxygen in the generator can be used as a tracer to detect the onset of combustion at 750°F (400°C), which can be monitored as the disappearance of oxygen in the retort off-gas. At a generator firing rate of 100 million Btu (106 GJ) per hour, about 18 hours will be required for the onset of ignition. The complete transition to air typically takes about 6 hours, at which time the generator can be shut down and moved to the next retort.

RETORTING OPERATION. After ignition, the retorts are typically operated without interruption until gas injection is terminated and water quenching begins. A simplified process flow diagram for operating two retorts is shown in the case history at the end of this chapter. Sumps behind the product level bulkheads are used for the collection, separation, measurement, and sampling of the bulkhead oil and water pumped from the retorts. After transport to the processing facilities, the off-gas can be processed through contact condensers. Suction blowers can be used to withdraw off-gas from the contact condensers and exhaust the gas to the stack, where the gas is discharged to the atmosphere by permit.

The off-gas from the retorts and the stack gas are typically analyzed by on-line gas chromatographs throughout the operation. Standard EPA isokinetic samples of the off-gas can be collected for daily analysis from the retorts at the product level bulkhead and from the off-gas at the base of the raise, top of the raise, exit of each contact condenser, and the stack. Stack isokinetic measurements can be used to determine the daily barrel equivalent of uncondensed C_5+ hydrocarbons exhausted up the stack. Water and light oil recovered at the contact condensers can be measured daily and sampled periodically for analysis.

Near the end of retorting, the off-gas temperature will eventually rise above 250°F (121°C) which represents the safe limit for the product level bulkheads and the retort processing will have to be terminated. If this occurs too early during retorting, it can cause a significant reduction in sweep efficiency and result in a loss of total oil production. It is also possible for oxygen breakthrough to occur, requiring termination of retorting. However, this has never been observed during Occidental's development program. In order to extend the life of the retorts, the off-gas can be cooled to reduce the thermal load on the bulkheads and downstream processing equipment. The off-gas can be cooled by (1) utilizing a water-spray system to cool the off-gas in the production drifts behind the bulkheads; (2) reducing or eliminating steam in the inlet gas; (3) reducing the inlet flow rate; and (4) injecting recycle gas instead of air.

SHALE OIL PRODUCTION. The shale oil recovery from modified in situ retorts can be expected to be on the order of 70% yield of the Fischer assay oil in place in the rubble that was actually blasted. This yield value is for retorts having an average shale grade of 15 to 20 gallons of shale oil/ton of shale (60 to 80 mL/kg). This oil production includes oil pumped from the retort sumps, oil mists and vapors condensed in contact condensers, condensable C_5 + vapors found in the stack gas, and a small amount of oil in the bulkhead water. The partitioning of the total product between these four streams for actual retort production is given in the case history segment (22.7.3). Cumulative production curves for modified in situ retorts are also given in 22.7.3.

It is believed that a yield value of 70% for modified in situ retorts is on the conservative side since one of the final two retorts constructed at the Logan Wash mine provided a higher yield and future retorting operations will always strive for the highest yield value possible. In addition, these final two retorts were constructed using first-generation technology. Improved technology has now been developed (discussed earlier in this segment) that will result in more uniform rubble beds and thus higher oil yields. Sandia National Laboratories has in fact estimated that this technology could provide increases of 30% or more in oil yield, which is significant (Hommert and Bickel, 1987). It is expected that future retorts will be located in richer shale than was available at the Logan Wash mine, and this will also provide higher yields since yield is a function of shale grade and increases with increasing grade. It should be noted that the definition of yield used here is based only on the rubble that was actually blasted in the retorts and does not account for oil residing in roof-sloughing rock and the retort walls that enter into the process.

22.7.3 UNDERGROUND RETORTING CASE HISTORY

22.7.3.1 Modified In Situ Development Background

The development of Occidental's modified in situ technology began in 1972 with the construction and processing of four underground retorts. The first three chambers were about 30 ft (9 m) square and 72 to 113 ft (22 to 34 m) high. These test retorts examined both vertical- and horizontal-mined void configurations at various rubble void fraction values. The first two used a single vertical raise in the center of each retort and a bottom room as the void, while the third used three horizontal rooms located at the top, bottom, and center of the retort volume as the void. The horizontal void test provided a slightly better yield than the other two. The fourth retort was 120 ft (36.6 m) square by 298 ft (90.8 m) high and used two vertical void slots extending parallel to one another across the cross section. The oil yield results for this retort were not as good as the small-scale test retorts. Rock stability problems involving sloughing of rock into the slots played a role in the reduced yield for Retort 4.

Retorts 5 and 6 were then constructed and processed under phase 1 of a joint Occidental/Department of Energy cooperative agreement that started in 1976 (Loucks, 1977). This program compared commercial-sized, vertical-void and horizontal-void retorts. Retort 6, the horizontal-void retort, resulted in significantly more oil recovery than the vertical-void design. This increase occurred in spite of a loss of access to the inlet piping system and subsequent loss of control over the combustion front

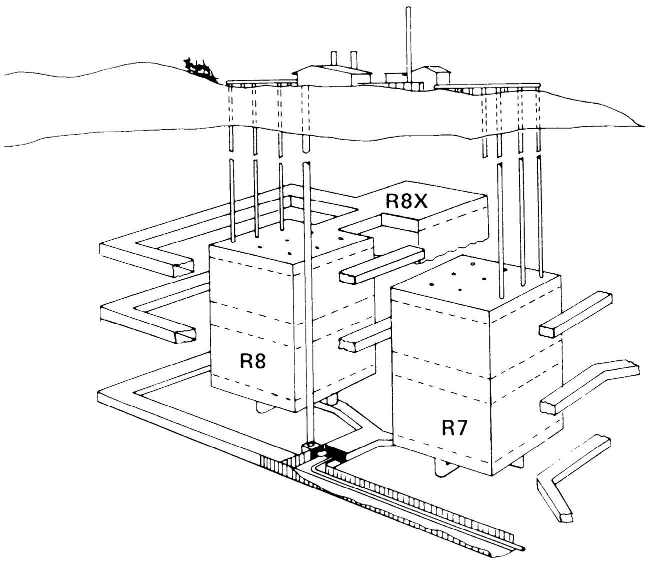

Fig. 22.7.11. isometric view Retorts 7 and 8 and Partial Retort 8X (Ricketts, 1982).

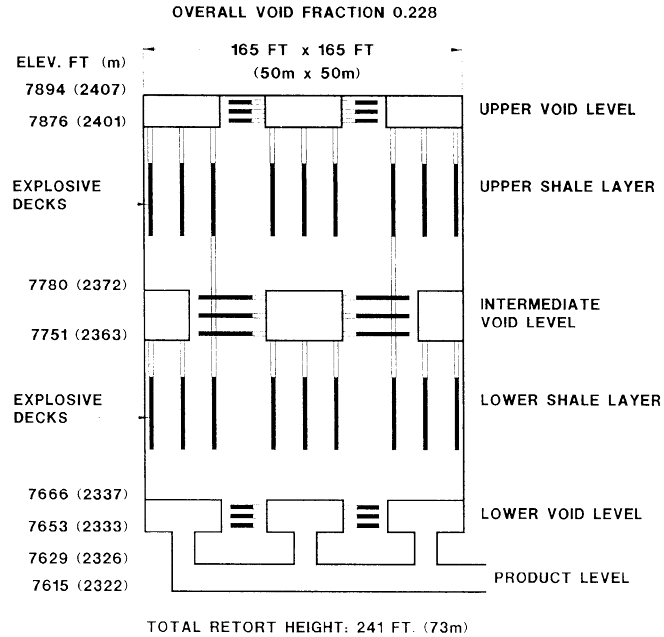

Fig. 22.7.12. Section view Retorts 7 and 8 blast design (Ricketts, 1982).

during the processing of Retort 6. Consequently, the horizontal-void design was used for phase 2 of the cooperative agreement that constructed and processed Retorts 7 and 8 (Nelson, 1981; Romig, 1981). Retorts 5 and 6 are well documented in government reports required under the cooperative agreement, and the processing performances have been modeled by government laboratories (Gregg and Campbell, 1980; Campbell, 1981). The final two retorts completed during Occidental's development program, Retorts 7 and 8, are described in detail in the following case history.

22.7.3.2 Retorts 7 and 8 Objectives

The primary objectives in operating Retorts 7 and 8 were to construct and process two side-by-side commercial-sized retorts in order to (1) establish the reproducibility of the blasting results for two commercial-sized retorts using the same retort design, blast design, and mined-out void volume; (2) start up and process two identically constructed side-by-side retorts connected to a common off-gas line; and (3) obtain rock mechanics and mine design data for a multiple retort system for use in ongoing commercial mine design efforts.

To increase the amount of rock mechanics data relevant to the commercial mine design, a partial height retort, Retort 8X, was added next to Retort 8 (Fig. 22.7.11). This partial retort had a full-scale cross section 165 ft (50 m) square, but was only 63 ft (19 m) high when rubblized as compared to about 240 ft (73 m) for Retorts 7 and 8. The distance between retorts 7 and 8 was about 160 ft (49 m), while the spacing between Retorts 8 and 8X was 50 ft (15 m), both of which were representative dimensions for the clusters of retorts envisioned in the commercial mine design. By adding Retort 8X, additional data on the stresses, deformations, and fracturing for two full-scale openings located very close to one another could be evaluated (Ricketts, 1982). In addition, Retort 8X was rubblized first, which increased the reliability and productivity for the subsequent full-scale blasting operations. The Retort 8X blast involved a total of 205 blastholes loaded with 143,100 lb (64,910 kg) of explosive in ANFO equivalent. This was a large-scale blasting operation even though it was only a partial retort.

22.7.3.3 Retorts 7 and 8 Design

Retorts 7 and 8 used a three void-level-design so that all the rock layers could be blasted into adjacent void levels at the same time. In this way, each rock layer expanded into the same amount of void volume. The design of these retorts (along with the blastholes used for rubblization) is given in Fig. 22.7.12. The retort design for both retorts consisted of three 165-ft (50-m) square horizontal-void levels, an upper level 18 ft (5.5 m) high, an intermediate level 29 ft (8.8 m) high, and a lower level 13 ft (4.0 m) high. There were two shale layers between these void levels, the upper 96 ft (29 m) thick and the lower 85 ft (26 m) thick. There was a product level 14 ft (4.3 m) high for collecting oil 24 ft (7.3 m) below the floor of the lower void level. The product level provided access for the retorting outlet system, which consisted of five 8-ft (2.4-m) diameter raises. One raise was located at the center of the retort cross section with the other four being positioned 24 ft (7.3 m) in from the center of each side wall, as measured perpendicularly in from the side walls to the raise centerlines.

The upper- and lower-void levels each contained two pillars 16 ft (4.9 m) wide by 150 ft (46 m) long. These pillars were oriented parallel to one another and were positioned about 52 ft (16 m) from the side walls that were parallel to the pillars, as measured to the pillar centerlines. The intermediate void levels each contained four 36-ft (11-m) square pillars with one pillar located at the center of each quadrant of the retort cross section. Thus the center of each pillar was located about 43 ft (13 m) in from each of the closest two side walls. These void level pillars were temporary structures used to support the void level roofs while drilling, explosive loading, and blasting operations were performed.

22.7.3.4 Retorts 7 and 8 Blasting Design and Results

The key to Occidental's modified in situ process is in its retort rubblization technology. The rubblization operation provides a rubble bed that is very large and must be uniformly and well fragmented to give a good oil yield from retorting. The blasting is done in a very confined configuration, which makes uniformity especially difficult. The entire chamber is detonated within a single blasting round, so blast effects must be understood and controlled to avoid extensive damage to the surrounding mine structure. Since the blasting is done to a limited void volume, and access to the rubble bed is difficult, the initial blasting round must perform as planned as secondary corrective type blasting is not possible.

The Retorts 7 and 8 blast design was the result of extensive underground blasting programs (Ricketts, 1982, 1984). The blasting tests and retort blasting patterns were designed using cratering characteristics (Redpath, 1977; Ricketts, 1980, 1987) that were related to conventional blasting patterns used during the development program and large-scale retort blasts. The main vertical blastholes for expanding the upper and lower shale layers and the horizontal pillar blastholes are shown in Fig. 22.7.12. The main vertical interior blastholes were 12 in. (305 mm) in diameter and were located in a 20-ft (6.1-m) spacing pattern, while the perimeter holes were $7\frac{3}{8}$ in. (187 mm) in diameter and were spaced 15 ft (4.6 m) apart. The pillar blastholes were 4 in. (102 mm) in diameter and were located in a 5-ft (1.5-m) spacing pattern. In the figure, the black sections in the blastholes represent the explosive columns while the white sections represent stemming material. All powder columns were center-initiated to give symmetric two-way blasting of the main shale layers and pillars. The pillar and main shale blasting sequences had to be coordinated correctly to ensure the pillars were properly removed and were being distributed within the void levels before the main layers were expanded. Thus the pillars were detonated sufficiently (on the order of 100 ms) before the main shale layers to ensure both proper breakage of the main shale layers and uniform distribution of pillar ejecta across the retort cross section. This delay time was verified full scale in the underground blasting programs and was used in the full-scale Retort 6 blast before it was used for Retorts 7 and 8.

The blasting sequence began at time = 0 when zero-delay seismic electric blasting caps on all three void levels were initiated. These caps initiated nonelectric detonating cord systems located on all three levels. The upper two levels had detonating cord networks both on the floor for the main vertical blastholes and on the pillars for the horizontal pillar blastholes. The lower level only required a detonating cord network for the pillars. The detonating cord system on each void level consisted of two independent trunkline systems passing over each hole. Each system was connected to a different downline leading to a delay cap within the powder column; thus all the powder columns were dual primed. The two trunkline networks on each void level were then cross-linked together at numerous locations for an added measure of redundancy. A nonelectric backup system for the electric system was included that connected the trunklines on all three void levels. The detonating cord systems initiated downline cords in the pillar holes and vertical holes within several milliseconds, the process subsequently propagating to the downhole delay blasting caps. These delay blasting caps then sat safely in the holes waiting to detonate at their prescribed times while the pillars were being blasted within the void levels.

The center regions of the pillars on all three levels were initiated first, followed by the upper and lower portions of the pillars 25 ms later. The pillars were blasted in two steps for Retorts 7 and 8 to reduce blasting damage to the retort roof and floor regions since the charges in the pillars closest to these area would have some relief away from these boundary areas if the center regions were blasted first. A delay time of about 100 ms was then provided before charges in the main shale layers were detonated. The first main layer charges were detonated at multiple locations across the cross section to improve the lateral uniformity of permeability in the rubble and reduce mounding of the top of the rubble pile. Subsequent delays occurred at 25-ms intervals at multiple locations across the retort while the final delay interval was along the edges of the retort. This was done so the edge charges would have additional relief away from the chamber boundaries, thus reducing fracturing into the chamber walls.

The results of the blasts are given in Fig. 22.7.13. Table 22.7.2 also presents a summary of these blasts. The average void fractions in the rubble beds and the remaining void heights above the rubble beds were very close to one another and to predicted values. These quantities were predicted using the limited void blasting curve which was described earlier. The tops of the rubble beds were very flat, as desired. Based on the very large rubble volumes and total retort heights involved in these blasts, a difference of only 0.3 ft (0.1 m) in the remaining void heights above the rubble beds is a remarkable result and an excellent demonstration of large-scale blasting reproducibility. These remaining voids are an important part of the design and serve as distribution chambers for the hot inert gases used during the ignition of the rubble beds. The Retorts 7 and 8 blasting results provide a strong

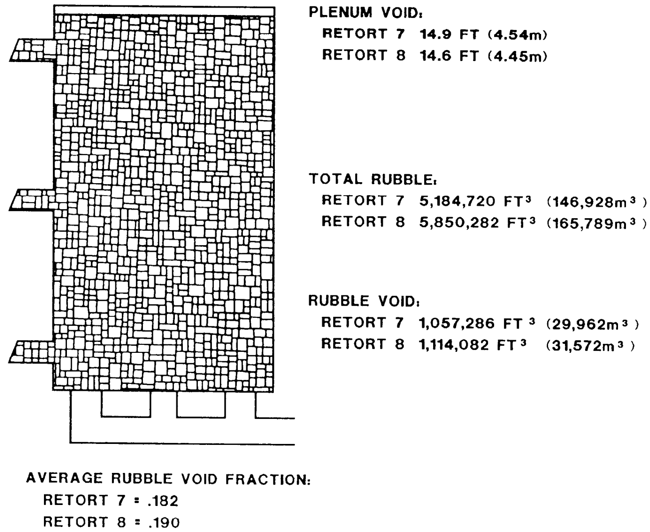

Fig. 22.7.13. Retorts 7 and 8 rubblization results (Ricketts, 1983).

Table 22.7.2. Retorts 7 and 8 Blasting Summary

	Retort 7	Retort 8
Date rubblized	21 Feb 1981	4 Apr 1981
Total number of blastholes	539	554
Main vertical holes	168	168
Pillar horizontal holes	371	386
Explosive weight ANFO equivalent, lb	539,163	545,622
(kg)	(244,564)	(247,494)
Total retort volume, ft^3	6,221,920	6,225,382
(m^3)	(176,185)	(176,283)
Rock blasted, tons	347,655	348,178
(t)	(315,393)	(315,867)
Powder factor, lb/ton	1.55	1.57
(kg/t)	(0.775)	(0.785)

endorsement to Occidental's large-scale rubblization technology, which has advanced far beyond normal blasting state of the art and is based on an easy-to-use, practical design tool related to cratering technology (Ricketts, 1987).

The fact that the average rubble void fraction values were fairly close to one another and the tops of the rubble beds were quite flat and level for these two retorts suggested similar permeability distributions existed in these two rubble beds. Flow testing on these retorts discussed in the following sections confirmed the uniformity and similarity of these two beds.

22.7.3.5 Processing of Retorts 7 and 8

A general discussion of modified in situ processing was given earlier. This previously presented material was developed from experience gained with Retorts 7 and 8. This segment presents a more detailed description of the various elements of the processing operation that apply specifically to Retorts 7 and 8.

CONSTRUCTION ACTIVITIES. After blasting, the two retorts were isolated both from the mine and from each other by using steel bulkheads located in the void level entry drifts. Two entry drifts, one running between Retorts 7 and 8 on the lower void level and the other between Retorts 8 and 8X on the upper void level (Fig. 22.7.11), were inaccessible after rubblization; therefore, it was necessary to construct barriers to flow between the retorts prior to rubblization. An effective and low-cost technique was used. It consist of filling the drift with sand, protected at each end by mine-run rock. Because leakage of retort gases was possible through the sand barrier into Retort 8X, and also potentially through the narrow pillar between Retort 8 and Retort 8X, a steel bulkhead was also installed in the entry drift between the Retort 8X upper void room and the upper level mine drift.

Processing facilities were located on the surface over the mine and included blowers for supplying process air, along with steam, to the retorts through pipes from the surface. Other blowers, operating in the suction mode, pulled the process gases through the retorts. Control valves at the product level bulkheads maintained subatmospheric pressure within each retort but neutral at the upper level bulkhead, to prevent leakage of retorting gases into the mine ventilation air.

The off-gas from each retort was separated for a sufficient distance from the product level bulkhead to permit sampling and flow-rate measurements. Then the streams were combined at the base of a cased raise for transport to the surface processing plant. There counter-flow direct-water-contact condensers were used to condense water and C_5+ hydrocarbons from the off-gas. A water-spray nozzle system was installed in the collection drift behind the product level bulkhead of each retort. Late in the operation of the retorts, they were used to cool the high-temperature off-gas to temperatures compatible with the bulkheads, downstream piping and processing equipment.

PROCESS MONITORING INSTRUMENTATION. An extensive network consisting of 1234 thermocouples and gas sample taps was placed in the rubble beds of both retorts after rubblization. Holes were drilled from access drifts through the intact shale surrounding the rubble beds and into the rubble to the desired location with the drill pipes left in place. Thermocouples were assembled around 0.5-in. (13-mm) diameter stainless steel gas-sampling tubes that were inserted into the drill pipes to the desired depths. The annulus between the tubing and the drill pipe was filled with grout to prevent convective heat transfer within the assembly. Provision was made to avoid plugging the open end of the gas-sampling tube with grout. Grout was also extruded into the annulus between the drill pipe and the intact shale surrounding the rubble bed to seal gas leaks between the

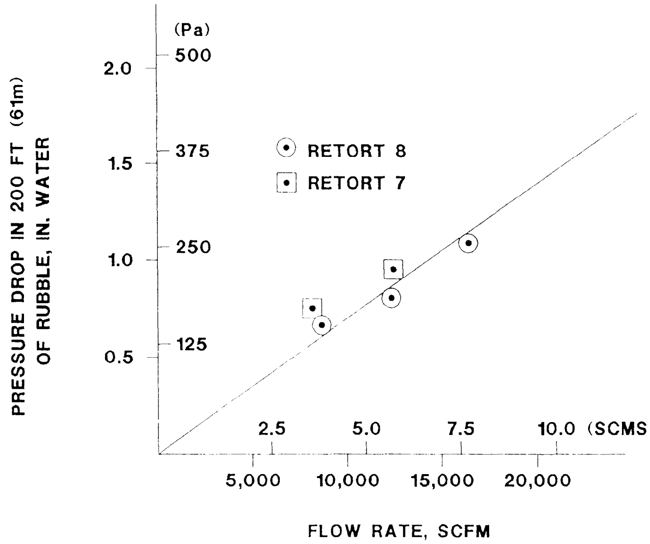

Fig. 22.7.14. Pressure-drop results in the upper 200 ft (60 m) of rubble (Stevens and Zahradnik, 1983).

retort chamber and the mine workings. Drillhole survey results and thermocouple/tubing lengths provided an accurate location of each thermocouple and gas sample tap for subsequent mapping of temperature, pressure, and gas-composition distributions within the rubble beds.

PRE-IGNITION TESTS ON RETORTS 7 AND 8. Pressure drop measurements were made for a series of cold-flow rates through the retorts using pressure taps distributed throughout the rubble beds and at the upper, intermediate, lower, and product-level bulkheads. Fig. 22.7.14 shows the pressure data for both retorts over the upper 200 ft (61.3 m) of rubble, plotted as a function of flow rate for a wide range of flow rates, including 12,000 scfm (5.7 scms), which was the inlet gas flow rate used during processing. The total pressure drop through the 18.5% void rubble is seen to be less than 1 in. water (249 Pa) to within about 40 ft (12.2 m) of the floor of the retorts at the operating flow rate. Initial measurements showed unacceptably high pressure drops within the 20 ft (6.1 m) of rubble above the floor of the retorts. Corrective measures were taken to enlarge the drawports at the bottom of both retorts and reduce the zone of turbulent flow in the region of converging flow lines in the rubble near the drawport exits. The drawports were enlarged until the total cold pressure drop was reduced in Retort 7 to 17 in. water (4.2 kPa) and in Retort 8 to 11 in. water (2.7 kPa) at design flow rates. During retorting, the hot pressure drops, as expected, increased to 75 in. water (18.7 kPa) and 50 in. water (12.4 kPa) for Retorts 7 and 8, respectively.

During retorting, the pressure drop through Retort 8 increased in a predictable manner. The pressure drop in Retort 7 exceeded predictions, indicating that the corrective measures taken in the bottom of Retort 7 were not as thorough as in Retort 8. Although some tracer tests were scheduled and conducted, these analyses were abandoned in favor of mapping the flow pattern using the steam front following ignition (Tyner et al., 1983; Bickel, 1983).

FULL-SCALE IGNITION PROCEDURE. For start-up of Retorts 7 and 8, a hot, shale oil-fired, inert-gas generator was used to inject hot (inert) products of combustion into the void above the bed. The gases were water quenched to 1600°F (870°C). A slight excess of oxygen was used in the generator as a tracer so the

Table 22.7.3. Retorts 7 and 8 Chronology of Processing Events

Event	Retort 7	Retort 8
Rubblization blast	02-21-81	04-04-81
Ignition—First attempt	01-13-82	12-20-81
—Interruption by equipment failure	01-15-82	12-22-81
—Second attempt	01-25-82	12-24-81
—HIGG off, ignition complete	01-29-82	12-28-81
First oil recovered	03-02-82	01-10-82
Steam turned on (design: 20% Steam)	03-13-82	01-22-82
Inlet gas increased to design flow rate (0.54 scfm/ft² or 2.7 mm/s)	03-15-82	03-15-82
Offgas temperature moved above steam plateau	07-15-82	06-15-82
Offgas cooling spray turned on	08-30-82	07-08-82
Injection steam removed	10-02-82	10-01-82
Airflow reduced	10-08-82	10-08-82
Recycle gas injection started	10-21-82	10-15-82
Recycle gas injection terminated and water quenching started	11-19-82	11-09-82
Blowers turned off	01-07-83	01-07-83
Contact condensers turned off	02-28-83	02-28-83

onset of combustion at 750°F (400°C) could be monitored by the consumption of the tracer oxygen, that is, the disappearance of oxygen in the retort off-gas. At a generator firing rate of 100 million Btu (106 GJ) per hour, about 18 hours was required for the onset of ignition. The complete transition to air took about 6 hours, at which time the generator was shut down and moved to the next retort.

There were some operational problems experienced during the ignition of both retorts. About 20 hours after starting the hot inert-gas generator on Retort 8 (the first retort ignited), a failure of the blower system was experienced that required 2 days to correct. During this period, the quantity of heat resident in the void above the rubble bed caused the roof to continually slough. Nevertheless, after repair of the blower system, Retort 8 was successfully ignited.

In Retort 7, about 10 ft (3 m) of the roof above the rubble bed fell onto the rubble surface in Sept. 1981, four months before ignition was attempted. Pilot plant tests indicated that start-up procedures would be stretched only a few hours by this occurrence. About 20 hours after starting the generator on Retort 7, leaks caused by corrosion in the flue-gas pipe were discovered. These were located between the generator and the void above the rubble bed and required an ignition shut down for repair. Replacement of this stainless steel pipe required 10 days, during which time extensive additional sloughing of the roof above the bed occurred. As in Retort 8, after repair of the problem, Retort 7 was successfully ignited.

Operation of Retorts 7 and 8. After ignition, the retorts were operated without interruption until gas injection was terminated and water quenching began. A chronology of the significant milestones during processing is given in Table 22.7.3. Fig. 22.7.15 shows a simplified process flow diagram for operating the retorts. Air and steam were fed to the retorts through the inlet pipes from the surface. Sumps behind the product level bulkheads permitted the collection, separation, measurement, and sampling of the bulkhead oil and water pumped from each retort.

Separate off-gas lines from the bulkheads to the common off-gas raise permitted flow rate measurements and sampling of the off-gas from each retort. After transport to the surface, the off-gas was processed through three parallel contact condensers (three different sized units were tested to develop design data for commercial application). Suction blowers withdrew off-gas from the contact condensers and exhausted it to the stack, where the flow rate was once again measured and the gas discharged to the atmosphere by permit.

The off-gas from each retort and the stack gas were analyzed by on-line gas chromatography throughout the operation. Standard EPA isokinetic samples of the off-gas were collected for daily analysis from each retort at the product level bulkhead and from the combined off-gas at the base of the raise, top of the raise, exit of each contact condenser, and the stack. Stack isokinetic measurements were used to determine the daily barrel equivalent of uncondensed C_5+ hydrocarbons exhausted up the stack. Water and light oil recovered at the contact condensers were measured daily and sampled periodically for analysis.

About halfway through the processing life of the retorts, the off-gas temperature began to rise above the steam plateau. This behavior, observed in previous retorts, is essentially a result of nonuniform front advance through the retorts. This phenomenon exists in any retort (even one with an ideal flat reaction front and uniform permeability) with concentrated or localized off-gas drawports, but is accentuated in cases where the reaction front is non-uniform. When the off-gas temperature rises above 250°F (120°C), which represents the safe limit for the product level bulkheads, the retort processing must be terminated. This could result in a significant reduction in sweep efficiency and, therefore, a loss in total retort production. In order to extend the life of the retorts, a plan to cool the off-gas and reduce the thermal load on the bulkheads and downstream processing equipment was developed. The plan consisted of the following steps: (1) utilize a water spray system to cool the off-gas in the drifts behind the bulkheads, (2) reduce or eliminate steam in the inlet gas, (3) reduce the inlet flow rate, and (4) inject recycle gas instead of air. The plan was implemented on both retorts, as shown in Table 22.7.3. The offgas was continuously cooled to about 180°F (82°C). The retorts were thus not shut down because of off-gas over-temperature, and as a result, retorting was extended by about three months and the oil yield increased accord-

Table 22.7.4. Partitioning of Product Oil

	Barrels (ML)	Percent
Bulkhead oil	121,835 (19.4)	60.9
Condensed light oil	18,903 (3.0)	9.5
Uncondensed light oil	54,690 (8.7)	27.3
Oil in water	4,682 (0.7)	2.3
Total	200,110 (31.8)	100.0

ingly. This was particularly important for Retorts 7 and 8 because the bottom half of the retorts contained the richer "Mahogany Zone" shale.

SHALE OIL PRODUCTION FOR RETORTS 7 AND 8. The combined oil recovery from these retorts totaled 200,110 barrels (31.8 ML), representing over 70% yield of the Fischer assay oil in place in the rubble that was actually blasted. This oil production included oil pumped from the retort sumps, oil mists, and vapors condensed in contact condensers, condensable C_5+ vapors found in the stack gas, and a small amount of oil in the bulkhead water. The partitioning of the total product between these four streams is shown in Table 22.7.4. The properties of condensed light shale oil, collected from the off-gas stream at the contact condensers, were very similar to those of military specifications for No. 2 diesel fuel. During the operation of the retorts, this product was tested and performed satisfactorily as fuel, without upgrading, for diesel-powered mine equipment.

Cumulative production curves for each retort, as well as the total, are shown in Fig. 22.7.16. The bulkhead oil portion of the production was directly measurable for each retort. The production rates measured after combining streams from both retorts (i.e., light shale oil from the contact condensers, uncondensed C_5+ lost to the stack, and oil in the process waters) were partitioned between Retorts 7 and 8 in accordance with the isokinetic sampling results on the off-gas at the exits from the product level bulkheads. These partitioned values were added to the respective bulkhead oil production values to arrive at the curves for Retorts 7 and 8.

Table 22.7.5. Retorts 7 and 8 Retorting and Results

	Retort 7	Retort 8	Total

Yield, % Fischer assay	65.0	76.4	70.6

Source: Stevens and Zahradnik, 1983.

It is clear that these two retorts performed differently. If the curves are moved along the time axis to account for the nominal one-month difference in ignition time, it becomes evident that the production of Retort 7 deviated significantly from that of Retort 8 after about Oct. 1, 1982, that is, late in the operation of Retort 7. This is attributed to the fact that the efforts to correct the high pressure drop in Retort 7 prior to ignition were not completely successful. This could have caused distortion of the flow lines near the bottom of the retort resulting in reduced sweep efficiency.

It is believed that the stated average yield of 70% for these two retorts is on the conservative side since the results in Table 22.7.5 indicate a higher yield for Retort 8. The definition of yield used here has been used previously by Occidental and others for evaluating modified in situ retorting performance. The definition is based only on the rubble that was actually blasted in the retorts and does not account for oil residing in roof-sloughing rock and the retort walls that enters into the process. In other reports (Nelson, 1981; Bickel, 1983) where material balances are part of the analyses, contributions for the walls and roof shale are incorporated, resulting in somewhat lower yield values.

Chapter 22.8
MARINE MINING

MICHAEL J. CRUICKSHANK

This chapter covers briefly the technical aspects of mining in the continental shelf and in the deep ocean. Marine mining, as an industry, is influenced by a heterogeneous mix of international entrepreneurs, advanced engineering companies, politicians, environmentalists, legal experts, long-time dredge operators, and a few old-line mining companies. There is no question that the "industry," such as it is, is here to stay, and that many aspects of the work done to date have been serious and well founded. It is still too early to generalize about marine mining technology, and discussing each activity on a case-by-case basis appears to be the most reasonable approach at this time. Some order has been established, however mineral deposit types have been classified, mining systems have been categorized, and legal regimes have been established. Nevertheless, there is still much to learn, because despite the interest engendered in the last three decades, there are few operating mines offshore, and the likelihood of new ones may be as dependent on the foibles of the politicians as on the market place.

22.8.1 MARINE MINING ENVIRONMENT

The marine environment distinguishes marine mining from conventional mining. Not only are the ore deposits associated with a very dynamic and unpredictable overburden of ocean waters, but the nature of the deposits themselves may be largely a result of interactions between the ocean and geologic systems. Furthermore, the requirement to work in the oceans—about which we still know very little compared to the terrestrial environment—not only makes extraordinary demands on mining engineers but causes intense concern among those who feel that mining may threaten their livelihood or the environment in some way. Thus it is appropriate to present some of the considerations that must be made with regard to the environment (Table 22.8.1), for to ignore these aspects prior to initiation of any marine mining venture is to invite frustration, failure, and despair.

22.8.1.1 Natural Systems

These systems, which include the air, the water, the solid earth, and all living things, are controlled by nature, and activities directed at the extraction of minerals from the marine environment must be designed around them.

Weather is a significant factor in working in the oceans; bad weather can effectively stop marine operations for days or months on end. Its variability and low predictability require that systems be designed for "worst case" scenarios. The potential for weather-induced problems must be factored into technical and economic analyses, and adequate weather and sea-state information must be made available at all times. Climatic conditions at sea, like any other mining environment, range from tropical to arctic. The influence of weather conditions is different if the operation is located in the open ocean or close to shore. Storms may be less of a hazard in the open ocean; during the monsoons in southeast Asia, most nearshore mining operations are closed down. Air quality may be a significant factor in analysis of environmental impact, particularly in operations close to shore where terrestrially derived limits may be applicable.

Hydrologic systems involve not only the open ocean, which covers 70% of the earth's surface area, but also the waters of coastal areas, which may be fresh, brackish, or salt, and may present a wide variety of significant physical conditions. Nearshore conditions may also be influenced by coastal morphology, resulting in such phenomena as tidal bores, longshore currents, breaking waves, and current gyres that could affect operations. Beach and nearshore operations are particularly susceptible to the effects of storms and wave conditions, and tidal activity can present significant variations in depth during each working day as well as increasing the potential for wave and storm damage during the equinox. The presence of fresh water aquifers extending onto the continental shelf, although not themselves presenting any hazard, may constrain a mining operation if there is danger of contaminating the aquifer by the intrusion of saltwater. In the open sea, surface conditions are generally well known and understood in terms of waves and currents; but in deep water, variations occur in the nature, direction, and intensity of water movement throughout the water column. For example, in the Pacific, the Cromwell Current, just north of the equator, flows west at a depth of about 1000 ft (300 m) beneath the easterly flowing surface equatorial current with a net velocity difference of about 6 knots. Other such phenomena exist throughout the ocean's depths and must be recognized and considered in the design of any mining operation. On the bottom, currents with speeds of 1 to 2 knots are not uncommon, even in the deep ocean, and boundary waves are frequently encountered at the interface between stratified water masses of different salinity and temperature. These differences in water properties also affect acoustic and electrical properties utilized in geophysical sensing.

The geologic systems of the world provide a continuum between the seabeds of the deep ocean trenches and the tops of the mountain ranges on the five continents. The processes by which the varying parts are formed and placed in their present juxtaposition is at least partially explained by the modern theories of plate tectonics, confirmed only recently by advances in the technology and understanding of marine geology and geophysics. Traditional theories of local and regional geologic processes have not been upset, however, and are still valid in explaining coastal and submarine morphology, and the formation of mineral deposits on the continental shelf and in the deep oceans (Cruickshank, 1990; also see Chapter 4.2).

Biological systems in the marine environment are extremely diverse and not as well understood as those on land. The major considerations for mining are whether any negative effects of the proposed operations on living creatures will be significant. At the present time it appears that, compared with similar operations on land, marine mining is relatively benign. However, because of the scarcity of data, not only on the ecological systems in question but also on actual mining operations at sea, there is little substantiating evidence to legally support such claims. Extensive research on biological systems has been carried out on the US Continental Shelf under the Environmental Studies Program of the Minerals Management Service, and five environmental impact statements (EISs) addressing the possibility of leasing have been prepared (see 22.8.3.4, for example). Similarly, for the deep

seabed, EISs and other studies conducted during their preparation are available (Anon., 1981a).

22.8.1.2 Marine Mineral Resources

Known mineral resources in the marine environment are as varied as those on land. In quantitative terms, the lack of three-dimensional data leaves many of the published numbers for marine minerals in the realm of speculation. Nevertheless, it appears that with our rapidly improving knowledge and understanding of earth system dynamics, reasonable extrapolations, at least in orders of magnitude, can be made (McKelvey, 1986; Cruickshank, 1978; Mero, 1965). Recoverable marine mineral resources may well exceed those on land, and may constitute the ultimate source of mineral materials for economically and ecologically sustainable development for survival in the future.

Marine mineral deposits may be classified according to their physical state as in Table 22.8.2, which lists the resources as unconsolidated, consolidated, or fluid, because these properties most influence the technology used in their extraction. More particularly, the unconsolidated deposits are amenable to dredging while the consolidated deposits require the application of some additional energy source for their removal. In the same context, they are also subdivided by being “on” the seabed or “beneath” the seabed. A further dichotomy, based on both technical and legal aspects, describes the mineral targets as being on the continental shelf or in the deep ocean basins. Some minerals, such as phosphorites, are found in both environments. Table 22.8.3 describes some potential resources of minerals that have been indicated within seabed areas under US jurisdiction, and Fig. 22.8.1 shows the extensive distribution of seabed minerals throughout the world’s oceans and exclusive economic zones (EEZs).

For principles of mineral prospecting and exploration as well as project geology applicable to placer deposits, see Sections 4 and 5 and Chapter 15.1, of this *Handbook.*

TARGETS IN THE CONTINENTAL SHELF. The continental shelves are basically submerged continental lands, and contain the complete suite of mineral resources that are found onshore as well as deposits resulting from the overlying marine environment. Mineral deposits that have been worked on the shelf include glacial and alluvial sands and gravels, biogenic materials such as shell and coral sands, detrital mineral sands, phosphorites, indurated sedimentary beds laid down in shallow seas, and other hard rock deposits such as veins and massive deposits typical of a continental environment.

Marine *sands and gravels* are for the most part derived from erosion of the continents followed by transportation of the erosion products to the sea by glaciers and rivers where they are sorted by the action of the waves and currents; other sands are formed by marine processes such as the breakdown of shells or coral beds, or the formation of oolitic deposits of glauconite or phosphorite in shallow waters. All these materials are prolific throughout the marine environment, and shelf deposits of sand and gravel are the bases for major industries in Japan and the European North Sea. Marine *phosphorites* vary in character depending on their genesis and are found as sands, crusts, and nodules in shallow basins, on the slopes of islands, and in tropical lagoons. Very extensive deposits of bedded marine phosphorites of Miocene Age are indicated offshore of the eastern United States and other areas (Table 22.8.4). *Mineral sands* containing gold, diamonds, or minerals of tin (cassiterite), titanium (rutile, leucoxene, ilemenite), and other metals, derived from the breakdown of igneous rocks, are distributed widely throughout the coastal areas of the world, and many of them are recoverable at

Table 22.8.3. Minerals Potential Within the U.S. Exclusive Economic Zone

Potential Seabed Resources of Strategic Minerals Within the U.S. 200-Mile Exclusive Economic Zone

Area	Commodity
1. Offshore Maine	Transition metals, chiefly lead and zinc, in shallow lodes
2. New York Bight and coastal New Jersey	Titanium, chiefly as rutile and ilmenite, possible rare earths, in placers
3. Southeast Atlantic coast	Zirconium, some titanium, rare earths in coastal and buried strand deposits; rock phosphorite below seafloor
4. Blake Plateau	Low-grade, transition metals in ferromanganese nodules; nodules for catalytic and scrubber uses
5. Offshore Texas	Titanium, zirconium, rare earths in tag placers off Corpus Christi; sulfide metals in salt dome cap rock lodes
6. Gulf of Mexico, continental slope	Probable disseminated metal sulfides in intraslope basins
7. Offshore California	Fine gold placers nearshore, particularly Crescent City area; possible platinum off northern California; phosphorite on offshore banks
8. Offshore Oregon-Washington	Chromium and platinum in shallow marine placers; transition metal sulfides in Juan de Fuca-Gorda rift (major exploration in progress, 1983)
9. Alaska coastal and shelf waters	Barite in shallow lodes in inlets of southeastern Alaska; platinum and gold in marine sands, southeastern Alaska; lode copper beneath Prince William Sound; platinum, gold, chromium in coastal placers between Cape Newenham and Kuskokwim River; gold, tungsten, rare earths, and tin in coastal placers, Yukon Delta to Bering Strait; coastal gold placers in Chukchi Sea north of Lapp Lagoon
10. Hawaii, offshore area	Ferromanganese crusts with manganese, possibly transition metals
11. Commonwealth of Puerto Rico, offshore	Disseminated metal sulfides in slope deposits on south side; minor gold placer on north shore
12. American Samoa	Offshore mineral potential unknown, but regional geologic setting suggests possible phosphorite and sulfide metals
13. Isolated Pacific islands, including Line Islands	Cobalt-rich manganese crusts on island flanks; possible transition metals, at depth, in manganese nodules
14. Commonwealth of Northern Mariana Islands and Guam	Sulfide metals off western side; possible sulfur boil deposits of transition metals off Tinnian and Saipan; local phosphorites; volcanic-related minerals in north
15. US waters of the Great Lakes	Lode copper deposits in Lake Superior; ferromanganese pellets in Green Bay, Lake Michigan; other areas unexplored for mineral resources

Source: J.R. Moore in Mangone, 1984.

the present time (Telecki et al., 1985). In many cases, the deposits have been concentrated by high-energy coastal processes and reworked, buried, or exposed during passage of the littoral zone between high and low stands of sea level. Although many nearshore deposits are known, the outer shelves are virtually unexplored, and indications of high-energy activity near the shelf edge during earlier periods of low sea level suggest a high potential for deposit formation in these areas. Improvement in the characterization of still-stands of sea level would assist in the identification of these resources.

TARGETS IN THE OCEAN BASINS. The structure of the ocean basins beyond the continental shelves consists mostly of basaltic seabeds interspersed with oceanic ridges, island arcs, continental remnants, and volcanic islands or seamounts. Overlying sediments are normally sparse in the areas of high relief and thicker in older and deeper areas. They derive mostly from erosion of adjacent continents and islands or from the skeletons of marine creatures, and in deep water may form fine granular deposits of foraminiferal (calcareous) or diatomaceous (siliceous) oozes. Other muds may be formed from the precipitation of minerals dissolved in hydrothermal fluids in the vicinity of diverging oceanic plate boundaries. Mineral deposits such as manganese nodules, cobalt crusts, and metalliferous sulfides are recent discoveries resulting from the study of deep ocean basins and seabed dynamics. Phosphorites in the tropical oceans and other mineral types yet to be discovered may play a significant part in the inventory of marine resources.

The first discovery of *manganese nodules* was made by the expedition of HMS Challenger in 1873. The nodules are potato-like encrustations of iron and manganese oxides, formed around a small nucleus, at depths usually between 17,000 and 20,000 ft (5000 and 6000 m). The minerals carry enrichments of cobalt, nickel, copper, and other metals scavenged from the seawater and represent a significant resource of some of the metals. Distribution of the nodules is widespread throughout all the oceans of the world (Anon., 1981c), but the areas of highest grade known at this time are in the Pacific Ocean between the Clarion and Clipperton fracture zones about 1200 mi (1930 km) west and south of Hawaii (Fig. 22.8.2). Of similar composition but occurring on the submerged portions of islands or seamounts between 2700 and 8000 ft (800 and 2400 m) are encrustations of metalliferous oxides known as *cobalt crusts.* These carry higher values of cobalt and platinum, up to 1.4% and 0.93 ppm, respectively, in certain cases, and they are also associated with phosphorus and rare earth elements. The crust deposits are widely distributed in the Pacific (Fig. 22.8.3) and with thicknesses ranging to 16 in. (400 mm), they may also represent a significant resource of the contained metals (Manheim and Lane-Bostwick, 1989, Table 22.8.5).

More recently discovered and of equal interest are the *metalliferous sulfides* that are formed in the vicinity of active plate boundaries throughout the world's oceans (Fig. 22.8.4). These deposits potentially occur in many different forms from surficial muds to deep seated masses at various depths beneath the seabeds (Table 22.8.6). They are generally formed by the interaction of superheated seawater with fractured crustal rocks, in convection cells caused by the intrusion of new or subducted plate materials, and they may be host to almost any of the metals, including copper, lead, zinc, silver, and gold, each of which has been reported in significant values from sampled outcrops on the seabed (McMurray, 1990; Scott, 1987). Although some of the deposit types postulated have not yet been located, their discovery is highly likely. Mineral deposits preserved within the crust or overlying sediments of moving plates may be carried to other locations within the ocean basins, and many examples are now found on land as the result of upthrusting of colliding plates (Sawkins, 1990).

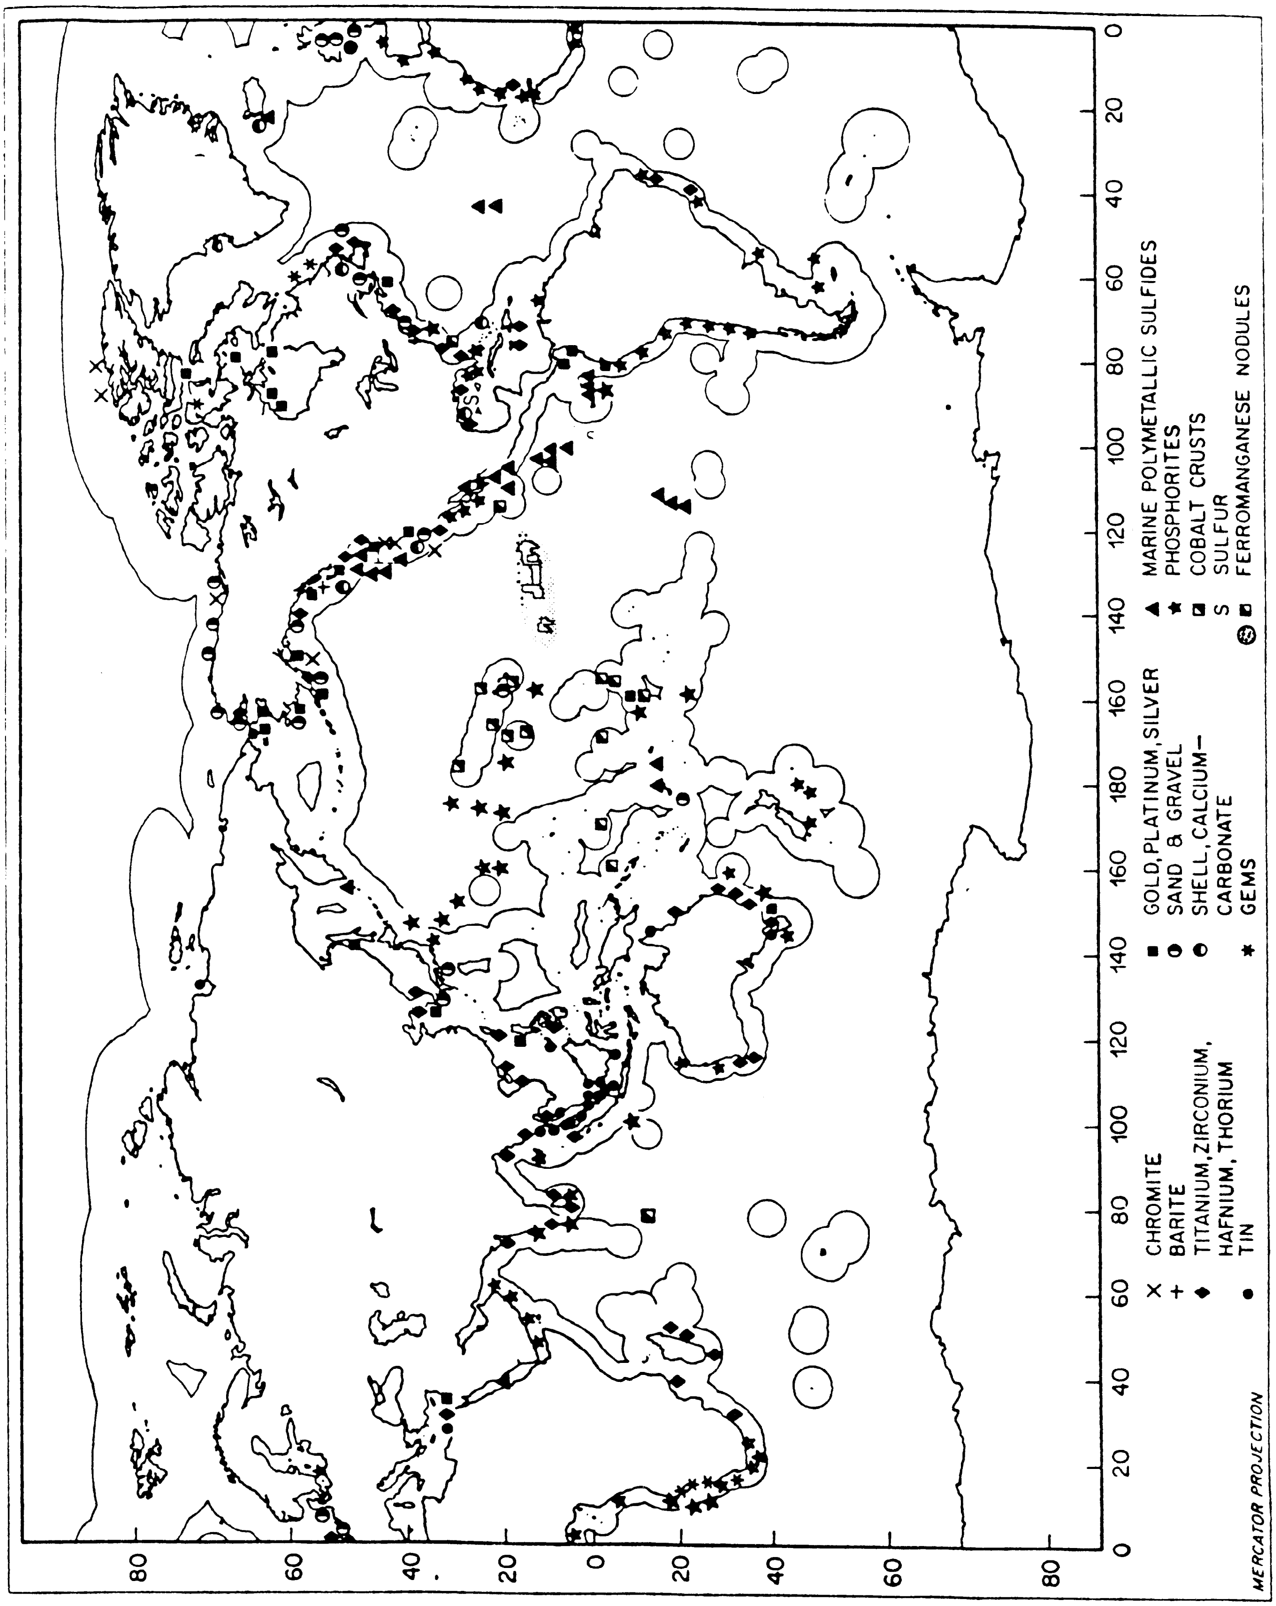

Fig. 22.8.1. World distribution of seabed mineral deposits (after Hoagland and Broadus, 1987).

Table 22.8.4. Distribution of Phosphorites in Miocene Sediments Along Continental Margins

Continental Margin	Region
East Atlantic	Portugal, Northwest Africa through South Africa, and Agulhas Bank
West Atlantic	North Carolina through Florida, Cuba, Venezuela, and Argentina
East Pacific	California through Baja California, Mexico, and Peru through Chile
West Pacific	Sakalin Island, Sea of Japan, Indonesia, Chatham Rise east of New Zealand, and East Australian shelf.

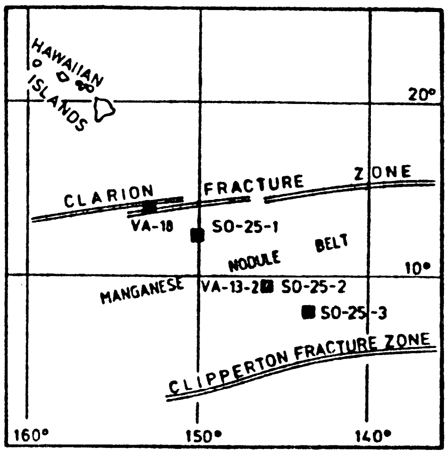

Fig. 22.8.2. Belt of high-grade manganese nodules between Clarion and Clipperton fracture zones in the Pacific Ocean (Teleki et al., 1985).

Ocean waters may represent the most significant source of minerals for sustainable recovery on the planet and include nearly all the known elements in some degree of solution. Fresh water springs are found offshore of many areas on the continental shelf, and high-temperature hydrothermal vents found at spreading centers around 10,000 ft (3000 m) of water depths are potential sources of enriched solutions of metals as well as heat energy. Current production of dissolved materials from seawater is limited to magnesium, magnesium compounds, salt, bromine, and heavy water (deuterium oxide), but the potential for extraction of materials from naturally enriched seawater sources may be high, and the resource is extremely large.

22.8.1.3 Artificial Systems

Unlike the natural systems, which are controlled by nature, artificial systems are artifacts of human society and have evolved in various ways to support human needs. Although theoretically changeable, the process of change may be very cumbersome. Some of the factors that have a strong impact on marine mining development are discussed below.

SOCIO-ECONOMIC FACTORS. Socio-economic factors are generally those supposedly involving the public good and may have very different connotations in a market economy as opposed to a centrally planned economy where the benefits and costs of any action may be evaluated under different rules (Chapter 3.1). Even in the area of environmental concerns, priorities may be set according to different baselines, particularly where poverty is an overriding factor in the economy. With certain bulk commodities such as sand and gravel, the market price is usually set locally based on specific needs. Metal markets, which drive the projected economics of most placer deposits and deep seabed minerals, are world markets that are not generally affected by the output of individual mines (Chapter 2.3). Major exceptions arise, however, in the examination of market effects of manganese nodules and crusts (Anon., 1986).

Without operating data, the benefits and costs of marine mining are not easily computed, as many interacting factors may affect the outcome and many of these cannot be easily quantified. Such analyses are extremely useful, however, and have been well described in the literature (Cruickshank, 1978). In most countries of the world, environmental impact analyses are required before commencing to develop mining operations offshore (Chapter 3.4). In the United States and Europe particularly, strict laws and guidelines prevail. Regulations for the United States under the National Environmental Policy Act (NEPA) are found in *Code of Federal Regulations,* CFR, Title 40, 1500-1508. Examples of impact statements for specific actions are discussed in 22.8.3.4.

LEGAL-POLITICAL FACTORS. Legal and political boundaries may be quite different from geologic and geographical boundaries. The outer continental shelf has several meanings in the United States, depending on whether it is referred to the AGI Glossary of Geology, the 1958 Convention on the Continental Shelf, the United Nations Law of the Sea Convention of 1980, or the 1983 United States Proclamation on the *Exclusive Economic Zone* (EEZ). The most significant legal boundaries of the oceans date from the 1980 Convention and include the 200-nautical mi EEZ, and The Area, (or International Seabeds), encompassing all seabeds beyond the jurisdiction of any state (Holser, 1988). Mining of the resources in The Area will come under the jurisdiction of the International Seabed Authority, headquartered in Jamaica. Examples of new EEZs and mineral occurrences in other countries in the Pacific are given in Cruickshank and Kincaid (1990).

In the United States, offshore mining operations within the EEZ are carried out under the authority of the Outer Continental Shelf Lands Act of 1953 (amended 1978) and accompanying regulations 30 CFR 280 for prospecting, 30 CFR 281 for leasing, and 30 CFR 282 for operating. Activities directed to the development of manganese nodules in The Area are authorized by the Deep Seabed Hard Mineral Resources Act of 1980, and accompanying regulations 15 CFR 971 for exploration, and 15 CFR 270 for commercial recovery. The Acts are administered by the Department of Interior's Minerals Management Service (MMS) and the National Oceanic and Atmospheric Administration (NOAA), respectively. Additional laws and regulations are followed with respect to potential environmental impacts, and these are discussed in the final programmatic environmental impact statements for gold mining off Alaska (Anon., 1990a) and for deep seabed mining (Anon., 1981a).

Typically, the laws of foreign countries relating to marine minerals are much simpler than those of the United States and generally are of the prospecting permit variety. In some states, there are no mining laws, and all concessions are granted on the basis of negotiations with the government. Any extensive research into the mining laws of another country should include contact with the appropriate desk of the country involved in the US Departments of State and Commerce. Consulates and embassies do not usually prove to be a fruitful source of information, particularly for developing nations (Krueger, 1969).

* MPM refers to crusts from the Mid-Pacific Mountains and Line Islands Ridge, at water depths of 2,600 m or less. MIDPAC refers to samples from all depths encompassed in the MIDPAC 81 cruise (n = 61; Halbach et al., 1982). NB refers to abyssal manganese nodules from the nodule belt area in the NE Pacific. Approximate ore abundance is 20 kg/m² for the crust deposits and 10 kg/m² for the abyssal nodules. Molybdenum metal values for the concentrations are taken from previous studies (Craig et al., 1982). Metal prices are for May 1983 (*Source:* Erzmetall 36 (1983) p. 397). Decimals are for computation only.
Recent trace element determinations of ferromanganese crust samples from MIDPAC 81 have shown that platinum may reach concentrations of up to 1.0 g/t (average content 0.5 g/t; range 0.3–1.0 g/t). This might be of additional commercial interest since presently mined platinum-bearing ores have contents of 1–2 g/t of platinum.
** Manganese (99.95%).
***Ferromanganese (78% Mn) recalculated to 100% Mn basis.
Conversion factors: 1 lb = 0.4536 kg, 1 ft = 0.3048 m, 1 ft² = 0.0929 m².

22.8.1.4 Environmental Hazards and Constraints

In the design of systems for marine mining, the possibilities of encountering hazards or other environmental constraints must be assessed early in the design process.

Natural hazards to operating in the marine environment appear in a variety of forms including high winds such as hurricanes or typhoons; freezing rain or snow; heavy swells, breaking waves, tsunamis, waterspouts, submarine countercurrents, and storm seas; slumping, turbidity currents, volcanic activity, and hydrothermal mega-events; fish attacks; and natural seawater toxicity.

Mitigation of potential environmental impacts can be a major concern in the design process and appropriate measures must be designed for and implemented. These matters will be considered in detail in the environmental impact analysis prepared before the commencement of operations. The potential impacts of a deepwater dredging system are illustrated in Fig. 22.8.5, and

Table 22.8.6. Metalliferous Sulfide Deposits Potentially Associated with Moving Plate Boundaries

Nature of resource model	Depth of occurrence	Examples: Seabed	Land	Grade upper 10%	Tonnage (median)	No. of deposits examined[a]
Geothermal energy	0–1.5 km	Active zones	Salton Sea			
Hot-vent fluids	Surficial	Active zones	Salton Sea			
Metalliferous muds	0–30 m	Red Sea	?	Cu 0.45, Zn 2.07, Au 0.5, Ag 30	664×10^6	1
Volcanogenic sediments (Mn)	Surficial	DSDP hole	Numerous	Mn 49, P 0.03	47×10^3	93
Surficial precipitates						
Individual stacks or mounds	Surficial	Active zones	?			
Coalesced stacks or mounds or cemented tallus	Surficial	Active zones	?			
Subseabed precipitates

avoidable and unavoidable impacts are summarized in Tables 22.8.7 and 22.8.8. For more detailed information, see the environmental case studies in 22.8.3.4.

22.8.2 TECHNOLOGY FOR MARINE MINING

22.8.2.1 Land-based Infrastructure

Marine operations need land bases, and the development of these follows the same principles applied to the development of any shoreside marine facility and will use existing infrastructure where possible. The availability of utilities, transportation facilities and services, and adequate space for docking, processing plants, and land disposal of waste are critical to marine operations. These are discussed in detail and referred to in a number of documents (Anon., 1983c; Cruickshank, 1988; Anon., 1990a).

22.8.2.2 Prerequisites for Marine Operations

Certain aspects of working in the oceans are common to all activities whether they are carried out for mining, oil and gas recovery, fishing, commerce, or defense. In basic terms, these include a vessel, a source of power, an understanding of the weather, a chart, a way to keep position, and a means of communication. Advances in technology for these systems are mostly driven by activities other than mining, and standard references are available, but where they are specifically relevant to minerals, state-of-the-art systems are discussed (Cruickshank and Marsden, 1973).

SHIPS AND PLATFORMS. There are three basic functions of platforms used in marine mining, namely, the support of equipment for observation and measurement, the support of tools and equipment for working with seabed materials (mining), and the transportation of personnel and materials. Platforms may be (1) airborne, floating, submerged, or in contact with the bottom; (2) self-propelled or stationary; and (3) manned or unmanned. Floating-platform size ranges from massive bucket ladder dredges weighing upward of 20,000 tons (18,000 t) to an individual diver weighing a few tens of pounds (kilograms). The design of marine platforms is a very specialized subject, and consideration of different factors is required for floating platforms and for platforms in contact with the bottom. Detailed design and construction generally are performed by the builder's yard, and include the preparation of working drawings, construction and launching. Roorda and Vertregt (1963) describe the design and construction of floating dredges in Europe for civil engineering purposes, and Scheffauer (1954) deals similarly with seagoing hopper dredges in the United States. There is no such treatise on mining dredges, but the reader is referred to Chapter 15.1 on placer mining and to other references at the end of that chapter dealing with dredge design.

Platforms in Contact with the Bottom—These do not as yet constitute a major requirement in marine mining plant design

Table 22.8.7. Avoidable Impacts of Marine Mining and Responsible Authorities in US

Potential Environmental Impacts	Avoidance/Mitigation Strategies	Relevant Federal Legislation/Authority: Statute	Regulations	Requirement	Agency
1. Deposition of dredged or fill material in waters of the United States and contiguous wetlands	Utilize upland disposal areas, contain spoil	Clean Water Act* (33 U.S.C. 1344)	33 CFR 323	Minimize deposition in wetlands and waters	COE/ EPA/ States
2. Interference with federally designated Marine sanctuaries	Avoid existing or potential Marine sanctuaries	Marine Protection-Research and Sanctuaries Act of 1972 (16 U.S.C. 1432–1433)	15 CFR 922	Preserve and protect Marine Sanctuaries	DOC
3. Interference with state designated Estuarine Sanctuaries	Avoid existing or potential Estuarine Sanctuaries	Coastal Zone Management Act of 1972 (16 U.S.C. 1461)	15 CFR 921	Preserve and protect Estuarine Sanctuaries	DOC/ States
4. Interference with historical and/or archaeological sites, structures, or objects	Perform adequate historic and archeologic surveys, avoid designated sites and structures	National Historic Preservation Act (16 U.S.C. 470f) Preservation of Historical & Archaeological Data Act (16 U.S.C. 469–469b). Exec. Order No 11593	36 CFR 800 36 CFR 800	Review by state and Federal officials to preserve and protect historic and archaeologic sites	State/ ACHP
5. Jeopardizing existence of endangered or threatened species or adversely modifying their habitats	Perform adequate biological surveys, avoid endangered species habitats	Endangered Species Act (16 U.S.C. 1531–1541)	50 CFR 17 50 CFR 222, 226, 227 50 CFR 402	Review to protect endangered and threatened species	All federal agencies FWS/ NMFS/ States
6. Harassment or "incidental taking" of marine mammals	Perform adequate biological surveys, avoid critical areas	Marine Mammal Protection Act (16 U.S.C. 1361–1382)	50 CFR 18 50 CFR 215–225	Protect marine mammals	FWS/ NMFS/ States
7. Increased risk of loss from or damage by flooding	Locate structures outside flood hazard areas	Exec. Order No. 11514 Exec. Order No. 11988	— —	No practicable alternative to encroaching on flood plain	All federal agencies
8. Destruction or modification of wetlands	Locate all development outside wetlands	Exec. Order No. 11990	—	Minimize effect on wetlands	All federal agencies
9. Conflict with designated Wilderness Areas	Locate away from designated Wilderness Areas	Wilderness Act* (16 U.S.C. 1131–1135)	43 CFR 19 36 CFR 293 50 CFR 35	Protect and preserve Wilderness Areas	DOI
10. Conflict with designated wild or scenic rivers	Locate away from designated Wild or Scenic Rivers	Wild and Scenic River Act (16 U.S.C. 1271–1286)		Protect and preserve Wild and Scenic Rivers	DOI
11. Conflict with Prime and Unique Farmland	Avoid areas of designated prime or unique farmland	16 U.S.C. 590 a–f	7 CFR 657	Protect Prime and Unique Farmland	USDA
12. Release of toxic or hazardous materials as a result of flood tsunami, hurricane, or seismic activity	Avoid natural hazard areas	Clean Water Act* 33 U.S.C. 1321 (c)(2) Resource Conservation and Recovery Act (42 U.S.C. 6901)	40 CFR 1510 40 CFR 260–267	Oil and hazardous substances spill contingency planning	EPA/CG

* The reader should note that the following are subject to the EPA consolidated permit program 40 CFR 122–125, 45 F.R. 33287–33558 (May 19, 1980):
—Resource Conservation and Recovery Act (Hazardous Waste Management Program)
—Safe Drinking Water Act (Underground Injection Control Program)
—Clean Water Act (National Pollutant Discharge Elimination System and Dredge and Fill Programs)
—Clean Air Act (Prevention of Significant Deterioration Program)

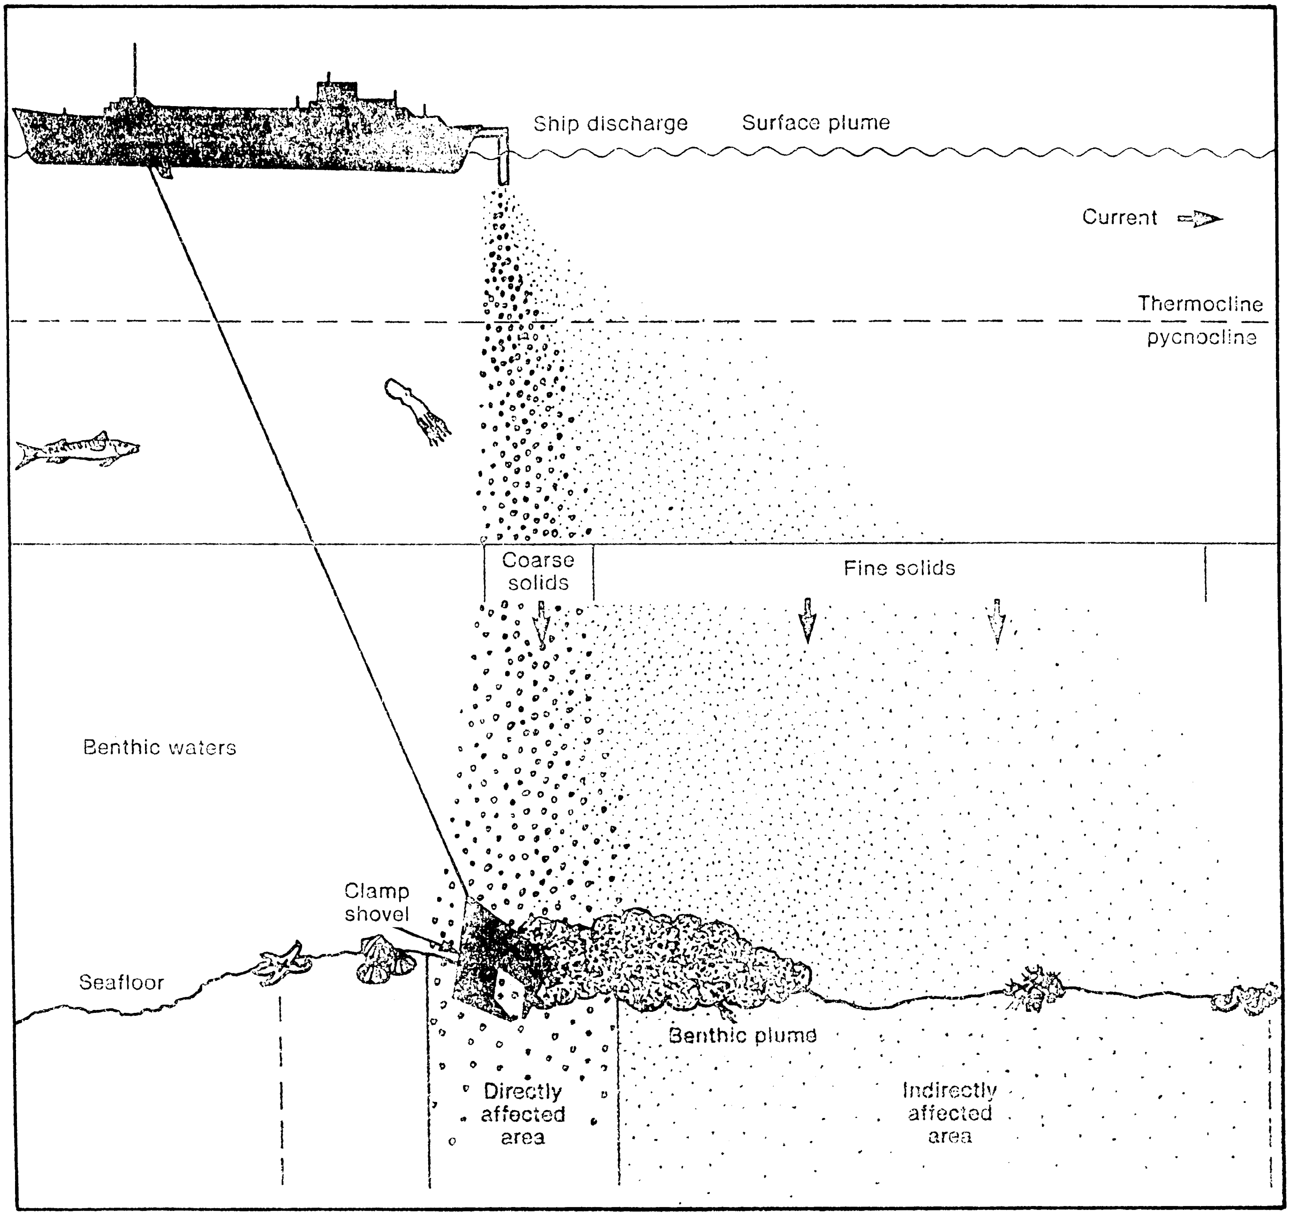

Fig. 22.8.5. Impacts of offshore mining on the marine environment (Anon., 1987a).

but are likely to be more important in the future, particularly for remote mining vehicles in deep water. In shallow water offshore, stationary platforms are used in the extraction of sulfur by the Frasch process and in the development of underground mines from artificial islands. In addition to the environmental considerations discussed for floating platforms, the design of fixed offshore structures should provide for extraneous loads due to earthquakes and for reduction in structural integrity due to fatigue and corrosion (Dean, 1969).

Acquisition of Platforms—Although construction of new platforms to suit each particular task is technically desirable, conversion of existing platforms is often necessary for other reasons. This mostly applies to ships, which may be purchased in used condition, or chartered on a bare boat, fully found or intermediate basis. Chartering of vessels for ocean operations requires specialized knowledge to insure the acquisition of an appropriate vessel and to avoid the assumption of unknown liabilities. Inexperienced charterers can find that they have obligated themselves to assume very large expenses of which they were unaware. Sometimes these may not even be properly chargeable to them. To protect themselves, charterers should always use the services of a competent admiralty attorney before making any commitment (Smith and Holm, 1969).

Conversion of seagoing vessels to mining dredges has been described by Boonyaprabhatsorn (1966), Webb (1965), and others, but none have had notable success. The trade-off of conversion or new construction should be considered very carefully in a production operation where the additional stress of mining excavation is added to those of seakeeping, or vice versa.

The costs of operating platforms at sea vary widely. Table 22.8.9 is useful as an indication of ownership costs for coastal vessels. Costs for mining vessels should be examined on a case-

Table 22.8.8. Unavoidable Impacts of Marine Mining and Responsible Authorities in US

Activity/Facility	Potential Environmental Impacts	Possible Mitigation Strategies	Major Relevant Federal Legislation: Statute	Regulations	Requirement	Agency
1. Transhipment from port to plant						
1.1 Channel and dockage	Marine traffic congestion, accidents	Improved navigation and traffic control	Ports and Waterways Safety Act (33, U.S.C. 1221–1227)	33 CFR 160–165	Conformance with safety regulations	USCG
	Dredging, bottom disruption	Optimum location and timing	Rivers and Harbors Act of 1899 (33 U.S.C. 403)	33 CFR 322	Permit	COE
	Modification of waters		Fish and Wildlife Coordination Act (16 U.S.C. 661–665)	50 CFR Part 470 Regulations reproposed 45 F.R. 83412, 12/18/80	Coordination	COE/FWS/ NMFS States
	Land use conflicts	Conformance with local land use plans	Coastal Zone Management Act of 1972 (16 U.S.C. 1456)	15 C.F.R. 930	Consistency with state Program	DOC/States
1.2 Marine terminal and transportation system	Construction noise	Equipment design and shielding	Noise Control Act (42 U.S.C. 4901–4917)	40 CFR 204 (const. equipment)	Conformance to equipment standards	EPA
	Operating noise	Buffer zones, quiet operations			Local controls	
	Dust	Containment and treatment	Clean Air Act* (42 U.S.C. 7410)	40 CFR 50–81	Conformance to standards, permits, monitoring, modeling.	EPA/States
	Liquid effluents	Containment and treatment	Clean Water Act* (33 U.S.C. 1311–1321, 1341–1345)	40 CFR 104–142	Conformance to standards, permits	EPA/States
	Land use conflicts	Conformance with local land use plans and coastal management programs	Coastal Zone Management Act of 1972 (16 U.S.C. 1456)	15 CFR 930	Consistency with state programs	DOC/States
2. Processing						
	Noise	Equipment design and shielding	Noise Control Act (42 U.S.C. 4901–4917)	40 CFR 204 (constr. equipment)	Conformance to equipment standards	EPA
	Dust, gaseous emissions	Process design, containment, and treatment; avoidance of "non-attainment" areas and Class I (pristine) areas	Clean Air Act* (42 U.S.C. 7401–7643)	40 CFR 50–81	Conformance to standards, permits, monitoring, modeling	EPA/States
	Liquid effluents	Process design, containment, and treatment	Clean Water Act* (33, U.S.C. 1311–1321, 1341–1345)	4 CFR 104–142	Conformance to standards, permits	EPA/States
	Energy consumption	Conservation, use of coal and/or other alternative fuels	Power Plant and Industrial Fuel Use Act of 1978 (92 Stat. 3291–3314)	18 CFR 285	Use of coal and/or other alternative fuels in new large power plants	DOE
	Land use conflicts	Conformance with local land use plans and coastal management program	Coastal Zone Management Act of 1972 (16 U.S.C. 1456)	15 CFR 930	Consistency with state programs	DOC/States

	Exposure to toxic or hazardous materials	Process design, containment, and treatment	Hazardous Materials Transportation Act (49 U.S.C. 1804–1806) Toxic Substances Control Act of 1976 (15 U.S.C. 2604–2627) Resource Conservation and Recovery Act* 42 U.S.C. 6901	41 CFR 171–179 40 CFR 715 et seq. 40 CFR 125? 40 CFR 260–267	Minimize exposure to toxic and hazardous materials	EPA/DOT
	Erosion and sedimentation, particularly during construction	Design and construction standards		40 CFR 260–2667	Local controls	EPA
3. Waste disposal 3.1 Onshore	Aquifer contamination	Optimum disposal area location, design and operation	Safe Drinking Water Act* (42 U.S.C. 300h–00i) Resource Conservation and Recovery Act (42 U.S.C. 6901)	40 CFR 146 40 CFR 260–267	Conformance to standards for underground injections	EPA/States
	Dust	Surface treatment of landfill, containment and treatment	Clean Air Act* (42 U.S.C. 7410)	40 CFR 50–82	Conformance to standards, permits, monitoring, modeling	EPA/States
	Contamination by toxic solid wastes	Optimum disposal area location, design, and operation	Resource Conservation and Recovery Act* (42 U.S.C. 6901–6979)	40 CFR 260–267 seq. 30 CFR 60?	Conformance to standards, permits	EPA/States
	Liquid effluents	Optimum disposal area location, design and operation; containment and treatment	Clean Water Act* (33 U.S.C. 1311–1321 1341–1345) Resource Conservation and Recovery Act (42 U.S.C. 6901)	40 CFR 104–142 40 CFR 260–267	Conformance to standards, permits	EPA/States
	Fossil fuel consumption	Energy conservation	Energy Supply and Environmental Coordination Act 15 U.S.C. 792		Regulate the use of oil and gas by power plants and other major fuel-burning installations	DOE
	Land use conflicts	Conformance with local land use plans and coastal management programs	Coastal Zone Management Act of 1972 (16 U.S.C. 1456)	15 CFR 930	Consistency with state programs	DOC/States
3.2 Offshore	Marine traffic congestion, accidents	Improved navigation and traffic control	Ports and Waterways Safety Act (33 U.S.C. 1221–1227)	33 CFR 160–165	Conformance with safety regulations	USCG
	Water pollution, bottom deposition, benthic smothering	Deposit well offshore in deep water, over infertile bottoms	Marine Protection Research & Sanctuaries Act of 1972 (33 U.S.C. 1411–1418)	40 CFR 220–229	Permits	EPA/COE?

* The reader should note that the following are subject to the EPA consolidated permit program 40 CFR 122–125, 45 F.R. 33287–33558 (May 19, 1980)

Source: Anon, 1966.

by-case basis, and the use of used vessels might be considered (see 22.8.3). A new 5500-ton (5000-t) capacity, 330-ft (100-m) suction hopper dredge for sand and gravel mining in the UK was priced at $18 million (Anon., 1990b), whereas total systems costs for manganese nodule mining operations have been projected at upward of $1 billion.

Power Sources. Power sources for use in marine mining operations are subject to many of the same limitations applying to remote areas on land. Selection of the optimum power source must be weighed against the following factors:

1. Amount of power required, including peak power and sustained load.
2. Availability of suitable generating equipment.
3. Cost.

Power sources for marine use are many and varied and are constantly being improved. Most existing mining operations offshore use conventional power sources such as portable diesel electric generators on dredges and central power plants in land-connected undersea mines. There is a trend to the use of gas turbine generators in the offshore oil industry, and these should be considered in any similar mining venture.

Table 22.8.10 indicates the magnitude of the power source required for some actual mining operations compared with some conceptual operations. The trade-offs between high-voltage ac and high-voltage dc also should be considered with regard to transmission loss. The use of nuclear energy has been discussed for future marine mining operations by Duckstad (1959). For submerged instrumentation and measurement, many portable power sources are available (Victor, 1970; Anon., 1968), and a reliable and continuous supply of power aboard floating platforms is available from conventional sources.

Environmental Forecasting. Forecasting of the weather conditions likely to be encountered is essential to the safe conduct of operations. The best long-range estimates of future environmental conditions are provided by statistical summaries of past occurrences. Such climatological information commonly is presented in atlas form. Table 22.8.11 lists some of the more available and useful references that provide similar information for other characteristics and parameters. In addition to material and information contained in the references, more detailed information may be obtained by writing to the director, National Oceanographic Data Center, Washington, DC 20390, or to the director, National Climatic Center (previously called National Weather Records Center), Ashville, NC 28801. If the information is not already available in processed or printed form, and if the observational data are available, processing of data in a required format is available to the requester at cost.

Climatological atlases can provide a general insight into the gross conditions expected in the area but do not provide detailed enough information for design or planning for specific locations.

Table 22.8.10. Power Requirements for Some Dredge and Land Mining Operations in Horsepower per Ton per Hour Throughput

Description	Annual Capacity, Tons	Installed Power, Hp	Hp/Ton*
Conventional Dredging (1–200 ft)			
Bangka 1, bucket dredge (135 ft)	7.6×10^6	3,600	3.4
Franciscan hydraulic "30" (52 ft)	19.0×10^6	10,800	4.4
Dinosaur grab dredge (174 ft)	3.6×10^6	2,000	4.0
Neumann bucketwheel (33 ft)	21×10^6	2,000	5.0
Deep Dredging (200–600 ft):			
Conceptual	$6–10 \times 10^6$	5–10,000	6.0–7.2
Deep Ocean Dredging (10–20,000 ft)			
Conceptual	$2–3 \times 10^6$	85–135,000	300.0
Bottom-Situated Mining System			
Conceptual	2.4×10^6	5,000	12.0
Surface Open Pit			
Toquepala, Peru	5.7×10^6	177,000	6.2
Mt Goldsworthy, Australia	2.5×10^6	NK	3.0
Underground			
Strasser, Sweden	1.5×10^6	—	11.2
Easton mine, UK	0.52×10^6	1,340	19.0

*Throughput per hour.

Such information usually requires a detailed analysis of original observational data and theoretical computations.

If very specialized information is needed, the services of a competent consultant may be desirable. Some professional societies, such as the American Meteorological Society, maintain lists of certified consultants. When the duration of local observations is not adequate, theoretical diagnostic procedures or "hindcasting" similar to those used in short-range forecasting may be applied. The accuracy of hindcasting can be improved significantly when actual local observations are available for a duplicate time period. These become even more important when short-term forecasting is planned or when high accuracy is needed. Therefore, an observation program should be established as soon as possible. The program may vary somewhat according to the information needed but generally should include a six-hour minimum frequency of observation.

Techniques for marine environmental observation are not standardized and should be developed on an as-needed basis.

NAVIGATION AND SURVEY SYSTEMS. Minerals operations at sea require access to maps and charts at an appropriate scale. These are usually available from local sources or from international suppliers as indicated in Table 22.8.11.

Nearly all navigation and survey at sea is now carried out electronically in real time. Only on very minor projects near to shore, where costs must be held to the absolute minimum, are the time-honored methods of navigation or survey, using compass, sextant, and lead line, utilized. Electronic positioning systems are available in a wide range of capabilities and costs (Anon., 1983a), but continuing advances in global positioning systems (GPSs) may render many of these obsolete.

The GPS is a satellite-based radio navigation system that provides worldwide three-dimensional coordinates and, since its introduction in the United States in 1983, its growth has been phenomenal. It is based on simultaneous range measurement to several satellites, which can provide instantaneous navigational accuracy positions and also, with little additional observational or computational effort, high-precision measurements (Hodges, Johnson, and Bingley, 1988). Due to the high accuracy, simplicity, and relatively low cost (under $5000 for the basic receiver in 1990), the GPS is likely to supersede all other methods used at sea at distances beyond line of sight.

Where accurate positioning is needed for seabed operations, positioning transponders must be located on the seabed and surveyed in from the platform or from a submersible.

POSITIONING AND CONTROL. Maintaining and relocating the position of a vessel or platform at sea to any degree of accuracy is a complicated operation even under ideal conditions. Some of the factors that affect this position maintenance are

1. Sea state (wave heights, periods, etc.).
2. Sea-floor properties (type, strength, etc.).
3. Weather (wind force, etc.).
4. Anchor (type, size, holding power, etc.).
5. Mooring lines (cable and chain, etc.).
6. Mooring configuration (three-point anchoring, eight-point, etc.).
7. Vessel characteristics (size, natural periods, etc.).
8. Tensions in mooring lines.
9. Currents (speed, direction).
10. Electronic equipment (computer, sonar, etc.).

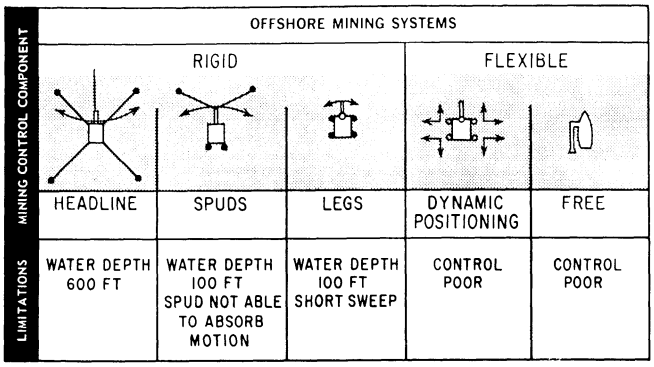

Fig. 22.8.6. Methods of dredge anchoring for mining system control. Conversion factor: 1 ft = 0.3048 in.

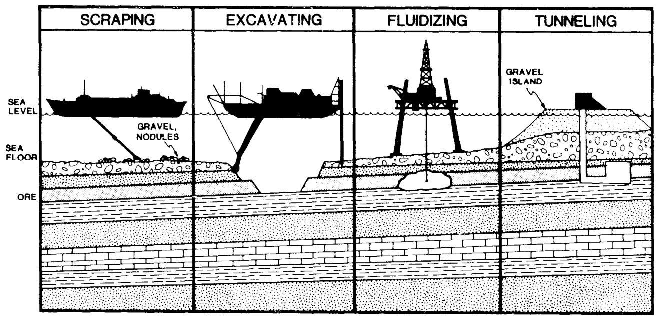

Fig. 22.8.7. Four basic methods of marine mining.

11. Vessel propulsion system (number of engines, horsepower, rating, type, bow thrusters, etc.).

Some of these factors are known, some are estimated, and some will have to be determined with models if the accuracy of the position is to be maintained within a few feet (meters) under a variety of sea and weather conditions.

For more detailed discussion of the different aspects of position control at sea, the reader is referred to Brink and Chung (1981), Graham, et al, (1969), and Macy (1966). Weigel (1964) lists 61 additional references.

Some methods of dredge anchoring for mining systems control are illustrated in Fig. 22.8.6. Deep-ocean mining dredges are not anchored, and because of the great depth, control of the mining device in a towed system is a major problem. The use of a self-propelled miner alleviates most of these problems but requires a much more complex system (see 22.8.3).

COMMUNICATION AND DATA PROCESSING. Communication between the operating platform and all other parts of the operating system, including the shoreside office, are prerequisites for successful operations at sea. Most communication problems have been resolved on the surface by the use of satellites, but some difficulties are still apparent in communication with remotely operated equipment in deep water. The use of fiber optics has been a major advance where tethered vehicles or equipment are employed (Anon., 1988).

Seabed mapping capabilities have been advanced considerably since the 1960s. Wide-swath mapping using side-scan sonar, similar to radar imagery, has been effected over large areas at rates of up to 10,425 mi^2 (27,000 km^2) each day. Detailed bathymetric mapping is now feasible using a variety of multibeam systems, giving horizontal and vertical accuracy within a few feet (meters) at a depth of 17,000 ft (5000 m). These methods are well summarized by the US Office of Technology Assessment (Anon., 1987), and other references are given therein.

Mineral exploration and mineral deposit characterization are both of paramount importance in the development of marine minerals. The reader is referred to some of the excellent treatises on this subject in which advances are constantly being made (Anon., 1987; Teleki et al., 1985; Cronan, 1986; Johnson, 1986).

22.8.2.3 Marine Mining Systems

There are four basic methods of mining solid minerals: (1) scraping or planing the surface, (2) excavating a pit, (3) removing them through a borehole in the form of a slurry or solution, and (4) tunneling into the deposit (Fig. 22.8.7). All deposits on land are mined by one or more adaptations of these methods, and marine mining is amenable to the same basic approaches whether on the continental shelf or in the deep seabeds. Each mining method has variations that may be tailored to a specific situation, and most of the deposit types can be mined by more than one method. Similarly, any one method can be applied to more than one deposit type (Cruickshank, 1978).

Marine mineral deposits, at or near the surface of the seabed, can be gathered by mechanical devices that scrape the seabed and gather the ore for lifting to the surface or for other treatment. In its simplest form, the action is like raking or shoveling or, in some cases, vacuum cleaning. Where a thick layer of hard material is present, the scraping action may be preceded by ripping or cutting. Mineral deposits lying wholly or partially beneath the seabed may be removed by excavation. The applicable mining methods range from those designed to recover free-flowing materials to those for excavating solid rock. Certain types of deposits may be mined by borehole methods using superheated water or high-pressure jets to transform the ore into a fluid or slurry, which is removed by pumping. In other cases, the minerals may be selectively leached and the valuable constituents recovered in solution. Deposits buried too deeply to excavate from the sea floor may also be mined by conventional underground mining methods using shafts and adits for access and ventilation, either from shore or from natural or artificial islands. The seabed location of these mines only slightly adds to the conventional problems of access, safe overhead cover, and ventilation.

This section further explains each of the mining systems listed on Table 22.8.12 and notes types of deposits with which it is normally used. For references describing commercial operations using these mining systems, see Cruickshank and Marsden (1973) and Cruickshank (1973).

SCRAPING. Although there are many variations, there are basically four mining systems that may be used to scrape the surface of the seabed. Two are wholly mechanical and two involve hydraulic action to lift the mined materials.

Dragline Dredge—Dredges of this type are used in offshore mining and deep seabed sampling, as well as in construction. Their use has been advocated for the recovery of seabed nodules and slabs of phosphorites (Mero, 1965). The material would be recovered by large dredge buckets that scrape slabs and nodules from the surface of the deposit and feed them into barges for transportation to shore (Fig. 22.8.8). Annual production at such an outer continental shelf (OCS) mine for phosphorite could be on the order of 400,000 tons (360,000 t), or roughly 180,000 yd^3 (138,000 m^3) of ore. This rate of production could involve a 50-yd^3 (38-m^3) bucket scraping an average of 20 tons (18 t) of phosphorite from the seabed every 20 min in a water depth of about 600 ft (180 m).

At an average abundance of 20 lb/ft (9 kg/m), nearly 2 mi^2 (5.2 km^2) of seabed would be mined annually. At a mine life of

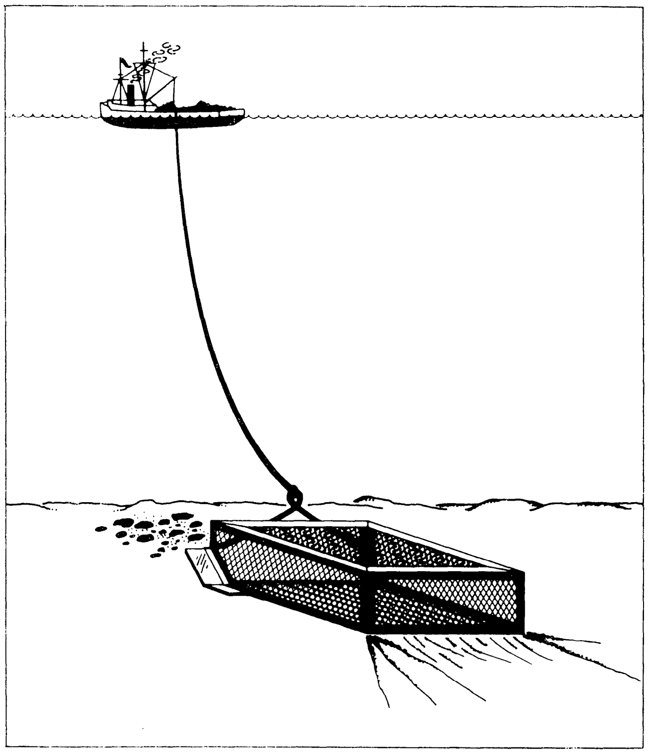

Fig. 22.8.8. Deep-water dragline dredge.

20 years, a total of 40 mi^2 (104 km^2) would be affected if the deposits were confined to the surface of the seabed.

Trailing Suction Dredge—A suction hopper dredge uses a pump to draw a slurry of bottom water and sediment into a riser or pipe leading to the mining vessel. As the sediment accumulates in the hopper, the water decants overboard. This system is used primarily for maintaining harbor channels. However, it is also used extensively for mining sand and gravel in water depths up to 120 ft (36 m) in the North and Baltic Seas (Padan, 1983). New vessels, such as the ARCO Avon launched in 1986, are designed to extend mining capability to depths of 150 ft (45 m) (Drinnan and Bliss, 1986). As its name implies, this type of dredge mines while in motion, creating numerous shallow trenches in the seabed, commonly about 3 ft (1 m) wide and 1 ft (0.3 m) deep (Fig. 22.8.9).

The trailing suction dredge uses one of several types of drag head with a coarse-grid steel framework across the opening of the suction head to prevent large rocks from entering the suction pipe. Coarser particle sizes are screened out and rejected after passing through the pump. Fine materials are washed overboard with the slurry overflow. In some cases, vibrating screens allow part of the sand fraction to be dumped back into the ocean, since the ratio of sand to gravel mined may differ from the desired marketable mix.

The use of sand and gravel as construction material requires that stringent measures be taken to avoid mining any clay layers, since the entire shipload could be contaminated and unmarketable. Additional detail on the equipment used and extensive photographic documentation are given by Hess (1971).

The volume of material that may be mined includes the sum of the marketable material, the fraction to be rejected, and the overburden initially stripped away. For example, in moving 1 million tons (0.9 Mt) of product to shore annually, an equal amount of sand might be rejected to reduce the sand/gravel ratio from 70:30 to a more marketable 40:60 (Anon., 1975). The 2 million tons (1.8 Mt) of annual excavation would result in a gradual lowering of the ocean floor by about 2 ft (0.6 m) over an area of 1 mi^2 (2.59 km^2) or about 2.1 million yd^3 (1.6 Mm^3).

Trailing suction dredges, modified for great depths, have also been used in tests to mine manganese nodules. Operating characteristics for this application are well documented (Anon., 1981a; Anon., 1984) (Fig. 22.8.10). Two basic systems or combinations use airlift or hydraulic lift with towed or self-propelled collectors. The complexities of the design for these systems are illustrated in Fig. 22.8.11 for a hydraulic lift with self-propelled collector as used by Ocean Mining Co. during successful tests in the Pacific.

Continuous Line Bucket Dredge (CLB)—This system (Fig. 22.8.12) has been tested for possible future use in recovering manganese nodules (Masuda et al., 1971) and is described in NOAA's EIS for deep seabed mining (Anon., 198 la). The CLB has also been proposed for mining phosphorite nodules and slabs and for cobalt crust mining; the original CLB system used one ship, empty buckets going down from the stern, and partially filled buckets coming in at the bow. The distance between the downward-moving and the upward-moving parts of the loop of the rope is dependent on the length of the ship and thus cannot be altered. Entanglement can be avoided by achieving an optimum combination of the ship speed and the length of the line or by the use of hydrodynamic deflectors. But the optimum combination may be disturbed by various other factors: the nature of the seabed, underwater currents, variations in the ship's course because of weather heading, or bad weather conditions.

To minimize these disadvantages, and to add to the flexibility of operation, a two-ship system has been designed where the empty buckets go down to the seabed from one ship and are brought up to a sister ship nearby. The distance between the descending and ascending parts of the loop and the curve of the loop can be influenced by the relative positioning of the two ships (Anon., 1984).

Crust Miner—Recent interest in manganese oxide crusts containing relatively high values of cobalt—and in some cases platinum—has led to proposals to develop the deposits. The manganese crusts vary in thickness from mere stains to layers about 15 in. (380 mm) thick and cover a variety of substrate rocks ranging from hard basalt to weak hyaloclastite. The physical properties of the crusts are similar to a hard coal, and they occur extensively in the Pacific on seamounts and submarine ridges at depths between 2600 and 7800 ft (800 and 2400 m). Mining systems proposed for this work include a vessel equipped with hydraulic lift systems and active bottom miners (Halkyard and Felix, 1987). The proposed system would be capable of breaking and removing the thin crust from the underlying rock and feeding it to a hydraulic lift system through a hydrocyclone to separate entrapped substrate (Fig. 22.8.13). The roughly cleaned ore would be pumped to the surface vessel for further cleaning and transport to shore.

Modular Mining System—In this system, an autonomous collector vehicle is launched with ballast material such that the weight in water of the ballast is equal to the weight in water of the nodules to be collected. The collector is designed to have sufficient buoyancy so that the vehicle is weightless in water. Thus, in descent, thrusters propel the unit down steadily against hydrodynamic resistance alone. The collector is propelled over the bottom, and as collection proceeds, ballast material is simultaneously ejected on an equal weight in water basis. In this manner, a small net weight in water of the collector is maintained. Mining is terminated shortly before ballast material ejection. Ballast material ejection is continued until the weight of

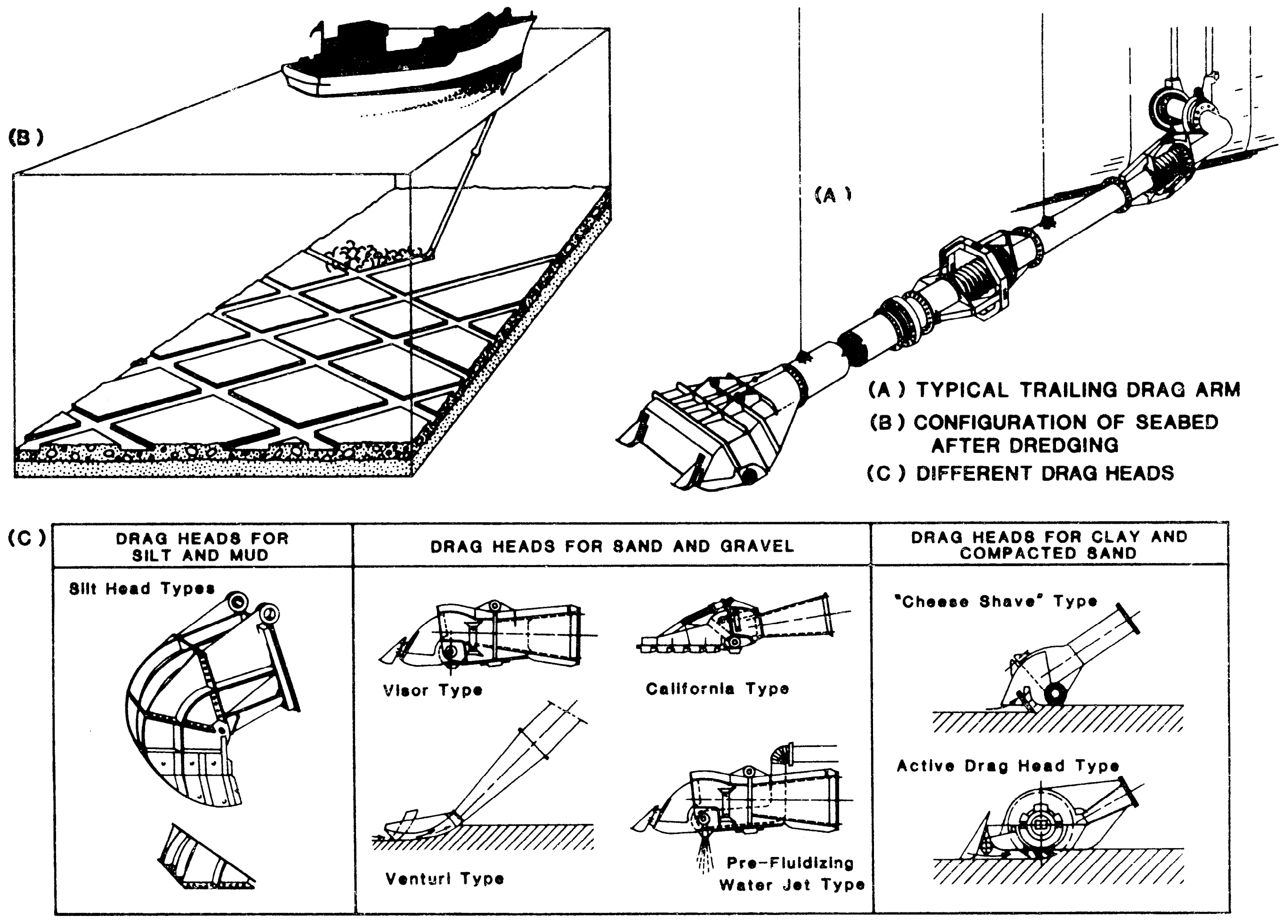

Fig. 22.8.9. Trailing suction hopper dredge and various drag heads.

the vehicle is zero or slightly negative. Finally, the vehicle is propelled by thrusters to the surface, docked with the surface ship, unloaded, serviced, and re-ballasted for a new mining cycle. In theory, very little onboard power is required to collect the nodules because the major source of energy is the potential energy of the ballast material. The operating principle of this system is illustrated in Fig. 22.8.14 (Anon., 1984). Processed tailings have been suggested for use as ballast. Advantage might be taken of ambient currents to propel the vehicle similarly to a sailplane or glider.

EXCAVATING. Mineral deposits that are located mostly within or under the seabed may be removed by excavation. These deposits include thick deposits of sands; metalliferous muds; layered or disseminated deposits of unconsolidated placer minerals or overlying bedrock; and deposits of consolidated minerals in vein, tabular, or massive form, which may extend for considerable distances into the bedrock. The mining system used will depend largely on the ease with which the material may be excavated and removed from its surrounding environment, the water depth, and the ocean climate in the area of operations (Cruickshank et al., 1969). Six examples of seabed mining operations are presented here that range from the excavation of free-flowing materials to the excavation of hard rock (also see Chapter 15.1).

Clamshell Bucket—Clamshell buckets have been used to mine sand and gravel in Japan and tin in Thailand, and to sample phosphorite off New Zealand. The buckets are mechanically actuated to bite into the seabed and remove material (Fig. 22.8.15). The need for multiple cables to actuate the grabs can cause complications, particularly in heavy seas where wave compensating devices may also be needed. Moreover, the clamshell is inefficient in clearing bedrock of fine materials. It is best suited for excavation of large-size granular material where accuracy of positioning and cleanup is not important. The size of buckets may range from a few cubic feet (cubic meters) to as much as 10 yd^3 (7.6 m^3).

Bucket Ladder Dredge—The bucket ladder consists of a chain of closely connected buckets mounted over a heavy digging arm or ladder (Fig. 22.8.16). It is most efficient for excavation of deposits containing boulders, clay, and/or tree stumps and weathered bedrock. Dredges of this type have been used successfully all over the world for mining gold, tin, and platinum placers and diamond deposits, although their use offshore has been limited to gold and tin. They are frequently used for clearing harbors because of their capability for digging into broken rock and coral. The bucket ladder delivers a virtually water-free product to the mineral processing plant on board the dredge. Discharge of water from the shipboard operations is limited to that needed to concentrate the valuable constituents by techniques based on the use of flowing water to remove the less dense materials. In the case of gold, the bulk of the concentrate recovered is only a few parts per million so that virtually all the material removed from the deposit is returned to the seabed.

Considerable turbulence accompanies these operations, which may involve the movement of up to 6.4 million yd^3 (4.9 Mm^3) of material per year. Bucket ladder dredges are limited

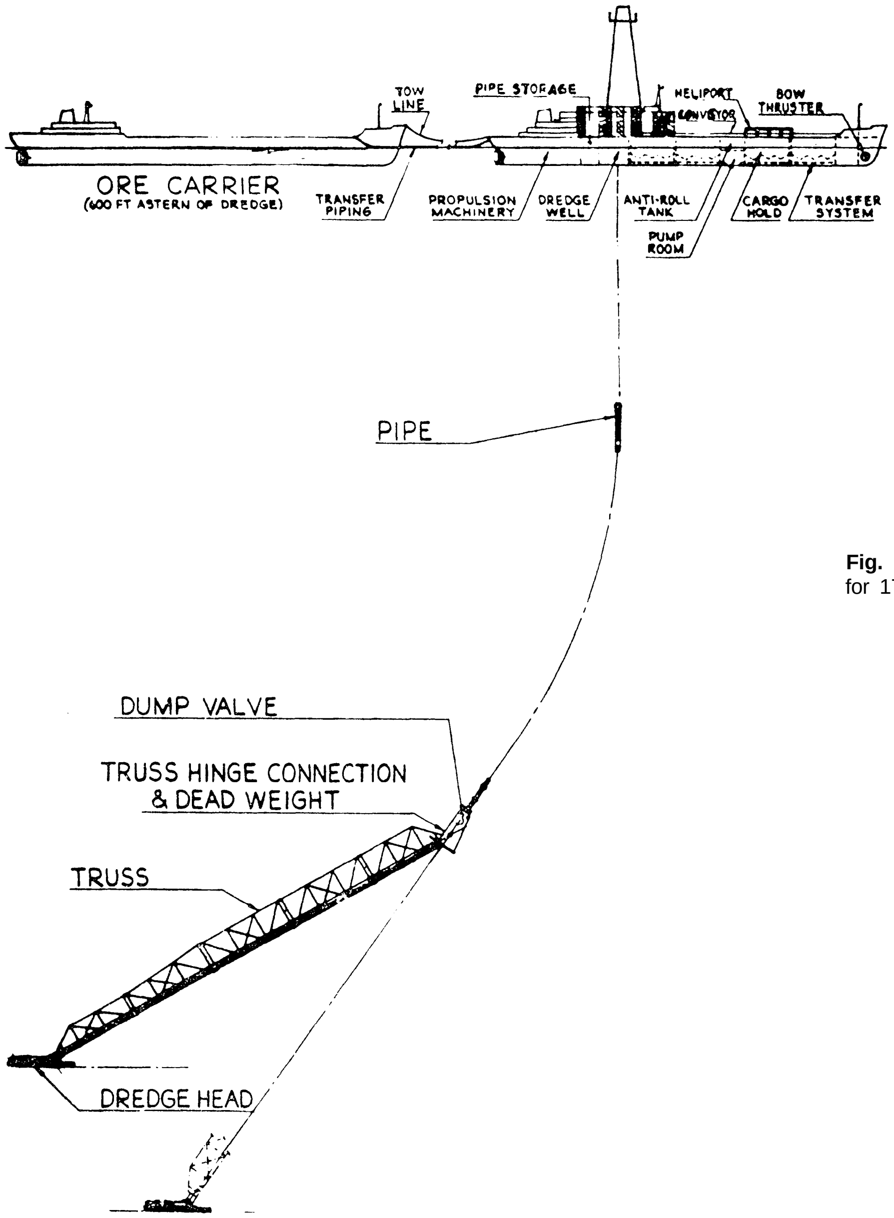

Fig. 22.8.10. Trailing suction hopper dredge for 17,000-ft (5000-m) water depth (Kaufman et al., 1985).

to depths of about 150 ft (45 m) and rarely operate at depths over 65 ft (20 m). Few of these dredges have been built for offshore mining in the last 20 yr, and it is likely that they will be superseded by the bucket wheel suction dredge.

Bucket Wheel Suction Dredge—Bucket wheel dredges use a small-diameter bucket wheel mounted on the suction ladder to excavate material. This combines the best aspects of the bucket ladder and suction dredges (Fig. 22.8.17). Very high torque or digging power can be applied to the wheel, which can deliver the excavated material directly into the mouth of a suction pipe for transport to the sea surface. Digging capability is equal to that of the bucket ladder with respect to ease of digging and bucket capacity, while the depth capability using submerged pumps is almost unlimited. The combination of simultaneous digging and suction at the seabed provides the option to either treat the ore on the vessel or pipe it to shore.

Stationary Suction Dredge—Anchored suction dredges (Fig. 22.8.18) are widely used in Japan for mining sand and gravel at depths less than 100 ft (30 m). These dredges have been used in Britain as well, although the vessels built since 1980 are virtually all trailing suction dredges (Drinnan and Bliss, 1986).

In contrast to the trenches left by trailing suction dredges, anchored suction dredges leave pits in the seabed. An anchored suction dredge has also been tested for mining metalliferous muds at a depth of 6500 ft (2000 m) in the Red Sea (Fig. 22.8.19). Mining involved the conversion of a deep drilling oil exploration vessel (the SEDCO 445) to carry a specially designed mud pump and delivery pipe that was lowered to the seabed in a manner similar to the lowering of a drill pipe. The pump was vibrated into the mud with a waterjet to fluidize the material and the ore pumped to the ship for treatment (see also 22.8.3.2).

Cutterhead Suction Dredge—Typically, cutterhead suction dredges are used to excavate fairly compacted, granular materials in water less than 100 ft (30 m) deep. The rotating cutterhead is usually an open basket with hardened teeth or cutting edges, somewhat like an over-sized dentist's drill (Fig. 22.8.20). The

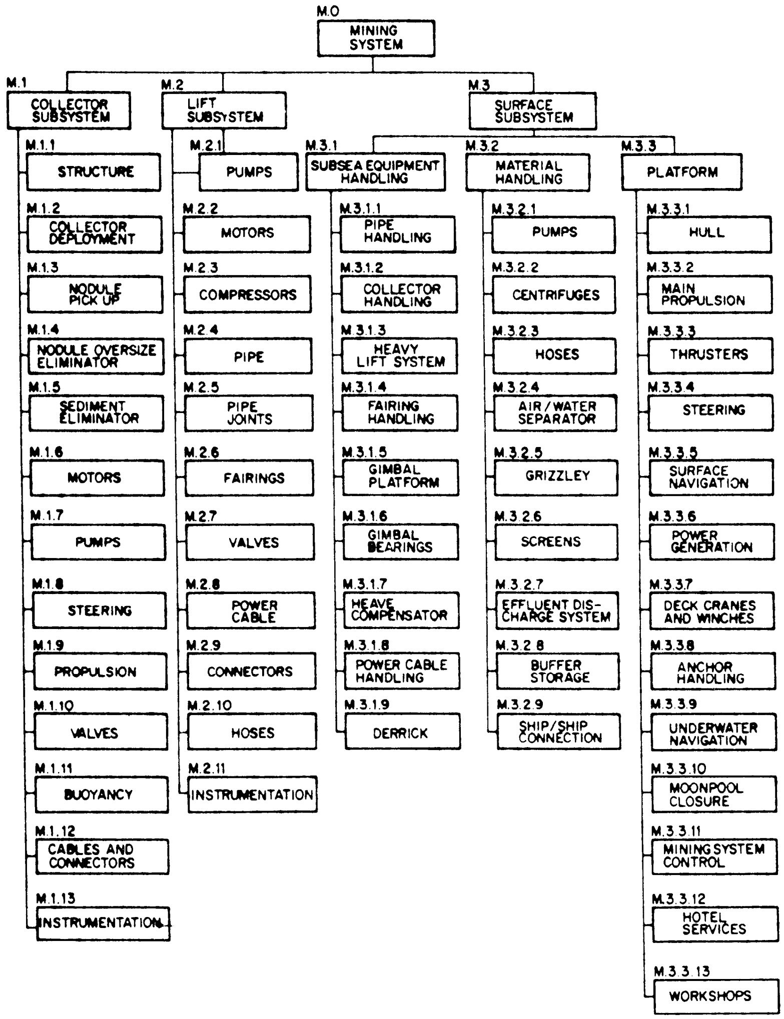

Fig. 22.8.11. Schematic of subsystems required for deep seabed suction dredge with self-propelled miner (Anon., 1984).

end of the suction pipe is normally located within the basket. In standard practice, the dredge is swung back and forth in an arc pivoted from a large post or spud attached to the stern. The dredge cutterhead cuts downward a short distance with each swing. Because the cutter rotates in one direction only, the bite is much stronger on one swing than the other. In mining for heavy mineral sands, the action of the cutter tends to disintegrate the material, allowing heavy minerals to separate, fall below the cut, and be left on the seabed. Cutter suction dredges have never been used successfully for mining gold, although they have been widely used for mining cassiterite (tin placers) in west Thailand where the deposits are rich enough to economically sustain the inefficient cleanup.

Suction dredges circulate large quantities of slurry that must be decanted on board the dredge or pumped ashore by pipeline. In either case, there is a significant discharge of water containing fine particulate materials. Treatment of the decanted solids may be unnecessary for construction sands and gravel but may be required for heavy minerals. The valuable constituent or concentrate from these ores will rarely amount to more than a small percentage of the materials mined. Therefore, more than 95% of the material dredged from such deposits must normally be disposed of either at the mine site or the shoreside treatment site.

The cutterhead suction dredge may also be equipped with a multiblade ripper to cut into moderately consolidated rock. Present use is limited to the excavation of soft rock, such as coal and shale. However, advances in rapid tunneling technology suggest that rock cutterheads could be designed for medium strength rocks, such as sandstone and limestone (Hignett and Banks, 1984; also see Chapters 9.1 and 22.1).

Drilling and Blasting—Deposits that are too hard to excavate by dredging must be broken by other means. The normal system for excavating hard-rock deposits is to drill into the deposit for the placement of explosives. Fracturing using highly pressurized fluids is also possible (Chapter 22.3) but would represent a very special case and is not considered here. Blasting of the material is only an intermediate step and would be followed by the gathering and lifting of the ore by one of the methods previously described. Blasting operations are designed to expend as much force as possible on fragmenting the ore so the water column effects are much lower than those from equivalent unconfined explosions.

With respect to the possibility of mining deep-seabed deposits that require fragmentation, many more aspects need to be examined. Technically acceptable means of drilling and fragmenting hard rock in deep water have not yet been developed. However, methods of gathering and lifting the fragmented material may be assumed to be similar to the methods developed for deep-seabed nodule mining. For drill-blast coverage see Chapter 9.2.

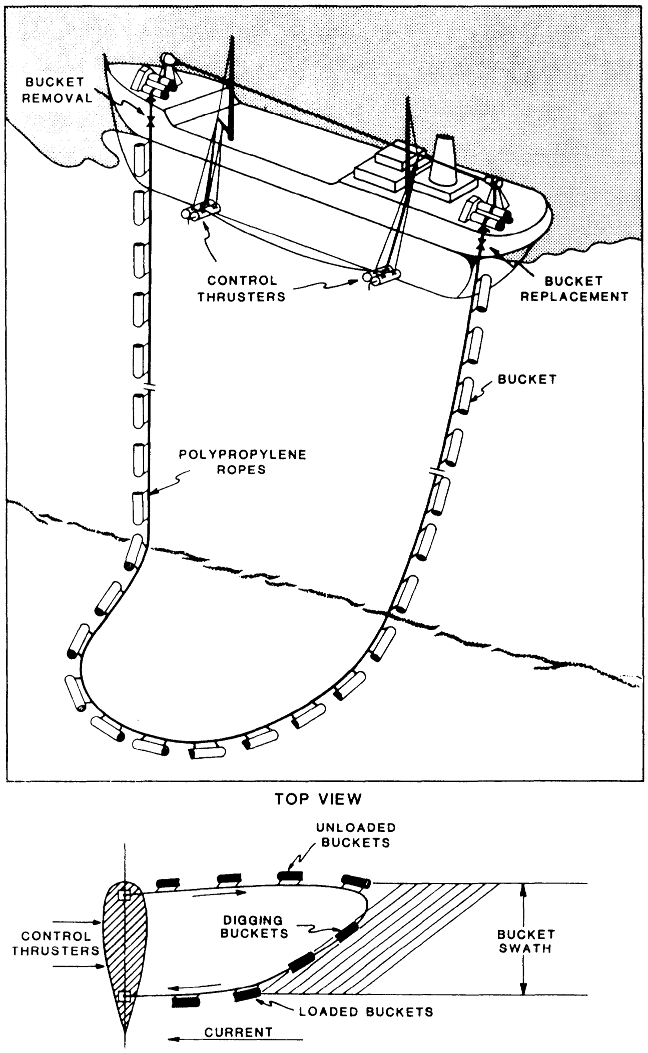

Fig. 22.8.12. Continuous line bucket dredge (Masuda et al., 1971).

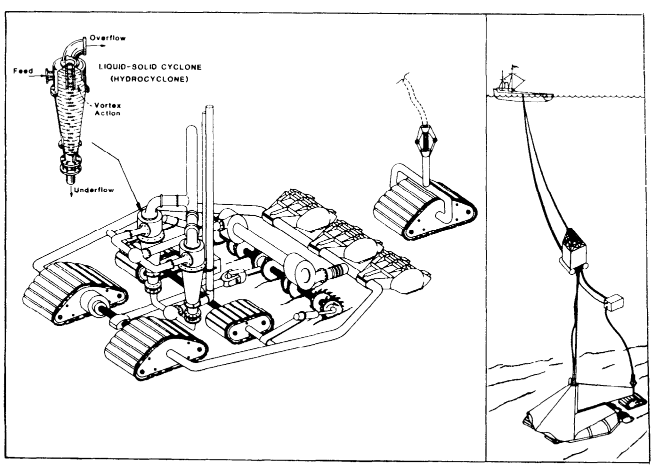

Fig. 22.8.13. Proposed deep-seabed cobalt crust mining machine (after Halkyard and Felix, 1987).

FLUIDIZING. *Fluidizing (Slurries).* Under proper conditions, certain types of unconsolidated or marginally consolidated mineral deposits may be mined as a fluid slurry through drillholes penetrating the sea-bed (Chapter 22.4). Sub-seabed sand was mined in this way in shallow waters offshore Japan in 1974 (Padan, 1983) and recent onshore experiments in Florida proved the capability of this approach in recovering phosphate from beneath thick overburden (Fig. 22.8.21). In the recovery of sulfur, super-heated water is pumped into the deposit to melt the sulfur so that it may be pumped out of the ground (see Chapter 15.3.2).

Fluidizing (Solutions)—Hard rock deposits that are amenable to hydrometallurgical treatment of their ores are potentially extractable by fluidizing methods (Fig. 22.8.22). The valuable constituent is dissolved in place, and the pregnant solution is removed through a borehole (Chapter 15.3). There are major unsolved problems in dealing with toxic or corrosive solvents used to enlarge fractures to provide a flow path for the solvent through the deposit and to selectively extract the desired metals in complex ores.

These problems are being overcome on land, however, and the methods developed there should be applicable in more sophisticated form to seabed deposits.

Effects of accidental spills of solvents would depend on the nature of the solvents and the sites impacted. They could be localized so long as the solvent is water soluble because of the rapid dilution prevailing in the oceans and the buffering capacity of seawater. However, the pollution potential cannot simply be ignored.

TUNNELING BENEATH THE SEA FLOOR. Underground mining by tunneling is commonly practiced in subsurface hard rock. In certain cases, sub-seabed deposits of bedded coal, potash, and ironstone, as well as veins of lead, copper, and tin have been mined by conventional underground methods. Entry to these mines is either from the shore or from natural or artificial islands in shallow waters (Fig. 22.8.23). The location of the mines in the seabed only slightly adds to conventional problems of access, safe overhead cover, and ventilation. The effect on the environment is similar to that for any shoreside mine. The possibility of developing underground access through seabed airlocks has been considered for special cases (Austin, 1967).

MINING OF METALLIFEROUS SULFIDES. Possible methods for mining the deep seabed deposits of metalliferous sulfides are indicated in Table 22.8.13.

22.8.2.4 Processing of Marine Ores

There are two areas in which the processing of marine ores calls for special treatment as distinguished from the processing of terrestrial ores. One is the effect of platform motion on separation processes carried out at sea; the other is in the extraction of metals from specifically marine ores such as manganese nodules and crusts. Some industrial materials such as specialty sands may require washing to remove saltwater, but for the most part, marine ores do not otherwise differ from those on land and use conventional methods of treatment.

Materials handling in the marine environment is complicated by the motions of the platform and the need in most cases for closed cycle systems and stringent controls to avoid spillage or contamination. These issues are normally addressed in the environmental analyses that are a part of the planning process. For offshore dredging systems, the reader is referred to Chapter 15.1 on placer mining; in the case of deep seabed mining, the problems would be addressed on a case-by-case basis.

SEPARATION PROCESSES. Processing technology applied to placer materials has been fairly well established over the years (Chapter 15.1). Due to the conservative nature of the industry,

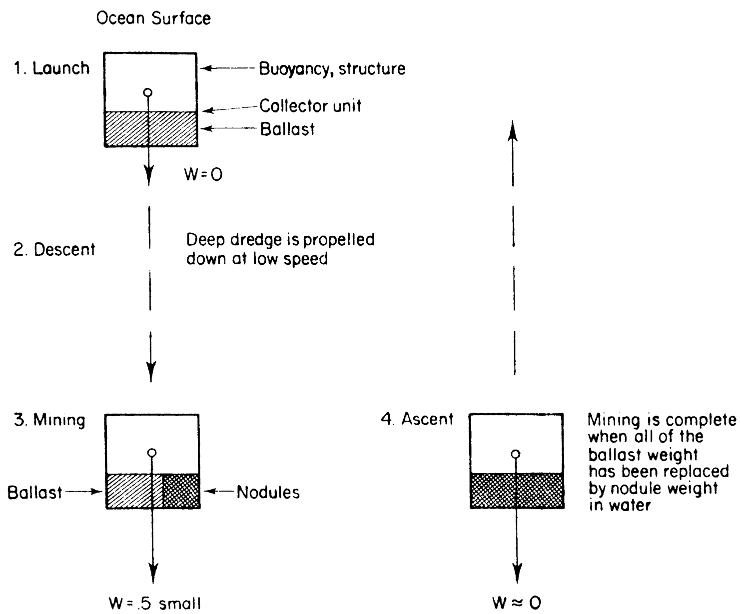

Fig. 22.8.14. Operating principal of a modular mining system for the deep seabed (Anon., 1984).

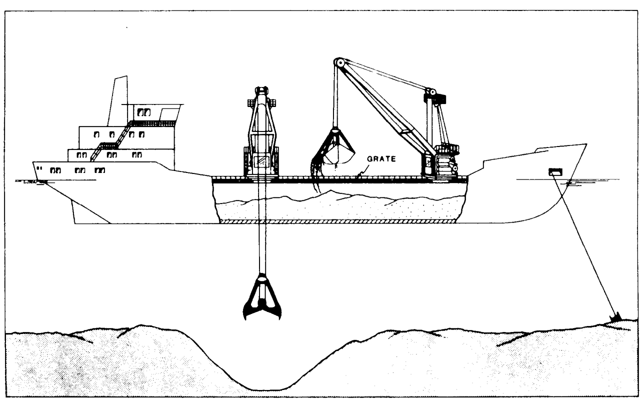

Fig. 22.8.15. Clamshell hopper dredge.

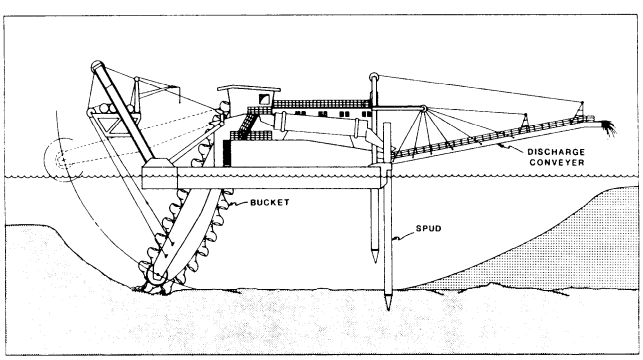

Fig. 22.8.16. Bucket ladder dredge with spuds for mining gold in sheltered waters.

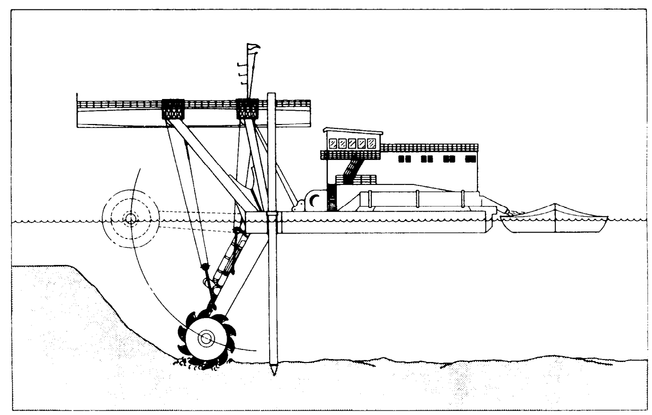

Fig. 22.8.17. Bucket wheel suction dredge with spuds for mining in sheltered waters.

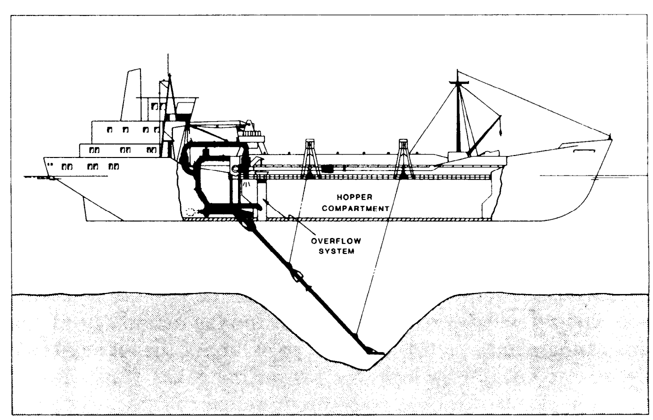

Fig. 22.8.18. Anchored suction hopper dredge for mining in shallow water.

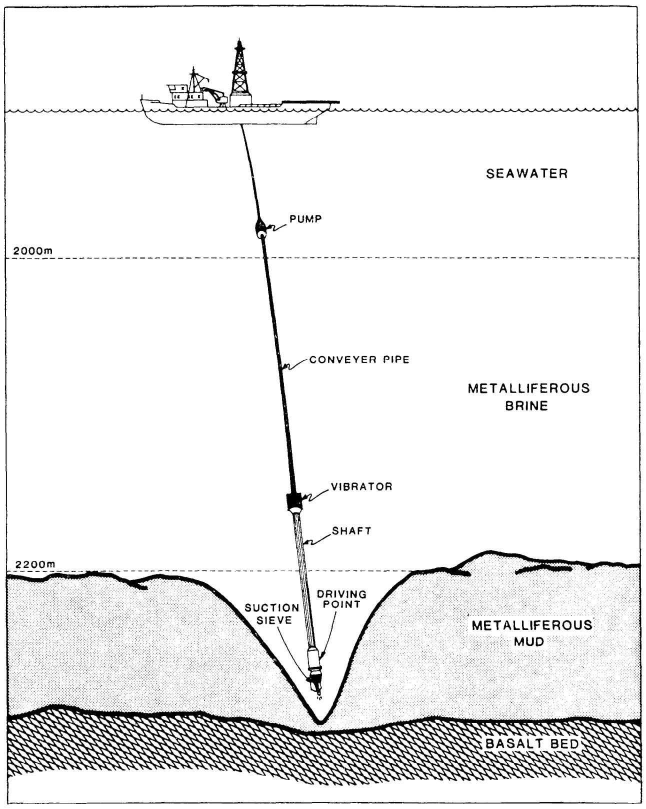

Fig. 22.8.19. Dynamically anchored suction dredge for mining in deep water.

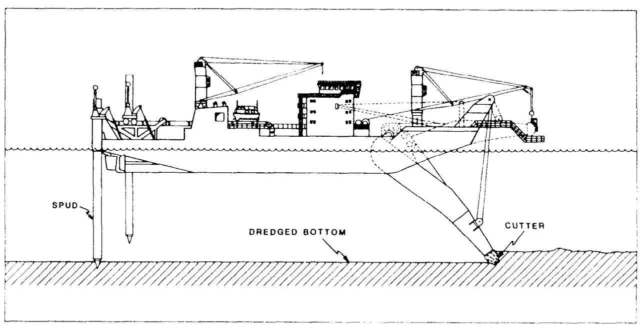

Fig. 22.8.20. Cutterhead suction dredge with spuds.

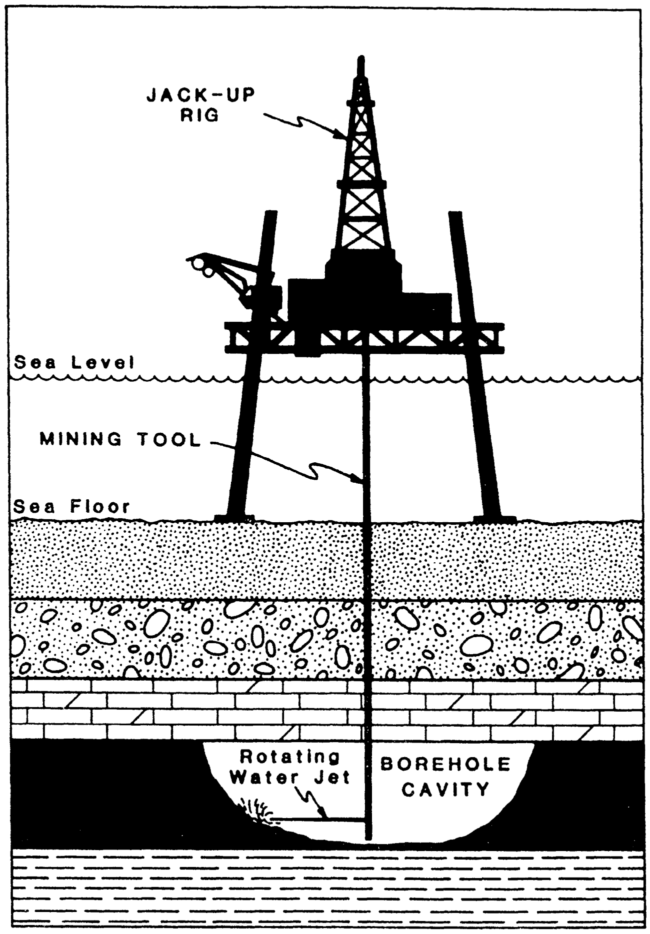

Fig. 22.8.21. Fluid mining by slurrying from a fixed platform in shallow water (after Hrabik and Godesky, 1985).

however, there is a great need for improvement utilizing newer technology, particularly as operators have to recover lower-grade materials and work very fine-grained deposits in the marine environment. The use of placer processing technology on board floating platforms subject to the rigors of the motions of the high seas has been quite limited to date. Thus in the selection of processing equipment for proposed operations at sea, considerable testing will be required to confirm the suitability of the processing plant in terms of both the nature of the material and the environment in which the processing takes place. Initial selection of treatment methods can be indicated from laboratory tests using a few pounds of sample, but in complex ores, which includes most placers, pilot plants to run tests on tens or hundreds of tons of sample are generally required. Table 22.8.14 lists the various options for separation applicable to marine placers (Cruickshank, 1988).

EXTRACTIVE PROCESSES FOR MANGANESE NODULES. The composition of manganese nodules and high-cobalt-manganese crusts is very similar, and extractive processes for nodules are generally assumed to be interchangeable (Haynes and Magyar, 1987).

Of the various processing schemes available for manganese nodule processing, five are considered most probable for first-generation commercial applications:

1. Gas reduction and ammoniacal leach (modified Caron).
2. Cuprion ammoniacal leach.
3. High-temperature and high-pressure sulfuric acid leach.
4. Reduction and hydrochloric acid leach.
5. Smelting and sulfuric acid leach.

The two ammoniacal and high-temperature and high-pressure sulfuric acid processes are designed to recover three metals (Co, Cu, and Ni), and the other two processes are designed to recover four metals (Co, Cu, Ni, and Mn). In the three-metal processes, manganese could also be recovered from the tailings if favorable economic conditions exist. This recovery would alter both the chemical and physical characteristics of the tailings. A variety of wastes is generated during nodule processing with tailings composing the majority of material. Other wastes generated are not generally unique to nodule processing and also constitute a small fraction of the waste. These wastes

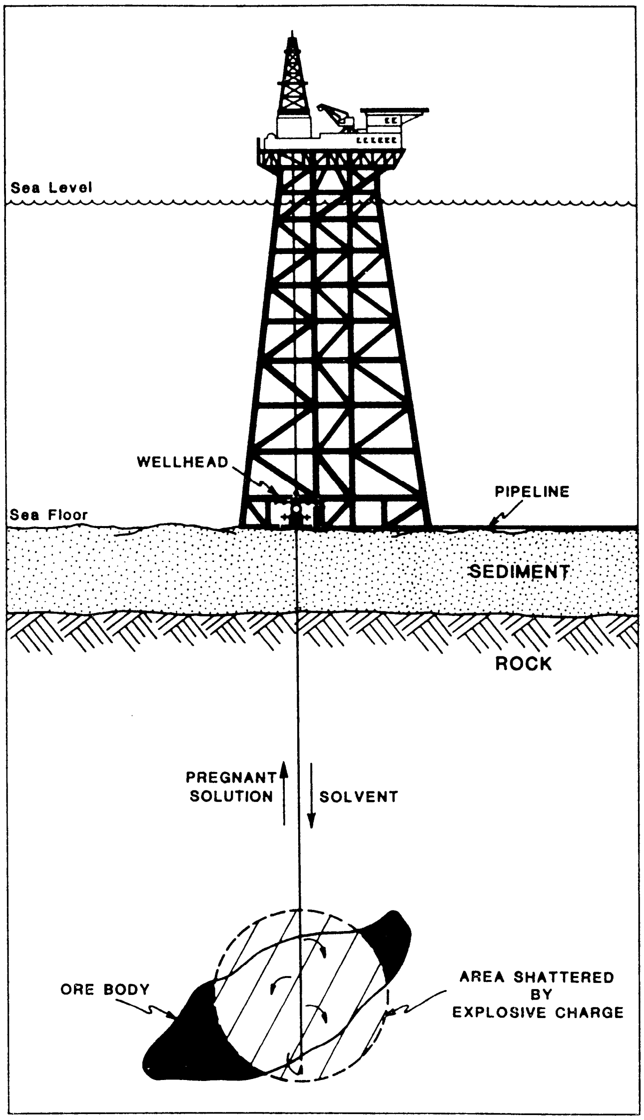

Fig. 22.8.22. Fluid mining by leaching of deep, hard-rock deposits, artificially fractured in place.

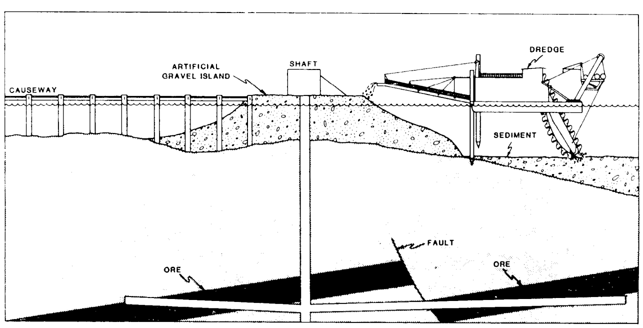

Fig. 22.8.23. Mining of subseabed deposits with access through an artificial island.

include utility and boiler ashes, scrubber sludges, electrowinning sludges, lime boil solids, and other miscellaneous plant wastes. Compositions of these wastes are generally known and not discussed further here. A brief flowsheet of each process is presented in Fig. 22.8.24 a-e. More thorough discussions of these processes are given elsewhere (Anon., 1987).

DISSOLVED MINERALS IN SEA WATER. For discussion on this subject, see Cruickshank and McIlhenney (1973). Salt, magnesium metal and compounds, fresh water, and bromine are recovered commercially. Principal recovery processes include precipitation and evaporation.

22.8.2.5 Technology for Environmental Impact Mitigation

The technology for environmental impact mitigation is developed on a case-by-case basis and is not well established at this time because impacts at sea are not well defined. Most studies done so far have documented discharges of waste materials from land-based mining operations or coastal smelters and refineries (Ellis, 1982). Other studies are listed in environmental impact statements for marine mining activities (see 22.8.3.4).

22.8.3 CASE STUDIES IN MARINE MINING

22.8.3.1 Dredging from the Continental Shelf

Dredging from the continental shelf is quite widespread, and selected operations for mineral sands are listed in Table 22.8.15. A useful reference for potential operations in US seabeds is Anon., 1979. Operations for sand and gravel are discussed in Chapter 15.1.

Tin in Indonesia (Zaalberg, 1970). Dredging for offshore tin deposits has been conducted off the island of Singkep since 1910 and the islands of Banka and Belitung since 1937. The deposits are drowned eluvials and alluvials in an area of still unresolved geomorphology. They are found in watersheds, valley terraces, and in valleys, and are concluded to be residual in character. The dredging operations in the 1950s are very well described by Zaalberg (1970), and specifications of some of the dredges presently operating are given in Table 22.8.15. All are bucket ladder dredges of the headline type. A typical flowsheet for the beneficiation process is shown in Fig. 22.8.25. A considerable auxiliary fleet of tugs, anchor boats, and motor launches is required to maintain the offshore operations, which involve dredging overburden first and then the ore-bearing ground.

The water is generally quite shallow, and in starting a new dredging block, an access channel for the dredge is prepared, and headlines and sidelines laid out with their anchors. After connection with the lines, the dredge usually removes overburden and ore alternately in an arc from side to side across the face determined by the headline. Normal width of cuts is 300 ft (100 m), but using multiple headlines, cuts up to 900 ft (300 m) can be made. At each pass, covering about 35 ft (100 m) in 15 min, the dredging ladder is lowered about 30 in. (800 mm) in normal ground or 18 in. (500 mm) in very hard ground. Care is needed to assure that the overburden in not discharged in a fashion that will allow it to contaminate the unmined ore, and the overburden cut does not usually advance much in front of the ore cut. Forward movement of about 4½ ft (1.4 m) per cut is controlled by markers on the headline or by sextant or electronic positioning. Hourly dredging rates of 600 yd^3 (500 m^3) allow the treatment plant to be put into operation about 18 hr after the commencement of overburden dredging. Cleaning of the bottom may be difficult and time-consuming in the presence of limestone

Table 22.8.13. Methods of Mining Potentially Applicable to Submarine Metalliferous Sulfides

gullies and pillars, which are common in the area. Assessment of the volume dredged is done by measuring the premined water depth and the depth of cut every 30 ft (10 m) and correcting for tidal variation. With the exception of holiday periods, the dredges work a 24-hr day throughout the year with the total downtime of 20% for daily repair and cleaning, holidays, storms, and docking. Recent figures indicate 120 hr/mo for maintenance, and a general overhaul every six to seven years.

Each dredge has a chief dredgemaster and four underdredgemasters. For two or three dredges working in close proximity there is an electrician and a mechanic. The crew consists of 104 men, divided into four watches, each watch or gang consisting of 21 men and a gang of 18 for general daytime work and two men for the motor launch. Each watch is for eight hours, so one watch is free, the gangs changing each week.

Storms are infrequent in Indonesian waters, but when the sea becomes too rough, the dredge is stopped and the ladder raised. If required, wedges can be placed between ladder and hull. If the ladder were to bump against the bottom during a gale, the large ladder bearings near the upper tumbler probably would be destroyed. Connection with the shore by launch is impossible during storms, so the crew has to stay on board to await calmer weather—usually no more than 24 hr.

Dredging costs attributable to salaries and wages are 34% materials including fuel 30%, transportation 11%, repair shop 7%, and miscellaneous 18%.

A yearly throughput of 4 million yd^3 (3 Mm^3) with a tin richness of one (0.1 oz/ft^3 or 1 kg/m^3) would produce 3300 tons (3000 t) of tin in ore. Present-day workings are, in general, not so rich, and values as low as 0.02 oz/ft^3 (0.2 kg/m^3) have been mined. To arrive at the direct revenue for the dredge, the costs of transportation, smelting, and selling of the product have to be deducted. In addition, overhead expenses, such as general office, hospital and so on, and a depreciation rate of 10%, have to be considered, though dredges last much longer than the 10 years originally estimated. Because of this, the fully amortized

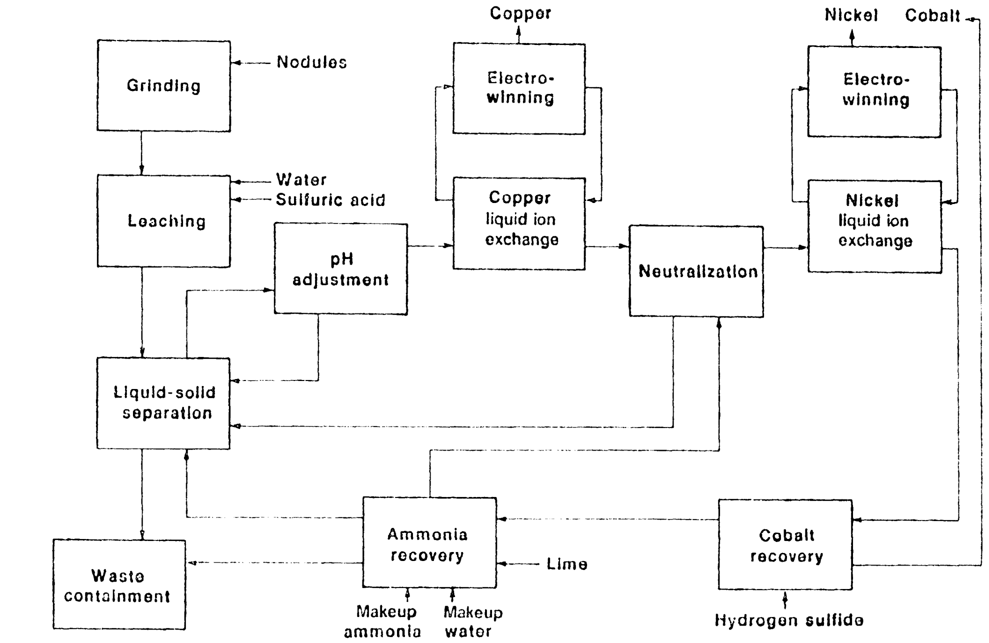
older dredges have been able to survive some of the later price shocks in the tin industry.

GOLD IN THE UNITED STATES (Anon., 1987). Gold-bearing beach sands were discovered and mined at Nome, AK, in 1906. Mining gradually extended inland from the current shoreline to old shorelines now above sea level. By 1906, about 4.5 million oz (128,000 kg) of alluvial gold had been mined from a 55 mi^2 (142 km^2) area. Early miners recognized that the Nome gold placers were formed by wave action and that additional deposits, formed when sea levels were lower, should be found in the adjacent offshore area (Fig. 22.8.26).

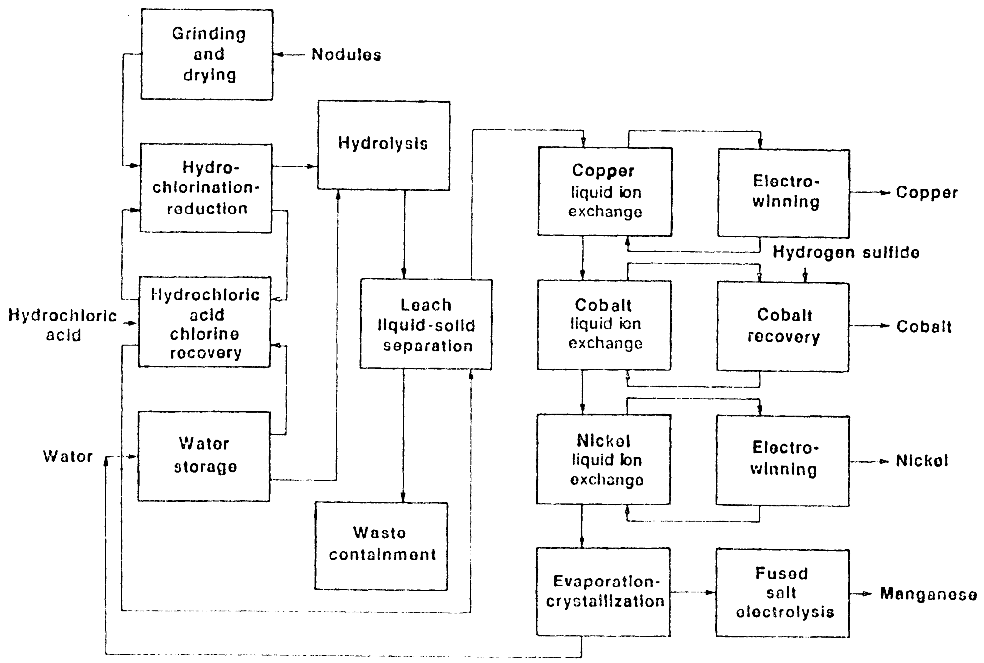
Two US companies, ASARCO and Shell Oil Co., sampled offshore deposits near Nome in 1964 and recovered alluvial gold. By 1969, proven offshore reserves of approximately 100 million yd^3 (76 Mm^3) of ore had been established. The rights to these reserves were acquired in 1985 by Inspiration Resources, which then began a pilot mining and testing program. This program was followed by mining tests with a bucket ladder dredge in 1986. All operations to date have taken place about 1½ mi (2.4 km) offshore in waters under the jurisdiction of the State of Alaska, although gold resources have been identified out to about 10 mi (16 km).

Water depths in the sound do not exceed 100 ft (30 m). Ten miles offshore, water is only 60 ft (18 m) deep. Gold-bearing sediments are a maximum of 30 ft (9 m) thick and consist of bedded sands, gravels, and clays alternating with occasional beds



c.

Fig. 22.8.24. cont.



d.

of cobbles and boulders. These sediments were sampled from the ice out to about 1½ mi (2.4 km) from the coast. Gold has been found further offshore, but reserves have not yet been fully delineated. Current mining sites are located 1½ mi (2.4 km) out in water depths averaging 30 ft (9 m) and in formations 6 to 30 ft (2 to 9 m) thick.

Norton Sound is ice-free and accessible to floating vessels only between June and October. During the winter, thick pack ice forms over the Sound. Waves reportedly do not exceed periods of 7 sec, but occasional sea-swells with longer periods may come from the west and southwest. Predominant winds are from the north and northeast. Currents and longshore drift are westward. Maximum tides are 6 ft (2 m).

Mining Technology—The bucket ladder dredge, Bima, was designed and built in Singapore in 1979 as a seagoing vessel for mining tin offshore Indonesia. The vessel was brought to Nome in July 1986 for preliminary tests, modified in Seattle, and began operation in July 1987. Its hull is 361 ft (110 m) long, 98 ft (30 m) wide, and 21 ft (6 m) deep. The entire vessel is of steel construction and weighs about 15,000 tons (13,500 t), including the dredging ladder and machinery. Freeboard is 10 ft (3 m) and draft 15 ft (4.5 m) with the ladder retracted.

The Bima is not self-propelled. It must be moved to and from the mining site by a tugboat. On site, the dredge is kept in position by five mooring lines attached to 7-ton (6-t) Danforth anchors. This anchoring arrangement allows the dredge to swing

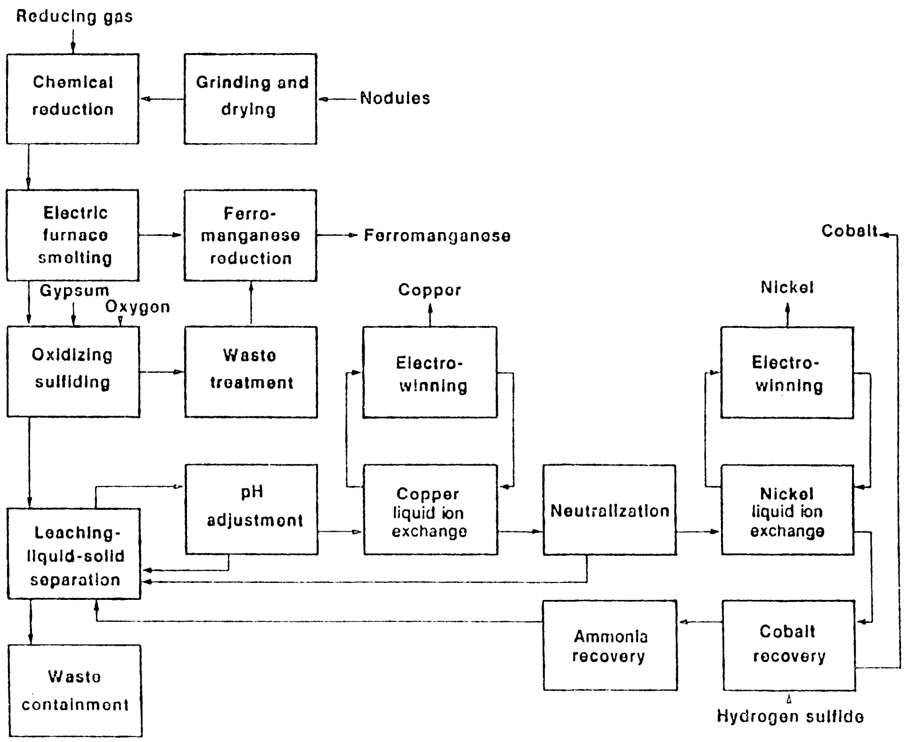


Fig. 22.8.24. cont.

e.

600 ft (180 m) from side to side on the headline and to advance while digging. The anchors are positioned and moved by a special auxiliary vessel.

A 15,000-hp (11,000-kW) diesel-electric power plant is used to operate the bucketline, the ore processing plant, the anchor winches, and the auxiliary systems. There is fuel storage on board for 2½ months of operation.

The Bima's dredge ladder and bucketline were originally designed to operate in 150 ft (45 m) of water. The dredge is able to mine from 25 to 100 ft (8 to 30 m) below the water line at the rate of 33 yd^3/min (25 m^3/min) or approximately 2000 yd^3/hr (1500 m^3/h). The Bima was designed to enable the mass of the ladder and bucketline to be decoupled from the motions of the hull by an automated system of hydraulic and air cylinders that act like very large springs. This feature keeps the buckets digging against the dredging face on the seabed while the hull may be heaving or pitching due to the motions of passing waves. During the trials of the Bima in Norton Sound from July to October 1986, it was not necessary to activate the system.

At-sea Processing—The Bima is equipped with a gravity processing plant to make a gold concentrate at the mining site. The throughput capacity of the plant is 2000 yd^3/hr (1500 m^3/h). The plant consists of two parallel inclined rotary trommels, 18 ft (5.4 m) in diameter and 60 ft (18 m) long. After removal of any large boulders, ore brought up by the dredge bucket slides down the trommels under the spray of powerful jets of seawater. The water jets are used to break up the clay and force sand and gravel smaller than 3/8 in. (9.5 mm) to pass through the trommel. Material coarser than 3/8 in. (9.5 mm) is discharged over the stern.

Material retained by the trommel is distributed in a seawater mixture to three circuits of jigs, beginning with six primary circular jigs, each 24 ft (7.2 m) in diameter. The concentrates from the circular jigs are then fed to cross-flow secondary and tertiary jigs. The jig concentrates are further refined on shaking tables before transport to shore for final gold separation and smelting into bullion. It is expected that about 22 lb (10 kg) of concentrate containing the gold will be produced by mining and processing approximately 50,000 tpd (45,000 t/d) of ore. The actual amounts of concentrate produced will depend on the quantity of heavy minerals associated with the gold at each location.

Environmental Effects—The ore processing plant on the Bima returns over 99.9% of the processed material to the seabed as tailings. Since the tailings do not undergo chemical treatment, local turbidity caused by particles that may remain in suspension is likely to be the most significant environmental impact. During pilot plant tests in 1985, Inspiration Resources found that turbidity could be minimized by discharging fine tailings through a flexible pipe near the seabed. Other potential environmental impacts could occur if diesel fuel is spilled, either as it is being transferred to the Bima or as a result of accidental piercing of the hull.

Operating Conditions—The Bima operates only between June and October (five months per year) because ice on Norton Sound prohibits operations during the winter months. Thus, without breakdowns or downtime due to weather and other causes, a theoretical yearly production of about 7.5 million yd^3 (5.7 M m^3) of ore is possible. During tests in 1986, Bima operated only a small fraction of the time available. This was due more to the nature of the trials than to downtime related to winds and waves. Assuming a mining efficiency (bucket filling) of 75% and operating efficiency of 80% (allowing for time to move and downtime due to weather), yearly production is limited to 4.5 million yd^3 (3.4 M m^3). If gold grades of 0.012 to 0.016 oz/yd^3 (488 to 650 mg/m^3) of ore are assumed, the yearly gold production would vary between 1.75 and 2.20 tons (1.6 t to 2 t) before any losses due to processing and refining.

The Bima has a crew averaging 12 persons per watch, three watches per day. Personnel are transported to and from Nome daily by helicopter. The operation also requires extensive maintenance, supply, and administrative facilities onshore. These facilities are manned by an additional 46 persons during the operating

season. During the winter months, the Bima is brought in to the Nome breakwater and protected by an ice caisson sprayed into place around it.

Capital and Operating Costs—Capital and operating cost estimates are based on a number of assumptions and must be considered first-order approximations. The estimates rely in part on published information that the Bima gold mining project will have a life of 16 years and will recover about 48,000 oz/yr (1500 kg/yr) of gold at operating costs of less that $200/oz ($6.43/g).

The Bima was constructed at a cost of $33 million in 1979. It is assumed that its purchase in 1986 as used equipment (sold because of the fall in the price of tin) is on the order of $5 million. Also assumed is that other capital costs, including ancillary facilities onshore, pilot-plant mining tests in 1985 and trials in

Conversion factors: 1 in. = 25.4 min, 1 ft = 0.3048 m, 1 yd^3 = 0.7646 m^3, 1 hp = 0.7457 kW, 1 ton = 0.9072 t.

1986, auxiliary vessels for prospecting and for tending anchors, shipyard modifications and alterations to the processing plant, and the cost of shipment of the Bima from Indonesia to Nome and to and from the shipyard near Seattle amount to another $10 to $15 million. Total capital costs are thus assumed to be between $15 and $20 million.

Annual operating costs for fuel, maintenance, insurance and administration, and personnel and overhead are estimated (to an accuracy of 25%) to be $7 million. At a production rate of 48,000 oz/yr (1500 kg/yr), a cash operating cost on the order of $150 to $175/oz ($4.82 to $5.63/g) is implied. At a mining rate of approximately 4.5 million yd^3/yr (3.4 M m^3/yr), direct costs would amount to $1.55/$yd^3$ ($2.00/$m^3$).

Assuming the price of gold to be $400/oz ($12.86/g), the projected pretax cash flow on production of 48,000 oz/yr (1500 kg/yr), would be approximately $12 million (after subtracting operating costs) on an investment of $17 million. Although this figure does not include debt service, it nevertheless indicates that

the Bima offshore gold mining project at Nome shows good promise of profitability if the operators are able to maintain production. This scenario illustrates that offshore gold mining is economically viable and technically feasible using a bucketline dredge under the conditions assumed.

DIAMONDS IN SOUTH WEST AFRICA (Webb, 1965; Nesbitt, 1967). Original concessions were granted to Marine Diamond Corp. by the South West African government from the Orange River to Deay Point, 176 mi (280 km) north, reaching from low-water mark to 3 nautical miles (5.5 km) seaward. The sea diamonds originated from kimberlite bodies within the drainage basin of the Orange River. They were transported by the river and deposited in economic concentration up and down the coast by the action of the sea. Diamondiferous gravels generally occur

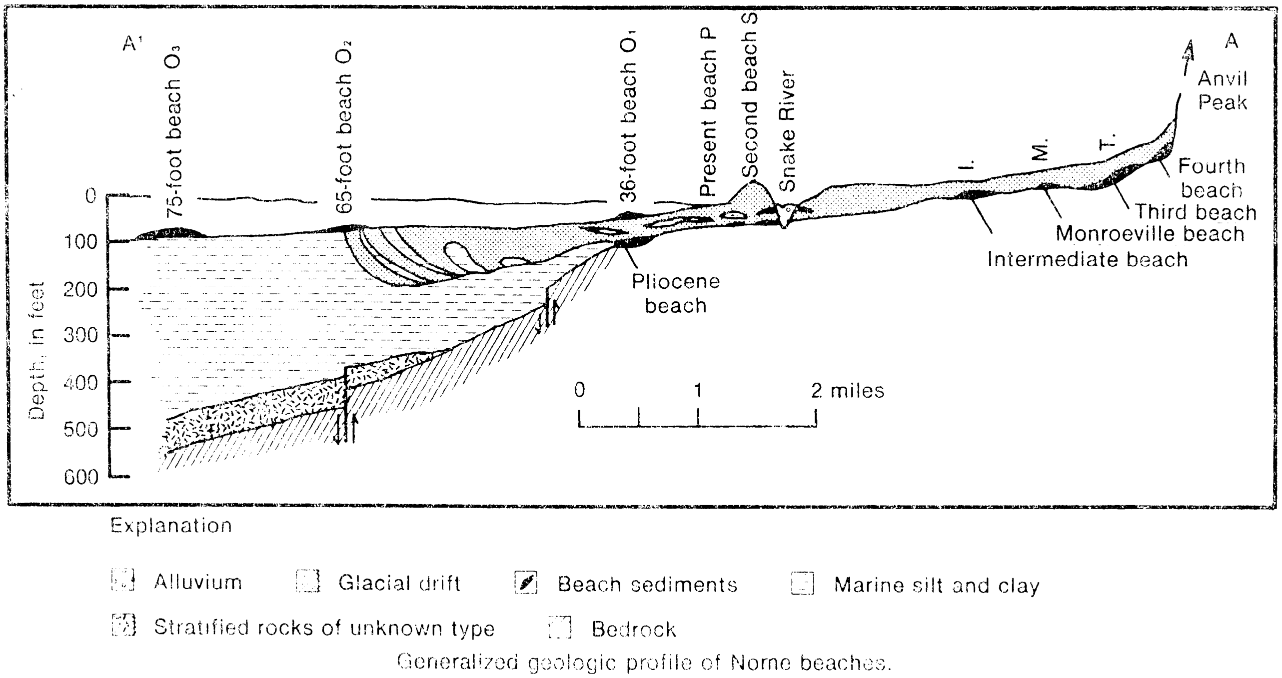

Fig. 22.8.26. Generalized profile of gold-bearing beaches at Nome (after Cobb 1973). Conversion factors: 1 ft = 0.3048 m, 1 mi = 1.609 km.

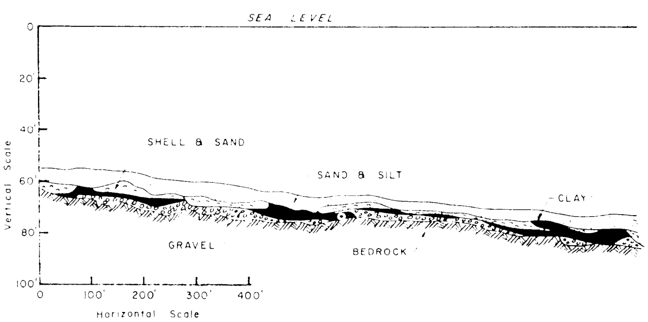

Fig. 22.8.27. Generalized profile of diamond-bearing beaches at Chameis Bay (after Nesbitt, 1967). Conversion factor: 1 ft = 0.3048 m.

immediately overlying the bedrock or in gullies or potholes (Fig. 22.8.27). Webb and Nesbitt described the sea mining operations and commensurate problems in some detail.

Present mining is conducted immediately to seaward of the breaker line. In this area, the waves are starting to form, thus increasing the swell frequency. From Aug. 1965 to May 1966, swells exceeded 5 ft (1.5 m) during 61% of the period, and exceeded 8 ft (2.4 m) during 41% of the period. During Mar. 1966, the highest mean daily significant height (MDSH) was 29 ft (9 m), and it was over 15 ft (5 m) during five days. To counter these difficult conditions, the mining barge Colpontoon is held by six anchors, two of these being classified as deep-sea anchors, which always are positioned seaward and to the stern of the barge. These deep-sea anchors serve to pull the barge away from the shore when the weather deteriorates. The other four are shallow maneuvering anchors. The anchor winch is situated mid-barge and the cables are taken along the decks through sheaves and fairleads out to the anchors.

The anchor spread embraces an area 3300 by 3300 ft (1000 by 1000 m), which lasts between one and two months. Positioning is by hydrodist .

On the Colpontoon, the flexible suction hoses are 12, 16, or 18 in. (304, 406, or 457 mm) in diameter. A smaller hose carries high-pressure water used to jet and disturb the sediments.

Using an airlift, the technique is to blow for 25 sec, then shut off and fill a receiver for 15 sec. One reason for doing this is to clear boulders away from the nozzle of the lift, the boulders being cleared when the load in the pipe drops away. Another reason is the inability of the airlift to raise the load when it becomes too dense.

Dredge pumps later replaced the airlifts with an 80% increase in volumetric efficiency.

The present method of spot dredging with flexible rubber hoses is the only one that has proved practical so far, but it suffers grave disadvantages, especially in clay or boulder horizons, as generally, much of the deposit is left behind, and little penetration is made to bedrock.

Powered by a 765-hp (570-kW) diesel, the 18-in. (457-mm) dredge pump can deliver as much as 13,000 gpm (820 L/s). Unfortunately, with the present unguided flexible hose, most of this 13,000 gpm (820 L/s) is water, not sediment. Data on the operation in Table 22.8.16 include some performance figures for the dredge Colpontoon.

In the treatment plant, dredge-pump delivery is piped to an 84-in. (2.1-m) diameter dewatering cyclone, designed to accept 13,000 gpm of pulp carrying 660 tph (600 t/h) of solids ranging in size from a maximum of 9 in. (228 mm) to micrometer slimes.

Water rejection from the cyclone averages 90%, while all material coarser than 0.04 in. (1 mm) reports as concentrate. A very low cyclone inlet pressure of 3 to 5 psi (21 to 34 kPa) is essential to minimize wear. A prototype cyclone constructed from ¾-in. (19-mm)-thick steel wore out in 24 hr; 3/8-in. (9.5-mm) Bennox lasted a week. An 8-in. (203-mm)-diameter cyclone was later cast from 1-in. (25-mm) Scaw metal.

Table 22.8.16. Typical Monthly Performance Figures for the Dredge Colpontoon

Average solid sediment dredged, tph	133
Operating time, hr	633
Lost time, hr	33
Total feed to heavy-media cyclone (−25 + 1.5 mm), tons	8,400
Average feed to heavy-media cyclone (−25 + 1.5 mm), tph	13.3
Highest recorded feed to heavy-media cyclone (−25 + 1.5 mm), tph	30
Lowest recorded feed to heavy-media cyclone (−25 + 1.5 mm), tph	1.5
Total carats produced	7,700
Total area worked, sq m	5,000

Maximum estimated swell height, ft	21

Conversion factors: 1 in. = 25.4 mm, 1 ft^2 = 0.0929 m^2, 1 ft = 0.3048 in., 1 mi = 1.6093 km, 1 ton = 0.9072 t.
Source: Nesbitt, 1967.

Large and very small diamonds are uncommon. Accordingly, the apertures of the primarily scalping and washing screens are, respectively, 1 in. (25 mm) and 0.06 in. (1.5 mm), and any solids outside this range are rejected immediately as waste. In most areas, the bulk of the plant feed to the heavy-media cyclone unit comprises seashells. At other times, a tenacious, sticky green clay constitutes the major component.

Together with a dense slurry of powdered ferrosilicon and water, the – 1-in. (25-mm) + 0.06-in. (1.5-mm) sediment is pumped into the heavy-media cyclone where the denser mineral components, including the diamond, are centrifuged and then escape through the cyclone spigot. Over 90% of the feed has a density less than diamond and can be rejected as waste from the cyclone overflow. Owing to the flat shape of seashells, shell rejection from the conventional design of cyclone is inefficient. This was corrected by redesigning the cyclone with a 60° frustum in place of the conventional 20°.

Heavy-media cyclone concentrate either is fed to a ball mill or treated directly by Pleitz jigs, the concentrates from which are finally sorted by hand for lack of a better method.

Although very efficient in diamond recovery, the heavy-media cyclone process has proved costly not only because of expensive capital equipment but also high operating costs. An alternative primary gravity concentrating system used on the research vessel, Barge 177, is a 5-ft (1.5-m) circular Cleaveland jig, which also is very suitable for the removal of seashells.

A typical processing flowsheet is given in Fig. 22.8.28, and Table 22.8.17 lists the equipment used on the Colpontoon.

Mining of the foreshore between high and low tide provides most of the production during the development of improved offshore techniques. Borchers, et al. (1970) describe in detail the construction of seawalls and the various mining methods.

22.8.3.2 Dredging from Deep Seabeds

Several hundred millions of dollars were spent in the 20 years since 1968 on research and development on deep-seabed mining systems. No full-scale systems have yet been built, but pilot tests have been run on several systems for the mining of manganese nodules at 17,000 ft (5000 m), a system for the collection of a bulk sample of metalliferous muds at 7300 ft (2200 m), and conceptual systems for cobalt crusts at about 3300 ft (1000 m). Some of these are described now in more detail.

R/V Deep Sea Miner II (Kaufman and Latimer, 1971; Kaufman, Latimer, and Tolefson, 1985). The OMA Deepsea Miner II tests spanned a two-year period (1977-1978) and included four major sea test campaigns. The tests were conducted at a test site within the OMA license exploration area, which is located about 1100 nautical mi (2037 km) southwest of San Diego, CA. Fig. 22.8.29 shows the location of the test site as well as boundaries of the OMA, OMI, and OMCO license areas that have been

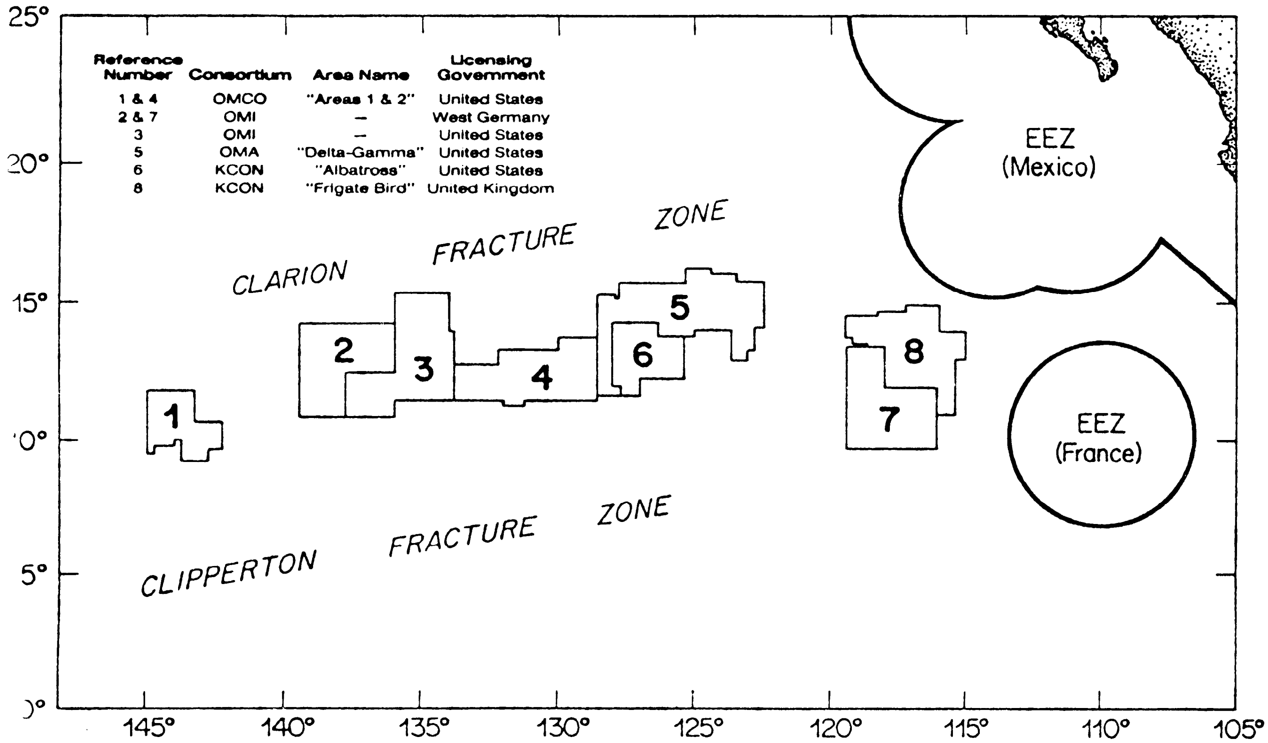

Fig. 22.8.29. Site location of manganese nodule tests.

issued by the US government pursuant to the Deep Seabed Hard Minerals Resources Act.

The mining system was divided into five principal subsystems:

1. Collector.
2. Mining Production Control/Integrated Navigation/Instrumentation.
3. Nodule Conduit/Nodule Lift.
4. Mining Platform including pipe handling and suspension and pipe storage.
5. Ore Transport and Transfer at Sea.

All subsystems were incorporated into the R/V DEEPSEA MINER II pilot tests except ore transport and transfer at sea.

Initial evaluation included study of the five fundamental engineering approaches: 1) the continuous line bucket, 2) the autonomous shuttle, 3) wireline basket dredging, 4) containers in a pipe, and 5) hydraulic dredging. The continuous hydraulic dredging approach was determined to be the most effective system for efficient first generation commercial mining.

Some of the major features of the continuous hydraulic test mining system are

1. High-strength steel dredge pipe (conduit) with hinged splitter plates for vortex suppression towed through water.
2. Pipe suspended at all times by a gimballed holding device located in a midship internal well (moonpool).
3. Gimbal and associated derrick structure passively aligned with the upper portion of pipe by means of rollers or a similar device installed on the lower portion of the derrick that projects below the gimbal.
4. Hydraulic main hoist cylinders mounted on the gimballed suspension device, in such a manner that the hoisting force is always approximately coincident with the axis of the upper portion of the pipe.
5. Airlift pump system.
6. Deadweight at the lower end of pipe to reduce curvature and bending stress from collector towing force.
7. A flexible hose connecting the lower end of pipe via a universal joint to the collector to accommodate variations in seabed relief.
8. A nodule collector or dredge at the end of the hose that is towed at the average speed of ship. The collector removes nodules from the seabed by hydraulic sluicing, but provides essentially clear, sediment-free water to the hose suction.

Some of the many alternative design features that were evaluated, or developed and evaluated, in arriving at the system configuration are provided on Table 22.8.18. It should be noted that self-propulsion of the collector was not a test or a commercial requirement. Steering of the collector is a commercial requirement but was not provided on the test.

The R/V Deepsea Miner II was approximately a one-fifth to one-quarter production-scale version of the commercial system. The ground rules for the design of the test apparatus did not require modeling of all components of the commercial system, but only the major ones and other devices that could not be analytically sized and designed with a high degree of confidence. Notwithstanding such latitude, the end product was very similar to a commercial design. The major areas of difference were the life span of some components as effected by corrosion, omission of some aspects of automation that would be provided on the commercial ship to reduce manning, reduction of pipestring deployment and retrieval time, and capability to operate and survive under all weather conditions.

Glomar Explorer Test (Welling, 1981). The basic limitation in seabed mine production is caused by nodule abundance. At an average nodule abundance of 2.04 lb/ft^2 (10 kg/m^2) and a miner speed of 3.2 fps (1 m/s), one can see that a 33-ft (10-m)-wide miner would deliver 220 lb/min (100 kg/s), 8640 tpd (8784 t/d) or 3,153,600 tpy (3,206,308 t/a) if 100% efficient. Of

Table 22.8.18. Design Options Evaluated by Deep Sea Ventures Inc. for Nodule Mining Test

ALTERNATIVE DESIGN FEATURES EVALUATED	
Pipe material:	Steel of various types.
	Aluminum.
	FRP.
	Composite.
Pipe structure (body):	Stepped in steel area.
	Stepped in steel area and flow area (airlift only).
Pipe joint installation:	Welded to upset pipe.
	Welded to plain end pipe.
	Threaded attachment.
Type of joint make-up:	Threaded (tool joint).
	Clamp ring.
	Others.
Main hoist force device:	Wireline.
	Hydraulic rams.
	Hydraulic cylinders.
	Load screw devices with recirculating ball bearings.
Main hoist sequence:	Hand over hand.
	Stop and go.
Main hoist yoke location:	Above gimbal.
	Below gimbal.
Gimballed derrick:	Passive alignment with pipe.
	Active (power driven alignment with pipe).
Pipe transfer:	Horizontal attitude.
	Vertical attitude.
Pipe stowage:	Above deck.
	Below deck.
Dredging methods:	Continuous slow traverse with collector following at same average speed.
	Stop and go with collector running a pattern on bottom.
	Continuous slow traverse with collector running pattern on bottom.
Collector nodule pickup:	Pick up of nodules and sediment with subsequent jetting to separate sediment.
	Pick up of nodules without sediment.
Nodule pickup mechanisms:	Scraper.
	Fixed tines or rakes.
	Rotary tines.
	Hydraulic sluicing (suction).
	Magnetic.
Nodule transport (collector):	In-line pump; and ductwork.
	Jet pump; and ductwork.
	Conveyors (includes mechanical belts).
	Hoppers/Feeders.
	Crushing/No crushing on bottom.
Collector steering:	Fins.
	Thrusters.
	Rudders.
Collector ground support:	Runners or skids.
	Track laying devices.
	Large fluid inflated rollers.
	Others.
Main pumping system:	Airlift.
	Submerged electrically driven centrifugal or multi-stage pumps along the line.
	Large multi-stage centrifugal pump at bottom.
	Reciprocating devices.
Airlift features:	Depth of injection.
	Pressurized or atmospheric discharge.
	Extraction and recompression.
Motor-pump features:	Pass nodules through pump.
	Nodules injected downstream by alternating holding chamber or rotary feeders.
	Others.
Mining platform:	Semisubmersible platforms.
	Swath.
	Catamaran.
	Flip ship.
	Conventional ship form.

Source: Kaufman and Latimer, 1971.

course, there are many things wrong with these simple figures: abundance is given in wet tons, production is given in dry tons, and wet tons contain 30% less metal than do dry tons. Fig. 22.8.30 illustrates the many considerations that contribute to production efficiency. The two factors considered are rate on the vertical axis and time on the horizontal axis. Rate times time describes the production or the area of the large rectangle. The losses in rate are pickup efficiency, fines losses, collector-down time, and interaction of the various systems. This can amount to a loss of one-third to one-half of the rate. The losses in time are due to such things as the mining ship in drydock, weather delays, breakdowns and repairs, logistic delays, and losses during turns. This can amount to one-quarter to one-third of the time.

Seafloor Characteristics—Knowledge of the terrain and nodule distribution of a mine site can only be known on a statistical basis. The three important factors—nodule grade, abundance, and terrain characteristics—determine the value and economics of a mine site. While preliminary investigations indicate some relationships between these three factors, there appear to be enough variations that one should strive for a mining system with wide operational characteristics.

Deep-Ocean Miner Characteristics—To obtain maximum efficiency, one of the functions considered essential was good mobility. This means control of speed and direction with minimum turning radius and maximum trafficability over varying soil properties.

Good miner mobility requires a flexible link between the miner and the end of the heavy pipe suspended from the surface ship, approximately 17,000 ft (5000 m) above. Because of the mass and the drag of the pipe and ship, the end of the pipe can appear quite rigid to the miner, and therefore, the pipe cannot act as a flexible link.

Another requirement was buffer storage of the nodules prior to pumping of the nodules up the pipe. Slurry systems require steady state conditions for maximum efficiency. Buffer storage in conjunction with miner speed variations will allow a greater variation in nodule abundance without loss of mining efficiency.

Additional requirements set forth were (1) raising and lowering of the mining head to allow for control of depth of cut and retraction for passage over small obstacles, (2) washing of the nodules to minimize the amount of clay pumped to the surface, (3) crushing of the nodules to establish an upper maximum size for slurry transport, (4) high-resolution sonar and TV systems for observation of the surrounding terrain, and (5) the necessary command and control system for real time data acquisition and control functions.

Instrumentation and Sea Tests—Extensive instrumentation and data recording were employed. Furthermore, every future large-scale operational system was incorporated into the test miner. The primary power was obtained by use of a high-voltage electrical cable strapped to the pipe and terminated in a transformer located in the equipment section on the bottom of the buffer. Electrical power of reduced voltage was then supplied from the transformer to a large electrical motor that drove a hydraulic pump, all located in the equipment section. The hydraulic power was in turn supplied to the miner by hydraulic lines forming a part of the umbilical lines. A series of electrically controlled valves on the miner metered the hydraulic power to the various motors on the miner. Fig. 22.8.31 is a photograph of the test miner as it was stowed in the large center well of the Glomar Explorer. The test miner's physical characteristic is dominated by (1) the Archimedes screw propulsion system, (2) the television and light boom extending forward, (3) the umbilical lines extending upward back and down to the bottom of the buffer, and (4) the buffer and equipment section located inside the two horizontal rings.

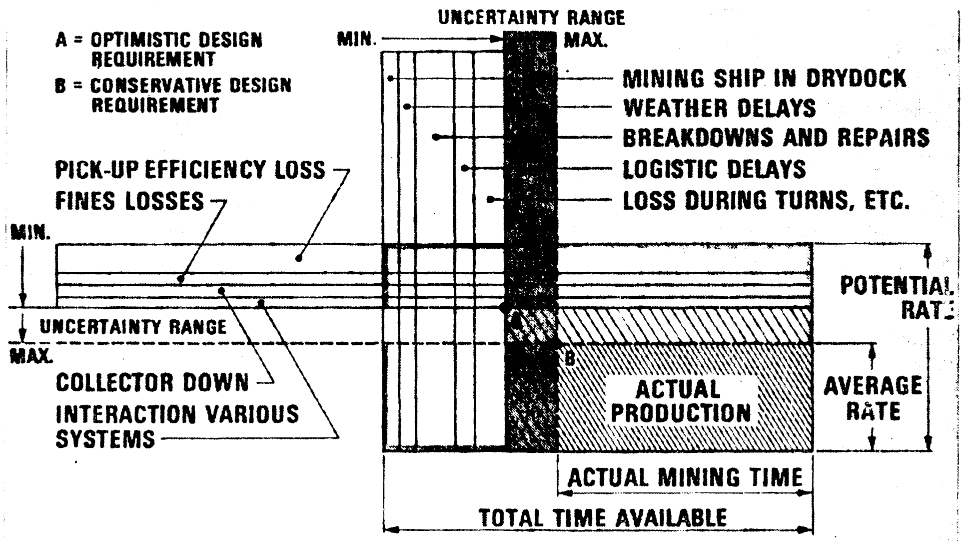

Fig. 22.8.30. Production efficiency for deep seabed mining system (after Welling, 1981).

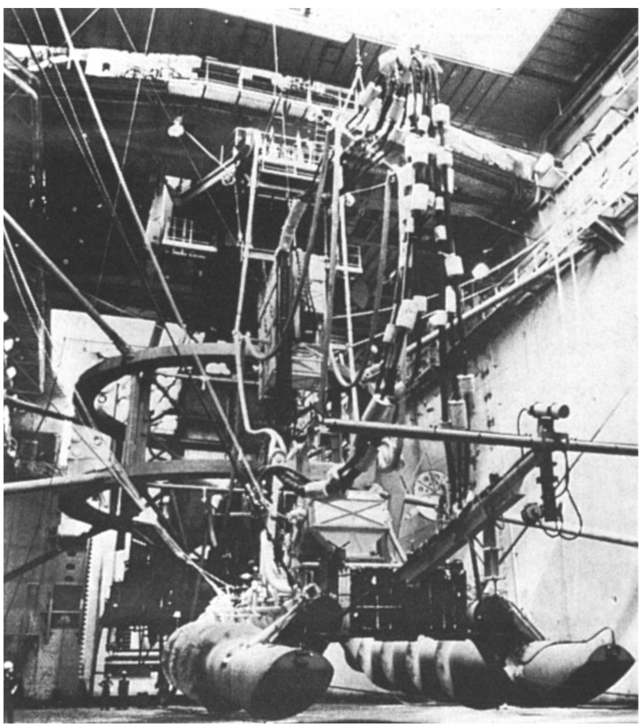

Fig. 22.8.31. Photograph of Lockheed test miner (*courtesy:* C.G. Welling).

The handling technology used for launching and retrieving the miner and buffer is unique. After the well is flooded, and the large doors are open, the miner is lowered until it hangs by the umbilical cord approximately 160 ft (50 m) below the keel. The whole system is then lowered to the ocean floor by makeup of 60-ft (18-m) sections of pipe. The launching and retrieval of the units weighing a total of several hundred tons was accomplished without major incident, even in the presence of sea surges of 20 ft (6 m) or more in the well.

Bottom Navigation Control—The principal information sent to the control room was obtained by use of sonar and television. Mounted on the buffer equipment section, which was approximately 60 ft (18 m) above the ocean floor and 60 ft (18 m) ahead of the miner, was a high-resolution scanning sonar. Also sonar systems are used for range and bearing from the miner as well as height from the ocean floor. Several sets of fixed and pan and tilt TV cameras are installed on both the buffer and miner providing detailed video information, which was fed to the main control consoles in the control room aboard ship. Multiple recording systems were employed so that a permanent record of the outputs of all sensors employed was obtained. This included video, sonar, electrical, hydraulic, and mechanical data. Post review and analysis of all the data reveal that sufficient engineering and operational information was obtained to give confidence in the design and expected performance of future pilot and commercial systems.

CONCLUSIONS. 1. A self-propelled vehicle in the weight range of 100 tons (90 t) or more can be successfully operated on the soft pelagic clays of the deep ocean floor.

2. The tests proved that sufficient control of the speed and manueverability of a large vehicle on the deep ocean floor can be achieved to allow efficient mining of manganese nodules.

3. Dynamic positioning of the surface ship obtainable by use of computer-controlled thrusters is sufficiently accurate to allow coordination of movement between the surface ship and the miner.

4. Large electrical and hydraulic power systems can be reliably operated at a depth of 17,000 ft (5000 m) by cable from a surface ship.

5. By the use of multiple sensors that measure range and bearing, speed and direction, voltage, amperage, pressure, rpm, position, and angle, sufficient information can be obtained on the mining status to allow adequate operational control of the miner.

6. All of the necessary data on the operation of the ship, pipe, and miner system can be displayed in a control room of the surface ship in such a manner as to allow timely control decisions.

7. Large systems with dimensions of 60 ft (18 m) or more and weighing several hundred tons can be successfully launched, placed upon the ocean floor, and retrieved in the sea state normally encountered in the mid-Pacific.

METALLIFEROUS SULFIDE MUDS FROM THE RED SEA (Anon., 1981b; Anon., 1986; Amann, 1989). Lying below 6700 ft (2000 m) of ordinary sea water at 68°F (20°C) and 670 ft (200 m) of concentrated brine at 1 ton/yd^3 (1.2 t/m^3) and 140 to 149°F (60 to 65°C), a metalliferous mud deposit extends over an

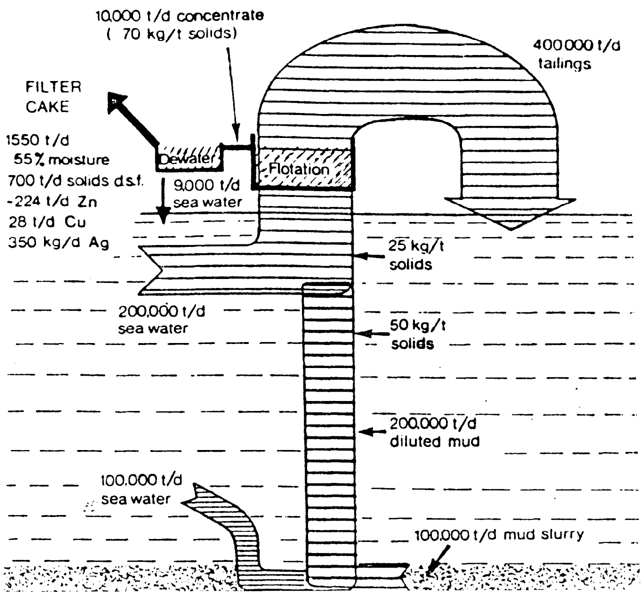

Fig. 22.8.32. Slurry cycle in Red Sea mining tests (after Anon., 1981 b). Conversion factors: 1 lb = 0.4536 kg, 1 ton = 0.9072 t.

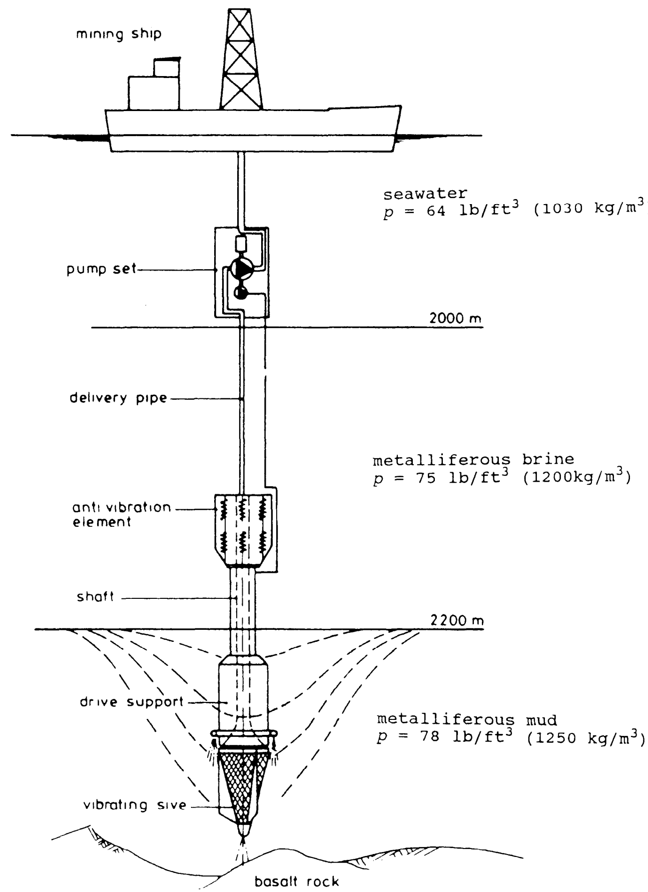

Fig. 22.8.33. Mining system components for Red Sea test on metalliferous muds (after Hahlbrock, 1979). Conversion factor: 1 ft = 0.3048 m.

area of 25 mi^2 (65 km^2) in the Red Sea. Although the surface is fairly even, the thickness varies from 7 to 100 ft (2 to 30 m), and the strata present may include two or three metal-enriched units. The consistency of the mud varies with depth but is most commonly similar to shoe polish. It is thought that deposition has resulted over a period of at least 25,000 years from the metal enrichment of seawater in contact with magma along a crustal fissure, followed by precipitation during cooling.

Pilot Mining Test: Concept to Trial—It was required to develop a three-month initial mining test leading to a pilot operation. Although the sediment is compacted to "shoe polish" at depth, on the surface it is quite soft, and the water content can be as high as 200%, the wet density 78 lb/ft^3 (1250 kg/m^3) and the shear strength 8.7 to 36 psi (60 to 250 Pa). Given this consistency pattern and an economic output requirement of around 220 tpd (200 t/d) contained metal, the production and pumping to surface of a mud slurry was seen to be the most effective route. However, because of the fine particle size of the sediments, slurrification of the muds in seawater yields a viscous suspension with unusual rheological properties: the muds are thixotropic and Bingham plastic, having a high initial shear strength. Therefore, considerable dilution is necessary to permit pumping to surface. To mobilize the required daily metals throughput, it would be necessary to extract 11,000 tpd (10,000 t/d) of in situ mud, creating 11,000 tons/day (10,000 tpd) of slurry in the process. As shown in Fig. 22.8.32, this 110,000 tons (100,000 t) must then be diluted with an equal amount of sea water before it can be pumped to the ship. Two options were initially considered, a plunger pump and a vibrating suction sieve, and the latter was selected.

The suction head designed by Orenstein and Koppel comprises a conical vibrating screen, which acts as a sieve vibrating in the axial direction, fitted to bars at the drive support which is configured to form a suction mouth. The slurry is directed from the head via a 67-ft (20-m) shaft, fitted with a vibration damping device, to the conveyor pipe string. The pressurized water used to help break up and then slurry the sediment is supplied by a pump set located 670 ft (200 m) higher with the slurry pumping equipment. The positioning equipment is fitted to the pipestring immediately above the damping device (Fig. 22.8.33).

Using this head, mining is affected by lowering the sieve through the sediment to a position just above the basalt base, loosening mud in the process by the combined effect of the waterjets and the vibrating screen. To accommodate different mud consistencies, the water pressure and vibration frequency can be adjusted to a certain extent, which also permits control of the slurry concentration. The vibration and downward taper of the sieve prevent clogging by oversize solids. As the head proceeds downward through the sediment, the loosened material flows over its top, sealing out the brine. The slurry density produced by the mining action is less than the 0.9 tons/yd^3 (1.1 t/m^3), which characterizes the brine zone, so that the vertical lift is effectively supported.

The major components of the pump unit are a main mud pump and electric motor, a flush pump to supply the pressure water to the suction head jets via a hose, and an electronic control unit with boxes to distribute power and provide connections between the main coaxial cable and the data transfer systems. A specially designed deep-sea power cable links the control unit and the suction head motor. This cable and the water supply hose are attached to the pipe string and shaft. The power for the underwater electric motors, instrumentation and control devices was to be provided by a 1000-kW, frequency-regulated generator and 440/3000-V transformer assembly on the mining vessel.

The mud pump eventually selected was a modified Worthington 4 UX-1, six-stage, centrifugal pipe-line-type pump, with oil-filled pressure-compensated bearings outside the pump body. The centrifugal type slurry pump first tested suffered severe bearing damage after two weeks of pumping Red Sea mud. Slurry, at 78 lb/ft^3 (1250 kg/m^3) average, could be pumped at 43 to 92 yd^3/hr (33 to 70 m^3/h) with a pump rotation speed of 2850 to 3560 rpm. The pump was driven by a water-filled, pressure-compensated 3000-V, 535-kW Pleuger motor, through a water-lubricated toothed coupling. The flush pump chosen was an 8-stage Pleuger submersible unit.

For transporting the abrasive, corrosive mud slurry to the mining ship and, at the same time, supporting the mining head, pump unit, and measuring devices, Preussag evaluated fiber-reinforced plastic pipes, high-pressure hoses, and steel oil drilling pipe. The plastic pipe interconnections proved unsatisfactory; the high-pressure hoses were expensive, did not easily withstand the starting of the submerged motors, and had not been used in large-diameter sizes. To support the 110-ton (100-t) static load, withstand the starting moments, and handle 39 to 92 yd^3/hr (30 to 70 m^3/h) slurry, an API Standard 5A drill pipe (25 Cr, 5 Mo steel) of 5-in. (127-mm) diameter was selected.

To permit proper control of the mining operation and to monitor operating conditions, a comprehensive instrumentation system was designed, to be installed at three locations: the mining head, in the pump unit, and at the storage tank entry on board ship.

Recovered as a relatively dilute slurry, containing not more than 5.8 lb/ft^3 (100 g/L) solids of fine particle size (80% at -2μm), the metalliferous muds are unlike any of the feeds usually supplied to mineral processing facilities. Yet since the muds contain only 3 to 6% zinc, up to 1% copper, and about 0.03 oz/ton (50 g/t) silver, some concentration prior to extractive metallurgy is essential.

Because it is not possible to blow air bubbles through a slurry containing more than about 3 lb/ft^3 (50 g/L) solids in the manner used in froth flotation, the application of that process was at first ruled out and direct leaching investigated instead. However, not only were attempts to achieve selective metals recovery unsuccessful either at atmospheric pressure or using oxygen pressure, the transport of large volumes of dilute slurry to the necessary land-based plant would be very costly. Similarly, thermal beneficiation would require prohibitively expensive dewatering and drying, and both these routes were abandoned.

When flotation processes were investigated, early success was, in fact, achieved (at Clausthal University) by the simple expedient of further diluting the slurry with sea water and limiting the solids content to less than 1.7 lb/ft^3 (30 g/L). Such a dilution immediately prior to the slurry entering the flotation circuit poses no particular problems on the mining vessel. The reagents used in the process are xanthate collectors with copper sulfate and sodium sulfide activation, standard and similar to those used for bulk sulfide flotation of complex sulfide ores. The process initially differed only in the use of sea water, elevated temperatures, and the dilute pulp; later it was discovered that elevated temperatures were unnecessary.

To assess the effects of ship motion on flotation, Preussag enlisted the help of the Warren Spring Laboratory at Stevenage, UK, where a heave motion simulator was available. The results of tests under rather severe simulated sea conditions of heave, roll, and pitch indicated that flotation was not adversely affected by ship motion. It was concluded that design would have to provide for pulp levels in the cell such that spillage of the froth was prevented, and that to produce 90,000 tpy (80,000 t/a) zinc in concentrate would require a total cell volume in the region of 176,550 ft^3 (5000 m^3), assuming a 70% recovery.

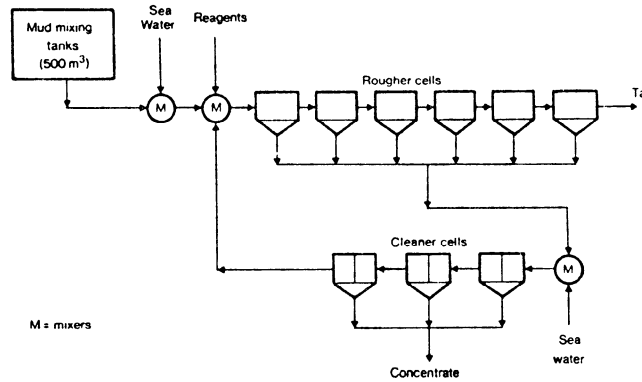

Fig. 22.8.34. Flotation plant on-board test vessel, SEDCO 445 (after Anon., 1981 b). Conversion factor: 1 ft^3 = 0.0283 m^3.

To perform the actual prepilot mining test, it was necessary to find a ship that could be positioned accurately above the chosen mining sites. The sophisticated drill ship *SESCO 445* was chosen because it was known to have an efficient navigation system, good stability at sea, and an experienced drill crew. The rig on board was able to lower the pipestring into the mud deposit in approximately 12 hr and retrieve it in 8 hr. Sediments were successfully pumped aboard for the first time on May 1, 1979, and it was established that the system could deliver mined slurry at a rate of 131 yd^3/hr (100 m^3/h). At first the density of the slurry was rather low and variable, but with experience, it became possible to deliver slurries that contained up to 5.8 lb/ft^3 (100 g/L) solids. The method of dynamic position fixing used for *SESCO 445*, with both surface and seabed radio beacons, proved to be highly accurate, and it is believed that this is the first time that the technique has been used for mining at depths greater than 3300 ft (1000 m). Several methods of mining were tested (crater, pattern, and trench) with use of both a reciprocating movement of the suction head and controlled ship movement. The data gathered were stored on computer for subsequent evaluation.

The flotation circuit supplied by Krupp for use on *SEDCO 445* was typically arranged as shown in Fig. 22.8.34, though several modifications were tried. The plant operated satisfactorily from shortly after start-up at a slurry feed rate of about 212 ft^3/hr (6 m^3/h) and a pulp density of about 1.7 lb/ft^3 (30 g/L). With experience, it was possible to obtain equally good results irrespective of the zinc grade in the mud (which varied according to the site mined). The concentration target was easily achieved and frequently exceeded, with grades of about 40% being recorded on several occasions. The concentrate tonnage target was also achieved, with recoveries being generally about 60% Zn.

On the basis of water oxygen content measurements in the Atlantis II Deep area and observations of the distribution of life forms in the Red Sea, it was decided to discharge tailings from the shipboard flotation plant at a depth of 1300 ft (400 m); at this depth, oxygen is at a minimum, and life lower down is very limited, while current speeds are also at a minimum so that the sediment could be expected to sink. The probable behavior of the tailings plume was modeled at Imperial College, London, prior to the test. To monitor the movement of the plume in practice, *Valdivia* was able to use its ARNAV navigational system in conjunction with a 30-kHz echo sounder, although during the day, plankton movements obscured the readings from the plume so that experiments were restricted to nighttime when the plankton stay near the surface. These observations showed that the plume behaved much as expected, though deep penetration was better than predicted by the model. The discharge penetrates to a depth of 4000 ft (1200 m) within 20 min, with a marked concentration occurring at 2700 ft (800 m). The solids are rapidly diluted, and after a few days the concentration in the plume may be less than twice the normal for Red Sea waters.

Extractive Metallurgy—Under subcontract to Preussag, Lurgi and Davy International prepared shortlists of potentially economically viable process technologies that might be used for zinc, copper, and silver extraction. Cyclone smelting was selected as the most attractive pyrometallurgical route but was abandoned because of the need for a low-salt feed. Four hydrometallurgical routes have been considered as well. Three of the processes involve chloride leaching, solvent extraction, and electrowinning steps according to rather different flowsheets. These are Duval's CLEAR process, modified to include a zinc recovery step; the Minemet process; and the Elkem process. The fourth route involves oxygen pressure leaching in the presence of chloride ion followed by the Comprex process being developed by Tecnicas Reunidas.

22.8.3.3 Mining of Subseabed Deposits

Undersea mining has been carried out by conventional methods from shoreside entries for at least 3000 yr since the Laurium mines were developed under the sea in ancient Greece. Underground mines with shaft entry from the coast or islands have recovered coal, iron ore, nickel-copper ores, tin, and limestones off the coasts of Alaska, Canada, England, Finland, France, Greece, Ireland, Japan, Spain, Taiwan, Turkey, and the United States. Although conventional mining methods prevail, solution mining methods are applicable to many deposits (see Chapter 15.3). Advances in rapid tunneling (Howard, 1976) and subsea technologies (Austin, 1967; Warfield and Parkinson, 1968) will give added incentives to the development of hard-rock deposits offshore (Wang and Cruickshank, 1969). Some current operations are listed in Table 22.8.19.

In general, underground mining is little affected by the marine environment, and additional costs commonly prevail only in the exploration and development phases. As deposits further offshore are discovered and developed, the nature of the environment will become more significant (McMurray, 1990).

22.8.3.4 Environmental Impact Assessment

A listing of completed environmental assessment documents on marine mining in the United States follows, with references:

Chapter 22.9
OTHER NOVEL MINING METHODS

PETER G. CHAMBERLAIN, ROGER J. MORRELL, DAVID A. LARSON, STERLING J. ANDERSON, DAVID P. LINDROTH, GEORGE A. SAVANICK, AND EGONS R. PODNIEKS

22.9.1 INTRODUCTION

PETER G. CHAMBERLAIN

Previous chapters of this section feature new methods that are beginning to play a strong role in mining. Each chapter presents a novel mining method that is moving from development into commercial practice. Other less-developed methods, however, are slowly gaining acceptance in the mining community. Some of these may have an important role in future mining. Others may vanish. With their development still in infancy, it is simply too early to determine their future impact on mining. The purpose of this chapter is to present enough information on these other methods to identify possible applications. Sources of further information are listed at the end of the chapter.

The following six methods are presented in this chapter:

22.9.2 A ripper miner concept of mechanically cutting mine development openings with one large, single bit.

22.9.3 A radial-axial rock-splitting device for mechanically creating development and production openings in mines.

22.9.4 Rock extraction with thermal energy.

22.9.5 Shock wave rock breakers for splitting oversize rock.

22.9.6 Lunar and planetary mining concepts.

22.9.7 Nuclear-assisted mining.

These methods all have a single common characteristic: they are not yet commercially available. Some have been extensively tested and may be commercially available before the end of the century. Others are still preliminary concepts and will not be practiced until well into the 21st century, if at all.

With such diverse methods, the scope of the information provided in this chapter varies considerably with the method. Since these methods are new, the information is based on experimental results rather than case histories. Where possible, the chapter presents the following information for each method:

1. Concept.
2. Background.
3. Implementation: mining operations, equipment design, factors influencing use, nature of the rock product.
4. Cost estimates.
5. Case histories (primarily field tests).
6. Future trends.

Insufficient information exists to provide a “cookbook” recipe for implementing these methods. Rather, the chapter attempts to provide background material that will stimulate potential users to seek updated data on particular applications.

For additional coverage of the fundamentals of rock breakage, the reader is referred to Chapters 9.1, 9.2, and the previous chapters of this section.

22.9.2 RIPPER MINER

PETER G. CHAMBERLAIN, R.J. MORRELL, AND D.A. LARSON

22.9.2.1 Concept

The US Bureau of Mines (USBM) is presently testing a concept for cutting and excavating underground openings in rock with a cutting head consisting of a single, large (12 to 24 in., or 0.3 to 0.6 m, wide) bit. The concept has been termed the *ripper miner method* (Morrell, Larson, and Schmidt, 1989).

The method features a steel or tungsten carbide bit that operators can easily remove from the cutting head for resharpening. During a cutting cycle, push-pull hydraulic cylinders force the bit from its starting position upward through an arc of about 185° (Fig. 22.9.1) (Schmidt, 1989). After each cut, the cutting head returns the bit to its starting position, rotates sideways to the next cutting position, and again moves the bit upward through the cutting arc. When the cutting strokes have completed one pass across the face, the cutting head advances the depth of cut desired and the process begins again.

The ripper miner cuts most rock, but is better suited for soft- and medium-strength rocks, such as sandstone, limestone, and shale. Equipped with a 130-hp (97-kW) hydraulic motor and a 12-in. (300-mm) bit, the machine is capable of advancing 5 fph (1.5 m/h) in a 10- by 10-ft (3- by 3-m) heading in rock with a compressive strength of 18,000 psi (120,000 kPa). The ripper miner is energy efficient because the large, slow-moving bit breaks rock in tension rather than crushing it as do other large drilling and boring machines.

22.9.2.2 Background

Where engineers can blast large volumes of rock at one time, the drill-blast-muck cycle provides a rapid and economical method of excavating rock. In small and confined underground openings, however, blasting efficiency and economy drop. The cyclic movements of personnel and equipment in and out of the openings during the performance of drilling, loading, blasting, roof support, and mucking operations limit productivity. Furthermore, blasting may damage the surrounding rock, increasing the necessary rock support.

These problems spawned much research over the past several decades to develop alternative mining methods. Mechanical excavation techniques have received the most attention. In essence, researchers hoped to introduce a mechanical-mining concept for hard rock similar in principle to the continuous-drum mining machines that have revolutionized coal mining. The costs, advance rate, and flexibility of blasting for excavating rock remained the standard of comparison. Methods studied in the Bureau and in private industry included tunnel boring machines (TBMs), roadheaders, continuous coal mining machines, raise borers, impactors, saws, and drills. These methods either could not fragment hard rock or could not do it as economically as could blasting.

USBM researchers sought a new approach to cut rock. They wanted to fracture the rock in tension rather than crushing it in compression to take advantage of rock’s inherently weak tensile strength. Bureau researchers developed the concept of cutting with a large, slow-moving bit that would allow large chips to spall ahead of the bit as it moved through the rock (Morrell and Larson, 1985). Researchers next tested the concept using 9-in.-(230-mm) wide bits at full-scale cuts in a 6- by 6-ft (2- by 2-m)

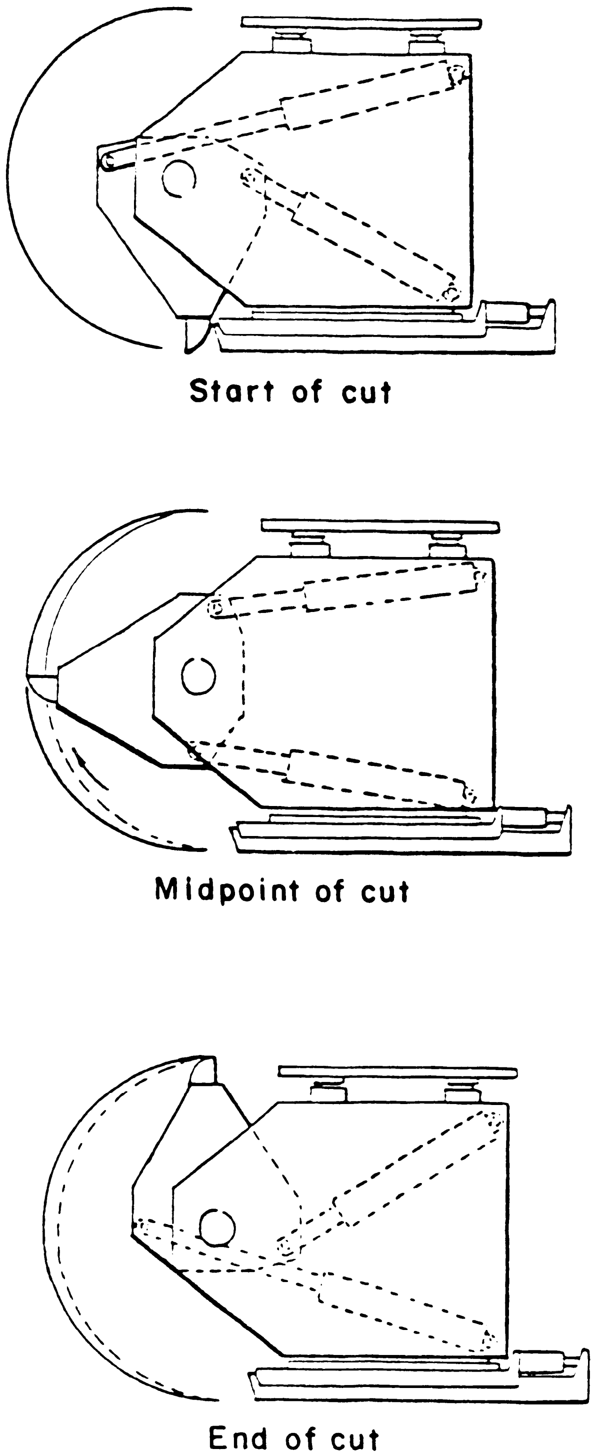

Fig. 22.9.1. Ripper miner concept showing cutting action (Larson et al., 1987).

simulated mine opening (Fig. 22.9.2). Researchers also fitted the machine with subsystems to rotate the cutting head sideways after each cutting sweep and to advance the cutting head after the bit had cut the full face. This configuration allowed research-

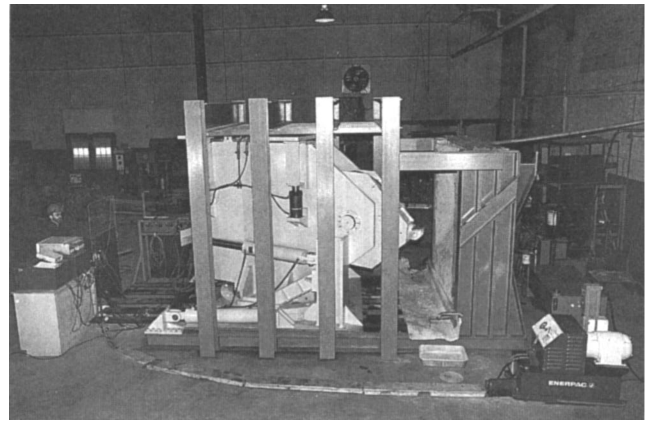

Fig. 22.9.2. Full-scale ripper miner cutting head cutting a concrete block during laboratory tests (Larson et al., 1987).

ers to establish cutting forces and energy requirements for confined side-kerf cuts as well as cuts in the central portion of the face.

These tests provided performance data on various cutting bits and demonstrated desired operating sequences (Larson, Morrell, and Swanson, 1987). The cutter cut rock more efficiently than could TBMs by cutting more of the rock in tension. This also yielded less dust, which could easily be suppressed with water sprays.

22.9.2.3 Implementation

MINING APPROACH. USBM engineers believe that the first commercial machines will be designed to excavate underground mine openings up to about 20 by 20 ft (6 by 6 m) in rock with 5000 to 30,000 psi (30,000 to 200,000 kPa) compressive strength. To establish the desired operating parameters, an engineer first determines the size of opening desired and the type of rock anticipated. The rock type may dictate the type of bit; full-scale laboratory experience indicates that the width of the bit should be about one-tenth the width of the opening.

To operate the machine in an underground heading, an operator would advance the cutting system by its thrust cylinders to a depth equal to the desired depth of cut. The depth of cut is usually one-third to one-half the width of cut.

The cutting head is then rotated horizontally to position the bit where the first cut begins. This can either be in the center or on one side of the face (Fig. 22.9.3).

The cutting system consists of push-pull cylinders that force the bit upward through an arc of about 185°. The rock pieces spall from the face ahead of the bit and fall onto the cutterhead. When the upward cut is completed, the operator swings the bit back down to its starting position. The rock cuttings drop into a chute. Each cut requires about 15 sec to complete. Repositioning between cuts requires an additional 15 sec for a total cycle time of 30 sec.

Although the cutter breaks the rock primarily in tension, some dust is generated by crushing during operation. Water jet nozzles mounted so that the spray covers the leading and trailing edges of the bit effectively reduce the dust to an acceptable level.

EQUIPMENT. The first commercial ripper miners will probably be built to cut rectangular openings 10 by 10 ft (3 by 3 m). Engineers believe that ripper miners eventually could be built to cut 20- by 20-ft (6- by 6-m) openings. The system for 10-ft (3-

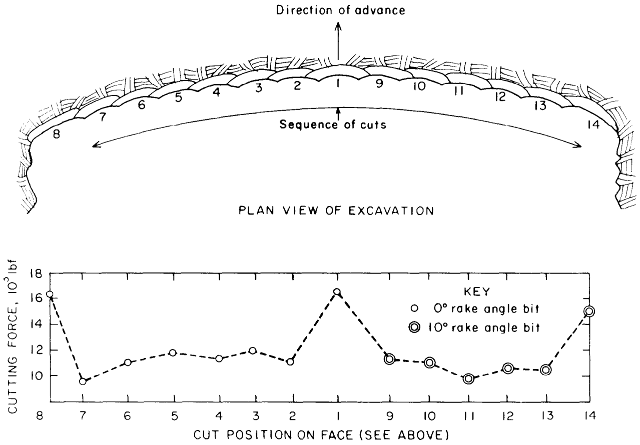

Fig. 22.9.3. Sequence of cutting positions for the ripper miner and corresponding cutting forces (Larson et al., 1987).

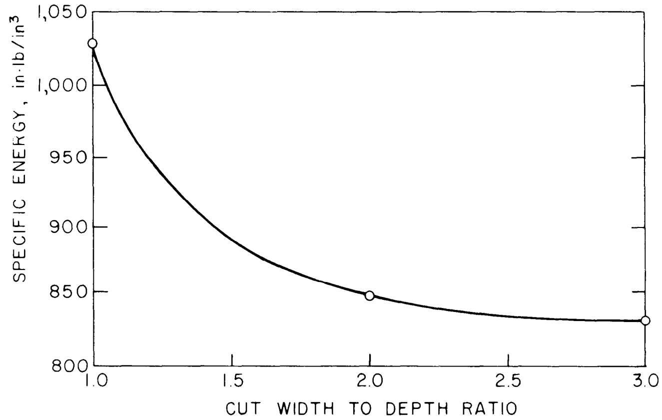

Fig. 22.9.5. Specific energy required to cut Indiana limestone as a function of the length-to-width ratio of the cut (Morrell, Larson, and Schmidt, 1989). Conversion factor: 1 in.-lbf/in.^{3} = 6.667 kJ.

Table 22.9.1. Ripper Miner Specifications

Subsystem	Specifications
Cutting	Two 8-in. diameter bore hydraulic cylinders; 150,000 lbf maximum at 3000 psi
Cutting speed	3½ in./sec at 30 gpm
Thrust	Two 6-in. diameter bore hydraulic cylinders; 600,000 lbf maximum at 10,000 psi
Rotation	Two 6-in. diameter bore hydraulic cylinders; 600,000 lbf at 10,000 psi
Hold-down	Four 100-ton jacks; two forward, two rear
Cutter	Each 9- to 12-in. wide; crown type, bolted on, heat-treated tool steel
Dust suppression	Water spray

Conversion factors: 1 in. = 25.4 mm, 1 ton = 0.9072 t, 1 lbf = 4.448 N, 1 psi = 6.895 kPa, 1 gpm = 0.0631 L/s.
Source: Morrell, Larson, and Schmidt, 1989.

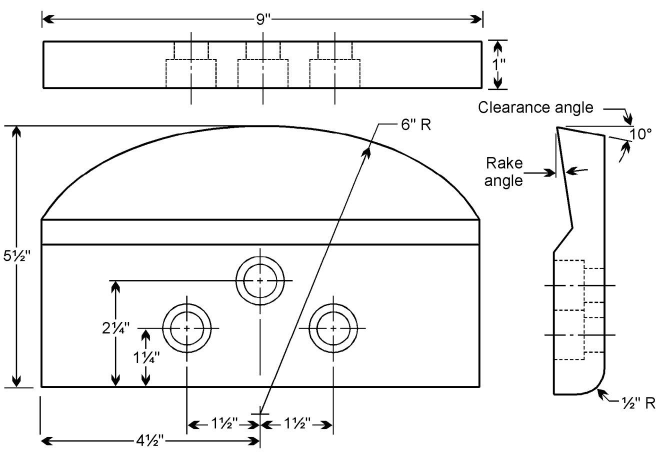

Fig. 22.9.4. Bit configuration for ripper miner (Larson et al., 1987).

m) headings will require approximately 200 hp (150 kW) to operate the cutting head with an 18-in. (460-mm) bit. Specifications for the various cylinders that comprise the operating systems of the full-scale ripper tester are provided in Table 22.9.1.

The heart of the cutting system is the bit. Drag bits 9 to 18 in. (230 to 460 mm) wide will be mounted in modest-sized machines. Bits up to 24 in. (610 mm) wide could be mounted in larger machines (Fig. 22.9.4).

The bits would be bolted to the cutter arm by three bolts to allow easy exchange for sharpening. Engineers estimate that the ripper miner could cut soft rock and coal for an entire shift before the operator must change bits. In hard, abrasive rocks, the bit may require changing five or more times. For most sedimentary rock, miners would change bits once or twice during each shift. One operator can change a bit in 5 min. Bits can be resharpened five to ten times.

Four water-spray jets comprise the dust-suppression system. These jets would be pointed toward all four sides of the bit to assure maximum dust suppression.

ROCK HANDLING AND PROCESSING REQUIREMENTS. The ripper miner cutting system produces coarser muck than would a TBM. Larger pieces result from the ability of the large, slow-moving bits to spall much of the rock with tensile forces. The largest pieces are about the same size as the cut; a 2-in. (50-mm) deep cut with a 9-in. (230-mm) wide bit would produce a maximum chip of about 2 by 9 in. (50 by 230 mm). By weight, more than 40% of the muck would be retained on a 2-in. (50-mm) screen and more than 70% on a 0.5-in. (13-mm) screen (Larson, Morrell, and Swanson, 1987).

Muck is dumped in a hopper in the machine at the end of each stroke. Materials handling would be most efficient if the machine were linked to a continuous conveying system. The muck could also be dumped in a shuttle car for transportation out of the heading.

FACTORS INFLUENCING USE. Rock strength controls the applications of the ripper miner concept. The cutting system has been tested on rocks with strengths over 45,000 psi (310,000 kPa). It appears most suited for sedimentary rocks with strengths between 5000 and 30,000 psi (30,000 and 200,000 kPa).

The ratio of the depth of cut to its width greatly influences the energy expended in cutting (Fig. 22.9.5) (Morrell, Larson, and Schmidt, 1989). The USBM believes that cutting at a depth at one-fourth to one-third of the bit width provides the best cutting efficiency.

Bit wear is governed by forces on the bit, speed of the bit, hardness of the material, and abrasiveness of the material being cut. Of these factors, the operator can most easily control bit speed. Wear studies on drag bits indicate that best life can be achieved at bit speeds of around 12 in./sec (300 mm/s) (Haspert, 1978).

Table 22.9.2. Ripper Miner Cost Calculations

Assume a 10- by 10-ft ripper mining machine cost of $250,000 with a 5-yr and 2500-shift life and 18,000-psi rock.

Ownership Costs	
1. Amortization of ripper miner $250,000/2500 shifts	$100/shift
2. Interest, taxes, and insurance—20% (average investment per year)/500 shifts	$60/shift
Operating Cost	
3. Power for ripper 200 hp = 148 kW at $0.05 for 5 hr	$37/shift
4. Maintenance cost 60% (of 1)	$60/shift
5. 18-in. wide cutter cost (assume two cutters/shift @ $150 each)	$300/shift
Labor Cost	
6. One operator $20/hr by 8 hr	$160/shift
TOTAL COST	$717/shift
TOTAL COST/TON ($717/317 tons)	$2.26/ton

Source: Larson, Morrell, and Swanson, 1987.

22.9.2.4 Costs

With reasonable allowances for delays, productivity of the ripper miner for driving a 10- by 10-ft (3- by 3-m) opening with an 18-in. (460-mm) bit moving at a speed of 12 in./sec (300 mm/s) and with a 6-in. (150-mm) depth of cut is estimated at about 300 tons (272 t)/shift. This was based on the following performance data: cutting and positioning time per stroke 30 sec; cutting time for one pass across the face (7 strokes) 3.5 min; instantaneous advance rate 8.5 fph (2.6 m/h); advance rate (assuming 5 hr operating time/shift) 42 ft (13 m)/shift; and tonnage rate 317 ton (288 t)/shift (Morrell, Larson, and Schmidt, 1989).

Capital costs for the cutting machine are estimated at $250,000 in 1989 dollars. This cost is based on a machine capable of cutting 10- by 10-ft (3- by 3-m) openings and fitted with a 200-hp (150-kW) motor to power the hydraulic cylinders. The machines are expected to last 5 years or 2500 shifts in 18,000-psi (120,000-kPa) rock.

Bits cost about $150 each. Cutters are expected to wear twice as fast as laboratory bits, and so two bits per shift is the basis for estimating bit costs.

Detailed estimated cost calculations are shown in Table 22.9.2. The 1987 cost per ton of rock excavated, $2.26, compares favorably with drilling and blasting costs of $2.60 for the same size opening ($2.49 vs. $2.87/t).

22.9.2.5 Future Trends

Manufacturing companies have expressed interest in the ripper miner concept. The USBM would like to award an exclusive license to manufacture the equipment. Hopefully, ripper miner systems will be commercially available in the 1990s. The first machines will probably target the tunneling and development markets.

Researchers continue to investigate improvements to the system that will facilitate cutting very hard rock. Several bits that cut hard rock much more efficiently are being tested. Thermal softening of rock ahead of the bit may also offer improved cutting speeds with lower forces and reduced bit wear. Kerfing with water jets may eventually progress to the point where operators could save energy and reduce cutting forces particularly at the edges of the openings.

Fig. 22.9.6. Drill-split fragmentation apparatus.

22.9.3 DRILL-SPLIT FRAGMENTATION WITH THE RADIAL-AXIAL SPLITTER

PETER G. CHAMBERLAIN AND STERLING J. ANDERSON

22.9.3.1 Concepts

Another new method of mechanically extracting rock is called *drill-split fragmentation.* The heart of this system is a unique splitter. This splitter applies both an axial and a radial load to a rock mass from within a drillhole (Fig. 22.9.6). In operation, the combined radial and axial forces fracture a plug of rock from the face. This system is an outgrowth of radial-loading splitters that miners use to trim mine and tunnel openings.

Since the hydraulic cylinder contains the reaction forces of excavation, the splitter can be light. Operators can carry the compact, light splitter with a drill on a common frame anywhere underground that they can carry a drill. Drill-split methods offer the same flexibility as do drill-blast methods to meet the excavation requirements. Drill-split equipment can excavate in any direction and create openings of any size or shape.

Developers designed the radial-axial splitter to perform as a primary underground rock excavation machine. It is especially well suited to applications where blasting excessively damages the rock wall or where blasting causes unacceptable vibrations or noise. The splitter has operated effectively in bedded and fractured rock without any apparent loss in efficiency. The splitter has proven effective in a broad range of rock types. In the laboratory, it has extracted plugs from large blocks of concrete, limestone (13,000 psi or 90,000 kPa, compressive strength), and granite (26,000 psi or 180,000 kPa, compressive strength). It performed well during tests in an underground limestone mine.

The drill-split method offers several appealing attributes. The splitter is easy to operate, requiring a skill level comparable to drilling. One operator can both drill and split rock from a single setup, reducing both the crew size and excavation time. Miners can excavate rock with a simple two-step, repetitive process. A nonviolent process, the drill-split method is compatible with nearby mining operations. Being essentially continuous, it avoids the production delays attendant in drill-blast methods. Drilling and splitting eliminates the safety problems associated

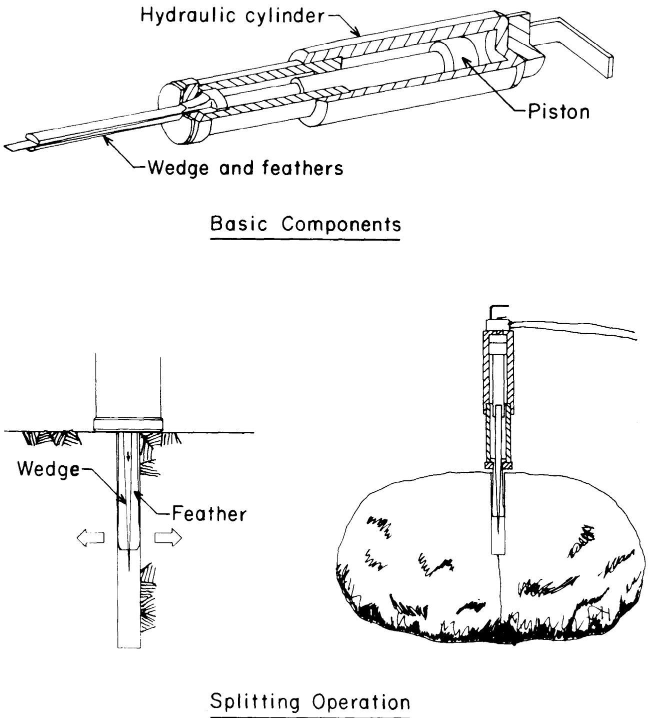

Fig. 22.9.7. Radial-demolition splitter (Anderson and Swanson, 1982).

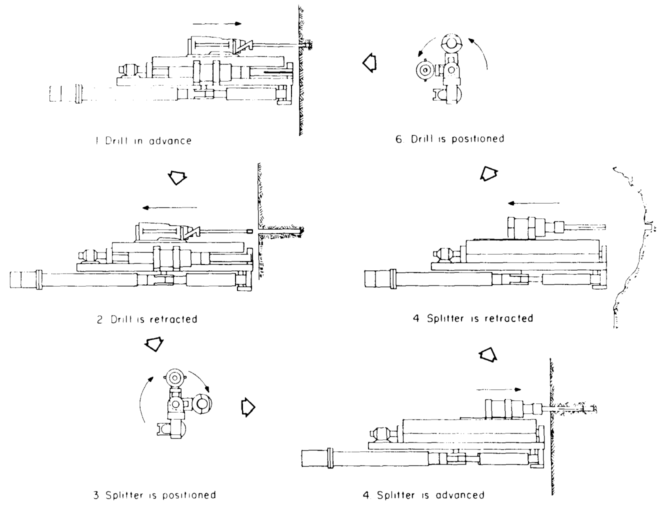

Fig. 22.9.8. Drill-split excavation sequence (Anderson and Swanson, 1987).

with blasting. Finally, the mine environment is healthier owing to the lack of blasting fumes and the reduction in dust.

22.9.3.2 Background

The basic concept of splitting rock with wedges in hole is not new. Workers in prehistoric societies split rock along pre-existing cracks with hammer-driven wedges. Commercially available splitters use hydraulically activated wedges to split boulders, split slate, trim mine openings, and demolish concrete structures.

These commercial splitters consist of a double-acting hydraulic cylinder, twin feathers, and a wedge (Fig. 22.9.7). During operation, a piston drives the wedge between the tapered feathers in a drillhole, creating radial loading against the wall of the hole. As the force increases, a fracture initiates and eventually propagates to the nearest free face.

Several investigators (Choulette et al., 1976; Clark and Maleki, 1978), and the USBM (Anderson and Swanson, 1982) attempted to develop primary mining schemes with these radial splitters. The researchers tried to fracture rock to free surfaces that were perpendicular to the face and parallel to the axis of drillholes. They wanted to excavate a longwall face with a series of side-by-side splits. Each operation of the splitter would hopefully break the rock to the free face created by the previous split. These experiments all met problems in fracturing the rock and in dislodging the fractured material. Such problems became more prevalent during experiments on driving headings.

An experimental tool developed by Institute CERAC in Switzerland combined radial and axial forces in a single drillhole. With this tool, an operator could fracture the rock without a free face parallel to the drillhole (Cooper, 1978; Cooper et al., 1980). USBM researchers began studying the technology to determine its mining potential. Using reduced-scale laboratory tests, the USBM measured the influence of various rock and operating parameters on the ability of the tool to split rock from a confined face (Anderson and Swanson, 1982).

From those experiments, the USBM conceived a mining system based on radial-axial splitting. The USBM incorporated specific unique features into the system to make it reliable, easy to operate, and economically viable. Full-scale tests at an operating limestone mine provide confidence that the method will soon appear in operating mines (Anderson and Swanson, 1987).

22.9.3.3 Implementation

MINING OPERATION. Mining crews could drill-split rock in many applications. Beside excavating development openings, operators could mine rock with the splitter in shrinkage stopes and underhand stopes. Operators could also mine rock in room and pillar and cut and fill operations with the splitter. The most likely early applications, however, will be driving development openings and specialized underground construction projects.

The sequence of operations for a drill-split excavation begins with the operator drilling a hole into the face (Fig. 22.9.8). The operator must drill the hole to the correct depth so the rod can push against the hole bottom. After drilling the hole, the operator rotates the drill out of the way and inserts the splitter. The operator then activates the cylinder. The radial force anchors the splitter, much like a rock bolt anchor, and generates the loads required to fracture the rock. These loads create a tensile stress field that fractures the rock in a bowl shape centered at the drillhole (Fig. 22.9.9). The fracture begins at the place in the hole that the feather is forced into the hole wall. It propagates in a curved path until it intersects the rock surface. The fracture usually meets the face at a distance from the hole of roughly 3½ times its depth. After the rock breaks, the operator again rotates the tools to drill the next hole. In large headings or for production applications, an automated excavation system may feature several such drill-splitter units mounted on one large carrier.

The required loads will vary with rock type. The operator must match the loads with each rock type encountered in a drift or tunnel.

Miners can drive blind headings in drifts with several configurations. Figs. 22.9.10 to 22.9.12 illustrate several possibilities. In the full-face technique, the center of the drift is advanced with

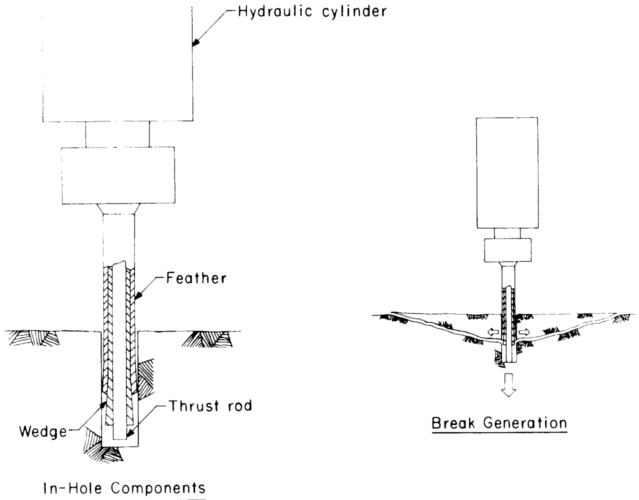

Fig. 22.9.9. Radial-axial splitter (Anderson and Swanson, 1982).

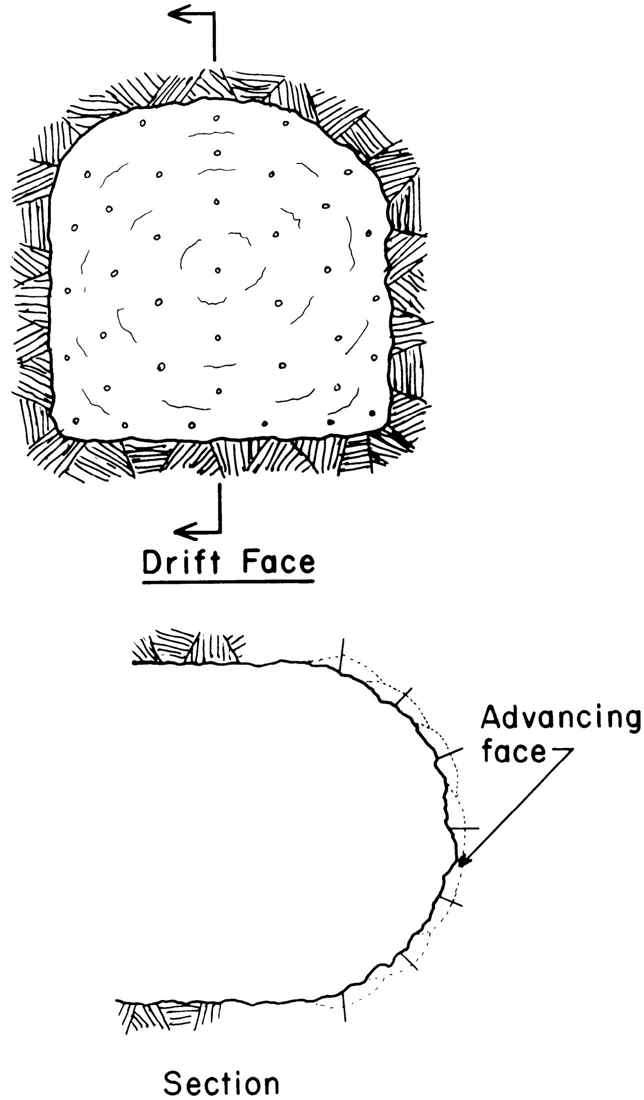

Fig. 22.9.11. Hemispherical-advance mining sequence (Anderson and Swanson, 1982).

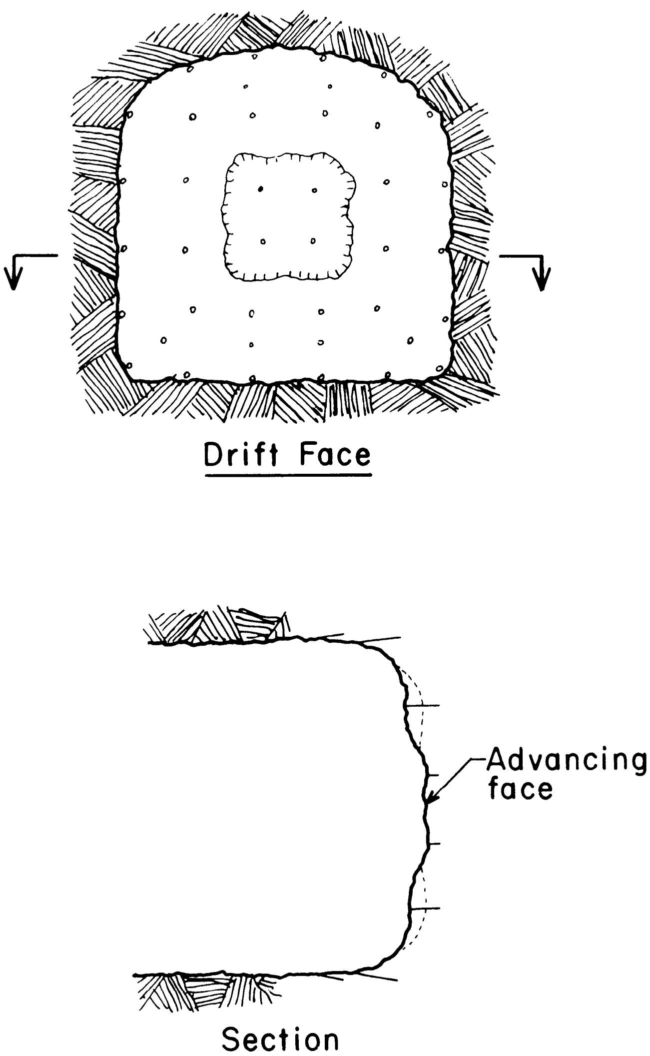

Fig. 22.9.10. Full-face-advance mining sequence (Anderson and Swanson, 1982).

the first break. Subsequent breaks work outward to the desired perimeter. All holes are drilled in the direction of advance. In the hemispherical technique, the operator again advances the center of the drift first. In this technique, however, the operator keeps the profile of the advance in a hemispherical shape by drilling the successive holes perpendicular to the curved surface of the advancing face. The third configuration, stepped-face advance, also begins with a central break. Instead of completing all the successive breaks to the perimeter, however, the operator begins a second advance as the first one widens sufficiently. The face eventually assumes a wide conical shape rather than a sharply stepped profile. The extraction forces and efficiency are roughly comparable among each configuration.

Operators must maintain the desired size and shape of opening. This focuses attention on excavating the highly confined corners of the drift. Two methods are available for removing the rock from sides and corners of the drift. First, the operator can slab the rock by drilling the perimeter hole at a slight outward

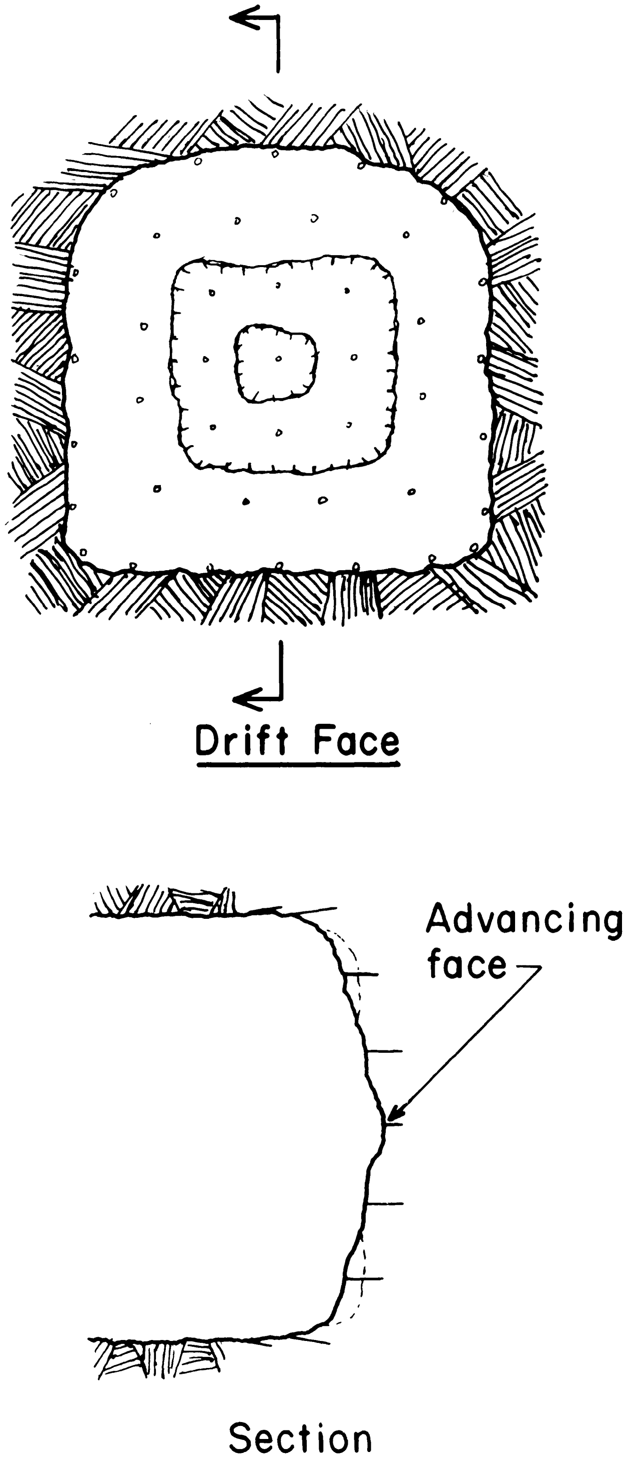

Fig. 22.9.12. Stepped-advance mining sequence (Anderson and Swanson, 1982).

angle. When the tool is operated in the radial mode, the rock spalls into the drift. Second, the operator can drill shallow holes perpendicular to the wall and pull the rock in the tool's normal radial-axial mode. Both methods work better if the face has advanced one or more rounds beyond the trimming activity.

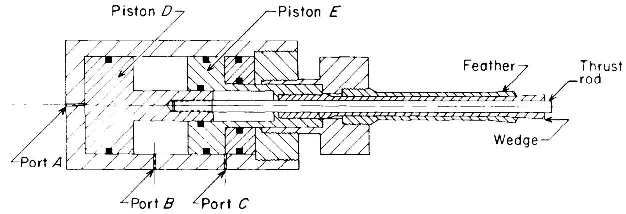

Fig. 22.9.13. Radial-axial splitter detail (Anderson and Swanson, 1982).

Operators can advance the face by following a prescribed pattern of holes. Or they can judge individual hole positions for the most efficient breakage, depending on the nature of the preceding breaks. New operators and automated systems require planned drilling patterns. To accommodate local geologic variations and varying quality of breaks, the planned drillholes will be spaced closer together than may be necessary. Experienced operators will develop the ability to position holes visually. They will be able to use fractures and bedding to help break the rock.

EQUIPMENT. The radial-axial splitter consists of a special hydraulic cylinder containing two independent pistons and the in-hole rock-breaking parts. The latter include the feather, wedge, and thrust rod (Fig. 22.9.13). The design of the rock-breaking parts is critical to successful operation of the splitter.

The wedge, concentrically located between the thrust rod and the feather, resembles a thick-walled tube with a cone-shaped forward end. Attached to one of the cylinder's two pistons, this wedge is drawn into the feather when the cylinder retracts its piston.

The feather is divided axially into four equal segments that expand radially as the wedge is withdrawn. It, too, has a cone-shaped forward end that has been constructed with various angles. In laboratory tests, this angle affects the operator's ability to anchor the tool in rocks of different strengths (Anderson and Swanson, 1987).

Relative hardness and brittleness of the feather and wedge must be balanced. A soft wedge combined with a hard feather wears very rapidly, and the wedge is soon rendered useless by excessive material creep. A hard wedge with a hard feather may cause brittle failure of either piece at stress concentration points. If the feather is too soft, its contact with the rock wears rapidly, eventually affecting its ability to hold. A reasonable compromise seems to be a wedge hardness of 56 Rockwell C and a feather hardness of 50 Rockwell C.

The thrust rod is attached to the cylinder's other piston. When the cylinder pushes this rod against the bottom of the hole, it produces an axial load in the rock mass.

Typically, the hydraulic system used to power the splitter operates up to 3000 psi (20,000 kPa) pressure. A splitter weighing just 80 lbm (36 kg) that works in a $1\frac{5}{8}$-in (40-mm) drillhole can generate up to 71,000 lbf (320 kN) of axial and 345,000 lbf (1550 kN) of radial load. This tool combined with a jackleg can be hand manipulated, yet break out rock to depths exceeding 7 in. (18 mm). Such a splitter typically produces about one-quarter ton (one-quarter t) of rock per break. A larger splitter that works in a 3-in. (76-mm) drillhole can generate up to 270,000 lbf (1200 kN) of axial and 650,000 lbf (2900 kN) of radial load. This tool by comparison can extract 4 tons (4 t) of rock per break.

The large splitter and drill are boom mounted on an air-powered, crawler-driven chassis that provides a rugged, mobile platform. The chassis holds the drill and splitter so an operator can align the splitter precisely over the previously drilled hole.

Table 22.9.3. Drill-Split Operating Schedule

Drilling operation:		
Collaring and drilling (penetration rate 50 in./min or 1.27 m/min)	min/hole	0.35
Drill repositioning	do	.27
Drill retraction	do	.10
Splitting operation:		
Indexing (includes rotation to splitter, insertion of splitter, retraction of splitter, rotation to drill)	do	.30
Splitting	do	.10
Total time to drill and split one hole	do	1.12
Total time to drill and split one round (28-hole round worked by a 3-boom jumbo)	min/round	11.20
Jumbo repositioning operation: (10-min repositioning time, every fourth round)	do	2.50
Total time for round	do	13.70
Advance rate (calculated): (based on 6 working hours per shift)	ft/shift	26.28

Assumptions: Splitter operating in a 2.5-in. (62-mm) hole, 15 in. (380 mm) deep, breaking at a depth of 12 in. (300 mm).
Source: Anderson and Swanson, 1982.
Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

The operator aligns the splitter and drill with a rotary actuator and mechanical stops. Alignment is very important; the efficiency of the drill-split method relies on the rapid alignment of the splitter with the drillhole.

Table 22.9.3 provides an analysis of the time devoted to each step of the operation. For a 10- by 10-ft (3- by 3-m) blind heading, an advance rate of 26 ft (7.8 m)/shift should be expected (based on 6 hr actual working time per shift). This advance rate is from a system consisting of three drill-split units on separate booms. Two miners could operate such a system in one heading.

The rock produced by drill-split methods may be mucked by various methods. Miners may attach muckers that use gathering arms or similar loading systems to drill-split equipment to produce a continuous miner. Other mining scenarios lend themselves to separate excavation and mucking equipment.

Factors Influencing Use. The amount of confinement affects the efficiency of excavation with splitters. Confinement is influenced by proximity to the excavation's perimeter, topography of the excavated face, and nearness to preceding breaks. Laboratory evidence points to a considerable decline in the amount of rock excavated per break as the confinement increases. This is difficult to quantify and outside the control of the operator. The effect of confining pressure caused by proximity to the excavation's perimeter or free faces is clearly shown in the shape of the crater (Fig. 22.9.14). Under greater confinement, the tool is less efficient. With less confinement, efficiency increases.

The insertion angle is under the operator's control and influences the amount of rock broken by the splitter and the forces required to break it (Fig. 22.9.15). At shallow angles or near a free face, the radial-axial splitter works as a simple radial splitter. It can be used to trim, shape, or enlarge openings. As the angle of insertion increases to vertical, the relative axial force necessary to extract the plug of rock increases.

Splitting efficiency and the fluctuations caused by confinement should be presented in the context of specific energy. A 3-in. (76-mm) splitter operating in an underground limestone mine produced an average of 1.25 ton (1.1 t) per break. The 3-in. (76-mm) diameter drillhole required for the splitter's operation averaged 15 in. (380 mm) deep. The overall specific energy for the drill-split operation was 180 in.-lbf/in.^{3} (1200 kJ). This number is a marked improvement over the equivalent number for other mechanical cutting methods, which can require 1000 in.-lbf/in.^{3} (7 MJ).

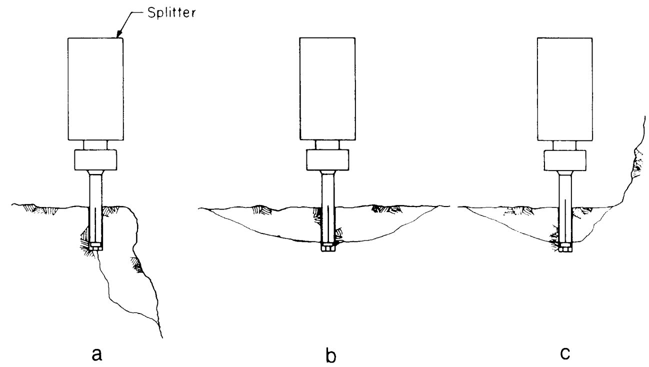

Fig. 22.9.14. Crater shape as affected by confinement. a) Bordered by a free face; b) Planer; c) Bordered by a confining wall (Anderson and Swanson, 1987).

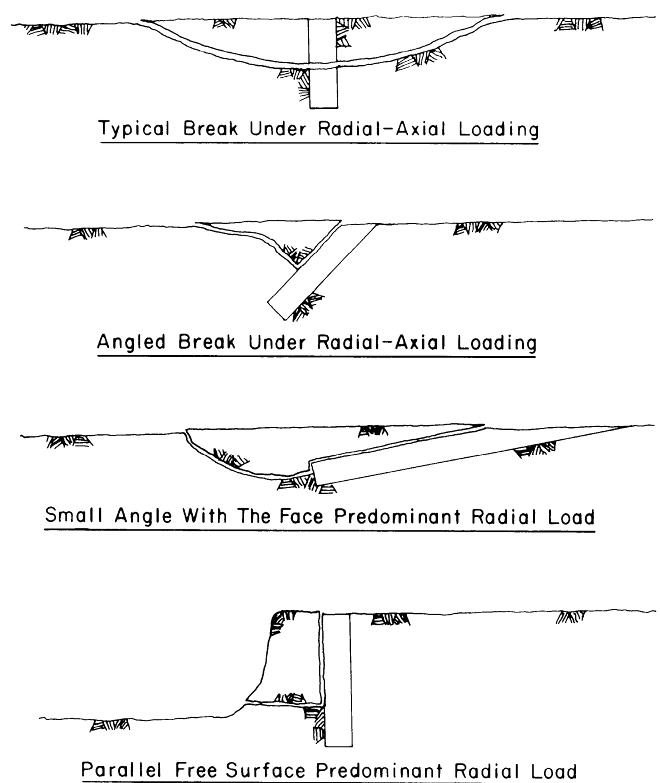

Fig. 22.9.15. Effect of insertion angle on crater shape (Anderson and Swanson, 1982).

Depth of break and rock toughness both exert influence over the forces necessary to excavate rock with the splitter. In tests on large limestone and granite blocks, the relationship between depth of break and axial force was defined by the following for limestone and granite, respectively:

$$A = 4{,}152D^{1.36} \quad (22.9.1)$$

$$A = 6{,}282D^{1.66} \quad (22.9.2)$$

where A is maximum axial force in lb, and D is depth of break in in.

The relationship between depth of break and radial force was defined for limestone and granite, respectively, as follows:

$$R = 13{,}134D^{1.40} \tag{22.9.3}$$

$$R = 24{,}212D^{1.60} \tag{22.9.4}$$

where R is maximum radial force in lbf.

These empirical relationships support the hypothesis set forth by Rhyming, Cooper, and Berlie (1980) that the breaking force is proportional to $D^{1.50}$.

Depth of break also governed the effectiveness of the splitter. For the limestone and granite tests at depths ranging from 1 to 7-½ in. (25 to 190 mm) and 0.75 to 4 in. (20 to 100 mm), respectively, the equation describing this effectiveness for limestone and granite was as follows:

$$W = 0.85D^{2.77} \tag{22.9.5}$$

$$W = 1.34D^{2.97} \tag{22.9.6}$$

where W is quantity of material removed in lb.

At any given depth, the volume of material removed is independent of the forces. The volume removed appears to be strictly a geometric consideration independent of the rock type. It can be approximated by the volume of a cone with a base radius 3½ times its height. The height equals the depth of break.

22.9.3.4 Costs

To help analyze the costs of the radial-axial splitter, USBM engineers estimated production rates for driving a 10- by 10-ft (3- by 3-m) opening. The excavation system consisted of three drill-split units on one chassis, run by two operators. The analysis assumed that 15-in. (380-mm) deep holes would be drilled for the splitters. It also assumed that operators would anchor the splitters to break the rock at an average depth of 12 in. (300 mm). About 28 breaks and 13.7 min were required to advance the full face 12 in. (300 mm). After every fourth advance of the face, the operator moved the chassis forward 4 ft (1.2 m). Based on 6 hr actual working time available per shift, the advance rate per shift averaged 26 ft (7.9 m). This translates to an excavation rate of 27 tph (24 t/h) (Anderson and Swanson, 1982). Table 22.9.4 provides an analysis of capital and operating costs for the radial-axial splitter in 1982 dollars. Inflating to 1988 dollars gives an ownership cost of $29.25/hr and total operating costs of $78.00/hr. The inflated cost becomes $4.26/ton ($4.70/t).

The radial-axial splitter cost $10,000 (1988 dollars) to build, and the entire system including the splitter, indexer, and crawler modifications cost under $25,000 (1988 dollars).

22.9.3.5 Case History

The USBM tested a radial-axial splitter in the Linwood Mining and Minerals Corp. underground limestone mine near Davenport, IA. Engineers operated the splitter in a blind heading on the lower level, 170 ft (51 m) below the surface. The roof was 23 ft (7 m) high, and the 40-ft (12-m) rooms were separated by 30-ft (9-m) pillars. The company continued normal mining operations during the testing.

In this field test, the USBM used the previously described crawler-mounted radial-axial splitter that operates in a 3-in. (76-mm) diameter drillhole. This tool and an air-powered rotary percussive drill were mounted together on a chassis. The chassis contained an indexing mechanism to permit the operator to rapidly align the splitter with the hole.

A diesel-driven compressor that generates 750 cfm (0.35 m^3/s) of air at 100 psi (700 kPa) produced the air needed by the machine. The splitter power was generated by a 2-hp (1.4-kW), air-driven hydraulic pump that was added to the crawler unit.

Operating through about 100 cycles, it mined approximately 125 tons (113 t) of ore. The average depth of break was 10 in. (250 mm), and loads required to fracture the rock averaged 65,000 lbf (250 kN) for the axial and 170,000 lbf (760 kN) for the radial modes. The 1¼-ton (1.1-t)/break average was larger than that predicted by the empirical relationships developed in the laboratory. Most rock pieces produced by the tool weighed from 20 to 300 lbm (9 to 140 kg).

The heading was mucked with the mine's normal mucking equipment, front-end loaders with 6-yd^3 (4-m^3) buckets. Miners mucked the face when it became difficult to work over the muckpile. During mucking, miners pulled the crawler out of the heading.

The field operation erased concerns about the tool's ability to excavate fractured and fissured rock and its ability to completely free the broken pieces from the rock mass. Occasionally the splitter lost its grip on part of the fractured rock plug when a majority of it fell away. If that happened, a normally spaced, subsequent break removed the remaining rock with no difficulty.

As a part of this test, the USBM completed a time study for the drill-split method. USBM researchers classified the drill-split operations into four categories: drilling, indexing (including all the time taken to replace the drill in the hole with the splitter), splitting, and repositioning the machine. The average times devoted to these operations were as follows:

Operation	Time (sec)
Drilling	50
Indexing	15
Splitting	150
Repositioning	60
Total	275

These operations averaged a total of 275 sec for the entire drill-split cycle with splitting consuming the most time. The splitting operation was slower in these tests than would be expected in commercial operations because an undersized hydraulic pump was used to power the tool. Splitting speeds of 15 sec are reasonable, and at such a rate, the average total time consumed would be reduced to 140 sec. In laboratory tests, the speed of the splitting process did not affect the quantity of rock excavated. The best total time achieved during the field test was 206 sec for a 10-in. (250-mm) break depth in which the splitting operation consumed 68 sec. The USBM believes that with operator experience and upgraded equipment, the average total time can be reduced further, to about 80 sec.

The USBM conducted the entire test in a blind heading. Holes were drilled with water flushing to control the dust. The splitting operation produced almost no dust. Although falling rock produced small amounts of dust, it caused no problem for the operators. This underground field test proved that the radial-axial splitter is an efficient primary rock excavator. Operators experienced little difficulty learning to operate the machine in these underground mining conditions.

22.9.3.6 Future Trends

Engineers anticipate that a variety of sizes will be manufactured for different excavation requirements. The tool may be

used singly or in multiple units. It break rocks nonviolently with little impact on the surrounding rock. Drill-split fragmentation is a flexible excavation method that can be adapted to meet a broad range of mining requirements.

The radial-axial splitter seems ready for commercial application. First uses in mines will probably concentrate on special underground construction projects. Rock excavation operations in heavily populated zones that preclude or restrict blasting also seem ideal early applications. Development openings in rock especially susceptible to blast damage provide yet another excellent opportunity to use the splitter.

22.9.4 THERMAL FRAGMENTATION AND EXCAVATION

PETER G. CHAMBERLAIN AND DAVID P. LINDROTH

22.9.4.1 Concept

Although mechanical mining and tunneling machines have dominated research on methods of extracting rock without blasting, *thermal fragmentation systems* hold promise for certain applications. Attempts to excavate rock with greater than 20,000 psi (140,000-kPa) compressive strength using continuous mechanical mining machines have met with marginal success. Commercially available machines excavate rock primarily with high compressive forces that crush the material at the rock-bit interface. Cutting hard rock with such machines requires excessively large forces. Bits wear and break rapidly under these conditions. Methods previously described in this chapter introduce the concept of fracturing rock in tension during excavation. Thermal methods present an alternate way to induce tensile stresses in the rock as a primary excavation technique or to augment mechanical excavation.

Although early experiments showed that thermal energy broke rock inefficiently, recent developments indicate more efficient applications. One such development is *microwave heating.* Microwave heating can fragment hard rock. It can also weaken rock to improve other mining or secondary breakage methods. Microwaves can penetrate rock and, as electromagnetic energy is converted to heat by rapid vibration of molecules at a location inside the rock, can create a thermal inclusion (hot spot) inside the rock. The hot rock then expands according to its specific thermal expansion, whereas the surrounding cool rock does not. The resulting swelling of the hot spot inside the rock causes tensile stresses in the surrounding rock, eventually fragmenting it. With rapid heating at high energy levels, microwave heating can fracture the rock sufficiently for mucking. The rock can also be heated with lower energy to induce just enough fractures to make it easy for mechanical methods such as a ripper miner machine (see 22.9.2) to complete the excavation.

Additional applications of high temperature could appear in future mines. Laser technology allows rapid kerfing that could make traditional mechanical excavation more efficient. With continuous miners and tunneling machines, the mechanical kerfing tools are subjected to extremely high wear because the rock is confined. A thin kerf, such as could be produced by lasers, relieves the confining forces. This allows the machine to cut the peripheral rock as easily as it cuts the interior rock.

Microwave researchers have fragmented extremely hard rocks in laboratory settings (Thirumalai, 1970). Technical feasibility is thus not a question. Before the methods can move to commercial application, however, researchers must complete considerably more fundamental testing and evaluation.

Spin-off microwave heating technology is also showing considerable promise. Microwave heating efficiently dries coal and limestone (Lindroth, 1986a). Microwaves could reduce metallurgical processing time and cut costs by heating ore particles in a shorter time than fossil fuel heating now does (McGill, Walkiewicz, and Smyltes, 1988).

22.9.4.2 Background

Mining with heat dates to the earliest prehistoric societies. The first hard-rock metal miners in this country mined copper from northern Michigan 2000 years ago. Their technique was simple; they built fires in mine pits. When the surrounding rock was hot, they doused it with cold water. They then beat the fractured ore with mauls to free it. The hundreds and perhaps thousands of mine pits dotting the region when the first Europeans arrived offered silent tribute to their success and industriousness.

Miners no longer heat rock to excavate it. Energy provided by chemicals (blasting) and mechanical methods break large volumes of rock efficiently and economically. Special problems, however, have periodically inspired research on ways to use high temperature to break rock. Such problems usually involve excavating very hard rocks that cannot be readily excavated with mechanical machines and where blasting is not desired.

The early research on excavating rocks by applying high temperatures focused on surface applications of heat. A rock surface was heated with high-temperature sources such as fossil-fuel torches, ionized-plasma torches, jet piercers, electron beams, and lasers. Heat was transferred to the interior of the rock by the slow process of conduction. The resultant thermal stresses caused some rocks to spall (those high in quartz, for instance) but most melted.

The high amounts of energy consumed to melt rock (without yielding appreciable thermal stresses) and the difficulty in removing molten rock from a face eliminated surface heating as a viable excavation technique for rocks that did not readily spall. A few applications for surface heat did reach operating mines. Miners “drilled” blastholes with jet piercers for several years in the extremely hard taconite ore of northern Minnesota. The high energy costs, however, doomed jet piercers when better rotary bits were developed for such rock.

Researchers began considering methods of internally heating rock to induce tensile stress without wasting energy by heating the surface. USBM and Soviet researchers investigated *high-frequency dielectric heating* for internally heating rocks that did not readily spall (Thirumalai, 1970). The first USBM experiments were conducted on rock blocks by inserting an array of copper electrodes. The thermal inclusion developed inside the electrode array. Blocks of basalt and granite fractured with a thermal inclusion that represented less than 2% of the rock volume. This fragmentation consumed 4 to 8 kWh/m^3 (14 to 29 J/m^3). Although the authors proposed a stoping method where large thermal inclusions would be created in the rock, no practical way of creating the inclusions using direct-contact electrodes was ever advanced.

The USBM is now investigating methods of dielectrically heating rock remotely using microwaves. Microwave energy is transferred to rock by a radiant-energy beam. Recent studies showed that the dielectric heating more effectively fractures rock at higher frequencies than those used in the early studies. USBM researchers presently conduct microwave research with a microwave source of 25 kW. It operates at a frequency of 2.45 billion cps (2.45 GHz).

Lasers have evolved over the past several decades for many industrial applications. High-power CO_2 lasers are routinely used to cut, weld, and machine metals. USBM research (Lindroth, 1984) has provided several possible applications of CO_2 lasers in mining. Lasers may be used to rapidly spall specific rock types such as quartzite or for scribing and lettering of building stone and monuments. One promising application is to cut a deep kerf in a rock face and then break out the rock inside the kerf by other means. For example, a laser could be used so that the beam would act as a gage cutter in a hard-rock tunneling system.

22.9.4.3 Possible Mining Operations

Electromagnetic energy in the form of microwaves offers several possible mining applications. Research and development efforts are still defining basic parameters, and specific systems for excavating rock have not been developed. Experience with fracturing rock using microwaves and the acquisition of the necessary engineering parameters, however, permits researchers to establish likely operating guidelines.

The core of any microwave excavation system will be the microwave generation unit. Microwaves generated at a frequency of 2.45 billion cps (2.45 GHz) with a power rating of 25 kW fracture large blocks of rock in laboratory settings and

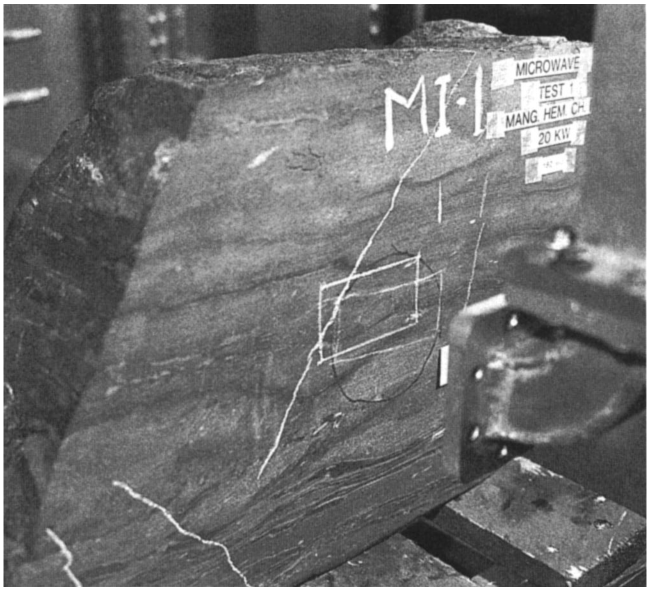

Fig. 22.9.16. Block of manganiferous iron ore in microwave irradiation laboratory test facility.

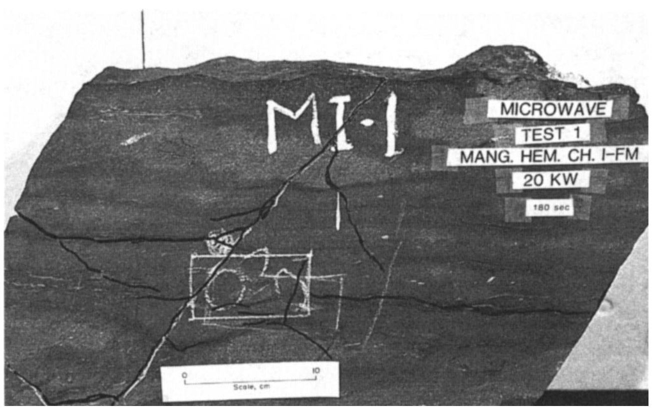

Fig. 22.9.17. Fracturing created in block of manganiferous iron ore after microwave irradiation for 180 sec.

represent a reasonable guide for size. Fig. 22.9.16 shows a 180-lbm (82-kg) rock being irradiated by this microwave device. Note the stand-off distance of about 6 in. (150 mm) in front of the open waveguide for the test. Fig. 22.9.17 shows the 180-lbm (82-kg) block of manganiferous cherty iron formation (Cuyuna Range) fractured after irradiation for a little over 20 sec. The black lines are the microwave-induced fractures, and the white are mineralization lines.

The microwaves penetrate the rock to a depth that is determined by the frequency of the electromagnetic wave and the rock's dielectric and magnetic properties. The objective is to rapidly create a hot inclusion inside the rock at a sufficient depth from the surface. The stresses created at the contact between the boundary of the inclusion and the surrounding cold rock are governed by the following relationship (Thirumalai, 1970):

$$\sigma = \mu\, E\, a\, T/(1\text{-}p) \tag{22.9.7}$$

where σ is stress, μ is a constant related to the shape of the inclusion and varies from 1 to $\frac{2}{3}$, E is Young's modulus, a is an expansion coefficient, T is temperature rise for the inclusion, and p is Poisson's ratio.

Thus, the stresses are independent of the size of the inclusion. Since the stresses induce tensile and shear fractures, the ability of microwaves to fracture rock also does not depend on compressive strength. This unique feature allows microwaves to fracture extremely hard rock not amenable to mechanical excavation.

The ability of the thermal inclusion to fracture rock grows as the temperature of the inclusion increases up to a maximum temperature. The internal temperature at which the stresses are maximized vary with rock type. Thirumalai (1970) found that for basalt, this maximum temperature averages about 930°F (500°C); for granite it averages 570°F (300°C). At higher temperatures, the Young's modulus falls and this rock softens, thus outweighing any benefit from a higher temperature rise. The hotter inclusion essentially dissipates the stresses without fracturing the rock.

Researchers have accumulated enough evidence to support the technical feasibility of fracturing many very hard rock types with microwave energy. Until further research establishes the engineering parameters of the optimum frequency, power, and energy density, the design of an economical primary excavation system remains conjectural.

A more energy-efficient application of microwaves may be to soften hard rock in advance of mechanical excavation. In this application, the rock is irradiated with microwave energy immediately ahead of the mechanical bit. As described above, the microwaves develop thermal stresses inside the rock, which generate fractures. As the bit passes through the rock, the rock is excavated with a lower force because of the network of thermal-generated fractures. Preliminary experiments revealed a 70% reduction in cutting force on drag bits when the rock was irradiated with microwave energy. USBM researchers are still studying this approach. They hope to develop data on proper combinations of mechanical cutting mode, cutting tool configuration, and microwave energy that will reduce mechanical cutting forces and energy consumption.

Research on the use of high-power lasers in mining showed a promising concept featuring the laser as a kerfing device. By cutting a deep kerf in hard rock, an operator could more easily break the rock between kerfs with mechanical or other primary excavation methods. For example, a laser beam could act as a gage cutter on TBMs (Carstens, 1972). Laser beams can make thin deep cuts by melting and vaporizing rock. Lasers easily cut kerfs in even the hardest rocks. High-energy lasers readily penetrate rocks with compressive strengths up to 73,000 psi (500 MPa). Even relatively low-power CO_2 lasers of a few hundred watts can create narrow cuts by spalling in certain rock types. For example, the USBM measured the mass of rock removed by a 100-W laser beam as a function of the power density (up to 570 W/mm^2) and beam scan rates for a quartzite (Fig. 22.9.18). The highest spalling rate was observed at a power density of only 2.5 W/mm^2 and a beam scan of 0.14 in./sec (3.5 mm/s).

For lasers up to 5-kW output (Carstens, 1972) and scanning speeds in the range of 0.83 to 3.35 in./sec (21 to 85 mm/s), the depth of penetration is linearly proportional to the beam power. Penetration depth is inversely proportional to the scanning speed. Within this range of scanning speeds, the product of speed times depth of cut was a constant for a given laser-beam output. Researchers expect that full-scale laser cutting tools will operate with 15-kW output.

These high-power lasers appear well suited as gage cutters for large tunneling machines in rock with compressive strengths over 40,000 psi (275,800 kPa). Present mechanical gage cutters

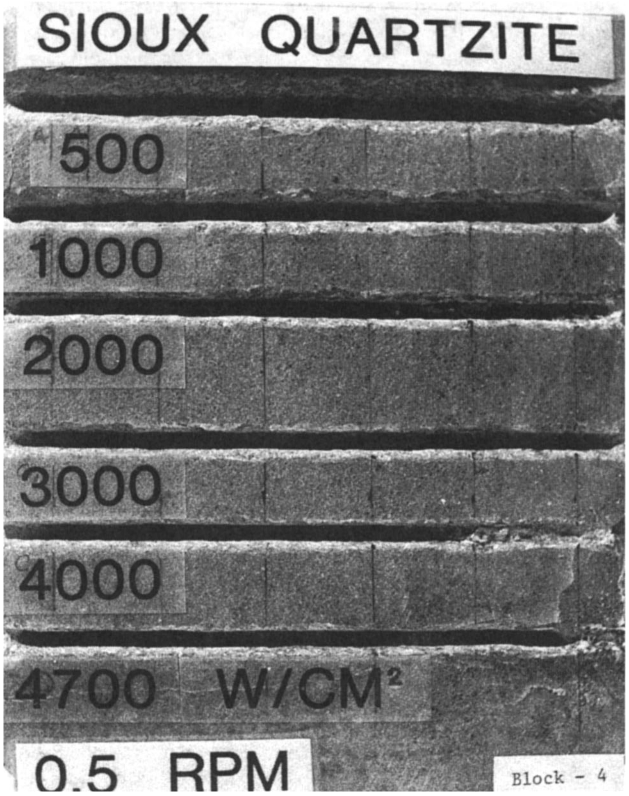

Fig. 22.9.18. Slots in quartzite created by scanning with 100-watt CO_2 laser beam at various power densities.

operate with a component of thrust acting radially outward; they must cut both the face and the wall of the tunnel. This complex loading shortens their life considerably. Much machine downtime is attributed to rapid wear of gage cutters. A single, highly focused laser beam, rotating at the same speed as the interior mechanical cutters, could cut a deep kerf and eliminate the need for gage cutters. Laser light remains coherent for long distances so that the laser would be located in a protective housing at a remote distance from the cutting head.

As an example of this application, a 10-ft (3-m) boring machine rotating at 9 rpm can penetrate 5 fph (1.5 m/h) in 40,000-psi (275,800-kPa) rock. This rotation causes a gage cutter linear velocity of 4.7 fps (1.436 m/s). To maintain a kerf depth corresponding to the advance rate achieved by the machine, a laser beam would have to cut a kerf 0.1 in. (3 mm) deep at that velocity. This is now possible with the experimental 4-kW laser previously described. With 15-kW lasers, such a kerfing system may be economically viable.

22.9.4.4 Costs

Microwave generators presently cost $2000 to $3000/kW. High-powered, CO_2 laser generators presently cost about $40,000/kW. As the high-power laser industry matures, the costs can be expected to drop considerably.

22.9.4.5 Future Trends

Key information to be determined before thermal fragmentation methods are applied to mining includes matching microwave frequency and power density for efficient fragmentation. As the fundamental data on frequency and power density become available, additional effort will be necessary to conceive practical means of applying the energy to the rock.

Thermal fragmentation suggests some interesting potential applications in the mining and minerals industry. Microwave energy applications in fragmenting and processing could blossom as equipment costs are reduced and efficiencies are increased. Many state-of-the-art mechanical excavation techniques may be enhanced by combining them with electromagnetic energy.

22.9.5 SHOCK WAVE ROCK BREAKERS

PETER G. CHAMBERLAIN AND GEORGE A. SAVANICK

For many years, engineers have known that *shock waves in water* cause considerable damage to structures. Nearby exploding ordinance, for example, can damage ships and submarines even without a direct hit. At least two devices are sold to break rock based on shock waves generated in water. One uses shotgun cartridges to create the shock wave, the other high-pressure gas cylinders.

22.9.5.1 Shotgun Cartridge Rock Breaker

CONCEPT. Hudco, Inc., Mentor, OH, markets a pulse breaker called the *water wedge* to break oversized rock and demolish concrete structures. To use the water wedge, an operator drills a hole in the rock to be broken and fills it with water. The tool is then inserted in the hole and charged with a shotgun cartridge. The cartridge is fired remotely with a rope lanyard. The explosion generates a stress wave in the water column. The resulting high pressure splits the rock in tension.

OPERATION. The pulse breaker is designed to break large boulders or oversize muck as well as demolish concrete structures where blasting is not desirable. To prepare an oversized rock for the pulse breaker, an operator drills a 1⅝-in. (40-mm) hole 15 or 21 in. (390 or 540 mm) deep. The operator then fills the hole with water using any convenient container.

The operator inserts the lower end of the breaker into the hole and charges the breaker with a 10- or 12-gage shotgun cartridge containing smokeless powder. The operator then retreats to a safe position and fires the cartridge using a 60-ft (18-m) rope lanyard. When the cartridge fires, it drives a plug down a transfer tube in the water-filled hole. The resultant high pressure (40,000 psi, or 275,800 kPa, with the 12-gage model) in the water transfers high tensile stresses to the walls of the hole. The rock breaks in tension along fracture planes parallel to the axis of the hole (Fig. 22.9.19).

The pulse breaker can break hard rocks having up to 62,000-psi (427,490-kPa) compressive strength. Its simple operation enables even unskilled workers to operate the breaker with little training.

EQUIPMENT. The water wedge pulse breaker is a portable, hand-held tool. It consists of a cartridge holder, firing mechanism, and downhole transfer tube assembly packaged into a unit weighing 22 lbm (10 kg). The operator may choose either a 15- or 21-in. (380- or 530-mm) tube assembly, depending on the size of rock typically split. Hole depth must be matched with tube length.

The stem of the transfer tube contains holes pointed in a radial direction. When the cartridge fires, the high pressure in the water forces the sleeve against the wall of the hole. This prevents the tool from being ejected from the hole.

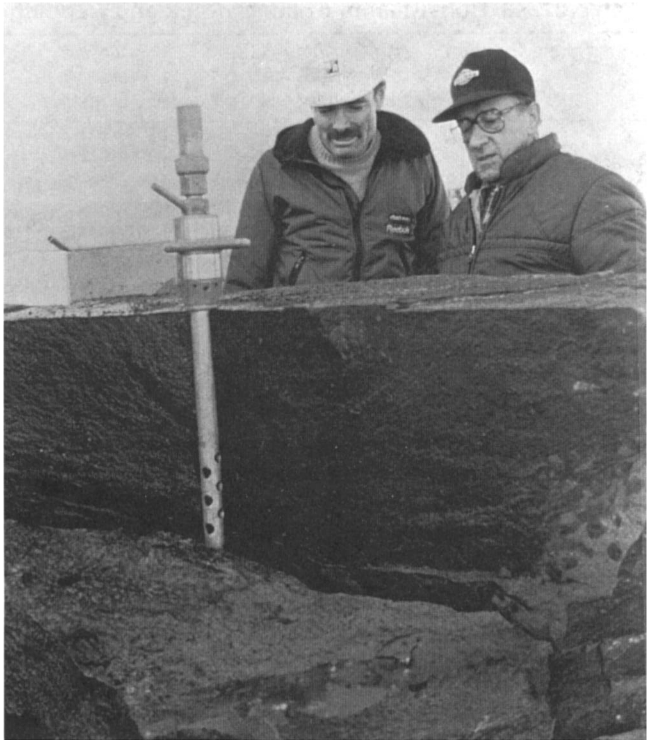

Fig. 22.9.19. Dresser basalt broken by pulse from 12-gage cartridge.

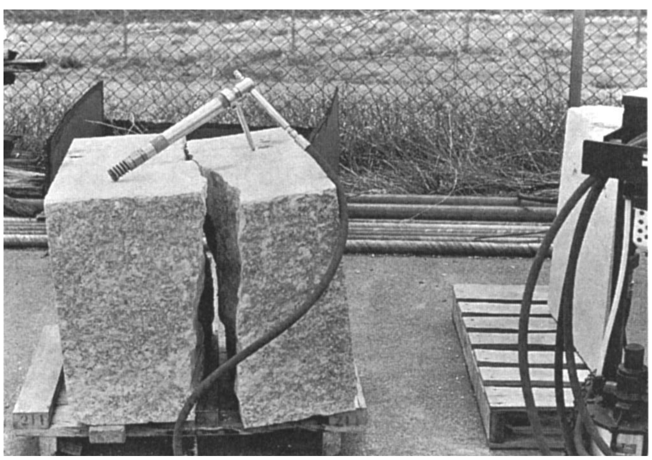

Fig. 22.9.20. Block of dolomite broken with a pulse from a water-charged accumulator.

22.9.5.2 Cheney Rock Breaker

CONCEPT. The *Cheney rock breaker* is another apparatus that splits rocks with high-pressure water pulses. First patented in Australia (Cheney, 1979), it breaks rock in a controlled manner from one or more holes drilled in rock. The operator inserts the rock breaker tool in a hole, locks it in place, and fills the hole with water through the tool's hollow stem. The operator then applies a sudden surge of pressure to the water by releasing a valve connected to a high-pressure accumulator. The pressure pulse in the drillhole splits the rock (Fig. 22.9.20). A mechanical feather/wedge assembly accentuates the pressure and directs the forces so that the operator can orient the fracture plane.

Cheney developed the rock breaker to overcome the problems of flyrock and eliminate the other hazards of blasting by controlling fracture. The method is particularly applicable to breaking oversize rock remaining from typical quarry blasting. Most quarries break oversize rock by detonating a blasting agent placed on the rock's surface. Such methods may cause flyrock and considerable air-blast noise. The Cheney rock breaker operating in one hole in a boulder represents one commercially available alternative.

The rock breaker can also presplit rock masses by using it in a line of holes. The operator drills a line of holes along a desired fracture plane. The tool, operated in successive holes, splits the rock along the plane containing the holes.

MINING OPERATIONS. To split rock with the rock breaker, an operator first drills one or more holes into the rock to be split and then inserts the downhole portion of the tool into the hole. The downhole portion consists of a hollow stem, expanding collet, and seal. By tightening a nut, the operator expands the seal and the split collet to secure the tool in the hole. Water is added through the hollow stem to fill the hole. The operator then applies a modest pressure to the water in the hole before sealing it. The unit is then charged by pressurizing a water-filled accumulator connected to the hollow stem. When the operator suddenly releases this higher pressure to the water in the hole through the hollow stem, the pressure pulse fractures the rock.

The pressure pulse in water rapidly transmits force to the rock. Since the water is nearly incompressible, however, the pressure almost instantly drops when the fracture initiates. The fracture thus propagates with much more control than fractures generated by conventional blasting practices.

To presplit a rock mass via a line of holes, the operator sequentially activates the rock breaker in each hole. A feather and wedge assembly forces the collet against the wall of the hole with the same mechanism as contained in a rock bolt anchor. The rock fractures along the plane of the split in the collet.

EQUIPMENT. The Cheney rock breaker is built by Almet Enterprises, Pty., and distributed by Laundry Investments, Pty., both of Australia.

The downhole assembly fits in a $1^1/_2$-in. (37.5-mm) hole. It consists essentially of a hollow tube or stem, a split expandable collet, and a seal. A bleed valve on top permits the operator to fill the hole with water so no air bubbles are trapped inside. A ratchet attached to a large nut outside the hole squeezes the seal until it securely anchors in the hole.

The power unit, connected to the downhole unit with a high-pressure hose, is completely portable. It consists essentially of a compressed air supply, pressure intensifier, and an accumulator half filled with water. These components are mounted on a two-wheeled cart. The pressure intensifier builds compressed air pressure in the upper half of the accumulator. When the operator releases a ball valve on the lower end of the accumulator, the accumulator discharges a pressure pulse of about 350 bar to the water in the hole. This pressure pulse generates about 90,000 lbf (400 kN) of radial force/foot (0.3 m) of hole.

CASE HISTORY. The Cheney rock breaker successfully split huge granite blocks during restructuring of a dockyard in the port of Gibraltar. Shand, Ltd., used the rock breaker while refurbishing an existing naval dockyard for commercial shipping. The company was hired to remove the four large steps on the walls of the dock against which vessels were previously moored. The granite steps were constructed in the 1890s. They extended for a length of 500 ft (150 m). Shand was not permitted to blast the steps. Other forms of demolition cost too much and consumed excessive time.

To remove the four granite steps, the contractor drilled a line of holes on 12-in. (300-mm) spacings over the length of the

steps and halfway in from the outer step. The Cheney rock breaker was activated in alternate holes, generating a hairline fracture. After the holes were drilled, operating the rock breaker consumed only a few minutes per hole. The contractor easily removed the steps with an impact hammer.

FUTURE TRENDS. Shock wave breakers offer a safe, portable, and inexpensive alternative to blasting in certain mining and quarrying operations. They seem ideally suited to breaking oversize rock in quarries, a duty frequently assigned to relatively inexperienced miners. They also function well in certain presplitting applications.

The advantages suggest that shock wave breakers will appear more frequently in open-pit mines and quarries. As their popularity expands, a broader range of configurations should become available.

22.9.6 LUNAR AND PLANETARY MINING

PETER G. CHAMBERLAIN AND EGONS R. PODNIEKS

22.9.6.1 Concepts

Mining in space, once strictly the realm of comic strips, now looms as a distinct possibility. *Astro-miners* could be mining on the Moon or on Mars and its moons by early in the 21st century. Two critical needs have drawn mining into future space planning—materials to support space missions and commercial exploitation of materials unavailable on Earth.

In 1989, the National Aeronautics and Space Administration (NASA) developed a new mission—the Space Exploration Initiative. Its goal would be to establish a sustained, self-sufficient presence in space. The effort would focus first on a permanent lunar outpost, with expansion to Mars and its moons. This outpost or base would require local life support and construction materials. The base would also function as a refueling station for extended space travel, requiring locally produced propellent components.

MATERIAL NEEDS. A prime requirement of a lunar outpost would be a liquid oxygen plant. Workers on the moon will need oxygen to breathe plus oxygen and hydrogen to make water. Initial oxygen requirements would average 165 tpy (150 t/a) for a 6- to 8-person crew (Table 22.9.5) (McKay, 1990). NASA estimates that 1100 tons (1000 t) of oxygen will be required each year to support full-scale lunar base activities. Lunar mining and processing operations can provide this oxygen and some hydrogen.

Extraterrestrial mining could provide other materials needed for outpost bases in space. Construction materials, for example, will be extremely expensive to transport from the Earth to the Moon. NASA contractors are evaluating the feasibility of preparing sintered blocks from lunar regolith. Liquid hydrogen and oxygen are the key ingredients of propellants for space travel. Astronauts could refuel at outpost bases with locally mined ingredients. Astronauts traveling to Mars would also benefit by being able to restock oxygen and water during a stop at the Moon. Without this capability, much of the payload contained in space launches from Earth must consist of life-support materials.

Beside mining and processing to support space missions, at least one possible commercial mining enterprise is being considered. Scientists are studying the fusion of deuterium and helium-3 as well as the more probable deuterium/tritium fusion for future US nuclear power plants. Apparent safety and efficiency benefits may favor fusion with helium-3. Unfortunately, very little helium-3 exists on earth. An extraterrestrial source is needed if deuterium/helium-3 fusion plants are to become a commercial reality. Helium-3 is deposited on the lunar surface by solar winds. Although the low concentrations of helium-3 on the Moon minimize chances of mining significant amounts of helium-3, at some future time the economics of energy supplies may warrant such production.

DEPOSITS. Two types of deposits offer hope for lunar mining. The first is oxide minerals in mare regions. Moon rock and regolith contain FeO, SiO_2, Al_2O_3, and TiO_2 (Table 22.9.6). Most attractive mining candidates for oxygen would be regions of mare containing concentrations of ilmenite, $FeO \cdot TiO_2$. Early mining operations for oxygen will likely focus on the loosely bound regolith. Although the regolith appears to contain 45% oxygen, only about 10% of the regolith is ilmenite. NASA scientists assume that the recoverable oxygen from these deposits would average about 3% (McKay, 1990).

The second type of deposit comprises the ions of hydrogen, helium, and helium-3 impinged upon the Moon's surface by solar winds. Solar winds are essentially ions of light gases—mostly hydrogen—streaming away from the sun. The ions deposited on

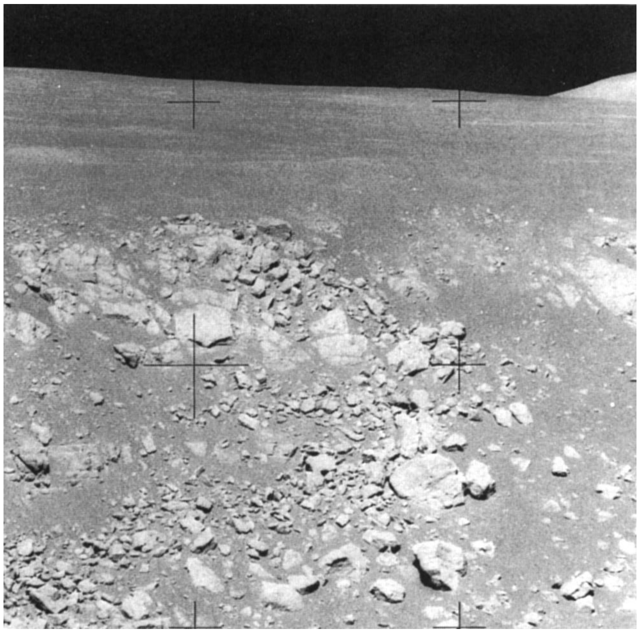

Fig. 22.9.21. Typical lunar regolith (*courtesy:* NASA, Houston, TX).

the Moon are more concentrated on the surface of small particles (less than 100 μm). Fortunately, approximately 80% of the soil is 8 to 125 μm (Wittenberg, Santarius, and Kulcinsky, 1986). Continual bombardment of the lunar surface by meteorites has stirred the particles to a depth of several meters. Mining operations would concentrate on the top 6 to 10 ft (2 or 3 m) of regolith (Fig. 22.9.21).

Hydrogen is the most abundant ion deposited by the solar winds. Scientists estimate that the regolith contains 20 to 200 ppm of hydrogen (Taylor, 1975). The hydrogen is easily driven off the surfaces of regolith particles at temperatures above 752°F (400°C). The big operational difficulty would be to trap the gases in the vacuum that exists at the moon's surface. For planning purposes, NASA scientists assume that recoverable hydrogen in the upper 10 ft (3 m) of regolith averages 50 ppm (McKay, 1990).

In regolith samples, the ratio of hydrogen to helium averages about 8.5:1. Although the ratio of helium-3 to helium is generally low, Apollo and Luna mission data indicate that the lunar regolith at some locations may contain 7 to 30 ppm helium-3.

22.9.6.2 Mining Activities in Space

MINING CONSIDERATIONS. Mining operations on the Moon or planets will be highly automated extensions of mining practices on earth. The most likely methods will be surface mining operations. Mining the unconsolidated regolith will essentially consist of digging and hauling material to a processing site (Register, 1989; Siekmeier and Podnieks, 1990). This mining will include the means to handle the boulders apparent in the regolith. Underground mining may evolve later if the benefits of protection from radiation, temperature extremes, and bombardment by solar wind and meteorites outweigh the lower productivity (Podnieks and Schmidt, 1990).

Fig. 22.9.22. Surface mining concept for lunar oxygen.

The lunar environment imposes severe restrictions on possible mining operations. Even the simplest tasks are difficult under the conditions present on the moon. Terrestrial mining equipment will not function well under these circumstances. Rather, completely new technology must be developed. Development of successful mining operations in space truly represents a monumental challenge.

OXYGEN MINING. Oxygen requirements have driven planning efforts to date. Although several processes for recovering oxygen have been proposed, the current thinking favors hydrogen reduction of ilmenite. The first mining operations on the moon would be to provide oxygen for an 8-person lunar base requiring a 165-ton (150-t) liquid oxygen extraction system. To annually recover 165 tons (150 t) of oxygen, miners would excavate 50,000 tons (45,000 t) of regolith per year.

Such amounts of "ore" could be provided from a surface mining operation. The mines would appear similar to sand and gravel operations on earth (Fig. 22.9.22). Since scientists believe that ilmenite is rather broadly dispersed in maria, astro-miners could select sites in easily accessible regions, relatively free from boulder fields.

For safety, miners would operate the equipment remotely from protective enclosures. They would go outside of shelter only to repair minor equipment malfunctions or to retrieve the equipment for major repairs.

Oxygen mining operations in regolith could also provide construction materials. For instance, tailings from the oxygen recovery process could be sintered into construction blocks. If tailings material does not sinter well, the bulk regolith could be mined, screened, and fed to a sintering process.

Underground mining operations could also provide oxygen for lunar base life support. These would be shallow, probably collared in escarpments at the edges of maria. Drifts in hard rock would allow miners access to draw down the loose regolith through a series of raises. Alternately, astro-miners could excavate ore in a simple room and pillar sequence with the drill-split tool described in 22.9.3. The USBM conceived an idea of excavating with a drill-split tool, then sealing the openings with microwave-induced melting to provide a safe working environment (Podnieks and Schmidt, 1990). Working in the drifts would protect the miners from radiation and micro-meteorite impacts. Temperature could also be controlled. Particularly if combined with construction activities, underground excavations for oxygen could also provide shelters and habitation sites for lunar base inhabitants.

HYDROGEN/HELIUM MINING. Considerably larger mining operations would be needed to recover sufficient hydrogen and/or helium than would be needed to recover oxygen. Mines for solar-wind implanted ions also may be configured differently than oxygen mines. Since the ions are concentrated in the upper few feet of the regolith, astro-miners would excavate only the upper 6 to 10 ft (2 to 3 m) of regolith.

For early activities on the moon, an eight-person base would require 16.5 tons (15 t) of hydrogen. At a hydrogen concentration of 50 ppm, workers would need to process 300,000 tons (270,000 t) of regolith to produce the required hydrogen. Miners would likely screen the regolith so only the material less than 100 μm would be processed. Since 80% of the regolith is less than 100 μm, miners would have to excavate an extra 25% of regolith. Mining operations thus must produce 375,000 tons (340,000 t) of regolith per year.

The retained regolith would be preheated and then placed in a solar-heated retort. At temperatures of around 1112°F (600°C), hydrogen, helium, carbon dioxide, carbon monoxide, and nitrogen trapped on the particles would be driven off and collected. Considerable study would be required to develop technology for collecting these gases under the lunar conditions of ultrahigh vacuum.

A fully operational lunar base, staffed by 15 to 20 people, would require about 130 tons (120 t) of hydrogen for water and for propellent (McKay, 1988). Such hydrogen production would require a mine producing 3 million tons (2.7 Mt)/yr of regolith. Sand and gravel operators on Earth commonly achieve such production rates. A crew of 15 to 20 people expected to perform other duties, however, will have a difficult time attaining these rates in the hostile lunar environment. The ability of lunar mining operations to provide adequate hydrogen for self-sufficiency may lag that of oxygen. Evidence of higher concentrations of hydrogen deposited on the surface of Mars and Phobos may make such mining operations more practical on those bodies.

Any commercial exploitation of helium-3 deposits on the Moon would require mining at a very large scale. One estimate of the helium-3 requirements predicts that the demand could reach 1 tpy (0.9 t/a) by 2030, 10 tpy (0.9 t/a) by 2035, and 200 tpy (180 t/a) by 2050. For 1 ton (0.9 t) of helium-3, about 120 million tons (110 Mt) of regolith must be mined (Wittenberg, Santorius, and Kulcinsky, 1986). The scope of operation needed for these requirements seems beyond those that will be available on the Moon early in the 21st century.

Although present efforts to develop mining concepts for space environments are based on conventional terrestrial technology, engineers will likely develop completely new concepts for recovering materials needed on the moon. At this time, such concepts are too speculative to include in this Handbook.

EQUIPMENT. Scientists have proposed every imaginable sort of mining equipment for lunar mining. Since thorough mining engineering studies have not been completed, however, any discussion on mining equipment is premature. Highly automated vehicles that dig, load, and transport the regolith to a storage pile would probably form the heart of the excavation system. They would function in a manner similar to scrapers or front-end loaders in construction activities on earth (Register, 1989; Siekmeier and Podnieks, 1990).

Alternative excavation equipment considerations would include separate vehicles for digging and for transporting the regolith. In such a system, excavating vehicles could dig the regolith similar to backhoes or shovels on Earth. Separate haulage vehicles like trucks would then haul the regolith to storage locations. Engineers will also evaluate the merits of closed conveyors instead of trucks. For early oxygen and hydrogen mining operations, engineers estimate that excavation machines would require about 9 tons (8 t) of capacity. One excavating machine could feed two or more haulage vehicles.

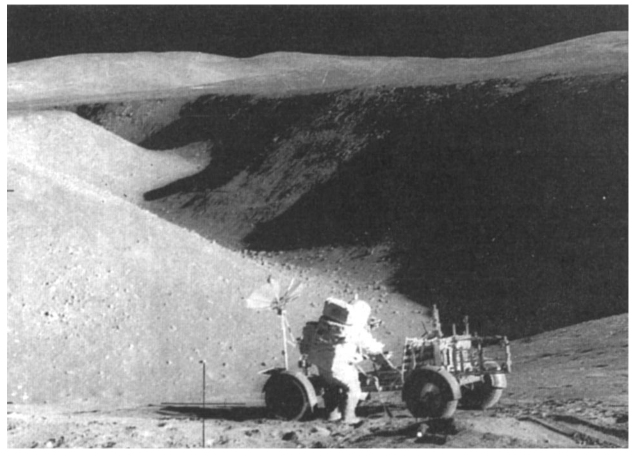

Fig. 22.9.23. Rover vehicle deployed on Moon (*courtesy:* NASA, Houston, TX).

Miners will probably size the regolith before it is processed. Grizzlies to reject boulders would be attached to excavating vehicles. Workers would size material down to ¼ in. (6 mm) with vibrating screens. Further sizing would be accomplished with cyclones. Workers would need a small conveyor to move the sized material into the processing plant.

Very little information is available on beneficiation. Researchers are investigating magnetic and other dry techniques for separation of ilmenite from other minerals in regolith.

Manufacturers will construct most equipment from advanced materials. Although terrestrial mining equipment does not contain much advanced material, the completely different economics of mining in space will force engineers to build equipment with high-strength, low-weight materials. The lower cost of transporting a lighter payload to the Moon will override higher equipment construction costs owing to advanced materials.

The great temperature extremes between day and night will influence equipment design, especially for surface operations. Since it will be difficult for equipment to efficiently operate in both extremes, engineers will probably design equipment to operate efficiently in one. At this time, designers favor high temperature operations. The surface mining equipment thus would operate during the 14-day lunar "day" and undergo maintenance during the 14-day lunar "night."

Experience in developing roving vehicles for sampling on the Moon and Mars will help engineers to design vehicles for excavating and moving lunar regolith (Fig. 22.9.23). Designers will include features that allow miners to operate the equipment with little actual human control. These vehicles would be highly automated and perhaps tele-operated (controlled by operators with television and "joy sticks"). Advanced artificial intelligence systems will be integrated into this equipment (see Chapter 22.2).

Engineers have not yet completed specific locomotion designs for space mining equipment. In addition to locomotion, excavation vehicles must also provide the traction necessary to excavate the regolith, perhaps via a stub inserted into the ground. NASA contractors are presently developing navigation and control systems for automated and/or remotely controlled sampling rovers, which could be adapted to mining machines. Present motor design studies should also benefit future mining vehicles. Mining vehicles would be electrically powered. NASA contractors are designing 1-MW nuclear-powered generators for lunar operations. Solar cells would be a key energy source for auxiliary equipment. Direct conversion of solar energy to provide heat for processing operations is a distinct possibility.

Mining operations to recover hydrogen and helium ions from the regolith could be several orders of magnitude larger than oxygen mining operations. Sufficient hydrogen for early lunar bases could be mined with the equipment described above. For larger amounts of hydrogen and for proposed amounts of helium-3, mining equipment becomes considerably more conjectural. The mines would cover a vast area but to a shallow depth. No mine on Earth has such a configuration. The large-volume mines on Earth use bucket wheel excavators and huge shovels to move material. Such equipment is not mobile enough to mine large areas each year. No large earth-moving equipment seems readily adaptable to the lunar environment. It is simply too premature to propose specific mining equipment for large-scale recovery of hydrogen and helium.

FACTORS INFLUENCING MINING EQUIPMENT AND METHODS. The lunar environment will profoundly influence the selection of mining equipment and methods (Podnieks, 1988). Apollo mission reports contain much information regarding potential environmental effects on lunar operations.

Dust was a significant problem for Apollo astronauts. Dust kicked up by walking, driving, and from engine exhaust obscured vision and coated equipment. A coating of dust, for instance, made it extremely difficult for an astronaut to remove a nut from a bolt during the Apollo 14 landing. The problems of the ubiquitous dust on bearings and other moving surfaces is readily apparent.

Operating at a gravity one-sixth that of Earth poses problems for operators and equipment. Body movements are completely different than movements on Earth. Equipment is much less stable at the lower gravity.

Without an atmosphere, the Moon suffers extreme temperature variations between night and day. At the Apollo 17 site, the surface temperature during the day was 231°F (111°C); during lunar night, temperatures at the same site were –275°F (–171°C). Such temperatures will pose extremely difficult operating conditions for mining equipment. Early miners will probably work only during the day because equipment design problems for operating in hot temperatures seem easier to overcome than those associated with cold temperatures. Surveyor III equipment left on the Moon was brittle (wire coatings) and weak (aluminum structures) when inspected by astronauts 2½ yr later.

The lack of atmosphere will pose additional problems in collecting gaseous products during any regolith processing. Operators will require completely closed systems to prevent the gases from escaping.

Radiation produced by cosmic rays, solar winds, and solar flare particles poses serious safety problems and could damage improperly shielded equipment. Micro-meteorite bombardment will also create a continual "sandblasting" attack on exposed equipment.

The combined effect of all aspects of the hostile lunar and planetary environment create a monumental challenge to design engineers. The development of mining equipment that functions well in this environment will be a noteworthy accomplishment.

22.9.6.3 Mining Costs

Costing a lunar or planetary mining operation differs completely from terrestrial mine cost analyses. Life support materials will be mined on the Moon if transportation costs exceed mining and processing costs. Given the high cost to transport cargo to the Moon, a mining operation may provide sufficient oxygen for life support at a lower cost. Engineers are determining the equipment, energy, and human resources necessary to mine oxygen on the Moon. Once these are determined, it will be possible to more accurately cost a mining operation.

Establishing costs for mining helium-3 and other solar-wind-deposited ions from the lunar regolith is almost impossible at this time. The technology is too doubtful to warrant speculation. Engineers have estimated that 1 ton (0.9 t) of helium-3 would replace an equivalent $1 billion in fossil fuel costs for electric power generation. This provides guidance for estimating the value of helium-3. Another way of examining the economics of mining helium-3 is to consider the value of a unit volume of regolith. At a helium-3 value of $1 billion/ton ($1.1 billion/t), the value of regolith averages about $8/ton ($9/t). This is not particularly impressive considering the great difficulties of mining.

22.9.6.4 Future Trends

Mining and processing oxygen seems the most likely mining operation to first appear in space. Local mining of construction materials—sintered blocks—also seems like a realistic possibility. Less likely but still under consideration are possible mining operations for recovering hydrogen, helium, and other ions deposited on the surface of the Moon, Mars, and Phobos.

Engineering feasibility studies are beginning to consider in more detail the possibility of lunar oxygen mining. Considerable research will be required before equipment can be developed to operate in the hostile lunar atmosphere.

22.9.7 NUCLEAR-ASSISTED MINING

PETER G. CHAMBERLAIN

22.9.7.1 Concept

During the 1960s, scientists and engineers considered a variety of techniques for applying the tremendous energy in *nuclear explosives* to mining systems. The first edition of the *SME Mining Engineering Handbook* (Cummins and Given, 1973) contained a section on these techniques (Russell, 1973). Since that time, little additional research on nuclear mining techniques has emerged. Public concern over environmental risks associated with nuclear energy, the nuclear test ban treaty, and uncertain availability discouraged further studies. Nevertheless, the concentrated energy and potentially low unit energy costs available in nuclear explosives may renew interest in using these devices in future mining operations. Consequently, selected portions of the *SME Handbook*, 1st ed., are reproduced below.

NUCLEAR EXPLOSIVES. In a nuclear explosion, the energy produced results from formation of different atomic nuclei by the redistribution of the protons and neutrons within the interacting nuclei. Nuclear energy is of much higher magnitude than chemical explosive energy considering equal masses and is released many times more rapidly. Nuclear explosions are produced by either fission or fusion. Fission occurs when a free (or unattached) neutron enters the nucleus of a fissionable atom. It can cause the nucleus to split into smaller parts, releasing large quantities of energy. Complete fission of 1 lbm (0.4 kg) of uranium can produce the energy equal to the detonation of about 9000 tons (8000 t) of TNT.

In nuclear fusion, a pair of light nuclei unite (or fuse) to form the nucleus of a heavier atom. Thus two deuterium (heavy hydrogen) nuclei may unite to form the nucleus of the heavier element helium. Such a reaction from 1 lbm (0.4 kg) of deuterium could theoretically release energy equivalent to about 20,000 tons (18,000 t) of TNT.

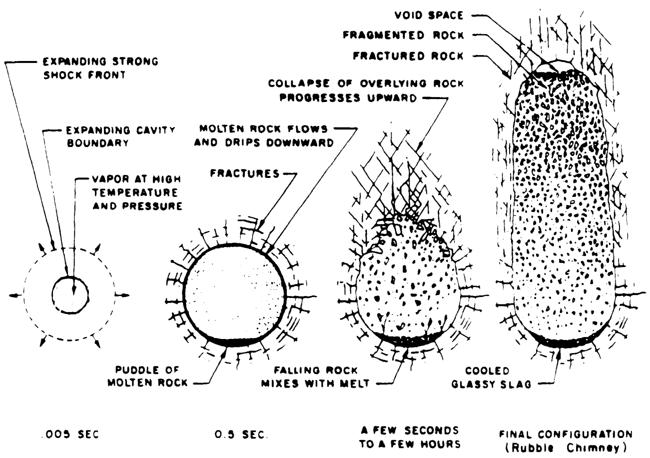

Fig. 22.9.24. Cavity growth during nuclear explosion for mining purposes (Russell, 1973).

By custom, the power of a nuclear explosion is expressed in terms of its energy release, or yield, compared with that from TNT. A nuclear explosive energy of 1 kiloton is defined as the prompt release of 10^{12} calories (4×10^9 Btu) of energy, and it is approximately equivalent to the energy released by detonating 1000 tons (900 t) of TNT.

UNDERGROUND MINING CONCEPTS. Formation of a rubble chimney, through collapse of the initially created cavity, is the basic concept for all current underground mining proposals using nuclear explosives. Both fission and fusion explosives have been used to produce rubble chimneys in a variety of rock types. Fig. 22.9.24 shows the sequence of events in cavity-chimney formation. The fractured zone surrounding the rubble chimney is vital to some proposed uses and is believed to extend from one to four cavity radii, depending on geology, depth of burial of explosive, and explosive yield. The technical and economical advantages of nuclear explosives appear to restrict their use in underground mining to large massive ore deposits where such large-scale blasts can be utilized to advantage. Proposed underground mining applications include the fracturing and fragmenting of large volumes of ore in preparation for block-cave-type mining and in situ leaching.

The term block caving has been used to describe ore extraction from nuclear-produced rubble chimneys. The success of this method assumes that ore can be extracted from such chimneys in formations that are not economically viable with other methods. Both the existence of such deposits and this cost relationship have yet to be proved.

The principle of in situ leaching has been proved and is widely used today (see Chapter 15.3). Recovery of valuable metals through ore broken or fractured by nuclear explosives offers many advantages, such as permitting large-scale mining operations in deep low-grade ore deposits with minimum disturbance of the surface topography. Such factors are becoming increasingly important as the need for natural resources increases and as any pollution of the environment becomes less acceptable.

CAVITY AND CHIMNEY FEATURES. Experimentation shows that cavities produced by nuclear explosives are roughly spherical in shape and are so considered when calculating dimensions or volumes. Cavity- and chimney-dimension formulas were derived empirically. Each formula contains a constant chosen according to the physical properties of the medium tested.

Cavity expansion probably continues until the internal gas pressure equals the pressure exerted by the surrounding rock mass, and this assumption was used in deriving the formula for cavity radius which follows (Anon, 1967):

$$R = C \times W^{1/2}/(\rho h)^{1/4} \qquad (22.9.8)$$

where R is cavity radius in ft; C is a constant for rock media; W is equivalent yield of nuclear explosive in kilotons of TNT; ρ is density of rock media in g/cm^3; and h is depth of burial in ft.

This formula is considered accurate to ±20% in changeable host rocks and to ±8% in one specific-type host rock. The following experimental values have been determined for the constant C in specific rock media (Hardwick, 1967):

Alluvium	86.6
Granodiorite	79.6
Salt	85.7
Tuff	104.6

The graphs in Russell (1973) indicate cavity radii for contained underground nuclear explosions of various yields and depths of burial in granite rock.

Present knowledge indicates little correlation between the size of the cavity formed and the physical and elastic properties of the surrounding rock. Porosity has a negligible effect on cavity size, but the presence or absence of pore water is significant—the higher the pore water content the larger the cavity.

In nearly all cases, the chimney formed above the initial nuclear explosive takes a roughly cylindrical shape slightly larger in diameter than the cavity. Unless collapse reaches the surface, the chimney roof usually is domed and contains a small rubble-free void. Chimney height H may be determined by the formula,

$$H = K R \qquad (22.9.9)$$

where K is a factor determined from rock type and depth of burial, and R is the cavity radius (Williams, Russell, and Sheridan, 1969). For granite, K = 4.35. A rule-of-thumb approximation is that chimney height is equal to 2½ cavity diameters. True height, of course, varies with rock type. Chimney heights for contained underground nuclear explosions of various yields and depths of burial in granite rock are indicated graphically in Russell (1973).

Estimates of rock broken by deeply buried nuclear explosives can be made. The graphs shown in Russell (1973) indicate the theoretical amount of rock broken by intermediate underground explosions at various depths of burial. Approximate tonnages of broken rock may be determined from these graphs, but variance occurs with the type of host rock. Rubble fragment sizes for two contained shots in granite are given in Table 22.9.7.

In the design of any underground mining system, both the yield and the emplacement depth of the nuclear explosive must be such that the resulting chimney does not extend to the surface. No method of equating these design criteria to all geologic conditions is presently known. However, experimental results indicate that an emplacement depth of at least 10 diameters of the designed cavity provides a suitable containment safety factor. Because cavity diameter depends on a variety of engineering and geologic factors, this 10-diameter rule is an approximation only. Where geologic conditions indicate strong fracturing or faulting, special detailed studies will be required to evaluate containment

Table 22.9.7. Fragment Size Distribution in Rubble Chimneys From Two Contained Nuclear Explosions

Sieve Size	% Passing	Sieve Size	% Passing
6ft	100	2 in.	20
5ft	95	1½ in.	16
4ft	88	1 in.	14
3ft	75	¾ in.	12
2ft	60	½ in.	10
1ft	40	⅜ in.	9
6in.	30	#4 (0.187 in.)	7
4in.	25		

Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m
Source: Russell, 1973.

problems. Recent studies by the Lawrence Radiation Laboratory have established that a buffer zone of rock 300 to 500 ft (90 to 150 m) thick (depending primarily on the rock characteristics) above the top of the predicted rubble chimney is sufficient for containment up to yields of several hundred kilotons.

[Author's and editor's note: Section 21.10, 1st ed. of the *Handbook,* provides additional information on specific proposed applications of nuclear explosives including block caving, in situ leaching, and in situ retorting. Cost estimates for the nuclear explosives, assuming that they could be sold for mining purposes, are also provided. So little interest is presently evidenced in nuclear-assisted mining, primarily because of radiation hazards, that the editors feel it inappropriate to provide more detail in this current edition.]

Section 23 Evaluation of Mining Methods and Systems

JAN M. MUTMANSKY, ASSOCIATE EDITOR AND SECTION COORDINATOR

Chapter 23.0
INTRODUCTION

JAN M. MUTMANSKY

Since 1973 when the first edition of the *SME Mining Engineering Handbook* was published, many significant changes have occurred in the US mining industry. The industry went through a fairly prosperous period immediately after 1973, but then many economic pressures came to bear on mining companies, particularly in the metal and coal branches of the industry. These pressures changed both the mining methods used and the general economics of the mining methods. As a result, the industry today is different in many ways than it was in 1973. A general summary of some of the more important changes that have come about will be provided here as well as some assessment of the effects of these changes on the choices of mining methods.

In the metal mining industry, the most significant trends were increased surface mining, the use of larger and more efficient equipment, and increased technology and automation. The primary impetus for these changes was unprecedented competition from foreign producers. In many cases, this competition came about because of the nationalization of foreign mines and the tendency for these mines to become a source of foreign exchange. Under these circumstances, the mines could be operated even though they were not profitable. As a result, domestic metal producers were unable to readily compete on the world metals market.

In response to this challenge, US producers became more competitive in a number of ways. One way was to close unprofitable mines and to emphasize more efficient mining methods. Consequently, many of the mines using traditional selective stoping methods were either closed or redesigned to produce in a more efficient manner. This led most metals companies toward bulk mining methods, either underground or surface. During much of the 1980s, little in the way of exploration or development of metals deposits was being accomplished except in the precious metals areas. In precious metals, change was also the order of the day as the use of open pit mining and heap leaching were greatly expanded.

In the coal industry, the early to middle 1970s was characterized by growth and generally high prices with the Arab oil embargo helping to elevate energy prices. Many new coal mines were initiated during this time period. Toward the end of the 1970s, however, the costs of production were continuing to rise significantly while the market prices for coal remained relatively stable. As a result, many smaller and less efficient coal operators were eliminated as productive capacity was significantly higher than the demand. During the late 1970s and the 1980s, the coal industry in general responded to economic pressures by substantially increasing productivity. From 1977 to 1987 alone, productivity nearly doubled in the underground coal industry as the producers fought to maintain their share of the competitive marketplace.

The strong prevailing shift of the previous decades towards greater percentages of coal production from surface mines ended during this period, apparently as a result of environmental problems and a reduced inventory of coal that could be easily extracted from surface operations. Instead, increased use of longwall mining, more reliable and productive continuous miners, improved roof bolters and bolting practices, use of dust scrubbers and remote control on continuous miners, and use of improved systems such as supersections all contributed to better productivity. In addition, the labor force matured and became sensitized to the need for productivity improvement during this period. As a result, the ways in which coal mining operations were managed changed more than the mining methods themselves. In addition, most coal mining companies concentrated on productivity improvements instead of new operations.

During the same period of time, the industrial minerals producers suffered fewer market problems than the other segments of the industry, probably due primarily to relatively strong domestic demand for industrial minerals and the inability of foreign producers to readily compete within the US due to transportation costs. However, foreign competition did hurt domestic production in some categories such as in the cement and fertilizer industries. One significant trend in the industrial minerals industry has been larger companies and larger mines, primarily as a result of the acquisitions tendency in industry in recent years. In addition, a trend toward more surface mining and less underground mining was also prevalent.

In terms of the selection of mining methods and systems, the period from 1973 to the present represents a problem due to the intense competition and a general lack of mine development. As a result, the record of costs for development of new mines is quite sparse and somewhat more difficult to interpret. Furthermore, the technology of mining has changed significantly since the last surge in minerals development projects. Thus cost prediction and the selection of mining methods based upon past costs may be more difficult than before. The only significant developments in recent years have been the surface gold leaching operations that have emerged throughout the western states. In addition, technological advancements have occurred with substantial applications of automation, monitoring, and computer control becoming commonplace in all segments of the industry.

Though automation and technology have been instituted by the mining companies as a necessary and desirable part of their operations, an additional change has been brought about by the public. This change is the emphasis on social and environmental concerns that all mining companies must now satisfy. Water pollution, air pollution, waste disposal, and reclamation requirements are all important considerations in the planning and development of future mining operations and will have a major bearing on the methods chosen and the estimation of costs. In addition, these considerations become important in the choice between surface and underground operations.

While the cost prediction phase of mining method selection has been affected, the other variables associated with the choice of a mining method have not changed significantly. Geologic and rock mechanics variables will normally be of prime importance in the elimination of unsuitable mining methods and in the final selection of the most efficient and safest methods. The geologic and mechanics parameters of the selection process currently may be more crucial, however, as the choice of the method will certainly affect the costs and the competitive nature of the marketplace requires that the most efficient method be chosen.

During the past two decades, the selection of mining methods and systems has certainly been impacted by the changes that have occurred. Many new social and environmental concerns have entered into the picture as have several new areas of technology. The choice of a mining method and other important decisions to be made before a mine can be developed are therefore more important than before if only because of the increasing number of social and governmental concerns that must be met. It is therefore imperative that minerals engineers use every means at their disposal to improve their decision-making procedures so that mining methods are properly chosen before mining is undertaken.

23.0.1 SECTION TOPICS

This section of the *Handbook* deals with the evaluation of mining methods, methods of providing costs for the methods, and selection of mining methods to suit the orebody conditions and related social and environmental constraints. Chapter 23.1, Selection Variables, enumerates the major variables that must be considered during the selection process for a mining method. This includes the geologic parameters and rock properties that are important in mining method selection and also a review of the social, political, labor, and environmental variables as well.

Chapter 23.2, Surface vs. Underground Methods, discusses in some detail the economics and practical variables involved in making the choice between surface and underground methods in an orebody where either can be used. Numerous engineering considerations used to make the decision, such as productivity, labor, safety, energy consumption, and environmental concerns, are also discussed. The chapter then emphasizes the economics of the decision with a detailed example to illustrate the various economic factors to be considered. In addition, it economically defines the proper point in the lifetime of a surface mine when conversion from surface to underground mining is warranted.

Several additional economic considerations related to evaluation of mining methods and systems are discussed in Chapter 23.3, Cost Comparison and Control. This chapter deals primarily with cost estimation methods, sources of cost data, cost updating, and previously published costs for various mining methods. In addition, the results of two cost surveys conducted in 1989 for inclusion in this chapter are presented. The two cost surveys cover coal mining methods and noncoal methods in separate subsections of the chapter. These costs are then compared with other cost values that have appeared in the literature. Finally, some concepts of cost control are presented.

The final chapter in this section, Chapter 23.4, Selection Procedure, outlines several aspects of the selection procedure for mining methods. The specific subtopics discussed within the chapter include a logical sequence of events for choosing a mining method, previous strategies used in the selection of a mining method, and some detailed ranking procedures for use in categorizing the suitability of mining methods under differing conditions. Finally, the chapter concludes with a logic flow diagram to be used in the process of selecting a mining method.

Chapter 23.1
SELECTION VARIABLES

DAVID E. NICHOLAS

23.1.1 GENERAL

Selection of an appropriate mining method is a complex task that requires consideration of many technical, economic, political, social, and historical factors. Mining methods considered in this chapter include traditional surface and underground methods, as well as non-traditional mining methods such as hydraulic mining, in situ leaching, gasification, robotics, and the like. The variables involved in a general consideration of mining method selection are very similar to those already discussed specifically in Section 16 for surface methods and in Section 21 for underground methods. This chapter concentrates mainly on technical and economic aspects of the selection process. However, the mining engineer needs to recognize and include the other considerations—political, social and historical—as well.

The most critical prerequisite for performing mining method selection is a good database. This becomes imperative for high-capital-cost operations where a decision based on inadequate data can be a costly mistake. Low-capital operations may require technical evaluation, but it is difficult to justify the cost of data collection and engineering.

The past approach of adopting the same mining method as that of a neighboring operation is not as appropriate as it once was. However, this does not mean that one cannot learn from or quantitatively compare mining plans to those of existing operations in the district or to similar deposits. The importance of a good database is even more critical for the evaluation of the more novel mining methods, as there is not the well of past experience to draw on that exists for traditional mining methods.

Although experience and engineering judgment still provide major input into the selection of a mining method, subtle differences in the characteristics of each deposit can usually be perceived only through a detailed analysis of the available data. It becomes the responsibility of the geologist and engineer to work together to ensure that all factors are considered in the mining method selection process.

The mining method that is ultimately selected should be one that the management is comfortable with and believes is feasible. In some cases, this may not correspond to the best method based on the ground conditions. In the early mining stages a more costly method might be chosen either because it has a higher reliability of meeting production requirements or because the labor force or operator is familiar with that method. As mining progresses, the method should be continually improved and refined to reflect the experience gained in daily mine operations.

23.1.2 INPUT PARAMETERS

There are six major parameters that should be considered when evaluating a mining method:

1. Physical and geologic characteristics of the deposit.
2. Ground conditions of the hanging wall, footwall, and ore zone.
3. Mining and capital costs.
4. Mining rate.
5. Availability and cost of labor.
6. Environmental regulations.

Of these parameters, physical and geologic characteristics and ground conditions should be the primary parameters considered in determining the most appropriate mining method(s).

23.1.2.1 Physical and Geologic Characteristics

A physical description of the deposit should include

1. General shape.
2. Ore thickness.
3. Plunge.
4. Depth below the surface.
5. Grade distribution.

These characteristics are best understood by the preparation of geologic sections and level maps from the drilling program. These maps should identify major rock types, alteration zones, and major structures, such as faults, veins, and fold axes. The level and cross-sectional maps should be drawn to the same scale as mine planning maps, and sections should be drawn without vertical exaggeration. A good general rule is that the area included on the maps should extend 1.75 times the depth beyond the limits of the ore body. Separate overlays depicting alteration zones and grade contours or ore blocks usually provide the best picture of spatial relationships in the ore body.

Geologic data are the most critical in terms of determining economic viability. In most cases, the engineer has developed a target model for the deposit prior to exploration, and certainly after the first ore intercept. During ore delineation drilling, the geologist not only must collect assay data but also metallurgical, geotechnical, hydrologic, and environmental data.

The basis for all understanding of the ore deposit is the geology, that is, rock type, alteration, and major geologic structures. The known geology should be put on one set of sections and level maps, and the interpreted geology shown on another set of sections and level maps. These interpreted maps are the more useful to the engineers. The geologist needs to make some interpretations even if the database is limited; on the other hand, the engineer should discuss these interpretations with the geologist, making it clear which geologic interpretations are well understood and which interpretations are conjecture based on limited data.

The assay data needed will depend on the type of material to be mined. Not only should the primary economic mineral be assayed or tested, but those less important but recoverable associated minerals should be tested, as well as minerals that can be detrimental to processing. The deposit should be zoned or contoured based on the mineral grade. This can be done using a block model or manually. The data should be interpreted in section as well as in plan, and related to the geology.

The metallurgical, geotechnical, hydrologic, and environmental data to be collected during drilling for ore definition varies greatly. Metallurgical data do not usually impact the type of mining method, although the data may impact whether the mining method must be able to provide a blended ore.

Hydrologic data do not usually impact the choice of mining method, except in determining the feasibility of in situ leaching; they do however, impact the design of the mining system. The primary hydrologic data needed are elevation of the groundwater table. Slug tests (Bouwer and Rice, 1976) in exploration drillholes can be used to provide a reasonable estimate of the transmissivity of the rock. This transmissivity data should be contoured and correlated with the geology.

Some of the geotechnical data, such as oriented core data, RQD (rock quality designation), fracture frequency, and estimated strength, can only be obtained from drill core (Chapter 10.5). This is easily collected (23.1.2.2). Most of the drilling in a deposit is in or near the mineralization. However, the mining method may be dictated by the ground conditions above, next to, or below the deposit. Consequently, it is necessary that drilling be done beyond the lower limit of the deposit by 50 to 100 ft (15 to 30 m). Holes drilled outside the limit of the deposit are very important from a geotechnical point of view and should be logged in as much detail as ore holes.

The above work applies to base metal, ferrous, and nonmetallic deposits. Each of these deposits is unique in terms of its geologic database and assay data requirements. For some of these deposits, it is not affordable to collect all of these data early on, or at least it is not common to do so. Therefore, drill core should be photographed before it is assayed, and whole core should be preserved for possible physical testing. Photographing the core also provides a permanent document of the core so that if some new understanding of the deposit occurs later in the mine life, the old holes can be reexamined via the photos.

23.1.2.2 Ground Conditions

Ground conditions of the ore zone, hanging wall, and footwall should be defined for the deposit. The basic components that define the ground conditions are

1. Rock substance shear strength.
2. Natural fracture and fault shear strength.
3. Orientation and location of major geologic structures (faults, folds, bedding).
4. Orientation, length, and spacing of joint sets.
5. In situ stress.
6. Hydrologic conditions.

The combination of all these parameters defines how the rock mass will behave. The rock mass can be described quantitatively by determining the individual parameters, or it can be classified by an RQD value. Neither approach is completely satisfying in determining the rock mass behavior. The classification approach is relatively easy to perform, but the choice of class is somewhat subjective, and each classification system has been aimed at predicting certain aspects of traditional mining. The biggest advantages of classifying are that it can be done as part of the geologic mapping and logging, and that a number of empirical correlations have been made from these classifications. Taking measurements of each of the components of the rock mass is the best way of determining the actual properties. However, the art/science of rock mechanics is still working on ways of combining the properties to come up with the rock mass strength.

Existing classification methods are listed in Table 10.5.1 in Chapter 10.5. They include Deere, 1968 (Table 23.1.1), Coates, 1970 (Table 23.1.2), Bieniawski, 1973 (see Table 10.5.2 in Chapter 10.5) Barton et al., 1974 (Fig. 23.1.1) and Laubscher, 1977 (Fig. 23.1.2). Classifications with the better empirical correlations are those of Bieniawski, Barton, and Laubscher.

ROCK SUBSTANCE SHEAR STRENGTH. This represents the strength of the rock *between* geologic structures. The intact rock shear strength is determined from uniaxial and triaxial compression tests (Fig. 23.1.3). It can be estimated from uniaxial compression and disk tension tests. At least three test specimens, preferably six per rock type per test type, are required. By selecting three specimens of each rock type from each drillhole, it is possible to build up a collection of specimens for later detailed testing. In addition, the elastic properties of Young's modulus and Poisson's ratio should be measured during the uniaxial test.

Point load testing of drill core can be done during the drilling program to provide a measure of the uniaxial compressive strength variability. This is most useful in deposits where geologic structures are limited and the rock strength is low enough to fail, that is, in the case of coal, potash, or uranium deposits.

Special evaluations such as creep testing may be required for material that flows, such as salt and potash.

NATURAL FRACTURE AND FAULT SHEAR STRENGTH. These are determined by direct shear tests (Fig. 23.1.3). Most failure paths will be controlled by these pre-existing geologic structures, making this test critical.

MAJOR GEOLOGIC STRUCTURES. These should be identified as to location, orientation, and thickness. This should be done as part of the normal geologic mapping and interpretation.

ROCK FABRIC. Those geologic structures that are too numerous and must be dealt with statistically should be mapped to determine the type of structure, orientation, length, and spacing. This can be done using cell mapping (Call, 1979), the detail line mapping technique (Call et al., 1976), or some similar method.

When only drill core is available, oriented core can be used, which will provide orientation and spacing data (Call et al., 1987). This technique is relatively inexpensive and requires only a full-time geologic technician on the drill rig to collect the data. This technique is difficult in highly fractured ground and may not provide sufficient data for its cost. Not all drillholes are oriented; usually three to six holes per deposit are required. For those drillholes not oriented, a measure of the fracture intensity is needed. The most common measure is rock quality designation. RQD is a modified core recovery where the sum of all pieces greater than two times the core diameter is divided by drill interval. RQD is commonly used, but one must be cautious in interpreting it. An RQD rating of 100% means only that all the pieces are at least 4 in. (100 mm) long for NX core; this can be attained either by all pieces being 4 in. (100 mm) long or all pieces being 1 m (3.3 ft) long. These two conditions represent different types of ground, but similar RQD values. Another measure of fracture intensity is the fracture frequency and percentage-broken zone. The fracture frequency is the number of whole core samples divided by the recovered drill interval, minus the interval of broken zone. The broken zone is that interval of non-whole core plus unrecovered core.

IN SITU STRESS. In situ stress measurements provide the orientation and magnitude of the stresses in the ground (Chapter 10.3). The parameters discussed above are needed to determine the strength of the rock mass, while the in situ stress provides the basis for determining the driving stress that could cause failure. Acceptance of the importance of taking in situ stress measurements is increasing; measurements are required for deep pits where stresses are high, and for any underground operation. Methods of measuring stress include the USBM overcoring (Hooker and Bickel, 1972), South Africa's CSIR "doorstopper" or triaxial cell (Leeman, 1969), and Australia's CSIRO triaxial cell (Fama and Pender, 1980). There are pros and cons to each of these methods, and improvements are being made constantly. The orientation of the stress is generally more accurate than the stress magnitude for any of the three techniques. The magnitude provides the relative difference in stresses, while the absolute value has a high variability. If stress measurements are not made, they can be inferred based on the geologic history, rock type, and proximity to geologic structures. Abel (1981) has developed a flow chart that provides a guesstimate of the in situ stress based on correlation between rock type and geologic structure, and stress measurement results.

Table 23.1.1. Deere's Classification of Rock

I. INTACT ROCK STRENGTH

Class	Description	Uniaxial Compressive Strength psi	Uniaxial Compressive Strength MPa
A	Very High Strength	> 32,000	> 220
B	High Strength	16,000–32,000	110–220
C	Medium Strength	8,000–16,000	55–110
D	Low Strength	4,000–8,000	27–55
E	Very Low Strength	< 4,000	< 27

II. INTACT ROCK MODULUS RATIO (E_t/σ_c)

Class	Description	Modulus Ratio
H	High Modulus Ratio	> 500
M	Average (Medium) Ratio	200–500
L	Low Modulus Ratio	< 200

III. TERMINOLOGY FOR JOINT SPACING

Description	Spacing of Joints	
Very Close	< 2 in.	< 50 mm
Close	2 in.–1 ft	50–300 mm
Moderately Close	1–3 ft	300 mm–1 m
Wide	3–10 ft	1 m–3 m
Very Wide	> 10 ft	> 3 m

IV. ROCK QUALITY DESIGNATION (RQD)

Description	% RQD
Very Poor	0–25
Poor	25–50
Fair	50–75
Good	75–90
Excellent	90–100

Table 23.1.2. Coate's Classification of Rock

I. SUBSTANCE STRENGTH

Description	Uniaxial Compressive Strength MPa	Uniaxial Compressive Strength psi
Strong	≥ 70	≥ 10,000
Weak	≤ 70	≤ 10,000

II. FORMATION (FRACTURING)

Massive:	Joint spacing > 6 ft (2 m)
Layered:	Bonding between layers is less than within layer
Blocky:	Joint spacing is between 1 ft (0.3 m) and 3 ft (1 m)
Broken:	Joint spacing is less than 1 ft (0.3 m)
Very Broken:	Joint spacing is less than 3 in. (80 mm)

Source: Coates, 1970.

HYDROLOGIC CONDITIONS. Hydrologic conditions contribute to the rock mass strength to the extent that, if water exists, the design must allow for a drainage program (Chapter 12.1). Most mining methods, with the exception of some hydraulic methods, do not deal well with water. The hydrologic data needed include elevation of the water table, transmissivity, and the storage coefficient.

23.1.2.3 Mining and Capital Costs

By nature, some mining methods have higher unit costs than others. The perceived relative cost is based on the fact that the deposit was mined using the method that was appropriate for its conditions. For example, block caving is generally considered the cheapest underground method. However, if mining a large deposit with widely spaced jointing and high strength, the cost of block caving would probably be prohibitive because the production rate would be too low for the number of men required. As our technology improves, what was once an expensive method may become less expensive. An example of this is underhand cut and fill. With the recent improvements in placing dense sandfill, underhand cut and fill should not require the labor or the amount of cement it did in years past to create a competent back to mine under. This may make the smaller deposits with moderate grade and poor ground more feasible. Consequently, although there may be an overall difference in mining costs, the mining method should still be chosen based on the ground conditions and ore geometry first; if the method is too expensive, then cheaper methods should be considered, realizing that the cheaper method may require new or unproven techniques, and that the operating costs may be higher than normal for that method. Table 23.1.3 shows an approximate ranking of different mining methods based on their relative operating costs (Hartman, 1987).

Capital requirements vary depending on the mining method, size of deposit, access requirements, and production rate. Unfortunately, most of the decisions on how to bring a deposit into

RQD: ROCK QUALITY DESIGNATION

J_n: Joint Set Number - Nine categories that define the number of joint sets ranging from massive to three joint sets to crushed rock.

J_r: Joint Roughness Number - Nine categories that describe the physical nature of the joint set ranging from discontinuous, to rough and planar, to filled with clay gouge so that the rock walls are not in contact.

J_a: Joint Alteration Number - Sixteen categories that describe the alteration along the joints ranging from tightly healed joints to filled with clay gouge, to zones of crushed rock.

J_w: Joint Water Reduction Factor - Six categories that define the water pressure ranging from dry to high flows.

SRF: Stress Reduction Factor - Sixteen categories that define the stress conditions for rock. Related to compressive strength and principal in situ stress.

ESR: Excavation Support Ratio - Six categories that define the type of opening being designed ranging from mine opening to underground nuclear power stations.

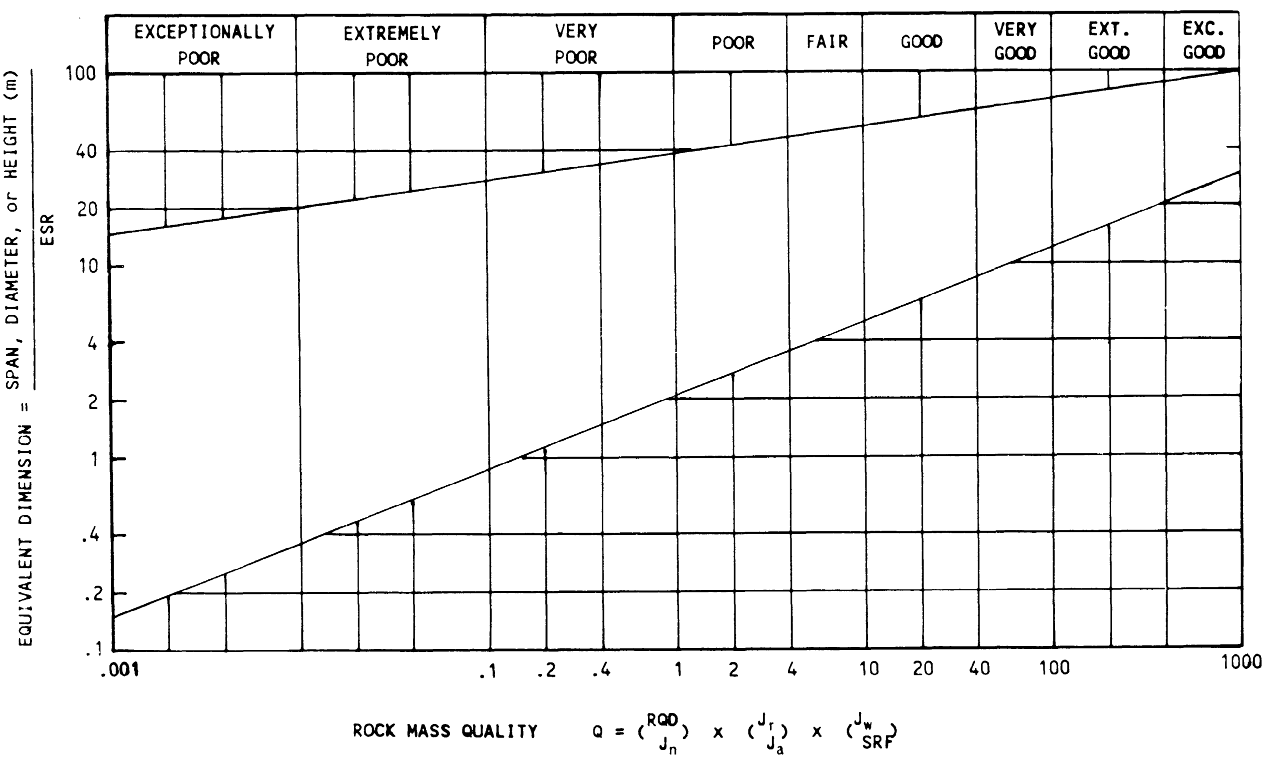

Fig. 23.1.1. Description of the NGI classification system (Barton et al., 1974).

production are controlled by the time value of money and not the nature of the deposit. The more capital required to start the project, the better the grade of the deposit must be and/or the faster it must be mined. The capital usually requires that the high-grade ore be mined first, which is not always the best sequence from a geotechnical or metallurgical point of view. In a block cave, one should start in the easy caving ground to ensure meeting production schedules. In an open stope, the usual mining sequence is to retreat from one direction to another or mine from the center out.

Often no one mining method is the most appropriate for a deposit, but rather two or three may be feasible. These methods should be economically evaluated to determine which will provide the best return on investment. In this way, one can define

A. MEANING OF THE RATINGS

those methods that are technically feasible and those that are the most economic. When considering less conventional techniques, the uncertainty of meeting production is high. Therefore the approach might be to choose a more traditional method, and at the same time begin a test area of the novel mining technique to prove its viability. If a novel method (Section 22) must be used, management needs to be willing to take the risk of developing a new method, and have the time and/or funding needed to make the method productive.

23.1.2.4 Mining Rate

The mining or production rate is a function of the capital costs, the size and grade of the deposit, and the location of the deposit. The mining rate does not usually have a major impact on choosing the mining method. The mining rate has more impact on how the ore is transferred out of the mine. Given that the deposit is physically large enough, the mining method can usually be expanded to meet the production needs.

When mining in countries with marginally stable governments, companies may wish to mine the deposit more quickly. This may mean high-grading the deposit rather than mining it to maximize the profits. In these situations, the mining method should be designed to high-grade and recover the lower-grade material later. Some commodities, such as industrial minerals, do not require a large production rate, so that even though a fast mining rate is possible, there is no sense in spending the capital if the rate will never be mined.

23.1.2.5 Availability and Cost of Labor

The abundance or lack of trained labor can be significant in the mining method selection process. It is important that the management and engineering staff be able to visualize the operation as a whole and deal with any problems that may develop in implementing it. The mine employees must be capable of performing the required tasks of the method, or suitable training programs must be planned. In some cases, the location of the deposit will have a significant impact on labor resources and thus the type of mining methods that can be considered. In general, where labor rates are high but the labor is well-educated/trained, techniques requiring sophisticated equipment should be possible (although labor must still be trained and supervised). Given these conditions, robotics and computerized equipment can be used. This will provide a high production rate per employee-shift and minimize operating costs. However, in countries where the cost of labor is low and education is limited, a method that requires a large labor force is feasible and probably preferable.

23.1.2.6 Environmental Regulations

Environmental regulations and requirements may limit the types of mining methods that can be selected (Chapters 3.4 and 7.3). Consideration of subsidence restrictions, groundwater contamination, tailings and waste disposal, and reclamation issues will all have to be taken into account during the method selection process. Although surface mining methods are generally lower in cost than underground methods, in the future the mining industry may be forced into choosing underground methods more often due to the fact that they generally have less impact on the surface environment. Surface subsidence limits are imposed on those deposits under existing non-mine structures and in wilderness areas. Improvements in backfill materials should help reduce this problem and allow maximum recovery of the deposit. Environmental regulations are likely to be one of the motivating forces for developing new mining methods. However, probably before this will happen, those deposits outside the United States will be mined using the more traditional mining methods. Groundwater will be more of an issue as our water sources are depleted in the United States (Chapter 12.1); this problem is not likely to occur in most of the developing countries. Dealing with the water regulations will not change the mining method, but rather its feasibility.

Other particular considerations in the mining method selection will usually be site specific. These considerations can include excessive ground temperature, proximity to inhabited areas or large bodies of water, and earthquake hazards.

23.1.3 SUMMARY

It is important that the geologists and engineers evaluating the deposit consider each of the selection variables before making a decision regarding mining method. In most situations, the controlling parameters that will define the feasible mining methods are

1. Tonnage, grade, shape, and depth of the deposit.
2. Ground conditions of the ore zone, hanging wall, and footwall.
3. Capital and operating expenses.

The evaluating engineer must recognize these controlling parameters and ensure that adequate data are available for the feasibility analysis to be performed.

Chapter 23.2
SURFACE VS. UNDERGROUND METHODS

DAN NILSSON

23.2.1 INTRODUCTION

Many deposits can be mined entirely with surface methods; others must be worked underground from the very beginning. Under similar circumstances, surface mining is normally regarded to be more advantageous than underground mining. In a choice between surface and underground methods, there are many factors to be taken into account, such as,

1. Size, shape, and depth of the deposit.
2. Rock conditions.
3. Productivities and machinery capacities.
4. Capital requirements and operating costs.
5. Ore recoveries and revenues.
6. Safety and injuries.
7. Environmental aspects.

Still other deposits can be mined first as open pits but must be worked underground later. The question arises: what is the optimal depth for changing over from surface to underground mining?

In this chapter, these factors will be discussed briefly. Some costs will be cited. Please note that although these costs are in the right order of magnitude at the time of this writing, they cannot be applied to any single mineral producer.

Table 23.2.1. Number of Noncoal Mines in the Western World by Production Rate

	Production Category (1000 tons of ore/yr)	Year 1967	1977	1987
Surface Mines	More than 3000	102	138	176
	1000–3000	109	142	116
	500–1000	81	64	86
	300–500	61	63	63
	150–300	68	53	81
	Total	421	459	522
Underground Mines	More than 3000	29	56	62
	1000–3000	144	140	125
	500–1000	116	119	121
	300–500	108	121	105
	150–300	116	157	178
	Total	563	593	592
	Grand Total	984	1052	1114

Note: The number of commodities in the surveys has changed over the years, so the figures above should be used with some caution. *Source:* Anon., 1968, 1978, 1988 (*Mining Magazine's* Annual Surveys). Conversion factor: 1 ton = 0.9072 t.

23.2.2 SURFACE VS. UNDERGROUND MINING TRENDS

In 1987, it was estimated that there were 1114 noncoal mines in the non-socialist world, producing an average each of more than 165,000 tons (150,000 t) of ore/year. These mines account for approximately 90% of the total output of ore in these countries. In addition, it was estimated that there were 6000 to 7000 smaller mines. Of these 1114 noncoal mines, 522 were surface mines and 592 underground. The average surface mine was much larger in production than the average underground mine. During the last two decades, the number of noncoal surface mines has increased from 421 to 522. Most of these new mines are large (Table 23.2.1). The number of underground mines has not changed as much.

In 1987, there were 1750 hard-coal and lignite mines in the non-socialist world, each with a mine production of more than 220,000 tons (200,000 t) of run-of-mine coal/year. These mines accounted for 80% of the output. About 60% were underground mines. The number of smaller mines was in the thousands. The number of US coal mines in 1985 producing more than 10,000 tons (9000 t) of clean coal annually was 3355. Of these, 1660 or 50% were surface mines. During the last decades, there has been a sharp reduction in the number of smaller coal mines, especially underground. Many large strip mines have been opened, especially in the western states. Most US underground coal mines are located in the eastern states.

In many countries, open pit mining is the predominant mining method. In 1987, some 90% of US crude ore production in metallic mines came from open pits, and production of industrial minerals was as much as 95%. The corresponding percentage of coal mines that were surface operations was 60%. During the last decade or so, the proportion of coal mined by surface methods has increased. In Canada, 72% of the 1986 metallic crude ore production came from surface mines. On the other hand, other countries depend heavily on underground mining. In Sweden, for example, some 80% of the annual crude ore production comes from underground mines.

Different mining methods are used for different minerals. Iron and copper ores are mostly mined in open pits. Most industrial minerals are mined in open pits (also called quarries). Lead, zinc, etc., are mined principally underground. Gold until now has been mined mostly underground, such as in South Africa, but during recent years, there has been a strong trend to surface gold mines, especially in the United States.

Large amounts of waste are also handled in surface mines. About twice as much waste as ore has been mined in US open pit metal mines during the recent decades, although stripping activities declined in the mid-1980s. In 1986, the average stripping ratio was 1.5 tons/ton (t/t). In 1986, the average stripping ratio of Canadian metal mines was 0.8 tons/ton (t/t).

23.2.3 MINE DEVELOPMENT

Surface mining of coal involves the removing of cover layers of soil and rock to expose the coal and then replacing and revegetating the soil when mining is completed. Surface mining is utilized when the coal seam is located relatively close to the surface, usually within 200 ft (60 m). Removal of the overburden takes place only a short time before coal mining takes place. For larger horizontal deposits, covered by large amounts of overburden and waste, much waste rock must be stripped away before ore production can start.

For steeply dipping ore bodies occurring near the surface, open pit mining can start with only a minimum of stripping, but when mining goes deeper, more and more waste rock must be removed. Waste rock in the open pit often must be removed many years before mining of the corresponding amount of ore at deeper benches is possible. The ultimate pit limits must therefore be known at an early point in time, and the interest rate cost for waste rock removal must be included in the economic evaluation of the ultimate pit depth.

Waste rock stripping should be delayed as long as possible to avoid high interest cost for all the money spent in waste stripping activities. The waste rock within the planned ultimate pit limits should, if possible, be mined out in a sequence of push-backs or expansions. Each push-back will make the pit deeper or larger and the pit life longer. The exact point in time when a new push-back must be started depends on machinery capacity, etc. More than one push-back can be in progress at the same time. Waste stripping activities can vary from year to year.

In an underground mine, hoisting shafts, ventilation shafts, and other major access openings require long-range planning from the very beginning if they are to meet the requirements of future workings at deeper levels. Underground mining is a complex undertaking, which includes the development of drifts, manways, rock support, etc. A large capital investment is often necessary before production can start.

It is very important that the underground mine design and the machinery capacities are properly chosen from the very beginning. By the time one discovers that the mine layout is wrong, or the capacity not what was expected, it is often too difficult to do anything about it. There are three reasons that explain how this may happen: (1) rock conditions often limit the possibility for reconstruction underground; (2) long construction and development times often mean that it is too late to correct mistakes after mining begins; and (3) the fact that mining is a highly capital-intensive business means that a planning mistake can destroy the profitability of the whole venture.

The development of a large underground mine can take from five to ten years. The interest cost during the construction time will thus be high and can account for up to 30 to 40% of the capital requirement before mining can start.

The possibility of using trucks for hauling the broken ore through inclined underground ramps up to the crusher on the surface should be examined in an actual operation. Such a solution can be very advantageous, especially in small- and medium-sized underground mines, to achieve early production and reduce capital requirements and interest costs.

23.2.4 PRODUCTIVITY, TIME UTILIZATION, AND LABOR COSTS

Normally, productivity in a surface mine is much higher than in a comparable underground mine (Table 23.2.2). This means that underground mines account for a disportionately larger percentage of the work force. In 1987, the average productivity in US open pit metal mines was about 53 tons (48 t) of waste and ore/employee-hr. The corresponding value underground was only 3.8 tons (3.4 t). The coal industry produced 5.4 tons (5.0 t) of clean coal/employee-hr in the surface mines in 1987, compared with only 2.4 tons (2.2 t) underground.

Productivity, especially in open pits, has improved significantly during recent decades, mostly as a result of the introduction of larger and more flexible equipment. Large open pits normally have a productivity that is much higher than smaller ones. Rock conditions and limited space constrain the use of larger equipment underground. Table 23.2.3 shows productivity in US coal mining by production size groups. The table shows that there are no major differences in productivity between surface mines and underground mines, or between different production size groups, as long as production is less than 1 million tons (0.9 Mt)/year. However, for a higher annual production, the surface mines show a considerably higher productivity.

Productivity, especially underground, strongly depends upon the mining method, the rock conditions, the kind of mineral, the degree of automation, etc. (Table 23.2.4). The huge Swedish underground iron ore mines have a productivity of approximately 12 to 15 tons (11 to 13 t) of ore/employee-hr. One reason behind the higher productivity in surface mines is that less working time is normally consumed for such things as transportation between the mine mouth and the working face. The higher productivity in surface mines thus makes the labor cost per ton produced lower than underground.

Wage agreements can make a difference in the daily, weekly, and yearly working time on the surface and underground. If an underground miner has a weekly working time of 40 hr/wk, his/

her colleague on the surface may be required to work 42 hours. This difference affects the size of the working force. Lower utilization of the working time underground works in the same direction.

Many surface mines operate 24 hr/day and almost 365 days/yr. The high capital requirements for purchase of open pit equipment make it important to use as many hours per year as possible so the number of machines can be reduced. In the case of a machinery breakdown, it is often easy to move the vehicle and replace it with a spare, so that ore production can resume. Underground mines, on the other hand, often must limit their daily, weekly, and yearly operating times because of the need for ventilation and maintenance. In the case of underground coal mines, tradition and union attitudes have so far prevented work crews from being rotated into weekend time slots. This makes the number of mines greater than what it could be with a higher equipment time utilization and the capital requirement higher per ton of capacity.

Often miners are also paid more per hour underground than for a similar job on the surface. This, in combination with better productivity and time utilization on the surface, will often result in a much higher labor cost per effective working hour underground than on the surface.

In surface mines, the largest part of the work force is normally employed in the transportation operations, especially in a large pit in which the haul distance between the face and the primary crusher on the surface can be long. In underground mines, especially in smaller ones, a larger part of the work force is engaged in drilling and blasting.

23.2.5 SAFETY AND INJURY RATES

Concern for health and safety in a mine is a prime responsibility of the mining engineer. During the last decade, the injury rate in the US mineral industry has been cut by some 50%, from some 40 injuries/million employee-hr to 20. The injury rate has dropped in surface mines as well as in underground mines (Table 23.2.5). But the injury rate is much higher underground than on the surface, some 40 compared to less than 20 injuries/million employee-hr. However, 1987 was a year with a high incidence rate.

Table 23.2.5. Injury Rate in the US Mineral Industry in 1987

	Injuries All Occurrences	Injury Rate/ Million Hours	Injury Rate/ Million Tons*
METALLIC MINES			
Surface	736	32.1	1.5
Underground	969	60.0	16.0
NONMETALLIC MINES			
Surface	332	25.6	N/A
Underground	344	43.7	N/A
COAL MINES			
Surface	2,710	27.9	5.1
Underground	12,124	79.0	33.3

* Tons of crude ore or clean coal, respectively.
Note: MSHA normally shows the incidence rate per 200,000 hours.
Source: Anon, 1987b (*Mine Injuries and Worktime Quarterly,* MSHA).

In addition, one may wish to account for the difference in productivity. If one takes this into account, one finds that the injury rate per million tons of product produced is 5 to 10 times higher underground than on the surface and 10 to 15 times higher per ton handled. From the standpoint of human welfare, it would thus be very advantageous if even more ore could be mined by surface methods.

23.2.6 ENVIRONMENTAL ASPECTS

A surface mine normally makes a deeper and more visible encroachment on the environment than an underground mine. The often large amount of waste and overburden must be placed somewhere. Noise and vibration often disturb the environs as well. It can be necessary to place a safety zone around a pit to protect people and equipment from fly rock.

Surface coal mine operators must comply with the strict requirements and regulations of the Federal Surface Mining Control and Reclamation Act of 1977. Coal industry reclamation must return surface mined land to productive use, such as agriculture, wildlife areas, and recreation sites.

Underground, there are environmental problems with respirable dusts, diesel fumes, gases from explosives, methane gas in coal mines, etc. The cost for ventilation often accounts for a considerable part of the cost for underground mining. The need for ventilation after blasting sometimes necessitates a shutdown of production for several hours. Only in very cold or hot climates do miners find it better to work underground than in a surface mine.

23.2.7 ENERGY CONSUMPTION

As a result of the soaring price of petroleum products in the early 1970s, the interest in energy conservation has been especially high during the last decade. Although the price has declined somewhat today, it is important to keep up the interest in energy consumption.

Published data indicates that most surface operations require 5 to 10 kWh energy equivalents/ton of rock handled. Most of this is diesel fuel, although the use of electric power has increased in recent years because of trolley-assist trucks and in-pit crushing and conveying. Underground mining normally requires an average of 15 to 30 kWh of energy equivalent/ton, with up to 50 kWh in smaller cut and fill operations. A large part of this is electricity. During recent years, electric trucks and load-haul-dump (LHD) equipment have been developed.

Although energy consumption/ton handled is much lower in a surface mine than in an underground mine, energy costs often account for a larger part of the total mining cost per ton of ore or per unit of metal extracted in a surface mine than in an underground mine. Future increases in the price of energy, especially of petroleum products, will reduce the competitiveness of surface mining methods as a consequence.

23.2.8 CONSUMPTION OF EXPLOSIVES

Removal of the overburden and coal in surface coal mining sometimes requires no drilling and blasting, but most rocks require that drilling and blasting be employed before materials handling occurs. The costs for drilling and blasting, however, are normally lower in a surface mine than underground. There are several reasons for this difference. First, surface haulage equipment, especially rear-dump trucks, can normally handle coarser material than underground equipment. This makes it possible to minimize the powder factor in surface mines. Also it is often possible to use larger hole diameters and spacing in surface drilling than in underground drilling. In surface operations, hole diameters of 10 to 15 in. (250 to 400 mm) are common, while most underground mines, typically use holes less than 6½ in. (165 mm). Tunneling and drifting usually are performed using even smaller hole sizes.

In a surface mine, one normally has multiple free surfaces or faces to blast to, while underground, only one face may be available. This makes a lower powder factor more feasible in surface mines. In those US surface metal mines where drilling and blasting are required, the average powder factor has been 0.3 to 0.5 lb/ton (0.5 to 0.7 kg/m^3) of blasted rock in situ in recent years. Underground, often twice the powder factor is required. But conditions vary significantly from mine to mine and with the type of rock.

The coal industry as a whole is the largest consumer of explosives, using some 70% of the total US industrial consumption. Nearly all of this is used in surface coal operations.

23.2.9 MINING COSTS

In surface mines, especially larger ones, the haul distance from the face to the primary crusher can be long, and the haulage cost will thus account for a large part of the total costs. In underground mines, especially smaller ones, the costs for development drilling and blasting are often more important. Drilling, blasting, loading, and haulage are examples of direct costs in a mine. In a cost calculation, it is important to also include auxiliary costs.

In a surface mine, auxiliary costs like rock support, water pumping, and road maintenance are normally small and account for about 10% of the total mining costs. Underground such auxiliary costs are higher, often 20 to 40% and include costs for ventilation, lighting, rock support, etc. The total cost per ton of material handled is normally much lower in a surface mine than in an underground mine.

In an estimation of the total cost per ton of ore or coal produced, one also has to take waste rock mining into account, especially in a surface mine where the stripping ratio can be high.

Table 23.2.6. Costs in a Surface Mine

Annual production: 5.0 million tpy (4.5 million t/yr)	
Corresponding to: 15,000 tons/day (13,500 t/day)	
Investment in mining equipment:	
Drilling and blasting	\$ 1.3 million
Loading	\$ 3.6 million
Haulage	\$ 7.1 million
	\$12.0 million
Annual capital cost (10%, 5 yr):	
\$12.0 million × 0.26 =	\$ 3.1 million/year
Capital cost/ton:	\$ 0.60/ton (\$0.67/t)
Operating cost:	
Drilling and blasting	\$ 0.30/ton (\$0.33/t)
Loading and haulage	\$ 0.80/ton (\$0.88/t)
Auxiliary costs	\$ 0.10/ton (\$0.12/t)
Total mining cost:	\$ 1.80/ton (\$2.00/t)

Note: 1988 costs.
Source: Calculated from Anon., 1987c (*Cost Estimating System Handbook*, US Bureau of Mines).

23.2.9.1 Surface Mining

The cost for surface mining varies from mine to mine. Larger mines have costs per ton handled which are considerably lower than in smaller operations. Table 23.2.6 shows an estimation of the total operating cost, including capital costs for mining equipment, for a surface mine. Of the total cost, \$1.80/ton (\$2.00/t) handled, loading and haulage accounts for 74%.

23.2.9.2 Underground Mining

Underground mining costs vary significantly from mine to mine and depend on such factors as production levels, mining method, rock support, etc. Cut and fill stoping is an expensive method. Block caving, on the other hand, can sometimes compete with surface mining. Table 23.2.7 shows an estimation of the operating costs in a medium-sized open stoping mine, using long, parallel, large-diameter blastholes. It is based upon material published by the Swedish Mining Research Foundation from its Luossavaara Research Mine in northern Sweden. The costs apply to the mining of a 330-ft (100-m) high block of this deposit. On the top of the block, a drilling level was developed. At the bottom of the block, there was a drawpoint level, where LHD equipment loaded the ore into trucks for haulage via an inclined ramp to the surface (Fig. 23.2.1).

Table 23.2.7 illustrates that a calculation of the costs for underground mining includes the estimation of the costs for many different items. The total cost is \$14/ton (\$15/t) of crude ore, of which development in this mine accounts for as much as 43%. The table also illustrates that underground mining, on a unit cost basis, is much more expensive than surface mining, although the difference in production volume, etc., make future conclusions difficult.

In a surface mine, a large part of the operating costs is variable. If a surface mine operator must decrease production, it is often possible to sell the mining equipment, because there is a large market for such equipment that is also used by other industries.

Underground mining requires more mine-specific equipment. In addition, large amounts of money are often invested in shafts and haulage systems. It is, therefore, more likely that an underground mine will keep producing as long as the revenues cover the variable operating costs, even though the operation is not profitable on an overall cost basis.

Table 23.2.7. Operating Costs in an Underground Mine

Production data summary:			
— Total amount of recoverable ore: 1.50 million tons (1.36 Mt) of which 100,000 tons are from development			
— Waste rock dilution: 10%	0.17 million ton (0.15 Mt)		
— Total amount of crude ore:	1.67 million tons (1.51 Mt)		
— Lifetime: 4 yr			
— Annual amount of crude ore:	0.42 million ton (0.38 Mt)		
— Annual amount of ore excluding waste:	0.38 million ton (0.34 Mt)		
Development costs:			$ Million
— Example drilling	18,000 ft ×	$30/ft	
	(5,500 m ×	$100/m)	= 0.6
— Drifts	10,000 ft ×	$400/ft	
	(3,000 m ×	$1,300/m)	= 4.0
— Raises	2,000 ft ×	$350/ft	
	(600 m ×	$1,200/m)	= 0.7
— Cable bolting	70,000 ft ×	$8/ft	
	(21,000 m ×	$30/m)	= 0.6

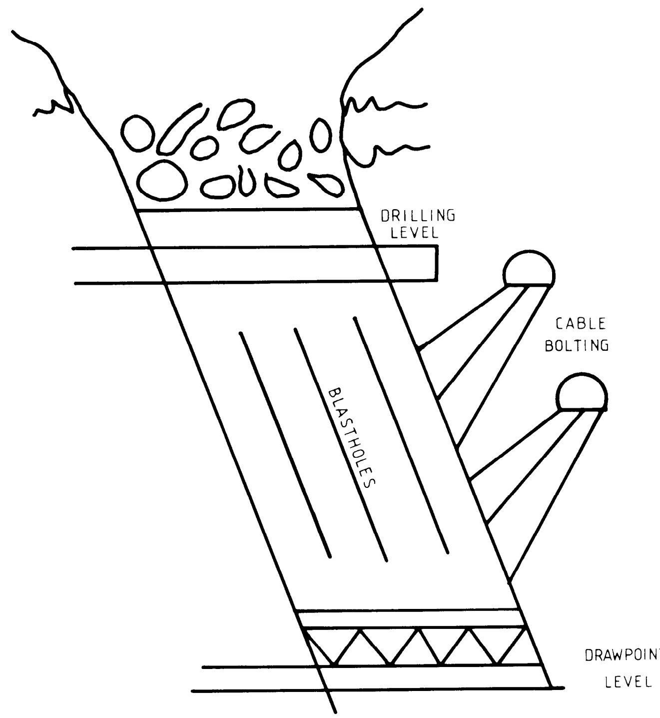

Fig. 23.2.1. Cross section through a medium-sized underground mine.

23.2.10 ORE RECOVERY, CUTOFF GRADE, AND WASTE ROCK DILUTION

In a surface mine, it is normally possible to recover almost all the mineral or coal one wants to mine. The recovery underground is usually lower and depends upon the mining method used. With cut and fill stoping, it is often possible to get a high recovery, but the cost is also high. With caving methods, it is normally not possible to extract all the blasted ore, because waste rock dilution will be too high (15 to 25% of the ore is normally left). With stoping methods and room and pillar mining, 15 to 25% of the ore is often left in supporting pillars.

Underground coal mining recovers an average of 50% of the coal with the room and pillar system and up to 80% using the longwall system. Underground mine costs are normally higher than surface mining costs, which means that a lower cutoff grade can normally be used in a surface mine. As a general rule, surface mining allows extraction of a larger part of a deposit than if underground methods are used.

Cut and fill mining is a selective but expensive mining method that makes high ore recovery and low dilution possible. This is also possible in the primary stages of room and pillar mining and open stoping. Other underground methods may result in waste rock dilution from caving roofs and hanging walls. Often 20 to 30% of the extracted tonnage is country rock, resulting in extra costs. Often such dilution has a coarse fragmentation, which causes extra costs and loss of capacity in underground mines.

23.2.11 GENERAL CONSIDERATIONS IN THE CHOICE BETWEEN SURFACE AND UNDERGROUND MINING

If an ore body or coal seam is situated at a relatively great depth, an experienced mining engineer can readily evaluate the

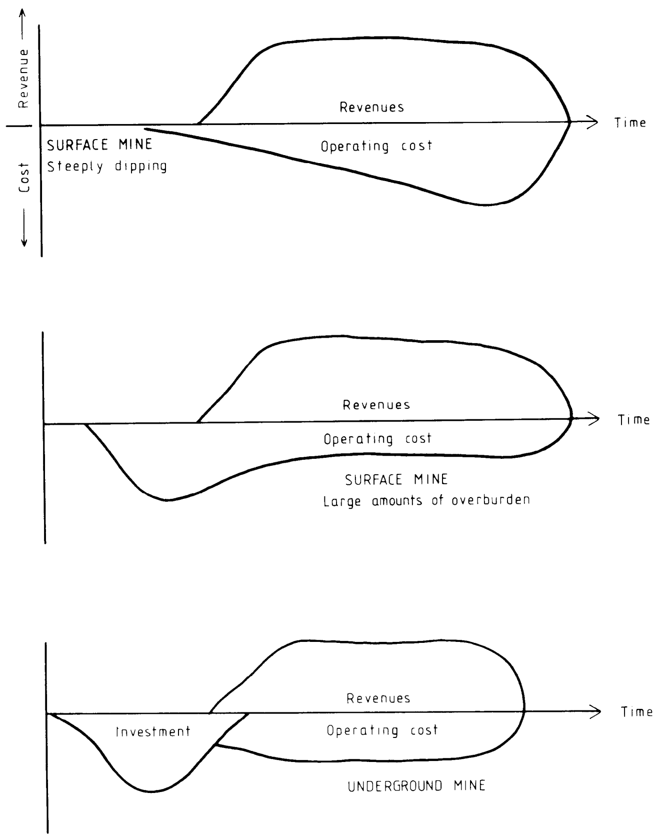

Fig. 23.2.2. Examples of cash-flow profiles for surface vs. underground mines.

possibility of surface mining by estimating the total stripping ratio for a surface mining venture. If the estimated stripping ratio essentially exceeds that of similar mines, surface mining can probably be ruled out. However, there are examples where bad rock and working conditions underground can make surface mining necessary in spite of a high stripping ratio. There are also examples where consideration of the environment around a mine site necessitates underground mining.

Secondly, there are cases where one has to go through a feasibility study before one can decide whether to use surface or underground methods. An economic comparison between open pit or underground mining of a deposit should begin with sound reserve and grade estimation. Cutoff grades, ore recovery, etc., will be different.

At the next stage, surface mine designs as well as underground mine designs must be studied; waste rock stripping, dilution, etc., should be estimated. A reasonable annual production rate must be selected, considering the market, the size of the reserve, capacity aspects, etc. Machinery, energy, and labor requirements should be studied for surface as well as for underground mining. Reasonable capital and operating cost estimates must be made, revenues estimated, and cash-flow profiles shown for each alternative.

These cash-flow profiles can be quite dissimilar, and the choice between a surface venture and an underground operation can thus affect a company's financial situation for many years, even if the final profitability for the two alternatives is the same. Fig. 23.2.2 illustrates how the cash-flow profiles can differ. The first case describes a steeply dipping ore body near the surface. In the beginning, waste stripping activities and thus the operating costs are low, especially if the equipment can be leased or a contractor used. As mining progresses deeper, more and more waste must be removed.

In the second case, a large amount of overburden and waste must be stripped before ore mining can start. This will require much capital in the early stage.

The third case describes an underground mine where large capital requirements are required before any revenues accrue. The life of the mine will also be shorter because of a lower recovery. The financial strength of a company can thus affect the choice. With a shortage of funds, it can be necessary and attractive to choose a solution that requires less capital.

Finally, surface and underground mining can be compared by calculating total mining costs, net present values, etc. In such a comparison, all factors and costs that are different between the two alternatives, as well as a discount rate, must be included. The possibility of future increases in productivity, automation, etc., should be studied and the effects of additional regulations and environmental restrictions discussed. Sensitivity and risk analyses should be used to show what happens in the case of future drops in demand, labor shortages, increased energy costs, etc.

23.2.12 STUDY OF HYPOTHETICAL DEPOSITS

To illustrate how to compare open pit with underground mining, two simplified examples are shown in the following. The first case is a horizontal deposit covered by large amounts of overburden. This deposit can be entirely mined out by open pit or underground methods. The second case is a steeply dipping deposit, which will initially be mined as an open pit but mined underground later.

The size of the deposit is the same: 3300 by 330 by 1650 ft (1000 by 100 by 500 m). This corresponds to a total amount of 165 million tons (150 Mt), given by:

$$3300\,\text{ft} \times 330\,\text{ft} \times 1650\,\text{ft} \times 0.09\,\text{tons/ft}^3 = 165 \times 10^6\,\text{tons}$$

$$(1000\,\text{m} \times 100\,\text{m} \times 500\,\text{m} \times 3.0\,\text{t/m}^3 = 150 \times 10^6\,\text{t})$$

The copper content averages 2% and is constant in all parts of the ore body. There are no byproduct metals present. The yearly crude ore production will be assumed to be 5 million tons (4.5 Mt)/yr.

With open pit mining, diesel trucks will haul the rock up to the surface. All open pits will have a slope angle of 45°. The crude ore will be milled in a plant on the surface. The' copper concentrate from the flotation plant will be transported to a smelter and refinery in the area for further processing, resulting in refined copper. The annual output of refined copper will be 75,000 tons, given by:

$$\begin{aligned}&5 \text{ million tpy} \times 2\% \text{ Cu} \times 75\% \text{ recovery}\\&= 75{,}000 \text{ tons/yr (68 kt)}\end{aligned}$$

In the case of underground mining, sublevel stoping with high blocks will be used with drawpoints and a loading level at the bottom of each block. It will be assumed that a haulage level is developed at the bottom of the ore body. The broken rock will be dumped from the loading levels into ore passes. From the bottom of the ore passes, trucks will haul the ore to a primary crushing station. The ore will then be hoisted up to the surface through a vertical shaft. The following costs will be used:

Waste rock stripping	\$1.80/ton (\$2.00/t) of waste
Open pit ore mining	\$1.80/ton (\$2.00/t) of ore
Underground mining	\$13.50/ton (\$15.00/t) of ore

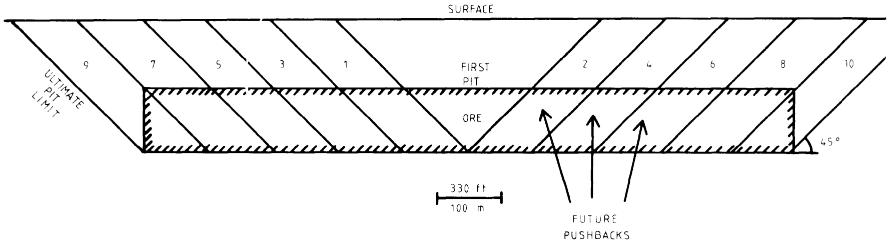

Fig. 23.2.3. Longitudinal section through hypothetical copper deposit.

Investment in underground mine	$75 million
Ore beneficiation and misc.	$40 million/year
Investment in mill and misc.	$200 million
Discount rate	10%

For the sake of simplicity, the mining cost assumed here will be independent of depth. Two different copper prices will be used: $2 and $3/kg of refined copper (corresponding to approximately $1 and $1.50/lb).

23.2.13 OPEN PIT OR UNDERGROUND MINING OF HORIZONTAL DEPOSIT WITH VARYING OVERBURDENDEPTH

Example 23.2.1. The deposit has a length of 3300 ft (1000 m), an average width of 1650 ft (500 m), and a thickness of 330 ft (100 m). Three cases will be assumed in which the deposit is covered by 330 ft (100 m), 500 ft (150 m), or 660 ft (200 m) of overburden. This deposit can be entirely mined by open pit or underground mining, and one has to choose the mining method from the very beginning.

To get open pit production started, a large amount of waste must first be removed. Additional parts of the ore area will later be available after new push-backs. These waste quantities will be higher the deeper the deposit is situated. Fig. 23.2.3 shows a longitudinal section through the deposit in the case of open pit mining. If the amount of overburden over the deposit is too thick, underground mining is of interest. The question is: How thick can the overburden be before that happens?

Table 23.2.8 shows some mine planning data. Before open pit ore production can start, a total of 81,145 and 230 million tons (73,132 t and 208 Mt) of waste must be removed. Assuming that an average two 55-ft (17-m) benches of overburden can be removed per year, waste rock stripping must start 3, 4.5, and 6 years before ore mining can be initiated.

Table 23.2.9 shows the calculation of the net present values (NPVs) for open pit mining and different thickness of the waste over the deposit; a comparison of results is as follows:

	NPV ($ Million)	
Waste Thickness	$1.00/lb ($2.00/kg)	$1.50/lb ($3.00/kg)
330 ft (100 m)	−84.9	+561.0
500 ft (150 m)	−340.4	+305.5
660 ft (200 m)	−658.9	−12.9

With $1.00/lb ($2.00/kg), all values are negative, which means that it will not be profitable to invest $200 million to get production started. But the values also show that, with a copper price of $1.50/lb ($3.00/kg), it would be profitable to invest $200 million, even if the deposit is covered by almost 660 ft (200 m) of overburden.

How will the possibility of using underground mining affect the conclusion? Table 23.2.10 shows the calculation of the NPV of the deposit mined underground. The table shows that, with a copper price of $1.00/lb ($2.00/kg), the revenues will not be high enough to cover operating costs. But at a price of $1.50/lb ($3.00/kg), it will be profitable to make all the investments and start underground mining.

If one compares the results from Tables 23.2.9 and 23.2.10, one can conclude that, as long as the deposit possesses less than

Table 23.2.8. Summary of Mine Planning Data for a Horizontal Deposit

ˣ Same costs used as for open pit mining. Waste rock dilution can increase these costs. Conversion factor: 1 ton = 0.9072 t.

550 ft (165 m) of waste, open pit mining is preferable. If the deposit is situated deeper, underground mining should be used. This solution indicates that open pit mining should be used as long as the average stripping ratio is less than 3.5 tons/ton (t/t). If more waste rock must be removed per ton of ore, underground mining is preferable. By simply comparing the capital values of all costs only, an approximate solution to a problem of this sort can be made. But, because of the difference in ore recovery, it is recommended also to include the revenues in any economic analysis.

23.2.14 OPTIMIZING DEPTH IN CONVERTING FROM OPEN PIT TO UNDERGROUND

When a surface mine is deepened, more and more waste rock must be removed. Surface mining can continue as long as the cost for mining another bench is lower than underground mining of that ore quantity and as long as the costs are covered by revenues. To understand how to optimize the depth in changing from open pit to underground mining, a simplified example is utilized.

Example 23.2.2. The deposit is a hypothetical, steeply dipping copper deposit, with the same dimensions as in the previous example: length of 3300 ft (1000 m), average width of 330 ft (100 m), and depth of 1650 ft (500 m). This deposit should first be mined with open pit methods. Four different open pit depths will be studied: 330, 500, 660, 825 ft (100, 150, 200 and 250 m). Table 23.2.11 summarizes some planning data for mining down

Table 23.2.11. Summary of Mine Planning Data for Steeply Dipping Deposit

	Final Open Pit Depth			
Open Pit Mining	330 ft (100 m)	500 ft (150 m)	660 ft (200 m)	825 ft (250 m)
Waste, million tons	40.2	98.0	173.4	281.4
Ore, million tons	33.0	50.0	66.0	83.0
Stripping ratio, average	1.2	1.9	2.6	3.4
Stripping ratio, for deepest part	2.5	3.3	4.7	6.5
Annual ore production, million tpy	5.0	5.0	5.0	5.0
Lifetime, yr	6.7	10.0	13.3	16.7
Waste rock stripping, million tpy	6.0	9.8	13.1	17.0
Underground				
In situ ore, million tons	132.0	115.0	99.0	82.0*
Lifetime, yr	21.3	18.7	16.0	13.1**

*given by: 165.0 − 83.0 = 82.0 million tons

$$** \text{ given by: } \frac{82.0 \text{ million tons} \times 0.8 \text{ recy.}}{5.0 \text{ million tons/yr}} = 13.1 \text{ yr}$$

Conversion factor: 1 ton = 0.9072 t.

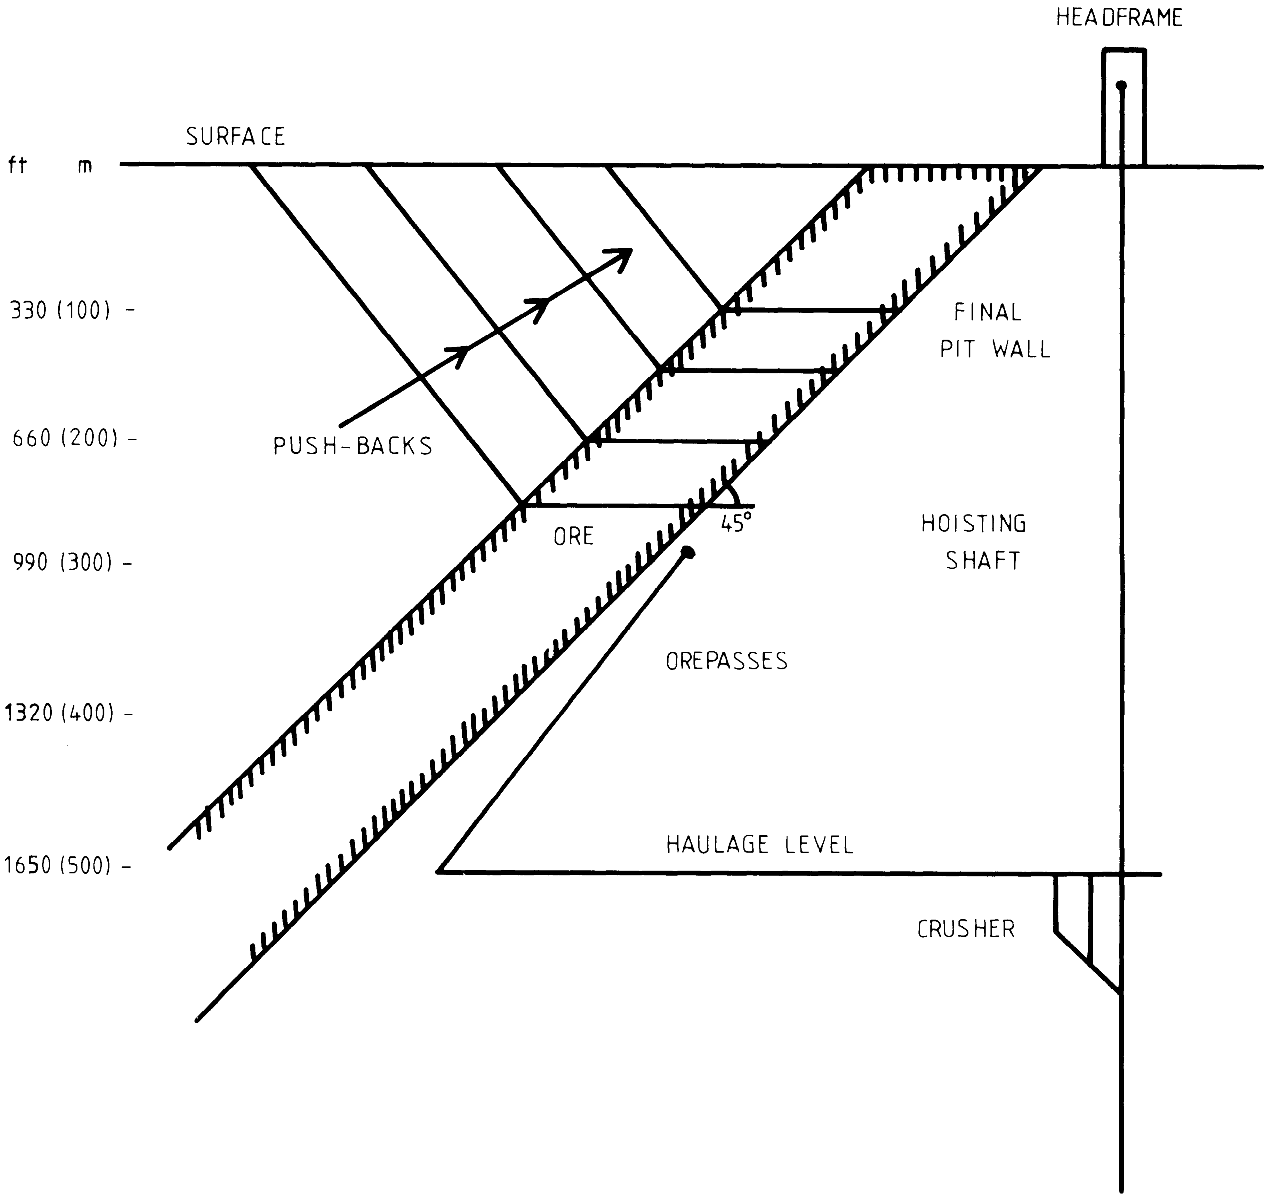

Fig. 23.2.4. Cross section through hypothetical steeply dipping copper deposit.

to the 1650-ft (500-m) depth. Fig. 23.2.4 shows a cross section through the ore body with alternative open pit depths as well as underground installations.

In an actual situation, detailed open pit layouts should be developed for each ultimate depth. As a next step, detailed mining plans, especially for overburden stripping, should be developed. (In the example below, however, simplified mining plans are used to avoid a lengthy description.)

There are two alternative ways to calculate the final pit depth:

1. Calculate the profit and cost of the ore at different ultimate pit depths. When the cost of deepening the pit exceeds the cost for underground mining, one should change to underground mining. If the cost for underground mining is higher than the corresponding revenue, underground mining is not profitable.

2. Calculate the NPV of the cash flow of the whole mine for different ultimate pit depths. The ultimate depth that yields the highest value will be the best alternative.

These two methods will yield approximately the same result, although each method has its advantages and disadvantages.

The disadvantage of the first method is that the values do not tell the reader anything about the total profitability of the whole mine, and that they cannot be compared with the capital requirement for ore processing plants, etc.

To determine total profitability, the NPV must be calculated. The first method also does not fully take into account the differences in ore recoveries. The second method will therefore be used here.

Table 23.2.12 shows the calculation of the NPV for different open pit alternatives:

	NPV ($ Million)	
Open Pit Depth	$1.00/lb ($2.00/kg)	$1.50/lb ($3.00/kg)
330 ft (100 m)	−16.4	301.5
500 ft (150 m)	−28.7	385.8
660 ft (200 m)	−42.5	442.8
825 ft (250 m)	−81.4	455.9

Table 23.2.12. Net Present Values of Different Open Pit Alternatives for Steeply Dipping Deposit

	Final Open Pit Depth			
	330 ft (100 m)	500 ft (150 m)	660 ft (200 m)	825 ft (250 m)
Revenues per year, $ million				
75,000 ton × $1800/ ton	135.0	135.0	135.0	135.0

NPV of annual income				
$34.7 million/year × 4.71ˣ	184.4			
$27.9 million/year × 6.14ˣ		171.3		
$21.9 million/year × 7.18ˣ			157.5	
$14.9 million/year × 7.96ˣ				118.6
Capital investment	−200.0	−200.0	−200.0	−200.0
Grand total @ $1.00/lb ($2/ kg)	−16.4	−28.7	−42.5	−81.4
Grand total @ $1.50/lb ($3/ kg)	+301.5	+385.8	+442.8	+455.9

ˣ Uniform series present value factors for 10% and 6.7, 10.0, 13.3, and 16.7 yr, respectively. Conversion factor: 1 ton = 0.9072 t.

Table 23.2.13. Net Present Values of Underground Mining of Steeply Dipping Deposit

Revenues	
75,000 ton × $1800/ton	= $ 135.0 million/year
Operating costs per year	
Ore Mining	
5.0 million tons × $13.50/ton	= $ −67.5 million/year
Ore beneficiation and misc.	= $ −40.0 million/year
Smelting and refining	= $ −40.5 million/year
Income per year, at $1.00/lb ($2/kg)	$ −13.0 million/year
Income per year, at $1.50/lb ($3/kg)	$ +54.5 million/year
Net present values at $1.50/lb ($3/kg)	
Net present values when underground mining starts	
330 ft (100 m):	$54.5 million tpy × 8.68ˣ − 75 = $398.0 million
500 ft (150 m):	$54.5 million tpy × 8.31ˣ − 75 = $378.0 million
660 ft (200 m):	$54.5 million tpy × 7.82ˣ − 75 = $351.2 million
825 ft (250 m):	$54.5 million tpy × 5.62ˣ − 75 = $231.3 million
Net present values when open pit mining starts at $1.50/lb ($3/kg)	
330 ft (100 m):	$398.0 million × 0.53ˣˣ = $210.9 million
500 ft (150 m):	$378.0 million × 0.39ˣˣ = $147.4 million
660 ft (200 m):	$351.2 million × 0.28ˣˣ = $ 98.3 million
825 ft (250 m):	$231.3 million × 0.20ˣˣ = $ 46.3 million

ˣ Uniform series present value factors for 10% and 21.3, 18.7, 16.0, and 13.1 yr, respectively.
ˣˣ Single present value factors for 10% and 6.7, 10.0, 13.3, and 16.7 yr, respectively.

Table 23.2.14. Net Present Values of Open Pit and Underground Mining of Steeply Dipping Deposit

	$ Million, at $1.50/lb ($3/kg)		
Depth	Open Pit	Underground	Total
330 ft (100 m):	301.5	210.9	512.4
500 ft (150 m):	385.8	147.4	533.2
660 ft (200 m):	442.8	98.3	541.1
825 ft (250 m):	455.9	46.3	502.2

At a price of $1.00/lb ($2.00/kg), all values are negative, which means that it will not be profitable to invest $200 million to get production started. The open pit can only be opened if ore beneficiation capacity, etc., is already available. In such a case, the pit should be limited to a depth of less than 330 ft (100 m).

The values also show that if the copper price increases by 50%, to $1.50/lb ($3.00/kg), the open pit can be deepened to 825 ft (250 m) in depth, and it will be profitable to invest money in the mill, etc., to get production started.

An important and often forgotten factor to include is the discount rate. If no discount rate had been included in the calculations above, one would incorrectly draw the conclusion that open pit mining would be economic to much deeper levels. A steeper final pit slope will reduce the necessary waste rock removal and make a deeper final pit possible.

It is now necessary to take the effects of future underground mining into account. Table 23.2.13 provides a study of the underground mining operation. With a $1.00/lb ($2.00/kg) price, the revenues are not high enough to cover the operating costs. Capital values for underground mining, at the point in time when underground mining can start, are as follows

	Capital Values ($ Million)	
Open Pit Depth	$1.00/lb ($2.00/kg)	$1.50/lb ($3.00/kg)
330 ft (100 m)	N.P.	398.0
500 ft (150 m)	N.P.	378.0
660 ft (200 m)	N.P.	351.2
825 ft (250 m)	N.P.	231.3

N.P. = Not Profitable

These cash flow values show that if the copper price (in the future) is only $1.00/lb ($2.00/kg), it will not be profitable to start underground mining, even if open pit mining has been used and the beneficiation plants, etc., are constructed and available. With a copper price of $1.50/lb ($3.00/kg), it will clearly be profitable to start underground mining when open pit mining is completed.

However, these values cannot be compared with the corresponding values for the open pit mining period. To do that, the underground values must be discounted to the same point in time.

The net present values for underground mining, when open pit mining starts, are as follows

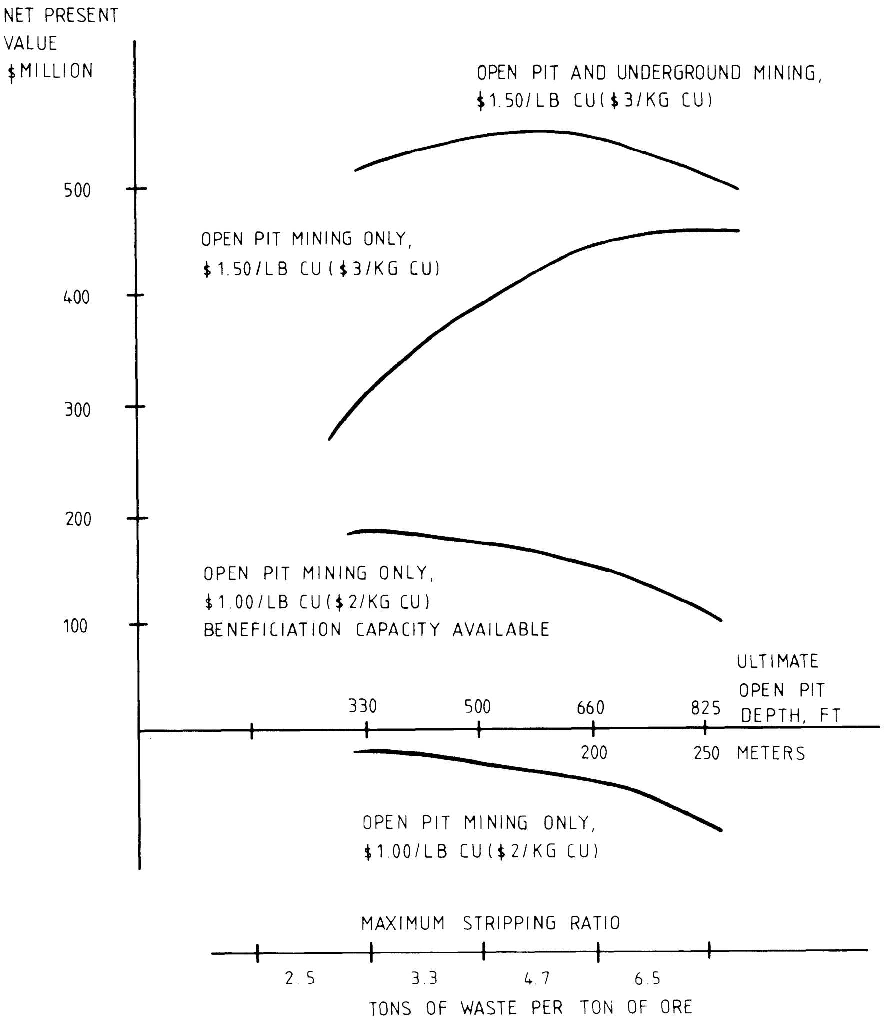

Fig. 23.2.5. Net present value of hypothetical steeply dipping copper deposit for different ultimate open pit depths.

	NPV ($ Million)	
Open Pit Depth	$1.00/lb ($2.00/kg)	$1.50/lb ($3.00/kg)
330 ft (100 m)	N.P	210.9
500 ft (150 m)	N.P	147.4
660 ft (200 m)	N.P	98.3
825 ft (250 m)	N.P	46.3

These values show that although underground mining at $1.50/lb ($3.00/kg) is quite profitable, the NPV is not very high because of the effects of the discount rate.

Finally, the NPV for the whole deposit can be found by adding the value of open pit and future underground mining (Table 23.2.14):

	NPV ($ Million)	
Open Pit Depth	$1.00/lb ($2.00/kg)	$1.50/lb ($3.00/kg)
330 ft (100 m)	−16.4	512.4
500 ft (150 m)	−28.7	533.2
660 ft (200 m)	−42.5	541.1
825 ft (250 m)	−81.4	502.2

The summary above shows that at $1.50/lb ($3.00/kg) Cu, the possibility of a profitable future underground mine will limit open pit mining to a final depth of 500 to 660 ft (150 to 200 m). This means that, in a case like this, one can accept a stripping rate of up to approximately 4.5 tons of waste/ton of ore (4.5 t/t) before one should change to underground mining.

The result is also shown in Fig. 23.2.5; this figure shows that the curves are rather flat around the optimal point, which means that it is not so important to choose a depth that is exactly optimal. With this material as a base, different types of sensitivity analyses can be performed and the effects of future changes in revenues and costs studied.

In the optimization above, the effects of increasing costs when mining at deeper levels has not been taken into account. However, these will have only a minor effect on the conclusions.

Chapter 23.3
COST COMPARISONS

JAN M. MUTMANSKY, STANLEY C. SUBOLESKI, T. ALAN O'HARA, AND K.V.K. PRASAD

23.3.1 INTRODUCTION

Evaluation and selection of mining methods is an involved process that requires a knowledge of mining methods as well as a strong working knowledge of the methods of cost estimation. Knowledge of both areas is necessary because the work of providing cost comparisons requires that the cost estimator be familiar with mining methods to provide accurate cost predictions. The choice of a mining method and the decision whether to pursue the development of a mining property are closely interrelated. Thus this chapter on cost comparisons can be applied to either of these engineering problems.

To introduce the topic of cost comparison, it is useful to establish a set of definitions for the types of cost estimates used in the various stages of consideration of a project. The American Association of Cost Engineers (AACE), an association of cost engineers and related personnel, has established one such set of definitions (Humphreys and Katell, 1981). The AACE estimates are given the following designations:

Type of Estimate	Accuracy	
Order-of-magnitude estimate	–30%	+50%
Preliminary estimate	–15%	+30%
Definitive estimate	–5%	+15%

In this classification scheme, the order-of-magnitude value is a very rough estimate, the preliminary estimate is normally associated with the budget authorization, and the definitive estimate is normally associated with the cost control on the project.

The US Bureau of Mines (USBM) has established a somewhat more complicated cost estimation classification (Lemons, 1988). Its estimation categories have the following definitions:

Type of Estimate	Accuracy
Order-of-magnitude estimate	± 35 to 50%
Factored estimate	± 30%
Budget authorization estimate	± 20%
Definitive estimate	± 10%
Detailed estimate	± 5%

This classification scheme employs similar definitions of accuracy to those of the AACE but adds the factored and detailed estimates. It should also be noted that the USBM scheme defines the accuracy in a somewhat different fashion, keeping positive and negative deviations from the estimates equal.

In our discussions here, we will refer to the three primary definitions outlined above, that is, to order-of-magnitude, preliminary, and definitive estimates. We favor the AACE definitions primarily because the positive deviations are greater than the negative deviations. It is our belief that this classification method is more realistic because cost underestimates are more common than overestimates. Individual estimators may wish to follow the USBM classification scheme.

23.3.2 COST ESTIMATION METHODS

Estimation of mineral industry costs is a specific field of endeavor pursued, in general, by engineering or financial personnel. In many ways, the discipline of cost estimation utilizes the general methods of cost estimation practiced in other fields. There are, however, some important differences that can complicate minerals cost estimation. First, cost information is not as available in the minerals field as it is in other areas. The construction and electronics industries are two examples where a considerable amount of cost information is available in the public domain. This is not true in the minerals industry. Second, the subject of cost engineering is complicated by the variability of the geologic environment and the inability of the minerals engineer to choose his working materials. This results in the actual costs being more variable and difficult to predict than costs for projects where the engineer can more completely control his engineering materials and components.

One additional complicating factor in mine estimating projects may be the remoteness of a given project. Unlike many engineering projects that are often located in urban areas with many competitive contractors, mining projects are often located at remote sites lacking in skilled labor and other resources. This remoteness may add both significant costs and the additional element of uncertainty to the project.

In spite of the differences that exist between minerals and other engineering projects, many of the cost estimation (or cost engineering) methods that are useful to the minerals estimator are procedures that come from the general field of cost estimation. Some of the more useful methods will be outlined in the next segments. Also to be discussed here are methods of updating costs, which should be a major help in projects where past data are being used to estimate a current project.

The three primary methods that are commonly used in the cost estimation field are (1) rough estimation methods (often used for order-of-magnitude estimates), (2) statistical or econometric methods for cost prediction (generally used for preliminary estimates), (3) accounting cost estimating methods that involve a detailed component-by-component approach to estimating, and (4) hybrid methods that involve a mixture of estimating methods. Accounting cost methods are often used for providing definitive estimates of a project. The following sections will outline some of the characteristics and features of these methods.

23.3.2.1 Rough Estimation Methods

Rough estimation methods can take a number of forms but are often performed using previous mining costs. The data are often utilized without discrimination based upon the specific parameters of the mining process. In other words, data from a mining method are simply lumped together without attempting to relate them to the precise conditions of mining, the specifics of the equipment used, or the degree of management exercised. The primary estimation method used may be based on the historical record for a particular category of mining. One such method has been called the *unit cost method* by Gentry and O'Neil (1984)

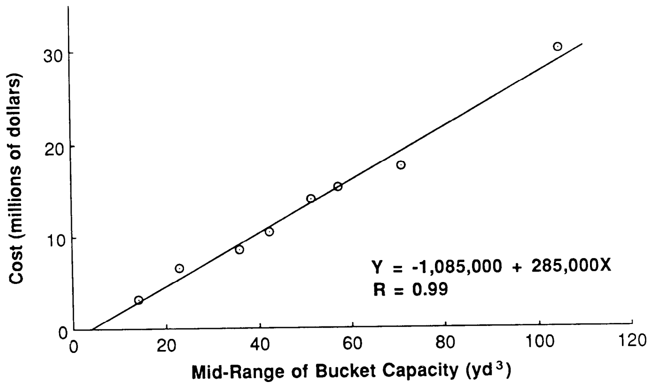

Fig. 23.3.1. Relationship between walking dragline mid-range bucket capacity and total cost (Schumacher, 1989, by permission). Conversion factor: 1 yd^3 = 0.7646 m^3.

because the costs are normally expressed in terms of dollars per annual ton of capacity of the operation or in other linear expressions based upon units of size or capacity. This method is often utilized simply because data necessary for a more complete analysis are not easy to obtain. In addition, it may be that the cost estimate does not require great accuracy. It should be noted, however, that rough estimation methods of this type will generally be used only for order-of-magnitude estimates. While rough estimation methods may be used for preliminary estimates, the accuracy may not be sufficient in all cases for preliminary estimates.

23.3.2.2 Statistical Cost Methods

A *statistical* or *econometric model* is any model that attempts to predict a dependent variable as a function of its independent variables (also often called its parameters). A statistical cost equation is one such econometric relationship that can be utilized in a cost estimation problem. A regression equation of this type will generally be of the form,

$$\text{Cost of an entity} = f(N \text{ parameters}) \tag{23.3.1}$$

in which cost of the entity is a function of N independent parameters of the entity, and N can be any number. To establish this type of a cost relationship, a variety of procedures and methods can be used with the emphasis on providing the equation from a statistical analysis of the data. For example, assume that the data plotted in Fig. 23.3.1 (Schumacher, 1989) represent the total costs of purchase and erection of walking draglines. If the data are plotted as shown, one might be justified in simply using the linear regression line as a cost estimation equation for the machines in a preliminary estimation. The regression equation can be used for any size of dragline with the understanding that some errors are inherent in the estimate. The correlation coefficient R will represent an important measure of the accuracy of the estimate because, when squared, it represents the percentage of the variation in the data explained by the regression. The unexplained variation will be the variation around the regression line and can be due to any number of variables such as manufacturing differences, design variations, or pricing idiosyncrasies.

A number of cost models have been published that may be quite useful to the engineer or accountant involved in cost estimation. Some of these are outlined in the upcoming paragraphs. The cost model that has been applied to the widest variety of cost relationships in both mining and mineral processing of metallic deposits is that outlined by the USBM (Anon., 1987a, 1987b). An additional publication (Stebbins, 1987) provides similar cost relationships for small placer mines. These cost estimating systems handbooks utilize a generalized approach based on the exponential regression function,

$$Y = a X^{b} \tag{23.3.2}$$

where X is the independent variable upon which the cost relationship is based, and a and b are the constants that are determined as a result of regression of X on Y. Some of the primary advantages of such a relationship are essentially that the equation can be applied to a wide variety of relationships, and that the regression line will appear as a straight line on log-log paper with the slope determining the parameter b. An additional advantage is that the cost models have been formatted into a Lotus 1-2-3 spreadsheet program for the convenience of users, and the spreadsheet program is available from the USBM.

The USBM states that their exponential cost regressions are based upon 5- to 7-point estimates of the cost that are derived using uniform cost data and that the estimates have an accuracy of ± 25%. A wide variety of cost relationships have been provided by the USBM in its publications including capital costs; costs of supplies, labor, and equipment operation for many underground and surface mining methods; exploration and development costs; transportation and mine plant costs; and capital, operating, and equipment costs associated with typical metallic mineral processing operations. One disadvantage of these publications is that no raw data or correlation information is presented along with the models. More will be said about these cost models later in this chapter.

Other cost models of the statistical type have been presented by O'Hara (1980, 1982, 1987). The models presented in these publications are often exponential like those of the USBM, but they tend not to be tied to one specific equation type. In addition, O'Hara also uses the econometric approach to choosing such variables as the manpower, equipment size, and other decision variables often considered at the same time as the cost estimate. Readers can assess the usefulness of these cost models by referring to Chapter 6.3 of this *Handbook* where examples of the cost equations have been provided.

In the area of coal and other sedimentary mineral beds, cost models have been constructed in the past by Toth (1981a, 1981b) and Toth and Annett (1981a, 1981b). These models cover the primary methods of mining coal by both underground and surface methods. The models tend to combine some of the statistical procedures with more detailed accounting cost models. While these models are now out of date due to changes in the technology of coal mining, they are of general interest because of their construction. The basic underground mining cost model utilized six of the major variables that affect the cost of underground coal mining: seam depth, seam thickness, seam grade, floor conditions, and methane liberation. The primary statistical equation used to initiate the model for a continuous miner cost estimation is as follows:

$$TPMS = (aH^2 + bH + c)\,(OEF)\,(AFT/390) \tag{23.3.3}$$

where $TPMS$ is output in tons per machine shift, H is seam thickness in feet, OEF is operator efficiency factor, AFT is available face time/shift in minutes, and the parameters a, b, and c are coefficients of a second-order polynomial obtained by regression. (Note: Most of the equations presented in this chapter are regression equations based upon English units. Because the equations do not apply to SI units, these units are not provided here.) This statistical relationship considers only the seam height as an independent variable, and so a separate regression was required for each combination of depth, grade, floor condition, roof condition, and methane emission considered. Data points for these regression relationships were generated using a computer simulation program. Similar relationships were generated for conventional and longwall mining as well. After the TPMS values are obtained, the overall cost prediction for the mining system is determined by calculating the capital requirements of the system, the labor and operating costs, and then the discounted cash flow of the proposed mining system.

Because prediction of the productivity of coal mine working sections is a major part of the battle in prediction of costs, a model that will accurately predict production or productivity is often as useful as a model that will estimate costs. Suboleski (1978) determined a multi-variable stepwise regression model for predicting productivity that extended the concept of regression models to include geologic, mining plan, equipment, geographic, and labor variables in the prediction process. The data for this model were obtained from questionnaires reporting the production from 326 operating coal mine sections using continuous miners. Depending on which variables were used and how the equations were constructed, the multiple-variable regressions were able to explain from 27 to 63% of the variance in the section production. Eight of the physical variables (seam height, roof quality, methane liberation, bottom quality, water, grades, depth of the seam, and hardness of the seam) were considered to have an effect on production. These variables are not under control of the engineer or mine manager and thus must be overcome through good planning and management of the mining operation.

Another statistical method that can be applied in estimation work is the method often called the cost ratio method (Gentry and O'Neil, 1984, pp. 120–126). In this procedure, a detailed capital cost estimate is prepared for certain essential categories of capital equipment necessary to equip the mine. Other costs (e.g., secondary equipment costs, development costs, costs of supplies, manpower costs, etc.) are then estimated from these capital costs by using cost ratios that relate other cost categories to the cost of the selected primary capital equipment. In most cases, this method is used primarily to estimate the capital costs of a project. However, the method can be applied to the overall operating costs if the labor and other operating costs can be reliably predicted as cost ratios of the primary capital equipment. A model by Ramani, Murray, and Manula (1977) performed this type of cost estimation for surface coal mining operations. Based on the models developed, the method was able to predict selling price of the coal within 15% for six varied surface mining operations.

In the statistical methods discussed in the preceding paragraphs, the cost estimations that result will all provide estimates in the preliminary estimate class if properly applied. However, each suffers from some shortcomings, and the cost estimator should be well aware of these so that no undue errors from the estimation procedure are introduced. If sufficient data are not available, or if the models are not appropriately applied, the accuracy of estimation may slip into the order of magnitude range.

23.3.2.3 Accounting Cost Models

An *accounting cost model* is a more detailed procedure for estimating costs based upon a component-by-component breakdown of the cost elements. The methods involve a complete accounting for all capital costs, labor costs, supply costs, power costs, etc., for each year of operation and discounted cost or cash flow analysis of the cost or income data. The cost estimator who uses this approach to estimation must have a thorough knowledge of the mining system and its component elements so that the cost computation is complete and accurately reflects the mining system. Under proper conditions of use, the accounting cost model can and does produce definitive estimates of the capital and operating costs of a mining operation.

Accounting cost models have been used and outlined in a number of publications of the USBM. Bureau personnel have published a series of analyses of coal mining costs that cover the room and pillar method using continuous miners (Katell, Hemingway, and Berkshire, 1975, 1976a), the longwall mining method (Duda and Hemingway, 1976a, 1976b), and strip mining (Katell, Hemingway, and Berkshire, 1976b). The approach outlined in these publications is to develop a detailed mining plan and then provide a set of calculations that provide a capital investment summary, labor requirements, depreciation schedule, power and water costs, estimated annual production cost, estimated development cost, estimated working capital and total capital investment, plus the discounted cash flow summary.

The primary advantage of such a costing method is the fact that it breaks the costs into elements and provides a cost estimating method and a cost control method simultaneously. The general method is easily computerized and can be readily understood by nearly everyone on the mine staff. The most crucial limitation in the use of this type of model in the cost estimation for a projected mine is the need for accurate labor requirements and productivity estimates to achieve a cost estimation. The accuracy of the method hinges primarily on these variables. While capital and supply costs are important in the determination of overall costs, they can normally be determined through standard cost reconnaissance methods. The accuracy of these estimates can probably be determined within 10%. However, due to the complexities of geologic and human variables, it is generally not possible to determine the productivity as accurately. Therefore, the accuracy of the productivity estimate is highly likely to determine the overall accuracy of the cost estimation method.

Accounting cost methods are often used to prepare definitive estimates for financing or budgeting purposes. It would therefore be important to keep estimation accuracy to ± 10%. This is very difficult to achieve before the mine is in operation. However, the same method of accounting for costs can be used after the mine is in operation with better results as then the planning engineers can more accurately predict how geologic and human variables will affect the productivity.

23.3.2.4 Hybrid Models

Many cost estimating procedures pursued during the exploration or prefeasibility stages of a mineral development project will require estimating accuracy somewhere between that provided by statistical models and that provided by detailed accounting models. When estimating in these situations, hybrid models that utilize both statistical and accounting procedures are often used. These procedures may use statistical models for estimating some of the component costs while accounting procedures may be used for others.

Using these procedures, the accuracy of the estimation will ordinarily be better than that for pure statistical methods due to the basic property of costs that are cumulative. This basic property states that the expected deviations in the estimated total cost of a project will be the square root of the sum of the squares of the deviations of the individual component costs. Using this procedure, the negative deviations in component costs have a tendency to negate positive deviations in other component costs. Thus the accuracy of hybrid models will have a tendency to increase if a more detailed approach is used and to decrease if a less detailed approach is used.

23.3.3 SOURCES OF COST INFORMATION

The minerals engineer working in mine planning and cost estimation does not have a large number of cost sources to help in the construction of cost estimates. There exist no comprehensive sources of cost data, and the information that is available often tends to be out of date by the time of publication. As a result, planning and cost engineers often try to maintain their own files on costs that they derive from various unpublished sources. However, several cost sources are worthy of note and these are outlined here.

The first source of information is the USBM cost-estimating system handbooks (Anon., 1987a and 1987b; Stebbins, 1987). These references contain many cost functions that cover capital and operating costs related to both mining and mineral processing of metal and nonmetal deposits. These handbooks are based entirely upon the exponential regression cost function (Eq. 23.3.2) and have been published with cost relationships that were in effect in 1984. As a result of the type of data used in the compilation of the cost functions and the need to update the data for current use, the cost relationships can be used only for rough or order-of-magnitude estimates. Nonetheless, the form of the regression relationship is useful, and the wide coverage of the USBM handbooks make them generally useful.

Additional cost information is found in the publications of O'Hara (1980, 1982, 1987) and in his work in Chapter 6.3 of this *Handbook*. O'Hara has developed a number of the important statistical cost relationships that exist in the minerals industry. To be used for cost estimation purposes, his cost functions also require updating. One of the advantages of his work is that it often includes relationships to accomplish the sizing of the equipment and the work force, an important consideration during the planning and cost estimation process for a mining operation.

An industry group that has published a considerable amount of cost information is the Northwest Mining Association. This group has published two volumes (Hoskins, 1982; Hoskins and Green, 1977) that contain a variety of papers on the cost elements of a mining operation. Many of these published presentations cover cost topics that have not been well covered elsewhere. Therefore, they may be of particular interest to minerals cost personnel for this reason.

An additional source of general information on cost estimation is the American Association of Cost Engineers, an international professional society headquartered in Morgantown, WV. This group has a monthly journal titled *Cost Engineering* and is dedicated to the dissemination of information on cost estimation, cost/schedule control, and project management. In addition, they maintain a certification program for cost engineers, conduct an annual meeting, and publish annual transactions. Advantages of membership in this association are that a large reference library is maintained and a computerized reference system that will provide information from the literature on a variety of cost engineering and related topics is available.

Another resource of interest to cost estimators is a subscription service on mining costs. *Mining Cost Service* (Schumacher, 1989) is a monthly publication of Western Mine Engineering of Spokane, WA, that provides cost information to subscribers on a variety of topics including electrical power, natural gas, transportation, labor, cost indexes, supplies, equipment, smelting, taxes, published cost models, and special articles. The data are gathered through a series of ongoing surveys of a network of mining companies, smelters, equipment and supply vendors, utilities, transportation companies, and government agencies. The cost service updates a category of costs each month, and every topic is updated each year. Therefore, the data are relatively recent in each category. An additional advantage of the service is that many of the data are provided on a regional basis (e.g., electric power and natural gas costs) so that the data will be relatively accurate for products and services that are location-dependent. *Mining Cost Service* also provides a selected list of vendors and other experts who have agreed to discuss equipment costs with subscribers whether or not a sale is imminent.

Finally, it should be mentioned that accurate cost estimates can often be achieved only through direct communication with the vendors who provide equipment, supplies, and services to the mining industry. In most cases, this can be performed as the projects move to their preconstruction stages and more definitive cost estimates are necessary. Equipment costs vary considerably over time as they frequently depend on market conditions and the size of the equipment purchase. Thus vendor quotations should be sought when detailed planning is complete. Accounting cost models require that definitive estimates be obtained from suppliers.

23.3.4 COST UPDATING METHODS

One of the problems that must constantly be dealt with in cost estimating is the updating of basic cost data to present cost values. This problem arises because costs for equipment and operating costs change over time, primarily as a function of inflation. The engineer or others involved in cost estimation will often find the need for updating old prices or costs taken from various sources and estimating current prices or costs from them. To perform this function, the practicing cost engineer must have cost indexes available that reflect the inflation in costs or prices over time. A cost index provides a means of comparing the costs or prices of a specific category of goods or services at specific points in time and thus will allow updating by relating costs to the index. The general equation to update a cost value is

$$\text{Current Cost} = \text{Past Cost} \times (\text{Current Cost Index/Past Cost Index}) \qquad (23.3.4)$$

In utilizing this relationship, it is necessary to know the date when the past cost was effective so that the past cost and the past cost index are matched in time. An application of this principle will be illustrated in examples later.

A variety of cost indexes are available to the minerals engineer for use in cost estimating work. Most of the indexes are not specific to the mining industry but contain index values that are applicable to the plants, equipment, and services used in the mining industry. An outline of several of the more important price indexes is provided here.

The *Producer Price Indexes* is a monthly publication of the US Department of Labor and covers a rather comprehensive array of products used in industry. Some of the prices are provided on an industry or commodity basis while others are provided on a stage-of-production basis. The index values are updated monthly based upon an extensive set of price quotations collected from suppliers of the products. As such, they probably contain more basic background data and are more useful than any other set of indexes. Table 23.3.1 contains a number of the index values from 1967 to the present for commodities that have

Table 23.3.1. Mining and Related Cost Indexes

Year	Mine Labor	Construction Labor	Construction Machinery & Equipment	Mine Machinery & Equipment	Mine Machinery Parts	Mine Drill Bits	Iron & Steel	Lumber	Refined Petroleum Products	Explosives	Truck Tires	Rubber & Plastic Products	Electric Power	Industrial Chemicals

* Value as of December 1987.

Notes: (1) Labor costs are $/hr values and were obtained from Anon., *Monthly Labor Review,* US Department of Labor, various issues.
(2) Commodity costs are relative values based upon 1982 = 100 (except for mine drillbits which are based upon December 1987 = 100) and were obtained from Anon., *Producer Price Indexes,* US Department of Labor, various issues.
(3) Some table values were updated using US Department of Labor computer outputs.

some relationship to mining costs. Table 23.3.1 also contains some labor indexes that are published monthly in the publication of the US Department of Labor entitled *Monthly Labor Review.* To use the price and labor indexes, it is generally necessary to simply reflect the price increases for the correct category of commodity.

Example 23.3.1. A given size and type of front-end loader was known to have a price of $330,000 in 1985. What is its estimated cost in 1989?

Solution. The 1989 cost for the loader can be estimated using the price index for construction machinery and equipment index or the mining machinery index from Table 23.3.1 However, loader prices may more accurately be reflected by the construction equipment index, and so the estimated 1989 cost is

$$\begin{aligned} \text{1989 Cost} &= \text{1985 Cost} \times (\text{1989 Index}/\text{1985 Index}) \\ &= \$330{,}000 \times (117.2/105.4) = \$367{,}000 \end{aligned}$$

In updating the cost of a loader, the updating procedure is relatively straightforward. In other estimations, a component-by-component procedure must be used to provide a current cost. An example of this procedure follows.

Example 23.3.2. A zinc mining company has a 1984 cost estimate for mining by the vertical crater retreat (VCR) method (Anon., 1987a, pp. 558–560) that indicates the following operating costs for a 2000-ton/day operation.

Labor cost	$1.00/ton
Supply cost	$1.31/ton
Equipment cost	$0.29/ton
Total operating cost	$2.60/ton

How should these costs be updated to 1989 values if the component-by-component procedure is to be used?

Solution. The basic procedure calls for updating each cost category in the estimation procedure using the most applicable cost indexes available. In studying the cost categories in Table 23.3.1, it is obvious that labor costs can best be updated by using the mine labor cost index. The equipment costs are updated using the mine machinery parts index as repair parts make up 48% of the equipment cost category. The cost of supplies can be related to the cost index for bits and steel as this constitutes 70% of the costs involved. However, the index is not continuous back to 1984 and the machinery parts index will be used instead. The updating proceeds as follows:

1989 Labor Cost = 1984 Labor Cost × (1989 Labor Index/1984 Labor Index)
= $1.00/ton × (13.26/11.63) = $1.14/ton

1989 Supplies Cost = 1984 Supplies Cost × (1989 Mine Machinery Parts Index/1984 Mine Machinery Parts Index)
= $1.31/ton × (113.0/104.5) = $1.42/ton

1989 Equipment Cost = 1984 Equipment Cost × (1989 Machinery Parts/1984 Mine Machinery Parts Index)
= $0.29/ton × (113.0/104.5) = $0.31/ton

1989 Total Operating Costs = 1989 Labor Cost + 1989 Supplies Cost + 1989 Equipment Cost = $2.87/ton

While *Producer Price Indexes* provides a measure of the fluctuation in the prices of individual products, it it often helpful to have an index that reflects the cost of erecting a completed processing facility. One index that provides a measure of this type of cost is the plant construction cost index that is published each month in *Chemical Engineering.* This is a composite index that reflects the prices of products used in constructing a plant, building materials, construction labor, plus staff labor costs. The index is designed to reflect the cost of construction of a typical chemical engineering plant and thus may not be equally accurate when projecting the cost of providing a minerals processing plant or a smelter. As a result, other indexes may be preferable for this purpose.

The Marshall and Swift Index is also published monthly in *Chemical Engineering.* The monthly values from this list provide indexes for the installed price of various categories of equipment. Like the *Chemical Engineering* index, it is compiled as a composite of numerous costs to reflect the equipment, materials, and labor required to install equipment in a given processing industry. One of the reasons that it is of interest to mineral engineers is that it provides a specific cost index for the mining and milling industry and thus provides useful information when projecting mine plant, processing, and smelting facilities.

Several other indexes are available as well. The *Engineering News-Record* index and the Nelson refinery construction cost index (published in *Oil and Gas Journal)* are described by Gentry and O'Neil (1984). Other indexes are also available to reflect various costs, particularly construction costs. The basic problem with most of these indexes is that they may or may not parallel the cost of minerals projects. The downturn in the minerals industry that occurred in the late 1970s and early 1980s was evidence of this as costs of mining equipment and construction did not rise as fast as that for other industries due to the competition that developed among vendors when mineral development projects became scarce. Thus an index should be chosen carefully so that it correctly reflects the costs of the minerals industry. Otherwise, alternative methods of updating should be developed.

23.3.5 MINING METHODS COST ESTIMATION

To provide working data on current operations, the authors conducted two surveys of mining companies. The first survey was oriented towards coal mining methods; the second was oriented towards mining methods applied to the noncoal minerals. The response to the questionnaires was good in some categories and poor in others, but a great deal of useful data was derived from the effort. A summary of each of the data sets is provided in the following, along with cost models and statistical results derived from the data. (Readers may also wish to refer to the topics on cost estimation in Chapter 6.3 and to the treatment on cost updating provided in 23.3.4.)

23.3.5.1 Cost Estimation in Coal Mining

The precise estimation of costs in coal mines can be a difficult task. While estimation may be readily accomplished to obtain a cost that is within $2 to $3/ton of the correct value, this range of error can affect the decision to proceed or not to proceed with a mining project. Thus final cost estimation should be done in great detail before proceeding with a project. The method presented here is one to obtain preliminary costs and should be considered as no more that ± 20% in accuracy, roughly the equivalent of a preliminary estimate. This segment offers some guidelines for estimating the operating costs of surface and underground coal mines.

Cost estimation in coal mining differs considerably, of course, for underground and surface operations. Within these two broad categories, costs tend to be largely a function of productivity. Thus the key in obtaining accurate estimates of operating costs is the accurate estimation of productivity. This is preferably in terms of tons per employee-hour, but initially must begin as tons per machine shift (or its surface mine equivalent, tons per "spread" per shift).

BACKGROUND ON OPERATING COST. Operating costs are usually categorized into fixed and variable costs, with the latter characterized as remaining constant per unit of production (within certain limits) and the former characterized as remaining constant per time period, regardless of the production (again, within limits). For both surface and underground mines, the list of "pure" variable costs is relatively short. These may be categorized as follows:

1. Royalty and wheelage.
2. Black lung excise tax.
3. Reclamation excise tax.
4. Severance tax.
5. Sales commission.
6. Most operating supplies.
7. Contractors paid by the ton.
8. Energy component of the power bill.
9. Maintenance parts and supplies.

Listing maintenance parts and supplies as a variable cost may be somewhat questionable as it may be argued that maintenance costs will fall as productivity rises. The counter argument is that machines only incur the need for maintenance as a result of usage. The conservative approach is to consider this category as a variable cost; it is probably more accurate to consider it as partially variable.

At the time of this writing (1989), most coal mines incur total costs of $20 to $35/ton, with total variable costs in the range of $8 to $13/ton. Therefore, given the large value of fixed costs per ton, it seems reasonable to expect that the total cost per ton would track productivity.

Productivity in many cases functions as an indicator of other mining costs as well, including variations in the total variable cost among mines. For example, in underground mines, low productivity may often be caused by poor roof conditions, necessitating additional cost in roof support. While roof support supplies are variable costs within both high- and low-productivity mines, the roof support cost will tend to be higher (per ton) in the low-productivity mine.

It is misleading, however, to consider that all differences in costs between mines can be explained by differences in productivity. Some of the other factors contributing to differences in costs among mines with identical productivities are outlined in the following.

Union/Nonunion Status—Items such as pension funding, benefit levels, pay rates, and retiree costs will cause differences in costs even among mines with the same productivity levels.

Severance Tax—Severance tax varies from 0 to levels approaching a 20% effective rate, depending upon state law.

Workmen's Compensation—Compensation rates vary considerably between states, and may vary among mines within the same state, depending upon the accident rate of the mine.

Plant Recoveries—Most preparation plant costs, most supply costs, and items such as trucking costs are a function of raw rather than clean production. Thus a difference in recovery will cause cost differences in addition to those caused by clean coal productivities.

Management Practices—Items such as choice of supplies, supply wastage, amount of overtime pay, etc., can affect costs independently of productivity.

Use of Contractors—Coal produced or trucked by contractors will not increase reported company employee-hours worked (i.e., reported productivity), but will add to the cost. Many companies also use maintenance and other direct-labor contractors that add to the cost but not the employee-hours worked by company personnel.

Other factors, such as the age of the mine, capital replacement policy, etc., also affect total cost. Thus it is important to keep in mind the location and operating practices of the mine for which the cost is to be estimated. The cost estimation procedures discussed later in this segment can then be adjusted for these specific features of the mine being analyzed.

COST SURVEY. To verify the results of the cost models presented within this section, a survey of costs and productivities at operating coal mines was conducted in midyear 1989. Results were obtained from 86 underground mines in eight states, and from 39 surface mines in seven states. Both union and nonunion mines responded to the survey. The survey asked for the following costs to be reported on a per-ton basis:

1. Mine cost.
2. Plant cost.
3. General and administrative costs.
4. All other costs.
5. Royalties.
6. Depreciation.
7. Total cost.

Data was also gathered on the specific types of costs included within each of these categories. In general, there was such a large variation between companies that only total cost, royalty, and depreciation were useful in generating cost models. Plant costs also showed a reasonable degree of consistency.

Information about a number of other items that were judged to be potentially significant in determining costs for each mine was also requested. These items, some of which are shown in summary form in Table 23.3.2, were then used to construct regression models of mine cost and productivity. A discussion of these models follows.

In general, the productivities reported by the mines responding to the survey tended to be higher than the average productivities reported for 1988 (the latest year available) by the Energy Information Administration (EIA) for most of the states (Anon., 1989). However, this does not detract from the cost models presented since cost is presented as a function of productivity and a wide range of productivities was represented in the data. The models that were developed to predict productivities are likely to be biased toward the high side, however. Table 23.3.3 shows the range of values for each important variable for underground mines. Fig. 23.3.2 shows a plot of costs as a function of productivity for continuous miners. The general trend in the data indicates the influence of productivity on cost. However, it also shows that while cost decreases with an increase in productivity, there are significant variations caused by geologic, equipment, and human variables.

Average productivity of the underground mines responding was 3.00 tons per employee-hour (tpeh), compared to the national average of 2.38 tpeh reported by the EIA for 1988. The average mining cost for the mines responding to the survey was $21.66/ton, but the average was clearly different for eastern and western mines, with the western mines being those in the Far West and the Illinois Basin. Table 23.3.4 shows the difference in cost for these regions and for certain states. The east/west difference is taken into account in the cost models by using a dummy variable to differentiate eastern and western mines. Note that the western mines also have higher productivities, and that this difference is greater than that reported by the EIA for these states.

For the surface mines, the reported average productivity was 5.58 tpeh versus a national average of 5.43 tpeh. The average total cost of mining was $23.13/ton, but this varied widely by region and has little meaning by itself.

In underground mines, nonunion mines were found to outperform union mines, with productivities of 3.72 and 2.65 tpeh, respectively. In addition, mines that paid incentives were also found to outproduce those that did not, with respective figures of 3.89 and 2.55 tpeh. Most union mines do not pay incentives, and most nonunion mines do; thus it is difficult to separate these effects. However, as shown in Table 23.3.2, there is some indication that incentives may be more significant in determining productivity than unionization.

UNDERGROUND COAL-MINE COST MODEL. This segment discusses two methods for estimating costs in underground coal mines. The first method is a more general procedure, while the second is based upon the results of the regression models developed from the cost survey described above. Both models attempt to estimate the total cash cost of production less royalty. Both assume that this cost is primarily a function of productivity, but that it will also be dependent upon other factors. In the case of the regression model, these factors are presence or absence of an incentive system, the preparation plant yield, and the average depth of the mine.

Notice that, in the case of the regression model, the yield is determined by engineering data, the average depth of the mine can also be readily ascertained, and the use of an incentive system is the choice of management. Thus estimating the cost of a mine continues to revolve about the determination of productivity. This is now discussed in further detail, both in general and as a separate regression model obtained from survey results.

Estimating Productivity—Productivity is the key to cost estimation and must be estimated as accurately as possible. One method is to estimate productivity from a regression model that has also been developed from the cost survey results; however, it should be kept in mind that the productivity of the average mine in the survey was greater than that reported by the EIA for the mining industry. Use of the model is likely to predict a productivity somewhat higher than that achieved in practice. Thus an alternative procedure is discussed. In this method, the following steps are used:

1. Estimate average tons per unit shift for the mine.
2. Estimate the number of employees to be used and the number of hours to be worked per year or per day.
3. Estimate the number of unit shifts to be worked per day or year, allowing for unscheduled downtime.
4. Calculate the annual production using the above estimates.
5. Calculate the tons per employee-year or tons per employee-hour for the operation. Once step 5 has been accomplished (or the tons per employee-hour has been determined by other means), then the regression model for mine cost may be used to determine total cost as follows:
6. Apply the productivity and the other required input to the regression model to predict the cash cost per ton (less royalty) of the operation.
7. Add the royalty and depreciation to the above number to obtain the total cost.

Step 1. Calculate the average tons per unit shift. Probably the best method of estimating tons per unit shift and consequent tons per day is to look at similar mines in the area or similar mines operated by the company because earlier studies have shown that management practices and regional factors may be as important as physical conditions in determining productivity (Suboleski and Manula, 1979). The figures from these similar mines should then be adjusted to account for the differences in

Table 23.3.2. Summary Data from the Underground Coal Cost Survey

Variable	All Mines	Longwall	Room and Pillar	
			Conventional	Continuous
No. of mines	73	15	6	69
States represented	8	7	2	8
Mean seam thickness (ft)	5.30	6.84	5.52	5.01
Mean seam depth (ft)	534	723	572	483
Age of mine (yr)	15	29	11	12
Mean mine size (million tons/yr)	0.8	1.8	1.5	0.6
Haulage distances (mi):				
Face to portal	2.5	4.7	4.7	1.9
Portal to plant	4.7	1.1	2.8	5.4
Plant to loadout	0.9	1.1	3.6	0.8
Total haulage distance	8.1	6.9	11.1	8.1
Plant yield (%)	68	70	71	67
Unit shifts/unit day:				
Longwall		2.62		
Conventional/continuous		1.69	1.87	1.81
Mean no. of employees		350	281	126
Mean hourly employees—underground		266	233	93
Mean salaried employees—underground		52	31	17
Total employees/unit shift		38.2	54.8	22.6
Underground employees/unit/day		34.8	51.4	20.1
Clean tons/employee-hour (CTEH)—all mines	3.00	2.62	2.82	3.06
CTEH—mines using incentives	3.89	3.60	3.50	4.04
CTEH—mines not using incentives	2.55	2.44	2.15	2.53
CTEH—union mines	2.65	2.44	2.15	2.71
CTEH—nonunion mines	3.72	3.60	3.50	3.68
% of mines using incentives	35%	20%	50%	38%
% of mines unionized	65%	73%	50%	65%
Clean tons/employee–year	4966	5249	5205	4511
Tons/unit shift		2298	759	505
Apparent employee–hours/year [(tons/ employee–yr) ÷ (tons/employee–hr)]	1655	1956	1829	1474
Mining cost/ton	21.66	20.64	20.01	21.55
Total cost/ton	28.78	29.61	25.19	28.70
Total cash cost—royalty	25.97	27.19	23.18	25.80

Conversion factors: 1 ft = 0.3048 m, 1 mi = 1.609 km, 1 ton = 0.9072 t.
Note: Data from 86 mines were received. However, only 73 of the data sets were sufficiently complete for this analysis. Also, some mines reported data for more than one method.

conditions expected between the proposed mine and the existing mines. For a possible methodology, see Suboleski and Manula (1979) and Manula and Suboleski (1979).

For continuous miner operations where comparable operations are not available, the following equation may be used. This equation is derived from regression analysis on the clean tons per unit shift (tpus) for continuous miners reported by 67 of the 86 mines participating in the cost survey. The regression has an unadjusted R^2 value of 0.57 (i.e., statistically the equation can account for 57% of the observed variation in tpus). Recall that the average productivity of the mines participating in the survey was higher than the average reported by the EIA, and thus the tons per unit shift predicted may well be higher than average as well, though this cannot be verified.

$$\begin{aligned} \mathrm{TPUS_c} &= 5.83(\mathrm{THICK}) + 267(\mathrm{INCEN}) \\ &- 49(\mathrm{UNION}) - 2.34(\mathrm{YIELD}) \\ &- 104(\mathrm{EAST}) - 67.2\,[\ln(\mathrm{DEPTH})] - 94 \end{aligned} \quad (23.3.5)$$

where $\mathrm{TPUS_c}$ is tons per unit shift for continuous miners, THICK is seam thickness in in., INCEN is 1 if an incentive plan is in place or 0 otherwise, UNION is 1 if the mine is unionized or 0 otherwise, YIELD is prep plant yield in % (use YIELD = 100.0 if no plant), EAST is 1 if the mine is in Appalachia or 0 if in the Illinois Basin or the Far West, DEPTH is depth in ft, and ln is the natural logarithm.

The mean value of productivity in the 67 mines with complete data used to develop the above equation was 503 clean tpus. The entire data set (for the 84 mines reporting sufficient data) showed productivity to be slightly higher in non-longwall mines as follows:

	No. of Mines	Mean Tons Per Unit Shift for Continuous Miners
All Mines	84	505
Longwall	15	408
Non-longwall	69	537

Example 23.3.3. Compare the expected productivity (for 1989) in tons per unit shift of an 8-ft nonunion mine with 100% yield (no cleaning) in the western states with a 6-ft union mine in Appalachia with no incentive plan and a 70% yield if both average 700 ft deep.

Table 23.3.3. Statistical Summary of Selected Survey Variables for Underground Coal Mines (Total Number of Mines = 86)

Variable	Mean	Standard Deviation	Range
Seam thickness (in.)	61.5	20.2	30–120
Depth (ft)	534	384	120–2000
Haulage distance (Portal to Plant)	2.46	2.14	0–12
Yield (%)	67.6	17.0	40–100
Longwall tons/shift (N = 16)	2298	1207	320–4500
Continuous miner tons/shift (N = 80)	505	306	160–1500
Conventional tons/shift (N = 6)	759	350	440–1325
Tons/employee–hour (all mines)	3.00	1.37	1.1–8.7
Annual production (million tons)	0.85	0.79	0.063–3.40
Total employees	163	153	10–720
Salaried employees (underground)	24	29	1–212
Hourly employees (underground)	118	109	8–484
Preparation cost ($/ton)	3.71	1.64	0.34–8.42
Total cost ($/ton)	28.79	6.52	15.06–44.31
Depreciation ($/ton)	1.76	1.13	0.07–5.54
Royalty ($/ton)	1.46	1.01	0.02–4.45
Cash cost* ($/ton)	25.57	6.39	12.40–42.39

*Cash cost = total cost − depreciation − royalty
Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm, 1 ton = 0.9072 t.

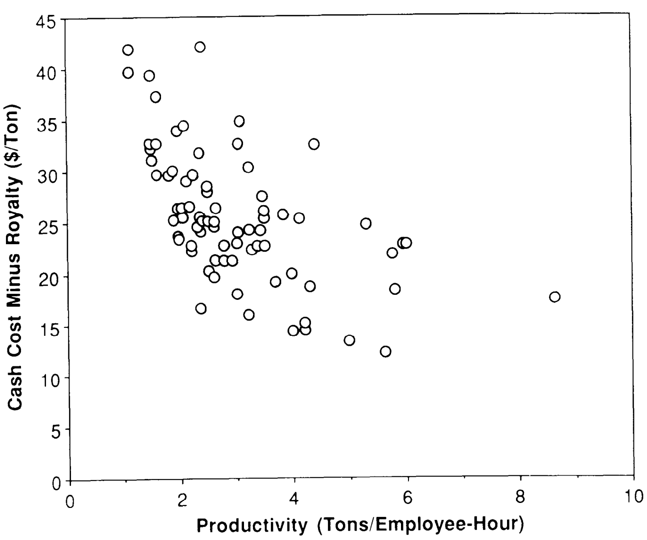

Fig. 23.3.2. Plot of cost survey results showing cash costs minus royalty vs. productivity for continuous miners. Conversion factor: 1 ton = 0.9072 t.

Solution.

For the 8-ft seam:

$$
\begin{aligned}
TPUS_c &= -94 + (5.83)(96) + (267)(1) - (49)(0) \\
&= -(2.34)(100) - (104)(0) + (67.2)(\ln 700) \\
&= -94 + 560 + 267 - 0 - 234 - 0 + 440 \\
&= 939 \text{ tpus}
\end{aligned}
$$

For the 6-ft seam:

$$
\begin{aligned}
TPUS_c &= -94 + (5.83)(72) + (267)(0) - (49)(1) \\
&= -(2.34)(70) - (104)(1) + (67.2)(\ln 700) \\
&= -94 + 420 + 0 - 49 - 164 + 440 \\
&= 553 \text{ tpus}
\end{aligned}
$$

Table 23.3.4. Differences in Underground Coal Mining and Productivity by State and Region

State	No. of Mines	Mean Cost ($/ton)	Mean Productivity (tons/employee–hour)
Pennsylvania	18	29.42	1.88
West Virginia	27	25.12	3.41
Kentucky	18	23.59	3.62
Virginia	10	27.96	2.69
Illinois	4	18.87	2.31
Colorado/Utah*	6	16.26	4.17
Region	**No. of Mines**	**Mean Cost ($/ton)**	**Mean Productivity (tons/employee–hour)**
East (PA, WV, KY, VA)	73	26.19	2.93
West (CO, UT, IL)	10	17.30	3.63

* Combined to provide a larger sample size.
Conversion factor: 1 ton = 0.9072 t.

Data were also gathered on longwall productivity. Here the mean value for the 13 mines with complete data was 2037 tpus; however, the values ranged from a minimum of 500 to a maximum of 4500. The mean value for shifts operated per day per unit was 2.62, indicating that most mines schedule three production shifts for their longwalls. While regression models were developed, it is believed that the wide range in values seen in longwall mining today is largely due to the rapidly changing technology in longwall mining; thus such a model may be misleading and is not presented here.

Step 2. Estimate number of employees and hours. One method that may be used to estimate the number of underground employees at newer mines is to calculate the number of face employees and apply a 1:1 ratio of outby to face employees. To this must be added the number of outside employees.

A second method is to use a "rule-of-thumb" to estimate total employees based on the number of unit shifts worked. Suggested employee numbers for several mine sizes are shown for mines using continuous miners:

One-section mine: 15 to 20 employees/unit shift (usually no plant)

Multi-section mine, less than 10 years old: 20 to 30 employees/unit shift (with plant)

Multi-section, 10 or more years old: 25 to 35 employees/unit shift (with plant)

The average number of employees per unit shift, based on the survey results, is shown in Table 23.3.2. It shows 35 underground workers and 38 total for longwall mines and 20 and 23 for all-continuous mines. For either type of mine, about 90% of the workers are underground, and 5 to 5.5 hourly workers are employed for each salaried employee.

A prediction equation for employees as a function of seam thickness, incentive plan and annual production was also developed using regression analysis, as follows:

$$
\begin{aligned}
TOTE_u &= 146.7(\ln(TPY)) - 72(INCEN) \\
&\quad - 1.7(THICK) - 1638 \qquad (23.3.6)
\end{aligned}
$$

where $TOTE_u$ is total number of employees for underground mines, TPY is annual production in tons per year, INCEN is 1 if an incentive plan is in place or 0 otherwise, and THICK is seam thickness in in. Note that neither the age or depth of the mine nor the total unit shifts per day proved to be significant variables for predicting total employees. This equation was developed for both longwall and non-longwall mines using 72 samples and has an R^2 value of 74%. The mean number of employees for the data set is 180.

Example 23.3.4. Estimate the total employees in two l-million-tpy mines, one in a 6-ft seam with no incentive system and the other in a 5-ft seam with an incentive plan.

Solution .

For the mine in the 6-ft seam and no incentive system:

$$\begin{aligned} TOTE_u &= (146.7)(1n\ 10^6) - (72)(0) - (1.7)(72) - 1638 \\ &= 267 \text{ employees} \end{aligned}$$

For the mine in the 5-ft seam with an incentive system:

$$\begin{aligned} TOTE, &= (146.7)(1n\ 10^6) - (72)(l) - (1.7)(60) - 1638 \\ &= 215 \text{ employees} \end{aligned}$$

Note that, at 220 days/year and 500 tpus, we would expect a 1-million-tpy mine to work 9 to 10 unit shifts/day. Thus the above figures are equivalent to 22 to 24 and 27 to 30 employees/unit shift.

Step 3. Calculate the tons per employee-hour. Calculation of tons per employee-hour may be accomplished in several ways. First, it may be estimated by adjusting the employee figure by a suitable absenteeism and overtime figure to arrive at average hours worked per day. This value is then divided into the average daily production. Both scheduled and unscheduled absenteeism must be accounted for, and both daily and extra-day (weekends, holidays) overtime must be counted.

A second, perhaps more accurate, method is to calculate tons mined per year and hours worked per year. This method allows for days in which the production unit is scheduled but does not work. This can be especially significant for longwall where two moves of one to two weeks or more may be encountered in a year. It is also significant, though to a lesser degree, in many continuous miner operations.

For 1988, the Energy Information Administration (EIA) has estimated that the average employee-hours worked per year was 1891. From the current survey, the employee-hours worked per year was estimated by dividing (tons/employee-year) by (tons/employee-hours). The calculated average was 1655 hours, but results varied widely by mining method, presence or absence of an incentive plan, etc.

Given the scheduled holidays, vacation, personal days, etc., the expected hours worked per year without overtime is 1688, as shown in Table 23.3.5, for a mine covered by the United Mine Workers of America (UMWA) agreement. Using this number and the EIA value for employee-hours worked per year, an expected overtime pay of 18% of straight-time pay is estimated. In practice, overtime is usually 10 to 15% of the straight-time pay.

The daily production must also be adjusted to full-year production by deleting scheduled and unscheduled idle days, and recalling that all sections are not in production on all scheduled days. From the survey, the reported tons per unit shift and reported tons per year were used to calculate the theoretical days worked per year. While this number varied widely, 220 days appeared to be the most frequent value. The exception to this rule was in non-union mines that paid incentives where an approximate average of 227 days was calculated. Note that these values are calculated and fluctuated widely.

A regression model was also developed from the results of the survey to estimate TPEH. The model has an R^2 value of only 46%.

Table 23.3.5. Expected Days to be Worked and Paid at a UMWA Coal Mine

Available days = 52 × 5 = 260			
Less: Holidays		11	
Regular vacation		10	
Floating vacation		4	
Graduated vacation		8	(Average?)
Sick and personal days		5	
Training		2	
Jury and bereavement		2	(Average?)
Idle days reporting, military leave		3	(Average?)
		45	
Days scheduled to be worked = 260 − 43	=	217	days
Unscheduled absenteeism @ 3.5%	=	8	
Days expected	=	211	
Hours expected = 211 × 8	=	1688	
Actual average hours worked (EIA, 1989)	=	1891	
Expected % overtime — 12			
Expected % overtime pay = 12 × 1.5	=	18%	
Expected overtime days = (1891 − 1688) ÷ 8	=	25	
Or, to summarize:			
Days paid per year			
Work days		211	
Scheduled days off		43	
Overtime days × 1.5 (25 × 1.5)		38	
Other*		2	
		294	days paid

* Paid 12 days for 10-day regular vacation period.

$$\begin{aligned} TPEH_u &= 5.01 + 0.029(THICK) + 1.13(INCEN) \\ &\quad - 0.016(YIELD) \\ &= -0.213[\ln(TPY)] - 0.177[\ln(AGE)] \qquad (23.3.7) \end{aligned}$$

where $TPEH_u$ is tons per employee-hour for underground mines, AGE is mine age in years, and the other variables are the same as before.

Step 4. Calculate cash costs of operations. After labor productivity has been established, the remainder of the costs may be estimated. To simplify this, the costs are categorized as follows:

1. Total labor.
2. Other mine cash costs.
   a. Operating and maintenance supplies.
   b. Power.
   c. Miscellaneous.
3. Other preparation plant cash costs.
4. General and administrative costs, miscellaneous other cash costs.
5. Royalties, taxes, and other costs based on the sales price.
   a. Royalties.
   b. Severance tax.
   c. Reclamation excise tax.
   d. Black lung excise tax.
   e. Sales commissions.
   f. Wheelage.

Total labor costs may be obtained by dividing the average cost per employee-year (approximately \$57,000 to \$60,000/year in 1990; see Table 23.3.6) by the tons per employee-year or, alternatively, the average cost per hour *worked* by the tons per employee-hour. At \$59,000 and 1890 hours, this is \$31.21/hour in 1990. Thus, it can be estimated that, at 2.38 tpeh, the average mine would have a total labor and benefits cost of about \$13.00/ton.

Other mine costs are simply operating and maintenance supplies, power, and miscellaneous expenses. In 1990, these likely

Table 23.3.6. Estimate of Cost per Employee–Year in Underground Coal Mines (1990)

Paid to Worker	
1. Average rate/year—$129.64/day × 294 days =	$38,114
2. Clothing allowance	$ 180
	$38,294
Payable on Wages	
1. Unemployment tax—3.5% × $8,000	$ 280
2. Social security—7.8%	$ 2,987
3. Workmens comp.—traumatic and black lung (estimated at 20% of wages)	$ 7,659
Subtotal	$10,926
Other	
1. Pension & benefit trusts $2.64/hr × 1891 hrs	$ 4,992
2. Training fund—$0.05/hr	$ 95
3. Medical & dental, life & disability insurance	$ 5,000
	$10,087
Labor cost for active employees	$59,307
Other potential labor costs:	
1. Incentive pay and bonuses	
2. Retiree medical	
3. Self-insured black lung	
4. Black lung excise tax	
5. Life and disability insurance for retirees	

ranged from a low of $4.50 to $5.00/ton to a high of $8.00 to $8.50/ton. Whether the mine falls within this range is largely determined by productivity, but is also affected by seam thickness and geographical location (with costs usually higher in the East). Longwall mines often have supply costs $2.00/ton lower than all-continuous operations.

Other plant costs are operating supplies, power, and miscellaneous costs. These costs vary from $0.75 to $2.00/ton depending on plant type, age, and size.

The average preparation cost in the survey was $3.71/ton including labor and benefits, with a minimum of $0.34 and a maximum of $8.42. The standard deviation was $1.64/ton. Trucking costs to and from the plant must also be accounted for, but will normally be a function of distance or other variables.

General and administrative costs usually range from $1.00 to $3.00/ton depending upon the mine size, the functions undertaken, and the total company size. The age of the mine is also important in that retirement benefit costs may be included here.

Insurance and property taxes may be hard to estimate in practice. However, each is ordinarily estimated at 1 to 2% of the value of the property on an annual basis.

Royalties and other costs based on the sales price are generally as follows:

1. Royalty.	4–8%
2. Severance tax.	2–20%
3. Reclamation excise tax.	$0.15/ton
4. Black lung excise tax.	$1.10/ton
5. Sales commissions.	1–3%
6. Wheelage.	$0.10/ton − 0.5% of the sales price

Regression Model—A regression model for adjusted cash cost was developed from a sample set of 68 mines and has an R^2 value of 0.69.

The model predicts the adjusted cash cost, which is defined as the total cash cost less royalties. To get total cost, the depreciation and royalty must be added to the number:

$$\mathrm{ACC_u} = 31.08 + \frac{27.85}{\mathrm{TPEH}} - 0.153(\mathrm{YIELD}) - 3.27(\mathrm{INCEN}) - 0.664[\ln(\mathrm{DEPTH})] \qquad (23.3.8)$$

where ACC_u is adjusted cash cost for underground mines.

Example 23.3.5. Estimate the adjusted cash cost of a mine averaging 3 tons/employee-hour, 70% yield, at a depth of 600 ft, with and without an incentive plan.

Solution.

$$\begin{aligned}\mathrm{ACC_u} &= 31.08 + \frac{27.85}{3} - (0.153)(70) - (3.27)(1) - (0.664)(\ln 600)\\ &= 31.08 + 9.28 - 10.71 - 3.27 - (0.664)(6.4)\\ &= \$22.14/\text{ton with an incentive plan}\end{aligned}$$

and $22.14 + 3.27 = \$25.41$/ton without an incentive plan.

Note that the model predicts that cost will decrease as depth increases. This is obviously seldom true in practice, but the reason for this anomaly was not readily apparent from the data. It may be related to the fact that longwalls are typically deeper than non-longwall mines, but this could not be verified from simple calculations.

Example 23.3.6. Compare the above cost to a prediction using the method discussed earlier. First, note that no adjustment is made for the presence or absence of an incentive system in this estimate.

Solution.

Total labor cost—$31.21/3:	$10.40/ton
Other mine cost—$4.50–$8.50/ton-pick lower end of range:	$4.50/ton
Other plant cost—$0.75–$2.00/ton-pick $1.50/ton (larger plant—complex cleaning):	$1.50/ton
Trucking—say, $2.00/ton:	$2.00/ton
General and administrative—$1.00–$3.00/ton, choose midpoint:	$2.00/ton
Royalties and other—omit royalties, Excise taxes—$1.25/ton Severance tax @ 4%—say, $1.20/ton:	$2.45/ton
Predicted cash cost less royalties:	$22.85/ton

Here the difference in estimates is $22.85/ton vs. $25.41/ton or about $2.50/ton. To resolve this difference, detailed mine planning must be undertaken.

SURFACE COAL-MINE COST MODEL. Underground coal mines tend to differ mainly in terms of seam thickness with virtually the same type of equipment and mining plan in each (the exception being the division between longwall and non-longwall mines). Surface mines, on the other hand, tend to differ by mining methods (single-pass contour, multi-pass contour, mountaintop removal, and area stripping, for example) as well as by mix of equipment (such as large draglines vs. small draglines, truck-shovel, front-end loaders, dozers, or combinations of this equipment in the same operation). Operating methods add more variety. For example, the dragline may work on the highwall side or the spoil side; it may also, through the use of extended benches, effectively work in between. Likewise, spoil may be casted using explosives, a dragline bench may be dug entirely by the dragline, or a significant part may be prestripped.

More examples may be offered, but the point is that it is very difficult to provide a relatively simple set of guidelines as were

Table 23.3.7. Statistical Summary of Selected Variables for Surface Coal Mines (Total Number of Mines = 39)

Variable	Mean	Standard Deviation	Range
Seam thickness (in.)—all seams	177	221	25–1320
Stripping ratio (yr^3/ton)	12.8	4.6	1.5–22
Distance to plant (mi)	0.3	0.7	0–3.0
Yield (%)	87.5	17	50–100
Dragline size (yd^3)	56.6	29.6	7–105
Overburden shovel size (yd^3)	21.4	5.4	13–27
Overburden loader size (yd^3)	13.0	1.0	10–15
Coal truck size (tons)	55.0	50.0	22–170
Tons/employee–hour	5.6	3.9	1.6–20.1
Tons/year (10^6)	1.5	3.0	0.021–13.5
Yd^3/year (10^6)	11.5	14.7	0.24–64.4
Hourly employees	59	57	3–204
Salaried employees	23	55	1–253
Mines on incentives (%)	58.3		
Union mines (%)	10.5		
Cost of preparation ($/ton)	1.91	1.04	0.28–4.30
Total cost ($/ton)	23.13	8.72	3.53–43.92
Depreciation ($/ton)	1.74	1.16	0.10–3.45
Royalties ($/ton)	1.48	1.22	0–5.19
Cash cost* ($/ton)	19.95	7.51	3.14–38.36

*Cash Cost = Total Cost − Depreciation − Royalty
Conversion factors: 1 in. = 25.4 mm, 1 mi = 1.609 km, 1 yd = 0.9144 m, 1 ton = 0.9072 t.

given for underground coal mines. Instead, some general discussion of the survey results will be given, followed by a discussion of regression models to predict manning.

Discussion of Survey Results—Complete, usable responses were obtained from 39 operations in eight states. These data are summarized in Table 23.3.7. (It should be noted that no responses were obtained from Illinois or Indiana, two of the primary area-stripping states.) The following primary stripping equipment was used (some mines used multiple stripping equipment):

	No. Mines
Large draglines	12
Stripping shovels	4
Loading shovels	14
Overburden front-end loaders	32

Most of the mines produced coal from seams of modest thickness, and only four, or 10%, were union. Of the nonunion mines, about two-thirds had an incentive plan. Only 16 washed their coal, and the average yield of those washing was 71%. The average cost of preparation was $2.10/ton, considerably less than the deep-mine average, reflecting perhaps the coarser size consistency and ability to do some in-pit separation with surface mining. The total cost vs. stripping ratio and the total cost vs. productivity for surface mining operations are shown in Figs. 23.3.3 and 23.3.4, respectively. Fig. 23.3.3 shows the dependence of the mining cost upon stripping ratio with the expected result that costs increase as the stripping ratio increases. In addition, cost decreases as the productivity increases, as illustrated in Fig. 23.3.4. These plots show, however, that there exists significant variation about the trend, probably as a result of different methods, equipment, and mining conditions.

The average strip ratios by state (for those states with more than one response) are shown in Table 23.3.8. Note that because the operator can chose his maximum stripping ratio with all but the area method, these may be an indicator of the maximum

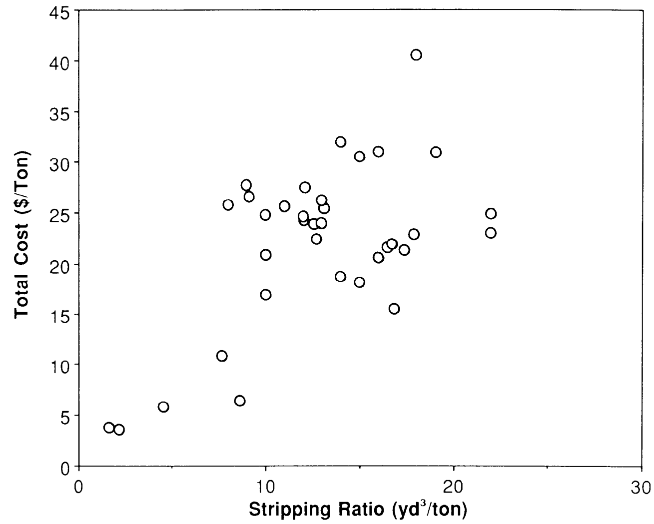

Fig. 23.3.3. Plot of cash survey results showing total cost vs. stripping ratio for surface mining operations. Conversion factors: 1 ton = 0.9072 t, 1 yd^3/ton = 0.8428 m^3/t.

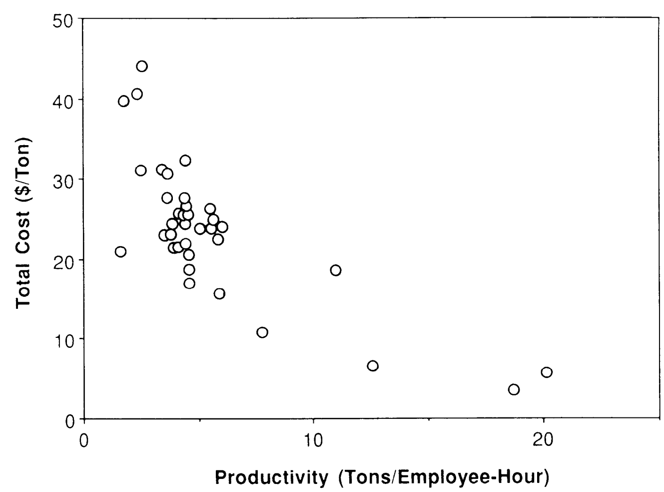

Fig. 23.3.4. Plot of cost survey results showing total cost vs. productivity for surface mining operations. Conversion factor: 1 ton = 0.9072 t.

Table 23.3.8. Average Stripping Ratio (yd^3/ton) for Surface Coal Mines Reported by State.

State	Number of Mines	Average	Range
Kentucky	17	13.7	10–19
North Dakota	3	6.9	4–9
Pennsylvania	4	17.3	10–22
Virginia	7	15.4	9–18
West Virginia	5	9.6	8–12
Wyoming	2	1.8	NA

Conversion factor: 1 yd^3/ton = 0.8428 m^3/t.

ratio economically minable at today's prices. It should be noted that the stripping ratios appear to reflect the energy content and the geographic location of the coal seams.

Regression Models—Regression models were developed to predict the total employees at a mine, the likely productivity in tpeh, and the cash cost of production less royalties. These are discussed here.

Total employees was found to be a function of the number of tons mined per year and whether or not a dragline larger than 20 yd^3 was used. The regression equation is as follows:

$$TOTE_{s1} = 64.8\,(BIGDG) + 30.28\,[\ln\,(TPY)] - 338.7 \qquad (23.3.9)$$

where $TOTE_{s1}$ is total employees for surface mines (method l), and BIGDG is 1 if a dragline larger than 20 yd^3 is used and 0 otherwise. This model predicted the employees with an R^2 value of 74%. The mean number of employees at the mines surveyed was 70.

A second model was also developed which takes stripping ratio into account; it also has an R^2 value of 74%:

$$TOTE_{s2} = 62.7(BIGDG) + 31.37[\ln\,(TPY)] + 0.66(RATIO) - 360.9 \qquad (23.3.10)$$

where $TOTE_{s2}$ is total employees, surface mines (method 2), and RATIO is yd^3 of overburden moved per ton of coal mined.

Example 23.3.7. Estimate the employment at a mine with an 18:1 strip ratio using a large dragline and producing 1 million tpy.

Solution.

$$\begin{aligned}\text{Using Eq. 23.3.9: } TOTE_{s1} &= 64.8(1) + 30.28[\ln(10^6)] - 338.7\\ &= 64.8 + 418.33 - 338.7\\ &= 144 \text{ employees}\\ \text{Using Eq. 23.3.10: } TOTE_{s2} &= 62.7(1) + 31.37[\ln(10^6)] + 0.66(18) - 360.9\\ &= 62.7 + 433.4 + 11.9 - 360.9\\ &= 147 \text{ employees}\end{aligned}$$

Compare this to a mine producing 500,000 tpy of coal, a 12:1 stripping ratio, and no dragline.

$$\begin{aligned}\text{Using Eq. 23.3.10: } TOTE_{s2} &= 62.7(0) + 31.37[\ln\,(500{,}000)] + 0.66(12) - 360.9\\ &= 0 + 411.7 + 7.9 - 360.9\\ &= 59 \text{ employees}\end{aligned}$$

An estimator for productivity was also developed from the survey data. The average productivity for all mines surveyed was 5.8 tpeh. In this model the key independent variables are mine size (tons per year), strip ratio, plant yield, and presence or absence of a union. This equation has an R^2 value of 75%:

$$TPEH_{s1} = 1.37[\ln(TPY)] - 0.60(RATIO) + 0.069(YIELD) - 3.27(UNION) - 10.24 \qquad (23.3.11)$$

where $TPEH_{s1}$ is tons per employee-hour for surface mines (method 1). Note that the sign on the coefficient of RATIO is opposite to that which would logically be expected.

An alternative equation, using mining plans as independent variables has an R^2 value of 73%

$$TPEH_{s2} = 1.27[\ln(TPY)] - 0.51(RATIO) + 0.058(YIELD) + 1.28(AREA) - 4.04(SPC) - 9.78 \qquad (23.3.12)$$

where $TPEH_{s2}$ is tons per employee-hour or surface mines (method 2), AREA is 1 if this is an area mine or 0 otherwise, and SPC is 1 if this is a single-pass contour mine or 0 otherwise.

Example 23.3.8. Estimate the tpeh for the two mines described above if they are union, the 18:1 ratio is an area mine, and the 12:1 ratio is a mountaintop removal operation, and both produce direct-shipping coal.

Solution.

For mine 1 using Eq. 23.3.11:

$$\begin{aligned}TPEH_{s1} &= 1.37(\ln(10^6)) - 0.60(18) + 0.069(100) - 3.27(1) - 10.24\\ &= 18.93 - 10.80 + 6.9 - 3.27 - 10.24\\ &= 1.52 \text{ tpeh}\end{aligned}$$

For mine 1 using Eq. 23.3.12:

$$\begin{aligned}TPEH_{s2} &= 1.27(\ln 10^6) - 0.51(18) + 0.058(100) + 1.28(1) - 4.04(0) - 9.78\\ &= 17.55 - 9.18 + 5.80 + 1.28 - 4.04 - 9.78\\ &= 1.63 \text{ tpeh}\end{aligned}$$

For mine 2 using Eq. 23.3.11:

$$\begin{aligned}TPEH_{s1} &= 1.37(\ln\ 500{,}000) - 0.6(12) + 0.069(100) - 3.27(1) - 10.24\\ &= 17.98 - 7.20 + 6.90 - 3.27 - 10.24\\ &= 4.17 \text{ tpeh}\end{aligned}$$

For mine 2 using Eq. 23.3.12:

$$\begin{aligned}TPEH_{s2} &= 1.27(\ln\ 500{,}000) - 0.51(12) + 0.058(100) + 1.28(0) - 4.04(0) - 9.78\\ &= 16.67 - 6.12 + 5.80 + 1.28(0) - 4.04(0) - 9.78\\ &= 6.57 \text{ tpeh}\end{aligned}$$

For the latter mine, the estimates are more uncertain.

The adjusted cash cost less royalties (ACCS) was found to be a function of the stripping ratio, yield, and mining plan. It may be noted that the average value of adjusted cash cost was $19.78/ton. The following model has an R^2 of 81%:

$$ACC_s = 39.99 + 0.69(RATIO) - 0.14(YIELD) - 1.45[\ln(TPY)] + 3.39(MTR) + 23.06(SPC) \qquad (23.3.13)$$

where ACC_s is adjusted cash cost for surface mines, MTR is 1 if this is a mountaintop removal mine or 0 otherwise.

Example 23.3.9. Using the two previous mines,

$$\begin{aligned}\text{Mine 1: } ACC_s &= 39.99 + 0.69(18) - 0.14(100) - 1.45(\ln 10^6) + 3.39(0) + 23.06(0)\\ &= \$18.87/\text{ton}\\ \text{Mine 2: } ACC_s &= 39.99 + 0.69(12) - 0.14(100) - 1.45(\ln 10^6) + 3.39(1) + 23.06(0)\\ &= \$18.12/\text{ton}\end{aligned}$$

Eq. 23.3.13 should probably not be used for single-pass contour mines because of a limited number of observations of this type of mining in the data set.

Table 23.3.9. Open Pit Noncoal Mine Cost Data (Effective Mid-1989)

Large-Size Mines (> 20 million tons/yr of Ore and Waste):

Mine	Commodity Group	Truck Size (tons)	Haul Length (mi)	Stripping Ratio		Cost Estimates ($/ton moved)						
				yd³/ton	tons/ton	Drilling	Blasting	Loading	Haulage	Auxiliary Cost[1]	Direct Mining[2]	Total Mining[3]

Conversion factors: 1 mi = 1.609 km, 1 yd = 0.9144 m, 1 ton = 0.9072 t.

23.3.5.2 Cost Estimation in Noncoal Mining

Costs related to the surface and underground mining of metals, industrial minerals, and other categories of noncoal minerals are not easy to find in the literature. To provide some useful cost data for this segment, questionnaires were prepared for both underground and surface mining. These were sent to a large number of mining companies with the help of the American Mining Congress. The authors acknowledge the AMC's considerable help in the provision of the costs below.

SURFACE MINING. Open pit mining has become the primary method of mining many of the base metals, gold, and industrial minerals in the United States and the costs reflect the obvious reason for this trend. The various categories of costs for 23 different open pit mines are presented in Table 23.3.9. It should be noted that data have been omitted from the table if they seemed to provide little enlightenment or if they had the potential for identifying the individual mines. The mines are quite well distributed geographically and represent both the metal and industrial minerals segments of the mining industry. The cost patterns in this table show a great deal about the cost of mining by the open pit method. First, it is rather clear that the costs of producing minerals by the open pit method have not risen very rapidly over the last two decades if the data are compared with open pit mining costs in Michaelson and Hammes (1968). Several reasons for this modest cost increase are apparent including a period of intense foreign competition plus continued increases in equipment size and efficiency.

Second, it seems apparent from the raw data that a significant decrease in costs occurs when the size of the mine is increased. This is shown in Table 23.3.10 where the average costs as a function of mine size are presented. The data thus reveal a trend that speaks highly of the desirability of larger operations. This is particularly striking when it is realized that the costs are shown to decrease with an increase in size for each category of cost (drilling, blasting, loading, hauling, and auxiliary costs) as well as for the overall direct mining costs. This appears to be primarily a result of the efficiency of larger equipment, though better engineering, planning, maintenance, and management may play a part as well.

Other attempts at finding significant statistical trends in the data by analyzing mining costs vs. truck size, mining costs vs. haul distance, and a number of other such relationships were not

Table 23.3.10. Open Pit Noncoal Mine Costs as a Function of Pit Production (Effective Mid-1989)

	Average Costs from Table 23.4.2 in $/ton mined					
	Drilling	Blasting	Loading	Haulage[1]	Auxiliary Costs[2]	Direct Mining[3]
Large-Size Mines (Production > 20 million tons/yr)	0.028	0.088	0.108	0.260	0.111	0.59
Medium-Size Mines (Production from 2 million to 20 million tons/yr)	0.093	0.105	0.157	0.345	0.214	0.85
Small-Size Mines (Production < 2 million tons/yr)	0.265	0.171	0.347	1.134	0.290	1.84

[1] Comparison of haulage costs may not be meaningful as haulage lengths vary.
[2] Cost of support, pumping, roads, etc.
[3] Sum of drilling, blasting, loading, haulage, hoisting, and auxiliary costs.
Conversion factor: 1 ton = 0.9072 t.

as successful. It may have been that there were too many variables related to the costs to easily find such trends in the data.

Another surface mining method for which some data were obtained is the stripping of phosphates with hydraulic transport of the ore to the processing facility. The costs reported for this mining method ranged from $6.00/ton to $12.50/ton. The extraction method used in these phosphate operations is more like a typical coal method than a metal or nonmetallic mining method. It is, however, unique to the phosphate industry that hydraulic transport is routinely used to move the ore material from the mining bench to the processing facility. It should be noted that the costs are based upon just a few mines. Thus the costs should be used with caution.

UNDERGROUND MINING. In attempting to gather cost data on underground mining, costs were solicited on a variety of methods using a common cost questionnaire. As might be expected, the amount of cost information received varied considerably with the mining method type. More information was received on room and pillar/stope and pillar mining methods than on other underground methods. The data are presented in Table 23.3.11 with the mines with a regular pillar pattern (room and pillar) separated from the mines with a random pillar pattern (stope and pillar). It should be noted that costs for mines with a regular pillar pattern are quite low, ranging from $2.90/ton to $7.00/ton. In general, these low costs can be attributed to the nature of the mineral deposits mined in these mines. The mines are primarily relatively soft evaporites that can be mined using continuous miners or conventional equipment. As a result of the productivity of that equipment and the general uniformity of conditions in these evaporite mines, mining costs are often among the lowest in the underground mining category.

The data in Table 23.3.11 relating to random pillar mines show costs ranging about twice as high as that for regular pillar mines with the range of direct mining costs being $4.07/ton to $9.81/ton for most of the mines. It should be noted, however, that costs for one mine using slushers in the stopes are considerably higher. In general, when one compares the costs for stope and pillar operations with those for room and pillar operations, it is clear that stope and pillar mines will have higher costs because of the harder rock, less uniform conditions, and other factors that make hard-rock mining more difficult than soft-rock mining. Nonetheless, it is difficult to draw any broad or sweeping conclusions because of the limited number of mines represented here.

One other mining method for which meaningful results were obtained is the cut and fill method. These data are presented in Table 23.3.12. While the number of mines reported is small, a general trend in the data is evident. When the data are divided into mines with veins narrower than 10 ft (3 m) and mines with veins greater than 10 ft (3 m), some fairly obvious cost differences are apparent. The mines exploiting veins greater than 10 ft (3 m) have costs from $35/ton to $41/ton while those exploiting veins less than 10 ft (3 m) have costs from $63/ton to $116/ton. Apparently, the vein or deposit size has the potential to significantly affect the costs due to the productivity improvement in larger stopes, particularly if more efficient load-haul-dump equipment can be utilized. These costs also tend to show one of the reasons that the mining of narrow-vein deposits is no longer widely practiced in this country. The costs of producing ore from these veins has been rising faster than other mining methods due to the labor-intensive nature of the methods and the inability to ease that situation through the use of larger, more efficient equipment.

Several other mining methods were represented in the data returned from the survey. However, none had more than a handful of mines represented in the final tally of cost figures. These are presented in Table 23.3.13 in summary form. Block caving still represents the least expensive of the traditional metal mining methods with costs reported in the $2.50/ton to $8.00/ton range (specific cost values were omitted here to prevent identification of individual mines). Methods with moderate costs in the survey results were the vertical crater retreat method ($20/ton to $30/ton), shrinkage stoping ($30/ton to $40/ton), and slusher stoping ($30/ton to $40/ton). Slusher stoping is defined here as the mining of open stopes with dips greater than that for which rubber-tired equipment can be used and less than that for which gravity can be used to extract the ore from the stope. This method is practiced in a few mines where other methods are generally not suitable. Because of the small number of observations for each mining method represented in Table 23.3.13, the costs should be used with great caution.

23.3.6 METHOD SELECTION CONSIDERATIONS

The selection of a mining method is a procedure that will involve many variables and considerations. Chapter 23.1, Selection Variables, outlines many of these variables in a general fashion. For surface methods, the geologic and geometric variables of the ore body will often be of most importance. For underground methods, particularly those aimed at metallic deposits, rock mechanics variables will often play a very big part in the choice of a mining method. This subject is an important part of the discussion in Chapter 23.4, Selection Procedure. However important geologic and geomechanics variables are in the choice of a method, economics and cost variables are also

Table 23.3.11. Room and Pillar/Stope and Pillar Noncoal Mine Cost Data (Effective Mid-1989)

Mines With a Regular Pillar Pattern (Primarily Evaporite Mines):

Mine	Million Tons/Yr	Equipment Type	Cost Estimates ($/ton) Drilling	Blasting	Loading	Haulage	Hoisting	Auxiliary Costs[1]	Direct Mining[2]	Total Mining[3]
A	>5	Continuous Miner			0.76	0.49	0.34	0.64	2.23	3.08
B	>5	Continuous Miner			1.36	1.49	0.34	0.64	3.83	5.18

Note: Missing values not provided by the source.
[1] Auxiliary costs include support, ventilation, pumping, power, etc.
[2] Sum of drilling, blasting, loading, haulage, hoisting, and auxiliary costs.
[3] Total mining costs include development, exploration, services, and administrative costs.
[4] Includes undercutting costs.
Conversion factor: 1 ton = 0.9072 t.

Table 23.3.12. Cut and Fill Mine Stoping Costs (Effective Mid-1989)

Mine	Ore Width (ft)	Equipment Type	Costs ($/ton) Drilling	Blasting	Loading	Haulage	Hoisting	Auxiliary Costs[1]	Direct Mining[2]	Total Mining[3]
A	>10	LHD	- - - - - - 17.37 - - - - - -			3.02	3.00	2.97	26.36	35.35
B	<10	Slusher/LHD	- - - - - - 34.00 - - - - - -			2.00	4.00	28.00	68.00	115.00
C	>10	LHD	- - - 2.30 - - -		3.30	2.92	1.57	10.73	20.82	41.31
D	<10	Slusher	- - - 5.26 - - -		3.67	5.33	4.65	25.04	43.95	80.35
E	<10	Slusher	- - - 4.15 - - -		3.74	3.08	2.18	20.95	34.10	62.68
F	<10	Slusher	- - - - - - 29.50 - - - - - -			4.50	4.30	18.50	56.80	116.00

[1] Auxiliary costs include support, fill, ventilation, pumping, power, etc.
[2] Sum of drilling, blasting, loading, haulage, hoisting, and auxiliary cost.
[3] Total mining costs include development, exploration, services, and administration costs.
Conversion factors: 1 ft = 0.3048 m, 1 ton = 0.9072 t.

Table 23.3.13. Costs Related to Other Mining Methods

Method	Direct Mining Cost ($/ton)
Block Caving	2.50– 8.00
Vertical Crater Retreat Mining	20.00–25.00
Shrinkage Stoping	30.00–40.00
Slusher Stoping	30.00–40.00

Note: These costs are based upon very small numbers of observations. The costs should therefore be considered as order-of-magnitude estimates only.
Conversion factor: 1 ton = 0.9072 t.

certain to be near the top of the list. It is therefore important that the mining engineer have some idea at the beginning of the method selection procedure as to how the various mining methods rank in the scale of costs. To provide some idea of how the methods compare in cost, Table 23.3.14 was compiled using two sources. The first source was the cost survey performed by the authors for this chapter. These costs were representative of the situation in mid-1989. The second source was the cost models of the USBM cost estimating system (Anon., 1987a). The costs derived from these models were calculated and updated to December 1988 and published by *Mining Cost Services* (Schumacher, 1989).

To render the cost values in Table 23.3.14 as comparable as possible, both sets of costs were reduced to the direct costs of mining that included the drilling, blasting, loading, haulage, hoisting, and auxiliary costs directly connected with the mining

Table 23.3.14. Summary and Comparison of Direct Mining Costs[1]

Mining Method/Conditions	Direct Mining Costs ($/ton) Handbook Survey (Mid-1989 Costs)	Mining Method/Conditions	Direct Mining Costs ($/ton) Cost Estimating System[2] (December 1988 Costs)
Metals and Nonmetallics:			
Open Pit Mining:		Open Pit (1:1 Stripping Ratio):	
Large Mines (> 20 million tons/yr)	$0.51–0.64	Large Mines[3] (> 20 million tons/yr)	$0.78
Medium Mines (2 to 20 million tons/yr)	0.39–1.19	Medium Mines[3] (2 to 20 million tons/yr)	0.84–1.13
Small Mines (< 2 million tons/yr)	1.01–4.20	Small Mines[3] (< 2 million tons/yr)	3.65–6.68
Phosphate stripping with hydraulic transport	6.00–12.50		
Room and Pillar Mining (Shaft Mines)	2.10–3.83	Room and Pillar (Adit Mine, 5500 to 16,500 tons/day)	2.00–2.89
		Room and Pillar (Shaft Mines, 5500 to 16,500 tons/day)	2.11–3.66
Stope and Pillar Mining (Diesel Equipment)	4.10–9.81		
Stope and Pillar Mining (Slusher)	53.67		
Cut and Fill Stoping (< 10-ft Vein, Slushers)	34.10–68.00	Cut and Fill (Adit Mine, 1100 tons/day)	34.31
Cut and Fill Stoping (> 10-ft Vein, LHDs)	20.82–26.36	Cut and Fill (Shaft Mines, 1100 tons/day)	42.10–43.13
Block Caving	2.50–8.00	Block Caving (44,000 tons/day)	1.86–2.44
Vertical Crater Retreat Mining	20.00–25.00	Vertical Crater Retreat (Adit Mine, 880 tons/day)	6.65
		Vertical Crater Retreat (Shaft Mine, 880 tons/day)	8.90–9.40
Shrinkage Stoping	30.00–40.00	Shrinkage (Adit Mine, 110 tons/day)	38.54
		Shrinkage (Shaft Mine, 110 tons/day)	64.85–65.10
Slusher Stoping	30.00–40.00		
Coal:			
Stripping	3.00–34.00		
Room and Pillar Conventional Mining	15.00–30.00		
Room and Pillar Continuous Mining	13.00–40.00		
Longwall Mining	12.00–34.00		

[1] Direct mining costs include drilling, blasting, loading, haulage, hoisting, and auxiliary costs. Administration, development, and processing costs have been excluded.
[2] These costs were calculated using costs supplied by *Mining Cost Service* (Schumacher, 1989, used with permission). The costs are based upon the 1984 cost models of the Bureau of Mines' Cost Estimating System. The costs were updated to December 1988 using updating techniques. Those values were then converted to direct mining costs per ton to make comparison possible.
[3] Yearly tonnages were calculated using daily tonnage and multiplying by 250 days/yr.
Conversion factor: 1 ton = 0.9072 t.

process. All administration, development, and processing costs have been omitted from the cost figures. In addition, an attempt was made to make the costs compatible in terms of the size of the operation and the mining variables (equipment utilized, type of mine opening, depth, vein width, etc.). The USBM costs were available only for noncoal mining methods, and thus no comparison is available for coal mining methods.

Comparison of the costs in Table 23.3.14 shows that the two cost sources are in good agreement on some of the methods and more variable on others. For example, both sources seem to provide smaller estimates for the costs for room and pillar and cut and fill mining. The costs for open pit mining and shrinkage stoping were somewhat different in the two sources, while the costs for block caving and the VCR method are relatively inconsistent. A number of possible reasons for these differences exist. First, most of the costs are based upon relatively few mines. Second, in our survey the mining companies were asked to provide costs that were free of development costs. Because these may not have been available, the cost values may not have been entirely consistent. Finally, variations in mining and accounting practices may contribute to the variations in the costs reported.

The costs reported here, while generally useful for general comparison purposes, must be considered as order-of-magnitude estimates only. They may help in the early evaluation of mining methods but must be reevaluated and made site- and condition-specific at the time that the methods have been narrowed down to a few candidates. At that time, both the operating and capital cost estimates must be assembled, and the estimates can be made using detailed estimating procedures that will allow both specifics of the method and specifics of the geology and the rock mechanics to be considered in the estimation process. In particular, it is important to construct a detailed capital requirements list to accurately estimate the capital cost of a new mine. Since there are few good sources in the literature that will provide much of this information, detailed listing and costing of capital goods will normally be necessary.

23.3.7 COST CONTROL

Due to the difficult situation in the minerals industry during the 1980s in which the industry has had to deal with foreign competition of an unprecedented level and intense domestic competition for the remaining market, cost control and cost reduction methods have become an important part of many mining operations. These endeavors often span the accounting, management, and engineering functions within an organization. Over the years, many different procedures have thus emerged with the industrial engineers leading in the development of procedures among the engineering disciplines. Cost control procedures have taken many different forms and variations. It would thus be impossible to mention them all here; instead, only the most important procedures are reviewed. Readers who are interested in more detailed lists of procedures should refer to the section by Scott (1971) in the *Industrial Engineering Handbook.*

23.3.7.1 Cost Control Procedures

COST ACCOUNTING AND ANALYSIS. Cost accounting is a procedure that allows an organization to make some measurement of performance that may help in the period-to-period management of costs. Nearly all minerals companies utilize cost accounting as a routine procedure so that unusual cost shifts can be studied for potential savings, so that production enhancement methods can be evaluated, and so that outstanding performances can be analyzed for their potential in other areas of the organization. Along with cost accounting procedures, it is often necessary to perform some analysis of the trends so that problem areas can be pinpointed, waste can be controlled, and better performance can be recognized. While this area of endeavor does not appear very glamorous, application of cost control procedures through cost accounting can provide an important tool to keep costs within limits.

BUDGETARY CONTROL. The use of budgets as a cost control procedure is, in many ways, similar to cost accounting in that it provides a procedure for measuring cost performances on a period-to-period basis in an organization. The budgetary control procedure, however, provides a target (the budget allocated) in order to provide a further means of control. The budgeting process will help to detect costs that are out of control and will enable different production units within the organization to compare costs and revise cost control methods. This would be particularly applicable in minerals companies where similar production units within an organization are performing the same job on a parallel basis.

METHODS ENGINEERING. Methods engineering is here meant to be the area of endeavor in which jobs are analyzed for their elements, measurements are made on the elements, and job improvements are made through standardization, job simplification, worker education, and other related methods. This area, which has been the province of the industrial engineer for many years, has seen many forms of application in the minerals industry over the years. The use of time and motion studies has, over time, produced more efficient and more productive operations. Other types of related activities, including better worker education, have also been emphasized at times. The emphasis in this area seems to shift from one type of activity to another, but the general strategy continues to be to analyze the activities involved and to make the most of the resources available.

OPERATIONS RESEARCH. Operation research, systems analysis, and statistical analysis are all related methods that have been used to control prices. In general, these methods are used to control prices through the use of the available resources in an optimal manner such that the costs are minimized or the profits maximized. These methods differ from the traditional cost control or cost reduction methods in that they make use of mathematical or statistical methods, sometimes quite complicated, to achieve the optimization of the system under study. While the methods are often classified as optimization methods rather than cost control methods, their influence on costs is obvious. Readers interested in a more complete description of these methods should refer to Chapter 8.3 of the *Handbook*, Systems Engineering.

PRODUCTIVITY IMPROVEMENT. One of the most important cost control and cost reduction techniques that has been practiced in the minerals industry has been productivity improvement. This has come about due to the necessity of remaining competitive in the minerals marketplace. Productivity improvement has come about through the use of larger or otherwise improved equipment, use of improved methods for performing certain mining procedures, and through better use of the available personnel in the mines. The value of productivity improvement as a cost reduction technique will be illustrated in the next section.

Table 23.3.15. Mining Costs at the Mine in Ex. 23.3.10

		Cost ($/ton)
Mine Cost		
1. Labor ($58,000)/(4158 tons/miner-yr)		$ 13.95
2. Supplies		
A. Operating	$2.50	
B. Maintenance and Repairs	$2.50	$ 5.00
3. Power		$ 0.70
4. Miscellaneous		$ 0.10
	Subtotal	$ 19.75
Plant Cost		
1. Labor ($58,000)/(46,200 tons/miner-yr)		$ 1.25
2. Supplies		$ 1.00
3. Power		$ 0.20
4. Contract Trucking		$ 1.00
	Subtotal	$ 3.45
General and Administrative		$ 2.00
Miscellaneous Variable Costs		
1. Reclamation Excise Tax		$ 0.15
2. Black Lung Excise Tax		$ 1.10
3. Royalty		$ 1.00
	Subtotal	$ 2.25
Depreciation and Amortization		$ 2.55
	Total	$ 30.00

23.3.7.2 Application in Minerals Production

The control and reduction of costs has been a primary concern of the minerals industry in the United States throughout the 1980s. A look at some of the possibilities available to mine management under strong competition can illustrate the procedures for cost reduction in the minerals industry. This will be accomplished through the use of an example that applies to the underground production of coal by the room and pillar mining method.

Example 23.3.10. A room and pillar mining operation is operating in an Appalachian coal seam that cannot be mined easily by surface or longwall mining methods. The company operating the mine has basically been pleased with the operation and its management over the past few years. The equipment is relatively new and well maintained and the nonunion workforce has been cooperative with management suggestions for productivity improvement. An abbreviated cost sheet showing various categories of costs on a per-ton basis is provided in Table 23.3.15.

The company has recently had to accept a one-year sales contract at $28/ton due to the competition in their area for the available coal market. To institute a cost reduction program, a new mine superintendent is appointed. He is charged with bringing the costs down below $28/ton within one year, with the threat that the mine will be closed after a year if the reduction cannot be achieved. The superintendent carefully studies the cost

Table 23.3.16. Mining Costs at the Mine in Ex. 23.3.10 After Supply and General and Administrative Cost Reductions

		Cost ($/ton)
Mine Cost		
1. Labor ($58,000)/(4158 tons/miner-yr)		$ 13.95
2. Supplies		
A. Operating	$2.00	
B. Maintenance and Repairs	$2.50	$ 4.50
3. Power		$ 0.70
4. Miscellaneous		$ 0.10
	Subtotal	$ 19.25
Plant Cost		
1. Labor ($58,000)/(46,200 tons/miner-yr)		$ 1.25
2. Supplies		$ 1.00
3. Power		$ 0.20
4. Contract Trucking		$ 1.00
	Subtotal	$ 3.45
General and Administrative		$ 1.50
Miscellaneous Variable Costs		
1. Reclamation Excise Tax		$ 0.15
2. Black Lung Excise Tax		$ 1.10
3. Royalty		$ 1.00
	Subtotal	$ 2.25
Depreciation and Amortization		$ 2.55
	Total	$ 29.00

data to determine where he can cut costs to achieve his goal. He targets two areas of costs that appear to him to be high: (1) operating supplies and (2) general and administrative costs. One of his top assistants is retiring, and one of the mine engineers has resigned. This gives him some opportunity to reduce the administrative and general staff, a strategy that he feels is both possible and desirable. In addition, he transfers a couple of other general staff members to other mines and achieves a 25% reduction in general and administrative costs that results in a $0.50/ton reduction in the cost of the coal.

At the same time, he institutes a program of holding down costs of operating supplies. He lets the work force know of the financial problems of the company and encourages them to help out by eliminating unnecessary waste of supplies. In addition, he has one of his staff members keep careful control over the supplies used and makes him responsible for ensuring that supplies are not abandoned underground.

After six months of intensive efforts, the reduction in supplies is 20% with an accompanying $0.50/ton savings in the cost of producing coal. The costs after the savings are achieved are given in Table 23.3.16. While the savings have helped, the overall goal of achieving a profit has not been achieved.

At this point, the superintendent clearly needs to make some other strategic move to further reduce his costs. Assuming that he targets productivity improvement as his only other feasible cost reduction technique, several possibilities may exist. First, he can appeal to the work force to improve productivity, using the (valid) threat of closure as incentive, or he can offer the workforce some financial incentive. The next example illustrates the logic of the second strategy.

Example 23.3.11. After considerable thought, the superintendent decides that the work force is doing productive work and that he feels the need to provide a monetary reward to the workers as the mine-saving strategy. He communicates the following to the workers. If the cost of $28/ton is bettered, the workers will share the profits with the company on a 70/30 basis with the workers sharing 30%. To determine what the results will be under different productivities, he prepares Table 23.3.17 which follows. The table clearly shows that it will take about a 5% increase in productivity to break even. Because the bonus is based on total costs, an improvement in productivity over 5% will provide both a profit and an incentive payment for the work force. The superintendent shares the information with everyone at the mine and hopes for the best.

Table 23.3.17. Costs and Related Information as a Function of Productivity Improvement (Ex. 23.3.11)

Productivity (tons/manshift)	Labor Cost ($/ton)	Cost Before Incentive ($/ton)	Incentive Per Employee ($/yr)	Cost After Incentive ($/ton)
17.0 (Status Quo)	$15.20	$29.00	$ 0	$29.00
17.9 (+5%)	14.48	28.00	0	28.00
18.7 (+10%)	13.28	27.09	1904	27.55
19.5 (+15%)	13.22	26.26	3811	27.13
20.4 (+20%)	12.67	25.50	5717	26.75
21.3 (+25%)	12.16	24.80	7623	26.40
22.1 (+30%)	11.69	24.16	9530	26.08
23.0 (+35%)	11.26	23.56	11436	25.78
23.8 (+40%)	10.86	23.01	13342	25.50

Assumptions:
1. Base supply cost is 20% fixed; base power cost is 70% fixed.
2. Incentive per employee based on 224.5 miner shifts per year.

The previous example shows several interesting results. First, the cutting of costs can produce some results, but a large leverage is often achieved when increasing productivity. As shown here, using typical coal mine costs, a 20% reduction in some costs does not greatly help the bottom line, but a 20% increase in productivity produces a much more significant cost reduction. Second, the use of incentives can be a powerful force to reduce costs. The use of incentives has often been achieved without any increase in accidents, but this must be emphasized in any incentive program through education of the work force and use of safety performance in the calculation of incentives so that the increase in productivity is not accompanied by an increase in accident rates.

Chapter 23.4
SELECTION PROCEDURE

DAVID E. NICHOLAS

23.4.1 GENERAL

The purpose of this section is to present the logical sequence of events to follow in choosing a mining method. Characteristics that have a major impact on the determination of the mining method (as discussed in Chapter 23.1, Selection Variables) are

1. Physical and geologic characteristics of the deposit.
2. Ground conditions of the hanging wall, footwall, and ore zone.
3. Mining and capital costs.
4. Mining rate.
5. Availability and cost of labor.
6. Environmental considerations.

What follows is a discussion of the work that should be done at each stage of developing the deposit to choose the appropriate mining method. There is no single appropriate mining method for a deposit; there are usually two or more feasible methods. Each method entails some inherent problems. Consequently, the optimum method is that method with the least problems.

Although this chapter is aimed at determining the appropriate mining’ method, the ultimate goals are to maximize company profits, maximize recovery of the mineral, and provide a safe environment for the miners (not necessarily in this order). These ultimate goals may appear to be mutually exclusive, but in fact are not. Maximizing the profit meets the business requirement of the company. Maximizing the recovery benefits the mining company as well as society. The more tons recovered, the less capital cost per ton, which is good for the company; maximum recovery of our natural resources means society has an adequate supply. Providing safety for the miners means the work force will be able to attain the productivity called for in the feasibility study.

For additional discussion of method comparisons, see Section 16 for surface mining and Section 21 for underground mining.

23.4.2 MINING METHODS FOR CONSIDERATION

Before the discussion of the actual process of mining method selection, it is important to understand the key characteristics required for each mining method. The following briefly summarizes the mining methods. (For more detailed descriptions of these methods, refer to Sections 14, 15, 18, 19, 20, and 22.) Readers who are already familiar with the various methods can proceed to 23.4.3, Selection Method Techniques.

OPEN PIT/OPEN CAST MINING. There are surface mining techniques in which the waste material is removed to uncover the ore. This category includes strip mining and quarrying. The equipment used to extract the waste and ore is generally mechanical but differs somewhat for each of these methods. The parameters of stripping ratio and slope angle are critical to all in determining whether the method is applicable. Open pit usually refers to metal mines (Chapter 14.1), open cast or strip mining (Chapter 14.3) generally refers to coal, and quarrying (Chapter 14.2) refers to construction materials and dimension stone such as limestone and granite.

PLACER MINING. Another surface method, placer mining is distinctive in that the ore is mined and initially concentrated using gravity and water. This method requires that adequate water is available, that the material to be mined is gravel-like in character, and that the mineral to be mined can be separated based on its density differences. Examples of placer mining are dredging and hydraulicking (Chapter 15.1).

SOLUTION MINING. Solution mining requires that the mineral can be recovered using water or some type of acid, with a minimum amount of crushing and no grinding. In situ solution mining (Chapter 15.3) involves mining the ore in place. A solution is injected into the ore formation via boreholes and recovered either from boreholes or underground drifts. Borehole mining is commonly used for salt and sulfur-type deposits. Surface leaching (Chapter 15.2) is a solution method where the ore is either recovered in place in dumps or is drilled and blasted and stacked in a heap or a vat. In order for the ore to be leached, it must have the correct chemical makeup and possess adequate porosity and permeability; good fragmentation is required so that the solutions can pass through and there is sufficient surface area.

BLOCK CAVING (Chapter 20.3). An area of rock is undercut so that it caves under its own weight; the overburden waste material is expected to cave as well. Any rock can be made to cave, but it must be determined how much area is needed in order to cave, what the size of the caved blocks will be, and whether the rock will cave fast enough. Therefore, the size distribution of the caved rock and the size (plan dimensions) of the deposit are critical parameters. This category includes panel and continuous caving. Within the bounds of block caving, there is still a choice to be made as to whether to use gravity, slusher, or LHD (load-haul-dump) extraction drifts. The ground conditions and the degree of fragmentation are the primary parameters in determining which of these approaches should be used.

Recent longhole drilling has resulted in a method called *forced caving* that is similar to block caving except that widely spaced sublevels are developed from which the rock is drilled and blasted, that is, induced caving. It is applied to those deposits that may not cave for the dimensions of the deposit.

LONGWALL/SHORTWALL MINING (Chapter 20.1). The deposit, generally a coal seam, is removed in a continuous operation along an extensive working face using a long series of props over the face and the working area. The ground above the mined out area caves and results in subsidence. This method requires relatively low strength ore that is nearly flat lying and extends over a large area.

ROOM AND PILLAR/STOPE AND PILLAR MINING (Chapters 18.1 and 18.2). In these similar methods, a grid of rooms or stopes is developed, leaving pillars to support the roof or back. The difference between these two methods is the height of the zone to be mined. The rooms/stopes and pillars may or may not be uniform in size, and the pillars may or may not be recovered at a later date. The ore geometry, which is a flat-lying deposit that is not much over 150 ft (50 m) thick, is the primary controlling factor of this method. The room/stope size and pillar size are determined based on the depth and strength of the ground.

SUBLEVEL STOPING (Chapter 18.4). An overhand mining method in which the ore is blasted by longholes from sublevels.

This method differs from stope and pillar in that the deposit is so large or thick that sublevels are required and the blasting requirements approach those of open pit operations. The ore is drawn off as it is blasted, leaving an open stope. The stopes are separated by pillars. The stopes may or may not be filled after mining is completed, and if filled, the pillars are usually recovered using the same method or some type of cut and fill stoping. The parameters that control this method are an appropriate geometry and competent enough ground to leave open stopes. As in room and pillar, the stope and pillar widths are determined by rock strength vs. depth as well as the stope height.

SUBLEVEL CAVING (Chapter 20.2). Sublevel caving is an induced caving method in which the ore is blasted by ring drilling from sublevel drifts. The overlying and hanging wall rock is expected to cave as the ore is drawn. This method is chosen when the ground does not cave on its own either because of the limited width of the deposit or incompetent rock. Draw control and maintaining the brow of the face are the key concerns of this method.

SHRINKAGE STOPING (Chapter 18.3). A stoping method in which the ore is blasted, with most of it being left in the stope to accumulate until blasting is completed. The broken ore is then drawn off all at once. This method is usually used in narrow, steep deposits where the walls are not competent enough to stand without some support, which is provided by the blasted muck.

CUT AND FILL STOPING (Chapter 19.1). A stoping method in which each slice of rock is removed after blasting and replaced with some type of fill material. There are a multitude of variations on this method such as overhand cut and fill, underhand cut and fill, and post-pillar cut and fill, each of which is used under different conditions. Overhand cut and fill is used in narrow, steeply dipping deposits where the ore is moderately to highly competent, the walls are weakly to highly competent, and the cost of fill is less than the cost of leaving pillars. An underhand cut and fill is used when the ore zone is an incompetent material and the back cannot be kept open using normal ground support. Post-pillar cut and fill is an overhand method that uses a room and pillar pattern; it is used to obtain higher productivity than is possible with overhand cut and fill. The pillars are designed to support only the immediate roof.

SQUARE SET STOPING (Chapter 19.2). Prisms of timber are formed to replace the rock mined and to support the surrounding rock. Associated with this category are other timbered stoping methods such as stull stoping. This method is used in cases where the ground is incompetent and the ore geometry is too wide and/or irregular for cut and fill stoping to be applied. This method is not commonly used today because of the high cost of timber and the intensive labor required.

TOP SLICING (Chapter 19.2). This method, too, is not often used today because of the high cost of labor to lay the timber mat. It has been more or less replaced by the cheaper method of sublevel caving. It is discussed here because some of the mining selection techniques include this method as an option. Mining is done from sublevel drifts where the rock is blasted. Overlying rock is separated from the ore by a timber mat. The overburden is expected to cave.

NOVEL MINING METHODS (Section 22). These mining methods are called "novel" because the technology is different or more innovative than that used in traditional methods. Novel methods that have already been considered and are either in the research and development stage or have actually been tried include these:

1. Rapid excavation.
2. Automation and robotics.
3. Hydraulic mining.
4. Methane drainage.
5. Underground gasification and combustion.
6. Underground retorting.
7. Marine mining.
8. Nuclear mining.

Rapid Excavation—This is a method in which the drill, blast, muck, and support cycle is replaced by continuous operation. This method requires that the ground be weak enough that it can be cut at a rate that will exceed normal mining. Rapid excavation could be applied to most of the mining methods discussed and especially to mine development and access drifts. Continuous mining of coal is the forerunner to rapid excavation in rock.

Automation and Robotics—This is not really a new method, but rather a new technology that could be applied to existing mining methods. The use of automation/robotics is not really as dependent on the geological parameters and ground conditions as it is on the knowledge of the engineers and labor force.

Hydraulic Mining—This method is dependent on the ground being able to be cut by a high-pressure water jet. Transporting the material once it is cut is one of the main technological problems.

Methane Drainage—The success of this method is a function of the "physical properties of the coal seam (diffusivity, reservoir pressure, permeability, and gas content), mining method (if in progress), and drainage method" (Hartman, 1987). The method is used in Europe but only now is gaining widespread acceptance in the United States to produce coalbed methane. This method is similar to borehole mining in which the wells are used to recover the methane.

Underground Gasification—This method is applied to coal and again is related to borehole mining, in which the coal is burned at one end and the gases given off are recovered at another borehole. Use of this method is based on whether the cost of burning the coal and recovering the gases is cheaper than traditional mining. The key parameters that impact the method are the fracturing of the coal and the chemical composition of the coal. This method may become more feasible in cases where the coal seam is too narrow for traditional methods, or in recovery of multiple seams, where the second seam is too close to the first to be recovered in a traditional fashion.

Underground Retorting—This method is being tried with oil shales and tar sands. The area is mined to some extent using traditional drifting techniques and pillar designs. Then the rock in the stope (retort) is blasted in place. Using the oil, it is released from the rock and recovered under the stope. This method would be chosen based on the retorting characteristics rather than on the mining parameters. The critical factor from a mining perspective would be the cost and methodology of fracturing the ground. The degree of fragmentation will impact the percentage recovery of the oil, which is probably the most critical concern nowadays.

Marine Mining—Marine mining is much like placer mining, in which the recovery is of a mineral that has been concentrated mechanically and can be mined without drilling and blasting. From a mining point of view, the key determinant is whether the material is low enough in strength that it can be dug or vacuumed. The political problems involved will probably be greater than the technical ones.

Nuclear Mining—The main advantage of this method is the highly efficient fracturing of the rock that can be achieved. The main drawbacks are the questionable working conditions for the miners, environmental pollution concerns, and political treaty prohibitions. This technique could be used to mine competent rock in a block caving style, similar to a forced or induced caving method.

23.4.3 SELECTION METHOD TECHNIQUES

In order to determine which mining method is feasible, we need to compare the characteristics of the deposit with those required for each mining method; the method(s) that best matches should be the one(s) considered technically feasible, and should *then* be evaluated economically. The selection techniques discussed deal with the first two parameters that determine a mining method, (1) the physical and geologic characteristics of the deposit, and (2) the ground conditions of the hanging wall, footwall, and ore zone. The techniques for evaluating mining methods are only attempts at defining and quantifying in a written format what miners in years past determined through discussion, previous experience, and intuition. Therefore, each of the method selection schemes presented here is similar and yet different, reflecting personal preferences in their emphasis. The purpose of discussing these techniques is not to critique them but simply to present the alternatives available to aid in selecting the most appropriate.

Most of the schemes are aimed at determining the appropriate *underground* method, as there are so many possible choices. However, the purpose of this chapter is to discuss the selection of the *best* mining methods, including *surface,* hydraulic, and other more novel methods. The method selection process should first determine whether the deposit should be mined using a more traditional surface, underground, or in situ leach mining method. A novel method should only be considered if traditional methods are not economically or technically feasible. To start a mine with a novel mining method requires adequate funding and an enormous commitment from the board of directors to technical development; the board must also have the patience to work out the technical problems.

If the deposit cannot be mined using a surface method, then an underground method should be considered. The mining method selection techniques are limited in that selection is based solely on the known physical parameters and rock strength characteristics. Sometimes several mining methods may appear to be equally feasible. In order to further determine which method(s) is the most suitable, the input variables of mining costs, mining rate, labor availability, and environmental regulations should be considered in more detail.

Note: None of the method selection systems deal with in situ stress. The techniques do account for the vertical stress via depth, but none of the methods discuss how a high horizontal stress impacts the choice of the mining method.

23.4.3.1 Boshkov and Wright

The classification system proposed by Boshkov and Wright (1973) in the *SME Mining Engineering Handbook,* 1st ed. (based on Peele, 1941), was one of the first qualitative classification schemes developed for underground method selection (Table 23.4.1). Their system assumes that the possibility of surface and underground mining has already been eliminated. It uses general descriptions of the ore thickness, ore dip, strength of the ore, and strength of the walls to identify common methods that have been applied in similar conditions. The results of this classification provide up to four methods that may be applicable.

23.4.3.2 Hartman

Hartman (1987) has developed a flow chart selection process for defining the mining method, based on the geometry of the deposit and the ground conditions of the ore zone (Fig. 23.4.1). This system is similar to that proposed by Boshkov and Wright, but is aimed at more specific mining methods. Hartman admits the method is qualitative and should be used as a first-pass approach. This classification includes surface and underground methods, coal, and hard rock.

23.4.3.3 Morrison

The classification system proposed by Morrison (1976) divides underground mining into three basic groups: (1) rigid pillar support, (2) controlled subsidence, and (3) caving (Fig. 23.4.2). General definitions of ore width, support type, and strain energy accumulation are used as the criteria for determining a mining method. This classification helps to demonstrate the selection continuum, choosing one method over another based on the various combinations of ground conditions. In this system, the ground conditions have already been evaluated to determine the type of support required.

23.4.3.4 Laubscher

The selection of an appropriate mass underground mining method has been presented by Laubscher (1981). The selection process is based on his rock mass classification system (see Chapter 23.1, Fig. 23.1.2), which adjusts for expected mining effects on the rock mass strength. Laubscher's scheme is aimed at the mass mining methods, primarily block caving vs stoping; his main emphasis is on cavability. The two parameters that determine whether a caving system is used over a stoping system are the degree of fracturing, RQD (rock quality designation), joint spacing, and the joint rating, which is a description of the character of the joint, i.e., waviness, filling, and water conditions (Fig. 23.4.3). This scheme puts emphasis on the jointing as the only control for determining cavability. Laubscher (1990) has recently modified the classification to relate his rock mass rating to the hydraulic radius (Fig. 23.4.4). By including the hydraulic radius, cavability becomes feasible for more competent rock if the area available for undercutting is large.

23.4.3.5 Nicholas

The classification proposed by Nicholas (1981) determines feasible mining methods by numerical ranking and thus is truly quantitative. The first step is to classify the ore geometry and grade distribution using Table 23.4.2. The rock mechanics characteristics of the ore zone, hanging wall, and footwall are similarly classified using Table 23.4.3. A numerical ranking is then performed by adding up the values of each mining method, using Tables 23.4.4 and 23.4.5. The values of the tables represent the suitability of a given characteristic for a particular mining method. A value of 3 or 4 indicates that the characteristic is preferred for the mining method. A value of 1 or 2 indicates that a characteristic is probably suited to that mining method, while a value of 0 indicates that a characteristic will probably not promote the use of that mining method, although it does not rule it out entirely. A value of –49 would indicate that a characteristic will completely eliminate consideration of that method. A recent modification to the system is the weighting of the categories for the ore geometry, ore zone, hanging wall, and footwall. To give each of these categories equal weight, the ore zone, hanging wall, and footwall need to be multiplied by 1.33 ($^{16}/_{12}$). However, the importance of each category is not equal; the ore geometry is more important than the ore zone, the ore zone more important than the hanging wall, and the hanging wall more important than the footwall. The proposed weighting for each category is summarized in Table 23.4.6; this weighting can be changed based on personal experience. The net weighting is then multiplied by each of the categories. Those two or three mining methods that have the highest overall positive numerical ranking should be economically analyzed.

The proposed values for the characteristics can be changed as our technical expertise with mining equipment and mining processes improves. In addition, each individual has a different point of view as to the relative importance of the various characteristics for each method.

Table 23.4.1. Applications of Underground Mining Methods

Type of Ore Body	Dip	Strength of Ore	Strength of Walls	Commonly Applied Methods of Mining
Thin beds	Flt	Stg	Stg	Open stopes with casual pillars

Table 23.4.2. Definition of Deposit Geometry and Grade Distribution

1) *General Shape/Width*	
equi-dimensional	all dimensions are on the same order of magnitude
platy—tabular	two dimensions are many times the thickness, which does not usually exceed 325 ft (100 m)
irregular	dimensions vary over short distances
2) *Ore Thickness*	
narrow	<30 ft (<10 m)
intermediate	30–100 ft (10–30 m)
thick	100–325 ft (30–100 m)
very thick	>325 ft (>100 m)
3) *Plunge*	
flat	<20°
intermediate	20°–55°
steep	>55°
4) *Depth Below Surface*	
provide actual depth	
5) *Grade Distribution*	
Uniform. The grade at any point in the deposit does not vary significantly from the mean grade for that deposit.	
Gradational. Grade values have zonal characteristics, and the grades change gradually from one to another.	
Erratic. Grade values change radically over short distances and do not exhibit any discernible pattern in their changes.

23.4.3.6 Example of Use of Selection Schemes

The following is an example and description of how to use the various classification schemes. The data presented are fabricated and aimed at being suitable input for Nicholas' scheme, but can be used for the other methods as well.

Input data	Description
General Deposit Shape	tabular or platy
Plan width	330 ft (100 m)
Ore thickness	300 ft (90 m)
Ore plunge	15°
Grade distribution	primarily disseminated
Depth	1150 ft (350 m)
Ore Zone	
Rock substance strength	12,000 psi (83 MPa)
Fracture spacing	3 frac/ft (10 frac/m)
RQD	40
Fracture shear strength	clean joint with a rough surface
Hanging Wall	
Rock substance strength	16,000 psi (110 MPa)
Fracture spacing	1.2 frac/ft (4 frac/m)
RQD	65
Fracture shear strength	clean joint with a rough surface
Footwall	
Rock substance strength	7,000 psi (48 MPa)
Fracture spacing	4.3 frac/ft (14 frac/m)
RQD	40
Fracture shear strength	joints coated with thin clay

Boshkov and Wright's method would classify this deposit as either "very thick beds" or "massive," with a "weak" ore and a "weak/strong" wall rock (Table 23.4.1). Based on this classification, feasible mining methods include top slicing, sublevel caving, block caving, square set stoping, and combined methods.

Hartman's method selection chart would show this deposit as either shallow or deep in depth. The ore strength would be moderate to weak, and the ore geometry would be tabular and massive, or thick (Fig. 23.4.1). The possible mining methods would be open pit mining, sublevel caving, and block caving.

Table 23.4.3. Rock Mechanics Characteristics

1) *Rock Substance Strength* (uniaxial strength/overburden pressure)		
weak	<8	
moderate	8–15	
strong	>15	
2) *Fracture Frequency*	No. of Fractures per (ft) (m)	% RQD
very close	>5 >16	0– 20
close	3–5 10–16	20– 40
wide	1–3 3–10	40– 70
very wide	<1 <3	70–100
3) *Fracture Shear Strength*		
weak	clean joint with a smooth surface or fill with material with strength less than rock substance strength	
moderate	clean joint with rough surface	
strong	joint is filled with a material that is equal to or stronger than rock substance strength	

Sources: Nicholas, 1981.

Morrison's method would classify this deposit as "invariably wide." Based on this, the mining methods possible are a caving method, top slicing, and sublevel caving.

Laubscher's system requires more information than that provided, but a guesstimate can be made from the data given. In actuality, one would have looked at the drill core and could therefore make the necessary measurements. Using Laubscher's classification (Fig. 23.1.2), the rating of the rock is 48, as follows:

RQD	6
Intact rock strength	8
Joint spacing	5
Joint condition	29
TOTAL	48

Using his first method selection, which is based primarily

on jointing, the ground would be considered either "marginal caving" or open stoping" (Fig. 23.4.3). The newer selection scheme, which uses the total mass rating and the hydraulic radius, indicates that a hydraulic radius of 28 is required for the deposit to cave (Fig. 23.4.4). A hydraulic radius of 28 is equivalent to a square area of 370 ft (112 m) or an area of 330 by 410 ft (100 by 125 m). This means that for our example, the deposit

Top Slicing	14	6	6	7	19	
Square Set Stoping	8	8	7	10	25	

must be undercut full width, and for a length greater than the width. This may mean that the production schedule will have to allow for additional time to undercut the large area or for some type of inducement. Either that or a sublevel cave operation may be used instead.

Nicholas' example is summarized in Table 23.4.7. The first step is to list the geometry/grade distribution and rock mechanics characteristics of the deposit (Table 23.4.7, column 1). The columns of characteristics in Tables 23.4.5 and 23.4.6 are then identified for the deposit, and the values summed for the geometry/grade distribution, ore zone rock mechanics, hanging wall rock mechanics, and footwall rock mechanics for each mining method (Table 23.4.7, columns 2 and 3).

The ore zone, hanging wall, and footwall should be multiplied by the weighting factors and then summed. This total should then be added to the geometry/grade distribution sum (Table 23.4.8). Using this type of characteristic grouping, one can see which grouping(s) reduce the chance of using a particular mining method, or, in cases where the total sum is nearly equal, one can determine which characteristics are the most suitable for the mining method. For the example given, the preferred mining methods would be open pit mining, top slicing, square set stoping, block caving, and sublevel caving.

All of the method selection techniques arrive at similar conclusions (Table 23.4.9). One might surmise that the conclusions were obvious from the beginning. This may be true for this example but is not so in all cases. Important factors may be overlooked; using a method selection scheme, one is forced to consider all of the parameters. As is shown by Nicholas' scheme, in which the main drawback to using sublevel caving is the poor ground conditions of the footwall, one unfavorable factor does not necessarily eliminate a method. Some technical problems can be overcome. Sublevel caving requires extensive drifting and ore pass work in the footwall, so the poor ground conditions will call for additional ground support, meaning development may take longer. This does not rule out the feasibility of the method;

Table 23.4.8. Characteristic Values Multiplied by Weighting Factors

Mining Method	Geometry/Grade Distribution	Rock Mechanics Characteristics				Grand Total
			HW	FW	Total	
Open Pit Mining	12	9	8.8	4.0	21.8	33.8
Block Caving	11	8	4.8	3.5	16.3	27.3

Top Slicing	
Square Set Stoping	Highest

it simply means that when performing the cost analysis, one should allow for a higher cost in the footwall development work.

None of the method selection systems deal with in situ stress. The techniques account for the vertical stress via depth, but none of the methods discuss how a high horizontal stress impacts the choice of the mining method.

Although the mining methods resulting from the selection process are all technically feasible, their mining costs may be significantly different. Based on Hartman's and Morrison's (Table 23.4.10) relative rankings of mining costs, those methods with the potentially lowest operating cost can be identified. However, these cost rankings represent averages, and the estimated cost provided the method is *appropriate* for the ground conditions; therefore the rankings should be used with caution.

On the basis of relative operating costs, the methods would be ranked as follows:

1. Open pit mining.
2. Block caving.
3. Sublevel caving.
4. Top slicing.
5. Square set stoping.

With this ranking established, we must next determine whether the deposit can be mined from the surface or if it must be mined underground.

23.4.4 STAGES IN THE SELECTION PROCESS

The mining method selection process is iterative, with each iteration correlating to the stages of development of the property. A deposit that is mined will go through roughly five stages:

1. Initial discovery of the mineralized zone.
2. Developmental drilling to outline reserves and a feasibility study.
3. Design and development of the deposit.
4. Revising and updating during production.
5. End of mine life.

The preceding section described how the key physical parameters of the deposit and the ground conditions are used to determine a feasible mining method. These techniques can be used in each iteration; what will change is the database, the degree of certainty in the economic analysis, and the consideration of the other parameters that determine the mining method such as costs, labor, and environmental regulations.

23.4.4.1 Stage 1: Initial Discovery

The exploration for a deposit is guided by corporate philosophy. The corporation should provide the exploration department with the rough target size and grade. (Exploration techniques are discussed in Section 4, Prospecting and Exploration.) Although the exploration geologist is trained in the required exploration techniques, he/she may not understand the economics behind the search for a particular mineral(s) with a minimum grade and/or tonnage. The basic economics should be discussed with the geologist so that he/she understands how the target was defined. What is found may not match the target exactly, but he/she will be able to assess how to change the exploration program to meet the corporate needs. This will also open the lines of communication between the geologist and the mining engineers for future mine planning.

As soon as a mineralized zone is discovered, an initial prediction of potential mining methods should be made. Primary considerations for the method choice should be the expected ore geometry and ground conditions, combined with engineering judgment and comparisons to nearby operations. The use of Boshkov and Wright's and/or Hartman's system is reasonable during this stage. Using these techniques should help identify which characteristics are critical for the mining method, so that the necessary data can be collected during the development drilling. The other method selection techniques could be used but the database would probably not be adequate.

In order to plan a better development drilling program, the possible mining methods should be costed out for capital and operating expenses at various production rates so that the size and grade of the target can be better defined in order to identify drilling limits.

23.4.4.2 Stage 2: Development Drilling and Feasibility

In stage 2, development drilling is performed to determine the tonnage and grade of the deposit as well as for the purpose of collecting metallurgical, geotechnical, hydrologic, and environmental data to determine mineral processing and mining methods. During or near the end of the development drilling program, a quantitative analysis of potential mining methods can be performed. This is usually a conceptual mine plan or a feasibility study.

The development drilling program should be designed to define the target size and/or the limits of the deposit. Therefore, the drill spacing is wide and a number of the holes are outside of the minable limits. The holes outside the deposit provide the rock mechanician with information on the area where the pit walls or access facilities will be. The geologist must find out from the metallurgist, rock mechanician, and mining engineer what data they each require from the drill core or cuttings. The drill pattern, drilling method, and logging techniques have to be determined based on the particular type of deposit; this is further discussed by Call (1979), and Peters (1978).

By stage 2, the database should be adequate to use Laubscher's or Nicholas' method selection technique. For a first pass, the more traditional mining methods should be considered. If conditions warrant investigation of more novel methods, then they should be considered after the traditional methods have been eliminated. As shown previously, a deposit may be mined either from the surface or underground. Chapter 23.2, Surface vs. Underground Methods, discusses in detail the process of choosing between these two. In general, if at all possible, a surface method should be chosen over an underground method, as surface mining involves fewer technical problems and generally yields more efficient productivities than underground methods. The decision between a surface and an underground method is usually an economic one, although environmental regulations may require the use of an underground method, even when it is less economic. Fig. 23.4.5 provides a rough guide as to when an underground method would be preferable to a surface method, based on mineral value and stripping ratio.

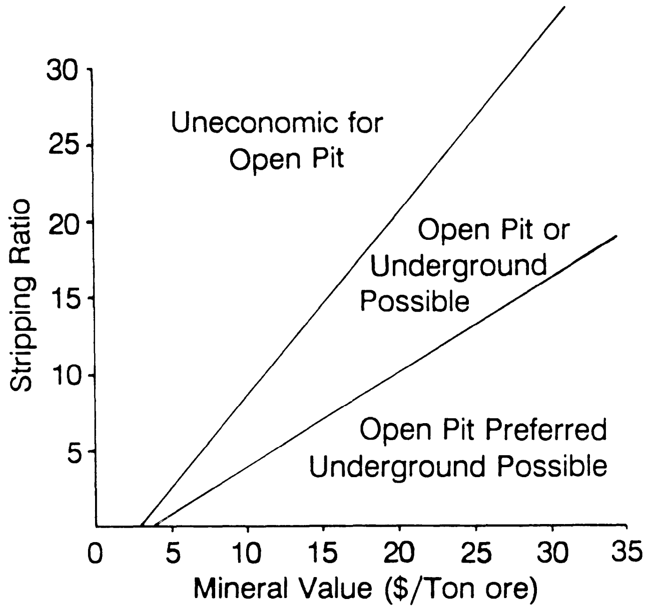

Fig. 23.4.5. Stripping ratio vs. mineral value.

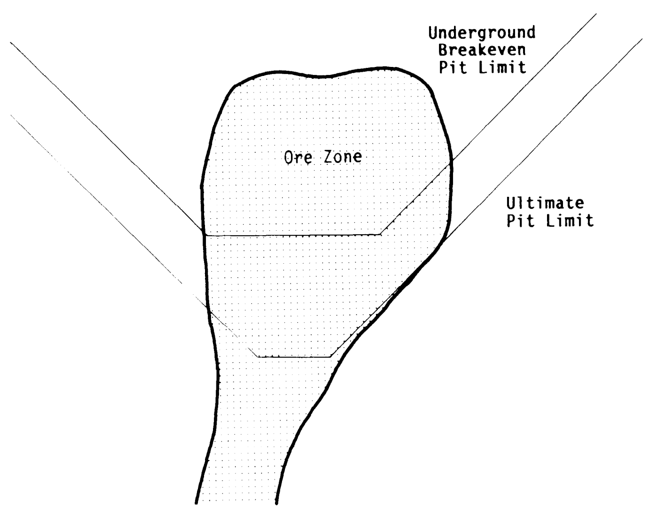

Fig. 23.4.6. Ultimate pit limit vs. underground breakeven pit limit.

A situation that is becoming more common is for the deposit to be mined as an open pit initially, recovering the deeper reserves later using an underground method. One of the key factors in planning this sequence of mining is to make sure there are adequate reserves *after* the open pit is mined to pay for the capital required to go underground. This can be done by mining the pit to the underground/open pit "breakeven" point rather than to the ultimate pit limits (Fig. 23.4.6).

If an underground method appears to be preferable, then one of the method selection techniques discussed in 23.4.3 should be used to provide two or three possible mining methods. These methods should then be economically analyzed to determine which method nets the best return on investment. The input

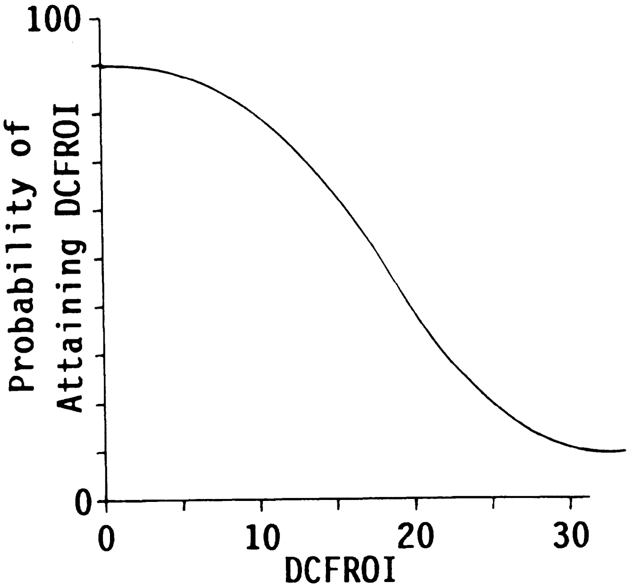

Fig. 23.4.7. Probability of attaining DCFROI.

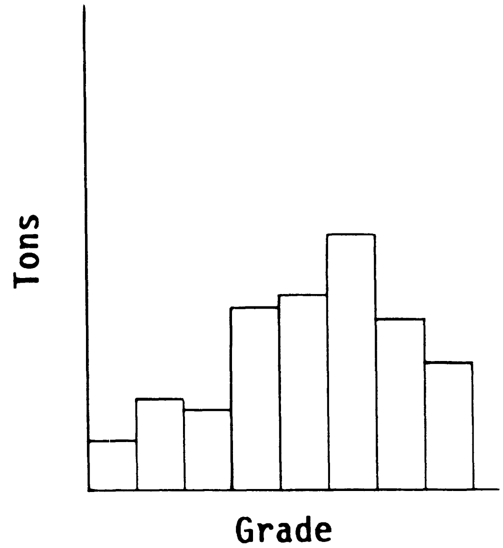
parameters for this cost analysis require some rough mining dimensions. These dimensions can be based on either the classification work or the judgment of the engineers doing the analysis. The key parameters for some of the main mining methods are discussed in 23.4.4.3.

The remaining parameters should be considered and the pros and cons of the feasible methods should be weighed based on the mining rate required by the corporation, the availability and type of labor, and the environmental regulations/considerations.

23.4.4.3 Stage 3: Design

In stage 3, the design stage, the mine plans for the most feasible method, as determined in stage 2, are evaluated. The calculation of minable reserves and determination of cutoff grades allows a detailed economic analysis to establish capitalization requirements and return on investment. With this information, final decisions on appropriate mining methods can be made. While this level of detailed planning on paper may appear to extend start-up time, it will always be more cost effective to discover mistakes on paper than to find errors in the field after mining has already begun. Still, a project can be evaluated "to death" or beyond the limits of the data. The evaluation needs to be based on an understanding of the variability of conditions and the quantity and quality of data. Mining is a risky business. Bankers understand risk analyses, and evaluations should be done in their language, presenting *distributions* of possible outcomes. As long as the probability of attaining a certain minimum DCFROI (discounted cash flow return on investment) (Fig. 23.4.7) is met, the property will be considered a viable proposition (Chapter 6.5). The probability required is a function of the corporate philosophy. The point here is that the accuracy of the design should not be any greater than the accuracy of the ore reserve or the mine design.

MINABLE RESERVES. The minable reserve defines what ore is recoverable for the possible mining methods. These reserves are the result of defining the mineral inventory, cutoff grade, and limitations imposed by ore thickness, lateral extent, or depth. The mineral inventory is the result of the drillhole data and geologic interpretations. Numerous methods exist to interpolate and extrapolate the ore grade from the drillholes, such as kriging, inverse square, and assigning the grade to an area of influence (see Chapter 5.6). Common methods used to calculate the mineral inventory include polygons, triangles, cross sections, and block models.



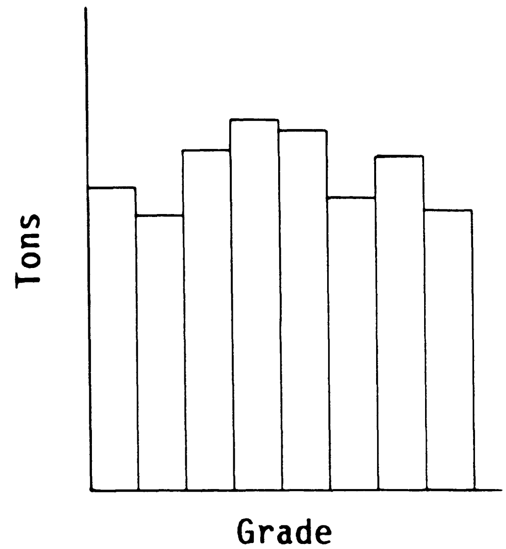


Fig. 23.4.8. Tons vs. grade frequency plot.

Determining the cutoff grade is an iterative process and can have a major impact on the minable reserves. The primary inputs required to determine the cutoff grade are the capital and operating costs. This information is not always available or accurate in the early phases of defining the minable reserve. The geologist should generate a grade and tonnage distribution to determine whether there is a natural grade cutoff, that is, a point at which mining below a certain grade does not add significantly to the tonnage (Fig. 23.4.8). If this is not the case, then estimates of operating and capital costs will have to be made. There are a number of philosophies on whether capital should be included in the cutoff grade (Marek and Welhener, 1985). Initially, cutoff grade should be determined with and without the capital.

CRITICAL DESIGN PARAMETERS. For each of the mining methods, several critical design parameters must be evaluated as part of the method selection process in order to make the economic analysis.

Open Pit Mining—The critical design parameter for the selection of an open pit mining method is the slope angle. This is because the slope angle and limit of the ore zone will permit the estimation of the stripping ratio, which will ultimately impact the economics of the selection (Soderberg and Rausch, 1968). An assessment of the final slope angles can be made by defining potential failure geometries from the orientation of the geologic structures and then choosing a slope angle that minimizes the number of daylighted structures. If structure, shear strength, length, and spacing are available, a stability analysis can also be performed. Chapter 10.4, Slope Stability, discusses in more detail the approaches to determining slope design.

Solution Mining—The critical parameter for solution mining is the recovery of the mineral. That is, the metallurgical constraints are more critical than the mining constraints. For in situ or surface leaching, the permeability and porosity are the limiting factors; these parameters can be improved by increased fragmentation from blasting. In borehole mining, design of the pump sizes and hole spacings are required. Vat or heap leaching is also controlled by fragment size distribution. The design of the crusher size and/or blasting and fracture spacing determine ultimate fragment size distribution.

Block Caving—The cavability of the deposit should be examined in greater detail than in stage 2. Once cavability is determined, the minimum drawpoint spacing, supportable drift size, and subsidence limit should also be defined. Any ground can be caved; cavability is a matter of how much area has to be undercut to sustain the cave and what the fragment size distribution of the caved muck will be. If the area of the deposit is too small to sustain the cave, then some type of inducement will be required.

Using Laubscher's classification or the pressure arch concept (Alder, Potts, and Walker, 1951), the undercut width required to sustain a cave can be estimated. Laubscher provides the hydraulic radius required based on his classification system. In the pressure arch concept, the rock is considered to have a maximum distance that it can transfer load. Although each deposit has its own transfer distance, a correlation between depth and maximum transfer distance has been determined (Fig. 23.4.9). Based on the pressure arch concept, if the undercut width does not exceed twice the maximum transfer distance, only the rock under the arch has the potential for caving. If the deposit is too small to sustain the cave, then some form of inducement, such as longhole blasting from sublevels or boundary weakening, may be needed.

Drawpoint spacing is primarily a function of the ore, along with overlying waste fragment size distribution and pillar strength. The smaller the fragment size, the closer the drawpoint spacing must be to minimize dilution. If the ore can be mined uniformly, the impact of the fragment size will be minimized. The rock mass between the drawpoints can be considered a pillar and used to determine the minimum drawpoint spacing. Loading on the pillar is difficult to determine, but estimates by Kendorski (1975) or Panek (1978) can be used in conjunction with a pillar analysis (Wilson, 1972) to determine load-carrying capacity. With the fragmentation curve and pillar design, a comparison of drawpoint spacing with existing operations can be made (Fig. 23.4.10).

The ore-gathering drift size and support required are important in estimating the cost of the mining method. Equipment selection may influence this decision, but the characteristics of the rock mass will indicate what is feasible and what is not. Use of the classification and support approaches (Barton, Lien, and Lunde, 1974) may provide some estimates of support requirements.

The subsidence limit should be defined for locating buildings and shafts that are to last the life of the deposit. In the absence of any major geologic structure, a 45° angle projected from the bottom of the ore zone is usually considered the closest to the deposit that one should locate long-term facilities. However, most actual ground movement takes place within a 60° angle from the deposit, unless a major fault exists which will control the limit of subsidence.

Longwall/Shortwall Mining—The critical parameters that must be analyzed in the feasibility of a longwall mining system are the expected stress field in the mining zone, the size of entry and barrier pillars, and the support of the entries. Brady and Brown (1985) emphasize how understanding the stress field will have an impact on all aspects of the mine plan (also see Chapter 10.5). The length of the face, advance rate, face support requirements, and behavior of the caving waste will all be influenced by the nature of the developing stress field. By understanding this stress field, it becomes possible to design the entry size, support requirements, and pillar sizes.

Room and Pillar/Stope and Pillar Mining—The three critical parameters in a stoping or room and pillar method are the width of the stopes or openings, the pillar size, and backfill requirements. In sublevel stoping, the width of the stope is a function of the immediate and intermediate roof (Alder, Potts, and Walker, 1951). The intermediate roof is characterized by the pressure arch concept. The maximum mining width without a barrier pillar is twice the maximum pressure arch. Barrier pillars spaced at twice the arch distance must be able to carry the tributary area load to the surface. The immediate roof is the ground under the pressure arch which will act as a beam, plate, or arch. Joint orientation, spacing, and length can be used to define the stope width. The pillars within the arch have to carry this rock mass only (Fig. 23.4.11).

Backfill is not commonly used in room and pillar mining because the pillars are designed to carry the load. However, if a large area is being mined, backfill could be used to minimize a failure area or to prevent the pillars from deteriorating with time.

Sublevel Stoping—The critical design parameters are similar to those for stope and pillar, except that the design must consider what the sublevel interval should be, if the stopes are to be filled, and whether sill pillars are needed. The sublevel interval is determined by the height of the ore and the pillar width. Backfilling is implemented so that pillars can be recovered, or to reduce the impact of a failed pillar; backfill also helps to minimize the required pillar width. A sill pillar is necessary in cases where the pillar width required is large, the sublevel interval is greater than 170 ft (50 m), or long-term access of the sublevel is required. Whenever possible, rock fill should be used, as it makes a solid, stiff fill. Tailings can be used for fill as long as they can be dewatered, preferably before they enter the stope. The addition of cement reduces dilution while mining the pillar. Adding cement probably does not improve the load-carrying capacity of the fill unless it is dewatered prior to placement.

Sublevel Caving—The critical parameters for sublevel caving are the cavability of the hanging wall, the sublevel drift size and required support, and the spacing between the sublevel drifts. Janelid and Kvapil (1966) and Kvapil (1982) have presented guidelines for the layout of a sublevel mine. The hanging wall must come in behind the ore zone; otherwise sublevel caving will not work. Using analyses similar to those used for block caving will provide an estimate of the dimensions needed to initiate the cave, as well as the impact of the fragment size distribution.

Vertical spacing of the drifts is mainly a function of equipment, but the horizontal spacing between drifts is determined by the width of the draw ellipsoid and the stability of the rock. Janelid and Kvapil related drift spacing to the distance between

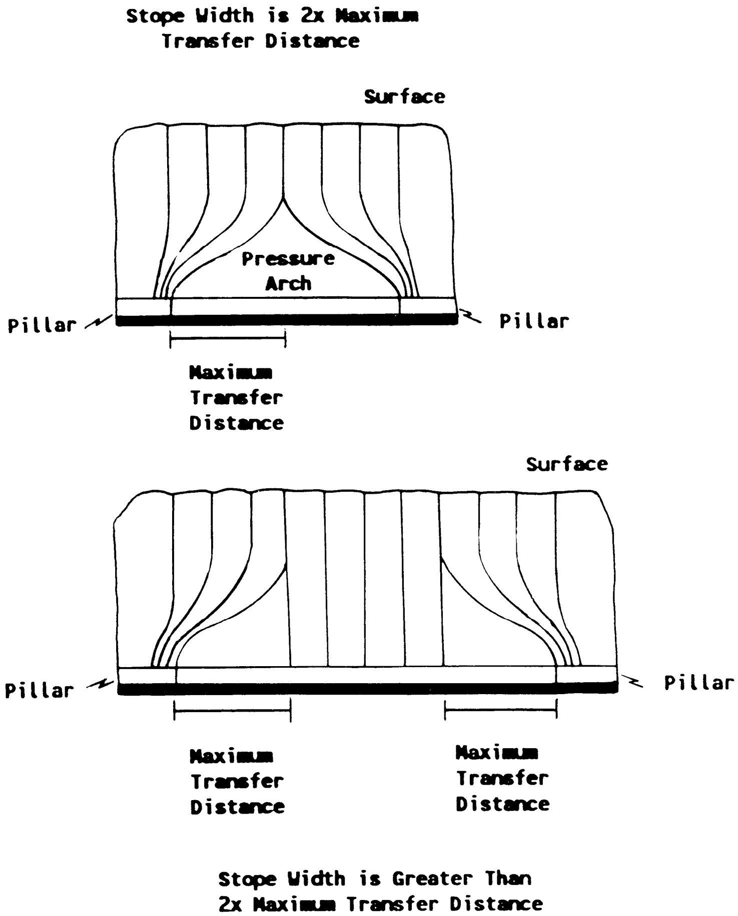

Fig. 23.4.9. Pressure arch concept.

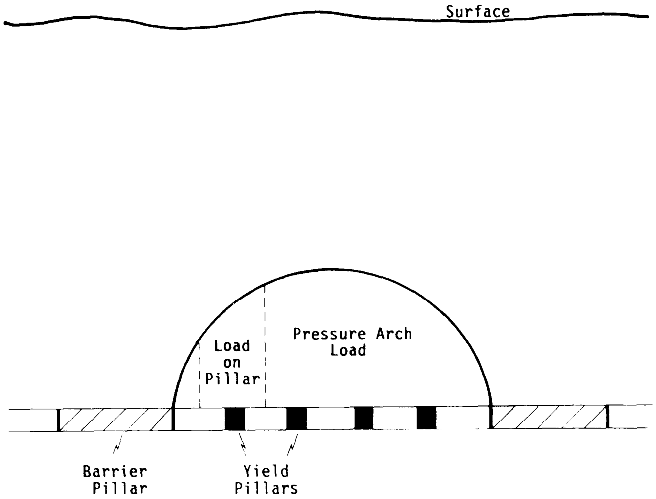

Fig. 23.4.11. Load on yield pillars.

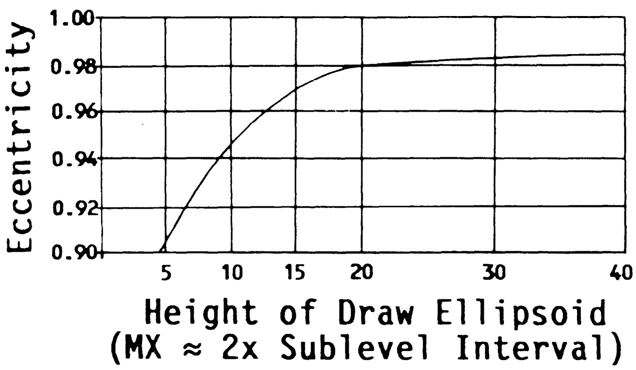

Fig. 23.4.12. Eccentricity vs. height of draw ellipsoid.

sublevels and the eccentricity of the ellipsoid (Fig. 23.4.12). The rock masses between the drifts can be considered pillars and analyzed as such.

Shrinkage Stoping—For shrinkage stoping, the same type of analysis must be made, but the cavability of the overlying rock must be evaluated as well. Support requirements can be estimated, as discussed under block caving.

The considerations for designing a room and pillar mine are basically identical to those made when designing a sublevel stoping method.

Cut and Fill Stoping—The critical parameters to consider in both overhand and underhand approaches to cut and fill stoping are the rock mass conditions in the ore zone, hanging wall, and footwall. MacMillan and Ferguson (1982) have presented guidelines for cut and fill mine planning.

For a very weak ore zone, it is necessary to design an artificial back in order to perform the mining process. If the ore zone is relatively competent, overhand mining must be designed to take into account the maximum stable exposure of the hanging wall. In both cases, the joint characteristics and stress field will play a critical role in predicting the rock's behavior.

In some cases, it may be necessary to leave pillars behind to aid in supporting the ore zone. Pillars used in cut and fill stoping should be designed on a yield concept to permit transfer of loads to the backfill material. The backfill material must be designed to be of sufficient density or stiffness to carry transferred loads after an acceptable deformation in the pillars and surrounding wall rock has occurred.

Square Set Stoping—The key to square set stoping is good timbermen. The timber sizes and spacing between timber supports can be designed. However, the design specifications should be considered an average, as adjustments will be made as mining progresses. The most difficult part is determining the load on the timbers, which can be estimated using one of the numerical analyses. Because of the high labor cost, materials handling becomes a major component of the operating cost.

24.4.4.4 Stage 4: Modification During Production

During initial development and production, the ground conditions and the ore geometry are better defined. Because of this additional information, the mine design should be modified to account for these changes. Just as the ore limits cannot be redefined without additional drilling, the ground conditions cannot be evaluated without additional data collection. This data collection should include additional structure, rock strength, and in situ stress measurements, as discussed in Chapter 23.1, and the ground response to mining should be monitored.

Monitoring can identify areas of potential instability much sooner than they can be observed by the naked eye. By the time cracks are visible, the rock mass strength may be reduced to the point where the movement cannot be stopped. Monitoring should be done using the simplest device possible, such as the tape extensometer, borehole extensometers, surveying, borehole inclinometers, or pressure cells. The tape extensometer and an EDM (electronic distance measurement) survey system are two of the easiest methods to use; the survey system is usually used in the open pit, while the tape extensometer is used predominantly underground. The EDM utilizes x, y, and z coordinates and plots the bearing, plunge, and amount of displacement. The tape extensometer measures the movement between two points, for example from rib to rib, back to floor, or rib to back. The data collection should include the stations monitored, and the date, time, and extent of mining.

The following discussion on data interpretation applies specifically to the tape extensometer, but is also applicable to survey monitoring. The data should be plotted as a cumulative displacement plot and a velocity plot (Fig. 23.4.13). The shape of the curve is more significant than the absolute value. On the cumulative displacement plot, a flat line means no movement, a constant sloping line means there is movement but the rate of movement (velocity) is constant; an increase in the slope of the line means the velocity is increasing, and a decrease in the slope of the line means the velocity is decreasing. The velocity plot usually shows more variability than the cumulative displacement plot. On a velocity plot, a flat line means the velocity (rate of movement) is constant, a constant slope means the velocity is either increasing or decreasing at some constant rate (i.e., constantly accelerating or decelerating), and a changing slope means the acceleration is increasing. By correlating the ground movement with the mining activity, we can determine when ground is being loaded to its limits. Unfortunately, it seems that unless there is an operational concern regarding ground movement, the monitoring does not get done. It should be part of the normal follow-up on the design, and used to compare with design changes.

Even though at this stage we know more about the deposit, making changes in the mining system is not necessarily easy. The access drifts and/or haulage systems can have a lead time requiring a three- to five-year delay before any changes in the mining system can actually be implemented. A change in the slope angle can be made at most any time during the operation.

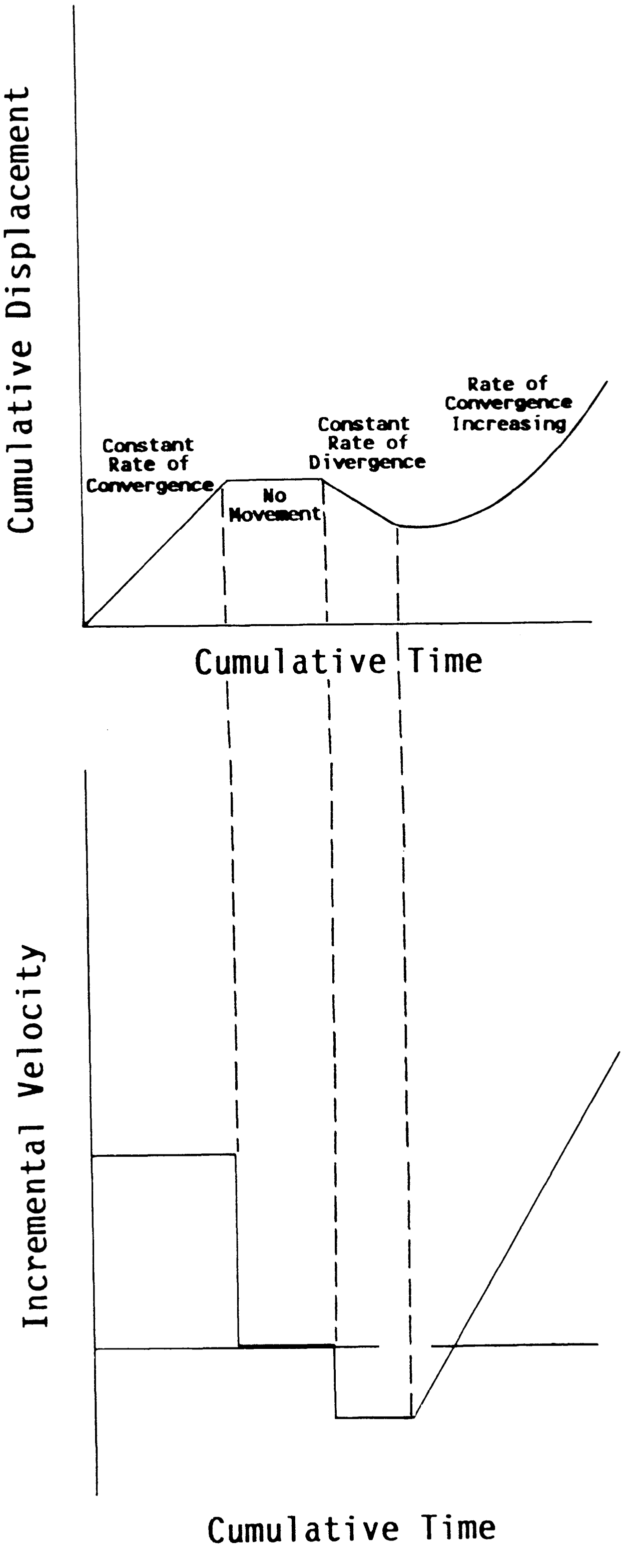

Fig. 23.4.13. Cumulative displacement plot and velocity plot.

Even though the design has been engineered in the feasibility study, the engineering approach at this point should be to broaden and improve the database and to re-evaluate the mine design during development and production.

23.4.4.5 Stage 5: End of Mine Life

By the end of the mine life, the approach to ore recovery has changed because the capital has been paid off and the main objective is simply to extend the mine life as long as possible. Because of this, there is more willingness to mine at a higher operating cost, a lower grade, and a lower chance of success. Therefore, the process of choosing how to mine the remaining ore (or ore not included in the original minable reserves) is similar to that discussed in stages 2 and 3; the difference lies in the level of risk, because the only alternative is to shut the operation down.

23.4.5 SUMMARY

In performing the mining method selection task, it is important to remember that no one method is able to meet all of the requirements and conditions. Rather, the appropriate mining method is that method that is technically feasible for the ore geometry and ground conditions, while also being a low-cost operation. This means that *the best mining method is the one with the technical problems that are the cheapest to deal with.* The mining engineer must balance all of the input parameters and select that method that appears to be the most suitable, making method selection both an art and a science. Still, by ensuring the maximum use of available data and performing detailed economic analyses on paper, the chances of making the most appropriate selection are vastly improved.

Section 24 Openings for Nonmining Purposes

MADAN M. SINGH, ASSOCIATE EDITOR AND SECTION COORDINATOR

Chapter 24.0
INTRODUCTION

MADAN M. SINGH

This section is unique to the Handbook in that it is the only section that deals with underground excavations for nonmining purposes. The editors were of the opinion that the section should be incorporated because the subject matter covered by the chapters is closely related to mining, and many mining engineers are currently involved in these activities. As we enter the decade of the 1990s activities in this category will increase, enhancing the relevance and utility of the material discussed.

As the population increases, especially in metropolitan areas, the necessity to go underground will be greater. At the present time, not only are subsurface shopping malls and pedways connecting buildings becoming commonplace, but structures as diverse as the Civil and Mining Engineering Building on the University of Minnesota campus, a road-and-fleet maintenance facility in Multnomah County, OR, and even an ice cream parlor (Dairy Queen) in northern Wisconsin have been constructed underground. Placing utilities below the surface has numerous advantages and is now customary. Rapid transit and highways through tunnels in urban areas have been the norm for many years, but subterranean stormwater reservoirs, power plants, industrial warehouses, and food storage silos are relatively new innovations. The philosophy of underground defense installations is ancient, but their requirements and designs have transformed radically as technology advances. The use of underground space for disposition of wastes is modern, since it is recently that environmental concerns and waste disposal costs have assumed increased significance.

As the reader peruses the following chapters, it should be borne in mind that many of the principles and technologies discussed therein in connection with a particular usage are applicable in numerous other situations. As our understanding of these factors improves, novel nonmining uses of subsurface space will emerge (e.g., the placement of an underground cable-operated people-mover in the Austrian ski village of Serfaus), thereby widening the scope of engineers trained in the fields of mining, geology, and geotechnology. Among the items of importance common to several underground usances are the effects of heat, water, and vibrations. Thus the effect of high temperatures on the surrounding strata are not only of significance to nuclear waste disposal and defense, but also critical to in situ coal gasification and retorting of oil shales. The better understanding of the flow of water through the ground is helpful for locating subterranean structures, modeling of toxic waste sites, and planning (effects on local aquifers) of new underground mines.

Civil works tunnels are reviewed in Chapter 24.1. These are located primarily in congested areas and, therefore, subject to constraints in location, geology, size, method of excavation, and support design and requirements. These may be built for a variety of different uses: rail transit, highways, water supply, wastewater storage and transport, utilities, pedestrian paths, and other purposes. Complexities in the design of these tunnels pose a challenge to the ingenuity and ability of the engineer.

Chapter 24.2 discusses the use of underground space for the purpose of bulk storage of materials (solid, liquid, and gaseous) and for generation of electrical power. Siting and design of the caverns for these uses requires detailed knowledge of the geology and support requirements, and special needs relevant to the purpose for which these are excavated. Pumped hydrostorage power plants, such as those in Bath County, VA, and near Rome, GA, have been constructed and successfully used. Schemes have also been suggested for the storage of pumped hydroelectric, compressed air, and superconducting electromagnetic energy. Unique facilities, such as for the superconducting super collider (SSC) proposed for construction near Fort Worth, TX, and the large electron-positron collider (LEP) and super proton synchrotron (SPS) operated by the European Organization for Nuclear Research (CERN) have been designed for research or other special uses.

A discourse on high-level nuclear waste repositories is presented in Chapter 24.3. In addition to engineering parameters, a host of societal factors (including regulatory and political issues) govern the siting and design of such facilities. The idea involved in the design is to encapsulate the hazardous nuclear waste in solid form in hermetically sealed canisters, and emplace it in a suitable. geologic formation, nearly 1000 to 3000 ft (300 to 1000 m) below the ground surface, so as to isolate it from the envirosphere and minimize the potential for human intrusion. Hydrological, thermal (generated by radioactive decay), geochemical, and long-term stability (including tectonic behavior) considerations are significant and need to be taken into account. The design life of the repository may be divided into the operational phase (first 100 years) and an isolation phase (10,000 years). Hence the adoption of mining methods that do not introduce potential flow paths for gaseous and fluid emissions and appropriate sealing of the openings created assume added importance. Regulations also require that the material be able to be retrieved, if desired, during the operational phase. Although the scope of this chapter is limited to high-level radioactive waste, repositories suitable for the underground disposal of low-level nuclear wastes, toxic wastes, and mixed wastes remain possibilities in the future.

The use of underground facilities for defense and security is a notion long used by mankind, although this has taken on renewed significance with the advent of nuclear weapons in this century. The concepts are noted in Chapter 24.4, although many aspects of the facilities remain classified. Even the use of a London underground tunnel as a factory for the production of vital machinery during World War II was disclosed to the public only after 40 years. The Scandinavian countries have adopted the use of underground shelters in the planning of communities, and have combined the military function with peacetime civilian uses to justify the costs. In the United States, several facilities have either been built (such as the communications and command center at Cheyenne Mountain in Colorado Springs, CO, the satellite tracking station near Spokane, WA, and scattered missile silos in the western states) or envisaged (such as deep basing for the MX-missile). Ingenious excavation and hardening requirements have been developed for utilization in such facilities.

Because the principles of excavation are covered so well elsewhere in this *Handbook* (Sections 9 and 10), the emphasis of the current chapters is on applications.

Chapter 24.1
CIVIL WORKS TUNNELS FOR VEHICLES, WATER, AND WASTEWATER

J.E. MONSEES AND W.H. HANSMIRE

24.1.1 INTRODUCTION

As the population and congestion of urban areas increase, the demand for civil works tunnels to provide transportation, convey water and wastewater, and serve as passageways for pedestrians and utilities also increases. No two tunnels are ever the same because of the wide variation of conditions applying to individual tunnels:

1. They may be in soft ground, soft rock, hard rock, or a mixed-face combination of these.
2. They may have different geologic conditions such as ground water, in situ stresses, or geologic structures.
3. They may be built by different methods and equipment and supported and lined by different methods.
4. They may have different end uses.

For all of these reasons, and more, it is not possible to discuss in a single *Handbook* chapter all of the considerations that go into planning, designing, constructing, and operating tunnels for civil works. (Indeed, it could be argued that to attempt to do so might mislead some into thinking that civil tunnels are simple structures.) In this chapter, the goal is to discuss some of the major considerations that go into a civil tunnel system and thereby to raise the level of awareness of the reader that such tunnels are very complex structures. If this goal can be met, then the reader's appreciation of at least the general considerations relating to civil tunnels will be heightened, and he/she will better understand where to turn for more information and for resolution of those considerations. [One publication that all readers of this chapter will want to have in their libraries is *Guidelines for Tunnel Lining Design* (O'Rourke, 1984).]

In the usual case, civil tunnels are built to serve the populace. Thus they must be built where the people are, and their end points are generally fixed by existing infrastructure. The reader should contrast this situation to many other tunnel systems, for example, waste repositories, military installations, and power tunnels. In these latter cases, it is usually part of the designer's challenge to locate the tunnels in the best possible geology.

Given that civil tunnels must be built between existing end points, the challenge is to optimize the design to accommodate conditions encountered in between those end points. This challenge can be very demanding on the engineer's training, experience, and ingenuity because the optimization process can require making difficult decisions concerning trade-offs among options that usually are not simple to characterize.

24.1.2 GEOTECHNICAL INVESTIGATIONS

Geotechnical investigations play a principal role in the development of a civil tunneling project. These investigations provide the description of the general geologic conditions, estimates of soil or rock properties, approximations of the loading and interaction conditions applicable to the tunnel, estimates of the ground behavior during construction, and estimates of the impact of tunneling on the nearby surface and subsurface.

Geotechnical investigations should be conducted in a stepwise fashion, proceeding through reconnaissance, a preliminary program, and a final program. Areas of special concern during the investigation are summarized in Table 24.1.1. More detailed discussions of methods appear in Sections 4, 5, and 10.

24.1.2.1 Reconnaissance

Reconnaissance is the first step in the geotechnical exploration process. It should start with a visit to the site by the geotechnical engineer or engineering geologist, during which the whole alignment is inspected, preferably on foot. Outcrops, existing cuts, drainage, existing improvements, and existing tunnels should be inspected. Geophysical exploration methods may be helpful, as are aerial or satellite photographs, ground surveys, and historical records of other soil exploration programs and construction projects in the same geology. From this reconnaissance, the preliminary boring program is planned.

24.1.2.2 Preliminary Boring Program

This program should provide borings on a general pattern with extra borings at special features (e.g., faults) that were identified during reconnaissance and at any special construction feature (e.g., shafts). The borehole exploration program should be coordinated with the needs of the designer and supervised by a geotechnical engineer. Frequently, borehole programs are preceded by plotting and evaluating the available borings of others. Standards are given by the American Society for Testing and Materials (Anon., 1983) for borehole sampling and testing methods that include auger borings, split-spoon, and thin-walled "undisturbed" sampling, as well as the standard penetration and field vane shear tests. Additional in situ tests in soil include cone penetration and pressuremeter tests.

Coring with double-tube or triple-tube core barrels is used to investigate rock conditions. The core is evaluated on the basis of primary fracturing, strength, and weathering. Special borehole methods in rock include oriented core sampling, borehole photography, gas monitoring, overcoring grout-injected specimens to evaluate joint characteristics and small-scale voids, various overcoring and hydrofracturing techniques to determine in situ stresses, as well as water pressure tests to estimate permeability.

Boreholes provide essential information about the groundwater, including perched, artesian, and depressed water levels. Piezometers can be installed in selected boreholes to determine initial conditions and monitor changes in groundwater levels related to construction (O'Rourke, 1984).

Field pumping tests provide valuable data on dewatering requirements and potential construction effect; on local groundwater. Deep test pits provide for direct observation of subsurface conditions and the collection of block, or hand-cut, samples. Shallow test pits at existing foundations and utilities can be used to evaluate structural response to tunneling and to monitor movements and distress at critical locations. Exploratory or pilot tunnels, adits, and shafts are used on large projects when difficult tunneling conditions are anticipated. In some cases, geophysical techniques may be appropriate to delineate the top of rock between boreholes or to distinguish different types of subsurface materials with downhole applications of the technique (O'Rourke, 1984).

Table 24.1.1. Areas of Special Concern in Geotechnical Investigation for Tunneling

Planning, Design, Production of Contract Documents		Construction Methods		Influence on Adjacent Structures and Environment	
Selection of Tunnel Alignment and Profile	• Overall subsurface conditions. • Major discontinuities, contacts, unconformities. • Adjacent buildings and underground facilities.	Excavation and Disposal of Muck	• Variations of in situ structure and rock hardness, obstructions and cementation in soft ground. • Effect of mixing with water, contamination, leachates.	Hazardous Conditions	• Sudden falls, running, or flowing material. • Explosive or toxic gases. • Corrosive soil or groundwater. • Ground impregnation by waste leachate, leaking petroleum, chemicals, and sewage. • Contaminated tunnel soil.
Prediction of Ground Behavior	• Soil-like or rock-like performance. • Ground loads, stability, and deformation. • Permeability, groundwater inflows. • Joints, slickensides, shears, and faults.	Ground Stabilization	• Inherent stability and stand-up time. • Permeability and suitability for grouting or freezing. • Blow-out potential in compressed air.	Effects on Adjacent Structures	• Ground loss from tunneling, consolidation, blasting vibrations. • Disruption of or interference with utilities.
Selection of Tunnel Cross Section and Lining	• Relative stiffness of lining and ground. • Stability of crown, invert, and walls. • Effect of in situ structure on opening shape. • Tunnel orientation relative to in situ stresses.	Groundwater Problems	• Quantity and flow concentrations. • Running or piping of materials. • Need for control measures: drawdown, compressed air, grouting.	Changes in Groundwater	• Effects on wells, plantings, and natural vegetation. • Widespread consolidation by drawdown. • Long-term changes of groundwater level.
Decision Between Water Pressure Resistance or Relief	• Groundwater amount and quality. • Special watertightness membranes, leakproofing. • Corrosion, precipitates, clogging by fines.	Variation in Ground Conditions	• Variations from average conditions. • Strata changes, elevation changes along contact surfaces. • Number and orientation of discontinuities and faults. • Mixed-face conditions.		

Source: O'Rourke, 1984.

Note: Potential hazards should be identified according to natural and man-made origins. Natural hazards include toxic and explosive gases and large groundwater inflow. Man-made hazards include leachates, petroleum and chemical wastes, sewage, and buried or abandoned structures. In general, man-made hazards are most likely to be encountered in urban projects.

24.1.2.3 Final Boring Program

The final boring program is the third step in the exploration process, but often takes the form of a continuation and expansion of the preliminary boring program. The major change is the increase in number of borings (or decrease in average boring spacing). Typically, the final boring program includes borings at a maximum average spacing of 300 ft (90 m), but for some projects this average spacing may be 100 ft (30 m). Note that borings should have closer spacing in reaches of changing or troublesome geology, and may have wider spacing elsewhere. From this final boring program, the geotechnical engineer should have the data needed to prepare subsurface investigation and interpretation reports containing the information summarized in Tables 24.1.2a and 24.1.2b.

24.1.2.4 Borings in Rock

Borings in rock are usually continuous and are taken by means of a rotary drill rig using multiple-tube core barrels. A geotechnical engineer or engineering geologist should be in direct supervision and control of all boring operations and prepare (or supervise preparation by a qualified technician) a drill log of every hole drilled. This drill log should generally include the following information:

1. Drilling depth and/or elevation.
2. Sample number and conditions.
3. Detailed description of stratigraphy and lithology.
4. Water level.
5. Core recovery.
6. RQD (rock quality designation).
7. Weathering.
8. Bedding and/or joint spacing.
9. Discontinuity description:
   a. Bedding or jointing.
   b. Dip.
   c. Filling—type and degree.
   d. Surface—condition and roughness.
   e. Permeability.

Table 24.1.2a. Information to be Considered for Subsurface Investigation Report

A. *Reconnaissance and Geologic Background*
- Identify and describe lithological and structural units from maps, outcrop examination, geologic background.
- List appropriate references on local or regional geology, groundwater studies.

B. *Boring Log, Exploration, and Field Test Information*
- Log or record made by professional on site including quantitative data on depths, sampling, and recovery.
- Methods and equipment used in drilling and sampling.
- Descriptions of each sample or core and overall strata descriptions.
- Observations made during drilling: rate of advance, drill water conditions, bit pressure and rpm.
- Water level measurements: including times, dates, correlation with drilling operations, rainfall or open water.
- Special details of rock cores: character of discontinuities, joint and fault attitudes, core sketches and core photographs (in color where appropriate).
- Data on in situ testing: pump or packer tests, geophysical tests, deformation or strength tests.
- Presence of boulders and other obstructions.

C. *Laboratory Test Information*
- Diagrams and data sheets detailing test procedures and test results.
- Correlations between various properties, such as sand shear strength and relative density, uniaxial compressive strength and rock index properties.
- Properties of soil or rock grouped by strata or lithological units.

D. *Background Reference Information*
- Listing of technical references.
- Listing of drawings and information on adjacent structures, utilities, preexisting conditions.
- Sources of boring and testing information from other projects.
- Availability for examination of rock cores and soil samples.

Source: Modified from O'Rourke, 1984.

Table 24.1.2b. Information to be Considered for Geotechnical Interpretation Report

A. *Geological and Geotechnical Conditions*
- Interpretive geologic maps, cross sections, and soil profiles, separating and describing principal strata as determined from the field and laboratory investigations.
- Generalized properties of the strata recommended and utilized in design.
- Conclusions as to tunneling conditions expected, based on the geotechnical interpretation.

B. *Explanation of Design Assumptions*
- Criteria, assumptions, properties, and constraints utilized in design.
- Explanation for derivation of features of the technical specifications and limitations on construction procedures.
- Geotechnical criteria to be met by contractor's submittals for temporary support, cofferdams, shop drawings, or value engineering proposals.

Source: Modified from O'Rourke, 1984.

f. Slickensides.

10. Remarks, observations.

In addition to these data, it may be desirable to obtain other properties, such as rock-mass moduli, in specially designed field tests.

24.1.2.5 Borings in Soil

Borings in soil should be taken with a modern sampling barrel that incorporates a sample catcher, and should be as nearly undisturbed as technology permits. As a minimum, tube samples should be taken at intervals of 5 ft (1.5 m) or at every change of geology. As with rock borings, soil borings should be under the direct supervision and control of a geotechnical engineer or engineering geologist. This supervisor should also prepare or supervise the preparation of boring logs that contain the following as a minimum:

1. Drilling depth and/or elevation.
2. Soil description following the Unified Soil Classification System.
3. Water level.
4. Penetration resistance.
5. Pocket penetrometer or shear vane.
6. Remarks, observations.
7. Permeability.

24.1.2.6 Laboratory Tests—Rock

Laboratory tests on rock samples generally should consist of the following:

1. Unit weight.
2. Unconfined compressive strength.
3. Triaxial strength parameters.*
4. Shear tests on joints and joint fillings.*
5. Modulus.*

*as project conditions require

Other special tests, such as hardness, slaking, or swelling tests, may be required for specific project or geologic conditions. The requirement for such special tests must come from the design and geotechnical engineers.

24.1.2.7 Laboratory Tests—Soil

Similarly, laboratory tests on soil samples generally should consist of the following:

1. Moisture content.
2. Atterberg limits.
3. Grain size distribution.
4. Unit weight.
5. Unconfined compressive strength.
6. Direct shear strength.*
7. Triaxial strength.*
8. Modulus.*
9. Consolidation.*

*as project conditions require

As above, special tests may be required by the geotechnical or design engineers.

24.1.3 SOFT-GROUND TUNNELING

Soft-ground tunneling is defined as tunneling in ground that could be excavated by hand tools, although such hand excavation rarely occurs in today's world (McCusker, 1982).

Table 24.1.3. Ground Classifications for Soft-ground Tunneling

Classification	Behavior	Typical Soil Types
Firm	Heading can be advanced without initial support, and final lining can be constructed before ground starts to move.	Loess above water table, hard clay, marl, cemented sand and gravel when not highly overstressed.
Raveling, slow, fast	Chucks or flakes of material begin to drop out of the arch or walls sometime after the ground has been exposed, due to loosening or to overstress and "brittle" fracture (ground separates or breaks along distinct surfaces, opposed to squeezing ground). In *fast raveling* ground, the process starts within a few minutes; otherwise the ground is *slow raveling.*	Residual soils or sand with small amounts of binder may be fast raveling below the water table, slow raveling above. Stiff fissured clays may be slow or fast raveling depending upon degree of overstress.
Squeezing	Ground squeezes or extrudes plastically into tunnel, without visible fracturing or loss of continuity, and without perceptible increase in water content. Ductile, plastic yield and flow due to overstress.	Ground with low strength. Rate of squeeze depends on degree of overstress. Occurs at shallow to medium depth in clay of very soft to medium consistency. Stiff to hard clay under high cover may move in combination of raveling at execution surface and squeezing at depth behind face.
Running: cohesive, running	Granular materials *without cohesion* are unstable at a slope greater than their angle of repose (±30°–35°). When exposed at steeper slopes they run like granulated sugar or dune sand until the slope flattens to the angle of repose.	Clean, dry granular materials. Apparent cohesion in moist sand, or weak cementation in any granular soil, may allow the material to stand for a brief period of raveling before it breaks down and runs. Such behavior is *cohesive running.*
Flowing	A mixture of soil and water flows into the tunnel like a viscous fluid. The material can enter the tunnel from the invert as well as from the face, crown, and wall, and can flow for great distances, completely filling the tunnel in some cases.	Below the water table in silt, sand, or gravel without enough clay content to give significant cohesion and plasticity. May also occur in highly sensitive clay when such material is disturbed.
Swelling	Ground absorbs water, increases in volume, and expands slowly into the tunnel.	Highly preconsolidated clay with plasticity index in excess of about 30, generally containing significant percentages of montmorillonite.

Source: Modified from Terzaghi by Heuer, McCusker, 1982.

24.1.3.1 Ground Classification

Ground classifications for soft-ground tunneling were proposed by Terzaghi (1977) and have been modified by several authors, notably Heuer and Virgens (1987). These classifications are described in Table 24.1.3 and approximately correlated to grain size in Fig. 24.1.1. For further discussion of the stability and behavior of soils in soft-ground tunnels, the reader should refer to McCusker (1982), Clough and Schmidt (1981), and Terzaghi (1977).

24.1.3.2 Tunneling Methods

Soft-ground tunnels are nearly always excavated by means of a tunnel shield that is usually, but not always, circular. Within the shield, which can be thought of as a "cookie cutter" pushed horizontally through the ground, the workers excavate the ground and erect the initial support system in relative safety. Shields were first designed by Brunel in London in 1825. The modern shield takes numerous forms:

1. Simple Brunel-like cylinders using shove jacks in the rear and breast jacks in the face, with excavation in free air by hand.
2. Mechanized digger shields using hydraulic diggers much like a backhoe to excavate, and breast jacks and tables to control the face.
3. Mechanized digger shields using rotating cutterheads to excavate and variable "shutter" or "guillotine" doors to control the face.
4. Slurry face machines that maintain pressure on the face with a slurry of excavated soil or outside material (bentonite) to support the face, with excavation by a rotating cutter.
5. Earth balance machines that support the face by trapping and controlling the material removed from the face, thereby maintaining a soil pressure on the face equal or nearly equal to its in situ pressure, with excavation by a rotating cutter.

Because of a myriad of geologic and tunneling conditions, soft-ground tunneling employs a corresponding myriad of combinations of tunneling equipment. Often, for example, the shield is coupled with compressed air to tunnel in conditions where the soil strength (and stability) is low or the water table is high or where both obtain. The compressed air improves the face stability and keeps water out, but, depending on pressure level, can lead to severe working-time restrictions due to decompression requirements. For a more thorough discussion of soft-ground tunnel equipment types and operations, readers are referred to Stack (1982). It is noted that US practice tends to lean toward the more basic tunnel shields summarized in items 1, 2, and 3 above, while European and Japanese practice tends to lean towards the more mechanized equipment summarized in items 4

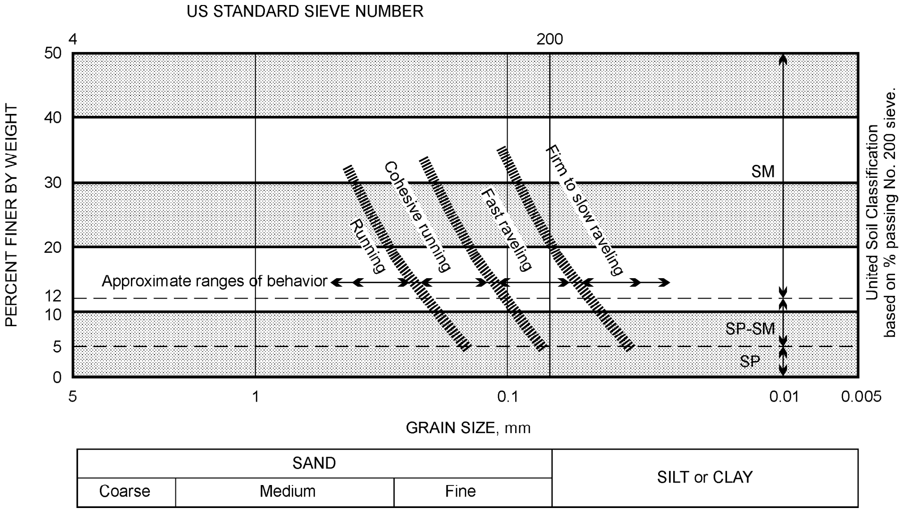

Fig. 24.1.1. Anticipated ground behavior based on D_{10} size. Shown for dense soil N 30, above water table (adapted from Heuer and Virgens, 1987).

and 5. Undoubtedly, the latter are the trend of the future and will be used more in the United States as time passes.

24.1.3.3 Soft-ground Tunnel Lining and Support

Soft-ground tunnels are typically supported by one of two general systems: (1) segmental precast concrete tunnel liners serving as both initial support and final lining, and (2) initial support by ribs and boards or low-cost precast concrete segments followed by a final lining of cast-in-place concrete. In some instances, but rarely in current times for extensive works, segmental steel or cast iron segments may be used as both initial support and final lining.

Precast Concrete Tunnel Liners. This lining serves as both the initial support and final lining. Construction is usually by traditional shield and the most severe loading the lining may experience is often at the time of construction. Fig. 24.1.2 illustrates one representative segment, its reinforcing, and bolt pocket layout.

The criteria for structural adequacy of the segmental lining are as follows:

1. Flexible behavior. The lining must be sufficiently flexible to be able to deform in response to an unbalanced load. Passive support pressures in the ground must be mobilized through ring deformations that do not induce unacceptable effects in the lining.

2. Sufficient strength for combined thrust and bending. Reinforced concrete design methodology is used to determine the design strength of the lining. In establishing the required strength, the behavior of the lining must be considered as being interactive with the surrounding ground. Special attention must also be given to the effective stiffness of the lining.

3. Constructability. Before the lining is subjected to earth loading, adequate provisions must be made for element handling, erection, bolting, shoving of the shield, expanding (sometimes), and grouting.

Design Approach. Structural capacity of the lining is determined in accordance with ACI 318; the lining is generally considered flexible, as originally outlined by Peck (1969). Hansmire et al. (1989) give an overview of design trends for flexible tunnel linings. Over time, research and experience have contributed to quantifying, refining, and broadening the lining design approach. For nearly all soft-ground tunnels, the tunnel lining is considered flexible, that is, one that deforms and interacts with the surrounding ground. The measure of flexibility is the flexibility ratio F, which is defined as

$$F = \frac{\dfrac{E_m}{(1 + \nu_m)}}{\dfrac{6EI}{(1 - \nu_\ell^2)} \dfrac{1}{R^3}} \tag{24.1.1}$$

where E_m is modulus of soil surrounding the tunnel, E is modulus of tunnel lining, I is moment of inertia of tunnel lining per unit length, $\nu_{m,\ell}$ is Poisson's ratio of soil and lining, respectively, and R is tunnel lining radius.

The relationship of moment in the lining to lining flexibility is illustrated for theoretical cases in Fig. 24.1.3. The moment has been made nondimensional as a moment coefficient by dividing by the factor γHR^2. For most practical applications, the lining can be considered flexible when $F > 10$.

The lining as installed has nonuniform properties about its periphery because of such items as bolt pockets and staggering of joints between rings. Joints between the segments act like partial hinges. The value of the moment of inertia varies from that of the solid section to a lower value at the nonuniformities. In view of these considerations, the lining usually does not behave as an intact, elastic ring of uniform stiffness.

Muir Wood (1975) suggests that owing to the influence of joints, the stiffness of the tunnel lining might be reduced to one-fourth the full lining value for an eight-segment lining. Analytical studies by Paul et al. (1983) of the effects of joints in segmented linings show the effective stiffness to be from 30 to 95% of the intact ring case. The reduction in stiffness was greatest for lower flexibility.

A further consideration in the stiffness of the tunnel lining is that reinforced concrete behaves in a nonlinear fashion. As the lining is subjected to thrust and bending, it cracks, behaves in a less stiff manner, and helps redistribute moment. Analysis, however, usually makes an assumption of linear properties. The result is that the linear analysis suggested herein typically underestimates the load-carrying capacity of the lining.

For analysis of strength required, the authors normally assume that the stiffness of the lining (EI) for the full section could be halved ($EI/2$). Parameter studies and design analysis use various values to test sensitivity to this assumption.

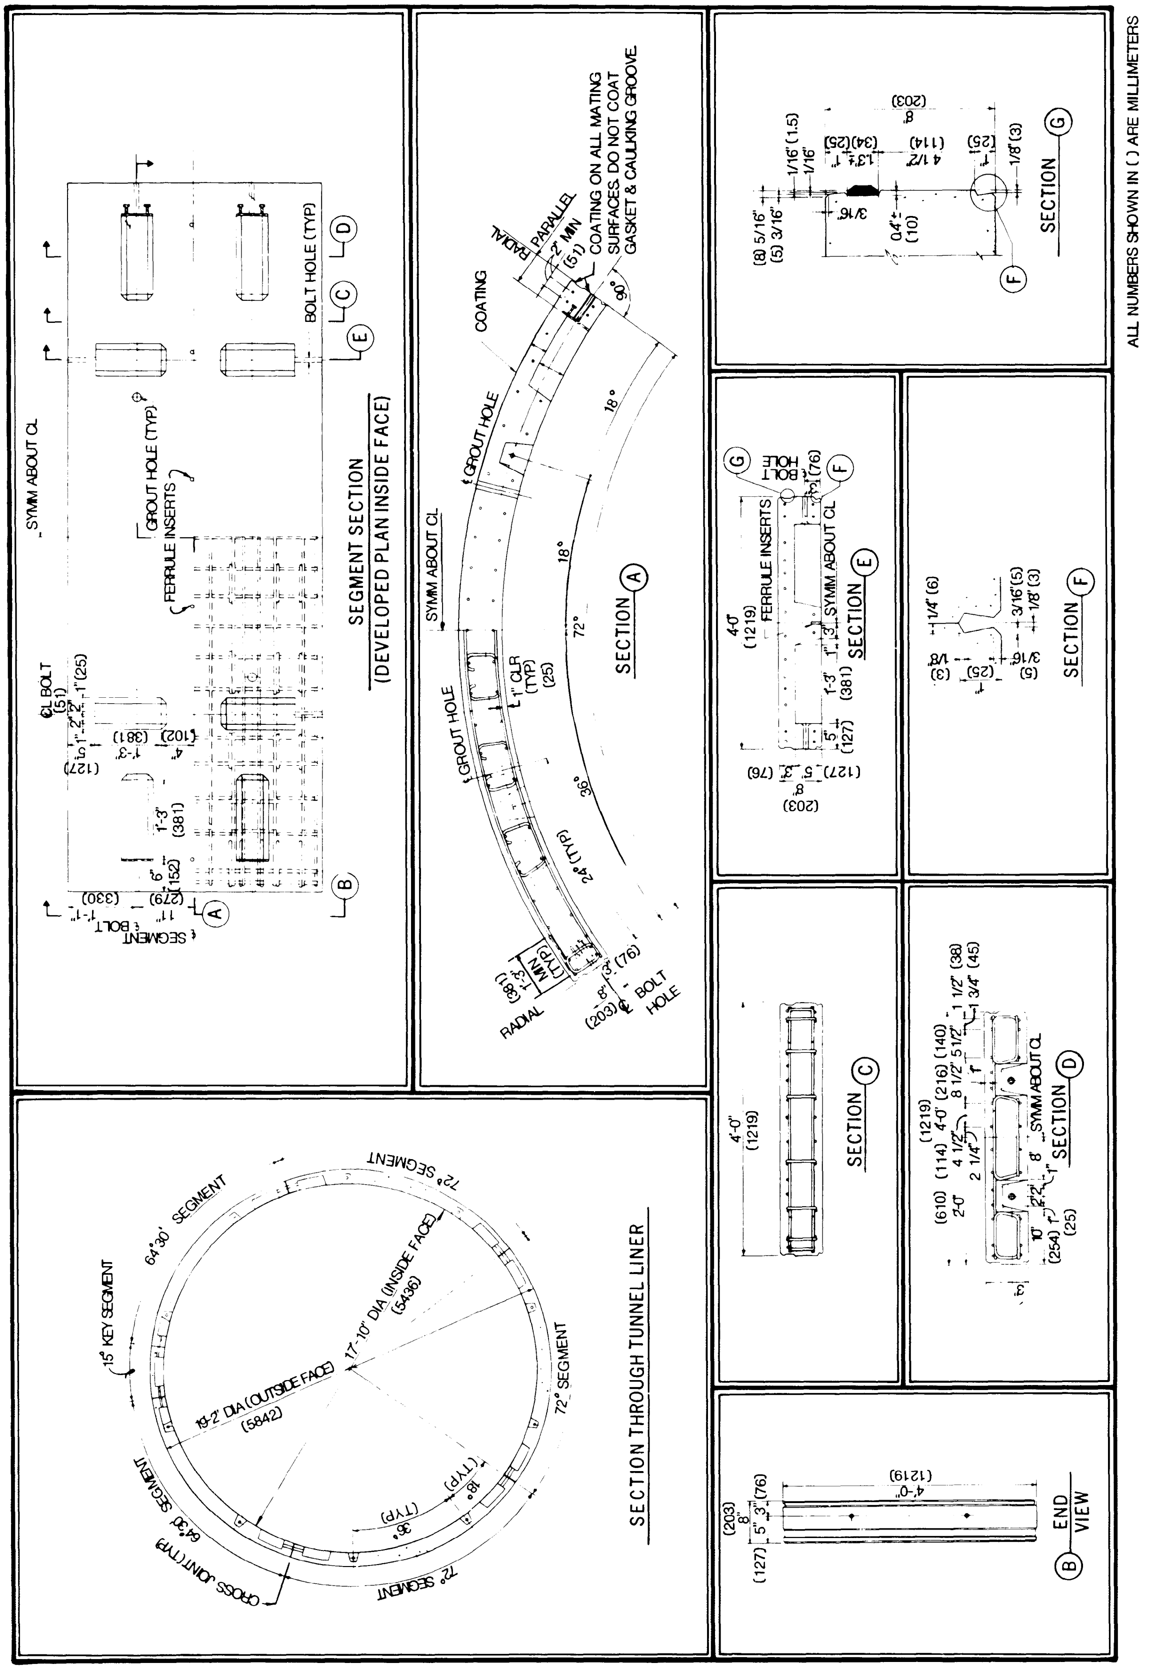

Fig. 24.1.2. Precast concrete segmented liners. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

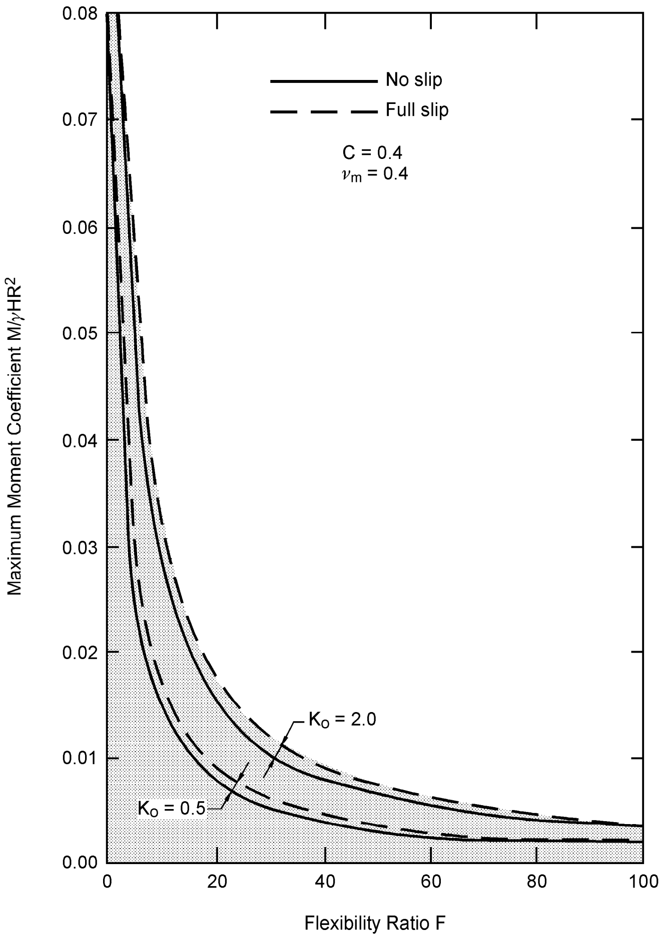

Fig. 24.1.3. Maximum moment coefficient as a function of the flexibility ratio (adapted from O'Rourke, 1984).

In all but the empirical methods (discussed later) for tunnel lining design, an assumption must be made about the state of stress in the ground prior to tunneling (K_o) or the ratio of unbalanced loads on the tunnel lining (K). As used herein, K_o is defined as the ratio of horizontal to vertical stress in the soil prior to tunneling. The parameter K is the ratio of unbalanced load (horizontal to vertical) that produces moment in the tunnel lining, and, except for a perfectly rigid lining, generally will be between the value of K_o and 1.0.

Most design approaches recognize that the lining must be able to withstand an "unbalanced loading" between vertical and horizontal forces. In conjunction with relative lining stiffness, the assumed final unbalanced loading will control the structural requirements for earth loading.

The assumption of a stress ratio K_o in two-dimensional analyses is inconsistent with the stress relief that results from excavation prior to lining installation. Stress is first relieved directly by excavation at the tunnel face. Furthermore, the lining is not installed at the face, but about one tunnel diameter behind. In a sand, or almost any soil except a soft clay, the actual loading may be a modest gravity loading of soil dropping into the tail void and would have little relation to the original state of stress in the ground.

If it is assumed that the initial stresses are unloaded during construction and will not be reestablished in the long term, extreme values of K_o cannot be used. In a sense, then, the selection of K_o is a judgmental factor that fits the designer's perception of an adequate design. For most projects, an unbalanced loading ratio of K or $K_o = 7/8$ is judged to be adequate for analysis (Schmidt, 1984; Hansmire et al., 1989).

The design must recognize that loading of a tunnel lining is different in nature from that of aboveground structures. The loading a tunnel lining will experience is often dictated by geologic details. The design approach is to select loadings consistent with geologic conditions and construction procedures. Maximum, or extreme, loadings are assumed to have little uncertainty. In such cases, there is no need to include an additional margin of safety by applying load factors. In the analysis of less extreme cases, a load factor would typically be used. This approach generally follows the philosophy expressed in O'Rourke (1984).

For analysis of most loadings, a load factor of 1.4 is recommended where deemed appropriate. When an earth loading equal to full overburden is used, the authors believe a load factor of 1.4 is excessive because loads generally cannot exceed full overburden.

DESIGN ANALYSIS. Realistic assumptions must be made in the analyses. Assumptions of various parameters must recognize not only the intrinsic properties of the lining but also the limitations of the analytical model in representing the true physical conditions.

The *empirical design approach* proposed by Peck (1969) assumes a lining load corresponding to full or partial overburden, and a bending moment corresponding to a diametric distortion of the lining. Moment in the lining is computed by the relationship

$$M = \frac{3EI}{R}\frac{\Delta D}{D} \tag{24.1.2}$$

where ΔD is diameter change and M is moment, with other terms as defined before.

The value of diametric distortion ($\Delta D/D$) is assumed on the basis of experience. A value of 0.5% was originally proposed, based on experience with segmented metallic linings. In general, a precast lining that is analyzed as an intact ring cannot be designed within ACI code requirements for such a distortion in the low-thrust range common to shallow tunnels where bending strength is exceeded without the beneficial action of lining thrust.

Schmidt (1984) recommends several values that depend on soil type. For dense sands, a range of $\Delta D/D$ from 0.05 to 0.25% is given. For recent subway project analysis purposes, the value of 0.5% $\Delta D/D$ has been used, but $EI/2$ was used for lining stiffness.

The *empirical method* with an assumed diameter change and full (or partial) overburden thrust is often regarded as the primary method of analysis. Using an adjusted lining stiffness, the lining must accordingly be designed for the resulting bending moment with the appropriately selected thrust. In general, for most civil tunnels, full overburden thrust is readily accommodated by a precast concrete lining and high thrust is desirable to offset the tensile component of bending. The more critical case is for low thrust, which may exist during construction immediately behind the shield, or in tunnels with very low cover. In such cases it may be necessary to control the ovalling distortion of the lining until grouting is complete.

Closed form solutions from continuum mechanics exist for computing thrust and moment in a tunnel lining. As presented in Ranken et al. (1978), this is termed "excavation loading." Compared to other approaches, this approach usually represents a lower bound. The value of such solutions is largely to illustrate the significance of lining flexibility to bending moment. The analysis is limited in that K_o must be assumed, and computations are usually directly proportional to the assumed depth of tunnel. This analysis best characterizes lining behavior where the lining is installed at the tunnel heading with minimal loosening of the ground. The closed-form interaction analyses poorly model the conditions in which loosening loading is expected to be the primary loading. On the other hand, the analyses may more closely represent long-term conditions for tunneling in weak ground where the lining may receive its major loading from long-term conditions in the surrounding ground.

Analyses using *closed-form* continuum mechanics equations provide a convenient tool for parameter studies. For the modest lateral earth pressure coefficients assumed, computed thrusts and bending movements should be well within the strength capacity of the lining.

Ground-lining interaction may also be modeled by a series of *beams and springs.* In a general structural frame analysis computer program, the lining is represented as a series of straight beams. Horizontal and vertical (or radial and tangential) springs model reaction of the soil. Assumed loads from earth and groundwater are input as forces at the joints. A gravity loading of soil acting as a dead load on the lining is simulated. Lateral loading is input at the tunnel sides as required to simulate an unbalanced loading on the tunnel lining. A soil reaction develops around the lining in accordance with the relative stiffness of lining and soil. The final loading on the lining is determined from the addition of the forces input and the forces resulting from lining-soil interaction. The final unbalanced loading on the lining generally will be less severe *(K* higher) than that assumed for input forces only.

Beam-spring methods of analysis are outwardly attractive because they simulate the real physical structure. Loads are imposed as in the analysis of an aboveground structure. Both gravity loads from disturbed soil above the tunnel, and groundwater loads are simulated directly.

One of the greatest areas of confusion in the beam-spring type of analysis is distinguishing between what causes thrust and what causes bending in the lining. Full overburden thrust does not necessarily mean the lining is carrying the dead weight of all directly overlying soils (a gravity load). Arching theories indicate that in a deep tunnel, it is not possible for a loosening load, as in a sand, to be as great as full overburden pressure. Significant thrust can come from interaction of the lining with a stressed medium, such as that existing near the tunnel heading. This is generally called "excavation loading." For high-input loads, the beam-spring analysis produces unrealistic results because the computed bending moment is directly proportional to the tunnel depth. A full overburden ground load therefore is not appropriate, particularly for many civil tunnels.

The conclusion regarding the beam-spring type of analysis is that loading must be restricted to a loosening load. This loosening load will be less than full overburden for tunnels with more than about two diameters of soil cover. With the beam-spring analysis restricted in this way, computed results for bending moment are similar to those obtained in the empirical approach.

Construction loads often represent some of the most severe loadings the tunnel lining experiences. Handling loads take place during construction and are not the result of earth loading. Several stages of handling of segments are required from the time of casting through final erection of segments into a ring within the tail of the shield.

A significant jacking load occurs on the circumferential joint of the segments as the tunnel shield is advanced by shoving on the previously erected tunnel lining. In general, reinforcing of the lining must be designed to accommodate the planned shield jacks about the tunnel periphery. Final design of the tunnel shield, including the shield jacking system, is the responsibility of the tunneling contractor. The contractor must, therefore, verify that the precast lining is compatible with the jacking system.

The ability of the lining to carry the jacking load is highly affected by details of the lining joint configuration and by eccentricity of the shield jack loading. Over the gross thickness of the lining, the average stress from jacking is usually acceptable. However, the requirements for a gasket and caulking groove in the lining may leave much less area for seating of the shield jack reaction. At bolt pockets, a locally weaker section exists. Finally, shield steering requirements often place very unbalanced jacking loads on the lining. To meet all these conditions, higher strength concrete and strict limitations on the center of force of the shield jacks may be required.

Grouting or segment ring expansion is required to fill the tail void that is created as the tunnel lining emerges from the tail of the shield. Typical grout holes should be uniformly spaced and grouting pressures controlled; grouting produces thrust that is beneficial in accommodating bending, but uneven grouting can produce bending. Experience shows the lining can usually withstand the loading from such grout pressures as a temporary loading.

CAST-IN-PLACE TUNNEL LININGS. The cast-in-place lining design recognizes that the tunnel is built in two stages. At the time of excavation, an initial support, consisting of simple precast segments or steel ribs with timber lagging, is erected and expanded against the soil immediately behind the tail of the shield. At that time, the initial supports absorb initial ground loads and undergo distortion. The final cast-in-place concrete lining is placed weeks or months later. Thus, at least initially, the final lining will not take load directly from the ground. The most significant loadings will be from contact grouting or from future stress changes such as those resulting from building construction over or near the tunnel.

Criteria for structural adequacy of the cast-in-place liner are as follows:

1. Sufficient strength for contact grouting.
2. Sufficient strength to accommodate future stress changes.
3. Constructability (minimum thickness for concreting).

It is recognized that cast-in-place linings have significant strength even without steel reinforcing. In pure thrust, the lining generally has more capacity than is required for loads from grouting, from other future influences, or from the extreme case of full overburden weight of soil. Bending resulting from unbalanced loading on the lining is usually the largest factor.

Steel reinforcing is sometimes placed at springline as an outside ring to give bending strength for the common case of slight vertical squatting deformation of the tunnel. If the lining were carrying significant thrust, the lining would theoretically have adequate capacity to accommodate bending without this reinforcing. Placement of the reinforcing is considered a conservative measure. The reinforcing does have a beneficial action in controlling cracking should bending take place.

In the crown over a 60° arc about the centerline, similar reinforcing is sometimes placed at the inside face of the lining. This reinforcing is included for structural reasons for the bending induced by squatting of the tunnel. As with the sidewalls, the reinforcing reduces or distributes cracking. The reinforcing is also desirable to maintain the integrity of the lining and to prevent the extremely remote possibility of a wedge or slab of concrete falling from the crown.

The general considerations summarized in the discussion regarding analysis for the precast lining apply in varying degrees for the cast-in-place lining. Two different approaches to analysis of the cast-in-place lining are recommended and are summarized in the following paragraphs.

Based on the premise that future construction may take place above or near the tunnels, it may be assumed in the *empirical approach* that a $\Delta D/D$ of approximately 0.25% may occur. This diameter change is assumed to occur because of a change in stress conditions resulting from excavation and later loading by building foundations or by other construction. Since the future buildings may be above or to the side of the tunnel, it is assumed that the $\Delta D/D$ might impact the tunnel from any direction. When making calculations involving $\Delta D/D$, an effective modulus of elasticity for concrete of $E/2$ may be assumed because any such deformations would occur over a long period of time. Creep experienced by the concrete as the result of this slow deformation would make the lining act with reduced stiffness. A soil loading of approximately one tunnel diameter is usually used, arguing that a properly installed initial support system will not permit significant loosening or other load development on the final lining.

Alternative analyses are also performed to evaluate the structural adequacy of the lining. A *beam-spring model,* similar to that discussed above, may be used in a structural analysis program to simulate the lining. Vertical and horizontal loadings must be assumed. Computations for several assumptions produce thrusts and moments that are analyzed by means of an interaction diagram.

For all of the analyses outlined above (i.e., precast and cast-in-place linings), values of moment and thrust in the lining are estimated, and it is necessary to compare them with allowable values. The recommended method for making this comparison is to use the moment-thrust diagram as summarized in the next section.

NONLINEAR RESPONSE OF CONCRETE LININGS. When the thrust and moment around the lining have been calculated, it is necessary to evaluate these quantities in comparison with allowable values. Normally, it is necessary to make this comparison only at locations where one of the quantities is maximum or where there is an abrupt change in the lining section. Moment and thrust interact strongly, so it is customary to check these parameters together by using the *moment-thrust (M-T) interaction diagram* to represent the allowable combinations. The *M-T* interaction diagram can be drawn for each section of the lining and depends only on the section dimensions and material properties.

One way to obtain an *M-T* interaction diagram is to use the procedure of the ACI Code (Anon., 1987). In this procedure, the combinations of moment and thrust, which cause theoretical failure of the section under unconfined conditions, are computed and shown on a diagram in which thrust and moment are the axes. A general *M-T* diagram for a tunnel lining is shown in Fig. 24.1.4. This diagram may represent the full lining section if it has constant dimensions and composition, or several such diagrams may be used to represent different lining sections.

To determine whether the section for which the *M-T* diagram in Fig. 24.1.4 is adequate, the moment and thrust combination obtained in the analysis should be plotted on a project-specific diagram like that shown. The material factor in the ACI Code procedure is used as a safety measure to cover uncertainties in material properties, determination of section resistance, and the difference between concrete strengths from cylinder tests and the structure. If the moment and thrust combination lies inside the diagram, the section is adequate. As discussed earlier, the loads on the lining may be multiplied by a load factor to give the moment and thrust combination an additional margin of safety. Readers should refer to O'Rourke (1984), Paul (1983), and Hansmire (1984) for a more thorough discussion of the *M-T* diagram and its application.

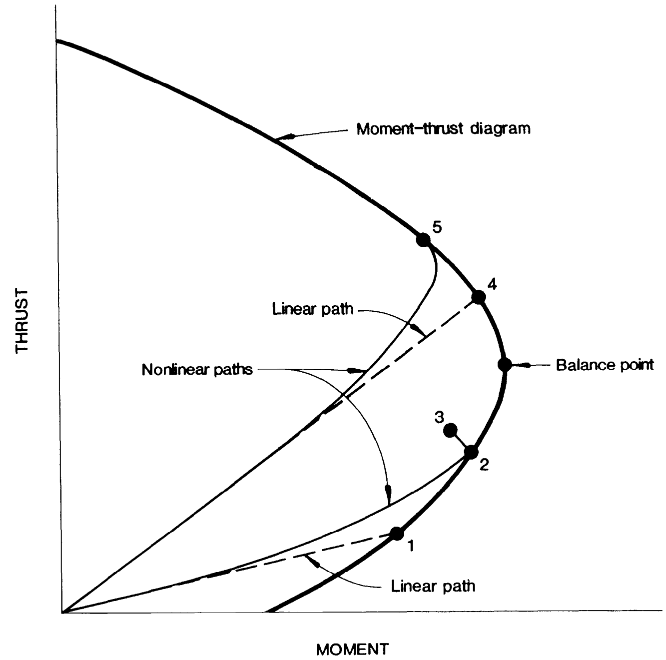

Fig. 24.1.4. General moment-thrust (*M-T*) diagram for a reinforced concrete lining with linear and nonlinear moment-thrust paths (adapted from O'Rourke, 1984).

24.1.4 SETTLEMENTS

It is a fact that ground movements take place during soft-ground tunnel construction. For most civil projects, the tunnels are shallow enough to result in surface settlements. However, few subsurface measurements were made about soil tunnels until the early 1970s. Since then, much has been learned from the Washington, DC, and Baltimore, MD, transit tunneling experiences about how ground movements around a tunnel are complexly related to surface settlements. In understanding these settlements, it is considered important to distinguish "volume of lost ground" from the "volume of settlement observed at the surface." Fig. 24.1.5 illustrates the distinction between the volume of lost ground and volume of surface settlements. Definitions are as follows:

1. *Volume of lost ground* (V_L): The sum of all ground movements taking place immediately about the tunnel periphery.
2. *Volume of surface settlement* (V_s): The sum of settlement at the ground surface.
3. *Volume change* (ΔV): Increases or decreases in soil volume above and adjacent to the tunnel.

For general usage, equating the volume of surface settlement to the volume of lost ground is acceptable. However, in many materials, increases in soil volume (or bulking) for a single tunnel can be very significant. Without allowance for volume increases, the surface settlements may be significantly overstated.

24.1.4.1 Volume of Lost Ground.

Lost ground occurs about the tunnel in three forms:

1. *Face loss:* Lost ground that occurs ahead of the shield in the form of soil squeezing, flowing, or running into the heading.
2. *Shield loss:* Lost ground that takes place from the time the leading edge of the shield passes a section until the tail of the shield passes that section. Shield loss takes place on account

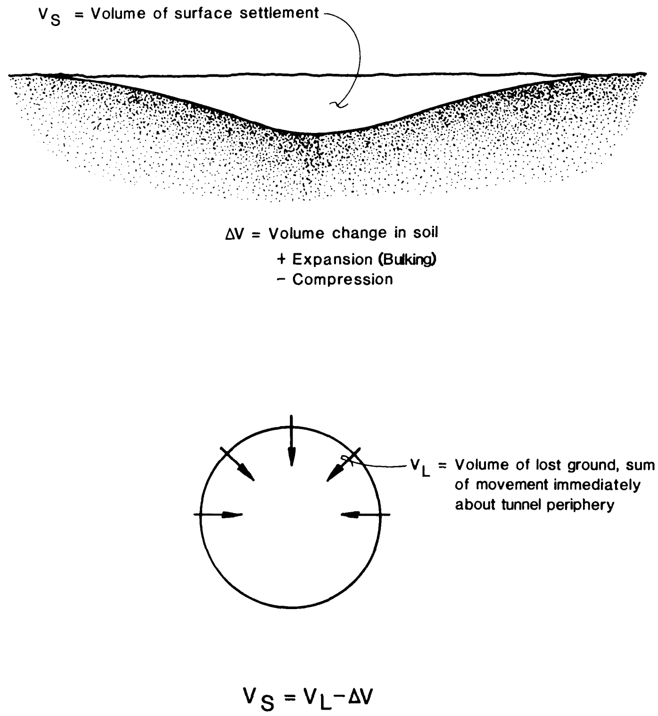

Fig. 24.1.5. Terminology for tunneling settlement and lost ground.

of shield actions (plowing, changes in pitch or yaw), from the void created by overcutters, or by overexcavation.

3. *Tail loss:* Lost ground that occurs after the tail of the shield passes a section. Tail loss results from insufficient filling of the tail void because of incomplete grouting or insufficient expansion of support members.

This segment presents judgmental expressions of the quality of the ground or workmanship in relation to tunneling. The following definitions are established:

1. *Good tunnel ground:* In most instances, this is synonymous with "firm ground" as defined by Peck (1969) or Terzaghi (1977).

2. *Good tunneling practice:* Expression used to describe the high quality and appropriateness of both tunneling procedure and workmanship for a particular ground condition. In general, this means

a. Tunnel face is supported as required to prevent loss through front of shield.

b. Shield design that minimizes ground disturbances (minimal overcutters, minimal overexcavation, easily steered, which means length/diameter < 0.9, unless articulated).

c. Tail loss minimized by preventing closure of tail void (such as by use of thin tail piece, good expansion of lining, and grouting behind lining during and after shove).

Two means are frequently used to estimate the volume of lost ground anticipated. The first uses past field measurements as precedents. The second uses estimates based on the source of lost ground.

Field measurements from past tunneling experiences in the United States are mostly from Washington, DC, and Baltimore, MD. Tunnels constructed with good procedures for tunneling in sand were able to achieve approximately 1% volume of lost ground. Average values measured were in the range of 1.5 to 3%.

Table 24.1.4. Volume of Lost Ground and Quality of Tunneling Practice

Case	V_L, %
1. Good practice in firm ground —Applies to better soils and excellent ground control	0.5
2. Good practice in slow raveling ground —Considered good ground	1.5
3. Fair practice —More shield and tail loss	2.5
4. Poor practice —Yet more shield loss —Tail void mostly unfilled	4.0

As an alternative to using past field measurements, estimates based on the source of lost ground may be used. As previously discussed, lost ground occurs in three forms: face loss, shield loss, and tail loss. The amount of lost ground is dependent on several factors relating to construction method and workmanship, as well as tunnel ground conditions. Estimates for volume lost for several cases are given in Table 24.1.4.

Larger ground losses can be encountered if large losses occur at the face. For example,

1. Boulders caught in the cutterhead of a shield with a rotating excavator could result in very large volumes of lost ground.

2. A run or flow of soils at the face of a shield could also result in significant ground losses.

3. Uncontrolled squeezing of clays or silts occur.

4. Consolidation settlements occur.

Such events are considered the result of poor workmanship (poor practice) and are to be avoided by strict contractual requirements.

On the basis of the foregoing concepts, a volume of lost ground equal to 1.5% of the tunnel volume is often used as a first approximation for analyses of tunneling settlements. This value applies to good tunneling practice in good tunneling ground and must be evaluated for each tunnel project.

For most practical computation purposes, the settlement analyses make several assumptions. For the individual tunnel, bulking is assumed for high soil cover areas. For shallow cover, volume of surface settlement for the individual tunnel is assumed equal to lost ground. Total settlements calculated for parallel tunnels are assumed equal to the straight addition of individual settlements for the first and second tunnels. No extra settlements are assumed for the pillar effect.

DISTRIBUTION OF SETTLEMENT. Generally, the shape of the settlement trough at the ground surface resembles that of an inverted bellshaped probability curve. This concept was used by Peck and others (including Schmidt, 1969) to correlate field measurements of trough width for several cases. Geometry of the settlement trough is illustrated in Fig. 24.1.6. In all cases in the calculations, the ground surface is assumed at the bottom of the building footing, and the influence of building stiffness is ignored.

The width of the settlement trough is measured by an "i-value," which is theoretically the horizontal distance from the location of maximum settlement to the point of inflection of the settlement curve. The maximum value of the surface settlement is theoretically equal to the volume of surface settlement divided by 2.5i.

Fig. 24.1.7 illustrates connections that have been made between settlement trough width and ground type through the use of the bell-shaped probability curve. The tunnel depth and settlement trough widths are simplified as ratios of the tunnel

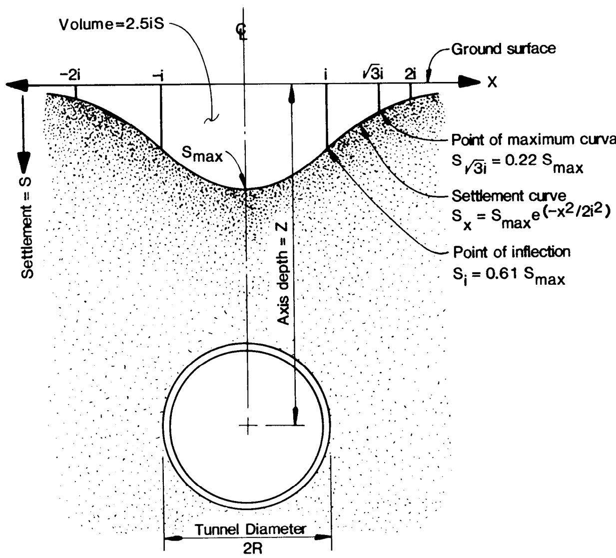

Fig. 24.1.6. Properties of probability curve as used to represent cross section of settlement trough above tunnel (adapted from Peck, 1969).

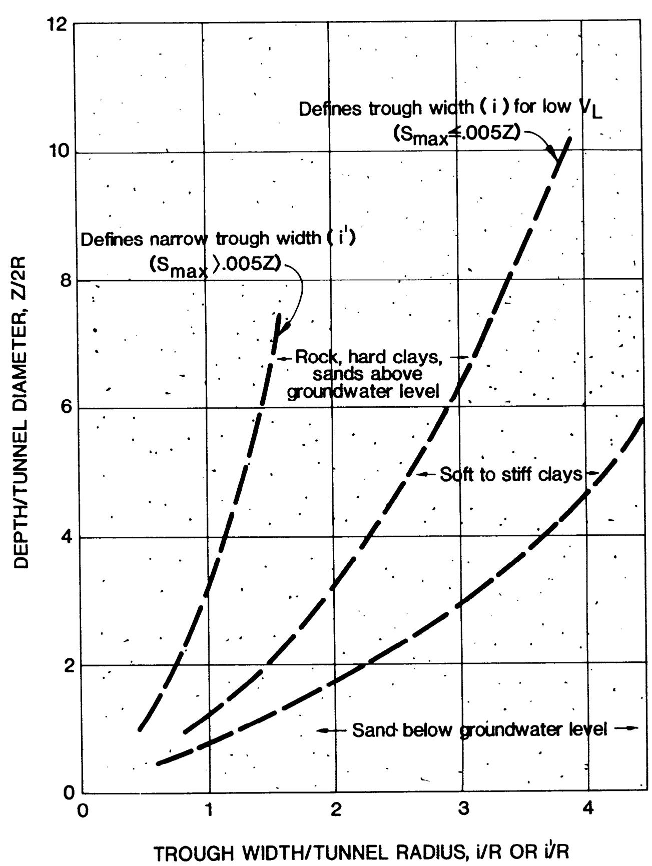

Fig. 24.1.7. Assumptions for width of settlement trough (adapted from Peck, 1969).

radius ($Z/2R$ and i/R). The trends in Fig. 24.1.7 illustrate that generally wider settlement troughs are associated with soft clays, while narrower troughs occur in stiffer materials such as dense sands. The deeper the tunnel, the wider the settlement trough.

Detailed field measurements have illustrated that the real and complex nature of tunnel settlements cannot be reduced to a simple precise correlation. For example, settlements will vary in a nonlinear way with the absolute magnitude of settlement (such as an ultimate case of forming a sinkhole at the ground surface). Also, geologic details such as stiff or loose layers of soil will strongly affect how ground loss about a tunnel becomes surface settlements. Detailed examples of actual measurements of ground movement about tunnels in sand are given in Cording and Hansmire (1975), and in clay in Palmer and Belshaw (1979, 1980). However, despite the inherent complexity, the correlations in Fig. 24.1.7 make possible a preliminary estimation of the settlement resulting from tunneling.

INFLUENCE OF SETTLEMENT—POTENTIAL FOR STRUCTURE DAMAGE. Having estimated the settlements (and recognizing that the estimates are often quite crude), the engineer should then evaluate the possible impact of that settlement on overlying structures. For reference in discussion, the following definitions from Boscardin and Cording (1989) of categories of building damage are made:

1. *Architectural damage:* Damage affecting the appearance of structures, usually related to cracks or separations in panel walls, floors, and finishes. Cracks in plaster walls greater than $\frac{1}{64}$-in. (0.4-mm) wide and cracks in masonry or rough concrete walls greater than $\frac{1}{32}$-in. (0.8mm) wide are considered to be representative of a threshold where damage is noticed and reported by building occupants.

2. *Functional damage:* Damage affecting the use of the structure, usually related to jammed doors and windows, cracking and falling plaster, tilting of walls and floors, and other damage that would require nonstructural repair to return the building to its full service capacity.

3. *Structural damage:* Damage affecting the stability of the structure, usually related to cracks or distortions in primary support elements such as beams, columns, and load-bearing walls.

Alternative methodologies exist for evaluating the influence of tunneling settlement on buildings. Many works exist on the subject, but a widely referenced one in civil works is Skempton and MacDonald (1956), who studied data from 98 buildings, 40 of which were damaged to some extent. The study included both framed and bearing-wall structures. Grant, Christian, and Vanmarke (1974) extended the study to 95 additional buildings, 56 of which had some damage. These results, along with the work of other investigators, were combined in a study by Wahls (1981). The results are astonishingly close in all cases, and permit evaluation of the influence of settlement on buildings by means of empirical correlation of building distortion (relative settlement between columns) to building damage. Such a correlation is given in Table 24.1.5.

It is generally agreed by all investigators, including the Soviets (Polshin and Tokar, 1957), that bearing-wall structures and plaster partitions are first cracked at an angular distortion of approximately $\frac{1}{300}$. Considering all of these factors, and to be conservative, it is recommended that the angular distortion be limited to one-half this amount, or $\frac{1}{600}$, and that absolute settlement of a column or footing be limited to 1 in. (25 mm).

The first line of defense in limiting possible damage from settlements induced by tunneling is to require and use tunneling equipment and methods that reduce the lost ground, including:

1. Full and proper face control at all times, especially during shoving of the shield.

Table 24.1.5. Limiting Angular Distortion

Category of potential damage	Angular Distortion
Danger to machinery sensitive to settlement	1/750
Danger to frames with diagonals	1/600
Safe limit for no cracking of buildings	1/500
First cracking of panel walls	1/300
Difficulties with overhead cranes	1/300
Tilting of high rigid buildings becomes visible	1/250
Considerable cracking of panel and brick walls	1/150
Danger of structural damage to general buildings	1/150
Safe limit for flexible brick walls, L/H 4[a]	1/150

Source: Wahls, 1981.
Note: [a] Safe limits include a factor of safety.

2. Limiting the length-to-diameter ratio for the shield.
3. Avoiding overexcavating or overcutting.
4. Rapid installation of ground support.
5. Rapid expansion, pea-gavelling, and/or contact grouting of ground support.

In special cases, other steps must also be considered, including:

1. Grouting or freezing the ground before tunneling.
2. Compaction grouting.
3. Underpinning structures by any of a group of methods.

24.1.5 ROCK TUNNELING

Rock tunneling is defined as tunneling in ground that could not reasonably be excavated by hand methods, that is, ground that requires excavation by drill and blast or tunnel boring machine methods. Readers will find the following discussion of rock tunneling less extensive than the preceding discussion of soft ground tunneling. This de-emphasis is warranted by extensive coverage of rock tunneling elsewhere in the *Handbook.*

24.1.5.1 Ground Classification

The pioneering systematized classification of rock for tunneling purposes was proposed by Terzaghi (1946). That classification is summarized in Table 24.1.6.

In 1968, Deere defined rock quality designation (RQD) as the core recovery (in percent) of sound pieces of core of 4 in. (100 mm) or greater in length (see Deere and Deere, 1989, for the latest illustration of RQD). For the first time, this permitted rock support to be based on a measurable quantity. A comparison of rock loads for the RQD system gave loads approximately 20% below those by Terzaghi (Table 24.1.7), and recommended loads for machine-driven tunnels at 25% below those for drill and blast tunnels (Deere et al., 1969). With this new system, approximate requirements for support systems could be given in terms of the RQD, as illustrated by Table 24.1.8.

In recent years, new classification systems have been proposed that add other factors to the RQD to develop support recommendations for rock loads (Barton, Lien, and Lunde, 1974, 1977; Bieniawski, 1974(b); Einstein, 1983; Hoek and Brown, 1980). The most important of these new systems are summarized in Table 24.1.9.

The writers have found that all systems require interpretation and judgment based on experience. It is recommended that initial decisions be based on the RQD. Final design may then incorporate a check by one or more of the more detailed methods based on the engineer's evaluation of the specific site conditions and requirements.

Table 24.1.6. Rock Load H_p, in feet or meters of Rock, on Roof of Support in Tunnel with Width B and Height H at Depth of More than 1.5C, where $C = B + H$

Rock Condition	Rock Load H_p	Remarks
1. Hard and intact	Zero	Light lining required only if spalling or popping occurs
2. Hard stratified or schistose	0.0 to 0.5B	Light support
3. Massive, moderately jointed	0.0 to 0.25B	Load may change erratically from point to point
4. Moderately blocky and seamy	0.25B to 0.35C	No side pressure
5. Very blocky and seamy	0.35C to 1.1C	Little or no side pressure
6. Completely crushed but completely intact	1.1C	Considerable side pressure. Requires continuous support for lower ends of ribs or circular ribs
7. Squeezing rock, moderate rock	1.1C to 2.1C	Heavy side pressure
8. Squeezing rock	2.1C to 4.5C	Circular ribs recommended
9. Swelling rock	Up to 200 ft (60 m) irrespective of C	Circular ribs required. May require yielding support

Source: Modified from Bickel and Kuesel, 1982.
Note: H_p, B, H, and C are inconsistent units; feet or meters.

24.1.5.2 Tunneling Methods

Civil tunnels in rock are driven either by tunnel boring machines or drill-and-blast methods. Depending upon the tunnel, *tunnel boring machines* (TBMs) come in numerous configurations, but all contain the same basic components (Bickel and Kuesel, 1982):

1. Excavation system (cutterhead).
2. Machine body.
3. Muck system.

These machines are capable of excavating rock with compressive strength up to approximately 30,000 psi (207 MPa). They generally cut a circular tunnel with diameters up to approximately 35 ft (10 m). Their selection and design is a highly specialized area and beyond the scope of this chapter.

Drill and blast methods may be required as a matter of practical choice or for special conditions, including the following:

1. Large openings.
2. Other than circular shapes.
3. High-strength or abrasive rock.
4. Highly variable rock.
5. Mixed-face conditions.
6. Short tunnel runs.

Blasting techniques are very similar to those explained elsewhere in this *Handbook* (see Chapter 9.2). There are, however, some differences that may apply to civil tunnels:

1. The structures are designed for a long life, and, therefore, rock damage may be of greater concern. Thus such items as control of powder factors and use of smooth-wall blasting methods may be more important.

Table 24.1.7. Comparison of Terzaghi and Deere Rock Loads for Tunnels Supported with Steel Sets

RQD	Joint Spacing mm	Joint Spacing in.	Description	Deere Rock Load For Tunnels Up to 40-ft (12-m) Diameter: Conventional	Deere Rock Load For Tunnels Up to 40-ft (12-m) Diameter: Boring Machine	Terzaghi Classification: Description	Rock Load: Initial	Rock Load: Final
		24				Hard and Intact	0	0
	500		Excellent	0 to $0.3B$	0 to $0.2B$	Hard, stratified or schistose	0	$0.25B$
90		12						
				$0.3B$ to $0.6B$	$0.0B$ to $0.4B$	Massive, moderately jointed	0	$0.5B$
80	200		Good			Moderately blocky and seamy	0	$0.25B$ to $0.35C$
		6						
70								
60			Fair	$0.6B$ to $1.3B$	$0.4B$ to $1.0B$	Very blocky, seamy and shattered	0 to $0.6C$	$0.35C$ to $1.1C$
50	100	4						
40			Poor	$1.3B$ to $2.0B$	$1.0B$ to $1.6B$			
30								
20				Excluding squeezing or swelling ground: $2.0B$ to $2.8B$	$1.6B$ to $2.2B$	Completely crushed, gravel and sand and squeezing and swelling rocks	$0.54C$ to $1.2C$	$0.62C$ up to 250 ft (75 m)
10	50	2	Very Poor	In squeezing and swelling ground: Rock load up to 250 ft (75 m)	Rock load up to 250 ft (75 m)

Note: B = width of tunnel
C = width plus height of tunnel

Table 24.1.8. Support Recommendations for Tunnels in Rock (20 to 40 ft, or 6 to 12 m in diameter)

Rock Quality	Tunneling Method	Alternative Support Systems: Steel Sets**	Rock Bolts*	Shotcrete
Excellent* RQD >90	A. Boring machine	None to occasional light set. Rock load 0.0 to 0.2*B*.***	None to occasional.	None to occasional local application.
	B. Conventional	None to occasional light set. Rock load 0.0 to 03.*B*.	None to occasional.	None to occasional local application.
Good* 75 < RQD < 90	A. Boring machine	Occasional light sets to pattern on 5 to 6 ft (1.5 to 1.8 m) center. Rock load 0.0 to 0.4*B*.	Occasional to pattern on 5 to 6 ft (1.5 to 1.8 m) center.	None to occasional local application 2 to 3 in. (50 to 75 mm).
	B. Conventional	Lights sets, 5 to 6 ft (1.5 to 1.8 m) center. Rock load 0.3 to 0.6*B*.	Pattern, 5 to 6 ft (1.5 to 1.8 m) center.	Occasional local application 2 to 3 in. (50 to 75 mm).
Fair 50 < RQD < 75	A. Boring machine	Light to medium sets, 5 to 6 ft (1.5 to 1.8 m) center. Rock load 0.4 to 1.0*B*.	Pattern, 4 to 6 ft (1.2 to 1.8 m) center.	2 to 4 in. (50 to 100 mm) on crown.
	B. Conventional	Light to medium sets, 4 to 5 ft (1.2 to 1.5 m) center. Rock load 0.6 to 1.3*B*.	Pattern, 3 to 5 ft (0.9 to 1.5 m) center.	4 in (100 mm) or more on crown and sides.
Poor** 25 < RQD < 50	A. Boring machine	Medium circular sets on 3 to 4 ft (0.9 to 1.2 m) center. Rock load 1.0 to 1.6*B*.	Pattern, 3 to 5 ft (0.9 to 1.5 m) center.	4 to 6 in. (100 to 150 mm) on crown and sides. Combine with bolts.
	B. Conventional	Medium to heavy sets on 2 to 4 ft (0.6 to 1.2 m) center. Rock load 1.3 to 2.00*B*.	Pattern, 2 to 4 ft (0.6 to 1.2 m) center.	6 in. (150 mm) or more on crown and sides. Combine with bolts.
Very poor⁺ RQD < 25 (Excluding squeezing or swelling ground)	A. Boring machine	Medium to heavy circular sets on 2 ft (0.6 m) center. Rock load 1.6 to 2.2*B*.	Pattern, 2 to 4 ft (0.6 to 1.2 m) center.	6 in. (150 mm) or more on whole section. Combine with medium sets.
	B. Conventional	Heavy circular sets on 2 ft (0.6 m) center. Rock load 2.0 to 2.8*B*.	Pattern, 3 ft (0.6 m) center.	6 in. (150 mm) or more on whole section. Combine with medium to heavy sets.
Very poor (Squeezing or swelling)	A. Boring machine	Very heavy circular sets on 2 ft (0.6 m) center. Rock load up to 250 ft (76 m).	Pattern, 2 to 3 ft (0.6 + 0.9 m) center.	6 in. (150 mm) or more on whole section. Combine with heavy sets.
	B. Conventional	Very heavy circular sets on 2 ft (0.6 m) center. Rock load up to 250 ft (76 m). Heavy sets.	Pattern, 2 to 3 ft (0.6 + 0.9 m) center.	6 in. (150 mm) or more on whole section. Combine with heavy sets.

Source: Adopted from Deere et al., 1969.

Note:* In good and excellent quality rock, the support requirement will in general be minimal but will be dependent upon joint geometry, tunnel diameter, and relative orientations of joints and tunnel.

** Lagging requirements will usually be zero in excellent rock and will range from up to 25% in good rock to 100% in very poor rock.

⁺ Mesh requirements usually will be zero in excellent rock and will range from occasional mesh (or straps) in good rock to 100% mesh in very poor rock.

*** *B* = tunnel width

Table 24.1.9. Summary of Important Rock Classifications

Classification (Approximate Time of Development)	Data Required	Methods Used	Support Recommended
Rock Quality Designation, RQD (1963)	• Core Measurement	• Index	• Steel sets (rock bolts shotcrete)
Rock Structure Rating, RSR (1972)	• Rock type • Joints • Groundwater	• Numerical ratings	• Steel sets (rock bolts, shotcrete)
Geomechanics, RMR (1973)	• RQD • Core strength • Joints • Groundwater	• Numerical ratings	• Shotcrete • Rock bolts • Cast concrete
NGI, Q-System (1974)	• RQD • Joints • Groundwater • Stress factor	• Numerical ratings	• Shotcrete • Rock bolts • Cast concrete

2. The structures are usually lined for their ultimate use. Control of line, grade, and geometry may be of greater impact.

24.1.5.3 Rock Tunnel Support and Lining

Rock tunnels are very similar to mining excavations except for two general, and sometimes critical, differences. First, their design lifetime is generally on the order of a century, or at least a few decades. Second, many civil tunnels will be continuously inhabited throughout their lifetimes by the general public. For these reasons, the final lining may have design considerations that are more conservative than those for mines.

Initial supports for civil tunnels are basically the same as for mines. In general, they consist of the use (individually or in combination) of rock bolts, dowels, shotcrete, wire mesh, and steel sets. The general goal of an initial support system is to provide the following characteristics:

1. Absence of rock falls.
2. Control of stress-induced local instability.
3. Absence of mass instability by "reinforcing" the rock, i.e., encouraging the rock to support itself.
4. Restriction of loosening.
5. Control of water.

Design of the initial support system follows techniques described elsewhere in this *Handbook* (see Chapter 10.5) and generally takes one of three general approaches:

1. Empirical:
   a. RQD index.
   b. Q rating.
   c. RSR rating.
   d. RMR rating.
2. Pseudo-theoretical:
   a. arch theory.
   b. beam theory.
   c. block configuration.
3. Theoretical:
   a. elastic.
   b. inelastic.
   c. block and ubiquitous joint analysis.
   d. finite element analysis.
   e. beam element analysis.

Final supports for such tunnels often consist primarily of a lining system to meet user requirements such as esthetics, or waterflow or airflow characteristics. Often this is the minimum lining that can be constructed because the initial support system usually reinforces, knits together, or confines the rock in such a manner that the rock actually provides the majority of its own initial support. It is also assumed that the final lining (usually shotcrete or cast-in-place concrete) is properly and tightly placed, and that any voids between lining and rock are properly and thoroughly contact-grouted. Under these conditions, there can be only very nominal (if any) movement or loosening of rock around the opening. With this minimal movement, the effectiveness of the self-supporting "rock arch" is not diminished, and the final lining likely will never be required to support other than nominal loosening loads.

As a check on the lining capacity, the writers suggest an application of (1) an analysis that accounts for lining-rock interaction (such as beam elements or finite elements) with no more than one diameter of rock load, and (2) an analysis that considers the lining resistance in shear to any wedges that were identified during construction and that could punch through as the result of the long-term deterioration of initial support elements.

24.1.6 MIXED-FACE TUNNELS

Tunnels are frequently driven in two vastly different materials, usually soft ground and overlying rock. Such tunnels are called *mixed-face tunnels* and present very special challenges to the tunnel engineer. This may be especially true when the mixed face consists of special cases such as flowing silt overlying stiff clay.

In these cases, tunnel design and construction are usually driven by the softer of the two materials, but ignoring the harder material can lead to serious problems. For example, if a TBM is used, it will normally have to be selected to cut the softer material and to provide maximum control for that same material. The frequent result is that the excavation process may tend to hang up on the harder material because it is more difficult to cut. Under these conditions, unless good control is maintained, the machine may continue to excavate and remove the soft material at a rate greater than that of the hard material. The obvious result is disproportionate removal or loss of control of the soft ground that can lead to (1) instability at the face, and (2) an increase in lost ground at the face over that attained in a full face of either of the materials. Similar problems occur with the work crews:

1. A soft-ground crew may not have the experience and skills necessary to shift to a drill and blast operation for part of the face.
2. Similarly, a hard-rock crew (especially if drill and blast techniques are being used) likely may not have the skills to provide the support and controlled excavation necessary to maintain stability of the soft-ground portion of the face.

Mixed-face tunneling can involve considerations of ground combinations, groundwater conditions, and construction methods that are legion and certainly beyond the scope of this *Handbook.* When mixed-face conditions are expected, the designers should start by studying Wilbur (1982) and Terzaghi (1977).

24.1.7 SPECIAL CONSIDERATIONS

The authors wish to acknowledge that a myriad of special considerations may arise regarding a civil tunneling design and construction project. Some have been discussed above, but these are by no means all that might be encountered. The following list is representative of other special considerations that may arise. Readers are referred to Terzaghi (1977), Bickel and Kuesel (1982), and O'Rourke (1984) for initial study, but as with mixed-face tunneling, for most cases it is recommended that the consulting services of a specialist be obtained for developing or reviewing the final design and/or the construction procedures:

1. Adjacent, crossed, stacked, or intersecting tunnels.
2. Compressed air for control of water or for face stability.
3. Controlled blasting.
4. Emergency provisions.
5. Freezing to control water or to improve stability.
6. Geophysical exploration techniques.
7. Groundwater control (during construction and permanently).
8. Grouting to control water, improve stability, or control settlement:
   a. chemical.
   b. cement.
   c. compaction.
   d. consolidation.
9. Hazardous conditions (e.g., chemicals, gas).
10. Muck removal and hoisting.

11. Other support construction types (spiling, breasting, forepoling, New Austrian Tunneling Method (NATM).
12. Seismic conditions.
13. Shield/tunneling machine design.
14. Special structures (e.g., portals, caverns, sunken tubes, nearby or intersecting tunnels).
15. Squeezing or swelling ground.
16. Ventilation, lighting, and other utilities.
17. Work and safety rules.

24.1.8 UNIQUE CHARACTERISTICS OF CIVIL TUNNELS

The segments above apply, for the most part at least, to all civil tunnels. There are, in addition, characteristics of each type of civil tunnel that make it unique from other tunnels. The following paragraphs summarize some of those unique characteristics for reference. Users of this *Handbook* should be aware that these unique characteristics may have a significant impact on the design and construction of civil tunnels. Their impact, in fact, may be far greater than might be inferred from the simple listing of characteristics.

24.1.8.1 Rail Transit Tunnels

1. Rail alignment restrictions require tight adherence to tunnel alignment, especially the horizontal alignment.
2. Ventilation requirements for the operating life of the tunnels must be considered.
3. Infiltration of water, gases, or ground contaminants must be tightly controlled.
4. Cathodic protection is required where direct current (dc) is used for train power.
5. Vibration impacts of transit trains on nearby structures may require use of isolation materials or special mounting pads.
6. The requirement to minimize damage from earthquakes must be considered in some areas.
7. Tunnel lining may require multiple embedment of utilities.
8. Cross passages/emergency access must be provided.

24.1.8.2 Highway Tunnels

1. Ventilation requirements for the life of the tunnels must be considered.
2. Infiltration of water, gases, or ground contamination must be tightly controlled.
3. The requirement to minimize damage from earthquakes must be considered in some areas.
4. Cross passages/emergency access must be provided.

24.1.8.3 Water Supply Tunnels

1. Alignment requirements can often be less severe than for vehicle tunnels.
2. Design for interior pressure may be required.
3. Smoothness of the final lining will impact flow capacity and may thus be a concern.
4. Embedments are usually not required.

24.1.8.4 Wastewater Tunnels

1. Horizontal alignment requirements may not be as severe, but vertical alignment requirements may be important to avoid low spots.
2. Exfiltration concerns may be important.
3. Settlement concerns may occur where tunnels must be shallow.
4. Embedments are usually not required.
5. Special designs are often required for inlet drop structures.
6. Corrosion-resistant liners are often required for long-term durability in acid-producing conditions.

Chapter 24.2
STORAGE AND POWER GENERATION

DAVID C. WILLETT

24.2.1 INTRODUCTION

Large permanent openings in rock are used for a number of functions associated with the bulk storage of solids, liquids, and gases, and with the generation and storage of electrical energy. Openings for these purposes, although large, are generally excavated by "conventional" civil engineering (full-face or heading and bench methods) as opposed to mining methods such as block caving, stoping, etc. Occasionally, if the configuration of the mined space is appropriate, the opportunity is taken to make use of openings, previously excavated for the extraction of minerals, for storage or other purposes.

In North America in general, other than for a few hydroelectric facilities, and some relatively small oil and gas storages, there are very few examples of the excavation of caverns in rock for purposes other than mineral extraction. In other parts of the world, however, particularly in Europe, and to a lesser extent in Asia, the use of caverns excavated in rock for purposes ranging from waste disposal and bulk storage, to recreational and even residential, is widely accepted and economically viable.

In North America, relatively small (up to 100,000 yd^3 or 76,500 m^3) caverns have been excavated for the bulk storage of crude oil, and a number of high vapor-pressure hydrocarbons such as propane, butane, propylene, and ethane, in rock types ranging from shales to limestones and granite. In Europe, however, primarily Scandinavia, extensive use has been made of large caverns (sometimes in excess of 1,000,000 yd^3 or 765,000 m^3) excavated for the specific purpose of storing crude oil and refined oil products. The currently largest single excavated underground oil storage facility (32 million bbl or 5 M m^3) is located in Korea. However, a major component (73 million bbl or 11.6 M m^3) of the US Strategic Petroleum Reserve program of crude oil storage is located in a previously excavated salt mine at Weeks Island, LA.

Temporary storage of flood waters is provided in deep tunnels in a number of North American cities, including notably Chicago (the Tunnel and Reservoir Plan, or TARP project) and, more recently, Milwaukee.

In the Kansas City area, extensive use is made of underground space created by many excavations for limestone. Uses of this space include bulk storage of solids, cold and refrigerated storage, manufacturing, general warehousing, and even retail office facilities.

Turning to energy production and storage, several major hydroelectric generating stations have been located underground in rock caverns in North America, including the Raccoon Mountain facility of TVA, the 5000-MW Churchill Falls power plant in Labrador, and the 3000-MW "Le Grande 2" (LG-2) plant near James Bay in the province of Quebec. These openings constitute some of the largest permanent man-made excavations in existence. At LG-2, for instance, the powerhouse cavern measures 80 ft span by 120 ft high by 1000 ft long (25 by 37 by 305 m).

Studies have also been made of the feasibility of locating nuclear generating plants underground; in Europe, a number of small plants were constructed in underground locations in the 1960s and early 1970s.

A number of bulk energy storage concepts currently being studied envisage the use of large underground openings. These concepts include Superconducting Magnetic Energy Storage (SMES), Compressed Air Energy Storage (CAES), and Underground Pumped Hydro (UPH).

The development and use of underground openings for these nonmining purposes is discussed in the following sections.

24.2.2 MINED OPENINGS FOR STORAGE PURPOSES

24.2.2.1 Gases

Although, as noted above, a number of small underground storages for gases such as natural gas have been developed in North America by conventional excavation techniques, by far the largest underground gas storage facilities are located either in previously depleted natural gas fields or in caverns that have been solution-mined in bedded or domed salt deposits. The technology associated with these major storage facilities is not within the purview of this chapter. For caverns in salt, see Chapter 15.3.

Typically, a mined facility will be located in a stratum of shale with bulk permeabilities in the region of 10^{-6} mm/sec in order to limit the leakage of gas from the cavern. Access for excavation is obtained through a small (3- to 5-ft-, or 1- to 2-m-diameter) shaft drilled from the surface and steel-lined. The caverns are generally excavated by the room and pillar method (Chapter 18.1)

In general, the containment of gas in unlined rock caverns is achieved by the low permeability of the surrounding rock mass. However, in fractured rock, containment can also be achieved provided that the necessary groundwater gradient is present. Suh et al. (1986) proposes that the depth of groundwater at the ceiling of the cavern should be greater than the maximum pressure head within the cavern plus a factor (ranging up to about 20% of the pressure head) depending upon the shape of the cavern. Although a number of proposals (e.g., Sagefors and Svemar, 1986) for methods by which liquefied natural gas (LNG) might be stored underground have been put forward, no successful prototype installation has yet been achieved.

24.2.2.2 Liquids

PURPOSE-EXCAVATED CAVERNS. Although at the time of writing, no major (larger than 1,000,000 bbl, or 159,000 M m^3) underground storage facilities for hydrocarbons have been developed by excavation in North America, many large storages have been constructed elsewhere, particularly in Europe. The liquid is stored in unlined caverns, usually excavated in jointed crystalline rock. Containment of the stored liquid is ensured either by locating the excavated cavern at such a depth below the natural groundwater level that the natural inflow of groundwater into the cavern prevents the seepage of the contained liquid or vapor, or by supplementing the groundwater pressure by means of a water injection system located in separate tunnels above the crown of the storage cavern.

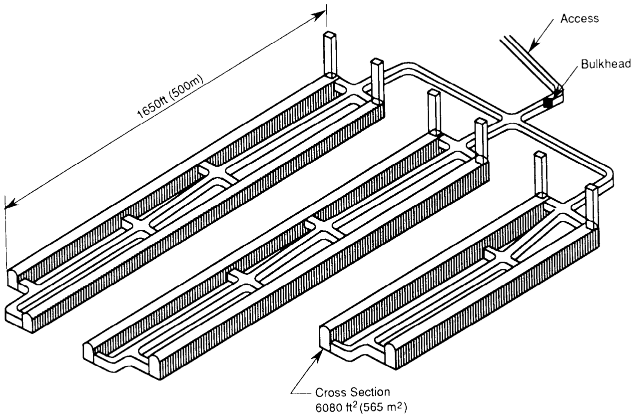

Fig. 24.2.1. Configuration of a typical large oil storage cavern in hard rock.

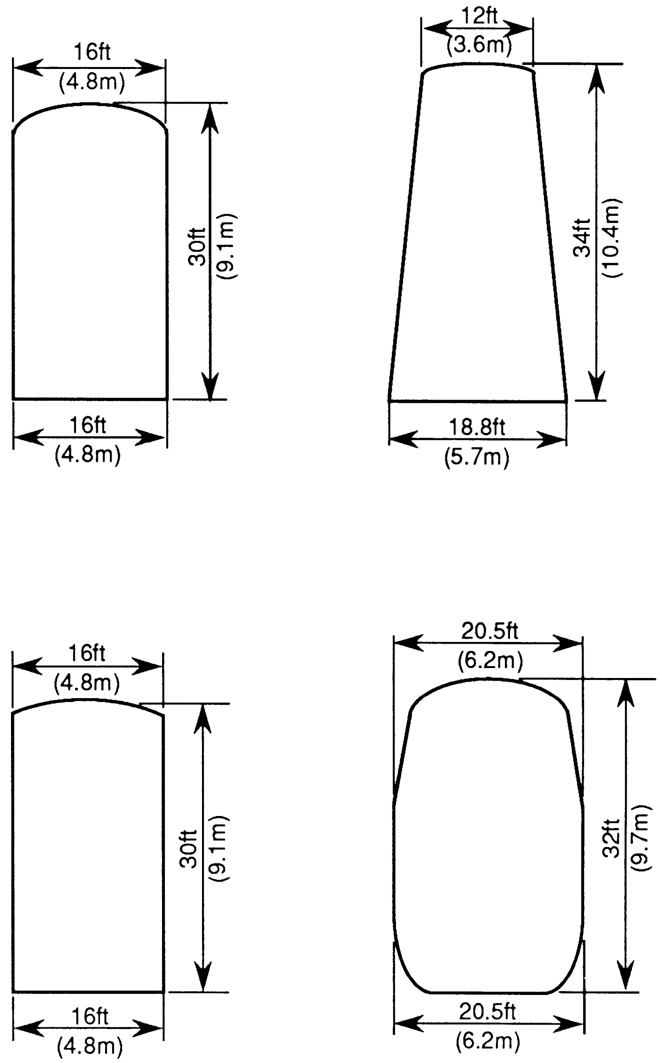

Fig. 24.2.2. Typical oil storage cavern cross sections.

Water entering the cavern collects as a "water bed" at the bottom of the stored oil and can be handled in one of three ways: fixed, variable level, or dry, depending upon the type of oil being stored and the relative economy of alternatives. Problems have been encountered with microbial growths at the oil-water interface with some types of oil or oil product.

A diagram of a typical large oil storage facility (Mongstad, Norway) is presented in Fig. 24.2.1. The principal characteristics of the caverns are shown as follows (Hosolen, 1986):

Volume stored:	8.17 million bbl (1.3 M m^3)
Cavern dimensions:	55 ft wide, 100 ft high, up to 1550 ft long (18 m wide, 33 m high, up to 510 m long)
Depth below ground level:	approximately 170 ft (55 m)

Overall Configuration—Depending upon the total volume to be stored, storage space is generally provided by one or more parallel unlined caverns excavated at some depth below rock surface in a competent rock mass. A key feature of the initial site selection will be the identification and characteristic of a suitable stratum; this will almost inevitably require a trade-off between the technical, logistical, economic, and environmental considerations.

Cavern Dimensions—Depending to some extent on the volume to be stored, but also upon the characteristics of the host rock, cavern sizes may range from 30 ft (10 m) span to as much as 60 or 70 ft (18 or 21 m) span and 100 or more ft (30 m) high. Typical cross sections of a number of caverns constructed by Neste Oy (Finland) are shown in Fig. 24.2.2. Walls of caverns intended for crude oil storage are often inclined inward towards the top to ensure that falling blocks do not strike sparks which might ignite the cavern contents.

Support—The basic principle in the design of reinforcement for any large underground opening is to help the rock mass support itself. As the majority of oil storage caverns excavated to date have been sited in hard competent crystalline rocks, reinforcement has been largely confined to rock bolting in the roof and walls; typically, bolt lengths in the roof have ranged from 0.15 to 0.30 times the cavern span, and in the walls from 0.10 to 0.20 times the cavern height (Johansson, 1986).

Supplementary reinforcement is often provided by pneumatically applied concrete (PAC); this is generally used either (1) un-reinforced to handle small potential fallouts or (2) reinforced with wire mesh in conjunction with rock bolts to provide more significant structural support in areas requiring arch continuity or wall support. More recently, fibre-reinforced PAC has been used with considerable success.

Containment—As discussed earlier (24.2.2.1), containment of both petroleum liquids and gases/vapors in caverns in jointed rock is ensured by providing a flow of groundwater into the cavern. In general, this can be obtained by locating the cavern so that the roof is at a depth below groundwater level, at least equal to the vapor pressure within the cavern. In situations where this is not feasible, artificial stimulation of flow into the cavern can be provided by the installation of either pressurized water injection tunnels or drillholes from the surface above the cavern.

Conversely, if groundwater conditions are such that there is excessive leakage into caverns, which in turn can lead either to excessive costs for pumping, or drainage of the water seal above the cavern, it may be necessary to embark on a program of grouting to reduce the flow.

Access—Access for construction is generally provided by means of an inclined road tunnel driven from the surface. When construction is completed, the tunnel is bulkheaded off, and such access as is required for the operation of the facility is obtained through vertical shafts to the surface, as shown in Fig. 24.2.1.

Construction—Caverns are generally constructed by conventional heading and bench methods. As noted above, roof and wall support during construction and for the permanent installation is provided by pneumatically applied concrete (PAC) if required, supplemented by wire mesh and rock bolts.

In planning the excavation, a number of considerations that are unique to oil storage come into play; these include

1. Maintenance of the groundwater level above the caverns
2. Scheduling the excavation to allow safe commissioning of the caverns finished first
3. Minimizing the size and extent of construction access that cannot be subsequently used for oil storage
4. Making best use of the opportunity for multiple face operation, with optimum scheduling of the various drilling, charging, scaling, and mucking crews

General—More than 100 major oil storage facilities of the type described above have been constructed in Europe. With the more recent oil surpluses, it is interesting to note that at least one of these storages has been converted to the storage of coal (Anon., 1988b).

USE OF EXISTING CAVERNS FOR STORAGE OF LIQUIDS. In North America, the only major underground oil storage facility in a mined cavern is located at Weeks Island, LA, in the previously excavated Weeks Island salt mine. This mine, located between 500 ft (150 m) and 850 ft (260 m) below ground level, was excavated in the period between 1910 and the present day. It was identified in 1976 as being suitable for conversion to oil storage, and the requisite modifications were made to facilitate the installation of the necessary equipment for the filling and withdrawal of crude oil.

In selecting the Weeks Island mine for oil storage, more than 3000 mines in the United States were examined for this possible use. The Weeks Island mine was selected from a short list of ten possible sites, principally on the basis of its capacity, its containment security, and its location relative to the major oil pipelines near the Gulf Coast.

24.2.2.3 Storage of Solids Underground

With the exception of radioactive wastes, discussed in Chapter 24.3, virtually all underground solids storage facilities in North America are based on the use of space previously excavated for the extraction of minerals. In a number of instances, however, these facilities have been extended for the specific purpose of providing additional space, the production of minerals—usually limestone—being of secondary importance.

Following procedures normally adopted for the extraction of limestone underground, these facilities have generally been excavated by the room and pillar technique. The majority are located in the general area of Kansas City; a listing and brief description of the principal currently operating facilities is set out in Table 24.2.1. Note that many are used not only for storage but also for a range of commercial and industrial purposes that benefit from the isolation and insulation provided by the underground environment, One of the largest refrigerated storage facilities in North America is located underground in this area.

In Norway, environmental pressures are such that a company involved in the processing of zinc ores has been required to develop an underground facility for the disposal of the solid wastes (Aarvoll et al., 1986). The caverns are excavated in a coarse-grained granitic gneiss.

24.2.3 MINED OPENINGS FOR POWER GENERATION FACILITIES

24.2.3.1 General

Worldwide, power plants for hydroelectric generation facilities have been constructed underground since the late 19th century. In North America, to date, 11 hydropower plants are located underground (Table 24.2.2).

The principal reason for locating these plants underground has been, in most cases, economy; the underground location is less costly than a similar scheme with the power plant at the surface. At the same time, a number of other benefits are often obtained, including aesthetic, environmental, and improved safety from external forces.

24.2.3.2 Siting

The decision to locate a hydroelectric power plant underground, and to select the most appropriate site having done so, requires the evaluation of a range of factors related primarily to the topography of the area, the distance between the planned headrace and tailrace, the need for surge chambers upstream or downstream of the power plant, and the depth of rock cover available along the planned route of the tunnels. Within this context, the known or projected geotechnical conditions related to rock quality, the presence of faults or other significant discontinuities and groundwater must be factored into the equation. The ultimate decision as to whether to site the power plant underground will, under most circumstances, be based on an assessment of the relative economy of the surface vs. underground siting.

From the geotechnical standpoint, the key factors relate to the ability of the proposed host rock to accommodate/support the excavation of a cavern, or a series of caverns, of a size required to house the necessary mechanical and electrical equipment without the need to provide costly and/or time-consuming support measures.

Guidance as to the quality of rock mass in which it is proposed to locate the required caverns can, in the first instance, be obtained through the application of one or more of the rock mass classification systems developed by a number of investigators (Hoek and Brown, 1982) (see also Chapter 24.1 and Section 10).

Development of the necessary input data upon which to base the rock-mass classification assessment will depend initially upon research of available literature and previous exploratory work. As the decision regarding the optimum location of the facility is firmed up, the need will arise to undertake exploratory work specifically aimed at providing the requisite data for the assessment and subsequently detailed design of the cavern.

24.2.3.3 Exploration

The optimum techniques to be adopted for obtaining the required data and, in fact, the type and extent of data required, will be different for each and every site. Many of the techniques used in conventional mining exploration (Chapters 4.3 and 4.4) are entirely appropriate for use here. Bearing in mind, however, that the ultimate objective is to develop permanent stable caverns, primary emphasis will be placed on obtaining information about the properties of the rock that affect its structural performance.

Typically, exploratory activities might include the following:

1. Initial assessment of regional geology using available geologic mapping, air photos, previous drilling records, photo interpretations, etc.

Table 24.2.1. Major US Underground Storage Sites

Location	Name	Description
Chester, IL	Midland Terminal	90 miles (145 km) south of St. Louis on the Mississippi River. 25-ft (8-m) ceiling heights, perfectly dry.
Lexington, KY	4th Street Tobacco Warehouse	Developing downtown. Will have document storage capability. Ceiling heights 25 to 50 ft (8 to 15 m). Active mine—aggregate.
Louisville, KY	Derby Developing Co.	Well located, in a near-suburban area. Expressway and zoo over the top. 28- to 110-ft (9- to 34-m) ceiling heights. 115 acres (47 hectares).
Carthage, MO	Carthage Marble Co. (CMC Inc.) PO Box 718 Carthage, MO 64836 (417) 358-2145	
Independence, MO	GeoSpace, Inc. 601 South M-291 Highway Independence, MO 64015	GeoSpace Executive Park is a subsurface development in the Metropolitan Kansas City area that will have 7.6 million net usable ft^2 (706,040 m^2) for office, manufacturing and warehouse, truck docks, parking, railways, roadways, and other common area. Slightly over one-half million net usable ft^2 (46,450 m^2) is currently developed in office, manufacturing and warehouse space.
Kansas City, MO	Grasis Corp.	Near Hunt Midwest. 250,000 ft^2, (23,225 m^2) total, 130,000 ft^2 (12,077 m^2) developed. Manufacturing facility with outside buildings, 25-ft (8-m) ceiling heights. Modified specifications.
Kansas City, MO	Hunt Midwest Enterprises, Inc. 8300 N.E. Underground Drive Kansas City, MO 64161	Land development company coordinating surface and underground development of 2500-acre (1012-hectare) master-planned community. Ceiling heights of 12 to 16 ft (4 to 5 m). Weatherproof docks. Rail served by Burlington Northern. Automatic fire protection.
Kansas City, MO	Prairie Mining	Unlimited space, in most affluent and prestigious area of Johnson County.
Neosko, MO	Southwest Lime Co. P.O. Box 816 Neosko, MO 64850 (417) 451-6806	
Springfield, MO	Griesemer Stone Company Rt. 2 Box 52 Springfield, MO 65802	1.2 million ft^2 (111,480 m^2) net usable space, sprinkled, dehumidified, lighting 10 foot-candles, 25-ft (8-m) stacking heights. Seven "buildings" 110,000 ft^2 (10,219 m^2)–340,000 ft^2 (31,586 m^2) in size, some cold storage. Rail to 6 of buildings, 30 boxcars. Truck docks (100 total), 24-hour security guard, dry storage for manufacturing (food, spices, Zenith TV picture tubes). 140,000 ft^2 (13,006 m^2) new space mined every day. Pillars on 80-ft (24-m) centers.
Warrenton, MO	Missouri Limestone	
Wampum, PA	Wampum Industrial Facility P.O. Box 486 Wampum, PA 16157 (412) 535-4308	Located on the Pennsylvania Turnpike near Pittsburgh. Over 2½ million ft^2 (232,250 m^2) of underground space offers clients current storage technology for all types of materials including classified documents, computer tapes and microfilm. 30-ft (9-m) diameter pillars. Unlimited floor loads. Specialized environmental control.

Table 24.2.2. Underground Hydroelectric Power Plants in North America

Name	State	Owner
United States		
Bear Swamp	MA	New England Power Company
Helms	CA	Pacific Gas and Electric
Northfield Mountain	MA	New England Electric Systems
Raccoon Mountain	TN	TVA
Boundary	WA	Seattle Power and Light
Bad Creek	NC	Duke Power
Balsam Meadow	CA	Southern California Edison
Canada		
Bersimis	PQ	Hydro Quebec
Chutes des Passes	PQ	Alcan
Churchill Falls	LB	Churchill Falls (Labrador) Corp.
Mica Creek	BC	BC Hydro
LeGrande II	PQ	Hydro Quebec

2. Detailed surface mapping, including identification of rock outcrops, strike, dip, jointing of exposed rock, etc., possibly supplemented by trenching to expose additional rock surfaces.

3. Geophysical exploration: of value primarily for extending information about near-surface features; can include such techniques as seismic refraction and reflection surveys, gravity meter, etc.

4. Diamond drilling: the staple and basic method of obtaining information about rock at depth. Key data to be obtained from the core include stratigraphy, jointing/fracturing, orientation, rock types, etc. May be supplemented by a variety of "down-hole" exploratory techniques, including borehole photography (still or video) and in situ stress determination by hydrofracturing techniques.

5. Exploratory adits: normally only developed once the location and orientation of the caverns have been essentially established. Provides first-hand information about in situ rock conditions and allows full-scale tests to determine parameters such as in-situ stress and bulk modulus of elasticity to be conducted.

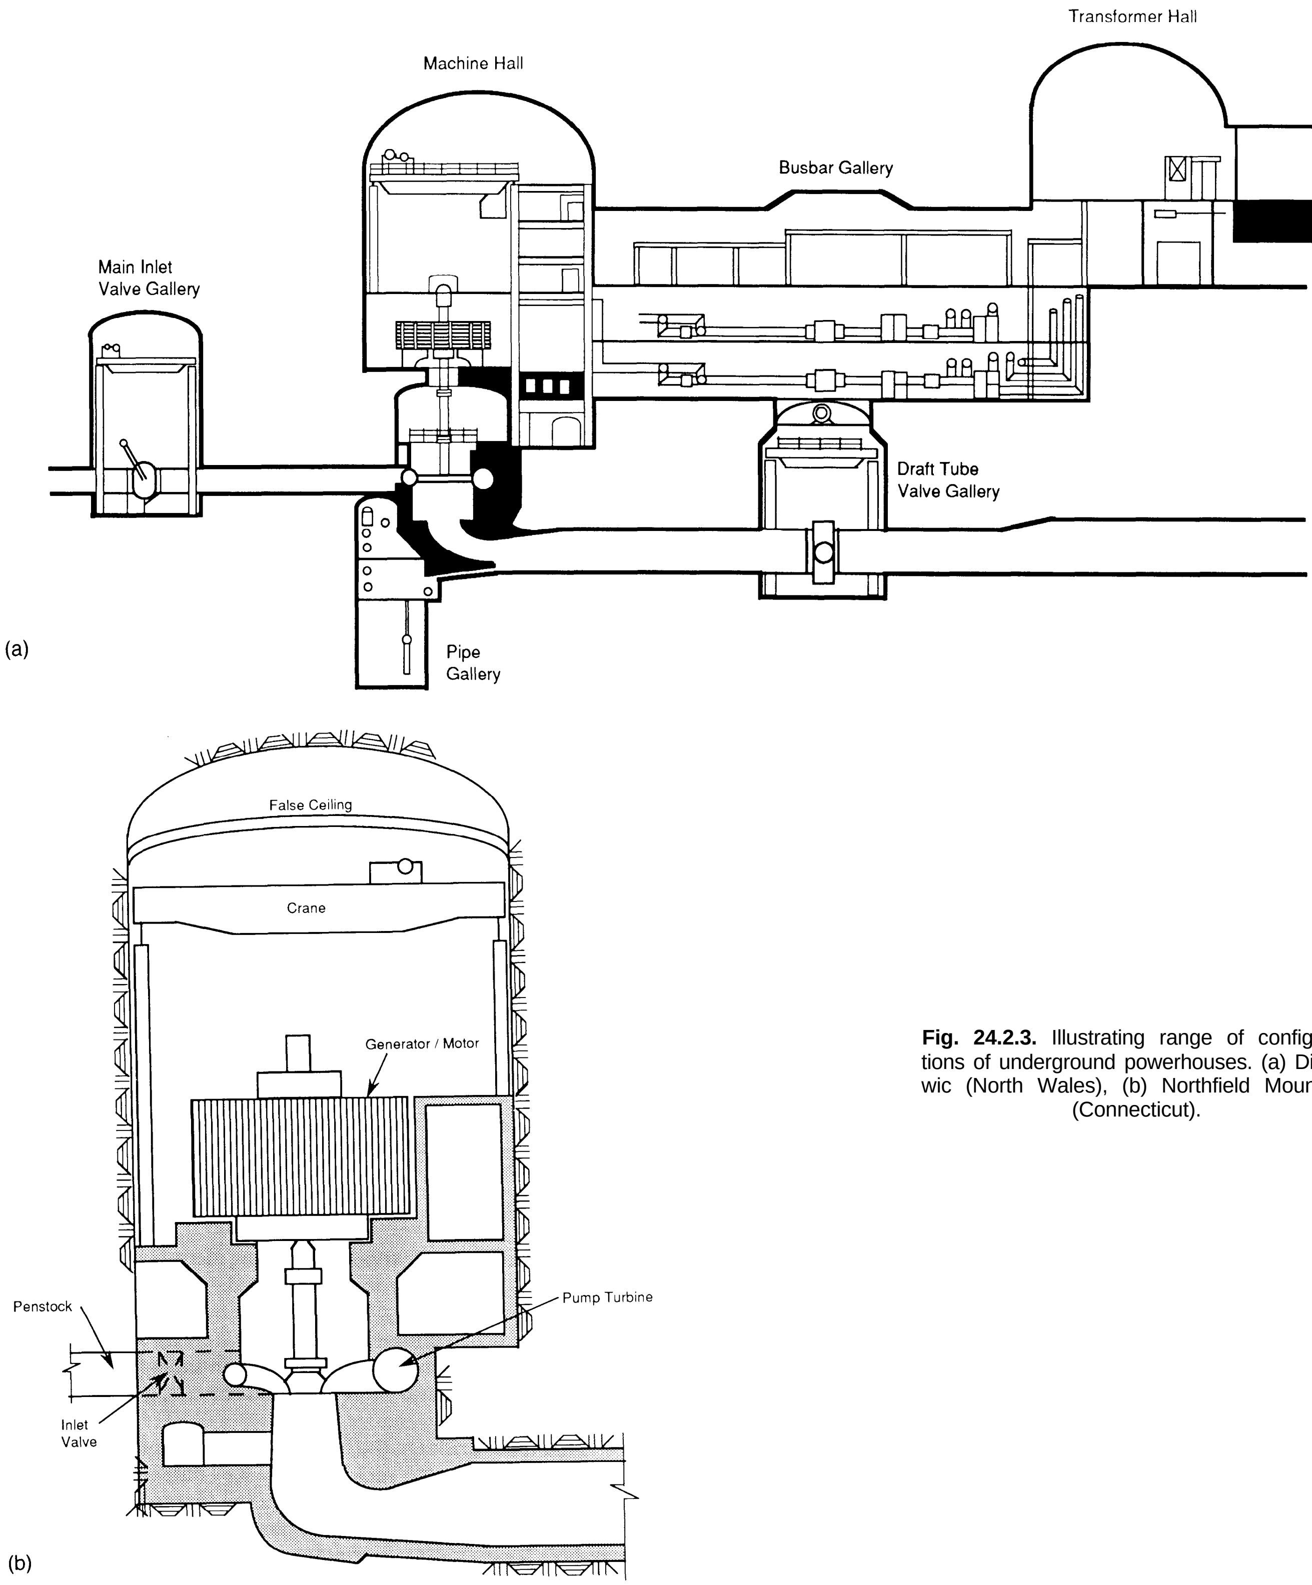

Fig. 24.2.3. Illustrating range of configurations of underground powerhouses. (a) Dinorwic (North Wales), (b) Northfield Mountain (Connecticut).

Typical adit dimensions range from 8 by 8 ft (2.4 by 2.4 m) up to 12 by 12 ft (4 by 4 m). Advantages of adits include the facility to allow bidders to obtain first-hand appreciation of rock conditions. Adits may also provide a useful first-stage for the excavation of large chambers.

24.2.3.4 Design

OVERALL ARRANGEMENT. Caverns for a hydroelectric facility must be designed to house the various mechanical and electrical components needed to generate and transmit electrical

Table 24.2.3. World's Largest Span Underground Power Plants

energy. Selection of the optimum configuration will require consideration of the structural characteristics of the rock mass in relation to the required dimensions and alternative arrangements available for the various components. Reference should be made to standard hydroelectric texts for a description of the dimensions and required configuration of the mechanical and electrical components. In many cases, the selection of the optimum arrangement revolves around the relative economy of housing all the components in one large cavern as opposed to using two or more smaller caverns. In making this selection, the cost of excavation and support of the alternative chamber sizes and the interaction of stresses around adjacent caverns require a good knowledge of the rock-mass characteristics provided by the exploration program discussed above.

The principal components to be housed within the overall power facility include:

1. Inlet valves (if required).
2. Turbine and generator (or pump/turbine and motor/generator).
3. Draft-tube gates or valves.
4. Transformers (if located underground).
5. Various mechanical and electrical subsystems.

Cross sections of two existing power plants illustrating the range of possible configurations are presented in Fig. 24.2.3 (a) and (b).

CAVERN DIMENSIONS. The required dimensions of the power plant cavern will depend primarily upon the size of the equipment to be installed and/or upon the number of the components to be located within the cavern. Space must be provided around the principal components to allow them to be installed and removed for maintenance and to accommodate the various electrical and mechanical subsystems, such as governors, excitation equipment, compressors, pumps, etc. Typically, spans in the range between 60 and 80 ft (18 and 24 m) are most frequently encountered; a listing of some of the world's largest span underground power plants is presented in Table 24.2.3.

SUPPORT. Because of the wide range of geotechnical conditions encountered in the construction of underground power plants, cavern support measures have ranged from a minimum of pattern rock bolting in high-quality rock to a full concrete lining with prestressed tendons in poor-quality rock. Fig. 24.2.4 illustrates a variety of cavern support measures in the following rock types:

1. Fortuna: Andesite, agglomerate and tuff.
2. Ohkawachi: Porphyyrite.

24.2.3.5 Construction

As with large oil storage caverns, the heading and bench method of excavation is generally adopted. This allows easier access for the installation of roof support measures during the initial stage of the work. The top heading may be excavated full-face or, for large spans, using a central subheading with side slashes. The sequence of excavation of the Churchill Falls caverns is shown in Fig. 24.2.5.

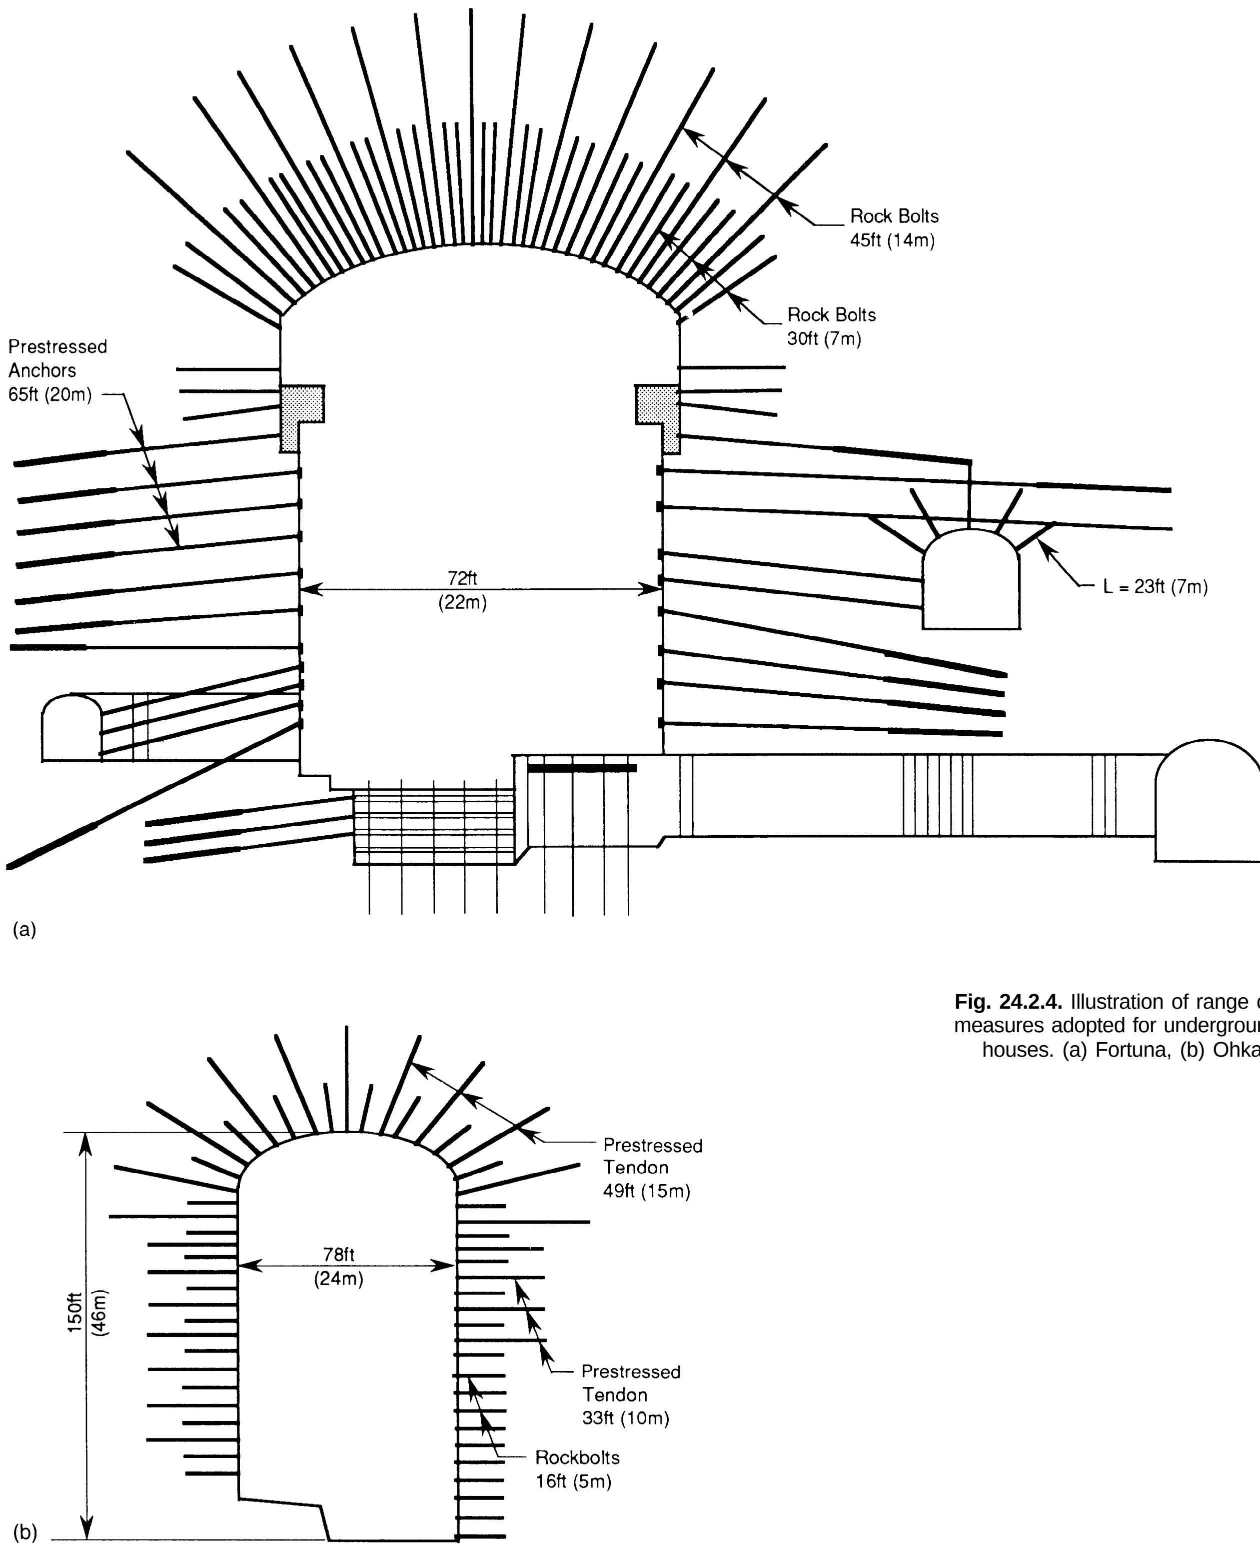

Fig. 24.2.4. Illustration of range of support measures adopted for underground power-houses. (a) Fortuna, (b) Ohkawachi.

To minimize damage and overbreak at the cavern walls, smooth blasting and presplitting techniques are used; the bench excavation may be drilled horizontally or vertically, depending upon the logistics of the access and spoil removal system.

24.2.4 ADVANCED ENERGY STORAGE CONCEPTS IN ROCK CAVERNS

In the period following the oil crisis of the mid- to late-1970s, a number of conceptual developments were proposed for

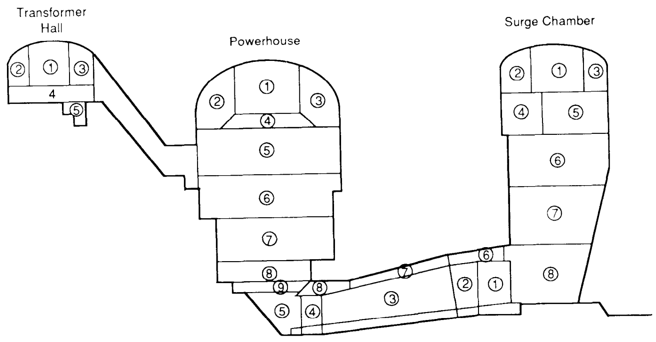

Fig. 24.2.5. Excavation sequence for Churchill Fails underground powerhouse.

the bulk storage of electrical energy in a number of forms; several of these concepts involved the use of large chambers excavated in rock. These included:

1. Underground pumped hydroelectric storage (UPH).
2. Compressed air energy storage (CAES).
3. Superconducting electromagnetic storage (SMES).

At the time of writing, none of these concepts has been developed into a prototype facility, but all three are still under active consideration.

24.2.4.1 Underground Pumped Hydroelectric Storage (UPH)

A definitive study of this concept was presented in a report commissioned by the Electric Power Research Institute (EPRI) (Anon., 1981). The concept proposes the use of caverns excavated at depths up to 5000 ft (1520 m) below ground level to be used as the lower reservoir of a pumped hydroelectric generating facility as illustrated in Fig. 24.2.6. The required excavated volume of these caverns could range up to 5 or even 10 million yd^3 (3.8 or 7.6 M m^3), depending upon the energy storage required. The EPRI report proposes that the reservoir caverns be excavated in the form of long parallel chambers, the size and configuration depending upon the characteristics of the host rock.

Although no UPH facilities have been constructed to date, a proposed facility near Akron, OH is noteworthy in that the use of an existing mine (the Norton limestone mine) is proposed to serve as the lower reservoir (Anon., 1989b), Fig. 24.2.7.

24.2.4.2 Compressed Air Energy Storage (CAES)

The compressed air energy storage concept involves the bulk storage of energy in the form of compressed air. The feasibility of the concept has been established by a prototype facility constructed at Huntorff in western Germany in 1979. At this facility, the air is stored at a pressure of 1000 psi (6.9 MPa) in two caverns, solution mined in salt. A similar facility has recently been completed by Alabama Electric Cooperative (Anon., 1988a).

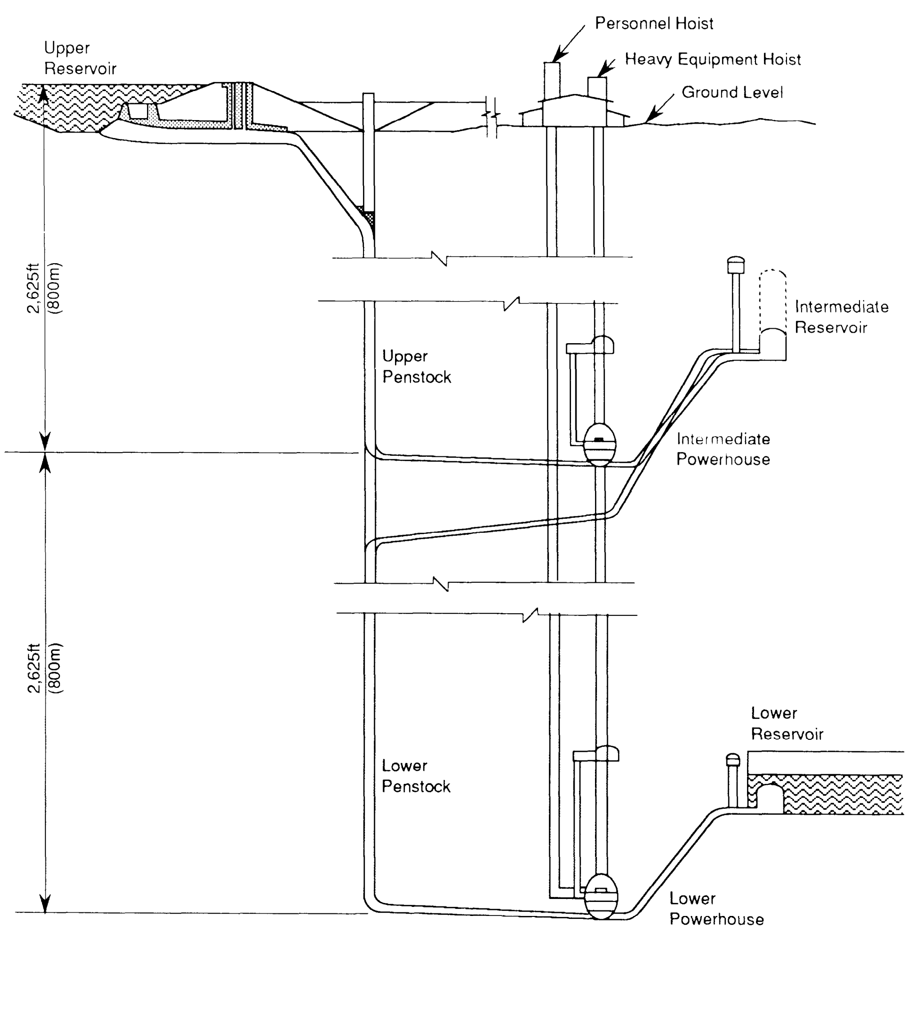

Fig. 24.2.6. Underground pumped storage concept.

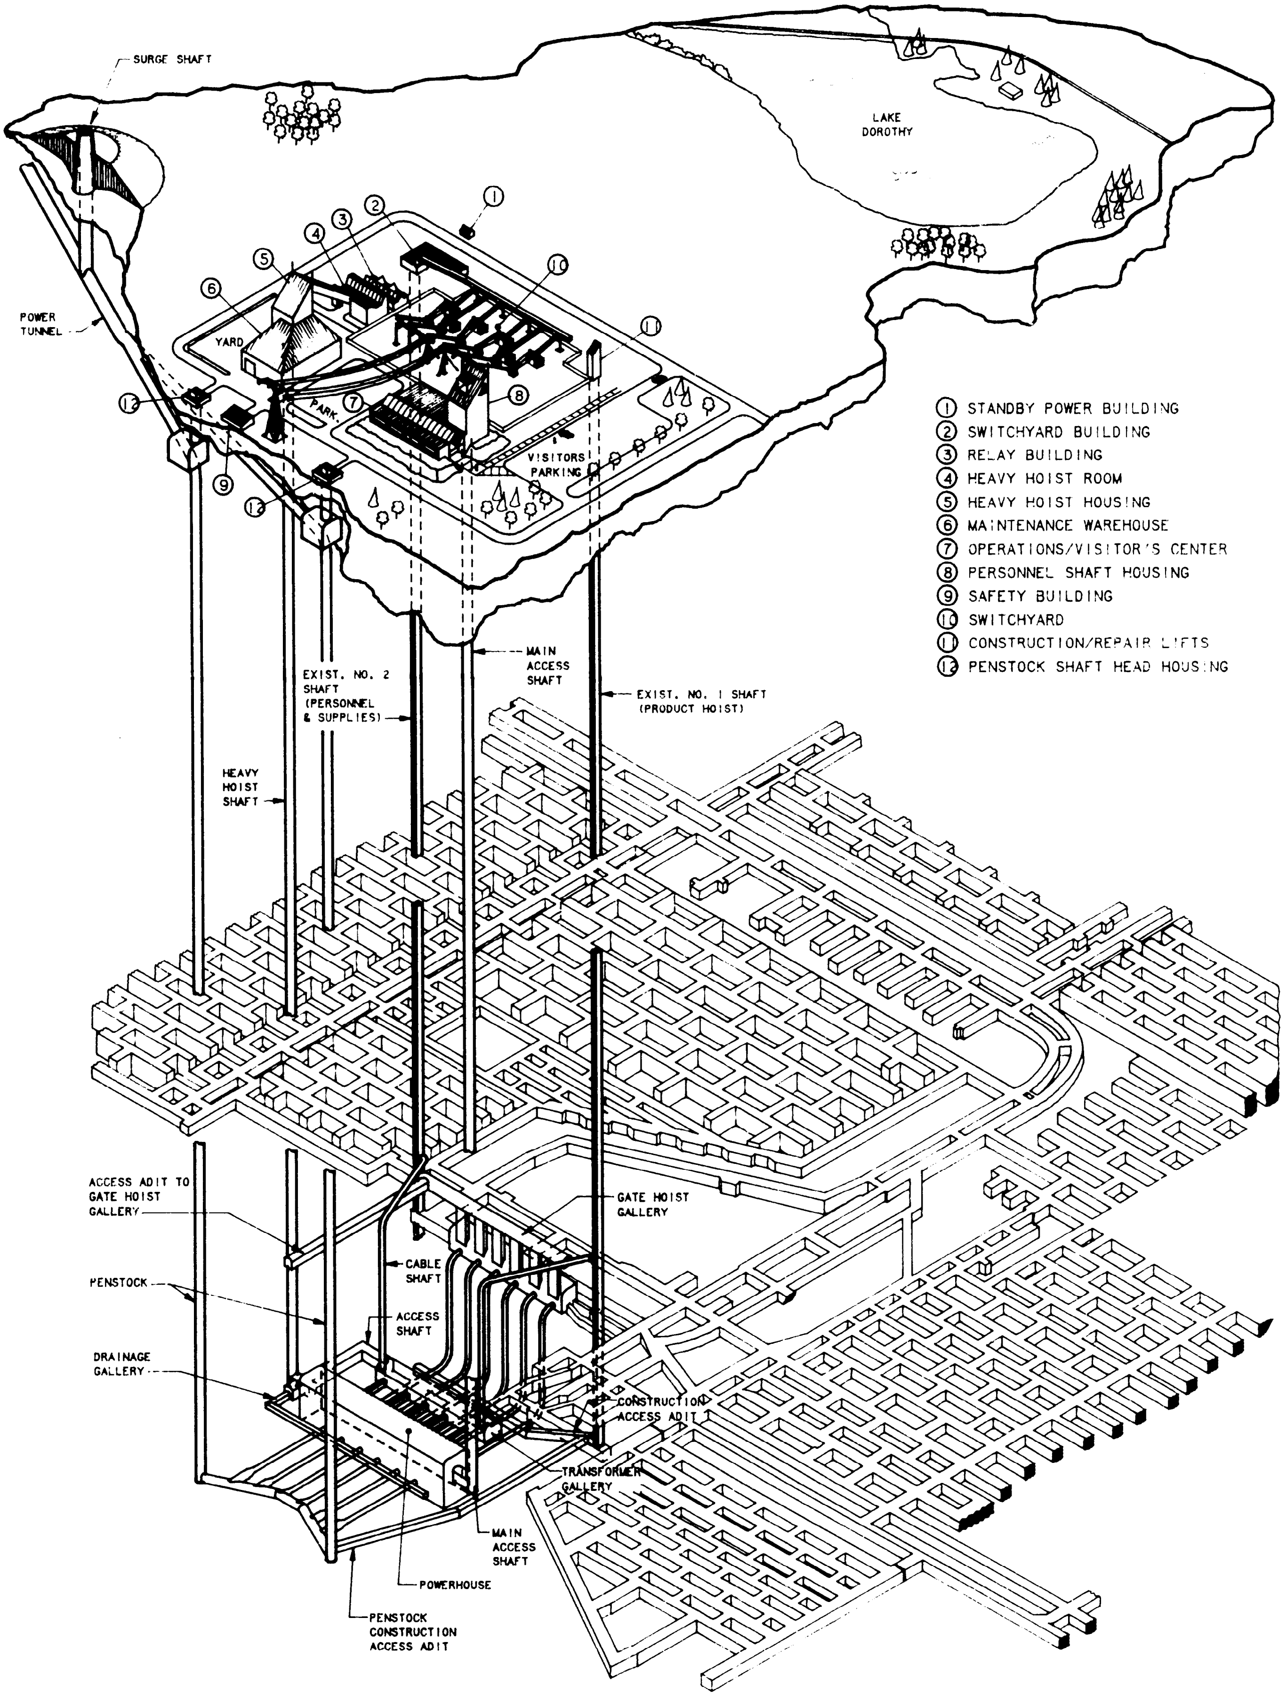

Fig. 24.2.7. Proposed underground pumped storage facility using an existing mine.

Studies of alternative means of storing large volumes of compressed air have included consideration of excavated caverns in hard rock (Anon., 1981). Possible cavern configurations have included large parallel caverns similar to those proposed for UPH and caverns excavated by room and pillar methods (Anon., 1988b).

24.2.4.3 Superconducting Electromagnetic Energy Storage (SMES)

Superconducting electromagnetic energy storage involves the storage of electrical energy in a closed electrical circuit cooled to subcritical temperatures. Laboratory scale tests have demonstrated the feasibility of the concept, and conceptual designs have been prepared for installations capable of storing up to 1000 MWh of electrical energy.

Because of the major forces, low temperatures, and high electrical fields involved in the concept, an underground location in rock has been proposed as the most appropriate for this development. No test or prototype installations have yet been constructed, although it is understood that the concept is under active consideration for the provision of the high-powered lasers required for the Strategic Defense Initiative (SDI) program.

Chapter 24.3
WASTE REPOSITORIES

DONALD L. VIETH AND MICHAEL D. VOEGELE

The discussion that follows addresses the basic concepts of a high-level radioactive waste repository, the fundamental rationale behind the concepts, the criteria covering its performance, and the considerations that must be addressed in the creation of such a facility. A *repository* is a complex facility that must accommodate a variety of factors, including those defined by the natural laws, requirements of regulatory agencies, and requirements established by political compromise. At the time of the preparation of this chapter, no high-level radioactive waste repository had either been formally designed or built. Many concepts are still being analyzed, evaluated, and debated; the technical basis for the details of the design has not been formally or authoritatively established. Conceptual designs (Anon., 1979a, 1979b, 1981, 1983, 1984, 1986a, 1986b; MacDougall et al., 1987) have been prepared for repositories in which various approaches have been examined in addressing some of the issues; however, the final or acceptable approach has not been formally adopted.

Because of the early stages of development of the repository concept, this chapter discusses the concepts of a repository and the factors affecting the analysis, evaluation, and selection of approaches to design of the underground facility and its component parts.

For aspects of cavern construction and radioactive waste disposal, see Chapter 15.3.1.

24.3.1 INTRODUCTION

24.3.1.1 Repository Concept

The method selected (Anon., 1980) for the disposal of high-level radioactive waste in the United States is disposal in deep geologic formations. The concept is to encapsulate the high-level radioactive waste as a stable, solid form in a high-quality, hermetically sealed canister and place it deep within a stable geologic formation somewhere between 1000 to 3000 ft (300 to 900 m) below the surface. A conceptual illustration of a geologic repository is presented in Fig. 24.3.1.

High-level radioactive waste is a material that is known to be hazardous to man, and the hazardous nature will remain for an extended period of time. The hazard is associated with the radiation emitted (alpha, beta, or gamma) from the material. The degree of hazard generally decreases with time, and the rate of decrease is determined by the half-life of the radionuclides involved. Half-lives vary from a few seconds to 10s and 100s of thousands of years. Because of the initial high radiation intensity of the hazardous material and the duration of its persistence, a method of disposal of high integrity, beyond that of all previous waste disposal options, had to be identified. The method would require structures with a stability far beyond that of recorded history (approximately 10,000 years). The only structures that satisfied the time stability criterion were geologic structures, some of which have been in place for a period ranging from 250 million to a billion years. A geologic repository was conceived as a means of utilizing the earth as a physical barrier to separate the radioactive materials from man and his environment; the stability of the formation was to ensure its long-term effectiveness. A geologic repository is expected to contain a nominal quantity of radioactive waste of 77,000 tons (70,000t) in the form of spent fuel elements (Anon., 1982). When the basic constraints of underground facility design and requirements for dissipating the thermal energy from the radioactive decay are considered, a repository is likely to cover an area of approximately 2 to 3 mi^2 (5 to 8 km^2) underground. A repository, when constructed, will be a room and pillar configuration, involving on the order of 190 mi (300 km) of passageways and drifts. To construct such a facility, it is estimated that in excess of 20 million tons of rock (roughly 300 million ft^3 or 8.5 M m^3) may have to be removed and a large percentage subsequently replaced in the passageways and other openings.

The design of a high-level radioactive waste repository will have to satisfy numerous objectives, often conflicting, which will have to be met on a simultaneous basis. The life of a repository can be divided into two distinct time periods, and the different functions that are required to be performed during each will have a significant impact on the philosophy and approach to its design. The two time periods are the operational phase (30 to 100 years in duration) and the isolation phase (10,000 years in duration); discussion of the functions of the repository system in this paper is divided into these two categories.

During the operational phase, the objectives of the design will be to facilitate (1) rock removal required in creating the labyrinth of passageways, (2) the emplacement of radioactive waste, (3) operational safety for underground workers, (4) control of the air supply, and (5) protection against the release of radioactive materials, if there should be an accident of a radiological nature. In the discussion that follows, activities occurring in the operational phase that can have significant impact on the performance of the repository system in the isolation phase are generally presented in the discussion regarding the isolation phase. For the isolation phase, the design objectives will be to control the conditions around the package containing the radioactive waste, if necessary, to control and divert water away from the waste package, to control and dissipate decay heat from the waste package, to prevent perturbation of the initial geologic structure in which the repository is located, to provide effective man-made barriers to replace the natural rock removed in order to emplace the waste, and to prevent releases and transport of radioactive materials.

Greater detail is provided in subsequent segments regarding each of these design requirements.

24.3.1.2 Relationship Between Repository and the Natural Environment

The natural environment referenced here includes the geologic, hydrologic, and geochemical conditions that exist in the earth before and during the time the repository is performing its function. Geologic disposal was selected as the method for disposing of high-level radioactive waste because of the need for a situation where long-term stability (250,000 to 1,000,000 years) could be expected. Geologic formations, known to be stable for

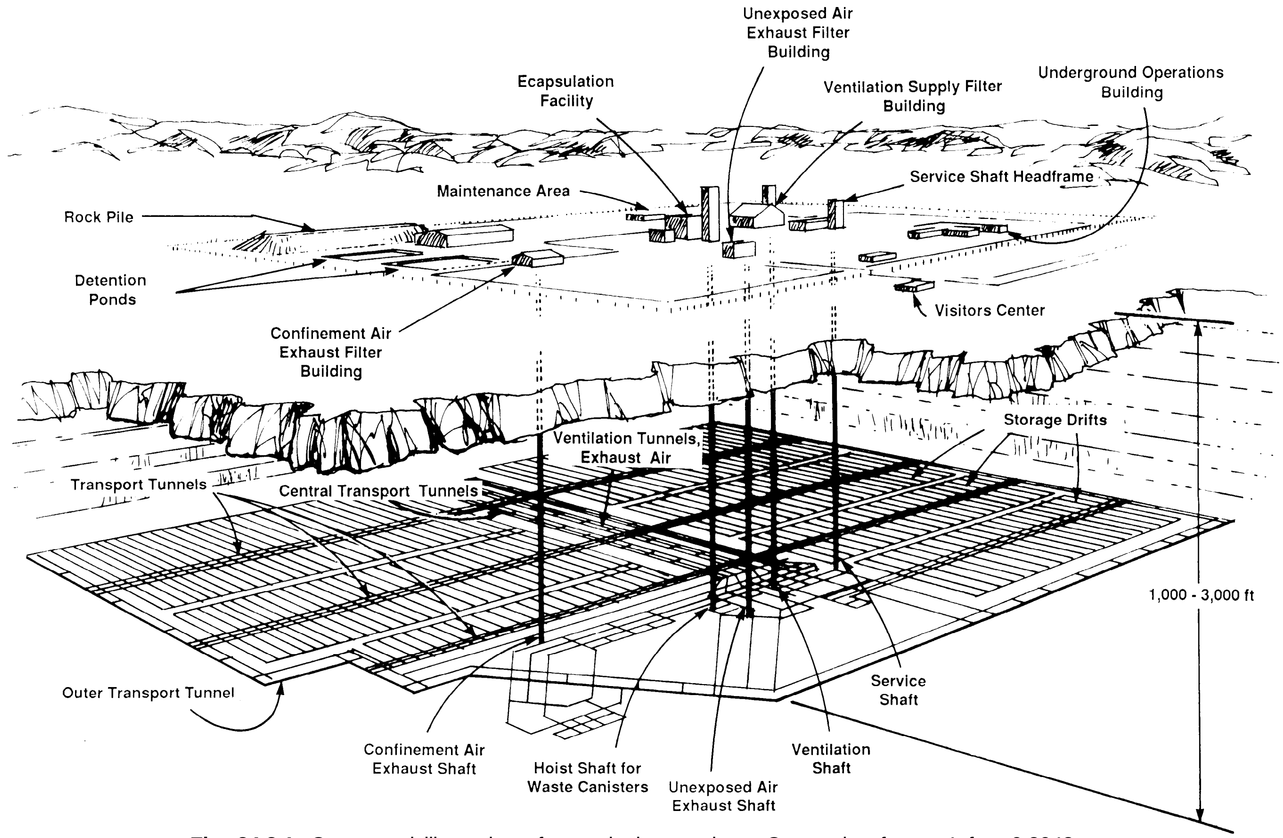

Fig. 24.3.1. Conceptual illustration of a geologic repository. Conversion factor: 1 ft = 0.3048 m.

periods of tens of millions of years, would serve as a significant physical barrier that would all but guarantee permanent separation of the solid, stable radioactive waste form from man's environment. While many naturally occurring materials can serve as effective barriers, the selection of a geologic medium would also be controlled primarily by its engineering and structural properties; a labyrinth of passageways over a 2- to 3-mi^2 (5- to 8-km^2) area would have to be designed and constructed to be structurally stable for a period of approximately 100 years.

Hydrologic conditions in the natural environment are also critical in that dissolution of or leaching of radionuclides from the waste form and the subsequent transport by water is considered the primary means by which radioactive materials can be brought back to the human environment. From this perspective, the smaller the amount of water available to interact with the waste, and the more benign from a chemical perspective, the better the situation. Because of this basic fact, there is a significant benefit to be obtained by placing a repository in the unsaturated (vadose) zone as opposed to the saturated zone (below the water table). The major difficulty is finding a location where the water table is 1000 to 3000 ft (300 to 900 m) below the surface. A repository placed below the water table, after the repository is closed and sealed, will eventually be resaturated with water. In such cases, there would be a significant quantity of water available for direct contact with the waste package. Depending on the depth below the water table, the hydrostatic head could be great enough to prevent the water from converting to vapor at 212°F (100°C), or lower temperatures at higher elevations, and thereby place superheated water in contact with the waste package. A situation with elevated temperatures and an electrolyte in direct contact with the waste package fosters a condition where corrosion rates and degradation mechanisms affecting the waste package are accelerated. If the waste package were to breach, then leach rates and dissolution rates for the waste form would be expected to be greater at elevated temperatures.

Repositories located in the vadose zone have a distinct physical advantage (Winograd, 1981) because the formation containing the repository will have significantly less free water and will not likely fill with water after the repository is sealed. (It is possible that a repository located in the vadose zone would flood after closure; however, it would require some significant force in nature to change the existing condition with regard to the water table.) Consequently, if there is no pool of standing water (natural electrolyte) in contact with the waste package, the potential for aqueous corrosion is significantly reduced. If the package were to be breached, then there is no significant quantity of water available to enter the waste package and leach or dissolve the waste form. With a paucity of water, there is substantially less capability for significant mass transport of radionuclides away from their point of emplacement. The possibility of transport of gas-phase radionuclides may, however, be greater in the vadose zone. While there may be many arguments about the details of hydrologic models for the unsaturated zone, the most elementary test is to consider the mass transport requirements to move radionuclides in the repository and the amount of water that will be available over time to affect the transport. While the velocity of water movement is often considered to be a critical factor (Anon., 1989a), the flux of water is a more fundamental parameter to consider in terms of the potential for mass transport of radionuclides.

The geochemistry of the environment can play an important role in the effectiveness of the repository, and there are numerous points that need to be considered. The chemical nature of the formation can affect the chemistry of the groundwater moving through it. With all other factors held constant, the less reactive the constituents in the water, the better the situation. Water will serve as an electrolyte, and chemical constituents in the water will affect how aggressive the electrolyte will be in the degradation of materials introduced into the system by man. The geochemistry of the geologic medium in and surrounding the repository proper is important from a chemical stability viewpoint. Heat from radioactive decay of the waste will raise the temperature of the rock, and elevated temperatures can lead to critical changes in the rock, such as driving off water of hydration from minerals in the formation. Change in chemical composition can produce physical and structural changes in the rock, primarily change in volume. Because of the volume of rock involved (several cubic miles or cubic kilometers), particular attention needs to be given to the active physical changes that might occur.

Geochemical conditions can also be positive in contributing to the isolation of waste. Certain minerals found in nature, for example, zeolites, have a chemical affinity for chemical constituents dissolved in water. When the water containing the dissolved constituents passes through solids containing zeolites, the constituents in the water will be removed from solution (Sherwood et al., 1975). If the dissolved constituents happen to be radionuclides, the zeolites would remove them from the water, thereby keeping radionuclides near the site of emplacement and promoting isolation.

The natural environment is critical to the repository in its ability to accomplish the objective for emplacing the waste in an operationally safe manner and for isolating the waste. When one considers the time required for waste isolation, the natural physical processes that will be in action continuously, and the size of the various components in the repository, as well as the repository, it is clear that the natural environment will dominate the control of release in comparison to the systems and materials introduced by man. The point to be made is that selecting the site for the repository with the proper combination of naturally occurring conditions is the most crucial part of the effort in creating a repository. A repository is significantly different from any other nuclear facility in that the major physical element of the repository that is, the site itself is in place at the outset of the effort, and man will have no role in putting the containment structure in place. It is essential to remember that when building a facility for man's use underground, it is not created by putting the materials structure in place but by taking material away.

24.3.1.3 Differences Between a Repository and Other Underground Structures

A repository will be a labyrinth of passageways covering an area on the order of 3 mi^2 (8 km^2) and, as such, might appear to be similar to other underground structures. While other underground facilities may be of similar size and extent, the purpose, requirements, and conditions of the repository make it significantly different. The penetration into the ground (shafts) and passageways are to support a primary objective, a method of getting the waste from the surface to its final resting place. Because of the long-term presence of the waste, the regulations governing its disposal strongly emphasize the requirement that no significant damage be done to the formation so that no unknown or difficult-to-seal pathway between the waste and the human environment be created.

The facility will also be different in that the waste introduced will have a gradual release of thermal energy (St. John, 1987) from radioactive decay. This will result in the ambient temperature of the repository increasing over a 200- to 400-yr period and then slowly returning to the natural ambient temperature after a total time of 400 to 800 yr. Depending on the location and timing of the waste emplacement, the temperature profile and associated thermal expansion and nonuniform stress fields could produce impacts on near-term operation and long-term isolation (Nitao, 1988). Temperature gradients can produce movement of water in the rock formation, especially for repositories in the vadose zone; controlling water movement in the repository is important and will require a good knowledge of the time, temperature, and location relationships. Temperature in the repository could eventually become a problem from an operational perspective. While a waste package may release energy at only a 1-kW rate (comparable to ten 100-W light bulbs in an emplacement hole) over a period of 40 years, the temperature of the rock surrounding the waste that absorbed the energy can reach a point where the conditions in the passageways will create a situation in which it is uncomfortable or difficult for humans to work. Consequently, the design must be able to accommodate innovative ways to keep the temperature of the work areas cool at a time when the repository is ready for closure. This is the timeframe when closure operations or retrieval operations would be implemented.

The long-term structural stability of the passageways is desired to support operations, yet the mined opening represents a preferential pathway for the movement of water underground. To avoid collapse of the openings, with a concomitant increase in the volume of formation in which water can move freely, it is considered prudent to backfill all passageways and openings as the surest method of preventing collapse. It is expected that the rock removed from the passages would be crushed, classified, and reinserted into the passageways. The crushed rock might be mixed with other materials to improve the ability of the backfilled passageways to resist deformation and to improve the ability of the backfill to retard the movement of water and radionuelides.

Shafts entering the earth will have to be backfilled and sealed. They clearly represent preferential pathways between the waste and human environment. The primary concern will be to seal the openings to ensure that water will not enter the repository and disrupt its initial condition.

24.3.1.4 Impact of Regulatory Approval Process on Design Approach

Before the repository can be built, a significant regulatory review and approval process must be completed. The specific technical requirements that must be satisfied are outlined in the *Code of Federal Regulations* (CFR) issued by the Nuclear Regulatory Commission (NRC). The technical regulations are presented in 10 CFR Part 60 (Anon., 1989a) while the details of the licensing procedure are outlined in 10 CFR Part 2 (Anon., 1990). Detailed information about the site, obtained from the site characterization program, along with a safety analysis report specified in 10 CFR 60.21 which examines and analyzes the repository design and its impact on short-term containment and long-term waste isolation characteristics, must first be reviewed and accepted by the NRC staff. Once accepted by the NRC staff, the case can be presented and argued before an Atomic Safety and Licensing Board. The Atomic Safety and Licensing Board currently consists of three judges, an environmental scientist, a physical scientist/engineer, and a lawyer. While this is the current structure, there are expectations the structure of the Board would change to reflect a broader scope of technical expertise. The panel constitutes an administrative law court, and the review is conducted within the context of a formal trial. In addition to the regulator (NRC) and the license applicant (Department of Energy or DOE), other parties, such as the representatives of the state in which the repository is to be built and whoever else is granted status by the Board, can be admitted to the proceedings as full participants with their lawyers challenging the technical data and analyses, and cross-examining scientists and engineers presenting the information about, and argument for, the proposed repository.

The objective of the Licensing Board is to identify issues of contention and hear the evidence in favor of and opposing the proposal, and to determine if the radiological hazard of the project falls within the approved guidelines. Because of the nature of the repository, that is, the length of time (10,000 yr) over which the repository will have to function, the basis on which to decide the safety aspects become somewhat diffuse. The rules established by the NRC under which to grant a construction authorization are embodied in 10 CFR Part 60. This rule identifies four major performance objectives pertinent to the postclosure performance of the repository that must be demonstrated in the regulatory review:

1. The prewaste emplacement groundwater travel time between the disturbed zone (around the repository) to the accessible environment must be greater than 1000 years.

2. The engineered barrier system cannot, on an annual basis, release more than 1 part in 100,000 of the radionuclides present at 1000 years after emplacement.

3. The waste package must provide essentially complete containment for 300 to 1000 years.

4. The release of radionuclides to the accessible environment over a 10,000-yr period cannot exceed the release limits (total curies) specified in 40 CFR Part 191 (a standard established by the Environmental Protection Agency) (Anon., 1986c).

These performance objectives appear to be well stated and quantifiable standards of judgment on which to base a decision. Fundamental questions pertain to the data set required, the analyses of that data set that will be considered acceptable, and the level of uncertainty or error bounds associated with the determinations that will be considered acceptable. It is evident from the time frames identified in each performance objective that they cannot be measured in the time proposed for the research and development or, for that matter, in a single human lifetime. Therefore, the basic parameters involved in each performance objective for a proposed site or design will have to be calculated based on models. In such a situation, there will be four different kinds of models involved in these estimates, which include a geologic model of the earth including its stratigraphy and spatial structure, a hydrologic model covering the location and movements of the groundwater, the physical models of the natural phenomena occurring at that location in that natural environment, and the mathematical models that reflect the various physical realities that allow for quantitative estimates of effects. Because of the complexity of these models, the spatial framework in which they must apply, and the temporal scale they must cover, it will be difficult, if not impossible, to validate the models in the traditional sense. Consequently, there will be substantial uncertainty as to the actual performance that will be achieved.

With this inherent uncertainty, there exists a fundamental motivation on the part of the regulators, who must approve the proposed site and the design of the underground facility within the context of "reasonable assurance" that it will perform, to compensate in order to ensure achievement of performance objectives. This approach is generally referred to as "conservatism." It is manifested in the assumptions that must be made about the conditions at the site and the bases established for the facility design. The basic philosophy that is manifest is the requirement to use conservative assumptions in models, considered to be inherently uncertain, in order to provide a reasonable picture of the likely outcome.

One approach of this kind has been utilized in the regulatory arena. Licensing of nuclear production and utilization facilities in the United States requires that building and system structures response to seismic events be analyzed (Anon., 1989b; Anon., 1977). Tectonic behavior of the earth is a physical process that cannot be confidently predicted or experimentally simulated, yet the understanding of the process and effects is important for predicting structural response to the seismic stimulus. Accordingly, regulatory precedence has been set in probabilistic prediction of tectonic behavior.

It is expected that this precedent will be applied to both the man-made surface facilities (100 years) and the underground facility (10,000 years). The longer time frames will lead to reduced confidence in the certainty in the predicted behavior. Through a combination of conservatism in the engineering design, conservatism in the prediction of the occurrence of tectonic phenomena, and conservatism in the magnitude of the tectonic phenomena, the applicant (DOE) must provide the requisite assurance to the NRC staff and the Licensing Board that the design is safe. Analysis (Subramanian et al., 1989; Koplik et al., 1982) of the design parameters and their impacts on safety have shown that there is minor reduction in risk to the public's health and safety by designing to extreme conservation and, under general circumstances, this avenue of design would not normally be considered prudent. However, in licensing cases, confidence in the safety of the design over long time periods is the imperative, and the enhanced conservatism is considered necessary to achieve "reasonable assurance."

24.3.1.5 Specific Factors That Must Be Considered

The design of the underground portion of the repository must accommodate a number of unusual design requirements. Three specific requirements include two different time frames for which the repository must perform, the need to rely on highly variable inhomogeneous material to provide for isolation of the waste, and the requirement to have a defense-in-depth concept by using multiple barriers to the release of radionuclides.

The repository will have to function in two different time frames. These time frames have been previously referred to as the operational phase and the isolation phase. The operational phase is the time when the repository is open; construction of new emplacement locations is underway; and receipt of and emplacing waste, executing the period of performance confirmation testing, and the closure, backfilling, and sealing phase is taking place. A point should be made about the process of constructing the repository. Initially, the shafts or ramps, underground maintenance areas, major passageways, and a limited number of emplacement areas will be constructed. It is estimated that it will require a minimum of five years to establish this underground base of operation. Once operational, both emplacement and construction activities will occur simultaneously in parts of the repository that are physically separated.

The time expected to emplace 77,000 tons (70,000 t) of high-level waste at the rate of 3300 tons (3000 t) per year is approximately 25 years (Anon., 1985; MacDougall et al., 1987). The NRC can require that the repository remain open for 50 years after the first waste is emplaced for the purpose of performance confirmation. At the end of the performance confirmation effort, the NRC must decide to either backfill and seal the repository or to retrieve the waste. For the retrieval operation, NRC regulations require that it be possible to retrieve all the waste in a time frame approximately equal to that required to emplace it. It is expected that the time to backfill all openings and passageways is less than the time to retrieve the waste (Anon., 1989a). Consequently, from a design perspective, the openings underground must be structurally stable for a time period of 80 to 100 years.

The second time frame that must be considered is the isolation period, which is nominally 10,000 years as specified in regulations (40 CFR Part 191). A longer time frame could be dictated by the decay of the radioactive materials in the repository.[a] The effectiveness of the repository in isolating the waste is most dependent on the intrinsic characteristics of the geologic, hydrologic, and geochemical environment in which the repository is located. The major point to be considered in the repository design is that the properties and character of the site, relied upon to meet the performance objectives, are not impacted by the construction, operation, or content of the repository to the extent that they no longer provide the means to isolate waste.

The decision as to the site where the repository will be located is the single most important decision that is made with respect to a repository. The site should be selected on the intrinsic characteristics of the geologic, hydrologic, and geochemical environment. This needs to be done in the framework of the regional geologic setting that provides some overall indication of long-term stability; stability that has to be judged in the context of tens of thousands to hundreds of thousands of years. The geologic medium is critical in that it becomes the engineering material in which the shafts and openings are constructed, and this will require stability in terms of a century. This judgment will have to be made in the estimates of conditions over a 2- to 3-mi^2 (5 to 8-km^2) area. The hydrologic regime is critical since water is the major means, in a stable geologic formation, by which radionuclides, contained in the solid waste, could possibly return to the human environment once buried 1000 ft (300 m) below the surface. Geochemical characteristics are critical since they will influence how aggressive a chemical environment the waste packages and waste form would have to resist over the required time and influence how closely temperatures would have to be controlled during the first 400 to 800 years the repository is in existence. The selection of the site establishes the boundary conditions that the designers must contend with in their attempt to establish a configuration for the underground facility to ensure that performance objectives can be achieved.

Site selection will affect the success of the efforts in a number of different ways. An ideal situation would be if the site were relatively elementary in structure and benign in character. Simplicity of geologic structure is desirable to limit the difficulty of characterizing the site and establishing an authoritative basis of "reasonable assurance" for the regulators and the Licensing Board that the site is understood well enough to approve its use.

A basic decision needs to be made regarding the hydrologic regime; that is, should the horizon in which the underground facility is located be above the water table (in the vadose zone) or below the water table. If the repository is located below the water table, the repository can be expected to resaturate with water after the repository is closed (unless it is in a sealed formation such as bedded salt). This is likely to create a more aggressive and corrosive environment for the first 400 to 800 years while the thermal energy is released with the waste package in intimate and constant contact with a hot or warm electrolyte. Corrosion and leaching potential in an electrolyte is likely to lead to failure of the waste package, leaching of radionuclides from the waste form, and transport of radionuclides in the abundant groundwater at a more rapid rate than if the groundwater were not present in a saturated condition. If the hydraulic head in the horizon is high, the temperature of the water in contact with the waste package could go above the boiling point of water, 212°F (100°C), due to the increased pressure.

Selection of a horizon in the vadose zone offers a potential for a more benign situation. In the vadose zone, there is far less potential for the waste package or waste form to be in constant contact with standing water (electrolyte). The waste package is more likely to experience conditions of low-temperature oxidation in a humid environment, as opposed to aqueous corrosion in an aggressive electrolyte. While water may come in contact on a periodic basis with the waste form, there is not likely to be continuous contact and flow of water to carry leached radionuclides downward through the repository and the geologic formation into the standing groundwater. The magnitude and nature of the flux of water past the waste package will determine the potential for significant mass transport of radionuclides out of the repository.

While the selection of a site can be the predominant step in creating a repository capable of achieving the desired performance objectives, it is recommended by the regulators that engineering measures, often called "engineered barriers," be utilized to help achieve performance objectives. The utilization of multiple barriers, both natural and engineered, is expected as part of an overall waste isolation system. The factor that is essential to keep in mind is the function the barrier is supposed to perform and the effectiveness of that barrier over the time frame that is involved. The current concept (Anon., 1988) is that the barriers to the movement of radionuclides from the point of waste emplacement include the waste form (for spent fuel, it is a uranium dioxide fuel pellet and the metal tubing in which it is sealed), the waste canister (a hermetically sealed metal canister), a backfill between the waste canister and the geologic medium, and the geologic medium between the backfill and the human environment. The first three items noted above would be considered an engineered barrier system in that they have been conceived, designed, and fabricated by man. All three of these items have been designed to retard the release of radionuclides. The effectiveness of each barrier needs to be evaluated on a case-by-case basis considering the materials involved, the hydrologic environment, and the chemical environment in which it must function. In general, three factors above all will control the effectiveness of the barrier: (1) the chemical affinity of the barrier material for the radionuclides, (2) the permeability of the barrier material to water, and (3) the physical size or dimension of the pathway through the barrier. Before final decisions are made, the true value of the engineered barrier needs to be evaluated in the context of the ability of the natural materials within the repository itself to retard the movement of radionuclides.

[a] A spent fuel element, depending on type—boiling water reactor (BWR) or pressure water reactor (PWR)—can have plutonium contents of 0.5 to 0.8% by weight. For a repository containing 77,000 tons (70,000 t) of heavy metal (in the form of spent fuel elements), a total plutonium content could range from 385 to 615 tons (350 to 560 t). The plutonium would eventually disappear by radioactive decay; the rule of thumb is that in 10 half-lives, the amount of the radionuclide would decrease by a factor of 1000. For Pu-239, with a half-life of 24,000 years, the 615 tons (560 t) would decrease to 1100 lb (500 kg) in 240,000 years. After 480,000 years, 20 half-lives, the total plutonium content in the repository (2 to 3 mi^2 or 5 to 8 km^2) would be 1.1 lb (500 g).

24.3.1.6 Basic Philosophical Principles that Affect the Approach to Repository Design

A number of basic considerations will affect the approach to the design of the underground portions of the repository. The most important consideration in the approach to the design is the fact that the earth, as it exists with its intrinsic positive and negative features, is the structure and material that will contain and isolate the waste. Characteristics that affect specific details of the design will be the strength of the rock and its time-dependent mechanical properties, the thermal conductivity, the chemical reactivity and stability of the rock, the hydrologic characteristics of the site and the region in which it is located, and the geologic structure of the formation. The designer will have had no influence in the creation of the geologic regime under consideration and will be able to do little to change the conditions in the geologic regime in which the wastes will be placed. The existing conditions are all that is available and the designer must work with them, utilizing them to achieve the isolation requirements.

The second point that needs to be considered is that the "underground facility" (the opening) itself will probably contribute little to achieve isolation. The most important feature in the design is the configuration of the facility, which will affect the distribution of the waste and, in effect, the thermal energy release distribution. The design and construction of the underground facility will do little to enhance the intrinsic ability of the earth to isolate the waste, but if not properly executed, the design and construction practices can affect the isolation in a negative manner. The primary function of the underground openings is to allow the waste to be moved from the surface to the point of final emplacement. They also provide for the removal of freshly mined rock and provide for ventilation. The concern for negative impacts focuses on several factors, including the creation of preferential pathways for radionuclides to move out of the repository and the potential for introduction of massive quantities of materials that could increase the mobility of the radionuclides. For example, organic materials are known to form chemically complex molecules with plutonium and, by doing so, to reduce the adsorption capability of the natural media for plutonium in aqueous solution (Sanchez et al., 1985). Organic materials in the form of diesel fuel, incompletely burned organics in engine exhaust, rubber on the ground from tire wear, and epoxy anchors in rock bolts are likely to be introduced. Care will be required in evaluating their effect and estimating the mass of materials introduced. The significance of the threat will be affected by the law of mass action and the tonnage of these materials that might be left in the repository when it is closed.

The third point is that the waste going into the repository is not a factor from a chemical compatibility viewpoint, but it can affect the design from a physical effects perspective. The effect is in the release of thermal energy from the decay of the radioactive materials. The release of the thermal energy into the geologic formation results in a temperature increase. The bulk of the thermal energy is released within the first 200 to 400 years. The control of the maximum increase in the temperature experienced by the geologic formation will depend on the energy content of the waste and the configuration of emplacement points. The energy content of the waste, especially in the form of spent fuel, will depend on the burn-up level experienced by the fuel while in the reactor and the aging time of the waste before emplacement. The maximum temperature desired in the repository will depend on a number of factors, including whether the repository is above or below the water table, the chemical reactivity and stability of the geologic medium, the coefficient of thermal expansion of the geologic medium, and the time to heat the surface of the passageways to a temperature in which it will be difficult for humans to work.

24.3.2 BASIC FUNCTIONS OF A REPOSITORY

24.3.2.1 Operational Phase

LIFETIME OF THE FACILITY. The lifetime of the repository facility is dictated by requirements to receive a specified amount of high-level radioactive waste and by the approach taken to the requirement to maintain the option to retrieve the waste. The requirement to maintain the option to retrieve the waste is discussed in detail in a subsequent section. It is sufficient to note here that there is a requirement to maintain the option to retrieve for a period of time and, if necessary, execute retrieval in a time period that is approximately equal to that required to emplace the waste. The Nuclear Waste Policy Act of 1982 (NWPA) (Anon., 1982) specifies that the first repository cannot receive more than the equivalent of 77,000 tons (70,000 t) prior to the development of a second repository. This requirement does not preclude the placement of more than 77,000 tons (70,000 t) in a repository; it only specifies that there be two repositories if more than 77,000 tons (70,000 t) is to be placed in one. The currently anticipated receipt rates for waste at the repository are specified by the DOE (Anon., 1985). The reference indicates that the repository should be accepting waste on a schedule that would result in a total of 77,000 tons (70,000 t) in a period of 25 yr. The schedule is predicated on a phased repository construction that would permit receipt of small amounts of waste in the first four years of operation. For purposes of this discussion, a period of 25 yr for emplacement of 77,000 tons (70,000 t) provides a reasonable estimate of the basic time period that is relevant to discussion of facility lifetime.

The required facility lifetime is based on the 25-yr time for receipt of waste and on the approach selected to maintain the option to retrieve the waste. For a repository for which it was planned to receive no more than 77,000 tons (70,000 t) of waste material, an estimate of the lifetime can be calculated in the following manner (Flores, 1986). The retrievability requirement of 10 CFR Part 60 states that the option to retrieve the wastes must be maintained throughout the period during which wastes are being emplaced and thereafter until the completion of the performance confirmation program and NRC review of the information obtained from that program. The requirement on retrievability in 10 CFR Part 60 indicates that to satisfy this objective, the Geologic Repository Operations Area (GROA) shall be designed so that any or all of the emplaced wastes can be retrieved on a reasonable schedule starting at any time up to 50 yr after waste emplacement operations are initiated, unless the Commission approves a different schedule. This different schedule would need to be established on a case-by-case basis consistent with the emplacement schedule and the planned performance confirmation program. Accordingly, activities related to retrieval could be occurring roughly 100 yr after the initiation of waste emplacement. Some flexibility in lifetime requirements could be accommodated within this schedule, however. Because the 50-yr requirement of 10 CFR Part 60 is twice as long as the period in which wastes are to be emplaced in this example, 25 yr will be devoted to simply monitoring the emplaced wastes and confirming the performance of the repository. A prudent engineering approach to retrieval could involve partial decommissioning of facilities, particularly those on the surface, and subsequent rehabilitation of the facilities important to the retrieval operations should it become necessary.

FACILITY DEVELOPMENT REQUIREMENTS. The development of the underground repository facility will probably proceed in much the same manner as the development of a comparably sized mine that could be developed under conditions that lend themselves to mechanization (MacDougall et al., 1987). Before a decision can be made regarding the suitability of a site for a repository, an exploratory shaft and a small area (up to several acres) for conducting investigations and tests must be constructed. The exploratory shafts could eventually be used in the operation of the repository, and the placement of the exploratory shaft and test area should consider the conceptual design of the orientation and configuration of the repository in the geologic formation. Conceptual illustrations of the underground portions of two different repositories are presented in Figs. 24.3.2 and 24.3.3. Fig. 24.3.2 reflects the design concepts for a repository in bedded salt formations that have no lateral boundary conditions created by the geologic formation. Fig. 24.3.3 presents the design of a proposed repository in a tuff formation that may be limited in the lateral directions by geologic structures. The primary purpose of the underground portion of the repository is to provide an area in which to dispose of waste materials. Thus the facility must provide access to a horizon selected for its isolation capabilities. Generally, this development would require multiple shafts to facilitate simultaneous construction and emplacement operations and maintain separate ventilation circuits. Depending on the depth of the selected horizon, there is no reason why one or more decline ramps could not be used in place of some shafts. Such ramps could actually offer safety advantages as compared to shafts and are, in fact, currently envisioned for use at the proposed repository site in a tuff formation at Yucca Mountain in Nevada (MacDougall et al., 1987).

Since it is a societal requirement that the first repository begin operation at the earliest possible date, it may not be possible to construct the entire repository before emplacement of waste begins. The initial development of the repository will cover the excavation of the underground area capable of receiving approximately 16,500 tons (15,000 t) of waste (five years receipt) prior to the initiation of operation (Anon., 1985). The size of the initial development is affected by the need to separate the ventilation systems for the area where emplacement of radioactive waste is occurring from the area where mining operations are occurring. The logic behind this situation is discussed under ventilation requirements.

The facility development must also consider the movement of excavated materials from two perspectives. First, the muck must be removed to enable the emplacement of waste canisters. Second, the muck could be used to backfill areas in which waste canisters had been placed. Backfilling could be accomplished concurrently with emplacement operations, but this decision would have to consider many factors and require specific approval by the NRC. Also, concurrent backfilling operations add an additional logistics problem to the underground operations, especially if all backfill materials must be crushed, classified to ensure particle size, and homogeneously mixed with added constituents to give the backfill desired geochemical or retardation characteristics. The use of decline ramps would also facilitate both the muck removal and backfilling operations, as a

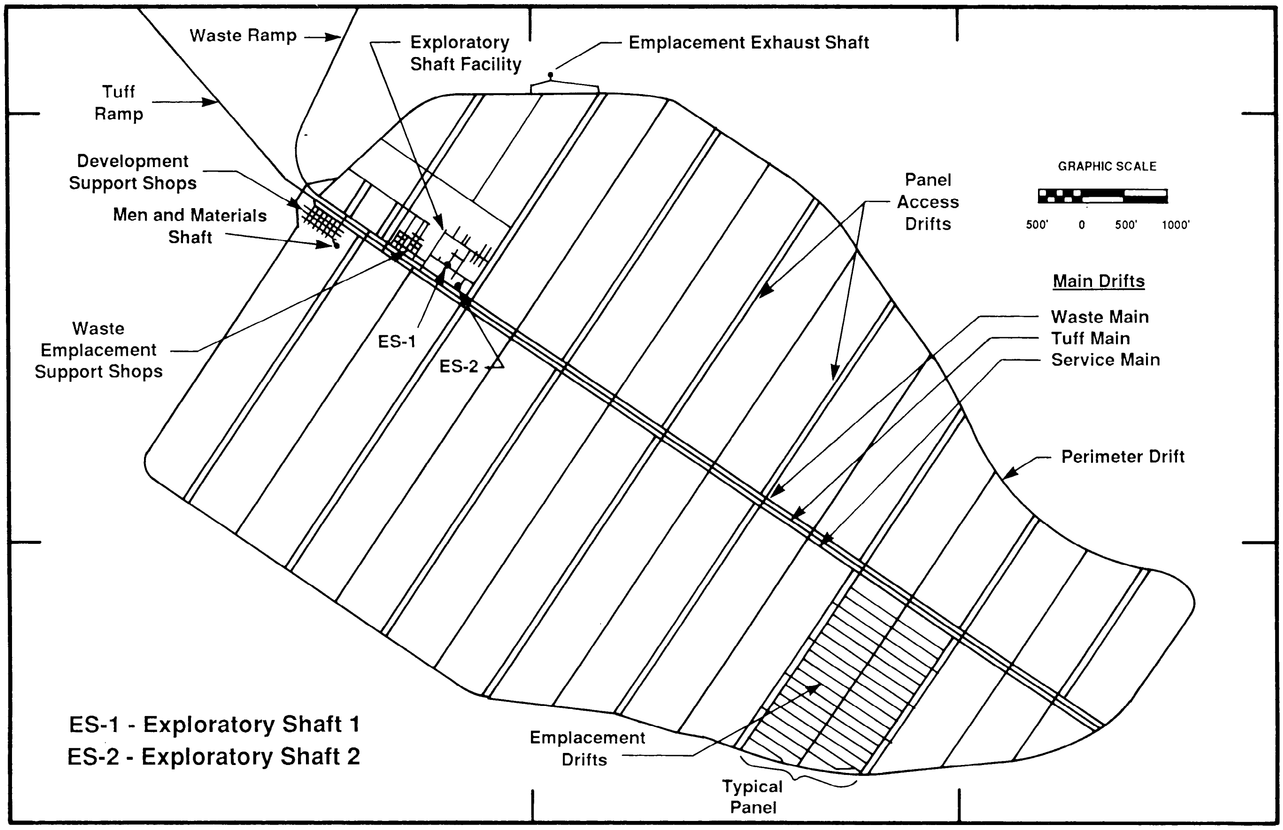

Fig. 24.3.3. Concept for a repository in a tuff formation. Conversion factor: 1 ft = 0.3048 m.

conveyor system could be implemented with possible attendant cost and efficiency benefits (MacDougall et al., 1987).

VENTILATION REQUIREMENTS. The regulatory requirements related to facility ventilation during the operational phase are derived from considerations that are related to public health and safety. Specifically, 10 CFR 60.133(g) contains a requirement that separate excavation and waste emplacement circuits be developed and maintained.

This requirement can be implemented in a conceptually straightforward manner by two ventilation systems designed to work in concert. The systems could be designed with a forced exhaust on the emplacement side of the ventilation circuit and a relatively positive ventilation pressure on the development or excavation side of the circuit. This is a safe arrangement in that loss of the ventilation fan(s) on either side of the circuit does not result in noncompliance with the regulatory requirement. If the exhaust fan(s) are lost, the positive pressure on the other side of the circuit should keep the ventilation flow in the correct direction; conversely, if the fan(s) are lost on the positive side of the circuit, the relatively negative pressures on the exhaust side of the circuit would prevent the airborne radionuclides, if released, from getting to the development side of the repository (MacDougall et al., 1987).

The ventilation systems do not have to be designed to work in concert, but there are apparent advantages in so doing. The primary disadvantage in a system where the circuits are not designed to work in concert is the potential for problems associated with leakage between the circuits.

The ventilation circuitry also is a primary element in compliance with the regulatory requirements to limit the release of radioactive materials that enable exposure of the public to airborne radionuclides during the operational period of the repository. Such radionuclides would generally only become available following an accident involving the rupture of a waste container. The method of choice to prevent releases following such an accident would probably be to use high-efficiency particulate-absorbing (HEPA) filters on the ventilation exhaust.

RETRIEVABILITY REQUIREMENTS. The principal reference to retrieval is contained in Section 122 of the NWPA (Anon., 1982) and states that the repository shall be designed and constructed to permit the retrieval of any spent nuclear fuel placed in such repository, during an appropriate period of operation of the facility, for any reason pertaining to the public health and safety, or the environment, or for the purpose of permitting the recovery of the economically valuable contents of such spent fuel.

The regulations, 10 CFR Part 60, require the implementation of these actions in 10 CFR 60.111(b) by stating that the geologic repository operations area be designed to preserve the option of waste retrieval throughout the period during which wastes are being emplaced, and thereafter until the completion of a performance confirmation program and Commission review of the information obtained from such a program. To satisfy this objective, the geologic repository operations area must be designed so that any or all of the emplaced waste could be retrieved on a reasonable schedule starting at any time up to 50 yr after waste emplacement operations are initiated, unless a different time period is approved or specified by the Commission. This different time period may be established on a case-by-case basis consistent with the emplacement schedule and planned performance confirmation program.

This requirement does not preclude decisions by the Commission to allow backfilling part or all, or permanent closure of, the geologic repository operations area prior to the end of the period of design for retrievability. A reasonable schedule for retrieval is one that would permit retrieval in about the same time as that devoted to construction of the geologic repository operations area and the emplacement of wastes.

The requirement to maintain the option to retrieve the emplaced waste results in either the requirement to maintain a stable facility, or to be able to reenter the facility and either remove any emplaced backfill, or in an extreme that could be encountered in temperature- or stress-sensitive rock formations, reexcavate the facility to recover the waste canisters.

For the single site selected for characterization by the US Congress, preliminary evaluations presented in the Site Characterization Plan for Yucca Mountain (Anon., 1988) indicate that stability can be maintained through the period of retrievability. Alternate evaluations (Brandshaug, 1989) produce similar conclusions and suggest that 50 yr of thermal and mechanical rock response has little effect on that development of joint slip beyond that produced from room excavation.

BACKFILL REQUIREMENTS. The term backfill in the repository has two specific connotations. In one case, it is used to identify the portion of the engineered barrier system that fills the volume in the emplacement hole between the waste package and the geologic medium or the host rock. In the second case, it refers to the material that will be used to fill the openings in the passageways and the shafts and/or ramps leading into the repository. While both applications have a common name and on the surface appear to have a common function, they are significantly different. Both backfills have a common interface where the emplacement holes intersect the passageway used to deliver the waste to the point of its permanent disposal.

The specific functions of the backfill that constitute the portion of the engineered barrier system adjacent to the waste canisters are covered in depth in that subsection. The primary function of the backfill that must be introduced into the openings, passageways, and shafts when it is decided that it is acceptable to close the repository is to provide some structural stability to the labyrinth of tunnels during the isolation phase. The backfill material will most likely be created by crushing and classifying the rock removed to create the opening in order to improve the packing density. The backfill is composed of a relatively noncompressible solid that, when filled into all the open space, can provide some structural support to the rock surrounding the opening. The efficiency of the backfill is dependent largely on the degree of compaction that can be obtained; its effectiveness will depend to some extent on the nature of the geologic medium in which the repository is located. If the repository is in a plastic, deformable medium with properties that are time dependent, there is still a possibility for subsidence in the opening since the backfill, if installed in particulate form in the field, would only achieve approximately 60% of maximum density. This leaves a 40% volume of void space that could slowly compact under the natural lithostatic load. In view of the structural strength of a nonplastic host rock and the low excavation ratio to be used in the repository, it is not likely that the openings will deform or collapse, thereby transferring the load to the backfill. If it becomes necessary to rely on the structural strength of the backfill to prevent subsidence, a careful program will have to be followed to ensure that the backfill does, in fact, provide structural resistance.

Since the backfill emplaced in the field has approximately 40% void space, it results in a fairly permeable material that will allow significant water movement if water enters the repository. Additions to the crushed host rock to alter its permeability are being considered (Fernandez and Freshley, 1984; Freshly, Dove and Fernandez, 1985a, 1985b). Bentonite, a mineral that increases in volume in the presence of water, has the ability to reduce the void space and permeability.

Backfill incorporating a material to minimize void space and permeability will be dependent on the geologic medium and its physical characteristics. For example, for a repository in salt, backfilling with bentonite is not likely to be needed. If any significant quantity of water enters a salt repository, it is a strong indication of a major failure in the seals, and the inclusion of a backfill in a water soluble media has little or no significance. For a repository in the vadose zone, a backfill with an expanding constituent seems to be of limited value; the value would be in a repository located beneath the water table in a formation that would be saturated with water.

CHEMICAL CONTAMINATION CONTROL. Chemical contamination control in the operational phase of the repository is of primary importance from an environmental perspective and an operational health and safety perspective. From either perspective, chemical contamination control at a repository is expected to be slightly different from that at other mines or underground facilities. First, environmental impacts will have to be mitigated and monitored as indicated by the provisions of the Resource Conservation and Recovery Act of 1976 (Anon., 1976). Secondly, all materials brought into the repository and their volume (tonnage) will have to be examined for mobility and interactive compatibility with the radionuclides.

RADIOLOGIC SAFETY REQUIREMENTS. The requirements of 10 CFR Part 60 related to radiological safety deal primarily with the release of airborne radionuclides during the operational phase of the repository. They are concerned with exposure of the public to these radionuclides. The requirements are manifested in a performance objective in 10 CFR Part 60.11 l(a) that states that the GROA shall be designed so that, until permanent closure has been completed, radiation exposures, radiation levels, and releases of radioactive materials to unrestricted areas will at all times be within the limits specified in 10 CFR Part 20 (Anon., 1989c). The regulation also sets forth general design criteria for the GROA in 10 CFR 60.131 to accomplish the goal as stated in the performance objective. These general design criteria specify that the design must incorporate means to limit the concentrations of radioactive materials in the air and means to limit the time required to work in the vicinity of the radioactive materials, including means to provide for limited access to such areas. The intent of these requirements can be met through the use of adequate shielding, designing equipment for ease of repair, and providing adequate space for ease of operations (MacDougall et al., 1987). The burden of compliance with this part of the regulation ultimately falls on the ventilation system which must be able to function to ensure that any such materials inadvertently released are not permitted to reach the public in amounts that violate the release standard.

An important concept in this part of the regulation is that of “structures, systems, and components important to (radiological) safety.” Generally, any item or activity that must be relied upon to to protect the public health and safety falls into this category. Also if an item or activity is not important to (radiological) safety, it is, in reality, not subject to regulation by the NRC. A notable example here is the safety requirements that are imposed on mines through the Mine Safety Health Administration (MSHA); NRC only regulates such aspects of the underground facility to the extent that worker protection may be necessary to provide reasonable assurance that all systems, structures, and components important to (radiological) safety can perform their intended functions. The structures, systems, and components important to (radiological) safety must be designed so that natural phenomena and environmental conditions anticipated at the GROA will not interfere with necessary safety functions.

The general design criteria in 10 CFR 60.131 describe particular design features that are intended to ensure the continuous operation of the structures, systems, and components important to (radiological) safety in the event of accidents or equipment failure. They require that the structures, systems, and components important to (radiological) safety be able to perform their intended functions in the event of fires, explosions or flooding. Consequently, they mandate, to the extent practicable, the use of noncombustible and heat resistant materials, as well as alarm and suppression systems. They further require instrumentation to monitor the performance of the structures, systems, and components important to (radiological) safety, as well as redundant means to ensure the continued function of the structures, systems, and components important to (radiological) safety in the event of an emergency. It is to be expected that, if a hoisting system is to be used to move the waste canisters underground, such system would fall into the category of a structure, system, or component important to (radiological) safety. Such hoists would have to be designed to preclude cage fall, be reliably locatable, incorporate interlocking systems that would fail in a safe manner, and include two independent indicators of when waste packages were ready to be loaded or unloaded.

Additional criteria related to radiologic safety for the surface facilities are found in 10 CFR 60.132. Generally, these criteria are related to safe handling and storage of radioactive materials at the surface. They result in a design that will accomplish fuel-rod handling and packaging into the waste canisters in a remotely operated hot cell facility. The design criteria also specify controls to be placed on effluent handling and disposal, as well as the treatment of low-level wastes generated at the site that do not need to be stored in the underground facility (MacDougall et al., 1987).

Closure Requirements. The regulatory requirements of 10 CFR Part 60 include particular requirements related to the permanent closure of the repository following its operational period. Specifically, the licensee is required to apply for an amendment to its license to receive and handle the radioactive wastes in order to close the facility. The application to amend the license will consist of an update to the original license application and environmental report, and must include information on the program of monitoring of the repository following permanent closure. Also, the application must include descriptions of the methods to be used to regulate or prevent activities that could impair the long-term isolation of emplaced wastes and to ensure that information relevant to the repository will be preserved for future generations. This will include the fabrication and use of monuments that have been designed to be as permanent as is practicable to identify the repository location. The closure would only be permitted if the performance confirmation program indicated through modeling of its performance that the facility was functioning as predicted.

From a design perspective, closure of the facility involves decommissioning of the underground facilities, including perhaps the removal of utilities and support components such as shaft liners. Sealing of the underground facility and its accesses, as well as boreholes drilled for exploration, is also an integral part of the facility closure. The removal of components, such as shaft liners, would primarily be undertaken to facilitate more effective sealing of the underground facility. It is incumbent upon the designers of the underground facility to anticipate possible methodologies for closure of the facility and incorporate means to facilitate closure into the design. A description of such design features will be included in the license application Safety Analysis Report as required under 10 CFR 60.21. The options available to the designer to meet this requirement are varied and generally are of the form of limiting or prohibiting activities that would preclude the effective closure of the facility.

Following the permanent closure of the facility and decontamination and decommissioning of the surface facilities, the licensee (DOE) will be required to apply for an amendment to terminate its license.

24.3.2.2 Isolation Phase

Waste Package Requirements. The core (the innermost part) of the engineered barrier system and the waste isolation system is the waste package. The regulations issued by the NRC establish a performance objective for the waste package in 10 CFR 60.113 that requires the waste package to provide for substantially complete containment for a period of 300 to 1000 yr.

This requirement is interpreted to mean that the characteristics of the waste package are such that radionuclides in a solid, liquid, or gaseous state will be held inside the boundaries of the package until the containment is breached. An interpretation of this requirement is that the waste package should have, as part of its structure, a hermetically sealed barrier (canister).

The waste package carries with it requirements to perform a number of functions. The specifications for the waste package (i.e., configuration, dimensions, fabrication methods, materials, test methods) must be developed to ensure the package can resist a series of expected and unanticipated events that it could likely experience in its nominal handling. The waste package must be considered as a candidate for the category of structures, systems, and components important to (radiological) safety. It should be kept in mind that some of the functions are time dependent and, after a minimum of 300 yr, these functions are not necessarily required. The functions the waste package could be expected to perform include:

1. Facilitate handling and transportation of the waste outside the repository facility.
2. Transmit thermal energy, released by the waste, to the environment.
3. Provide for handling in the repository (from surface to point of emplacement).
4. Provide a continuous barrier of extremely low permeability (hermetic seal) to prevent water from contacting the waste form and to prevent release of radionuclides (in a solid, liquid, or gas state).
5. Provide for retarding release of radionuclides once a hermetically sealed canister is breached.

Since the waste package is likely to be a structure, component, or system important to (radiological) safety, as well as to long-term isolation, it is expected that there will be extensive controls on the quality of this item. The nominal expectation is that the waste package will be fabricated from a material processed in a manner that is totally under the control of man. In this effort, the most significant decision is which material will be used. The material must satisfy two basic constraints: (1) it must be capable of meeting the containment requirement within the thermal and chemical environment in which it must perform, and (2) it must be capable of being fabricated into the hermetically sealed canister of the desired configuration. If the containment of radionuclides is an essential criterion used in obtaining approval to construct the repository, it is possible that the engineering technology available to fabricate the waste package can influence the selection of the site. The material selection is likely to be dictated by the environment that will exist in the repository (which includes the temperature profile during its lifetime, presence of an electrolyte, and chemical aggressiveness of the environment); the opposite can be true in that materials available to construct a waste package can set limits on the geologic, hydrologic, and geochemical conditions that can be selected for the repository.

Material selection will be more art than science. Two basic philosophies can be followed in the selection of the material. The philosophies center on the selection of a material with a high corrosion resistance capable of withstanding the environment with minimal effects or the use of a sacrificial material that will readily corrode, but by well-understood mechanisms, at well-established rates. The latent basis for successful selection of either material will depend solely on the ability to convince the NRC staff and the Licensing Board that mechanisms leading to failure are well understood and that the potential for failure, preventing achievement of the performance objective, is low.

Selection of materials that have high corrosion resistance and can provide the 300 to 1000 years of containment in the expected environment is an approach fostered by the expectation that groundwater (electrolyte) can and will be a major factor affecting the containment requirement. Metals and alloys that have high resistance to corrosion often exhibit failure characteristics (i.e., they fracture creating a breach in a waste package) that are considered unpredictable and difficult to evaluate. For example, stainless steel or titanium, which owe their high corrosion resistance to the passivation mechanism, often fail by stress corrosion cracking or hydrogen embrittlement. These failure mechanisms have long incubation periods and occur in a precipitous manner with little or no indication of the impending failure. While it may be possible to achieve the performance objective using such a material, it may be difficult to amass the data necessary to establish the compelling case that all failure mechanisms are well known and the knowledge can serve as the basis for such a decision.

An alternative approach is the selection of a material that has a moderate corrosion rate, but one for which the corrosion mechanism is well understood. The rationale for this approach is that with such material, other failure mechanisms, such as stress corrosion cracking, are not likely to occur in those materials. It is argued that it is possible to have confidence in the evaluations of these materials because of the apparent lack of the precipitous and difficult-to-characterize failure mechanism.

Regardless of which approach is chosen, the same fundamental data and analyses will be required to demonstrate that there will be reasonable assurance that the performance objective will be achieved and that the off-normal schemes of failure mechanisms have been examined and demonstrated as not likely to compromise performance. Data requirements will be driven by the NRC staff, the Licensing Board, and the other parties raising issues; neither approach can be given preferential treatment.

The development of the engineered barrier system and the waste isolation system requires an understanding of two different concepts: (1) the actions taken in the design and implementation of the system to achieve performance, and (2) the actions taken to demonstrate or provide reasonable assurance that performance objectives will be achieved. In this area, it is quite possible that all actions taken will provide for achievement of performance, but because it cannot be readily demonstrated and documented to the extent acceptable in an administrative law court, the proposed actions may not be accepted.

In the current mined geologic repository concept that is predicated on a situation where the United States has not developed an industry for reprocessing of spent fuel from commercial power reactors, the waste form expected for disposal is spent fuel elements (Anon., 1980). A fuel element is composed of an array (17 by 17, 15 by 15, or 8 by 8) of fuel rods (uranium dioxide ceramic pellets in stainless steel or zircalloy tubes) varying in length between 12 and 14 ft (3.6 and 4.2 m). A fuel element from a PWR weighs approximately 1320 to 1540 lb (600 kg to 700 kg), and for a BWR weighs approximately 550 to 660 lb (250 kg to 300 kg). These are illustrated in Fig. 24.3.4. A single fuel element or multiple fuel elements will be placed in a long, cylindrical canister and hermetically sealed. The number of fuel elements in a canister will depend on the thermal power output of each fuel element and the maximum allowable temperature in either the canister, the backfill that might surround the waste package, or the geologic media of the repository.

ENGINEERED BARRIER SYSTEM REQUIREMENTS. The engineered barrier system consists of the waste form, the waste package, and the backfill. The requirements of 10 CFR 60.113 establish a performance objective for the engineered barrier system that requires the release rate of any radionuclide from the engineered barrier system following the containment period shall not exceed one part in 100,000 per year of the inventory of that radionuclide calculated to be present at 1000 yr following permanent closure.

This barrier must be created using some material that has the properties, both chemical or physical, to support the execution of the function desired by the engineered barrier system. In addition to the materials, the method of assembling or fabricating the system into the desired configuration will also significantly affect the performance of the system. The functions that are minimally expected of the engineered barrier system are as follows:

1. Retard the release of radionuclides from the waste package.

2. Transfer the thermal energy, released within the waste package, to the geologic medium.

3. Control the rate at which water reaches the waste package.

4. Alter the groundwater chemistry that reaches the waste package or waste form.

Materials that usually receive preference for the engineered barrier system are ones that have high retardation coefficients. Materials that have those characteristics are usually complex inorganic oxides or silicates such as zeolites or bentonite. In powdered form, with a large surface to volume ratio, it can create a continuous form with uniform porosity and low permeability that can easily create a situation for effective sorption of radionuelides and control of water movement. However, the packing density of powders emplaced in the field to create a continuous barrier reach about 60% of theoretical density. The solid powders have poor thermal conductivity and, with 40% void space (be it water or air), create a good thermal insulator. This approach has the ability to keep the released thermal energy in the waste package, increasing its temperature.

FACILITY DESIGN AND CONSTRUCTION REQUIREMENTS. *Geometric Considerations*—The primary focus of compliance for postclosure performance of the repository is the performance objectives of 10 CFR Part 60. The regulation also embodies specific design criteria in 10 CFR 60.130 through 60.135. These specific design criteria are grouped to address, generally, surface facilities, operational phase requirements for the subsurface facilities and postclosure (isolation phase) performance requirements on the design. The postclosure design concerns, called additional design criteria in 10 CFR 60.133, specify design considerations intended to ensure that design and construction of the subsurface facilities of the repository are carried out in a manner that the repository assists the geologic setting in meeting the performance objectives.

The physical layout of the repository encompasses factors that, when varied, can have an impact upon the ability of the repository to comply with the performance objectives. The relevant factors include the depth of the repository and its geometric

	PWR	BWR
Fuel Element Array	17 × 17	8 × 8
Assembly Total Weight, lb (kg)	1,450 (658)	705 (320)
Uranium/Assembly, lb (kg)	1,015 (461)	415 (189)
Fuel Element OD, in. (mm)	0.37 (9.4)	0.49 (12.4)
Fuel Elements/Assembly	264	63

Fig. 24.3.4. Schematic diagram of commercial nuclear power reactor fuel elements. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

configuration, including orientation of the drifts. The depth of the repository can have impacts upon compliance with the performance objectives. Generally, a deeper repository would have a longer travel path length for radionuclides transport. A repository located at a depth greater than 1000 ft (300 m) would be considered favorable under 10 CFR 60.122. This depth generally correlates to a depth deeper than typical depths of water wells. A repository deeper than 1000 ft (300 m) would be relatively safe from inadvertent penetration by development of a water well.

The geometric configuration of the underground repository also can be varied to result in different impacts on the ability of the repository to comply with the performance objectives. Although the actual wording of this requirement of 10 CFR 60.133(a)(1) is to select a configuration that contributes to containment and isolation, pragmatically, it may not be possible to design a layout that reliably contributes to isolation over the required 10,000-yr period of isolation. It is likely, however, that certain geometric configurations will result in lessened impact. Specifically, good mine development and layout practice dictates (Hoek and Brown, 1979) that natural fracture orientation and in situ stress state be considered in selecting drift configuration and orientation. This would also be expected to lessen postclosure impacts. A drift layout that would minimize support requirements would generally be expected to have the least impact on the ability of the site to isolate waste as it would be expected to minimize rock movements. An additional factor is relevant, however, for repository design. The effects of the stresses and displacements induced by the heat generated by the waste should also be considered in determining an acceptable configuration.

The intent of this portion of the regulation was addressed in the conceptual design of a repository to be located above the water table. In that design, a dipping repository configuration was to be developed. That facility would have been built in dipping strata; arguably, limiting the crossing of stratigraphic boundaries could contribute to isolation. Of more interest, relevant to the intent of this requirement, is the fact that such an attitude makes the repository self-draining, which is particularly appropriate for an unsaturated zone repository, should any significant quantity of water enter the repository.

Flexibility to Accommodate Specific Site Conditions—An important aspect of the regulatory requirements related to the design of the underground facility of the repository is the requirement of 10 CFR 60.133(a)(2) to maintain sufficient flexibility to accommodate site-specific conditions. Generally, the site-specific conditions that must be accommodated are those that are more likely to lead to a postclosure impact (loss of containment or isolation) or a preclosure impact (worker safety, excavation stability, or loss of ability to retrieve). The design of the underground facility of the repository needs to anticipate the possibility of encountering such conditions and have contingency plans in place to be able to deal with such conditions when encountered. Examples of site-specific conditions that would have to be accommodated include fault or shear zones with potential for rock mass movement or water-bearing zones where none were expected. The contingency plans would detail the manner in which the areas of anomalous conditions would be avoided or their effects mitigated.

The authorization to construct the repository facility will be granted subject to conditions imposed by the NRC that are structured to ensure that the actual construction of the repository is in rock conditions as described in the license application. To be in compliance with these imposed conditions requires that the calculations about compliance with the regulations bound the range of conditions that are encountered in the repository construction. If the conditions within which the repository is constructed are different from those for which the authorization was granted, the construction of the repository must be able to accommodate this. The contingency plans should provide the mechanism for accommodating these differing conditions. Should they be insufficient to do so, then the construction of the repository could not proceed until the effects of the differing conditions had been assessed and the construction authorization amended.

Underground Openings—The design of the underground openings must take into consideration several regulatory requirements related to the stability of the underground excavations. As previously noted, 10 CFR Part 60 imposes opening stability requirements or considerations on the facility for aspects of the facility related to retrievability or to worker safety to the extent that it is relevant to the successful operation of items important to safety. The typical MSHA-type safety considerations are beyond the purview of the NRC but are expected to be imposed on the repository underground facility through mandatory requirements of the licensee.

There are two additional design criteria of 10 CFR 60.133 that impose excavation stability-related requirements on the repository underground facility. The first of these is 10 CFR 60.133(e)(2), which states that openings in the underground facility must be designed to reduce the potential for deleterious rock movement or fracturing of the overlying or surrounding rock. The other requirement is found in 10 CFR 60.133(f), which states that the design of the underground facility shall incorporate excavation methods that will limit the potential for creating a preferential pathway for groundwater to contact the waste packages or for radionuclide migration to the accessible environment. These two requirements deal with conceptually similar aspects of impacts on the capability of the site to contain and isolate waste. They both deal with the creation of pathways, typically manifested as cracks or fractures, that would shorten travel times or otherwise promote preferential radionuclide transport.

Fluids and Materials Control—Fluids and materials control in the underground facility are relevant to the postclosure performance of the repository in that materials to be used in the underground facility have the potential to affect the transport of radionuclides to the accessible environment (e.g., see 24.3.1.6). Fluid and material control are implicitly recognized in 10 CFR 60.133(h), wherein the requirement that the engineered barrier system be designed to assist the geologic setting in meeting the postclosure performance objectives is stated. Also 10 CFR 60.130 explicitly requires the incorporation of specific design features that are needed for the facility to achieve compliance with the performance objectives. It is likely that fluid or material control could fall into this category.

Likely effects of materials used in the construction and operation of the underground facility are related to chemical complexing of the materials with the radionuclides, resulting in an enhanced travel time for the complexed ion relative to that of the radionuclide. Components of the epoxies used in rock bolt anchorage systems, as well as cementitious materials, have the potential to interact with the radionuclides, and they must be carefully examined in the context of the geochemical composition of the rock mass and the naturally occurring waters. For this particular example, a practical solution may be found in the use of bolting schemes utilizing concepts similar to those of the split set or swellex techniques, provided that the ferrous oxide materials resulting from the degradation of the steel bolts do not lead to a similar problem in complexing with the radionuclides.

The materials used can also degrade the expected corrosion response of the waste package if care is not exercised in the selection of the materials used in construction and operation of the underground facility. Alternately, a reasonable control program could permit the use of virtually any material, provided that means to prevent undesirable materials from contacting the waste packages could effectively be implemented. The previously mentioned concerns about organic materials (tire rubber, fuel and oil spills, etc.) may be amenable to control through the use of a scheme that placed a thin layer of fine particulate material on the floors of the drifts. Such a material could be effective in trapping the organics and could be subsequently scraped up at the time of closure of the facility.

For a repository in the unsaturated zone, the amount of water used in the construction and operation of the facility can also have an impact on the ability of the repository to comply with the release standards imposed by the performance objectives. Unrestricted use of water has the potential to modify the hydrologic properties of the site to the degree that the character of the unsaturated zone no longer functions to impede the transport of radionuclides. Specifically, this would occur if sufficient water were available to saturate a previously unsaturated volume of rock for a sufficient period of time to enable the development of saturated pathways to the accessible environment. The character of the unsaturated zone makes it unlikely that such pathways could be developed and maintained for sufficient periods to affect the performance of the site, if reasonable controls are placed on the amounts of water used in construction and operation of the facility.

Thermal Loads—The emplacement of the radioactive fuel elements into the rock at the repository horizon entails a significant quantity of heat energy that will be dissipated into the volume of rock surrounding the repository. The effects of this heat can be manifested through expansion of the rock and possible resulting fracturing and rock mass property degradation (St. John, 1987). The heat can also affect the geochemical and hydrologic properties of the rock mass as well as the hydrologic response of the area surrounding the repository. The effects of the heat can be managed during the operational period of the repository through ventilation and perhaps even involving refrigeration. However, the major effects of the heat load will be manifested during the postclosure time frame when the facility is not accessible for temperature control. The primary approach available to the designer to manage the effects of heat in this time frame is to control the areal power density. Practically, this is accomplished by separating the canisters sufficiently to limit the deleterious effects of the heat load.

The design criteria for the underground facility specify, in 10 CFR 60.133(i), that the underground facility shall be designed so that the performance objectives will be met, taking into account the predicted thermal and thermomechanical response of the host rock, the surrounding strata, and the groundwater system. This requirement is simply a statement that the demonstration of compliance with the postclosure performance objectives must consider the effects of the heat generated by the emplaced wastes. The effects of this heat need to be considered relative to compliance with the post-closure performance objectives. The effects of heat and their relationship to compliance with the postclosure performance objectives fall generally into one of two categories: (1) near-field, or roughly canister scale, effects; and (2) far-field, or roughly repository scale and larger, effects. The near-field effects, which involve higher temperatures and more severe rock mass property degradation, are important to the two performance objectives related to the waste packages. These performance objectives dictate a containment period (equivalent to a waste package lifetime) and a maximum permissible release rate for radionuclides from the canisters once containment is no longer effective. Temperature is an important parameter in determining the waste package environment, which together with the canister materials, form the basic engineered system which must comply with these performance objectives. The areal power density probably results in second-order effects on the waste package environment as compared to the effects of the canister temperature itself.

The repository scale effects of the heat due to the emplaced wastes must be considered in the demonstration of compliance with the prewaste emplacement groundwater travel time performance objective. The prewaste emplacement groundwater travel time performance objective must consider the effects of the heat of the emplaced wastes in calculating the extent of the disturbed zone, which is the boundary from which the travel time to the accessible environment is calculated. The disturbed zone is intended to be of sufficient extent such that the significant effects of the repository construction and functioning would be limited beyond it. Evaluations performed to date (Gordon et al., 1986) suggest that the effects of temperature are the most significant consideration in determining the extent of the disturbed zone.

Repository (and larger) scale temperature effects are important in the demonstration of compliance with the remaining postclosure performance objective, which addresses total radionuclide releases to the accessible environment. The effects of temperature need to be considered relative to the design of the underground facility, with regard to possible impacts on the ability of the repository to comply with the performance objective. Such impacts include effects of the heat of the emplaced wastes that could affect the rock mass properties in a manner that would limit the effectiveness of the site in preventing releases of radionuclides to the accessible environment. These effects

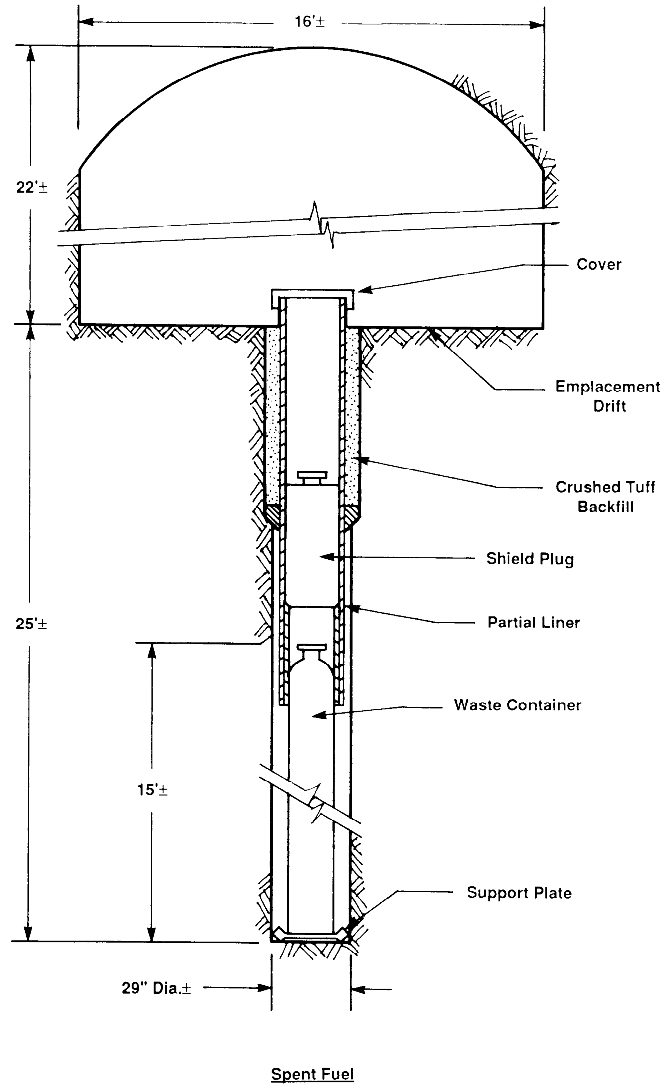

Fig. 24.3.5. Schematic diagram of single waste canister in vertical emplacement hole. Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

could be related to deleterious changes to the structural character of the rock mass such that preferential pathways could be created. Such effects could be related to structural instabilities in the excavation itself, resulting from thermally induced stresses, or they could be the result of larger-scale rock-mass responses such as thermally induced uplift or subsidence.

The design of the facility can accommodate such effects through design parameters including the areal power density, the extraction ratio, and the orientation and layout of the facility. The spacing of the waste canisters and the excavation extraction ratios effectively determine the decay heat power density for the repository. The areal power density can also be affected by the scheme chosen by which the waste canisters will be emplaced, either horizontal or vertical (MacDougall et al., 1987). In the vertical emplacement scheme, illustrated in Fig. 24.3.5, single canisters would be placed in the borehole in the floor of the drift. In the horizontal configuration, illustrated in Fig. 24.3.6, one or more canisters would be placed in long holes in the sidewalls of the drift. Vertical emplacement holes are generally limited to one canister, while long horizontal holes can be constructed to

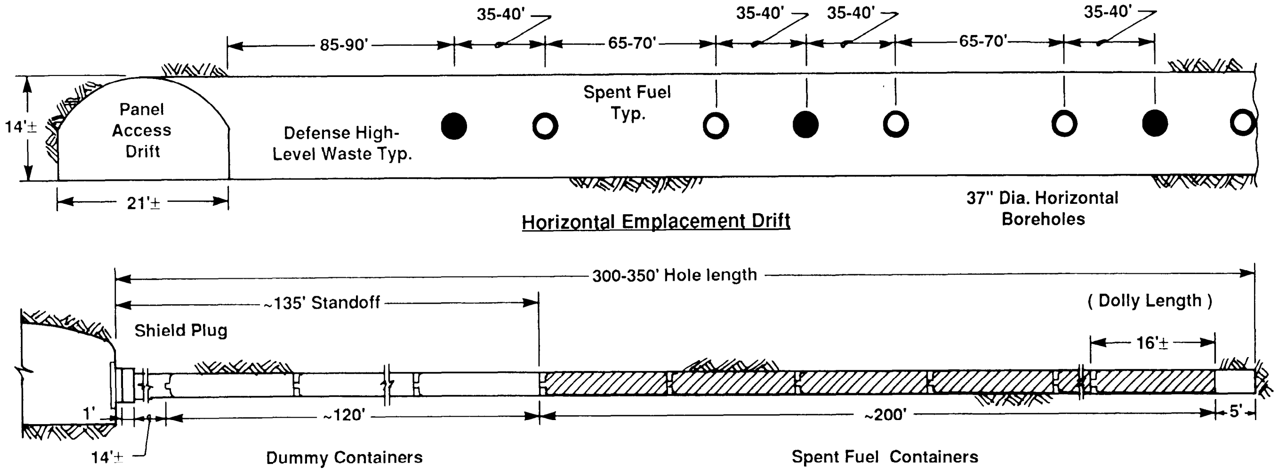

Fig. 24.3.6. Schematic diagram of multiple waste canisters in horizontal emplacement hole. Conversion factor: 1 ft = 0.3048 m.

accommodate numerous canisters. The horizontal emplacement scheme has two inherent advantages: (1) fewer drifts or passageways must be mined, and (2) a greater standoff distance between the drift wall and the last canister can significantly increase the time required for the temperature of the drift to increase over the nominal underground temperature. This second point could be critical in ensuring the long-term retrievability option. However, there are disadvantages with the horizontal concept in that construction of large-diameter (greater than 36-in. or 1-m) boreholes of the desired length has yet to be demonstrated in hard rock and the retrieval is probably less certain in the horizontal scheme.

On a scale larger than the repository, the effects of the heat resulting from the emplaced wastes have the potential to affect the hydrologic character of the surrounding rock. In a repository beneath the water table, such effects could be related to density changes of the water and concomitant affects on the direction of water movement. For a repository in the unsaturated zone, the effects are more likely to be related to drying of the rock mass and subsequent saturation of the rock mass as the vapors condense, resulting in relatively rapid flowpaths where none existed prior to the condensation. The amount of heat associated with the repository also raises questions of whether there is sufficient energy available to influence geologic processes in the region of the site; the possibility for such interactions must be considered in evaluations of compliance with the performance objective.

Sealing Requirements for Shafts and Boreholes—The general requirement for sealing of shafts and boreholes in 10 CFR 60.134 states that seals must be designed so that following permanent closure, the boreholes and shafts do not become pathways that compromise the ability of the repository to meet the postclosure performance objectives. This requirement further states that the materials and emplacement methods for seals shall be selected to reduce to the extent practical, the potential for creating a preferential pathway for groundwater to contact the waste packages and the potential for radionuclide migration through existing pathways. Techniques for sealing exploratory boreholes and shafts are in widespread use throughout the industry; it is unlikely, however, that such techniques have ever been examined for their ability to perform as intended on the time scale of interest for the postclosure performance of a repository (Fernandez and Freshley, 1984; Fernandez, Hinkebein, and Case, 1989).

The regulations issued by NRC (10 CFR Part 60) require that the repository be sealed when the repository is closed and decommissioned. The specific requirement states that the seals for shafts and boreholes shall be designed so that following permanent closure, the shafts do not become pathways that compromise the geologic repository's ability to meet performance objectives.

These sealing requirements are based on the assumption that a virgin site has no significant preferential pathways by which radionuclides can return to the surface. Drilling a borehole or constructing a shaft changes this basic situation by creating an opening extending from the surface to the horizon of the proposed repository. For large openings, two areas must be considered. The first is the opening itself in which a seal of some material will have to be placed. A conceptual illustration of a seal and its components is outlined in Fig. 24.3.7. The second is the annulus around the opening which will be disturbed by the creation of the shaft and in which the characteristic of the rock will be altered in a negative manner. In this volume, which is defined by a volume equal to about one radius of the opening, the permeability of the rock is judged to increase by two orders of magnitude, thereby making this portion of the repository more susceptible to movement of water.

Sealing of the shaft openings will require that a material of some type be placed in the opening. The material will have to be evaluated within the context of a number of factors. Obviously, it must have excellent long-term characteristics; that is, it will not change to a significant level with time; the material must be capable of making a tight interface with the host rock; it must form a strong mechanical or chemical bond with the host rock; and it cannot have significant shrinkage with time, or a crack will form at the interface between the seal and the host rock.

Practically, this sealing requirement will have to be addressed from at least two perspectives. First, detailed investigations will need to be carried out to ascertain the particular materials and sealing techniques that can be demonstrated to have the capability to comply with the intent of this requirement or at least support a convincing argument that they either have a high likelihood of success or that their nonperformance will not significantly affect the overall repository performance. (The latter argument may be appropriate for a repository in the unsaturated zone.) The desired materials and emplacement techniques will have to be compatible with the intrinsic character of the rock mass to be sealed. This can probably best be accomplished with materials that are geochemically similar to the host rock and that will not degrade significantly over the required time period. Materials with a potential to passively reinforce the intended performance of the seals would be ideal if they can be

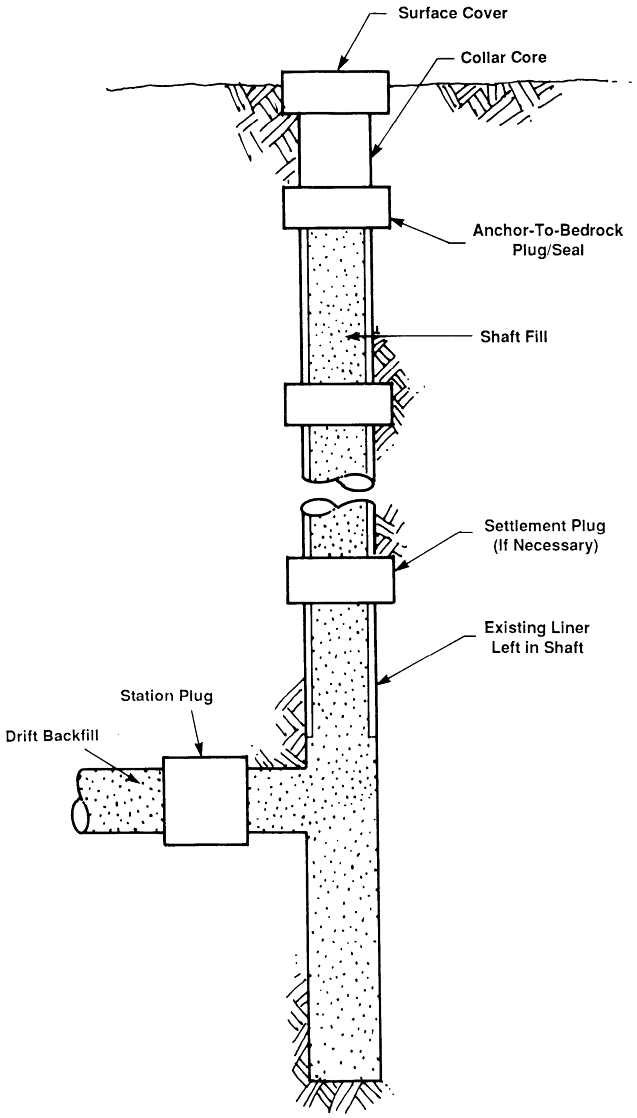

Fig. 24.3.7. Conceptual illustration of shaft seal configuration.

found. A material that could function in this manner would encourage precipitation of material in the groundwater encountering the seals that would clog any pathways that developed as the seals deteriorated.

The second perspective important to sealing that must be considered is related to the fact that it is unlikely that the sealing materials will be fully developed and the emplacement techniques finalized prior to the start of repository construction. This problem must be dealt with through an approach that recognizes the importance of limiting any impacts to the rock mass that would affect the ability to successfully emplace seals at a later date. Generally, this will require geochemical compatibility of materials used during construction with candidate sealing materials and excavation techniques that limit damage to the rock mass, particularly in areas where it is anticipated that seals will be emplaced.

Chapter 24.4
MILITARY AND DEFENSE INSTALLATIONS

DWAYNE D. PIEPENBURG AND DENNIS J. LACHEL

24.4.1 INTRODUCTION

Native Americans, particularly those in the Southwest, are known to have used natural caves as their homes. Throughout North America and the remainder of the world, people have used natural and man-made caves and quarries for storage of materials and equipment and as a place to gather for security. These underground facilities restricted avenues of attack and made for easier defense of the facility.

Although the continental United States has been fortunate not to be involved with a war on its soil since the Civil War, US soldiers are aware of the benefits of underground facilities from their experiences in World Wars I and II, the Korean Conflict, and in Vietnam. These experiences vary from the common use of foxholes for personal protection to massive concrete bunkers along the Normandy beaches and the Maginot Line in France and Germany.

One of the most famous underground fortifications is the Rock of Gibraltar, which was captured by the British from the Spanish in 1704 after fierce fighting. The labyrinth of tunnels and chambers extend for more than 25 mi (40 km) within the Rock of Gibraltar. Today the Rock of Gibraltar serves as the headquarters for the Gibraltar Mediterranean Command of the North Atlantic Treaty Organization (Guthrie, 1987).

The development of nuclear weapons in the 1940s with their massive destructive power had a major impact on the use of shallow and deep underground facilities for defense purposes. This chapter of the *Handbook* describes the types of facilities that range from near-surface to deep underground and from man-made to natural, and describes the military and defense uses of underground facilities. Because of their purpose and use, it is not possible to describe these facilities in detail. However, the information provided should give a general idea of underground facilities for military and defense purposes.

As with any underground facility, the method of construction is a function of the geology, size of opening, depth, and degree of rock disturbance acceptable to the long-term operation of the facility. Most of the early deep underground defense facilities in rock were excavated with conventional drill-and-blast techniques. More recent facilities have been excavated with controlled blasting techniques where drillhole half rounds are clearly visible after muck removal. It is also possible to use full-face tunneling machines. However, to date, this has not been standard practice.

Because an underground facility is primarily dependent on the rock in which it is constructed for its strength or ability to resist nuclear weapon-generated ground shock, it is important that the excavation of the rock leave the remaining rock in an undisturbed state. A comparison of tunnel construction methods reveals that mechanical excavation techniques, especially full-faced tunnel boring machines, leave the rock surrounding the tunnel in essentially an undisturbed condition. Other methods of excavation, particularly uncontrolled drill and blast, can produce significant overbreak and rock fractures that extend several feet (meters) into the surrounding rock. Construction of underground facilities should therefore consider the in situ rock conditions and use an appropriate method of excavation to preserve the inherent strength of the rock.

Tunnel support is clearly a function of the type of rock and its associated in situ characteristics, groundwater conditions, depth of facility, and magnitude of predicted dynamic weapon-generated ground shock conditions. In most instances, deep underground facilities are located at a depth so as to avoid severe dynamic effects, and therefore standard support techniques used for civil and mining projects are most often used to reinforce tunnels for defense purposes.

In some instances it may be beneficial to install complex rock support systems. For example, to provide extra protection for unique or critical pieces of equipment or activities and personnel or to strengthen locally weak and jointed rock, it may be necessary to install composite structural liners of steel plate and reinforced concrete or structural liners of reinforced concrete or steel surrounded by crushable material. Lightweight, nonporous, low-strength concrete has been used as crushable backing for test structures at the Nevada Test Site.

Complex support systems are inefficient and very expensive to install. In most instances, large quantities of rock must be excavated to accommodate the large thicknesses of steel, concrete, and crushable packing.

Preliminary design of reinforcing for tunnels and shafts is normally accomplished by applying simple, closed-form methods of analysis (Newmark, 1969; Hendron and Aiyer, 1972). Final designs frequently rely on computer codes that have been calibrated against actual results from structural tests conducted at the Nevada Test Site. The actual design criteria are specified by the design agency and are frequently a function of the purpose and endurance requirements of the facility.

Because the audience for which this *Handbook* is intended is knowledgeable in the excavation and support techniques available to the underground mining and construction industries, and due to the many variations possible, excavation and support techniques and systems are not discussed in great detail.

24.4.2 TYPES OF UNDERGROUND FACILITIES

Underground facilities can be shallow or deep. They can be formed by new excavation or by the modification of naturally formed caves or previously excavated cavities and tunnels. This section will describe the primary types of facilities, near-surface cut and cover, shallow underground, deep underground, and existing excavations.

24.4.2.1 Near-surface Cut and Cover

Hardened concrete bunkers built in World War II, Minuteman missile silos in the Dakotas and Wyoming, and weapon-storage magazines are all excellent examples of defense facilities constructed as near-surface cut and cover facilities. These facilities are generally fabricated from reinforced concrete and are surface flush or covered with an earthen mound.

Construction of these facilities, for the most part, follows conventional civil construction procedures. However, the one major modification to conventional construction is the concrete thickness and quantity of steel reinforcement added to the concrete to form the structural elements of the facility. Special design manuals are available from both the US Army Corps of Engineers (Anon., 1986a) and the US Air Force (Schuster, Sauer, and Cooper, 1987) to aid in the design of near-surface cut and cover facilities.

Cut and cover facilities represent the first effort to improve survivability from conventional and nuclear weapon effects and terrorists. Fundamentally, they have been used to place operational military defense systems out of the way of the aboveground weapon-generated blast effects. These cut and cover facilities are relatively inexpensive to construct when compared to deep underground facilities but have lower limits of strength or "hardness." As nuclear weapons become more accurate, these facilities become less survivable and are less attractive for military and defense facilities.

24.4.2.2 Shallow Underground

This class of underground facility is generally less than 100 ft (30 m) deep and may be constructed as a cut and cover or as an underground excavation project. Command modules for the Minuteman missile silos were constructed as cut and cover facilities but have significant amounts of earth above them to enhance their protection from nuclear weapon effects. The decision to use a shallow underground facility in lieu of a near-surface cut and cover facility is generally dictated by the contents of the facility, its criticality of mission operation and tradeoffs between depth, and simply adding more concrete and steel to a surface-flush facility.

Shallow underground facilities are normally equipped with stronger blast doors and valves and more complex air filtration systems than the near-surface facilities to permit greater use in a nuclear contaminated environment. These facilities are more costly to construct but offer increased survivability to the contents of the facility.

Frequently, shallow underground facilities are provided additional protection against earth-penetrating weapons by placing large rock rubble or concrete slabs on the surface directly above the buried facility. The layers of rubble or concrete are designed to damage, deflect, or reduce the effectiveness of an attacking weapon.

Underground civil defense facilities throughout Scandinavia are constructed using drill-and-blast tunneling procedures. These facilities are seldom more than one or two tunnel diameters deep. In many instances, civil defense facilities in Scandinavia are excavated into the side of hard-rock hills.

24.4.2.3 Deep Underground

Deep underground facilities are generally several hundred feet (meters) deep and are constructed by tunneling horizontally into the side of a mesa or mountain with sufficient relief to provide the desired depth of earth cover. It is also possible to construct deep underground facilities by ramping or shafting vertically down to the desired depth of the facility. In most instances, where land is readily available, ramping down is more economical than shafting for muck removal during the construction of a large underground facility and for ease of buildback and routine operations.

Deep facilities can be excavated by drill and blast or mechanical means. Today mechanical means would be preferred because they result in less damage to the in situ rock around the opening.

Deep underground tunnels and cavities are not sensitive to damage from airblast effects if blast doors and valves of adequate resistance are provided for all openings connecting the underground facility with the surface. However, highly accurate nuclear weapons detonated as ground bursts within close proximity of a point directly above the facility generate a large ground shock that can collapse the rock tunnels. For maximum effectiveness and economy, it is important to design the facilities at a depth that offers balanced survivability against airblast effects and ground shock effects. Shock and vibration isolation for personnel and equipment, effective airblast doors and valves, and tunnel support systems must be balanced one against the other to eliminate overdesign of one or more of the protective systems.

24.4.2.4 Existing Excavations

Excavating rock and soil to develop underground facilities is expensive. Therefore, an existing cave, mine, or rock quarry that meets or nearly meets operational needs and provides the necessary level of protection against weapon effects and terrorist attacks represents a real cost savings. Even if some expansion and modification must be completed to meet all requirements, the development of existing or previously developed underground openings is attractive to the defense planner.

Unfortunately, mines are initially opened for the recovery of natural resources such as coal and minerals. Consequently, most mines are located in thin beds or seams or in highly fractured or weak host rock. Therefore, mine operations in the United States seldom produce underground space that is suitable for defense facilities.

Limestone quarries represent the one major exception and, if available, could be used for defense facilities. In the United States, few quarries of sufficient size exist except at Kansas City, which has been developed as an extensive commercial and industrial complex (Stauffer, 1974) (also see Chapter 24.2).

24.4.3 MILITARY USES OF UNDERGROUND FACILITIES

Underground facilities are defensive in nature. They are designed to provide protection against a direct attack from conventional and nuclear weapons and from terrorists so that the protected assets can be used to recover from that attack or to serve as a basis from which to launch a counterattack. The US government has developed a limited number of underground facilities. Currently, underground facilities are used for the storage of nuclear weapons; storage of other war fighting resources such as gas and oil; weapon emplacement; command, control, and communications centers; and nuclear weapons test and development. Research and development projects have focused on plans for the emplacement of strategic weapons in shallow and deep underground facilities.

Other countries throughout the world have developed underground facilities for a much wider variety of defense purposes. Sweden, as an example, is known to have underground hangars for military fighter aircraft, underground dry dock and repair facilities for submarines and small ships, and underground facilities for retractable radars and coastal artillery (Winqvist and Mellgren, 1988).

Civil defense is a major concern of every community in Scandinavia. According to published literature from Soviet/Warsaw Pact Countries, these countries also place major emphasis on developing whole cities and large civil defense facilities underground (Goure, 1978; Anon., 1988).

The next segment briefly describes these uses of underground facilities

24.4.3.1 Storage and Protection of Weapons, Equipment, and Supplies

This category of underground installation probably represents the simplest of all. Its primary function is to provide environmental, sabotage, and blast protection to stockpiled weapons, equipment, and supplies. With limited use by personnel, air handling, lighting, and overall safety requirements can be minimized to that required only for long-term preservation of the stored materials or equipment. Water tightness and humidity control represent the critical components of the environment of these installations. Temperature control is less critical since the earth surrounding the installation provides a very satisfactory and stable temperature environment, unless extraordinary conditions are encountered.

Weapon storage facilities constructed as cut and cover bunkers can be found at almost any military installation. US military forces have developed definitive designs for these shallow-buried facilities. Monzano Air Base in New Mexico is an example where tunnels were cut into the side of a hard-rock mountain for the specified purpose of storing weapons.

The use of salt domes and specifically excavated large cavities for the storage of crude oil and the use of underground quarries for the storage of equipment, records, and supplies are examples of using underground space for the storage of critical military resources. Underground limestone quarries and mines for other minerals are available in nearly every country. Many countries, including the United States, have either retrofitted some of this existing underground space for civil defense, including natural disasters, or developed detailed plans that could be implemented in relatively short order should international events dictate such action (Wright et al., 1976).

24.4.3.2 Command, Control, and Communications Centers

Communications represents one of the most critical elements of any military system. Without the capability to accurately transmit information to command, control, and gather data, it is exceptionally difficult to provide for the defense of a country. With the advent of intercontinental ballistic missiles, the need for secure command, control, and communications facilities in the continental United States has been greatly emphasized. President Reagan in October 1981 clearly stated that this country needed and would develop such secure facilities.

One of the oldest and largest deep underground facilities that forms a vital link in the defense of the United States is located in Cheyenne Mountain outside Colorado Springs, CO. This facility was constructed in the 1960s and consists of large openings, each containing three-story steel buildings on steel springs and shock absorbers. The rock is reinforced with standard grouted rock bolts. Fig. 24.4.1 shows one of the tunnels with its steel building (Norrell, 1963).

In the event of a nuclear war, vital information would be gathered by satellites. To ensure that the data collected would be available to national civilian and military leaders, special shallow-buried facilities have been constructed. According to a published article (Anon., 1986b), the US Air Force has constructed a satellite tracking station in Spokane, WA, capable of withstanding and remaining functional during a nuclear attack. This facility has a 52-in. (1320-mm) thick concrete roof and 18-in. (457-mm) thick concrete walls built integrally to ensure adequate protection against electromagnetic pulses associated with nuclear blasts.

Norway and Sweden have developed shallow-buried retractable radar systems as part of their coastal defense system. Fig. 24.4.2 shows an artist's sketch of one of these facilities. The facilities were constructed in hard rock, using carefully controlled blasting procedures. In peacetime, these radar facilities support civil aviation operations (Winqvist and Mellgren, 1988).

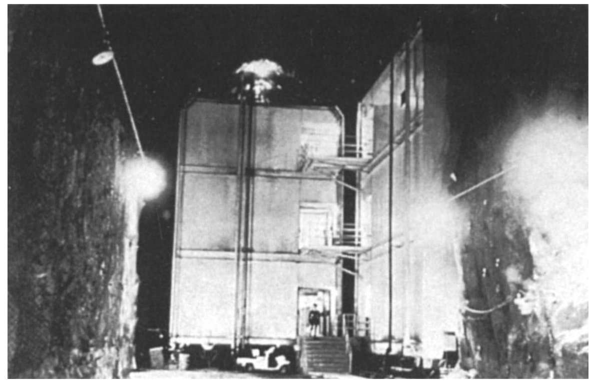

Fig. 24.4.1. Typical tunnel cross section and interior three-story building at Cheyenne Mountain complex (permission: US Air Force Space Command).

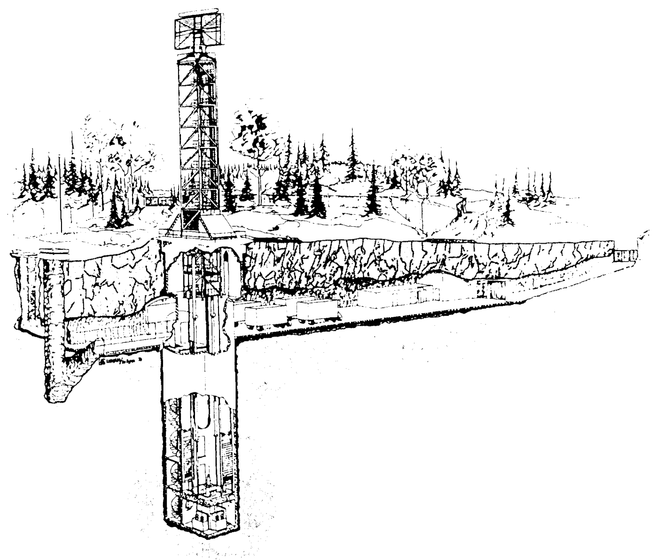

Fig. 24.4.2. PS-80 radar station with vertically retractable antennae (permission: Royal Swedish Academy of Engineering Sciences).

24.4.3.3 Weapon Emplacement and Transport

The Maginot Line still represents one of the best examples of a mechanized artillery system that was constructed in an underground facility. Modern-day versions of that system are currently operated by Norway and Sweden (Fig. 24.4.3). In these countries, the facilities are several stories deeper than those at the Maginot Line and are constructed in hard rock. From the ground surface, only the turret is visible. The separate units are independent as far as electricity, water, oil, and personnel requirements are concerned. Stringent demands are made on the environment in which personnel live (Winqvist and Mellgren, 1988).

The Royal Swedish Navy has developed an underground facility at Musko in hard rock for the support of submarines and small ships. These large tunnels are located in competent rock and, as shown in Fig. 24.4.4, require minimum rock reinforcement (Winqvist and Mellgren, 1988; Anon., 1986c).

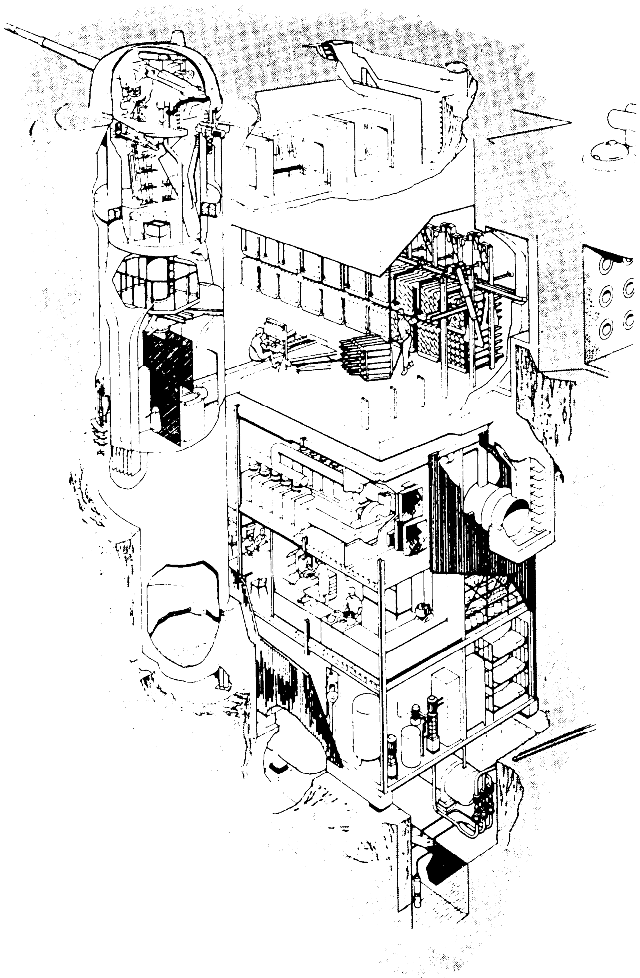

Fig. 24.4.3. A 120-mm ERSTA turret gun (permission: Royal Swedish Academy of Engineering Sciences).

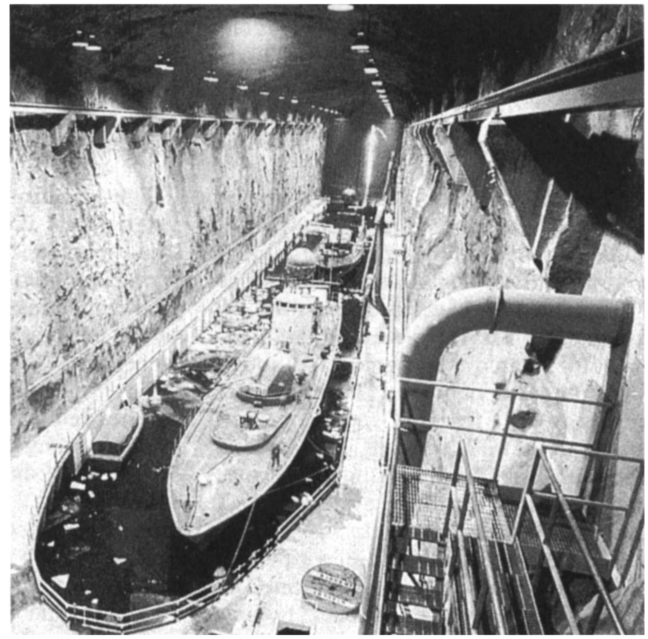

Fig. 24.4.4. Royal Swedish Navy facility at Musko in Sweden (permission: Tunnels & Tunnelling, London).

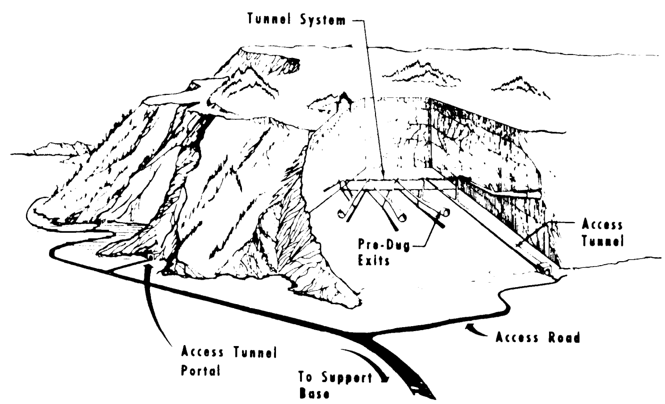

Fig. 24.4.5. Cutaway view of an artist's concept of a deep underground missile base (permission: DNA).

Strategic nuclear weapons have formed the backbone of the US deterrent posture for nearly 30 years. As new nuclear weapon systems are developed by potential enemies, it remains the goal of this country to protect its strategic retaliatory force (Berry, 1982). To this end, the US Air Force completed a major research and development project to design a deep underground missile basing system. One of the early artist's concepts is shown in Fig. 24.4.5. The basing concept consisted of several hundred miles (kilometers) of subway-size tunnels through which missiles on transporters would move to randomly assigned launch portals should the United States come under nuclear attack. Other, more closely spaced tunnels would be used for personnel living quarters, power plants, administrative offices, and other support activities. A unique requirement of this concept of missile basing was the need to "dig-out" through potential rubble zones using mechanical means of rock excavation. This concept was demonstrated by the US Air Force at the Nevada Test Site (Phelps, 1983).

24.4.3.4 Weapon Test and Development

In 1963, then President John F. Kennedy signed a treaty with the Soviet Union to halt all atmospheric testing of nuclear weapons. Immediately following that treaty, the United States and the Soviet Union began testing nuclear weapons deep underground. The testing procedure is designed to ensure that all weapon fission products are contained in underground cavities and tunnels. The Defense Nuclear Agency (DNA), as the designated agency to investigate nuclear weapon effects, and the Department of Energy (DOE), as the designated agency to develop nuclear weapons, conduct underground tests at the Nevada Test Site (NTS).

DOE tests are accomplished in deep vertical holes drilled into the flat valley floor of the NTS. The holes are drilled with blind down-hole drills and lined only where necessary, generally only to the depth of the alluvial overburden. After the nuclear device and the diagnostic instrumentation have been installed, the hole is backfilled with material in accordance with testing procedures to ensure full containment of the fission products.

DNA conducts its weapon effects tests in a series of underground tunnels. Two types of tunnel configurations have been

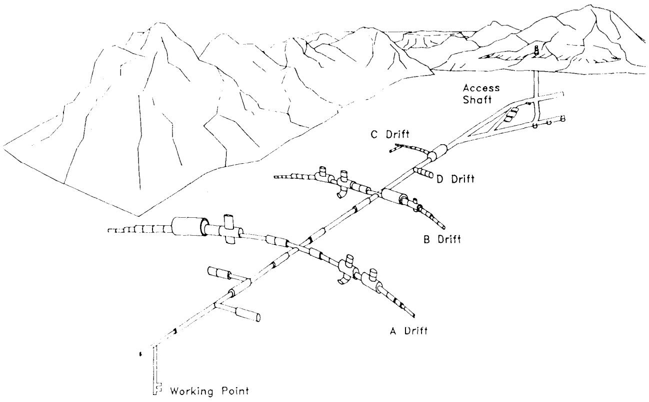

Fig. 24.4.6. Dedicated underground structures test (permission: DNA).

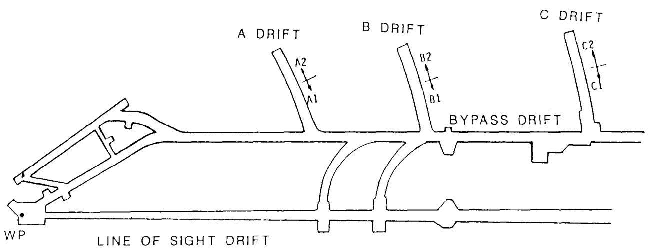

Fig. 24.4.7. Underground structures tests as part of line-of-sight weapon effects test (permission: DNA).

used for testing the hardness and survivability of underground tunnels and cavities. One tunnel configuration is a dedicated test of techniques specifically designed to provide the necessary support or reinforcement to the rock tunnels so that they can withstand the dynamic effects associated with nuclear weapon-generated ground shock. An example of this type test configuration is shown in Fig. 24.4.6. Various rock support or reinforcement techniques including rock bolts, composite concrete and steel liners, and concrete and steel liners with lightweight crushable concrete backpacking have been tested as part of these tests.

The second tunnel configuration used by DNA consists of a horizontal pipe, referred to as a line-of-sight (LOS) pipe, that guides selected elements of the nuclear fission process to impact on test objects, such as missile guidance components, so that the performance of these components can be evaluated in the selected nuclear weapon environment. As shown in Fig. 24.4.7, DNA frequently constructs a limited number of test tunnels, shown as drifts A, B, and C, for evaluation against the associated nuclear weapon-generated ground shock effects.

24.4.3.5 Protection of Personnel, Civil Defense

Civil defense, or the protection of a country's population in time of war, is the goal of every country. The United States, through its Federal Emergency Management Agency, develops plans for the safety and security of people from natural disasters as well as from wartime conditions (Wright et al., 1976). Specific shelter areas have been constructed in the basements of office buildings in large metropolitan areas (Chester and Zimmerman, 1987). In addition, plans have been made for the use of existing underground space in the event of a major war. Other countries, including the Soviet Union, have elaborate system of underground facilities for civil defense purposes (Goure, 1978; Anon., 1988).

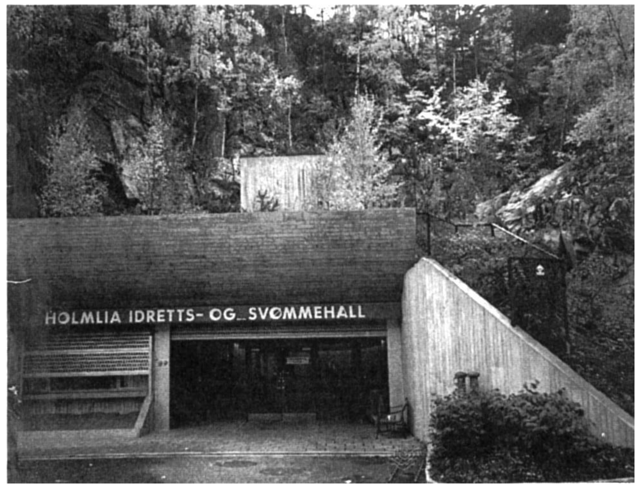

Fig. 24.4.8. Entrance to underground civil defense and sports facility at Holmlia, Norway (photograph: D. Piepenburg).

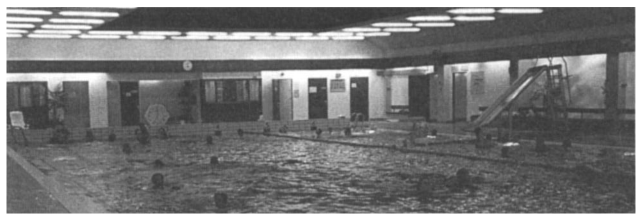

Fig. 24.4.9. Swimming pool in underground civil defense and sports facility, Holmlia, Norway (photograph: D. Piepenburg).

Sweden and Norway have developed an elaborate system of underground civil defense facilities (Winqvist and Mellgren, 1988; Rygh, 1982; Broch and Rygh, 1988). The extent of these facilities can best be portrayed by the fact that there is shelter space for some 6 million people in Sweden and 2 million people in Norway. This corresponds to 70% of the Swedish population and 50% of the Norwegian population.

In both Norway and Sweden, underground shelters are designed into the masterplan for each community. Moreover, these facilities are designed to meet peacetime sports activity requirements for young and old alike. Shown in Fig. 24.4.8 is the entrance to the Norwegian underground facility at Holmlia. Once inside, the facility is much like any other large sports facility with its swimming pool (Fig. 24.4.9) and its basketball and other indoor courts (Fig. 24.4.10).

The underground civil defense facilities in Norway and Sweden are equipped with air filtration systems, water storage facilities, and, as shown in Fig. 24.4.11, blast doors. Decontamination rooms are also provided near the blast doors to ensure that the inside environment remains free of radiation fallout and other contaminants that might adhere to personnel clothing.

Finland has also developed an extensive network of underground facilities for civil defense. Their underground facilities are constructed in hard rock and are designed for use during peacetime. Some underground facilities in Finland are used for

Fig. 24.4.10. Open courts in underground civil defense and sports facility, Holmlia, Norway (photograph: D. Piepenburg).

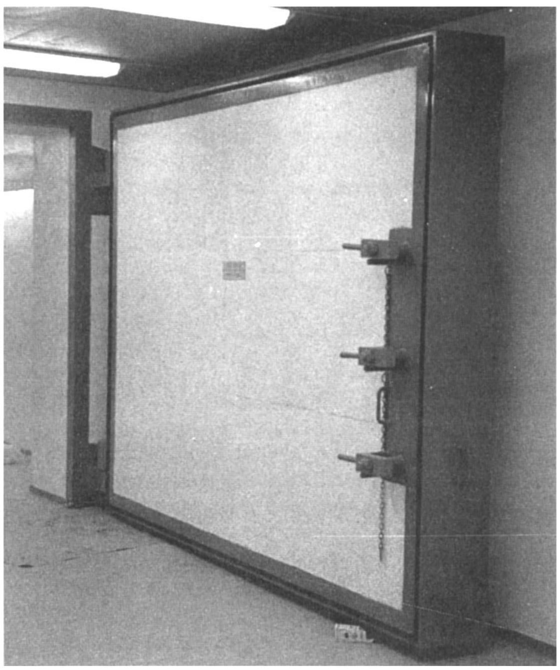

Fig. 24.4.11. Blast doors at Holmlia, Norway, civil defense and sports facility (photograph: D. Piepenburg).

sports halls, car parking, and at least one is used as a concert hall (Saari and Roinisto, 1986).

24.4.3.6 Industrial Plants and Storage of Supplies

The final activity to be discussed where underground space can be effectively used for defense purposes is industrial plants and storage of supplies. For the purposes of this discussion, the authors focus on the facilities at the greater Kansas City underground complex (also see Chapter 24.2).

Kansas City is located on a massive limestone formation that has afforded it significant opportunities for the development of factories, warehouses, and offices in underground openings (Stauffer, 1974). The physiographic and geologic features of this limestone formation are ideal for the development of underground facilities for industrial and commercial purposes. Six of the primary features are shown numbered in Fig. 24.4.12. These features are (1) a massively bedded limestone, (2) sufficient thickness, (3) an overlying impermeable shale, (4) level stratigraphy, (5) a competent overburden, and (6) natural accessibility.

The effective development of this underground space was prompted by several factors:

1. Availability of open space as a byproduct of limestone quarry operations.
2. Energy efficiency of operating in an underground facility where temperature variations are minimized.
3. Quality of the environment for manufacturing sensitive instruments.
4. Relative low cost of developing and maintaining the facility.

The underground industrial space at Kansas City also houses a lawnmower parts factory that uses the high bearing capacity of the rock floors for its heavy tooling and milling equipment. A sailboat factory uses the underground facility because the humidity is easily controlled during the setting of lacquers and glues used in the manufacturing process. Similarly, printing shops and automotive manufacturers use the quarried space to take advantage of the easily controlled humidity. According to Stauffer (1974), metal machinery and factory equipment do not rust. Spare parts can be stored for long periods without damage. Such companies as Allis Chalmers Farm Equipment and Ford Motor Co. store parts in the quarries at Kansas City.

Low or easily controlled humidity and the ease with which overall security can be maintained are attractive features to companies for storage of critical records. Large storage vaults protect records for use in case of natural or wartime disasters.

24.4.4 SUMMARY

The structures described in this chapter represent but a select number of the underground facilities used primarily for defense purposes. Many countries have developed extensive complexes of these facilities. However, the United States, because of its isolated location relative to the European and Asian continents, has not found it necessary to invest the same level of resources in underground facilities.

Technically, the capabilities exist in this country to construct underground facilities and reinforce them to withstand the ground shock effects produced by nuclear weapons. However, because the initial costs can be high, other forms of defense have been pursued by the US Department of Defense.

RICHARD B. STEIN, SECTION COORDINATOR

Chapter 25.0
INTRODUCTION

RICHARD B. STEIN

Section 25 has been assembled to give the geological, mining, or metallurgical engineer an overview of some of the important downstream operations that typically follow mining activities. This subject is obviously too broad and complex to be covered in detail within this *Handbook*. However, the engineer will be interested to learn about the basic fundamentals, and especially how they might affect the economics of the total project from prospecting and mining through to metals recovery and marketing. In this way, it is hoped that the engineer will have a better overall appreciation for the technical and commercial prospects of a mining and metal-producing project.

Chapter 25.1
METALLURGICAL SAMPLING AND TESTING

ALLAN D. TAYLOR

In the first stages, the value of mineral deposits is often judged from chemical analysis of the available samples. However, very soon there arises a need to make an economic assessment of the potential project. Unless the ore will be shipped and sold without treatment, a determination must be made of the amount of valuable mineral that will be recovered into salable products and the quality of these products. This requires a metallurgical testing program. Chronologically, in the life of a mine, it commences during the mineral exploration stage and continues through exploitation (Section 5).

The ultimate objectives of the metallurgical test program are to:

1. Define the optimum treatment scheme.
2. Define the product characteristics.
3. Define the geometallurgy of the deposit.
4. Develop the production schedule for the project.
5. Develop criteria for the commercial plant.
6. Produce the final metallurgical report.

The objectives listed are all interrelated, and no single one can be attained without considering the impact of others. Consequently, attaining the objectives must be approached in stages, with each phase of the work designed to produce a higher confidence level for the combined objectives. For example, it would be foolish to think the optimum treatment scheme could be defined independently of the commercial plant criteria; these criteria will in turn determine the plant costs, the product characteristics, and the schedule of production that can be maintained.

The final metallurgical report should contain all of the information developed in the test program (both positive and negative) and the information required for an independent reviewer to assess the quality and reliability of the work. It should express the confidence that could be justifiably placed in a project evaluation based on that work. Further, the report should be a complete and reliable source for all process-related information required by an independent contractor to design and construct the commercial treatment plant, including major equipment criteria.

One early goal of the program will be to develop a clear understanding of what has been termed the *geometallurgy* of the deposit. This includes the spatial distribution of the values and their metallurgical response characteristics. This understanding is absolutely essential to the development of a rational mining and treatment plan, even on a conceptual basis. Only the depth and detail of that understanding, and the confidence level that may be assigned to the projected results, will vary as project development proceeds.

Developing the metallurgical testing program to define the geometallurgy of the deposit and select the optimum treatment scheme involves the utilization of all of the available information on geology, mineralogy, chemistry, and metallurgy, Also required are the mining plan or plans and their influence on the production of the ore that will be delivered to the processing facilities over the effective life of the operation. The development of this knowledge into a clear definition of the project is iterative, and will only be complete when the deposit has been mined out. The understanding must be developed to an appropriate level for each stage of the project development, from preliminary assessment through prefeasibility, detail design, and operation of the project.

In order to proceed with definition of the geometallurgy, the sample collection and testing program must be carefully planned and executed. Unfortunately, there is no simple formula for the development of the plan. The quantity and distribution of samples taken and the testing to be done must be assessed on the basis of the available knowledge. Each succeeding phase of the test program must be designed to bring the level of that knowledge to a new, higher plateau.

The samples that are readily available for early testing may be quite limited, but it must be recognized that the information derived can be no better than the samples. If they are not reasonably representative of the ore to be produced, this phase of the work may have to be repeated. In the meantime, decisions based on the results may be wrong.

If the deposit is near surface, and trench samples are available, there is usually no problem in obtaining samples for metallurgical testing. For deeper deposits, the drill cores taken for geological, mineralogical, and chemical analysis will often provide suitable material for the initial bench-scale metallurgical testing. However, while some metallurgical unit operations can be adequately assessed on the basis of laboratory testwork, others may require larger-scale testing. Crushing and rod and ball mill grinding can often be sufficiently proven by laboratory testing, but autogenous and semi-autogenous grinding almost always require pilot-plant-scale testing, at least prior to final plant design, and this may require several hundred tons of sample. Bulk flotation, which is a common means for concentrating many sulfides and some oxide and nonmetallic ores, can often be assessed on the basis of laboratory tests. The differential flotation of complex ores, such as copper-molybdenum, may require larger-scale testing, since the secondary mineral content may be too low to allow the collection of adequately sized samples from laboratory tests. Gold ores, and particularly placer gold deposits, are notoriously difficult to assess, partly because of the very low quantity of valuable mineral—which is the target—and the tendency for it to be concentrated in nuggets. Very large samples may be required for accurate assessment. In any case, sufficient sampling and testing must be done to provide the necessary information, whatever the difficulty.

Since mineral deposits are seldom if ever uniform, it is always a mistake to try to produce a single representative sample and to place faith on the results of testing. The appropriate approach is to identify the extremes and the more average types of ore. Then samples from each of these groups are tested until sufficient understanding has been developed to support an acceptable level of confidence in the interpretation of the deposit characteristics. Naturally, a great deal of care must be taken in applying variability established for one unit process to a different one, since the basis of separation may be different.

Once underway, the metallurgical test program must be carefully monitored to assure that all test data are analyzed to provide the maximum guidance for subsequent testwork. The test directors must be alert to indications of the need for modifying the program, and must be willing to make the appropriate changes when needed. However, the program cannot be allowed to drift from one idea to another without clear objectives. The attempt to merely follow the directions indicated by the results of current tests is a program destined for gross inefficiency and possible failure.

25.1.1 ORE CHARACTERIZATION

In most mineral deposits, there is sufficient variation to justify the development of several categories to describe different types of ore. Chemical analysis is one appropriate property, as is mineralogy, but neither is sufficient. The ore types should properly be based on the expected metallurgical response as well.

It is always best to have a substantial amount of petrographic work done on many samples before establishing the types, since simple sight criteria can be misleading. The petrographic work should be directed to yield the maximum of metallurgical information, since differences that are not significant from a geologic or ore genesis view may be critical to the metallurgy. In particular, the size of the valuable and gangue mineral grains is of vital interest to the metallurgist, and relatively slight variation in the sizes can have a profound effect on mineral dressing response. The degree of interlocking of valuable and gangue minerals is also of prime interest, as well as the particular minerals involved in the interlocking. Naturally, the relative amounts of the different species is important, since many ores contain more than one mineral carrying value, and each mineral will usually have a different metallurgical response. The gangue minerals are also important, since each one may cause different degrees of difficulty in the separation process.

For example, even small amounts of talc can make flotation difficult, and relatively small changes in carbonates may mean the difference in the economic viability of an acid leach procedure. Even low levels of oxidation may be very important in certain cases such as flotation, since even a slight tarnish of the mineral surface may drastically affect its separation characteristics. Certain other properties, including hardness, brittleness, fracture patterns, specific gravity, etc., may be important, as well as rheological functions of slurries derived from ground products. Unfortunately, important differences often go undetected in the early examinations. Only alert cooperation between the petrographer and the metallurgist will provide the proper recognition of these characteristics, and of their importance.

Finally, the metallurgical tests become one more ore characterization tool, usually the final criteria, but are often more cumbersome than other procedures. Therefore, one of the goals of the test program is to develop correlations with other characterization methods that allow confident prediction of the metallurgical results to be expected from a particular ore type or a specific lot of ore, based on simpler evaluation methods.

25.1.2 SAMPLING

Each metallurgical test sample should be selected to provide the appropriate material for the testwork to be performed. The amount of sample, the method of taking it, the location within the deposit, and the chemical, mineralogic, and physical characteristics should be determined beforehand, to the extent possible. This requires that the metallurgical test program be defined in as much detail as possible prior to attempting to take the sample.

It must be recognized that proper sampling is expensive, and the subsequent handling and testing usually even more so. Further, the decisions that are based on the test results will have a major effect on the future of the property. Therefore, the entire operation merits the full attention of all parties that can contribute to the selection of the sampling criteria, the performance of the actual sampling, the characterization of the sample, and the subsequent handling and storage of the material.

The selection of the sample criteria will be based on the best available understanding of the geology, the chemical and mineralogic composition of the ore zones, and the mining plan. The objectives of the test program for the particular sample must also be considered.

The quantity of material needed to provide a representative sample will clearly increase as the maximum rock size in the sample increases. The mineralogical characteristics are also a factor in selecting the quantity of material needed for a representative sample. For example, ores containing only a few large, randomly distributed particles of the valuable constituent will require larger samples than more uniform ores. Guidelines for estimation of minimum sample size are available (Cooper, 1983; Ottley, 1985).

The actual sampling technique must not only produce the quantity of sample desired from the selected mineralized zone, but it must deliver the sample in the proper physical condition. Especially for bulk samples, care must be taken that the sampling technique does not destroy the essential physical characteristics of the material. For example, underground mine blasting procedures could produce material too fine or too fractured to provide appropriate samples for autogenous grinding tests.

Finally, the verification of the geological, mineralogical, chemical, and physical characteristics of the sample must be done carefully to assure that the sample does, in fact, have the characteristics desired, and is appropriate for the testing planned. It may be far better to discard a sample that does not meet the specified criteria than to proceed with the testwork on material that will not give the information desired, or may actually produce misleading results.

The last item, the handling and storage of the sample, must be carefully planned and performed to avoid both contamination and any physical or chemical alteration of the sample that could affect the test results. Many metallurgical processes are affected by the size of the material, the moisture content, and exposure to the atmosphere. For example, reactive sulfides may require storage under nitrogen, rather than air.

25.1.3 TESTING

Metallurgical testing may include mineral processing, extractive metallurgy, and refining, depending on the ore and the mineral values to be recovered. Mineral processing alone includes sizing, comminution, concentration, and dewatering. Concentration itself is a broad field, including gravity, froth flotation, magnetic, and electrostatic separation processes. Similarly, extractive metallurgy encompasses hydro-, pyro-, and electro-metallurgical procedures. These are broad fields, but certain basic principles can be addressed. For example, it has already been emphasized that metallurgical testing should be approached as an organized program, with the objectives defined and understood for each phase. Once it has been determined that a deposit contains potentially profitable quantities of values, the objective becomes the determination of the procedure that will most effectively produce the best marketable products. Given that objective, it is obvious that the metallurgical testing must be designed to produce much more than just an elegant technical solution. If the ore has to be ground and concentrated, it is essential to establish that the product will in fact be marketable. It is equally essential that the testing determine not only the conditions and the procedure involved, but also the size and number of commercially available equipment units that will be required, so that a plant design can be developed and the capital and operating costs can be estimated.

Perhaps the most valuable and satisfying professional experience comes from the development of an innovative solution to technical problems, but it must be recognized that major technical innovations are extremely rare, and even more rarely are they a commercial success in a new project. If established commercial procedures are incapable of yielding a profitable project design, it should be recognized that the development of even a very attractive innovation will ordinarily be an expensive and time-consuming program.

The following description of the phases of a complete test program is naturally only indicative of what may be appropriate. Metallurgical test programs specific to heap and dump leaching and in situ mining are found in Chapters 15.2 and 15.3, respectively.

25.1.3.1 Test Program: Phase I

The initial testing will select the most appropriate treatment scheme, whether simple sizing, with or without some comminution or size reduction, or more complex treatment such as concentration.

Additionally, a standardized test for evaluating additional samples as they become available should be developed and verified by sufficient replication to establish the repeatability and the variation that will be expected in the results when treating a single standardized sample. This should be done to allow proper assessment of the significance of future test results.

The standardized test must be applicable to the samples that will be derived from the ongoing exploration and development work. In some cases, the standard test may not need to cover the entire treatment scheme. For example, bulk flotation of complex sulfide deposits may be sufficient for a standardized test even though the final treatment plant may include complex differential flotation circuits.

25.1.3.2 Test Program: Phase II

Phase II work will ordinarily involve the application of the standard test developed in Phase I to as wide a selection of samples from the deposit as is practicable. This is done to confirm the suitability of the treatment scheme and also to further define the geometallurgy of the deposit.

It must be remembered that it is always possible that growing knowledge may require a change to the treatment scheme or to the sampling program, and if this occurs, the entire program, including sampling, should be reevaluated.

25.1.3.3 Test Program: Phase III

Most major metallurgical projects will require a final phase of demonstration testing in a pilot-scale facility to prove the process prior to final design and construction. This type of testing is always expensive, and from that point, the need for thorough planning is perhaps even more important than in the earlier phases.

One attractive approach is to build a pilot facility on the property and operate it until acceptable data have been developed. In this circumstance, the sample production can be carried on concurrently with the testing, and there is much greater flexibility in both the quantity and type of ore that can be made available. It is not necessary to produce excess sample, and there is no risk of running out of proper ore. Occasionally, such a plant becomes the prototype for the commercial facility and actually recovers enough values to offset all or at least a portion of the costs of the test program.

On the other hand, it is usually far less expensive to use an existing facility, if one is available. The access to skilled staff and superior support facilities are also important considerations.

Chapter 25.2
STORAGE AND TRANSPORTATION OF MINERALS

WILLIAM L. PRICE

25.2.1 INTRODUCTION

Temporary storage of mineral products and their further transportation to processors or customers are essential operations.

Storage is a requirement in order to interface between two discontinuous mineral operations, whatever they may be. Few flowsheets can be planned as completely continuous operations from start to finish. Even though planned as a continuous operation, if any one operation stops for any reason without surge pile storage, then every other phase would have to stop—a catastrophic event. However, with even modestly sized surge pile storage, all the remaining phases can be kept in operation for a reasonable time.

Transportation, in particular, is a discontinuous or batch process as compared to a relatively continuous mining or processing operation. This intermittent movement of materials makes storage facilities at transportation points an absolute essential. The cost of transporting minerals to a processing plant or to the ultimate consumer can easily equal or exceed the cost of producing the mineral itself. This fact necessitates giving serious consideration to facility location with regards to transportation—for example, locating to take advantage of low-cost water transportation vs. rail or truck.

In selecting a storage or transportation system, the normal economic equation of high initial investment coupled with low operating cost vs. the reverse, applies dramatically. As an example, either low-cost, highly labor intensive front-end loaders or a high-cost automated reclaiming method with minimum labor cost may be chosen. Thus an economic evaluation of a number of alternatives must be made in order to select the optimum storage or transportation loading/unloading approach for a given situation.

With a long-term trend toward increased labor rates, the facility designer should also try to predict future labor costs. These could help justify additional first-cost expenditures for storage or transportation systems.

In storage and transportation a general trend over many years has been the replacement of batch-type operations with continuous operations. Examples:

Batch-Type Operations (High Labor Cost)	Continuous-Type Operations (Low Labor Cost)
1. Trucking to destination	1. Belt conveying
2. Loading individual railroad cars	2. 100-car unit trains
3. Using front-end loaders or clamshell grab buckets	3. Using continuous reclaimers, e.g., bucket wheel excavator

The following presentation covers the significant transportation and storage methods that have withstood the test of time. Many innovative schemes have surfaced over the last 50 years, and a few have proceeded as far as their initial operating installations. However, with the process of economic attrition, many have died with no further installations and will not be discussed due to space limitations.

25.2.2 STORAGE

25.2.2.1 Open Storage

A system of piles exposed to the weather predominates in the storage of mineral products, especially for the lower-valued commodities. Unless there are environmental reasons or the mineral can be damaged by the elements, open storage is a natural choice with a seemingly endless array of pile layouts. (Figs. 25.2.1 to 25.2.3) A typical open storage pile is shown in Fig. 25.2.4.

Creating an open stockpile in its simplest form is done by employing a sloped belt conveyor. The mineral discharged to the ground forms the stockpile, and as long as segregation or breakage is not a problem, the simplest open conical pile storage is provided. If the stacking conveyor is mounted on rails or is track- or wheel-mounted to permit it to travel, a variety of tent-shaped piles can be created with unlimited storage possibilities. With the tonnage in a conical pile increasing as the cube of the height, and the tent-shaped pile tonnage increasing as the square of the height, and with no modifying factors, the highest practical pile represents the lowest nominal storage cost per ton. These open piles can be extended outward with earthmoving equipment for additional "dead" storage. Pile height is governed by permissible ground loading, segregation by size, and degradation by falling from the conveyor discharge.

Reclaiming from open piles generally falls into two categories. First, the mineral can be recovered by gravity to some type of feeder that places it on the reclaim belt conveyor (Fig. 25.2.5). Second, mechanical devices can dig and elevate the stored mineral—again to be placed on a belt conveyor. The minimum investment approach involves using standardized earthmoving equipment such as front-end loaders or pan scrapers. This approach also requires the highest labor cost per ton. A gravity-type draw-down conical pile is the next most expensive and suffers from the fact that only about 25% of the pile is available as live reclaimable storage. The remaining 75% must be recovered at a higher cost with earthmoving equipment. To gain higher percentages of live storage, tent-shaped piles are recommended using rotary plows, raking devices (Fig. 25.2.6), or bucket wheel reclaimers (Fig. 25.2.7). While this class of equipment represents significantly higher investment, labor cost per ton is significantly lower since it can be operated remotely from a control tower and can be automated rather easily. The other obvious advantage is the improvement in the percentage of live storage. Crawler-mounted bucket wheel reclaimers may be substituted for rail-mounted equipment.

25.2.2.2 Covered Storage

The significant extra cost per ton of mineral product for covered storage is usually justified in one of two ways: either environmental control regulations require it, or the mineral product will be damaged by exposure to the elements. For low-tonnage requirements, *prefabricated storage bins* can represent an economical solution. They are available in many shapes and sizes and can be quickly erected. They allow gravity reclaim to trucks or conveyor belts with a minimum of engineering.

Cableway drag scraper arrangement-low capacity.

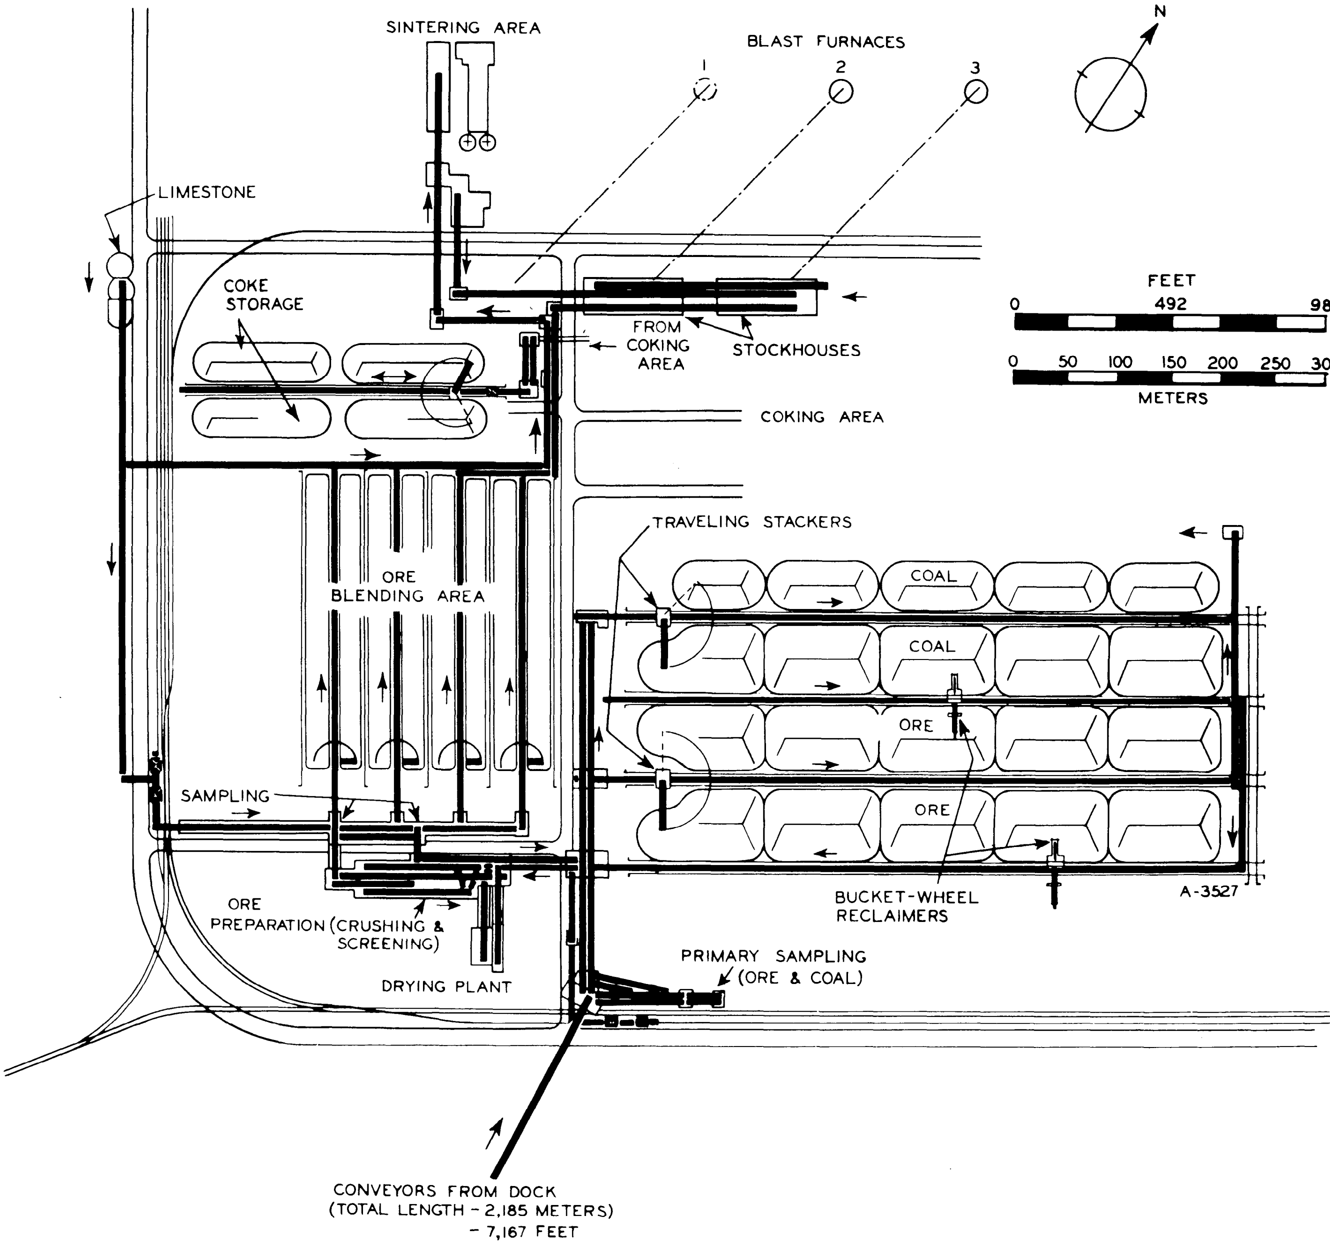

Fig. 25.2.4. Typical open pile storage complex for handling iron ore and coal for a steel mill (*courtesy:* A.T. Yu).

Silos offer economical storage in 12,000-ton (10,900-t) units (Fig. 25.2.8) and have become rather standardized in concept. For the storage of large tonnages of coal, the 70-ft (21-m) diameter slip-formed concrete silo is in common usage. It is fed by a long sloping belt conveyor sized to match the mine output. Reclaiming is by gravity via a set of gates in the silo bottoms. Cross-connected feeder belts bring the product to a common point. From there it can be loaded to unit trains, trucks, conveyor belts, or other systems. The silo contents have a basic problem of "rat-holing" with the mineral hanging up around the perimeter. If this collapses all at once, there could be potentially disastrous results. Concrete silos have failed structurally because of this type of hang-up and quick release of the silo contents.

Gravity-assisted reclaim for silo storage attempts to solve this problem. One popular approach is manufactured under the trade name "Eurosilo." This design offers a rotating horizontal screw or raking device traveling in a radial pattern. The rake moves mineral toward the center of the silo where it drops down a central vertical pipe to a discharge conveyor at grade level. Mineral hangups are thus prevented.

A *hemispherical roof structure* (Fig. 25.2.9) is often used in place of conventional open storage methods. The structural design follows conventional practice but tends to be individually designed for the specific situation at hand. To afford protection for tent-shaped piles, *rectangular roof structures* (free-span) (Fig. 25.2.10) are commonly used to provide covered storage for many mineral products. Although similar in configuration, they also are usually designed individually.

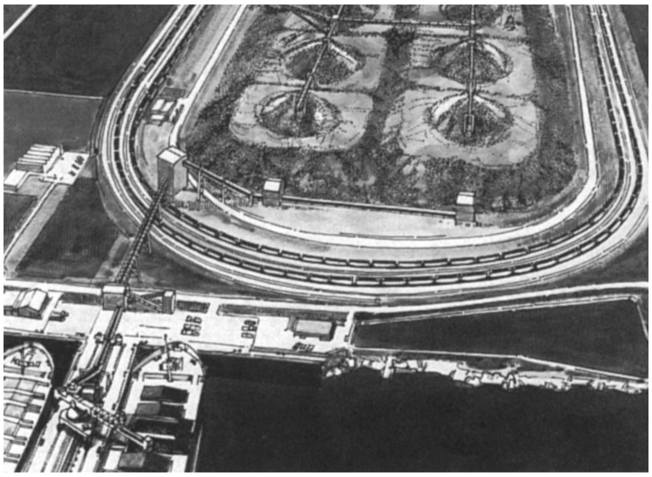

Fig. 25.2.5. Open storage piles using gravity drawn down to feed underground conveyor belts (*courtesy:* McNally-Wellman).

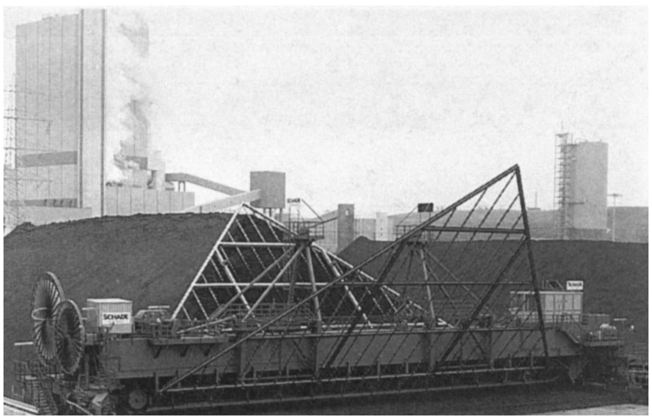

Fig. 25.2.6. Bridge scraper-reclaimer handling coal with 164-ft (50-m) span and 1125 tph (1020 t/h) capacity (*courtesy:* McNally-Wellman).

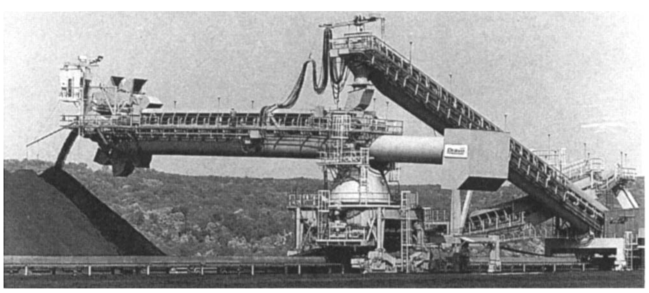

Fig. 25.2.7. Typical rail-mounted bucket wheel stacker-reclaimer used in the open storage complex (*courtesy:* McNally-Wellman).

Due to increased pressures to conform to environmental regulations, particularly dust control, the application of covered storage has seen a steady growth.

Fig. 25.2.8. Covered storage complex with rectangular covered roof at left for long-term storage. This feeds the concrete silo in center foreground. Unit train will pass under silo for flood loading (*courtesy:* PEBCO).

25.2.2.3 Blending and Mixing

In addition to the normal problems of open or closed storage, the operator of the storage yard often discovers the *necessity for blending* the incoming mineral product. This is caused by a need for greater uniformity in the product leaving the storage yard than existed in the incoming mine product. One obvious reason for this need would be variations in the chemistry or grade of mined product in various sections of the mine. Whatever the reason, this new blending function will add cost to the storage and reclaiming function. The governing requirement becomes the *permitted variation* or uniformity required in the product shipped out (Fig. 25.2.11).

There exists a certain amount of natural mixing each time the product is handled. This is accentuated by conical pile storage and a crude mixing can be accomplished by selective reclaiming with a clamshell bucket or front-end loader to blend the shipped product.

A more expensive approach is to draw varying products from different storage bins onto a common belt conveyor. As shown in Fig. 25.2.11, a crude or sophisticated proportioning method can be used depending on the need. *Bin blending to a belt* may prove adequate for reasonable capacity storage requirements. If not, a more complex and expensive *chevron-type open storage pile* is recommended (Fig. 25.2.12). This approach embodies the storage of tremendous tonnages on the ground, which may be required for other reasons. With a traveling stacker that continuously traverses the length of the tent-shaped pile, very thin layers from different mine sources are bedded on the continuously growing pile. Essential to this blending system is a *pile arrangement* which permits simultaneous bedding of one pile while a previously bedded pile is being reclaimed and shipped out.

To accomplish the above, the reclaimer is moved to the end of the rails and then onto traversing tracks set at right angles. The reclaimer is then moved to the next track where a prepared, blended pile is ready for reclaiming. A *full-height reclaimer* is required with a full height rake to insure the best blending by the traversing bucket wheel or wheels. A somewhat better product uniformity is inherent when reclaiming with a drum-type reclaimer (Fig. 25.2.13) as it automatically recovers mineral across the full width of the pile at one time. Other types of blending reclaimers include rake-type reclaimers. On large installations, there can be multiple twin-pile arrangements that afford larger capacity storage.

25.2.3 TRANSPORTATION

For basic materials handling coverage, see Chapter 9.3 in this *Handbook.*

25.2.3.1 Belt Conveyors

Belt conveyors, because of their simplicity and universality, have quickly become indispensable in the layout of a storage facility. They permit maximizing the use of ground space and allow the designer tremendous flexibility in his flow scheme. The current parameters for belt conveyors include 20, 35, and 45° troughing idlers with the 35° replacing the older 20° as the most popular roll configuration today. Use of the former permits a gain of 28% in capacity. Commercial belting and hardware are available up to 120 in. (3.0 m) in width. An important factor in selecting minimum normal belt width is to select a figure at least three times the maximum lump size.

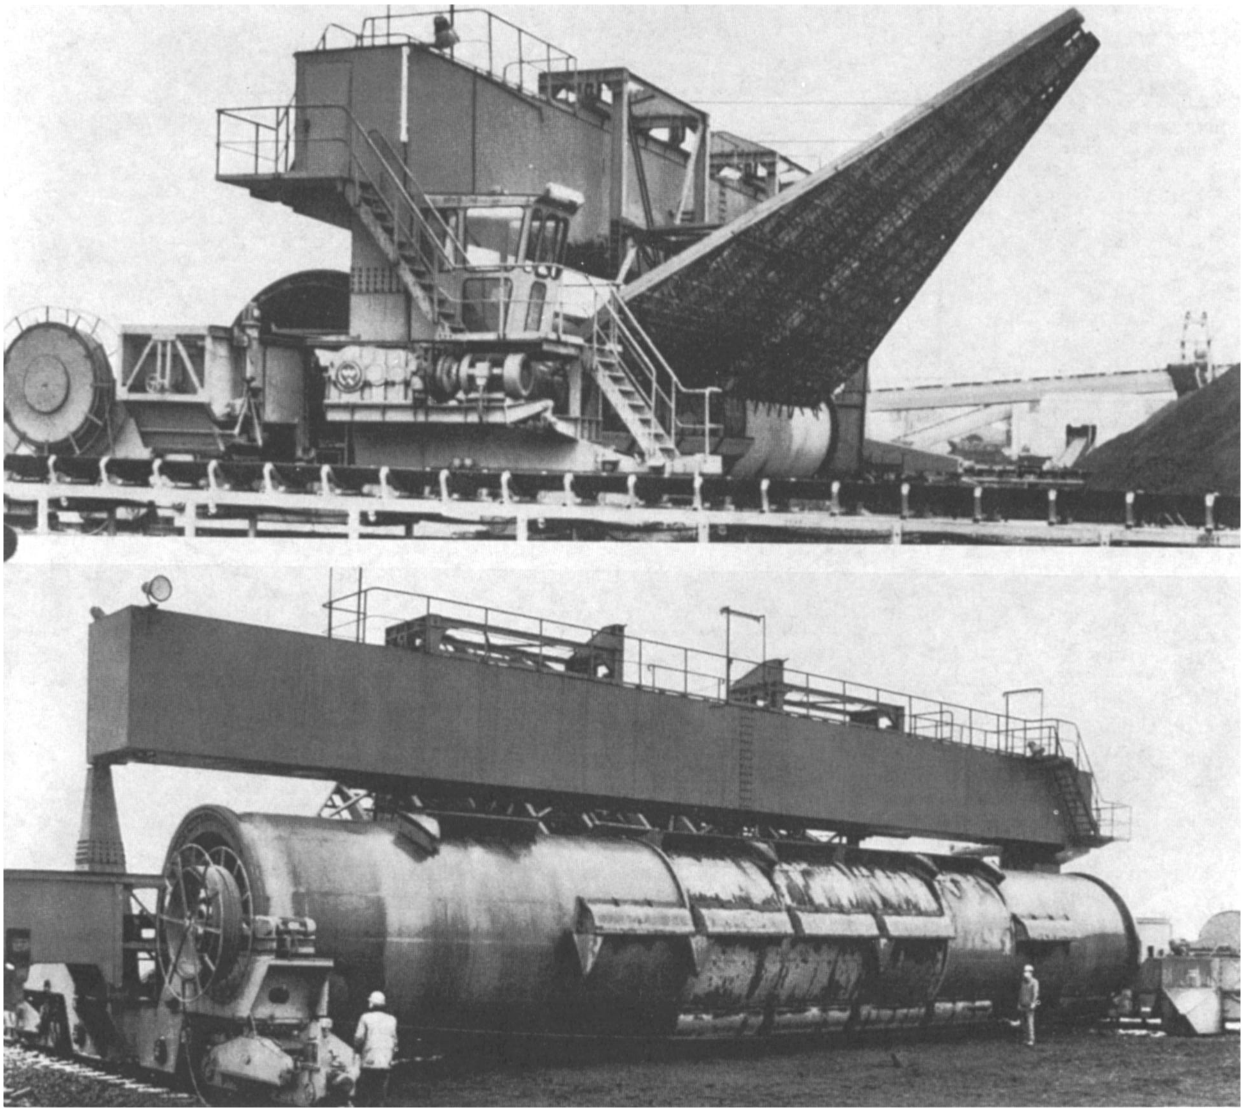

Fig. 25.2.13. Arrangement of drum-type blending reclaimer that samples full width of blended pile continuously as it advances.

For conventional belt layouts with unsophisticated loading chutes, belt speeds from 300 to 600 fpm (1.5 to 3 m/s) are workable. Belt speeds of 900 fpm (4.5 m/s) are common with properly designed loading and transfer points, especially on overland belts.

Actual *belt conveyor designs* for normal uses involve empirical calculations as prescribed in the Conveyor Equipment Manufacturers' Association (CEMA) manual. These designs readily lend themselves to computerized calculations that are quickly performed. The more recent development of using steel cable belting extends the belt conveyor's possibilities far beyond those achieved with original cord belting.

The most common conveyor operating problem is misalignment of the belt flight causing the belt to track to one side or the other. If not corrected immediately, the belt will destroy itself with edge wear against the structure.

In multi-flight layouts, particularly, *belt transfer points* are critical. If not designed correctly, the results can produce excessive belt wear, poor tracking, degradation of the mineral, and excessive dusting, among other problems. In laying out an *overland belt conveyor,* (Fig. 25.2.14) the designer should try for as few transfer points as possible to achieve the lowest capital investment. Many factors affect the layout including the general topography and location of power supply points that can affect drive locations for the various flights.

One significant option for the above is a unique design named the *cable-belt conveyor* (Fig. 25.2.15). This utilizes continuous twin wire ropes from beginning to end. This system requires only one drive station, which tensions the wire ropes rather than the belting. With the belting riding on top of the wire ropes, it serves as the product carrier only.

Another innovative approach simplifying the task of the overland conveyor designer is the use of *curved belt layout* Where a conventional overland belt layout would require various transfer points to miss existing obstacles, it is now possible to run continuous flights by laying out a curve to circumvent the obstacles. This has obvious cost advantages.

A radical departure from previous conveyor belt practice involves the *pipe belt* (Fig. 25.2.16). Here, instead of laying open in the conventional trough, the belt is rolled into a tubular pipe

Fig. 25.2.14. Ten-mile (16-km) long cable belt overland conveyor from mine to open storage. Bucket wheel stacker-reclaimer supplies barge loading river dock (*courtesy:* McNally-Wellman).

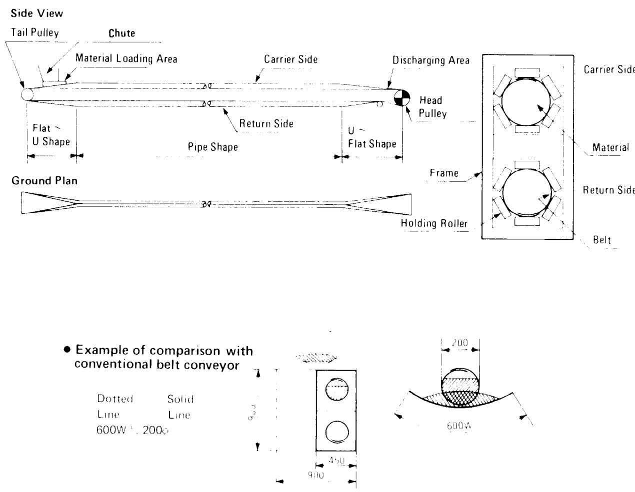

Fig. 25.2.16. Pipe conveyor configuration. Belting is restrained in tubular cross section (*courtesy:* Pipe Conveyor Co. Ltd.).

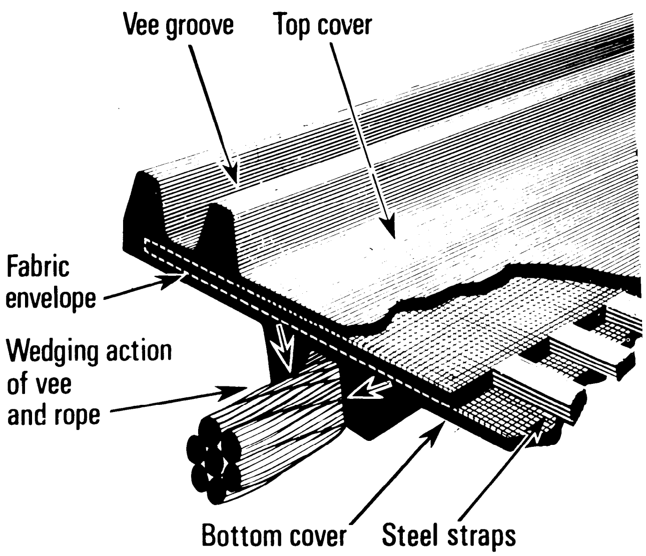

Fig. 25.2.15. Cable belt conveyor. Typical cross section.

cross section. The belt is restrained by special idlers. By acting as a pipe, spillage is minimized with external wind protection no longer needed for environmental reasons. In addition, since the mineral can no longer roll back, much steeper belt angles are a possibility with their consequent savings in required length and investment.

Steep-angle belts eliminate the basic disadvantage of the sloping belt; which requires a long and costly horizontal distance to gain elevation. One successful approach has been the *flexible side wall belt* (Fig. 25.2.17). The belt cross section utilizes a flat rubber bottom strand with corrugated rubber sides extending upwards at right angles. These enclose vertical flights that act as pockets to trap the mineral. This configuration permits loading the belt in the horizontal position where, as soon as required, by use of restraining pulleys, the belt can turn at a right angle to a vertical run. It can return to the horizontal again at the top to discharge the mineral. Minimal horizontal distance is required for this slope giving the designer almost complete flexibility in layout.

Another steep-angle approach employs a *sandwich belt* (Fig. 25.2.18) riding atop the steeply sloped and troughed carrying belt. Perfected by use on bucket wheel excavators, this arrangement permits extremely steep conveyor angles to be used with obvious advantages. Inverted troughing idlers are required above the top sandwich belt to prevent gaps between the upper and lower belts.

Shiftable ground belts can service a mobile belt discharge that is normally moved at right angles to the ground belt to follow an excavator. This arrangement permits use of ground belts fed by a bucket wheel excavator or other digging device. These must periodically advance into a new face at right angles to the belt line. To permit this belt shifting, the belt frame is loosely built and rests on ground sleds. The sleds are connected longitudinally by a rail section. When it becomes necessary to shift the ground belt, a crawler-mounted dozer travels parallel to the belt with a roller hook set over the rail section. While advancing, the belt frame snakes over in the direction of the dozer pull. This is repeated as often as necessary to obtain the required lateral shifting.

Traveling trippers are used to discharge from any desired point along a long horizontal belt. This offers great flexibility for storage layouts by making tent-shaped piles where the tripper can dump the mineral onto a traveling stacker to make a storage pile alongside.

Belt enclosures are a necessity where wind can blow fines from a belt or the mineral must be protected from the elements. Vertical side boards are often adequate for wind problems while complete half-circle covers, usually of corrugated metal, cover the entire troughed belt. Often the belt is completely enclosed in a structural steel tube with sufficient space for man access alongside. This design affords the maximum environmental protection and permits heating of the belt at reasonable expense if required.

25.2.3.2 Truck Transportation of Mineral Products

The transportation of mined products by truck within the mine and from mine to processing plant is covered elsewhere in this *Handbook.* These mine-related operations tend to utilize off-the-road-type trucks and equipment of a very specialized nature with extremely large capacities.

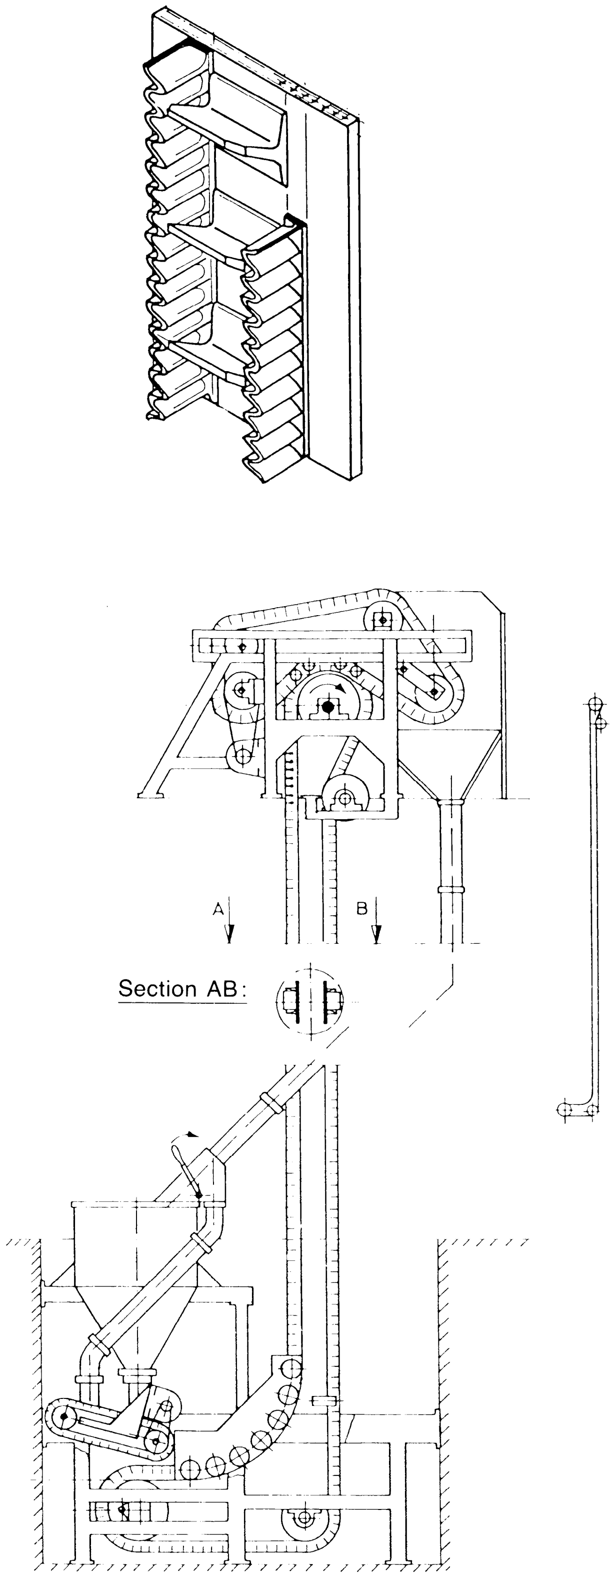

Fig. 25.2.17. Steep-angle conveyor using flexible side wall belts with accordian sides and pockets (*courtesy:* Scholtz).

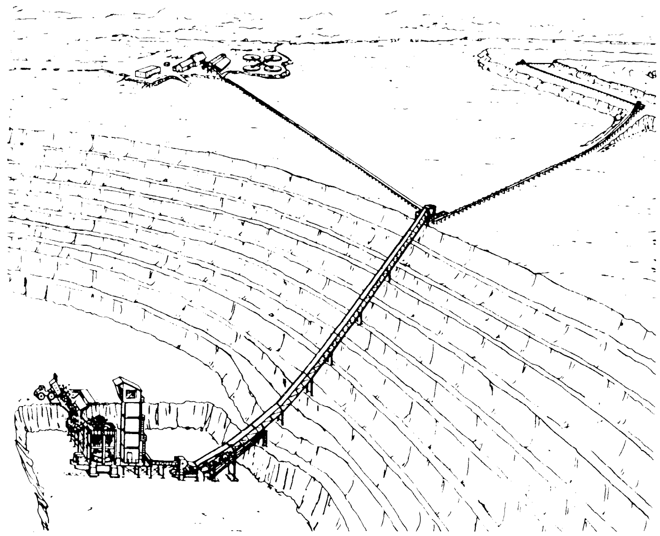

Fig. 25.2.18. Steep-angle conveyor in pit using sandwich belt retainer construction (*courtesy:* Continental Conveyor Co.).

Fig. 25.2.19. Loading minerals into the frame-type trailer is done by front-end loader. Smooth interior avoids mineral buildup (*courtesy:* Fruehauf Corp.).

Transportation of mined products to market by truck tends to be less significant on a tonnage basis than other methods of transportation described herein. Truck transportation has a high cost per ton-mile, which limits it to special situations. Bulk movement is described since most minerals will move in this fashion rather than in packaged or break-bulk shipments.

Trucks designed for the movement of minerals are divided into two general classifications. The first is an *end dump* design. Figs. 25.2.19 and 25.2.20 illustrate two configurations, namely frame-type vs. frameless construction. As always, the objective is to gain more payload. Aluminum construction is another alternative to achieve this purpose. The other classification is that of *bottom dump* design as shown in Fig. 25.2.21. This, of course, requires a special unloading facility, normally a long grated hopper leading to feeders and belt conveyors. This design offers a fast unloading cycle time.

Transporting minerals with small particle size is done economically with *closed pressure trucks* (Fig. 25.2.22). These are designed to pneumatically handle dusty, small-sized products. Thus, air pressure is used to discharge and move the mineral product for a considerable distance through hose or piping. Discharging vertically to a storage bin is the normal procedure. The truck body itself is compartmented so that the cargo can slide by gravity to the discharge ports where the airflow sends it through the discharge pipe, typically 4 in. (102 mm) in diameter.

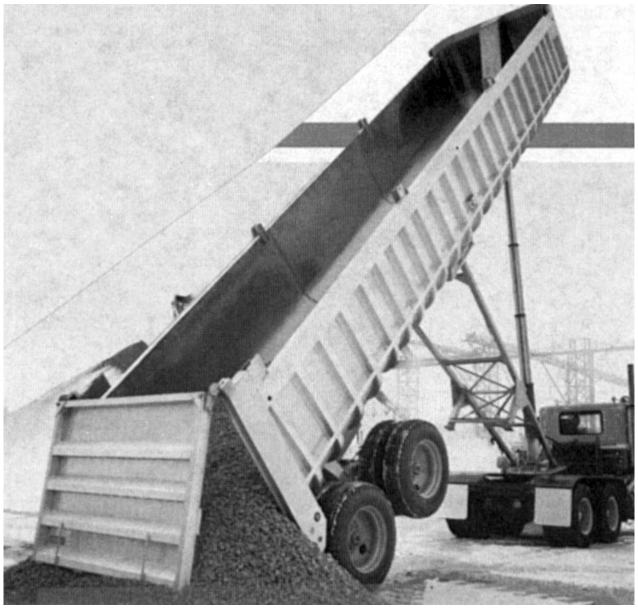

Fig. 25.2.20. Frameless trailer dumping mineral contents at desired location (*courtesy:* Fruehauf Corp.).

Fig. 25.2.21. Bottom-dump tandem trailers being loaded simultaneously by twin conveyor belts. Entire bottom is opened for discharge over receiving hopper (*courtesy:* Continental Conveyor Co.).

The advent of this type of truck has practically eliminated the use of bucket elevators to elevate fine products to bin storage.

Some containerization of sophisticated bulk minerals occurs and standardized truck containers are used.

Size and weight limits for truck transportation have steadily increased over the years. The growth of interstate highways offers faster turnaround times, and a new 13 ft 6 in. (4.43 m) vertical clearance allowance simplifies routing. One basic advantage of truck transportation is that the loading and unloading facilities are less expensive than those for competing systems. This factor could be particularly significant if the mineral deposit

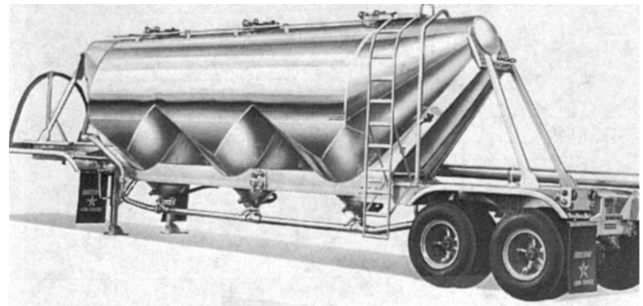

Fig. 25.2.22. Pressurized trailer with 1000-ft^3 (28-m^3) capacity allows air discharge of finely-sized mineral product via hose to overhead bins. Examples: cement, lime, etc. (*courtesy:* Fruehauf Co.).

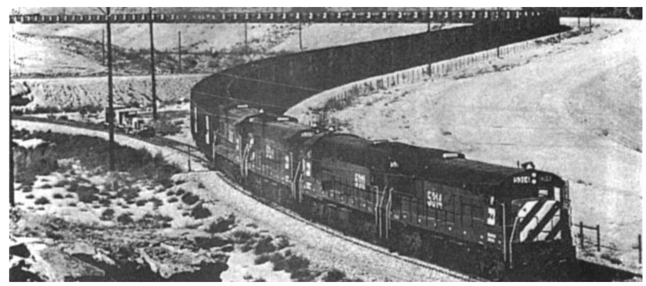

Fig. 25.2.23. Hundred-car unit train enroute from mine to final destination with four power units.

has a very short predicted life and cannot justify elaborate loading and unloading facilities.

25.2.3.3 Rail Transportation

The mining engineer normally has practically no control over the actual transportation of the mined product once the loaded rail car is turned over to a common carrier railroad. He does, however, retain control of the loading and unloading of the actual cars and can be instrumental in the selection of the type of train used. Several possible alternatives are discussed in some detail to help in the selection of the method to be used.

A partial train load will fit many situations and is normally loaded in an unsophisticated manner. For a typical user loading out small to medium tonnages of mined product per year, the normal procedure is for the common carrier to drop off the requested number of empty cars. Since allowed loading time is not critical, the plant operator moves the empties under the loading conveyor or storage bin with a car puller or shifting locomotive. Movements are matched to the loading tonnage rate required. If accurate car weights are required, weigh belt conveyors or track scales can be used.

The most significant breakthrough in keeping the railroads competitive was the introduction of the *unit train* concept in the early 1960s (Fig. 25.2.23). For the first time, a complete trainload of up to 100 cars was handled as a unit in all phases of the operation: loading, transport, and unloading. This mass movement of mined product gave rise to a new set of operating rules whereby the loading and unloading times must be rigidly controlled, typically four hours each. These concepts required new systems and equipment to accomplish the necessary handling rates. Assuming the unit train consisted of 100 cars at 100 tons

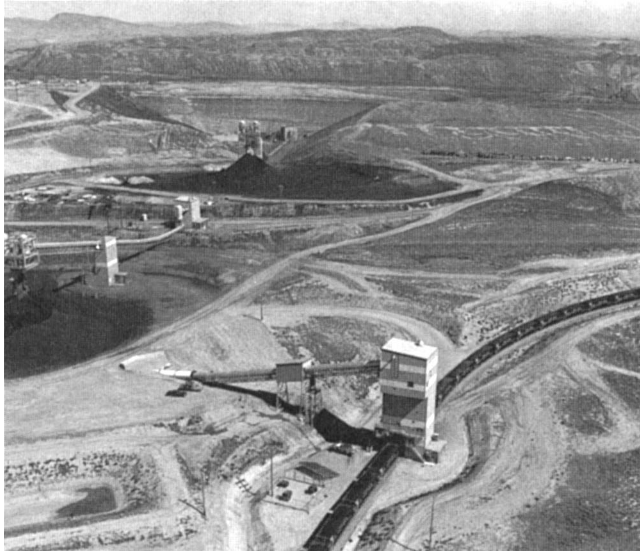

Fig. 25.2.24. Unit train loading facility. Storage bin fed by sloping conveyor stores sufficient coal for continuous loading of 100-car unit train with 100 tons (91 t) per car. (*courtesy:* A.T. Yu).

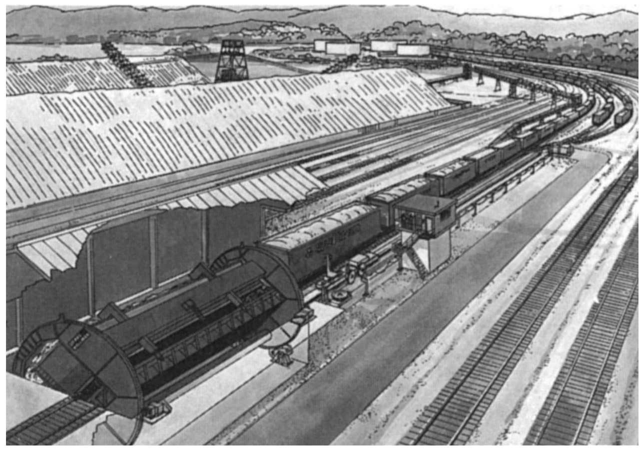

Fig. 25.2.25. Unit train car dumper facility. Each car is dumped after being advanced one car length by train positioner. Adjacent open storage piles reclaimed by rake reclaimer (*courtesy:* McNally-Wellman).

(91 t) each, it became necessary to store at least 10,000 tons (9070 t) of mined product in a state immediately accessible to the train loading points. The most popular method that evolved is the use of a 12,000-net-ton (10,885-t) capacity concrete silo that is filled continuously from the mine while awaiting the unit train. When the train arrives, the mined product is loaded into the cars in a four-hr period. One popular method of accomplishing this is by running the train directly beneath the silo bottom and "flood loading" each car as it passes beneath the loading chute (Fig. 25.2.24). Thus an average loading rate of about 2500 tons (2268 t)/hr is achieved. To achieve maximum efficiency with the unit train concept, it is essential that the cars be loaded to their weight limit as accurately as practical. This may require a secondary topping off operation. If there is significant loss from the top of the open cars in transit, crusting agents can be applied to the mineral surface to cut down on windage loss in transit.

When a high-tonnage unloading rate is not required and capital expenditure is to be minimized, the use of *bottom-dump hopper cars* is a logical choice. Each car can be shifted over a hopper beneath the tracks and the bottom gates manually opened to discharge the contents to the hopper, feeder, and conveyor belts that move the mineral products to their destination. Car movers are normally adequate for this service.

In the case of the unit train, a *rotary car dumper* is generally used where the quick discharge of a loaded railroad car (hopper type) is required. With this device, each car is turned upside down and the mineral contents discharged to a large hopper that feeds belt conveyors leading to the ultimate destination (Fig. 25.2.25). Normally, it is necessary to uncouple each car so that it enters the dumper unattached (Fig. 25.2.26). The only exception to this is when a unit train is designed with rotary couplers that permit dumping without breaking the train. With stricter environmental regulations (25.2.4), dust control at a car dumper is becoming mandatory and requires a complete enclosure and an exhaust system feeding a bag-house filter.

To achieve a high unloading rate, it becomes essential to move the cars in and out of the dumper quickly. One popular method employs a shifter locomotive, either manually or remotely controlled. These power units can handle a group of cars or an entire unit train. An alternate choice is a mechanical, remotely controlled train positioner that can handle a full unit trainload of cars. This device drops a power arm over the coupler and advances one car length before disengaging to return to the next car. Rotary couplers are required to avoid uncoupling cars.

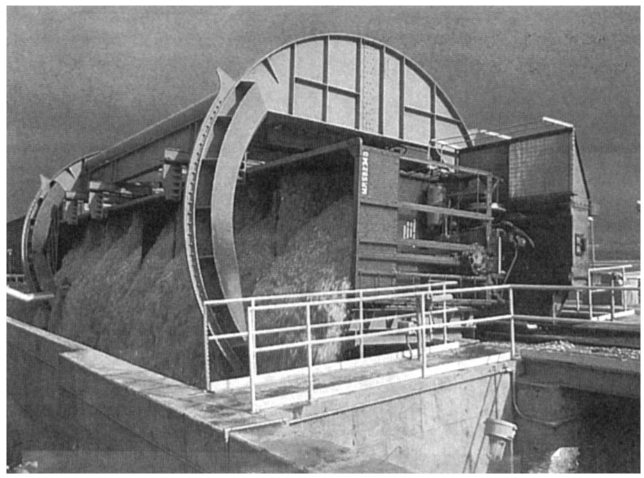

Fig. 25.2.26. Detailed view of mechanism in car dumper showing vertical clamps that hold car against bottom platen. A complete enclosure would be needed to control dusting (*courtesy:* McNally-Wellman).

The highest unloading rate possible can be achieved by the use of special *high trestle side-discharge cars* (Fig. 25.2.27). As the train approaches the trestle over the designated stock pile discharge point, each loaded car is tripped open by a device alongside the track and empties its complete contents where desired in a matter of seconds.

There are two significant factors to be evaluated in considering this trestle unloading system. The first is the additional significant investment for the cars with special quick-opening doors. The second factor is the selection of a location where

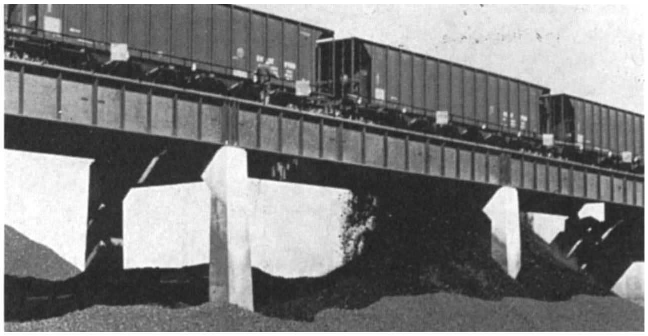

Fig. 25.2.27. Rapid discharge rail car facility. Cars are remotely opened while atop the trestle. Discharge is complete within seconds. Doors are automatically closed (*courtesy:* Ortner Car Co.).

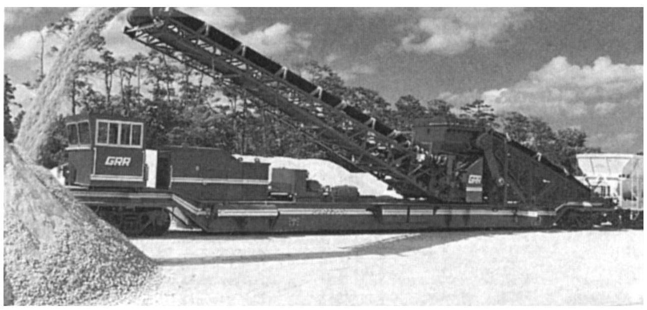

Fig. 25.2.28. "Dump-Train" arrangement features continuous conveyor belt under cars for full length of train. Discharge boom can be swiveled to desired position.

dropping the mineral product from trestle height to the ground will not create an environmental dust problem. If these two problems are addressed successfully, extremely high rates of discharge are possible.

One unique train unloading approach is that of the *self-unloading train* (Fig. 25.2.28) recently placed in operation. This innovative design consists of a train of about 30 cars permanently connected and containing a conveyor belt running under the full length of the train. The belt restrains the loaded mineral product at the bottom of each car hopper. Held loosely while traveling, the full-length belt is tightened at the straight-line unloading destination. Similar to a self-unloading ship, the train-long belt draws product from all of the cars and discharges the entire trainload at one end via a stacking conveyor that feeds the storage pile.

In extremely cold weather, if the loaded cars are permitted to sit idle or the trip is time consuming, the mineral product may become frozen in the cars. This situation can present serious operating problems in attempting to unload the cars. After thawing the car, large frozen lumps must be broken up on the car dumper grating in order to pass through to the feeders and belts. If freezing in the cars is the normal situation, then car thawing facilities become a necessity. The latest system utilizes microwave heating.

25.2.3.4 Marine Transportation

In planning for the transportation of mineral products to market, the use of marine transportation should be considered.

Fig. 25.2.29. Traveling clamshell grab bucket used to unload deep water vessels (*courtesy:* McNally-Wellman).

It becomes a logical choice for many reasons. If speed of delivery is not essential, high annual tonnages justify the investment in specialized equipment, and overseas destinations are often involved. Even if the marine transportation segment must be coupled with overland movement, it is normally possible to justify marine loading and unloading equipment due to the savings inherent in low-cost water movement. Recent years have seen low-value mineral products move competitively for unprecedented distances by water. Some examples would be the movement of coal from West Virginia to Florida by water, barite shipment from China to ports on the Gulf of Mexico, cement clinker movement across the oceans, and shipment of low-cost aggregates from Europe to the USA. Obviously, low-cost backhauls can be a governing factor.

For *ocean transport of minerals,* the primary governing factor which determines vessel size and configuration is whether the ship must pass through the Panama Canal. Vessels which can do so are grouped loosely as *"Panamax"* types, approximately 40,000-deadweight-ton (39,339-t) capacity, with 42-ft. (13.8-m) draft and less than 110-ft. (36-m) beam. Coincidentally, many US ports have the same draft limitation. When it is decided to ignore the Canal limitations, the maximum ship size becomes an economic one. There are now many ships of 100,000 to 300,000-deadweight-ton (98,340- to 295,044-t) capacity, with even larger sizes available for special situations. Planned backhauls of non-mineral cargoes can affect the basic design of these bulk mineral carriers. The selection becomes involved with the dredged depths of desired ports of call. Even this normal port depth limitation can be circumvented by "offloading" in deep water outside the port.

The *unloading of ocean vessels* becomes a significant cost-per-ton factor. Following the historical days when bulk carriers were unloaded by hand, the standard method of unloading minerals has been with the conventional *clamshell grab bucket unloader,* either whirler type or straight-line configuration (Fig. 25.2.29). To increase hourly capacity, the size of the unloading bucket has grown steadily. However, buckets beyond present capacity seem uneconomical at this time due to cycle time disadvantages relative to the other unloading systems described below.

While the cleanup of the ship's hold was originally done by main bucket alone, practically all unloaders now lower earth-

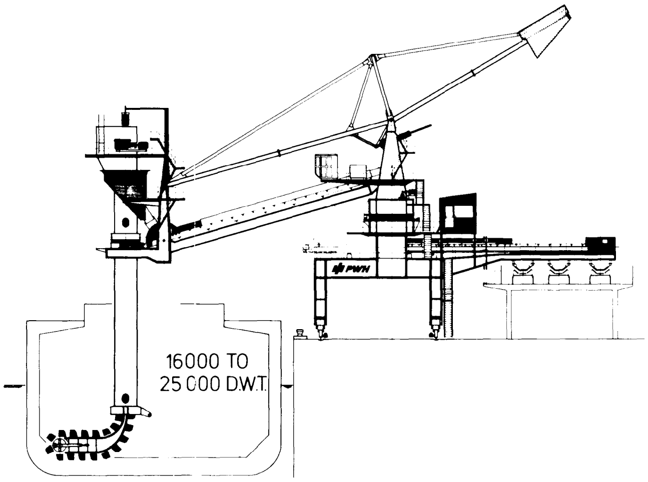

Fig. 25.2.30. Continuous ship unloader using bucket chain system to unload ocean-going ship (*courtesy:* P.W.H.).

moving-type equipment into the hold to speed up the cleanup and turnaround time for the ship. The "efficiency index," or the actual unloading rate achieved from start to finish divided by the free digging rate is normally much lower than one (usually 0.5, or less).

The desire to improve this index number and minimize elapsed unloading time prompted the search for improved equipment and led to development of *continuous ship unloaders.* One type is the dock-supported *bucket chain continuous ship unloader* (Fig. 25.2.30). Where the operator is faced with large, open hatch ships and sufficient annual tonnage, the higher cost of this unloader can be justified when considering the demurrage costs of the ship while in port.

The actual configuration of the vertical bucket arrangement varies as does the method of loading the buckets. Some variations include steel buckets on steel chains, steel buckets on rubber belting, and rubber pocket belts loaded by digging wheels. After being elevated to a sufficient height above the ship's deck, the mineral product is transferred to a horizontal belt conveyor headed towards shore and then to the dock belt conveyor and storage pile.

As contrasted to the bucket chain approach, the *vertical-screw continuous ship unloader* employs an encased vertical screw to dig the mineral in the ship's hold, then elevate it to the horizontal transfer belt. This design tends to have a lighter machinery weight allowing lighter dock construction. *Other continuous unloading methods* include vertical twin "sandwich belts" that trap the mineral between belts and elevate it out of the ship's hold. "Marine legs" trap the mineral between a steel chain flight and steel casing to allow vertical movement. *Pneumatic unloaders* are used on powdery mineral products.

Lake, coastal, and gulf transport is a significant factor in the economics of US mineral transportation. The basic difference between this type vessel and ocean ships is one of size and draft. Although there are some *self-unloading ships* used in ocean bulk trades, the preponderance of this type of equipment is found on the Great Lakes and Gulf of Mexico (Fig. 25.2.31). The relatively short turnaround times for mineral cargoes can justify the extra ship cost and the lost payload caused by carrying this extra machinery. The normal configuration consists of one or two conveyor belts extending for the length of the ship beneath the hoppers in the ship's hold. These discharge to the belt by gravity.

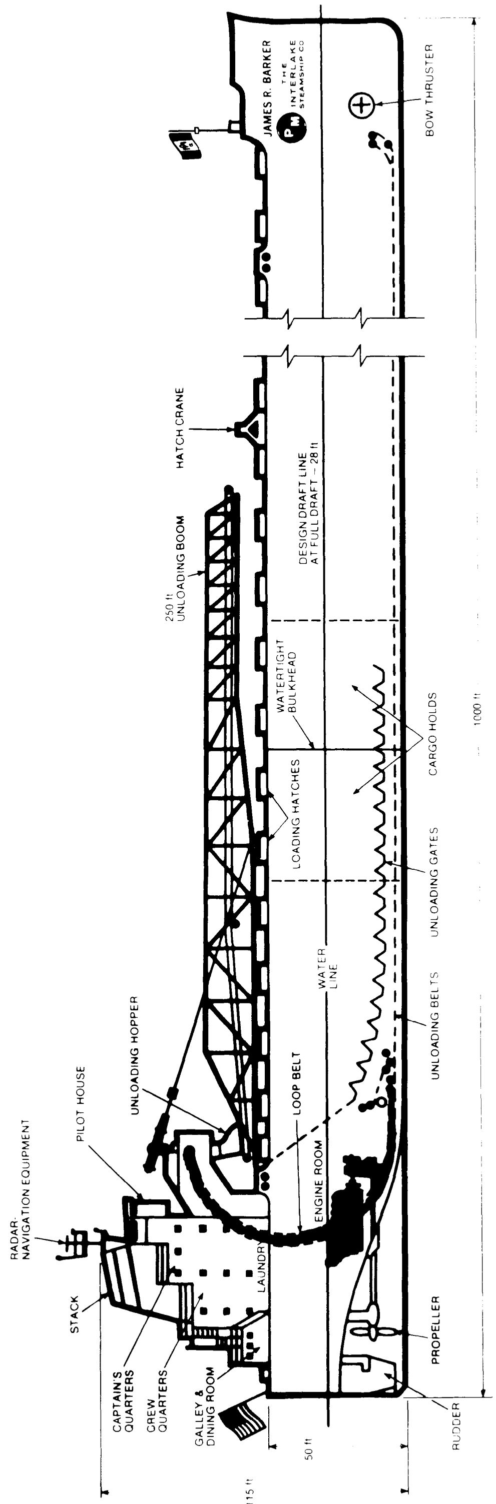

Fig. 25.2.31. Cross section of loop belt self-unloading ship. Deck boom conveyor can swing to either side (*courtesy:* Stephens Adamson). Conversion factor: 1 ft = 0.3048 m.

Once the belt conveyor reaches the end of the ship, there are various methods of elevating the mineral product. The height above deck must be sufficient to reach the normally pivoting discharge belt which unloads to a hopper on the dock. Some of these elevating methods include: "sandwich belt" arrangements, circular wheels to elevate, and rubber "pocket belts." Extremely high unloading rates, up to 20,000 tons (18,142 t)/hr, are possible. The user on shore has practically no investment on the dock except for the take-away belt to land storage.

Inland marine transportation permits tremendous tonnages of mineral products to be moved to destination via the Mississippi river system (Fig. 25.2.32). Together with all of its tributaries, this covers the basic heartland of the United States from mine to ultimate user and at an extremely low cost per ton-mile. For example, over 100 million tons (90 Mt) of coal/yr are moved from mine to power plants and other users by this means of transportation. Since most power plants require cooling water and the inland rivers provide the cheapest transportation possibility, a river location is very advantageous for a coal-burning power plant.

Since the inland river system is based on slack-water navigation with locks and dams, it is the lock sizes that determine the *limitations to equipment sizes* (Fig. 25.2.33). Early lock sizes of 56 by 360 ft (18.3 by 118 m) set a barge size of 26 by 175 ft (8.5 by 57.4 m) that would carry some 900 tons (817 t) in a 9-ft (2.74-m) draft channel. A group of six of these barges with a towboat became a standard tow. Beginning in 1929, lock sizes of 110 by 600 ft (33.5 by 183 m) on the Ohio River set a barge size of 35 by 195 ft (10.7 by 59.4 m) carrying some 1500 tons (1362 t) in a 9-ft (2.74-m) deep channel. The larger locks increased the standard size tow to 15 barges with towboat, moving over 22,000 tons (19,956 t) in one tow (Fig. 25.2.34). In the 1970s, modernization of lock sizes to 1200 by 110 ft (366 by 33.5 m) allowed the standard tow to pass through in a single lockage.

Economic towboat sizes range from 2000 to 6000 hp (1492 to 4476 kW) with some being powered with up to 10,000 hp (7460 kW) when moving a maximum of 30 barges down the open river section of the Mississippi River to the Gulf Coast.

Unloading of river barges began with the familiar clamshell bucket, and in the 1960s the *continuous barge unloader* made its appearance (Fig. 25.2.35). Since the standard open river barge offers access to all its mineral cargo, the entire contents can be unloaded in two or three longitudinal passes dependent on the bucket ladder configuration. Free digging rates of 5000 tons (4535 t)/hr are common using the 1500-ton (1361-t) capacity barge. These high-speed units have become the standard method of unloading at most power plants.

25.2.3.5 Overland Slurry Pipeline Transportation*

Unlike all other forms of transportation addressed in this chapter, *slurry pipelining* utilizes a stationary system with the mineral in motion. In truck, rail, and marine systems, the units are in motion, with the mineral payload being motionless relative to the transporting vehicle.

An overland slurry transportation facility is a system of pipelines, pump stations, and associated process facilities working in conjunction to move a water-crushed mineral mixture, (Stripling and Holter, 1981). At the head of the system is the slurry preparation facility. Grinding and slurrification equipment produce a controlled solid-water mixture for injection into the pipeline system. The pipeline is sized and designed by considering the hydraulic characteristics of the solid-liquid two-phase flow. Pump stations are positioned at appropriate locations along the pipeline to input energy. Several types of pumps may be utilized, but again consideration must be made for the two-phase nature of the flow. The terminal point of a slurry system will have facilities and equipment for storing, thickening, and dewatering the slurry. With growing environmental concerns, the water from the liquid-solid separation step may require clarification or other treatment prior to discharge. Throughout the transportation facility, instrumentation and controls will be used to measure variables (flow, pressure, density, etc.) and implement an operational philosophy.

The purpose of this section is to describe the components of a slurry transportation system and to show the special design considerations required for each component. Criteria are presented for the overall system design considering the interrelationships of the various components.

ECONOMIC FEASIBILITY. Slurry transport has proven to be technically and economically viable for coal, iron ore concentrates, sulfide concentrates, limestone (for Portland cement manufacture), and phosphate minerals. Economically feasible slurry pipeline projects tend to have large volume point-to-point transportation requirements and/or special conditions such as very rugged, inhospitable terrain between the transportation points. Slurry pipelines have significant initial capital costs but low operating costs. Slurry pipelines, therefore, have relatively low exposure to cost escalation. Finally, each project is a special situation and the transportation economics should be developed for the alternatives (rail, truck, marine, and slurry pipeline) and then compared.

PIPELINE HYDRAULIC CONSIDERATIONS. The design of a slurry pipeline is determined largely by hydraulic considerations. The solid particle size distribution selected for the slurry will have a major impact on the whole transportation system (including pumps, slurry preparation, and utilization facilities). The size consist that is finally selected should minimize cost of preparation, pipeline pumping, and dewatering while maintaining favorable hydraulic characteristics within the pipeline.

Once the solid particle size distribution has been defined, the slurry composition is established as to percentage of solids and liquid. Depending on the particular mineral, solids concentrations may typically vary from 40 to 65% by weight.

Hydraulic design involves consideration of the critical velocity or lowest permissible mean flow velocity, which insures deposit-free transport of the solid phase. If the average flow velocity is below critical velocity, the solid particles will begin to settle out and deposit on the bottom of the pipe. The migration of these particles in the lower pipe cross section can lead to excessive pipeline wear and restriction or blockage of the pipe cross section where pipeline slopes change from negative to positive. Frictional pressure losses also increase when the particles travel along the bottom pipe wall. Because of these adverse effects, it is advisable to operate slurry pipelines at flows above critical velocity.

Pipe friction pressure loss, particle attrition, pipeline plugging, transient flow, slack line flow and cavitation are other hydraulic characteristics that must be considered when designing a slurry pipeline. These and other aspects are discussed in more detail by Zandi (1971) and Stripling and Holter (1981).

PUMP STATION DESIGN. Slurry pipelines will have one or a number of pump stations at appropriate locations. The size and exact placement of the stations will be determined by a steady-state hydraulic analysis. Both centrifugal and positive displacement pumps can be used to pass slurries. The choice is dictated by the required discharge pressure. Frazier (1971), Willis and Truscott (1978), Sellgren (1979), and Childs (1979) further discuss the specifics of slurry pumps.

Centrifugal slurry pumps are low-head, high-volume devices and are often used for in-plant pumping plus providing suction to mainline pumps. A number of parallel, positive displacement

Fig. 25.2.34. Typical inland river 15-barge tow of 1500-ton (1360-t) capacity.

machines are appropriate for mainline pumping. Flexibility can be provided by using variable speed drives on some mainline pumps. Pulsation dampeners, accumulators and/or signal biasing circuits should be used to reduce flow-induced pressure pulsations. Standpipes can be a very effective method of reducing pulsations on the suction side of positive displacement pumps.

Slurry pipeline systems need not operate as "tight-line" systems. Each pump station may well have an agitated storage tank on its suction side.

SLURRY PREPARATION. The solid portion of the slurry must be crushed to the specified size distribution before entering the system. Crushing and/or grinding may be necessary. Bernstrom (1977) has discussed the preparation process for a coal slurry. Wasp, Kenny, and Gandhi (1977) describe several slurrification techniques using devices such as gravity feed chutes and hopper-shaped sumps.

SLURRY UTILIZATION. In order to build flexibility into a slurry transport system, storage facilities will be required at the terminal locations. This storage capacity "uncouples" the pipeline facility from the ultimate activities at the terminal. In this manner, the pipeline can be operated in a steady-state condition, and fluctuations in volume can be made up with stored product.

Various techniques are available for dewatering a mineral slurry. Vacuum and pressure filters, centrifuges, hydrocyclones, and thermal drying are examples which may be used alone or in combination.

INSTRUMENTATION AND CONTROLS. The control of a slurry pipeline system is similar to that for regular crude oil pipelines in several respects. A supervisory control and data acquisition (SCADA) system is used to monitor and control process variables at various locations from a central control point. Some pump stations may be fully or partially automated and require few if any operating personnel. The initial or primary pump station should use flow as the principal control parameter with process override systems providing for flow, station suction, and discharge pressure control. Booster or secondary pump stations should be controlled on suction pressure with a discharge pressure override system. Control valves should be used sparingly and limited to startup, shutdown, and bypass-type situations.

The initial pump station area is a critical location for process monitoring and control. The slurry must be inspected to assure the solid-liquid mixture has the required properties before it is passed into the pipeline. Injection of an off-specification slurry into the hydraulic system could cause significant problems. Density of the slurry must be monitored, since improper values of density can lead to formation of slurry plugs or create undesirable friction pressure drops. Indeed, a section of pipe before the first mainline pump station should be selected to determine the actual friction pressure drop to be expected in the pipeline system. Slurry particle size distribution should be checked periodically. Finally, slurry acidity or alkalinity should be maintained at a level that will reduce erosion/corrosion of the pipeline.

Liptak (1967) and Andrew (1974) present a general discussion of slurry instrumentation and controls. Buckwalter (1976) and Zahid (1977) discuss particular aspects associated with positive displacement pumping.

OVERALL SYSTEM OPTIMIZATION. The construction of a slurry transportation system can be an expensive undertaking. Thus, for a particular project, there is a considerable economic

Fig. 25.2.36. Generalized approach for dust control system for open storage piles including pile surface moistening, surface crusting agent, transfer point dust suppression, and vacuum dust collection system.

incentive to optimize the total system. This optimization can be achieved by selecting the slurry preparation, pipeline-pumping, slurry utilization system with minimum cost. However, this selection process is no small task. A pilot plant study may be required for the various elements of the system to determine a cost equation that is a function of several variables. Crushing-grinding-preparation costs must be determined for slurries of different particle size distribution, concentration, and quality. Test loop studies are necessary to estimate the pressure loss in pipelines of various diameters flowing with slurries at different velocities, concentrations, and particle size distributions.

25.2.4 ENVIRONMENTAL CONSIDERATIONS

Environmental regulations with regards to storage and transportation are in a state of flux at the present time since governmental regulations are not firmly resolved and depend somewhat on local interpretation. When any new storage project is under consideration, it is essential that a detailed environmental study be made and that an environmental impact statement be prepared, if required by the permitting process.

The two most significant environmental effects possible are in the areas of (1) surface water drainage from open storage piles and (2) dust control. The latter includes both wind-borne dust from pile surfaces and dust from transfer points as the mineral is handled. A generalized approach to dust control is shown in Fig. 25.2.36. The particle-size ranges for various types of dust are given in Fig. 25.2.37.

Surface drainage predictions require topographic layouts with stream locations pinpointed. Soil porosity is critical and

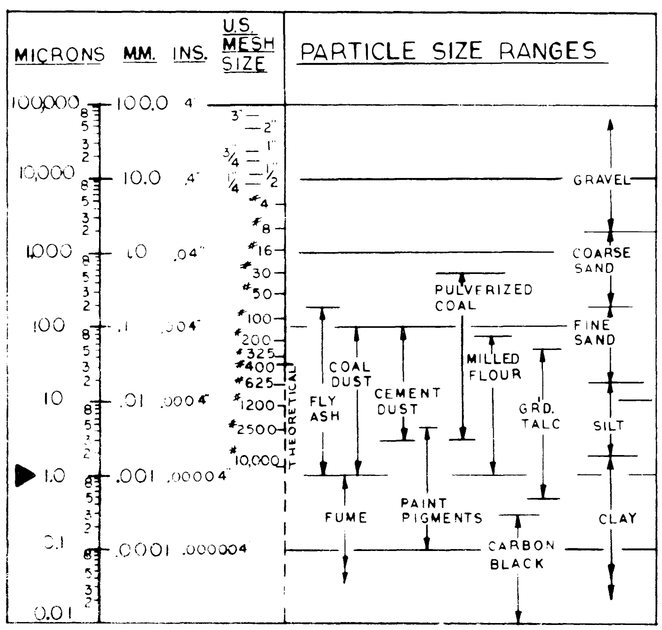

Fig. 25.2.37. Dust particle size range with comparisons for various commodities.

core sampling can help predict the path of contaminated surface drainage. With topographical data and proposed pile layouts, collection ponds can be laid out to intercept surface drainage. Here water treatment can be accomplished so that the runoff from the settling pond will be acceptable as it enters the local streams. Control of acidity through pH readings and the addition of alkaline reagents such as lime is a very common corrective measure.

Dust control at open storage piles requires a study of the prevailing wind situation and the location of populated areas near the site. One potential trouble spot occurs when the fine mineral is dropped from a significant height to the top of the open storage pile. This problem is best controlled by an adjustable height stacking conveyor belt to limit free fall. Dust generated from the surface of open piles can be controlled somewhat by the addition of a water spray system. When the mineral fines are subject to long-term storage, a surface crusting agent can help alleviate loss of wind blown fines from the pile surface.

Transfer point dust is normally controlled by water spray headers set up in the belt conveyor transfer housing or by dry air evacuation systems. To make the water more effective in wetting down the dust, a surfactant is metered into the water supply to the spray headers. By reducing surface tension, the water can more effectively penetrate the dust particles for dust control.

Conveyor belt covers aid significantly in controlling the action of wind as it passes over the moving belt. The ultimate in such dust control occurs when the entire belt conveyor is enclosed in a fabricated steel tube.

Dust collection, while an expensive process, is often mandated by local conditions. At the significant dust generation points, including transfer points, the area is hooded and the offending dust is vacuumed off and piped to a filter location, usually a bag filter setup where the dust is removed from the air.

With an ever-heightened public awareness of environmental pollution, the mineral storage operator can anticipate increased attention to dust problems. This will necessitate additional expenditures and require more vigilant daily operating controls. In many locations, this pollution problem has led to covered storage replacing open storage.

Chapter 25.3
MINERAL PROCESSING

W.J. SCHLITT, M.I. CALLOW, V.P. KENYEN, AND R.S. PIZARRO

25.3.0 INTRODUCTION

W.J. SCHLITT

Mineral processing is, in general, the most important downstream operation for mining engineers. This is because most mined material—from hard-rock ores to coal to industrial minerals—is subjected to some type of comminution or beneficiation operation. In most cases, several unit operations are performed sequentially in order to produce a marketable product or feed to an extraction operation such as leaching or smelting.

A tremendous number of unit operations are included under the broad heading of mineral processing. The breadth reflects the need to beneficiate everything from dense, competent hard-rock ores to solid-fuel minerals like coal or oil shale to a wide range of industrial minerals that include hard, dense materials; soft, sticky clays; and light, fluffy minerals like vermiculite.

Comminution or size reduction is typically the first unit operation to which mined material is subjected. *Crushing* describes the breakage at coarse sizes, while *grinding* covers size reduction for fine particles. The run-of-mine ore is typically subjected to primary crushing in jaw or gyratory crushers, then secondary/tertiary crushing using cone crushers, roll crushers, hammer mills, or impactors. Crushing is generally followed by grinding. In this operation, material is reduced from about 12 to 25 mm (0.5 to 1.0 in.) down to very fine particle sizes. The grinding may employ rod mills, ball mills, autogenous or semiautogenous mills, pebble mills, roller mills, fluid energy mills, or other types of grinding mills.

Concurrent with crushing and grinding are the *classification* operations that sort and separate the crushed or ground particles on the basis of size and/or weight. The classification may be done by *screening* using stationary or vibrating screens or with sieve-bend screens. *Hydrocyclones* or mechanical classifiers (spiral, rake, or drag units) may also be used.

Comminution and classification are often followed by *concentration.* This is commonly done by *flotation,* a method that collects values, or less frequently, rejects gangue constituents in a stable froth. This involves use of aeration and/or agitation in conjunction with reagents that affect the surface chemistry of the fine particles. Another approach to concentration involves *gravity systems* (heavy media separation, centrifugal specific gravity separation, jigging, tabling, and flowing film concentration). Gravity operations are less common than flotation, but are still widely used in coal preparation, beach sand processing, and placer operations. *Magnetic* and *electrostatic methods of concentration* and separation also find some application in mineral processing, for example, magnetite concentration.

Other operations of importance in mineral processing include mixing, thickening, clarifying, filtering, and drying. A wide range of mechanical equipment is used in these applications. Important ancillary operations include materials handling and feeding, particle agglomeration (pelletizing, briquetting, or sintering), and such activities as dust control, water treatment, and tailings disposal.

The following segments are not intended to be comprehensive—there are the *SME Mineral Processing Handbook* and many other authoritative publications for this purpose. However, the most universal operations are covered in order to give the miner some perspective on what happens to his ore once it leaves the mine. These key unit operations include crushing, grinding, screening, hydrocycloning, flotation, gravity concentration, and magnetic separation. Each of these topics is covered in sufficient depth to give the reader some feel for the principles and practices involved.

25.3.1 CRUSHING

M.I. CALLOW AND V.P. KENYEN

Crushing is the first stage in the comminution unit operation. Two very different crushing methods are used depending on the type of rock to be crushed. As a broad principle, hard abrasive rocks are crushed by compression between wear-resistant surfaces, and softer less-abrasive materials are crushed by impact, shear, or also by compressive mechanisms.

Hard-rock, run-of-mine material has to be reduced to the desired product size in progressive stages of compressive crushing because the reduction ratio available in each stage is limited to about 6:1. Hard-rock crushers—typically, jaw, gyratory, and cone crushers—crush by nipping the rock between stationary and moving wear-resistant surfaces. The reduction ratio in each stage is controlled by the angle between the two surfaces that is required to hold the rock as the surfaces move together in the crushing motion. If the angle is too large, the rock will not be gripped, and if too small, the available reduction ratio will not be exploited. The rock is subjected to multiple impacts as it falls by gravity through the crusher.

In processes that subsequently grind the ore to finer sizes in rod mills and/or ball mills, the crushing plant product is typically in the size range of –38 mm (–1-1/2 in.) to as fine as –9.5 mm (–3/8 in.). This is normally accomplished in three or four stages designated as the primary, secondary, tertiary, and quaternary crushing stages. An example of the performance of each stage is as follows:

Crushing Stage	Typical Crushers	Feed Size Range	Product Size Range
Primary	Jaw or Gyratory	Up to 1524 mm (60 in.)	152 to 305 mm (6 to 12 in.)
Secondary	Cone	152 to 457 mm (6 to 18 in.)	37 to 127 mm (1¼ to 5 in.)
Tertiary	Cone	19 to 152 mm (3/4 to 6 in.)	5 to 25 mm (3/16 to 1 in.)

In processes that subsequently grind the ore in autogenous or semi-autogenous mills, only primary crushing is required.

The main factors that control the selection of hard-rock crushing equipment and the design of a crushing circuit are

1. Tonnage rate.
2. Top size and size distribution of feed.
3. Desired product size.
4. Method of feeding.
5. Ore characteristics.
   a. Work index.

b. Bulk density.
c. Abrasivity.
d. Compressive strength.
e. Clay content.

A large selection of crushing methods is available for crushing softer, less abrasive ores. In addition to the compressive crushing described above, crushing by impactors and hammermills provides a far greater reduction ratio since the technique is not restrained by the angle of nip. Traditionally, impact crushers have been used on ores containing less than 5% silica. Phosphates, limestone, barite, and coals are examples. Impact crushers have also been used on higher-silica, sticky ores, such as Wyoming uranium sandstones with high clay content, but maintenance was extremely high.

The purpose of this segment is to describe the general application of crushing techniques. Departures from normal practice, of which there are many, can be examined and explored in more detail in other publications.

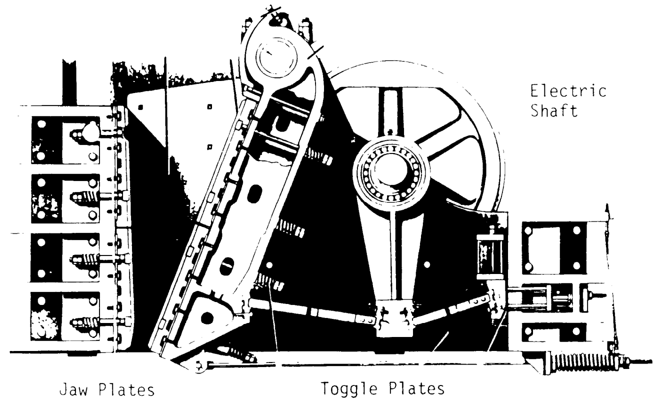

Fig. 25.3.1.1. Double-toggle jaw crusher (*courtesy:* Allis Chalmers).

25.3.1.1 Definition of Terms

Terms commonly used in defining some properties of the feed material, crusher sizing, and operating criteria are as follows.

FEED CHARACTERISTICS.

Bond Work Index—This index is most commonly used to calculate the power (measured in kilowatts or horsepower) required to crush a rock from a given feed size to a given product size. It is determined by a twin-pendulum impact crusher test on –76 mm + 51 mm (–3 in. + 2 in.) pieces of rock, square in cross section. Crusher power is calculated from the standard Bond equation (Eqs. 25.3.1.1 and 25.3.1.2) as illustrated later in this segment.

Compressive Strength—The compressive strength of a rock is determined by crushing cylindrical samples 51 mm (2 in.) in diameter by 51 mm (2 in.) in length in a universal tester. This provides a comparative measure of the resistance of a rock to compressive crushing.

Abrasion Index—This index is a measure of the abrasivity of the rock during crushing. A number of test methods are available, such as the Los Angeles Abrasion Test and the Deral Abrasion Test, but the most commonly used method is Bond's method in which a 76- by 25- by 6-mm (3- by 1- by 1/4-in.) piece of 500 Brinell SAE 4325 chrome-nickel-molybdenum steel rotates in a falling stream of ore under standard conditions and the weight loss is measured. The abrasion index A_i is then used to empirically predict wear rates of crusher liners.

CRUSHER SETTINGS. Crushers are adjusted to produce a selected product size. There are three main parameters which are interrelated.

Closed-side Setting (CSS)—This is the minimum distance between the surfaces at the closed position.

Open-side Setting (OSS)—This is the maximum distance between the surfaces at the open position.

Throw—This is the distance in the direction of compression that the moving wear surface travels between the open-side setting and the closed-side setting.

Both the open-side and closed-side settings are used in tabulations of crusher performance, and care should be taken to check the type of setting used in each case.

25.3.1.2 Primary Crushers

Gyratory crushers are used as the primary crusher for high-tonnage open pit operations with throughputs above 450 t/h (500 tph) because jaw crushers do not have enough capacity. Below 450 t/h (500 tph), jaw crushers generally are used because of their lower cost. Jaw crushers are also selected for underground crushing plants if the shaft diameter limits the size of equipment that can be handled. For surface installations with over 450 t/h (500 tph), both crushers should be considered. Some of the differences between jaw and gyratory crushers are as follows:

1. The capacity of a gyratory crusher is much greater than that of a jaw crusher handling the same size of feed.
2. Gyratory crushers can be choke fed by direct dumping from trucks. Jaw crushers cannot be choke fed; they require a scalping grizzly and a feeder.
3. Jaw crushers typically require less maintenance. Since the liners are reversible, the scrap metal loss is usually low.
4. The ratio of full load to idling power is about 2.2 for jaw crushers and 3.3 for gyratory crushers. Therefore, the gyratory that idles more also saves more while idling. In terms of reduction tons, the gyratory does double the work for the same expenditure of energy.
5. A gyratory primary crushing installation will normally cost more than a jaw crusher installation. There are, however, a number of trade-offs, and an engineering estimate is often required.

25.3.1.3 Jaw Crushers

There have been many types of *jaw crushers* designed and built since the first US patent was issued in 1830. They fall into three groups: Blake type (double toggle), Dodge type, and single toggle (overhead eccentric). The Blake-type double-toggle crusher (Fig. 25.3.1.1) and the single-toggle crusher (Fig. 25.3.1.2), however, dominate the market.

The double-toggle crusher is preferred for heavy-duty crushing on hard material. It is heavier and more expensive than a single-toggle crusher for a given duty. Justification for selecting a double-toggle crusher will therefore be needed for each application. Some of the factors in this analysis are

1. Compressive strength of the rock.
2. Work index.
3. Feed size and reduction ratio.
4. Abrasion index.
5. Life of the mine.
6. Capital cost.

The size of a jaw crusher is measured by its feed opening (gape) and length. For example, 610 by 914 mm (24 by 36 in.), or 2436, indicates a distance of 610 mm (24 in.) from fixed jaw

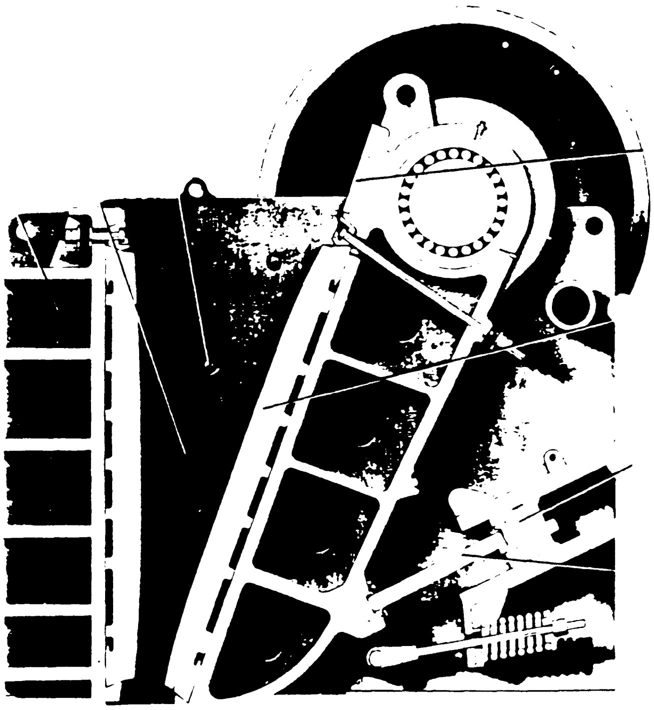

Fig. 25.3.1.2. Single-toggle jaw crusher (*courtesy:* Allis Chalmers).

plate to moving jaw plate where the feed enters, and 914 mm (36 in.) is the dimension across the jaw plates.

DESCRIPTION.

Double-toggle Jaw Crusher—The double-toggle crusher drives the moving jaw through an eccentric shaft, which moves the front and rear toggles up and down at each revolution of the shaft, closing the jaws on the downstroke and opening them on the upstroke. The toggles are held in the toggle seats by the spring-loaded tension rods. Minor setting changes to the crusher are made by changing shims between the main crusher frame and the rear toggle block. Major adjustments are made by changing the length of the front toggle.

Crusher Sizing—Jaw crushers are sized on the basis of the maximum lump size to be crushed and/or the tonnage rate to be crushed. Maximum lump size should not exceed 80% of the gape. For example, a 610- by 914-mm (24- by 36-in.), or 2436 crusher, will accept a maximum lump size of 610 by 0.8 = 488 mm (19 in.). In actual operations, the crusher will occasionally accept lumps up to the gape size, as long as bridging does not occur.

In open pit operations, the maximum lump size may be controlled by the size of the shovel dipper. Under these circumstances, a guide to crusher size can be obtained from Table 25.3.1.1.

Approximate capacities of double-toggle jaw crushers are available from crusher manufacturers and are provided in Table 25.3.1.2.

Single-toggle Crusher—This type of crusher is also called an overhead eccentric crusher. Reference to Fig. 25.3.1.2 will illustrate the reason for this name. The overhead eccentric is an integral part of the moving plate, which moves up and down with the rotation of the eccentric. The single toggle is pivoted at the base of the moving plate and causes the jaw to move in an arc. This results in a pinching action between the moving and stationary plates. The toggle is held in the toggle seats by the compression spring. Major adjustments to the crusher setting

Table 25.3.1.1. Smallest Jaw Crusher for Various Shovel Dippers

Capacity of Dipper		Jaw Crusher Size Recommended	
yd^3	(m^3)	in.	(mm)
$\frac{3}{4}$	(0.57)	30 × 36	(762 × 914)
1	(0.76)	30 × 36	(762 × 914)
$1\frac{1}{2}$	(1.15)	36 × 42	(914 × 1067)
$1\frac{3}{4}$	(1.34)	42 × 48	(1067 × 1219)
2	(1.53)	42 × 48	(1067 × 1219)
$2\frac{1}{2}$	(1.91)	48 × 60	(1219 × 1524)
3	(2.29)	48 × 60	(1219 × 1524)
$3\frac{1}{2}$	(2.68)	48 × 60	(1219 × 1524)
4	(3.06)	56 × 72	(1422 × 1829)
5 to 10	(3.8 to 7.6)	66 × 86	(1676 × 2184)

Source: Fuller Co.

are made by changing the toggle length. Minor adjustments are made by changing shims between the toggle block and the mainframe. The toggle is designed to shear or break in the event tramp material enters the crusher.

The single-toggle crusher is of much lighter construction than the double-toggle Blake-type crushers. For example, a 610 by 914-mm (24 by 36-in.) single-toggle crusher weighs about 14,512 kg (32,000 lb), whereas a double-toggle crusher of the same size weighs 25,678 kg (65,000 lb).

CRUSHER SIZING. Similar to the double-toggle crusher, the single-toggle crushers are selected either on the basis of maximum lump size to be crushed, or the tonnage rate to be crushed, or both.

2.5.3.1.4 Gyratory Crushers

A *gyratory crusher* is a gravity-type machine. Materials flow from top to bottom. It receives a large, coarse feed, usually run-of-mine, and its product usually requires additional crushing. Gyratory crushers can be used for primary or secondary crushing. This segment describes gyratory crushers for primary crushing. Secondary gyratory crushers are described under secondary crushing.

DESCRIPTION. A primary gyratory crusher is illustrated in Fig. 25.3.1.3. The crushing action is caused by the closing of the gap between the mantle line (movable) mounted on the central vertical spindle and the concave liners (fixed) mounted on the main frame of the crusher. The gap is opened and closed by an eccentric on the bottom of the spindle that causes the central vertical spindle to gyrate. The vertical spindle is free to rotate around its own axis. The crusher illustrated is a short-shaft suspended spindle type, meaning that the main shaft is suspended at the top and that the eccentric is mounted above the gear. The short-shaft design has superceded the long-shaft design in which the eccentric is mounted below the gear.

Gyratory crushers have been built in three types: suspended spindle, supported spindle, and fixed spindle. The supported-spindle and the suspended-spindle types are most common.

There are two suspended-spindle gyratory crusher designs: the short shaft and the long shaft. The short-shaft design is the modern design in which the eccentric is located above the level gear. The main frame has two sections; the upper shell supports the concaves while the lower shell contains the eccentric and the pinion shaft. The bevel gear and pinion provide rotation of the eccentric. The crusher is either belt-driven or has direct drive.

4	(3.06)	48 or 60	(1219 or 1524)
5 to 10	(3.8 to 7.6)	60 or 72	(1524 or 1829)

Source: Fuller Co.

Crusher Speed—The speeds listed in the tables are pinion shaft rpms.

Crusher Settings—Both closed-side settings (CSS) and open-side settings (OSS) are used for gyratory crushers. In contrast to the jaw crusher setting where closed-side settings are used, open-side settings are used in sizing gyratory crushers.

GYRATORY CRUSHER SIZING. The crusher is selected on the basis of feed size or tonnage rate or both. A rule of thumb is that 80% of the feed to the crusher should have a maximum one-way dimension of less than two-thirds of the nominal feed opening. This has limited value since in most cases, the average size distribution of the feed to the crusher is, at best, an educated guess. A more useful approach is to relate crusher size to the size of the shovel dipper in the pit. This is shown in Table 25.3.1.3.

Capacities of short-shaft, primary gyratory crushers, as provided in manufacturers' catalogs, are shown in Table 25.3.1.4, and the percentage of product passing a square opening is shown in Table 25.3.1.5.

Table 25.3.1.5. Percentage of Product Passing a Square Opening Equal to Open-side Setting of Gyratory Crusher

Feed material	Run of mine	Scalped	Scalped and recombined with fines
Limestone	90	85	88
Granite	82	75	80
Trap rock	75	70	75
Ores	90	85	85

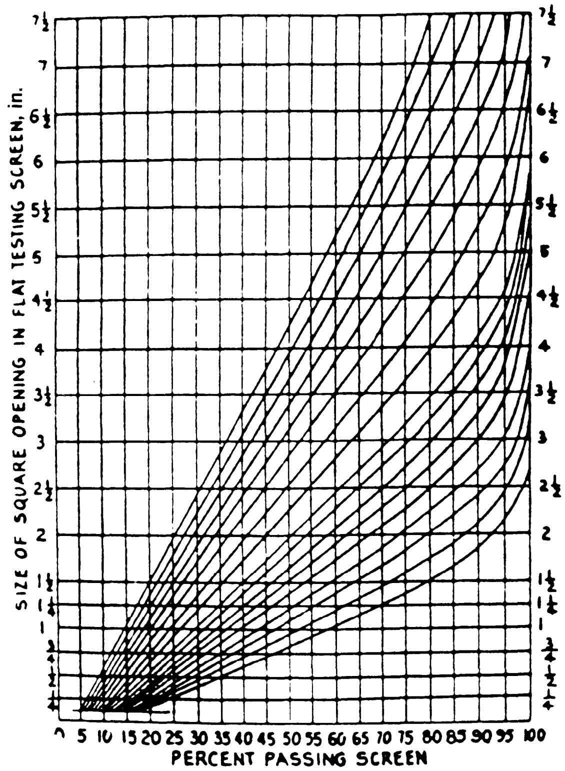

Fig. 25.3.1.4. Typical crusher size-distribution for under 7½ in. (190 mm) opening. Conversion factor: 1 in. = 25.4 mm.

Discharge Product Size. Figs. 25.3.1.4 and 25.3.1.5 illustrate typical discharge product size distributions for gyratory crushers. These size distributions should only be considered as good approximations based on actual screen analyses. In practice, the distribution will vary depending on many factors, one of which is the rock type. To determine the expected product from a crusher set at a predetermined discharge opening, obtain from Table 25.3.1.2 the approximate percentage of feed that will pass an opening equivalent to the crusher setting. The intersection of two axes will provide the product curve for the specific application.

25.3.1.5 Power Calculation

The crusher motor size is determined using Bond's crusher work index. The relation used for calculating the approximate unit power consumption is

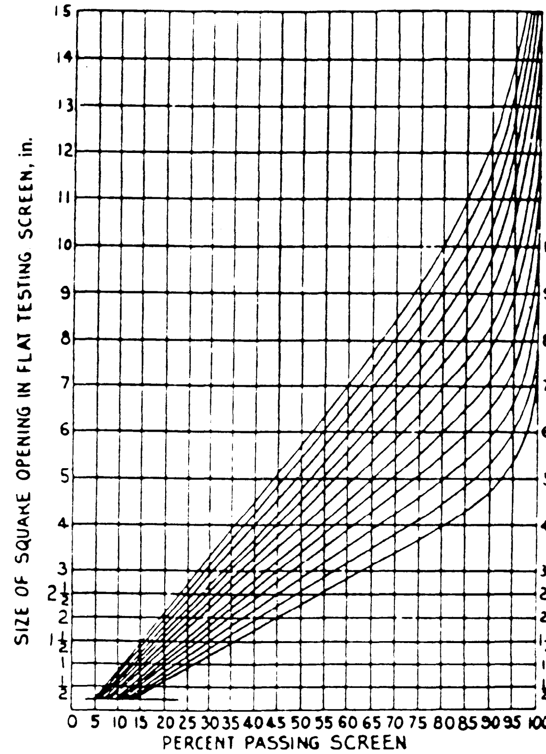

Fig. 25.3.1.5. Typical crusher-product size-distribution curves for open-side discharge over 7½ in. (190 mm). Conversion factor: 1 in. = 25.4 mm.

$$W = W_i \times 11.0 \times (\sqrt{F_{80}} - \sqrt{P_{80}}) / (\sqrt{F_{80}} \times \sqrt{P_{80}}) \qquad (25.3.1.1)$$

where W is specific power required in kWh/t, P_{80} is 80% passing size of the product in μm, and F_{80} is 80% passing size of the feed in μm or 2/3 of the crusher feed opening.

To find total power in kW, the calculated specific power is multiplied by a factor of 0.75 for primary crushing and 1.00 for secondary crushing:

$$\text{Total kW} = (\text{crusher capacity}) \times (W) \times (\text{factor}) \qquad (25.3.1.2)$$

This method of power calculation can be used for calculating the approximate power of primary jaw and gyratory crushers, secondary gyratory crushers, and cone crushers. For empirical values of work index for different materials, see Table 25.3.2.4.

An example of the use of the formula follows.

Example 25.3.1.1. Assume a copper ore with Bond crusher work index of 14.2. The design feed rate is 1800 t/h (2000 tph). An Allis Chalmers 5474 crusher is selected with an open-side setting of 165 mm (6-1/2 in.).

Solution. Feed size F_{80} = 914,400 (36 in.) (66% of crusher feed openings).

$$\text{Product Size } P80 = 139{,}700 \text{ mm (5.5 in.)}$$

$$W = 14.2 \times 11.0 \times (\sqrt{914{,}400} - \sqrt{139{,}700}) / (\sqrt{914{,}400} \times \sqrt{139{,}700})$$

$$W = 0.255 \text{ kWh/t (0.310 hp/ton)}$$

$$\text{Total power} = 0.255 \times 1800 \times 0.75 = 345 \text{ kW (465 hp)}$$

25.3.1.6 Cone Crushers

Cone crushers are exclusively used for secondary and tertiary crushing. The cone crusher operates in much the same way as the gyratory crusher except it operates at a higher speed. It has a flatter crushing chamber designed to give higher capacity and reduction ratio. The aim is to increase retention time of material in the crushing chamber or to reduce the velocity of material through the crushing chamber to allow multiple impacts to occur (higher reduction ratio).

The two most common types of cone crushers used in metal mining in North America are the Symons cone crushers manufactured by Nordberg and the Hydrocone crushers manufactured by Boliden-Allis (formerly Allis Chalmers). There are several other types manufactured throughout the world; the information contained here, however, is based on data from Nordberg and Allis Chalmers.

DEFINITION OF TERMS.

Crusher Sizing—Nordberg designates the crusher sizes by the mantle diameter measured in feet. At present, crushers ranging in size from 0.6 to 3 m (2 to 10 ft) are manufactured. Nordberg's descriptions of Symons cone crushers in general are vague but understood by the industry through common usage. Allis Chalmers' designations are a little more specific. These define both the feed opening and mantle diameter in inches. For example, Model 10-84 means a crusher with 254-mm (10-in.) feed opening and 2134-mm (84-in.) mantle diameter.

DESCRIPTIONS.

Symons Cone Crushers—Nordberg has two major types of cone crushers, a standard cone crusher that is used for secondary crushing applications and a short-head cone crusher that is used for tertiary crushing applications. Both types are made in sizes ranging from 0.6 to 3 m (2 to 10 ft). Over 1000 2-m (7-ft) crushers are in operation, but the 3-m (10-ft) crusher has found only limited application and is now being superseded by a high-capacity smaller unit (MP 1000).

The major difference between standard and short-head cone crushers is the shape of the crushing cavities. Standard cone crushers are designed to make a product ranging from 12.5 mm (1/2 in.) to more than 63.5 mm (2-1/2 in.) in both open and closed circuits. They may be furnished with fine, medium, coarse, or extra coarse cavities to meet variations in feed and end product size.

Short-head crushers as shown in Fig. 25.3.1.6 have a steeper head angle and a more parallel crushing cavity than standard machines. They are designed to produce a crushed product ranging from 3.2 mm (1/8 in.) to 19.0 mm (3/4 in.) in closed circuit with the appropriate screens. They may also be furnished with fine, medium, coarse, or extra coarse crushing cavities to meet variations in feed size and desired product size.

Nordberg also produces three other series of cone crushers: Omnicone, Gyrodisc, and Waterflush™ Wet Cone (Fig. 25.3.1.7) crushers. Omnicone requires less headroom and is available in sizes 940 to 1524 mm (37 to 60 in.) (note the change in measuring mantle diameter in inches instead of feet). Omnicone crushers should be considered as an alternative for mobile plants and low-tonnage plants.

Gyrodisc is a fine-product crushing machine and is capable of crushing hard, clean material down to –4.76 mm (4 mesh). It could, therefore, be a potential replacement for rod mills in a conventional crushing and grinding flowsheet. In the Gyrodisc crusher, crushing is achieved by a combination of impact and attrition. It will not handle wet sticky material nor will it handle material with excessive fines. Gyrodisc crushers are available from 914 to 2134 mm (36 to 84 in.).

Wet Cone crushers (WF Series) use Waterflush™ technology in which water is added to the crusher to flush fines through the crushing cavity. It is claimed that flushing produces a significant amount of flaky, shaped particles that break easily during ball milling. This results in elimination of the rod mill and a major reduction in overall comminution power requirements.

All Nordberg cone crushers are driven through a pinion mounted on a countershaft. The pinion drives the gear, which rotates the eccentric. The eccentric causes the main shaft head and mantle liner to gyrate, opening and closing the gap with the stationary bowl liner. The main shaft and head are supported on a spherical bronze socket liner. All assemblies except for the countershaft are removed from the top of the machine.

The crusher setting is adjusted by rotating the bowl, which has external threads that are screwed into a matching set of internal threads on the adjustment ring mounted on the main frame. On current models, the bowl is rotated by hydraulic rams mounted on the main frame. Tramp iron entering the crusher causes a spring release system to enlarge the crushing gap, allowing the tramp iron to pass. If the crusher becomes jammed, clearing jacks powered by a portable hydraulic raise the pack adjustment ring and bowl permitting noncrushable material to pass. The Omnicone has no springs, and protection is provided by a nitrogen/hydraulic accumulator system.

Approximate capacities for the standard and short-head crusher models are given in Tables 25.3.1.6 and 25.3.1.7. The capacities shown are neither maximum nor minimum and are based on results secured in actual practice. The figures are in short tons and apply to materials weighing 1602 kg/m^3 (100 lb/ft^3) and are based on a properly graded feed.

Screen analyses of crusher product at different crusher settings are listed in Table 25.3.1.8. It will be noted that for average ore, the tables are based on 70% of the product being finer than the constant closed-side setting. For hard ore, the tables are based on 60% passing the closed-side setting.

ALLIS CHALMERS HYDROCONE CRUSHERS: Allis Chalmers does not distinguish between a standard and short-head design but uses the same basic crusher for both secondary and tertiary crushing. The appropriate crusher is selected for each service by changing the crushing chamber design. Up to six different chamber designs are available for the 2134 mm (84 in.) (mantle diameter) model, which is the largest crusher in the series; fewer alternatives are available in the smaller sizes.

Allis Chalmers offers six sizes of crushers. Approximate open circuit capacities are shown in Table 25.3.1.9. Qualifications listed in the table should be noted.

25.3.1.7 Other Primary, Secondary, and Tertiary Compression Crushers

There are other *compression crushers* that should be considered for particular applications.

Mineral Sizers, manufactured by the MMD Group of Companies, Derbys, UK, can handle material up to 1.0 m^3 (35 ft^3) with a maximum throughput of up to 3180 t/h (3500 tph). The crusher has twin shafts which can be fitted with a range of teeth or picks. It is suitable for use on materials with compressive strengths in excess of 276,000 kPa (40,000 psi). The crusher is not suitable for low-abrasion ores.

The Stamler feeder/breaker, manufactured by the W.R. Stamler Corp., Millersburg, KY, is also a rotary pick breaker. The unit consists of a dump hopper, feeder, and single rotary pick breaker illustrated in Fig. 25.3.1.8. It can handle material up to a compressive strength of 207,000 kPa (30,000 psi) on a continuous basis. Maximum feed size is 1.2 by 1.8 by 1.8 m (4 by 6 by 6 ft) to produce a 203-mm (8-in.) product at up to

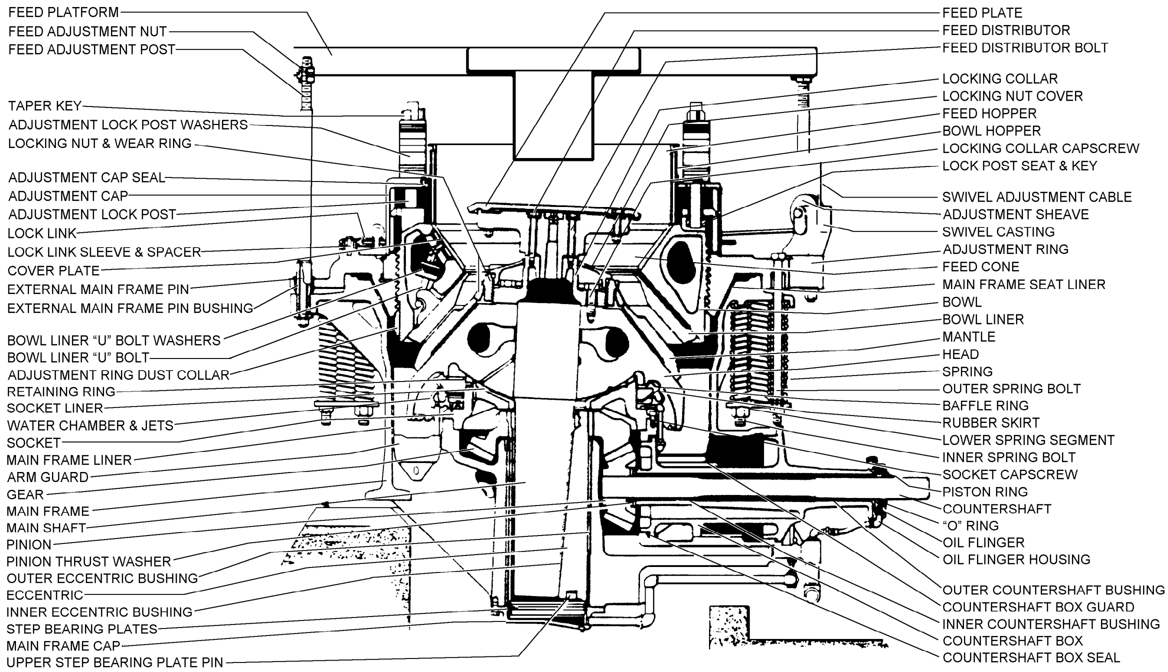

Fig. 25.3.1.6. Symons short-head, extra-heavy-duty cone crusher (*courtesy:* Rexnord, Inc.).

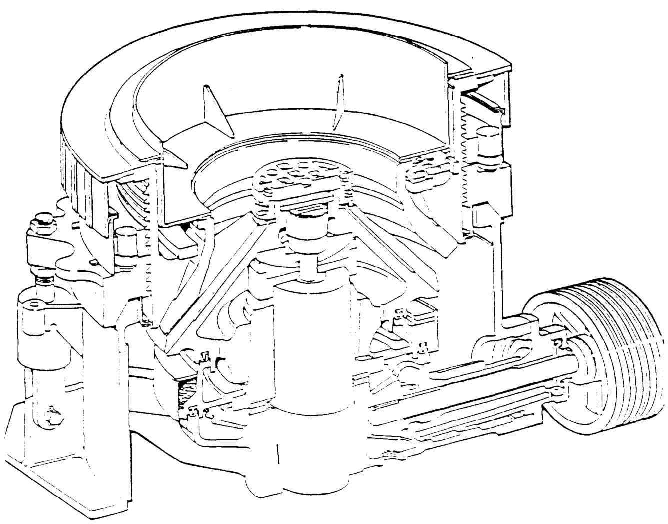

Fig. 25.3.1.7. Water flush cone crusher (*courtesy:* Nordberg, Inc.).

1800 t/h (2000 tph). The crusher is most suitable for low-abrasion ores.

Roll crushers, after a long and illustrious career, have virtually disappeared as tertiary crushers in the metal mining industry. They are still used to crush coal, and recently interest is being shown in a high-pressure roll crusher for very fine crushing. This roll crusher is described in the grinding section.

IMPACTORS AND HAMMERMILLS. There are numerous types of impactors and hammermills. The more common types are as follows:

A. Impactors.
  1. Common single rotor.
  2. Common double rotor.
  3. Single rotor reversible.
  4. Double rotor impactor with center feed.
B. Hammermills.
  1. Non-reversible hammermills.
  2. Non-reversible non-clog hammermills.
  3. Single rotor reversible hammermills.
  4. Ring-type hammermills.

Capacity—The capacity of a machine of given width is affected by the diameter of the hammer circle, the mass of moving parts, the tip speed, and the manner of feeding. Feed must penetrate the hammer circle if the full crushing surface is to be utilized. This calls for a balance between falling velocities and rotor velocities that differs considerably among various machines on the market.

Tables 25.3.1.10 and 25.3.1.11 list the approximate capacities for Universal impactors and hammermills manufactured by the Pettibone Corp.

25.3.1.8 Impact Crushing

Impact crushers crush by striking pieces of rock while in free fall and hurling them at high speed against stationary surfaces. Because the impact crusher depends for its effectiveness upon high velocity, wear is greater than in the slower-moving jaw and cone-type crushers. For this reason, its use is normally limited to relatively soft, friable, and sticky rocks that are characteristic of many nonmetallic mineral deposits.

Modern usage differentiates between the impactor and the hammermill. The impactor relies primarily on the impact of hammers (fixed or free-swinging) and secondarily upon pieces striking one another or steel surfaces; the hammermill relies on both the centrifugal impact force of free-swinging hammers and the attrition and shear action between these hammers and well-placed grates suspended at the bottom just below the hammer circle.

A recent innovation in impact crushing is the Barmac autogenous crushing mill, which is being applied with success to

hard abrasive material only previously crushed by compressive crushers.

The basic principle of impact breaking is the total use of rotor energy in the reduction of the material. Kinetic energy is imparted to a particle of the material, and this energy is used chiefly to break down the bonding of the particle structure. The particle breaks along its planes of weakness and, as a result, produces a natural grain-shaped product.

Product gradation is a function of rotor speed and friability of the material. An increase in rotor speed or friability of material leads to an increase in the proportion of fines produced. Conversely, a decrease in rotor speed or friability of material will decrease the proportion of fines in the product. This is illustrated in Table 25.3.1.12.

The desired product gradation is an important factor in choosing between an impactor and a hammermill. This is illustrated by the size-distribution curve. Fig. 25.3.1.9 indicates the differences in products obtained from crushing an average limestone in both an impactor and a hammermill operating with approximately the same hammer tip speed. The hammermill yields an overall finer product gradation.

25.3.1.9 Crushing Circuit Design

A typical three-stage crushing circuit in metal mining application is shown in Fig. 25.3.1.10. This illustrates the step-by-step reduction of a run-of-mine ore in the primary, secondary, and tertiary crushing stages to a feed size suitable for the subsequent grinding stage. There are many variations in circuit design, but the basic design and equipment selection techniques are common to all circuits.

The operating schedule for each stage of crushing determines the tonnage rate for that stage. Typically, the primary crusher operates at the same schedule as ore deliveries from the mine. The surge pile after the primary crusher will allow the secondary and tertiary crushers to operate on a different schedule. In the example shown, all stages of crushing operate on the same schedule.

As stated earlier, the gyratory crusher is sized on the basis of feed size and/or tonnage rate.

The tonnage and size distribution of the gyratory crusher product will determine the double-deck screen size and the tons of feed fed to the secondary cone crusher. The secondary crusher

* Capacities shown are based on open-circuit operation and on properly sized, clean, dry, scalped, friable feed weighing 100 lb/ft.^{3}

† Actual horsepower required depends on stone hardness, ratio of reduction, etc. Consult Allis-Chalmers before purchasing motors.

‡ Hydroclone crushers with 2-arm spider top shells are normally used as secondary crushers and operated in open circuit. Those with 3-arm spider top shells are normally used as third- or fourth-stage crushers, sometimes operated in open circuit, but more often in closed circuit.

§ Capacities are based on closed-circuit operation and on properly sized, clean, dry, scalped, fiable feed weighing 100 lb/ft^3. Maximum Hydroclone control pressure, 500 psi. After Allis-Chalmers.

Conversion factor: 1 ton = 0.9072 t.

Note: The results shown above indicate an average analysis of stone crushed by a single-rotor, two-hammer crusher working in dry, free-crushing medium hard limestone. No guarantee of product sizing can be inferred, since stone varies from area to area along with other local conditions. These are typical gradations for the speeds shown. Coarser or finer gradings can be achieved by making speed changes.

is sized from the standard cone capacity tables based on feed rate to the crusher and the type of cavity required to yield the desired product gradation.

Tertiary crushers are sized from the short-head cone capacity tables based on the tonnage rate, screen size and crusher setting. The relationship between the crusher setting and screen size determines the circulating load that can be calculated from the production gradation curves and screen efficiency.

25.3.2 GRINDING

M.I. CALLOW AND V.P. KENYEN

Grinding is the further reduction of crushed products to a size suitable for a subsequent concentration process. This is normally achieved by tumbling the crushed ore together with a grinding media, in a rotating cylinder or a stirred vertical cylinder. The grinding media may be steel balls, rods, or rock pebbles. Most of the energy is consumed in keeping the mill or stirrer and media in motion, and only a very small part is used to perform the useful work of breaking the ore that surrounds the media.

Grinding is statistical in nature. The feed ore has a particle size distribution that depends on the ore characteristics and the crushing process. When ground, there is a certain probability that any given piece will be broken. The objective of grinding circuit design is therefore to select conditions that increase the probability of breaking particular size particles. This must be accomplished at the optimum combination of capital and operating costs to minimize the total cost over the life of the mine. Grinding is a low-efficiency, power-intensive process and typi-

tally can account for up to 40% of the total plant direct operating cost.

This segment basically describes wet grinding of mineral-bearing ores by autogenous and semi-autogenous mills, rod mills, ball mills, and tower mills.

25.3.2.1 Mill Types

Mills are identified by the type of grinding media. Each type of mill is adapted to certain grinding applications that must be evaluated to select the optimum mill for each grinding task. Common mill types and their characteristics are discussed in the following.

ROD MILLS. Rod mills are horizontal, cylindrical, rotating shells loaded with rods that grind the ore by tumbling within the shell. Fig. 25.3.2.1 shows a cutaway view of an overflow rod mill. To prevent the conditions leading to rod-charge tangling, the length-to-diameter ratio is maintained at 1.4 to 1.6. Where this ratio becomes less than 1.25, the risk of tangling increases rapidly. The practical limit of a good quality rod (i.e., a rod that will not tangle) is 6.1 m (20 ft). Because of this limitation, the largest rod mill size is 4.6 m diameter by 6.6 m long (15 by 21.5 ft), using 6.1-m (20-ft) rods and drawing from 1640 to 1715 kW (2200 to 2300 hp).

Rod mills accept feed up to about 50 mm (2 in.) and produce a product in the size range of – 3000 to – 270 μm (–4 to –35 mesh). Grinding action is by line contact between the rods extending the length of the mill. Rods tumble and spin in roughly parallel alignment simulating a series of roll crushers. This results in preferential grinding of coarse material and minimizes production of slimes.

Of the three main types of rod mill—overflow, end peripheral discharge, and center peripheral discharge—only the overflow mill is in common usage. Wet grinding rod mills are normally used in the mineral processing industry. Dry grinding is used in some areas; however, it is confronted with problems and should be avoided except where absolutely necessary. The advantages and disadvantages of rod milling are as follows:

Advantages.

1. Rod mills operate at lower speed than ball mills since the rods are rolled and not cascaded.

2. For an equivalent grind, a rod mill uses less steel than a ball mill because of the lower speed and better contact between the media and ore.

Disadvantages.

1. The rod charge must be maintained in good working condition, and broken and worn rods must be removed. Rod mills usually require greater operator attention. It is important that the rods stay essentially parallel to one another. If rods become misaligned, grinding action is lost and, more importantly, rod tangles occur.

2. Maximum rod length is limited to about 6.1 m (20 ft). This in turn limits the length, diameter, and hence capacity of rod mills.

3. The heavier rods acting upon the lifters and liners result in greater maintenance requirements on the liner systems.

Conversion factors: 1 ft = 0.3048 m, 1 ton = 0.9072 t, 1 hp = 0.7457 kW.

Rod mills normally carry 35 to 65% rod charge by volume. The limits on charge level are (1) keeping the feed end trunnion open so that feed will get into the mill, and (2) keeping the rod charge low so rods will not work their way into discharge openings where they can cause rod tangling.

The following expression is used to determine the power draw by a rod mill (English units):

$$kW_r = 1.07\ D^{1/3}\ (6.3 - 5.4\ V_p)\ fC_s \qquad (25.3.2.1)$$

where kW_r is kilowatts per short ton (2000 lb) of rods, D is mill diameter inside liners in ft, V_P is fraction of mill volume loaded with rods, and fC_s is fraction of critical speed.

Table 25.3.2.1 lists many sizes of rod mills, giving speed, loading, and power data.

BALL MILLS. Ball mills are used following rod mills for grinding the ores to a finer size. They are also used as primary mills following fine crushing of ores. Ball mills accept feed in the size range 6.4 to – 25 mm (¼ to – 1 in.). The product size range can vary between – 270 to – 37 µm (– 35 to – 400 mesh). The ore is normally ground with cast or forged steel balls. Grinding action is by point-to-point contact between balls and shell liners and between the balls themselves. Ball mills vary in length-to-diameter ratio (L/D) ranging from less than 1:1 to greater than 2:1. There are no fixed rules on proper L/D ratios because these vary with the circuits used, ore type, feed size, and overall grinding requirement. Typically, a short ball mill has a lower retention time; consequently, it produces a coarser product. A long ball mill, sometimes called a *tube mill,* has a higher retention time and produces a finer product with less tramp oversize.

There are two common types of ball mills: grate discharge and overflow discharge.

Grate Discharge Ball Mills—Grate discharge mills are normally used when minimum fine production is needed. As ball mill sizes have increased over the years, overflow mills have become predominant, and grate discharge mills are rarely selected today.

Overflow Ball Mills—The overflow ball mill is illustrated in Fig. 25.3.2.2. As the name implies, in an overflow mill, the slurry discharges from the mill by overflowing the discharge trunnion. Over the years, the size of ball mills has increased steadily as the size of concentrators has increased significantly. The largest mills manufactured to date are by Rauma-Repola of Finland for a

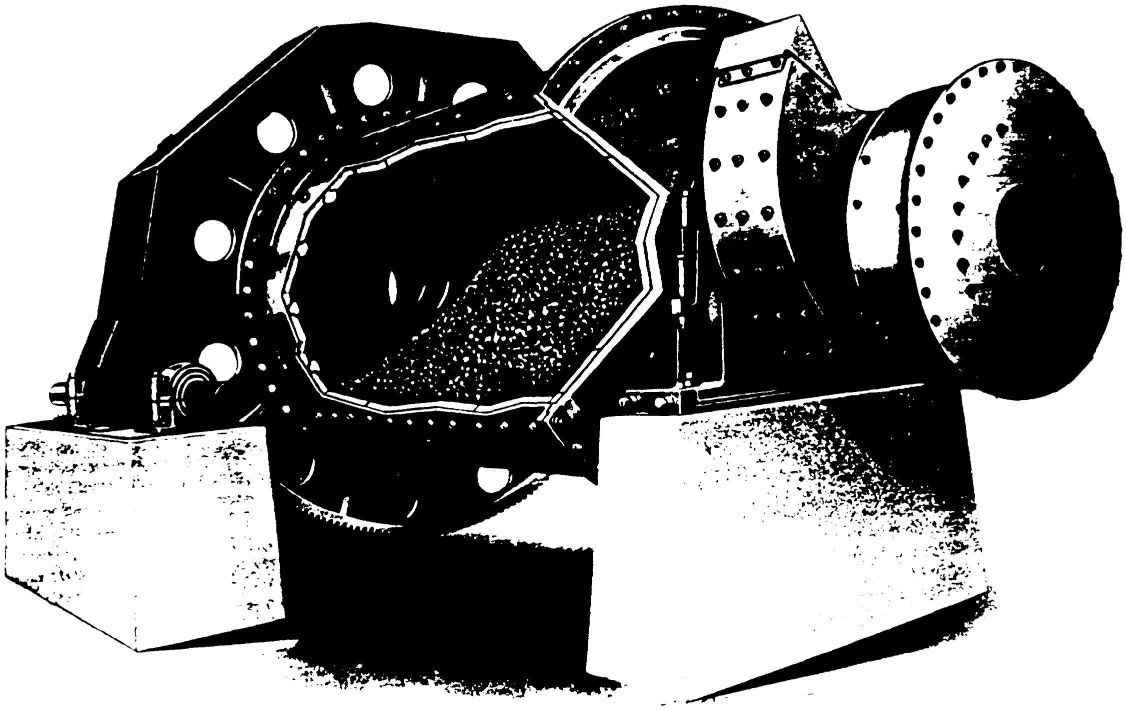

Fig. 25.3.2.2. Cutaway view of overflow ball mill (*courtesy:* Allis Chalmers).

Russian client. The mills are 6.4 m (21 ft) in diameter by 9.6 m (31.5 ft) in length, and each mill is driven by a 9620-kW (12,900-hp) wrap-around motor in which the drum carries the rotor windings that rotate within the stator mounted around the outside of the mill. Ball mills up to 5.5 m (18 ft) in diameter by 7.3 m (24 ft) in length with 4470-kW (6000-hp) motors and conventional drives are currently operating.

PEBBLE MILLS. Pebble mills are similar to ball mills but use nonmetallic grinding media such as porcelain balls, flint pebbles, and most often the ore itself as the grinding media. The bulk density of a pebble charge is less than the bulk density of the steel charge of a ball mill; consequently, for a comparable power draw, the size of a pebble mill is larger than a ball mill. Pebble mills are often used as dry mills and where iron contamination is detrimental to product quality.

Wet closed-circuit pebble mills are gaining acceptance as secondary autogenous mills. Even though they are not popular in North America, they have been widely adopted in South Africa.

In the metal mining industry, pebble mills follow primary autogenous or semi-autogenous primary grinding. Sized pebbles (ore) are either screened out of the ore stream in a crushing plant or extracted from the primary autogenous mill and fed to the pebble mill in a controlled manner to maintain constant power draw. For more detail on pebble mill applications, readers are referred to Crocker (1985).

AUTOGENOUS MILLS. Autogenous mills use large pieces of either run-of-mine or primary crushed ore as grinding media. This is different from the pebble mill which uses sized or graded rocks as grinding media. The predominant grinding mechanism in autogenous grinding is attrition with limited grinding by impact. For an ore to successfully grind autogenously, the ore must be competent, and it must break along grain boundaries at the desired product size. Another requirement is that the finer sizes should break easily and should be removed from the mill; otherwise, there will be a critical size buildup.

Critical size is the size that is too small to serve as effective grinding media and is yet too large to be broken down by large pieces. This size ordinarily ranges from 51 to 19 mm (2 to 3/4 in.) in diameter. If ore is hard to break, it will accumulate in the mill charge and decrease mill throughput.

Autogenous grinding has two advantages: it reduces metal wear and eliminates secondary and tertiary crushing stages. Thus it offers a savings in capital and operating costs.

Autogenous mills are available for both wet and dry grinding. The development of the dry-grinding AeroFall mill in the 1950s triggered the later North American development of wet grinding mills that now dominate the metal mining industry. Wet autogenous mills had considerable success in grinding hard, competent, and heavy iron ores in the 1960s, but as the application of autogenous grinding has widened, semi-autogenous grinding has evolved as the dominant technique, particularly on copper ores. The diameter of North American autogenous mills is normally two to three times the length, while South African and some European mills have approximately 1:1 diameter-to-length ratio. The ore charge is usually 25 to 35% of the mill volume.

Autogenous mills have grate discharges to retain the coarse grinding media in the mill.

An autogenous mill is shown in Fig. 25.3.2.3.

SEMI-AUTOGENOUS MILLS. Sometimes the ore may not have competent rocks to act as grinding media, or the ore body occasionally may have poor quality rocks that are not suitable grinding media. In such situations, *semi-autogenous mills* may be used.

In semi-autogenous grinding, the competent rocks are supplemented with steel balls in an amount of 2 to 10% of the total mill volume. The mill geometry of the semi-autogenous mill is the same as the autogenous mill with modifications in the structural design to account for the increased weight of media, pull, and impact. Ball sizes are typically from 76 to 127 mm (3 to 5 in.) in diameter.

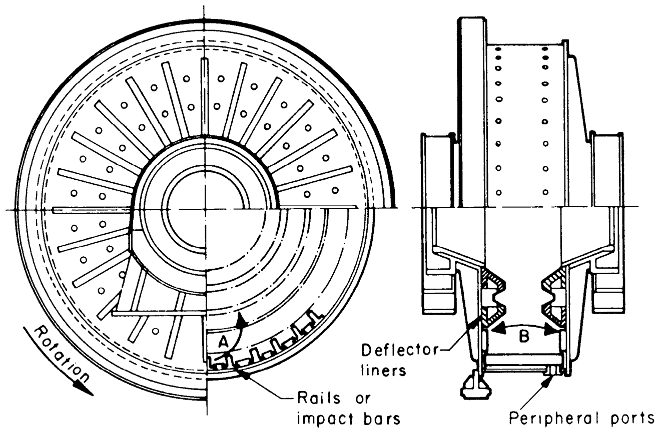

Fig. 25.3.2.3. Cross section of AeroFall mill (*courtesy:* AeroFall Mills, Ltd.).

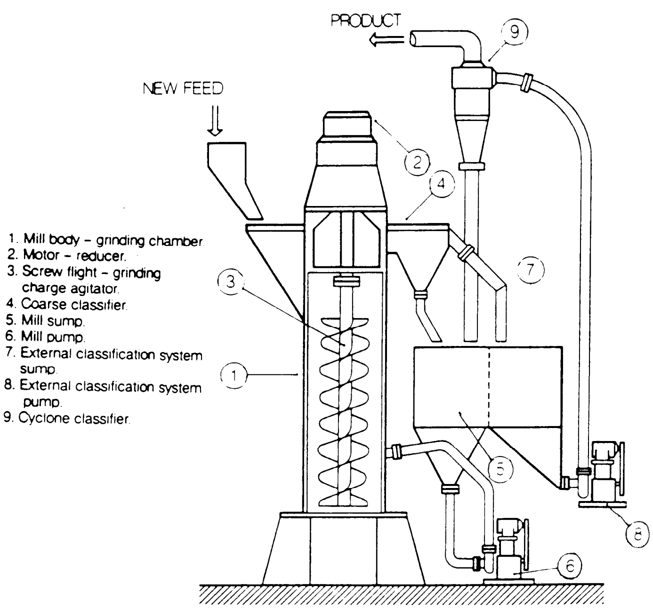

Fig. 25.3.2.4. Typical tower mill wet grinding system.

TOWER MILLS. The tower mill, invented in Japan, was originally used for fine regrinding. As the tower mill has become more accepted in North America, the range of application has expanded, and now tower mills are used in place of ball mills in low-tonnage secondary grinding circuits.

The tower mill illustrated in Fig. 25.3.2.4 consists of a vertical grinding vessel with a central shaft screw-shaped impeller. The screw impeller rotates and moves the grinding media up through the central portion of the grinding compartment and down through the outer portion. Grinding media such as steel balls, ceramic pebbles, or natural pebbles are charged into the grinding chamber and cover the screw flight agitator. Material to be ground is fed into the top, center, or bottom of the main body depending on the application and size of the feed. Grinding occurs by a combination of impingement and rubbing among the grinding balls and grinding balls against the screw and mill liners.

Tower mills are used both as dry- and wet-type mills. Dry grinding systems use air classifiers and fans, and wet grinding systems use a cyclone classifier to remove the product.

Advantages claimed by the tower mill manufacturers are a smaller area of installation, less noise (usually below 85 dB), simplicity of foundation, lower installation cost, and lower operating cost. Concurrent grinding and leaching can also be accommodated.

OTHER GRINDING MACHINES. Other, less-used grinding mills include roller mill, fluid energy mill, cage mill, vibratory ball mill, and vibra energy mill. For details of these equipment, readers are referred to the *SME Mineral Processing Handbook* (Weiss, 1985).

25.3.2.2 Mill Sizing and Selection

Rod mills and ball mills are sized based on the Bond work index obtained from standard Bond ball mill or rod mill grindability tests that are described elsewhere (e.g., see 25.3.1.5). It is much more difficult to size autogenous mills since there are no small-scale tests, such as the Bond work index tests, that adequately define the autogenous grinding characteristics of an ore. Autogenous grinding is also much more sensitive to change in ore type than conventional mills such as rod and ball mills.

It is therefore imperative that as a first step, a competency test is made on different types of ore from the same ore body. If the rocks are competent, it should be followed with a pilot plant test. A 1.5- or 1.8-m (5- or 6-ft) diameter mill is normally required to provide sufficient data to confidently size an autogenous or semi-autogenous mill.

BASIC POWER CALCULATION FOR ROD AND BALL MILLS. Once the work index (W_i) has been determined, the power requirement and mill size can be calculated from Bond's Third Theory equation as follows, rearranged from Eq. 25.3.1.1:

$$W = (10\ W_i/\sqrt{P_{80}}) - (10\ W_i/\sqrt{F_{80}}) \qquad (25.3.2.2)$$

where W is power consumption in kWh/ton of feed, P_{80} is size in μm that 80% of the product passes, and F_{80} is size in μm that 80% of the feed passes.

This calculation gives the power required at the following standard reference points:

1. Rod milling: wet open-circuit grinding in a 2.4-m (8-ft) diameter (inside liners) rod mill.

2. Ball milling: wet closed-circuit grinding in a 2.4-m (8-ft) diameter (inside liners) ball mill.

3. The calculated power is the power required at the pinion shaft of the mill and includes mill trunnion bearing and gear and pinion losses, but does not include motor losses or losses in any other drive component such as reducers and clutches.

CORRECTION FACTORS. In studying plant mill performance, a number of factors have been found that cause the work indices calculated from plant operating data to vary from the work indices obtained from Bond grindability tests. These factors, basically efficiency and inefficiency factors resulting from equipment size, grinding media, and circuit used, are the following:

CF_1 Dry grinding.
CF_2 Open-circuit ball milling.
CF_3 Mill diameter.
CF_4 Oversized feed.
CF_5 Grinds finer than 80% passing 74 μm (200 mesh).
CF_6 Too small or too large reduction ratio, rod mill.
CF_7 Too small a reduction ratio, ball mill.

The basic power W calculated in Eq. 25.3.2.2 should therefore be adjusted in accordance with the correction factors (CF_1 to CF_7) as follows:

CORRECTION FACTOR l—CF_1 (dry grinding) = 1.3.

Table 25.3.2.2. Open-circuit Ball Milling Correction Factor

Reference % Passing	Correction Factor 2 (CF_2)
50	1.035
60	1.05
70	1.10
80	1.20
90	1.40
92	1.46
95	1.57
98	1.70

Table 25.3.2.3. Material Size Conversion For 80% Passing Feed or Product Size

	80% Passing Equivalent	
Material size	μm (F) or (P)	$\sqrt{F}$ or $\sqrt{P}$
99%—1½ in.	25,000	158.0
99%—1 in.	18,000	134.0
99%—¾ in.	12,000	109.5
99%—½ in.	8,500	92.2
99%—⅜ in.	6,000	77.4
99%—3 mesh	4,200	64.8
99%—4 mesh	3,000	54.8
99%—6 mesh	2,100	45.8
99%—8 mesh	1,500	38.7
99%—10 mesh	1,000	31.6
99%—14 mesh	800	28.3
99%—20 mesh	550	23.4
99%—28 mesh	400	20.0
99%—35 mesh	270	15.4
99%—48 mesh	150	12.25
99%—65 mesh	105	10.25
99%—100 mesh	72	8.48
99%—150 mesh	55	7.42
99%—200 mesh	36	6.00
99%—325 mesh	20	4.47

CORRECTION FACTOR 2—CF_2 (open-circuit ball milling); see values in Table 25.3.2.2.

CORRECTION FACTOR 3—CF_3 (diameter) $CF_3 = (8/D_1)^{0.2}$ (or 0.914 minimum value) where D_1 is the mill diameter inside liners. The gain in grinding efficiency with increasing mill diameter ends at about 3.8 m (12.5 ft) inside the liners. The use of the diameter efficiency factor beyond this point does not give the correlation between W_{io} and W_i. The diameter efficiency factor for diameters larger than 3.8 m (12.5 ft) inside the liners should be the same as used for mills 3.8 m (12.5 ft) inside the liners; namely, 0.914.

CORRECTION FACTOR 4—CF_4 (oversized feed).

Optimum Feed Size F_o.

Ball Mill:

$F_o = 4000 \times \sqrt{(13/W_i)}$

If $F_{80} > F_o$, then

$CF_4 = [R_r + (W_i - 7) \times (F_{80} - F_o)/F_o]/R_r$

where $R_r = F_{80}/P_{80}$.

Rod Mill:

$F_o = 16{,}000 \times \sqrt{(13/W_i)}$

If $F_{80} > F_o$, then $CF_4 = 1.000$.

CORRECTION FACTOR 5—CF_5 (fineness of grind).

If $P_{80} < 74$ μm (200 mesh), then $CF_5 = (P_{80} + 10.3) / (1.145 \times P_{80})$

If $P > 74$ μm (200 mesh), then $CF_5 = 1.000$.

CORRECTION FACTOR 6—CF_6 (ratio of reduction, rod milling).

Optimum Reduction Ratio: $R_{r_o} = 8 + 5L/D_1$

where L = mill length, inside liners.

Reduction Ratio: $R_r = F_{80}/P_{80}$

$CF_6 = 1 + (R_r - R_{r_o})^2/150.$

CORRECTION FACTOR 7—CF_7 (low ratio of reduction, ball milling).

If $R_r < 3$, then

$CF_7 = [20\ (R_r - 1.35) + 2.6] / [20\ (R_r - 1.35)]$

If $R_r \geq 3$, then $CF_7 = 1.000$.

An example of the application of correction factors is as follows.

Example 25.3.2.1. Assume a ball mill operating in closed circuit. Work index is 13.0, feed size is 95–99% – 12.5 mm (½ in.), product size is 75% –74 μm (200 mesh), feed rate is 54.5 t/h (60 tph).

Solution. First, convert the feed and product sizes to 80% passing sizes. From Table 25.3.2.3, material size conversion, select 8500 as the F_{80} size for 99% passing 12.5 mm (½ in.). From the product size 75% passing 74 μm (200 mesh), the P_{80} size can be determined from a distribution curve or approximated from the Gates-Gaudin-Schumann relationship as follows:

Size 2 = (% passing size 2/% passing size 1)^2 × size 1

$P_{80} = (80/75)^2 \times 74$ μm $= 84$ μm

Inserting the 80% passing sizes and work index in Bond's formula gives:

$W = (10W_i/\sqrt{P_{80}}) - (10W_i/\sqrt{F_{80}})$

$W = (10 \times 13)/\sqrt{84} - (10 \times 13)\ \sqrt{8500} = 12.8$ kWh/t

The power required is:

(12.8 kWh/t) × (60 tph) = 770 kW (1030 hp)

From the mill size tables (25.3.2.1) in this segment, the horsepower calculated for an overflow ball mill corresponds to a 3.5 m (11.5 ft) in diameter by 4.6 m (15 ft) in length mill. The diameter inside the shell is 3.5 m (11.5 ft), and the diameter inside the liners D_1 is 3.4 m (11 ft).

The basic power W is corrected as follows:

In this example, correction factors CF_1 and CF_2 are not applicable.

CORRECTION FACTOR CF_3: $(8/11)^{0.2} = 0.938$

CORRECTION FACTOR CF_4:

$F_o = 4000 \times \sqrt{(13/W_i)} = 4000 \times \sqrt{(13/13)} = 4000$

$F_{80} = 8500$

since $F_{80} > F_o$, reduction ratio $R_r = \dfrac{8500}{84} = 101.2$

therefore, $CF_4 = [101.2 + (13 - 7) \times (8500 - 4000)/4000] / 101.2 = 1.067$

CORRECTION FACTOR CF_5:

Since $P_{80} = 84$ μm and $P_{80} > 74$ μm, $CF_5 = 1$

CORRECTION FACTOR CF_6 is not applicable.

CORRECTION FACTOR CF_7 is not applicable.

The final calculated horsepower is obtained by multiplying the base horsepower by each applicable correction factor:

$$(770) \times (0.938) \times (1.067) \times (1) = 771 \text{ kW } (1031 \text{ hp})$$

In this instance, there is not much difference from the uncorrected value. The mill size corresponding to the calculated horsepower is therefore the same, 3.5 m (11.5 ft) in diameter by 4.6 m (15 ft) in length.

POWER CALCULATION FOR AUTOGENOUS AND SEMI-AUTOGENOUS MILLS. It has been found that as a general rule, power requirements to grind a tonne (ton) of ore in a test mill to a given size can usually be duplicated in a large commercial mill. This assumes that the test work is carried out under carefully controlled conditions with good power measurements. It is generally found that in the small test mill, the load should be maintained between 25 and 30% of mill volume. The total power drawn under these conditions can be used for scale up to larger mills and to obtain unit power requirements per tonne (ton) of ore treated.

Various researchers and manufacturers have used many formulas for arriving at the total power requirements of a commercial mill. Many of the early wet autogenous mills were underpowered and had to operate at lower load levels, particularly if a ball charge had to be added to obtain the throughput. Such a situation increases both the liner and ball wear. It is therefore essential to have enough installed power on the commercial mill.

In general, most scale-up formulas use an exponent of the mill diameters and a direct comparison of mill lengths to arrive at a multiplying factor for the scale-up of the test mill power. The exponent used for mill diameters has varied from 2.4 to 3.0.

For wet mills, an exponent of 2.65 should be used to arrive at the power to drive the commercial mill provided that good power measurements have been taken in the test mill at a known charge level between 25 and 30%. The power on the test mill is always given in new kW, and the power on the commercial mill is generally measured as gross power. Therefore, using the relationship (in SI units):

$$P_C = P_T \times (L_C/L_T) \times [(D_C/D_T)^{2.65}]/0.95 \qquad (25.3.2.3)$$

should give the required power of the mill motor on the commercial mill in which P_C is gross power of the commercial mill in kW, P_T is net power of the test mill in kW, D_C is nominal diameter of the commercial mill in meters, D_T is nominal diameter of the test mill in meters, L_C is nominal length of the commercial mill in meters, and L_T is nominal length of the test mill in meters. Gross power is the power input to the mill motor, and net power is the power actually consumed in grinding after deducting mechanical and electrical losses.

This equation has been used to check the actual power obtained on commercial mills against the calculated figures. These cases were taken from actual test work where it is known that the work was carefully carried out and correctly supervised. In most cases the calculated figure from test work is generally conservative or safe for the design of commercial power requirements.

To find the nominal capacity of the mill in tonnes (tons) per hour, 90% of the gross power should be divided by the net grinding power per tonne (ton) obtained in the test mill.

Analyses of the data from operating dry AeroFall mills shows that mill power varies as the diameter raised to the 2.8 power and as the effective length. Specifically, the power drawn by mills of standard design treating normal ores under optimized conditions may be calculated from (in SI units):

$$P = 0.00100 \times W \times D^{2.8} \times L \qquad (25.3.2.4)$$

where P is motor input in kW for direct driven mills, W is the bulk density of the mill load in kg/m^3, D is mill diameter (inside shell liner) in m, and L is mill length inside the liners in meters.

The calculated power requirements of a commercial mill should also be compared with operating mills with corrections for differences in size and in bulk density of the mill loads.

All manufacturers have their own methods for arriving at mill power. It is therefore important to submit the test data to the manufacturer to verify that the mill will have the correct installed motor size.

In summary:

1. Take careful power measurements on the test mill with the load in mill between 25 and 30% of total mill volume.

2. Scale-up by formula to obtain mill motor size for commercial mill.

3. Compare this power requirement with mills of comparable size using correction for difference in bulk density of the mill load or the load plus ball charge.

4. Obtain nominal capacity of the mill by dividing 90% of the mill input power by the net kWh/t (ton) obtained in the test work.

5. Submit test data to mill manufacturer for verification that the commercial mill is correctly sized and powered to produce the required tonnage.

OTHER CONSIDERATIONS.

1. The Bond Third Theory also provides a simple yet accurate mathematical formula for comparing and studying grinding circuits and variables within these circuits.

The comparison of work indices is given as work index calculated from the plant operating data W_{io} divided by the work index obtained from the Bond grindability test W_i:

$$W_{io}/W_i \qquad (25.3.2.5)$$

Using the work index obtained from the grindability test as the standard for comparison can be a measure of the efficiency or inefficiency of the operating mills. Some plants do this on a regular basis.

2. The feed to the standard Bond ball mill grindability test is – 3.36 mm (–6 mesh). The coarser fraction of a – 12.5-mm (– 1/2-in.) single-stage ball mill feed is not included in the feed to the grindability ball mill. The – 12.5-mm (– 1/2-in.) feed to a standard Bond rod mill grindability test includes the coarse fraction of a single-stage ball mill feed. To obtain the complete grindability picture of an ore when selecting a single-stage ball mill, it is advisable to run both rod and ball mill grindability tests.

If there is a difference in the work indices obtained from the rod mill and the ball mill grindability tests, which frequently occurs, then, particularly if the rod mill test work index is higher, a two-step calculation should be made to determine the required grinding power. The rod mill work index should be used to calculate from the plant ball mill feed size to 80% passing 2100 μm. The calculation from 2100 to the desired product size is made using the work index from the ball mill grindability test. The sum of these two gives the total power per tonne (ton) required for grinding.

3. For rod mills, the power drawn varies as the diameter D to the 2.33 power ($D^{2.33}$), and for ball mills, the power drawn varies as the diameter to the 2.3 power ($D^{2.3}$). This is a change from the previously stated exponential factors of from 2.4 to 2.6.

4. The weight of the steel charge in a mill can be estimated as follows (in SI units):

$$C_w = (D^2/4)\ \pi\ V_p L Cd/1000 \qquad (25.3.2.6)$$

where C_w is charge weight in tonnes, D is mill diameter inside liners in m; V_p is percentage of mill volume loaded with charge; L for rod mills is rod length in m, or for ball mills, it is the effective length of grinding compartment in m; and Cd is density of the media including voids in kg/m^3.

When the actual weight per cubic meter including voids for the media is not available, the following weights including voids can be used to estimate the weight of media (charge) in the mill:

Table 25.3.2.4. Average Bond Work Indices of Materials

Material	Sp Gr	W_i	Material	Sp Gr	W_i
Andesite	2.84	22.13	Lead ore	3.44	11.40

New rods 6250 kg/m^3 (390 lb/ft^3).

Worn-in rod charge (culled) 5770 kg/m^3 (360 lb/ft^3); (not culled) less than 5610 kg/m^3 (350 lb/ft^3) depending upon amount of broken rods in the charge.

Forged steel balls worn-in 4640/m^3 (290 lb/ft^3).

Cast iron balls worn-in 4160 kg/m^3 (260 lb/ft^3) or less, depending upon quality.

5. If a work index is not available from test work or equivalent plant operations, then the values in Table 25.3.2.4 can be used to obtain a first approximation.

GRINDING RODS. Grinding rods range in size from 38.1 to 101.6 mm (1.5 to 4 in.) in diameter and are normally 3.04 to 6.10 m (10 to 20 ft) in length, depending on the length of the mill. Their size and shape practically dictate that they be made from rolled steel bars. The rods are cut to their specified length, usually with a cut-off wheel, which produces a square cut. They are machine-straightened, usually to a tolerance of 6.35 mm (0.25 in.) maximum deviation from a straight line in 1.52 m (5 ft). Some rod users may specify a tolerance of 3.18 mm (⅛ in.) in 1.52 m (5 ft). Straight rods are easier to charge with a rod-charging machine; they are less prone to tangling of the charge and are less likely to break prematurely in service. They also do a better job of grinding.

For many years, practically all grinding rods were made from an unalloyed steel that contained 0.80 to 1.00% carbon, 0.30 to 0.90% manganese, 0.040% maximum phosphorus, and 0.050% maximum sulfur. They were used in their as-rolled condition with a hardness range of 240 to 300 Brinell. The larger-diameter rods tend to be softer than the smaller-diameter rods. AISI grade 1095 steel was usually specified. This type of steel is still extensively used for grinding rods, though it is now being replaced at a number of operations by harder and more abrasion-resistant grades of low-alloy steel (Table 25.3.2.5).

GRINDING BALLS. Grinding balls for tumbling mills range in size from 127-mm (5-in.) maximum diameter down to about 19-mm (¾-in.) minimum diameter. Currently, there is very little production of balls larger than 102-mm (4-in.) diameter, except for semi-autogenous mills. Balls smaller than 19-mm ¾-in.) diameter may be supplied on special order from the larger suppliers (Table 25.3.2.6).

GRINDING ROD AND BALL WEAR RATES. Bond (1958) had made extensive studies of the abrasiveness of various metals and minerals. By determining the work index W_i and abrasion index

Table 25.3.2.5. Grinding Rod Data

Rod Size (In.)	Wt/Ft (Lb)	Ft/Ton*	Surface Area (ft²/ton)
1½	6.0	333.3	131
2	10.8	185.2	98
2½	16.8	119.1	78
3	24.0	83.3	65
3½	32.8	61.0	56
4	42.8	46.7	49
5	67.0	29.9	39

* This column enables a quick calculation of the number of rods required. Assume 25 tons of 3½″ diameter × 19′6″ rods are required.

$$\text{No. of rods} = \frac{61 \times 25}{19.5} = 78 \text{ rods.}$$

Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 lb = 0.4536 kg, 1 ton = 0.9072 t.

Table 25.3.2.6. Grinding Ball Data

Ball Diam. (In.)	Wt. Each (Lb)	No./Ton	Surface Area (ft²/ton)
¾	0.063	31,994	392.2
1	0.148	13,497	294.1
1¼	0.290	6,911	235.3
1½	0.501	3,999	196.1
2	1.187	1,687	147.1
2½	2.318	864	117.6
3	4.006	500	98.0
3½	6.361	315	84.0
4	9.495	211	73.5
5	18.544	108	58.8

Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 lb = 0.4536 kg, 1 ton = 0.9072 t.

A_i in a specially designed laboratory machine, he was able to predict the wear of rods and balls in specific grinding operations. His relationships on rod and ball wear are as follows.

Wet rod mills:

$$\text{Rod wear in kg/kWh} = 0.16\,(A_i - 0.020)^{0.30} \qquad (25.3.2.7.)$$

Wet ball mills:

$$\text{Ball wear in kg/kWh} = 0.16\,(A_i - 0.015)^{1/3} \qquad (25.3.2.8.)$$

Dry ball mills:

$$\text{Ball wear in kg/kWh} = 0.023\,\sqrt{A_i} \qquad (25.3.2.9)$$

The foregoing equations were developed from the actual wear data supplied from a large number of grinding operations. Since there has been a continuing trend toward the use of more abrasion-resistant rods and balls since the collection of Bond's data, it will be necessary to reduce the constants in Bond's equations to bring them in line with this trend.

Heat-treated alloy-steel rods, as supplied by US manufacturers, cost 12 to 15% more than the 1095 steel rods. As is indicated in Table 25.3.2.7, 1095 steel rods wear at rates that are from 36 to 191% faster than the alloy rods. It appears, therefore, that the use of the alloy rods can be economically justified in rod-milling operations.

Table 25.3.2.7. Consumption of Grinding Rods in Various Ores

Type of ore	Rod diam., in.	Wear rates, lb/ton		Difference, %
		Alloy	High carbon	
Taconite	4	0.82	1.25	52
Ilmenite	2½	0.43	1.25	191
Lead-zinc	3½	0.83	1.15	39
Copper	4	0.65	0.90	38
Uranium	2½	0.58	0.90	55
Copper	4	0.61	0.83	36
Copper	3	0.36	0.53	47

Source: Armco Steel Corp. Data from 1095 steel rods.
Conversion factors: 1 in. = 25.4 mm, 1 lb = 0.4536 kg, 1 ton = 0.9072 t.

The consumption of balls for various grinding operations is shown in Table 25.3.2.8.

25.3.2.3 Mill Liners

Some of the more successful sections that have been used for rod mill liners are illustrated in Fig. 25.3.2.5. The choice of the particular design from the six basic types shown in this figure is influenced by numerous factors that include mill speed and diameter, size of rods used, abrasiveness and size of the mill feed, discharge level of the pulp, and toughness of the material in the liners. There is no one liner design that is best for all mills; however, the single-wave design (similar to that shown in Fig. 25.3.2.5a is currently the most popular for heavy-duty service in modern large-diameter mills. When installed, it is typically about 76.2 mm (3 in.) thick in the valleys and 152 to 178 mm (6 to 7 in.) thick at the top of the wave.

There is a fairly definite correlation between the size of balls in a mill and the design used for liners. The larger sizes of balls are used for coarse mill feeds, which tend to produce high wear rates on the liners. Consequently, the liners are usually made thicker and with higher or more waves or ribs to extend their life. In fine or secondary mill grinding with small balls, the wear rates on the liners are slower, which, in turn, permits the use of thinner liners with lower waves or fewer lifters. The smaller balls also produce less impact so that more brittle materials may be used in the liners.

Fig. 25.3.2.6 illustrates the more successful cross-sectional designs of shell liners made from cast ferrous materials. Cast liners, while still very popular, are now faced with increasing competition from rolled steel, rubber, and ceramic liners.

LINER LIFE. Consumption of steel and iron rod and ball mill linings, when expressed in pounds per ton of mill feed, may range from a high value of about 0.25 kg/t (0.5 lb/ton) for a ball mill wet grinding abrasive ore down to a low value of about 0.0005 kg/t (0.001 lb/ton) for dry grinding soft limestone or cement clinker.

Table 25.3.2.9 lists typical wear rates of liners in 15 high-tonnage milling installations in the United States and Canada that are involved in primary grinding of low-grade ores.

Since about 1961, there has been a marked growth in the use of rubber linings throughout the world. Much of this growth is due to the development of successful designs by the rubber manufacturers. The principal use of rubber linings has been in

fine-grinding operations, where they are capable of providing excellent wear life. The liners generally involve the use of molded plates wedged between molded lifter bars, as shown in Fig. 25.3.2.7.

25.3.2.4 Mill Drives

Many different types of drives can be used on grinding mills, depending on the size of the mill and torque requirements. Drive types range from V-belts to multi-pinion to gearless drives. Only the most popular types are discussed here.

RING GEAR AND SINGLE PINION. Fig. 25.3.2.8 shows several pinion mill drives. The single pinion (Fig. 25.3.2.8a and b) is by far the most popular drive arrangement because of its simplicity. The pinion can be driven by a slow-speed motor (approximately 150 to 250 rpm) or a combination of a higher-speed motor (600 to 1200 rpm) and speed reducer. This type of drive may use single-helical, double-helical, or spur gears.

This type of drive is commonly used on mills up to 2980 kW (4000 hp) and in some cases can be used on mills up to 3730 kW (5000 hp). Flexible couplings or air clutches are used to connect the drive motor and/or speed reducer to the pinion shaft. Use of the clutch reduces the starting torque requirements of the motor and the power demand on the electrical system.

RING GEAR AND MULTI-PINION DRIVES. Fig. 25.3.2.8 also shows dual pinion drives. Currently, this arrangement is the

most popular for drives 3730 to 8950 kW (5000 to 12,000 hp). As in the case of the single pinion drive, slow- or high-speed motors can be used, as well as air clutches or flexible couplings.

The major problem with this type of drive is maintaining the load division between the pinions. The load division can be accomplished by either mechanical or electrical means, or a combination of both. The most popular and successful method to date has been electrical load division.

GEARLESS DRIVE. Fig. 25.3.2.9 shows the gearless or "wrap-around" drive. This type of drive consists of an ultra-low-speed synchronous motor running at mill speed, driving the mill without the use of gears. The motor can be "wrapped" around the mill with the rotor mounted on the mill shell or mill trunnion. Alternatively, it may be independently mounted and directly connected to the mill trunnion.

This type of drive offers variable speed with either constant torque or constant horsepower. In general, gearless drive becomes economical somewhere between 11,200 to 14,900 kW (15,000 to 20,000 hp).

25.3.2.5 Grinding Circuits

The grinding circuit reduces the feed material to a size needed for further processing. Both wet and dry grinding are used. In dry grinding, the moisture content is generally kept below 5%. If subsequent processing is a dry process, then dry grinding is favored. Wet grinding requires less power for a given grind and is typically chosen if there are no special circumstances.

Open- and Closed-circuit Grinding—Grinding may be done either by open or closed circuit. In open circuit, grinding material makes one pass through the mill and is discharged to subsequent processing. In closed-circuit grinding, each pass through the mill is followed by classification. The coarse material is returned to the mill for additional grinding while the fine material is discharged to subsequent processing.

Open-circuit Grinding—Open-circuit grinding should be considered if the following apply:

1. There is another stage of grinding that follows.
2. The reduction ratio is small.
3. The size gradient is not critical. Some undersize and oversize can be tolerated.

Closed-circuit Grinding—Closed-circuit grinding produces a closer-sized-product range than open-circuit grinding. Mill discharge in a closed circuit is separated by a classifier into coarse and fine material. The coarse material recycles to the mill, and the fine material discharges to the next processing stage. The size split is controlled by the classifier.

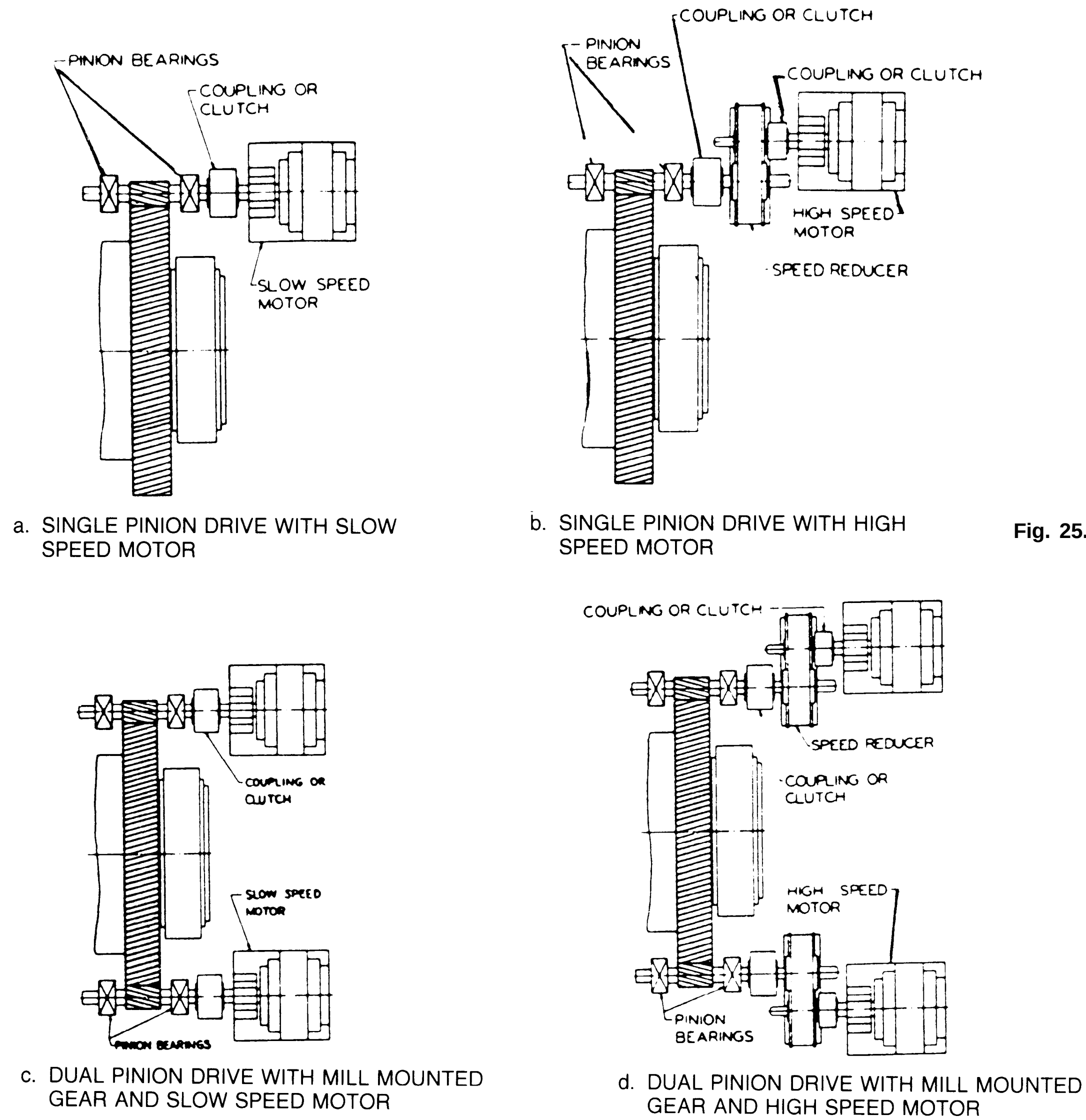

Fig. 25.3.2.8. Pinion mill drives.

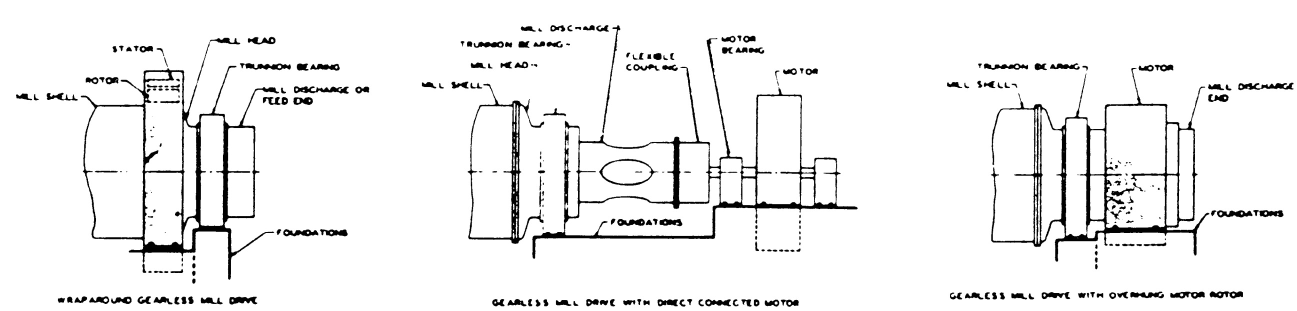

Fig. 25.3.2.9. Wrap-around gearless mill drives.

Closed-circuit grinding creates a *circulating load* which is defined as the ratio of the weight of the coarse material returned to the mill by the classifier to the weight of new feed.

SINGLE AND MULTISTAGE GRINDING. Grinding circuits may be either single stage or multistage. Single-stage grinding uses one mill per stage. Single-stage grinding may be either open or closed circuit in a rod, ball, autogenous, or semi-autogenous mill. Multistage grinding may use a combination of rod, ball, autogenous, or semi-autogenous mills in open or closed circuits.

CIRCUIT SELECTION. For years, an overlap has existed between fine crushing and coarse grinding, particularly coarse rod milling. In the last 25 years, the use of autogenous or semi-autogenous grinding (SAG) to do the work of secondary/tertiary crushing and rod milling (i.e., grinding primary crusher discharge to produce feed for a second grinding stage or, in some cases, final product) has added fuel to the argument. More recently, autogenous and SAG mills capable of drawing about 8950 kW (12,000 hp) with capacities of 450 to 1800 t/h (500 to

the question of capital cost and the advantages and disadvantages of using one large machine to do a major portion of the work required.

At the same time, work has been done to improve the capacity, energy utilization, and availability of cone crushers for secondary and tertiary crushing to make finer feed for the rod mills and single-stage ball mills. Today mechanical reliability is available, and its demonstrated ability to crush to 80% passing 6.4 mm (¼ in.) encroaches on some of the work traditionally done by rod mills. In fact, for some applications, they eliminate rod mills completely in that single-stage ball mills can accept this product as feed if it contains only a small oversized feed factor.

Obvious in both of these developments is an attempt to eliminate, or at least reduce substantially, the wear of steel and iron grinding media and wear parts, particularly steel grinding rods.

Comparison of circuits utilizing autogenous or semi-autogenous grinding with those using cone crushing is the subject of a number of papers. Two international symposia contained papers comparing autogenous and semi-autogenous grinding with conventional circuits (circuits with secondary and tertiary crushing). From these, it is apparent that the energy consumption in the comminution machines is lower in conventional circuits than in circuits using autogenous or semi-autogenous primary mills; and, in general, the reverse is true for operating cost. Operating cost depends on the amount of work done by secondary/tertiary crushing and grinding in the conventional circuit and that done by the primary mill in a circuit using an autogenous or semi-autogenous mill.

RANKING CIRCUITS. Comminution consultants for Boliden-Allis have identified eight basic comminution circuits (see Rowland, 1987). In practice, there are variations of these circuits, such as in-circuit beneficiation steps and crushers in the primary autogenous grinding circuit, to fit specific ore characteristics. Circuits in which the coarse part of the primary mill discharge is crushed in a cone crusher, then either returned to the primary mill as circulatory load or fed to the secondary stage, are called ABC circuits (autogenous mill-ball mill-crusher circuits) (Table 25.3.2.10).

Among the parameters, item 8, test work, is of particular importance. It spells out the need for ore testing and lists specific tests required to specify equipment for each circuit. This is the first step in circuit selection, as it defines the physical characteristics of the ore needed to select the comminution circuit and the process equipment needed in that circuit.

Both the rankings and their significances can vary with each ore deposit. Therefore, an independent comparison should be made for any specific study.

25.3.3 SCREENING

V.P. KENYEN

Screening is a unit operation that is an essential part of many different processes. The term applies to the mechanical separation of particles on the basis of size. This separation is accomplished on a screening surface with uniformly sized apertures. Particles larger than these apertures are rejected and pass over the surface, while those smaller (in at least two dimensions) are accepted and pass through. Many other terms are applied to this operation including sizing, sifting, sieving, and separation.

Most commonly, screens are used in conjunction with size-reduction operations, but they are found in other applications such as washing, dewatering, desliming, hedusting, scalping, concentration, and conveying.

Screens are used for processing a wide variety of materials, ranging from the fineness of talc up to boulders as large as 1.8 by 1.8 m (6 by 6 ft). Openings in screening surfaces may be as small as 127 μm (0.005 in.) or as large as 200 or 250 mm (8 or 10 in.), with some as large as 460 mm (18 in.).

There are two types of screens: stationary and dynamic (vibrating). Tables 25.3.3.1 and 25.3.3.2 show the principal types and applications of stationary and dynamic screens in use today.

Table 25.3.3.1. Types of Stationary Screens

Type and Mode of Operation	Application
1. *Grizzly:* Consists of a set of parallel bars, rods, or rails with a uniformly clear opening; often tapered from feed to discharge end to provide self-cleaning characteristics. Opening size is set by the maximum size of rock that can be safely delivered to and handled by equipment following. Grizzlies may be level, for use over bins or inclined for use ahead of crushers or belts.	Scalp out large rock using grizzly between truck dump and bin. Allow fines to bypass crusher, thus reducing load on machine.
2. *Static sieve:* Consists of a set of parallel profile bars or wires positioned at right angles to line of flow, and usually sloped at incline of 45° or more to the horizontal. Bars may form a flat, curved, or multi-sloped surface. Generally used only on wet screening operation.	Used for size separation, scalping, entering in range of 2 mm (10 mesh) and finer.

Source: Weiss, 1985.

Table 25.3.3.2. Types of Dynamic Screens

Type and Mode of Operation	Application
1. *Vibrating screen:* A screen with motion in a vertical plane which operates, generally, above 600 cpm at less than 25.4-mm (1-in.) stroke. Two arrangements are available; inclined or horizontal screening surface. Available with mechanical or electromagnetic vibrators that apply motion either to screen frame or screening surface.	See also inclined and horizontal.
2. *Inclined vibrating screen:* A vibrating screen arranged with an inclined screening surface. Material is fed in at the upper end and flows down the incline aided by the vibrating force. Circular stroke stratifies the bed, bringing fines down to the screen surface for separation. Coarse discharges over the end of the screen.	High-capacity units for separation of a wide range of particle sizes. Also used for scalping and trash removal.
3. *Horizontal vibrating screen:* A vibrating screen arranged with a horizontal screening surface. Material is fed in at back end and is moved over the length of screen by a positive pulsating stroke that throws the material up and forward, and withdraws deck down and backward. Material remains on the screen longer, and efficiency and accuracy of sizing are high.	Close sizing of medium-sized particles. Dewatering or media-recovery. Installations where headroom is limited.
4. *Oscillating screen:* A screen with linear motion, generally, in the larger stroke and slower speed (100 to 400 rpm) range.	Generally, used in -13 mm $+$ 250 μm ($-\frac{1}{2}$ in. $+$ 60 mesh) range. Light, free-flowing materials can be separated at 74 μm (200 mesh) and less.
5. *Reciprocating screen (shaking screen):* A screen with substantially linear motion in the plane of the main frame. Stroke is normally in range of 25 to 102 mm (1 to 4 in.), with speed from 30 to 200 cpm. Unit is slightly inclined and may be suspended from rods or cables, or supported from base by durable flat springs.	Units may be used for both conveying and size separation. Low capacity and high maintenance are handicaps. Good for accurate sizing of large lumps.
6. *High-speed screen:* A relative term referring to the operating frequency of a screen. Generally applied to those operating in excess of 3000 rpm or cycles per minute. Vibrator or exciter may be mechanical or electromagnetic.	Generally used for fine and ultra-fine screening.
7. *Vibrating grizzly:* Consists of a set of parallel bars or rails with a uniform clear opening space set for the maximum size of rock that can be safely delivered to and handled by the equipment that follows. Mechanical or electromagnetic vibrator provides positive force to move material permitting use of flatter slopes than those required by stationary grizzlies (10° vs. 45°).	Used to scalp out large rock for crushing, fines pass through readily because of large openings and are bypassed around the crusher. Often combined with feeder to save space and headroom.
8. *Revolving screen:* This is also referred to as trommel, scrubber, or barrel screen and is a cylinder on a shaft, mounted on rollers, with the screen surface forming the circumference. Screening surface may be wire cloth or perforated plate. The cylinder is open at both ends and inclined at a slight angle. These screens revolve at low speeds, usually 15 to 20 rpm. Both capacity and efficiency of these units are low when compared with vibrating screens.	Used for scrubbing and washing wet, sticky materials, and making a rough size separation. Used for wet sizing of sand and gravel in wet-process sand plants.

Source: Weiss, 1985.

25.3.3.1 Vibrating Screen Description

Vibrating screens are the most widely used in the mineral processing industry. The largest conventional vibrating screens installed to date are two 3.6 by 8.5 m (12 by 28 ft) Allis-Chalmers screens at Ok Tedi. Fig. 25.3.3.1 shows the main elements of a vibrating screen. Some of these are discussed below.

When selecting the type of deck coverings, the abrasive and sticky nature of the ore must be considered. Metallic decks have long been the surface of choice. Lately, however, there has been a major increase in the use of rubber and polyurethane screen decks. These screens come as small panels that can be replaced individually. Rubber decks are manufactured by Linetex, Trelleberg, and Skega among others, and polyurethane decks are manufactured by Polydeck Screen Corp.

Generally, the function of the top deck of multisurface screens is to relieve the load on the lower deck(s). Therefore, accurate sizing by the top deck is not necessary. A good practice is to use double-tapered, stepped cast grizzly bars, usually made of manganese or manganese steel for impact and abrasion resistance. Alternate materials such as high-chromium iron (26% Cr) are sometimes used; however, that material is so brittle that it does not stand up well under impact conditions.

One of two configurations is normally used on the lower or sizing surfaces (decks). These are the long-slot and rod types. The long-slot, or Ty-rod type of woven wire cloth provides the advantages of both increased throughput capacity and anti-blinding action as a result of secondary vibrations in the long wires. The rod-type deck is constructed from individual rods of high-carbon oil-tempered steel with a hardness of 46 to 48 Rockwell C. Rods are held in rubber end holders and intermediate spacers. The rubber allows the rods to move with secondary vibration to help alleviate buildup of sticky ore and relieve wedge blinding. This type of deck gives reasonably good life and high capacity.

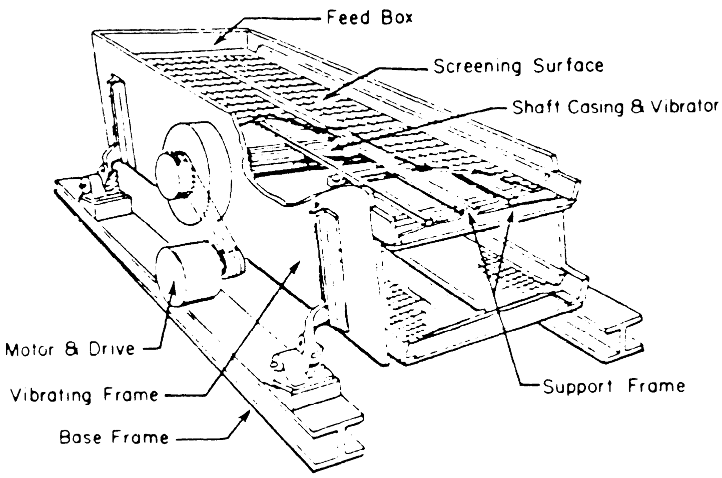

Fig. 25.3.3.1. Main elements of a vibrating screen (Weiss, 1985).

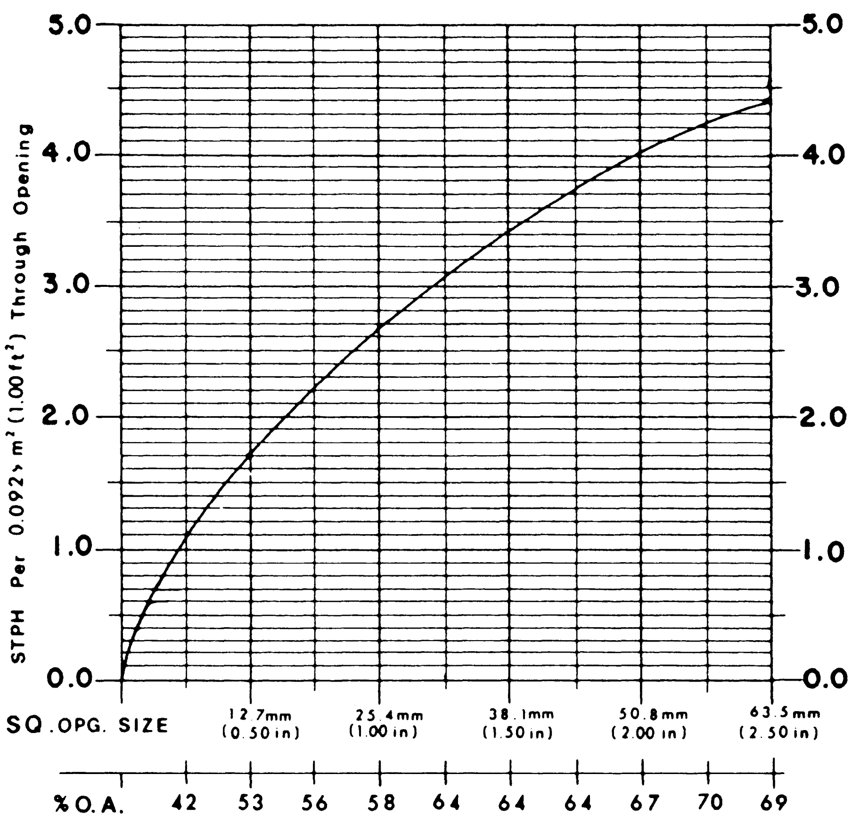

Fig. 25.3.3.2. Basic screen capacity (for ores having 1602-kg/m^3 or 100-lb/ft^3 bulk density) (Weiss, 1985).

25.3.3.2 Vibrating Screen Size Selection

The generally accepted approach to determining the screen area is the throughput method, which is based upon the amount of material (weight per hour) that will pass through 0.0929 m^2 (1.0 ft^2) of a screen deck having a specific opening.

The total required screen area A in square meters is given by the relation,

$$A = U/(C \times BD \times F \times E \times S \times D \times O \times W) \quad (25.3.3.1)$$

where U is tonnes per hour of screen undersize in the feed, C is basic screen capacity from Fig. 25.3.3.2, BD is bulk density expressed as the fraction found by dividing the density of the feed material (kg/m^3 or lb/ft^3) by 1602 kg/m^3 or 100 lb/ft^3, and F, E, S, D, O, and W are modifying factors defined in the following.

BASIC CAPACITY. The basic capacity curve representing the value of C for the various openings is based on a material with a bulk density of 1602 kg/m^3 (100 lb/ft^3). Since most metallic ores have similar screening characteristics, the C value for any ore can be determined by a simple ratio of densities.

The curve shown in Fig. 25.3.3.2 should be used for metallic ores only.

MODIFYING FACTORS. Many variables affect the screenability of a particular material. Only those that significantly affect the sizing of a screen are discussed here.

Table 25.3.3.3. Fines and Efficiency Factors

Halfsize, %*	Fines F	Efficiency E
0	.44	
10	.55	
20	.70	
30	.80	
40	1.00	
50	1.20	
60	1.40	
70	1.80	2.25

Table 23.3.3.4. Slotted Deck Opening Factors

Typical Deck Preparations	Length/ Width Ratio	Slotted Opening Factor S
Square and Slight Rectangular Openings	<2	1.0
Rectangular Openings Ton-Cap	>2 but <4	1.15
Slotted Openings Ty-Rod	>4 but <25	1.2
Parallel Rod Decks	>25	SP 1.4* RA 1.3

*SP = Slots parallel to flow, RA = Slots right angles to flow
Source: Weiss, 1985.

Fines Factor F—The *fines factor* is a measure of the amount of material, in the feed to a screen deck, which is less than one-half the size of the opening in the deck. It is a measure of the difficulty of screening when compared to 40% fines (F = 1.00), which is the C value used for the basic capacity. Table 25.3.3.3 gives the values for fines factors.

For calculating the fines factor, use the percentage of half-size coming to the particular deck, expressed as a percentage of the feed to that deck. For example, if the top deck has a 38mm (1.50-in.) opening and the bottom deck has a 12.5mm (0.50-in.) opening, and the feed analysis is 70% passing 38 mm, 50% passing 12.5 mm, and 35% passing 6.3 mm, then the fines factor for the bottom deck would be 35/70 = 50%.

Efficiency Factor E—The *efficiency of separation* is expressed as the ratio of the amount of material that actually passes the opening divided by the amount in the feed that should pass. "Commercially perfect" screening is considered to be 95% efficient. Therefore, the factor for 95% is 1.00 as indicated in Table 25.3.3.3. For scalping and crusher relief applications, an efficiency of 80 to 85% is generally acceptable.

Slot Factor S—The *slotted opening factor* compensates for the tendency of more particles to pass through the screening medium due to a fewer number of cross bars or wires obstructing the particle paths through the deck. The values for various slot configurations are given in Table 25.3.3.4.

Deck Factor D—The *deck factor* (Table 25.3.3.5) allows for the fact that stratification does not take place at the extreme end of the deck, so the bulk of the fines does not fall through until the material has traveled a short distance down the deck. Therefore, except for the top deck, the entire feed does not land on the feed end, which results in some of the screening area being ineffective.

Table 25.3.3.5. Deck Factor

Deck	Deck Factor D
Top	1.00
2nd	0.90
3rd	0.80

Table 25.3.3.6. Wet Screening Factor

Size Opening (In. square)	W
1/32	1.25
1/16	3.00
1/8 and 3/16	3.50
5/16	3.00
3/8	2.50
1/2	1.75
3/4	1.35
1	1.25
+2	1.00

Source: Weiss, 1985. Conversion factor: 1 in. = 25.4 mm.

Open Area Factor O—The *open area factor* gives the ratio between the actual open area of the screen and the wire deck openings assumed in the standard capacity curve.

For example, if a deck with 36% open area was used for a 24-mm (0.95-in.) separation, the factor would be 36/58 or 0.62. Alternately, if a deck with 72% open area was used, the factor would be 72/58 or 1.24.

Wet Screening Factor W—A factor is applied when *wet screening* is used. The benefit derived from wet screening varies with the opening size, and the factors are given in Table 25.3.3.6.

The advantage of wet screening is realized only when the correct amount of water is used. The recommended volume for efficient wet screening varies from a minimum of 11.35 L/min (3 gpm) to 18.92 L/min (5 gpm) per 0.765 m^3 (1.0 yd^3) of feed material.

Example 25.3.3.1. To illustrate the selection procedure, the following sample problem is used.

Iron ore is fed at 272 t/h (300 tph). Bulk density of the ore is 2082 kg/m^3 (130 lb/ft^3), with 8% moisture. Size analysis of the ore is as follows:

Size Fraction	Cumulative % Passing
38 mm (1½ in.)	100.00
25 mm (1 in.)	98.00
19 mm (¾ in.)	92.00
12.5 mm (½ in.)	65.00
6.3 mm (¼ in.)	33.00

Separation required: 12.7 mm (½ in.), using dry screening.

Solution.

$A = (300\text{ tph}) \times (.65) / (C \times BD \times F \times E \times E \times S)$

$C = 1.7\text{ t}/0.09\text{ m}^2$, $BD = 2{,}082/1{,}602 = 1.30$, $F = 0.86$ (33%),

$E = 1.00$ (95%), $D = 1.00$ (top), and $S = 1.2$ (Ty-Rod cloth)

$A = 195\text{ tph}/(1.7)(1.3)(0.86)(1.00)(1.00)(1.2)$

$= 195\text{ tph}/(2.28\text{ tph}/0.0929\text{ m}^2/\text{ft}^2) = 7.95\text{ m}^2\ (85.5\text{ ft}^2)$

Table 25.3.3.7. Rate of Material Travel on Inclined Circle-Throw Screens with Counterflow Rotation

Angle, °	Flow rate, m/min (fpm)
18	18.29 (60)
20	24.39 (80)
22	30.48 (100)
25	36.58 (120)

Source: Weiss, 1985.

The 7.95-m^2 (85.5-ft^2) area represents the net effective screen area required. To allow for the space taken up by tension rails, center clamps, and openings that are blocked by cloth support bars, 10% is added to the net area.

$$7.95 + 0.79 = 8.74 \text{ m}^2 \text{ } (94.0 \text{ ft}^2).$$

A commercial screen with at least 8.74 m^2 (94.0 ft^2) of area should be selected, keeping in mind that the length-to-width ratio should be at least 2:1 for effective screening. Therefore, the tentative size of the screen should be 1.83 × 4.87 m (6 × 16 ft), with a total area of 8.91 m^2 (96.0 ft^2).

The depth of bed of material passing over the deck must be checked to be sure it is within acceptable limits. The depth of bed at the discharge end of the deck should not be more than four times the size of the deck opening. For example, if the deck opening is 12.5 mm (½ in.), the depth of bed at the discharge end should not be more than 50.8 mm (2 in.).

To determine the depth of bed, refer to Fig. 25.3.3.3, which gives the capacity per centimeter (2.54 in.) of depth for various widths, based on a rate of material travel of 18.29 m/min (60 fpm).

Rates of travel for various angles of installation are given in Table 25.3.3.7. the bed depth obtained from fig. 25.3.3.3 is adjusted by the ratio of 18.29 m/min (60 fpm) divided by the rate of travel of the tentative installation angle. Crushing plant screens are usually installed at 20 to 25°, with the majority being at 20°.

Checking the example shows that a 1.83-m (6-ft) wide screen will have 4.6 t/h/cm (116 tph/in.) depth of bed. The depth of bed passing over the deck, therefore, is 105/4.6 = 22.8 mm (0.90 in.). This is below the maximum allowed depth of 50.8 mm (2.0 in.). If the screen is installed at 20°, the depth of bed will be somewhat less.

In conclusion, one 1.83 × 4.87 m (6.0 × 16.0 ft) inclined, circle throw screen will be sufficient to screen the iron ore.

When calculating double-deck screen areas, each deck should be treated as a separate problem.

RECIRCULATING LOAD. When the screen is in closed circuit with a crusher, the approach to screen selection is slightly different. The total feed rate to the screen including recirculating load and the size analysis of the total feed should be calculated. For an example of how to size a screen with a recirculating load, the reader is referred to Section 3E on screening of the *SME Mineral Processing Handbook* (Weiss, 1985).

25.3.3.3 High-speed Screens

High-speed screens are used for very fine separations. The screen produces a high-frequency (3600 rpm) and low-amplitude vibration that breaks the fluid surface tension and promotes close screen/particle contact.

An example of a typical high-speed screen is the Derrick Multifeed screen illustrated in Fig. 25.3.3.4. A particularly interesting application is the successful replacement of cyclones in some closed-circuit grinding circuits where the higher separation efficiency of the screen has resulted in significant increases in capacity.

25.3.3.4 Sieve-bend Screens

Sieve-bend screens are high-capacity screening devices that utilize stationary, concave, wedge-bar screening surfaces. A complete sieve bend is comprised of a feed distribution chamber, a structure for holding the screen surface, and collection chambers or chutes for oversize and undersize materials. In devices used in metallurgical applications, provision is usually made for reversal of the direction of flow over the surface, either by rotating

Table 25.3.3.8. Typical Sieve Bend Types and Sizes

Type sieve bend	Radius, in.	Surface length, in.	Available widths, ft	Typical bar spacing, mm	Max. capacity feed, gpm per ft width	Required installation height, ft	Required floor area, ft^2 per ft width	Approx. weight, lb	Capital cost, $*

Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m, 1 ft^2 = 0.0929 m^2, 1 lb = 0.4536 kg, 1 gpm = 3.785/min.

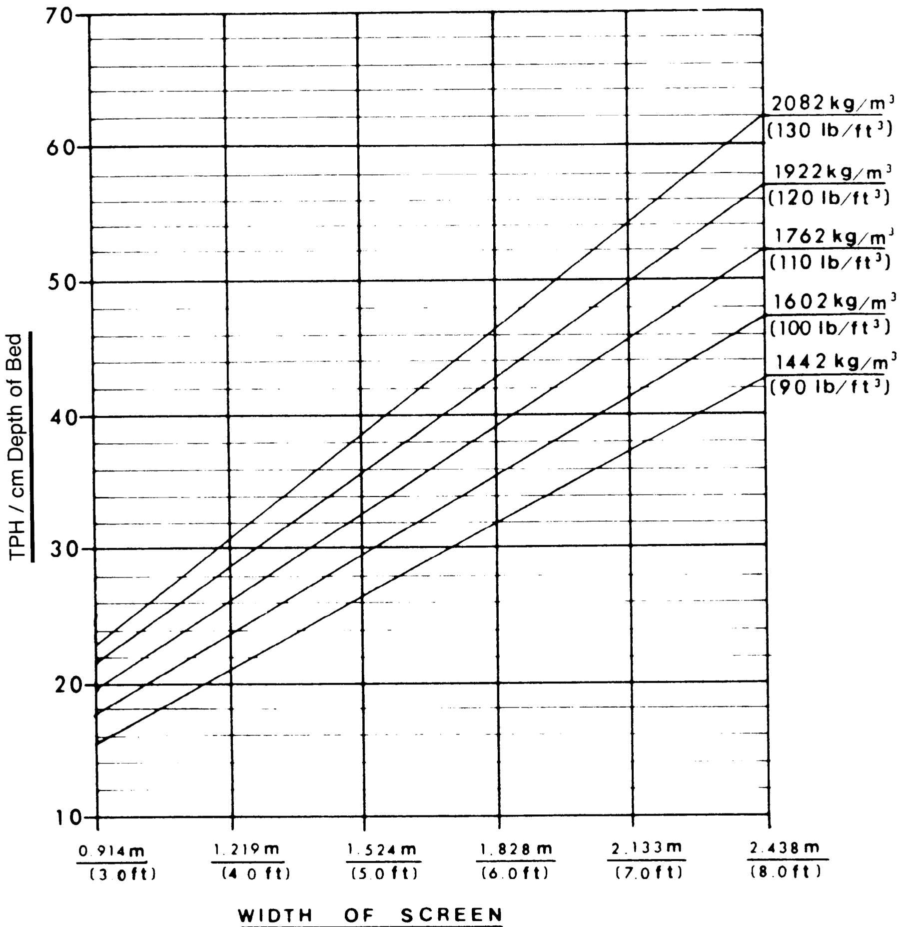

Fig. 25.3.3.3. Depth of bed chart (based on 18.29-m/min, or 60 fpm flow rate) (Weiss, 1985).

the surface or by changing the feed nozzle position. The size of the unit varies in height from 1.5 to 2.4 m (5 to 8 ft) and in width from 0.61 to 2.4 m (2 to 8 ft).

The orientation of the wedge-bar surface is such that the slots between the wedge bars are perpendicular to the flow of feed material over the surface. The feed is distributed evenly and tangentially over the width of the screen surface. A variety of means is used to accomplish this including simple gravity weir feeds, long slotted nozzles, and a multiplicity of round nozzles. A typical gravity-fed weir-type nozzle is shown in Fig. 25.3.3.5. Most sieve bends are fed by gravity in such a manner that a falling height of approximately 500 mm (20 in.) is provided before the feed meets the screen surface. In some cases where fine bar spacings (200 μm or less) are used, it is necessary that the feed stream meets the screen surface at a higher velocity. In such circumstances, pressurized nozzle feed arrangements are used.

For fine separations (200 μm or less), gravity feeding with a rapped or vibrated surface can be used. Such a device, known as a Rapifine screen, has found application in iron ore and coal beneficiation. A variety of low-frequency (6 to 10 raps/min) mechanical rappers mounted behind the screen deck are used. They impact the surface with a force of 1.4 to 3.4 J (1 to 2.5 ft-lb). Sieve bends are constructed of carbon steel, stainless steel, and composite materials.

Sieve-bend screens are used for separations in the range of 0.15 to 3 mm (0.0059 to 0.118 in.). Unlike hydrocyclones whose classification efficiency depends on the specific gravity of the particle and percentage solids of the feed, the efficiency of sieve-bend screens depends upon the particle size. As opposed to hydrocyclones, it can be fed at much higher percent solids, such as 45 to 50% solids by volume.

SIZING OF SIEVE-BEND SCREENS. To determine the size of the sieve bends, first the diameter of separation should be determined. By definition, this is the diameter of particle that reports 95% to the oversize fraction. Then the slot opening is determined from Fig. 25.3.3.6, which gives the slot opening for a given separation size. Using Fig. 23.3.3.7, the capacity of screen surface for a given slot opening is then determined. Data given in Fig. 23.3.3.7 are only for gravity-fed screens using bar widths of 2.3 mm (0.090 in.), and correlate the maximum volumetric feed rate in liters (gallons) per minute per linear meter (foot) of sieve-bend screen width. Reference to Table 25.3.3.8 then provides the specification for the screen so that number of linear meters (feet) required for given process capacity can be determined.

25.3.3.5 Other Screens

Revolving screens or trommels find application in breaking up and screening loosely cemented materials and alluvials. They are mainly used on tin and gold dredges, and other alluvial operations and in washing and sizing sands and gravels. In washing operations, water is jetted on to the material through nozzles from a spurge pipe down the center of the trommel.

25.3.4 HYDROCYCLONING

V.P. KENYEN

Used to accomplish size separation of solids carried in slurries, the *hydrocyclone,* or liquid cyclone, as it is often called, is in most cases an extremely simple mechanical device with no moving parts. It is cylindroconical in shape, varying in size from a few millimeters (tenths of inches) to as large as perhaps 254 mm (10 in.) in diameter. The length-to-diameter ratio varies over a large range from 2:1 to 10:1. Weights of hydrocyclones vary from a few hundred grams (ounces) to several thousand kilograms (pounds), depending upon size and materials of construction.

The hydrocyclone depends on external power for its operation. Most commonly, a continuous flow centrifugal pump is used. Occasionally, it can also be operated using gravity feed systems provided sufficient head is available. Feed velocity head and pressure head are converted to both angular and linear acceleration, creating a cyclone effect where the angular acceleration increases as the feed liquid moves from the outside wall of the cyclone toward the axis of rotation. As the angular acceleration increases, the centrifugal forces also increase, causing the separation of particles by size and/or specific gravity.

Fig. 25.3.4.1 shows a typical cyclone geometrical configuration, while Fig. 25.3.4.2 illustrates the action of a cyclone.

25.3.4.1 Cyclone Components

The following terminologies are normally used in the classification of hydrocyclones.

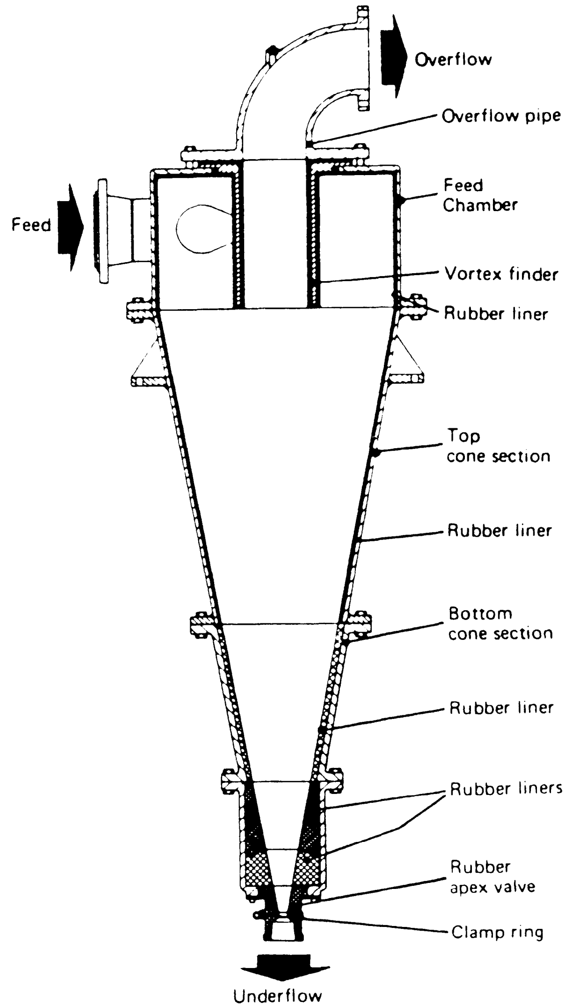

Fig. 25.3.4.1. Typical cyclone geometrical configuration (*courtesy:* Dorr-Oliver Co.).

FEED NOZZLE. Usually, the feed nozzle is tangent to the inside diameter of the cyclone. Since there are no moving parts within the cyclone, or power attachment directly connected to it, the spinning action required to develop the separating forces depends upon the feed velocity of the slurry entering the feed chamber tangentially. For a given size of cyclone, high pressure, caused by high velocity, yields a finer separation. While the smaller-diameter cyclones often respond to higher pressure in the range of 407 to 690 kPa (59 to 100 psi) gage, the normal operating velocity of most hydrocyclones is 39 to 66 m/s (12 to 20 fps).

VORTEX FINDER. At the top of the feed section, there is a flat plate through which projects the overflow or vortex finder. The vortex finder extends down into the feed chamber, terminating below the juncture of the cylindrical feed section with the conical section of the cyclone. The function of the vortex finder is to discharge the finer fraction of the feed to the process. Normally, the vortex finder is the largest nozzle in the liquid cyclone, and it discharges most of the water or liquid being fed to the cyclone. Fig. 25.3.4.3 gives the approximate relationship between cyclone diameter and feed nozzle size.

APEX VALVE. The smallest cross section of the cone on the hydrocyclone forms the apex nozzle. The apex orifice is the

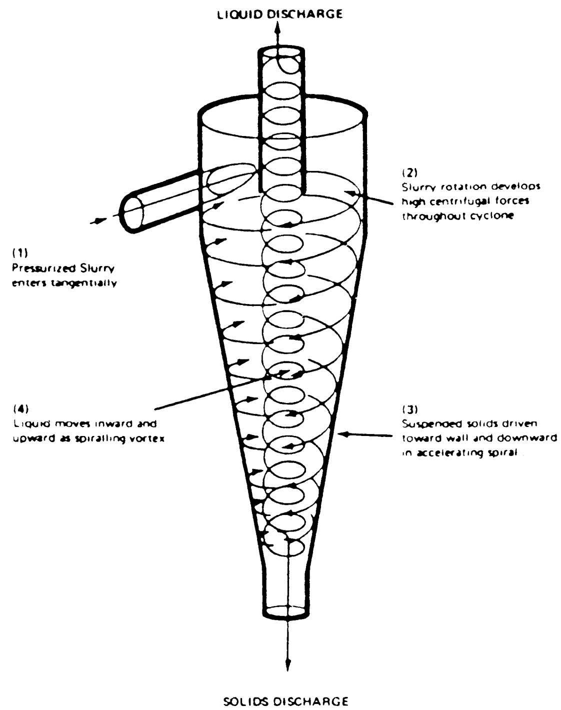

Fig. 25.3.4.2. Typical action within the cyclone (*courtesy:* Picenco International, Inc.).

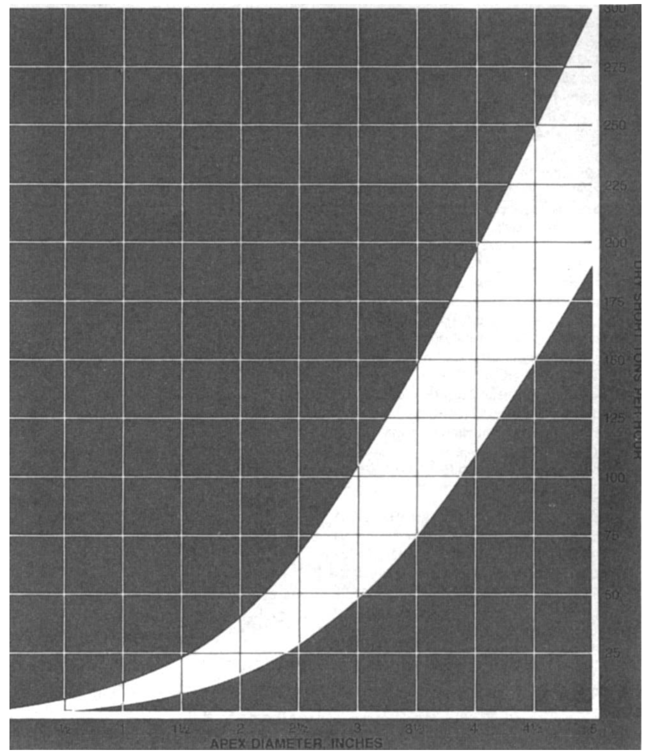

Fig. 25.3.4.4. Apex capacity chart (Krebs Engineers). Conversion factors: 1 in. = 25.4 mm, 1 tph = 0.9072 t/h.

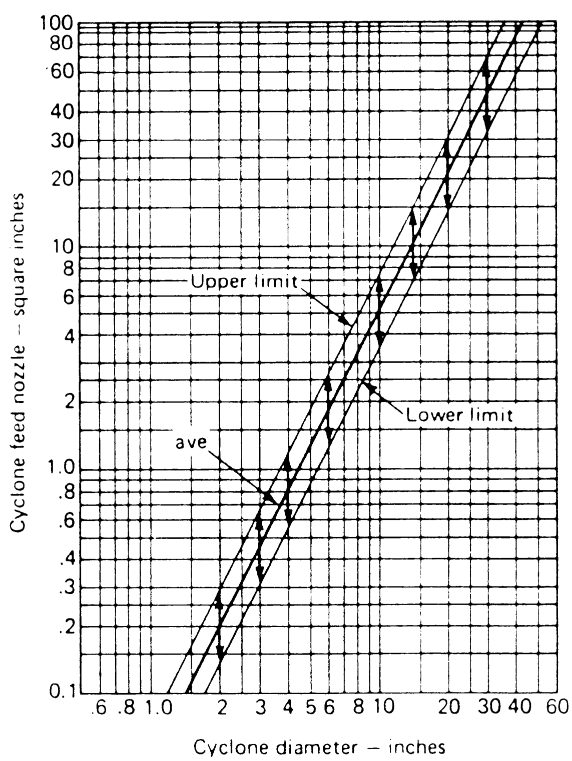

Fig. 25.3.4.3. Approximate cyclone feed-nozzle area vs. cyclone diameter (Weiss, 1985). Conversion factors: 1 in. = 25.4 mm, 1 in.^{2} = 645 mm^2.

smallest orifice in a hydrocyclone, and the coarse fractions of the particles are discharged through it at a higher percentage solids than the feed. Apex valves are made of either hard abrasion-resistant materials or natural gum rubber.

APEX SELECTION. The apex size is critical to proper cyclone performance. For each application, the required circulating load establishes the amount of solids which must be passed through the cyclone underflow.

Underflow density of 50 to 53% by volume is typical for primary grinding circuits; for regrind circuits, 40 to 45% by volume is typical. Therefore, using these guidelines, the apex can be sized.

Fig. 25.3.4.4 shows the approximate apex solid capacity for various apex diameters.

CLASSIFICATION AND SIZE OF SEPARATION. Historically, *classification* is defined as the particle size at which 1 to 3% report to the overflow, with the coarser particles reporting to the cyclone underflow. This is also referred to as the "mesh of separation." Lately, classification is defined as the size at which 50% of the solids reports to the overflow and the other 50% reports to the underflow. This theoretical particle size is defined as "*D*50." Fig. 25.3.4.5 shows an actual and corrected recovery curves. Note the actual curve does not reach zero probability because part of the underflow product is carried into the underflow as water or void filling solids. When the necessary correction is applied, a "corrected" recovery curve is obtained.

To further utilize this graph and make it applicable to any *D*50 point, each particle size is divided by the *D*50 value and a "reduced" recovery curve, as shown in Fig. 25.3.4.6, is obtained. Recent investigations have shown that this curve remains constant over a wide range of cyclone diameters.

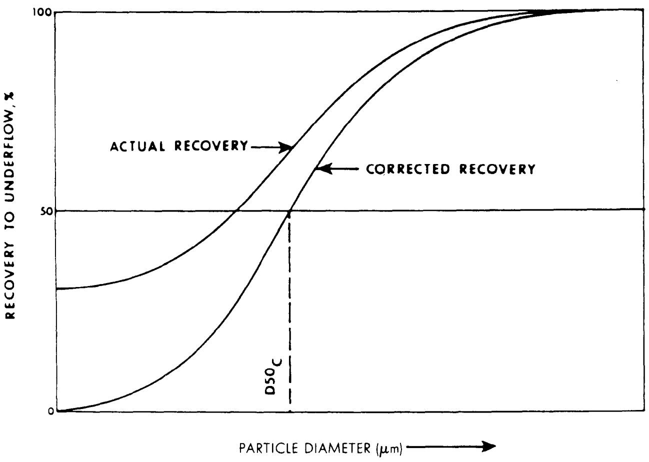

Fig. 25.3.4.5. Particle recovery curves (Arterburn, 1982).

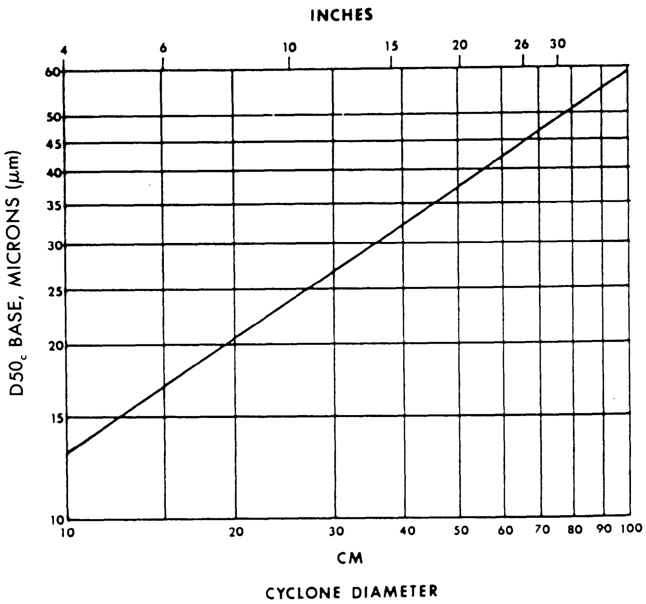

Fig. 25.3.4.6. Cyclone diameter vs. $D50_c$ for standard cyclone (Arterburn, 1982).

Factors affecting sharpness of separation include specific gravity of the solid particle mix, shape and surface character of the particles, pulp viscosity, pulp density, and size analysis vs. desired cut point.

25.3.4.2 Typical Applications

The application of cyclones is based on their ability to separate particle suspensions in accordance with particle size, density, and solids concentration. A general listing of cyclone applications is shown in Table 25.3.4.1. Cyclone operation can be divided into four types of operations: (1) coarse separations, 840 μm (about 20 mesh) maximum to 74 μm (200 mesh) minimum; (2) fine separations, desliming from 74 μm (200 mesh) maximum to 5 μm minimum; (3) desanding or desliming separations where one product is washed exceptionally clean by one or more stages of cycloning; and (4) combinations of coarse separations and fine separations using a coarse primary step followed by second-stage fine separation. Examples of cyclone applications are described here.

CLOSED-CIRCUIT GRINDING. Cyclones are widely used in closed-circuit grinding operations. While the cyclone is more flexible than certain other types of wet-classifying devices, it is less flexible as a classifier in a closed-circuit grinding system than in open-circuit classification systems. This is because the quality of the cyclone feed depends upon the rate and grindability of the ore being fed to the grinding system, and the ability of the grinding mill to grind it to the desired liberation size. Some changes can be made in the size, geometry, and operating conditions of the cyclone to modify the classification in a closed-circuit grinding system, and therefore control the circulating load, but the effect of these modifications is limited. The classification ability of the cyclone is more a function of correct mill sizing and operational control than the constraints that can be placed on the cyclone.

There is considerable controversy regarding the use of classification devices in closed-circuit grinding systems. Generally, the higher the circulating load, the narrower the size range of the final ground product. Conversely, the absence of a circulating load (i.e., an open-circuit grind) will tend to produce the largest oversize and the finest slime.

The cyclone is an inefficient classification device that tends to return to the grinding unit a good deal of finished material finer than the size required for subsequent concentrating process. At the same time, there is a heavy-media concentrating effect in cyclone classification, so that for a given liberation size, the cyclone tends to produce an overflow product slightly coarser than some other types of classifiers. It appears that this heavy-media effect can be an important feature when considering cyclones in closed-circuit grinding operations.

DESLIMING. Cyclones are used to deslime flotation feed, which minimizes reagent consumption and improves both recovery and grade. They are also used to produce a relatively slime-free sand material that is used for tailings-dam berm building and underground backfill. For such backfill, the mill tailings are often cycloned once at the mill, then again with clean water just before emplacement. The object is to maximize permeability so that water will drain freely away from the backfill sand. Desliming has been used in the production of specialty sands, such as glass sand, sand blasting sand, and filter sand, where the elimination of certain size of fine material is required.

Desliming is often used in the preparation of coal, and in some cases to wash slimy material away from coarser ore fractions that are amenable to solution leaching. Desliming, or more correctly, classification, is used on certain grades of clay in order to maintain approximate size-range consistency.

WASHING. Washing is another form of desliming. In some cases, however, it is construed as the washing out of a leach solution from ore solids, such as in the countercurrent washing of leach tailings. Cyclones are used for repeated washing of ores that are treated by flotation in order to remove reagent-consuming slimes or to remove undesirable reagents remaining from previous stages of flotation.

FEEDING AND DISCHARGING. Proper delivery of the slurry to the cyclone or cyclones is very critical. A velocity of 2 to 3 m/s (7 to 10 fps) is high enough to prevent particles from settling, even in horizontal pipe sections, but low enough to minimize wear.

If the slurry is to be distributed to several cyclones operating in parallel, extreme care should be given to the design of the slurry distribution system, and a radial type manifold is recommended. This is a system where the cyclones are fed from a central circular chamber. When properly designed, the central chamber becomes a mixing area, and the line velocity is lowered

Table 25.3.4.1. Applications of Hydrocyclones

Type of application	Kind of operation	Application: Purpose	Application: Description
Clarifying of turbid liquids	Main line	Complete clarification	Ore washing water
	Bypass line		Coal washing water
		Partial clarification	Drilling mud regeneration
			Waste water
Prethickening	Before dumps	Formation of angle of repose	Backfill tailings
	Before screens	Reduction of effluent and capacity increase	Quartz sand
	Before filters		Alumina
	Before centrifuges		Residue salts
	Before thickeners		Potash, coal
		Reduction of rake load	Mineral concentrates
Post-thickening	Effluent of screens, centrifuges, and filters	Recovery	Precipitates
			Residues
Sorting	Equal settling	Small particle size range	Decoaling of sand, leach precipitates, mineral mixtures
	Unsymetrical size distribution	Probability differences	Clays
	Heavy-media washing	Coarse fraction	Ores, coal
Washing by dilution	Re-thickening of washed slurries	Multi-stage washing	Uranium, precious metals
		Counter-current washing	Leaching
	Closed-circuit operations: coarse fractions,	Closed-circuit grinding	Ores, cement rock
	fine fractions	Crystal sizing	Alumina
Wet classifying	Classification	Classified products	Tailings dams, sand, filters, nonmetallics
	Degritting	Wear protection	Ores, sand
		Protection against oversize	
		Fine grades production	Chalk, graphite, kaolin, bentonite
	Desliming	Slime removal	Preflotation treatment
		Fines removal from coarse products	Sand
			Backfill tailings
			Drilling mud

Source: Weiss, 1985.

to approximately 0.6 to 0.9 m/s (2 to 3 fps). This will ensure that each cyclone is fed with the same slurry concentration.

To conserve space, both overflow and underflow launders are mounted inside the circle of cyclones, usually surrounding or underneath the radial feed manifold. The most economical construction usually has both the overflow and underflow launders welded around the central feed pipe, assuming it is fed from below. In some instances, the cyclones are mounted vertically, in which case an annulus for collection of underflow products is necessary.

25.3.4.3 Sizing and Selection of Cyclones

The objective in designing a cyclone is to produce an overflow from the cyclone that has a certain size distribution, defined as the percentage passing a specified micron size. An empirical relationship shown in Table 25.3.4.2 is used to relate the overflow size distribution to the $D50$ required to produce the specified separation.

Several factors influence classification. Important among them are percentage solids by volume, pressure drop, specific gravity, and viscosity. There are numerous other factors, such as inlet area and vortex finder size, as well; however, these variables are relatively minor and may be neglected for the preliminary sizing and selection.

CORRECTION FACTORS. Correction factors are applied to determine the size of separation or $D50$ (application) a cyclone can achieve:

$$D50\,(\text{application}) = D50(\text{base}) \times C_1 \times C_2 \times C_3 \quad (25.3.4.1)$$

Table 25.3.4.2. Relationship of $D50_c$ to Overflow Size Distribution

Required Overflow Size Distribution (Percent Passing) of Specified Size, μm	Multiplier (To Be Multiplied Times Size, μm)
98.8	0.54
95.0	0.73
90.0	0.91
80.0	1.25
70.0	1.67
60.0	2.08
50.0	2.78

Example: Produce an overflow of 80% passing 149 μm (100 mesh).
Multiplier from Table 1 at 80% passing = 1.25.
Size for application = 149 μm (100 mesh).
$D50_C$ required = 1.25 × 149 = 186 μm for application.
Source: Arterburn, 1982.

where $D50$ (base) is the µm size that a "standard cyclone" can achieve operating under the base conditions (Fig. 25.3.4.6) C_1 is the correction for the influence of cyclone feed concentration (percent solids by volume) (Fig. 25.3.4.7), C_2 is the correction for the influence of pressure drop (Fig. 25.3.4.8), and C_3 is the correction for the influence of specific gravity (Fig. 25.3.4.9).

FLOW RATE. The volume of water that a given cyclone can handle is related to the pressure drop across the cyclone. The relationship between the flow rate and pressure drop for several different sizes of cyclone is shown in Fig. 25.3.4.10.

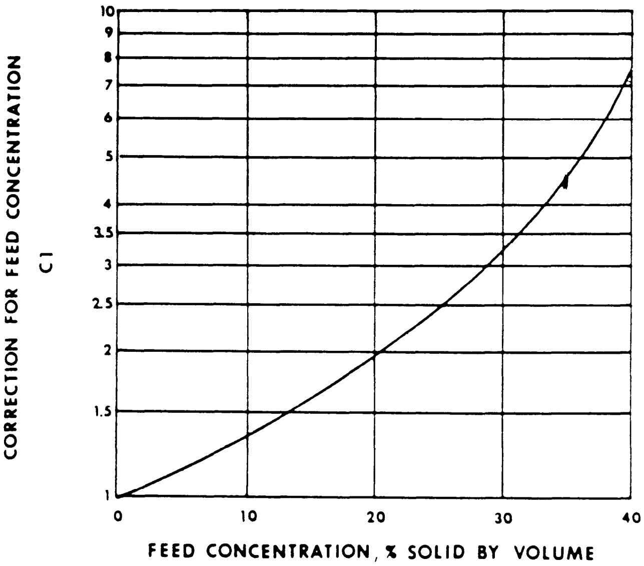

Fig. 25.3.4.7. Influence of feed concentration on separation (Arterburn, 1982).

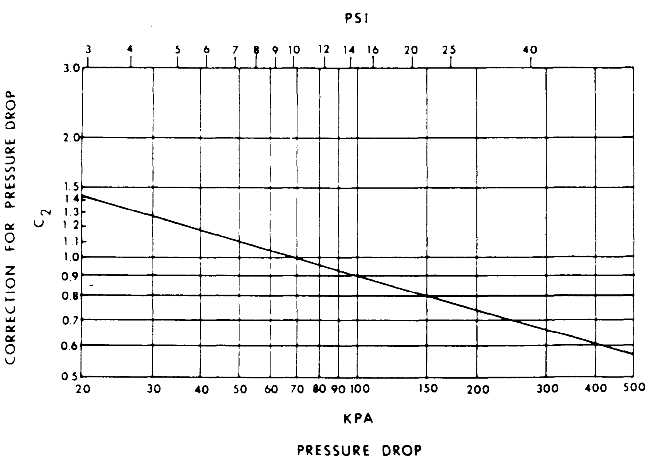

Fig. 25.3.4.8. Influence of pressure drop on separation (Arterburn, 1982).

Some correction is necessary to correct the "water" flow rate for the "slurry" flow rate. However, for preliminary estimates, a correction is not made since the capacity of the cyclone treating a slurry is greater than the one treating water.

The vortex finder size and inlet area of a cyclone also have an effect on the volumetric flow rate that a cyclone can handle. Increasing the vortex finder or inlet areas increases the capacity. Conversely, decreasing the vortex finder or inlet areas decreases the capacity.

25.3.4.4 Cyclone Sizing

Example 25.3.4.1. Select the size and number of cyclones for a rod mill/ball mill circuit where new feed to the rod mill is 200 t/h (220 tph). Both mill discharges join together at the cyclone feed sump and are pumped to the cyclones. The overflow is to be 60% – 74 μm (–200 mesh) at 40% solids by weight. The

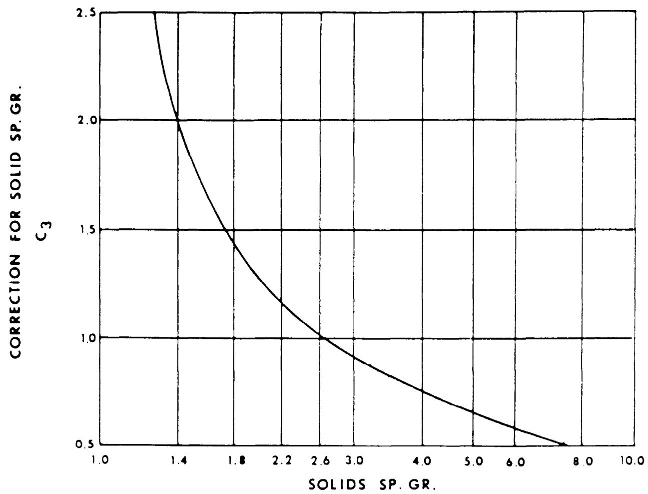

Fig. 25.3.4.9. Influence of solids specific gravity on separation (in. water) (Arterburn, 1982).

underflow becomes ball mill feed. The specific gravity of the solids is 2.9, and the estimated circulating load is 225%.

Solution.

STEP 1. Calculate the material balance from known information.

Overflow:	
Solids	200 t/h (220 tph)
Water	300 t/h (330 tph)
Slurry	500 t/h (550 tph)
Solids by wt.	40%
Sp. Gr. slurry	1.355
Slurry	102 L/s (1624 USGPM)
Underflow:	
Solids	450 t/h (495 tph)
Water	150 t/h (165 tph)
Slurry	600 t/h (660 tph)
Solids by wt	75%
Sp. Gr. slurry	1.966
Slurry	85 L/s (1342 USGPM)
Feed (sum of overflow and underflow):	
Solids	650 t/h (715 tph)
Water	450 t/h (495 tph)
Slurry	1100 t/h (1210 tph)
Solids by wt	59.1%
Sp. Gr. slurry	1.632
Slurrys	187 L/s (2967 USGPM)
Solids by vol	33.2%

STEP 2. Calculate the required $D50$ for the specified overflow of 60% passing 74 μm.

From Table 25.3.4.2, the multiplier at 60% passing 74 μm = 2.08. $D50$ (application) = 74 × 2.08 = 154 μm.

STEP 3. Calculate the cyclone diameter.

From Figs. 25.3.4.7, 25.3.4.8, and 25.3.4.9, obtain C_1, C_2, and C_3, respectively.

C_1, correction for feed density = 4.09

C_2, correction for P = 1.1

(Pressure drop assumed to be 50 kPa (7 psi)

C_3, correction for specific gravity of solids = 0.93

Calculate the cyclone diameter.

$D50$ (application) = $D50(\text{base}) \times C_1 \times C_2 \times C_3$

$154 = D50(\text{base}) \times 4.09 \times 1.1 \times 0.93$

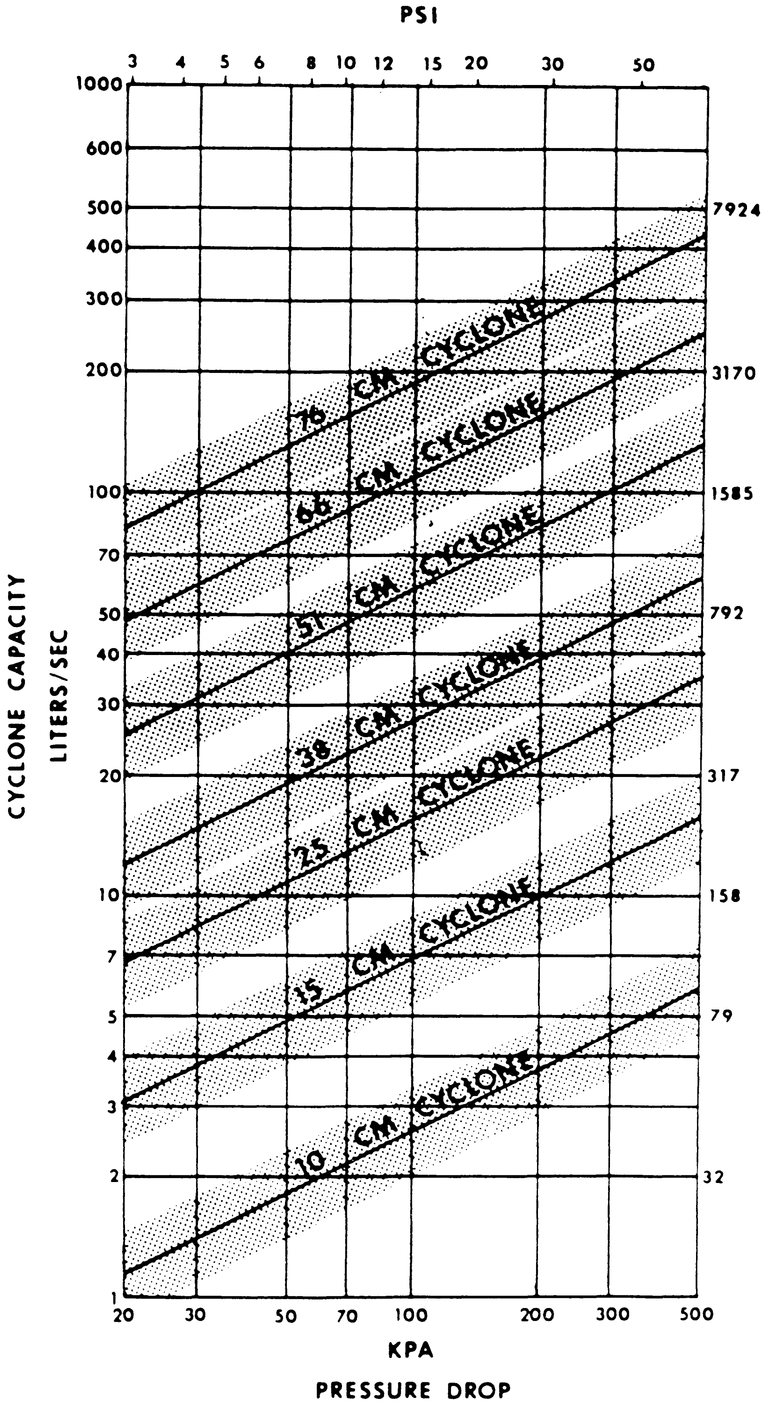

Fig. 25.3.4.10. Water capacity for standard cyclone (Arterburn, 1982).

*D*50 (base) = 37 μm

Referring to Fig. 25.3.4.6, use a 510-mm (20-in.) diameter cyclone.

STEP 4. Calculate the number of cyclones required.

From Fig. 25.3.4.10, using a 510-mm (20-in.) diameter cyclone at 50 kPa (7 psi) pressure:

Flowrate = 40 L/s (634 USGPM)

Total feed flow to the cyclones = 187 L/s (2964 USGPM)

Number of cyclones required = 187 L/s at 40 L/s per cyclone
= 4.7 or 5

STEP 5. Calculate the apex size.

Total underflow = 450 t/h (495 tph)

Underflow per cyclone = 450/5 = 90 t/h (99 tph)

From Fig. 25.3.4.4, use a 94-mm (3.75-in.) diameter apex.

25.3.5 FLOTATION

R.S. Pizarro

Flotation is a physicochemical process for the separation of finely divided solids from one another. Separation of these (dissimilar) discrete solids from each other is effected by the selective attachment of the particle surface to a gas bubble or a liquid, whichever the case may be. The attachment of the particle to either gas or liquid phase is, in most cases, greatly assisted by a modification of the particle surface by surface active (surfactant) chemicals.

The extremely complex environment in which separation takes place is made up of three phases: (1) the liquid phase (generally water), which is chemically and physically very active; (2) the gaseous phase (generally air), which is relatively simple; and the (3) solid phase, which can be considered as infinitely variable. Gas bubbles act as balloons and provide the necessary buoyancy to carry selected minerals to the surface of the three-phase pulp where a stable froth holds the mineral, allowing it to be skimmed off as a concentrate. In the meantime, materials that have not been preferentially attached to air bubbles remain submerged and pass out of the process as a tailing.

It is safe to say that without the development of froth flotation as known today, the mining industry would never have reached its present state of development. Virtually the entire world supply of copper, lead, zinc, nickel, silver, and numerous other metals is first collected from low-grade ores as a flotation froth. Flotation has made it possible to utilize both low-grade and complex ores that would have been worthless had it been necessary to rely on the classical methods of gravity concentration. In a world that calls for ever-increasing tonnages of metals, flotation has made possible the exploitation of hundreds of millions of tons of material that otherwise would not have been economic.

Historically, the earliest attempts at flotation were concentrated on the recovery of copper, lead, and zinc. These were followed in turn by recovery of other metallic minerals including nickel, molybdenum, manganese, chromium, cobalt, and tungsten. Work was pushed on the recovery of nonmetallic or industrial minerals, and today huge tonnages of phosphate and potash are produced for fertilizers and detergents. Industrial minerals such as mica, fluorite, feldspar, beryl, and barite are upgraded by froth flotation. Fine coal, formerly discarded as waste to pollute the countryside, is recovered by flotation. In Saskatchewan, the recovery of potassium chloride (sylvite) from sodium chloride (halite) has had a tremendous impact on the provincial economy. All in all, it has been estimated that at least 100 different minerals are currently being recovered by flotation.

Outside the mining world, flotation has been applied in the chemical, paper, and food processing industries. Some typical applications in these fields are recovery of waste solids from process streams; recovery of silver from photographic solutions and film; removal of oils, fats, greases, and fibers from plant flows; removal of sulfur from rayon spinning baths; recovery of cellulose from pulp mill waste; removal of ink from waste paper; separation of wheat hulls from kernels, and recovery of bitumen from tar sands.

The effect of flotation upon industry is well illustrated by its effects on copper mining. In the face of rapidly increasing costs from 1935 to 1960, annual copper production in the United States increased from 313 to 1116 kt (345,000 to 1,230,000 tons). At the same time, the average grade of ore treated dropped from 1.57 to 0.72% Cu. Today open pit mines are operating profitably with cutoff grades as low as 0.25% Cu.

To gain an understanding of flotation theory and mechanics, it is necessary to study in depth the chemical and physical properties of surfaces as well as to establish the effect that changes in composition of the bulk phases have on the nature of the three interfaces: solid-gas, solid-liquid, and liquid-gas. With but few exceptions, inorganic solids are almost completely wetted by an aqueous phase. Accordingly, in order that flotation be able to proceed, the solid-liquid interface must be partially (and preferably completely) replaced by a solid-gas interface. The replacement of fluid by gas is contrived by the addition of suitable reagents to the aqueous phase, the resultant surface reaction leaving the solid surface with a *hydrophobic* (water repelling) film. Essentially, flotation chemistry is based on reactions at the interfaces that cause water to be displaced in favor of air to which the particle can remain attached, if and when it contacts mobile bubbles.

In order to successfully exploit the differences in surface properties of minerals, they must be ground to approximately 205 µm (65 mesh). Light minerals such as coal are sometimes separated at sizes as coarse as 1650 µm (10 mesh) under relatively quiescent conditions of froth formation. However, it has been noticed that collision, acceleration, and erratic motion all tend to shear large particles from their sites on the bubble walls. At the opposite end of the sizing scale, the surface characteristics of all particles in the pulp tend to become similar. With 3- to 5-µm particles, it is almost impossible at this time to first control and then exploit the surface properties to the degree necessary to differentiate between gangue and valuable mineral. For all practical purposes, one considers flotation limited to sizes between 205 µm (65 mesh) and 37 µm (400 mesh) (Currie, 1973).

25.3.5.1 Froth Flotation—Summary Of Process

In the flotation process, adhesion is obtained between surface coated mineral particles and air bubbles that are rising through a pulp. Enough buoyancy is provided by the bubble to cause the combination to rise and to form a reasonably stable froth that can be removed by skimming. The steps that make up the unit operation of flotation are the following:

1. The ore is ground in water to at least 297 µm (48 mesh).
2. The pulp thus formed is diluted with water to a consistency between 25 and 45% solids by weight.
3. Small quantities of surfactant chemicals are added to the pulp to modify the surfaces of specific minerals.

4. Another reagent specifically chosen to affect the mineral to be recovered by flotation is added. It gives the mineral particle an aerophilic surface (i.e., water repellent).

5. Another reagent is then added that assists in establishing a stable froth at the surface.

6. The chemically treated pulp, in a suitable container, has air introduced either by agitation or by the direct addition of low-pressure air.

7. The mineral-bearing froth that rises to the surface is skimmed off. The impoverished pulp passes on through a series of containers or cells in order to provide both time and opportunity for mineral particles to contact coursing air bubbles and to be recovered in the froth.

In any presentation of flotation theory, it does no harm to emphasize strongly that flotation is a surface phenomenon. An *aerophilic* (or hydrophobic) particle in a flotation system is one that is strongly attracted to an air interface; on the other hand, a *hydrophilic* particle in the same environment tends to stay covered with water. The differential conditions that promote separation of aerophilic particles from hydrophilic ones are surface phenomena. In this chapter, the development of flotation theory is predicated on the outstanding importance of the hydrated envelope surrounding all mineral particles in a pulp. Efforts will be made to establish the forces that attach both physicochemical and air films to the solids in the pulp. Each and every particle has both surface and mass. The chemical envelope applied to the particle develops either the aerophilic or hydrophilic character of the surface. Thus the nature of the underlying matter has, in the final analysis, very little effect on the environment. Literally, we float surfaces, and only incidentally what lies beneath the surface is recovered (Currie, 1973).

25.3.5.2 Particle Surface

It is usual to regard the changes which take place on the surface of a mineral particle in a pulp as resulting from an equilibrium state between hydrated ions (complexes) in solution and the charged surface of the particle. If the polar strength of the water molecule is greater than the attraction binding a mineral ion into its crystal lattice, then the mineral ion will migrate into the aqueous phase. The stronger the water molecule attracts, the wetter the particle surface becomes.

Surface is defined as a two-dimensional unit: length and breadth lacking thickness. However, this is not a descriptive enough picture for the study of surface chemistry. A particle that has been naturally sheared from its main mass, as for instance in a crusher or grinding mill, has exposed on its surface many partial faces of unit cell forms. The atoms of these cells are arranged according to definite patterns, and bonds, which result from the ability of a nucleus to give or receive electrons, are developed in each cell unit. There are three types of recognized primary chemical bonds: covalent, ionic, and metallic. Covalent and ionic bonds are the important forces in the flotation system.

1. *Covalent bonding* is the type of bond that exists between atoms, both of which are electron acceptors. Typical covalent bonds exist when the atoms involved are identical, as when two chlorine atoms come together and pool two electrons to form molecular chlorine. However, covalent bonding does not require bonded atoms to be identical. SO_2 and CO_2 both exhibit covalent bonding.

2. *Ionic bonding* is the type of bond produced when one atom of a pair readily accepts an electron, and the other atom readily parts with one. A transfer of an electron takes place, and a structure that is composed of ions is the result.

Ionic bonding differs from covalent bonding in that any cation will attract any anion and will repel any other cation. This really means that the bonding is not a permanent state that involves two ions; rather, it is an indiscriminate affair between any anion and any cation. Covalent bonding can be thought of as directional while ionic bonding is nondirectional. In a solid state, ionic bonds will bring about the condition of ions of alternating polarity. In the liquid state, the ionic bond does not produce an ordered array of ions, but statistically more cations surround anions than like ions surround each other. A solid or liquid whose bonds are ionic is capable of indefinite expansion in all directions, remembering always that at the solid or liquid surface there exists a force condition unlike that within the body of the substance.

25.3.5.3 Flotation Reagents

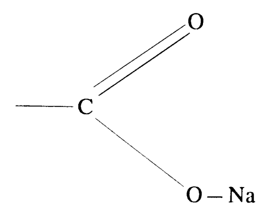
COLLECTORS. *Collectors* are the substances used in flotation to render certain selected minerals water repellent. In practically every case, collectors are organic substances. The minerals are made water repellent by the adsorption of collector ions or molecules on the mineral surface. Under these conditions, the energy level of the hydrated (water-wetted) mineral surface is reduced to a point where the formation of a three-phase contact perimeter is possible when the mineral particle contacts a bubble.

A characteristic of most collectors is a complex molecule lacking symmetry in structure and consisting of two parts that differ in properties—one polar and one nonpolar.

The nonpolar part of the molecule is a hydrocarbon radical that undergoes little or no reaction with water dipoles, and that accordingly has pronounced water repellent properties. This water repellent property is due to the presence in the hydrocarbon radical of only very weak van der Waals forces while the hydrocarbon chain bonding is strong (-C-C).

In contrast to the nonpolar part of the molecule, the polar part can react with water. Compounds which have distinguishable polar and nonpolar parts are called heteropolar. A typical heteropolar molecule is sodium oleate ($C_{17}H_{33}COONa$). The hydrocarbon radical is the nonpolar part and has practically no reactivity with water.

The polar part is



In the adsorption of these collectors on a mineral surface, the nonpolar part is oriented to the water phase and the polar part toward the mineral phase. This orientation is what actually makes the mineral surface water repellent.

Classification of Collectors—Collectors are classified according to their ability to dissociate into ions in an aqueous solution and with regard to the type of ion that produces the water-repellent effect. Where a collector dissociates into an anion and cation, the ion that is the direct cause of the water repellent action is considered as the active ion and the other as non-active. The water-repellent ion structure always includes a hydrocarbon radical, the presence of which ensures that the mineral is water repellent. However, hydrocarbons do not exist in the free state and are unable to attach themselves directly to a mineral surface. Therefore, the repellent ion structure includes a second group of atoms (in addition to the hydrocarbon) to form a link between the hydrocarbon and mineral surface. This linking group is called the solidophil group. Thus a water-repellent collector ion includes a hydrocarbon radical linked to a solidophil group. The

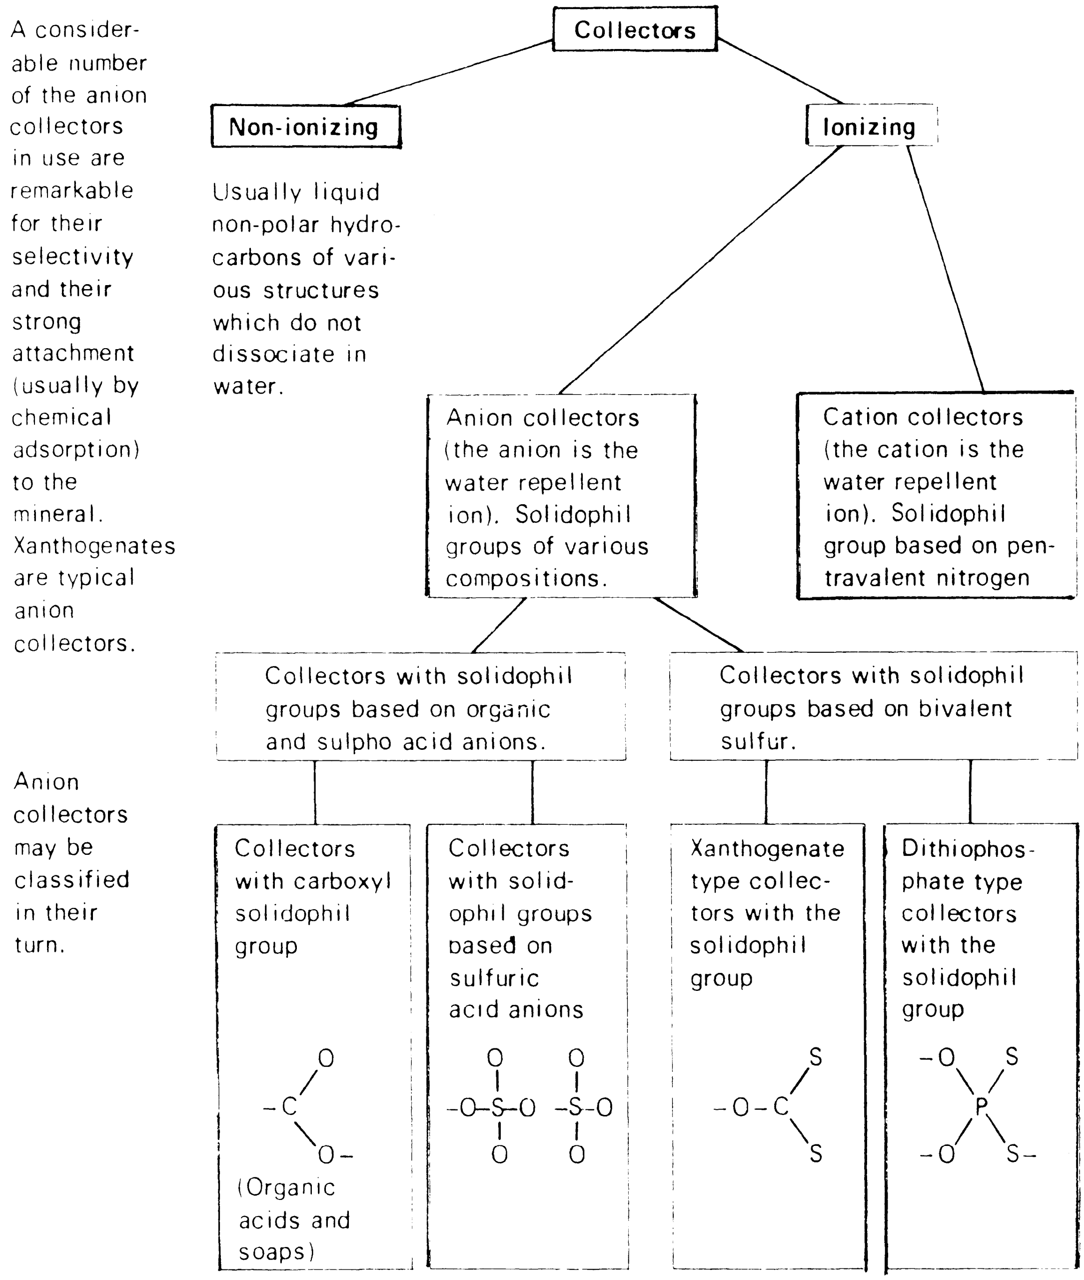


Fig. 25.3.5.1. Classification of flotation collectors (Currie, 1973).
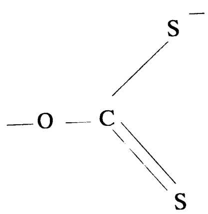
Note: Collectors are classified according to the above with regard to ionic dissociation, anion and cation activity in relation to the mineral surface and solidophil group structure. Anion collectors are, therefore, those in which the anion (negatively charged) renders the mineral water repellent. Cation collectors are those where water repellence is secured by the cation (positively charged).

water-repellent effect is directly associated with the length of the hydrocarbon group, while the solidophil controls both the strength and selectivity of the ion attachment to the mineral surface.

As shown in Fig. 25.3.5.1, collectors can be classified according to ionic dissociation, anionic and cationic activity in relation to the mineral surface, and solidophil group structure. Anion collectors are, therefore, those in which the anion (negatively charged) renders the mineral water repellent. Cation collectors are those where water repellence is secured by the cation (positively charged).

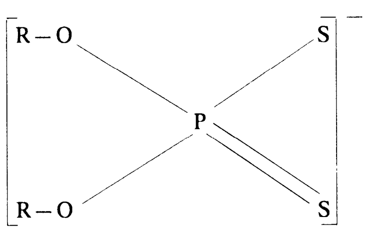
Anion Collectors—Many of the anion collectors in use are noted for their remarkable selectivity and strong attachment (e.g., xanthate). In this type of collector, the solidophil group contains bivalent sulfur. Xanthates are salts of xanthic acid, which in turn is a product of an alcohol and carbon disulfide.

The active anion is 
and the connecting group is



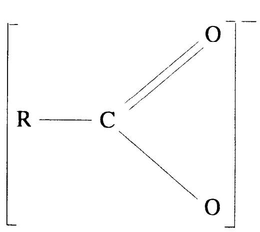
Xanthates are among the most highly selective and effective collectors for sulfide mineral flotation.

Another anion collector with bivalent sulfur in the solidophil is the dithiophosphate group (trade name Aerofloat). Like xanthate, the dithiophosphate collectors are of major importance in sulfide flotation. Dithiophosphates differ from xanthates in that they have pentavalent phosphorous in the solidophil group in place of carbon. The anion is



The cation is either Na or H, and attachment to a sulfide mineral surface is even stronger than with a xanthate.

Anions with a carboxyl solidophil group (e.g., oleic acid, sodium oleate) find application in the flotation of minerals that have the alkali earth metals as cations, that is, Ca, Ba, Mg, and Sr as well as some carbonate, oxide, and sulfate minerals. The anion is

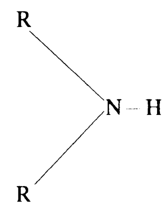


Cation Collectors—The characteristic feature of a cation collector is that the cation is the water-repelling agent, again consisting of a hydrocarbon radical and a solidophil group chemically bonded to it. The principal element in most cation collectors is nitrogen as an amino group. The anions of this type of collector are usually halides that take no active part in the reaction with the mineral.

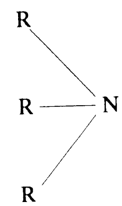
In contrast to anion-type collectors where collector attachment to the mineral is very strong, cation collector attachment is usually weak, and desorption can be made to take place by reducing concentration, that is, by diluting the pulp.

Cation collectors are used principally for flotation of silicates and certain rare metal oxides. As yet, application of this type of collector is limited.

One of the most commonly used cation collectors is the amine group, which is an organic complex derived from NH_4 and NH_3 when hydrogen atoms are replaced by aliphatic, aromatic or heterocyclic radicals. When one atom of hydrogen is replaced, a primary amine is formed with the general formula $R - NH_2$. The replacement of two hydrogen atoms gives



and the replacement of three hydrogen atoms gives



In an aqueous solution, an amine is complexed thus:

$$R - NH_2 + H_2O \rightleftharpoons [RNH_3]^+ + OH^- \qquad (25.3.5.1)$$

When an amine is used to float silica for example, the reactions are believed to be:

$$[SiO_3^-] + [RNH_3]^+ \xrightarrow{\text{ads.}} SiO_3 - NH_3R \qquad (25.3.5.2)$$

The attachment of a collector ion to a mineral surface by adsorption results in a pronounced weakening of the fields of force set up by the surface atoms (or ions) in the crystal lattice of the mineral. The bonds between water dipoles and the mineral surface have been broken and replaced by the more stable and stronger bonds set up by the collector reagent radicals. It is believed that this latter type of bond is more efficient from the aspect of usage of the surface (tension) energy. The requirements of the second law of thermodynamics have been met; namely, an overall decrease in the system free energy and adsorption is accordingly a spontaneous reaction. In these circumstances, the appearance of the water-repellent collector group in the hydrated or double-layer zone at the mineral surface (the water repellent groups having no reaction with water) reduces the stability and thickness of the hydrated layer. With the reduction of the hydrated layer, the development of a three-phase contact perimeter is possible, and an air bubble can attach itself to the mineral. For example, the strength of attachment of lead sulfide particles to an air-water interface in pure H_2O is 9.2 dynes/cm (0.63×10^{-3} lbf/ft) of the attachment line and 59.7 dynes/cm (4.1×10^{-3} lbf/ft) in a 5.5-mg/L (46×10^{-6} lb/gal) solution of potassium ethyl xanthate (Currie, 1973).

FROTHERS. *Frothing agents* are surface active substances, which by concentrating at the air-water interface help to keep air bubbles dispersed and prevent their coalescence. Frothing agents increase the stability of the flotation froth by decreasing the free surface energy of the bubble.

Frother Action—When a mineral particle surface has been made water repellent by the collector, stability of attachment of the particle to the bubble depends on frother efficiency. Frothers are heteropolar surface-active organic substances that can be adsorbed on an air-water interface.

Pure liquids with nonpolar, polar, or heteropolar structures (i.e., water, kerosene, alcohol) do not produce stable froths when agitated with air. The bubbles that are produced break down quickly. However, if a small amount of a heteropolar surface-active substance is added to the water, a fairly stable froth will follow on the introduction of air in dispersed form. When the surface-active molecules react with the water, the water dipoles react with the polar groups and hydrate them; little or no reaction occurs with the nonpolar hydrocarbon grouping. The result is to force the hydrocarbon grouping into the air phase. In effect, adsorption of the frother in the surface layer of the water has taken place, with the nonpolar group being air oriented.

Consider a system in which the heteropolar molecules of a liquid of low surface tension γ in dynes/cm have been more or less evenly dispersed throughout water. If a low-solubility liquid such as pine oil (γ = 27 dynes/cm or 1.8×10^{-3} lbf/ft) has been added, the action will proceed along the following lines. All the molecules continue to move as before, so that from time to time, one of the pine oil molecules reaches the surface. Its condition is considerably different from a molecule of water at the surface. The downward force of attraction of the pine oil is slightly less than one-third of the force exerted on the pine oil by a molecule of water in the same plane; the net result is that the main body of water exerts an outward force against the pine oil. The molecules of pine oil thus find their way to an interface and stay there, resulting in the lowering of the surface tension at the interface with production of foam.

Bubble wall strength is increased by the intense reaction between the polar group of the frother and water dipoles. It requires considerably greater force to destroy these walls by bubble collision than when bubbles come into contact in the absence of a frother. If, for instance, any strong local pressure is exerted on the bubble skin, the distortion in the surface increases the area and hence decreases frother concentration in the surface. This results in a local increase in surface tension with more resistance to collapse (Fig. 25.3.5.2).

Frother Composition and Structure—The most effective frothers include in their composition one of the following polar groups:

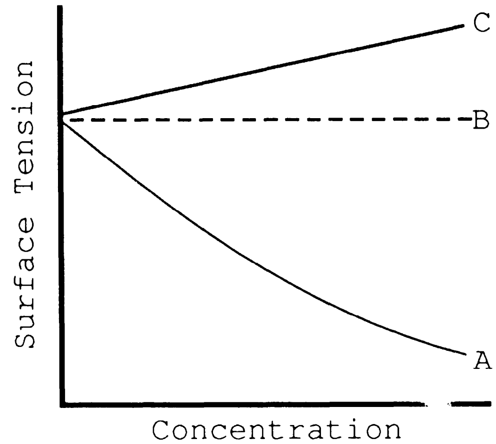
Hydroxil: OH^-

Carboxyl: 
Carbonyl: $=C=O$

Amino: NH_2^-

Sulfo: $—OSO_2\ OH$ or $SO_2\ OH^-$

The hydrophobic group consists of a hydrocarbon chain or a cyclic hydrocarbon radical. The most common frothers are



Legend:
A. Addition of surfactant with frother properties.
B. Pure H_2O γ = 72.75 dyne/cm (5.0×10^{-3} lbf/ft)
C. Addition of inorganic compound (non-frother) - electrolyte

Fig. 25.3.5.2. Changes in surface tension of water with additions of other compounds

those containing the OH group, that is pine oils, $C_{10}H_{17}OH$; cresols, $CH_3C_6H_4OH$; and alcohols such as $CH_{11}OH$. The OH group has strong hydrophilic properties and is only sparingly adsorbed on minerals, thus producing a minimum collecting effect.

Frothers must be soluble to some extent in order to get a uniform distribution and good surface active properties. Solubility will vary from 0.001% up to the 3 to 4% range. As a general rule, the presence of 1 or 2 polar groups in the molecule will give it suitable frothing properties, and an increase in the number of polar groups with the same hydrocarbon radical does not improve frothing. Frother strength is also connected with the structure and length of the nonpolar group. For instance CH_3OH does not form a froth; C_2H_5OH is a weak frother while the frothing properties improve as we go from ethyl to propyl, butyl, and amyl alcohols. To be effective as a frother, a minimum of six carbon atoms is required in the nonpolar group. If the nonpolar group becomes too long, frothing power drops off due to the decrease in solubility. Cetyl alcohol ($C_{16}H_{33}OH$) has no frothing power because of its very low solubility; introducing a sulfo group into a molecule of this alcohol makes it soluble and a very good frother ($C_{16}H_{33} \cdot SO_4H$). Thus a combination of frothers may sometimes be better than any of the individual frothers.

Frothers with a hydroxyl polar group (–OH) alcohol have no collector properties, and for this reason they are preferred over other frothers. Frothers with the carboxyl group (COOH) are both frothers and collectors.

To obtain equivalent froth, it is necessary to add the following amounts of the respective frothing agent per tonne of water:

terpineol	77 g
hexyl alcohol	63 g
heptyl alcohol	42 g
octyl alcohol	25 g

While the most important function of a frother is to form a stable froth which permits removal of a concentrate, frothers have other valuable uses in a flotation circuit. These are

1. Result in the formation of finer bubbles—that is, improve air dispersion in a flotation cell.
2. Prevent coalescence of separate air bubbles.
3. Decrease the rate at which bubbles rise to the surface of the pulp.
4. Affect collector action.
5. Increase bubble wall strength and the stability of the froth formed when mineralized bubbles rise to the surface.

Frother Application—Pine oil is a widely used frother whose frothing power is dependent on its content of terpineol, $C_{10}H_{17}OH$. Once a reliable source of supply is established, changes should be made with caution since it is not always possible to get a product of constant composition from different suppliers.

Cresol or cresylic acid, $CH_3C_6H_4{\cdot}OH$, is produced from coal tar and is a strong frother. It is toxic and burns.

Methylisobutylcarbinol, propylene glycol amyl ester (Dowfrother 250), and other high-molecular-weight alcohols are equally effective compared with pine oil and cresylic acid, and consumption is about 40% of the older style reagents. The synthetic products have a guaranteed composition that makes for ease of control in the plant.

In flotation practice, a variety of froth conditions are encountered that are influenced by the type of frother and collector used, type of ore solids present, mineral slimes, pH of pulp, etc. For instance, in the flotation of sulfide ores, a froth column 50 to 70 mm (2 to 3 in.) deep is usual, and it carries a well-mineralized layer at its surface. This type of froth will allow the removal of its mineral load down to an almost barren froth level, uncolored except for a small quantity of slime. This condition is also met with in nonmetallics, but more likely in nonmetallic flotation is the heavily flocculated oily curd held up by a thick bubble cushion. This type of froth occurs when a fatty acid, used as a collector and frother, causes a drop in froth volume as it is removed.

FLOTATION MODIFIERS. In addition to providing collector adsorption to produce floatability, surface treatment must also control selectivity through preferential adsorption of collector by the mineral to be floated and prevention of its adsorption by other minerals. This is rarely possible by use of collectors alone, since any mineral assemblage will usually contain more than one mineral that responds to a particular collector. Thus thiol collectors for sulfide minerals can develop floatability with all sulfides. Amines used to float silica from hematite ores will also float hematite if the pH is lowered. Similar conditions prevail with most collectors under practical conditions. The only circumstance permitting absolute selectivity is that of a naturally floatable mineral such as molybdenite, which in principle requires only a frother for flotation; in fact, the main problems with molybdenum ores are flotation of coarse middlings and the mechanical carryover of fine gangue. It is evident, therefore, that most flotation systems require additional reagents to control selectivity, with the effect described as depression, and the reagents, depressants.

Depressant—A *depressant* is a reagent that inhibits or prevents absorption of a collector by a mineral and hence prevents its flotation.

Activator—An *activator* is a reagent that enhances or assists adsorption of a collector.

pH Modifier—A *pH modifier* is a reagent that changes the hydrogen ion concentration of the pulp, the purpose being to either increase or decrease the adsorption of collector as may be derived. The following demonstrates how modifying agents function:

1. pH control

Lime	CaO
Soda ash	Na_2CO_3
Caustic soda	NaOH
Acid	H_2SO_4, HCl, HF

2. pH modification

With few exceptions, the effectiveness of all flotation agents depends greatly on the concentration of hydrogen or hydroxil ion in the pulp solution. One of the primary objects of flotation research is to discover the optimum pH for any given combination of reagents and ore. Most flotation plants treating sulfide ores operate with an alkaline pulp to give optimum metallurgy as well as to keep corrosion at a minimum. Very few plants operate in an acid circuit; this is usually only the case when minerals are being floated from the tailing of an acid leach.

The stability of reagent coatings can be described by their solubility products. The less soluble a compound, the less it dissociates into ions. Considering the flotation of galena using either xanthate or aerofloat as a collector and NaOH for pH control, the reactions are

$$PbS + NaOH \rightleftharpoons Pb(OH)_2 + 2Na^+ + S^= \qquad (25.3.5.3)$$

$$Pb(OH)_2 + (C_2H_5OS_2)^- \rightleftharpoons$$
$$Pb(OH) \cdot C_2H_5OCS_2 + OH \text{ (adsorbed)} \qquad (25.3.5.4)$$

Alkalinity is most commonly regulated with CaO and Na_2CO_3. NaOH can also be used but is more expensive. On account of its availability and low cost, lime is used in all circuits where the calcium ion is not objectionable, including most zinc and copper circuits. Some minerals, notably pyrite and galena have a tendency to adsorb calcium ions in preference to a collector and are thus not so easily floated in a lime pulp. This difficulty is eliminated by the use of soda ash which precipitates naturally occurring calcium ions as well as producing the necessary alkalinity.

Cationic Agents—Although most metal ions can be considered as resurfacing agents, there are only a few in common use. Copper ion is used in the flotation of sphalerite, which normally does not adsorb xanthate to any extent. The copper ion is added to the pulp as $CuSO_4$; copper ion replaces zinc ion in the mineral lattice, forming a CuS film on the sphalerite. The sphalerite then behaves as a copper mineral on which xanthate can be adsorbed and the mineral floated.

The electromotive series of metals can be used to determine the suitability of any metal as an active agent for any other particular metal. Any metal in the series will displace from solution those metals appearing below it. Copper ions would thus be suitable for activating nickel, cobalt, iron, and zinc sulfides before the addition of xanthate collector. Calcium is the most common reagent added to resurface pyrite and other ion minerals to depress them (render them completely wettable) in the presence of xanthate. Calcium and barium ions are used to resurface silica and other acidic minerals to make them floatable with fatty acid type collectors (activation).

Anionic Agents—The principal anion-active resurfacing agents include sulfides, cyanides, carbonates, and phosphates as well as certain oxidizing and reducing agents. The control of surface oxidation with heat causes considerable variation in flotation selectivity.

Oxidizing agents such as sodium hypochlorite (NaOCl) and potassium permanganate ($KMnO_4$) are effective as depressants for Cu, Fe, and Co sulfides in lime pulps. As an example, the separation of copper and molybdenum sulfides can be carried out by depressing the copper sulfide with sodium hypochlorite.

Reducing agents are also of real importance in flotation. In the flotation of galena, sodium sulfite (Na_2SO_3) or sodium bisulfite ($NaHSO_3$) is used to control excess oxidation. These compounds are particularly effective on ores containing copper minerals. Without a reducing agent, the copper mineral during grinding tends to oxidize, becoming more soluble. The resultant copper (and/or lead) ion may then activate the sphalerite, causing it to float in the lead concentrate. The addition of the reducing agent Na_2SO_3 prevents the oxidation and the resultant activation of sphalerite.

Sodium sulfide (Na_2S) is used to resurface cerussite ($PbCO_3$), cuprite (Cu_2O), azurite ($2CuCO_3 \cdot Cu(OH)_2$), and other oxide minerals, with a sulfide, to make them floatable (activated) with xanthate collectors. In small amounts, sodium sulfide may be used to reactivate pyrite, pyrrhotite, and other sulfides that have been depressed by lime or cyanide; however, the sulfide ion used in excess will depress all sulfide minerals.

Cyanides, usually added as sodium cyanide, are used for the resurfacing and depression of iron, copper, and zinc sulfide minerals. The ions of these metals form very stable complex compounds with cyanide. It has been observed that minerals with metallic ions that do not form such compounds with cyanide (e.g., Pb, Bi, Sn, Sb, and As) are not depressed by cyanide. The greater the solubility of a metal xanthate in cyanide, the less stable is the attachment of the collector to the corresponding mineral surface. The reactions are thought to be

$$ZnS \rightleftharpoons Zn^{++} + S^{=} \tag{25.3.5.5}$$

$$Zn^{++} + 2CN^{-} \rightleftharpoons Zn(CN)_2 \tag{25.3.5.6}$$

$$Zn(CN)_2 + 2CN^{-} \rightleftharpoons Zn(CN)_4^{=} \tag{25.3.5.7}$$

The $Zn(CN)_4$= radical then forms the insoluble complex with other cations, thus preventing collector adsorption. The same reactions occur with Fe and Cu, with the requirement of high CN^- concentrations in the case of Cu to achieve the desired result.

Another way to prevent activation of a mineral such as sphalerite is to add a salt of the ion that becomes displaced during activation (e.g., Zn^{++}). For instance, we could write for activation,

$$ZnS \overset{Zn^{++}}{} + Cu^{++} \rightleftharpoons ZnS \overset{Cu^{++}}{} + Zn^{++} \tag{25.3.5.8}$$

If we increase the concentration of the Zn^{++} in the solution by introducing, say, $ZnSO_4$, we can cause the above reaction to reverse and thus prevent activation.

The action of other depressants such as Na_2SO_3, $Na_2S_2O_3$, and NH_4OH is similar to the depressive action of cyanide as described above.

The depressive effect of $K_2Cr_2O_7$ and K_2CrO_4 is regarded as due to adsorption of CrO_4= anions on the surfaces of galena and pyrite in a type of chemical absorption.

25.3.5.4 Flotation Machines

CURRENT MODELS. Flotation machines now in use can be divided into four classes.

Mechanical—The most common type is characterized by a mechanically driven impeller that agitates the pulp and disperses air into it. Each impeller produces nearly ideal mixing in its vessel. It is normal to have a number of impellers in series. Within this class, there are two subdivisions:

1. Pulp flow. "Cell-to-cell" machines have weirs between each impeller; "open-flow" machines do not.

2. Aeration. "Supercharged" machines receive air from a blower; "self aerating" machines use the vortex created by the impeller to induce air.

Pneumatic—Machines in this class have no impeller and rely upon compressed air to agitate and/or aerate the pulp.

Froth Separators—In these, the incoming feed is introduced from above, onto the froth bed, and not into the pulp zone.

Column—The essential feature of column machines is a countercurrent flow of air bubbles and slurry, or of pulp and wash water.

A few machines do not fall neatly into any of these classes.

Mechanical and pneumatic machines have been in use for several decades whereas froth separators and columns are both some 20 years old. The mechanical machines have dominated the industry for many years, particularly in the West. Pneumatic types are now rarely seen, and froth separators have yet to gain wide acceptance. However, column flotation is gaining popularity based on its low capital and operating costs, particularly in copper-cleaning flotation circuits.

The dominance of mechanical machines is more a question of commercial realities than of design excellence. Major western manufacturers make only this type, and most flotation engineers are familiar with no other. The alternative designs are sold into limited geographical and/or commodity areas and encounter resistance elsewhere because of the lack of reference installations. No one wishes to be the buyer of a potentially disastrous machine. This conservatism is reinforced by an incomplete understanding of the mechanisms of flotation and a very slow rate of product development.

DESIGN DEVELOPMENTS—MECHANICAL MACHINES. A very comprehensive review of flotation machines was produced by Harris (1976). Designs created since Harris wrote, of which there are many, are here designated as "new". These and some of the more interesting older designs still available are described below, while small machines of semi-industrial or pilot plant size are, in general, excluded.

In recent years, new machines have been developed and many older designs modified. New designs are intended to have a specific technical advantage (better air dispersion, better flotation of fine particles, reduced reagent consumption, etc.), while most of the modifications to existing machines are intended to reduce overall costs, use new materials, or rectify a design defect.

Cost reduction is achieved in several ways:

1. Larger machines. As machine size increases, plant capital costs are reduced because machine weight and building volume are reduced. There are fewer banks of cells and mechanisms that imply lower costs for electricals, reagent feeding, process controls, pumps and piping, etc. Operating costs are reduced because of lower power consumption, reduced maintenance and operating labor, reduced total cost of wear parts, etc.

2. Mechanical redesign. Modern machines are generally simpler, easier to maintain, and cheaper to manufacture (in real terms) than their predecessors.

Modern materials such as cast and sprayed polyurethanes, abrasion resistant plate, ceramics, and troweling compounds can give enhanced protection against abrasion, corrosion, and the action of flotation reagents.

The first mechanical machines were of the "cell-to-cell" type. They were complicated in comparison with designs such as the Forrester pneumatic machine, and this led to the introduction of the "open-flow" concept. Over a period of some 30 years, these two types were cautiously developed to a unit capacity of about 2.8 m^3 (100 ft^3). At this point, the open-flow machines were in the ascendancy, for several reasons:

1. Simpler, cheaper construction.
2. Simpler maintenance.
3. Better suspension of coarse solids.
4. Higher unit capacity.

However, cell-to-cell machines were particularly useful in small plants and multi-stage cleaner floats (such as fluorspar) where the pumping action of the impellers permitted the transfer of intermediate flows without external pumps. A period of relatively rapid development then occurred in which open-flow machines were introduced up to 14 m^3 (500 ft^3) while conventional cell-to-cell machines developed more slowly to 5.67 m^3 (200 ft^3) and, eventually, also to 14 m^3 (500 ft^3). The most important application of these large cell-to-cell machines was in fine-coal cleaning where the users reported a significant improvement of selectivity over open-flow designs. More recently, open-flow machines have become available in sizes up to 42.5 m^3 (1500 ft^3).

Concurrent with this expansion of the more conventional mechanical units, the Maxwell cell was introduced in sizes up to 57 m^3 (2000 ft^3).

MECHANICAL CELL MANUFACTURERS. Aker Trondelag A/S is a well-established heavy engineering firm in Trondheim, Norway. The Aker flotation machine is a relatively new design developed in 1977–78. Initial sales were confined to the domestic market where the machine was well received; it has now become available elsewhere. Aker machines up to 40 m^3 (1412 ft^3) are now in use treating a variety of sulfide ores, upgrading iron ore, and separating quartz from feldspar. They are in use as roughers, scavengers, and cleaners.

The original design criteria for the Aker flotation machine were a high air-dispersion capacity, good solids suspension, and a quiescent pulp surface; these appear to have been achieved. The machine is said to be easy to maintain.

Booth Co. of Salt Lake City, UT, makes a flotation machine that is probably little known outside the western US and Peru where it is in use principally in rougher flotation. This machine is self-aerating and has a relatively shallow tank and an aerating impeller not far below the pulp surface. To promote pulp agitation, an axial flow propeller is mounted some distance lower on the impeller shaft. The tank is a truncated rectangular form with no interior baffles and a vertical plate between each impeller to restrict the pulp flow to the base of the tank.

The specific airflow through the pulp (based upon the manufacturer's figures) is noticeably higher than for any other machine, but is paid for by a high power consumption. In the event that the rate of flotation is more rapid in the Booth machine than in other designs, the higher power cost may be justified. Unlike all other machines, this airflow is unregulated.

Denver Equipment Division, Joy Industrial Equipment Co., of Colorado Springs, CO, sells a range of single mechanism D-R cells (redesigned since the Harris review) ranging from 2.8 m^3 (100 ft^3) to 36.1 m^3 (1275 ft^3). In addition, special purpose coal flotation machines up to 14.2 m^3 (500 ft^3) are available that use smaller impellers than their mineral counterparts or lower impeller speed. The company no longer manufactures double-mechanism machines.

The Denver D-R machine is used for a wide range of commodities, and for roughing, scavenging and cleaning operations. The coal machine, with its smaller impeller and lower power consumption, was developed to handle the lower-density pulps typical of the industry.

Galigher Co. of Salt Lake City, UT, has redesigned the large Agitair machines, added larger units, and stopped producing multiple-spindle machines. The new range of Agitair cells extends from 5.7 m^3 (200 ft^3) to 42.5 m^3 (1500 ft^3) and includes coal flotation machines from 8.5 m^3 (300 ft^3) to 28.3 m^3 (1000 ft^3) that use impellers from the next smallest mineral flotation machine.

The original Agitair stabilizer occupied all the outer areas of the tank. A circular stabilizer was developed, much like the stabilizer used in the Aker and OK machines, and this stabilizer is incorporated in the new designs.

The new tanks are somewhat deeper than their predecessors, having a modified truncated rectangular form and featuring a "double break" to prevent sanding. The tanks are also baffled to reduce excessive turbulence at the froth lip and have a vertical division plate between cells that constrains the pulp flow to the impeller region.

The drive head assembly has been redesigned to facilitate easy adjustment of the impeller-to-stabilizer clearance and for easier maintenance. The largest machine incorporates a shaft-mounted reducer to enable a high-speed motor and small V-belt sheave to be used.

Like the Denver D-R, the Agitair machine has enjoyed wide acceptance over the whole spectrum of commodities and cell functions.

Units made by Wemco of Sacramento, CA, have been extensively used in the flotation of copper sulfides in the rougher circuits. Larger and more efficient cells of 42 m^3 (1500 ft^3) and more recently of 85 m^3 (3000 ft^3) have met with good acceptance in the industry. Some of the features of these machines are

1. Self-induced air supply.
2. Aeration mechanism located well above the tank bottom.
3. High slurry circulation.
4. Large design clearances.

Wemco cells are equipped with the one + one rotor-dispenser design that produces a large dispersion of fine air bubbles for maximum recoveries. The large clearances between the rotor and dispenser eliminate the erosive action that prematurely wears the impeller/diffusers. The machine is simple, sturdy, and easy to operate.

Outokumpu Oy of Espoo, Finland, is a state-owned mining organization well known for its sophisticated products. When Harris wrote his paper, the OK flotation machine was available in only two sizes (nos. 3 and 16). The range has now been increased and extends up to 50 m^3 (1500 ft^3).

The OK impeller is a radical departure from the flat turbine form that is most commonly used by other manufacturers. It suggests a half grapefruit and consists of a number of narrow vertical slots communicating with the air passage in the hollow shaft. The slots taper downwards, and the top of the impeller is closed by a horizontal disk. As the impeller rotates, pulp is accelerated in the slots and expelled near the point of maximum diameter; this pulp flow is replaced by fresh pulp which enters the slots near their base where the diameter and peripheral speed are less. Thus the impeller acts rather as a pump drawing in pulp at the base of the cell and expelling it upwards. Air is blown down the shaft and is mixed into the pulp flow by the pumping action. The impeller is surrounded by a simple circular stator, similar to that used in the Aker machine. The OK impeller tapers downwards and does not become sanded in during a shut down; it can be restarted under load.

The tanks up to 8 m^3 (280 ft^3) are rectangular, with baffles. The 38-m^3 (1340-ft^3) tank is U shaped, and the 16-m^3 (560-ft^3) tank is now available in either form. The U shape gives a lighter, cheaper construction, and must also contribute very substantially to the hydrodynamic performance of the mechanism.

The OK machine is used widely in the flotation of sulfides, and in the processing of precious metals ores, iron ore, clays, tin, and tungsten ores. It is used in hydrometallurgical plants as a gas dispersion agitator.

The Sala BFP flotation machines formerly made by Sala International AB of Sala, Sweden, have now been replaced by the AS series. Harris included data on three members of the latter, the AS2-6, AS2-8, and AS4-13 of 6-, 8- and 13-m^3 (210-, 280-, and 460-ft^3) capacity, respectively. The AS4-13 has now been deleted and the series has been extended considerably. AS2 machines have two impellers, while AS4 designates four.

The Sala AS series is noticeably different from its competitors, the differences stemming from the design principles adopted. Whereas most manufacturers seek to achieve ideal mixing, with vertical flows to promote solids suspension, the Sala design aims to minimize vertical circulation. It is believed by the designers that the naturally occurring stratification in the pulp is beneficial to the flotation process. To this end, the impeller is positioned just below a horizontal hood that extends out to, and supports, the stabilizer. All slurry flow into the impeller is from below.

The impeller is a flat disc, with vertical, radial blades on both surfaces; the disc edge is cut back behind the trailing edge of the blades. The upper blades expel air that is blown down a standpipe, and the lower blades expel slurry from the central base area of the tank.

The impeller design is claimed to give two important advantages. Firstly, it disburses the air into very closely sized, fine bubbles that are correctly sized for the flotation process, particularly for fine particles. Secondly, because the air dispersion and pulp circulation functions are performed by the two impeller surfaces, they are independent.

The Sala machines are used to process a wide range of mineral commodities: base metals, iron ores, coal, and industrial minerals.

Figs. 25.3.5.3 and 25.3.5.4 show schematically the main features of the different cells described.

COLUMN FLOTATION. A significant development in flotation over the past few years has been the increasing industrial use of flotation columns, primarily in Canada. The column differs dramatically from conventional mechanical flotation machines both in design and operating philosophy, which has been a principal reason for its slow acceptance by the mineral industry. The concept was developed in the 1960s (Wheeler, 1966; Boutin and Wheeler, 1967), and since then, plant and laboratory columns have been marketed commercially by Column Flotation Company of Canada, Ltd. In 1980–81 at Mines Gaspe, Canada, three columns replaced 13 conventional cleaners in a molybdenum upgrading circuit, with superior results (Coffin and Miszcdak, 1982). Since then many of the copper/molybdenum producers in British Columbia have installed columns for molybdenum cleaning, including Gibraltar, Lornex, Highmont, and Island Cooper. There now appears to be widespread interest in flotation columns.

The column is particularly attractive for applications involving multiple cleaning stages and can upgrade in a single stage compared with several stages of mechanical cells. This results in simpler, more controllable circuits. Importantly, the column itself is well suited to computer control.

Description—A flotation column resembles a counter-current bubble column. It is typically 10 to 13 m (35 to 45 ft) high and 0.5 to 2 m (2 to 7 ft) in diameter (either circular or square in cross section). A schematic diagram is shown in Fig. 25.3.5.5, with the flow of solids and water illustrated in Fig. 25.3.5.6. Reagent-conditioned feed enters the column 2 to 3 m (7 to 10 ft) from the top and flows downward against a rising swarm of gas bubbles. Tailings are withdrawn at the column bottom. The feed and tailings flow rates are measured, and the tailings flow is controlled at a rate slightly greater (1 to 15%) than that of the feed; this is called a positive bias. The bias is provided by washwater added from a distribution of pipes located just below the lip of the column, beneath the top of the froth. Fig. 25.3.5.6 shows that part of the washwater travels down the column and part exits with the concentrate. No feed water should exit with the concentrate. Gas enters the column at the bottom through a distribution of rubber or cloth spargers. There is no mechanical agitation.

Three zones of differing rheology can be identified (Fig. 25.3.5.5). Zone 1 is the particle collection zone, a three-phase counter-current bubble column, with gas bubbles 10 to 40 mm (0.4 to 1.6 in.) in diameter, superficial gas velocity v_g up to 50 mm/s (1.0 fpm) and superficial slurry velocity v_l of 5 to 20 mm/s (0.1 to 0.4 fpm). Zone 2 is the cleaning zone, a deep (1 to 2 m, or 3 to 6 ft) packed bubble bed generated by the downward flow of washwater; washwater superficial velocity v_w is 5 to 10 mm/s (0.1 to 0.2 fpm). The interface between zones 1 and 2 is very distinct. Zone 3 is a conventional froth, extending tens of millimeters (a few inches) above the wash water pipes. Its sole purpose is to act as a medium for the transport of collected solids over the lip of the column.

The objective of wash water addition and operation with a positive bias is to prevent feed water, and therefore gangue particles, from reaching the concentrate. Liquid tracer tests at Mines Gaspe (Dobby and Finch, 1985) showed that less than 1% of the feed water reports to the concentrate. The column virtually eliminates the recovery of hydrophilic gangue particles, in contrast to conventional flotation machines where recovery by physical entrainment is inevitable (Trahar, 1981). The unique cleaning action of a flotation column is largely responsible for its ability to upgrade a fine-sized concentrate in a single step.

Column Design—At Gibraltar, columns are made of readily available pipe; the launders of the smaller-diameter columns are also made of pipe. It is important that the columns are vertical to avoid channeling.

Wash water is added through an array of perforated steel pipes. The water should be added at minimum pressure, to give a sprinkle rather than a spray. Launder spray water is also used; a nozzle delivering a fan-spray was necessary to break the froth.

The air spargers are a series of 25- to 50-mm (1- to 2-in.) diameter pipes, perforated and covered with filter cloth. These cloths last from about two months (in high-hardness water) to ten months. There is some evidence that the cloth gives large-diameter bubbles (3 mm or 0.1 in.), and alternative materials are being examined. A back-up set of spargers can be included, to be switched on when a rupture in the running set is detected. Replacement of spargers will mean a column shut-down; a running spare column may, therefore, be worth considering.

The only troublesome area has been the tail port, which is prone to high wear at the control valve. The control valve is critical; it is the only moving part of the column, and its performance is crucial in controlling smoothly the small changes in flow rate demanded to meet the bias set-point. At times, the flow rate can be low enough to sand the tails line; consequently, pipe sizes should be designed for flow velocities well above the critical.

The original tail port design, a butterfly valve in the line to a pump box, was abandoned in favor of connecting the pump directly to the column and using an in-line dart valve (Fig. 25.3.5.7). The dart and dart seat are made of silicon carbide ceramic. At the time of writing, this has not been replaced for seven months; in comparison, neoprene lasted 10 days.

This final design has been quite successful. A dart with little taper gives a smooth response to instrument control. The taper is, however, critical and must be determined for each application. Advantages of the system are that the pump uses some of the

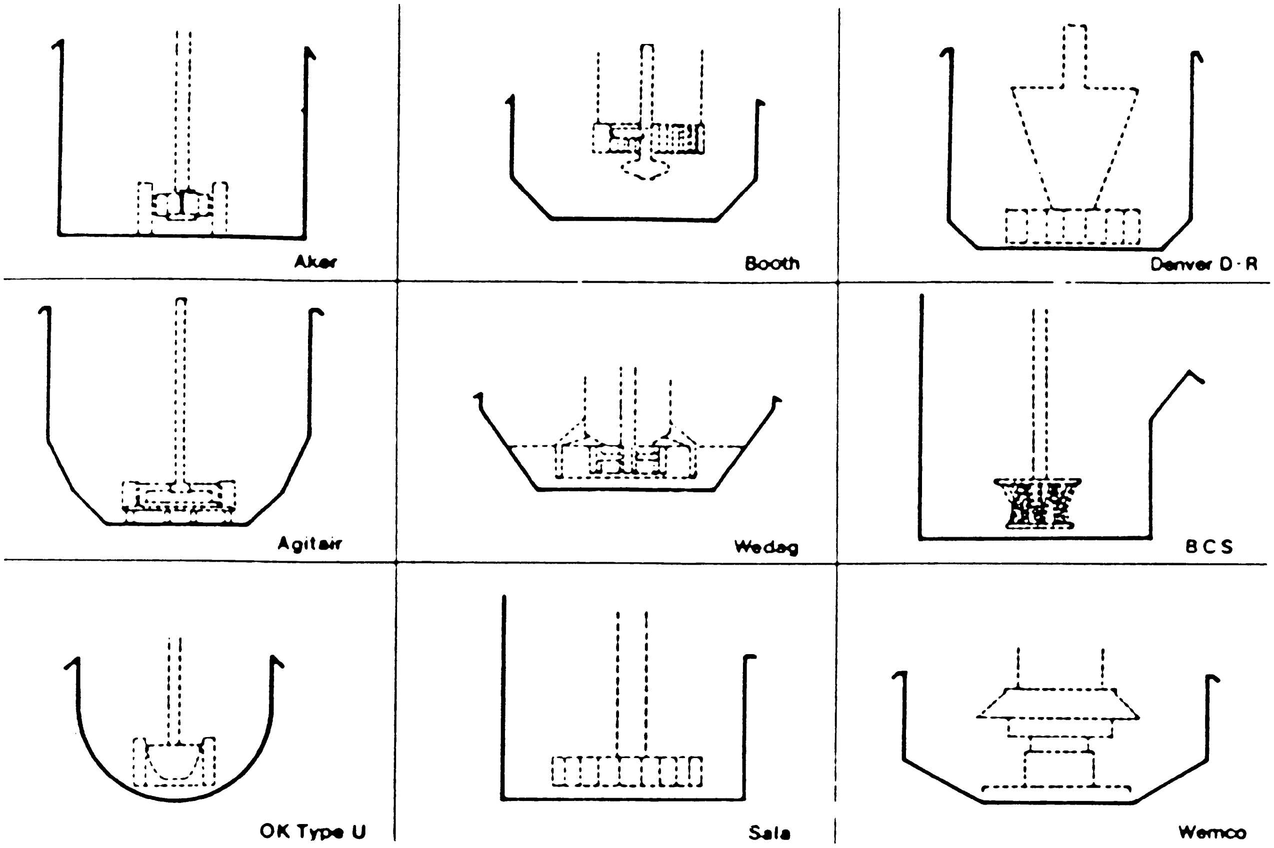


Fig. 25.3.5.3. Cell tank profiles of open-flow machines (Young, 1982).

column's static head, no spillages occur, and the flowmeter always operates under flooded conditions.

Column Operation— 1. *Axial Mixing in Collection Zone.* The collection zone is where particle recovery occurs. Therefore, mixing has a profound influence on recovery.

Residence time distribution studies, both solid and liquid, were conducted at Mines Gaspe on 0.5- and 1.0-m (18- and 36-in.) columns. The data were modeled by a plug flow dispersion model (Dobby and Finch, 1985), and two mixing parameters were extracted: (1) the mean residence time; and (2) the vessel dispersion number, $N = D/uL$, where u is particle velocity (liquid velocity plus relative particle settling velocity), L is length of the collection zone, and D is the axial dispersion coefficient. D was related to d, the column diameter in m (ft), as follows:

$$D = 0.063\, d \tag{25.3.5.9}$$

The vessel dispersion number and mean residence time can, therefore, be estimated for a given column size. When combined with a suitable flotation model (e.g., first-order with fast- and slow-floating fractions), the capacity/recovery relationship of the column can be predicted.

2. *Wash Water.* With respect to column control, the wash water has three functions: (1) to supply the make-up bias (which provides the cleaning action; (2) to maintain pulp level (i.e., zone 1, zone 2 interface location); and (3) to achieve the required water content in zone 3 to permit unhindered overflow of concentrate.

The bias must be positive ($Q_T/Q_F > 1$). The bias is controlled at a set point; commonly, Q_T/Q_F is 1.01 to 1.15. The minimum bias is desirable to minimize wash water demand and maximize residence time and, therefore, recovery. Concentrate grade does not seem to deteriorate at low bias, but close control is required.

The overflow must have a minimum water content for the solids to freely overflow, otherwise recovery drops. Overflow (i.e., concentrate) solids flowrate can be correlated with concentrate percentage solids. Since concentrate grade does not vary greatly, concentrate solids flow rate can be calculated for a given combination of solids feed rate, feed grade, and desired recovery (e.g., 98%). This is exploited in controlling column recovery.

3. *Gas Rate.* An attempt has been made to distinguish between the role of gas rate in the collection zone and that in the cleaning zone. A laboratory column 50 mm (2 in.) in diameter was modified to study the collection zone only. Mass recovery of a sample of final copper concentrate at Gibraltar was measured as a function of gas rate v_g. Fig. 25.3.5.8 shows that recovery (and therefore, the collection rate constant, k) reaches a plateau around 17 to 25 mm/s (0.3 to 0.5 fpm). This effect can be understood from the dependence of k on v_g, bubble diameter d_b, and bubble collection efficiency E_k, namely:

$$k \propto \frac{v_g\, E_k}{d_b} \tag{25.3.5.10}$$

Fig. 25.3.5.8 shows that, in contrast, the plant typically operates in the range of 25 to 40 mm/s (0.5 to 0.8 fpm). This may in part reflect coarser bubbles (with lower E_k) in the plant, but the suggestion is that extra air is required to carry material through the cleaning zone.

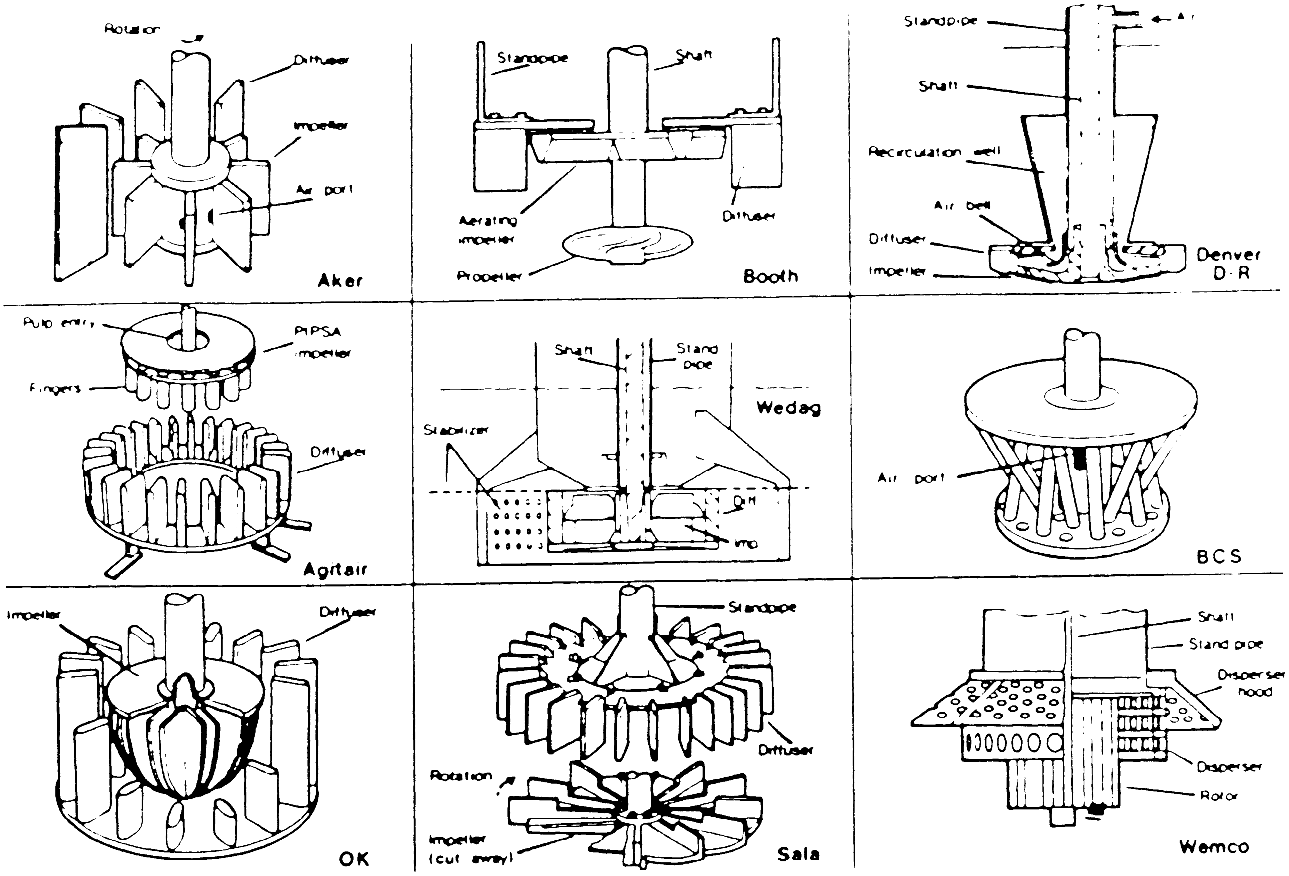

Fig. 25.3.5.4. Impeller mechanism details of open-flow machines (Young, 1982).

4. *Gas Holdup.* Mines Gaspe reported that recovery could be correlated with gas rate (Coffin and Miszcdak, 1982); this was not found at Gibraltar. This may be because bubble size is also a factor; a change in frother would change bubble size and alter the dependence of recovery on gas rate.

A measure, which includes both gas rate and bubble size, is the gas holdup, the fraction of air in the air/slurry mixture. Holdup varies directly with gas rate and inversely with bubble size (smaller bubbles rise more slowly giving longer retention time and increased holdup).

The maximum holdup is about 20 to 24%. Above this, solids start to accumulate in the column and eventually exit to tailings. This condition is identified by rapid changes in holdup (2 to 4%/min). This phenomenon is probably related to the transition from a homogeneous bubbling regime to a churning regime (Shah et al., 1982).

Instrumentation and Control—Manual control of a column is not feasible, instrumentation and some degree of automatic control is a necessity.

The control configuration under test at Gibraltar is shown in Fig. 25.3.5.6. There are three control loops: bias control, level control, and the wash water/gas holdup interaction.

Experience has shown that the bias and level control loops are the minimum requirement for stable operation of the column. The last loop is designed to control column performance. In comparison to conventional cells, the goal of performance control seems more attainable.

25.3.5.5 Concentrator Flotation Circuits—Commercial Applications to Copper Ores: San Manuel Concentrator

The San Manuel plant came into production in 1955 as a state-of-the-art, 36,000-t/d (40,000-tpd) operation. After crushing at mine and mill-site facilities, 13 grinding sections prepare the ore for flotation. Each grinding section has an open-circuited rod mill, whose product is sumped and pumped to cyclones that operate in closed circuit with two downstream ball mills. The feed to the grinding circuit has a Bond work index of 14 kWh/ton.

The ball mill cyclones overflow a 28%-solids pulp at 8% + 65 mesh and 58% − 200 mesh. Bulk Cu-Mo flotation roughers are arranged in eight lines, each of which produces a concentrate that grades 9 to 12% copper and a finished tailing.

The rougher concentrate combines with regrind mill discharge, and the pulp is pumped to regrind cyclones, which overflow a pulp for two-stage cleaning and underflow a spigot product for regrinding. The bulk cleaner concentrate is typically 76 to 78% –325 mesh and assays about 29.5% Cu and 1% Mo. This bulk Cu-Mo concentrate is thickened and conditioned with sodium cyanide and sodium hydrosulfide for flotation of molybdenite from the copper sulfides.

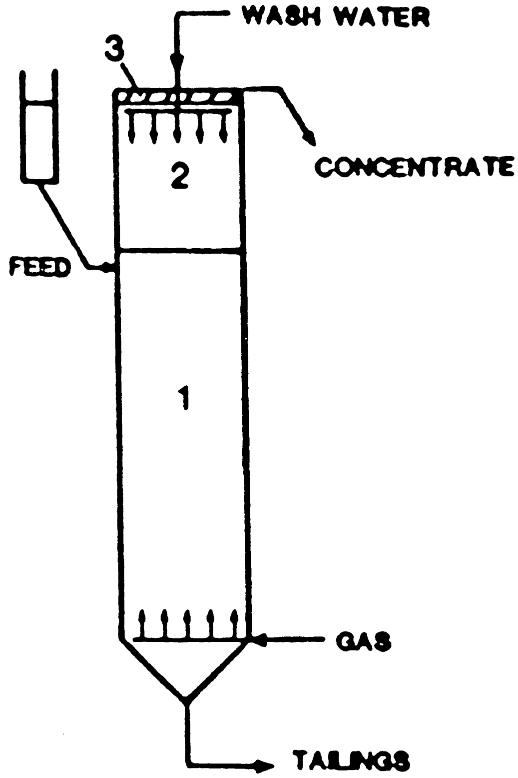

Fig. 25.3.5.5. Schematic illustration of flotation column. 1) Collection zone; 2) cleaning zone; 3) thin froth layer (Dobby, Amelunxen and Finch, 1985).

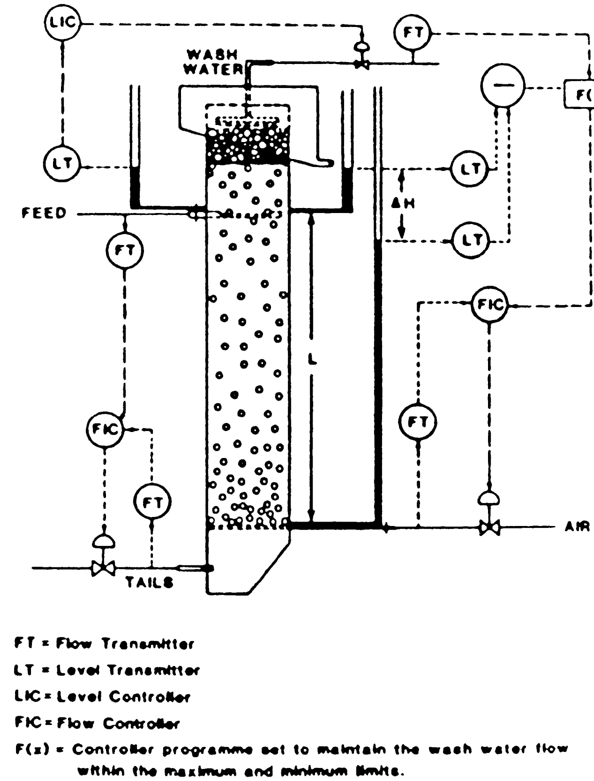

Fig. 25.3.5.6. Schematic diagram of column flotation unit showing flows of solids and water, plus control circuit loops (Dobby, Amelunxen and Finch, 1985).

Rougher flotation consists of five identical sections having a total of 780 Galigher 1.1-m^3 (40-ft^3) cells. The Galighers are belt driven, with one 11.2 kW (15 hp) motor for every two cells.

The 780 Galigher cells in rougher sections one through five are being replaced by 10 Maxwell 56.6-m^3 (2000-ft^3) cells and 80 Wemco 8.5-m^3 (300-ft^3) machines. Included in this project is the installation of on-line X-ray analytical equipment and mass-flow rougher control.

Downstream from the eight parallel flotation sections, eight ball mills, each functioning in closed circuit with cyclones, regrind the rougher concentrate to 76 to 78% –325 mesh. The reground concentrate is cleaned in two stages.

The original cleaner circuits are aligned in eight sections. Each section is equipped with two parallel lines of first cleaners, composed of 14 Agitair 12-m^3 (40-ft^3) cells per line, followed by a refloat of this first cleaner concentrate in an eight-cell final cleaner, also composed of the same Agitair cells.

COLUMN FLOTATION. In April 1986, two column flotation cells, operating in parallel, were installed to replace one of the eight conventional two-stage cleaner lines. Both cells were 12 m (40 ft) high; one was 1.5 m (5 ft) in diameter and the other 1.8 m (6 ft) in diameter. On the basis of operating experience with these cells, the column cells in the remaining seven lines will be standardized at 2-m (6-ft) diameter.

The new column cells replaced 28 first cleaners and eight final cleaners, each 12 m^3 (40 ft^3) in capacity. A test program was then outlined that involved evaluating the cells over a wide range of operating conditions. The major variables examined were the effects of varied pulp level, wash water, and airflow rates. Once an optimum range was established for each variable, automatic control was investigated. Clingan and McGregor (1987) discussed this column-cell experience but cautioned that the San Manuel experience may not be typical of concentrators at other mines, because the San Manuel ore body and mining method lend themselves to the production of a very consistent feed.

The San Manuel investigations involved a three-loop control strategy, as described by Amelunxen (1985). He also notes the need for enough column-cell wash water to replace water in the gangue that in conventional cells would be carried in the froth, a situation termed a positive bias. Another way of describing positive bias is to say that the tailing flow rate is greater than the feed flow rate. A conventional flotation machine always operates with a negative bias.

With other variables constant, a range of wash water flow rates from 0 to 10 L/s (0 to 160 gpm), equivalent to a bias of 0.85 to 1.25, was evaluated for each cell. As expected, the results indicated that the concentrate grade decreased below a bias of 1.00. No change was noted in copper or molybdenum recovery from a bias of 0.85 to 1.15, but above 1.15, molybdenum recovery decreased. No difference in metallurgical results was detected between a bias of 1.00 and 1.15, equivalent to about 3.8 to 7.6 L/s (60 to 120 gpm).

Airflow rate proved to be the most important operating parameter in the overall performance of the flotation columns. The ratio of airflow rate to cell volume, expressed as liters/min to liters (gallons/minute to gallons), can have dramatic effects on recovery and concentrate grade and was a valid way of correlating cell performance on the two columns of different size.

Because the airflow rate is the most important operating parameter, the sparger is the most important fixture on the column cell. The importance of generating small bubbles cannot

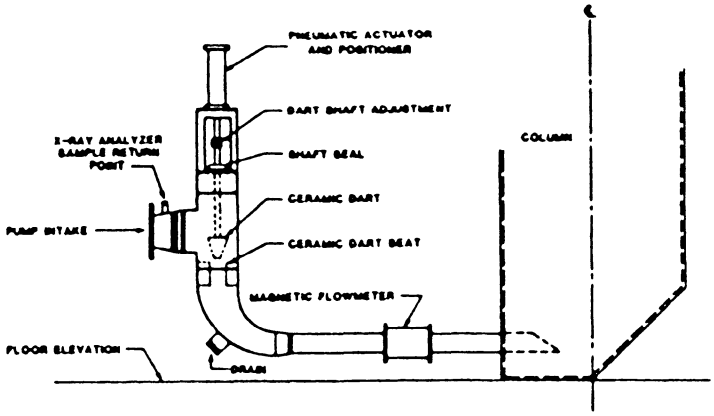

Fig. 25.3.5.7. Current design for tails port on column flotation unit (Dobby, Amelunxen and Finch, 1985).

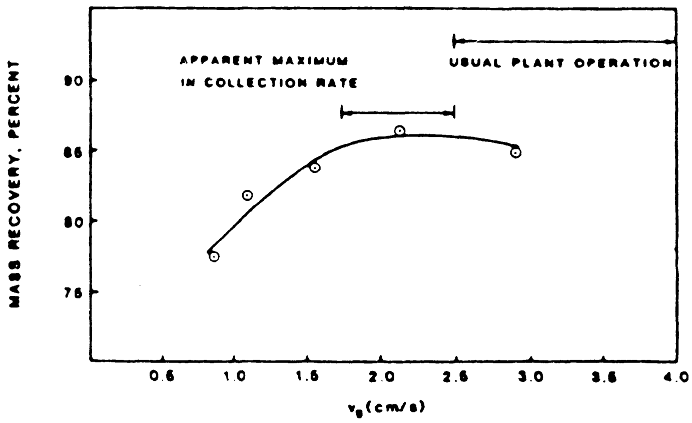

Fig. 25.3.5.8. Mass recovery of copper concentrate vs. superficial gas velocity in column flotation cell (Dobby, Amelunxen and Finch, 1985). Conversion factor: 1 in./sec = 2.54 cm/s.

be overstated (Clingan and McGregor, 1987), as these are more effective in contacting the copper mineral particles.

COMPARING CELL RESULTS. In terms of copper recovery and grade, the San Manuel authors report that results attained with single-stage column cleaners and two-stage conventional cleaners are about equal. Column cells produce a concentrate grading 29.83% Cu at a sulfide copper recovery of 90.36%. Conventional two-stage cleaners produce a concentrate grading 29.99% Cu at a sulfide copper recovery of 90.12%.

However, they observe that the copper concentrate grade at San Manuel is directly related to the degree of liberation in the regrind circuit. When comparing the conventional two-stage cleaners to the one-stage column cleaners at equivalent degrees of liberation, as measured at 44 μm (325 mesh), the one-stage column cleaner produces a higher concentrate grade.

Clingan and McGregor (1987) note that the molybdenum recovery in the bulk CU-MO column cell concentrate increased by a minimum of five percentage points compared to recovery by conventional two-stage cleaners. Such a remarkable gain greatly enhances the economics of the installation. While the San Manuel authors say that the reasons for the gain are now unknown, they point out that column cells are widely considered to be superior to conventional cells in the recovery of finer particle sizes. Since the bulk of the molybdenum losses at San Manuel are in the finer fractions, the results there may add some credence to this generalization.

25.3.6 GRAVITY CONCENTRATION

V.P. Kenyen

Gravity concentration is the method of separating particles of mixed sizes, shapes, and specific gravities by using the force of gravity and/or centrifugal force. The nature of the process is such that size and shape classification are an inherent part of the process. It is not the difference in specific gravity that causes the differences in movement of particles but their weight in a common medium. A particle of high specific gravity and small size will have the same movement in a given fluid medium as another particle of lower specific gravity and larger size. Since a mixture of broken (mineral) grains has an extended size range, size control must be imposed so that the differential motion of the particles reflects the differences in specific gravity. (For size control, see 25.3.3 and 25.3.4 on screening and hydrocycloning.)

Gravity concentration provides a simple, high-capacity, low-cost means of concentrating ores. It works best for rich ores, for ores showing a coarse liberation size, for large volumes of ore with low-value minerals, for placer deposits, and as a preconcentration step.

Simultaneously achieving both a high recovery and a high grade is usually not possible in gravity concentration. Therefore, gravity concentration is commonly used as a rougher to achieve high recovery, followed by another type of process such as flotation (see 25.3.5) to make a high-grade concentrate. Lode ores are most difficult to process. During the comminution step, some fines are always produced, and these very fine particles are not effectively recovered by gravity concentration techniques. The efficiency of gravity methods for concentrating most heavy mineral placer deposits is automatically high since nature has already removed the nonrecoverable fines.

Gravity concentration is usually not competitive with either flotation or hydrometallurgy for the treatment of low-grade ores in which the valuable minerals are locked intimately with gangue in fine grains. The main problems preventing widespread adoption of gravity concentration techniques are twofold: (1) the need to separate, effectively, particles with small specific gravity differences; and (2) the need to develop efficient, high-capacity devices for the treatment of mineral fines (–75 μm).

The criterion proposed by Taggart for determining the applicability of gravity separations is given below. The relation is based on the equal settling ratios of two particles:

$$\text{concentration criterion} = (\rho_h - \rho_m)/(\rho_l - \rho_m) \qquad (25.3.6.1)$$

where ρ_h is the specific gravity of the heavy mineral, ρ_l is the specific gravity of the light mineral, and ρ_m is the specific gravity of the fluid medium.

The size range of applicability for gravity concentration, assuming viscosity effects can be ignored, is then obtained from Table 25.3.6.1. When the criterion is less than 1.25, gravity

Table 25.3.6.1. Values of Concentration Criterion

Criterion	Size of applicability
2.5	Separation easy down to fine sand, 74 μm (200 mesh)
2.5–1.75	Separation effective to 149 μm (100 mesh)
1.75–1.50	Separation possible to 1.68 mm (10 mesh), but difficult
1.50–1.25	Separation possible to 6.35 mm (¼ in.), but difficult
1.25	Relative processes impossible but absolute processes (e.g., heavy media) possible

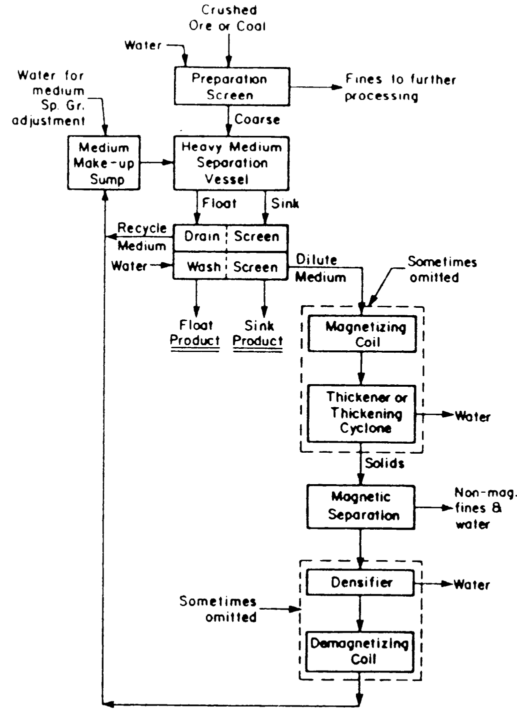

Fig. 25.3.6.1. Typical flowsheet for heavy media separation (Aplan, 1985).

concentration based on the differential particle velocity is not possible. However, concentration is possible by heavy media techniques using either true liquids or suspensions of solids such as ferrosilicon.

A number of *gravity separation* devices are available in the market. Primary among them are jigs, tables, spiral classifiers, and heavy media cyclones. Numerous other devices are available as well. Some of these are discussed in detail below.

25.3.6.1 Heavy Media Separation (HMS)

Heavy media concentration is an effective method of separating two or more minerals of different specific gravities. This requires a medium whose specific gravity is intermediate between the specific gravities of the two minerals to be separated. Other methods of gravity separation (e.g., jigs, tables, spirals) require close particle sizing and a specific gravity difference of at least one unit between the minerals to be separated. However, the HMS technique can be used over a wide size range and a narrow gravity difference.

Commercial separation in the specific gravity range of 1.3 to 3.8 is possible. The particle size treated ranges from 150 to 200 mm (6 to 8 in.) down to 3.3 mm (0.13 in. or 6 mesh). Particles greater than about 13 mm (½ in.) are usually treated in a "static" bath; a heavy media cyclone is generally used for particles less than 13 mm (½ in.) in size.

The basic steps involved in heavy media processes are (1) feed preparation, (2) heavy media separation, and (3) media removal and recovery. Many flowsheet variations are possible, and a typical flowsheet is given in Fig. 25.3.6.1.

HMS offers the following potential advantages:

1. Rejection of the waste at a coarse size, which causes less environmental problems.
2. Relatively low capital requirement.

Table 25.3.6.2. Materials Used for Heavy Medium

Material	Density, g/cm^3	Typical Size Range Used, μm
Shale*	2.0–2.6 (highly variable)	—
Quartz	2.65	Nominal 417 $\times$ 147 (35 $\times$ 100 mesh)
Barite	4.5	74 (200 mesh)
Magnetite	5.18	44 (325 mesh)
Ferrosilicon (15% Si)	6.8	208 (65 mesh)
Galena	7.8	208 (65 mesh)
Lead	11.35	—

* Used in some cyclonic heavy medium separations

3. Relatively low operating and maintenance costs.
4. Ability to make sharp separations.
5. Ability to change the specific gravity of separation quickly to meet changing conditions.
6. Ability to remove products continuously.
7. Ability to treat a broad range of feed sizes.
8. Ease of start-up and shutdown without loss of separating efficiency.
9. High capacity with the use of relatively little floor space.
10. Supply of uniform feed to a subsequent concentration step.

DENSE MEDIA SEPARATION. The most important means of making a dense medium separation is to use a suspension of fine, heavy particles in water as a pseudo fluid. The use of this heavy medium to effect a separation between two particles of differing density is one of the major means of gravity concentration, and its use has been growing rapidly.

The settling rate of a relatively coarse particle (above about 1.6 mm or 10 mesh) settling in a suspension of fine particles (both assumed spherical) is given by Newton's equation:

$$V_m = d \times g \times [(4 \times \rho_s - \rho_m)/(3 \times Q \times \rho_m)]^{1/2} \quad (25.3.6.2)$$

where V_m is the maximum settling velocity in cm/s; Q is the coefficient of resistance, 0.4 for a sphere, and 2 to 3 for "blocky" particles; ρ_s is the specific gravity of the solid to be separated in g/cm^3; ρ_m is the apparent density of the suspension in g/cm^3; d is the particle diameter in cm; and g is the acceleration due to gravity (980 cm/s^2). Under the appropriate conditions, the density of a true fluid may be replaced by the apparent density of the suspension ρ_m in this equation.

The above equation does not show the effect of viscosity. However, if the medium becomes too viscous, it will reduce the particle settling rate and hence the efficiency of separation.

HEAVY MEDIUM SOLIDS. Table 25.3.6.2 lists materials that can be used as the heavy medium. The three most common media in use today are quartz, magnetite, and ferrosilicon, though galena was used extensively in the 1930s and 1940s for ore separations.

Magnetite is normally used for coal preparation, and ferrosilicon (FeSi) is used for ore separation. This is the 15% silicon grade that is an eutectoid composition. There are two types of FeSi—the ground FeSi manufactured in the United States and the atomized FeSi manufactured in Europe. Ground FeSi is used for separations at densities up to 3.2 g/cm^3 (200 lb/ft^3). If higher operating gravities are desired (up to 3.8 g/cm^3 or 240 lb/ft^3), atomized FeSi is used.

Process and Equipment—There are at least 74 heavy media separators that have been used at one time or another. These are divided into three basic groups: static separators, quasi-static separators, and dynamic separators. The effective size range of these separators is given in Table 25.3.6.3.

The type of equipment most suited for a given process is dependent upon the feed size and efficiency of the separating vessel. Pilot plant testing will be very helpful in determining the latter parameter.

Feed Preparation—The first step in heavy media separation is to prepare the feed by wet screening. This is done to (1) size the ore into different fractions for subsequent treatment by various concentrating devices, (2) remove the slimes that increase the viscosity of the medium, thus resulting in poor efficiency, and (3) prewet the ore or coal.

For coarse screening, woven wire is generally used, but for relatively fine screening, wedgewire deck should be considered. For sizing sticky, hard-to-screen ores, which have a tendency to blind the screens, flip-flow polyurethane screens are recommended. These have been successfully used for screening materials 1 to 30 mm (0.04 to 1.18 in.) in size. Because of the trampoline-like motion of the elastic screen panel, this type of screen is almost non-blinding.

Medium Recovery—The medium is recovered from the sink and float fractions by the drain and wash screens. DSM screens, sometimes referred to in the coal industry as sieve bends, are preferred as drain screens as these are very efficient in removing the fine medium. Where blinding is a problem, polyurethane screens are used.

When a single screen has the capacity to handle both the sink and float fractions, a divider is installed along the length of the screen to keep the products separate.

The medium recovered from the drain screens is returned to the medium sump for recirculation in the medium circuit. The medium removed by washing is returned to the dilute medium sump as it is too dilute and, in many instances, is contaminated with fine impurities. Therefore, prior to return to the medium sump for reuse, it should be cleaned and thickened. Wet magnetic separators, with permanent magnets, are normally used for cleaning and recovery.

Single-drum magnetic separators are common; however, when the medium is dilute and the feed volume is large, multiple drum separators should be used. For optimum results, the magnetic separators are fed at 30 to 35% solids by weight.

The efficiency of the magnetic separator depends on the magnetic susceptibility of the media and the rate at which the unit is fed. Satisfactory results are obtained when the separators are fed at the proper feed rate.

Magnetic separators are available in 762-, 914-, and 1219-mm (30-, 36-, and 48-in.) diameter with magnet widths to 3 m (10 ft). The respective capacities are 48, 63, and 85 m^3/h/m (515, 675, and 915 ft^3/hr/ft) of drum width.

Table 25.3.6.4. Typical Media Consumption in Heavy Media Separators

Type of Vessel	Media Loss (g/t)
Drum	150
WEMCO Cone	130
Cyclones	300
DynaWhirlpool	435

Conversion factor: 1 oz/ton = 31.25 g/t.

The importance of designing an adequate medium recovery circuit cannot be overemphasized. Attention should be given to details so that medium losses can be kept at a minimum. With increasing medium costs in mind, designers have been developing more sophisticated recovery circuits.

Media losses vary considerably. In general, higher losses are associated with the finer sizes of material processed and the fineness of the medium itself. Losses on the static-type separators are usually low. On cyclones or DynaWhirlpool (DWP) plants, the losses are generally higher. Table 25.3.6.4 shows media losses experienced in heavy media operations.

HEAVY MEDIA CYCLONE. Although cyclones were originally developed for use as classifiers or thickeners, it was later found that they could also serve effectively as heavy media separators.

As the medium and mineral particles are fed through the feed orifice, a vortex forms in the cyclone with a hollow air core extending from the overflow to the underflow orifice. Under the influence of centrifugal force, high specific-gravity particles move through the medium to the wall of the cyclone and descend in a spiral flow pattern to the underflow orifice. Those particles in the feed stream, lower in specific gravity than the feed medium, follow the major portion of the flow to the center of the core where they are caught in the high-velocity, upward, central current and are carried out through the overflow orifice.

In heavy media cyclone operation, the specific gravity of the medium is the main control within acceptable ranges of viscosity. However, other variables, such as cyclone size, feed pressure, cone angles, and orifice size, can also affect results. The principal design variables and their effects on operation follow:

Cyclone Diameter—Heavy-media cyclones are used in various sizes from 50 to 610 mm (2 to 24 in.) in diameter. The approximate volumetric capacities of these cyclones are shown in Table 25.3.6.5.

The performance of any separating device can best be shown by partition, or error, curves. Typical curves for the performance of a heavy media cyclone processing coal at two separating gravities are shown in Fig. 25.3.6.2. These curves represent the distribution to refuse of each specific gravity increment of the feed. They are drawn by plotting the recovery to refuse of each specific

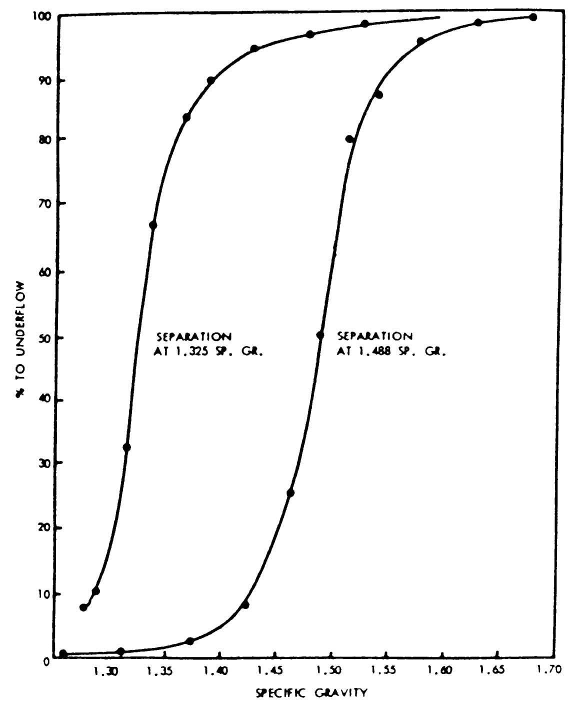

Fig. 25.3.6.2. Performance curves for heavy medium cyclone (Aplan, 1985).

gravity fraction of the feed against the midpoint of the specific gravity range involved. As a standard means of comparing the sharpness of separation of any process, the ecart probable (EP) method can be used. The ecart probable, or probable error, is defined as one-half the specific gravity interval corresponding to recovery values of 25 and 75%. The specific gravity of separation is the specific gravity point that corresponds to 50% recovery and is generally higher than the specific gravity of the medium.

DYNAWHIRLPOOL (DWP). Similar to the heavy media cyclone, the DynaWhirlpool is a stationary-body-type device used for making specific gravity separation, but it differs from the cyclone in its design and critical operating variables.

Design Features—The DynaWhirlpool vessel, shown in Fig. 25.6.3.3, consists of a hollow cylinder fitted with cover plates having central openings. The vessel has tangential orifices at either end of the cylinder. The medium is admitted under pressure through the bottom tangential orifice, and a vertical flow pattern is established in the cylinder. The flow discharged through the central bottom opening is lower in specific gravity

Table 25.3.6.5. Effect of Cyclone Diameter on Capacity

Diameter, in.	Material processed, tph			Volume processed at 8–10 psig, gpm	Orifice diam, in.		
	1.35 sp gr	2.0 sp gr	3.0 sp gr		Feed	Overflow	Underflow
2	0.5	0.7	1.0	10	½	1	⅜
8	7.5	11.0	17.0	150	1½	2½	1
14	25.0	37.0	56.0	450	4	6	5
20	50.0	74.0	110.0	750	6	8	6
24	70.0	103.0	156.0	1,000	8	10	7

Conversion factors: 1 in. = 25.4 mm, 1 psi = 6.8948 kPa, 1 gal/min = 3.79 L/min, 1 tph = 0.9072 t/h.

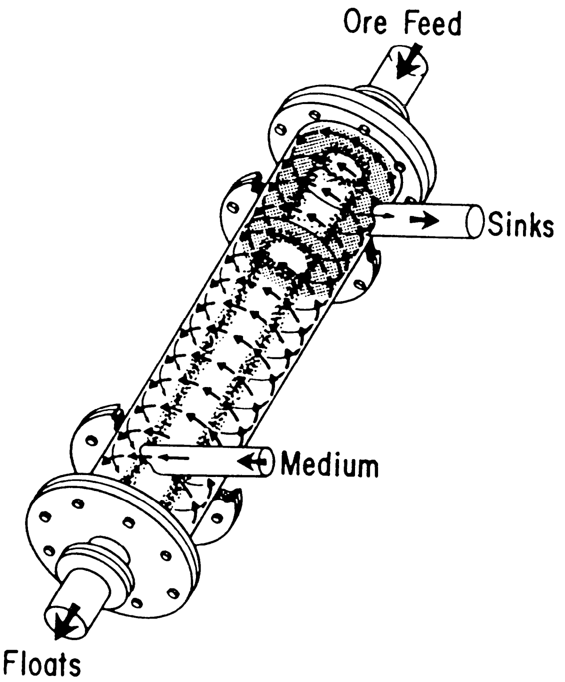

Fig. 25.3.6.3. Cutaway view of DynaWhirlpool vessel (Aplan, 1985).

than the feed medium. The material discharged from the upper tangential opening is higher in specific gravity than the feed medium.

By placing the cylinder in a slightly inclined position and selecting a smaller orifice for the top central opening than the bottom central opening, the device can be operated without medium discharging through the top central orifice. When ore particles and a portion of the feed medium are fed through this opening, they impinge on the rotating body of fluid. Particles of specific gravity lower than that of the rotating medium do not penetrate into the body of the medium and are discharged through the bottom central opening. Particles with a higher specific gravity than that of the rotating liquid settle toward the wall and are discharged through the top tangential opening. An advantage of this unit is that only the feed medium needs to be pumped, with the ore being fed directly into the device by gravity.

25.3.6.2 Jigging

In *jigging*, a mixture of ore particles is supported on a perforated plate or screen in a layer or "bed" with a depth many times the thickness of the largest particle. By subjecting the bed to an alternating rising and falling (pulsating) flow of fluid, the particles of high specific gravity travel to the bottom of the bed while the particles of lower specific gravity collect at the top.

FIXED-BED JIGS. All modern jigs are of the fixed-bed type in which the liquid pulse passes up and down through the jig bed, which is retained on a stationary screen. The different types of fixed-bed jigs are listed in Table 25.3.6.6. The older makes of jigs are described in Taggart (1951).

Variations in two modern jigs are discussed in the following.

Remer Jig—This jig has four important differences from the rest of the moving-hutch types: (1) the screen is continuous over all four compartments—stratification is therefore uninterrupted over the whole length of the jig; (2) all four compartments are actuated by a common mechanism; (3) the driving mechanism has two motions, a normal jig pulse of 80 to 120 strokes/min on which is imposed a fast (200 to 300 per min) pulse; (4) upflow water can be controlled individually in each of the four hutches.

Cleaveland IHC Jig—The special design features of this jig are (1) it is a circular jig in plan view; (2) the jig compartments are trapezoidal to reduce the effect of excessive top water; (3) the hydraulic-driven diaphragm stroke can be easily modulated; (4) the radial arrangement of the jig compartments saves space, provides for simplified feed distribution, and allows for the use of a raking device which levels the jig bed surface as it rotates.

METALLIC ORE JIGGING. In general, jigging operations have one of two objectives. Either they involve cobbing operations to discard waste rock before final processing of the crude concentrate, or they recover finished concentrates from ores in which the mineral grains are liberated.

Jigs are used to recover coal, diamonds, barite, concrete aggregate (from bank-run gravel), and heavy minerals of all kinds that occur in decomposed rocks or can be liberated by comminution without being reduced to slimes.

The greater part of the world's tin is concentrated by jigs. In the most modern tin dredges, diaphragm jigs such as the Yuba and more recently the Cleaveland seem to be preferred. In the concentration of fine heavy minerals from decomposed granitic rocks in Africa, good recoveries of tantalite, columbite, and cassiterite are obtained, down to 50 μm (300 mesh).

Use of jigs to recover gold and other precious metals is widely practiced since the high specific gravity differential makes good recoveries possible with very little operating attention. Jigs have the ability to adsorb large fluctuations in ore grade, tonnage rate, and dilution—all characteristics of placer and dredge operations. Also, since the metal concentrate is always hutched, losses due to theft are easily prevented. In dredge operations, diaphragm jigs are the most common, but in lode mining operations, the Denver Mineral Separation jig is commonly used.

Jig control has traditionally depended on the operator's skill. Modern practice may utilize instrumental control.

Given fixed machine parameters, practical operation requires adjustment of the state of bed dilution and particle stratification. To maintain this condition, the controls available to the operator are feed rate, rate of concentrate withdrawal, and hutch water addition. Any instrumentation and control should therefore include bed density sensing as well as solid flow measurement, with feed back loops to the feed, water, and discharge regulation devices.

Jigs use a large amount of water, so reclamation of water with recycling is standard practice. Clean water is not necessary, as clay and fully suspended slimes do not appreciably affect results up to a specific gravity of 1.05. However, provision must be made to clarify enough water to stay below this level. In some cases, chemical additions may help.

With few exceptions, but with some precautions, jig plants can be scaled up from pilot plant results. Every detail of the mechanical action of the pilot plant must be transferred to the industrial plant. Such factors as stroke speed, amplitude, and modulation; feed size distribution; and water velocity and distribution, must all be reproducible. For design purposes, it is useful to make specific gravity determinations on the pilot plant products and the plant feed and to construct distribution curves. These will permit efficiency comparisons with the specification curves for the industrial equipment. Within reasonable limits, imperfection coefficients from these curves are independent of feed changes.

25.3.6.3 Wet Concentrating Tables

The modern *wet concentrating table* is a rectangular- or rhomboid-shaped deck, with riffles, that is operated in essentially a horizontal plane. A drive mechanism imparts a differential motion to the deck along its long axis while water flows by gravity along the short axis. Tables are currently employed for processing coal, barite, beach sands, chromite, glass sand, garnet, iron, manganese, mica, phosphate, potash, tantalum, tin, titanium, tungsten, and zircon.

The development of froth flotation in the 1920s, with its superior selectivity and capacity to concentrate finely ground ores, sharply reduced the use of shaking tables for sulfide ore concentration. As a consequence, only a few firms now manufacture tables for concentrating precious and base metal ores.

The separation effected on a wet concentrating table is the result of numerous mineral dressing principles simultaneously acting on the table feed. These include flowing-film concentration, hindered settling, consolidation trickling, and asymmetrical acceleration.

In practice, a slurry of solids and water is fed to the upper edge of the sloping table. As the suspended material moves across the table, it is caught and forms pools behind the longitudinal riffles. The differential shaking action of the deck causes size classification and specific gravity stratification. As a result, particles with similar specific gravities become arranged vertically according to size.

Once the beds are formed, the addition of more slurry and the action of the flow of cross water causes shearing of the top layers of the stratified particles, thereby forcing the lower specific gravity and coarser particles to cascade over the riffles toward the lower side of the table. The depth of the riffles and the bed thickness decrease from the drive mechanism end to the discharge end of the table. This results in continuous flowing film concentration of the increasingly finer-sized and higher-density particles as these particles move longitudinally along the table.

The differential drive mechanism is so designed that at the end of the backward stroke (deck moving toward drive end), the deck and hence the particles on the deck surface are momentarily at rest. The deck is then accelerated forward until, at the end of the stroke, the direction of travel is rapidly reversed. The particles on the deck, which moved with the deck on the forward stroke, will now slide forward owing to their momentum while the deck reverses its direction and starts on its backward stroke. Thus the particles always travel toward the discharge end of the table.

The idealized size and specific gravity stratification of the table action are shown in Fig. 25.3.6.4. Height and placement of the riffles and irregularities in feed rate, deck surface, table motion, and water supply and distribution all exert influences that will modify the idealized behavior of the feed pulp. The presence of middling particles, slimes, and marked differences in the size, shape, and porosity of particles of the same minerals also materially affect table action.

Table Operating Factors. To achieve maximum performance, attention must be given to the various operating conditions. Water and solids feed rates, size consist of the feed, and mechanical settings of the table are interdependent; prolonged changes of the table feed will require changes in the mechanical settings of the table.

Manufacturers' recommendations range from 230 to 285 rpm, with a 31.8 to 19-mm (1¼- to ¾-in.) stroke for coarse

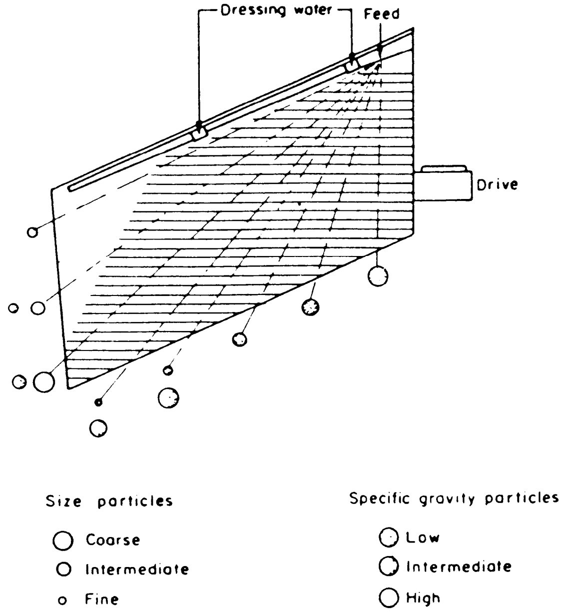

Fig. 25.3.6.4. Distribution of table products by particle size and specific gravity (Aplan, 1985).

sands. For finely sized material, the recommended range is 285 to 325 rpm, with a 19- to 10-mm (¾-in. to ⅜-in. stroke. Speeds and strokes for tabling coal are about the same as for ores.

NATURE OF FEED. Tabling involves both size and specific gravity separations that are influenced by the shape, porosity, and size consist of the mineral particles. Therefore, size classification of table feed is one practical way to improve table performance and increase table capacity. Modern multiple-cell hydraulic classifiers are simple, inexpensive, and can effectively sort crushed and ground materials by free and hindered settling. They discharge, at a constant rate, classified products suitable for tabling, sorting concentrate particles that have equal settling rates.

The largest particle size that can be effectively treated on tables is about 18 mm (¾ in.) when washing coal and about 1.65 mm (10 mesh) when washing ores. For ores of high specific gravity, the minimum effective size for beneficiation is below 44 µm (325 mesh).

RIFFLING. Tables are of two basic types: (1) sand tables, which are characterized by deep and extensive riffle systems necessary to effectively process coarser size material; and (2) slime tables, which are characterized by shallow riffles to minimize the disturbance in a bed of fine particles. The latter still allows the cascading of the fine material that is necessary for removing the low-density particles.

CAPACITY. The capacity of a table treating either metallic or nonmetallic ore is determined by the size and specific gravity of the material being tabled and whether the operation is a roughing or a cleaning one. The capacity of a table treating 1.65- to 1.17-mm (10- to 14-mesh) top-sized ore is about 1.8 t/h (2 tph) per deck. Slime tables producing a finished ore concentrate treat as little as 0.1 t/h (0.11 tph) per deck. The recommended capacity for coals having top sizes of 18 mm (¾ in.), 9.5 mm (⅜ in.), and 589 µm (28 mesh) is 13.5, 11, and 4.5 t/h (15, 12, and 5 tph) per deck, respectively. In actual practice where the washability of the feed is relatively good, overloads of up to 25% are often handled with little difficulty. However, where a high Percentage of near-separating gravity material is present, any overload to the table will greatly reduce the separation efficiency.

WATER CONSUMPTION. Water consumption is dependent on the size of feed and type of operation, that is, roughing or cleaning. In roughing operations, up to 2900 L of water/t of ore (700 gal/ton) is required. In cleaning, more water is used, ranging up to 4000 L/t (960 gal/ton). Slime ore treatment water requirements range from 3325 to as much as 4000 L/t (800 to 960 gal/ton).

A portion of the water is added directly to the table from a trough along the upper side (Fig. 25.3.6.4). This "dressing" water is necessary to assure complete mobility of the material on the table. Dressing water amounts to about 25% of the total water used in wet tabling.

TABLE FLOWSHEETS. Fig. 25.3.6.5 shows a typical table flowsheet for tantalite ore. The ore is processed over nine triple-deck tables in the primary circuit. In the cleaning circuit, the rougher concentrate is processed over three single deck tables. The tantalite concentrate is then dried. Coarse primary and secondary middlings are crushed and recirculated to maximize recovery.

Table 25.3.6.7 shows general operating parameters for a number of commercially available shaking tables as provided by the manufacturers.

25.3.6.4 Spirals

Since their introduction 30 years ago, spirals have become widely used. There are over 25,000 currently in use for concen-

trating hematite, ilmenite, zircon, rutile, tungsten ore, chromite, and coal. Spirals usually have low capital and operating costs and low energy consumption.

A *spiral* consists of a curved channel. Wash water is supplied in an auxiliary trough from which it can be deflected into the main pulp stream. A cross section of the device is shown schematically in Fig. 25.3.6.6.

SPIRAL OPERATION. Feed pulp and wash water volumes are the most important operating parameters and vary between 57 and 113 L/min (15 and 30 gpm) for the feed and 11 and 57 L/min (3 and 15 gpm) for wash water. When either volume is too low, it causes a sluggish flow and sand bar formation occurs, resulting in a reduction of both concentrate grade and spiral capacity. On the other hand, excessive volumes cause the high specific-gravity mineral to be swept wide of the upper port, resulting in sand bar formation in the lower turns. This also results in lower recovery and capacity. The coarser the feed, the higher the optimum feed rate, since a higher pulp density is needed to crowd the large high specific gravity particles into the concentrate.

Feed size is usually between 1.16 mm and 74 μm (14 and 200 mesh), but with iron ore, up to 2.3 mm (8 mesh) material may be treated to make a rougher concentrate, provided a high pulp density is used. This prevents the larger high-specific-gravity particles from migrating towards the tailings. The resulting concentrate is difficult to clean, however, unless it is stripped of the +0.5 mm (28 mesh) material by classification. Usually, recovery falls off rapidly below 74 μm (200 mesh), but with a few high-specific-gravity minerals can be good down to 44 μm (325 mesh). Pulp density is usually between 20 and 30% solids.

Australian beach sand practice generally is to use 25 to 30% solids, but the operations are fairly good over the range 15 to 40% solids. Throughput varies from 0.4 to 2.2 t/h (0.4 to 2.4 tph) per machine, dependent on the feed size. On Australian beach deposits, the capacity of the normal 610- and 1067-mm (24- and 42-in.) spirals used by Rutile and Zircon Mines, Ltd. ranges from 0.4 to 2.2 t/h (0.4 to 2.4 tph), depending on the feed grade, degree of concentration, and recovery. The Wyong spirals have throughputs up to 3.7 t/h (4.1 tph) of feed carrying about 1% heavy minerals.

There are other types of gravity concentrators such as the flowing film concentrator, Bartles-Mozley concentrator, and Reichert Cone, which are used in special cases. Details on these are beyond the scope of this book, and readers are referred to the *SME Mineral Processing Handbook* (Weiss, 1985).

25.3.6.5 Laboratory Testing

The first step involved in developing a gravity separation flowsheet is to perform the heavy liquid analysis of the sample

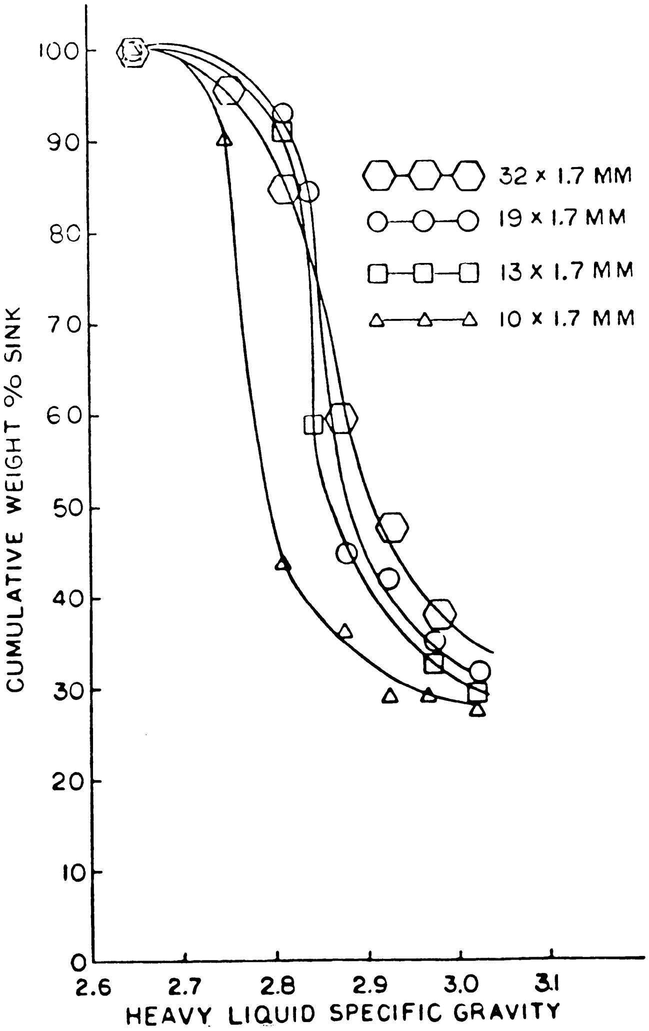

Fig. 25.3.6.7. Washability curve of a Mexican fluorite ore (Srinivasa, 1981). Conversion factor: 1 in. = 25.4 mm.

to determine the washability of the coal or ore. This analysis establishes the size of separation of the ore and the specific gravity of separation.

A complete sequential sink-float analysis of the ore, at close specific-gravity intervals, should be made in order to get a complete understanding of the ore's response to heavy liquid separation. Heavy liquids commonly used in the heavy liquid tests are methylene iodide (3.3 sp. gr.), tetra-bromoethane (2.96 sp. gr.), and methylene bromide (2.48 sp. gr.). Clerici solution is used for specific gravities exceeding 3.2. Ethylene dibutyl phthalate or carbon tetrachloride is used for dilution to intermediate densities. Caution should be exercised in handling the organic liquids. Most of them are toxic, and some are absorbed by the skin on contact. Laboratory tests should therefore be performed in a well-ventilated area.

Washability curves prepared from the heavy liquid analysis are given in Fig. 25.3.6.7. They show that the weight recovery of the sink fraction, at a given specific gravity, decreases at finer sizes. This indicates possible liberation of the values from the gangue particles. Grade-recovery curves (Fig. 25.3.6.8) show that the highest recovery is obtained at 19 mm (¾ in.) size. This indicates that there is an optimum size at which the best

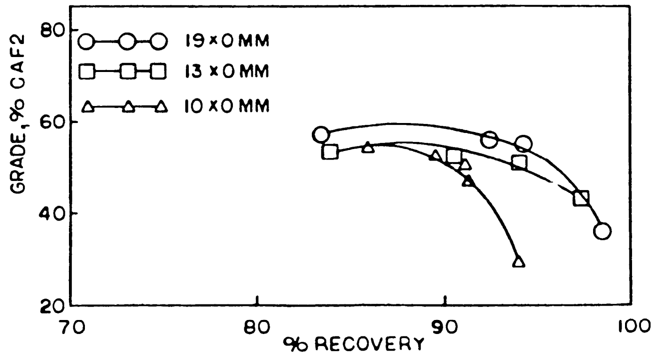

Fig. 25.3.6.8. Grade vs. recovery of a fluorite sample (Srinivasa, 1981). Conversion factor: 1 in. = 25.4 mm.

metallurgical results are obtained. It is therefore obvious that a washability curve alone will not provide the optimum conditions for separation. An analysis of the results is necessary.

25.3.7 MAGNETIC SEPARATION

V.P. KENYEN

Magnetic separation is a means of concentrating or separating minerals with paramagnetic properties from nonmagnetic gangue particles. Preventive magnets are also used for the removal of tramp iron in crusher feed and other bulk material streams. This discussion is limited to concentration. Application of magnetic separators for removal of tramp iron is covered in several of the works listed in the bibliography.

25.3.7.1 Wet Magnetic Separators

There are two types of magnetic separators, wet and dry. The wet unit could be a drum separator, a magnetic filter, or a high-intensity wet magnetic separator.

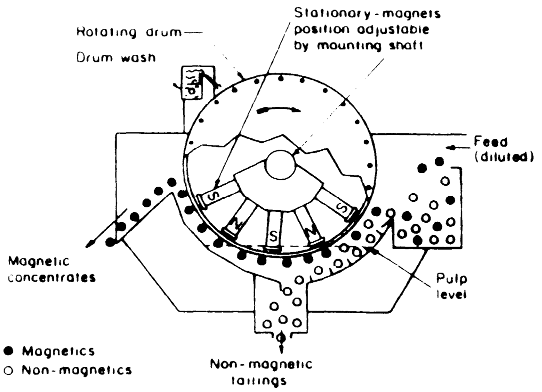

Fig. 25.3.7.1. Concurrent wet-drum separator (Bronkala, 1978, p. 471).

Wet drums are used to concentrate finely divided, strongly magnetic material. Three types of drum separators are available: concurrent, countercurrent, and counterrotation. Concurrent drums (Fig. 25.3.7.1) are used for cobbing of –6-mm (–0.25 in.) particles, countercurrent drums are used for finishing operations at –210 µm (–65 mesh), and counterrotation drums are used for roughing operations on –1.7 mm (–10 mesh) ore.

Wet magnetic drums are constructed of either permanent or electromagnets. A large majority of installations use permanent magnet drums because of their dependability and lower operating and maintenance costs. Electromagnetic drums are used where extremely high magnetic fields are desired or where simple electromagnetic field control is desired.

Commercial wet-drum separators come in diameters of 0.76, 0.91, and 1.2 m (2.4, 2.9, and 3.8 ft). Multiple (double or triple) drums are used for cobbing and finishing. Normal feed rates to the magnetic separators are as follows:

Cobbers 100 to 169 m^3/h/m (1075 to 1820 ft^3/hr/ft) of magnet width

Roughers 100 to 130 m^3/h/m (1075 to 1400 ft^3/hr/ft) of magnet width

Finishers 70 to 105 m^3/h/m (750 to 1130 ft^3/hr/ft) of magnet width

25.3.7.2 Dry Magnetic Separators

Based on the magnetic field intensity they develop, dry magnetic separators are classified as high-, moderate-, or low-intensity separators. High-intensity separators remove weakly magnetic particles, moderate-intensity separators remove moderately responsive magnetic particles, and low-intensity separators remove paramagnetic particles. The physical condition of the particles influences the selection of the dry magnetic separator.

There are two types of dry separators, the cross belt and the induced roll. The cross belt picks the magnetics off the feed belt and discharges them to the side. This has been used for concentrating wolframite and monazite.

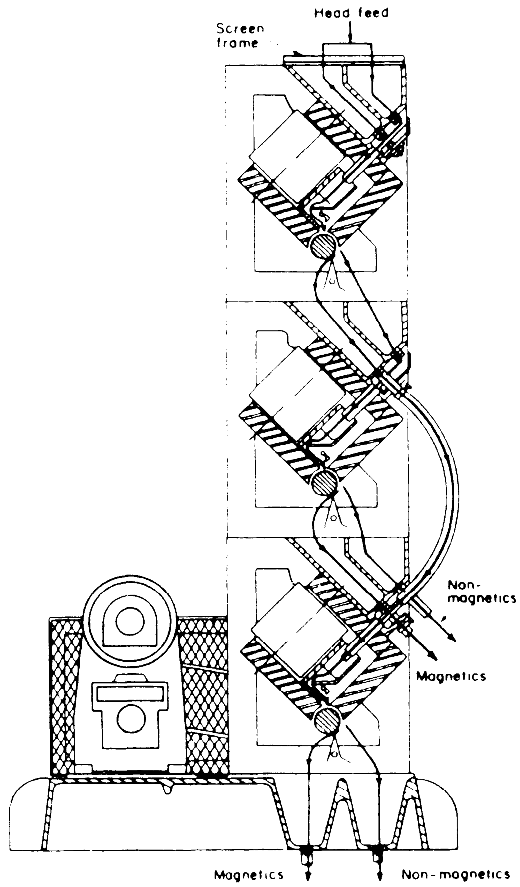

Fig. 25.3.7.2. Operating principle of induced-roll magnetic separator (Bronkala, 1978, p. 476).

The induced roll separator is used to concentrate and purify chemicals and minerals. The most frequently used purifying-type induced separator is the 0.76-m (30-in.) wide, three-field, twin-type separator having 1.5 m (60 in.) of total feed width. Such a unit is shown in Fig. 25.3.7.2 and will clean 2.7 to 6.4 t/h (3 to 7 tph) of product.

Chapter 25.4
CHEMICAL AND ELECTROLYTIC PROCESSING

JOHN A. WELLS, WAYNE R. HOPKINS, AND RICHARD B. STEIN

The subject matter of this chapter is too vast to give even a cursory overview. There are many excellent text and reference books that treat individual topics in detail relating to chemical and electrolytic processing. Rather than attempt to treat the whole range of subject matter, this chapter will concentrate on new and emerging process technologies relating to chemical and electrochemical processes for recovery of gold, copper, zinc, aluminum, and magnesium.

25.4.1 GOLD PROCESSING

JOHN A. WELLS

The traditional circuit for gold recovery is the Merrill-Crowe method using zinc precipitation. It has been largely replaced by carbon-in-pulp and carbon-in-leach circuits, followed by electrowinning, and their newer technologies will be described in detail below.

25.4.1.1 Carbon-in-pulp

In the last decade, no subject has received greater attention in the field of extractive metallurgy than *carbon-in-pulp* (CIP) and the closely related *carbon-in-leach* (CIL) *processes.* This is a direct response to the relatively high price of gold that resulted in the development of many new mines.

The success of a CIP plant is centered around the adsorption operation. This section must work well, and gold adsorption in excess of 99.5% should be the target of both designers and operators. Such a figure is not always achieved, and reasons for this will be proposed.

Although CIP has been the popular choice for the majority of new plants, the Merrill-Crowe process has a history of successful applications. CIP is particularly suited to those ores that exhibit poor solids-liquids separation, as the filtration stage is eliminated. Adsorption tanks are much easier to install and operate than vacuum filtration (frequently two stages) with the associated repulping and vacuum systems.

Capital costs for CIP are generally 65 to 85% of those for Merrill-Crowe. However, for ore with high precious metal values, the Merrill-Crowe system has lower costs, as shown in the following:

Plant Capacity		Grade above which Merrill-Crowe capital costs are lower: Precious Metal Content*	
tpd	t/d	oz/ton	g/t
900	817	0.48	15
1800	1633	0.80	25
4500	4082	1.13	35

* Gold plus Silver content.

These numbers are site specific and based upon a generic study. They indicate why CIP is so popular, as there are few gold mines found today with grades in excess of those shown above. The reason for the less favorable economics of CIP at high grades is the large quantity of carbon that is required, and the large elution and regeneration section that is necessary to process it. Many gold mines contain an appreciable silver content, which puts the combined precious metal value well in excess of those shown above. For this reason, as well as the relatively lower kinetics of silver adsorption on carbon, new plants for silver and silver-gold deposits frequently continue to utilize Merrill-Crowe. Operating costs for CIP plants have been steadily reduced as improvements have been made to the process. Several estimates have been made comparing the two, and generally CIP operating costs are believed to be 80 to 90% of those of Merrill-Crowe.

CIP-FEED PREPARATION. The major problem experienced by the first generation of CIP plants was contamination of all stages of the process by the tramp oversize carried forward from the grinding circuit. This oversize material includes wood chips, plastic, and coarse solids. With the interstage screening systems installed in adsorption, this coarse material accumulates in the process and ultimately contaminates the carbon in all stages of adsorption, elution, and regeneration, and contributes to screen blockages and eductor chokes.

Many methods of removing this material from the system were developed, none of which were wholly successful. The long-term solution had to be prevention rather than cure, and this was achieved by the development of superior feed slurry screens and, more recently, by the development of the linear screen.

The selection of feed screens is therefore a critical element of CIP plant design. The screens are usually vibratory and utilize either wire mesh decks (which generally have a short life due to wear or more frequently tearing) or polyurethane screen panels. These latter panels have an extended life with good wear resistance but provide less open area and therefore, lower capacity in terms of cubic feet (cubic meters) of pulp per square foot (square meter) of screen area. The screens are typically 28 or 35 mesh, to remove both oversize and "near-size" material. An interesting innovation that works particularly well is the concept of reversing the slope of the screen, such that the feed end is lower than the discharge end. The oversize slowly moves up the screen. This effectively dewaters the oversize and prevents excess slurry from passing over the screen which is often a feature of "down slope" screens. Vibrating feed screens have a capacity of 100 to 130 $ft^3/ft^2/hr$ (30 to 40 $m^3/m^2/h$), but figures as low as 60 and as high as 200 $ft^3/ft^2/hr$ (18 to 60 $m^3/m^2/h$), have been reported (density and viscosity being major determinants of screen capacity). Non-vibrating screens have a much lower capacity and require frequent cleaning.

A recent innovation in CIP feed preparation is the linear screen shown in Fig. 25.4.1.1. These machines resemble typical belt filters and comprise a polyester filament cloth supported on rollers over a head and tail pulley. The slurry is distributed over the filter using a feed box that has a perforated plate bottom. The slurry drains through the cloth into the underpan, and the oversize is carried to the head of the screen from which it is

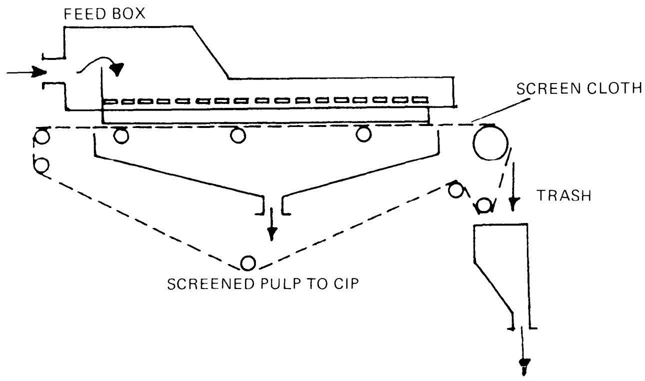

Fig. 25.4.1.1. Linear screen.

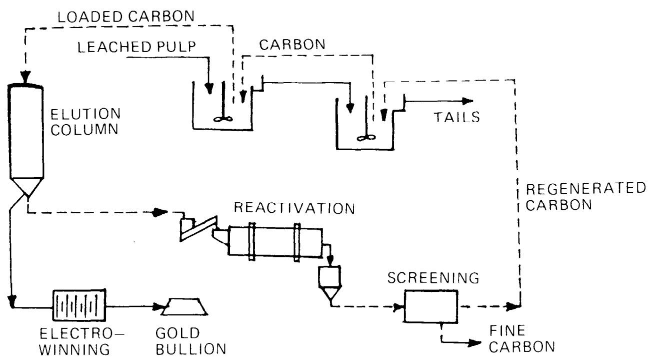

Fig. 25.4.1.2. Typical CIP circuit.

removed by a wash spray. These units often provide excellent results, with high throughputs of 165 $ft^3/ft^2/hr$ (50 $m^3/m^2/h$) at 99% availability and over 2500 hours cloth life. One mine reported that the woodchip content in the CIP pulp of 0.7 lb/1000 gal or 0.08 g/L was almost entirely eliminated.

One aspect of plant design that is frequently overlooked is the subsequent handling and disposal of the screen oversize. If the oversize product is wet, or a wash spray is used, the product may require secondary screen for dewatering. A small vibrating screen or sieve bend is suitable for this purpose. The solid residue should fall into a collecting box, which must be both big enough to hold a day's production and accessible enough for ease of removal. Alternatively, the residue can be repulped and pumped to the final tailing box.

CIP-ADSORPTION. A typical CIP adsorption section comprises a series of mechanically agitated tanks, often with a height-diameter ratio of 1:1, each tank providing a residence time of between 1.0 and 1.5 hours. A typical CIP circuit featuring adsorption tanks, elution, reactivation, and electrowinning is shown in Fig. 25.4.1.2.

Several publications have discussed the role of modeling for adsorption circuits, whereby the relationship between the key variables is developed (gold tenors, residence time, number of stages). For any given set of circumstances, the gold adsorption efficiency will increase with the number of stages. However, beyond a certain number of stages, the incremental return (i.e., gold recovery) is less than the additional costs incurred. Typically, gold adsorption is 60 to 70% per stage. As a very general approximation, six adsorption stages would appear to be the optimum for precious metal grades of 0.32 to 0.65 oz/ton (10 to 20 g/t). Fewer stages are not generally recommended due to the potential for short circuiting. Further stages may be added for particularly high-grade ores or if there is evidence of poor kinetics. However, it is advisable to keep the number of stages as low as possible in order to minimize capital and operating costs and the carbon inventory (high carbon inventories increase carbon consumption through attrition, increase the possibility of fouling, and increase gold in-process inventory). Plant design should however, be such that space is available for future expansion of adsorption capacity if required.

In order to achieve low barren solution values and achieve the target recovery of 99.5% gold adsorption, a critical parameter is the carbon activity (the maintenance of that is dependent upon the other unit operations which are described elsewhere).

The carbon should be loaded to as high a gold value as possible, and this value can be predicted by testwork and the use of the models referred to above. As a general rule, loadings of 30 oz/ton (1000 g/t) (gold/carbon) should be possible for 0.03 oz/ton (1 g/t) in the mill feed.

Mechanical agitation in CIP has largely displaced air agitation. It has been shown to be better both metallurgically and operationally. Power requirements are proportional to D^5 (D is impeller diameter). From operating data, this is typically 0.001 to 0.002 kW/ft^3 (0.05 to 0.10 kW/m^3) for 13- to 23-ft (4-to 7-m) diameter tanks.

The adsorption tanks may be installed in a straight line, with a drop between tanks of approximately 1.5 ft (0.5 m), or in an offset pattern. Other adsorption tank systems have been proposed, including one continuous vessel, separated into individual compartments by screens. However, the individual tank system remains the overwhelming choice at this time.

Transfer of carbon between stages is generally achieved by recessed-impeller-type pumps, suspended in the top of the tanks. These have replaced airlifts, which were used in the first CIP plants. Plant and test data conclusively show that carbon is hard and withstands pumping action. In general, the movement of carbon by pumping is recommended throughout CIP plants, and is preferable to eductors that require large volumes of high-pressure water and have a tendency to choke.

An interesting debate remains the issue of tank support. In South Africa, most tanks are installed with a concrete support, all tanks having the same dimension. An alternative to this is the false-bottom concept, which is popular in North America.

CIP INTERSTAGE SCREENS. Interstage screens are installed in each stage of adsorption to retain carbon but allow pulp to flow through the circuit. For finely ground gold ore pulps (i.e., typically 70% finer than 74 μm) the following screening sizes are usually employed for CIP/CIL operations.

Carbon Size	1–3 mm (6–16 mesh)
Prescreening	0.6 mm (28 mesh)
Interstage Screens	0.8 mm (20 mesh)
Final Catch Screens	0.6 mm (28 mesh)

Interstage screening is a critical feature of CIP operations. Many operations have performed below expectations due to capacity constraints or low efficiency of these screens.

25.4.1.2 Carbon-in-leach

Soon after the introduction of CIP, it was considered by some that the adsorption and leaching circuits could be combined into one unit operation. Reasons for this included the following:

1. The larger leach vessels would overcome interstage screen space limitations frequently experienced with the smaller adsorption tanks.

2. Extra dissolution had been observed on pulps passing through a CIP circuit, and it was considered that the addition of carbon early in the leach cycle might enhance the dissolution and, most importantly, prevent or reduce any preg-robbing tendencies in the ore.

3. Estimates of the capital expenditure indicated that the combined operation (CIL) would be 20% less costly than CIP.

Subsequent experience with CIP and CIL has shown that the actual results achieved in practice make comparison of the two more difficult than expected. Both systems work well in site-specific applications and achieve the desired results. The following general comments can be made.

1. Many of the early problems experienced with CIP were in retrospect due to peripheral problems such as poor screening and regeneration, rather than some fundamental problem in adsorption. However, when leaching and adsorption are combined in one vessel, technical problems increase rather than diminish. The resolution of poor gold recovery becomes more difficult to ascertain (i.e., is it poor dissolution, poor adsorption, or a combination of the two?). The concept of a simpler operation for CIL does not materialize in practice.

2. CIL is probably cheaper than CIP, but not much, and the difference is possibly less than 10% (and less than 1% of total project costs). Savings in tanks and agitators are partially or wholly offset by the greater carbon and gold inventory. (CIL inventories are approximately twice that of CIP. Greater carbon inventories in turn lead to greater carbon losses through attrition.) In addition, it can be argued that the higher carbon inventory will cause more adsorption of contaminants as the carbon stays longer in the adsorption circuit.

3. The CIL circuit operates with much lower carbon concentrations, typically 40 to 65 lb/1000 gal (5 to 8 g/L), and this results in the forward transfer of significantly greater volumes of pulp. This increases the load on the interstage screens, and calls for larger transfer pumps that frequently operate continuously. This high volume of pulp transfer undoubtedly contributes significantly to back mixing and in turn poor gold loading profiles and carbon distribution. The result is lower overall gold recovery.

4. Combining the processes can inhibit the optimization of the operational conditions for either process as the conditions can often be in conflict. Leaching may require high cyanide and lime levels and mixing rates. These are all detrimental to the adsorption process. Similarly, higher temperatures enhance leaching, but are detrimental to adsorption.

The reason that CIL is frequently installed in new plants is because some ores contain significant quantities (0.25% or more) of carbonaceous material. Under these circumstances, CIL, with the early addition of active carbon, reduces the effect of “preg robbers”. Whether this advantage is greater than the disadvantages of CIL is site-specific, and confirmatory test work and economic analysis should be completed prior to a final decision.

25.4.1.3 Carbon Regeneration

The successful application of CIP is dependent upon multiple use of the carbon through many adsorption-elution cycles. As the activity of the carbon is the main criterion that governs the gold recovery from solution, then it follows that some form of regeneration will be necessary.

Several types of kilns have have been proposed and tried for thermal regeneration. The conventional rotary kiln remains the most popular choice. Other kilns have been proposed, tested, or installed, resulting in various degrees of success. These include fluid bed, multiple hearth, resistive heating, conveyor belt, and indirect heat furnaces. Most operations continue to prefer the conventional rotary kilns.

During adsorption a whole host of organic and inorganic chemicals accumulate on the carbon (if they are present in the pulp), together with the precious metals. Thus water quality is important in the CIP process. Organics that may be present due to accidental spills or that are residual from effluent treatment plants (if such water is used by the plant) are particularly strongly adsorbed and foul the carbon. Thus the objectives of reactivation are to remove the adsorbates and return the carbon to, or near to its original quality in terms of activity. [Regeneration also includes periodic acid washes that remove the lime scale that can foul the carbon.]

25.4.1.4 Carbon Stripping (Elution)

Loaded carbon is periodically transferred from the number one contactor (either CIP or CIL) to the carbon stripping circuit. Stripping is also commonly referred to as elution.

In the stripping circuit, the gold is removed from the carbon into a pregnant solution. The gold (and silver) is generally recovered from this pregnant solution by electrowinning (as described in 25.4.1.5) or by zinc precipitation (Merrill-Crowe).

In stripping, the loaded carbon is first screened to separate the carbon from slurry or solution. The carbon is then transferred into a vertical strip column. A hot (230 to 266°F or 110 to 130°C) dilute solution, (usually a caustic/cyanide mix) is then pumped up through the column, this strips the adsorbed gold from the carbon. Usually a warm hydrochloric acid wash is also employed, either before or after stripping, to remove other materials, such as carbonates, that if left would ultimately blind the carbon.

Two approaches to stripping have been developed, namely the Zadra Process (common in North America) and the A.A.R.L. Process (developed and used in South Africa). Both systems have their proponents. As long as they are correctly designed, both systems work well and allow efficient stripping of the precious metals. Atmospheric stripping (temperature below 212°F or 100°C) is very slow and is seldom used.

25.4.1.5 Gold Electrowinning

Electrowinning is frequently used to recover gold from the pregnant solutions generated by the hot elution of gold from loaded carbon. It is a simple technology which has been successfully applied at many new gold mines throughout the world during the past 10 years. The electrowinning cells are typically small tanks, with 15- to 175-ft^3 (0.5- to 5.0-m^3) capacity, and are fabricated from a wide range of materials. The cells contain stainless steel plate anodes. The cathodes are usually in the form of steel wool in polypropylene cases. Gold is deposited at the cathode, together with evolution of hydrogen, and the predominant reaction at the anode is the generation of oxygen.

GOLD ELECTROWINNING CELLS. Parallel to the rapid development of carbon-in-pulp technology, considerable efforts have been made in cell development. As the technology has evolved, there has been a general acceptance of the rectangular, open-bath-type cell, with the other types being used less frequently. In this type of cell, the cathodes and anodes are suspended vertically in a rectangular tank, as shown in Fig. 25.4.1.3. The size of the tank and the numbers of electrodes are determined by the volume and tenor of electrolyte. The anodes are 316 stainless steel perforated plates or woven wire mesh (generally 1-mm wire, woven at a 3-mm pitch). The cathodes are polypropylene boxes, filled with stainless steel or mild steel wire wool. A stainless steel frame is incorporated into the cathode box to

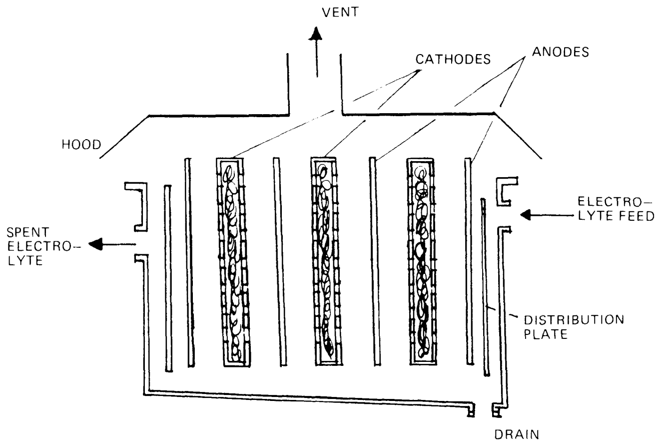

Fig. 25.4.1.3. Rectangular-type gold electrowinning cell.

add mechanical strength and provide electrical distribution across the whole cathode area. A typical cathode box would have dimensions of 12 by 150 by 150 in. (50 by 600 by 600 mm) and contain between 2 and 4 lb (1 and 2 kg) of steel wool. A steel wool packing density of 1.8 lb/ft^3 (30 kg/m^3) is the norm.

The cells are generally manufactured from either stainless steel (in which case, good insulation is necessary to prevent stray currents) or of plastic and fiberglass. Although lower in cost, care must be taken with plastic and fiberglass units in order to provide mechanical strength and durability. Operating data for a typical cell are as follows:

Cell size ($L \times W \times H$)	in.	$35 \times 28 \times 25$
	(mm)	$(900 \times 720 \times 640)$
Volume	ft^3	14
	(m^3)	(0.4)
Flow rate	ft^3/min	5
	(m^3/min)	(0.15)
Residence time	min	2.7
Cell current	A	500–800
Cell voltage	V	3–5
Number of cathodes		6
Number of anodes		7
E (single-pass efficiency)	%	70

25.4.2 COPPER PROCESSING

WAYNE R. HOPKINS

25.4.2.1 Solvent Extraction: Principles

For the commercial production of copper via solvent extraction, the common reagents are chelating, copper-specific species where the reactions are a hydrogen ion cycle as shown in Eq. 25.4.2.1 (and where R is the reagent molecule):

in extraction *in stripping*

$$2RH_{(org)} + Cu^{2+}SO_4{}^{2-}{}_{(aq)} \rightleftharpoons R_2Cu_{(org)} + H_2SO_{4(aq)} \quad (25.4.2.1)$$

with the direction of the reaction being controlled by hydrogen ion concentration.

These reagents demonstrate:

1. Fast reaction kinetics.
2. A high selectivity for the metal over a wide pH range.
3. Good stripping characteristics of the organic extract by change of parameters using acid levels in associated spent electrolyte of less than 1.2 lb/gal (150 g/L).
4. Rapid coalescence.
5. High solubility in the organic diluent and low solubility in the aqueous phase.
6. Low rate of degradation by hydrolysis, etc.
7. Low toxicity.
8. High flash point.

Diluent such as kerosene is used to reduce the viscosity of the extractant reagent and facilitate contact of the reagent with the aqueous solution. Such diluent is a mixture of paraffins, napthenes, and aromatics. Depending largely on the proportion of aromatic material, the diluent has some effect on the equilibrium, extraction kinetics, and phase separation. In copper systems, diluents are always high-flash-point (169 to 172°F, or 76 to 78°C) kerosenes to avoid the fire danger.

The stripping operation is the reverse of the extraction. In this step the loaded organic from the extractors is stripped of its loaded copper ions and converted back to a form appropriate for return to the extraction step. A chemical environment is employed that will cause the desired product to leave the organic phase and distribute into a concentrated aqueous solution from which it can be recovered. In addition, the stripping operation must restore the solvent to original activity for extraction.

25.4.2.2 Solvent Extraction: Equipment

The function of the liquid-liquid contactor is to bring two liquid phases together to allow maximum mass transfer between them and then to separate them prior to further contacting or processing.

There are a large number of contactor designs that fall into two categories: stagewise and differential. Column contactors are an example of differential contactors and are commonly used in the petroleum industry; they may be unagitated or agitated mechanically or by pulsing. Another example of a differential contactor is the centrifugal contactor. Mixer-settlers are stagewise contactors.

Several commercial firms offer proprietary mixer and settler designs that incorporate recent improvements, with the latter using the pumping type of mixer in order to avoid the cost of large interstage pumps. Of the earlier pumping mixers, the most widely used pump-mix impeller is the Denver-General Mills design, which has the turbine located at the bottom of the mixer tank. The turbine is a flat disc with radial blades beneath. It is mounted only 0.8 to 1.2 in. (20 to 30 mm) from the tank bottom, which then acts as a second impeller shroud and minimizes recirculation. Another type is the Davy design, which is mounted centrally in the mixer tank and is fed by a draft tube to the impeller eye. A compromise design has been developed using a Denver-type impeller at the tank center above a draft tube carrying a flat annular section that provides the second shroud. It is double shrouded with eight backswept vanes and may be fitted with spoiler blades. All these designs are used at tip speeds of less than 20 fps (400 m/min) to reduce secondary haze formation, and entrainments of organic continuous stage are normally 50 to 100 ppm.

The primary organic/aqueous dispersion formed in the mixer is allowed to disengage in the settler, where clean layers of each phase form by coalescence. The dispersed phase feed to the settler from the mixer should ideally consist of droplets with a narrow size range distribution. The bulk of the droplets produced are generally larger than 50 to 100 μm and are referred

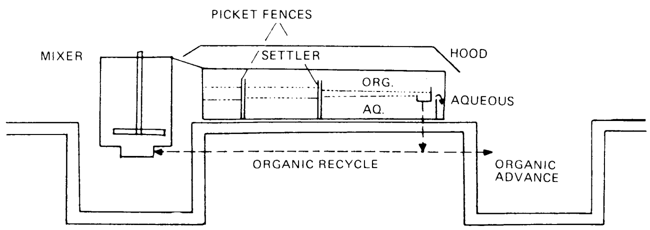

Fig. 25.4.2.1. Conventional mixer-settler (on grade).

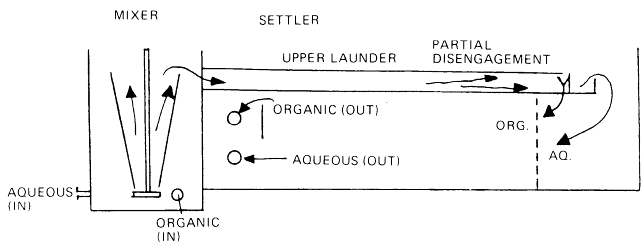

Fig. 25.4.2.2. Krebs mixer-settler.

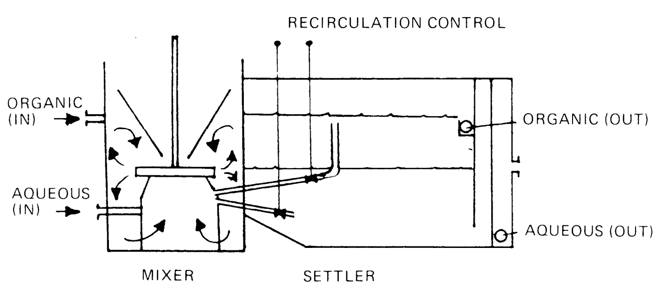

Fig. 25.4.2.3. Outokumpu mixer-settler.

to as the primary dispersion. Settlers are basically shallow rectangular tanks with a dispersion inlet at one end consisting of a baffle arrangement that directs the incoming mixture into the dispersion band existing in the settler. This introduction is kept at a controlled level by adjusting the height of the aqueous weir. This method of introduction reduces the formation of secondary entrainment by preventing the redispersion of the settled phase. At the opposite end of the settler, weirs separate clear organic and aqueous phases. Typical settler sizing is based on flowrates of about $3ft^3/ft^2/min$ ($5\ m^3/m^2/h$).

A typical configuration for the conventional pumping mixer and settler combination is shown in Fig. 25.4.2.1. The designs offered by Krebs (Fig. 25.4.2.2) and Outokumpu (Fig. 25.4.2.3) are the most recent in the field.

An important comment is useful as regards protection from potential fire hazards due to the flammability of the organic liquids. The fire protection system is normally arrived at on a case-by-case basis in conjunction with the operator's insurance underwriter. The aim of the firefighting system must be to extinguish any fire within about 10 minutes and to ensure that the adjacent mixer-settler units are cooled sufficiently to prevent extension of the fire. If a fire with the kerosene-type liquid is not extinguished in this period, then it is most probable that serious and extensive fire damage will result, putting the plant out of operation for a long period. The attainment of high temperatures during prolonged combustion will make the fire especially dangerous as the aqueous layer beneath the organic layer will boil and generate large quantities of steam which may eject burning organic droplets.

25.4.2.3 Electrowinning

Electrowinning is the final step in the production of metal from the recovery plant associated with a leaching operation. It consists of the electrowinning tankhouse, associated electrolyte pumps and tankage, materials handling equipment for starting sheet production, and product cathode packaging and shipping. Although the technology has been in place for about 100 years, the features of modern electrowinning (EW) tankhouses relate mostly to reduction in capital and operating costs and improvement in the copper cathode quality. The notable improvements in capital cost are due to (1) use of higher current density, (2) larger cathodes, and (3) use of improved corrosion-resistant materials of construction.

Use of a higher current density plays a very significant role in minimizing capital investment requirements for an electrowinning plant. Both pilot and commercial solvent extraction/electrowinning plants have shown that higher current densities are feasible for the relatively purer electrolytes produced. Operation of conventional type cells at 28 A/ft^2 (300 A/m^2) is now accepted.

Use of larger cathodes generally results in a better physical and chemical quality product. This is because the rough and often more impure copper occurs around the edges of the cathode. Use of larger cathodes results in capital investment cost savings.

1. The physical size of the cathode should be considered from a materials handling standpoint. This is particularly important when handling thin starting sheets to be sure they are not bent, etc.

2. The dimensions of the cathode should be chosen to allow interchangeability with other tankhouses. This may be important during startup when starting sheets may have to be purchased from outside sources to augment the production being built up in-house.

Taking all these into account, a size of 39- by 39-in. (1- by l-m) immersed cathode is appropriate. This is the commonest size in use. The spacing and number of cathodes per cell is based largely on personal experience and preference; however, there are some factors to consider:

1. Cathode spacings generally fall in the range of 3 to 4 in. (75 to 115 mm). The shorter dimension favors shorter cells (or more cathodes per cell) and a lower electrolyte IR drop. The wider spacing can result in improved flow conditions between electrodes, use of thicker (longer life) anodes, and some decrease in electrical shorts.

2. Over the years, the number of cathodes per cell has increased up to around 60. The main factors here are electrolyte flow patterns and keeping the cell short enough to allow for efficient crane handling of the cathodes. It is usual practice to choose a number divisible by 3 and (often, as well, by 2, e.g., 48). This simplifies cell-pulling techniques where every third cathode is pulled from the cell by the crane bale. Thus, as this pulling is done "live" with no interruption of power to disturb the anodic condition of the lead anodes, the current density on the cathodes remaining in the cell is increased only by 50% during the short duration of the pull.

Improvements in operating costs arise from fewer manual operations generated from fewer EW cells (when these are of maximum size and operate at the highest current density commensurate with product purity), improved tankhouse layout, and reduced stray current losses. For this last item, it is unusual for modern tankhouses to experience stray current losses in excess of 1%. This has largely been due to the widespread use of plastic piping systems for electrolyte recirculation in place of the earlier lead piping and the adoption of nonconducting cell linings.

Improvements in cathode quality have allowed the newer EW facilities to consistently produce product better than 99.99% Cu and, at least in one case, better than 99.999%. This improvement has arisen since the advent of solvent extraction of leach solutions, which enables electrowinning tankhouse operators to electrolyse very pure electrolytes. A difficulty remains in that the acid content required for effective stripping of the loaded organic produces an electrolyte of considerably higher acidity than that found in traditional leach solutions. This acid is sufficient to attack the lead anodes usually used in electrowinning, but the use of alloyed lead (with calcium, antimony, tin, etc.) and cobalt additions can control this phenomenon. It has been known since the 1920s that the presence of up to 100 ppm of cobalt in copper sulphate electrolyte modified the morphological structure of the oxide layer of a polarized lead anode, with a high proportion of PbO_2 being formed.

This earlier work has been rediscovered and the technique is now widely applied in tankhouses associated with solvent extraction plants. Cobalt levels are usually in the range of 60 to 100 ppm, partly dependent on current density. Very high-purity cathodes are obtained using such cobalt-modified anodes with usual lead levels of less than 5 ppm being reported. A similar preferred formation of a PbO_2 is observed if the anodes are pretreated by electrolysing in fluoride solutions before loading into the tankhouse cells. This is a well-known technique used with the lead/silver anodes of zinc electrowinning.

A drawback in the system is inherent in the solvent extraction unit operation. This is the carry-over of iron by the reagent and the necessary bleeding off of this iron from the tankhouse to control electrolyte iron levels. This bleed also causes cobalt losses which is a high-cost additive.

Of major concern in modern solvent extraction/electrowinning installations is the generation of acid mist which collects in the tankhouse building above the cells. This is caused by anodicly generated oxygen bubbles carrying the mist up from the electrolyte surface in the cell. In earlier leach/electrowin units, the problem was largely overcome by the use of foam-generating additives, such as Dowfax 2A1, which provide a foam blanket on the cell surfaces. Unfortunately, virtually all of the previously used surfactant materials are incompatible with solvent extraction circuits where their surfactant properties have deleterious effects on settling and extraction characteristics. AFFF type foams are suitable, but dosage control has been a problem. An effective solution is to use two or three layers of polyolefin balls of proprietary design on the cell surfaces. These reduce mist generation by 70 to 80%. There are objections to their use, usually quoted as “they get everywhere.” Electrowinning plants of large size associated with solvent extraction plants have been forced to use these ball covers to meet OSHA (Occupational Safety and Health Act) requirements, and as a result, excellent cell designs have been developed that retain the balls on the electrolyte surface very effectively.

If the proper precautions are taken, plants can comply with the local equivalent of the 1 mg/m^3 standard for an 8-hour exposure as required by OHSA in the United States. To achieve this level, the plant would operate at 0.8 to 1.0 lb/gal (100 to 130 g/L) H_2SO_4 and current density of approximately 18.5 to 23 A/ft^2 (200 to 250 A/m^2).

25.4.2.4 Electrorefining

Unlike an EW operation, which merely recovers copper, *electrorefining* actually purifies the copper. Electrolytic refining of copper starts with an impure copper anode cast directly from a refinery furnace. The impure anode and a pure copper cathode, usually a starting sheet, are suspended in an electrolyte of copper sulfate and sulfuric acid. Direct current applied to the cell causes the anode copper to go into solution with corresponding amounts of copper being plated out onto the cathode. The electrochemical reactions at the electrodes are equivalent, but reversed, and the overall component of cell voltage from the electrode reactions is zero. There is essentially no net change of copper content in the solution, the only changes in solution composition being increases in the contents of impurities in the electrolyte. Metals above Cu in the electrochemical series will not discharge at a cathode as long as copper ions are present. Thus copper can be separated from other metals and impurities in an electrolyte bath. Copper is sufficiently electropositive to hydrogen in this solution to allow its deposition at high-current efficiency within a wide range of concentration, electrolyte temperature, and current density.

In contrast to electrowinning where precious metal values in the ore body are left in the gangue during leaching, the electrorefinery is able to recover these important constituents. Such metals as gold, silver, platinum, palladium, selenium, and tellurium report through upstream processing and finally report the blister copper cast into the cell anodes. During electrolysis, these impurities fall to the cell floor (rather than deposit), forming slimes that are further treated for their recovery. This anode slime must be removed after every load of anodes or every second load have been consumed (i.e., every one or two months). The refinery has two conditions to deal with apart from deposition of copper at the cathode: increasing impurities in the electrolyte and problems due to the presence of significant amounts of slimes. As stated above, the latter are cleared from the anodes and cells, but the only method of electrolyte purification is to drain off and discard some electrolyte to keep the concentration of impurities below a certain economic limit.

Improvements in electrorefining have been made in recent times mostly in the realm of automation to reduce labor costs: (1) infrared spotters can detect shorts, (2) laser spotters can position crane loads exactly above the cells, and (3) “jumbo” cells can save on capital cost and reduced handling. These improvements are best exemplified by the Naoshima refinery in Japan and the 419,000-tpy (380,000-t/a) Amarillo plant of Asarco in Texas. Automated anode handling systems take loads of closely stacked anodes, mill or twist the lugs so they hang true in the cells, separate them at the correct cell spacing, and place them along conveyors or in racks ready for pick up by the crane. Starting sheet stripping lines are partially automated; blanks are stripped and prepared on a conveyor and accumulated at the correct spacing for crane pickup. The conveyor passes on to take up deposit blanks left by the crane; these are dip washed and stripped (usually manually) of deposits by strippers working on both sides of the blanks as they pass by on the conveyor. Blanks are then returned for reloading into the cells.

Improvements are also being made in the area of impurity control in the circulating electrolyte and better control of addition agents (glue, thiourea, chloride) used to promote smooth growth. The newest ideas for impurity control will see increasing use of solid and liquid ion exchange/solvent extraction, tailor-made for removal of specific impurities.

25.4.3 ZINC PROCESSING

WAYNE R. HOPKINS

25.4.3.1 Solvent Extraction

The production of special high-grade (SHG) zinc from sulfide concentrates utilizes a final zinc electrowinning step. The successful electrodispositon of zinc in this process depends upon solution purity, but there was no universally applicable solution purification process available until the advent of the Espindesa Process by Technicas Reunidas in Spain. This process employs a two-stage solvent extraction operation. The first stage extracts pure zinc chloride from an impure feed leach liquor, and the second stage produces a pure zinc sulfate solution from the zinc chloride. The extreme selectivity of the solvent extraction stages permits removal of those impurities deleterious to electrolysis.

An anion extraction reagent, a secondary amine, that removes the zinc as an anionic chloride complex is used in the first step. Extraction proceeds according to Eq. 25.4.3.1.

$$2R_2NH_2Cl_{(org)} + ZnCl_{2(aq)} \rightarrow (R_2NH_2)_2ZnCl_2{}^{2+}{}_{(org)} + 2Cl^-{}_{(aq)} \quad (25.4.3.1)$$

This is followed by a washing stage where the loaded organic is washed in acidified water to remove entrained aqueous feed and any other metal ions that may have been co-extracted with the zinc into the organic. The wash water is returned to the extraction stage, joining the feed. Next, the zinc is stripped from the organic with water in accordance with the reaction:

$$(R_2NH_2)_2ZnCl_{4(org)} + H_2O_{(aq)} \rightarrow 2R_2NH_2Cl_{(org)} + Zn^{2+}{}_{(aq)} + 2Cl^-{}_{(org)} \quad (25.4.3.2)$$

The organic extractant is regenerated and can be returned to the extraction stage. Only copper and cadmium are partially extracted with the zinc and pass on to the second part of the extraction process. In this second extraction step, the zinc is removed as the normal metal cation Zn^{++} using di-2-ethyl hexylphosphoric acid (D2EHPA) as the active reagent, which is also diluted in kerosene. The reaction is

$$2(RO)_2PO_2H_{(org)} + Zn^{2+}{}_{(aq)} \rightleftharpoons [(RO_2)PO_2]_2Zn_{(org)} + 2H^+{}_{(aq)} \quad (25.4.3.3)$$

Control of pH is important. At pH values above 2.8, Cu and Cd can co-extract with the zinc, while low pH reaction kinetics are slow. Loaded organic phase is first washed with dilute acid to remove aqueous entrainment, particularly chloride ions. Any copper and cadmium ions extracted with the zinc in the first stage are removed in the second-stage raffinate. Spent sulfate electrolyte from the zinc electrowinning plant is used to strip the loaded organic. This produces a strong electrolyte at 0.6 to 0.7 lb/gal (80 to 90 g/L) zinc. Any organic entrainment is reduced to 1 to 5 ppm by coalescence using settling tanks and charcoal filters.

25.4.3.2 Electrowinning

In this process step, the purified zinc sulfate solution is decomposed by direct current; zinc is deposited at the cathode, oxygen is liberated at the anode, and sulfuric acid is formed by the combination of hydrogen and sulfate ions. This produces the spent electrolyte that is used to leach the zinc calcine or to strip the solvent extraction organic reagent.

Cells are of concrete construction similar to copper electrowinning and are lined with PVC. The number of electrodes per cell is typically 35 to 50. The newer type anodes are constructed of a 1% silver-lead alloy. Alloyed anodes reduce voltage and slightly decrease the current efficiency but cause less contamination of the cathode with lead. Cathodes are constructed of aluminum sheet. Both anode and cathode have copper head bars. Typical electrode dimension are 40 by 25 in. (1000 by 600 mm). In some cases, where mechanical striping and handling are employed, electrodes up to 60 by 35 in. (1500 by 900 mm) are used. Cells are connected electrically in series using Walker multiple connections, and are usually arranged in units of 150 to 200 cells. The cells are arranged in tiers or "half sections" in a similar way to copper tankhouses, with current being carried to and from these and across the back busbars by copper busbar multileaf units.

Neutral solution is added to the electrolytic cells in controlled amounts, using a circulation circuit similar to that for copper electrowinning. The objective is to keep the zinc content and the acid content of the electrolyte constant. In the so-called low-acid plants, acid strength of the electrolyte is held at a level between 0.8 and 1.6 lb/gal (100 and 200 g/L) of sulfuric acid. The deposit character is modified using additions of glue, gum arabic, silicic acid, and strontium carbonate.

Current density, varies among plants from 18.5 to over 90 A/ft^2 (200 to over 1000 A/m^2). Most plants operate in the range of 55 to 65 a/ft^2 (600 to 700 A/m^2). In general, a higher current density means higher voltage per cell, higher acid strength needed, increased cooling load, faster deposition, less floor space and less solution to handle, better purification, closer electrode spacing, and a need for heating leach solutions. Choice of current density depends on how these various factors balance up at each plant location.

Frequent cleaning of cells is also necessary owing to the slimes that form on the anodes and on the cell bottoms. This is largely manganese dioxide, brought in with the electrolyte, where it is added to oxidize iron in the neutral leach. It forms on the anode as a slime coating, and although much of it falls off as a sludge into the bottom of the cell, the remainder has to be removed once it builds up beyond a certain point.

In modern installations, the deposited zinc is mechanically stripped from the aluminum cathodes. The principle of all mechanical stripping is similar; that is, the cathode is loosened by hammering or by short-travel, pneumatically operated knives, then the deposit is removed by a large knife moving across or down the face of the cathode. Mechanical stripping has been made possible by the ability to control the complete process of purification and electrolysis to achieve very consistent conditions. As a result, the adhesion of the zinc to the aluminum cathode remains constant, and the zinc can be removed using the same mechanical effort each time. Fully automated tankhouses are now operating with sophisticated computer logic control of all operations.

25.4.4 MOLTEN SALT ELECTROLYSIS

RICHARD B. STEIN

Three important metals are produced industrially by electrolysis in fused salts—aluminum, magnesium, and sodium—and their annual production is on the order of thousands of tons (tonnes): aluminum 1200 (1100), magnesium 220 (200), and sodium 75 (160). Aside from magnesium (where about 35% of its

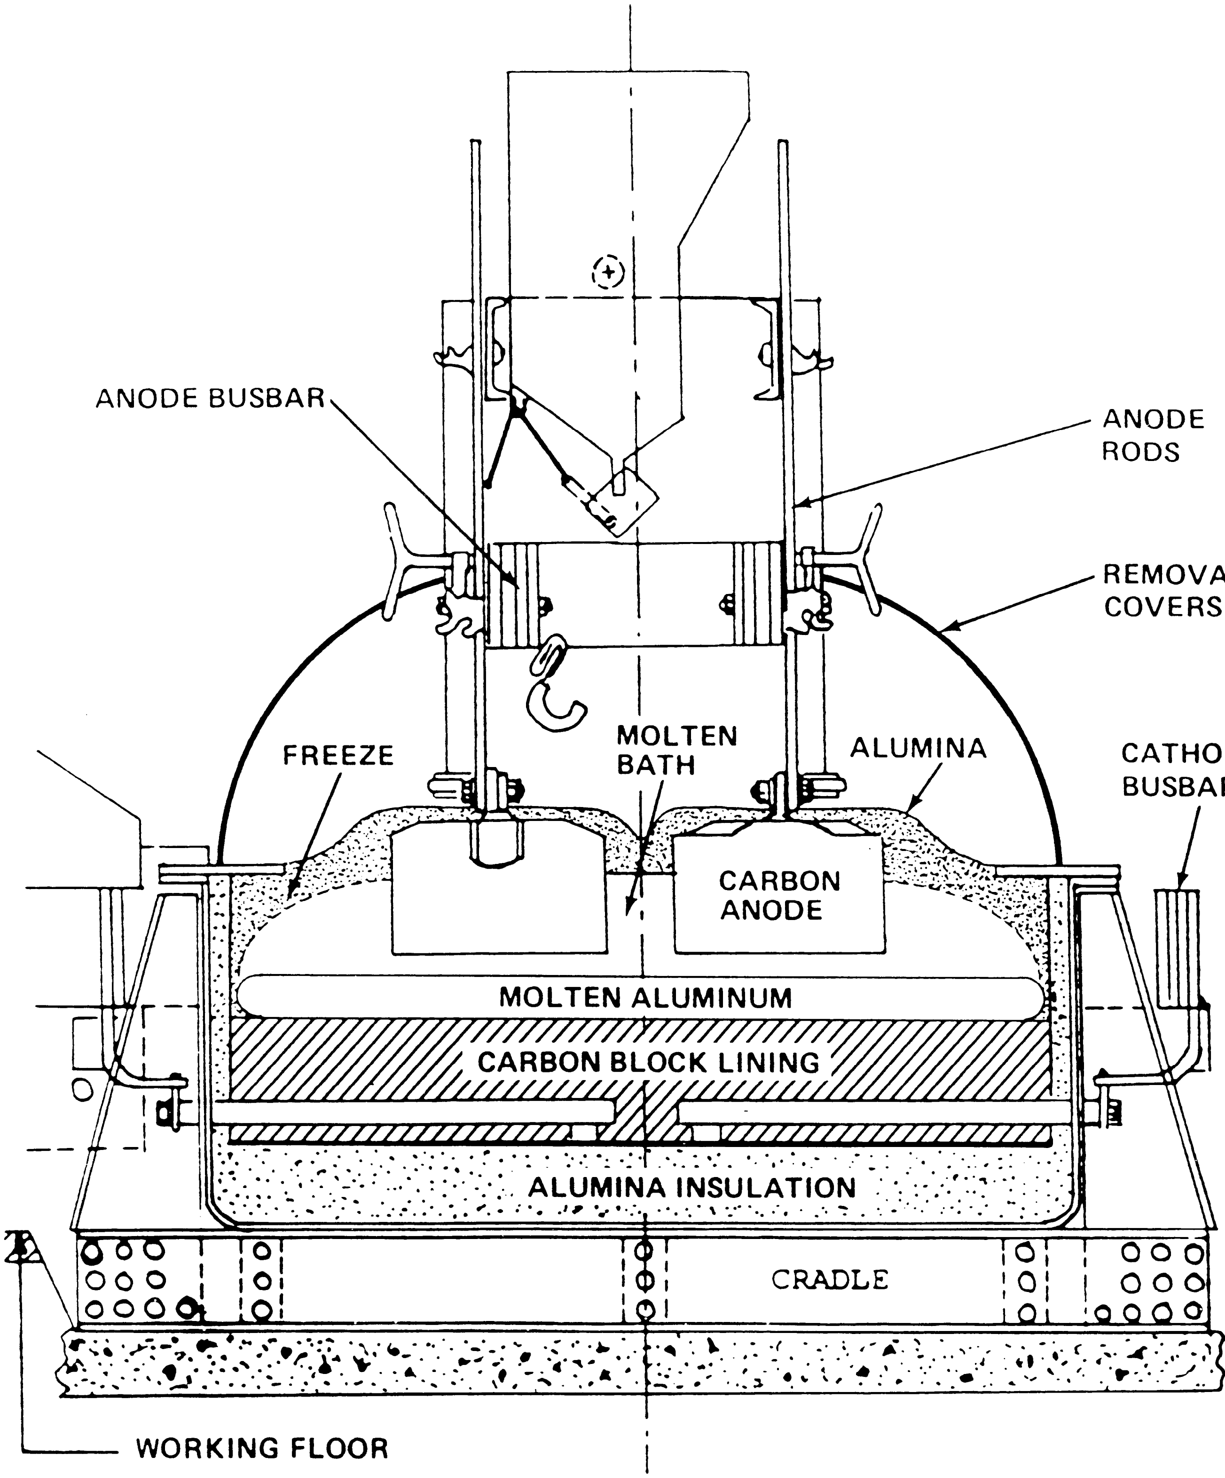

Fig. 25.4.4.1. Typical aluminum reduction cell.

production is by thermic reduction using ferrosilicon), there is no alternative method for other commercial-scale production. Magnesium and sodium are electrolyzed in mixed chloride baths at operating temperatures of 1076 to 1292°F (580 to 700°C) employing eutectic salt baths to lower the temperature. Aluminum electrolysis is practiced in a molten fluoride bath at about 1760°F (960°C).

25.4.4.1 Aluminum

Aluminum was an exotic rare metal until 1888 when Hall in America and Heroult in France independently discovered that aluminum oxide could be dissolved in the natural fluoride mineral cryolite, which is an equimolal mixture of sodium and aluminum fluorides. Cryolite melts at 1854°F (1012°C) and when

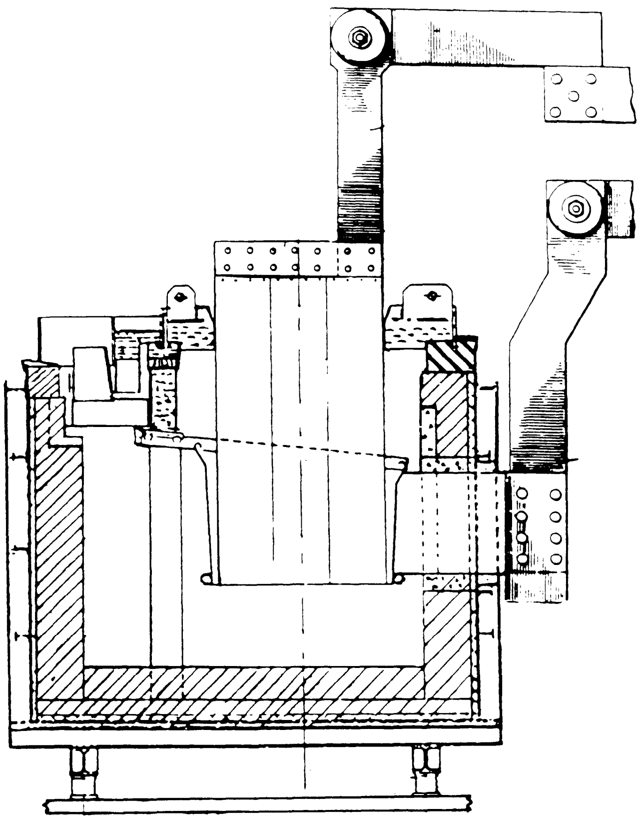

Fig. 25.4.4.2. Magnesium electrolyzer cell (Can. Patent No. 3,396,094).

it dissolves about 2 to 5% aluminum oxide, the bath is sufficiently molten to ionize the aluminum oxide. This bath will support electrolysis at 1724 to 1796°F (940 to 980°C) due to fluid action of bath additions, typically lithium, calcium, and aluminum fluorides.

Over the past 100 years, electrolytic cell design has matured, and in recent years it was driven by considerations of intensive capital costs, high energy costs, and need to eliminate fluoride emissions. Most modern aluminum reduction plants typically employ a line of cells of the type shown in Fig. 25.4.4.1, arranged in a potroom about 1300 ft (400 m) long and containing sufficient pots to produce 120,000 tpy (109,000 t/a) of metal.

The cells measure typically 33 to 46 ft (10 to 14 m) long, 10 to 16 ft (3 to 5 m) wide and 3 to 5 ft (1 to 1.5 m) high and are constructed of an outer steel shell, thermal insulation, carbon block lining, and suspended prebaked anodes of semi-graphitized petroleum coke. Even though the size and shape have continually changed because of the combined corrosive action of molten fluroides and molten metal, the materials of construction have remained essentially unaltered. The individual cells are hooded with covers, and an efficient gas collection and scrubbing system eliminates the cell gas emissions.

Within the cell electrolyte, the aluminum oxide is ionized, and metal is deposited at the cathode, and oxygen and carbon react at the bath-anode interface. The overall chemical reaction is

$$2Al_2O_3 + 3C \rightarrow 4Al + 3CO_2\uparrow \qquad (25.4.4.1)$$

whereby about 2 lb (0.9 kg) of Al_2O_3 and 0.5 lb (0.2 kg) of carbon (consumbable anode) make 1 lb (0.45 kg) of metal and 1.2 lb (0.54 kg) of gas to the scrubbers.

Economic trade-offs have driven the pot current to about 180,000 to 300,000 A at about 4.5 V dc across the cell. The cell inefficiences of ohmic resistance and polarization furnish the internal heat to maintain the high temperature. Power consumption is about 6.1 kWh/lb (13.5 kWh/kg) of metal product.

In operation, the cell contains about 0.5 to 4.0 in. (10 to 100 mm) of molten aluminum lying on the carbon cathode. A layer of 5 to 10 in. (120 to 250 mm) of molten electrolyte floats atop the metal pad, and above the molten electrolyte is a crust of frozen electrolyte. A special pot-tending, crust-breaking machine is used to make holes in the crust on a fixed schedule for alumina addition to restore the bath composition. Another special machine carries a vacuum crucible for aspirating a cell-day of production, typically one ton of metal, which is delivered to the casthouse for purification and ingot casting.

In addition to metal production and handling, a modern plant contains facilities for alumina storage; mixing, forming and baking of anodes; pot rebuilding; machinery services; pollution control; electric power; transportation, etc.

25.4.4.2 Magnesium

About three-quarters of the world's magnesium is produced by fused salt electrolysis, of which about one-half is based on sea water and the balance on brines, bitterns, carnallite, or other sources of magnesium chloride.

In the seawater process, the magnesium content of seawater is precipitated with calcined dolomite, and the resulting magnesium hydroxide is converted to chloride using recycled hydrochloric acid from the electrolytic cells. After recovery of magnesium chloride from the seawater, the cell feed is a hemihydrate, $MgCl_2 \cdot ½H_2O$, whose electrolysis requires consumable graphite anodes (as in aluminum reduction) at the rate of 0.1 lb/lb (kg/kg) of metal, plus external heat. Power consumption is said to be 8.0 kWh/lb (17.6 kWh/kg) for this process, which dates back to World War II.

The latest magnesium processes use anhydrous chloride and permanent graphite anodes which last from 2 to 5 years. The cells are completely sealed, and a typical cell will produce about 1 tpd (0.9 t/d) of metal and nearly pure chlorine gas at about 2.5 tons/ton (t/t) of metal. The process can start with chloride-containing brines that require purification, evaporation, dehydration, and chlorination to produce molten, anhydrous cell feed, or else can start with magnesite and carbon and use cell chlorine to make molten, anhydrous cell feed in specialized reactors upstream of the electrolysis.

In the modern diaphragmless cell in Fig. 25.4.4.2, the electrolyte is a mixture of $MgCl_2$-KCl-NaCl-$CaCl_2$ at 1292°F (700°C) with a density such that magnesium metal product floats, rather than sinks as in aluminum electrolysis. Each graphite block anode is surrounded by a steel cathode with sloping ends and sides which induce convective flow, causing metal globules to rise and coalesce in the upper collection pipe and then be conveyed to metal collection chamber at the front of the cell. Metal is removed once or twice per day by a vacuum crucible and taken to the casthouse for pouring into ingots. The power consumption for this type of electrolytic cell is about 6.35 kWh/lb (14 kWh/kg) of metal product, and compared to the seawater process consumes essentially no graphite and produces a pure chlorine byproduct.

Chapter 25.5
SALES AND MARKETING

BRIAN NOLK

The sales and marketing of mineral products is a distinctive activity within a mining company and operates in a relatively subjective mode rather than the more familiar scientific modes of geology, mining engineering, etc. This chapter attempts to explain the often volatile and seemingly erratic operations of the marketing process to the more classically trained person. Information on pricing and trading is presented in Chapter 2.3.

It is important to remember that the engineering and operationing functions of any company are affected by the success, or failure of the marketing staff, and that there is no point in mining or processing any material that cannot be sold at a profit. Geologic, engineering, and operations professionals are forced to work within a multi-year time frame for the discovery, delineation, study, and engineering development of mineral deposits. For example, a large copper deposit may require as long as seven years to develop. Due to the evergrowing complexity of the environmental requirements, this period is getting even longer. It follows that any economic considerations that can delay the process, or terminate it completely by undermining the viability of the entire deposit, are often considered contrary and unfair by those who have worked so hard and so well for the project.

However, the marketing strategies that a company may choose to employ can work to ameliorate the risks inherent in any mining venture. The more a company knows about the commercial viability of a project, and the ways the viability can be enhanced, the easier it is for that company to get on with the engineering and mining tasks. It is a matter of knowing which strategies exist and which may best fit a given enterprise.

Included below are some basics of marketing and sales for the layman to consider. The hope is that understanding the mechanics of these economic forces will make living with them easier.

25.5.1 MARKETING PHILOSOPHY

The linkage in the long chain between producers and end consumers, connecting each group to the next one down the material chain, is the sales and marketing activity. It must be remembered that a material is often sold at several stages of its life. In the case of copper, for example, sales activity can occur at the stage of ores and concentrates, intermediate metal (such as blister copper), refined metal (such as electrowon or electrolytic cathode), alloyed unwrought metal (such as brass billet), semifinished products, finished products, and back again as scrap.

At each step of this chain, the material is bought and sold or, if processed internally, at least priced for that purpose. At each step, the producer may seek to hedge his risks and to price his physical inventory for accounting and insurance purposes. Thus "sold" is meant to include the step in an internal process where the value of the material is determined. Again, to use copper as an example, a copper mining company will want to know the market for concentrates as well as that for blister, to determine whether it is worthwhile building, or more commonly, upgrading a smelter. The market for concentrates can often be completely different from that of the metal, and a business decision will have to be made regarding the disposition of concentrates.

The internal selling of concentrates to a company's own smelter is a valid marketing exercise. It helps a company evaluate whether its materials should be continued on down the chain, or whether the owner should halt the process and either find a substitute source or substitute material, or in some other way interrupt the chain.

The relative glut or shortage of a material at any stage in this chain will have some effect on the sales and marketing of the other materials along the chain, but the glut or shortage may not affect the entire chain equally. For example, if a disruption occurs at a major copper refinery, there may be a temporary shortage of refined metal and by-products due to the refinery problem. Accordingly, the price of copper cathode may jump sharply as available refinery capacity limits the immediate availability of refined metal.

What must be remembered by participants in the mining industry is that the increasing internationalization of the minerals commodities markets will cause any relative surplus or shortage of a material on the other side of the world to have some impact on the domestic market, either directly or indirectly. While this has been always true of many minerals, the impact is greater now than it ever was. This is something to remember when one discovers that the market price for the mineral product has dropped since last year, even though the domestic demand has remained roughly the same. If a new project in Brazil or China has come on-line in the interim, the economics of the world market have changed, and there is no use fighting facts.

25.5.2 TYPES OF TRANSACTIONS

It is necessary to sort out the types of transactions that fall within the marketing and sales framework. Some of the sales transactions at each of these individual steps are quite straightforward, involving individual contracts of sale with fixed prices and tonnages, and some are quite complex, involving multi-year contracts with periodic pricing linked to terminal exchange price formulas for various levels of tonnage, sometimes involving currencies other than the one the producer would prefer. A description follows of the various methods of marketing and pricing, from the most straightforward to the most complex, with emphasis on how these prices are used by the industry.

25.5.3 PRODUCER PRICING

Still quite common in the United States and some other areas of the world, producer pricing is a straightforward mechanism by which a minerals producer establishes a price for its product by announcing to key customers and the media a fixed price of the day (or month, quarter, etc.). Producers set prices they feel are reasonable and competitive, and which they have the authority to alter at their convenience. Consumers can contract in set amounts, commonly in increments of short tons per month for delivery, with the pricing set as "pricing in effect at time of delivery." In general, it is possible for producers to maintain producer pricing control of their products when there are few competing producers of the same material or where the products are so specialized that it is not a commodity at all. In those instances, producers can maintain contractual relationships with their specific customers, based on an annual or quarterly negotiation.

An example, in copper, would be specific purity specifications of copper such as oxygen-free, high conductivity (OFHC), or a specialized fabricated shape. Other materials which still use producer pricing are specialized ferroalloys with specific compositions.

Producers have other pricing options that they may from time to time employ. In times of price volatility, they may wish to abrogate some of their pricing responsibilities. Rather than forcing their marketing staff to make daily, or even hourly, determinations of fair selling value of the company's products, they may wish to hitch their entire marketing wagon to a free market indicator, such as an exchange price like the London Metal Exchange (LME) or Commodity Exchange (Comex) futures contract, or even to a published free market transaction quote, such as is published by international metals journals (e.g., *Metal Bulletin* or *Metals Week*). This system uses a deferred price system, since neither the seller nor the consumer knows the exact level of price that will be in effect when the metal is delivered. Nonetheless, they both know that it will be in the parameters of the existing free market. If a copper producer sets his copper cathode price on the basis of an exchange price—say, the Comex average settlement price for the month of shipment of this product— plus 4.5¢/lb (9.9¢/kg) for his margin, he can sell his metal forward. If he can then spot buy his raw materials—say, blister copper at Comex minus 15¢/lb (33¢/kg)—then he has effectively locked in a margin. Regardless of where the market goes, he is settled in at a profitable margin, assuming that 19.5¢/lb (43¢/kg) is sufficient to cover his refining and handling costs, with profit included.

The message is that both buyers and sellers need to choose the same pricing mechanisms, whether the producer price, or other free market indicators, whether a published free market quote or an exchange based price. Then both can proceed with some confidence to build in a margin which comfortably covers their operations.

25.5.4 EXCHANGE BASED PRICING

An area of increasing importance for the metals and minerals industry is the trading in futures and options contracts for these materials. No producers can afford to ignore the impact of exchange trading of metals as the basis of price discovery and hedging potential. Exchange trading of metals has a long history, with a recognizable forerunner of the London Metal Exchange setting up shop in the 1870s to trade in copper and tin. The LME is still a major center for trading in copper, as well as aluminum, lead, zinc, and nickel.

Other exchanges and markets have long established roles in the metals world, particularly Switzerland and London for gold, where various groups have helped establish a daily quote for bullion. In the United States, there are several exchanges with well established contracts for trading metals, including the Commodity Exchange, in New York and New York Mercantile Exchange and the three Chicago exchanges, the Chicago Board of Trade, the Chicago Mercantile Exchange, and the MidAmerica Commodity Exchange. The Kuala Lumpur Commodity Exchange has a longstanding contract for trading in tin, and the Tokyo Commodity Exchange has a platinum contract of growing importance to the industry.

Exchange trading of metals offers several important services to the industry as a whole, even for those who do not actively participate in the exchange trading itself. Chief among the services offered is *price discovery,* for the commodities traded and by extension to the comparable materials both up and down the materials chain, by the use of premiums and discounts from the exchange traded price.

The importance of prices, as discovered by terminal exchanges, is that they are within the scope of the various contract specifications, quite representative of world prices for the commodities in the various currencies and grades used by consumers. Thus people who might immediately question the value of a terminal market price for a metal that they buy or sell in a different geographic area can be made to see that the price discovery service offered by an exchange is, in many cases, one of the best systems over the longer term.

A good example of the phenomenon is in copper, where several exchanges offer contracts in the metal, all with varying specifications and in several different currencies, but usually within small percentage points of each other despite the widely diverging needs, supply factors, currency fluctuations, and underlying economic factors. The price set by the exchange(s) is the price of copper, like it or not, and that is the foundation of the exchanges.

Table B3a. Room Temperature Creep Coefficients for Rocks

Rock Type	Time (t) (s)	Differential Stress (Pa)	Strain	Constant
Andesite	1.2×10^6	10^4	10^{-5}	7.1×10^{-7}
Basalt	5.2×10^5	10^4	10^{-4}	8.0×10^{-6}
Gabbro	2.6×10^5	10^4	10^{-4}	8.3×10^{-7}
Granite	1.7×10^5	10^5	10^{-5}	8.5×10^{-6}
Granite	1.0×10^6	10^5	10^{-4}	7.2×10^{-6}
Granite	8.6×10^2	10^5	10^{-3}	1.7×10^{-4}
Granodiorite	2.6×10^5	10^4	10^{-4}	8.2×10^{-6}
Granodiorite	5.2×10^5	10^4	10^{-5}	7.8×10^{-7}
Limestone	8.6×10^4	10^5	7×10^{-3}	6.4×10^{-3}
Quartzite	1.7×10^6	10^4	10^{-3}	7.0×10^{-5}
Rhyolite	8.6×10^7	10^4	10^{-4}	5.5×10^{-6}
Rock Salt	3.1×10^6	10^4	10^{-2}	2.1×10^{-4}
Rock Salt	8.6×10^4	10^4	2×10^{-3}	3.0×10^{-3}
Sandstone	8.6×10^2	10^2	10^{-2}	1.7×10^{-3}
Shale	8.6×10^4	10^4	10^{-3}	9.1×10^{-5}
Shale	1.2×10^8	10^3	10^{-2}	5.4×10^{-4}

Table B3b. Room Temperature Effect of Stress on Creep of Rocks

Rock Type	Maximum Strain (10^{-3})	Maximum Stress (MPa)	Exponent (n)	Hydrostatic Pressure (MPa)	Reference
Alabaster (in water)	1	360	1.8	0	Evans et al., 1937
Gabbro	0.01	10	1.0	0	Lomnitz, 1956
Granite	1	350	3.3	0	Evans et al.,1937
Granite	3	100	3.0	0	Matsushima, 1960
Granodiorite	0.2	10	1.0	0	Lomnitz, 1956
Halite	20	30	1.9	0	Kendall, 1958
Limestone	200	670	5.0	1000	Griggs, 1936
Limestone	7	140	1.7	0	Kendall, 1958
Limestone	5	350	3.0	70	Kendall, 1958
Limestone	4	410	7.9	100	Kendall, 1958
Limestone	300	580	3.7	200	Robertson, 1960
Limestone	180	630	1.8	300	Robertson, 1960
Limestone	100	560	1.8	400	Robertson, 1960
Shale	3	10	2.7	0	Phillips, 1932
Slate	1	360	1.8	0	Evans et al., 1937

Applicable Equation, $\dot{\varepsilon} = A\sigma^n$
Source: Robertson, 1960.

Table B3c. Temperature Relationships for Creep

Relationship	Restrictions	Reference
(1) $\dot{\varepsilon} = A \exp(-q/RT)$		Arrhenius, 1889
(2) $\dot{\varepsilon} = \dot{\varepsilon}_o \exp(-q/RT) \sinh \frac{\sigma}{\sigma_o}$		Kauzmann, 1941; Ree et al., 1960
(3) $\dot{\varepsilon} = \dot{\varepsilon}_o \exp(-q/RT)\, \sigma^n$	$n = 2$ to 8 $10^9 > \dot{\varepsilon}/D > 10^2$	Weertman, 1962
(4) $\dot{\varepsilon} = A \exp(-q/RT) \exp(B\sigma)$		Sherby et al., 1967
(5) $\dot{\varepsilon} = A(G/T) \exp(-q/RT)\ (\sigma/G)$		Weertman, 1957,1968; Barrett et al., 1965
(6) $\dot{\varepsilon} = A\sigma D_v / L^2 T$	$\varepsilon/D < 10^2$	Nabarro, 1948; Herring, 1950
(7) $\dot{\varepsilon} = A\sigma D_g / L^3 T$		Coble, 1963
(8) $\dot{\varepsilon} = A \exp(q - b\sigma/RT)$		Kauzmann, 1941

NOMENCLATURE

A,B,D,n	constants
D_g	diffusivity, grain boundary
D_v	diffusivity, volume
G	shear modulus
L	length
q	activation energy of a solid
R	universal gas constant
T	absolute temperature
$\dot{\varepsilon}$	creep or strain rate
σ	normal stress

Conversion factor: 1000 psi = 6.8948 MPa

Table C. Engineering Properties of Rocks

Engineering property	Symbol	Nature: field(F) Laboratory (L) Derived (D)	Method of measurement	Units of measure	Use in engineered construction	Limitations	Ref.
Unit weight	γ	L	Volumetric displacement in water; weight per unit volume; usually weighed as oven dried but may be specified on several other bases.	kg/m^3	Weight, per unit volume, of entire rock; primary term in many computations; useful in computing in situ stress.	Expected statistical variances in the more porous rocks.	1 35 26
Moisture content	w	L	Oven drying.	%	Effect of moisture variations on other physical properties considered in data evaluation and assessment.	Varies seasonally and under influences of construction activities; of little use to refer to tabulations by other except as a condition of specific property test.	35 26
Porosity	n	L	20.106 mm^3 sample placed in porosimeter device.	%	Indication of ability to retain fluids or gases.	Often highly depth dependent.	45 26 21 35
Coefficient of permeability	k	L/F	Cylinder of rock placed in pereameter (L) or pressured water flow into borehold (F).	cm/s	Yield of water for dewatering purposes; determination of pore water distribution for support design of slope stability analyses, planning for grouting.	Field tests require careful isolation (packing) of borehold segment or interest; avoid high-pressure hydrotracturing; greatly influenced by discontinuities.	21
Compressive strength	c_o	L	Uniaxial or Triaxial conditions, in universal test machine; strain gages used for moduli determinations.	Pa	Index classification test; load bearing capacity; other properties according to Mohr failure concept; slope stability; mine pillar stress; subsidence; excavation, blasting, drilling and mole boring performance.	Avoid unrepresentative anisotropic fabric elements or discontinuities; select representative sample; consider data scatter; L/D ratio is quite important (standard is 2.1); peak strength is obtained.	T-15 13 30 T-24 T-25 34 28
Induced tensile strength	T_o	L	Point-bearing compression of compression of tabular cylindrical specimen (Brazilian test); more classical tensile pull test is not generally utilized.	Pa	Load-bearing capacity under tension.	Introduces a contributory compressive stress, therefore not a true determination of tensile strength; magnifies effect of microdefects; theoretically of greater T_o than direct-test value.	T-15 56 20 13 T-23 34 26

Engineering property	Symbol	Nature: field(F) Laboratory (L) Derived (D)	Method of measurement	Units of measure	Use in engineered construction	Limitations	Ref.
Unconfined shear strength	S_o	L/F	Direct shear box, utilizing natural discontinuities or planes or weakness; also triaxial compression test which initiates shear failure on basis of sample geometry or inherent weaknesses.	Pa; ø(deg); c(Pa)	Index classification test; load-bearing capacity; slope stability; mine pillar stress; subsidence.	Slope stability; residual friction angle ($ø_r$); strong effect by anisotropy.	T-15 32 25 38 16 28
Abrasivity	g	L	400g crushed rock rotated in paddle-and-drum test device.	Dimensionless	Resistance to abrasion as indicator of percussion drillability index.	Must be carefully related to petrographic nature of rock lithology and fabric in order to provide for meaningful assessment of effect.	9 52
Hardness			Small laboratory test holding devices for impact. Height or rebound of small diamond-tipped device.	Dimensionless	Indicator or relative hardness; useful in tunnel boring rate estimates.		
Shore scleroscope	H_r	L			As above	Multiple readings are required to overcome effect of sharp point impact on very small area.	59 58 63
Schmidt rebound	H_s	L		Dimensionless	As above	Softer rock breaks on impact; must use Type L device of minimal energy.	41
Taber	H_a	L		Dimensionless	As above		T-23
Total	H_t	L		Dimensionless			T-26 T-27
Sonic velocity	v	L	Core sample, held in accoustical bench; subjected to pulsation of electrically-generated mechanical vibration.	km/s	Computational input for calculation of E, G, and K.	Difficult to accommodate fabric anisotropies; difficult to know volume tested in situ; does not introduce time-dependent strain variations in derived properties	19 44 3
Seismic velocity Compressional Shear	 V_p V_s	F	Mechanical or explosive energy wave arrival sensed by geophone, timer, and recorder; measured on ground surface or in borehole configurations.	km/s	As above, indicator of overall maturity of rock due to averaging effect on wave travel paths, depending on geophone/energy source array.	Degree of saturation important; test does not introduce nonlinear, time-dependent strain-variation in derived properties; most valid in homogeneous and isotropic rock.	49 3 28

Poisson's ratio	u	D	Calculated from sonic/seismic velocity tests or by use of electrical resistance strain gages on compression tests.	Dimensionless; in range 0 to 0.5.	Computational input for calculation of stress distribution patterns and of predicted strain in elastic media; required for finite element modeling.	Difficult to extroplate laboratory measurement to field conditions; often estimated without testing; best approximation is from triaxial compression test at confinement equivalent to in situ conditions.	47 3 28
Modulus of rigidity	G	D	As above	Pa	Indicator of seismic design stiffness.	Strain-related.	49
Bulk modulus	K	D	As above	Pa		Strain-related.	49
Tangent modulus of elasticity (Young's modulus, or modulus of deformation)	E_r	L	Triaxial compression in universal test machine; electrical resistance strain gages.	Pa	The fundamental stress-strain relationship; input for static displacement computations and for dynamic, seismic analyses.	Requires accommodation of any anisotropy of rock fabric and model in situ conditions.	T-6 4 28
Secant modulus of elesticity	E_s	L	As above	Pa	Alternate expression of the fundamental stress-strain relationship.	As above.	3
Swelling slake durability	I_s I_D	L L	Rotational cyclic immersion in water; measure percent loss by weight; measure swelling displacement (d) and initial weight of specimen L (I_s = d/L x 100); measure slaking weight percentages lost in wetting cycles.	Dimensionless (0—100)	Indication of relative resistance to weathering on exposure to elements.	Semi-quantitative, in use, swell potential is proportional to confining pressure; slake potential relates to moisture exposure and water chemistry at site.	36 26

Conversion factors:

1 lb = 0.4536 kg
1 lb/ft^3 = 16.0185 kg/m^3
1 in./sec = 2.54 cm/s
1 psf = 47.88 Pa
1 psi= 6894.8 Pa

Table D. Properties of Common Minerals

Mineral	Chemical Composition	Crystal System	Streak	Color	Specific Gravity	Hardness
Acanthite	Ag_2S	Morph.: isometric	Black, may mark paper	Gray-black	7.3	2-2.5
Allanite	Ce, La, Th epidote	Monoclinic	Colorless	Brown to pitch-black	3.5-4.2	5.5-6
Alunite	$KAl_3(SO_4)_2(OH)_6$	Hexagonal	Colorless	White, grayish, red	2.6-2.8	4
Amblygonite	$LiAlFPO_4$	Triclinic	Colorless	White, pale green or blue	3.0-3.1	6
Amphibole Group	Essentially hydrous Ca-Mg-Fe silicates	Monoclinic	Colorless	White, green, black	3.0-3.3	5-6
Andalusite	Al_2SiO_5	Orthorhombic	Colorless	Reddish-brown, flesh-red, olive-green	3.16-3.20	7.5
Anglesite	$PbSO_4$	Orthorhombic	Colorless	Colorless or white. Gray-brown when impure	6.2-6.4	3
Anhydrite	$CaSO_4$	Orthorhombic	Colorless	Colorless, white, blue, gray, red	2.89-2.98	3-3.5
Anthophylite	$(Mg,Fe)_7(Si_8O_{22})(OH)_2$	Orthorhombic and monoclinic	Colorless	Gray, clove brown, green	2.85-.3.2	5.5-6
Antlerite	$Cu_3(SO_4)(OH)_4$	Orthorhombic	Light green	Dark emerald-green	3.9±	3.5-4
Apatite	$Ca_5(PO_4)_3(F,Cl,OH)$	Appears amorphous	Colorless	White, yellow, brown, gray	2.6-2.9	3-5
	$Ca_5(PO_4)_3(F,Cl,OH)$	Hexagonal	Colorless	Green, blue, violet, brown, colorless	3.15-3.20	5
Aragonite	$CaCO_3$	Orthorhombic	Colorless	Colorless, white	2.95	3.5-4
Arsenopyrite	FeAsS	Monoclinic	Black	Silver- or tin-white	6.0-6.2	5.5-6
Atacamite	$Cu_2Cl(OH)_3$	Orthorhombic	Light green	Dark emerald-green	3.75-3.77	3-3.5
Azurite	$Cu_3(CO_3)(OH)_2$	Monoclinic	Light blue	Intense azure-blue	3.77	3.5-4
Barite	$BaSO_4$	Orthorhombic	Colorless	Colorless, white, blue, yellow, red	4.5	3-3.5
Bauxite	A mixture of Al hydroxides		Colorless	Yellow, brown, gray, white	2.0-2.55	1-3
Beryl	$Be_3Al_2(Si_6O_{18})$	Hexagonal	Colorless	Bluish-green, yellow, pink, colorless	2.65-2.8	7.5-8
Biotite	$K(Mg, Fe)_3(AlSi_3O_{10})(OH)_2$	Monoclinic	Colorless	Dark brown, green to black; may be yellow	2.95-3	2.5-3

Mineral	Chemical Composition	Crystal System	Streak	Color	Specific Gravity	Hardness
Borax	$Na_2B_4O_5(OH)_4 \cdot 8H_2O)$	Monoclinic	Colorless	Colorless or white	1.7±	2-2.5
Bornite	Cu_5FeS_4	Morph.: isometric	Black	Fresh surface bronish-bronze; purple tarnish	5.1	3
Brochantite	$CuSO_4 \cdot 3Cu(OH)_2$	Orthorhombic	Pale green	Emerald green to blackish green	3.9	3.5-4
Brucite	$Mg(OH)_2$	Hexagonal	Colorless	White, gray, green	2.39	2.5
Calcite	$CaCO_3$	Hexagonal	Colorless	Colorless, white, and variously tinted	2.71	3
Cassiterite	SnO_2	Tetragonal	Light brown	Brown to black	6.8-7.1	6-7
	SnO_2	Tetragonal	Colorless	Reddish-brown to black	6.8-7.1	6-7
Celestite	$SrSO_4$	Orthorhombic	Colorless	Colorless, white, blue, red	3.95-3.97	3-3.5
Cerussite	$PbCO_3$	Orthorhombic	Colorless	Colorless or white	6.55	3-3.5
Chalcocite	Cu_2S	Morph.: orthorhombic	Gray-black	Steel-gray. May tarnish to dead black on exposure	5.7	2.5-3
Chalcopyrite	$CuFeS_2$	Tetragonal	Black	Brass-yellow	4.1-4.3	3.5-4
Chlorite	$Mg, Fe_3(Si,Al)_4O_{10}(OH)_2(Mg,Fe)_3(OH)_6$	Monoclinic	Colorless	Green of various shades	2.6-2.9	2-2.5
Chromite	$FeCr_2O_4$	Isometric	Dark brown to black	Iron-black to brownish-black	4.6	5.5
Chrysocolla	$\sim Cu_4H_4Si_4O_{10}(OH)_8$	Amorphous	Very light blue	Light green to turquoise-blue	2.0-2.4	2-4
Cinnabar	HgS	Hexagonal	Bright red	Red to vermillion	8.1	2-2.5
Clinozoisite	$Ca_2Al_3O(SiO_4)(Si_2O_7)(OH)$	Monoclinic	Colorless	Grayish-white, green, pink	3.25-3.37	6-6.5
Cobaltite-Gersdorffite	(Co, Fe)AsS-NiAsS	Pseudoisometric	Black	Silver- or tin-white	6.33	5.5
Colemanite	$CaB_3O_4(OH)_3 \cdot H_2O$	Monoclinic	Colorless	Colorless, white	2.42	4-4.5
Copper	Cu	Isometric	Copper-red, shiny	Copper-red on fresh surface; black tarnish	8.9	2.5-3
Corundum	Al_2O_3	Hexagonal	Colorless	Colorless, gray, blue, red, yellow brown, green	3.95-4.1	9

Covellite	CuS	Hexagonal	Black. May mark paper	Blue; may tarnish to blue-black	4.6	1.5-2
Cuprite	Cu_2O	Isometric	Red-brown to Indian red	Red-brown to deep red. Ruby-red if transparent	6.0	3.5-4
Diamond	C	Isometric	Colorless	Colorless, yellow, red, blue, black	3.5	10
Dolomite	$CaMg(CO_3)_2$	Hexagonal	Colorless	Colorless, white, pink	2.85	3.5-4
Enargite	Cu_3AsS_4	Orthorhombic	Black	Gray-black	4.4	3
Enstatite	$MgSiO_3$	Orthorhombic	Colorless	Gray-brown, green, bronze-brown, black	3.2-3.5	5.5
Epidote	$Ca_2(Al,Fe)Al_2O(SiO_4)(Si_2O_7)(OH)$	Monoclinic	Colorless	Yellowish to blackish green	3.35-3.45	6-7
Erythrite	$Co_3(AsO_4)_2{\cdot}8H_2O$	Monoclinic	Pink	Red to pink	2.95	1.5-2.5
Fluorite	CaF_2	Isometric	Colorless	Colorless, violet, green, yellow, pink	3.18	4
Galena	PbS	Isometric	Gray-btack	Blue-black to lead-gray	7.6	2.5
Garnet	$A_3B_2(SiO_4)_3$	Isometric	Colorless	Usually brown to red. Also yellow, green, pink	3.5-4.3	6.5-7.5
Goethite	$\alpha FeO{\cdot}OH$	Orthorhombic	Yellow-brown, yellow ocher	Dark-brown to black	4.37	5-5.5
Gold	Au	Isometric	Gold-yellow, shiny	Gold-yellow	15.0-19.3	2.5-3
Graphite	C	Hexagonal	Black	Steel-gray to iron black	2.23	1-1.5
Grunerite	$(Mg,Fe)_7Si_8O_{22}(OH)_2$	Orthorhombic and monoclinic	Colorless	Gray, clove-brown, green	2.85-3.2	5.5-6
Gypsum	$CaSO_4{\cdot}2H_2O$	Monoclinic	Colorless	Colorless, white, gray. May be colored by impurities	2.32	2
Halite	$NaCl$	Isometric	Colorless	Colorless, white, red, blue	2.1-2.3	2.5
Hematite	Fe_2O_3	Hexagonal	Red-brown	Red to vermillion	5.2	1+
	Fe_2O_3	Hexagonal	Red-brown, Indian red	Dark brown to steel-gray to black	4.8-5.3	5.5-6.5

Mineral	Chemical Composition	Crystal System	Streak	Color	Specific Gravity	Hardness
Hemimorphite	$Zn_4(Si_2O_7)(OH)_2 \cdot H_2O$	Orthorhombic	Colorless	White, pale green, blue	3.4-3.5	4.5-5
Ilmenite	$FeTiO_3$	Hexagonal	Dark brown to black	Black	4.7	5.5-6
Jamesonite	$Pb_4FeSb_5S_{14}$	Monoclinic	Black	Gray-black	5.5-6.0	2-3
Kaolinite	$Al_2Si_2O_5(OH)_4$	Triclinic	Colorless	White; may be darker	2.6-2.63	2-2.5
Kernite	$Na_2B_4O_6(OH)_2 \cdot 3H_2O$	Monoclinic	Colorless	Colorless or white to gray	1.95	3
Kyanite	Al_2SiO_5	Triclinic	Colorless	Blue, usually darker at center	3.56-3.66	5-7
Lazurite	$(Na,Ca)_8(AlSiO_4)6(SO_4,S, Cl)_2$	Isometric	Colorless	Deep azure blue, greenish blue	2.4-2.45	5-5.5
Lepidolite	$K(Li, Al)_{2-3}(AlSi_3O_{10})(O, OH, F)_2$	Monoclinic	Colorless	Lilac, grayish white	2.8-3.0	2.5-4
Leucite	$KAlSi_2O_6$	Pseudoisometric	Colorless	Gray, white, colorless	2.45-2.50	5.5-6
Magnesite	$MgCO_3$	Hexagonal	Colorless	Colorless. White, yellow, gray, brown	3.0-3.2	3.5-5
Magnetite	Fe_3O_4	Isometric	Black	Black	5.18	6
Malachite	$Cu_2CO_3(OH)_2$	Monoclinic	Light green	Bright green	3.9-4.03	3.5-4
Manganite	$MnO(OH)$	Morph.: orthorhombic	Dark brown to black	Steel-gray to iron-black	4.3	4
Marcasite	FeS_2	Isometric	Black	Pale yellow to almost white	4.9	6-6.5
Margarite	$CaAl_2(Al_2Si_2O_{10})(OH)_2$	Monoclinic	Colorless	Pink, gray, white	3.0-3.1	3.5-5
Microcline	$KAlSi_3O_8$	Triclinic	Colorless	Colorless, white, gray, cream, red, green	2.54-2.56	6
Microcrystalline Quartz	SiO_2		Colorless	Light brown, yellow, red, green	2.6	7
Millerite	NiS	Hexagonal	Black	Brass-yellow. Slender crystals greenish	5.5	3-3.5
Molybdenite	MoS_2	Hexagonal	Black to greenish black	Blue-black	4.7	1-1.5
Monazite	$(Ce, La, Y, Th)PO_4$	Monoclinic	Colorless	Yellowish-to reddish-brown	5.0-5.3	5-5.5
Muscovite	$KAl_2(AlSi_3O_{10})(OH)_2$	Monoclinic	Colorless	Pale brown, green yellow, white	2.76-2.88	2-2.5
Natrolite	$Na_2Al_2Si_3O_{10} \cdot 2H_2O$	Orthorhombic	Colorless	Colorless, white	2.25	5-5.5
Nepheline	$(Na, K)AlSiO_4$	Hexagonal	Colorless	Colorless gray, greenish, reddish	2.55-2.65	5.5-6

Nickeline (Niccolite)	NiAs	Hexagonal	Black	Pale copper-red. May be silver-white, pinkish	7.8	5-5.5
Olivine	$(Mg, Fe)_2SiO_4$	Orthorhombic	Colorless	Olive to grayish-green, brown	3.27-4.37	6.5-7
Opal	$SiO_2 \cdot nH_2O$	Essentially amorphous	Colorless	Colorless, white, yellow, red, brown	1.9-2.2	5-6
Orpiment	As_2S_3	Monoclinic	Pale yellow	Lemon-yellow	3.49	1.5-2
Orthoclase	$KAlSi_3O_8$	Monoclinic	Colorless	Colorless, white, gray, cream, red, green	2.54-2.56	6
Pentlandite	$(Fe, Ni)_9S_8$	Isometric	Black	Brownish-bronze	4.6-5.0	3.5-4
Phlogopite	$KMg_3(AlSi_3O_{10})(OH)_2$	Monoclinic	Colorless	Yellowish-brown, green-white	2.86	2.5-3
Plagioclase	Various proportions of albite, $NaAlSi_3O_8$, and anorthite, $CaAl_2Si_2O_8$	Triclinic	Colorless	Colorless, white, gray bluish. Often shows play of colors	2.62 (ab)-2.76 (an)	6
Platinum	Pt	Isometric	Gray, shiny	White or steel-gray	14-19	4-4.5
Prehnite	$Ca_2Al(AlSi_3O_{10})(OH)_2$	Orthorhombic	Colorless	Apple-green, gray, white	2.8-2.95	6-6.5
Proustite	Ag_3AsS_3	Hexagonal	Bright red	Ruby-red	5.55	2-2.5
Pyrargyrite	Ag_3SbS_3	Hexagonal	Red-brown, Indian red	Deep red to black	5.8	2.5
Pyrite	FeS_2	Isometric	Black	Pale brass-yellow	5.0	6-6.5
Pyrolusite	MnO_2	Tetragonal	Black	Iron-black	4.7	1-2
Pyromorphite	$Pb_5(PO_4)_3Cl$	Hexagonal	Colorless	Green, brown, yellow, gray	6.5-7.1	3.5-4
Pyrophylite	$Al_2Si_4O_{10}(OH)_2$	Monoclinic	Colorless	White, apple green, gray. When impure, as in soapstone, dark green to almost black	2.8-2.9	1-2
Pyroxene Group	Essentially Ca-Mg-Fe silicates	Monoclinic	Colorless	White, green, black	3.1-3.5	5-6
Pyrrhotite	$Fe_{1-x}S$	Morph.: hexagonal	Black	Brownish-bronze	4.6	4
Quartz	SiO_2	Hexagonal	Colorless	Colorless, white, smoky. Variously colored.	2.65	7
Realgar	AsS	Monoclinic	Orange-yellow	Deep red	3.48	1.5-2
Rhodochrosite	$MnCO_3$	Hexagonal	Colorless	Pink, rose-red	3.45-3.6	3.5-4.5

Mineral	Chemical Composition	Crystal System	Streak	Color	Specific Gravity	Hardness
Rhodonite	$MnSiO_3$	Triclinic	Colorless	Rose-red, pink, brown	3.58-3.70	5.5-6
Rutile	TiO_2	Tetragonal	Colorless to light brown	Reddish-brown to black	4.18-4.25	6-6.5
Scapolite	Essentially Na, Ca aluminum silicate	Tetragonal	Colorless	White, pink, gray, green, brown	2.65-2.74	5-6
Scheelite	$CaWO_4$	Tetragonal	Colorless	White, yellow, green, brown	5.9-6.1	4.5-5
Scorodite	$FeAsO_4 \cdot 2H_2O$	Orthorhombic	Colorless	Leek green to liver-brown	3.1-3.3	3.5-4
Serpentine	$Mg_3Si_2O_5(OH)_4$	Monoclinic	Colorless	Olive- to blackish-green, yellow-green, white	2.3-2.66	2-5
Siderite	$FeCO_3$	Hexagonal	Colorless, brown	Light to dark brown	3.83-3.88	3.5-4
Sillimanite	Al_2SiO_5	Orthorhombic	Colorless	Hair-brown, brown, gray, grayish-green	3.23	6-7
Silver	Ag	Isometric	Silver-white, shiny	Silver-white on fresh surface. Black tarnish	10.5	2.5-3
Skutterudite-Nickel skutterudite	$(Co, Ni, Fe)As_3$-$(Ni,Co, Fe)As_3$	Isometric	Black	Silver- or tin-white	6.1-6.9	5.5
Smithsonite	$ZnCO_3$	Hexagonal	Colorless	Brown, green, blue, pink, white	4.35-4.40	5
Sodalite	$Na_6(AlSiO_4)_6Cl_2$	Isometric	Colorless	White, gray, blue, green	2.15-2.3	5.5-6
Sphalerite	ZnS	Isometric	Light to dark brown	Dark brown to coal-black. More rarely yellow or red	3.9-4.1	3.5-4
Spinel	$MgAl_2O_4$	Isometric	Colorless	Red, black, blue, green, brown	3.6-4.0	8
Spodumene	$LiAlSi_2O_6$	Monoclinic	Colorless	White, gray, pink, green	3.15-3.20	6.5-7
Staurolite	$Fe_2Al_9O_6(SiO_4)_4(O,OH)_2$	Pseudo-orthorhombic	Colorless	Red-brown to brownish-black	3.65-3.75	7-7.5
Stibnite	Sb_2S_3	Orthorhombic	Gray-black	Blue-black	4.5	2
Stilbite	$NaCa_2Al_5Si_{13}O_{36} \cdot 14H_2O$	Monoclinic	Colorless	White, yellow brown, red	2.1-2.2	3.5-4
Strontianite	$SrCO_3$	Orthorhombic	Colorless	Colorless white	3.7	3.5-4
Sulfur	S	Orthorhombic	Colorless, pale yellow	Pale yellow	2.05-2.09	1.5-2.5
Sylvite	KCl	Isometric	Colorless	Colorless or white	1.99	2

Talc	$Mg_3Si_4O_{10}(OH)_2$	Monoclinic	Colorless	White apple-green, gray. When impure as in soapstone, dark green to almost black	2.7-2.8	1
Tenorite	CuO	Triclinic	Dark brown to black	Pitchy black	6.5	3-4
Tetrahedrite	$(Cu, Fe, Zn, Ag)_{12}Sb_4S_{13}$	Isometric	Black; may have brown tinge	Steel-gray. May tarnish to dead black on exposure	4.7-5.0	3-4.5
Titanite	$CaTiO(SiO_4)$	Monoclinic	Colorless	Brown, gray, green, yellow	3.4-3.55	5-5.5
Topaz	$Al_2SiO_4(F,OH)_2$	Orthorhombic	Colorless	Colorless yellow, pink, bluish, greenish	3.4-3.6	8
Tourmaline	Complex boron silicate of Na-Ca-Al-Mg-Fe-Mn	Hexagonal	Colorless	Black, green, brown, blue, red, pink, white	3.0-3.25	7-7.5
Turquoise	$CuAl_6(PO_4)_4(OH)_8{\cdot}5H_2O$	Triclinic	Colorless	Blue, bluish-green, green	2.6-2.8	6
Ulexite	$NaCaB_5O_6(OH){\cdot}5H_2O$	Triclinic	Colorless	White	1.95	1
Uraninite	UO_2	Isometric	Dark brown to black	Black	9.0-9.7	5.5
Vesuvianite	Complex hydrous Ca-Mg-Fe-Al silicate	Tetragonal	Colorless	Green, brown yellow, blue, red	3.35-4.45	6.5
Wavellite	$Al_3(PO_4)_2(OH)_3{\cdot}5H_2O$	Orthorhombic	Colorless	Yellow, green, white, brown	2.33	3.5-4
Willemite	Zn_2SiO_4	Hexagonal	Colorless	Yellow-green, white blue, gray, brown	3.9-4.2	5.5
Witherite	$BaCO_3$	Orthorhombic	Colorless	Colorless, white	4.3	3.5
Wolframite	$(Fe, Mn)WO_4$	Monoclinic	Brown to black	Brown to black	7.0-7.5	5-5.5
Wollastonite	$CaSiO_3$	Triclinic	Colorless	Colorless, white, gray	2.8-2.9	5-5.5
Wulfenite	$PbMoO_4$	Tetragonal	Colorless	Yellow, orange, red, gray, green	6.8±	3
Zircon	$ZrSiO_4$	Tetragonal	Colorless	Brown, red, gray, green, colorless	4.68	7.5

Properties of Common Minerals with Emphasis on Ore Minerals

This table contains properties of some common minerals arranged in alphabetical order. Emphasis has been placed on common ore minerals, including those minerals important in the examination of weathered outcrops. The properties were compiled primarily from the determinative tables found in

Klein, C., and Hurlbut, C.S., Jr., 1985, *Manual of Mineralogy,* 20th ed., John Wiley and Sons, New York, pp. 531-563.

The table normally presents the predominant crystal system found in hand specimens. Other crystal forms often exist for individual minerals. A more exhaustive list of these crystal systems can be found in the following reference:

Bayliss, P., Erd, R.C., Mrose, M.E., Sabina, A.P., Smith, D.K., 1986, *Mineral Powder Diffraction File,* International Center for Diffraction Data, Swarthmore, PA, 1390 pp.

Editing of this appendix table, selection of pertinent minerals, and addition of some of the ore minerals were performed by Dr. Willard C. Lacy, Lacy and Associates, Green Valley, AZ, and Dr. Donald E. Ranta, Phelps Dodge Mining Company, Lakewood, CO. The editors acknowledge their help.

Permission to use the information from Klein and Hurlbut was provided by John Wiley and Sons. Readers who need a determinative form of the table for identification of unknown minerals should refer to the tables provided in the reference above by Klein and Hurlbut.

Table E. Material Properties and Characteristics

Material	Bank Density (lb/ft^3)	Loose Density (lb/ft^3)	Angle of Repose (degrees)	Angle of Incline (degrees)
Alumina	--	60	22	18
Ammonium nitrate	--	45	--	--
Asbestos ore	--	81	30-44	--
Ashes, dry	--	35-40	40	22
Ashes, wet	--	45-50	50	25
Bauxite, ground,dry	--	68	20-31	17-20
Bauxite, run of mine	100-160	75-120	31	18
Bauxite, crushed, 3 x 0 in.	--	75-85	30-44	20
Clay, compact, natural bed	109	82	--	--
Clay, dense, tough or wet	111	83	--	--
Clay, dry	85	68	--	--
Clay, dry excavated	69	--	--	--
Clay, dry in lump, loose	--	60-70	35	20
Clay, fines	--	100-120	35	20-22
Clay, light (kaolin)	104	80	--	--
Clay and gravel, dry	100	71	--	--
Clay and gravel, wet	114	81	--	--
Chrome ore	--	125-140	30-44	--
Cinders, coal	--	40-45	35	22
Coal, anthracite	81-85	60-63	27	16
Coal, anthracite, sized	--	55-60	27	16
Coal, bituminous	70	50-52	45-55	22-24
Coal, bituminous, mined, sized	--	45-55	35	16
Coal, bituminous, mined, run-of-mine	--	45-55	38	18
Coal, bituminous, mined, slack, 1/2 in. & under	--	43-50	40	22
Coal, bituminous, strip, not cleaned	--	50-60	--	--
Coal, lignite	--	40-45	38	22
Coke	--	24-31	--	--
Coke, breeze, 1/4 in. & under	--	25-34	30-45	20

Material	Bank Density (lb/ft^3)	Loose Density (lb/ft^3)	Angle of Repose (degrees)	Angle of Incline (degrees)
Coke, loose	--	23-35	30-44	--
Coke, petroleum	--	35-40	--	20
Copper ore	141	100-160	--	20
Earth, dry	104	57-83	35	20
Earth, dry, loam	78	57-68	--	--
Earth, moist	100	75-85	--	22
Earth, wet	125	100-104	--	
Earth, wet, containing clay	--	100-110	45	23
Earth, sand, gravel	115	98	--	--

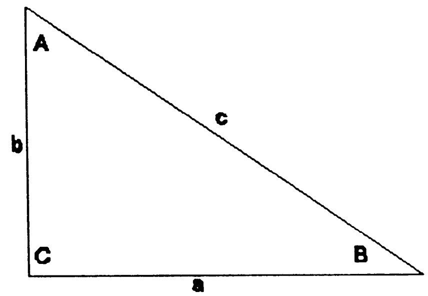
Table G. Geometrical Relationships and Mensuration Formulas

Right Triangle

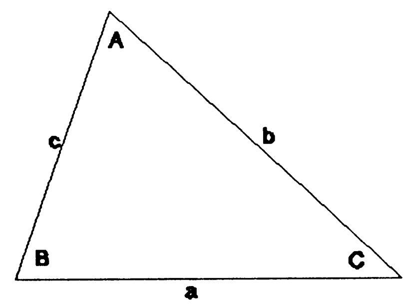


$$\sin A = \frac{a}{c}, \cos A = \frac{b}{c}, \tan A = \frac{a}{b}$$

$$c = \sqrt{a^2 = b^2}$$

$$\text{Area} = \frac{1}{2} a\, b$$

Oblique Triangle



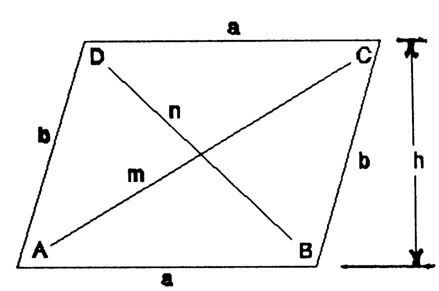
$$\frac{\sin A}{a} = \frac{\sin B}{b} = \frac{\sin C}{c}$$

$$c^2 = a^2 + b^2 - 2ab \cos C$$

$$\text{Area} = \frac{1}{2} ab \sin C$$

$$s = \frac{1}{2} a + b + c, \text{ Area} = \sqrt{s(s-a)(s-b)(s-c)}$$

Parallelogram



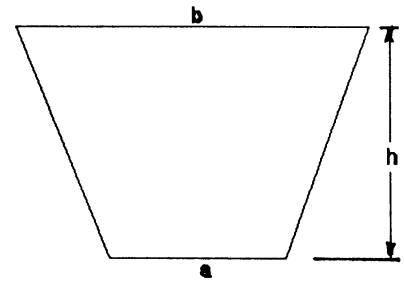
$$h = b \sin A, \text{ Area} = ah = ab \sin A$$

$$m = \sqrt{a^2 + b^2 + 2ab \cos A}$$

$$n = \sqrt{a^2 + b^2 - 2ab \cos A}$$

Trapezoid

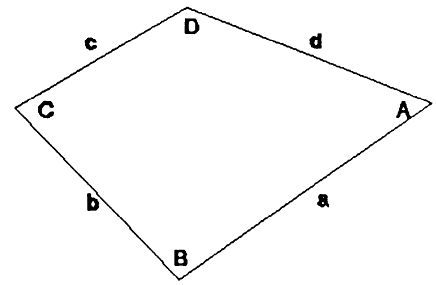
$$\text{Area} = \frac{1}{2}(a+b)\,h$$



Quadrilaterial

$$s = \frac{1}{2}(a+b+c+d)$$

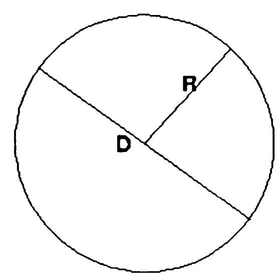
$$\text{Area} = \sqrt{(s-a)(s-b)(s-c)(s-d) - abcd\cos^2\frac{A+C}{2}}$$



Circle ($\pi = 3.14159...$)

$$\text{Circumference} = 2\pi R = \pi D$$

$$\text{Area} = \pi R^2 = \frac{1}{4}\pi D^2$$



Sector and Segment

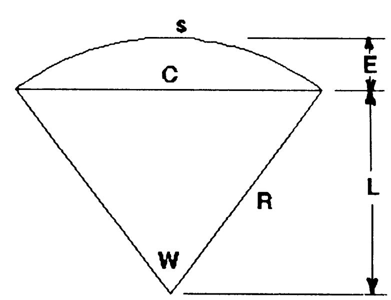
$$L = R\cos\frac{W}{2}$$

$$\text{cord length }(C) = 2\frac{R\sin W}{2}$$

$$\text{arc length }(s) = R\ \frac{W}{2},\ W(\text{radians})$$

$$\text{Area (sector)} = \frac{1}{2}R^2 W$$

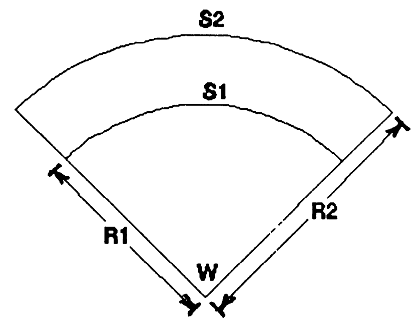
$$\text{Area (segment)} = \frac{1}{2}R^2(W - \sin W)$$



Annulus

$$\text{Area} = \frac{1}{2} W\,(R1 + R2)\,(R2 - R1)$$

$$\text{Area} = \frac{1}{2}\,(R2 - R1)\,(s1 + s2)$$

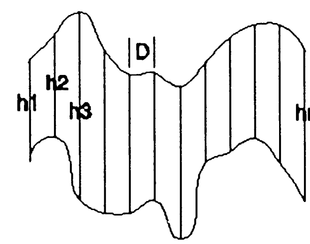


Plane Areas

Divide the two-dimensional area into n-1 strips of length h1, h2, h3, . . . hn (h1 and/or hn may be zero). D is the common separation between lines

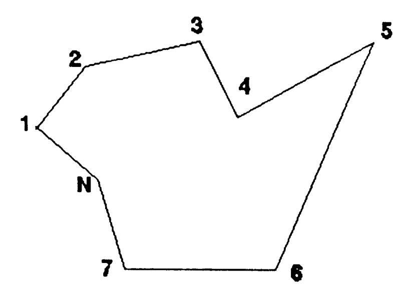
Trapezoidal Rule (approximate)

$$\text{Area} = D\left[\frac{1}{2}h\,1 + h\,2 + h\,3 + \ldots h\,(n-1) + \frac{1}{2}H\,(n)\right]$$



Simpson's Rule (approximate) where n is odd.

$$\text{Area} = \frac{1}{3}D\,[h1 + 4h2 + 2h3 + 4h4 + \ldots + 2h(n-2) + 4h(n-1) + h(n)]$$



Area by coordinates (exact) x1,y1 coordinates of point 1

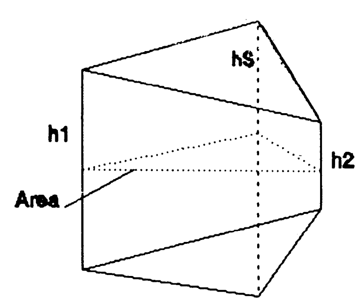
$$\text{Area} = \frac{1}{2}[x1\,(y2 - y(n)) + x2\,(y3 - y1) + \ldots + x(n)\,(y1 - y(n-1))]$$

$$\text{Area} = \frac{1}{2}[y1\,(x2 - x(n)) + y2\,(x3 - x1) + \ldots + y(n)\,(x1 - x(n-1))]$$

Triangular Prism

$$\text{Volume} = \frac{1}{3}A\,(h1 + h2 + h3)$$

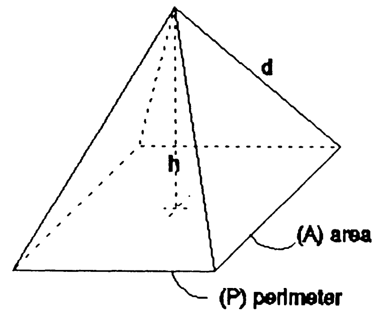
where A = area of right section



Pyramid

$$\text{Lateral surface area} = \frac{1}{2}(Pd)$$

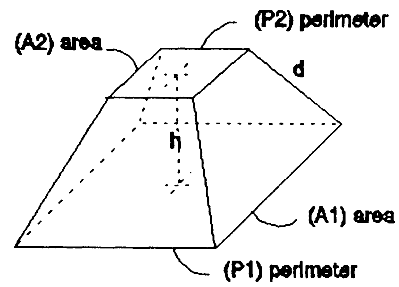
$$\text{Volume} = \frac{1}{3}(Ah)$$



Frustum of a Pyramid

$$\text{Lateral surface area} = \frac{1}{2}(P1 + P2)d$$

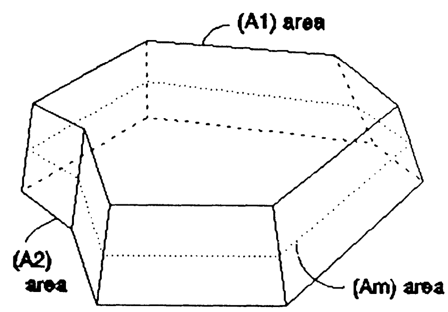
$$\text{Volume} = \frac{1}{3}h\left(A1 + A2 + \sqrt{A1A2}\right)$$



Prismatoid

Top and bottom surfaces must be parallel. Al is the surface area of the top, A2 is the surface area of the bottom, A(m) is the surface area of midsection, and h is the altitude.

$$\text{Volume} = \frac{1}{6}h\ (A1 + 4A(m) + A2)$$

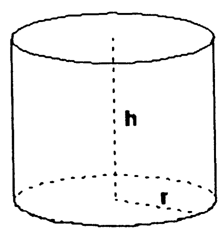


Right Circular Cylinder

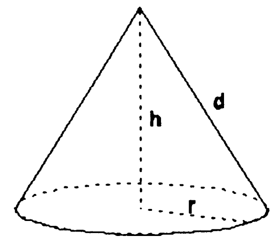
Lateral surface area = $2\pi\ r\ h$

Total surface area = $2\pi\ r\ (r+h)$

Volume = $\pi\ r^2\ h$



Right Circular Cone

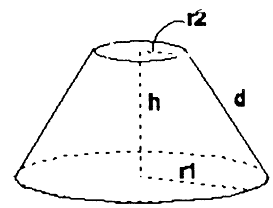


$$\text{Lateral surface area} = \pi\, r \sqrt{r^2 + h^2}$$

$$\text{Total surface area} = \pi\, r \left(r + \sqrt{r^2 + h^2} \right)$$

$$\text{Volume} = \frac{1}{3} \pi\, r^2\, h$$

Frustum of a Right Circular Cone

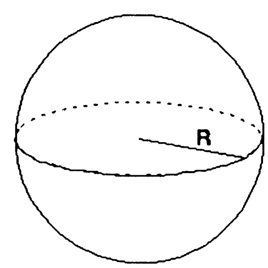


$$\text{Total surface area} = \pi[r1^2 + r2^2 + (r1 + r\ )]$$

$$\text{Lateral surface area} = \pi(r1 + r2)\sqrt{(r1 - r2)^2 + h^2}$$

$$\text{Total surface area} = \pi[r1^2 + r2^2 + (r1 + r2)\sqrt{(r1 - r2)^2 + h^2}\ ]$$

Sphere

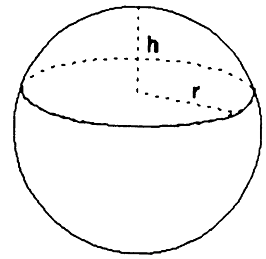


$$\text{Surface area} = 4\pi R^2$$

$$\text{Volume} = \frac{4}{3}\pi R^3$$

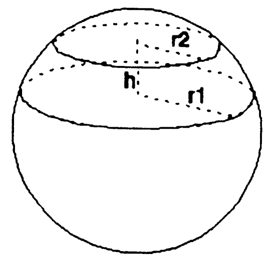
Spherical Segment with One Base

Surface area = $2 \pi R h$



$$\text{Volume} = \frac{1}{3} \pi h^2 (3 R - h) = \frac{1}{6} \pi h (3 r^2 + h^2)$$

Spherical Segment with Two Bases



Surface area = $2 \pi r h$

$$\text{Volume} = \frac{1}{6} \pi h \left[3 (r1)^2 + 3 (r2)^2 + h^2 \right]$$

Table I. Ship Measures

Ship measurements are of 5 kinds. In the US and in British countries, the ton = 2,240 lb; where the metric ton is used, 2,204.6 lb.

(I) *Displacement* is total wt in tons of a vessel and its contents. Displacement "light" = wt of vessel without stores, bunker fuel, or cargo; displacement "loaded" = total wt, including the last 3 items.

(2) *Cargo tonnage* is expressed on the basis of either "weight" or "cubic measurement." "Measurement ton" is usually 40 ft^3 (as in the US); in some countries, 42 ft^3.

(3) Gross *tonnage* applies to the vessel itself, not to cargo, and is the contents in ft^3 of its closed-in spaces, divided by 100 (assuming a vessel-ton to be 100 ft^3). "Register" states both gross and net tonnage, and is about the same under US and British rules.

(4) *Net tonnage* is gross tonnage, less deductions for space occupied by crew, engine room and fuel, and for navigation; that is, the space available for passengers and cargo. As a ton of cargo usually occupies much less than 100 ft^3, see (2), cargo tonnage generally exceeds both net and gross tonnage.

(5) *Deadweight tonnage* is the number of tons a vessel can carry, of cargo, stores, and fuel. It is the difference between tons of water displaced when the vessel is "light" and when submerged to "load line" (which is often shown on the vessel's side by the "Plimsoll mark"). Capacity for weight cargo is less than dead-weight tonnage.

Examples of relative measurements. (*a*) An ordinary freight steamer: net tonnage, 4,000; gross tonnage, 6,000; deadweight capacity, 10,000 tons; displacement, loaded, 13,350 tons. (*b*) Oil tanker, Standard Oil Co. of California, launched 1938: net tonnage, 4,934; gross tonnage, 8,298; deadweight capacity, 12,800 tons; displacement, loaded, 17,320 tons.

Conversion factors: 1 ton = 0.9072 t, 1 ft^3 = 0.02832 m^3.

Table K. Time Value of Money Factors for Discrete Compounding

The time value of money relationships provided here are based upon the notations used in D.W. Gentryand T.J. O'Neil, *Mine Investment Analysis*, 1984, SME-AIME, New York, 502 pp.

Symbols used in the equations and tables are as follows:

F = a future sum of money in \$.

P = a present single sum of money in \$.

A = the amount of a single payment in a series of n equal payments, each payment to be made at the end of a period in \$.

i = effective interest rate per period, expressed as a decimal (e.g., 5% = 0.05).

n = number of interest periods (usually n = numbers of years; however, other periods, e.g., months, quarters, may apply instead).

g = an arithmetic amount by which a payment increases each period in \$.

The tables that follow provide seven times the value of money factors that are defined below along with a method for applying each factor.

(1) *Single Payment Compound Amount Factor:*

$$F/P_{i,n} = (1 + i)^n$$

Use this factor to multiply a present amount P to determine what future amount F will accumulate over n periods at an effective interest rate i per period.

(2) *Single Payment Present Worth Factor:*

$$P/F_{i,n} = \frac{1}{(1+i)^n}$$

Use this factor to multiply a future sum F to determine its equivalent present worth P where the present is n periods earlier at an effective interest rate i per period.

(3) *Uniform Series Compound Amount Factor:*

$$F/A_{i,n} = [(1+i)^n - 1]/i$$

Multiply the end-of-period payment A by this factor to determine the future sum F that will accumulate after n such payments at an effective interest rate i per period.

(4) *Sinking Fund Factor:*

$$A/F_{i,n} = \frac{1}{[(1+i)^n - 1]/i}$$

Use this factor to multiply a future sum F to determine the equivalent end-of-period payments A for n earlier periods at an effective interest rate i per period.

(5) *Present Worth Factor:*

$$P/A_{i,n} = \frac{[(1+i)^n - 1]}{i(1+i)^n}$$

Multiply this factor by and end-of-period payment A made for n periods to determine an equivalent present sum P at an effective interest rate i per period.

(6) *Capital Recovery Factor:*

$$A/P_{i,n} = \frac{i(1+i)^n}{\left[(1+i)^n - 1\right]}$$

Use this factor to multiply by a present amount P to determine an equivalent future series of end-of-period payments A over n periods at an effective interest rate i per period.

(7) *Uniform Gradient Series Factor:*

$$A/G_{i,n} = \frac{1}{i} - \frac{n}{i}(A/F_{i,n})$$

$$= \frac{1}{i} - \frac{n}{\left[(1+i)^n - 1\right]}$$

Use the above relationship to determine the end-of-period payments A that is equivalent in present value to n payments starting at \$0 at the end of period 1 and increasing by an amount G per period until the end of period n.

1/2% Interest Factors

n	Single Payment: Compound-amount factor (To find F Given P, F/P i,n)	Single Payment: Present-worth factor (To find P Given F, P/F i,n)	Equal Payment Series: Compound-amount factor (To find F Given A, F/A i,n)	Equal Payment Series: Sinking-fund factor (To find A Given F, A/F i,n)	Equal Payment Series: Present-worth factor (To find P Given A, P/A i,n)	Equal Payment Series: Capital-recovery factor (To find A Given P, A/P i,n)	Uniform gradient-series factor (To find A Given G, A/G i,n)
