During the drilling periods, a number of monitoring wells were installed in specific aquifer horizons throughout Twentymile Park. These wells were incorporated into a hydrologic monitoring program and designed to take advantage of drillholes that intersected saturated aquifers directly above and below the Wadge and Wolf Creek seams.

Two project-specific field mapping efforts were completed in the Twentymile Park area. The Twentymile and Trout Creek Sandstone outcrops were mapped, and all the accessible Wadge seam open pit highwalls were recorded with joint and fault data noted. Field mapping was found to be one of the most useful and cost-effective sources of structural and stratigraphic data.

Lineament studies were conducted to address regional structural questions and utilized satellite imagery and high-altitude photographs, in addition to computer-enhanced low-altitude areal photographs.

Surface geophysical surveys were also utilized to locate and help evaluate local structural features. Field surveys included resistivity, induced polarization, very low frequency-electromagnetic (VLF-EM), and high-resolution seismic traverses.

All sites and access routes were inspected by registered archeologists to confirm that no sites of prehistoric or historic significance were disturbed in the exploration process. As far as possible, all sites impacted by exploration activities were reclaimed by recontouring, replacing topsoil, fertilizing, and seeding the same year as impacted.

Phase I Highlights—The first phase of the exploration drilling program was started in September 1981, and extended until March 1982. During this time, 36 deep drillholes were completed and surveyed (43,850 ft or 13.4 km drilled, and 3929 ft or 1198 m cored), predominantly in the Tow Creek area (Fig. 5.8.3.1). This phase of the program was primarily designed to define geologic structure, seam thickness, coal quality, hydrology, and geotechnical properties of the coal and rock strata.

In addition to the normal coring program, four holes were designated for extensive continuous coring below a specific depth to evaluate interburden properties. A velocity survey profile (VSP) program was completed for two holes. Continuous coring was accomplished in only one hole because of the time and cost was substantially more than anticipated. Nine sites were completed as hydrologic monitor sites.

During this early phase, a project evaluation task group was formed to assess the economic feasibility of mining the Twentymile Park underground coal reserves. Conceptual engineering utilizing incoming geologic data shifted emphasis from the Tow Creek to the Foidel Creek area (Fig. 5.8.3.1). (Pre-1981 evaluations indicated that the initial access should be into the Tow Creek area, with entries driven from a site near abandoned strip pits.) Preliminary results of this phase of exploration indicated that this access should not be evaluated further due to complex geologic structure with intense fracturing and faulting, combined with steep gradients.

In addition to the foregoing, results of phase I indicated that a high priority should be given to the geotechnical program and that it should include in-situ stress measurements. Further, the old 1979 test mine area (Middle Creek) should be included in the studies so it could be used as a "yardstick" for comparison with the Tow Creek and Foidel Creek reserves.

This first phase of exploration established a sizable reserve for the Wadge seam based on a minimum seam thickness of 5 ft (1.5 m) and seam dips less than 15% gradient (Fig. 5.8.3.4). The Wadge reserves for the Foidel Creek and Tow Creek areas totaled over 230 million tons (209 Mt) of in-place coal and suggested a controlled minable reserve of over 140 million tons (127 Mt).

Phase II Highlights—The second phase of exploration was planned to define geologic factors impacting mine planning and feasibility. This phase included additional drilling, mapping, strength testing, stress measurement, oriented core, pump tests, washability tests, geophysical surveys, satellite imagery, high-resolution seismic, and depositional modeling. Studies were concentrated in the area of the first five years of planned mining, with detail in other areas sufficient for long-term mine planning and economic feasibility.

During this second phase, 35 deep coal exploration holes were drilled and logged (44,100 ft or 13.4 km drilled, and 3895 ft or 1187 m cored). All were cored to recover roof, coal, and floor, and 16 were completed as hydrologic monitor wells. A total of 30 mi (48.3 km) of resistivity lines was completed, 10 mi (16.1 km) of high-resolution seismic lines were shot, 7 mi (12.1 km) of VLF-EM survey lines were run, 6 aquifer tests were performed, and 6 mi (10.5 km) of deep seismic data were acquired. Fifteen shallow (250 ft or 76 m) holes were also drilled to investigate possible offset in the Twentymile Sandstone.

Results of phase II and detailed strata analyses indicated that the proposed Foidel Creek portal site exhibited reserve characteristics that were substantially superior to those present in all other potential sites (Fig. 5.8.3.5). Additional drilling and seismic and resistivity surveys were recommended to obtain data adjacent to the major faults and to validate the structural model in the proposed pilot mine area. In addition, another monitor well was proposed in the mine area to analyze potential hydrologic hazards.

Potential impacts by geologic features on production were identified (Fig. 5.8.3.6) and their cumulative effect overlain on the reserve area. Significant concern in the proposed pilot mine area focused on potential hydrologic impacts and dilution effects from exposed roof strata.

Phase III Highlights—This phase of the program entailed the development of water wells for mine consumption, one deep water-monitor well and two alluvial monitor wells. Concurrent with the Foidel Creek mine start-up, eight drillholes were placed to gain greater structural control and to test rock strength and conditions in the test mine area. A l-mi (1.6-km) portion of seismic line was reshot, and approximately 5 mi (8 km) of surface induced polarization (IP)-resistivity survey data were gathered.

Table 5.8.3.1. Wadge Seam Quality Variation (As Received)[a]

	Top Coal	Mid Seam	Bottom Coal	Full Seam
Moisture, %	9.1	8.6	8.2	8.6
Ash, %	12.1	8.1	11.7	8.8
Sulfur, (%)	0.6	0.4	0.5	0.5
Heating Value,				
Btu/lb	10,900	11,600	11,100	11,500
(Mj/kg)	(25.35)	(26.98)	(25.81)	(26.86)

[a]These statistics are averaged for the total in-place Twentymile Park reserves base.

Several miles of VLF-EM data were also gathered. Over 9400 ft (2865 m) of rotary drilling were completed during this phase of the program, and 225 ft (69 m) of core were recovered. Portions of the earlier planned seismic surveys were dropped, due to potential scattering effects created in areas of previous surface mining. Rock mechanics and coal quality analyses were immediately incorporated into the planning and evaluation of the developing pilot mine. Ongoing hydrologic monitoring suggested hydrologic effects would lessen deeper in the basin because of the "tight" nature of most discontinuities. A selected mid-seam mining zone was chosen from detailed quality data for optimum ROM product, as shown in Table 5.8.3.1.

5.8.3.4 Project Costs

Exploration and project evaluation costs varied widely over the three phases of the program but reflect progressive levels of concern, typical pricing, and a strong focus on state-of-the-art exploration technology and detailed data gathering and interpretation. Analysis and interpretation efforts typically bridged the program phases but are reflected, as best as possible, in their relative categories (Table 5.8.3.2).

Phase I costs approximated $0.9 million. Significant costs were tied to direct drilling expenses 56% (plugging and coring, fuel, soap, etc.), staff support (11%), down-hole geophysics (8%), and geotechnical analysis (7%). Relatively mild winter weather kept access costs under control during this phase to an unusual degree.

Phase II and exploratory interpretive efforts resulted in an overall cost of over $2.2 million. Major expenditures were incurred by geotechnical consultants (18%), geophysical surveys (18%), and direct drilling (32%). Geotechnical testing and the hydrology program consumed 6% each of the budget.

Phase III, which was conducted concurrently with the startup of the pilot mine, cost slightly over $0.2 million. Principal expenditures were from drilling activities (28%) and hydrological studies (23%).

Overall, a total of nearly $3.3 million was spent on a 3-year exploratory, evaluation, and permitting effort to bring a previously undeveloped underground coal resource to an identified coal reserve in a producing state. Percentage breakdowns of major expense categories are depicted in Table 5.8.3.3.

As would be expected, drilling/coring was found to be the best way to obtain data at specific locations on the property, with rotary costs equaling about $5.70/ft ($18.70/m) overall ($48.75/ft or $160/m, for conventional coring, and recovering oriented core cost about $60.75 ft ($199.31 m). Costs associated with these rates are shown in Table 5.8.3.4.

Table 5.8.3.2. Cost Breakdown by Phase, Twentymile Park Exploration Program

Expenditure	Phase I	Phase II	Phase III	Total
Archeology	$ 8,700	$ 4,800	$ —	$ 13,500
Site preparation/ reclamation	25,600	27,750	6,700	60,050
Mobilization	3,000	2,000	1,000	6,000
Rotary drill	250,950	251,170	52,180	613,450
3-in. (76-mm) core	168,520	219,180	12,005	399,705
6-in. (152-mm) core	—	181,600	—	181,600
Cementing	23,890	24,200	4,150	52,240
Misc. supplies	32,670	73,875	16,710	123,255
Hydrologic	20,850	119,450	53,005	193,305
Geophysical logging	73,445	71,995	12,550	157,990
Geotechnical	56,550	136,350	13,000	205,900
Geophysical	20,000	340,285	19,020	379,305
Analytical	28,700	26,250	4,200	59,150
Rental equipment	10,200	8,125	5,450	23,775
Survey	6,180	11,750	3,600	21,530
Computer	—	18,500	2,080	20,580
Project evaluation	—	112,100	2,900	115,000
Geotechnical consultants	—	430,000	—	430,000
Staff support	98,335	100,795	17,220	216,350
Staff G&A	33,920	41,315	5,820	81,055
Total Project	$861,510	$2,201,490	$231,590	$3,294,590

Table 5.8.3.3. Percentage Breakdown of Major Cost Items, Total Project

Category	Percentage, %
Direct drilling	1
Hydrologic	6
Drillhole geophysics	5
Geotechnical	12
Surface geophysics	12
Field staff	9
Project evaluation	17
Quality analysis	2
Other	6
Total	100

Table 5.8.3.4. Typical Additional Costs to Direct Drilling Rates

Item	$/ft	$/m
Roadwork/site preparation	0.55	1.80
Geophysical logging	1.47	4.80
Rental equipment	0.22	0.72
Staff support	2.10	6.90

Drilling rates were approximately 17 ft/hr (5.2 m/hr) and coring rates generally about 2 ft/hr (0.61 m/hr). (Bit and mud costs are included in the $5.70/ft ($18.70/m) expense and were nearly $1.10/ft ($3.61/m) and $0.71/ft ($2.33/m), respectively.)

High-resolution seismic and resistivity—I.P. surveys were found to be effective tools to define structure across broad areas of the Twentymile Park Basin. Costs for these items equalled $25,000 to $30,000/mi ($15,530 to $18,640/km) and $2200/mi ($1370/km), respectively. The methods had to be used in conjunction with other types of data input. Actual field mapping and VLF-EM surveys were found to be very cost effective at about $300/day/individual field person.

5.8.3.5 Project Results

The Twentymile Park exploration and evaluation effort lead directly to the timely and successful development of a phased underground pilot mine during a period of economic contraction in the coal industry. The detailed evaluation enhanced confidence levels on all key aspects of resource minability.

Results of the project follow:

1. An in-place underground coal reserve of over 400 million tons (363 Mt) of controlled Wadge and Wolf Creek coal was delineated, of which 230 million tons (209 Mt) are accessible via the Wadge seam.
2. The minable Wadge seam underlying the Twentymile Park area contains a high-quality, low-sulfur coal reserve characterized by extreme lateral continuity and generally superior mining conditions.
3. The strata containing the Wadge seam has undergone deformational episodes, but discontinuities are generally predictable and can be recognized in the mine planning process.
4. Modeling of the groundwater hydrology indicated that water inflow rates for a full mine operation could be over 1500 gpm (95 L/s) at periodic peaks and reach equilibrium levels around 900 gpm (57 L/s).
5. Geotechnical data allowed optimum mine plan layout to minimize in-situ stress and entry deterioration. Pillar sizing, cavability, and roof and floor stability were also addressed and resolved.

Through the development period, development production averaged over 700 tons (635 t)/machine-shift, with highs ranging up to 1000 tons (907 t)/machine-shift. Mine product has been marketed on a ROM basis averaging about 10.0% ash, 0.46% sulfur, and 11,000 Btu/lb (25.6 MJ/Kg). A main source of dilution to the coal product is cap rock (roof coal is difficult to hold), although high production rates minimize the impact. Water inflow rates have been much lower than anticipated, due primarily to closure of discontinuities in deeper portions of the basin.

Because of the success of the pilot mine, the mine permit was revised to reflect a stand-alone underground mining operation during application for renewal in late 1984. (The mine permit was issued in late 1987 by the Colorado Mined Land Reclamation Board.) By early 1989 over 12,000 ft (3660 m) of mains had been developed in Cyprus' Foidel Creek mine; a variable cover pillar section had been developed and pulled to evaluate caving characteristics and a three-entry longwall gateroad plan developed.

In the latter part of 1988, management of the Cyprus Coal Co. approved the purchase of a new 640-ft (195-m) face longwall to take advantage of the proven uniform conditions of the Wadge seam and to improve mine productivity and overall ROM quality. A longwall face was installed in the mine during 1989. Average raw tons per longwall shift for the first six months of 1991 averaged over 6300.

Section 6 Mine Evaluation and Investment Analysis

DONALD W. GENTRY, ASSOCIATE EDITOR AND SECTION COORDINATOR

Chapter 6.0
INTRODUCTION

DONALD W. GENTRY

This section deals with one of the most fascinating aspects of mining—the evaluation of mine investment opportunities. Before proceeding further, it is important to clarify the meaning of some fundamental terms used frequently in the text.

6.0.1.1 Mine Valuation vs. Evaluation

The words "valuation" and "evaluation" in a mining context are often used interchangeably. However, for the purposes of this section, a distinction is made between the two terms in accordance with commonly accepted practice. The word *valuation* in a mining project context has the rather narrow meaning of placing a dollar or other currency value on the worth of the project as a whole. In other words, the value of a mining project refers to a measure of the desirability of ownership of that property. As such, the major item of interest is, "what is the mine worth?," or "what is the value of the mine?" The value of a mining project may actually be determined in the marketplace at any specific point in time, or it may be estimated by one of several methods. The topic of mine valuation is discussed in more detail in Chapter 6.1.

The word *evaluation* in a mining project context connotes the broader meaning of determining the numerical values of all possible factors or variables that are important in establishing the worth of a mining project. In other words, mine evaluation denotes the assessment of the relative economic viability of the mining project or investment opportunity. In this regard, estimates of project ore reserves, mining rates, revenues, costs, expected returns and associated risks, etc., as well as the dollar worth, are made for each project or investment opportunity available to the organization. Various aspects of the mine evaluation procedure are discussed in detail in subsequent chapters contained in this section. For instance, Chapter 6.2 discusses mine feasibility studies, Chapter 6.3 describes procedures for estimating capital and operating costs, while Chapter 6.4 deals with project operating strategies.

6.0.1.2 Investment Analysis

In this section the term *investment analysis* connotes continuation of the project evaluation process. That is, after the numerical values of all possible project variables have been estimated and the dollar worth of the entire project determined, appropriate evaluation criteria are calculated for each investment opportunity available to the firm. All projects are then ranked

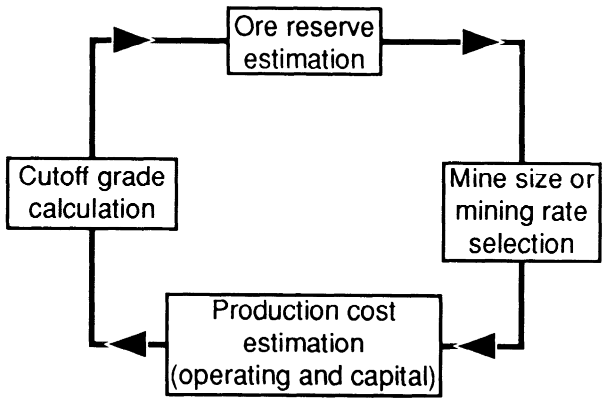

Fig. 6.0.1. Generalized iterative procedure for mine evaluation.

according to the preferred investment criteria and incorporated into the corporate capital budgeting process. Chapter 6.5 discusses mining project investment analysis as it relates to estimating project economic viability.

The mine evaluation procedure used for investment analysis is usually iterative in nature. The general procedure may be represented by Fig. 6.0.1 (Gentry and O'Neil, 1984). The tonnage and grade of the estimated ore reserve established from the exploration program are important variables in determining optimum mine size. Mine size, in turn, affects production costs, as economics of scale are often enjoyed with larger production rates. Finally, the level of production costs for the project as a whole determines what material can be mined at a profit (cutoff grade) and therefore determines the magnitude of the ore reserve.

The important point here is to recognize that each time a variable changes, the analyst must assess the impact of this change on all other project variables and on the subsequent financial and economic results. This iterative procedure must be repeated until the most economical design is achieved for the mining project being analyzed. This is, indeed, a time-consuming process, but it represents the essence of the mine evaluation process for investment analysis purposes.

6.0.1.3 Capital Budgeting

As noted in the previous section and as discussed in detail in Chapter 6.5, the mine evaluation procedure and associated investment analysis are incorporated into the corporate capital budgeting process. The capital budgeting process refers to the sequence of decisions that ultimately lead to the firm's acceptance or rejection of investment proposals along with subsequent management of the proposals accepted (Gentry and O'Neil, 1984). The capital budgeting process is normally considered to comprise the activities of planning, evaluation, selection, implementation, control, and, finally, continual reevaluation and auditing of results. In essence, *capital budgeting* is that element of capital investment dealing with the allocation of capital to projects in some optimal manner. The perceived benefits from these projects are projected to be realized at some time in the future.

After the firm has reconciled the investment decision, the financing decision must be addressed. The financing decision concerns the selection of source(s) and timing of new capital necessary to implement the investment decisions. This aspect of financing mining projects is discussed in Chapter 6.6.

6.0.1.4 Wealth Maximization

Although economic theory usually assumes that both private and public organizations strive to maximize profits from their investment decisions, various portions of this section are formulated on the premise that the fundamental objective of any private organization is to maximize its value or wealth to its owners (stockholders). In this sense, the term *wealth* refers to the total current market value of the firm's assets. In the case of corporations, the wealth or value is considered to be represented by the market price of the firm's common stock.

It is important to note that wealth maximization is a more appropriate and inclusive goal for a firm than profit maximization. Indeed, there is a difference between the two objectives in most situations. For example, there are a number of ways for a firm to increase profits, but many of these activities would rarely cause net shareholder worth to increase. Indications are that total profits are not as important to the investment community as are other indicators. Over the long term, the success or failure of an organization will be a function of how well the management of the organization handles investment and financing decisions, for the results of these decisions will directly impact the value of the firm in the marketplace.

6.0.1.5 Mining as a Unique Investment Environment

Certainly the investment environment associated with the mining industry is unique when compared with the environment encountered by most other industries. Section 2 of this book discusses various aspects of minerals commodities markets, supply-demand relationships, pricing, trading, and taxation issues that are often unique to the mining industry. Many of these unique characteristics are the result of some fundamental features of the minerals industry, which, in their combination, result in a unique business environment. These special features are described by Gentry (1988) and Gentry and O'Neil (1984) as follows.

Capital Intensity: Mining ventures are extremely capital intensive. Although the magnitude of the capital investment required for a new mining venture varies with the type of commodity, mining method, mine size, location, and other parameters, major new mines may require financial commitments that range from $500 million up to as much as $8 to $10 billion. The infrastructure alone for mines in remote locations may cost several hundred million dollars. Even small, high-grade precious-metals operations that employ a small work force may require multi-million dollar investment.

Cost Structure: The capital intensity results in a unique cost structure for the mining industry. The total average cost of production—including fixed and variable costs—per unit of salable product is often higher than the marginal or variable cost for the same unit. The average cost includes a high fixed-cost component, which primarily represents capital recovery. Consequently, in periods of low demand and price, a mining operation may be covering its marginal cost but actually losing money if the average cost per unit is considered.

Also, because high fixed costs represent a large component of a mining operation's total costs, the breakeven production level for mining facilities is closer to capacity than for other types of facilities with lower fixed costs. This is one reason why operators attempt to run mines at capacity, often employing three-shift, seven-day/week work schedules.

Long Preproduction Periods: Once the occurrence of an ore deposit has been established, several years of intensive effort are required before the property is brought on stream and ore is produced on a continuous basis. The preproduction period may range from 3 to 12 years, depending on the mining and processing methods, size and location of the deposit, and complexity of the operating and environmental licensing procedures, as well as other factors.

The significance of these long lead times is amplified when considered in conjunction with the capital intensity of the industry. Not only are companies committing extremely large capital resources to a new mining venture, but they also are exposed financially for a considerable period prior to project start-up. The longer the lead time, the higher is the probability of undesirable change in key engineering and economic parameters that were utilized in the initial investment decision. Also since expenditures of capital are required throughout the preproduction period, the longer the lead time, the greater are the returns required to offset the lost investment opportunities represented by the preproduction period.

Nonrenewable Resource: The aspect of the minerals industry that perhaps distinguishes it most from other industries is the fact that it deals with the extraction of a nonrenewable resource. The implications of a depletable resource are numerous. For example, one result is that revenues from mining are derived from a piecemeal disposal of the project's major asset, the ore body. As a result, the return of and return on the capital investment must be obtained within the finite life of the ore body. This unique feature has led many countries to provide for special tax treatment of mining ventures in the form of a depletion (or equivalent) allowance.

Because mines have finite lives that are determined by the size of the ore deposit and the mining rate, new deposits must be discovered and developed through continuing programs of exploration. Also the fact that a mining operation has a finite life may cause government agencies to require special concessions from the developer as a result of the finite nature of the benefits. One example may be special fiscal requirements that stem from the realization that government-provided infrastructure will no longer be required after the inevitable exhaustion of the deposit.

Indestructibility of Product: Another special feature of the mining industry centers on the fact that many metals are, essentially, indestructible. The consequence is a secondary market and a reduction in the amount of primary ore necessary to provide the required supply. Recycling has considerable economic advantages due to energy and other cost savings and contributes significant percentages to the US consumption of such metals as aluminum, copper, lead, zinc, silver, and iron and steel. In addition to reduced energy consumption and further increase in supply, recycling also affects metals markets in the following ways (Gocht et al., 1988):

1. The new supplier can weaken oligopolistic or monopolistic market positions.

2. World trade diminishes because recycling takes place directly in the consuming countries, with few exceptions.

3. Mineral resources are preserved.

4. Recycling of waste contributes to protecting the environment.

In the planning for any new mining venture, projections of recycling volumes and the growth in secondary markets should be included when estimating the overall future supply of the commodity considered for production.

High Risk: In addition to the obvious risks associated with capital intensity and long preproduction periods, the risks associated with mining ventures include some that may be under the control of the investor and others that are clearly uncontrollable. In general, these risks may be placed under the general headings of technical risks (geologic and engineering risks), economic or market risks, and political risks.

Although technical risks have been notably reduced in recent years, business risk—the chance of major loss due to market factors—has increased dramatically. This has been caused, fundamentally, by two primary factors: the rapidly rising capital requirements of new projects and the increasingly unpredictable future economic conditions. These difficulties, of course, are compounded by the long preproduction periods required for large, new mining projects (O'Neil, 1982).

In addition to the obvious risks associated with mineral markets and widely fluctuating metals prices, another economic risk is that associated with inflation. The impact of high rates of inflation on mineral project evaluation can be significant indeed. Also related to inflation, monetary exchange rates have recently become an important consideration in mine evaluation. When a firm sells its product in one currency and buys services in another, changes in exchange rates between the currencies can have grave consequences.

Political risk, although often overlooked, has become increasingly important in recent years when considering mining investments. There is an accelerating trend to greater participation in mining projects by host governments throughout the world. In the limit this can take the form of outright expropriation. Therefore, mining companies contemplating any new venture must assess these growing political risks to ensure that the added financial exposure is warranted.

The chapters that follow deal with the more important issues associated with mine valuation, mining project evaluation, investment analysis, and mine financing. The reader is referred to the references at the end of each chapter for further information on these topics.

Chapter 6.1
MINE VALUATION*

DONALD W. GENTRY AND THOMAS J. O'NEIL

As noted in the introduction to this section, the term *mine valuation* implies the assigning of a dollar or other currency value to the worth of a mine or mining project and provides a measure of the desirability of ownership of that property. As such, several types of value may be encountered in performing a mine valuation study. These are

1. Market value.
2. Full cash value.
3. Salvage value.
4. Replacement value.
5. Capitalized value.
6. Book value.
7. Assessed value.
8. Insured value.

Each of these has a specific meaning that can be applied to determine a monetary amount in a specific situation.

Of interest in this chapter is the broader question of "what is the value of the mine?," or "what is the mine worth?" In this context the value of interest is the market value of the property. *Market value* is the value (price) established in a public market by exchange between a willing buyer and a willing seller when neither is under duress to complete the transaction. Thus the term *market* suggests the idea of barter.

The term market value is often used synonymously with the term fair market value. The courts have come to accept the legal definition of *fair market value* as the amount in cash, or in terms reasonably equivalent to cash, for which in all probability the property would be sold by a knowledgeable owner willing but not obligated to sell to a knowledgeable purchaser who desired but is not obligated to buy. Therefore, the *determination* of market value of a specific mining property can only be made by the market through an actual sales transaction, in accordance with the foregoing caveats pertaining to the absence of duress on the part of either the seller or the buyer.

Typically, mineral economists, appraisers, and government tax officials, among others, are concerned with the *estimation* of market value for mineral properties. This estimated market value must be based on the time and conditions existing as of a specified date. Consequently, market value is a dynamic property that constantly changes as market conditions and expectations change. Following is a discussion of the approaches most often utilized to estimate the market value of mining properties. The specific recommended methodology for estimating the value of a mining project is provided in Chapter 6.2.

6.1.1 APPROACHES TO MINE VALUATION

To estimate the market value of any asset, most appraisers initially consider three generally accepted approaches to value estimation. All three approaches are based on the very important appraisal principle of substitution. A closer look at each of these approaches and its applicability to mining or mineral properties is provided in the following discussion.

6.1.1.1 Cost Approach

The *cost approach* to mine valuation attempts to determine the depreciated replacement cost for the asset in question. That is, what would it cost to reproduce an asset of identical quality and state of repair? The fundamental concept with this approach is that a purchaser would not be justified in paying more for a property than it would cost him to acquire land and construct improvements that had comparable utility with no undue delay.

The cost approach is rarely applicable in mining because the correlation between construction costs and the value of the property is very imperfect. For example, if one were to build mines with production capacities of 100 tpd (90 t/day) each, one on a very rich ore deposit and one on an economically marginal deposit, construction costs might be very similar, but fair market values of the two mines would, clearly, be substantially different.

Another problem arises when the cost approach is applied to newly discovered mineral properties that have no surface improvements or equipment of any kind. The very nature of mineral exploration and mining dictates that the discovery value of an ore deposit is generally greater than the cost incurred in making that discovery. If this were not true in the aggregate, investment could not be justified for exploration. Furthermore, the notion of estimating the cost of acquiring a comparable asset (ore body) is not very useful. This cost could, for example, be infinite if nature failed to provide a duplicate for explorationists to find.

The cost approach is not only the least applicable method in the valuation of mining properties, but it generally is the least reliable also.

6.1.1.2 Market (Comparable Sales) Approach

This approach is considered by most appraisers and the courts to provide the best indicator of fair market value, since it reflects the balance of supply and demand in the marketplace. The *market approach* assumes that a purchaser would not be justified in paying more for a property than it would cost him to acquire an equally desirable substitute property. The concept of market value also presumes conditions of an open market, exposure for a reasonable time, knowledgeable buyers and sellers, absence of pressure on either the seller to sell or the buyer to buy, and a sufficient number of transactions to create a stable market.

The market approach encounters serious practical problems when applied to mining transactions. This is mainly due to two facts: first, there are very few sales of mining properties, and therefore few comparative data are available; and, second, since each mineral deposit is unique in quality, size, geographical location, degree of development, and many other parameters, any market data are of modest value at best. To be applicable, the market data must not only relate to similar assets but must also be for a similar point in time.

* This chapter is compiled exclusively from materials contained in Chapters 1 and 2 of *Mine Investment Analysis* by D.W. Gentry and T.J. O'Neil (1984) and from the article "Minerals Project Evaluation — An Overview" by D.W. Gentry (1988).

Experience in the area of mineral property transactions suggests that the open-market, unpressurized dealing and other assumptions previously mentioned in association with this approach are seldom reflected in reality. When such criteria and assumptions are met, it is often extremely difficult to ascertain the actual or true value of the sale because of stipulations pertaining to production commitments, deferred payments, exchanges of stock, production payments, and other subtle factors that can affect the value significantly.

6.1.1.3 Income (Earnings) Approach

With the *income approach,* the value of an asset or investment-type property is estimated by calculating future annual net earnings generated from the producing property or asset and then discounting this earnings stream to the present time by the use of an appropriate discount rate. The approach assumes that a purchaser would not be justified in paying more to acquire income-producing property than the present value of the income stream to be derived from the property. Because of the calculation procedure utilized, many analysts refer to this as the capitalized income approach.

In essence, the income approach is one step removed from the market (comparable sales) approach. If comparable sales data are unavailable or if one is estimating the value of a mineral commodity in situ, it is possible to arrive at a value estimate by combining the selling price of the commodity *produced* with the associated costs of producing it from the property in question. By proper incorporation of these data into a discounted cash flow analysis, it is possible to arrive at an estimate of property value even in the absence of actual production. It is important to remember, however, that the estimate thus obtained is not a direct estimate of the market value of a commodity in place, but rather an estimate of potential income generated from mining and selling the commodity.

Capitalized future income is a unit valuation method. That is, a single value is assigned to the ore deposit, to surface and subsurface improvements, and to all real and personal property used in the production process. To a considerable degree, real property at mines has value only because of the presence of ore, and unit valuation is therefore appropriate.

Because mines have limited operating horizons, and because there are well-established markets for most mineral commodities, the income approach is widely used in valuing mineral properties. The approach is commonly used by the mining industry in the assessment of investment rates of return and to determine appropriate purchase prices for mines or mineral prospects. From a practical standpoint, the income approach has the added capability of incorporating more obtainable, realistic data for analysis and therefore is the preferred approach to mine valuation. In addition, the income approach is consistent with the generally accepted definition of the value of a mineral property. That is, the value of a mining or mineral property at a specific point of time is simply the present value of all the future net annual proceeds that are expected to accrue from ownership. The basic element in the income approach to mine valuation is the pro forma income statement, which is discussed in more detail in Chapter 6.2.

6.1.1.4 Other Types of Value

As mentioned at the beginning of this chapter, there are several types of value that may be encountered when performing mine evaluation studies. Following are brief descriptions of some of them.

Salvage Value: Salvage is the net sum, over and above the cost of removal and sale, realized for a property or asset when it is retired from service. Salvage value and scrap value are synonymous when the property or asset retired from service is scrapped for the value of its materials.

Replacement Value: Replacement value refers to the existing value of a property or asset as determined on the basis of what it would cost to replace the property or its service with at least equally satisfactory and comparable property and service. The concept of replacement value is fundamental to the cost approach utilized by appraisers.

Book Value: Book value is the original investment in the property or asset as carried on the organization's books less any cumulative allowance for depreciation or amortization entered on the books.

Assessed Value: The assessed value of a property is the value entered on the official assessor's records as the value of the property applicable in determining the amount of ad valorem taxes to be paid by the property owner.

Insured Value: The insured value of a property refers to that value at which the property has been insured against loss or disaster. This value is generally associated with replacement value for tangible assets and earning capacity for property such as mines (ore deposits).

Capitalized Value: The capitalized value of a property is the sum of discounted future annual net earnings generated by the property. The capitalized value concept is synonymous with the income approach to value estimation for mining properties.

6.1.2 PURPOSE OF MINE VALUATION STUDIES

There are many reasons for conducting studies on estimating the value of a mining property. Regardless of the specific purpose for estimating the value of a mining property, the ultimate objective of the study is to arrive at a monetary value or worth for the property in question. A specific value, or range in values, for a specific property is often required for one or more of the following purposes.

6.1.2.1 Acquisition

The acquisition of mineral properties may transpire at any point in time between a raw prospect and an actual operating mine. Obviously, the actual amount of data available on a property will depend upon where it lies within this spectrum. Depending upon the state of development of the property, the purchaser is acquiring assets with varying levels of risk. As such, the estimated value of the property must reflect not only the potential of the mineral deposit but also the relative risks associated with these assets. Certainly the distribution of value estimates for an existing operating mine would be expected to have a rather low variance as contrasted to that for a raw prospect.

6.1.2.2 Taxation

Mineral properties must also be valued for taxation purposes. Perhaps the classic example here is with ad valorem property taxes, levied by most state and local governments. The difficulty with value estimation of a mineral property for taxation purposes is that a *single* value is required for property worth.

Most states have enacted tax provisions that attempt to approximate the value of a mineral property through a formula or other mechanism that rarely serves as an adequate measure of property value for an actual sale. These mechanisms are seldom based on strong economic foundations and only serve as a convenient proxy for mineral property values. As a result, significant discrepancies can occur between the appraised value of a property for tax purposes and the value as perceived in the marketplace.

6.1.2.3 Financing

The mode, mechanism, and magnitude of financing new mining properties or ventures are functions of the estimated property or project value. Certainly, the risk of default must also be considered in mining and must be assessed in regard to the perceived intrinsic value of the property. This aspect is becoming increasingly important in view of the popularity of international joint ventures as a means of dispersing project risks.

The fundamental concern of lending institutions is not whether a specific rate of return is achieved by the project owner, but rather that the project will generate adequate cash flows to service the acquired debt. Thus lenders approach mine valuation studies from a different perspective.

6.1.2.4 Regulatory Requirements

Even the federal government has found it necessary to wrestle with the problems associated with estimating the value of federally controlled mineral lands. This results from the fact that the leasing of federal lands for some mineral commodities is through the competitive bidding process, and the government is obligated by law to accept no bid that is less than the fair market value of the mineral occurrence. As a result, the federal government is often required to estimate the value of certain leases prior to competitive bidding in order to assure that bonus bids and royalty provisions represent fair market value and are therefore acceptable. The federal government is faced with a similar valuation problem when determining or negotiating royalty provisions on other leased minerals.

Chapter 6.2
MINE FEASIBILITY STUDIES*

DONALD W. GENTRY AND THOMAS J. O'NEIL

Feasibility studies are the heart of the mine evaluation process. A *feasibility study* of a mining project represents an engineering/economic appraisal of the commercial viability of that project. As such, it is the result of a relatively formal procedure for assessing the various relationships that exist among the myriad of factors that directly or indirectly affect the project in question. In essence, the objective of a feasibility study is to clarify the basic factors that govern the chances for project success. Once all the factors relative to the project have been defined and studied, an attempt is made to quantify as many variables as possible in order to arrive at a potential value or worth of the property.

As a mining project progresses from raw exploration through to the time when a management decision is made to develop and mine the property, a number of analyses will be conducted on the property, each of which will be based on increasing amounts of data, will require increasing amounts of time (and therefore expense) to prepare, and will have increasing degrees of accuracy. For example, as exploration occurs on a mining property, the intersection of mineralization by a few drillholes typically triggers the need for some type of initial analysis to assist with necessary decision making. These types of studies are identified by various names (Gocht et al., 1988; Taylor, 1977), but in each case they are designed to answer questions pertaining to (1) what magnitude of deposit might exist rather than what is known to exist, (2) should further expenditures be incurred to look for what might exist, (3) should the project be abandoned, or (4) what additional effort and/or expense is necessary before making any of these decisions.

Assuming a favorable decision for continuation of the project, the next sequence of decisions must be predicated on studies utilizing much more detailed information. These so-called prefeasibility studies or intermediate economic studies are based on increasing amounts of data pertaining to geologic information, preliminary engineering designs and plans for mining and processing facilities, and initial estimates of project revenues and costs. They are constructed to support a continuum of decisions relating to the next major spending requirement. Intermediate economic studies of this type typically contain the following information and analysis (Gocht et al., 1988):

1. *Project Description:* geographic area, existing access routes, topography, climate, project history, concessionary terms, schedule for development of mine and any processing facilities.
2. Geology: regional geology, detailed description of the project area, preliminary reserve calculations, plans for detailed target evaluation.
3. *Mining:* geometry of the ore body, proposed mining plan (and alternatives), required plant and equipment.
4. *Processing:* technical descriptions of the ore and concentrate, processing facilities.
5. *Other Operating Needs:* availability of energy, water, spare parts, and equipment (diesel oil, explosives, replacement parts, etc.).
6. *Transportation:* description of the additional, necessary transportation facilities (roads, air strips, bridges, harbors, rail lines).
7. *Towns and Related Facilities:* housing for workers, schools for children of workers, medical facilities, company offices.
8. *Labor Requirements:* estimates of work force broken down according to qualifications (skills) and local availability.
9. *Environmental Protection:* plans to reduce or minimize environmental damage, description of relevant environmental legislation.
10. *Legal Considerations:* review of mining laws, taxation, foreign-investment regulations, political risk.
11. *Economic Analysis:* cost estimates for plant and equipment, infrastructure, materials, labor, other factors; market analysis, including production, consumption, and price formation for the relevant minerals; revenue forecasts based on expected production and mineral prices; cash flow and net present value analysis; sensitivity analysis.

Assuming the project continues to appear favorable throughout the intermediate economic studies, as these studies progressively focus more on engineering and economic aspects and less on geologic parameters, the project must be formally assessed through a comprehensive feasibility study. The feasibility study represents a detailed analysis of all the parameters contained in the intermediate economic studies, along with other pertinent factors relating to political and legal aspects affecting project viability. Specific data requirements for incorporation into feasibility studies are contained in the following segment of this chapter; however, in general, the study contains analyses of the project's geology and deposit characteristics, mineralogy, mineral processing characteristics, designs and plans for mining and processing equipment requirements, construction schedules, investment requirements and timing, estimates of revenues and costs, marketing plans, cash flow calculations, sources and methods of financing, and risk and sensitivity analyses of important project variables. As stated previously, the purpose of the feasibility study is to assess the technical and economic viability of the project and to assist the organization in making the "go/no-go" decision regarding project development.

Although there is no prescribed format for reporting the results of a project feasibility study, the final report must fulfill the following essential functions (Taylor, 1977):

1. Provide a comprehensive framework of established and detailed facts concerning the mineral project.
2. Present an appropriate scheme of exploitation complete with plans, designs, equipment lists, etc., in sufficient detail for accurate cost estimation and associated economic results.
3. Indicate the most likely profitability on investment in the project, assuming the project is equipped and operated as specified in the report.
4. Provide an assessment of pertinent legal factors, financing alternatives, fiscal regimes, environmental regulations, and risk and sensitivity analyses on important technical, economic, political, and financial variables affecting the project.
5. Present all information in a manner intelligible to the owner and suitable for presentation to prospective partners or to sources of finance. The document must be "bankable."

---

* This chapter draws heavily from various chapters in *Mine Investment Analysis* by D.W. Gentry and T. J. O'Neil (1984).

6.2.1 DATA REQUIREMENTS

Nothing improves the results of a project feasibility study more than good input data. Unfortunately, those preparing feasibility studies for mining projects never possess all the information they would like. In addition to inadequacy or unavailability of some needed data, care must be taken not to overlook any variable that may influence project viability. In this regard, it is often helpful to compile an outline of factors to be considered when preparing feasibility studies on mining properties.

6.2.1.1 Factors for Consideration

Table 6.2.1. is an outline of some of the pertinent variables that must be studied, considered, and analyzed when evaluating mining properties. The significance of each variable will be a function of the specific property being investigated and the mineral commodity (metallic, nonmetallic, fuel) involved. Nonetheless, all these variables should be assessed during preparation of the final feasibility study.

A review of Table 6.2.1. suggests there are some fundamental issues that are applicable to all mining property feasibility studies—regardless of the commodity involved. For instance, one of the first tasks associated with any mining property is estimating the magnitude and quality of the ore reserves (Chapter 5.6). Ore is, of course, an economic term and is a function of commodity prices, production costs, mining method, recoveries, dilution, and a number of other variables. Because ore reserves are determined by ever-changing economic conditions, the exact amount of ore contained in a deposit cannot be precisely determined until production ceases. This uncertainty with respect to ore reserves has a significant impact on the evaluation of mineral properties where long-term contracts at stipulated selling prices are not available.

Production technology is another key area of concern when performing mining feasibility studies. Technological advancements in equipment, mineral processing, and other areas can significantly impact projected operating and capital costs. A good example of the impact of technology changes on mining costs is the comparison between direct mining costs per ton (tonne) of rock for underground and surface operations. While underground operating costs have been increasing at significant rates in recent years (mainly because of the lack of major technological advancements and the labor intensity that exists), unit operating costs at surface operations have changed far less. The technological advancements in mining equipment, yielding productivity increases, have prevented direct operating costs in surface operations from escalating at the rates experienced by underground producers. The relative stability in surface operating costs has not been entirely free, however. The technological advancements in mining equipment that contributed to this stability in operating costs carried with them significant increases in capital costs.

Operating and capital cost requirements must be determined separately when formulating the feasibility study. However, in the limiting case, it is the combination of the magnitude and timing of both these costs that ultimately influence the analysis. Any changes in future production technologies must be carefully analyzed and the impact assessed on overall operating and capital cost requirements. The estimation of capital and operating costs for mining projects that have not progressed to the detailed planning and layout stage is discussed in Chapter 6.3.

Another area of fundamental interest in feasibility studies of mining properties that requires considerable data generation and analysis is the estimation of project revenues. The timing and magnitude of mining revenues depends upon factors such as ore reserves, production rates, commodity prices, markets, and metallurgical recoveries. These variables are often extremely difficult to estimate or predict—particularly for commodities traded in international markets. This topic is discussed in more detail in the following portion of this chapter.

The overall operating environment is another area of major concern. In recent years, the national and, to a lesser but growing extent, the international operating environment of mining properties has been impacted significantly by environmental and other regulatory requirements. These constraints have invariably increased operating and capital cost requirements for the industry and have reduced or delayed the production of mineral commodities. The operating environment of mining operations is also affected by direct economic variables, such as royalties and taxes mandated by federal, state, and local taxing authorities. All these costs, whether direct or indirect, impact profit margins, ore reserves, mineral conservation, and ultimately project viability.

6.2.1.2 Variable Quantification

As stated previously, the objective of any feasibility study is to assess, clarify, and ultimately quantify the basic factors that govern the chances for project success. Once all the geologic, engineering, and other technology-related factors relative to the property have been defined and studied, an attempt is made to quantify as many of the variables as possible to arrive at a potential value or worth of the property. In this regard, two general categories of quantification are extremely important yet quite troublesome to compute: revenue estimation and cost estimation.

Revenue Estimation: Annual mine revenue is calculated by multiplying the number of units produced and sold throughout the year by the sales price received per unit. While the arithmetic associated with calculating annual mine revenue is trivial, determining the best value to use for each of these two critical variables is much more difficult.

There are a number of important considerations in estimating the number of units produced and sold annually. For example, estimates must be made of the tonnage of ore produced, the grade of ore mined (including dilution), the percentage recovery of the valuable mineral in the ore, and, finally, the number of payable units available for sale.

The second major component of the mine revenue calculation is the unit sales price. Estimating future mineral prices—particularly prices far enough into the future to be of use in mine investment analysis—is much more difficult than estimating the production-related variables and is an exercise in which a high error of estimation invariably exists. As pointed out in Section 2.0, mineral prices, like those of any other product, are ultimately determined by supply and demand. However, there are major complications on both sides of the supply-demand equation that seriously impair the value of quantitative econometric modeling for estimating mineral prices.

Clearly, the analysis of supply and demand for most mineral commodities is complicated. In fact, few analysts are willing to suggest that reliable forecasts of prices useful in mine investment analysis are possible. The current popular approach to this problem is for analysts to occupy safer ground and issue price *projections*—that is, prices that are likely if certain assumed events actually occur.

Regardless of the difficulties associated with forecasting or projecting mineral prices into the future, estimates of mining project annual revenue must be established. Generally, fungible

Table 6.2.1. Salient Factors Requiring Consideration in a Mining Project Feasibility Study

I. Information on Deposit
  A. Geology
    1. Mineralization: type, grade, uniformity
    2. Geologic structure
    3. Rock types: physical properties
    4. Extent of leached or oxidized zones
    5. Possible genesis
  B. Geometry
    1. Size, shape, and attitude
    2. Continuity
    3. Depth
  C. Geography
    1. Location: proximity to population centers, supply depots, services
    2. Topography
    3. Access
    4. Climatic conditions
    5. Surface conditions: vegetation, stream diversion
    6. Political boundaries
  D. Exploration
    1. Historical: district, property
    2. Current program
    3. Reserves
      a. Tonnage-grade curve for deposit, distribution classification; computation of complete mineral inventory (geological and mining reserves) segregated by ore body, ore type, elevation and grade categories
      b. Derivation of dilution and mining recovery estimates for mining reserves.
    4. Sampling: types, procedures, spacing
    5. Assaying: procedures, check assaying
    6. Proposed program
II. Information on General Project Economics
  A. Markets
    1. Marketable form of product: concentrates, direct shipping ore, specifications, regulations, restrictions
    2. Market location and alternatives: likely purchasers, direct purchase vs. toll treatment
    3. Expected price levels and trends: supply-demand, competitive cost levels, new source of product substitutions, tariffs
    4. Sales characteristics: further treatment, sales terms, letters of intent, contract duration, provisions for amendments and cost escalations, procedures/requirements for sampling, assaying, and umpiring.
  B. Transportation
    1. Property access
    2. Product transportation: methods, distance, costs
  C. Utilities
    1. Electric power: availability, location, ownership right-of-way, costs
    2. Natural gas: availability, location, costs
    3. Alternatives: on-site generation
  D. Land, Water, and Mineral Rights
    1. Ownership: surface, mineral, water, acquisition or securement by option or otherwise, costs
    2. Acreage requirements: concentrator site, waste dump location, tailings pond location, shops, offices, changehouses, laboratories, sundry buildings, etc.
  E. Water
    1. Potable and process: sources, quantity, quality, availability, costs
    2. Mine water: quantity, quality, depth and service, drainage method, treatment
  F. Labor
    1. Availability and type: skilled/unskilled in mining
    2. Rates and trends
    3. Degree of organization: structure and strength
    4. Local/district labor history
    5. Housing and transport of employees
  G. Government Considerations
    1. Taxation: federal, state, local
      a. Organization of the enterprise
      b. Tax authorities and regimes
      c. Special concessions, negotiating procedures, duration
      d. Division of distributable profits
    2. Reclamation and operating requirements and trends: pollution, construction, operating and related permits, reporting requirements
    3. Zoning
    4. Proposed and pending mining legislation
    5. Legal issues: employment laws, licenses and permits, currency exchange, expatriation of profits, agreements among partners, type of operating entity for tax and other purposes.
  H. Financing
    1. Alternatives: sources, magnitudes, issues of ownership
    2. Obligations: repayment of debt, interest
    3. Type of operating entity: organizational structure
    4. Division of profits: legal considerations
III. Mining Method Selection
  A. Physical Controls
    1. Strength: ore, waste, relative
    2. Uniformity: mineralization, blending requirements
    3. Continuity: mineralization
    4. Geology: structure
    5. Surface disturbance: subsidence
    6. Geometry
  B. Selectivity
    1. Dilution, ore recovery estimates
    2. Waste mining and disposal
  C. Preproduction Requirements
    1. Preproduction development or mining requirements: quantity, methods, time
    2. Layout and plans: schedule
    3. Capital requirements
  D. Production Requirements
    1. Relative production
    2. Continuing development: methods, quantity, time requirements
    3. Labor and equipment requirements
    4. Capital requirements vs. availability
IV. Processing Methods
  A. Mineralogy
    1. Properties of ore: metallurgical, chemical, physical
    2. Ore hardness
  B. Alternative Processes
    1. Type and stages of extraction process
    2. Degree of processing: nature and quality of products
    3. Establish flowsheet: calculation of quantities flowing, specification of recovery and product grade
    4. Production schedule
  C. Production Quality vs. Specifications
  D. Recoveries and Product Quality
    1. Estimate effects of variations in ore type or head grade
  E. Plant Layout
    1. Capital requirements
    2. Space requirements
    3. Proximity to deposit
V. Capital and Operating Cost Estimates
  A. Capital Costs
    1. Exploration
    2. Preproduction development (may also be considered operating costs)
      a. Site preparation
      b. Development of deposit for extraction
    3. Working capital
      a. Spares and supplies (inventory)
      b. Initial operations
      c. Financing costs (when appropriate)

4. Mining
   a. Site preparation
   b. Mine buildings
   c. Mine equipment: freight, taxes and erection costs, replacement schedule
   d. Engineering and contingency fees
5. Mill

commodities—such as most metals traded on exchanges—suffer from the greatest future price uncertainty. Most metal markets are notoriously cyclical, and the amplitude and the period of the cycles defy accurate prediction. The recommended approach to mineral price forecasting is not limited to the application of any one or two specific analytical techniques, and it definitely is not a mechanical process. Rather, it is a painstaking blend of economic theory, industry analysis, market analysis, and competitor analysis combined with sound, experienced judgment.

Cost Estimation: The economic evaluation portion of a feasibility study ultimately must be based on information that provides an answer to the question, "what is it going to cost?" Unfortunately, the answer to this question is not simple, primarily because of the significant misunderstandings associated with cost data. Therefore, the components of so-called "total production cost" or "total operating cost," for example, must be carefully identified and defined.

When preparing a mine feasibility study, it is essential also to distinguish between operating costs, expenses, and capital costs. *Operating costs* are considered to be all expenses incurred at the plant site, whereas *general expenses* are off-site management or corporate-level expenditures. This latter classification of expenses may be directly related to mine or plant size, or it may contain indirect items incurred by headquarters and allocated across all production divisions in accordance with some corporate allocation scenario.

Direct costs, or variable costs, relate to items such as labor, materials, energy, and supplies that are consumed directly in the production process and are used roughly in direct proportion to the level of production. On the other hand, *indirect costs,* or fixed costs, are expenditures that are independent of the level of production—at least over certain ranges. It is obvious that, in the limit, few costs are absolutely fixed.

Capital costs (or first cost, or capital investment) are those expenditures made to acquire or develop capital assets, the benefits of which will be derived over several years. The largest portion of capital costs is incurred in the initial stages of project start-up, but some capital expenditures are incurred annually throughout the life of the mine.

In general, capital costs fall into one of three classes, depending on the treatment of the cost for tax purposes. These are depreciable investment, expensed or amortizable investment, and nondeductible investment. Because of differing tax treatments, the *type* of capital expenditure involved can be a very important factor in the evaluation of a new project, in addition to its magnitude.

The estimation of operating and capital costs for mining projects is extremely difficult and must be performed with great care. Chapter 6.3 illustrates procedures for estimating initial capital and operating costs for mining projects being analyzed via intermediate economic studies. However, the final feasibility must contain operating and capital cost estimates based on actual design and layout drawings, manning tables, flow charts, and equipment lists, specifications, and manufacturer quotations. These estimates should be predicated on data relative to unit operations, job functions, job requirements, timetables, and so on. This requires considerable time and effort; there are few, if any, acceptable shortcuts.

6.2.2 CASH FLOW ANALYSIS

The importance of the *pro forma* income statement in establishing the value of a mining project via the income (earnings) approach was alluded to in Chapter 6.1. Inasmuch as there are generally major differences between accounting profits and actual net cash benefits derived from an investment, investors are using almost exclusively the concept of project cash flows as the primary measure of real benefits produced by a capital project. This is predicated on the knowledge that cash flow analyses and accounting concepts depict investments differently, as a result of the timing of costs, and on the belief that the proper method for evaluating a capital investment is to compare the present investment outlay with the expected positive net cash flows that will accrue from the project in the future. In making this comparison, it is essential that the timing of the various cash flows be recognized by the use of an appropriate interest (discount) rate. This aspect of cash flow analysis is discussed briefly in the following portion of this chapter.

As indicated, cash flow analyses relate the expenditures associated with investment to the subsequent revenues or benefits generated from such investment. Cash flows are routinely calculated on an annual basis for evaluation purposes and are determined by subtracting the annual cash outflows from the annual cash inflows that result from the investment. Consequently, a cash flow analysis may be performed for any investment with which income and expenditure are associated. Also the annual cash flows resulting from an investment may be either positive or negative. Typically, the net annual cash flows for a new mining property will be negative during the preproduction years due to large capital expenditures. After production commences, the cash flows will usually be positive, and an inflow of cash results from investment in the project.

In the US income tax law, net annual cash flow is treated basically as a combination of two components: the return *on* the investment and the recoupment *of* the investment. In the minerals industry, net cash flow is generally defined as net profit after taxes plus depreciation and depletion minus capital expenditures and working capital. Within this definition, net profit after taxes represents the return on the investment, whereas depreciation and depletion represent the recoupment of the investment.

In a cash flow analysis, each investment receives credit for income taxes saved. Since the accounting allowances for depreci-

Preproduction Period	
Exploration expenses	Land and mineral rights
Water rights	Environmental costs
Mine and plant capital requirements	Development costs
Sunk costs	Financial structure
Working capital	Administration
Production Period	
Price	Capital investment—replacement of expansions
Processing costs	Royalty
Recovery	Mining cost
Postconcentrate cost	Development cost
Revenues and percent removable	Exploration cost
Grade	General and administration
Investment tax credit	Insurance
State taxes	Production rate in tons per year
Federal taxes	Financial year production begins
Depletion rate	Percent production not sent to processing plant
Depreciation	Operating days per year
Postproduction	
Salvage value	Contractual and reclamation expenditures

Source: Laing, 1977.

ation and depletion reduce the amount of taxable income (and therefore reduce the amount of taxes paid), they have the effect of saving the organization money. Consequently, they constitute a credit in the cash flow calculation and are added to net income after taxes. It must be recognized that depreciation and depletion are noncash items and do not actually "flow" anywhere.

Table 6.2.2. illustrates the components and basic calculation procedure for determining annual cash flows for a mining project. Table 6.2.3. lists some of the more important parameters relating to preproduction, production, and postproduction mining activities that require consideration in the preparation of cash flow analyses. The appropriate use and manipulation of these input variables are an extremely important facet of the cash flow analysis. The concept of a cash flow analysis is a particularly useful technique for the evaluation of mineral-related projects because of the important impact of the depletion allowance in the United States.

In view of the foregoing, it is worthwhile to reiterate the fact that in a cash flow analysis, each investment receives credit for income taxes saved. Therefore, for profitable organizations, it is advantageous to maximize pretax deductions and thereby reduce the amount of taxable income and, consequently, income taxes paid. In order to take advantage of these tax savings as soon as possible, the firm would opt to expense all possible expenditures in the year incurred as opposed to capitalizing them followed by subsequent write-offs over the amortization period. Although the total amount of the pretax deduction would be the same in either case, by expensing as soon as possible, the firm realizes an earlier return of the resulting tax savings. This early return of tax savings enables the firm to utilize these dollars sooner than would otherwise be possible.

6.2.3 TIME VALUE OF MONEY

If it were not for the existence of interest, the analysis of investment opportunities would be greatly simplified. In the absence of interest, investors would be indifferent as to when cash outlays are made or cash benefits received. It would, in fact, be irrelevant whether the outlays preceded or followed inflows, as long as both amounts are known with certainty.

Of course, it does make a considerable difference whether, for example, a firm receives $1 million now or five years from now. The reason is that money does have a value, which is a function of time. Interest is how this time value is measured.

Interest is generally defined as money paid for the use of borrowed money. Interest may be likened to a rental charge for using an asset over some specific time period. The rate of interest is the ratio of the interest chargeable at the end of a specific period of time to the money owed, or borrowed, at the beginning of that period. Interest exists to compensate for a number of concerns experienced by lenders; these are related primarily to risk, inflation, transaction costs, opportunity costs, and postponement of pleasures. The level of interest is, like the price of other assets, determined by supply and demand.

The history, philosophy, and theoretical underpinnings of interest are covered exhaustively in a large number of texts and reference books (e.g., Newman, 1980; Smith, 1973). This material need not be repeated here.

It is sufficient simply to recognize that money has earning power. That is, the timing of when payments are made and earnings are received in a capital project is very important.

6.2.3.1 Interest Formulas

Cash flows at different points in time are related by a series of six basic interest formulas. These formulas in turn are based on five variables, as follows:

> F is a future sum of money, P is a present sum of money, A is a payment in a series of n equal payments, made at the end of each period of interest, i is effective interest rate per period, and n is number of interest periods.

Every interest problem is composed of four of these variables: three are given, and the fourth must be determined. The standard notation for describing the particular type of problem involved lists all four variables of concern, in the following manner:

For example: *(F/P,i,n)*, means, "Find *F*, given *P,i,* and *n*"

Similarly, *(A/F,i,n)*, means, "Find *A*, given *F,i,* and *n*"

The notation is often shortened to simply *F/P* or *A/F*, etc., where it is understood that *i* and *n* are given. This notation is widely accepted in the field of engineering economy.

The six basic interest equations are developed and described.

1. Single payment compound amount, *(F/P,i,n)*.

$$F = P(1+i)^n \qquad (6.2.1)$$

Example 6.2.1. Find the amount that will accrue at the end of 7 years if \$1250 is invested now at 8%, compounded annually. Given: P = \$1250, n = 7 years, i = 8%.

Solution.

$$F = P(1+i) = \$1250\ (1+0.08)^7 = \$2142.28$$

The quantity $(1+i)^n$ = *(F/P,i,n)* has, like other interest factors, been tabulated for various values of *i* and *n* in so-called interest tables. Such tables are provided in the appendix of this volume for select interest rates and discrete compounding.

However, many hand-held calculators can now solve such problems directly so that interest tables are becoming less necessary.

2. Single payment, present worth *(P/F,i,n)*.

This is Eq. 6.2.1 solved for *P*.

$$P = F/(1+i)^n \qquad (6.2.2)$$

Example 6.2.2. If \$6500 will be needed in 5 years, how much should be invested now at an interest rate of 7.5%, compounded annually?

Solution. Given: F = \$6500, n = 5 years, i = 7.5%

$$P = F(1+i)^n$$
$$P = \$6500/(1+0.075)^5 = \$4527.63$$

Using interest tables to solve this problem becomes somewhat more difficult because one must interpolate between 7 and 8%. For most interest problems, a linear interpolation is satisfactory. The widespread use of programmed calculators and computers for solving interest problems facilitates exact solutions so that interpolation is often unnecessary. However, the intellectual problem of calculating exact solutions from highly inexact data is of major concern in all investment studies.

3. Uniform series, compound amount *(F/A,i,n)*.

Here the concern is to determine the terminal amount when equal annual payments are made to an interest-bearing account for a specified number of years. It is important at this point to recall that *A* is defined as occurring at the *end* of the interest period. Therefore, for

$$n = 1,\ F = A$$
$$n = 2,\ F = A(1+i) + A \qquad (6.2.3)$$
$$n = 3,\ F = A(1+i)^2 + A(1+i) + A$$

or in general,

$$F = A(1+i)^{n-1} + A(1+i)^{n-2} + \ldots + A(1+i) + A$$
$$= A[(1+i)^{n-1} + (1+i)^{n-2} + \ldots + (1+i) + 1]$$

Multiplying Eq. 6.2.3 by $(1+i)$ yields

$$F(1+i) = A[(1+i)^n + (1+i)^{n-1} + \ldots \qquad (6.2.4)$$
$$+ (1+i)^2 + (1+i)]$$

Now subtracting Eq. 6.2.3 from 6.2.4,

$$iF = A[(1+i)^n - 1]$$

or (6.2.5)

$$F = \frac{A[(1+i)^n - 1]}{i}$$

Example 6.2.3. If payments of \$725 are made at the end of each year for 12 years to an account which pays interest at the rate of 9% per year, what will be the terminal amount?

Solution .

$$F = \frac{A[(1+i)^n - 1]}{i}$$

$$= \frac{725[(1+0.09)^{12} - 1]}{0.09} = \$14{,}602.02$$

It obviously makes a considerable difference if the annual payments are made at the beginning of the year (an *annuity due)* rather than at the end of the year (an *immediate annuity).* However, the end-of-year convention is more common, and nearly all interest tables and computer programs are constructed on this basis. To verify easily that any particular table or computer program adheres to this convention, note that for n = 1, F = A regardless of the interest rate.

4. Uniform series, sinking fund, *(A/F,i,n)*.

Solving Eq. 6.2.5 for *A* will enable the analyst to determine what annual payments must be made to accumulate a specified amount by some future date at an interest rate *i:*

$$A = iF/[(1+i)^n - 1] \qquad (6.2.6)$$

Example 6.2.4. With interest at 6%, how much must be deposited at the end of each year to yield a final amount of \$2825 in 7 years?

Solution .

$$A = iF/[(1+i)^n - 1]$$
$$A = 0.06\ (\$2825)/[(1+0.06)^7 - 1]$$
$$= \$336.58$$

The concept of a sinking fund is well known, so that the *A/F* interest factor is often called the *sinking fund factor*.

5. Uniform series, present worth *(P/A,i,n)*.

This type of problem arises when the current value of a future series of cash flows is desired. This is often the case with investments in securities where an expenditure now will provide equal interest or dividend payments for several future periods.

For Eq. 6.2.5,

$$F = \frac{A[(1+i)^n - 1]}{i}$$

Substitute Eq. 6.2.1,

$$F = P(1+i)^n$$

$$P(1+i)^n = \frac{A[(1+i)^n - 1]}{i}$$

and

$$P = \frac{A[(1+i)^n - 1]}{i(1+i)^n} \qquad (6.2.7)$$

Example 6.2.5. An investment will yield $610 at the end of each year for 15 years. If interest is 10%, what is the maximum purchase price (i.e., present value) for this investment?

Solution.

$$P = \frac{A[(1+i)^n - 1]}{i(1+i)^n}$$

$$= \frac{610[(1+0.1)^{15} - 1]}{0.1(1+0.1)^{15}}$$

$$= \$4639.71$$

6. Uniform series, capital recovery, *(A/P,i,n)*

This is the reverse of the previous problem, and the equation is derived simply by solving Eq. 6.2.7 for *A:*

$$A = \frac{iP(1+i)^n}{[(1+i)^n - 1]}$$

Example 6.2.6. If an investment opportunity is offered now for $3500, how much must it yield at the end of every year for 6 years to justify the investment if interest is 12%?

Solution.

$$A = \frac{iP(1+i)^n}{[(1+i)^n - 1]}$$

$$= \frac{0.12\ (\$3500)\ (1+0.12)^6}{[(1+0.12)^6 - 1]}$$

$$= \$851.67$$

The preceding formulas pertain to annual compounding and, where *A* enters the problem, to annual cash flows. In practice, these constraints are routinely violated as neither payments/receipts nor compounding need be on an annual basis. In fact, there is a continuous spectrum of possibilities with discrete annual compounding and discrete cash flows at one end of the continuum, and continuous compounding and continuous flow of funds at the other end. The reader interested in learning more about the procedures for handling specific cases within this spectrum is referred to Chapter 3 in Gentry and O'Neil (1984).

6.2.3.2 Interest Factor Relationships

The relationships between the interest factors identified in the preceding formulas are often not as clear as they might be—particularly when values are extracted from interest tables. Following are some relationships based on given values of *i* and *n*.

1. The single payment compound amount factor *(F/P,i,n)* and the single payment present value factor *(P/F,i,n)* are reciprocals:

$$\frac{1}{(P/F,i,n)} = (F/P,i,n)$$

2. The sinking fund factor *(A/F,i,n)* and the compound amount factor for an annuity *(F/A,i,n)* are reciprocals:

$$\frac{1}{(A/F,i,n)} = (F/A,i,n)$$

3. The capital recovery factor *(A/P,i,n)* and the present value factor for an annuity *(P/A,i,n)* are reciprocals:

$$\frac{1}{(A/P,i,n)} = (P/A,i,n)$$

4. The capital recovery factor *(A/P,i,n)* is equal to the sinking fund factor *(A/F,i,n)* plus interest rate:

$$(A/P,i,n) = (A/F,i,n) + i$$

5. The present value factor for an annuity *(P/A,i,n)* is equal to the sum of the first n terms of single payment value factors *(P/F,i,n):*

$$(P/A,i,n) = (P/F,i,1) + (P/F,i,2) + \ldots + (P/F,i,n)$$

6. The compound amount factor for an annuity *(F/A,i,n)* is equal to 1.00 plus the sum of the first (n-l) terms of the single-payment compound amount factor *(F/P,i,n):*

$$(F/A,i,n) = 1.00 + (F/P,i,1) + (F/P,i,2) + \ldots + (F/P,i,n\text{-}1)$$

6.2.4. SELECTING A DISCOUNT RATE

As indicated in the previous section of this chapter, future project receipts and expenditures must be discounted to permit valid comparisons with current cash flows. Although the concept of discounting is widely accepted, selection of an appropriate discount rate has been the source of considerable debate and much disagreement.

The fact that interest exists suggests that all money has a cost associated with its use. The cost of this money may be the result of either explicit or implicit charges or some combination of the two. Indeed, any time an individual or a firm consumes less than the total earnings generated in a specified time period, that individual or corporation has either consciously or unconsciously decided to "invest" these excess funds in some type of activity—even if the funds are maintained in a cash account.

Intuitively, it seems reasonable to accept the fact that no money is free. Certainly, there is a cost associated with raising investment capital. For instance, there is a cost associated with going to the debt markets and borrowing money for investment purposes. This explicit cost of borrowing results from the fact that interest exists. Similarly, it is important to recognize that an investor who purchases the firm's common stock (equity) has the same expectations of making a return on his investment as a banker who loans money. Additionally, it is important to

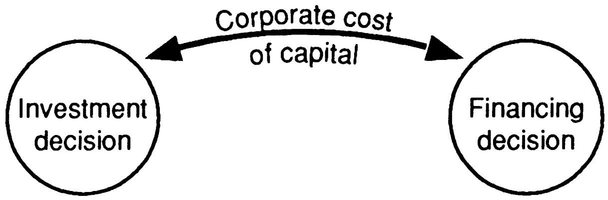

Fig. 6.2.1. Relationship between investment decision and financing decision.

recognize that a firm may allocate investment capital to alternative investment opportunities that may be available and that promise specific rates of return on the investment capital. This concept of alternative investment opportunities suggests that there also are *opportunity costs* (implicit costs) associated with investment capital. Clearly, then, there are explicit and implicit costs associated with procuring and utilizing investment capital, and, at least to some extent, these costs are influenced by inflationary trends and expectations.

Remembering that the firm's primary objective should be the maximization of shareholder wealth, it then intuitively seems reasonable to suggest that the firm should not invest in any project where the anticipated return does not exceed the cost of funds (capital) committed to the project. Indeed, if the firm always invests in projects having returns in excess of the cost of capital committed to them, then the wealth of the firm (as measured by the price of common stock) should be increased to the stockholders. This cost of funds, known as the *cost of capital,* is the direct linkage between investment policy and the firm's objective.

Further, the cost of capital also relates the financing decision to the investment decision. Indeed, the cost of capital is the *only* link between these two decisions. The relationship between the financing decision and the investment decision in corporate finance via the cost of capital is illustrated in Fig. 6.2.1.

An alternative way to view the cost of capital is to recognize that the *minimum acceptable rate of return* (MARR) on an investment may be defined as the minimum rate of return a firm must earn on its investments in order to leave unchanged the value of existing shares of its common stock. Investing at the cost of capital will achieve this objective, and therefore the MARR is quantitatively equal to the cost of capital. The logical conclusion from this observation is that this cost of capital represents the "hurdle rate" or the appropriate discount rate to be used in conjunction with discounted cash flow analyses of investment opportunities.

6.2.4.1 Components of Discount Rate

Following are four major components to the discount rate. Some of these components stem from sound theoretical and practical foundations, while others are judgmental. Rarely is the combined discount rate calculated by summing these separate components, as the capital markets do a good job of determining the overall cost of funds to various uses. Nonetheless, the combined rate must be sufficient to cover these four elements.

Base Opportunity Cost: There is always some base opportunity cost associated with procuring and utilizing investment capital. This cost is the return foregone by diverting funds from the next most attractive project and exists whether the funds are obtained externally or internally. In either case, funds appropriated for a particular use will carry a cost related to the return those funds could have achieved elsewhere. The other components of the discount rate are typically added to this base opportunity cost for investment capital.

Transaction Cost: Whether corporate investment capital is procured from the debt market or the equity market, the firm will experience transaction costs regardless of whether or not a new security issue is involved. These costs include broker and investment banker fees, costs of prospectuses and various filings, sales discounts, and other flotation costs. Although the aggregate transaction costs are generally much less than the base opportunity cost, they are significant and should be incorporated into the determination of the appropriate discount rate.

Increment for Risk: The cost of procuring funds, either debt or equity, includes a component for the investor's perception of risk. Consequently, some organizations add some *additional* percentage increment for risk to the cost of raising investment capital before applying this rate to discounted cash flow analyses. The rationale here is that high-risk projects should be discounted at some higher rate to compensate for their relative riskiness.

There are two fundamental problems associated with this approach to accounting for project risk. First, the increments for risk assigned to the discount rate are subjective by nature and cannot be quantitatively equated to project risk in any systematic manner. The second problem with this procedure is the manner in which project risk (business risk) is addressed. Clearly, the discount rate only adjusts for the present value of money; it does not by itself adjust for project business risk, as measured by the variability in annual project cash flows. Thus the discount rate provides no information on how annual project cash flows might vary, nor does it provide any insight into why these cash flows might fluctuate from year to year. Consequently, the discount rate does not provide a measure of project risk and, in general, should not be used to do so. Superior approaches to accounting for project risk are discussed in Chapter 6.5.

Increment for Inflation: It seems reasonable to assume that investment capital raised in the marketplace includes some cost premium for investor expectations of future inflation. Therefore, presumably a market-determined cost of capital includes a component that is based on investors' perceptions of future inflation. As a result, this market-determined cost of capital should be used as the appropriate discount rate when analyzing inflation-adjusted project cash flows. The amount of downward adjustment in the market-derived cost of capital for use with constant-dollar analyses can be shown to be roughly equal to the general rate of inflation.

6.2.4.2 Cost of Specific Types of Capital

The manner in which a firm chooses to finance itself will largely determine the cost of capital to the organization, since each source of financing has a specific cost. Thus the *capital structure* of the firm, defined as the mix of long-term sources of funds used to finance assets, becomes important in that the resulting cost of capital to the firm directly influences the investment decision. Since the firm's investment decisions influence common stock prices and therefore the value of the firm, the capital structure of the firm and the resulting cost of capital become key parameters in corporate finance.

Many corporations choose to develop a capital structure by utilizing a mixture of debt, preferred stock, and equity financing. Each of the various financial instruments available within these general categories has its own specific cost to the organization. The cost of each specific type of financing follows; however, the cost is essentially that rate which equates the funds received with all discounted future outlays relevant to that source. This may be expressed as

$$I_o = \frac{C_1}{(1+k)} + \frac{C_2}{(1+k)^2} + \ldots\ldots + \frac{C_i}{(1+k)^i} \quad (6.2.9)$$

where I_o is net proceeds received at time zero, C_i is cash outflow in the ith period, and k is cost of this specific source of financing. The C_i's are fairly easily determined in the case of debt and preferred stock financing. Equity financing costs, however, have generated a great deal of debate, and, while Eq. 6.2.9 applies in theory, one of several proposed simplifying approximations must be adopted to determine the costs of equity financing in practice.

Cost of Debt: In keeping with the preceding discussion, the cost of debt is that discount rate that equates net proceeds from the debt issue to the future cash outlays. Further, these future payments are net of taxes. This is very significant with debt financing since interest payments, unlike dividends, are tax deductible. If k_d is the cost of debt and k is the yield to maturity of the debt issue determined by the application of Eq. 6.2.9, then

$$k_d = (1 - t)^k \quad (6.2.10)$$

where t is the marginal corporate tax rate.

Cost of Preferred Stock: In theory, because preferred stock dividends do not represent a legal obligation on the part of the firm, preferred stocks offer a distinct advantage over debt financing. In practice, however, the omission of a preferred stock dividend is viewed by the financial community as an indication of serious financial difficulty in the firm. Thus firms usually view preferred stock dividend payments as de facto obligations.

The cost of preferred stock is usually computed in a manner similar to debt perpetuities since both instruments have fixed annual costs and no maturity. There is one important difference, however. Preferred stock dividend payments are not tax deductible to the firm.

If the annual dividend paid is D dollars, and I_o represents the net proceeds per share for a new stock issue, the cost of preferred stock, k_P, is

$$k_p = \frac{D}{I_o} \quad (6.2.11)$$

From an investment viewpoint, preferred stocks offer one advantage over bond investments to a corporation. Eighty-five percent of the dividend income to the corporation is nontaxable, while interest income from bonds is taxable at the full applicable rate.

Cost of Equity Capital: Equity financing comes from two sources—new common stock issues and retained earnings. Clearly, there is a cost of funds obtained through the issuance of new common stock. Proceeds from such a transaction must be invested to return sufficient earnings to maintain the firm's earnings per share. While all analysts agree that there are real costs involved in equity financing through the issuance of common stock, no such agreement exists on calculating these costs in practice.

The so-called *dividend valuation model* is one of the popular methods for calculating the cost of equity financing. The premise for this model is that common stocks only have a value because of an expected future stream of dividends. In theory, this model is consistent with the generalized cost of capital model previously discussed and may be represented as

$$P_o = \frac{D_1}{(1+k_e)} + \frac{D_2}{(1+k_e)^2} + \ldots\ldots + \frac{D_i}{(1+k_e)^i} = \sum_{i=1}^{\infty} \frac{D_i}{(1+k_e)} \quad (6.2.12)$$

where P_O is value of stock at time O, D_i is dividend payment in the ith year, and k_e is cost of equity applicable to firms in this risk class.

Obviously, dividend payments in future periods are unknown at the present time. Investors, however, have subjective estimates of what these payments will be, and these estimates are generally based on the current dividend and the historical long-run growth of dividends. An intuitive expression of these relationships might be:

$$k_e = \frac{D_o}{P_o} + g \quad (6.2.13)$$

where D_o is current dividend and g is annual growth rate of dividends.

Another popular method for computing the cost of common stock financing is the *earnings:price ratio* (E/P ratio). This approach is based on the assumption that investors really purchase earnings when buying common stock and that anticipated future earnings per share determine the value of a share of common stock.

The E/P model obviously is more suitable than the dividend valuation model for firms that pay low dividends or none at all. For firms that have strong earnings growth records, a growth term is sometimes appropriate in the E/P model to reflect shareholder expectations that such growth will continue. The mathematical expression for this model is

$$k_e = E/P_o + g \quad (6.2.14)$$

where E represents current earnings per share, P_O is value of stock at present, and g is growth term for earnings per share.

It should be noted that both of these models incorporate market prices for common stock. However, if a new common issue is planned, net proceeds per share, P_f should be used rather than the current market price, P_O. P_f will be lower than P_O by the amount of discount required to sell the new issue, plus the underwriting costs.

Although other models exist for estimating the cost of equity, they are more complex to use in practice and are not covered here (see Gentry and O'Neil, 1984, for more complete coverage).

That there is also a cost of *retained earnings* (net profits minus dividends) is less obvious than for common stock. However, if the firm retains, rather than distributes, earnings, and if it is dedicated to the maximization of shareholder wealth, it clearly must invest these funds above some minimum rate of return. Furthermore, the minimum rate in general is the cost of common stock financing, for this is the rate the investor implicitly agreed to by purchasing stock in the first place. If no investment opportunities are available to the firm above this minimum rate, all earnings should be returned to the owners (shareholders) to enable them to reinvest the funds themselves. Thus the cost of retained earnings is equal to the cost of common stock financing adjusted, where applicable, for flotation costs.

Readers interested in the application of the foregoing equations to calculating a firm's cost of capital are referred to Chapter 11 in Gentry and O'Neil (1984).

6.2.4.3 Weighted Average Cost of Capital

Given that each of the various types of financing available to a corporation has a specific cost, it seems reasonable to conclude that it should be possible to combine these various forms of financing into a corporate capital structure that would result in a minimum weighted average cost of capital to the firm. In other words, the implication is that there should be an optimum capital structure that minimizes the firm's weighted average cost of capital. Thus if a firm finances itself in this optimum manner, it should generate the lowest possible weighted average cost of capital. If this cost of capital is then used as the appropriate discount rate when evaluating new investment opportunities, the firm should find that more investments become acceptable. This should subsequently result in an optimum investment program and generate more wealth to shareholders.

Gentry and O'Neil (1984) provide more extensive discussions on the issues of optimum capital structures, marginal weighted average cost of capital calculations, and the practical problems associated with these calculations.

6.2.4.4 Common Errors in Evaluation

One of the most common errors made in discounted cash flow financial analysis involves using the cost of specific financing in evaluating projects rather than the average cost of all capital used by the firm. When a capital project involves an expenditure of, say, $20 million through a bank loan carrying an interest rate of 12%, it often is difficult to understand that (1) the interest charges from the loan should *not* be levied against the project for evaluation purposes, and (2) the appropriate discount rate to use is *not* 12% (or its approximate after-tax equivalent), but rather the marginal weighted average cost of *all* capital used by the firm.

Another common error in financial analyses is the inappropriate use of a market-derived cost of capital as the discount rate with constant dollar project cash flow estimates. These errors are sufficiently common to deserve further discussion.

Error No. 1: Charging Specific Capital Costs to the Project. The cost of capital, being the link between the investment decision and the financing decision, occupies a unique place in the evaluation procedure. All other project costs (i.e., operating costs, plant overhead, depreciation, etc.) are handled explicitly in the pro forma income statement. The cost of capital, however, *is* the discount rate and does not receive a separate line in these statements. While such a procedure may be applicable in other types of economic studies or analyses of financing alternatives, it is incorrect to do so in discounted cash flow analyses.

Unfortunately, this procedure has led many practitioners to believe that the cost of funds has been omitted in the analysis and should be listed separately in a manner similar to the other cost items. This misconception occurs most frequently when debt capital is raised and the accompanying interest payments are not charged directly to the project in the discounted cash flow return on investment (DCFROI) calculations. However, it is important to recognize that to do so would clearly double-count the cost of capital—once through the discount rate and a second time through the explicit interest charges. This point is illustrated in the following.

Example 6.2.7. (Gentry and O'Neil, 1984)

Suppose Hikki Mining Co. contemplates an investment opportunity having the following anticipated revenues and costs.

Investment = $100
Net annual cash flows (year 1-5) = $27.74
Cost of capital = 12%
NPV = $27.74 $(P/A, 12, 5) - 100 = 0$

In other words, the project should just break even after returning the investment plus the 12% cost of capital. This is verified in the following.

Solution .

	Year 1	2	3	4	5	Total	
Cost of capital @ 12%	12.00	10.11	8.00	5.63	2.97	38.71	
Total money owed before year-end payment	112.00	94.37	74.63	52.49	27.72		
General payment	27.74	27.74	27.74	27.74	27.74	138.70	Total payments
Money owed after year-end payment	84.26	66.63	46.86	24.75	—		
						100.00	Principal

Thus the discounting procedure assures that all project costs are covered—including return *of* and return *on* capital. To have levied financing charges explicitly against the project prior to discounting would clearly have forced the project to pay these costs twice.

Nonetheless, it continues to bother many that interest payments resulting from additional debt obligations are not charged directly to the project, even though these obligations must be met from the earning power of the firm's investments. This has caused some firms to incorporate a procedure whereby projects are evaluated on (1) a full equity basis and (2) various degrees of debt leveraging. The following example serves to illustrate the types of calculations resulting from this *improper* procedure.

Example 6.2.8. (Gentry and O'Neil, 1984)

An underground conveyor system is proposed to reduce haulage costs at a zinc mine. Benefits to be derived from this project are estimated to be $200,000 annual savings in operating costs. Depreciation is straight-line, and the income tax rate is 50%. Depletion is constrained by 22% of gross income from mining and can, therefore, be ignored as being constant in all alternatives. If the total investment is estimated to be $1,146,000, and the service life is 12 years with no salvage value, calculate the rate of return on equity capital for (1) all equity case, (2) 50/50, debt/equity financing, and (3) 95/5, debt/equity financing.

Assume the before-tax cost of debt is 8% compounded annually, and for simplicity assume that the entire principal amount will be repaid at the termination of the project.

Solution .

1. Equity investment
   A. $1,146,000
   B. $ 573,000
   C. $ 57,000
2. Debt investment to be repaid at the end of the year 12
   A. 0
   B. $ 573,000
   C. $1,088,700
3. Annual cash flows

	Case A	Case B	Case C
Net operating savings	$200,000	$200,000	$200,000
Less: depreciation	— 95,500	— 95,500	— 95,500
: interest	0	— 45,840	— 87,096
Pretax net income	104,500	58,660	17,404
Less: income tax	52,250	29,330	8,702
Incremental net profit	52,250	29,330	8,702
Add: depreciation	95,500	95,500	95,500
Incremental net cash flow	$147,750	$124,830	$104,202

4. DCF return on equity

Case A: $\$1,146,000 = 147,750\ (P/A,\ i,\ 12)$
$i = 7.5\%$

Case B: $573,000 = 124,830 ($P/A$, i, 12)–573,000)(P/F, i, 12)
i = 14.8%

Case C: $57,300 = 104,202 ($P/A$, i, 12)–1,088,700 (P/F, i, 12)
i = 182.5%

The foregoing analysis seems to suggest that the use of debt financing can turn a very marginal project into one yielding a phenomenal rate of return. However, it must be recognized that the DCFROI on the equity portion of the investment is always increased with leveraged financing if the after-tax cost of debt is less than the DCFROI of the project figured for the all-equity case. Thus the most marginal of investments can often be made to appear positively superb when a high percentage of debt capital is used!

A basic principle of investment analysis is that a project must stand on its own merits and must compete for funds on an equal basis with other investment opportunities. Each such opportunity must share fully in the benefits of debt leveraging if the same weighted marginal average cost of capital is used for all projects.

In summary, the following should always be observed in project investment analysis:

1. To avoid counting capital costs twice, do not charge costs of specific capital sources against the project. These charges are embedded in the discount rate.

2. Calculate returns on investments on total capital invested (i.e., all-equity case) to insure that all projects are compared on an equal basis.

Error No. 2: Using Specific Capital Costs as the Discount Rate. Debt financing is the source of another common error in capital project evaluations. There is a tendency on the part of some analysts to use the cost of a specific source of financing—rather than a weighted average of all capital sources—as the discount rate in measuring the attractiveness of a project. The following example illustrates this flaw.

Example 6.2.9. (after Quirin, 1967)

Global Mineral Ventures, Inc. was presented with a similar set of investment opportunities in three successive years, as shown:

	Year 1		Year 2		Year 3	
Project	**Amount of investment $**	**Rate of return $**	**Amount of investment $**	**Rate of return $**	**Amount of investment $**	**Rate of return $**
A	100,000	20	100,000	20	100,000	20
B	200,000	15	200,000	15	200,000	15
C	200,000	11	200,000	11	200,000	11
D	200,000	8	200,000	8	200,000	8
E	200,000	6	200,000	6	200,000	6

Solution.

In year one, Global had no long-term debt, and the corporate treasurer found that the full $900,000 could be raised by selling debentures bearing an annual interest rate of 5½%. He convinced Global's board that, since every project returned more than 5½%, they should all be accepted.

In year two, the treasurer was able to borrow a further $700,000 at 7%, and using the same logic as the previous year, accepted all projects except E, which offered a return below the 7% marginal cost of debt.

In the third year, however, Global's treasurer found only a limited amount of additional debt available to him—$100,000 at 18% from a finance company. Since this was still below the estimated 19% for a new equity issue, the treasurer used the debt to accept only project A.

Thus over the three-year period by using the cost of a specific source of debt as his investment criterion, the treasurer had invested $1.7 million at a weighted average return of 12%. It is clear, however, that the treasurer's eagerness to accept projects in year 1 precluded the acceptance of better projects in year 3. In fact, the same $1.7 million could have been invested to yield an average rate of 13.3% by accepting projects in the following sequence:

Year 1 A, B, C, D
Year 2 A, B, C
Year 3 A, B, C

This example illustrates that debt financing is only possible if an adequate equity base exists. Clearly, the marginal cost of capital is not simply the cost of debt but also the cost of equity that will be required in the future to support the added debt. Thus every investment must carry its proportionate share of the necessary—but higher cost—equity funds whenever debt is added to the capital structure of the firm. In the foregoing example, using the marginal weighted average cost of *all* capital sources would have resulted in rejecting the lower-value projects in year one, thereby permitting the acceptance of higher-value projects in year three.

In summary, it is important to recognize that it is incorrect to use the cost of a specific source of capital as the cash flow discount rate, or equivalently, as the minimum acceptable rate of return for capital projects.

Error No. 3: Using the Appropriate Discount Rate with Inflated and Constant Dollar Cash Flows. Some organizations insist on performing cash flow analyses in terms of constant dollars, while others prefer to perform analyses in terms of inflated cash flows. Although the preparation of constant dollar pro forma cash flows is highly recommended to promote better technical understanding of the project, discounting should always be performed on inflated dollars to avoid miscalculation of income taxes. Although there are specific virtues associated with both approaches, the important point here is to recognize that a market-determined cost of capital includes a component that is based on investors' perceptions of future inflation. As a result, this market-derived cost of capital should be used as the appropriate discount rate when analyzing inflation-adjusted project cash flows. If this rate is applied to project cash flows that are not adjusted for inflation, the project will be seriously *undervalued*. The amount of downward adjustment in the market-derived cost of capital for use with constant-dollar analysis is roughly equal to the general rate of inflation.

A more complete discussion of the impact and treatment of inflation in mining investment decision analysis is provided in Chapter 10 of Gentry and O'Neil (1984).

6.2.5 AN ITERATIVE PROCESS

This chapter has focused on the engineering and economic parameters associated with project feasibility studies. Estimates necessary for the quantification of many of these parameters in the pro forma income statement are provided in Chapter 6.3. The calculation of project net annual cash flows can be performed after completion of the pro forma income statement using the appropriate cost of capital or discount rate. Given these estimates of relative benefits, costs, and annual cash flows for a project, it then becomes necessary to convert these estimates into measures of relative desirability or attractiveness. The criteria and techniques typically utilized to determine project acceptability or desirability are the topics of discussion in Chapter 6.5.

It must be remembered, however, that completion of a feasibility study or an intermediate economic study incorporating one set of project parameters represents only one alternative in an iterative process. As noted in the introduction to this section, the process of evaluating mine investment opportunities is iterative nature. Each time a project variable or parameter changes, it is necessary to assess the impact of this change on all other project variables and on the subsequent financial results.

This iterative process must be repeated until the most economic design is achieved for the project being analyzed. This may require changes in cutoff grade, mining reserves, mine size or mining rate, or alternative extraction scenarios having differing capital and operating cost characteristics. Whatever the case, the most efficient combination of project parameters must be combined to meet the firm's primary objective: wealth maximization to its shareholders.

Chapter 6.3
COSTS AND COST ESTIMATION

T. Alan O'Hara and Stanley C. Suboleski

6.3.1 ESTIMATION OF COSTS

A mineralized deposit should not be developed into a mine unless the estimated annual operating profit after taxes is judged to be sufficient to recover, with interest, the estimated capital cost of developing the mine. The accuracy of estimation of capital costs and operating costs depends on the quality of the technical assessment and knowledge of expected mining and mineral processing conditions.

6.3.1.1 Cost Estimation for Preliminary Feasibility Studies

Estimation of capital and operating costs of a proposed mining venture is usually required after ore reserves have been determined, but before major capital costs are committed for detailed ore exploration, mine design layout, detailed metallurgical studies, and general plant design. At this stage of preliminary feasibility studies, there is usually insufficient technical knowledge to accurately estimate costs, and costs are estimated approximately to provide guidance on probable mine feasibility, optimum plant size, and possible need for additional geological studies and further exploration to prove and extend possible ore reserves. Estimates of costs are based primarily on computed average costs of existing mining projects and operations, with appropriate allowances for general site conditions, mining methods, and milling processes.

The costs estimated in a preliminary feasibility study are unlikely to be more accurate than ± 20%, and this degree of accuracy is insufficient to provide a sound basis for major mine financing or confident assurance of a profitable mining operation.

6.3.1.2 Estimation of Costs for Detailed Feasibility Studies

Estimation of costs with an accuracy of ± 10%, which is needed for a detailed feasibility study, requires completion of extensive technical work and studies on mine planning, general plant layout and design, environmental studies, and assessment of supplies, labor, and equipment required for mining, milling, and service operations. The cost and time required for the completion of the technical activities to permit accurate cost estimation required for a detailed feasibility study may not be warranted if the preliminary study indicates the proposed mining venture will not be adequately profitable.

Accurate capital costs are estimated from the lengths, sizes, and unit costs of planned mine development; manufacturers' quotations for specific equipment; quantities and contractors' unit costs for excavation, concrete foundations, and installations of piping, electric services, and equipment.

Accurate operating costs are estimated from the quantities and unit costs of all components of supplies and labor, as determined by accurate knowledge of the ore body, the mine planning, and the plant design.

Any aspect of the mine, plant, or service facilities that is not adequately determined in terms of technical requirements and quantities of supplies, labor, and construction requirements is incorporated in a contingency allowance, that is added to capital costs and operating costs. The contingency allowance expresses the probability of capital costs and operating costs being higher than anticipated when it is difficult to determine the precise characteristics of an aspect of the mine or plant.

Because accurate cost estimation requires tailoring of mine and plant design and operating characteristics to the localized characteristics of the ore body and plant site, the actual capital costs and operating costs of apparently similar mines should not unduly influence the estimated capital costs and operating costs of a prospective mining venture. The experienced cost estimator should attempt to visit one or more mines with known similarities to the prospective mine, so that a judgment may be made as to whether the local conditions at the visited mine are more or less favorable than those at the prospective mine. This judgment should be reflected in the estimate of higher or lower operating costs for the proposed operation.

Unlike capital cost estimation, which is based primarily on the size and unique nature of the mine and plant site, estimation of operating costs depends on the assessment of the probability of imperfect coordination of human effort in equipment operation and consumption of supplies.

To standardize calculations, the majority of the equations employed here are stated in English units. Also the emphasis in this chapter is on noncoal mining.

6.3.2 ASSESSMENT OF MINING CONDITIONS AFFECTING COSTS

The capital costs and operating costs of a mining project will be influenced by many factors that must be assessed before costs can be estimated for a preliminary feasibility study. The most important factor affecting costs is the size of the mine and processing plant as expressed in terms of tons of ore mined and milled per day of operation.

6.3.2.1 Mine Size or Production Rate

After discovery of an ore body, the mining and milling rate for the proposed mine project should be chosen such that the operating profit maximizes the return on capital invested in developing the mine and constructing the plant and services. If the mine size is too large in relation to the reasonably assured ore reserves, the operating life of the mine will be too short to yield an adequate return on capital invested in the mine project, and there will be insufficient opportunity to adjust or correct plant defects or operating inefficiencies before the ore reserve tonnage is significantly depleted.

If the mine size is too small in relation to ore reserve tonnage, the operating profit will be too small to recover invested capital and necessary return over the first few years of operation. After the mine is placed in production, the capital cost of enlarging the mine plant will be much higher than the additional cost of an initially enlarged mine plant.

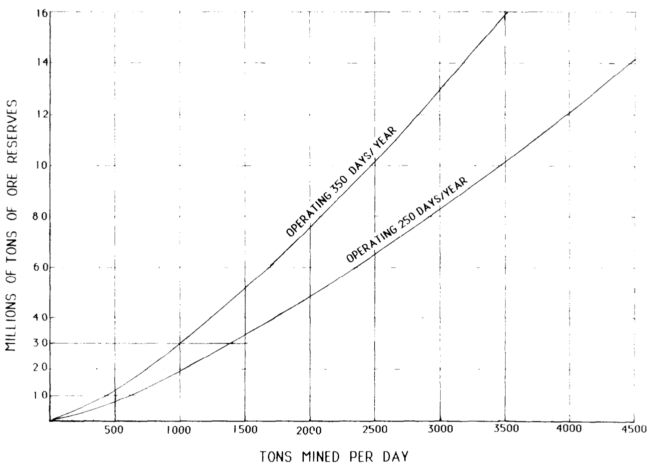

Fig. 6.3.1. Daily tonnage rate vs. ore reserves.

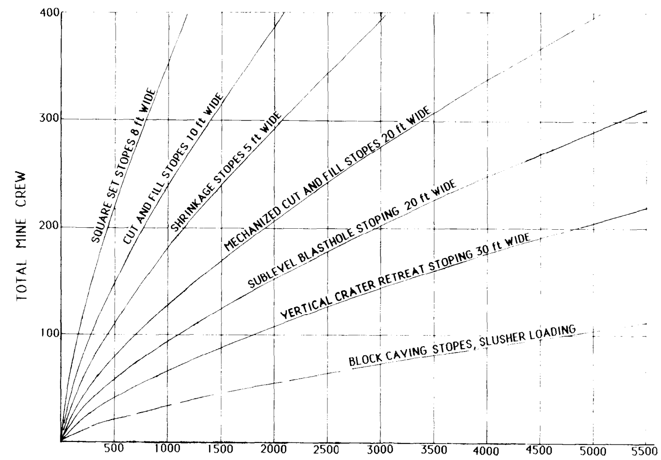

Fig. 6.3.2. Underground mine crew for various stoping methods and ore widths.

A useful guide to the optimum mine tonnage rate is the Taylor (1986) formula (Fig. 6.3.1). This formula, modified for English short ton units, is

$$\text{Optimum mine tonnage rate } T = \frac{4.88\, T_r^{0.75}}{D_{yr}} \qquad (6.3.1)$$

where T is short tons (2000 lb) of ore mined or milled per operating day, T_r is estimated short tons of diluted ore reserves that are judged to be reasonably assured (i.e., proven ore plus probable ore, but excluding possible ore with no assurance of its existence), and D_{yr} is the number of days per year of operation at full capacity. D_{yr} is approximately 250 for a mine operating on a 5-day week and 350 for a mine or mill operating continuously 7 days per week with only minor shutdowns or holidays per year.

6.3.2.2 Personnel Requirements

Operating costs and capital costs are influenced by the number of personnel required to operate the mine, mill, and services at any specific daily tonnage rate, because the number of personnel required varies with the methods to be used for mining and milling and whether or not the mine plant is extensively mechanized or computerized.

Guides for the number of personnel required for mining, milling, and services follow.

For underground mines the following relationships may be used to estimate the number of mine personnel required for mines using various mining methods (Fig. 6.3.2). T is the short tons of ore mined per day, W is the average stope width in feet, and Nmn is the number of persons required by the mine.

$Nmn = 8.0\ T^{0.7}/W^{0.5}$ for unmechanized square set mines (6.3.2)

$= 6.5\ T^{0.7}/W^{0.5}$ for small mines resuing narrow veins (6.3.3)

$= 6.0\ T^{0.7}/W^{0.5}$ for unmechanized cut and fill mines (6.3.4)

$= 2.5\ T^{0.7}/W^{0.3}$ for mechanized cut and fill mines (6.3.5)

$= 3.2\ T^{0.7}/W^{0.5}$ for unmechanized shrinkage mines (6.3.6)

For mining methods unsuitable for narrow stopes, where the slope width W is typically greater than 20 ft (6 m):

$Nmn = 0.75\ T^{0.7}$ for sublevel stoping mines with blastholes of small diameter (1 to 2 in. or 25 to 50 mm) (6.3.7)

$= 0.53\ T^{0.7}$ for vertical crater retreat mines using large diameter (3 to 6 in. or 75 to 150 mm) blastholes (6.3.8)

$= 0.72\ T^{0.7}$ for room and pillar mines in flat dipping hard rock (6.3.9)

$= 0.38\ T^{0.7}$ for room and pillar mines in flat-bedded, soft rock (increase up to 70% if mine is water-bearing) (6.3.10)

$= 0.35\ T^{0.7}$ for block caving mines using load-haul-dump equipment for loading ore (6.3.11)

$= 0.27\ T^{0.7}$ for block caving mines using slusher loading (6.3.12)

$= 0.42\ T^{0.7}$ for continuous mining in flat-seam mines (6.3.13)

The number of mine personnel required in open pit mines may be estimated from the following formulas in which Nop is number of open pit personnel and T_p is tons of ore and waste mined daily.

$Nop = 0.034\ T_p^{0.8}$ for open pit mines in hard rock using shovels and trucks for loading and haulage of ore and waste (6.3.14)

$= 0.024\ T_p^{0.8}$ for open pit mines in competent soft rock (6.3.15)

The number of mill personnel Nml required to operate mills treating T tons of high-grade underground ore daily may be estimated from the following formulas:

$Nml = 0.78\ T^{0.6}$ for cyanidation of precious metal ores (6.3.16)

$= 0.57\ T^{0.6}$ for differential flotation of base metal ores (6.3.17)

$= 0.95\ T^{0.6}$ for leaching, solvent extraction, and precipitation of uranium ores (6.3.18)

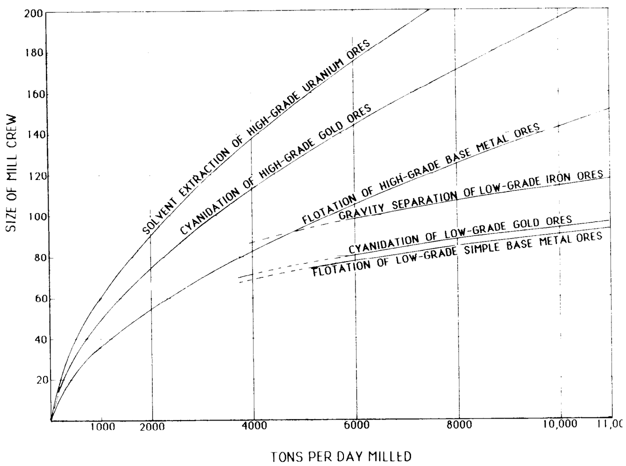

Fig. 6.3.3. Mill crew vs. mill process and size.

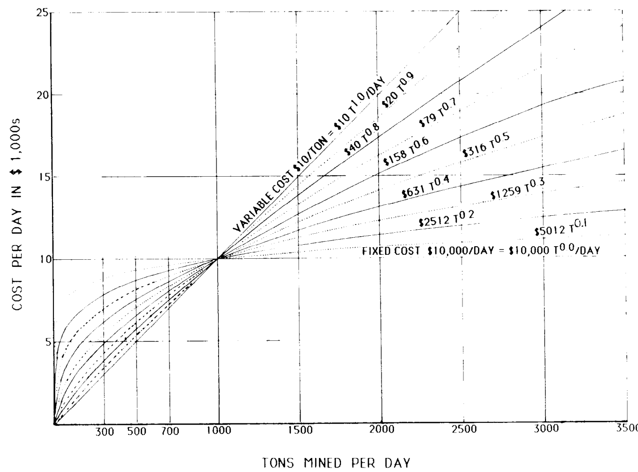

Fig. 6.3.4. Patterns of cost variability.

The number of mill personnel *Nml* required to operate mills treating *T* tons of low-grade ore mined by open pit methods may be estimated from the following formulas:

$Nml = 5.90\ T^{0.3}$ for cyanidation of precious metal ores (6.3.19)
$= 5.70\ T^{0.3}$ for flotation of low-grade base metal ores (6.3.20)
$= 7.20\ T^{0.3}$ for gravity concentration of iron ores (6.3.21)

See Fig. 6.3.3 for mill crew vs. mill process and size.

The number of service personnel *Nsv* may be estimated as a percentage of the total mine and mill personnel as shown below:

Nsv = 37.5% of ($Nmn + Nml$) for medium and large underground mines that are mechanized in drilling and ore transport (6.3.22)
= 20.6% of ($Nmn + Nml$) for small and medium underground mines with manual drilling and little mechanization (6.3.23)
= 25.4% of ($Nop + Nml$) for open pits mining low-grade ore (6.3.24)

The number of administrative and technical personnel *Nat* required for a mining and milling plant may be estimated as a percentage of the total required for mining, milling, and services:

Nat = 12% of ($Nmn + Nml + Nsv$) for underground mines and mills (6.3.25)
= 11% of ($Nop + Nml + Nsv$) for open pit mines and mills (6.3.26)

It should be noted that the formulas for personnel required for mining, milling, services, and administrative and technical activities do not allow for personnel required for smelters, refineries, mine townsite services, concentrate transport, or offsite head offices, because these services may not be required for many mine projects. Whenever these services can be financially justified for the mine project circumstances, the additional personnel should be estimated separately.

Patterns of cost variability are shown in Fig. 6.3.4.

6.3.2.3 Electrical Power Demand

The peak load in kilowatts per month and the average daily power consumption in kilowatt hours can be estimated from the following formulas:

Peak load in kW $= 165\ T^{0.5}$ for underground mines milling T tons of ore daily (6.3.27)
$= 78\ T^{0.6}$ for open pit mines milling T tons of ore daily (6.3.28)

Power consumed in kWh/day $= 1800\ T^{0.57}$ for underground mines hoisting ore to a surface concentrator (6.3.29)
$= 1400\ T^{0.6}$ for open pit mines with shovel and truck haulage to concentrator (6.3.30)

Typically, the concentrator and related facilities account for about 85% of the total power consumption for open pit mines and concentrators, whereas the concentrator and related facilities account for only about 45% of the total power consumption for underground mines hoisting ore to a surface concentrator.

6.3.2.4 Mine Site Clearing

Area A to be cleared in acres $= 0.0173\ T_p^{0.9}$ for open pits mining T_p tons of ore and waste daily (6.3.31)

The area to be cleared extends to the ultimate pit limits.

Area A to be cleared in acres $= 0.011\ T^{0.7}$ for underground mines hoisting ore up a central shaft around which service buildings are sited. This area to be cleared does not include the mill and accessory buildings (6.3.32)

Area A to be cleared in acres $= 0.05\ T^{0.5}$ for concentrator building, crusher building, substation, warehouse, and ancillary buildings (6.3.33)

6.3.2.5 Assessment of Underground Mines

Costs of a proposed mining project are difficult to estimate unless the specific underground conditions are numerically assessible. These should be assessed by a person familiar with the site topography, ground conditions, and structural geology of the ore body.

Underground Mine Drainage System: This system comprises the underground sumps, multistage pumps, controls, standby pumps, and piping for pumping drainage water from the mine. The cost of this system is a function of the total installed horsepower of the operating pumps (but excluding the standby pumps), which in turn is a function of the total of the gallons per minute (liters per second) multiplied by the pumping head in feet (meters) for each of the installed pumping stations.

The rate of pumping in gallons per minute (US) for each pump is several times the inflow at each station sump, and the pumping head will typically be between 400 and 1500 ft (120 and 450 m). It is difficult to estimate the probable inflow of water in an ore body that has been drilled but not developed by underground crosscuts, drifts, and raises. However, some indication of whether the water inflow will be slight or heavy can be attained by examination of the drill core data to determine the presence of faulted water-bearing zones and drilling records showing loss of drilling water.

Total pump system horsepower Hp = total of (gpm × Hd)/2350 (for all pump stations) (6.3.34)

This formula assumes metric units are converted to US gallons per minute and to feet of pumping head in numerically determining the horsepower required at each pumping station. In general, when the pumping system has not been planned in detail, the installed pump horsepower can be approximately estimated from the following formulas:

Installed horsepower Hp $= 8.0\ T^{0.5}$ for dry mines with little inflow and mine depth less than 1000 ft (300 m) (6.3.35)

$= 26\ T^{0.5}$ to $32\ T^{0.5}$ for mines with medium inflow and 1500 to 3000 ft (460 to 900 m) depth. (6.3.36)

$= 62\ T^{0.5}$ for mines with heavy inflow (6.3.37)

Underground Ventilation System: The cost of installing and operating a ventilation system varies with the total installed horsepower of all mine fans in the system. The total installed horsepower varies with the total quantity of air in cubic feet per minute, multiplied by the average fan pressure in inches water required to move this quantity of air. In general, larger mines require larger quantities of air than smaller mines, but the fan pressure required to move larger quantities of air increases in relation to the square of the velocity. The larger mines usually have larger development openings and larger bulk mining stopes, thus the average fan pressure in large mines is generally not much larger than in small mines ventilated by smaller quantities of air.

Quantity of air required Q in cfm:

$Q = 1400\ T^{0.8}$ for underground gold and metal mines (6.3.38)

$= 1900\ T^{0.8}$ for underground uranium mines (6.3.39)

$= 500\ T^{0.8}$ for underground nonmetallic mines without dust of a siliceous nature (6.3.40)

Typical fan pressure $= 2.4\ T^{0.1}$ in. water (6.3.41)

Total installed fan Hp = Q cfm × in. water/3800 (6.3.42)

$= 0.88\ T^{0.9}$ approximately (6.3.43)

The typical fan pressure and installed horsepower may vary widely if mine openings are small in relation to tonnage of ore mined daily.

Compressed Air Plant:

Capacity of plant C in cfm $= 170\ T^{0.5}$ for underground mines using small-hole drilling and stoping by shrinkage or cut and fill methods in medium-width stopes (6.3.44)

$= 230\ T^{0.5}$ for small underground mines using small-hole drilling, air-powered slushers, and loaders in narrow stopes (6.3.45)

$= 130\ T^{0.5}$ for large underground mines using large blastholes in wide stopes with diesel-powered mechanized equipment for loading (6.3.46)

Hoisting Equipment: Two types of hoists are used in hoisting ore in underground mines: double-drum hoists and friction hoists. Double-drum hoists are suitable for hoisting ore or transporting men and supplies from several different levels for all sizes of mines. Friction hoists are suitable for deep mines hoisting ore from the lowest level and generally consume less power than double-drum mines hoisting the same tonnage from deep levels. Despite the operating economies of friction hoists, double-drum hoists are more often used because they are applicable over a wider range of operating conditions, and also because of the availability of used double-drum hoists that can be reserviced for operations at less cost and sooner than purchasing a complete new hoist.

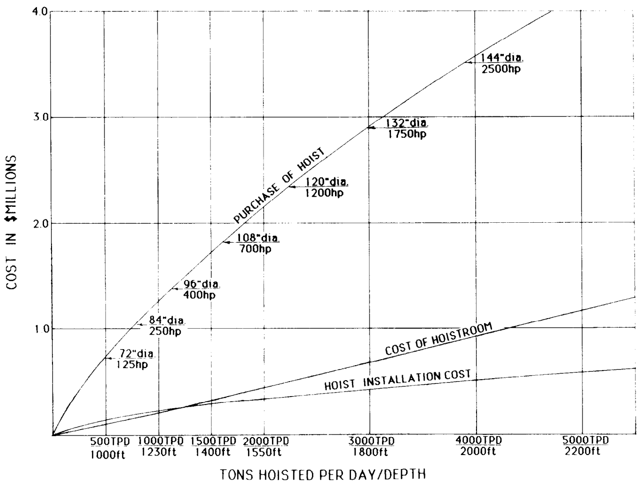

Fig. 6.3.5. Costs of hoisting plant.

The cost of a double-drum hoisting plant (Fig. 6.3.5) depends on the hoist drum diameter D in inches and on the horsepower of the hoist motor Hp, which in turn will be dependent on the loaded skip weight and rope speed. Usually small mines hoisting less than 1500 tons of ore in two 8-hr shifts/day install one hoist with combined skips and cage to hoist ore and transport miners and supplies. Medium-sized mines hoisting 2000 to 4000 tpd generally install one large hoist for hoisting ore only and a second smaller hoist for transporting miners and supplies in a multi-compartment shaft. Larger mines hoisting more than 5000 tpd will generally have two separate hoisting plants.

The optimum rope speed S in feet per minute (fpm) for hoisting ore is about:

$$S \text{ in fpm} = 1.6\, h^{0.5}\, T^{0.4} \text{ for hoisting } T \text{ tpd from a depth of } h \text{ ft} \tag{6.3.47}$$

The rope speed for transporting miners and supplies is generally about 30% slower than the optimum rope speed for hoisting ore.

The hoist drum diameter D in inches should be about

$$D = 4.13\, T^{0.3}\, h^{0.14} \tag{6.3.48}$$

The total installed horsepower of the hoist motor, or motors, should be:

$$\text{Horsepower Hp} = 0.5\,(D/100)^{2.4}\, S \text{ where } D \text{ is drum diameter in in. and } S \text{ is the rope speed in fpm} \tag{6.3.49}$$

Transport of miners and supplies is normally at slower rope speeds by a hoist with a drum diameter at least 80 times the rope diameter, and the hoisting rope diameter must be such that there is an adequate safety factor when hoisting the cage with the maximum load of miners and equipment.

The area A of the hoist room required for double-drum hoists with drum diameters of D inches will need to be about:

$$A(\text{in ft}^2) = 0.10\, D^{2.2} \text{for one double-drum hoist} \tag{6.3.50}$$

$$= 0.085\,(D_1^{2.2} + D_2^{2.2}) \text{ for two double-drum hoists with drum diameters } D_1 \text{ and } D_2 \tag{6.3.51}$$

Headframe Size: The height of the headframe above the shaft collar must be sufficient to allow the skips to dump into ore bins that must have storage capacity of ore adequate for the daily tonnage rate, plus a safe vertical distance for skip overtravel and hoist braking distance below the sheave center elevation.

The headframe height H in feet of the sheave center above the shaft collar is shown by:

$$\text{Headframe height } H = 8.0\, T^{0.3} + 1.2\, S^{0.5} \tag{6.3.52}$$

in which T is the tons of ore mined daily, which is hoisted to surface ore bins 16 hr/day, 5 days/week, and S is the rope speed in fpm. The 8.0 $T^{0.3}$ factor represents the allowance for skip dump height and the 1.2 $S^{0.5}$ factor represents the allowance for skip overtravel.

The weight of structural steel W in pounds in a steel headframe with a sheave center height of H ft is approximately:

$$W = 0.12\, H^3\, (D/100)^2 \text{ for a headframe safely designed for the breaking strength of the hoist ropes of a diameter not less than 1/80th of the drum diameter of the hoist} \tag{6.3.53}$$

If the headframe also serves another smaller hoist employed as a cage hoist, the weight of structural steel should be increased by about 20%.

Shaft Area: Because of the trend to more extensive mechanization of mines over the last two decades, the cross-sectional area of shafts sunk during the 1980s is somewhat larger in order to deliver and service larger loading and drilling equipment to the underground workings.

The shaft area A in square feet of rectangular shafts hoisting T tons of ore daily is now:

$$A = 24\, T^{0.3} \text{ for underground mines hoisting up to 5000 tpd in two skip compartments and cage hoisting miners and supplies in cage compartments} \tag{6.3.54}$$

The shaft diameter (D in feet) of circular shafts for skip hoisting ore and cage hoisting miners and supplies is:

$$D = 5.5\, T^{0.15} \text{ for circular shafts of underground mines hoisting less than 5000 tpd and transporting miners, supplies and equipment in separate cage compartments} \tag{6.3.55}$$

See Fig. 6.3.6 for shaft sinking costs vs. shaft depth.

6.3.2.6 Mine Development Required for Underground Mines

Mine development consists of two items: (1) development of drifts, crosscuts, ramps, raises, orepasses, ventilation raises, substations, and sumps to provide access to and services for the mining of sufficient ore for the first few years of mine production; and (2) stope preparation of sufficient stopes to permit subsequent mining of ore for six months, during which time current stope preparation will have prepared sufficient ore for a further six months of mining.

The costs of development (Fig. 6.3.7) for ore access and mine services (Fig. 6.3.8) together with the cost of initial stope preparation are considered to be preproduction capital costs, and mine development costs are typically the largest component of

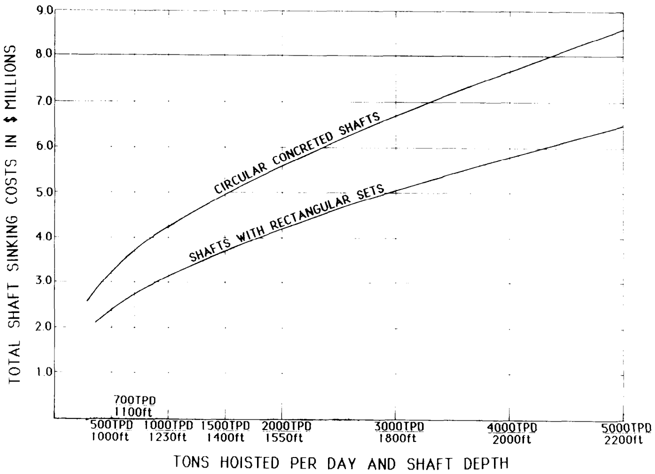

Fig. 6.3.6. Shaft sinking costs vs. shaft depth.

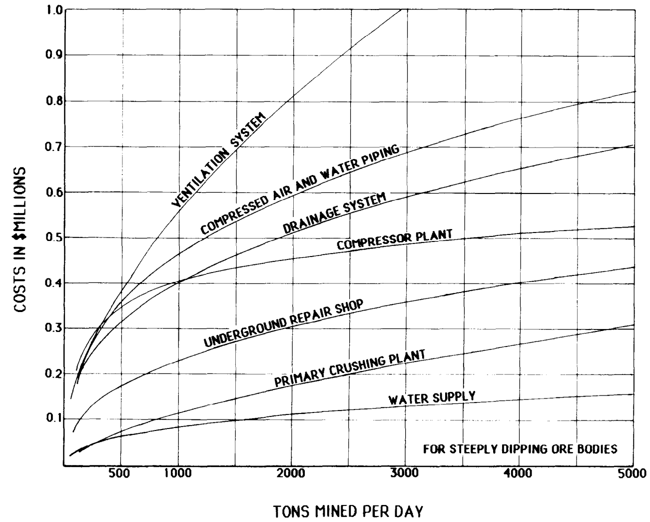

Fig. 6.3.8. Costs of mine services.

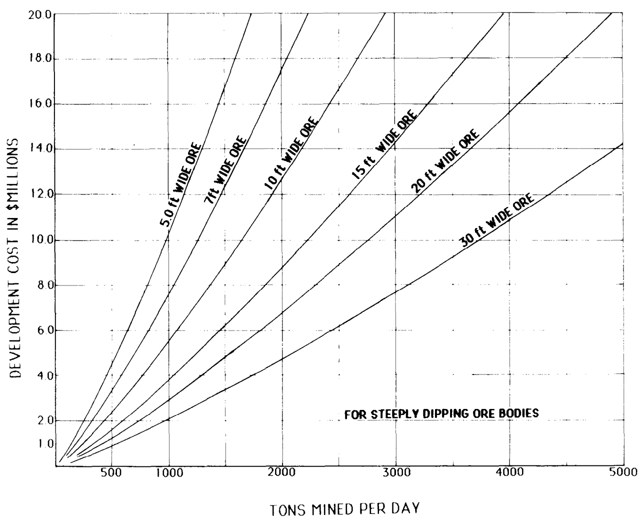

Fig. 6.3.7. Cost of mine development.

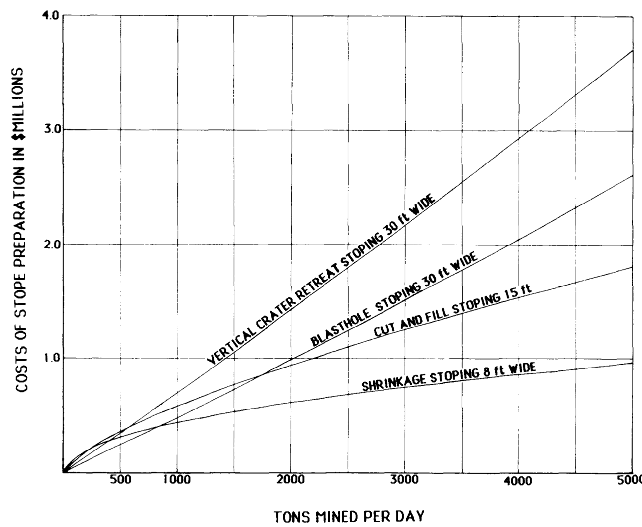

Fig. 6.3.9. Costs of preparing stopes for mining 125 days of ore.

mining capital cost and requires the longest time period of any mine activity in preparing the mine for production.

Mine development is often the most difficult cost to estimate of all preproduction capital costs prior to detailed mine planning, because of the uncertainty of many optional development plans that may or may not be suitable for subsequent efficient mine production.

In general, the mine development for a new mine should access ore equal to 1800 days of production and prepare stope ore equal to 125 days of production (Fig. 6.3.9). Less development leads to problems in maintaining steady ore production, and more development may be excessively costly.

The amount of mine development varies in relation to the volume of ore reserves, rather than the tonnage of ore reserves, so that an ore with a high specific gravity requires less development in waste to access this ore than an ore with a lower specific gravity.

One ton of ore with a typical specific gravity of 2.7 has an in situ volume of 11.866 ft^3; therefore, the ore reserve tonnage of T_r tons has a volume of:

$$\text{Ore reserve volume in ft}^3 = 32.04\ T_r\ /\ \text{SG} \qquad (6.3.56)$$

where SG is the specific gravity of the ore.

The estimator should estimate the length and height (in feet) of the rectangular shape, which fully encloses 1800 days of ore tonnage in the longitudinal section (or the length and width of 1800 days of ore tonnage in a flat-lying ore body). This length and height (or length and width) determines the amount of mine development necessary. The normal location of the ore hoisting shaft is generally near the center of gravity of the rectangular shape but offset from the ore zone by 200 ft or more. Mines in mountainous areas may be accessed by adits that extend well beyond the ore zone, and for such mines that do not require a hoisting plant, the mine development required is determined by the number and lengths of these adits.

When mine planning has not been done, an approximate measure of the amount of mine development required may be estimated from the length and height (or length and width) of the shape enclosing 1800 days of ore reserve tonnage, but the cost of the mine development will also depend on the sizes of the drifts, crosscuts, ramps, orepasses, raises, and various excavations. In general, the cost per foot of any excavation of sectional area A in square feet is proportional to the 0.6 exponent of the area A. Thus one can relate the cost per foot of length of any sized excavation of cross-sectional area A to the cost per foot of a standard 8 × 8-ft drift by the following ratios:

Drifts or crosscuts of cross-sectional area A	$0.0825\ A^{0.6}$
Inclined ramps of cross-sectional area A	$0.0970\ A^{0.6}$
Timbered raise @ 60° of cross-sectional area A	$0.1122\ A^{0.6}$
Bare raise @ 50° of cross-sectional area A	$0.0923\ A^{0.6}$
Service excavations of cross-sectional area A	$0.0948\ A^{0.6}$

By using these cost ratios, it is possible to convert all mine development openings into equivalent feet of 8 × 8-ft drift that would cost the same.

In general, the larger-tonnage mines require larger drifts, ramps, crosscuts, ventilation raises, orepasses, and service excavations than smaller mines, because the larger mines use larger equipment and move larger quantities of air and larger tonnages of ore through the mine openings.

The amount of mine development expressed in equivalent length of 8 × 8-ft drift is difficult to determine by any universal formula because of the variety of shapes and sizes of mine ore bodies. The amount of development required to access and service ore equivalent to 1800 times the daily tonnage has been estimated for hypothetical steeply dipping ore bodies. These hypothetical ore bodies are assumed to dip at 80°, to have a specific gravity of 2.7, to have a horizontal extent that is twice the vertical extent, and to have waste distributed over 30% of the overall extent of ore. The average width of ore in each ore body is assumed to increase by 63% for each doubling of daily mining rate. The results of this hypothetical study are tabulated below:

Mining rate in tpd	500	1000	2000	4000	8000
Ore width in ft	5.0	8.1	13.2	21.4	34.8
Height of ore in ft	1230	1491	1654	1835	2036
Length of ore in ft	2460	2982	3308	3670	4072

Amount of development in equivalent length of 8 × 8-ft drift:

Shaft stations, etc.	2290	3639	5299	7720	11,255
Levels and ramps	21,068	35,552	50,278	71,103	100,550
Orepasses and pockets	1149	1941	3013	4679	7269
Vent raises, manways	3069	5297	8902	15,347	26,954
Service excavations	422	724	1263	2248	4085
Total ft of 8 × 8-ft	27,998	47,153	68,755	101,097	150,111

The results of this study indicate that the following formulas should apply to development in similar shaped ore bodies, which have an average ore width of W ft and a tonnage rate of T tpd:

$$\text{Equivalent ft of } 8 \times 8\text{-ft drift} = 74.29\ T^{1.2}/W^{0.9} \tag{6.3.57}$$

If the specific gravity of the ore differs from 2.7, this formula converts to:

$$\text{Equivalent ft of } 8 \times 8\text{-ft drift} = 244.66\ (T/\mathrm{SG})^{1.2}/W^{0.9} \tag{6.3.58}$$

These formulas may be used to compute the approximate amount of mine development for steeply dipping ore bodies of similar shape to that shown, but if the ore body differs drastically in shape, attitude, and width, the formulas become unreliable.

6.3.2.7 Stope Preparation for 125 Days of Ore at Daily Tonnage Rate

The amount of stope preparation for any given vertical area of ore depends on the stoping method, the level interval, and the degree of mechanization intended for stoping practice. Since the tonnage contained in any vertical area of ore depends directly on the width of the ore, the amount of preparation required for an ore tonnage equivalent to 125 days of mine production normally varies inversely with the ore width.

Although larger mines generally mine ore from wide ore bodies, whereas small mines typically mine ore from narrow ore bodies, some small mines may have portions of their ore bodies that are locally quite wide. In such instances, the small mine may develop the locally wide portion of the ore body with larger development openings to utilize larger mobile mucking and drilling equipment.

The formulas shown in the following offer guides to the amount of stope preparation required for mines with differing stoping methods, different daily tonnage rates, and differing ore widths.

Amount of stope development for 125 days of stoping, expressed as equivalent length of 8 × 8-ft drift:

Feet of 8 × 8-ft drift = $72\ T^{0.48}\ W^{0.2}$ for shrinkage stoping mines in steeply dipping ore bodies with ore less than 15 ft wide in which T is the number of tons mined daily and W is ore width in feet (6.3.59)

Feet of 8 × 8-ft drift = $8.15 T^{0.7}\ W^{0.5}$ for cut and fill stoping mines with ore less than 15 ft in width (6.3.60)

Feet of 8 × 8-ft drift = $16.25\ T^{1.06}/W^{0.6}$ for blasthole stoping mines that have ore widths over 15 ft (6.3.61)

Feet of 8 × 8-ft drift = $24.5\ T^{1.04}/W^{0.6}$ for vertical crater retreat mines that have ore widths over 20 ft (6.3.62)

Feet of 8 × 8-ft drift = $185\ T^{0.6}\ H^{0.2}$ for block caving mines stoping flat-lying ore at least 40 ft thick. H is the height of ore stoped (6.3.63)

It may be noted that stoping methods, such as shrinkage and cut and fill that require the least amount of stope preparation per stope, are usually higher in operating costs per ton than the bulk mining methods such as blasthole mining, VCR (vertical crater retreat) stoping, or block caving.

6.3.2.8 Assessment of Open Pit Mines

Open pit mines may have a greater diversity of ore body shape and daily tonnage of ore than underground mines. However, since waste overlying the ore is removed prior to open pit ore mining, the method of mining the ore is not influenced by the need to support waste from diluting the ore. The capital and operating costs of open pit mines is influenced by the number and sizes of equipment for drilling, blasting, loading, and haulage of open pit ore and waste.

The typical open pit mine in North America produces about 43,000 tpd (39 kt/day) of ore and waste from a pit depth of about 400 to 500 ft (120 to 150 m), with an oval shaped periphery 2200 ft (670 m) wide and 4700 ft (1430 m) long. Pit benches are typically 40 ft (12 m) high, and the overall pit slope (excluding roads) is about 57° in pits with competent rock, and 44° in pits with oxidized or altered rock, with in-pit haulage road gradients averaging 9%.

Pits may vary greatly in shape, size, and pit slope, especially in mountainous areas or where the ore and/or waste rock varies greatly in competence. The formulas shown in the following for equipment sizing, preproduction stripping, and maintenance facilities presume that the shape and type of open pit is similar, except in daily tonnage, to the typical open pit described previously.

Size and Number of Open Pit Drills: The size, hole diameter, and number of drills required depends on the tons of ore and waste to be drilled off daily. In general, there should be not less than two drills, and not more than four, for open pit mines mining less than 60,000 tpd (54.4 kt) of ore and waste. In medium-drillable rock, with a penetration rate of about 500 ft (152 m) per shift, the tons of ore or waste that is drilled off by a drill with a hole diameter of d inches is:

$$\text{Tons of ore or waste } T_p \text{ per day} = 170\ d^2 \tag{6.3.64}$$

$$\text{For easily drillable rock, } T_p \text{ per day} = 230\ d^2 \tag{6.3.65}$$

$$\text{For hard drilling rock, } T_p \text{ per day} = 100\ d^2 \tag{6.3.66}$$

Typically, drill hole sizes have standard diameters (in inches) of 4, 6.5, 7.875, 9.875, 10.625, 12.25, 13.25, and 15 (or 102, 165, 200, 250, 270, 310, 336, and 380 mm); thus drill selection will be limited to one of these sizes. For tonnages up to 25,000 tpd (22.7 kt/day), two drills of appropriate hole diameter should be chosen, three drills should be adequate for up to 60,000 tpd (54.4 kt/day), and four or more drills will be required for daily tonnages over 60,000.

Size and Number of Shovels Required: The optimum shovel size S in cubic yards of dipper size in relation to daily tonnage of ore and waste (T_p) to be loaded daily is

$$S = 0.145\ T_p^{0.4} \tag{6.3.67}$$

The number of shovels N_s with dipper size S that will be required to load a total of T_p tons of ore and waste daily will be

$$N_s = 0.011\ (T_p)^{0.8}/S \tag{6.3.68}$$

In practice, the size of shovel chosen will be one with a standard dipper size close to the size calculated by Eq. 6.3.67, but the number of shovels N_s required is usually a fractional number that should be rounded off to the nearest smaller unit number. The omitted fractional number expresses the need for either a smaller-sized shovel or a front-end loader for supplemental loading service, as long as this smaller shovel or front end loader is adequate to load into trucks of a size appropriate to the shovels with dipper size S

Size and Number of Trucks Required: The optimum truck size t in tons that is well matched with shovels of S bucket size in cubic yards is

$$\text{Truck size } t \text{ in tons} = 9.0\ S^{1.1} \tag{6.3.69}$$

The total number of trucks N_t oft tons capacity required for the open pit truck fleet, plus an allowance for trucks under repair, should be approximated by the following formula:

$$\text{Number of trucks required } N_t = 0.25\ T_p^{0.8}/t \tag{6.3.70}$$

The formula for N_t determines the size of the truck fleet under the typical conditions where the average haulage distance and gradient outside the pit periphery is less than the haulage distance and gradient inside the pit periphery. If the waste dump and the ore dump over the primary crusher are well removed from the pit boundaries, or if the haulage road beyond the pit has a steep gradient, it may be necessary to increase the truck fleet size to allow for the longer trip time per load.

Amount of Preproduction Waste Stripping: Before open pit mining can begin, the soil and rock overburden above the ore must be stripped to expose sufficient ore to supply the planned daily tonnage of ore for four to six months. The soil overburden should be stripped to the peripheral limits of the ultimate pit and an estimate made of its amount. An acre of moist soil that averages 10 ft (3 m) in thickness contains about 23,000 tons (20.9 kt) of soil; thus if the area of the ultimate pit periphery is known and the average soil thickness can be found from drilling logs or ultrasonic techniques, the amount of soil overburden can be calculated.

It is assumed that the location and area of the uppermost ore, sufficient for four to six months of mining, can be determined from ore body mapping, and the average thickness and area of the waste rock overlying this ore can be computed. Each acre of waste rock that averages 10 ft (3 m) in thickness contains about 40,000 tons (36 kt) of waste.

Because of the inverted conical shape of the ultimate open pit, the waste/ore tonnage ratio at each horizontal bench decreases with each lower bench, but the uppermost ore bench to be exposed typically has a waste/ore ratio of at least twice the waste/ore ratio of the ultimate pit. If insufficient ore is exposed by the preproduction stripping of waste, it may become difficult to continue mining ore because of the proximity of waste benches where blasting, loading, and haulage of waste may interfere with ore mining.

Open Pit Maintenance Facilities: The size of maintenance facilities for repair and maintenance of open pit equipment depends primarily on the number and size of the main haulage trucks, which in turn depends on the daily tonnage of ore and waste to be hauled. Repair and maintenance of the shovels and drills, which are slow in moving, is normally performed on the site by mobile repair vehicles.

The area in square feet required by the open pit maintenance shop, which should be located close to the open pit, is as follows:

$$\text{Area of open pit repair shop} = 360\ T_p^{0.4} \tag{6.3.71}$$

Thus the areas of repair shops required for open pit mines are:

Mine size, tpd	10,000	20,000	40,000	80,000
Repair shop area, ft^2	14,300	18,900	25,000	33,000

6.3.2.9 Assessment of Miscellaneous Characteristics of Mine Projects

In addition to the numerical assessments of various mining features there are many other characteristics that cannot be easily assessed numerically, but which affect capital costs and operating costs. These characteristics can be described or tested so that a judgment can be made as to their effect on costs.

Climate at Mine Location: Weather station records at localized towns, airports, and specific sites should be collected and analyzed in terms of topographic similarity, exposure to prevailing winds, differences in elevation, which tend to decrease temperatures by 5 °F for each 1000-ft (9.1 °C for each 1000 m) increase in elevation, and differences in growth of plants and trees.

Climatic factors may affect building design, seasonal restrictions on pouring of concrete, leaching of metals from ore, size and cost of heating plants, etc.

Access to Mine Plant: The estimator should determine the distance and regional topography between the mine site and the nearest terminal of roads, power lines, and railroads, plus the nearest town where employees could find housing within acceptable commuting distance to the mine plant.

Construction Materials: The estimator should investigate the nearest site where adequate quantity and quality of gravel, water, and tailings storage can be obtained or stored. The sensitivity to pollution of the environment must be assessed and a study of the environmental impact of the mine plant by a team of experts may be warranted at an early stage.

Metallurgical Testing: Testing of drill core samples suggests the preferable ore processing method and the probable recovery of valuable minerals by ore processing. In general, these tests will indicate, but not positively assure, metallurgical performance. However, bulk samples of ore for comprehensive testing and/or pilot plant tests are preferable. The cost of extensive metallurgical testing or pilot plant runs of bulk samples may not be justified before the preliminary feasibility study.

Geologic Assessment: The geologist should examine the core samples, core recovery, and the records of core drilling to assess faulting or areas of incompetent wall rock. This could provide the necessary information on the probable selection of mining method, need for rock bolting of drifts and crosscuts, preferred areas for shaft location or drainage water sumps.

Overburden Removal: Assessment of overburden depth from drilling records and the general competence of subsurface rock strata offers guides to the amount of excavation and foundations for the surface plant.

Location: If the location of the mine is so remote that it is not feasible for employees to commute to work from an existing townsite with adequate available housing and service facilities, it may be necessary to establish a mine townsite or trailer camp adjacent to the mine. The site of such a mine townsite or trailer camp must be chosen with great care and concern for the quality of life of the subsequent residents.

6.3.2.10 General Characteristics of Capital Costs and Operating Costs

Cost formulas are offered as estimators of capital costs and operating costs where the numerical value of the main factor or factors affecting these costs is incorporated into an algebraic equation of the form

$$\text{Cost} = KQ^x, \text{ or Cost} = KQ^x\,T^Y$$

where K is a constant, Q and T represent the numerical value of the factor or factors having the greatest influence on the costs, and x and y are exponents (normally between zero and 1.0) that measure the rate at which changes in the value of Q or T result in changes in costs.

Conventional accounting practices tend to regard costs as being either *fixed* (i.e., costs that remain relatively constant regardless of the size or complexity of the mining plant) or *variable* (i.e., costs that vary in direct relationship to some quantity Q that reflects the size of the mining plant). Alternatively, some costs may be considered to be a mixture of fixed costs and variable costs.

In mining practice, however, no costs are truly fixed or truly variable, neither are they a mixture of fixed and variable costs. It is more accurate to regard all mining costs as being somewhere between slightly variable (cost $= KQ^{0.1}$) and strongly variable (cost $= KQ^{0.9}$).

Virtually all items of purchased capital cost vary with plant capacity C at an exponent of about 0.6 or 0.7; consequently one large item of equipment will invariably be less costly to purchase and install than two smaller items of equipment with the same total capacity. Most items of labor cost per day vary in relation to daily tonnage at an exponent of between 0.4 and 0.8, whereas most items of supplies vary with tonnage at an exponent of between 0.6 and 0.9. The net result of this cost behavior is that if two or more mines are operated in the same manner under the same conditions, the lowest operating cost per ton will be attained by the mine with the largest tonnage output per day.

6.3.3 COST GUIDES FOR CAPITAL COSTS OF MINING PROJECTS

The cost formulas for mining projects described in this segment are based on the actual costs of mine projects completed since 1980, which have been escalated by statistical indices to the equivalent costs for the third quarter of 1988.

6.3.3.1 Underground Mine Projects

Site Clearing: The capital cost of clearing the site for the mine headframe, hoistroom, changehouse, and miscellaneous service buildings depends on the area A in acres to be cleared and, to some extent, the density of tree growth and the slope of the area to be cleared. The choice of site for the hoisting plant allows a limited amount of flexibility to optimize the costs of clearing the site, while avoiding adverse rock conditions for sinking the shaft or unstable ground for the headframe and hoist room foundations.

The area to be cleared can be determined by Eq. 6.3.32 or by judgment of the local site conditions:

$$\text{Clearing cost for mine site} = \$2000\,A^{0.9} \qquad (6.3.72)$$

Capital Cost of Shaft Sinking: The cost of shaft sinking depends on the area of the shaft, which can be estimated from Eqs. 6.3.54 for rectangular shafts or 6.3.55 for circular concreted shafts. The costs of sinking a shaft include a fixed cost of erecting a temporary sinking plant and concreting the shaft collar.

The major cost for shafts sunk 1000 ft (300 m) or more is the unit cost of shaft sinking per foot (meter) of shaft. These unit costs tend to increase as the shaft deepens because of the longer hoisting trip time for hoisting shaft muck. The unit costs also include the cost of excavating shaft stations as the shaft deepens:

$$\text{Fixed costs for rectangular shafts} = \$140{,}000\,A^{0.25} \qquad (6.3.73)$$

$$\text{Unit costs per ft} \times \text{shaft depth in ft} = \$139\,A^{0.45}\,D_s^{1.05} \qquad (6.3.74)$$

where A is area in ft^2 of the rectangular shaft sets and D_s is shaft depth in ft.

$$\text{Fixed costs for circular shafts} = \$135{,}000\,d^{0.5} \qquad (6.3.75)$$

$$\text{Unit costs per ft} \times \text{shaft depth} = \$307\,d^{0.7}D_s^{1.05} \qquad (6.3.76)$$

where d is concreted shaft diameter in ft and D_s is shaft depth in ft.

Capital Costs of Hoisting Plant: The cost of the hoisting plant depends on the size and type of hoist, or hoists, hoisting rope speeds, shaft depth, and the tons to be hoisted per day. For mines hoisting less than 1500 tpd in two 8-hr shifts, it is probable that the optimum hoisting system will be a double-drum hoist with combination skip/cages for hoisting ore and transporting miners and supplies. This hoist should have a drum diameter D in inches as determined by Eq. 6.3.48, and a motor horsepower Hp as determined by Eq. 6.3.49, if the rope speed is close to the optimum rope speed S in feet per minute as determined by Eq. 6.3.47.

Cost of hoist: $= \$700\ D^{1.4}\ \mathrm{Hp}^{0.2}$ for new hoist skipping ore plus cage service (6.3.77)

$= \$540\ D^{1.4}\ \mathrm{Hp}^{0.2}$ for reconditioned used hoist shipping ore plus cage service (6.3.78)

$= \$700\ (0.9\ D)^{1.4}\ \mathrm{Hp}^{0.2}$ for new hoist for ore skipping only. (Drum diameter needs to be only 90% of D as determined by Eq. 6.3.48.) (6.3.79)

$= \$700\ (0.8\ D)^{1.4}\ \mathrm{Hp}^{0.2}$ for new hoist for cage service only. Hoist drum diameter needs to be only 80% of D as determined by Eq. 6.3.48 (6.3.80)

Hoist installation $= \$64\ D^{1.8}$ for installing a hoist with an actual drum diameter of D inches (6.3.81)

Hoistroom construction $= \$4.90\ A^{1.4}$ for a hoistroom with an area of A square feet as determined by Eqs. 6.3.50 and 6.3.51 (6.3.82)

Capital Cost of Headframe: The cost of the headframe depends on the weight of steel required, which in turn depends on the height H in feet and the breaking strength of the hoist rope. Eqs. 6.3.52 and 6.3.53 estimate the headframe height and the weight of steel in the headframe.

Cost of headframe structure $= \$19\ (W)^{0.9}$ for single-hoist headframe structure including shaft collar and foundations (6.3.83)

$= \$19(1.2W)^{0.9}$ for two-hoist headframe structure with shaft collar and foundations (6.3.84)

Note: Add 15% to costs if headframe is sheathed and insulated, with heating plant to ensure moist ore never freezes in skip dumps and ore bins. Cost of enclosed ore bins, skips and skip dumps, cages, and counterweights will tend to vary with daily tonnage, but costs are also affected when the mill operates for more days per week than the mine, thus requiring more ore storage for weekend milling.

Cost of ore bins, skips, etc. $= \$700\ T^{0.7}$ for mines that operate the same work schedule as the mill (6.3.85)

$= \$1150\ T^{0.7}$ for mines that operate 5 days/week while the mill and crusher operate continuously (6.3.86)

Mine Development and Stope Preparation: The amount of mine development and stope preparation that must be completed in the preproduction phase before the mine can start production of ore is discussed in 6.3.2. This amount of development, expressed in terms of equivalent footage of 8 × 8-ft drift is shown in Eqs. 6.3.57 to 6.3.63. The estimated cost of an 8 × 8-ft drift in 1988 is $148/ft of drift.

The cost of $148/ft for an 8 × 8-ft drift is appropriate for hard-rock drifting requiring little or no rockbolting. In incompetent rock requiring extensive rockbolting or grouting of water inflow, this unit cost should be increased.

The cost of mine development for a steeply dipping ore body with ore having a specific gravity of 2.7, an average ore width of W ft, and an expected production rate of T tons of ore daily would be:

Mine development cost $= \$11{,}000\ T^{1.2}/W^{0.9}$ (6.3.87)

$= \$36{,}200\ (T/\mathrm{SG})^{1.2}/W^{0.9}$ when SG is the specific gravity of ore greater than 2.7 (6.3.88)

The cost of initial stope preparation of ore stopes containing ore equivalent to 125 times the expected daily tonnage of ore to be mined depends on the type of stoping method to be employed as shown in the following:

Cost $= \$10{,}620\ T^{0.48}\ W^{0.2}$ for shrinkage stopes (6.3.89)

$= \$1{,}200\ T^{0.7}\ W^{0.5}$ for cut and fill stopes (6.3.90)

$= \$2{,}400\ T^{1.06}/W^{0.6}$ for blasthole stopes (6.3.91)

$= \$3{,}630\ T^{1.04}/W^{0.6}$ for VCR stopes (6.3.92)

$= \$27{,}400\ T^{0.6}\ H^{0.2}$ for block caving stopes (H is stope thickness in feet) (6.3.93)

Cost of Drilling, Loading, and Haulage Equipment: This cost includes all equipment for drilling, loading, and hauling ore, where such equipment is not fixed in place nor installed on foundations.

The mobile equipment cost of similarly equipped mines varies with tons mined daily, but mines with the same daily tonnage may vary in the cost and degree of mechanization if the mines have differing ore widths.

The width of ore in the stopes determines the feasible use of mobile drills, large capacity loaders, and haulage equipment. To accommodate such equipment, larger stope development openings are required. Mines with narrow ore bodies are restricted in the choice of stoping method; drilling is performed with manually controlled drills, and ore loading or scraping is accomplished with small air-powered equipment.

$$\text{Cost of equipment} = \$24{,}600\ T^{0.8}/W^{0.3} \qquad (6.3.94)$$

Although a highly mechanized mine will attain a higher productivity in tons per manshift than an unmechanized mine, it also will require more extensive ventilation and a larger maintenance crew and facilities.

Cost of Mine Ventilation System: The cost of the ventilation system is influenced by the extent of mechanization in the activities of drilling, loading, and haulage, but this cost will be somewhat lessened by the large development openings necessary to accommodate this equipment.

Ventilation costs are adversely affected when the mine is very deep and increased air temperatures at depth decrease human energy and comfort. The quantity of ventilation air and the costs are also increased if siliceous dust or radiation emanates from the mining of ore.

In general, the most reliable measurement of the cost of the installed ventilation system is the total installed horsepower (Hp) of all ventilation fans in the system. The total installed horsepower can be estimated from Eqs. 6.3.38 to 6.3.43.

Cost of ventilation system = $14,000 $\mathrm{Hp}^{0.6}$ for gold and base metal mines (6.3.95)
= $16,800 $\mathrm{Hp}^{0.6}$ for uranium mines (6.3.96)
= $7,500 $\mathrm{Hp}^{0.6}$ for nonmetallic mines without siliceous dust (6.3.97)

Cost of Mine Pumping System: The cost of the mine drainage system depends on the total installed pump horsepower (Hp) as estimated in Eqs. 6.3.34 to 6.3.37. This cost includes the concreting of dams and pump stations, the installed cost of pumps, the cost of standby pumps, the installation of piping from pump stations to shafts (but shaft piping is included in shaft sinking costs), pump control equipment, and sludge removal equipment.

Pumping system cost = $3,400 $\mathrm{Hp}^{0.7}$ for mines with medium water inflow and 1500 to 3000 ft (460 to 910 m) depth (6.3.98)
= $1,400 $\mathrm{Hp}^{0.7}$ for shallow mines with little water inflow and depth of less than 1000 ft (300 m) (6.3.99)
= $5,800 $\mathrm{Hp}^{0.7}$ for mines with heavy water inflow at depths below 1000 ft (300 m) (6.3.100)

Cost of Water Supply System: The cost of the water supply system depends primarily on the amount of drilling and the type of drills used for mine development. Small tonnage mines typically use jacklegs and stopers for drilling, but the larger tonnage mines typically use larger jumbo drills and large-bore drilling in stopes and development. A typical 500-tpd mine uses about 43,000 gal (162 kL) of water daily, while a typical 8000-tpd mine uses about 230,000 gal (870 kL) per day.

$$\text{Cost of water supply} = \$5{,}300\ T^{0.4} \qquad (6.3.101)$$

where T is tons of ore mined daily.

Cost of Primary Crusher Installed Underground: The primary crusher is usually installed underground, except in small mines where the stoped ore is finely broken with little oversize. Primary crushing of ore prior to hoisting reduces problems with hangups in skip loading pockets, skip dumps, and conveyor transport of mined ore.

Jaw crushers are suitable for primary crushing of stoped ore for underground mines, except very large underground mines over 10,000 tpd (9 kt/day) where the size of rock broken in stopes requires a gyratory crusher. Jaw crushers are available in sizes from 24 × 36 in. (610 × 910 mm) to 48 × 60 in. (1220 × 1520 mm) and require much less head room for installation than gyratory crushers.

The area (A in square inches) of the feed opening for jaw crushers determines the ore capacity in tons per day T that can be crushed in most hard rock mines:

$$= 29\ T^{0.5} \qquad (6.3.102)$$

$$\text{Cost of jaw crusher} = \$24.50\ A^{1.2} \qquad (6.3.103)$$

$$= \$1{,}370\ T^{0.6} \text{ approximately} \qquad (6.3.104)$$

The cost of installing a jaw crusher in an excavated crusher station, including foundations, ore feeder system, and dust collection, is:

$$\text{Installation cost} = \$\ 210\ T^{0.7} \qquad (6.3.105)$$

Cost of Underground Repair Shop: Although small mines producing less than 600 tpd (544 t/day) of ore typically have a surface repair shop to service mining equipment plus small mobile equipment from the mill and services, large mines, which are extensively mechanized with large equipment, usually prefer to locate the mine repair shop underground to avoid delays in hoisting the mine equipment to a surface repair shop.

The cost of equipping and stabilizing an underground repair shop excavation for mines with an ore production of T tons of ore daily is estimated to be:

$$\text{Cost of maintenance shop} = \$14{,}600\ T^{0.4} \qquad (6.3.106)$$

This maintenance shop is usually located adjacent to the hoisting shaft and may also include a facility where rock drills are serviced.

Cost of Mine Compressor Plant: The compressed air capacity C in cubic feet per minute required for underground mines can be estimated from Eqs. 6.3.44, 6.3.45, and 6.3.46. The cost of the compressors and all accessory equipment installed in a compressor house on concrete foundations can then be estimated as follows:

$$\text{Cost of compressor plant} = \$920\ C^{0.7} \qquad (6.3.107)$$

Cost of Compressed Air and Water Distribution: The cost of piping installed to distribute compressed air and water to all working places in the mine depends mainly on the length of lateral development expressed in equivalent length of 8 × 8-ft drift, and partly on the total compressor capacity in cubic feet per minute. The length of lateral development L is usually a function of daily mined tonnage T and stope width W:

$$\text{Length of lateral development } L \text{ in ft} = 1276\ T^{0.6}/W^{0.4} \qquad (6.3.108)$$

$$\text{Cost of pipe installation underground} = \$2.80 L^{0.9}\ C^{0.3} \qquad (6.3.109)$$

Cost of Fill Distribution System (for Cut and Fill Mines): The cost of the hydraulic fill system depends on the length of lateral development L in feet and on the tons per day of ore T mined by the cut and fill method.

$$\text{Cost of fill distribution} = \$1.30\ L^{0.9}\ T^{0.6} \qquad (6.3.110)$$

Cost of Underground Electrical Distribution: The cost of

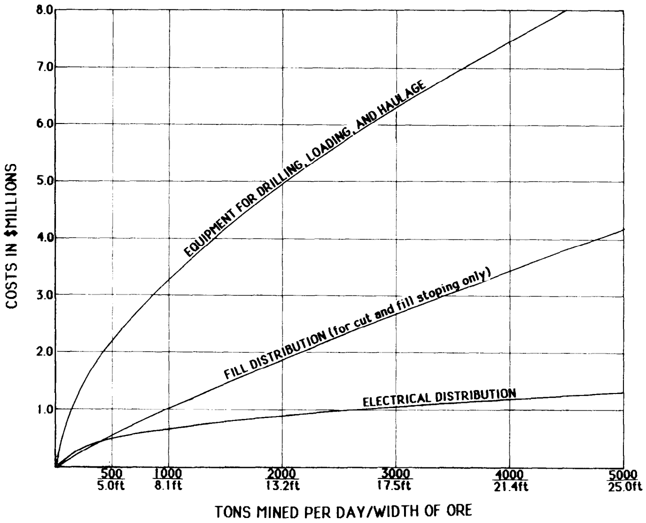

Fig. 6.3.10. Mobile equipment, fill and electrical.

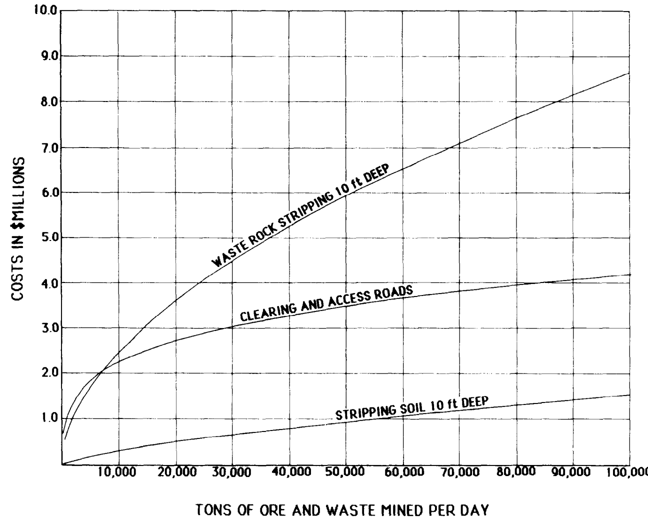

Fig. 6.3.11. Clearing, stripping, and road costs for open pit mines.

substations and power cables underground depends on the average peak load of the mine in kilowatts, as estimated from Eq. 6.3.27 that determines the overall peak load for an underground mine and a surface mill. Since the surface hoist is fed from the surface electrical distribution, the power consumption and peak load of the mine facilities located underground generally will not absorb more than 15% of the total electrical load. Thus if the plant peak load in kilowatts is estimated to be 165 $T^{0.5}$ for a mine and mill producing T tons of ore daily, the portion of this load that is attributable to the underground mining facilities is about 24.75 $T^{0.5}$ in kW

The cost of installing the underground substations and power cables is estimated to be:

$$\text{Cost} = \$1600\,(\text{kW})^{0.9} \tag{6.3.111}$$

where kW is the portion of the peak load attributable to the underground facilities.

See Fig. 6.3.10 for costs of mobile equipment, fill, and electrical distribution.

6.3.3.2 Open Pit Mine Projects

The cost formulas for open pit mines were derived from the actual costs of North American mine projects completed since 1980. The weighted average cost for each item of capital cost has been escalated by statistical indices to be appropriate for the third quarter of 1988.

Clearing Costs for Open Pit Mines: The capital cost for clearing the area where the open pit is located depends on the area A in acres (see Eq. 6.3.31) and the clearing cost per acre.

$$\text{Total clearing cost} = \$1600\,A^{0.9} \text{ for 20\% slopes with light tree growth} \tag{6.3.112}$$

$$= \$300\,A^{0.9} \text{ for flat land with shrubs and no trees} \tag{6.3.113}$$

$$= \$2000\,A^{0.9} \text{ for 30\% slopes with heavy trees} \tag{6.3.114}$$

Clearing, stripping, and road costs for open pit mines are shown in Fig. 6.3.11.

Preproduction Waste Stripping: If T_s is the tons of soil, and T_w is the tons of waste rock that must be stripped to expose an amount of ore to sustain four to six months ore production, then the estimated costs of waste stripping will be

$$\text{Soil stripping costs} = \$3.20\,T_s^{0.8} \text{ for soil not more than 20 ft deep} \tag{6.3.115}$$

$$\text{Waste stripping costs} = \$340\,T_w^{0.6} \text{ for rock requiring blasting, loading, and haulage} \tag{6.3.116}$$

Cost of Open Pit Drilling Equipment: The cost of drilling equipment depends on the number of drills Nd and the hole diameter d in inches drilled in order to prepare the daily tonnage of ore and waste rock for production (see Eqs. 6.3.64, 6.3.65, and 6.3.66).

$$\text{Drilling equipment cost} = Nd \times \$20{,}000\; d^{1.8} \tag{6.3.117}$$

This formula includes a 25% allowance for drilling and blasting supplies and accessory equipment.

Cost of Shovels and Loading Equipment: The cost of loading equipment depends primarily on the number Ns and size S in cubic yards of the shovels, as shown by Eqs. 6.3.67 and 6.3.68. The total cost of the fleet of shovels supplemented by auxiliary bulldozers and front end loaders will be

$$\text{Loading equipment cost} = Ns \times \$510{,}000\; S^{0.8} \tag{6.3.118}$$

Cost of Trucks and Accessory Road Maintenance Equipment: The cost of haulage equipment depends primarily on the number Nt of trucks, and the truck size (t in tons), as shown by Eqs. 6.3.69 and 6.3.70.

$$\text{Haulage equipment cost} = Nt \times \$20{,}400\; t^{0.9} \tag{6.3.119}$$

Open pit equipment costs are shown in Fig. 6.3.12.

Cost of Open Pit Maintenance Facilities: The cost of constructing and equipping the pit maintenance shop varies with

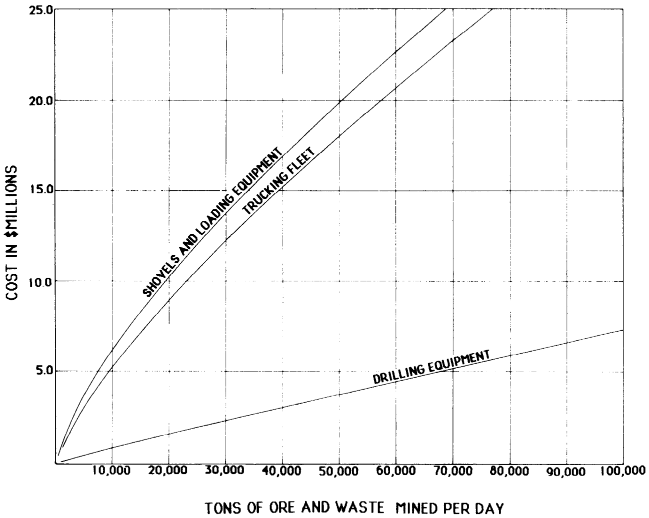

Fig. 6.3.12. Open pit equipment costs.

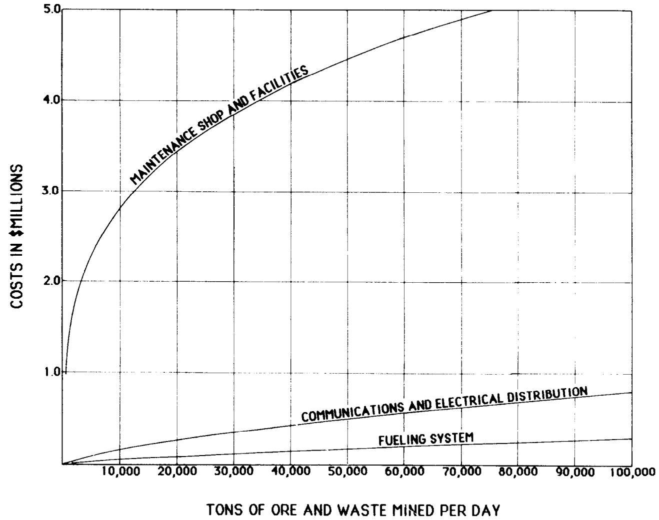

Fig. 6.3.13. Open pit services costs.

the shop area A in square feet as shown by Eq. 6.3.71 and the size t of the trucks in the truck fleet.

$$\text{Cost of pit maintenance facilities} = \$6000\, A^{0.6}\, t^{0.1} \tag{6.3.120}$$

Cost of Open Pit Communications and Electrical Distribution: This cost includes the installed costs for a surface telephone system with mobile and base radio units with one or more repeaters depending on the size of the mine. The electrical distribution includes the installed costs of primary substations, transmission lines, portable skid-mount transformers, and trailing cables, all of which depend on the size of the open pit mine as measured by the daily tons T_p of ore and waste mined.

$$\text{Cost of communications/electrical} = \$250\, T_p^{0.7} \tag{6.3.121}$$

Cost of Open Pit Fueling System: This cost includes the storage and services for diesel fuel, gasoline, lubricants, and coolants for the truck haulage fleet and mobile service vehicles

$$\text{Cost of fueling system} = \$28\, T_p^{0.8} \tag{6.3.122}$$

Open pit services costs are shown in Fig. 6.3.13.

6.3.3.3 Concentrator and Surface Facilities for Mine Projects

It is assumed that the mill operates at three 8-hr shifts for 7 days/week, regardless of the shifts worked by the underground mine or the open pit mine. Some underground mines operate 2 shifts/day, 5 days/week; but other underground mines and most open pit mines operate for 7 days/week. Thus the daily tonnage of ore milled may be the same as the daily tonnage of ore mined, or it may be only 71% of this tonnage.

The crushing plant may operate for 5, 6, or 7 days/week, depending on the mine schedule and whether or not there is adequate fine ore storage capacity to keep the mill supplied with ore when the crusher is shut down for repairs or regular maintenance.

The cost guides in this section are based on the assumption that the mill capacity is 7 1% of the daily tonnage mined 5 days/week, and that the crushing plant has the same daily capacity as the mine, but will work 6 days/week to ensure that the mill will be supplied with crushed ore if the fine ore bins have insufficient capacity to keep the mill supplied with ore during the two-day mine shutdown. In all cases where costs are presented as a function of T tons of ore daily, the number T is the daily capacity in tons of the facility being costed, regardless of whether the facility works 5, 6, or 7 days/week.

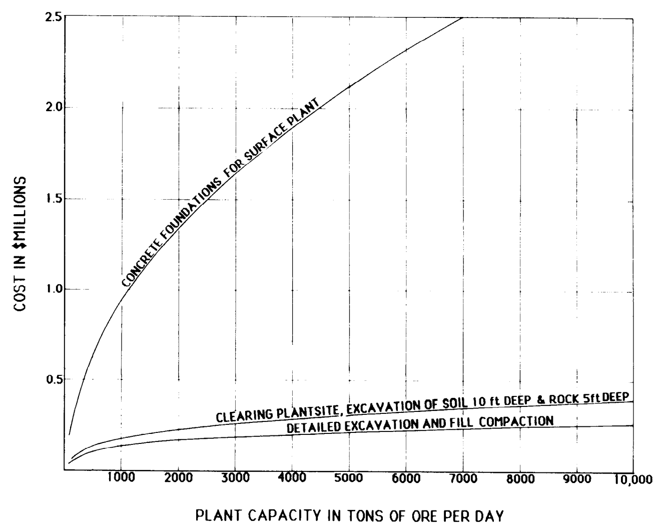

Fig. 6.3.14. Surface plant clearing, excavation, and foundations.

Clearing Costs for Concentrator, Crushing Plant, and Service Facilities: The area A in acres that must be cleared (Fig. 6.3.14) of trees, roots, and shrubs before construction of the concentrator and related facilities can begin is shown in Eq. 6.3.33. In addition to this clearing, roads must be constructed from the nearest existing suitable road to provide access to the site of the concentrator, the hoisting plant, the proposed tailings basin, and the source of water supply.

Costs for clearing and access roads for the surface plant are estimated to be:

Clearing costs = $2000 $A^{0.9}$ for lightly treed area with slopes of not more than 20% gradient (6.3.123)

Access roads = $280,000 per mile for 30-ft (9-m) wide graveled road in mildly hilly region (6.3.124)

These formulas should be modified ± 30% for more adverse or more favorable slope and tree growth conditions.

Excavation of Overburden: Soil overburden must be stripped wherever buildings and facilities are to be sited. The cost of stripping soil overburden *Do* feet deep over an area of *A* acres will be:

$$\text{Cost of soil stripping} = \$1000\ A^{0.8}\ Do \qquad (6.3.125)$$

After the soil overburden is removed and the underlying rock or basal strata is exposed, this rock or strata will require localized removal, probably by drilling and blasting, to establish sound foundation conditions over levelled areas for the plant buildings and plant equipment. If there are *Cu* cubic yards of rock requiring drilling, blasting, and haulage to a dump site, this mass excavation will cost:

$$\text{Cost of mass excavation:} = \$200\ Cu^{0.7} \qquad (6.3.126)$$

for excavations of up to 100,000 yd^3 (76 km^3)

If the mass excavation is in rock that can be broken by ripping, the mass excavation will cost only 20% of the foregoing costs.

When the mass excavation has been completed, detailed excavation to tailor the rock surface to the exact levels for pouring concrete foundations can be done. At the same time, suitable fill will be placed and compacted over level areas where deep trenches of soft soil have been removed. If there are *Cd* cubic yards of rock to be excavated by detailed excavation and *Fc* cubic yards of compacted fill to be placed, the cost will be:

$$\text{Excavation and fill compaction} = \$850\ Cd^{0.6} + \$75\ Fc^{0.7} \qquad (6.3.127)$$

Concrete Foundations for Concentrator Building: Concrete costs for the foundations of the concentrator building, fine ore bins, and concentrator equipment probably will cost between $350 and $900/$yd^3$, depending on whether the concrete pour is for a simple form with little reinforcing steel or for a complex form that is heavily reinforced. The concrete cost may be significantly higher per cubic yard if concrete is scheduled to be poured in winter months when the temperature is below 40 °F (4.4 °C) and heating of aggregate and water and heating of concrete forms is required for sound concrete.

It is difficult to estimate the shape and volume of concrete forms before these forms have been designed, and hence concrete costs related to concrete volume are unreliable for preliminary estimation.

$$\text{Approximate concrete foundation costs} = \$30{,}000\ T^{0.5} \qquad (6.3.128)$$

for concentrators milling *T* tons daily (assuming no difficulties).

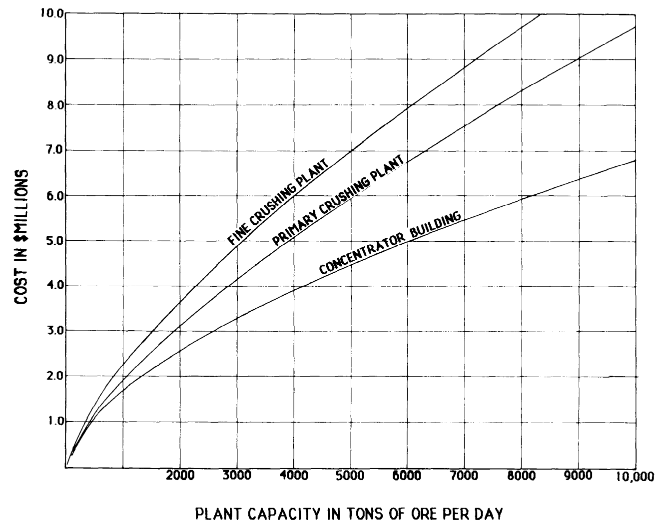

Fig. 6.3.15. Concentrator building and crushing plant costs.

Concentrator Building Costs: The cost of the concentrator building (Fig. 6.3.15) includes all costs of constructing the building above the concrete foundations and enclosing the building, plus the cost of internal offices, laboratories, and changerooms; however, it does not include the cost of process equipment, piping, or electrical wiring, because these items are included in the costs of each functional area. The equipment in operating concentrators generates a substantial amount of heat and comfortable working conditions can be attained with little or no insulation, as long as the concentrator is located in a region with a mild climate.

$$\text{Cost of building} = \$27{,}000\ T^{0.6} \qquad (6.3.129)$$

for flotation mills milling *T* tons of ore daily and located in a mild climate.

A "mild climate" is defined as a region where the degree days are about 7000 (in °F) or 4000 (in °C) per year. Weather stations usually record the "degree days" (°F × *D*, or °C × *D*), which represents the average number of days times the degrees that the temperature is below 65°F or 18°C. In hot climates, where freezing temperatures are not experienced, the building costs may be reduced by only partially enclosing the building and by locating thickeners and other hydrometallurgical equipment outside the building. In cold climates, the additional cost of insulation, heating, and snow loading is likely to increase the building cost by about 10% for each increase of 1800°F × *D* above 7000 (or 1000°C × *D* above 4000).

Primary Crushing Plant with Gyratory Crusher: Although nearly all underground mines place the primary crusher underground to eliminate problems in loading skips and conveyors prior to hoisting the ore, open pit mines generally place the primary crusher on the surface outside the pit, within convenient conveying distance to the coarse ore stockpile and the fine ore crushing plant. Open pit trucks normally discharge ore into a truck dump grizzly mounted over the gyratory crusher, which discharges crushed ore to a conveyor. Because of the headroom required to operate and discharge the crushed ore from a gyratory crusher, a substantial excavation and volume of concrete is required for the primary crusher plant. The cost of the primary crusher depends on the size and capacity of the gyratory crusher selected for an open pit mining *T* tons of ore daily:

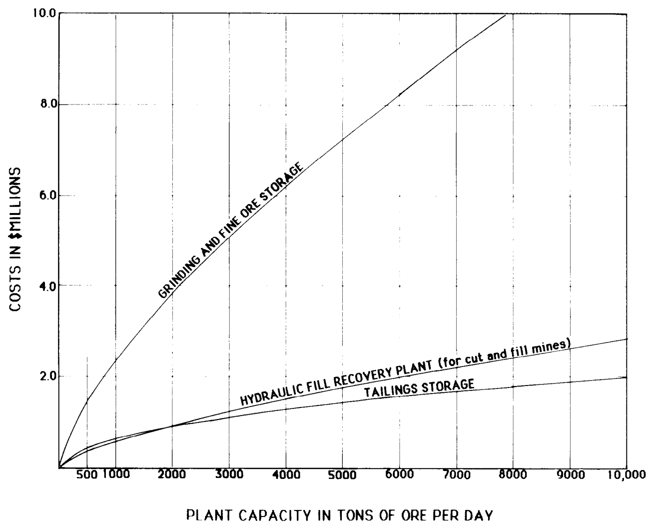

Fig. 6.3.16. Grinding, storage bins, and tailings storage.

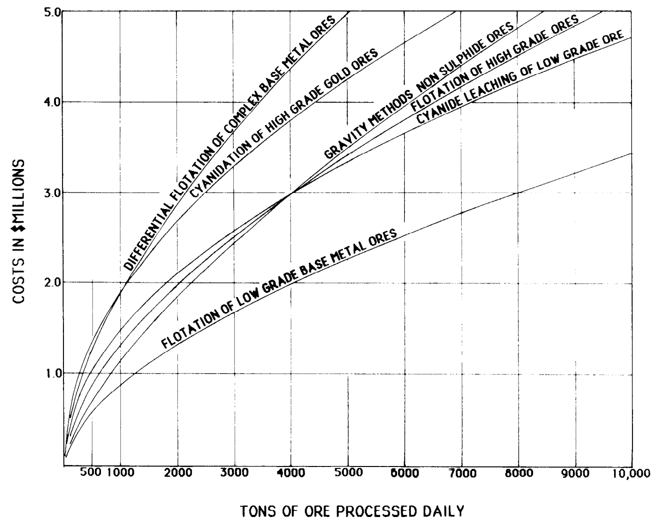

Fig. 6.3.17. Costs of processing section.

$$\text{Cost of gyratory crusher} = \$63\ T^{0.9} \tag{6.3.130}$$

The cost of excavating and concreting the foundations for the primary crusher, installing the crusher, construction of the truck dump and grizzly, plus the coarse ore conveyor and feeder under the crusher is:

$$\text{Cost of primary crushing plant} = \$15{,}000\ T^{0.7} \quad \text{(excluding crusher cost)} \tag{6.3.131}$$

Cost of Fine Ore Crushing and Conveyors: This cost includes the crushing plant building, installed equipment and conveyors.

$$\text{Cost of fine ore crushing plant} = \$18{,}000\ T^{0.7} \tag{6.3.132}$$

Note: Cost may be 12% higher if conveyors must be enclosed and heated.

Grinding Section and Fine Ore Storage Costs: The fine storage bins must have sufficient live capacity to provide mill feed for at least the number of days that the crushing plant is idle per week. The cost of the fine ore bins (Fig. 6.3.16) will be proportional to the weight of steel used in constructing these bins, and the weight of steel will be proportional to $T^{0.7}$, where T is the tons of ore milled daily.

The size and cost of the grinding mills depend on the tons of ore to be ground daily by each mill, but they also depend on the hardness of the ore as measured by the work index and the fineness of grind that is required to attain the desired concentration and recovery of valuable minerals.

Cost of grinding and bins = $18,700 $T^{0.7}$ for medium hard ore with a work index of 15, ground to 70% passing 200 mesh (6.3.133)

= $12,500 $T^{0.7}$ for soft ores ground to 55% passing 200 mesh (6.3.134)

= $22,500 $T^{0.7}$ for hard ores with a work index of higher than 17, ground to 85% passing 200 mesh (6.3.135)

Cost of Processing Section and Related Sections: The capital costs in this section cover the purchase and installation of all equipment required to concentrate or extract valuable minerals from the slurried ground ore, and process the concentrates or extracted minerals into dried solids or impure metals that are directly salable as dry concentrates, ingots of precious metals, uranium yellowcake, or impure metallic gravity concentrates of alloy metals. These capital costs include equipment and tanks for thickening, filtering, precipitation, leaching, solvent extraction, etc., plus all process piping, electrical wiring, and process control.

Process costs (Fig. 6.3.17) for different types of ore by different methods are listed in the following in relation to the tons of ore milled daily T.

1. High-grade gold ores leached by cyanidation, followed by zinc dust precipitation of gold by Merrill Crowe process, filtering, drying, and gold refining:

$$\text{Process capital costs} = \$60{,}200\ T^{0.5} \tag{6.3.136}$$

2. Low-grade ores, cyanide leaching, CIP (carbon-in-pulp) or CIL (carbon-in-leach) adsorption, refining:

$$\text{Process capital costs} = \$47{,}300\ T^{0.5} \tag{6.3.137}$$

3. High-grade gold ores with base metal sulfides; cyanide leaching, secondary flotation, carbon adsorption by CIP or CIL process, filtering, thickening, drying, and refining:

$$\text{Process capital costs} = \$103{,}200\ T^{0.5} \tag{6.3.138}$$

4. Simple low-grade base metal ores of copper with minor content of gold, which can be recovered as smelter credits. Flotation, thickening, filtering, and drying of auriferous copper concentrates:

$$\text{Process capital costs} = \$13{,}700\ T^{0.6} \tag{6.3.139}$$

5. Pyritic gold/silver ores where the precious metals are locked in the pyritic minerals. Differential flotation, selective roasting, recovery of deleterious materials, cyanidation, thickening, precipitation, filtering, and refining.

$$\text{Process capital costs} = \$180{,}000\ T^{0.5} \tag{6.3.140}$$

6. High-grade Cu/Pb ores, Cu/Zn ores, Pb/Zn ores, Cu/Ni ores. Recovery by differential flotation, thickening, filtering, and drying of separate concentrates:

$$\text{Process capital costs} = \$20{,}600\ T^{0.6} \tag{6.3.141}$$

7. Complex base metal ores containing at least three valuable metals, with recoverable minor amounts of precious metals; Cu/Zn/Pb ores, Pb/Zn/Ag ores, Cu/Pb/Ag ores, Cu/Zn/Au ores. Recovery by differential flotation, separate thickening, filtering, and drying of several concentrates and/or bulk concentrates.

$$\text{Process capital costs} = \$30{,}100\ T^{0.6} \tag{6.3.142}$$

8. Nonsulfide ores containing specialty metals such as columbium (niobium), tantalum, tungsten, and tin in minerals that do not respond to flotation, and which are separated by specialized gravity concentration methods:

$$\text{Process capital costs} = \$5000\ T^{0.7} \text{ to } \$13{,}000\ T^{0.7} \tag{6.3.143}$$

9. Uranium ores: acid leaching, countercurrent decantation, clarification, solvent extraction and yellowcake precipitation:

$$\text{Process capital costs} = \$150{,}000\ T^{0.5} \text{ to } \$200{,}000\ T^{0.5} \tag{6.3.144}$$

Capital Cost of Initial Tailings Storage: There are many aspects of tailings storage such as topography, distance from mill to tailings site, localized environmental concerns, etc., that could drastically alter the costs of tailings storage. If, however, all adverse aspects are absent, and a suitable tailings site is available within two miles of the mill, and the nature of the tailings does not have adverse environmental effects, the minimum cost of tailings storage may be:

$$\text{Minimum tailings storage cost} = \$20{,}000\ T^{0.5} \tag{6.3.145}$$

Very few mines have such favorable conditions, and if the area topography is steep or the environmental constraints are stringent, the tailings storage costs could be several times as high as the foregoing cost guide.

Capital Costs of Hydraulic Fill Recovery/Storage: If the underground mine uses the cut and fill stoping method, the hydraulic fill requirements usually can be attained from the tailings by cyclone recovery of the coarser sizes in the ground tailings. The recovery of suitable fill material is usually imposed on the mill plant personnel, as is the storage and slurrying of the recovered fill. The cost of the fill recovery and storage plant is:

$$\text{Cost of fill recovery and storage} = \$4500\ T^{0.7} \tag{6.3.146}$$

Capital Cost of Water Supply System: The cost of fresh water pumping plants, reclaim water plants, and provision for fire protection water supply, plus potable water supply, varies according to the local topography and the proximity and nature of nearby sources of year-round supplies of water. If there is a suitable source of water within two miles of the mill, and the intervening topography is moderately level, the water supply system would cost:

$$\text{Cost of water supply system} = \$14{,}000\ T^{0.6} \tag{6.3.147}$$

The cost of the water supply system for the mine, mill, and plant (but excluding the mine water distribution system) will be much higher if the local topography is steep and rugged or if there are severe constraints on sources of fresh water.

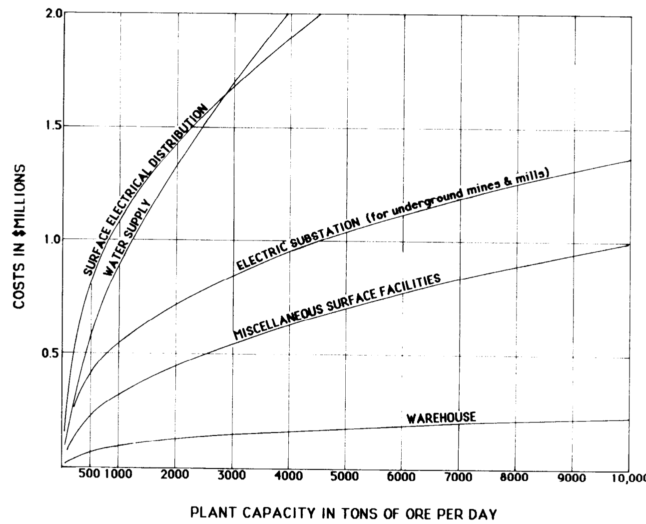

Fig. 6.3.18. Costs of plant service facilities.

Cost of Electrical Substation and Surface Electrical Distribution: The capital cost of electrical facilities for a mining/milling plant depends primarily on the size of the electrical peak load in kilowatts, which can be estimated by Eqs. 6.3.27 and 6.3.28. The cost of power supply depends on whether the power is generated by an existing electric-utility or by a mine diesel-electric plant. Small mines in remote areas may be forced to generate their own electric power, because the cost of a lengthy transmission line from an existing utility may be too high due to the low peak load and low electric power consumption of a small mine.

If the mine is supplied with utility power, the cost of a utility substation with step-down transformers will be

$$\text{Cost of substation} = \$580\ (\text{kW})^{0.8} \tag{6.3.148}$$

where kW is peak load.

The cost of installing low-voltage power distribution to the surface concentrator, crushing plant, and surface facilities, including the mine hoist and compressor plant but excluding the distribution to the surface open pit or the underground mine, is likely to be

$$\text{Cost of surface power distribution} = \$1150\ (\text{kW})^{0.8} \tag{6.3.149}$$

A diesel-electric generating plant may be required for a small mine in a remote area or by a larger mine supplied with utility power that may require a standby electric power plant for protection of vital equipment.

Costs of plant service facilities are shown in Fig. 6.3.18.

$$\text{Cost of diesel-electric plant} = \$6000\ (\text{kW})^{0.8} \tag{6.3.150}$$

Cost of General Plant Services: These costs include the costs of constructing, furnishing, and equipping the general administrative office, general warehouse, electrical and mechanical repair shop (for smaller mill equipment and services equipment), vehicle garages, changehouses, first aid and mine rescue stations, security stations plus general purpose vehicles, parking lots, and yard fencing.

The size of the buildings tends to depend on the number of employees served by each building, which can be estimated by Eqs. 6.3.2 to 6.3.26. It is necessary to estimate the building size in square feet before estimating building cost, which will vary with the area of each type of building.

1. Administrative office. The floor space per person tends to increase as the number of administrative and technical staff *Nat* becomes larger. This reflects the more complex records of accounting and technical staff and the consequent requirement of more space for computer facilities, mining plans, and reference file facilities.

$$\text{Office area } A \text{ required in ft}^2 = 35\ (Nat)^{1.3} \qquad (6.3.151)$$

$$\text{Cost of office} = \$155\, A^{0.9} \qquad (6.3.152)$$

2. Surface plant maintenance shop. Maintenance personnel *Nsv* will require about 85 ft^2/person for maintenance and repair of movable equipment from the mill and service departments.

$$\text{Cost of shop} = \$102 \times (85 \times Nsv)^{0.9} \qquad (6.3.153)$$

3. Mine changehouse. The mine changehouse requires about 24 ft^2/person on the mine payroll (*Nmn* for underground mines or *Nop* for open pit mines) and includes the first aid station and mine rescue facilities.

$$\text{Changehouse cost} = \$125 \times (24 \times Nmn)^{0.9} \qquad (6.3.154)$$

4. Surface warehouse. This should accommodate all supplies and spare parts for the mine, mill, and service facilities that must be kept indoors. Bulky supplies such as rough lumber, structural steel, etc., can be stored outdoors in most climates.

$$\text{Surface warehouse cost} = \$5750\, T^{0.4} \qquad (6.3.155)$$

where T is tons milled per day.

5. Miscellaneous surface facilities. This includes general purpose vehicles and garages, security stations and fencing, parking lots, and miscellaneous services.

$$\text{Miscellaneous surface facilities} = \$10{,}000\, T^{0.5} \qquad (6.3.156)$$

6.3.3.4 Mine Project Overhead Costs

In addition to the direct costs for specific facilities for a mine project, which may total many millions of dollars, there are substantial costs and expenses involved in project design, general site costs, supervision and administration, and provision of working capital. These overhead costs (Fig. 6.9.19) may be estimated as a function of the total direct costs D in dollars.

Engineering: This includes the costs of feasibility studies, environmental impact studies, design engineering, equipment specifications and procurement, and specialized consulting services:

$$\text{Engineering costs} = \$2.30\, D^{0.8} \qquad (6.3.157)$$

General Site Costs: This includes construction camp costs, specialized construction equipment, and general construction site costs:

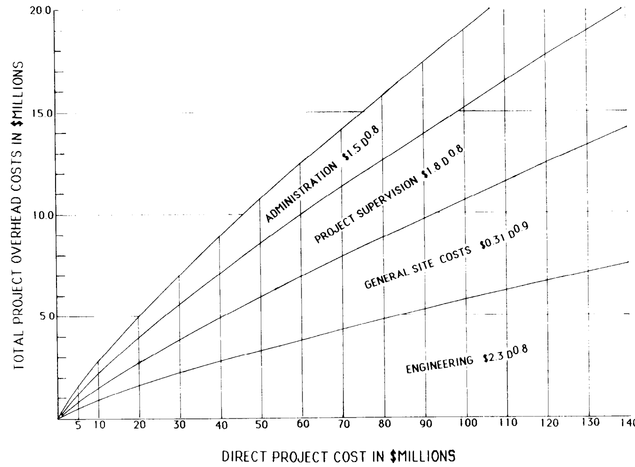

Fig. 6.3.19. Project overhead vs. direct costs.

$$\text{General site costs} = \$0.310\, D^{0.9} \qquad (6.3.158)$$

Project Supervision: This includes project supervision, scheduling and budgeting, and construction management:

$$\text{Project supervision costs} = \$1.80\, D^{0.8} \qquad (6.3.159)$$

Administration: This includes local office administration by corporate owner's representatives, accounting and payment of general contractor, legal costs, plus preproduction employment of key operating staff:

$$\text{Administration costs} = \$1.50\, D^{0.8} \qquad (6.3.160)$$

Project overhead costs as a percentage of direct project costs tend to vary depending on the size and complexity of the project; the lower percentages of 4 to 6% would be typical for $100 million projects and conventional technology, whereas the higher percentages of 8 to 11% would apply to smaller $10 million projects that are technically novel or complex.

Working Capital: The allowance for working capital for a mining project should be sufficient to cover all operating costs plus purchase of the initial inventory of capital spares and parts until revenue is received from smelters or purchasers of metallic products. The time period elapsing before receipt of revenue sufficient to pay imminent operating costs will vary depending on the smelter terms or marketing terms, but the typical allowance is about 10 weeks after the concentrator is operating at full capacity.

Typical working capital allowance
= operating costs for 10 weeks

after commissioning of concentrator plus cost of purchasing initial inventory of capital spares and parts.

Whenever the mine or mill design is based on extensive usage of reconditioned used equipment, there is a higher frequency of equipment downtime that requires additional time allowance of working capital; this will decrease the apparent savings of used equipment.

6.3.4 COST GUIDES FOR OPERATING COSTS OF MINES AND MILLS

The cost guides provided in the form cost = KT^x compute the cost of each mining activity as a function of the tons T of ore mined and express this cost as a cost per day of mining activity. The cost per ton can be derived from the formula by dividing the cost per day by the tons mined per day so that cost per ton $= KT^x/T$ which equals $K/T^{(1-x)}$. Thus if 100 $T^{0.7}$ represents the cost per day, the cost per ton $= 100/T^{0.3}$.

When a mine is producing T tons per day from all mining methods, but the mining method being costed produces only t tons of ore per day, then the cost of the mining method per day equals $Kt/T^{(1-x)}$, although the cost per ton remains at K/T^{1-x}.

6.3.4.1 Underground Mine Operating Costs per Day

The cost per day for different mining methods includes the cost of labor and supplies for drilling, blasting, ground support, loading, and haulage of stoped ore from each stope. This cost covers work done by the stoping and mucking crew only and does not include labor and supplies involved in crushing, transport, and hoisting of ore; neither does it include general mine services, supervision, or mine activities that are not specific to the mining methods being used to recover ore from the stopes.

Stoping Costs:

1.	Shrinkage stoping costs	$= \$146\ T^{0.6}$ per day	(6.3.161)
2.	Cut and fill stoping costs	$= \$185\ T^{0.6}$ per day	(6.3.162)
3.	Fill distribution	$= \$22\ T^{0.7}$ per day	(6.3.163)
4.	Longhole stoping costs	$= \$160\ T^{0.6}$ per day	(6.3.164)
5.	Fill distribution for bulk filling longhole stopes	$= \$12\ T^{0.7}$ per day	(6.3.165)
6.	VCR stoping costs	$= \$125\ T^{0.6}$ per day	(6.3.166)
7.	Room and pillar stoping costs (hard rock)	$= \$130\ T^{0.6}$ per day	(6.3.167)
8.	Room and pillar stoping costs (soft rock)	$= \$85\ T^{0.6}$ per day	(6.3.168)
9.	Sublevel caving costs	$= \$115\ T^{0.6}$ per day	(6.3.169)
10.	Block caving costs	$= \$105\ T^{0.6}$ per day	(6.3.170)

These cost guides to stoping costs are based on the presumption that the stope widths (or heights) are as follows: shrinkage 8 ft (2.4 m), cut and fill 15 ft (4.6 m), longhole stoping and VCR stoping 30 ft (9.1 m), room and pillar stoping 12 ft (3.7 m) high, but if the actual width W(or height H) differs from the assumed width Wa (or height Ha), the stoping costs should be corrected by the ratio of the assumed width divided by the actual width with the quotient taken to the 0.4 power.

$$\text{Stoping cost correction} = (Wa/W)^{0.4}, \text{ or } (Ha/H)^{0.4} \quad (6.3.171)$$

Stope Preparation Costs per Day: Stope preparation costs may be estimated as follows:

$$\text{Preparation costs} = \$85\ T^{0.48}\ W^{0.2} \text{ for shrinkage stopes} \quad (6.3.172)$$
$$= \$9.60\ T^{0.7}\ W^{0.5} \text{ for cut and fill stopes} \quad (6.3.173)$$
$$= \$19.20\ T^{1.06}/W^{0.6} \text{ for blasthole stopes} \quad (6.3.174)$$
$$= \$29.04\ T^{1.04}/W^{0.6} \text{ for VCR stopes} \quad (6.3.175)$$
$$= \$2{,}200\ T^{0.6}\ H^{0.2} \text{ for block caving stopes} \quad (6.3.176)$$

Crushing and Hoisting Costs per Day: When underground ore is crushed and hoisted, the cost per day depends primarily on the tons of ore crushed or hoisted per day. The size of ore fragments to be crushed or hoisted makes little difference to the daily crushing cost or daily hoisting cost; consequently the type of stoping method employed has little effect on crushing costs or hoisting costs.

$$\text{Crushing costs per day} = \$2.00\ T^{0.8} \quad (6.3.177)$$

$$\text{Hoisting costs per day} = \$4.70\ T^{0.8} \quad (6.3.178)$$

Cost of Mine General Services: This cost includes all labor and supplies required to maintain all direct mine services, including ventilation, pumping of drainage water, repair and maintenance of mine equipment, maintenance of development levels and ground support, plus mine supervisory staff. This cost includes all cost items that are not already costed previously and that are directly supervised by mine supervision; it should not include any "distributive costs," which are allocated and supervised by staff other than the mine supervision.

General service costs should be retained in the department that has supervisory responsibility over the activity that incurred these costs. Thus the cost of electric power utilized by the mine, concentrator, and general services should not be allocated to each department on some expedient basis, unless each departmental usage of electric power is metered directly and for which the departmental supervision is to be held accountable.

Thus the cost formulas shown in the following for mine general services apply only for those costs that are committed by personnel under the supervision of mine staff.

$$\text{Cost of mine general services} = \$75\ T^{0.8} \quad (6.3.179)$$

$$\text{Cost of mine supervision} = \$12\ T^{0.7} \quad (6.3.180)$$

6.3.4.2 Open Pit Operating Costs per Day

The operating costs of open pit mines depends on the size and numbers of drills, shovels, and trucks, which in turn is dependent on the tons per day of ore and waste. In most open pit mines mining low grade ore, there is little if any difference in the specific gravities, blasting characteristics, and drillabilities of ore or waste, and the haulage distance to the ore dump usually does not differ very much from the waste haulage distance. Consequently, the cost of mining a ton of ore will be virtually the same as the cost of mining a ton of waste.

The cost of open pit mining can be assessed against the total ore and waste tonnage (T_p) mined daily.

Drilling cost per day	$= \$\ 1.90\ T_p^{0.7}$	(6.3.181)
Blasting cost per day	$= \$\ 3.17\ T_p^{0.7}$	(6.3.182)
Loading cost per day	$= \$\ 2.67\ T_p^{0.7}$	(6.3.183)
Haulage cost per day	$= \$18.07\ T_p^{0.6}$	(6.3.184)
General services cost per day	$= \$\ 6.65\ T_p^{0.7}$	(6.3.185)

The open pit general services cost includes the cost of pit maintenance, road grading, waste dump grading, pumping, and open pit supervision, but it does not include the cost of primary crushing or electric power.

6.3.4.3 Concentrator and Services Operating Costs per Day

The operating costs per day for the crusher, concentrator, and general surface facilities are grouped together, because these costs are generally interrelated in terms of sequential activities applied to the run-of-mine ore as received from the mine to convert this ore into a salable product shipped from the plant to the purchaser. Thus, although the gyratory crusher may be located at the edge of the open pit, the costs of operating it are grouped under milling costs, rather than as open pit operating costs, as the first stage of ore treatment. Conversely, the cost of operating an underground jaw crusher is usually considered a mining cost because it is operated and repaired by the mine crew.

The cost of treatment of tailings in storage, or the cost of recovery of coarse tailings for mine backfill, and the cost of gold refining, or the contract trucking of concentrates from the mill to the purchaser, can be regarded as the final stages of ore treatment.

Operating costs that apply to the complete mining and milling plant, such as electric power consumption, which is metered only at the main electric substation, is grouped with concentrator costs. This results because the concentrator is usually the largest consumer of power in the mining and milling complex, and because most attempts to allocate power costs to different sections of the plant are uncertain at best, unless the power distribution to each section of the plant is separately metered.

The design of the milling flowsheet is usually optimized after extensive testwork on the types of processes tailored to the characteristics of the ore; at the preliminary feasibility stage however, the optimum processing requirements are not known with accuracy, and the costs of processing can only be approximately estimated.

The following cost guides are offered as rough estimates of crushing and concentrating costs per day.

Primary Crushing Costs per Day: This cost includes the cost of primary crushing, the cost of conveying the primary crushed ore to the coarse ore stockpile, plus operating costs of the coarse ore stockpile.

Crushing costs per day = $7.90 $T^{0.6}$ for open pits and mills (6.3.186)

= $2.00 $T^{0.8}$ for underground mines and mills (usually included in mining costs) (6.3.187)

Fine Crushing and Conveying Costs per Day: This includes fine crushing, conveying from coarse ore storage, and conveying to the fine ore bins.

Fine crushing costs per day = $12.60 $T^{0.6}$ (6.3.188)

Grinding and Fine Ore Bins Cost per Day: This cost includes the fine ore bin storage and the rod mills, ball mills, and/or SAG (semiautogenous grinding) mills:

Grinding section costs per day = $4.90 $T^{0.8}$ (6.3.189)

Process Section Costs per Day: This includes the operating costs of all sections that involve concentration of ore by flotation or by gravity, leaching of metals from ore, thickening of slurries, ion exchange, precipitation, filtering, drying, and recovery of metallic concentrates, or deleterious materials that would otherwise penalize smelter revenue.

Processing costs per day = $65.00 $T^{0.6}$ for cyanidation of gold/silver ores (6.3.190)

= $54 $T^{0.6}$ for flotation of simple base metal ores (6.3.191)

= $34 to $41 $T^{0.7}$ for complex base metal ores varying in complexity (6.3.192)

= $65 $T^{0.7}$ for uranium ores by leaching, CCD, solvent extraction, and precipitation (6.3.193)

= $45 $T^{0.7}$ for nonflotable nonsulfide ores responding to gravity separation (6.3.194)

Tailings costs per day = $0.92 $T^{0.8}$ for all concentrators (6.3.195)

Assaying costs per day = $1.27 $T^{0.8}$ for all concentrators (6.3.196)

Supervision, maintenance, and general costs per day = $40.80 $T^{0.6}$ for all concentrators (6.3.197)

Processing costs should be decreased to 55% of those shown by the foregoing formulas when low-grade ore, typically mined by open pit mining, is being treated by a concentrator that rejects tailings at an early stage.

Electrical Power Costs per Day: The peak load and daily electric power consumption of the mine plant, consisting of an underground mine or open pit, crushing plant and concentrator, plus surface services and general administration office can be estimated from Eqs. 6.3.27, 6.3.28, 6.3.29, and 6.3.30. These equations indicate that a small underground mine and plant processing 500 tpd (454 t/day) of ore will have a peak load of about 3700 kW, and a daily consumption of about 62,000 kWh.

Under these conditions, the unit cost of power is typically about 8¢/kWh, and the unit cost is normally reduced for larger mines that use larger quantities of electric power. Usually, the unit cost of electric power is reduced in stages by about 4.3% each time the power consumption is doubled, and by using these typical assumptions, it is possible to estimate the daily cost of electric power for mines and mills larger than 500 tpd.

Cost of electric power = $ 164 $T^{0.56}$/day for underground mines and plants processing T tons of ore/day (6.3.198)

= $145 $T^{0.56}$/day for open pit mines and plants processing T tons of ore/day (6.3.199)

Surface Services Cost per Day: The daily cost of each person in the surface maintenance and general services departments is estimated to be $141 in wages and fringe benefits, plus an average cost of $16 in supplies consumed. If the number of maintenance and general services personnel is *Nsv* as estimated from Eqs. 6.3.22, 6.3.23, and 6.3.24, then the daily costs of maintenance and general services departments is

Services cost per day = $157 *Nsv* (6.3.200)

Costs of Administration and Technical Staff: The daily costs of the administrative and technical staff, including supplies and services required by them, plus fixed costs for local property taxes and legal fees paid by administrative services, are proportional to the number of staff *Nat,* as estimated in Eqs. 6.3.25 and 6.3.26.

Each staff person is estimated to cost on the average $185 in salary per day, and to consume $37.60 in supplies and services per day.

Total cost per day for administrative and technical staff salaries and supplies $= \$222.60\ Nat$ (6.3.201)

6.3.5. CONCLUSION

The consequences of inaccurate estimation of capital and operating costs in feasibility studies may include the commitment of major amounts of capital funds before it is realized that the mining project will not be profitable, or the rejection of a proposed mining project that could be profitable. Accurate cost estimation is possible only after a substantial amount of technical activity has been competently completed. This technical activity should include the following:

General mine planning of all mine development, including scaled maps and drawings from which the lengths, quantities, and unit costs of all mine excavations and openings can be estimated.

Assessment of the sizes, types, numbers, and prices of mine and mill equipment that will be required for the planned rate of production.

Environmental impact studies for the regional area surrounding the proposed mine site and the nature and content of all fluids and gases that will be discharged from the mine and plant.

Metallurgical tests of bulk samples of mine ore treated by the proposed concentrator process.

General plant layout must be completed to show the dimensions of all plant buildings and the depth and amount of excavation required for sound building and equipment foundations. Access roads, transmission lines, water lines, and tailings lines must be mapped and the topography contoured.

Cost formulas can provide some guidance as to the order to magnitude of capital and operating costs, but the accurate estimation of costs depends on measured quantities taken from the design planning, plus unit costs quoted by contractors or derived from unit costs of recently completed projects similar in nature. In general, the accurate estimation of project costs must be entrusted to consulting engineering firms and project management firms with experience in many similar projects.

Most mining engineers employed in operating mines do not have the necessary expertise or training to determine the design features or costs of surface mining plants, and these should be determined by experienced firms employing engineers skilled in civil, structural, mechanical, chemical, metallurgical, and electrical engineering.

Additional assistance in cost estimation may be obtained from the following sources or publications:

1. *General Construction Estimation Standards,* 6 volumes, revised annually, published by Richardson Engineering Services, Inc., P.O. Box 1055, San Marcos, CA 92069.
2. *Means Construction Costs,* revised annually, and published by Robert Snow Means Co. Inc., 100 Construction Pl., Kingston, MA 02364.
3. *US Bureau of Mines Cost Estimating System Handbook,* 2 volumes, Information Circular 9142 (surface and underground mining), and Information Circular 9143 (mineral processing). Mining and milling costs are as of January 1984. The two volumes, IC 9142 and IC 9143, are available from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402
4. *Canadian Construction Costs: Yardsticks for Costing,* revised annually; available from Southam Business Publications, 1450 Don Mills Rd., Don Mills, ON, Canada, M3B 2X7.
5. *Mining and Mineral Processing Equipment Costs and Preliminary Capital Cost Estimations,* Special Vol. 25, 1982; published by The Canadian Institute of Mining and Metallurgy, 1 Place Alexis Nihon, 1210-3400 de Maisonneuve Blvd. W., Montreal, PQ, Canada H3Z 3B8.

Chapter 6.4
PROJECT OPERATING STRATEGY

DONALD D. HAAS

6.4.1 INTRODUCTION

The purpose of this chapter is to assist the owner of a mining property in the development of the proper strategy for bringing the property into production. The owner basically has five alternatives, or a combination of these five alternatives, for bringing the property into production. The five alternatives are (1) develop the property solely as the owner and operator, (2) employ a contract miner to perform some or all of the development and/or mining, (3) employ a contract miner to initiate production and to establish an operating mine and subsequently then, as an owner/operator, to operate the entire property, (4) lease the property to an established mining company or developer for exploitation, and (5) joint venture the project with another mining company.

Each of these alternatives is described in detail in 6.4.2, and each has its unique advantages and disadvantages. The use of any particular alternative depends on the advantages and disadvantages of a unique set of circumstances, the economic consequences of the alternatives, and the corporate philosophy of the property owner.

6.4.1.1 Definitions

The following definitions are provided to minimize misunderstandings that might otherwise occur when analyzing the operating strategies offered in this chapter.

Owner: The owner is the individual or company that has ownership and/or control of a property. In this chapter, the owner is attempting to develop the property into an operating mine.

Owner/Operator: This term refers to a condition where the owner of the mineral resources, either through actual ownership of the mining claims or a lease of mining claims, fee land, or other type of ownership from others, is the entity that constructs, initiates and continues mining production, and operates the milling and/or processing facilities. Some of the work on the project may be under contract to others, but total control and operation of the mine and plant are the responsibility of the owner.

Contract Mining: For surface mining, contract mining is, at a minimum, the removal of waste or overburden, the extraction of ore, and the delivery of that ore to a processing facility. For underground mining, contract mining is, at a minimum, the development of the workings, the extraction of ore from stopes or other production openings, and the delivery of that ore to the client, either at the shaft loading pocket or at the surface. Contract mining may include many other activities for both surface and underground mining. For example, in surface mining, other activities may include development of an infrastructure for the operation; construction of access to the site; clearing and grubbing the site; the removal, stockpiling, and replacement of topsoil; water control around the mine area; crushing and other preprocessing activities; construction of the processing facilities; and management and/or operation of the ore processing plant. For underground mining, these activities may include development of access to the site; development of the underground mine (including construction of the headframe or other surface facilities); sinking the shaft; development of the stations and levels; and construction, operation, or management of the processing facilities.

Startup: The startup portion of a mining operation, sometimes called mine development, is that period of time during which access to the mine is being developed (other than the access needed for exploration activities); the main haul roads are being constructed; the initial shaft, incline, or adit is being driven; the first pit or cut is being established; the haulage system is being developed; and the mine is being brought to full production levels. These activities also include stabilizing the labor force for the mine, establishing supervisory personnel and staff activities, and stabilizing the production and costs of the operation.

Lease: A contract that allows an individual or company other than the owner of the property to develop and operate a mine on a property, produce a product, and sell the product. The owner derives benefit from the leasing of the property either through a royalty arrangement such as a sharing of the revenues or profits from the operation, a set fee per weight of ore or refined product, or a flat fee per period of time.

Joint Venture: A joint venture is the joining of two or more companies for the purpose of developing and operating a mining property. A joint venture, as used in this chapter, is a joint operation where each partner brings a needed knowledge or expertise to an operation and is not to be confused with joint ventures formed for the purpose of providing financing for the project or formed for the purpose of acquiring a property for only one of the parties to operate. Marketing of the mineral may be a needed knowledge. A joint venture merely to share the risk of a project is not addressed. This type would be the result of corporate philosophy, not necessarily economics. The interested reader is referred to Gentry and O'Neil (l984) for more extensive discussions on the various forms and the financial implications of joint ventures utilized in the minerals industries.

6.4.2 PROJECT ALTERNATIVES

A more detailed discussion of the five major project alternatives follows, along with some of the major ramifications, advantages, and disadvantages of each. The owner of a property must consider the different alternatives for the development of a property before selecting the appropriate alternative.

6.4.2.1 Owner/Operator

The owner/operator alternative is the most common system of mine development; consequently, the bulk of this section addresses this type of alternative. The owner of the property either stakes the ground or acquires leases to the property for the expressed purpose of developing the property into a profitable mining operation. The staking of claims or the acquisition of leases may have occurred long before a determination is made to develop the property into a mine.

The feasibility studies necessary to assist with the decision to develop the property into a mine are discussed in detail in Chapter 6.2 of this section. Chapter 6.3 outlines methods and procedures for developing cost estimates for mining properties. Analyses of the investment decision and the financing of the operation are discussed in Chapters 6.5 and 6.6 of this section, respectively.

The owner/operator may decide to contract some of the activities at the mine such as detailed design and/or construction of the milling and processing plant, the erection of mining equipment, construction of access to the property, and even some removal of overburden, and still be classified owner/operator of the project. The owner/operator mines and processes the ore in the normal operation of the project.

Advantages and Disadvantages: The primary advantage of the owner/operator alternative is the total control the owner has of the development and exploitation of the property. In each of the other alternatives, the owner must relinquish some control of at least some aspect of the operation. The owner directly gains any advantages from reduced costs or improved recoveries at the operation. For example, when a contractor is employed, the owner is dependent upon the good mining practices of the contract miner for recovery of all the ore and for minimizing dilution in mining of the ore. Also for the same basic reason in a lease, the owner is dependent on the lessee recovering all the ore in the pit or in the stopes and then extracting the mineral commodity from the ore.

The owner's profit is dependent generally upon the amount of product sold. Thus it is advantageous to have total control over all aspects of the operation that directly influence this parameter.

A disadvantage is that the owner may experience higher cost per volume of commodity recovered using his own operation than using a contract miner or leasing the property to someone who possesses more expertise or efficiency. Typically, the owner reduces the risks associated with operating costs by employing a contract miner or by leasing the property. Or the owner shares the risk by obtaining a joint venture partner or partners.

The fact that the owner retains all risks associated with development of the property may be either an advantage or disadvantage. The owner loses if the cost of mining or processing increases; similarly, he gains if the cost decreases. The owner loses if the amount or grade of ore developed does not exist; he gains if there is more or higher-grade ore than anticipated.

6.4.2.2 Contract Miner

For a surface mine, the contract miner operates the mine, including the removal of overburden waste, mines the ore, and delivers the ore to a milling or processing facility. For underground mining, the contract miner develops the workings, extracts the ore from the stopes or production openings, and delivers that ore to the client, either at the shaft loading pocket or at the surface. The contract miner may perform many other tasks for the owner, including construction of access to the site and other preproduction activities; crushing, milling and other processing activities; reclamation of the site after mining is complete; development of the underground mine; construction of the headframe and other surface facilities; sinking the shaft; and station and level development. The contract miner does not generally operate a processing plant for the owner, due to the difficulty in monitoring the contract miner's efficiency in recovering the marketable commodity from the ore. The contract miner may operate the processing plant during start-up, but the owner generally assumes responsibility for operations shortly after the operation reaches full production and the processing facility has been debugged.

Advantages and Disadvantages: As an owner considers whether or not to contract all or a portion of his operation, he is faced with a choice that has both positive and negative consequences no matter what the decision. Each property situation is different; therefore, there is no universally superior answer for the industry. Such factors as the financial strength of the owner, degree of development of the mine plan, corporate philosophy concerning control and growth, mine location, possible parallel operations at other sites controlled by the owner, etc., all come into consideration when determining which course to follow.

The following list of advantages and disadvantages should be viewed and evaluated on a site-by-site basis, and each item should be weighed as to its relative importance under the specific circumstances associated with the property and the controlling interest.

Possible Advantages—

1. Contract mining reduces the magnitude of initial capital investment required to bring the property into production. The owner already has invested considerable capital resources in exploration and/or acquisition, engineering, and permitting for the mine. The capital outlay for equipment represents a substantial load on company resources and could restrict activities or even be an insurmountable barrier to bringing the property into production. The capital funding from the owner is preserved for the construction of the processing plant, other facilities, and possibly other mining properties. The financial resources of the owner are conserved by using a contract miner.

2. Contract mining reduces direct payroll and administrative costs. Items such as recruiting, training, and supervision become the responsibility of the contract miner, along with the responsibility of health care benefits, insurance, and all the other costs and planning required to maintain a qualified work force.

3. Contract mining supplies a well-defined fixed cost for the mining operation. An owner should develop an estimate of mining costs, but it is difficult to anticipate and accurately estimate all cost items such as maintenance, accidents, equipment availability, and so forth. Since the contractor has control over these activities, he assumes all the risks for any cost increases that might be incurred.

4. Fixed operating expenses may facilitate financing for the project. If a respectable contractor is chosen and operating costs are contractually defined, financial institutions often recognize that the project has a better chance of meeting projected costs and production levels because the contractor has assumed some of the risks inherent in project start-up. This, of course, largely is dependent on a properly engineered mine plan.

5. The owner has greater flexibility during the life of the mine. Should the owner buy all necessary equipment at the start of production and then, for example, wish to increase or decrease production because of any number of changes in key project variables, the owner may find that the wrong equipment was purchased to perform the required function efficiently. The owner is then faced with a possible financial loss while trying to sell some equipment and procure other replacements. Most active contract miners are also construction companies; it is probable they can change out the equipment with an adjustment to unit costs that saves money for the owner.

6. A good contract mining agreement improves efficiency for the project. The contract miner typically has had to win the award on a competitive basis. To do so, the contractor uses production figures based on experience in similar circumstances; the only way the contract miner can show a profit is to meet or exceed these projections. When circumstances arise that defeat these objectives, the contract miner makes every effort to overcome the problem. Where necessary, he works with the owner to correct conditions he cannot control. (An example would be if the contractor becomes ore-bound or waste-bound, he may not be able to get full utilization from his crews and equipment.) Although this may seem to be a problem, it is actually an advan-

tage, since it forces the owner and operator to work jointly to keep overall costs down. Without this relationship, especially at a profitable mine site, additional inefficiencies may be tolerated because the mine is providing an adequate profit margin. For a more complete discussion of this aspect, see Haas, 1989.

7. Contract mining reduces costs for mines with short lives. The owner may have other operations where equipment can be placed in use as a mine curtails production. However, if this is not the case, the owner faces extraordinary losses as the owner is forced to depreciate the cost of equipment over an inordinately short time period. In contrast, contractors usually depreciate equipment over its expected life rather than on a project basis, since the contractor can transfer the equipment from job to job.

Disadvantages—

1. The owner relinquishes some control of the project. It is necessary for the owner to work closely with the contract miner to ensure that the overall operation enables the contractor to meet required production projections.

2. Total operating costs per unit of mined material may be higher than those resulting from an owner/operator property. However, this observation should not be determined subjectively; it must be determined based on careful financial evaluations utilizing *all* costs (operating and capital), annual cash flows, and time value of money concepts. Such an evaluation from a cost minimization standpoint is provided in 6.4.7.

3. Selection of an inefficient and unreliable contract miner is a risk. Choosing the wrong contract miner brings on more problems than normally encountered when operations are conducted by the owner. The owner must evaluate the contract mining company being considered to ensure it has the financial resources, personnel, experience, and general operating philosophy necessary to meet project needs. This is best accomplished by checking qualifications carefully and asking pertinent questions at pre-award meetings.

6.4.2.3 Contract Miner During Start-up

The owner of a mining property may wish to use a contract miner during project start-up so as to alleviate some of the problems normally associated with start-up and to reduce capital requirements during this period. The contract miner also may be used to perform many of the preproduction activities at the mine and thereby reduce the number of contractors working on a project site during preproduction. A contractor may be employed especially during the start-up of a processing facility to utilize his experience and expertise in debugging the process and in developing the procedures necessary for efficient operation.

The contract mining bidding process and the procedures for monitoring the contractor are the same as when using a contractor for continuing operation. These are discussed in subsequent portions of this chapter.

Advantages and Disadvantages: The same basic advantages and disadvantages apply to the use of a contract miner during project start-up as they do for an entire mine project, except that they exist for only a short period of time—the preproduction development period. The advantages, in addition to those previously stated, are

1. Work crews are established by the contract miner. The contract miner recruits the hourly work force during the development period. The owner may choose to employ all or part of this work force when the contract miner's obligations are completed. Also, all or a portion of the contractor's staff labor may be employed by the owner. A distinct advantage of this arrangement is that the owner has not had to develop the training programs necessary or to perform the selection and "weeding out" process in establishing a work force.

2. Contractor's equipment may be acquired by the owner. If desired, the owner can construct the agreement with the contract miner so that the owner can acquire the needed equipment for continuing operation. This equipment can be purchased by the owner at reduced prices (fair market value for used equipment or other agreed upon method) and reduce the initial capital investment. Also the owner can select the equipment desired for maximum operating efficiency and minimum operating costs under the operating procedures or techniques planned.

6.4.2.4 Leasing of the Property

Leasing of a mining property usually occurs when the owner of the property does not have the financial capability, expertise, or desire to explore, develop, and/or operate a mining project. Leasing normally involves the transfer of all rights to explore, develop, and operate the property to another individual, organization, or company.

Leasing a mining property to another person or company has the principal advantages of reduced risk and reduced investment in financial and human resources. Mine development is extremely risky in terms of financial and human factors. An old adage in mining is that for every 100 discoveries made, one is worthy of being called a prospect and deserving of significant investment in an effort to explore further. Furthermore, for every 10 prospects, one makes a mine that develops sufficient returns to reimburse the owner for the investment of finances and personnel. The investment to explore, develop, and operate a mine is significant and is generally in the order of tens of millions or hundreds of millions of dollars. Some owners of potential mining properties do not have sufficient financial resources to explore, develop, and operate a mine. If the necessary financial strength is not available, either from the owner directly or through external financing, the owner may wish to either lease the property to a company with the required financial strength or joint venture the property.

The primary disadvantages of leasing are the loss of control over property development and the loss of significant upside potential from mine operations if a major ore body is discovered or high-grade ore is located. The loss of control does not allow the owner to direct subsequent efforts in exploration, development, and operation. If a large or high-grade ore body is discovered and/or the mining venture is very profitable, the lessor receives only the negotiated royalty. Some of this disadvantage can be mitigated by negotiating the royalty provision based on net profits from the mining venture; however, this approach also increases the owner's risk by reducing overall return if the mining venture is only marginally profitable.

6.4.2.5 Joint Venture

Joint ventures usually involve the affiliation of two or more companies in order to benefit from the expertise of all companies and the property ownership of one of these companies. Joint ventures, as the term is used in this chapter, represent the partnership of two or more companies to develop a mining property for the purpose of benefitting from the combined technical and/or operating expertise of the companies and not as a means to finance the venture.

The major advantages in using a joint venture are the benefits derived from the expertise of another company and the sharing of risks. Sometimes, after a property has been discovered and explored to the extent that a viable project appears to be a distinct possibility, the owner often determines he is deficient in the expertise needed to exploit the property to its fullest potential. Joint venturing the project with one or more other companies is one of the means of obtaining the desired expertise for the successful exploitation of the deposit. Also some projects may become too large or complex for one company to undertake. In this case, the company may desire to share the risk of the development with another company through a joint venture.

The major disadvantages of using a joint venture are the sharing of proceeds of the project and the loss of control. When a project is developed jointly, the owner must share some of the proceeds with the partner(s). If the expertise gained with the partner(s) does not exceed the cost of sharing the proceeds, a joint venture probably is not the alternative to be used. Also, when a project is developed jointly, decisions regarding property development must be shared. Each partner needs to have sufficient voice in the decisions to protect their investment and to insure an adequate return on his investment.

6.4.3 CONTRACT MINING BIDDING PROCESS

The contract mining bidding process involves several steps to develop a workable agreement with the successful contractor who will perform contract mining on the owner's project. These steps are as follows: (1) develop the bidder's list, (2) prepare the request for proposal (RFP), (3) develop the proposal by the bidder, (4) evaluate the proposals, (5) select the contract miner, and (6) write the agreement. Each of the ensuing discusses briefly the suggested procedures to be followed and the importance of the relevant factors in each area.

6.4.3.1 Developing the Bidder's List

The role of contract mining companies to provide services for the mining of ore and waste and the crushing and transportation of ore has increased significantly in the past decade. Although the concept of contract mining is not new, the scope of services provided is growing.

The basic concept of limiting contract miners to early-stage development and other preproduction activities has changed dramatically. The primary reasons for this change are (1) owners may not want to commit the necessary human or financial resources to operate a mine, (2) the owner does not desire to purchase and maintain an equipment fleet, (3) the owner does not wish to invest in developing a professional operating staff and skilled labor force for short-term projects, (4) the financial risk capital for the owner is minimized, and/or (5) the contractor shares in the risks of mining property start-up and operation.

The goal of the entire contract-mining bidding process is to (1) select the most qualified bidder, (2) obtain the lowest competitive cost, and (3) permit both parties to make a reasonable profit.

After a mine owner decides to utilize contractor services to operate the proposed mine, a bidder's list of qualified contract miners must be developed. Ideally, the mine owner wants to award the contract to the most qualified contract miner, while obtaining the lowest competitive unit costs. The resulting owner/contractor relationship should enable both to realize a profit on the ensuing activities.

Compiling a bidder's list can be either formal and structured or informal. The formal procedure involves preparing a request for qualifications (RFQ) and sending it to potential bidders who, in turn, respond with a qualification proposal detailing their capabilities to perform contract mining. Information requested in the RFQ is generally divided into two categories: (1) company profile and general information and (2) project-specific qualifications.

The company profile generally includes five components: (1) general company data, (2) type of organization, (3) financial resources and references, (4) approach to work, and (5) personnel resources. *General company data* should include the company's name, address, and contact person. *Type of organization* should indicate if the firm is incorporated, the date and state of incorporation, the parent company (if applicable) or major subsidiary to be used, and an organizational chart or list of company officers.

Financial resources and references should include average annual income (revenue) and backlog, banking and bonding references, bonding capacity, any significant pending litigation, and the company's latest annual report or financial statement. *Approach to work* should indicate the type of work typically performed by the contractor's own forces, what work is generally subcontracted to others, the existence of an affirmative action program and other desired or mandated programs, details of safety programs and the record of those programs, affiliation with any labor organization, and the dollar value limits (maximum and minimum) for work undertaken by the contractor. *Personnel resources* should detail the number and types of personnel generally available for contract mining work by category and location.

Project-specific information is divided into three areas: (1) the contractor's approach to the project, (2) the proposed project personnel and organizational structure, and (3) the company or personnel experience relative to the project. *Approach to the project* should include the type of venture (joint venture or prime contractor with subcontractors) and the role each will have in the project. It should also include a preliminary project schedule, equipment availability and status report, and the type of agreement (including reimbursement) anticipated, preferred, and/or acceptable to the contractor. *The personnel and project organization* should include a preliminary project organizational chart, identification of key project personnel (including alternates) and their resumes, and the availability of these individuals for the project. Although most contractors are unable to totally commit personnel in a RFQ response, they can supply a list of people who may be available for assignment. *Relative project experience* should address directly related operating experience, experience on projects similar to the one being considered, and any other project experience that the contractor wishes to include in the evaluation of his credentials. Client references should include company name, address, phone number, and contact person.

Upon receipt of the completed qualifications proposal, the owner's technical staff evaluates each contractor's qualifications carefully. Particular items requiring careful scrutiny are the contractor's previous experience in performing similar work, the ability to finance the contract mining portion of the project (purchase the required equipment, working capital, etc.), the work force (number and type of personnel) available, and the working relations with mine owners on existing and/or completed projects. Using this and similar data, the owner's technical staff can determine which bidders are qualified and reputable contract miners. Certain risks and problems are encountered, particularly in meeting production levels and maintaining grade control, when owners engage the services of a contractor with little or no mining experience.

As opposed to this formal procedure, an informal approach is more often used in the mining industry because of the close association of individuals and companies—particularly in distinctive segments of the mining industry. Each company has its own method of compiling a list of qualified contractors to be considered and included in the distribution of a request for proposal. Generally, these companies contact other mining companies that are or have been using contractors (industry recommendations) or rely on the internal resources of in-house personnel ("networking," the use of prior contact with individuals to determine appropriate contract miners for inclusion in the process). Business development personnel of contract miners can also provide a list of current and past experiences, along with client references.

The goal of this procedure is the same as for the formal procedure—to develop a list of qualified bidders. Although this method involves less time and money, it runs the risk of being influenced by the personal biases of the technical reviewers and/or decision makers.

In summary, once a mining company decides to employ a contract miner, it is desirable to select the most qualified contract miner. The compilation of a qualified bidder's list is one of the more important aspects of overall screening and selection of the contractor. Contract miners can provide valuable services; therefore, selection of the most qualified and reputable miner is an important decision to overall company performance.

6.4.3.2 Preparation of the Request for Proposal

In preparing the request for proposal (RFP), it is important to include as much pertinent information as possible. The topics that should be covered in a request for proposal are (1) scope of work, (2) site visit, (3) proposal due date, (4) proposal format, (5) contractual terms, (6) statement of qualifications, (7) acceptability of alternatives, (8) seasonal operating constraints, and (9) list of owner-furnished items.

The most important of this information is the scope of work. Without a complete scope of work, the job will not be bid accurately, and wide differences will exist between competing contractors. It then becomes very difficult to determine if this difference is due to a competitive edge or a misunderstanding of the work to be performed. If the winning contractor misunderstands the scope of work, then major problems often occur after the job commences that may force the contractor to renegotiate the agreement or possibly even default. The final result is delays in start-up, expensive cost overruns, and an adverse effect on the credibility of the contractor.

Scope of Work: A complete *scope of work* covers every aspect of the work expected of the contractor and any exclusions to be incorporated in the contractor's bid. Exclusions may comprise such items as operating crushing facilities and processing plants, mine planning, and construction of facilities.

The scope of work should include the following components:

1. *Expected Life of the Mine.* This is important to the contractor because it has great impact on the economics of almost all aspects pertaining to the contractor's bid, from equipment selection to unit prices.

2. *The Mining Schedule.* The mining schedule should include a timetable for major events during the life of the mine. These events may include initial construction completion dates, expected date of full-scale operation, significant shifts between mining areas, and periods of reduced or increased production levels. This timetable allows the contractor to determine when specific equipment is needed at the site and to anticipate manpower levels.

3. *Planned Mining Rates.* The owner's engineering staff should have a well-developed plan for the movement of ore and waste throughout the life of the mine to maximize cash flow and ore recovery rates. The life of the mine and the mining rate must be balanced to minimize operating costs and to avoid improper equipment selection. If the crushing or processing facilities have previously been selected, it is very important to include its capacities, along with any equipment size constraints that these may impose, such as maximum allowable size of the material fed to the crusher, feed rate of the crusher, etc.

4. *Detailed Mine Plans.* These plans should include all mining areas and associated phased production, as described in item 2. In addition, all construction required for site development, such as roads, shop and office locations, topsoil stockpiles, and impoundments that the contractor may be required to build, or must plan his work around, should be included. The physical layout of the mine, including bench heights, ramps and grades, stockpiles, waste dumps, crusher locations, leach pads or tailings ponds, and loadout facilities are of extreme importance to the contractor, if a competitive bid is to result. A well-engineered set of plans helps to alleviate any problems or questions that may arise about the scope of work. The thoroughness of these plans indicates to the contractor the level of mining competence that can be expected when the job commences. For example in underground mines, this section should make the contractor aware of final dimensions of all excavations, whether or not overbreak is acceptable, if ground support is required, if the excavation is to be a permanent installation with specifications or if it will be left to the contractor's discretion, depending on ground conditions. Details of timber or steel support structures must be clearly articulated. If significant amounts of water are anticipated, what facilities, both underground and on surface, will be required to handle the inflow?

5. *Miscellaneous Restrictions.* The scope of work must indicate any restrictions that may be imposed by the owner or as the result of specific geologic conditions. Typically, especially in precious-metal mines, the size of the blast patterns is restricted by the owner so that the drill cuttings can be used to determine ore grade and delineate ore zones. Environmental constraints, such as areas and methods for waste disposal or special material handling, should be carefully delineated. The abrasiveness and hardness of the material can greatly affect the type of equipment required, as well as the associated maintenance program.

For an underground mine, an accurate description is needed of the physical and administrative environment that will control the contractor's operation, underground construction, and mining operations' work in a restricted environment. These constraints, in part, are due to the physical limits placed on the excavations, but in a large sense they stem from the logistics of moving men, materials, and equipment in and out of the mine. The contractor must know if his operations are to be coordinated with other schedules and, if so, what are the rules that govern these schedules. The contractor also must be made aware of any unusual operating constraints that would affect performance. For example, do agreements with state or local authorities exist that restrict ground vibrations from blasting or other applicable restrictions?

Other Basic Information: In addition to the scope of work, there are a number of other basic items that should be included in the RFP. These items are just as important as the scope of work, although not nearly as comprehensive. Following is a list of some of the critical items that must be included, depending on site-specific circumstances.

1. *Invitation to Visit the Site.* Arrangements should be made for each potential bidder to make an on-site inspection. Proper coordination of this visit includes representatives of key personnel from the mine's management group in order to observe the contractor's team and assess the overall knowledge level of the team.

2. *Proposal Due Date.* A deadline for receiving all proposals from contractors must be specified and adhered to if subsequent problems are to be avoided.

3. *Proposal Format.* In order for the owner to properly evaluate and compare bids, there must be a stipulated format or form on which all contractors submit bids. This format should include specific tasks or functions for which the owner is requesting unit costs. In short, the bid form should include a method of pricing for every cost item described in the scope of work.

4. *Contractual Terms Required by Owner.* The owner may impose certain requirements or constraints on the contractor resulting from regulatory agencies, financial backers, or other agencies. Other terms may cover the recourse both parties have through errors and omissions in the bid, as well as arbitration procedures. Other items that may be included are proof of insurance, liability, clauses for termination or suspension, force majeure, clauses for agreement modifications, contractor's warranty, records and accounting, subcontracting, title to materials found, and agreement interpretation. Because of the important role these items play in maintaining the cooperation and working relationship between the owner and the contractor, fair allowances must be made for both parties in the agreement.

5. *Statement of Qualifications.* A statement of qualifications is required to assist the owner in selecting a competent contractor who can perform the job effectively. By allowing each bidder to state their qualifications and verifying information presented on past jobs, the owner can gain insight into how well each contractor performed on similar projects.

6. *Alternatives Developed by Bidding Contractors.* Some of the bidding contractors may develop alternative ideas concerning a portion of the scope of work that results in the same end product but may provide a competitive advantage to that contractor. The proposal should include a clause stipulating the amount of flexibility, if any, acceptable to the owner.

7. *Seasonal Operating Constraints.* Many jobs have seasonal constraints or are hampered by extreme weather conditions. Knowledge of these conditions is important to the contractor, since it directly affects equipment utilization, manpower fluctuations, and other operating procedures and costs.

8. *Owner-Furnished Utilities and Facilities.* If utilities are available at the site, then the local rates for these should be included, along with any utilities that may be furnished by the owner. If no utilities exist at the site, it is even more important to note this so the contractor can evaluate the needs and include appropriate provisions in the bid. This is also important for facilities, such as shops, offices, fuel and oil storage, water sources, and so on. Any plans for site locations of the contractor's facilities must be included in the proposal.

In summary, without a complete and comprehensive request for proposal, the owner will not receive accurate bids from contractors. When the RFP includes the type of information discussed, a congenial and cooperative atmosphere between the owner and successful bidder should prevail throughout the relationship.

6.4.3.3 Proposal Preparation by the Bidder

One of the most important considerations in preparing a proposal is often the most overlooked by bidders. The proposal must present information to the owner that outlines how the operator will meet the *needs of the owner.* The best starting point in preparing a proposal is to ascertain from the owner exactly what is expected from the successful bidder. This is accomplished through personal meetings, site visits, and a thorough review of the request for proposal. A well-prepared proposal outlines the human and financial resources, including experience, expertise, and equipment available to the contractor and how the contractor intends to mobilize these resources to the benefit of the owner.

The proposal should contain a clear description of the scope of services being offered. This may be accomplished in narrative and/or in reference to the request for proposal. A project plan should be offered describing specific components of the operator's proposed operations. This may include equipment lists, maintenance programs, safety programs, environmental safeguards, coordination with the owner, on-site support facilities, home-office support, and so on.

The proposal should also present an organization chart and the names of key individuals who will be assigned to the project, along with their resumes. Because each contractor may be bidding on several projects at the same time, it may be necessary to offer more than one person for each position. Listing more than one person for each position allows the owner to select his or her preference. It then becomes necessary during the pre-award meeting to commit specific people to the project.

Where appropriate, the contractor may include a project schedule indicating production rates and concurrence with the overall mine plan.

A good proposal also will contain a company resume giving background information and specific data on similar projects. Financial information, indicating that the company has the resources necessary to be responsive to the scope of the project, should be provided as well.

The commercial portion of the proposal should provide the unit price basis for compensation in the format provided in the request for proposal. Other information that should be included, if not required in the request for proposal, is the method of measuring work progress, schedule, procedure for invoicing, and the turnaround time for payment. The operator should delineate any special concerns or clarifications to requests made in the request for proposal.

The proposed contractor expects to perform a specific scope of work in a professional and profitable manner. Certainly the proposal is prepared with this in mind. The contractor must remember that the owner also has expectations for the planned venture. If the contractor prepares the proposal with consideration for these needs, the offering will receive a more favorable reception.

6.4.3.4 Evaluation of the Proposal

The most important aspect of the contract mining bidding process is the selection of a qualified and reliable contractor to perform the work. Evaluation of the proposal provides the owner an opportunity to select the best contractor available for the project. The mine owner, through the technical review team, must evaluate carefully the credentials of each bidder. Along with providing recommendations to management, the technical review team should narrow the field to two or three final candidates. The primary factors in the evaluation of contractors and the associated bids are (1) cost for the project (the price submitted by the bidders), (2) qualifications of the contractor and associated personnel, (3) availability of contractor equipment and personnel, (4) ability of the contractor to perform the required tasks, (5) contractual terms, and (6) owner/contractor relationship.

Cost alone should not be the deciding factor. A combination of all the foregoing factors, weighted by the importance of each factor to the owner, will yield the best selection. An evaluation and selection based on many factors is illustrated in 6.4.3.5.

The process is facilitated if the owner provides the contractor with an outline or format for the proposal to be submitted. The evaluation of all submitted proposals will be greatly simplified and the evaluation results more valid and consistent with the outline or format.

Cost: The contractor's bid "price" for performing the scope of work is the "cost" to the owner. The contractor's proposal is the entire document submitted, while the bid is the "price" or "cost" section of the proposal.

If the proposal is organized and properly detailed, the cost portion of the bid should be the easiest portion to analyze and evaluate. In order to compare the bids, unit costs must be converted to total dollars for the scope of work to be performed by the contractor on an annual or period basis. The owner also should evaluate the sensitivity of costs to changes in conditions. For example, the following questions need to be addressed. How will gold price fluctuations affect the owner's costs incurred? What would be the effect on profitability and continued operation of the mine if the price of gold rose to $600/oz ($19.29/g) or fell to $200/oz ($6.43/g)? Also, what would be the effect on the mine plan and the ratio of waste to ore tons if the price of gold rose to $600/oz ($19.29/g) or fell to $200/oz ($6.43/g)? What would be the effect if the ore control, based on blasthole drill samples, found more or less ore than planned? What would be the effect if processing the ore was more or less efficient, in terms of both processing costs and recoveries, than planned?

In evaluating the prices submitted by the contractor, two main methods of analysis generally are used: (1) total cost for the work provided by the contractor and (2) project discounted cash flow. The *total cost method* involves determining the total cost of the bid by multiplying the unit costs by the expected volumes and adding any lump sum bid items. The *discounted cash flow method* involves converting the costs into total dollars for each time period and discounting this stream of cash flows at an appropriate discount rate to determine the present value of the cost of the bid. The total cost method has the advantages of being simpler to analyze, appropriate for short contracts, and suitable for constant volumes/tonnages of material to be moved. The discounted cash flow method is more complex to perform; however, it has distinct advantages for longer-term contracts and is suitable for changing volumes/tonnages of material to be moved. When in doubt, the discounted cash flow method is recommended for all comparative analyses.

Three examples are provided to illustrate these two methods for bid comparison and evaluation. The first example (6.4.1) shows the effect of different lump sum mobilization costs with the appropriate changes in unit prices (cost) on the evaluation of bids. The second example (6.4.2) shows the effect of changing volumes over time on the evaluation of bids. The third example (6.4.3) illustrates the difference in single unit price bidding vs. unit prices as a function of production levels and years.

The analyses are simplified to enable easy analysis and explanation. The numbers utilized are selected to provide a contrast between the two methods and are not necessarily representative of actual prices for any specific set of mining conditions. The present value (present cost) determination is simplified in these analyses by not considering tax implications, assuming constant production rates throughout each year, assuming end-of-year cash flows for the annual costs, and by not considering the effect on working capital. A 15% discount rate is used to determine the present value (present cost).

Example 6.4.1. Mobilization Costs vs. Unit Price.

The bid prices received from contractor X and contractor Y are shown in Chart 1.

Chart 1

	Bids	
Bid Volumes	Contractor X	Contractor Y
Mobilization	$600,000	$200,000
Year 1 — 1,000,000 tons	$1.00/ton	$l.10/ton
Year 2 — 1,000,000 tons	$1.00/ton	$l.10/ton
Year 3 — 1,000,000 tons	$1.00/ton	$1.10/ton
Year 4 — 1,000,000 tons	$1.00/ton	$1.10/ton
Year 5 — 1,000,000 tons	$1.00/ton	$1.10/ton

Solution. Total Cost Analysis Method.

The bid unit prices are converted to total dollars per year and added to the mobilization cost to determine the total cost. (See Chart 2.)

Chart 2

Bid Volumes	Contractor X	Contractor Y
Mobilization	$ 600,000	$ 200,000
Year 1 — 1,000,000 tons	$1,000,000	$1,100,000
Year 2 — 1,000,000 tons	$1,000,000	$1,100,000
Year 3 — 1,000,000 tons	$1,000,000	$1,100,000
Year 4 — 1,000,000 tons	$1,000,000	$1,100,000
Year 5 — 1,000,000 tons	$1,000,000	$1,100,000
Total	$5,600,000	$5,700,000

The lowest cost bid utilizing this analysis is contractor X, with a total undiscounted cost difference of $100,000.

Solution. Discounted Cash Flow Analysis Method.

Using the annual cash flows developed previously, the present value of these costs is calculated. The discount factors illustrated in Chart 3 represent a 15% discount rate.

Chart 3

Year	Discount Factor	Contractor X	Contractor Y
−1	1.00000	$ 600,000	$ 200,000
1	0.869565	$ 869,565	$ 956,522
2	0.756144	$ 756,144	$ 831,758
3	0.657516	$ 657,516	$ 723,268
4	0.571753	$ 571,753	$ 628,928
5	0.497177	$ 497,177	$ 546,895
Total		$3,952,155	$3,887,371

The lowest cost bid by this analysis is contractor Y, with a cost difference of $64,784.

Note that the analysis method affected the results of the analysis and the preferred contractor based only on the bid cost. This example shows that the discounted cash flow method is clearly superior for comparisons of this type.

Example 6.4.2. Changing Volumes Over Time.

Bids have been received from contractor X and contractor Y as shown in Chart 4.

Chart 4

	Bids	
Bid Volumes	Contractor X	Contractor Y
Mobilization	$600,000	$200,000
Year 1 — 1,500,000 tons	$1.00/ton	$l.10/ton
Year 2 — 1,500,000 tons	$1.00/ton	$1.10/ton
Year 3 — 1,000,000 tons	$1.00/ton	$1.10/ton
Year 4 — 500,000 tons	$1.00/ton	$1.10/ton
Year 5 — 500,000 tons	$1.00/ton	$1.10/ton

Solution. Total Cost Analysis Method (Chart 5).

Chart 5

Bid Volumes	Contractor X	Contractor Y
Mobilization	$ 600,000	$ 200,000
Year 1 — 1,500,000 tons	$1,500,000	$1,650,000
Year 2 — 1,500,000 tons	$1,500,000	$1,650,000
Year 3 — 1,000,000 tons	$1,000,000	$1,100,000
Year 4 — 500,000 tons	$ 500,000	$ 550,000
Year 5 — 500,000 tons	$ 500,000	$ 550,000
Total	$5,600,000	$5,700,000

The lowest cost bid by this analysis is contractor X, and the total cost difference remains at $100,000.

Solution. Discounted Cash Flow Analysis Method.

Using the annual cash flows developed previously, the present value of these costs is calculated. The discount factors illustrated in Chart 6 represent a 15% discount rate.

Chart 6

Year	Discount Factor	Contractor X	Contractor Y
−1	1.000000	$ 600,000	$ 200,000
1	0.869565	$1,304,348	$1,434,782
2	0.756144	$1,134,216	$1,247,638
3	0.657516	$ 657,516	$ 723,268
4	0.571753	$ 285,876	$ 314,464
5	0.497177	$ 248,589	$ 273,447
Total		$4,230,545	$4,193,599

Lowest cost bid by this analysis is contractor Y, but the cost difference is only $36,946.

Note that the analysis method affected the results of the analysis and the preferred contractor based only on the bid cost.

Example 6.4.3. Single Unit Pricing vs. Variable Unit Pricing.

Bids have been received from contractor X and contractor Y as shown in Chart 7.

Chart 7

	Bids	
Bid Volumes	Contractor X	Contractor Y
Mobilization	$600,000	$600,000
Year 1 — 1,500,000 tons	$1.00/ton	$0.90/ton
Year 2 — 1,500,000 tons	$1.00/ton	$0.90/ton
Year 3 — 1,000,000 tons	$1.00/ton	$1.00/ton
Year 4 — 500,000 tons	$1.00/ton	$1.35/ton
Year 5 — 500,000 tons	$1.00/ton	$1.35/ton

Solution. Total Cost Analysis Method (Chart 8).

Chart 8

Bid Volumes	Contractor X	Contractor Y
Mobilization	$ 600,000	$ 600,000
Year 1 — 1,500,000 tons	$1,500,000	$1,350,000
Year 2 — 1,500,000 tons	$1,500,000	$1,350,000
Year 3 — 1,000,000 tons	$1,000,000	$1,000,000
Year 4 — 500,000 tons	$ 500,000	$ 675,000
Year 5 — 500,000 tons	$ 500,000	$ 675,000
Total	$5,600,000	$5,650,000

Lowest cost bid by this analysis is contractor X, and the total cost difference is $50,000.

Solution. Discounted Cash Flow Analysis Method.

Using the annual cash flows developed previously, the present value of these costs is calculated. The discount factors illustrated in Chart 9 represent a 15% discount rate.

Chart 9

Year	Discount Factor	Contractor X	Contractor Y
–1	1.000000	$ 600,000	$ 600,000
1	0.869565	$1,304,348	$1,173,913
2	0.756144	$1,134,216	$1,020,794
3	0.657516	$ 657,516	$ 657,516
4	0.571753	$ 285,876	$ 385,933
5	0.497177	$ 248,589	$ 335,594
Total		$4,230,545	$4,173,750

The lowest cost bid by this analysis is contractor Y, and the cost difference is $56,795.

Note that the analysis method affected the results of the analysis and the preferred contractor based only on the bid cost.

As illustrated by the foregoing examples, selection of the type of analysis influences the results and the selection of the preferred contractor based only on the bid cost evaluation. The type of analysis employed by the owner should be communicated to the contractor, because the contractor may structure a bid to enhance his competitive position and still meet their financial goals using the concept of equivalency resulting from time value of money concepts. It is necessary to reiterate the fact that cost is only one of several factors requiring consideration when evaluating proposals from contractors. A total evaluation and selection is illustrated in 6.4.3.5.

Qualifications: Qualifications of the contractor and associated personnel are important to project success. The owner should evaluate the experience of the contractor and staff in performing the type of project envisioned and similar projects completed. Important issues relate to questions, such as, does the contractor recognize the importance of ore control? How does ore control impact the viability of the project? Does the contractor have appropriate personnel on the project (e.g., a mine engineer and safety engineer) to perform the required tasks? Can the contractor mobilize equipment and personnel in an appropriate time frame to meet the owner's schedule?

During the technical evaluation of the proposals, a suitable rating system should be utilized to insure appropriate ranking of the various proposals and contractors. The rating system (see 6.4.3.5) must be developed by the owner to perform the tasks expected of the contractor. For example, if water control is a major concern, the availability or on-staff placement of a hydrologist should be reflected in the ratings.

If the owner does not desire to develop a complex rating system, the technical evaluation should at least rank the proposals in general terms for the qualifications of the contractor and associated personnel.

Equipment and Personnel Availability: Although the contractor must have the senior-level staff personnel and equipment necessary to perform the required tasks, it is usually preferable, for both the owner and the contractor, to hire a maximum number of local qualified personnel to ensure a stable work force. For the proposal, the contractor should provide a list of individuals to be considered for the project, with some positions listing more than one person if the contractor so desires. The listing of several candidates allows the owner to select from several individuals and, therefore, obtain the best-suited personnel for the project. Once a short list of two or three contractors is developed, a firm commitment can be solicited for the personnel desired on the project.

The equipment required to perform the scope of work can either be part of the contractor's existing fleet or purchased specifically for the project from vendors. The owner should inquire into the availability of major pieces of equipment from the contractor's fleet or availability from vendors. Along with equipment availability, the owner should check into the condition of the equipment to insure that it is capable of handling the work required. The performance of the contractor in providing equipment for previous projects also provides additional information for the evaluation of the proposal.

As with the contractor's qualifications, a rating system should be developed to rank the various candidates. The rating system and the weighting of each variable should reflect the importance given to the availability of personnel and equipment.

Ability to Perform: The ability of the contractor to perform the required tasks should be reviewed, including both financial and execution abilities. Financial ability can be determined by a review of the financial status of the contractor. The owner must establish if the contractor has the financial strength to purchase the required equipment and to provide necessary working capital to perform the work specified. An analysis of the annual report, plus other financial reports requested in the RFP along with research on the level of performance on previous contracts, should provide the information necessary for the evaluation.

The contractor's ability to execute the required tasks must be assessed by the owner. Can the contractor hire, train, and maintain a stable and qualified work force? The factors necessary to develop a rating system in this critical area are obtained primarily from previous work on other similar projects.

As stated previously, a rating system should be developed to rank the various candidates. The rating system and the weighting of this area should reflect the importance given to the contractor's ability to perform.

Contractual Terms: The contractual terms of the agreement must be acceptable to both the owner and the contractor. Each party to the agreement should review the concerns of the other to determine the relative importance of the conditions requested. Although the owner usually rates this area either "acceptable" or "not acceptable," the owner may wish to rank the concerns expressed by the contractor in relation to their importance. If the variances requested by the contractor are not acceptable, the owner should contact the contractor to determine the reason and the importance of the variance and the acceptability of alternative wording or conditions.

Owner/Contractor Relationship: The most important aspect of the evaluation is the owner/contractor relationship. An adversarial relationship creates additional work for both parties and probably impacts the overall cost and profitability of the project. The owner should check the relationship the contractor has or had with other clients on several current and/or previous projects. It must be remembered that the owner/contractor relationship is a two-way street. As stated for the other factors, the owner should develop a rating system on owner/contractor relationship for ranking the proposals.

6.4.3.5 Selecting the Contract Miner

Selecting the contract miner for a project should be relatively simple if the steps for developing the bid list and preparing the request for proposals previously discussed are followed completely. It is very important for the selection process to incorporate analysis of all parameters and not cost only.

Selection Criteria: Before the bids are received, the owner should develop a selection system based on criteria determined to be reasonable for the organization and the job to be performed. The selection system should be based on the criteria established and the weighting of those criteria. A sample system is described in the following paragraphs.

A sample selection weighting table is shown in Example 6.4.4 that follows. The factors were taken from the evaluation criteria discussed earlier in the chapter. After the factors have been established, ranking of the factors should be determined. Cost, although not the only factor, is usually ranked as the most important factor. The ability to perform the job was determined to be the second most important factor because the owner wants to be assured that the desired work is performed satisfactorily. The third factor is the qualifications of the contractor and his personnel, followed by the owner/contractor relations. The contractual terms factor was determined to be fifth in importance, followed by the availability of equipment and personnel. The owner may have other factors to add to the list or he may put more or less importance on each. However, this system should be developed prior to receipt of proposals so as to remove any bias that may develop after the bids are received. A sample set of factors and weighting is shown in Chart 10.

Example 6.4.4. Contractor Selection.

Chart 10. Weighting Table

Factors	Ranking		Weighting
Cost	1		40%
Qualifications — Contractor		9%	
— Personnel		9%	
Total	3		18%
Availability — Equipment		2%	
— Personnel		2%	
Total	6		4%
Ability to perform	2		20%
Contractual terms	5		5%
Owner/Contractor relationship	4		13%
Total			100%

Solution. A simplified sample evaluation is provided based on a fictitious request for proposal. The RFP was for a precious-metal mine in Nevada with production requirements as shown in Chart 11.

Chart 11. Production

Year	Tons
1	1,000,000
2	2,000,000
3	2,000,000
4	1,500,000
5	1,000,000
Total	7,500,000

Five bids were received with the pricing as shown in Chart 12.

Chart 12. Prices ($/ton)

Year	Contractors # 1	# 2	# 3	# 4	# 5
Mob	$800,000	$400,000	$200,000	$400,000	$300,000
1	$1.50/ton	$1.25/ton	$1.60/ton	$1.70/ton	$1.40/ton
2	$1.00	$1.25	$1.15	$1.20	$1.35
3	$1.00	$1.25	$1.15	$1.20	$1.35
4	$1.20	$1.25	$1.30	$1.30	$1.30
5	$1.40	$1.25	$1.50	$1.40	$1.30
Demob	$600,000	$200,000	$200,000	$400,000	$300,000

The total annual costs are shown in Chart 13.

Chart 13. Annual Costs ($)

Year	Contractors # 1	# 2	# 3	# 4	# 5
—1	$ 800,000	$ 400,000	$ 200,000	$ 400,000	$ 300,000
1	$ 1,500,000	$1,250,000	$ 1,600,000	$ 1,700,000	$ 1,400,000
2	$ 2,000,000	$2,500,000	$ 2,300,000	$ 2,400,000	$ 2,700,000
3	$ 2,000,000	$2,500,000	$ 2,300,000	$ 2,400,000	$ 2,700,000
4	$ 1,800,000	$1,875,000	$ 1,950,000	$ 1,950,000	$ 1,950,000
5	$ 1,400,000	$1,250,000	$ 1,500,000	$ 1,400,000	$ 1,300,000
6	$ 600,000	$ 200,000	$ 200,000	$ 400,000	$ 300,000
Total	$10,100,000	$9,975,000	$10,050,000	$10,650,000	$10,650,000

The proper evaluation technique for a project of this duration is a discounted cash flow analysis. The present value determination was simplified by not considering tax implications, assuming constant production rates throughout each year, assuming end-of-year cash flows, and not considering the effect on working capital. Using a 15% discount rate, the present value of the cash flows was calculated and is shown in Chart 14.

Chart 14. Present Value of Cash Flows

Year	Contractors # 1	# 2	# 3	# 4	# 5
—1	$ 800,000	$ 400,000	$ 200,000	$ 400,000	$ 300,000
1	$ 1,304,348	$1,086,956	$ 1,391,304	$ 1,478,261	$ 1,217,391
2	$ 1,512,288	$1,890,360	$ 1,739,131	$ 1,814,746	$ 2,041,589
3	$ 1,315,032	$1,643,790	$ 1,512,287	$ 1,578,038	$ 1,775,293
4	$ 1,029,155	$1,072,037	$ 1,114,918	$ 1,114,918	$ 1,114,918
5	$ 696,048	$ 621,471	$ 745,766	$ 696,048	$ 646,330
6	$ 259,397	$ 86,466	$ 86,466	$ 172,931	$ 129,698
Total	$ 6,916,268	$6,801,080	$ 6,789,872	$ 7,254,942	$ 7,255,219

These figures illustrate that the lowest bid in total dollars is not necessarily the lowest cost to the owner. In this case, the lowest present value is actually the second lowest bid.

The information submitted by the contractors (except cost), based on the criteria listed above in the weighting table, is summarized as follows.

Qualifications

Contractor

#1 A large and experienced contractor miner with 10 operating mines.

#2 A highway contractor with no mining experience but has many years in highway construction.

#3 A highway contractor with one small operating mine and considerable experience in highway construction.

#4 A small contract mining company with 2 small operating mines.

#5 A combination highway contractor and contract miner with operating contract mines.

Personnel

#1 The project manager is a mining engineer with 20 years experience, all in metal mines. The foremen have 5 to 10 years experience, mostly in mines. The engineer is a mining engineer with five years experience, all in metal mines.

#2 The project manager is nondegreed with 20 years experience in highway construction, but none in mining. The foremen have 5 to 10 years experience in highway construction, but none in mining. The contractor is not planning to have an engineer on the job.

#3 The project manager is a civil engineer with 15 years experience of which 2 years were in a metal mine. The foremen have 5 to 10 years experience with half of the foremen with two years in a metal mine. The contractor proposes to use a civil engineer from the home office on a part-time basis.

#4 The project manager is a mining engineer with 10 years experience, half in metal mines and half in coal mines. The foremen have an average of five years of experience with about half of them experienced in metal mines. The engineer is a mining engineer with five years experience in metal mines.

#5 The project manager is a civil engineer with 20 years experience, half in metal mines and half in highway construction. The foremen have 5 to 15 years experience with half of the foremen having half of their experience in metal mining. The contractor proposes to use a mining engineer from the home office on a part-time basis.

Availability

Equipment

#1 The major pieces of equipment will come from existing mines with 10% being purchased new from equipment companies. The used equipment is two to three years old and in reasonably good shape.

#2 Approximately 75% of the equipment will be purchased new with 25% of the equipment purchased used, and only a minor amount will be obtained from the existing highway construction fleet. The new equipment is available from the vendors, currently under conditionary order, and in the vendor's inventory.

#3 Approximately 30% of the equipment will be purchased new, 50% of the equipment will be purchased used, and the remaining 20% will be obtained from the existing mine operation or from the existing highway construction fleet. The exact equipment for purchase has not been identified.

#4 Approximately 50% of the equipment will come from existing mines, 25% will be purchased new, and 25% will be purchased used. Existing equipment is in good condition. The used equipment has not been located. The new equipment is under conditionary order and in stock.

#5 Most of the equipment will come from existing mines, 10% will be purchased used, and 10% will be purchased new. Existing equipment is in fair to poor condition.

Personnel

#1 All personnel are available from existing mines, and they have provided two to three alternative persons for the significant positions.

#2 Most of the personnel are available from existing construction jobs, with only minor positions hired for this project.

#3 Most of the personnel are available from existing mines, but half of the foremen are hired from outside the company.

#4 Over half the personnel are available from existing mines, but half of the foremen and the mine engineer are hired from outside the company.

#5 Over half the personnel will be hired from outside the company, including the mine manager and the mine engineer.

Ability to Perform

#1 The contractor has proven his ability to perform from existing mining operations and has developed well-run operations in difficult situations.

#2 Although the contractor does not have experience in mining, he has proven his ability to perform well on highway construction work in difficult situations.

3 The contractor has limited experience in mining and has had difficulty in satisfactorily meeting performance standards of the project for both the mine and some of his construction projects.

#4 The contractor has limited experience in mining but has performed acceptably in the two mines he is currently operating.

#5 The contractor has had some difficulty in one of the mines he is currently operating but has performed well in the other mines and has an excellent reputation as a highway contractor.

Contractual Terms

#1 The contractor took exception to many terms and conditions of the draft contract transmitted with the RFP that the owner believes to be important. The contractor has expressed a desire to negotiate with the owner.

#2 The contractor accepted the draft contract as transmitted with no exception.

#3 The contractor took only one exception to the draft contract; it was a minor clause that the owner has no objection to changing.

#4 The contractor has expressed a desire to discuss several of the major terms and conditions.

#5 The contractor took exception to a few of the major terms and conditions and many of the minor terms.

Owner/Client Relationship

The owner has contacted all of the clients of the contractors with mining operations and most of the clients of the contractors with highway construction work. A list of questions was compiled to insure that all clients were asked the same questions. Also the owner provided space for general comments on the relationship with the clients.

#1 All clients made favorable comments about this contractor. They commended the contractor on his working relationship with them to make a better project for both the contractor and the client.

#2 All clients made favorable comments about this contractor.

#3 Most of the highway construction clients made acceptable comments about the contractor but indicated that some problems had occurred. The client for the mining project expressed some concern about the contractor's desire to work with the client.

#4 The clients had generally favorable comments to make about the contractor, but they also stated that no serious problems had occurred to test the working relationship.

#5 Most of the clients, both from the highway work and the mines, had good comments, but one of the mining clients and one of the highway clients had problems in dealing with the contractor.

With the information describing the proposals that were received for this project, the owner now ranks each of the factors for each of the contractors, as shown in Chart 15. The ranking for each factor has a maximum of 10 points. Receipt of 10 points is a perfect score for that particular factor, or is the lowest bid in the case of costs. The procedure used for quantifying the cost factor in the system devised is 10 points minus the percentage difference in price. For example,

Lowest bid (present worth) = \$6,789,872

Bid being evaluated = \$6,916,268

$$\text{Percentage difference} = \frac{\$6,916,268 - \$6,789,872}{\$6,789,872} \times 100$$

$$= 1.862\%$$

Ranking = 10 – 1.862 = 8.138

Chart 15. Table of Ranking

Factors	Contractors 1	2	3	4	5
Cost	8.138	9.835	10.000	3.151	3.588
Qualifications — Contractor	10	5	7	7	9
— Personnel	9	5	7	9	8
Availability — Equipment	8	9	5	7	3
— Personnel	10	9	7	5	2
Ability to perform	10	8	3	9	6
Contractual terms	2	10	9	7	5
Owner/Contractor relationship	10	9	6	8	3

Now that the factors have been ranked for each of the contractors, the table for determining the selection can be made. The selection table (Chart 16) uses the ranking for each contractor for each factor and the weighting of each of the factors to quantify each factor for each contractor in relation to the other contractors. The selection table that follows quantifies the example given:

Chart 16. Selection Table (Ranking times Weighting)

Factors	Contractors				
Cost	3.255	3.934	4.000	1.260	1.435
Qualifications — Contractor	0.900	0.450	0.630	0.630	0.810
— Personnel	0.810	0.450	0.630	0.810	0.720
Availability — Equipment	0.160	0.180	0.100	0.140	0.060
— Personnel	0.200	0.180	0.140	0.100	0.040
Ability to perform	2.000	1.600	0.600	1.800	1.200
Contractual terms	0.100	0.500	0.450	0.350	0.250
Owner/Contractor relationship	1.300	1.170	0.780	1.040	0.390
Total	8.725	8.464	7.330	6.130	4.905

Using the system described, the successful contractor is #1, even though he did not have the lowest cost bid. The lowest bid submitted actually ranked third in the final analysis. This system states that factors such as "ability to perform," "qualifications," and "owner/client relationship" are important in the selection of a mining contractor. This system helps to ensure that the mine will be successful in the mining of the ore, the removal of the waste, and achieving the lowest total cost for the product being extracted.

6.4.3.6 Writing the Agreement

Two points should be considered as the owner and contract miner negotiate an agreement. First, the primary objective of each company is wealth maximization, as discussed in the Introduction, 6.0. The best agreement is one where this goal can be achieved by both parties, and the best project is one where all parties benefit. As soon as either party to the agreement begins to lose money or feels that a *fair* rate of return is not being achieved, the entire relationship typically deteriorates to the detriment of the project. Presumably, a negotiated agreement represents an agreement perceived to be equitable and fair to both parties. Events occurring after the agreement is negotiated may alter this situation, although this alone is rarely a reason to renegotiate unless both parties agree to do so. The contract miner should not look at the profits of the owner and feel he deserves a greater share. The proposal was made on the basis of a reasonable return, and the contract miner should be satisfied with that. At the same time, the owner should not begrudge profits of the contract miner but realize these are the cost of doing business. This relationship can be complex; it also must be based on both parties being reasonable and acknowledging the need for adjustments as a result of changes encountered during performance of the agreement.

Second, the contract miner is usually a construction company, and historically, performance is measured by increased production. The client, or owner in this case, generally has a stipulated production schedule and may not be interested in increasing the materials-handling portion of the operation beyond the capacity of the downstream recovery or processing facilities. The primary considerations usually are for constant production with much care given to the segregation of ore from waste. This requires a philosophical adjustment for the contract mining company—one that is best learned through experience. The owner should ensure that this requirement is understood and defined clearly in the agreement.

Preparing a good agreement sets the stage for a good project. The documents should be as detailed as possible in outlining the specific responsibilities of both parties. The parties to the agreement should be identified, along with any contractual obligations of parent companies or other third parties. A detailed scope of work is critical to obtaining desired performance in all areas covered by or affected by the contract miner. Specific responsibilities should be delineated based on the mine plan, the subsequent request for proposals, and the final bid documents. Quantities and production rates must be specified, and limits to variations on these figures must be established. (This is required because the contract miner based his proposal on crews, equipment, and support required to operate efficiently at a given production rate. Decreasing production by one-half does not decrease costs by an equal amount.) The specifications used during the bidding phase should be made part of the agreement. These specifications normally include such items as mine drawings, mine design, and operating criteria. The contract miner's proposal also should be made part of the agreement. In addition, any qualifications, assumptions, or clarifications made by the contract miner in developing the bid should be included.

Another important item that should be included in the agreement is the procedures between the owner and contract miner for coordinating identification and segregation of ore and waste. Responsibility for support activities, such as surveying, sampling, laboratory analysis, etc., also should be specified. Typically, samples are taken during drilling, and analysis is completed with sufficient lead time such that the contract miner is able to keep equipment and crews fully occupied. The plan and agreement should allow enough flexibility of operation so the project will not become ore-bound or waste-bound. The owner should realize that if this limitation is not avoided, the contract miner will incur expenses for equipment downtime.

A good agreement also has provisions for the contract miner to be compensated for work that becomes necessary but is not outlined in the specific responsibilities section of the agreement. This usually takes the form of hourly or daily rates for personnel and equipment, sometimes called "Force Account" rates. With such a provision, the owner is provided flexibility in calling on the contract miner to perform small, nonproductive activities such as access roads, snow removal, pad construction, etc.

The agreement should also list the responsible party for utility costs and installation, along with any limitations that may exist.

The financial or payment section of the agreement can be quoted as unit price, fixed price, or cost-plus-a-fee. The unit price contract is the type of agreement used most often for contract mining. The agreement has a unit price per weight or volume for the production plus, typically, lump sum payments for items such as mobilization, demobilization, etc. The fixed price contract is not generally used in contract mining. Its pricing is a lump sum for the work to be performed. The cost-plus-a-fee type agreement is not typically used in contract mining. It reimburses the contractor for his costs plus a fee established by the agreement.

Where the agreement duration is over one year, provisions should be made for escalation and de-escalation based on a weighted formula using various price indexes (labor, fuel, explosives, etc.). The premise is that as prices escalate, the market price of the salable product will move in the same direction, and the parties will maintain equality in the agreement. Without such a provision, the owner is asking the contract miner to assume all risks resulting from inflation—a risk he generally is hesitant to take. If provisions for escalation are not included in the agreement, the contract miner would include a contingency in the price and that contingency would probably be more expensive than having the owner assume the risk. In most contract mining agreements, the owner accepts and bears the risk of inflation. For a more detailed discussion, read the appropriate section in Gentry and O'Neil (1984).

The financial or payment section also should stipulate the method for measuring work performed, price schedule, invoicing and payment timing requirements, and other pertinent information. Delineation of the pay items should stipulate the responsible party for measurement, method of measurement, and any verification documents required.

Other primary sections must be included in the agreement to address mutually acceptable terms concerning changed conditions, premium and penalty, liability and indemnification, disputes, delays (force majeure provisions), suspensions, terminations, and default. These sections often require the greatest amount of discussion to reach a mutually agreeable agreement. Premiums and penalties should be used together so that the contractor is not only motivated to avoid penalties, but also to obtain premiums. The areas for premiums and penalties, if used, require accurate and readily definable terms and conditions.

Additional contract sections should include methods for modifying the agreement, the assignability of the agreement, and methods of notification and communication between the parties.

The agreement should include as much written detail and definitions as practical. It should anticipate and provide for solutions to unanticipated conditions that may occur at a later date. Provisions should be flexible enough to accommodate actual field conditions. If this approach is used in writing the agreement, it will be to the mutual benefit of all parties, and disagreements during the performance of the agreement should be minimized.

6.4.3.7 Typical Agreement Headings

Table 6.4.1 lists the headings of topics typically addressed in an agreement. Every agreement is different, because one agreement can not cover all the specifics of each different type of mine operations, property characteristics, commodities, contract miner attributes, and owner traits.

6.4.4 MONITORING THE CONTRACT MINER

Monitoring the contract miner's performance is important to ensure that the contract miner is performing the work desired by the owner to make the project a profitable venture. Monitoring the various risk factors discussed subsequently greatly assist in assuring profitability. Mining always has been and continues to be a complex and risky business. It is rare to have an initial mine design and plan remain constant through the start-up and production of an operation without experiencing at least some major changes.

These changes may be aligned with metallurgical or materials handling characteristics of the ore body and could dictate many changes to the operation. The results of these changes could include revised mine plans; changed mining practices, including ore control; and modified contractual terms, including mining volumes, prices, and equipment. The changes could even dictate closure or sale of the project before, during, or after development.

The owner's risk in developing a new project can be affected by many factors, such as overall mining and recovery methodology; recovery characteristics of the ore; front-end capital investments for exploration, acquisition, and development; ore tonnage and grade; metal sales; marketing strategy; and variations due to external factors. Monitoring the contract miner lessens the owner's risk by competitive bidding and selection, grade control, mining practice, mine design, contract terms, pricing, overall performance, visibility, working relationships, equipment, and productivity.

The owner can lessen overall project risk through the selection of a competent contract miner. Selection of the wrong contractor will lead to increased management requirements on the part of the owner, as well as increased costs due to poor overall performance.

The secret to making a contract mining situation work becomes one of mutual understanding and trust of each party's problems. Therefore, the concept of working together toward a common goal should be the first objective of both parties.

6.4.4.1 Owner/Contract Miner Interface

The contract miner and owner interface at many places in the mine operation. The contract miner must attempt to use the equipment to ensure optimum productivity at minimum cost. Grade control procedures are normally the owner's responsibility to design and implement. However, if ore is hauled to the waste dump and waste is hauled to the crusher, both parties loose. The owner must design the pit, haul roads, and dumps to effect low-cost production and should continually work with the contractor to improve designs. The contractor also should be formulating better and improved ways to perform his work. An effective design must be produced and implemented to control the project. Contract terms must be monitored on a continual basis to ensure factual record keeping and to ensure that engineering information is being produced and monitored. Payment and material production schedules must be agreed to on a regular basis.

The overall performance of the contractor is very important in terms of perception by outsiders. If the mining contractor has continual difficulty meeting the agreed upon goals, the end result will not be achieved and the owner will incur economic loss, and credibility problems will result. The owner must monitor the visual appearance of the premises and mode of operation conducted by the contractor. Sometimes the wrong picture will negatively impact future opportunities for both parties. The working relationship and openness of the owner/contractor can impact each party. As an example, a wage increase given by the contractor could impact the owner in other areas of the mine. These items affect overall labor relations and need to be discussed and planned in advance to lessen negative impacts. As the contractor works on the owner's property, the protection of property should be considered with respect to contamination and damage through misuse. The selection of equipment by the contractor should be discussed with the owner to avoid a mismatch and offset any potential productivity problems. Environmental issues must be discussed by both parties and impacts to performance levels and expectations addressed immediately. Impacts on towns and communities should be a concern of both owner and contractor with regard to quality of work force, services, etc.

Both parties must be good citizens. Human welfare and safety are a common concern.

6.4.4.2 Formal Methods of Implementation

Formal methods of implementation should include regularly scheduled production meetings; material reports on daily, weekly, and monthly basis; monthly billing and audit sequence; quarterly operations review; and ongoing communication in the working environment.

6.4.5 MINE LEASING PROCESS

The purpose of leasing a mining property to a mining company or other entity is to transfer some or all of the rights to explore, develop, and operate the property to a company in exchange for certain considerations such as cash, royalty provisions, or other type of reward. This section discusses in general the mine leasing process and the major items for consideration in leasing a property. The process is discussed in the following order: (1) property evaluation, (2) property rights, (3) objectives and goals, (4) marketing the property, (5) negotiating the lease, and (6) an outline of a mining lease. In this section, the *lessor* is referred to as the person or entity who owns or controls the property and is desiring to lease the property to another person or entity. The *lessee* is referred to as the person or entity who is obtaining operating and ownership rights to a property through the lease.

6.4.5.1 Property Evaluation

An accurate and objective evaluation of the property is essential in the leasing process. Without appropriate knowledge of the value of the property, it is difficult to determine the objectives and goals for leasing the property, marketing the property, or negotiating a lease. Other chapters in this section (e.g., 6.1 and 6.2) go into details of property evaluation.

6.4.5.2 Property Rights

When leasing a mining property, it is important to specify the property rights that are being sold or transferred. The main types of property rights are (1) fee land, (2) unpatented mining claims, (3) patented mining claims, and (4) leased land from a private landowner or governmental entity. A title examination is important to determine who has title to the property and what rights they have to the property. Other chapters in this *Handbook* (e.g., 3.2 Mining Law) go into details of title examination. Property rights may be restricted to one or some or all of the minerals, to surface or underground mining rights, or restricted surface rights with the mineral rights, or total surface and mineral rights. The end product should be an accurate title report of the property to be leased and the rights pertaining thereto.

6.4.5.3 Goals and Objectives

The goals and objectives of the lessor are critical to the leasing process. The goals of the leasing process should be developed in detail and thoroughly defined so that the lessor can direct the process to achieve those goals. The lease must contain the necessary incentives and provisions to ensure that lessor goals and objectives are accomplished.

6.4.5.4 Marketing the Property

Before the lessor starts to market the property, he must determine to whom he wants to market the property and how much is he willing to spend on the marketing effort. The major types of entities who may lease a mineral property are established mining companies, new or recently established mining companies, organizations desiring to become mining companies, and promotional companies.

The major ways to market a property are to (1) advertise it, (2) list the property with a real estate broker, (3) list the property with a listing agency, and (4) direct contact with mining companies or venture capital firms who promote mining properties.

The places to advertise a property are (1) in local and/or regional newspapers, (2) in national newspapers, (3) in trade publications, and (4) at trade shows and conferences. The latter two places listed provide better direction to potential lessees.

6.4.5.5 Negotiating a Lease

In negotiating a lease, it is important to remember that the lease must be fair to all parties involved in the lease or problems will occur throughout the life of the lease. The "real" objectives of the lessor and the lessee must be understood at the start of negotiations. The lessor must determine if production or simply income is the primary objective. The lease must be site-specific and product-specific because general leases do not and cannot contain all the terms and conditions appropriate for all or even most situations. During negotiations, it is necessary to recognize that nothing is binding until a letter of understanding (or letter of intent) or a contract is signed.

Listed are the subject areas normally covered in lease negotiations. (Zierold, 1989) A brief discussion of each item follows this listing:

Lease term	Attorney's fees
Payments to lessor	Arbitration
Work commitments	Force majeure
Operator rights	Notices
Indemnifications	Assignment of rights
Responsibility for taxes	Lessee rights
Default and forfeiture	Assessment work
Recordation of lease	

Lease Terms: The term of the lease must be determined, specified as primary term and secondary term. They should be defined as specific dates, not as "per anniversary date" or other vaguely defined nomenclature. Also the terms and conditions for renewal of the lease should be negotiated. It is important to identify the term for lease renewals and, if on production only, are periods of nonproduction allowed and for what cause and length of nonproduction.

Payments to Lessor: Payments to the lessor are generally divided into three categories: (1) signature bonus or payment, (2) periodic payments, and (3) production royalties. The signature bonus is a payment or commitment to pay at the time the contract is signed. This payment can be in terms of cash or stock or other remuneration. The signature bonus as well as the periodic payments represent compensation for loss of possession. The signature bonus should cover all or most of the costs of the lessor in marketing the property and negotiating a lease.

The periodic payments can be rent, minimum royalties, minimum advance royalties, or other types of payments. These payments also represent compensation for loss of possession of the property. Rent payments are only for possession of the property. Royalty payments are payments for production of the property. Minimum royalty sets a minimum payment per period of time that must be paid, but the payment could be higher depending upon the quantity of production. Minimum advance royalties set minimum payments per period of time, but any payments over the payment required by the amount of production are a credit to the producer and recoupable when production payments exceed the minimum royalties. The minimum or advance minimum royalties can be established in terms of dollars per period of time, or set on a scale that changes as time passes, or they can be escalated bases on certain index(es). The escalation can be based on the price of the mineral or a governmental index (e.g., consumer price index, producers price index, etc.).

Production royalties vary considerably with commodity and location. On commodity, for example, a high-grade gold deposit has a much higher value than a gravel deposit. Also a gravel deposit near downtown New York City has a much higher value than a gravel deposit in central Nevada. The basis of the royalty can be established on dollars per weight or volume (generally for bulk materials like gravel), on percentage of gross value of the product produced (generally for more valuable commodities like metals), on the percentage of net operating profit of the operating venture, or a combination of these bases. For the bases

Source: Zierold, 1989.

stated previously, it is very important to define all terms on which the payment is to be made.

The dollars per weight royalty and the percentage of gross revenue have lower risks for the lessor, who in turn has less potential to achieve higher returns for his property. The percentage of profit royalty has higher risks because the lessor is captive to the operating efficiencies of the operator, but the potential for higher returns is greater.

Work Commitments: The work commitments for a project depend on the objectives of the lessor and the lessee. The lessor normally seeks some commitments to perform work, in a timely manner, if his objective is to get the property into production. However, if the lessor's objective is to receive income, especially in the short term, he may reduce or eliminate work commitments in favor of higher payments for signature bonus and/or higher periodic payments. If the project is highly speculative, work commitments are normally kept to a minimum.

Lessee's Rights and Obligations: The lessee's rights and obligations in the development of the property must be clearly defined. The lessee's right should be stated to develop and operate a mine, to disturb the surface as required, to use any of the surface for mining and nonmining-related activities, and so forth. The lessee should have the right and the obligation to obtain all permits required for the exploration, development, and operation of the mine and also be responsible for any and all required reclamation. The requirement for regular and thorough reports throughout the lease should be included.

Indemnification: An agreement on indemnification must be reached in the negotiations, including insurance claims and indemnification of the leases. Indemnification is the means of compensating for loss or damage.

Responsibility for Taxes: The responsibility for all taxes must be stated in the contract. The party responsible for all taxes associated with the property and any tax savings or obligations resulting from exploration, development, and operation should be stated. These taxes include property taxes, production taxes, severance taxes, and personal property taxes.

Default and Forfeiture: The basis on which both parties can terminate the contract should be defined. For example, if the lessee determines that he no longer wants to lease the property, what notification and obligations does the lessee have? If the lessee fails to make periodic or production payments, does the lessor have the right to terminate the agreement and what are both parties' obligations on such a termination?

The liability for taxes, payments, reclamation, vendor liens, production royalty, etc., should be stated. Long-term liabilities, such as waste dumps, tailings, toxic material, etc., need to be addressed. This may require that the lessee actually obtain ownership for that portion of the land that has any long-term liability potential. The property rights must be addressed as to equipment and improvements on the land and time frames to remove or pay for the cost of moving. The information that the lessee must provide to the lessor should be stated, such as drill results, assay values, geologic mapping, mine planning, etc. The disposition of interpretive reports must be specifically stated, because most mining companies do not want to provide such information to the lessor. The contract should also include relinquishment of the lease at the time of termination, including the recordation of the relinquishment at the appropriate county court house. Also if the lessee has staked any additional mining claims in a defined area of interest around the lessor's property, the lessor has the right to have those claims "quitclaimed" to him, at his option.

A quitclaim is a legal document for the transfer of title from one person to another.

Recordation of Lease: The contract should address the filing of the lease or a memorandum of the lease in the appropriate county court house. The responsibility for creating and filing the memorandum of the lease should be stated.

Attorney's Fees: The handling of attorney's fees, if a disagreement occurs between the parties, should be addressed. This statement might be that the party that loses the claim pays both parties attorney's fees. Another method could be that each party pays his own attorney's fees, unless the claim is determined to be frivolous by the appropriate judicial authority.

Arbitration: If the parties decide to use arbitration to settle disagreements between them, the procedures for such arbitration should be addressed in the contract.

Force Majeure: What makes up "force majeure" should be defined in the contract. Force majeure is an event or effect that cannot be reasonably anticipated or controlled, such as an "act of God." What types of force majeure will the lessor allow and the lessee willing to accept? The terms must be stated as to the lease obligation that can be put on hold and the obligations that must be met during force majeure. Work commitments are usually put on hold in case of force majeure but payments to the lessor generally continue.

Notices: Names and addresses for notices must be included in the contract. They are used for the making of payments, notices of default, notices of force majeure, and any other notices or communications stated in the contract.

Assignment of Rights: The rights of the lessee to assign the lease to other parties should be stated. The lessor may decide to restrict the assignment to the lessee or a subsidiary of the lessee or may accept any assignment subject to his approval that will not be unjustly withheld. If the lease is assigned to another party, what if any are the rights and obligations of the original lessee?

Lessor Rights: The rights of the lessor to entry onto the property should be stated, including his/her rights to other activities on the area (if he legally has those rights, such as timber sales, grazing rights, etc.). The lessor must have reasonable right of inspection to determine the work being performed by the lessee and to assess compliance with the lease requirements. The lessor should receive, at least annually, a report from the lessee on all appropriate activities on the property.

Assessment Work: The lease must state which party is responsible for performing and recording assessment work on unpatented mining claims, if any are part of the lease. Assessment work is usually performed and recorded by the lessee. Notification and copies of the recordation must be stated so that the lessor has time to perform and record the assessment work if it is not performed and recorded by the lessee.

A typical table of contents of a lease agreement is given in Table 6.4.2.

6.4.5.6 Royalty Rates

Royalty rates vary considerably with conditions like the commodity, grade (quality), location, and demand for the commodity. Typical royalty rates have been published in *Mining Engineering* (Bourne, 1988, 1989).

6.4.6 JOINT VENTURE PROCESS

The purpose of entering into a joint venture agreement generally is to obtain expertise and experience not currently available within the sponsoring company. Another purpose, or possibly an additional purpose. of a joint venture is to share the risk of property development. A definite need should be established before a search is undertaken to find a joint venture partner. The following paragraphs start with the definition of the need for a joint venture, the formal search procedure, the informal search procedure, the request for proposal, the evaluation of the proposals, the negotiation of the contract, and a list of typical headings addressed in the contract.

6.4.6.1 Definition of Need

Before initiating the search for a joint venture partner, the owner should carefully determine the need and desire for a joint venture and define the conditions and requirements for the development of the project. The project should be defined in detail as to the current status, the work required to develop the project, a tentative schedule for development, the technical specifications of the project, an estimate of capital and operating costs, areas of concern that may affect the development, and specific areas of expertise that may be required. An *honest* appraisal of the expertise available in the owner's company is very important in the analysis and determination of need. This project definition will greatly assist in the determination and definition of need. Also the project definition will be needed in the development of the request for proposal.

An example of the potential of a joint venture is provided. The sample project is a precious-metal mine with a production schedule as shown in Chart 17.

Example 6.4.5. Joint Venture Benefits.

Chart 17. Production Schedule (1000 tons)

Year	Ore	Waste
—1	—	2,000
1	500	4,000
2	1,000	4,000
3	1,000	4,000
4	1,000	2,000
5	1,000	1,000
Total	4,500	17,000

The ore contains gold at an average grade of 0.08 oz/ton (2.74 g/t) with a sales price of $400/oz ($12.86/g). Recovery in the heap leach and process plant is expected to be 60%. The projected operating and capital costs for the project are shown in Chart 18.

Chart 18. Owner/Operator Capital and Operating Costs ($1000 and $/ton)

	Mine		Plant	
Year	Capital	Operating	Capital	Operating
—1	$5,000	$0.60	$12,000	$3.50
1	—	$0.60	—	$3.50
2	—	$0.60	—	$3.50
3	—	$0.60	—	$3.50
4	—	$0.60	—	$3.50
5	—	$0.60	—	$3.50

Solution. In order to perform a simplified analysis of the project, it is assumed that all capital is depreciated on a straight-line basis over the life of the project and there is no salvage value. Federal income taxes are 34% (no state or local income taxes), and the depletion allowance is 15%. The annual cash flows are calculated as shown in Chart 19.

Chart 19. Cash Flow Analysis ($1000)

Years	—1	1	2	3	4	5
Revenue	-0-	$9,600	$19,200	$19,200	$19,200	$19,200
Operating costs (–)	$ 1,200	$4,450	$ 6,500	$ 6,500	$ 5,300	$ 4,700
Operating income	($ 1,200)	$5,150	$12,700	$12,700	$13,900	$14,500
Depreciation (–)	$ 833	$3,233	$ 3,234	$ 3,233	$ 3,233	$ 3,234
Depletion (–)	-0-	$ 958	$ 2,880	$ 2,880	$ 2,880	$ 2,880
Taxable income	($ 2,033)	$ 958	$ 6,586	$ 6,587	$ 7,787	$ 8,386
Income tax (–)	($ 691)	$ 326	$ 2,239	$ 2,239	$ 2,647	$ 2,851
After tax income	($ 1,342)	$ 632	$ 4,347	$ 4,438	$ 5,140	$ 5,535
Depreciation (+)	$ 833	$3,233	$ 3,234	$ 3,233	$ 3,233	$ 3,234
Depletion (+)	-0-	$ 958	$ 2,880	$ 2,880	$ 2,880	$ 2,880
Capital (–)	$ 17,000	-0-	-0-	-0-	-0-	-0-
Salvages (+)	-0-	-0-	-0-	-0-	-0-	-0-
Cash flow	($ 17,509)	$4,824	$10,461	$10,461	$11,253	$11,649

The annual cash flows calculated in the foregoing, along with the discount factors and present values for the project, are shown in Chart 20.

Chart 20. Present Value ($1000)

Year	Cash Flow	Discount Factors	Present Value
—1	(17,509)	1.000000	(17,509)
1	4,824	0.869565	4,195
2	10,461	0.756144	7,910
3	10,461	0.657516	6,878
4	11,253	0.571753	6,434
5	11,649	0.497177	5,791
Total	31,139		13,699

If a joint venture partner is used and the partner has expertise in processing, the recovery of gold in the processing plant is assumed to increase to 70%, and the plant capital and operating costs are reduced as shown in Chart 21.

Chart 21. Joint Venture Capital and Operating Costs
($1000 and $/ton)

	Mine		Plant	
Year	Capital	Operating	Capital	Operating
—1	$5,000	$0.60	$10,000	$3.00
1	—	$0.60	—	$3.00
2	—	$0.60	—	$3.00
3	—	$0.60	—	$3.00
4	—	$0.60	—	$3.00
5	—	$0.60	—	$3.00

Per the joint venture agreement, the joint venture partner spends the first $10,000,000 in cost, and then all costs are shared in a 50/50 basis including the profits.

The same assumptions used in the owner case applies to the joint venture case. The year-by-year cash flows are calculated as shown in Chart 22.

Chart 22. Cash Flow Analysis ($1000)

Years	—1	1	2	3	4	5
Revenue	-0-	$11,200	$22,400	$22,400	$22,400	$22,400
Operating costs (–)	$ 1,200	$ 4,200	$ 6,000	$ 6,000	$ 4,800	$ 4,200
Operating income	($ 1,200)	$ 7,000	$16,400	$16,400	$17,600	$18,200
Depreciation (–)	$ 833	$ 2,833	$ 2,834	$ 2,833	$ 2,833	$ 2,834
Depletion (–)	-0-	$ 1,680	$ 3,360	$ 3,360	$ 3,360	$ 3,360
Taxable income	($ 2,033)	$ 2,487	$10,206	$10,207	$11,407	$12,006
Income tax (–)	($ 691)	$ 845	$ 3,470	$ 3,470	$ 3,878	$ 4,082
After tax income	($ 1,342)	$ 1,642	$ 6,736	$ 6,737	$ 7,529	$ 7,924
Depreciation (+)	$ 833	$ 2,833	$ 2,834	$ 2,833	$ 2,833	$ 2,834
Depletion (+)	-0-	$ 1,680	$ 3,360	$ 3,360	$ 3,360	$ 3,360
Capital (–)	$15,000	-0-	-0-	-0-	-0-	-0-
Salvage (+)	-0-	-0-	-0-	-0-	-0-	-0-
Cash flow	($15,509)	$ 6,155	$12,930	$12,930	$13,722	$14,118

The annual cash flows as calculated previously, along with the discount factors and present values, are shown in Chart 23, with the present value determined based on a 15% discount rate. The cash flows represent the cash flows for the project first, and then for the owner.

Chart 23. Project Present Value ($1000)

Year	Cash Flow	Discount Factors	Present Value

Total	27,173		16,494

6.4.6.2 Search for Joint Venture Partner

The search for potential joint venture partners can be either formal or informal. An informal search is generally used because the owner and/or some of the people working for the owner have a working knowledge of the mining companies, or other companies engaged in or interested in engaging in the industry, that have the expertise and financial capability to assist in the development of a project. The formal search involves (1) using a consultant with expertise in the area of need to compile a list of potential joint venture partners, (2) researching professional publications for companies with the appropriate expertise, and/or (3) employing other means to compile a list of appropriate companies. Compilation of the list should include, at a minimum, a preliminary review of the expertise level and financial capabilities of the companies being considered. The review should include prior history with the required type of expertise, corporate and public records of the company, and their reputation in the industry. Compilation of the list of appropriate companies should be the only significant difference between the formal and informal methods unless the owner is predisposed to select a particular joint venture partner.

6.4.6.3 Request for Proposal

Depending on the review of the expertise and financial capabilities of the potential joint venture partners, the list should be reduced to those companies with the appropriate qualification. The request for proposal can be either formal or informal. The formal approach includes the development of a formal request for proposal that is submitted to the list of companies finalized in the selection process in the foregoing. This system tends to make the proposals easier to evaluate because terms, conditions, and format of the proposal have been established.

The informal method is more difficult to evaluate because each company will provide its proposal in a different format, and comparison between companies is more difficult. However, the informal method allows the proposing companies to be more innovative and original in their thought and structure of the presentation. The project definition discussed previously is an excellent means to convey the specifications of the project.

6.4.6.4 Evaluation of the Proposals

Evaluation of the proposal is extremely important in selecting the appropriate joint venture partner. The suggested procedure is very similar to that used in selecting the contract miner, except for the areas to be considered. The major areas to be considered are corporate history, number of operations, successes and failures, number and successes in other joint ventures, individual personnel involved and their ability to relate to your personnel, and common corporate philosophy. The final list developed by the owner may differ from these, but it should cover at least these basic areas. For example, corporate philosophy may be divided into organizational structure, accounting methods, ethics, etc.

The following example provides a format for developing a weighting table (Chart 24) for the evaluation. The numbers inserted on the list are provided simply to illustrate the procedure and not to represent a particular set of circumstances.

Example 6.4.6. Joint Venture Partner Evaluation.

Chart 24. Weighting Table

Area	Ranking	Weighting
Corporate history	3	10%
Number of total operations	11	3%
Number of similar operations	5	8%
Technical expertise	4	10%
Successes/failures	9	5%
Number of joint ventures	8	5%
Successes/Failure in joint ventures	10	4%
Individual people competence	7	7%
Relations with individuals	6	8%
Corporate philosophy	2	15%
Financial offer	1	25%
Total		100%

Following the development of the weighting table, a value must be developed for each of the categories. The value is often judgmental but should be quantitative wherever possible. The value may be, at a minimum, merely a ranking of the individual companies. A value between 1 and 10 for each category is suggested. This value is then multiplied by the weighting developed in the weighting table to determine the weighted value. The weighted values are added together to narrow the list of potential partners. Depending on the results of the evaluation, the joint venture may be narrowed to two or three or may actually indicate the preferred company. An example of a value table and an evaluation table is shown in Chart 25. The value table provides the ranking of the individual companies while the evaluation table provides the results of applying the weighting of each area to the ranking provided in the value table. Again the numbers inserted on the table are provided simply to illustrate the procedure and not to represent a particular set of circumstances.

Solution.

Chart 25. Value Table

Area	Weighting	Companies 1	2	3
Corporate history	10%	10	6	8
Number of total operations	3%	9	8	10
Number of similar operations	8%	2	6	9
Technical expertise	10%	4	7	8
Successes/Failures	5%	2	6	7
Number of joint ventures	5%	8	5	1
Successes/Failures in joint venture	4%	4	8	9
Individual people competence	7%	6	9	8
Relations with individuals	8%	4	8	9
Corporate philosophy	15%	3	9	7
Financial offer	25%	10	9	8

Evaluation Table

Area	Weighting	Companies 1	2	3
Corporate history	10%	1.00	0.60	0.80
Number of total operations	3%	0.27	0.24	0.30
Number of similar operations	8%	0.16	0.48	0.72
Technical expertise	10%	0.40	0.70	0.80
Successes/Failures	5%	0.10	0.30	0.35
Number of joint ventures	5%	0.40	0.25	0.05
Successes/Failures in joint ventures	4%	0.16	0.32	0.36
Individual people competence	7%	0.42	0.63	0.56
Relations with individuals	8%	0.32	0.64	0.72
Corporate philosophy	15%	0.45	1.35	1.05
Financial offer	25%	2.50	2.25	2.00
Total	100%	6.18	7.76	7.71

If, as shown in this case, two of the companies' evaluations are too closely ranked to make the final selection, the two companies should be invited to discuss their proposal in more detail with the owner. These discussions may include a formal presentation and/or informal dialogue on the project and the proposal. Some of the values chosen for the companies may change and thus change the evaluation. This process will lead to the designation of the selected company.

6.4.6.5 Negotiating the Contract

Negotiation of the contract for the joint venture is similar to the negotiation of a lease, as illustrated in 6.4.5.5. The contract must be perceived as fair to all parties involved in order for the joint venture to be successful. The objectives of both parties must be stated at the start of negotiations and should be consistent with the request for proposal provided by the owner and with the proposal provided by the potential joint venture partner.

Listed in the following is the general content of normal negotiations. A discussion of each item follows the listing. The joint venture agreement that results from these negotiations can be in many configurations and structures. Each agreement is individualized for each particular joint venture and is extremely dependent on the companies involved. A general outline is provided in Table 6.4.3, but the content of the negotiations dictates the important aspects of the agreement.

Type of Joint Venture
Term of Joint Venture
Area of Commitment to the Joint Venture
Personnel Assignments and Obligations
Financial Responsibilities
Operating Responsibilities
Organizational Structure-Joint Venture
Accounting Methods
Default
Arbitration
Notices

Type of Joint Venture: The joint venture can take many forms, from a loosely associated partnership to the formation of a corporation to handle the joint venture. The type selected depends on the tax implications for all parties, the operating responsibilities of the parties, the liabilities that the parties are willing to accept, and the individual desires of the parties with respect to ownership.

Term of Joint Venture: The term of the joint venture is generally determined by either the time required to fully exploit the property committed to the joint venture or the desires of the parties to have a longer-term relationship. The term may be flexible to account for the unknowns in the property being developed.

Area of Commitment to the Joint Venture: The boundaries of land, mineral, depth, etc., committed to the joint venture must be defined in detail to reduce the potential for disagreements in the future as to the land (claims) that are involved or the mineral that is being developed. Some parties may commit only the surface minable or underground minable reserves to the joint venture. Definition of the terms of surface or underground minable must be delineated in detail to reduce potential conflicts in the future.

Personnel Assignments and/or Obligations: Each party may commit certain personnel or types of personnel to the joint venture, either on a full-time basis (possibly as an employee of the joint venture) or on a part-time basis. For example, one of the parties may commit to provide the metallurgical expertise to ensure the optimum performance of the processing facility.

Financial Responsibilities: These responsibilities are often defined to some degree in the proposal and during discussions of the proposal. These responsibilities must be well defined, and the accountability of the expenditure of these funds also must be defined. For example, if one party was to expend the first $10,000,000 on the development, was the commitment to provide the joint venture with the funds or for that party to expend the funds as it performed the work? The commitment of funds for property development is generally well defined, but the ability of the joint venture to call for additional funds also must be carefully articulated. This commitment may vary, depending on whether the need is for ongoing operation or for expansion of the mine or for additional development. If one of the parties is unwilling or unable to provide committed or additional funding, the change of ownership division must be stated or the recourse available to the other party.

Operating Responsibilities: Any responsibilities or commitments by the parties to perform part of the operation or development of the project must be defined. For example, is one party going to operate the mine and the other party operate the processing plant? If that is the case, the interface between the parties must be defined, that is, party A puts the ore in the stockpiles

at location B. Also the accounting for the expenditures charged to the joint venture must be defined.

Organizational Structure: The structure of the organization is determined by the type of joint venture and the operating responsibilities of the parties. Following those designations, the structure will dictate the responsibilities and authorities of the personnel working for the joint venture or committed to or working on the joint venture to correspond with these designations. The definition of responsibilities that dictate the organizational structure assists in developing accountability in the operation. Also, the structure of the management committee must be defined for the overall direction of the joint venture, including the decision-making powers.

Accounting Methods: The accounting methods to be used for the joint venture must be designated so that the parties know how to handle the accounting for their company and how it will impact their financial status. This should include not only those methods needed for "accounting" purposes but also how individual cost items are going to be traced for purposes of analyzing the efficiency of the operation.

Default: The basis by which each party can terminate this agreement must be defined. This area is frequently overlooked or handled on a cursory basis. In developing the default terms and conditions, a pessimistic point of view often must be used to ensure that potential defaults are addressed in a realistic manner. Also, long-term liabilities of the parties and the property must be addressed, including environmental and personnel factors.

Arbitration: The method for settling disagreements should be stated in the agreement. If arbitration is to be used, the method of arbitrating the difference should be delineated. If another method is to be used, that method should be stated and the procedures defined.

Notices: The names and addresses for notices must be included in the agreement. The names and addresses are used for the transfer of funds, notices of default, and any other notices or communications stated in the agreement.

6.4.7 EVALUATION OF ALTERNATIVES

As a basis for discussing the evaluation of alternative methods of developing a property, a hypothetical mining project is selected as an example. The evaluation discussed in this section of the chapter is strictly an economic evaluation based on the expected costs of each of the alternative methods of developing and operating the property. Factors other than economics may enter into the decision making, such as corporate philosophy, risks, ability to finance the project, etc. The costs given in the following are costs typical of an open pit, heap-leach, gold-mining operation in Nevada, but do not represent any one operation. However, the procedure shown can be used in any mine operation, whether it is open pit or underground, precious metal or base metal, or metallic or industrial or energy fuel.

Example 6.4.7. Alternative Development Methods.

Base Criteria—Basic criteria for the property and the mine operation are shown as follows:

Minable reserves	10,000,000 tons (9.1 Mt)
Grade	0.06 oz/ton gold (2.06 g/t)
Strip ratio	2.5 tons waste/ton ore (2.5 t waste/t ore)
Production rate	2,000,000 tpy (1.8 Mt/a)

Capital and Operating Costs—Capital and operating costs shown in the following are illustrated from the perspective of the owner of the property. The operating and capital costs are its costs as determined by an estimate prepared according to the procedure of Chapter 6.3. The contract mining costs assumes the owner decided to use a contract miner to remove the overburden, mine and crush the ore, and place the crushed ore on the heap leach pad. The leasing alternative assumes the property was leased to a mining company that mined and produced the ore according to the same production schedule as the other alternatives. The lease assumes a straight royalty basis and includes a signature bonus and periodic payments. The joint venture alternative assumes a joint venture partner was selected for its mining expertise. The owner performed the exploration prior to the development of the joint venture. The joint venture partner expended the first $10,000,000 of the development as his buy-in.

6.4.7.1 Owner/Operator

The analysis has been simplified to illustrate the evaluation process. All the complexities of all possible ventures could not be addressed in one example.

The owner has determined that the mine will be operated on the production schedule shown in Chart 26.

Chart 26. Production Schedule (1000 tons)

Year	Ore	Waste	Total
—1	-0-	2,000	2,000
1	2,000	5,000	7,000
2	2,000	5,000	7,000
3	2,000	5,000	7,000
4	2,000	5,000	7,000
5	2,000	3,000	5,000
Total	10,000	25,000	35,000

The owner has performed a cost estimate and has determined that expected capital and operating costs are as follows:

Capital Costs	
Mobile equipment	$ 7,750,000
Crushing and agglomeration	$ 6,250,000
Leach pad and plant	$ 7,000,000
Ancillary Facilities	$ 4,000,000
Infrastructure	$ 2,000,000
Total	$27,000,000
Operating Costs	
Ore mining	$0.70/ton ($0.77/t)
Waste removal	$0.65/ton ($0.72/t)
Crushing and agglomerating	$0.80/ton ($0.88/t)
Heap construction	$0.30/ton ($0.33/t)
Leach pad and plant operation	$2.85/ton ($3.14/t)
Overhead	$2,200,000/yr

The capital costs include the mobilization (freight and erection) of equipment and working capital for the project. The operating costs for the tasks are labor and supplies only (including operating costs). Supervision, property taxes, insurance, etc., are contained in overhead cost.

In the exploration and development of the property, the owner has spent $6,000,000 in exploration and development drilling and in permitting and other developmental costs. The preproduction and development years are designated as year —3, —2, and —1. These preproduction and development costs were incurred as follows: year — 3, $2,000,000; year —2, $3,000,000; year — 1, $l,000,000. These costs have been capitalized and amortized over the ore production years. The annual amortization cost is $1,200,000.

The annual operating costs for the project are shown in Chart 27.

Chart 27. Annual Operating Costs ($1000)

Year	Ore	Waste	Crush/ agglom.	Heap constr.	Leach & plant	Overhead	Total
—1	-0-	$ 1,300	-0-	-0-	-0-	$ 2,200	$ 3,500
1	$1,400	$ 3,250	$1,600	$ 600	$ 5,700	$ 2,200	$14,750
2	$1,400	$ 3,250	$1,600	$ 600	$ 5,700	$ 2,200	$14,750
3	$1,400	$ 3,250	$1,600	$ 600	$ 5,700	$ 2,200	$14,750
4	$1,400	$ 3,250	$1,600	$ 600	$ 5,700	$ 2,200	$14,750
5	$1,400	$ 1,950	$1,600	$ 600	$ 5,700	$ 2,200	$13,450
Total	$7,000	$16,250	$8,000	$3,000	$28,500	$13,200	$75,950

For simplification, the depreciation base for all applicable capital is established at 10 years, straight-line, with zero salvage value. The depreciation for the project is $2,700,000/yr. Salvage value on projects less than 10 years is assumed to be book value and is taken in the last year of project life. The salvage value reflects the recoupment of working capital and the demobilization of the equipment.

Revenue for the project is calculated on an average ore assay of 0.06 oz/ton (2.06 g/t) of gold with an average recovery of 70% and an average gold price of $400/oz ($12.86/g). The annual revenue for this project is $33,600,000 with a total project revenue of $168,000,000.

A simplified cash flow analysis is shown in Chart 28. No royalty exists on the mining claims. Taxes, other than income tax, are included in the overhead. (Nevada does not have a corporate income tax.) The federal tax rate is assumed to be 34%. The tax calculation assumes consolidated returns with other operations so that tax losses can be taken in the year in which they occur.

Chart 28. Cash Flow Analysis ($1000)

Years	—3	—2	—1	1	2	3	4	5	Total
Revenue	-0-	-0-	-0-	$33,600	$33,600	$33,600	$33,600	$33,600	$168,000
Operating costs (–)	-0-	-0-	$ 3,500	$14,750	$14,750	$14,750	$14,750	$13,450	$ 75,950
Operating income	-0-	-0-	($ 3,500)	$18,850	$18,850	$18,850	$18,850	$20,150	$ 92,050
Depreciation (–)	-0-	-0-	$ 2,700	$ 2,700	$ 2,700	$ 2,700	$ 2,700	$ 2,700	$ 16,200
Amortization (–)	-0-	-0-	-0-	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 6,000
Depletion (–)	-0-	-0-	-0-	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 25,200
Taxable income	-0-	-0-	($ 6,200)	$ 9,910	$ 9,910	$ 9,910	$ 9,910	$11,210	$ 44,650
Income tax (–)	-0-	-0-	($ 2,108)	$ 3,369	$ 3,369	$ 3,369	$ 3,369	$ 3,811	$ 15,179
After tax income	-0-	-0-	($ 4,092)	$ 6,541	$ 6,541	$ 6,541	$ 6,541	$ 7,399	$ 29,471
Depreciation (+)	-0-	-0-	$ 2,700	$ 2,700	$ 2,700	$ 2,700	$ 2,700	$ 2,700	$ 16,200
Amortization (+)	-0-	-0-	-0-	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 6,000
Depletion (+)	-0-	-0-	-0-	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 25,200
Exploration/Development (–)	$ 2,000	$ 3,000	$ 1,000	-0-	-0-	-0-	-0-	-0-	$ 6,000
Capital (–)	-0-	-0-	$27,000	-0-	-0-	-0-	-0-	-0-	$ 27,000
Salvage (+)	-0-	-0-	-0-	-0-	-0-	-0-	-0-	$10,800	$ 10,800
Cash flow	($2,000)	($3,000)	($29,392)	$15,481	$15,481	$15,481	$15,481	$27,139	$ 54,671

The cash flows developed in the foregoing were discounted at 15% to determine the present value of the cash flows, as shown in Chart 29.

Chart 29. Present Value ($1000)

Year	Cash Flow	Discount Factors	Present Value
—3	(2,000)	1.000000	(2,000)
—2	(3,000)	0.869565	(2,609)
—1	(29,392)	0.756144	(22,225)
1	15,481	0.657516	10,179
2	15,481	0.571753	8,851
3	15,481	0.497177	7,697
4	15,481	0.432328	6,693
5	27,139	0.375937	10,203
Total	54,671		16,789

6.4.7.2 Contract Miner

The same operation example is used in this case as was used in the owner/operator case. The only difference is consideration of a contract miner to perform the waste removal, ore mining, crushing and agglomerating, and the placement of the crushed and agglomerated ore on the leach pad. The owner has developed a bidder's list of contractors and transmitted an RFP to the contractors on the bidder's list. The owner has received proposals from the contractors and has selected the best contractor based on the price, the qualifications of the contractor and his personnel, the availability of equipment and personnel, the ability to perform the job, the contractual terms, and the type of owner/contract miner relationship he expects. The contract miner's bid is as follows:

Ore mining	$1.15/ton of ore ($1.27/t)
Waste removal	$1.10/ton of waste ($1.21/t)
Crushing and agglomeration	$1.50/ton of ore ($1.65/t)
Heap construction	$0.50/ton of ore ($0.55/t)

The owner's expected cost for the remaining operations are

Capital Costs	
Leach pad and plant	$7,000,000
Infrastructure	$2,000,000
Total	$9,000,000
Operating Costs	
Leach pad & plant operation	$2.85/ton of ore ($3.14/t)
Overhead	$1,000,000/yr

In the exploration and development of the property, the owner has spent $6,000,000 in exploration and development drilling and in permitting and other developmental costs. These costs were incurred as follows: year — 3, $2,000,000; year —2, $3,000,000; year — 1, $1,000,000. These costs have been capitalized and amortized over the ore production years. The annual amortization cost is $1,200,000.

The annual operating costs for this operation are shown in Chart 30.

Chart 30. Annual Operating Costs ($1000)

Year	Ore	Waste	Crush/ agglom.	Heap constr.	Leach & plant	Overhead	Total
—1	-0-	$ 2,200	-0-	-0-	-0-	$1,000	$ 3,200
1	$ 2,300	$ 5,500	$ 3,000	$1,000	$ 5,700	$1,000	$18,500
2	$ 2,300	$ 5,500	$ 3,000	$1,000	$ 5,700	$1,000	$18,500
3	$ 2,300	$ 5,500	$ 3,000	$1,000	$ 5,700	$1,000	$18,500
4	$ 2,300	$ 5,500	$ 3,000	$1,000	$ 5,700	$1,000	$18,500
5	$ 2,300	$ 3,300	$ 3,000	$1,000	$ 5,700	$1,000	$16,300
Total	$11,500	$27,500	$15,000	$5,000	$28,500	$6,000	$93,500

For simplification, the depreciation period for all applicable capital is taken as 10 years and assumed to be straight-line with no salvage. The depreciation for the project is $900,000/yr. Salvage value on projects less than 10 years is assumed to be book value and is taken in the last year of project life. The salvage value reflects the recoupment of working capital and the demobilization of the equipment.

Revenue for the project is calculated on an average ore assay of 0.06 oz/ton (2.06 g/t) of gold with an average recovery of 70% and an average gold price of $400/oz ($12.86/g). The annual revenue for this project is $33,600,000 with a total project revenue of $168,000,000.

A simplified cash flow analysis is shown in Chart 31. No royalty exists on the mining claims. Taxes, other than income tax, are included in the overhead. The federal tax rate is assumed at 34%. The tax calculation assumes consolidated returns with other operations so that tax losses can be taken in the year in which they occur.

Chart 31. Cash Flow Analysis ($1000)

Years	—3	—2	—1	1	2	3	4	5	Total
Revenue	-0-	-0-	-0-	$33,600	$33,600	$33,600	$33,600	$33,600	$168,000
Operating costs (–)	-0-	-0-	$ 3,200	$18,500	$18,500	$18,500	$18,500	$16,300	$ 93,500
Operating income	-0-	-0-	($ 3,200)	$15,100	$15,100	$15,100	$15,100	$17,300	$ 74,500
Depreciation (–)	-0-	-0-	$ 900	$ 900	$ 900	$ 900	$ 900	$ 900	$ 5,400
Amortization (–)	-0-	-0-	-0-	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 6,000
Depletion (–)	-0-	-0-	-0-	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 25,200
Taxable income	-0-	-0-	($ 4,100)	$ 7,960	$ 7,960	$ 7,960	$ 7,960	$10,160	$ 37,900
Income tax (–)	-0-	-0-	($ 1,394)	$ 2,706	$ 2,706	$ 2,706	$ 2,706	$ 3,454	$ 12,884
After tax income	-0-	-0-	($ 2,706)	$ 5,254	$ 5,254	$ 5,254	$ 5,254	$ 6,706	$ 25,016
Depreciation (+)	-0-	-0-	$ 900	$ 900	$ 900	$ 900	$ 900	$ 900	$ 5,400
Amortization (+)	-0-	-0-	-0-	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 6,000
Depletion (+)	-0-	-0-	-0-	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 5,040	$ 25,200
Exploration/Development (–)	$ 2,000	$ 3,000	$ 1,000	-0-	-0-	-0-	-0-	-0-	$ 6,000
Capital (–)	-0-	-0-	$ 9,000	-0-	-0-	-0-	-0-	-0-	$ 9,000
Salvage (+)	-0-	-0-	-0-	-0-	-0-	-0-	-0-	$ 3,600	$ 3,600
Cash flow	($2,000)	($3,000)	($11,806)	$12,394	$12,394	$12,394	$12,394	$17,446	$ 50,216

The cash flows developed previously were discounted at 15% to determine the present value of the cash flows, as illustrated in the owner/operator case with the present value determined to be $19,778,000.

6.4.7.3 Lease

In the lease case example, the owner has decided to lease the property to a mining company. The payment terms call for a signature bonus of $50,000, a minimum annual advance royalty of $100,000/yr, and a royalty rate of 5% of gross value. The signature bonus occurs in year —2. The owner spent $40,000 on marketing the property and negotiating the lease. He also spends $5,000/yr monitoring the lessee when the lessee is not mining ore and $25,000/yr when the lessee is mining ore. He has not experienced or will not experience any other costs or any capital investment.

A simplified cash flow analysis is shown in Chart 32. The federal tax rate is assumed to be 34%.

Chart 32. Cash Flow Analysis ($1000)

Years	—3	— 2	— 1	1	2	3	4	5	Total
Payments	$ 50	$ 100	$ 100	$ 1680	$ 1680	$ 1680	$ 1680	$ 1680	$ 8650
Deduct advances (–)	—	—	—	$ 200	—	—	—	—	$ 200
Net revenue	$ 50	$ 100	$ 100	$ 1480	$ 1680	$ 1680	$ 1680	$ 1680	$ 8450
Costs (–)	$ 40	$ 5	$ 5	$ 25	$ 25	$ 25	$ 25	$ 25	$ 175
Net income	$ 10	$ 95	$ 95	$ 1455	$ 1655	$ 1655	$ 1655	$ 1655	$ 8275
Depletion (–)	-0-	-0-	-0-	$ 252	$ 252	$ 252	$ 252	$ 252	$ 1260
Taxable income	$ 10	$ 95	$ 95	$ 1203	$ 1403	$ 1403	$ 1403	$ 1403	$ 7015
Income tax (–)	$ 3	$ 32	$ 32	$ 409	$ 477	$ 477	$ 477	$ 477	$ 2385
After tax income	$ 7	$ 63	$ 63	$ 794	$ 926	$ 926	$ 926	$ 926	$ 4630
Depletion (+)	-0-	-0-	-0-	$ 252	$ 252	$ 252	$ 252	$ 252	$ 1260
Cash flow	$ 7	$ 63	$ 63	$ 1046	$ 1178	$ 1178	$ 1178	$ 1178	$ 5890

These cash flows were discounted at 15% to determine the present value of the cash flows, as illustrated in the owner/operator case, with the present value determined to be $3,008,000.

6.4.7.4 Joint Venture

The same operating example is used in this case as was used in the owner/operator case. The only difference is the use of a joint venture to exploit the property. The joint venture partner that was selected by the owner has mining expertise that will help the project. Also the joint venture partner has equipment available to use. The joint venture has determined that the mine will be operated on the production schedule shown in Chart 33.

Chart 33. Production Schedule (1000 tons)

Year	Ore	Waste	Total
—1	-0-	2,000	2,000
1	2,000	5,000	7,000
2	2,000	5,000	7,000
3	2,000	5,000	7,000
4	2,000	5,000	7,000
5	2,000	3,000	5,000
Total	10,000	25,000	35,000

The joint venture has developed a cost estimate of the project for the joint venture: this estimate follows. The owner should note that the operating costs are lower, which reflect the expertise gained from the joint venture partner. Also the capital costs are lower, reflecting the low book value equipment available from the joint venture partner.

Capital Costs

Mobile equipment	$ 4,750,000
Crushing and agglomeration	$ 6,250,000
Leach pad and plant	$ 7,000,000
Ancillary facilities	$ 3,000,000
Infrastructure	$ 2,000,000
Total	$23,000,000

Operating Costs

Ore mining	$0.65/ton	($0.72/t)
Waste removal	$0.60/ton	($0.66/t)
Crushing and agglomerating	$0.80/ton	($0.88/t)
Heap construction	$0.30/ton	($0.33/t)
Leach pad and plant operation	$2.85/ton	($3.14/t)
Overhead	$2,200,000/yr	

The capital costs include mobilization (freight and erection) of the equipment and working capital for the project. The operating costs for the tasks are labor and supplies only. Supervision, property taxes, insurance, etc., are included in the overhead cost.

In the exploration and development of the property, the owner has spent $6,000,000 in exploration and development drilling and in permitting and other developmental costs. These costs were incurred as follows: year — 3, $2,000,000; year —2, $3,000,000; year — 1, $1,000,000. These costs have been capitalized and amortized over the ore production years. The annual amortization cost is $1,200,000. The joint venture partner will invest the first $10,000,000 in the project as his buy-in.

The annual operating costs for the project are shown in Chart 34.

Chart 34. Annual Operating Costs ($1000)

Year	Ore	Waste	Crush/ agglom.	Heap constr.	Leach & plant	Overhead	Total
—1	-0-	$ 1,200	-0-	-0-	-0-	$ 2,200	$ 3,400
1	$1,300	$ 3,000	$1,600	$ 600	$ 5,700	$ 2,200	$14,400
2	$1,300	$ 3,000	$1,600	$ 600	$ 5,700	$ 2,200	$14,400
3	$1,300	$ 3,000	$1,600	$ 600	$ 5,700	$ 2,200	$14,400
4	$1,300	$ 3,000	$1,600	$ 600	$ 5,700	$ 2,200	$14,400
5	$1,300	$ 1,800	$1,600	$ 600	$ 5,700	$ 2,200	$13,200
Total	$6,500	$15,000	$8,000	$3,000	$28,500	$13,200	$74,200

For simplification, the depreciation for all applicable capital is established at 10 years, straight-line, with no salvage. The depreciation for the project is $2,300,000/year. Salvage value on projects less than 10 years is assumed to be book value and is taken in the last year of the project. The salvage value reflects the recoupment of working capital and the demobilization of the equipment.

Revenue for the project is calculated on an average ore assay of 0.063 oz/ton (2.06 g/t) of gold with an average recovery of 70% and an average gold price of $400/oz ($12.86/g). The slightly higher grade reflects the superior ore control techniques employed in mining the ore. The annual revenue for this project is $35,280,000 with a total project revenue of $176,400,000.

A simplified cash flow analysis is shown in Chart 35. No royalty exists on the mining claims. Taxes, other than income tax, are included in the overhead. Again, the federal tax rate is assumed to be 34%. The tax calculation assumes consolidated returns with other operations so that tax losses can be taken in the year in which they occur.

Chart 35. Cash Flow Analysis ($1000)

Years	—3	—2	—1	1	2	3	4	5	Total
Revenue	-0-	-0-	-0-	$35,280	$35,280	$35,280	$35,280	$35,280	$176,400
Operating costs (–)	-0-	-0-	$ 3,400	$14,400	$14,400	$14,400	$14,400	$13,200	$ 74,200
Operating income	-0-	-0-	($ 3,400)	$20,880	$20,880	$20,880	$20,880	$22,080	$102,200
Depreciation (–)	-0-	-0-	$ 2,300	$ 2,300	$ 2,300	$ 2,300	$ 2,300	$ 2,300	$ 13,800
Amortization (–)	-0-	-0-	-0-	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 6,000
Depletion (–)	-0-	-0-	-0-	$ 5,292	$ 5,292	$ 5,292	$ 5,292	$ 5,292	$ 26,460
Taxable income	-0-	-0-	($ 5,700)	$12,088	$12,088	$12,088	$12,088	$13,288	$ 55,940
Income tax (–)	-0-	-0-	($ 1,938)	$ 4,110	$ 4,110	$ 4,110	$ 4,110	$ 4,518	$ 19,020
After tax income	-0-	-0-	($ 3,762)	$ 7,978	$ 7,978	$ 7,978	$ 7,978	$ 8,770	$ 36,920
Depreciation (+)	-0-	-0-	$ 2,300	$ 2,300	$ 2,300	$ 2,300	$ 2,300	$ 2,300	$ 13,800
Amortization (+)	-0-	-0-	-0-	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 1,200	$ 6,000
Depletion (+)	-0-	-0-	-0-	$ 5,292	$ 5,292	$ 5,292	$ 5,292	$ 5,292	$ 26,460
Exploration/Development (–)	$ 2,000	$ 3,000	$ 1,000	-0-	-0-	-0-	-0-	-0-	$ 6,000
Capital (–)	-0-	-0-	$23,000	-0-	-0-	-0-	-0-	-0-	$ 23,000
Salvage (+)	-0-	-0-	-0-	-0-	-0-	-0-	-0-	$ 9,200	$ 9,200
Cash flow	($2,000)	($3,000)	($25,462)	$16,770	$16,770	$16,770	$16,770	$26,762	$ 63,380

The cash flows developed were discounted at 15% to determine the present value of the cash flows, as illustrated in the owner/operator case, with the present value determined to be $22,402,000 for the joint venture.

The net present value for the owner can be determined by subtracting the $10,000,000 invested in year — 1 by the joint venture partner and using half of all the cash flows except the exploration and development expenses. The exploration and development expenses were spent prior to the joint venture agreement in years — 3 and —2, and we assume the agreement between the companies was based on that. The cash flows just developed were discounted at 15% to determine the present value of the cash flows, as illustrated in the owner/operator case, with the present value for the owner determined to be $14,982,000.

6.4.7.5 Evaluation Summary

Results of the evaluation of the four alternatives using the examples stated previously are shown in the following:

Alternative	Net Present Value
Owner/Operator	$16,789,000
Contract miner	$19,778,000
Lease	$ 3,008,000
Joint venture	$14,982,000

The numbers used here are simulated and should not be construed as an endorsement of contract mining as the proper economic choice in all circumstances. The choice, using net present value only, is the use of the contract miner. The second choice would be the owner/operator; the third choice would be the joint venture; the fourth choice would be the lease. However, other factors may enter into the decision making. Corporate philosophy may dictate that the company desires to become an owner/operator and is unwilling to use a contract miner. The accuracy of the cost number used in the evaluation must be considered when making the decision. Possibly, an upside potential exists for lowering the costs such that the owner/operator is the preferred alternative. Another overriding consideration may be that the inability to raise capital to invest in the operation or the desire to reduce the risks of the project either dictates the use of a contract miner or possibly even the lease alternative. The decision is seldom black or white, and many factors must be considered when making the decision.

6.4.8 CORPORATE PHILOSOPHY

The philosophy of the corporation can and should play an important role in the decision on project strategy. The corporation should develop both short-term and long-range goals. These goals should reflect the philosophy of the corporation with respect to the development of mining properties. Short-term goals may be different than long-range goals. The establishment of these goals is discussed in the following. The development of goals and objectives and the strategy to achieve the goals is given a cursory discussion in the following paragraphs. For a more detailed discussion of goals, objectives, and strategy, see Quinn, et al. (1988).

6.4.8.1 Short-term Goals

The short-term goals of a company establish where the company expects to be five years hence. These goals should be well thought out to insure they are supportive of the long-range goals.

The goals should be well defined in quantitative terms. A strategy should be developed on how to achieve the goals. This strategy should be detailed sufficiently to know just how the company plans to achieve the goals and that the resources, both in terms of human and fiscal resources, are committed to the achievement of the stated goals.

6.4.8.2 Long-range Goals

The long-range goals of the company should be developed with considerable thought into the long-range profitability and business direction (strategy) of the company. These goals must be set so that the short-term goals and the strategies to achieve those goals can complement the long-range goals. These long-range goals may dictate the actions taken on the development of an individual mining property. If the company is an established mining company, the actions may be dictated purely by economic analyses. However, if a company is currently a small mining company and desires to become a major supplier in the market of a particular commodity, it may desire to mine the property itself as an owner/operator to assist in the growth of the company. A company just getting into the mining business may desire to have a contract miner during start-up and then take over the property later to establish itself in the expertise of mining. A company that does not have expertise in the mining of a commodity and does not have the goal to become a mining company may use a contract miner for all aspects of the mining venture or lease the property to another company for development and operation.

6.4.8.3 Areas of Expertise

A company must review the expertise it has or lacks when making the decision on the development and operation of a mine. If a company has the expertise, it can utilize that expertise and experience to develop the mine to the optimum. However, if the company is missing the needed expertise, it must decide whether or not it wants to acquire the expertise. If it desires to acquire the expertise, the company can either directly hire outside personnel or hire a contract miner for the start-up and then hire selected personnel from the contract miner to acquire the expertise. If the company does not desire to acquire the expertise, they can use a contract miner for all aspects or lease the property to another company.

Chapter 6.5
INVESTMENT ANALYSIS

THOMAS J. O'NEIL AND DONALD W. GENTRY

6.5.1 OBJECTIVES

Previous chapters of this section provide insight and guidance into selecting and quantifying input variables pursuant to the financial evaluation of a mining venture. Chapter 6.5 takes the analysis to the next step: putting the data into an analytical framework to help determine whether the contemplated investment should be carried out. The basic approach in most such analytical models is the same. The goal is to determine whether or not the project will provide cash benefits sufficiently in excess of the cash costs of establishing and operating the project to justify (1) the cost of funds employed and (2) the risk involved.

Although the project evaluation tools described herein are very useful for decision-making purposes, the analyst must remember always that there is no substitute for accurate input data. Virtually every troubled mining project can trace its difficulties to poor estimates of key variables, not to the use of some improper project evaluation method.

6.5.2 TYPES OF EVALUATIONS

As a raw exploration prospect travels the long, tortuous path to become an operating mine, and as detailed in Chapter 6.2 of this section, it is almost continuously subjected to evaluation. The level of effort and choice of analytical method vary considerably, however, depending on the specific objectives of the evaluation.

6.5.2.1 Stage of Development

Early in the exploration phase, the goal is generally to determine whether the next stage of exploration spending is justified. This often is a fairly subjective and limited evaluation, because typically little hard data are available.

As the prospect continues into progressively more costly exploration and development stages, the evaluation becomes more detailed. One of the discounted cash flow techniques is generally employed in such studies (intermediate economic studies) when exploration has reached a relatively advanced stage.

For the final investment decision, a thorough financial analysis is mandatory for all significant capital investments. Furthermore, for most mining investments, complete sensitivity analysis and risk assessment also are essential.

6.5.2.2 Purpose of the Evaluation

Although the evaluation process is almost continuous, there are specific milepost evaluations that are common in the mining industry. Three standard mileposts are the prefeasibility study, feasibility study, and bankable feasibility study. The level of effort and detail in the financial analysis of the project increases as a project progresses through this sequence.

As described in Chapter 6.2, the *prefeasibility study* is generally the first broad engineering-economic review of the project as a commercial venture. The study typically involves a broad range of disciplines producing input data, some for the first time. The objective of the prefeasibility study is to (1) determine the overall merit of the project at a relatively early stage and (2) identify the key variables upon which the project's viability relies and that, therefore, usually require further investigation.

The formal prefeasibility study can take from one to six months to complete, depending on the size and complexity of the project; and the financial analysis generally is fairly modest, with usually only a few sensitivities on key variables.

When the project has been sufficiently explored and tested to reduce the technical risks to reasonable levels, a final *comprehensive feasibility study* is undertaken. This is the principal document justifying capital investment in the project and, as such, should contain a complete financial analysis of the project, analysis of key variables, and assessment of downside risks and upside potential. The feasibility study usually requires three to nine months to complete—again depending on the size and complexity of the project, but also on the amount of additional data the report authors must independently develop to complete the study.

With the growth of external financing of mining ventures, another version of the feasibility study, the *bankable feasibility study*, is sometimes required. This is, in general, an even more exhaustive version of the feasibility study, usually performed by impartial consultant(s) selected by the lender. The objective is to satisfy the financier about the ability of the project to repay the loans. For this reason, some of the topics that may be of less concern to the owner (e.g., debt servicing) must be treated in great detail here.

Financial analysis in bankable feasibility studies is complex and tailored to meet the needs of the funding agency. Leveraged economic analysis may be employed, particularly when gold loans or other project financings are contemplated.

6.5.3 INVESTMENT CRITERIA

When a company is confronted with several investment opportunities, it becomes necessary to evaluate the attractiveness of each proposal. Any evaluation criterion utilized should provide company management with a means of distinguishing between acceptable projects in a consistent manner. In other words, the criterion should help answer the question, "Is project A and/or project B good enough to justify capital investment by the company?" To provide this necessary information for investment decision making, any satisfactory evaluation criterion must respect two basic principles:

1. Bigger benefits are preferable to smaller benefits.
2. Early benefits are preferable to later benefits.

The following project evaluation criteria section are not intended to represent an exhaustive list available to the analyst. Rather, those discussed represent the major evaluation criteria utilized for evaluation investment proposals within the minerals industry.

6.5.3.1 Simplified Criteria

A number of simplified methods for assessing the investment value of capital projects have evolved. The most common of these are presented in this chapter.

Table 6.5.1. Accounting (Average) Rate of Return

	Year 1	Year 2	Year 3	Year 4	Average
Net operating income	$3,000	$4,000	$5,000	$6,000	$4,500
Depreciation	2,000	2,000	2,000	2,000	2,000
Taxable income	1,000	2,000	3,000	4,000	2,500
Taxes @ 50%	500	1,000	1,500	2,000	1,250
Net profit	500	1,000	1,500	2,000	1,250
Book value:					
January 1	$10,000	$8,000	$6,000	$4,000	
December 31	8,000	6,000	4,000	2,000	
Average	9,000	7,000	5,000	3,000	6,000

$$\text{Average rate of return} = \frac{1250}{6000} \times 100 = 20.8\%$$

Degree of Necessity: There are times when company management must make investment decisions based only on limited quantitative data of dubious accuracy. These types of investments may be referred to as *degree of necessity* investments and are characterized by the fact that the decisions are either obvious or can be quantified only to a limited degree. To illustrate the concept, suppose the main production hoist at a large, profitable underground mine suddenly failed. Under these conditions, it is conceivable that some comparative analyses could be performed in order to help decide what kind, model, etc., of hoist should be purchased. However, the investment decision to actually purchase a new hoist need not be predicated on rigorous economic analyses resulting in calculated rates of return or some other yardstick of profitability, unless the operation is already marginal. Indeed, performing a formal benefit/cost analysis for an investment proposal indicated in this example is not a simple task, and, in this case, may simply delay the actual decision required.

Other examples closely related to the minerals industry are expenditures in the areas of research and development (R&D) and exploration. How much, if any, capital should be allocated to R&D activities? What quantity of capital should be allocated to exploration activities ? Should this be a fixed percentage of the annual corporate budget, some amount commensurate with industry average, or what?

Clearly these kinds of investment decisions fall within the realm of management judgment and are predicated more on corporate strategies than on any specific economic criterion. Thus some major investment decisions can not be easily analyzed with quantitative criteria.

Accounting Rate of Return: One of the more common versions of the accounting rate of return calculation is often referred to as the average rate of return. The average rate of return is calculated by dividing average annual profits after taxes by the average investment in the project (average book value after deducting depreciation).

Example 6.5.1. Table 6.5.1 illustrates the calculation procedure for determining the average rate of return on a project requiring an investment of $10,000 with an estimated salvage value of $2,000 at the end of year 4. Estimated annual profits are given. Depreciation is on a straight-line basis.

Another version of the accounting rate of return uses original investment for the denominator rather than average book value. In the example presented, the calculation would be represented as $1{,}250/10{,}000 \times 100 = 12.5\%$. This version is somewhat less informative since income is averaged but investment is not. However, as an approximation to the internal rate of return (see discussion on Internal Rate of Return), it usually provides better results than using the average investment.

The primary advantages of the accounting rate of return criterion are (1) it is simple to calculate, (2) it makes use of readily available accounting information, and (3) it provides a “rate of return” number to which most managers seem to relate. Once the calculation has been performed for a project, the rate can be compared with the company’s required, or cutoff, rate to determine whether the project should be accepted or rejected.

The principal disadvantages of the method are that (1) it is based on accounting profits rather than actual cash flows, and (2) it does not take into account the timing of these profits. These are very serious disadvantages, as they violate some basic concepts and requirements set forth in this chapter. In reality, it takes little additional effort to work with actual annual cash flows and incorporate the concept of time value of money into the analysis.

Payback (Payout) Period: One of the most common evaluation criteria used by mining companies is the payback or payout period. The payback period is simply the number of years required for the cash income from a project to return the initial cash investment in the project. Although benefits resulting from the investment can be measured in terms of net profit for calculation purposes, modern practice has resulted in the use of annual net cash flows for the denominator.

Example 6.5.2. Table 6.5.2 illustrates five investment proposals having identical capital investment requirements but differing expected annual cash flows and lives. The payback period is calculated for each.

The investment decision criterion for this technique suggests that if the calculated payback period for an investment proposal is less than some maximum value acceptable to the company, the proposal is accepted; if not, it is rejected. In other words an investment proposal having a payback period of three years is acceptable to a company having a hurdle value of five years and is preferable to a second project having a payback period of four years.

An interesting situation arises when calculating the payback period for a typical new mining venture where several years of negative cash flows (investment) are anticipated prior to project start up. Should the payback period start from the beginning of investment or the beginning of positive cash flow? That is, is the payback period for the project in Fig. 6.5.1 four years or nine years?

Table 6.5.2. Payback Period

	Annual Net Cash Flows				
	Proposal A	Proposal B	Proposal C	Proposal D	Proposal E
Initial investment	$10,000	$10,000	$10,000	$10,000	$10,000
Project year 1	2,000	7,000	1,000	6,000	6,000
2	2,000	2,000	2,000	2,000	2,000
3	2,000	1,000	7,000	2,000	2,000
4	2,000	2,000	2,000	-0-	3,000
5	2,000			-0-	4,000
6	2,000			-0-	1,000
7	2,000			-0-	1,000
8				-0-	500
Payback period, years	5.0	3.0	3.0	3.0	3.0

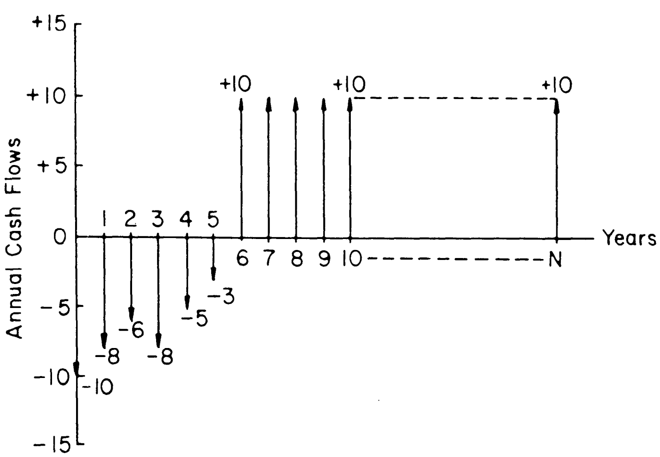

Fig. 6.5.1. Annual cash flows for a new mining project, illustrating effect of preproduction period on payback period calculation.

Table 6.5.3. Discounted Payback Period

Proposal A		Present worth factor, (P/F) at 7%	Present value of cash flows
Initial investment:	$10,000	1.0	$10,000
Cash flows:			
Project year 1	$2,000	0.9346	1,869
2	$2,000	0.8734	1,747
3	$2,000	0.8163	1,633
4	$2,000	0.7629	1,526
5	$2,000	0.7130	1,426
6	$2,000	0.6663	1,333
7	$2,000	0.6228	1,246
Undiscounted payback period	5.0 yr	Discounted payback period	6.4

From an economic and financial standpoint, the investment payback period is theoretically more correct, because it represents the commitment of investment throughout the preproduction period, particularly the opportunity cost associated with the investment during this period. However, both payback period calculations provide useful information to the decision maker, and *consistency* in application is the most important feature. It is often important to know how long it will take to recoup the investment in a project after actual start-up. When such information can aid in helping management make the correct investment decision, it should be used even though it may not be theoretically as correct as another calculation procedure.

The payback period criterion has some significant disadvantages. First, the payback period fails to consider cash flows after the payback period; therefore, it cannot be regarded as a suitable measure of profitability. For example, proposals D and E in Table 6.5.2 have identical payback periods and would be rated equally by the criterion. However, proposal D never earns a profit, while proposal E continues to generate income after its payout period. Obviously, proposal E is better than proposal D, but the payback period does not recognize this distinction.

An additional disadvantage of the method is that it does not consider the magnitude or timing of cash flows during the payback period. Rather, it only considers the recovery or payback interval as a whole. For example, proposals B and C in Table 6.5.2 have identical payback periods. However, proposal B is clearly preferable to proposal C because of the large return of funds early in proposal life that could then be reinvested by the firm. When time value of money concepts are taken into consideration, one proposal may be clearly preferable to the other, even though the payback period does not indicate this difference. This troublesome point may be alleviated by calculating a *discounted payback period* for investment proposals. The discounted payback period for proposal A in Table 6.5.2 is calculated in Table 6.5.3. As expected, the discounted payback period will always result in a longer payback interval than the undiscounted calculation procedure.

The last major disadvantage with the payback period is the problem of establishing the appropriate hurdle rate or maximum acceptable value. Someone must decide whether or not a proposal having, say, a four-year payback period is acceptable. Establishing this rate, or hurdle, is often the result of subjective and arbitrary decisions. Should one hurdle rate be applied to all investment proposals even though some may be considerably more risky than others? What should the appropriate hurdle rate be, and how is it determined for investments having varying degrees of risk? Purely subjective determinations are often unsatisfactory when utilizing analytical techniques to assist with investment proposal decision making.

A payback period is, however, widely used for the following reasons:

1. Payback period is simple and easy to calculate and also provides a single number that can be used as an index of proposal profitability.

2. Payback period provides some protection to management from exposure to excessive risk. Although risky investments should have shorter payback periods due to the risk involved, someone still has to decide what an acceptable payback period should be. These are often subjective decisions having no theoretical basis. Alternatives for analyzing risk in mining ventures that are inherently superior to simply adjusting the payback period are discussed in 6.5.5.

3. Some argue that payback period can minimize "lost opportunity risk" to the firm because cash inflows will be returned to the firm within a short span of time, thus allowing the firm to seize unexpected investment opportunities that may become available.

An objective appraisal of the payback period indicates that it can provide some useful information to the decision maker when considering investment proposals. However, the technique has too many drawbacks to be used alone. It should *not* be used as the sole quantitative tool for making investment decisions, but rather in a supplementary role to the other more sophisticated methods. Many firms use the payback period criterion as a hurdle that investment proposals must clear before progressing to more rigorous and sophisticated forms of analyses.

6.5.3.2 Discounted Cash Flow Methods

Any one of the several discounted cash flow methods (DCF) discussed in this part is superior to the simplified methods described in 6.5.3.1. The DCF methods require (1) determination of periodic project cash flows over some uniform planning period and (2) consideration of the time value of money through the use of an appropriate interest rate.

Essentially these methods compare the cash benefits from a project with the cash costs of the project, both adjusted for timing by the use of an interest rate.

Present, Future, and Annual Value: The *present value* (PV), or present worth, method of measuring investment proposal desirability is a widely used technique. The term present value (PV) simply represents an amount of money at the present time (t = 0) that is equivalent to some sequence of future cash flows discounted at a specified interest rate. In other words, this technique recognizes the time value of money and provides for the calculation of an amount at the present time that is equivalent in value to a series of future cash flows.

Present value calculations are most frequently performed to determine the present worth of income-producing property, such as an existing mining operation. If the future annual cash flows can be estimated, then by selecting an appropriate interest rate, the present value of the property can be calculated. This value should provide a reasonable estimate of the price at which the property could be bought or sold.

In the more general case of investment proposal evaluation, one is interested in determining the difference between cash outflows and cash inflows associated with the proposal on a present-value basis. This calculation procedure is referred to as the *net present value* (NPV) method and is simply the difference between the sum of the present value of all cash inflows and the sum of the present value of all cash outflows. NPV can be expressed as follows:

$$\text{Net present value} = \Sigma \text{ present value of cash benefits} - \Sigma \text{ present value of cash costs} \quad (6.5.1)$$

If the NPV of the proposal is a positive value (NPV> 0), then the project should be accepted. A positive NPV indicates that the investment proposal will provide for the recovery of invested capital, a return on the unrecovered capital throughout the project life at the stipulated interest rate utilized in the calculation, as well as some surplus amount. In other words, the project promises to yield a return in excess of that rate used in the calculation procedure. If the rate used in the calculation is the rate of return investors expect the firm to earn on investments, then proposals having a positive NPV should increase the wealth of the firm. Similarly, proposals yielding a negative NPV at the required discount rate should be rejected.

The following example illustrates the calculation procedure for net present value determinations.

Example 6.5.3. Given the following conditions:

Initial investment:	$100,000
Project life:	10 years
Salvage value:	$ 20,000
Annual receipts:	$ 40,000
Annual disbursements:	$ 22,000

Minimum acceptable rate of return (discount rate): 12%

Calculate the NPV.

Solution. Use Eq. 6.5.1.

	Present Value
1. Annual receipts = $40,000 (*P/A*,12%,10)	$226,000
2. Salvage value = $20,000 (*P/F*,12%,10)	6,440
Total PV of cash inflows:	$232,440
3. Annual disbursements = $22,000 (*P/A*, 12%,10)	124,300
4. Initial investment =	100,000
Total PV of cash outflows	$224,300
Net present value (NPV):(PV inflow-PV outflow):	$ 8,140

Since the NPV > 0 in the foregoing example, the project should be accepted according to this criterion. Note that annual *net* benefits (receipts – disbursements) could have been discounted as a single stream, and the NPV would be the same. This is *not* the case for the benefit/cost ratio criterion (see Benefit/Cost Ratio) where separate discounting of receipts and disbursements is essential.

Under certain conditions, the present value concept also can be used for evaluating projects on a cost basis. For example, it is often desirable to determine what it will cost, in today's equivalent, to operate alternative pieces of equipment over some future period. When comparing investment proposals the NPV decision criterion would suggest that the proposal promising the largest PV of inflows should be selected, or if working with costs, the proposal promising the lowest PV of outflows should be selected. However, the analyst must use caution in any study based upon cost minimization. Often the lowest cost alternative is to do nothing; the objective function really is to minimize cost *subject to the completion of some particular task.* Thus selection of the alternative based on minimum PV of costs assumes that alternative can perform the required assignment.

It is instructive to calculate the net present value associated with different interest rates for an investment proposal (see Fig. 6.5.2.). This shows that the present value of an investment proposal is a function of the interest rate selected. The connection between the interest rate selected for calculation purposes and the firm's required rate of return is obvious, in that only those projects promising a positive NPV at the required rate of return should be accepted.

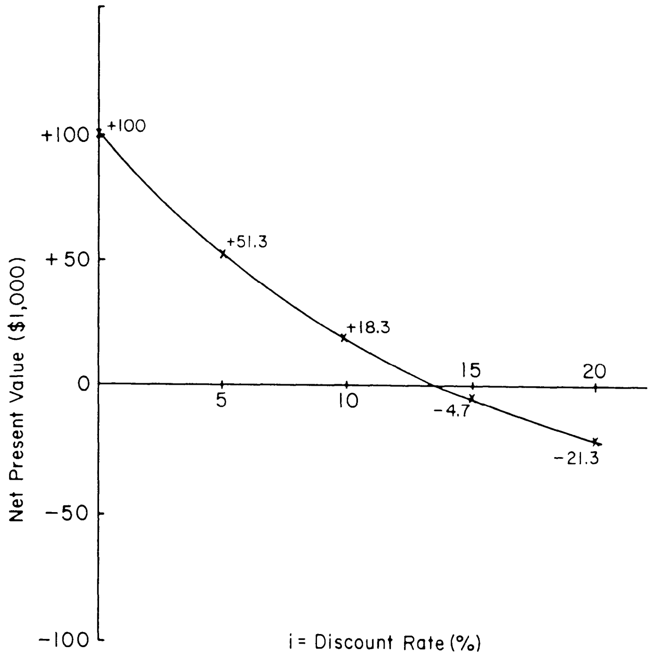

Fig. 6.5.2. Present value profile for previous example.

Investment proposals can also be evaluated on the basis of how much money they will accumulate at some future point in time, usually the end of project life. Value determinations calculated in this manner are referred to as *future values* and represent the future worth amount for a specific proposal at some point in time at a given interest rate.

Recognizing the time-value-of-money concept, it is apparent that this method is just the reverse of the present value concept. In fact, the future value amount can be calculated by first determining the present value amount of the cash flows in the following manner.

$$F = P\ (F/P,\ i,\ n) \tag{6.5.2}$$

Likewise,

$$P = F\ (P/F,\ i,\ n) \tag{6.5.3}$$

In other words, for given values of interest rate i and years n, the future value amount is simply the present value times a constant. Consequently, if an investment proposal has a present value amount two times as large as an alternative proposal's present value, it will also have a future value amount two times as large as the alternative proposal.

In view of the foregoing discussion, it makes no theoretical difference if projects are evaluated on the basis of future values or present values. However, most project evaluators prefer to work in terms of present value amounts, probably because they are considering amounts in equivalent dollars at the time the accept/reject decision is under consideration ($t = 0$). In general most investment decisions in the minerals industry are based on present value determinations rather than future value determinations.

There are times when it may be more convenient to evaluate investment proposals in terms of *annual value* or *annual cost,* as opposed to present value or future value amounts in the aggregate. For example, many analysts prefer to compare pieces of operating equipment in terms of annual costs simply because associated benefits are often difficult to quantify and cost records are readily available.

Annual value refers to a *uniform annual series of money (annuity)* for a given period of time, which is equivalent in amount to a specified sequence of annual cash flows under consideration. The concept of equivalency suggests that the equivalent annual value for a series of cash flows can be determined by first calculating the present value amount of the actual cash flow series and then multiplying this amount by the *capital recovery factor* that is, in effect, an annualizing factor. Therefore, the annual value amount [sometimes referred to as the *equivalent uniform annual value* (EUAV) may be represented as follows:

$$\text{Annual value (EUAV)} = (\text{PV of cash flows}) \times \text{capital recovery factor} \tag{6.5.4}$$

The following example is intended to demonstrate the calculation procedure for determining the annual value of a project and to illustrate the cost relationship with the present value method.

Example 6.5.4. Suppose a new piece of equipment is being considered for purchase which promises to generate annual benefits in the amount of $10,000, annual costs of $5000, and a life of 10 years. If the initial cost of the machine is $40,000 and the expected salvage value at the end of 10 years is $2000, what is the net annual worth if interest on investment capital is 10%?

Solution. Use Eq. 6.5.2.

		Annual Worth
Benefits:	$10,000/yr	$10,000
Salvage:	$ 2,000 (*A/F,* 10% 10)	125
Costs:	$ 5,000/yr	— 5,000
Investment:	$40,000 (*A/P,* 10%, 10)	— 6,508
	Net annual value:	— 1,383

Since the net annual value is less than 0, the calculation shows that the project is expected to earn less than the 10% interest rate used.

Comments—Present, future, and annual values are all measures of equivalency and differ only in the times at which they are determined. Therefore, for fixed values of i and n, the techniques provide consistent bases for comparison of investment proposals. They will all provide the same accept/reject decision for the proposal in question.

Benefit/Cost Ratio: The *benefit/cost ratio* (B/C ratio), sometimes referred to as the *profitability index* (PI), is generally defined as the ratio of the sum of present value of future benefits to the sum of the present value of present and future investment outlays and other costs. This ratio is expressed as follows:

$$\text{B/C ratio (PI)} = \frac{\Sigma\text{PV of net cash inflows}}{\Sigma\text{PV of net cash outflows}} \tag{6.5.5}$$

In order to perform this calculation an interest rate must be specified prior to present value determination. If the calculation results in a PI > 1.0, the investment proposal should be accepted; if not, it should be rejected. This is the same as saying the project should be accepted if it has a NPV > 0. Indeed, the only difference between the NPV calculation and the PI calculation is that the NPV is the *difference* between the present value of inflows and outflows, whereas the PI is the *ratio* between the two.

For any given project, the NPV method and the PI method will provide the same accept/reject decision, assuming the calculation is performed at the same interest rate. However if a *choice* must be made between two investment proposals, these methods may provide inconsistent project rankings. This aspect is illustrated in the following example.

Example 6.5.5.

	Project A	Project B
Present value cash inflows	$500,000	$100,000
Present value cash outflows	$300,000	$ 50,000
Net present value	$200,000	$ 50,000
Benefit/cost ratio	1.67	2.0

Which of these present-value-based techniques is correct, and why do they provide different rankings? There are really two answers to these questions. In absolute terms, the expected economic contribution of project A to the firm is greater than that promised by project B. This aspect is correctly represented by the NPV technique. However, the B/C ratio reflects the *relative profitability* of the two projects. In this case, the B/C ratio indicates that project B promises a greater return per dollar of outflow. Stated in other terms, the relative gain from the capital resources committed to project B is greater than from those committed to project A.

If A and B are mutually exclusive projects, an important question to ask is, "What happens to the extra $400,000 if project B is selected?" If this is invested in a third project, X, then the correct comparison is the B/C ratio for A with the composite B/C ratio for projects B and X.

The PI is the one investment criterion where it makes a difference whether one treats separate streams of benefits and costs rather than net benefits. Separate discounting of benefits and costs is preferable (Gentry and O'Neil, 1984).

In summary, the NPV method is preferred for determining the absolute expected economic contribution of a project. However, it is often relative profitability of a project that is of interest, particularly in capital-rationing situations, and it is here that the project-ranking capability of the B/C ratio is most appropriate.

Internal Rate of Return: When evaluators in the minerals industry speak of a rate of return on an investment proposed, they are almost always referring to the so-called *discounted cash flow return on investment (DCF-ROI)* or the *discounted cash flow rate of return (DCF-ROR).* These terms are special versions of the more generic term, *internal rate of return (IRR),* or marginal efficiency of capital. This criterion is employed more in the minerals industry for investment proposal evaluation than perhaps any other technique.

The internal rate of return is defined as the interest rate that equates the sum of the present value of cash inflows with the sum of the present value of cash outflows for a project. This is the same as defining the IRR as the rate that satisfies each of the following expressions:

$$\begin{aligned} \Sigma\text{PV cash inflows} - \Sigma\text{PV cash outflows} &= 0 \\ \text{NPV} &= 0 \\ \text{PI} &= 1.0 \\ \Sigma\text{PV cash inflows} &= \Sigma\text{PV cash outflows} \end{aligned} \tag{6.5.5}$$

In general, the calculation procedure involves a trial-and-error solution, unless the annual cash flows subsequent to the investment take the form of an annuity. The following examples illustrate the calculation procedures for determining the internal rate of return.

Example 6.5.6. Given an investment project having the following annual cash flows, find the IRR.

Year	Cash Flow
0	$ — 30,000
1	— 1,000
2	5,000
3	5,500
4	4,000
5	17,000
6	20,000
7	20,000
8	— 2,000
9	10,000

Solution: Step 1. Pick an interest rate and solve for the NPV. Try 15%.

$$\begin{aligned} \text{NPV} = &-30{,}000\ (1.0) - 1{,}000\ (P/F,1,15\%) + 5{,}000\ (P/F,2,15) \\ &+ 5{,}500\ (P/F,\ 3,15) + 4{,}000(P/F,4,15) + 17{,}000(P/F,5,15) + 20{,}000(P/F,6,15) + 20{,}000(P/F,7,15) \\ &- 2{,}000(P/F,8,15) + 10{,}000(P/F,9,15) \\ = &\ \$+5{,}619 \end{aligned}$$

Since the NPV > 0, 15% is not the IRR. It now becomes necessary to select a higher interest rate in order to reduce the NPV value. If r = 20% is used, the NPV = $-1,664 and, therefore, this rate is too high. By interpolation, the correct value for the IRR is determined to be 18.7%.

Example 6.5.7. Given an investment that promises the following uniform annual cash flows, find the IRR.

Year	Cash Flow
0	$ — 20,000
1	6,000
2	6,000
3	6,000
4	6,000
5	6,000

Solution. Since the annual cash flows subsequent to the investment are in the form of an annuity, the solution is simpler and takes the following form:

$$\begin{aligned} \Sigma\text{PV outflows} &= \Sigma\text{PV inflows} \\ \$20{,}000 &= 6{,}000(P/A,5,\text{X}\%) \\ \frac{20{,}000}{6{,}000} &= (P/A,5,\text{X}\%) \\ 3.33 &= (P/A,5,\text{X}\%) \end{aligned}$$

The solution is found by looking for the value 3.33 under the P/A column for n = 5 years in the appropriate interest table. The value 3.33 lies between 15 and 16%. By interpolation, the correct IRR is 15.2%. Most hand-held business calculators have pre-programmed IRR routines for the rapid solution of all such problems.

The acceptance or rejection of a project based on the IRR criterion is made by comparing the calculated rate with the required rate of return, or cutoff rate, established by the firm. If the IRR exceeds the required rate the project should be recommended; if not, it should be rejected.

Because the internal rate of return is such a popular evaluation criterion throughout the minerals industry and others, it deserves careful scrutiny to ensure that it is truly worthy of this popularity. The following points are offered for consideration:

1. Even though the IRR provides for the determination of an internal percentage rate, it still must be compared with the

hurdle, cutoff, or required rate of return established by the firm before the accept/reject decision can be made. Presumably this stipulated required rate of return established by the firm is related to the firm's cost of capital or required cutoff rate and carries with it the implicit borrowing and reinvestment assumptions of any discounting process. If this is not the case, and the required rate of return is a subjectively determined value, then similar criticism to that offered in the payback period discussion is warranted.

2. Perhaps the most significant problem associated with the IRR lies in what engineers and managers perceive it to mean. When people speak of a project's projected rate of return they typically are thinking in terms of the project's "rate of return on investment." This implication brings forth some interesting questions.

a. What is the real return generated by a project? Should this return be measured in terms of profits or cash flows, since cash flows represent a return on and a return of investment?

b. What is the investment? Since part of the investment is returned annually, the amount of investment remaining must be continually declining. Therefore, *all* of the investment is not working on an an annual basis. Consequently, what should be used for "investment" in the calculation procedure?

Clearly, these are complex questions, and anyone who has worked in the area of project evaluation appreciates the difficulty involved in arriving at answers. However, these questions do illustrate some misconceptions many individuals have with respect to the meaning of the term rate of return.

The *rate of return* calculated in the foregoing fashion is the percentage or rate of interest earned on the *unrecovered* portion of the investment such that the cash flow schedule makes the unrecovered investment equal to zero at the end of the investment's life. Thus the *whole* of the investment can only earn the calculated rate of return if the intermediate cash flows are reinvested at the calculated rate for the remaining life of the project.

Because the IRR is merely the mathematical solution to an algebraic equation, some questions regarding its suitability as an investment criterion have arisen under certain circumstances. Some of these questions concern the following:

1. Implicit reinvest assumptions.
2. Multiple solving rates.
3. Appropriate hurdle rates.

Among these problems, only the second—multiple solving rates—occasionally prevents the IRR from accurately ranking investment proposals. A necessary but not sufficient condition for there to be more than one interest rate that will solve the basic IRR equation is that there must be more than one sign reversal in the cash flows. A typical investment proposal contains one such reversal: cash outflow during construction followed by cash inflow during operation. If additional sign reversals occur, additional solving rates may exist. In such a case, no one solving rate is any more valid than any other, and, therefore, some other investment criterion should be used.

The reader is referred to Gentry and O'Neil (1984) for a complete discussion of the three potential problem areas cited.

In spite of the limitations mentioned, the IRR remains widely used in the minerals industry. Virtually every new mining project must pass an IRR test before construction approval is granted.

6.5.3.3 Comparison of Methods

The following discussion relates to some specific relationships among evaluation criteria which are generally of interest to investment proposal analysts.

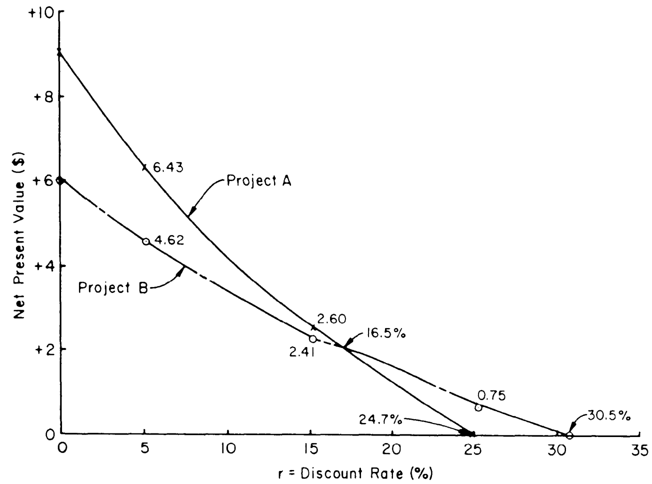

Fig. 6.5.3. Present value profiles for two projects, showing NPV and IRR values.

IRR vs. Payback Period: The internal rate of return and the payback period continue to be two of the more popular evaluation techniques utilized in the minerals industry. Although some relationships do exist between these criteria, they occur under some rather unique circumstances. For instance, where projects have long lives, substantially in excess of the payback period, and where income streams are uniform each year, the payback period is a good approximation to the reciprocal of the internal rate of return. In the unique case where $n \to \infty$, this relationship exists precisely.

IRR vs. NPV: The internal rate of return and the present value methods provide identical accept/reject answers for a single investment proposal. However, it is important to recognize that these two discounted cash flow techniques can give contradictory results when comparing mutually exclusive projects (only one can be selected). Consider two mutually exclusive investment proposals, A and B, which are expected to generate annual cash flows as follows:

	Annual cash flows ($1,000s)	
Year	Project A	Project B
0	$−10	$−10
1	1	7
2	5	5
3	6	3
4	7	1

Fig. 6.5.3 illustrates the net present value profiles for each of these projects. Notice that the IRR for projects A and B are 24.7 and 30.5%, respectively. Therefore, project B is considered superior to project A. However, if the required rate of return were 15% the NPV of proposals A and B is 2.60 and 2.41, respectively, and project A is preferred to project B because it contributes more wealth to the firm. At a required rate of approximately 16.5%, there is virtually no difference between the two projects.

The conflict between these two criteria is the result of different implied assumptions for reinvestment rates for funds generated by the projects. The internal rate of return method assumes that received funds are reinvested at the IRR over the remaining life of the project. The present value method assumes reinvestment at a rate equal to the required rate of return used as the discount rate.

In view of this conflict, which method is best for evaluating investment proposals? The answer to this question depends upon what is considered to be the appropriate reinvestment rate for the intermediate cash flows generated by the project. If one must choose between these two techniques, most believe the present value method is superior—at least from a theoretical standpoint.

When using the internal rate of return to rank projects, a high reinvestment rate is assumed for a proposal having a high IRR whereas a proposal having a low IRR carries with it a low reinvestment rate assumption. Only by coincidence will the IRR calculated be the same as the reinvestment rate actually available to the firm for intermediate cash flows. Also there is seldom any sound reason to assume that reinvestment opportunities following one project would be more favorable than those following another project.

In contrast, the present value method assumes the required rate of return is the reinvestment rate which remains the same for *all* proposals. This rate is intended to represent the minimum return on opportunities available to the firm. This may introduce some conservatism into the calculation, since actual reinvestment rates may exceed these minimum rates. Nonetheless, it has the advantage of being applied consistently to all investment proposals. For these reasons the present value method is preferred over the IRR method for ranking projects, remembering that only in the case of mutually exclusive projects can this conflict arise.

6.5.4 EVALUATING ALTERNATIVES

The previous discussions dealt primarily with the problem of evaluating individual investment projects from the standpoint of measuring proposal acceptability to the firm. The evaluation criteria discussed are simply methods for helping the firm make the appropriate accept/reject decision for a given investment proposal. However, the final investment decision is not based solely on the outcome of the accept/reject decision resulting from evaluation of the investment proposal. Rather, an investment decision also must be based on determination of which of the acceptable investment proposals are best in terms of meeting the objectives of the firm. Consequently, the problem is not one of simply asking, “Are projects A and B acceptable to the firm,” but also, “Is project A better or worse than project B?” It is this problem of ranking or evaluating investment alternatives that is discussed briefly here.

Since these issues are essential to the problem of *capital budgeting,* it may be beneficial to place the problem in proper perspective. Briefly, capital budgeting is the process of allocating available capital in an optimal manner to investment proposals, the benefits from which are to be realized in the future. In a general sense, capital budgeting encompasses:

1. Generation of investment proposals.
2. Estimation of annual cash flows for the proposals.
3. Evaluation of the cash flows.
4. Selection of projects based on an acceptance criterion.
5. Continuous reevaluation of the proposals after acceptance or for investment.

This final selection of projects for investment is based on determination of which projects are acceptable to the firm and, ultimately, the relative desirability of these investment proposals. This latter aspect of evaluating investment alternatives is critical to the capital budgeting process.

Most financial managers view the capital budgeting problem as one concerned with the choice of a group of investment projects from a larger suite of *acceptable* proposals. This problem of *budgeting* capital stems from one or more constraints which prohibit the funding of all acceptable projects available to the firm. If there were no capital constraints imposed, the firm would simply invest in all *acceptable* proposals. Unfortunately, few firms have this luxury, and the general case finds constraints of one form or another imposed on the organization that affect the ultimate investment decision. Typically, these constraints result from a shortage of available capital for new investment proposals, although restrictions of materials and supplies, limited labor availability and management talent, and the mutual exclusiveness of investment proposals also may exist.

If the financial objective of the firm is—it should be—to maximize stockholder wealth, then capital budgeting decisions should be based on the following basic principles (Stevens, 1979, p. 157):

1. Every increment of capital expenditure must justify itself, and

2. An acceptable investment proposal today is better than the speculation that a better proposal will become available in the future.

Dependent vs. Independent Projects: An investment proposal is said to be *independent* when the acceptance of this proposal from a suite of proposals has no effect on the acceptance of any of the other proposals contained in the suite. It is doubtful if very many proposals in a firm are truly independent, but they generally are considered to be independent if they are functionally different. For example, proposals concerning the purchase of a new rotary drill rig, air conditioning the corporate office building, and undertaking a new marketing campaign would generally be considered to be independent proposals.

The capital budgeting problem associated with choosing between independent investment proposal alternatives generally is quite easy. Under these conditions, an appropriate evaluation criterion is used to make the accept/reject decision. These criterion values can then be ranked and the relative proposal desirability determined.

A potential problem with ranking independent investment proposals arises when the IRR and present value methods are used. As pointed out earlier the IRR method will give consistent results with the present value method for accept/reject decisions. However, these criteria can provide inconsistent ranking of independent investment proposals, as previously discussed and illustrated in Fig. 6.2.3.

The more general case involving investment proposals is where they are not independent but are related to one another in such a way that the acceptance of one proposal from within the suite of proposals will influence the acceptance of others. The most common case of investment proposal interdependencies is that of *mutually exclusive* proposals. Mutually exclusive proposals refer to the situation where a group of proposals are related to one another in such a manner that the acceptance of one proposal precludes the acceptance of any of the other proposals. An example of mutually exclusive investment proposals might be the situation where a mine requires an additional piece of primary loading equipment. The investment proposals to be considered might include an electric shovel, hydraulic shovel, and front-end loader. The selection of any one of these proposals would preclude any of the other options from further consideration, since only one alternative is necessary to perform the job. Mutually exclusive investment proposals are a special case of the capital budgeting problem. The appropriate method for analyzing and ranking mutually exclusive proposals is covered later in this chapter.

It is perhaps important to note that whenever there is *capital rationing*—constraints on the amount of capital available for investments—and the aggregate investment cost of all acceptable proposals exceeds the capital available for investment, financial interdependencies are introduced between investment proposals. This may occur, for example, when one project that ranks lower than another is accepted so that a higher return on the entire capital budget is achieved. These interdependencies can occur whether the proposals are inherently independent, contingent, or mutually exclusive. Although these interdependencies are often not obvious, they are, nonetheless, introduced whenever budget constraints are imposed and amplify the importance of the capital budgeting problem.

Three particular situations that may be encountered with mutually exclusive projects are discussed in the following.

6.5.4.1. Projects Having Unequal Lives

The comparison of mutually exclusive investment proposal alternatives having different lives is a common one and represents a special case in the capital budgeting exercise.

It should be noted that the capital budgeting decision in this case concerns investing in two courses of action, not just investing in two projects. The fundamental consideration centers on the total economic impact generated by each of the two courses of action at a given point in the future. Also these opportunities need not be mutually exclusive. For instance, under the constraints of capital rationing, one may be faced with the classic problem of investing in a large, long-life mine promising a modest rate of return vs. small, short-life mines promising high rates of return. An important question here is, "Can the firm continue to generate small-mine reinvestment opportunities (i.e., what are the reinvestment assumptions)?"

When comparing investment proposal alternatives with unequal lives, the basic principle that all alternatives under consideration must be compared over the same time span is fundamental to sound decision making. Equal time spans for investment alternatives must be assumed if the effect of undertaking one alternative is to be compared directly with the effect of undertaking any other alternative.

The basis for comparing mutually exclusive investment proposal alternatives with unequal lives is generally based on one of the following three common assumptions regarding future alternatives (Stevens, 1979, p. 161):

1. Assume that money generated (cash flows) by each alternative will be invested by the firm in other assets that will earn the minimum or required rate of return for a period of time equal to the life of the longest alternative.

2. Assume that each investment alternative will recycle for a period of time equal to the least common multiple of the alternatives' lives. When alternatives are recycled under this assumption, the initial investment, life, salvage value, and annual disbursements are assumed to be identical to the estimates used for the first life cycle.

3. Make specific assumptions (estimates) about future investment opportunities for a period of time equal to the life of the longest alternative.

The appropriate assumption to use will depend upon the type of problem and the assumption which is believed to be the most accurate representation of the future. The following example illustrates assumption 1.

Example 6.5.8. Suppose the following cash flows represent two mutually exclusive investment proposals which have to deal with expanding a mine's production. If the required rate is 12%, which alternative should be selected?

Solution.

Year	Annual Cash Flows ($1000s) Project A	Project B
0	$– 150	$–200
1	55	60
2	55	60
3	55	60
4	55	60
5	55	60
6		60
7		60
8		60
IRR	24.3%	24.9%

The IRR indicates that project B is slightly more profitable than project A. Calculating the NPV of both projects using a required rate of return of 12% yields the following:

$$\begin{aligned} NPV_A &= 55(F/A,12\%,5)(F/P,12\%,3)(P/F,12\%,8) - 150 \\ &= 55(6.353)(1.405)(0.4039) - 150 = 48.29 \\ NPV_B &= (F/A,12\%,8)(P/F,12\%,8) - 200 \\ & \quad 60(12.300)(0.4039) - 200 = 98.06 \end{aligned}$$

The NPV analysis suggests that project B will maximize the value to the firm, and therefore project B should be accepted under assumption 1. Obviously, standard NPV discounting could have been used in the example rather than the circuitous route of forward compounding followed by discounting.

Assumption 2 is often applied to situations where mutually exclusive investment proposal alternatives are measured in terms of negative cash flows. These are typically investment proposals common to most operating divisions and pertain to cost comparisons or equipment replacement alternatives. The following illustrates this procedure.

Example 6.5.9. Assume the following two machines can perform a given job equally well. If the initial investment and annual disbursements are as given and the required rate of return is 10%, which machine should be selected?

	Machine X	Machine Y
Initial investment ($1000s)	150	200
Annual operating disbursements ($1000s)	18	10
Life	5 yr	10 yr
Salvage value ($1000s)	2	0

Solution. Under assumption 2, comparison of the two machine alternatives may be represented as follows:

Year	Annual Cash Flows ($1000s) Machine X	Machine Y
0	−150	−200
1	− 18	− 10
2	− 18	− 10
3	− 18	− 10
4	− 18	− 10
5	− 18, +2, −150	− 10
6	− 18	− 10
7	− 18	− 10
8	− 18	− 10
9	− 18	− 10
10	− 18, +2	− 10

The NPV calculations are as follows:

$$
\begin{aligned}
NPV_x &= -18(P/A,10\%,10) + 2(P/F,10\%,5) - 150(P/F,10\%,5) - 150 + 2(P/F,10\%,10) \\
&= -18(6.1446) + 2(0.6209) - 150(0.6209) - 150 + 2(0.3856) \\
&= \$-351.73
\end{aligned}
$$

$$
\begin{aligned}
NPV_y &= -10(P/A,10\%,10) - 200 \\
&= -10(6.1446) - 200 \\
&= \$-261.45
\end{aligned}
$$

Expressed in equivalent uniform annual costs (EUAC) the machines would have the following costs:

$$
\begin{aligned}
EUAC_x &= (-351.73)(0.1628) = \$-57.26 \\
EUAC_y &= (-261.45)(0.1628) = \$-42.56
\end{aligned}
$$

Based on this analysis, machine Y promises the firm an annual cost savings of $14,700 (57,260 — 42,560) per year over the 10-year interval, if it is selected over machine X. Therefore, machine Y is the preferred alternative.

The reader is referred to Gentry and O'Neil (1984) for a further discussion of the strengths and weaknesses of the three approaches described for evaluating projects with unequal lives.

6.5.4.2 Projects Having Unequal Investment

When comparing mutually exclusive investment proposal alternatives, there are two main principles that should apply. These are as follows (Canada, 1971, p. 62):

1. Each increment of investment capital must justify itself.
2. Compare a higher investment project against a lower investment only if the lower investment project is justified.

Based on these principles, the criterion for choosing between investment proposal alternatives then becomes, "select the proposal that requires the highest investment for which each increment of invested capital is justified."

It is this concept of "bigger is better" that is discussed in this section. Obviously, if two proposals have the same indicated rate of return but different initial investment requirements, the project requiring the larger investment will generate the largest magnitude of total benefits or wealth to the firm. In essence, the problem is one of maximizing use of the investment dollar.

Optimizing use of the investment dollar is really not a troublesome issue in the situation where a firm has adequate investment capital available to undertake all investment proposals that promise returns in excess of the firm's required rate of return. Under these conditions the wealth of the firm will, in theory, be maximized by simply investing in all projects that surpass the cutoff rate. However, where capital rationing does exist, the problem of optimum utilization is an important one.

Under the capital-rationing constraint, all investment proposals that exceed the firm's required or cutoff rate may not be chosen for investment. Additionally, the firm may generate more wealth by selecting several smaller, less profitable proposals that fully utilize the capital budget than to accept one large investment proposal that results in only partial utilization of the budget. The following illustrates this concept.

Example 6.5.10. Suppose that the following investment proposals were available to a firm. If the capital budget constraint is $500,000 for the period, select the optimal investment portfolio.

Proposal	Profitability Index	Initial Capital Investment
7	1.14	$400,000
3	1.13	200,000
5	1.11	300,000
4	1.05	250,000

Solution. The objective is to find that combination of investment proposals that provide the highest net present value to the firm. There are three primary combinations:

Alternative No. 1

Proposal 7: $400,000(1.14 – 1.0) = $56,000 = NPV

Alternative No. 2

Proposal 3: $200,000(1.13 – 1.0) = $26,000
Proposal 5: $300,000(1.11 – 1.0) = 33,000
NPV $59,000

Alternative No. 3

Proposal 3: $200,000(1.13 – 1.0) = $26,000
Proposal 4: $250,000(1.05 – 1.0) = 12,500
NPV $38,500

This solution shows that alternative No. 2 (proposal 3 and 5) should be chosen since the NPV to the firm is maximized with the selection of these proposals. The reason is that more of the available budget is utilized with this combination of proposals, even though a more profitable individual proposal was available to the firm.

This example also illustrates the importance of initial capital outlays when functioning under the constraints of capital budgeting. Implied in the foregoing example is the assumption that uninvested capital has a NPV = 0. This is the same as assuming it is placed in an investment that has a yield equal to the required rate of return. If it cannot be reinvested such that NPV is equal to 0, then full utilization of the investment capital available is even more important.

6.5.4.3 Incremental (Marginal) Analysis

In the preceding section it was noted that one of the main principles that should apply when comparing mutually exclusive investment proposal alternatives is that each increment of investment capital must justify itself. This is an aspect that is often overlooked in many analyses, but one that is fundamental to the capital budgeting problem—particularly under capital-rationing constraints.

Incremental or marginal analysis is a technique that can help the evaluator choose between mutually exclusive projects having unequal investments. The concept is to

1. Calculate the differential investments and annual cash flows between the projects.
2. Compare the calculated rate of return on the differential cash flows with the required rate of return.

If this rate exceeds the required rate, the additional incremental investment is justified.

Example 6.5.11. Suppose the following cash flow estimates represent four mutually exclusive investment proposals. If the firm's required rate of return is 15%, which proposal should be chosen?

Year	Cash Flows Proposal A	Proposal B	Proposal C	Proposal D
0	$ — 12,000	$ — 15,000	$ — 19,000	$—21,000
1	3,000	3,700	4,200	4,600
↓	3,000	3,700	4,200	4,600
	3,000	3,700	4,200	4,600
	3,000	3,700	4,200	4,600
	3,000	3,700	4,200	4,600
10	3,000	3,700	4,200	4,600
IRR (%)	21.4	21.0	17.8	17.5
NPV (at 15%)	3,056	3,569	2,079	2,086

Solution. The IRR for all the proposals exceeds the 15% required rate of return, and, therefore, each would be acceptable to the firm. However, if only one proposal is required, the IRR criterion suggests that proposal A is superior.

At this point it is necessary to perform a rate of return calculation on each increment to determine if the incremental proposal investments can be justified. A comparison between proposals A and B shows:

$$\text{B/A:}(P/A,r\%,10) = \frac{15{,}000 - 12{,}000}{3700 - 3000} = 4.2857$$

$$r = 19.36\%$$

This indicates that proposal B is preferred to proposal A because the return on the incremental investment of $3000 exceeds 15%. The next comparison is between proposals C and B.

$$\text{C/B:}(P/A,r\%,10) = \frac{19{,}000 - 15{,}000}{4200 - 3700} = 8.00$$

$$r = 4.2870$$

This comparison indicates that proposal C should be eliminated because the return on the incremental investment of $4000 is less than the required rate of 15%. The last comparison is between proposals D and B.

$$\text{D/B:}(P/A,r\%,10) = \frac{21{,}000 - 15{,}000}{4600 - 3700} = 6.6667$$

$$r = 8.14\%$$

The final comparison indicates that the rate of return on this incremental investment is also less than the required rate, and therefore proposal B is the final choice.

In part 6.5.3.3 of this chapter, a comparison was made between the IRR and NPV criteria with respect to inconsistent rankings of investment proposals. The simple example used to demonstrate this feature was as follows:

Year	Annual Cash Flows ($1000s) Project A	Project B
0	$–10	$–10
1	1	7
2	5	5
3	6	3
4	7	1
IRR (%)	24.7	30.5
NPV (15%)	2.60	2.41
Required rate of return:	15%	

If an incremental analysis were performed on this example, the following would result:

Year	Incremental Cash Flows, A-B ($1000s)
0	0
1	−6
2	0
3	3
4	6

The IRR that equates $–6 at the end of year 1 with $3 and $6 at the end of years 3 and 4, respectively, is 16.54%. Because this rate exceeds the required rate of return of 15%, project A should be selected, even though project B has the larger IRR.

It is interesting and important to note that both of these examples illustrate situations where the proposal with the largest IRR is not necessarily the best proposal, when mutually exclusive proposals are being considered. Proposal choice in the mutually exclusive case is, of course, dependent upon the required rate of return and the associated reinvestment rate assumption discussed earlier in this chapter. The incremental analysis illustrated in both examples resulted in choosing investment proposals with the highest net present values. These proposals could have been selected simply by comparing NPV values initially. Therefore, it is possible to generalize and state that the internal rate of return and net present value methods give the same results in capital budgeting problems, if *incremental analysis* is used on mutually exclusive projects.

6.5.5. HANDLING RISK

Although the preceding sections of this chapter describe the type of evaluations frequently performed in the mining industry, it has been assumed that input data are known with certainty—clearly an erroneous simplification. In reality, estimates of ore grade, mining cost, metal price, etc., are subject to varying degrees of uncertainty due to the inability to predict the future with much precision.

Risk, in the context of this discussion, is the unforeseen deviation of individual cash flows from expected values for a capital project. For a mining venture, the source of this uncertainty could be any number of factors relating to items such as ore grade, ore reserve tonnage, operating costs, product prices, etc. With conventional deterministic evaluations, a point estimate of each of these factors is made. Subsequent operating results usually reveal these estimates to be in error, thus giving rise to different cash flows than expected.

A firm can take uncertainty into account in many ways. A discussion of some of the more common traditional methods follows.

6.5.5.1 Simplified Approaches

One method used to compensate for risk is to demand shorter payout periods for riskier projects. Aside from the shortcomings of the payout period as a capital investment criterion, the technique encounters additional problems here. Payout period does not measure risk directly; in fact, it is a rather poor measure of profitability. Risk in the early years of a project (when cash inflows are most important) is not affected by the payout period. Risk is considered only by ignoring cash flows after the payout period. By adjusting the maximum acceptable payout period, risk may be resolved sooner, but it will not be diminished.

Difficulty arises with risk-adjusted payout periods as to how much adjustment to make for a particular project. One might agree that the maximum acceptable payout period for a large new mine in a politically turbulent part of the world should be less than for a similar investment in the United States. The question is, of course, "How much less?" for which there is no valid, objective answer. Subjective decisions are required and considerable arbitrariness can creep into the decision. The decision maker can select any course of action he or she pleases simply by assigning prohibitive maximum acceptable payout periods for all other alternatives.

As supplementary information, the payout period is useful in studying the uncertainty in an investment project. Risk-adjusted payout period, however, is a poor primary method for accounting for risk in capital projects.

Risk Adjusted Discount Rate: It is very common for firms to require risky projects to have higher rates of return on investment than safer ones. For example, a firm might establish three classes of capital projects and associated rates of returns as follows:

Class 1: Replacement of equipment in an ongoing operation. Market is known, technology is proven, so that risk is fairly low. Maybe a discount rate of 10% is acceptable here.

Class 2: Expansion of present mine or plant facilities. Many technical problems have already been solved, but there may be a question in marketing. Can the additional output be sold at pre-expansion prices? The added risk here may indicate that a higher discount rate is in order, say, 15%.

Class 3: Opening of a new operation, entering a new market, etc. Here the sources of uncertainty are many, justifying, perhaps, 20% as the minimum acceptable rate of return on such projects.

The magnitudes of the discount rates used in the foregoing example are not important; only the concept of risk-adjusted discount rates is being demonstrated.

The major drawback of this method is the same as with risk-adjusted payout period—subjective establishment of hurdle values. There is no method for assigning acceptable risk-adjusted rates of return to individual projects in an objective manner, so inconsistency is inevitable. Nonetheless, the method is easy to apply and is not likely to disappear soon.

Risk-Adjusted Input Parameters: When considering the extensive uncertainty encountered in evaluating new copper mining ventures, industry executives often compensate for this risk by using very low prices for copper. Similarly, conservative values for other input parameters, such as mining costs, ore grade, etc., during the evaluation stage can screen out all but the best projects. Of course, by being excessively conservative, all projects can be rejected, and this is a real danger with risk-adjusted input parameters. When more than one variable is adjusted, compounded conservatism can easily reject nearly any project. Also subjectivity in quantifying the risk-adjusted variables causes the same type of problems as discussed previously.

6.5.5.2 Sensitivity Analysis

The term "sensitivity analysis" simply describes the process of determining the sensitivity of the results of the project to changes in any one input variable. For example, how sensitive is the project NPV (or IRR, etc.) to changes in, say, ore grade? Only one variable is changed in each iteration to isolate the impact of that variable. In the subsequent section on probabilistic risk analysis, this restriction is relaxed, as simultaneous changes are permitted in several variables.

Sensitivity analysis is a very simple approach to studying project risk. It is intuitively appealing and is, therefore, very widely used. Often, after identifying the most important variables, many firms extend the method by combining changes in two or three variables at once to study the combined impacts. Another common extension of the method is to compute an "upside case" combining favorable values for the key variables, and—more important—a "downside" case where adverse values of several important variables occur simultaneously.

Sensitivity results are frequently plotted in simple graphical form to illustrate the risk attributable to each variable.

A number of sensitivity analyses have been calculated for the Bullion Mining Co. example, discussed in 6.5.6. The reader should work through one or two annual cash flows to become comfortable with the procedure.

6.5.5.3 Probabilistic Risk Analysis

In capital intensive mining projects where investments exceeding $100 million are common, treating uncertainty exclusively with one of the arbitrary methods or with sensitivity analysis may be unsatisfactory. More quantitative data relevant to the sources and magnitude of risk can be developed, and, with such large sums at stake, additional analysis is certainly justified. Rather than using "ignorance factors" to discount risk, an attempt should be made to identify specific sources and estimate the magnitude of this risk. By quantifying risk in this manner, it is possible to estimate the chance of achieving a given level of profitability with a specific project. Management then has much more information at its disposal, so that an intelligent assessment can be made between risk and expected profits.

Stochastic Risk Analysis Models: The general method by which the level and magnitude of risk associated with capital projects in mining is determined is to establish probability distributions for the input variables rather than treating each of these parameters as being known with certainty. For example, in the deterministic case, an ore grade of 3.4% Zn may be used, when it is clear that in reality, the ore grade may be as low as 2.5% Zn or as high as 4.7% Zn. This possible range of values for ore grade can now be recognized by establishing a probability distribution for ore grade. Furthermore, with recent advances in geostatistical methods of ore reserve estimation, analysts no longer need rely on subjective probability estimates by experts to establish these distributions.

The probability distributions for the input variables can be assumed to be either discrete or continuous, the latter usually being the more realistic case.

In the case of *discrete probability distributions,* and with the aid of a computer, the analyst can easily compute an exhaustive set of all possible outcomes, along with the respective probability of occurrence for each. This probability distribution of outcomes can then be examined to quantify the level of risk associated with the project. For example, if the firm's minimum acceptable IRR is 15%, the distribution of outcomes can provide the probability that the IRR > 15%, or the Pr[IRR < 12%], and so forth. For an example illustrating the use of discrete probability distributions for risk analysis, see Gentry and O'Neil (1984).

With *continuous probability distributions* for input variables, the process is directly analogous. That is, values for each input variable are selected from individual continuous probability distributions and the IRR, or some other investment criterion, is determined. Here, however, because continuous probability distribution functions are used, there are an infinite number of possible outcomes, so an exhaustive set of outcomes can not be calculated.

To overcome this obstacle, a system of random, or Monte Carlo, sampling can be employed to choose values for individual variables in calculating a value for the investment criterion. If this process is repeated many times, a continuous probability distribution of possible outcomes will emerge. In all but the most trivial examples of this type of risk analysis, computer assistance is required due to the large number of iterations usually required before a stable distribution of outcomes is created. Once the distribution is created, however, project risk is again quantified, and probabilities of exceeding various levels of profitability can be easily determined. (Again the reader is referred to Gentry and O'Neil, 1984, for further discussion and examples of probabilistic risk analysis.)

The field of risk analysis of capital investments has advanced far beyond the fundamental approaches described in the foregoing. In particular, greater attention has been given to interdependent variables and events. That is, the system described above assumed independence of input variables and either independence or perfect dependence of project performance over time. For example, ore head grade and metallurgical recovery are two variables that frequently are interdependent. Therefore, independent random samples of each variable might yield incorrect results. Furthermore, project performance from period to period also rarely is independent. O'Hara (1982) has suggested one approach to solving this problem in mining evaluations. However, although an active research area, risk analysis in general has not gained wide acceptance in the mining industry, and therefore further discussion here is not warranted.

6.5.5.4 Competitive Cost Position

Generally, the most crucial variable in a mining evaluation is the one least amenable to accurate prediction: commodity price. Many mineral products are priced daily in world markets, and such price movements are influenced by a wide variety of unpredictable stimuli. Most mine owners have learned a painful lesson with mines constructed in the anticipation of rising commodity prices. Unless those mines are low cost producers, cyclical troughs in the price cycle can produce disastrous results even though the long-run price trend may be upward.

As a consequence of the relative unpredictability of mineral prices, many mining firms stress competitive cost analysis as the most important risk analysis technique. The basic theory is that only by being a relatively low-cost producer can a miner withstand market downturns. Other higher cost mines should, therefore, be forced to curtail production earlier in a falling market, thus reducing supply and helping restore satisfactory prices.

Most major companies pay great attention to the position a prospective new mine occupies on the world competitive cost curve. If its production cost per unit of salable product is in the upper 50% of all production, it is best to reexamine the project carefully, even if the current spot price for the commodity suggests a satisfactory ROI. Unless marketing arrangements assure a commodity price sufficiently high to protect the project in down markets, mine investors should strive for production costs in the lower 50% of all producers.

6.5.6 EXAMPLE EVALUATION

A prospective gold-mining operation, Bullion Mining Co., has been constructed to illustrate the evaluation techniques described in Chapter 6.5. This hypothetical but realistic example should be studied closely by the reader to understand the investment analysis methods demonstrated.

The following financial model (Example 6.5.12) represents the evaluation of a gold deposit. The assumption is that the deposit will be open pit mined. The gold ore then would be put through a crushing and grinding circuit before treatment in a carbon-in-leach (CIL) process to extract the gold. The final product would be gold doré, which would be shipped to a gold refinery where pure gold bars are produced for sale on the gold bullion markets.

The model assumes a mining reserve of 3.6 million tons @ 0.133 oz/ton gold comprising three separate deposits, A, B, and C. The reserves of the deposits are A: 1.1 million tons @ 0.145 oz/ton gold and stripping ratio of 9.2:1 (waste:ore); B: 1.7 million tons @ 0.136 oz/ton gold and stripping ratio of 12.3:1; C: 0.8 million tons @ 0.110 oz/ton gold and a stripping ratio of 13.5:1. It is assumed that 25% of the waste overlying the ore would be prestripped before any ore is mined. The cost of this is capitalized. The CIL process recovers 93% of the gold from the ore. The mining and processing operating costs are detailed in the model, along with the capital costs of constructing the mine. The mining of ore is assumed to be performed by a contract mining company so that the capital cost of development is reduced, while the cost of mining is comensurately increased. The mine is assumed to be isolated and requires a small camp to house the personnel in single accommodation while working at the mine and transporting the personnel to a town for their days off. The fixed administration cost allows for the cost of general administration (e.g. accounting, purchasing, and stores) and the operating cost of a single accommodation camp and transport of personnel in and out of the site.

The sensitivity analysis considered three variables: gold price, capital cost, and tax rate level. The project's viability is most sensitive to the price of gold, which relates directly to the revenue of the operation. A similar effect on the viability is caused by variations in the grade of the ore, tonnage throughput, and recovery of gold. The revenue equation is

$$\text{Revenue} = \text{Throughput} \times \text{Ore Grade} \times \text{Recovery} \times \text{Gold Price} \tag{6.5.6}$$

The other major variables in the evaluation are operating costs and the total mining reserve. The effect of a change in stripping ratio will change the quantity of material mined and so directly affect the operating cost.

Chapter 6.6
MINE FINANCING

C. Richard Tinsley

For a mining engineer absorbed in technical and day-to-day managerial responsibilities, the world of mine finance often seems remote and somewhat mystical. This chapter illustrates that the factors requiring consideration in financing are stunningly simple, although variations, combinations, and synthetic constructions evolve each year and must be checked to ascertain if any offers unique qualities that make financing cheaper and/or easier.

The market sources for money vary from seed investors and tax-shelter monies gambled on the potentially high returns from minerals exploration through to banks and insurance companies that only want to deal with ongoing, cash-rich companies where they feel secure about repayment. An important concept to always remember is that the financier's expected return is proportional to the riskiness of the investment.

Much of this chapter draws heavily from the book, *Finance for the Minerals Industry,* edited by Richard Tinsley, Mark Emerson, and Randy Eppler and published by SME (1985). This reference volume is recommended for further reading on the topics presented in this chapter.

6.6.1 FINANCIAL OBJECTIVES OF A MINING COMPANY

For simplicity, a mining company is assumed to evolve through three stages: an exploration company or syndicate, a development company, and an operating company.

The *exploration company/syndicate* continually seeks risk monies, while the promoters try to retain as much of the equity and as little of the future financing obligations as possible. In general, there are two types of exploration companies: those dedicated to finding and developing a mine and those, usually managed by geologists, that simply develop mineral prospects to an appealing stage and then sell out to reinvest in other exploration.

The *development company* usually has one or two interesting exploration successes, each of which requires financing for further drilling and feasibility studies before actual mine development can be financed. Some junior companies specialize in redeveloping defunct mines or restructuring troubled operations as a means to finance mine development.

Operating companies often fund exploration from internally generated cash flow or they use their financial clout to joint venture the development of a property. An operating company normally has a very different set of financing objectives. Revenue needs to be hedged in the volatile commodity and currency markets. Flexible working capital financing for labor and supplies—and perhaps also to cover stockpiles, freight, and distribution costs—has to be available. Capital costs require servicing, including interest and principal on debt obligations, dividends paid to the suppliers of equity, and the accounting for depletion to reflect replacement of the original ore body. In addition, the government's share via taxes and infrastructure charges, together with fixed costs of administration and most of a mine's labor charges, combine to diminish the financial margin available for future exploration, plant expansions, and replacement equipment.

6.6.1.1 Funding Decision: Capital Structure

A number of theories exist on the best capital structure for a company. Van Horne (1977) summarizes the necessary balance of equity and borrowed money as follows:

"The optimal capital structure for a company includes both equity and debt. Since the interest on borrowed money is deductible from profits for tax purposes, using someone else's money creates an equivalent lower capital cost for the same item purchased."

Besides tax reduction, debt leverages the return on equity which is usually the objective of those in control of the company (i.e., the shareholders and the management team). However, leverage cuts both ways. Van Horne goes on to state that:

"As the ratio of borrowed money to equity money increases, the interest payments and the rate of interest itself become so large that profits may disappear entirely and bankruptcy threatens. The latter situation has an associated cost since assets may have to be sold at distressed prices and lawyer's fees may be substantial in any bankruptcy proceeding."

The exploration company has a capital structure consisting largely of equity or tax-sheltered funds. *Equity* can be raised from individuals, companies, the stock market, occasionally governments and multilateral agencies, investment funds and partnerships, and through the provision of services. *Tax-shelter monies* usually pass the company's tax deductions from exploration and drilling to the investors, either directly or through share/trust structures.

Table 6.6.1 Exploration Company Balance Sheet

	$000
Current Assets	$250
Current Liabilities	(10)
Working Capital	$240
Mineral Properties	2250
Plant and Equipment	50
Shareholders Equity	$2540

When looking at the general formula for a company's balance sheet, one can see that an exploration company's *assets* are basically equal to the equity invested to date, as illustrated in Table 6.6.1. Langdon (1985) offers the following representation of this relationship:

$$\text{Assets} = \text{Liabilities} + \text{Equity}$$

Liabilities are the creditors' rights to assets, and equity is the owners' rights to those assets. When a company begins to the develop mineral projects, the relationship of liabilities to equity (the capital structure) starts to assume increasing importance. The effect of leverage is shown in the following table, in which 50% tax applies, and the interest cost on debt is 10% per annum:

	No Debt				50% Debt			
Return on assets	5%	−10%	−25%	−50%	−5%	−10%	−25%	−50%
Return on equity	2.5%	−5%	−12.5%	−25%	−0%	−5%	−20%	−45%

Carraghiaur (1982) divides up the mine predevelopment and financing process into two stages: delineation drilling and underground exploration/bulk sampling.

Table 6.6.2 illustrates the transition during the development phase towards the use of financial leverage in a company's capital structure. The first critical decision is when to finance a mine development. It is often said that "mines are made, not found" and the development financing is often the reason. However, the availability and relative cost of each financing source changes according to economic conditions. In times of a bear stock market, the effective use of a public stock offering becomes extremely difficult as a vehicle for raising money. At the trough of commodity price cycles, major mining companies often withdraw completely from joint venturing and slash their own exploration budgets. The challenge is to identify which sources of investment financing are currently or prospectively available and the information and development structure that appeals to each.

A mining engineer's generalist background can often be an advantage in this regard since he or she has (or should have) a better idea than most of the value of the project or company (i.e., the intangible or potential worth that cannot be represented adequately in a financial pro-forma projection). He/she also knows, or should know, the technical risks involved. Two projects may look the same on paper, but a good financier must have an accurate sense of when to take whatever development financing can be obtained, based on the availability of funding sources, and of when to hold out based on his/her evaluation of future developments (Cruft, 1985).

These mine development financing decisions are important to the genesis of the capital structure of the operating company. This is summarized in Table 6.6.3.

A theoretical relationship between asset structure and overall capital structure is called the *matching principle,* which simply states that one should finance short-term needs with short-term sources and long-term needs with long-term sources (Langdon, 1985). As can be seen in Fig. 6.6.1, the entity is deemed to be a growing concern, and the growth in current assets requires permanent financing. Also the variations in current assets are those matched with short-term financing.

It is these variations in future cash flows that all financiers attempt to model. Bankers want to see that interest and principal repayments can be met during troughs in project earnings, and investors want to see that adequate dividends will emerge in better times. As a rule of thumb, miners producing materials tradable on a commodity exchange can expect a capital structure of 50% equity:50% debt for very cyclical commodities, unless the debt itself is correlated to that commodity (e.g., a gold loan for a gold mine). A mine with highly predictable cash flows—one keyed to a strong sales contract with take-or-pay provisions (now rare) and escalation clauses—perhaps can move its leverage up to 90 to 100%. A mine with cash flows that are difficult to predict, as with many industrial minerals, can expect to attract very little traditional debt financing.

Financial theorists often disagree on whether an optimal capital structure exists for an operating company. Langdon (1985) and Gentry and O'Neil (1984) summarize the three ap-

Table 6.6.2. Financing Alterations during Predevelopment

Finance Sources	Delineation Drilling	Underground Exploration Bulk Sample	Mine Development
Investment/tax partnerships	X		
Venture Capital	X	X

Table 6.6.3. Components of Capital Structure

Assets	=	Liabilities	+	Equity
Current Assets Cash Marketable securities Accounts receivable Inventory		Current Liabilities Accounts payable Notes payable Current portion of long-term debt Taxes Lease payments		Common Shares Preferred shares Share premium above par Retained earnings
Long-Term Assets Mine/plant Buildings Equipment Land Mineral rights Ore reserves		Long-term liabilities Bank loans Bonds Debentures Long-term notes Leases Subordinated debt		Subordinated debt?

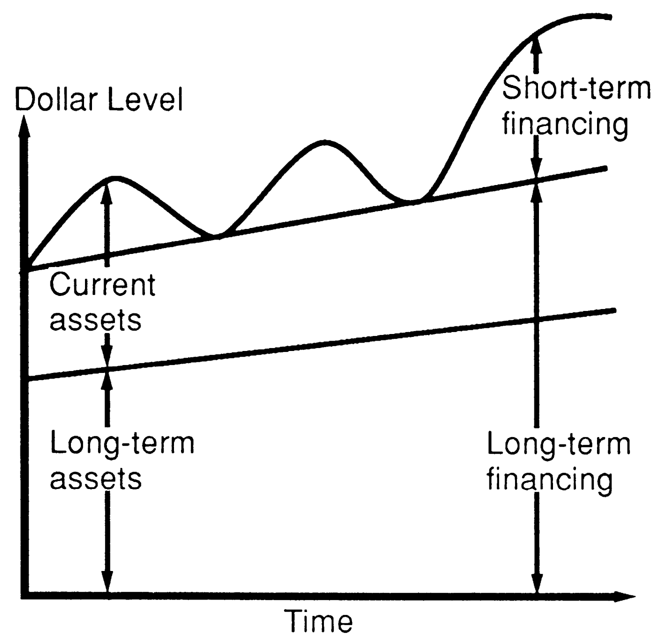

Fig. 6.6.1. Matching principle for financing assets.

proaches normally advocated on this topic—net income, net operating income, and traditional.

The *net income* and *net operating income* approaches assume that debt proceeds are used to repurchase common shares. Most mining companies seem to have better uses for their debt proceeds although major companies have recently adopted this approach as a defensive measure against corporate raiders awash with leveraged buy-out funds. The *traditional method* assumes that the optimal structure occurs just before the leverage level starts to raise the corporation's cost of shares and debt instruments because a threshold of perceived risk has been crossed—usually at or near the industry average debt:equity ratio.

6.6.1.2 Cost of Capital

The corporate cost of capital is discussed in detail in Chapter 6.2 and by Schenck (1985) in the same breadth as discount rates for project valuation and selection. Schenck gives a good example for calculating the cost of capital for an operating company.

Example 6.6.1. Calculation of weighted cost of capital.

Finance Source	% of New Capital	cost, % per annum	After-Tax cost
Bank loans, unsecured	15%	16%	9.6%
Mortgage bond	20%	14%	8.4%
Equipment leases	15%	16%	9.6%
Preferred shares, new	4%	17%	17%
Common shares, new	5%	22%	22%
Internal funds	41%	19%	19%
	100%		16.2%

The weighted average cost of capital is much lower than the cost of new shares. Why? The answer results partially from the deductibility of the interest expense and lease payments from the company's income tax obligation. Therefore, the income tax actually paid is reduced, and thus more money is available to the organization on an after-tax basis.

But such an approach does not measure the impact of different risk factors inherent to the project upon the capital structure or whether or not the cost of capital has any real importance in mine financing. Leverage improves the rate of return, especially in an inflationary environment (Cole, 1985), and the amount of leverage that can be obtained from the financial marketplace varies widely according to the risk profile, especially the mineral/metal product price volatility.

Some of these risks inherent in mine financing are in Table 6.6.4. (Tinsley, 1985).

In the extreme, past equity may be ignored in a financing decision using all debt. In general, the various cost-of-capital measures used in evaluations (e.g., NPV, IRR, ROI and payback, and the methods described in Chapter 6.5) do not provide an adequate means to compare or select a project for development if it is financed.

How then can one judge financing costs? One method is to measure the future cash flow coverage of debt service. This ratio is the annual net cash flow after tax (adjusted for the tax reduction due deduction of interest) divided by the annual principal plus interest charges, all done on a conservative base-case projection. Example 6.6.2 shows a simple start-up project financing with $15 million debt at 10% interest.

Example 6.6.2. Debt service coverage calculation, $ Million.

Year	1	2	3	4
Net revenues	$15	$20	$30	$32
Total cash costs and interest	10	12	14	16
Net Tax Paid	0	3	5	6
Net cash flow	$ 5	$5	$11	$10
Principal repayment	2	2	4	4
Interest Charges	1.5	1.3	1.1	0.8
Debt service	$ 3.5	$ 3.3	$ 5.1	$ 4.8
Debt service coverage ratio	1.42	1.52	2.16	2.08

Table 6.6.4. Assumption of Risks in a Mine Budget Financing

Risk Category	Absorbed by	If "Risky" by
Reserve	Financier	Reserve warranty
Operating; technical		Management agreement, Company, warranty
Cost	Financier	Contract
Management	Financier	Contract
Infrastructure	Financier	Consumer, government
Environmental	Financier, bonding	Company
Market	Financier, contract	Buy-back, take-or-pay
Political	Financier	Insurers, government
Force majeure	Financier, insurers	Company
Foreign exchange	Financier, company	Hedging
Funding	Financier	Swaps, hedging
Participant Agreement, contract	Financier	Joint venture
Engineering	Financier	Insurers, guarantee
Completion	Company	Construction, financier
Syndication	Financier (underwritten)	Company (best efforts)
Legal	Financier	Insurers

If this ratio is around 3 to 4:1, then venture capitalists usually can be attracted. If the ratio is 2 to 3:1, then mining companies often will assume the role of project financiers. If the ratio on the downside case is 1.5:1 or more, then most banks and leasing companies will be participants, but on a secured basis. If a producing project is being acquired by a leveraged buy out, the ratio needs to be a minimum 1.6:1 for the base case, although lower ratios may be tolerable for a year or two (during the turnaround). Strangely, the public markets do not seem to make any judgments about this ratio, preferring instead earnings per share calculations based on net income (not net cash flow) as established by the accounting profession. This further reinforces the notion of some that cost of capital is not critical for mine financing.

6.6.1.3 Changing Market for Funding

A single source of funding is seldom sufficient for all stages of a project or for all the requirements of an operating company. With some 30 to 40 different sources of funding, how can an individual or company make the right selection?

A short historical review will illustrate the changes that have occurred in the financial marketplace. In the mid-l800s, bonds and stocks were major sources of capital for the mining industry, the latter witnessing some famous investments and frauds. Europe, and in particular Britain, was a major source of these monies. In the 1930s, the petroleum industry thrived on production payment financing, especially in Texas. In the 1950s and 1960s, most mining industry financing came from internally generated funds with the notable exception of the aluminium industry, which required debt due to the sheer magnitude of the capital programs (Robinson, 1985).

In the 1960s, commodities with long-term sales contracts, such as iron ore (Australia) and coal (United States), began to attract large-scale bank project financings. The West Germans introduced a tax deduction for investment in mineral exploration overseas to help secure supplies of strategic minerals. Some 600 million deutschemarks (US$200 million) poured into US and Canadian exploration in the late 1960s to early 1970s. West German investments in overseas mine developments also became significant, especially in nickel and copper. The 1970s saw a wave of bank project financings that crested in the mid-1980s.

Canada introduced flow-through share financing in the early 1980s that passed the tax deduction of exploration to the investor in a company's shares. This reached its zenith of some C$l billion per annum in 1988 just prior to its termination in 1989. After the stock market crash of October 1987, any other equity funding sources for exploration essentially dried up.

In the early 1980s, gold loans became widely available in Australia. While still relying on bank project-finance-style guarantees, it nevertheless raised the debt level for new gold projects from 50 to 100% in many cases. At the same time, bonds convertible into gold or shares became popular in Europe, even for junior mining companies in minimum $20 million amounts. The 1987 crash and declining gold prices combined to halt further bond issues.

The US market for high-yield bonds (amounting to $180 billion in 1988), also known as junk bonds, was tapped in 1988 for a privatization of Magma Copper via a leveraged buyout using a $200 million copper-indexed junk bond. Such a subordinated structure would have been unthinkable in 1981 when commodity-indexed bonds briefly came into vogue.

Finally, in the 18 months leading up to the October 1987 stock market crash, billions of dollars in equity were raised by mining companies large and small, which provided the former an opportunity for the retirement of debt that had spiralled with depressed commodity prices prevalent in the first half of the 1980s.

One needs to invest time in assessing when and how to approach the financial markets. As a general rule, unless a finance professional such as a merchant/investment banker or stockbroker is used, it will take one to two years to obtain a feel for the market. Besides establishing some broad parameters such as the amount of further equity/dilution desired, percentage leverage, legal security issues, covenant structures, and the overall timetable, one will determine quickly that future flexibility assumes preeminence among financial objectives, and the cost of funding is pushed to a distant third place after availability of funding.

Early and continuous contact with the financial marketplace also will highlight structural aspects critical in the exploration and development/feasibility process (e.g., minimum reserves, maximum financing size, requirement for offtake contract or hedging mechanisms). This can save embarrassment when premature requests for financing are declined. All too often, the whole mine development process gets stalled while attention is turned to securing the financing mix that may require changes in the feasibility study itself.

6.6.2 EXPLORATION FUNDING

New and improved versions of exploration finance seem to emerge willy-nilly but are usually related to satisfying the changing objectives of the risk capitalist. The following sources of funding are often used in combination, but the principle remains the same. Normally, the earlier the grubstake stage, the greater the percentage of the action to the grubstaker.

6.6.2.1 Private Companies

Exploration funds are often raised privately, either as syndicates of individuals or in private companies established to take advantage of the tax deductions associated with exploration activities. Some tax regimes specify a maximum number of investors in such a company (e.g., Subchapter S corporations in the United States must have 25 or less investors).

6.6.2.2 Tax-loss Funding

Limited partnerships are another form of syndicate where the entrepreneur/geologist or fledgling miner acts as general partner putting up a small proportion of the money and charging a management fee while the limited partners put up the bulk of the funds.

These partnerships are the most prevalent means of tax-loss funding in the United States, although recent rule changes restrict the loss to the amount of money actually at risk. This has reduced the availability of such funds, but it remains tax effective.

In Canada, a means of a tax effective investment is provided by flow-through financing whereby shares could be offered at up to an 80% premium to the present share price, provided these monies were spent on bona fide minerals exploration. The flow-through shareholder was entitled to a tax deduction of 150% or more of the funds invested.

In Australia, trust structures have been developed, most notably for petroleum exploration, where the investor gets a progressive tax deduction as funds are spent on exploration. The trusts are listed on the stock exchange to provide some liquidity to the trust holders and to record how much tax deduction remains.

The disadvantage with tax-loss funding is that the investors tend to focus on the tax angle alone. These investors can be awkward to deal with in the transition to a development company.

6.6.2.3 New Listings/Floats

The public is often tapped as a source of funds, usually through the issuance of shares or trust units, which are listed on stock exchanges as a means of providing trading liquidity. All stock exchanges have regulations that are designed to require adequate disclosure of activities, financial and technical audits, and to restrain insiders from abusing their position.

Before proceeding to the prospectus stage, the exploration company should have obtained proper title to its tenements and claims. It is rare when an initial public offering or float succeeds based only on a geological concept.

The information requirements for a prospectus are summarized in the following. Because it is a legal document, it is fairly expensive to develop. Preparation costs for a simple prospectus may be as low as $50,000, but $150,000 to $250,000 may be closer to the mark for a medium-sized issue. If underwriting fees and expenses of 5 to 15% are added, then one can see that public offerings of much less than $1 million are not worthwhile.

The purchasers of junior mining/exploration company securities are, for the most part, unsophisticated investors with limited financial resources. Generally, junior companies doing public offerings should present several properties for which exploration funds will be devoted, so as to offer the investor some spread of risk in light of the great odds against the ultimate economic viability of any one relatively untested prospect (Chender, 1985). Alternatively, a substantial percentage of the offering proceeds may be dedicated to new properties, in which case the public (and the underwriters) will need to be convinced that the company's management is particularly capable of undertaking this activity successfully.

The main aspect to consider in a public offering is how much equity will be sold to the public, and a range of 20 to 45% seems prevalent. Beyond the equity yielded initially, a thoughtful share issue also will provide for future financing if the exploration is successful. This can be accomplished by issuing options or warrants to the original investors to buy shares at a premium of 20 to 100% over the next few years. Although this procedure represents further dilution, it is an automatic and inexpensive way to raise finance. Sometimes these options are listed, which gives the investor (but not the issuer) additional liquidity if liquidation of this entitlement is desired.

6.6.2.4 Private Placements

Before going public, a company may arrange an offering of unregistered securities or, where debt can be sustained by the balance sheet, by a private placement of debentures. A *debenture* is an unsecured bond. In fact, one should consider requiring an underwriter of a share offering to do a small private placement as a precursor to a public issue (1) to cover the issue costs and (2) to test overall support and placement power. Public companies also can do private placements usually within limited bands of discounts and premiums, around 15 to 20% from the present share price. Such shares have trading restrictions and usually cannot be sold for at least one year.

The advantages with private placements are speed and the much lower cost of the selling document in contrast to a full-blown prospectus. This results because the placees are deemed to be professional investors who should know the worth of the information presented rather than the gullible public.

Shares placed privately to initial seed investors may be registered along with a subsequent public offering (again with selling period restrictions) and the return to the original investors may be quite substantial. It is this process that provides the promoter with his return.

The term promoter should not necessarily be a dirty word according to Brock (1985) who goes on to point out that although junior explorers spent only 28% of the total funds, in this case in Ontario between 1951 and 1974, they were responsible for 62% of all economic discoveries (Freyman, 1978).

6.6.2.5 Joint Venture

Given the equity yielded in private placements, public offerings, and tax-loss funding, the exploration company ultimately faces the dilemma of diluting itself out of existence if major drilling or land payments are required or, indeed, if a mine has to be developed. The alternative is to dilute the property itself by giving up a piece to a larger source of funds, typically a major mining company.

There are dozens of nuances in attracting such financing but several generalities apply.

1. An option is granted for a sufficient period of time to whet the major company's appetite, usually 60 to 90 days. A small up-front payment may be made for this option, say $10,000 to $50,000, and if the major company wishes to continue the arrangement, then a further payment on exercise of the option may be required, say an additional $20,000 to $200,000.

2. Progressive exploration commitments must be made within specified time limits, usually the first 12 months, and escalating annually for several years.

3. The major company covers all property and government payments.

4. The major company either earns its position progressively or else has a one-shot position to its base percentage after all monies have been spent, a certain defined exploration success achieved (say, 100,000 oz or 3100 kg of gold in proven reserves), or a positive feasibility study/development decision reached.

5. If the major company is to finance and operate any mine development, it will usually require a majority interest. At this stage, the junior company can either contribute development costs pro-rata or be diluted to a carried interest or a royalty, such as a net smelter return (NSR) interest or a net profits interest (NPI).

6. Sometimes all of the foregoing is substituted by escalating lease payments and a royalty, perhaps up to a ceiling dollar amount.

7. The junior company may reserve a right to back into a percentage equity by paying a premium or matching the major's funding at some given time benchmarks.

Variations on these themes are legion, and the mining engineer is advised to track the progress of recent similar deals and to be open to negotiations with a number of parties before settling the fate of the joint venture. Corporate objectives such as managing an eventual operation and funding other projects, often impinge on this process and require care so that the exploration company cannot be squeezed out by the major. Brooks (1985) recommends tailoring the financing proposal to address the corporate philosophy of each major company.

6.6.2.6 Farm-in/Farm-out

The principles of joint venturing apply here for a party to earn in or venture out an interest in an individual prospect. The difference is that a farm-out may only be an interim exploration step with both the farmee and the original holder knowing that major financing will still be required if a discovery is made. In a sense, this preserves the option to go to the public markets rather than having one's destiny in the hands of the major company in a joint venture arrangement.

6.6.2.7 Venture Capital

Venture capital, sometimes referred to as mezzanine financing, is made available by sophisticated financial institutions or funds that believe a high return can be achieved by using their marketing, financing, and management skills to convert a promising prospect into a mine. By bridging to the development stage, they can extract a high fee from the high added value from their money and advice (Boettcher, 1985).

The venture capitalist seeks high returns, as follows:

Seed capital	100–300%	Equity
Second or third stage	30–45 %	Intermediate
Fourth stage/bridge	25–35 %	Mezzanine

These returns can either be in equity, or, more usually, loans convertible into equity, or with equity kickers such as options/warrants or royalties (e.g., NSR, NPI, or production payment interests).

Venture capital is an alternative to a public offering, but one must anticipate stronger management oversight instead of the stock exchange regulations. At the back of every venture capitalist's mind lurks the question of how it would manage the venture if the present management fails. Some mining companies with separate operating arms act as venture capitalists with the knowledge that, in a default, they will step in and operate the development.

6.6.6.8 Government Funding

One should be aware of government programs, especially aid grants to foreign countries, as a means to provide seed capital to exploration programs overseas. The United Nations Development Program is active in regional exploration, and the World Bank sometimes will fund more advanced projects. Naturally, these funds are not without some disincentives such as local involvement, bureaucratic delays, and more substantial paperwork. But international agency involvement may open more land and information sources than would otherwise be available. Government export-credit programs can sometimes be used to finance the technical services required to complete a feasibility study, again with ties to that country's professionals.

6.6.3 MINE DEVELOPMENT FUNDING

Once exploration funding has brought forward a project suitable for development, the mining engineer needs to change his/her geological/financial hat for one closer to the green eyeshade of the banker, accountant, lawyer, and tax advisor, since all these skills are required. Before proceeding, it is important to review four fundamental financial measures:

1. *Cash flow* is the actual quantum of cash in and out and ignores such accounting items as depreciation and depletion, except to determine the actual tax payable. No accruals or provisions are accommodated to reach the proverbial bottom line. A good way to look at the concept of cash flow is to view it as a source and application of funds. The determination of project cash flows is discussed in detail in Chapter 6.2.

2. The impact of *taxation* must be thoroughly understood, especially the impact of interest, dividends, and cross-border payments— not just at the federal or central government level but at the state, provincial, and local levels as well. One should also be aware of indirect taxation on imported equipment, hidden costs in rail freights and port charges, and infrastructure contributions. And, finally, a basic understanding of the lease-vs.-buy decision necessitates a thorough analysis of taxation issues.

3. The question of *net income* requires an understanding of depreciation and depletion rules. It remains the main measure for determining earnings per share, although this measure is being supplanted now by the realization that cash flow is a more direct measure of corporate health.

4. *Coverage* is a measure used to examine the health of debt repayments. It is the annual net cash flow coverage of either the debt service (principal plus tax-adjusted interest) or just the unadjusted interest charges (see Example 6.6.2). Other coverages are worth noting, such as (a) residual coverage after the financing has been repaid and (b) NPV coverage compared with the outstanding debt.

In today's financial world, it is unusual not to have a financial model built on a computer that can be changed readily to accommodate different technical and financial assumptions. A base-case projection uses tested and conservative assumptions. Downside sensitivities examine the individual and combined impacts of such factors as lower grades, variable commodity prices, higher operating costs, delays in start-up, inability to reach capacity, or deficiencies in reserves. As discussed previously in 6.6.1.2, the risk profile for a mine development should now be at a stage where coverage levels of 1.5 to 2:1 are achievable. If the project is better than that, has good reserves, and is in the lower quartile of operating costs worldwide, then one can command the mine development financing process. Money is always available for good projects.

Many of the principles of exploration funding hold for mine developments, but a wider spectrum of sources now is available—chiefly due to the willingness of debt providers to come aboard the capital structure because of the lower risk profile. The capital structure for a company that has just built a new project with its development capital is given in Table 6.6.5.

6.6.3.1 Equity Financing

Major mine developments in South Africa are all equity financed by hundreds of millions of dollars. This is the exception rather than the rule, since most companies seek leverage of their hard-earned equity dollar. New equity is usually derived from an issue of shares to the public, or it may be created by the issuance of shares for a property or in exchange for services.

Shares are either common shares or preferred shares. *Common shareholders* are the owners of the company and entitled to vote on its destiny. *Preferred shareholders* have a preference to the company's net income for a dividend, but if there is no income, they receive no return. Sometimes these accrued deficiencies have to be repaid before common shareholders see a return. Preferred shares often are convertible into common shares or redeemable by the company at a given time or at a predetermined price or ratio. Given this quasi-debt character of preference shares, it is sometimes argued that preferred stock is neither pure equity or debt. Gentry and O'Neil (1984) provide more discussion on this topic.

6.6.3.2 Tax-driven Financing

The main tax-driven financing mechanism for a mine development is through leasing of plant and equipment, whereby the lessor owns the equipment and claims the relevant tax deductions. Lease payments include amortization of capital and are fully deductible from income for tax purposes. It is this concept that makes financial leasing work effectively (Ravenscroft, 1985).

Most mine developments have a surfeit of tax-loss carry forwards, investment tax credits, and the normal depreciation and depletion deductions from taxable income; therefore, it is often preferable to pass these tax deductions on to someone else. However, in any lease-vs.-buy analysis, one soon realizes that even though the effective interest rate on the lease seems to be advantageous, in fact, it is an expensive source of funds. Generally, it is preferable for a mining company generating profits to own its equipment instead. Leasing is also relatively inflexible, and early prepayments are severely penalized.

Leveraged leasing has evolved for long-term financing of big-ticket capital equipment. Here the owner borrows 70 to 85% of the cost of the equipment and includes loan interest in its tax calculations. These are so complex that sophisticated computer programs have evolved to handle the lease rate optimization process. Safeguards are built in to cover defaults, changes in tax laws, and to provide sinking funds to cover the negative cash flows later in the project (Ravenscroft, 1985). While seeming to offer a terrifically low interest rate, in fact this financing is fairly expensive on an after-tax basis, due to the relatively high return (well in excess of 20% per annum), expected by the equity provider in a leveraged lease. This disadvantage is often outweighed by the large dollars available and very long-term character of leveraged leases.

Like all financings, it is worthwhile to shop around, as the mix of debt and equity and repayment structures causes significant differences in lease costs. One variation sometimes in vogue is double-dip leveraged leasing where the lender or equity player may be able to claim a tax deduction in two countries, thus enabling it to quote a lower effective lease interest rate.

Besides leases, trusts are also tax-effective in some countries especially if they can eliminate one level of taxation (viz. the trust itself is not taxed whereas a company would have been). In essence, the trustholder is deemed to be in the mining business and directly entitled to the income deductions individually. Certain royalty trusts in the United States have this feature.

6.6.3.3 Project Financing

The premise upon which project finance is based is that future cash flows from the project alone are sufficient to repay the loan raised to build the project. The assets so constructed are held as collateral security. The company, aside from initial completion guarantees and perhaps support of the sales offtake, is not otherwise liable to repay the loan. Banks are the primary sources of these funds, usually for projects in excess of $5 million but potentially up to the hundreds of millions of dollars.

The banks assess the risks involved (Tinsley, 1985) and run numerous cash-flow sensitivities to test their favorite downside cases, the results of which are used to size the amount of debt they are willing to advance, the length (term) of the loan, how loan repayments are made (e.g., tied to a percentage of net cash flow), and the cost of their money (inevitably a margin or spread above a floating interest rate such as the US prime rate or the popular London InterBank Offered Rate, LIBOR). Up-front cash costs of project financings are usually 1/2 to 1%, and legal/documentation costs are the primary expense. Sometimes these can be rolled up into the loan itself. Ongoing margins range from 3/8 to 2% above the floating benchmark interest rate depending on the project and parent company risks.

The structures and supports are surprisingly flexible, with the level of debt closely related to the volatility of commodity prices and the certainty of offtake/sales (Tinsley, 1985). A level of 70 to 80% debt is quite common; a few cases reach and even exceed 100% debt. In the latter case, banks have become comfortable with the achievability of capital cost estimates, compared with the huge cost overruns that plagued the industry in the late 1960s to 1970s, and are reducing corporate support precompletion. Loan terms are also stretching to 10 to 14 years.

US and Canadian banks dominated the business until the mid-1980s. Now European, Japanese, and Australian banks have learned risk-evaluation techniques and are becoming active in this process. Although primarily used by development companies, some operating companies use project finance to isolate a major new development or to finance one or two projects in an environment where money is required for a number of developments (Wightman, 1985). Sometimes project financing is part of an acquisition package.

Many variations exist, such as production payments, advanced sales, buy-back, or throughput agreements, and may have large differences in recourse (access to the parent to repay the project financing), force majeure flexibility, and repayment methodologies. One should set clear objectives internally before approaching the banks and ask the banks to suggest the most suitable structure.

6.6.3.4 Commodity-linked Financing

As pointed out before, the market risk is the most difficult to accommodate in mine financing. The development of silver-indexed bonds for Sunshine Mining (Schreiber and Neuhaus, 1985) in 1980 started a trend of precious metal-related financings culminating in very sophisticated gold loans and hedging structures. Some petroleum-indexed financings have come and gone.

Three varieties of *commodity-linked financing* exist. The first is in an international currency with a monetary interest rate that rises and falls, usually not below a set level, with the commodity price. Magma Copper's high-yield US dollar bond has an interest rate (coupon) linked to the price of copper.

The second is where the loan and interest payments are denominated in the commodity itself. Gold loans are the classic here where, say, 100,000 oz (3100 kg) is advanced to build the mine with the loan to be repaid over five years at an interest rate of 3% per annum. Although monetized for financing purposes, it is obvious that if the price of gold doubles, the loan principal amount and the interest rate have doubled in monetary terms. Because of this feature, gold loans usually only rely on 15 to 30% of a mine's annual output for repayment. Gold loans still require all of the risk-assessment due diligence for a project financing with an added complication of cash margin calls, should gold prices exceed the agreed margin-free limit of credit. Hedging of production by selling forward is recommended to cover mine operating costs (together with a currency hedge if costs are not in US dollars), and floor-price programs are used to ensure basic economic survival by the use of put options to ensure a minimum sales price is received. Each bullion source has its own favorite structure, but these are typical:

Margin-free limit:	$50 to $100/oz above the strike price (the day the loan is advanced)
Hedging:	Not more than 50% of output
Floor prices:	$50 to $75/oz below the strike price.

The third style of commodity-linked financing is a public issue of a bond, note, or certificate that is convertible into a given quantity of the metal by a certain date. The interest rate (coupon), usually fixed, is reduced because the investor retains an upside from the strike price that, in this case, is usually at a premium to the spot price. Gold and silver are the most popular with Europe, particularly Switzerland, the main source of these funds.

This third style of commodity convertible issue has witnessed various security structures to ensure that the metal is actually there upon conversion or that the issue can be repaid in cash if it is not converted. Originally, the metal or its equivalent was held by a trustee (defeasance) and progressively released. Mining projects were used next as collateral security followed by cash-collateral by defeasance or deep-discount bonds. It can now be accomplished unsecured and unsubordinated for good names, project developments, or acquisitions.

6.6.3.5 Contract Mining

Contract mining may be an indirect means of financing since the contractor may pay for all the equipment. A classic example is where the contract-mined ore is delivered to trucks to be hauled to a nearby custom mill that charges, say, 35% of the metal content as its tolling charge. In some instances the contract miner may also be paid as a percentage of the metal content thus requiring attention to dilution. The intricacies of contract mining are discussed in detail in Chapter 6.4.

6.6.3.6 Advanced Sales

Advanced sales are often used within project financing, but in some cases, notably uranium, it may be a stand-alone source of financing from a consumer. The consumer usually will receive some sort of security, such as a mortgage/lien on the mine and development, a guarantee from the mining company, or a percentage of the equity possibly leading to control in the event of a default. Naturally, operating and capital costs need to match the advanced sale price and quantity, as usually such a consumer will not cover cost overrun or other elements of operating risks. A production payment is a type of advanced sale. The miner sells a production payment interest in the minerals to be produced repayable up to a given dollar amount. Banks or companies are the buyers/lenders. While a recognized structure under US law, it is more difficult to reproduce elsewhere because of legal differences in the security of tenure to minerals.

6.6.3.7 Supplier/Buyer Credits

Equipment suppliers often have government financial incentives driven by the need to support the national manufacturing industries. Individual manufacturers may arrange preferential financing terms for their whole range of output, which they parcel out to individual mines or companies. And many governments grant low-cost export credits if the equipment is, obviously, exported (Rides, 1985).

When the feasibility study has been prepared and quotes are being sought, one should canvass a wide range of suppliers and ask for their medium to long-term availability for financing. It is anomalous that the best terms are most usually available from overseas, due to export incentives rather than the local market that may have the added ignominy of sales taxes on equipment. However, import duties and freight often reduce the overseas advantage.

The advantage to the supplier is that these programs often are linked to export insurance. The advantage to the buyer is access to fixed-cost, and medium-term financing at a lower rate than market. The disadvantages include the need to deal with government bureaucracy, the requirement for credit support (perhaps via the project-finance bankers), and the relatively inflexible terms and conditions. However, for projects with large equipment needs such as an open pit mine or a dredging project, this source of funds will be hard to ignore (deGavre, 1985). It is important not to order the equipment until this finance commitment is secured.

6.6.3.8 Governments

Some governments, including those in less developed countries (LDCs), have pools of funds available to stimulate their nationals into investing in overseas minerals projects. The strategy is either the diversity of minerals supply sources or to sell equipment. Sometimes it is political, as with the French in central Africa.

These funds, usually debt but sometimes equity, are for moderate-to large-scale projects and are provided on surprisingly advantageous conditions. The Ok Tedi copper mine financing in Papua New Guinea is typical of the desire of governments to cofinance. Banks ($150 million), government export-credit agencies ($488 million), and the US government agency OPIC ($50 million) were joined as lenders by an agency of the West Germany government, KFW, for $100 million (McGill, 1985). This combination also is a powerful consortium to counterbalance political risk.

Once the doyen of large mine project financings, the multilateral World Bank has now decided instead to concentrate on agricultural and more labor-intensive projects. However, it is still providing funds to assist national governments in minerals policy formulation together with some exploration and feasibility studies. Furthermore, its sister agency, the International Finance Corp. (IFC), is active as a provider of seed equity in LDC. The IFC conducts its own mine reviews and also likes to be a coinvestor and cofinancier in project development. Its multilateral nature again diminishes political risk for a project, since most national governments are loathe to attack/nationalize a project in which it is involved.

A two-year minimum time period should be allowed to brief and negotiate with government agencies. Early dialogue is a must and the assistance of a bank coordinator probably essential. One must also be sensitive to the internal and external politics surrounding these entities. The key advantage, besides a political risk shield, is the very long-term nature of the debt, sometimes subordinated to the bank project financing and paid out last.

6.6.3.9 Public Offerings

The approach to the share markets for an exploration company was discussed in 6.6.2.3. For a development or operating company, however, access to the share markets has to be on an underwritten basis. Brokers and their analysts need to be involved early so that when the feasibility study is finalized, it is the last step rather than the first step in seeking their support (Hodge et al., 1985). It is important to distinguish between dealing with the bankers, who want comfort on the downside, and dealing with brokers/underwriters who live for the sparkle of the upside.

Underwriting agreements are reasonably simple and usually have triggers due to the outbreak of war, or declines in commodity prices or stock market indices that can cancel the underwriting commitment. Lead underwriters (who charge an up-front fee of 5 to 15% for their services) often syndicate their commitment to subunderwriting brokers, but sometimes a company may be a subunderwriter. The agreed issue price for the shares relates to valuations of the company (plus its new development), stock market conditions, and the size of the issue relative to the total shares outstanding (dilution). In the end, judgment matching the skill of the underwriter with the perception of the company/project to boost the underlying share price will determine the pricing and conditions. Once priced, share issues proceed quite quickly.

Bonds are another form of public finance where a company has an acceptable credit rating or, more recently where the bond is convertible into shares, a given amount of both. A bond is a publicly traded financial instrument, usually with a fixed-interest rate and relatively long term (maturity) and having a general security over a company by a debenture or guarantee. The purchasers are usually large financial institutions in the United States or Canada or more widely held in Europe (e.g., the so-called “Belgian dentist” who invests in Eurobonds).

Up-front fees are high, 2 to 3%; registration procedures are difficult and expensive, $200,000 to $500,000; and it is difficult to link to a mine development (Ulatowski, 1985). However, the emerging marketplace for high-yield securities means that unsecured bond issues are now possible for medium- to large-sized miners.

The Vancouver Stock Exchange is the mecca for exploration floats, followed closely by the Australia Stock Exchange. The Alberta Exchange permits blind pool offerings where no specific purpose is required. The Toronto, Montreal, and Denver exchanges come next, but usually for more established and medium-sized issuers. The London Unlisted Securities Market and the London Stock Exchange also see successful junior floats, especially for European minerals prospects. Local stock exchanges in Asia are starting to provide funds, albeit for exploration and development within their respective countries or the nearby region.

Warrants can also be used to raise money for a mine development. Canadian gold producers have issued gold purchase warrants, which are a right to purchase usually 0.02 oz (0.62 g) of gold at a given price. In this way they have raised $2 to $3 million from essentially forward-call options while providing a listed "gold play" for their shareholders. The warrant or option for either shares or to purchase product may be a sweetener to a share or bond issue as a means to increase the size of the financing or to lower its cost. Large amounts ($20 to $40 million plus) can be raised for large gold mine developments as cofinancings with a project financing (Tinsley, 1988). This is the reverse of the miner's call option, used in conjunction with a gold loan.

Commercial paper has been in vogue for 100 years in the United States, usually for very short terms, 30 to 90 days (Yablonsky et al., 1985). It has now been used as a funding source in large Australian project financings by using the banks to substitute for the credit risk by a letter of credit (LC), either jointly or by a fronting bank's LC. Although a semi-public and very liquid market it is highly ratings sensitive. Unfortunately, most mining companies do not have good credit ratings.

6.6.3.10 Joint Ventures

Special considerations must be given to joint venture financings, especially unincorporated ones (Cockburn, 1985). Problems with security, control, and management can complicate the structure, recourse, and legal security for a project financing. Instead of solving these problems and fighting the coventurers, one should look for synergy to help bolster the financing, such that one company provides the management, one the market offtake, one most of the financing, and another the equity, and readjusting joint venture interests later according to the success and contribution of each.

International joint ventures need special attention to jurisdiction cross-border and taxation impacts. And the management agreement, development agreement, joint venture agreement (JVA), and the sales agency agreements take time to settle, unfortunately, sometimes a few years.

6.6.3.11 Institutions/Insurance Companies

Insurance companies, pension-plan investors, mutual funds managers, and investment advisors all comprise a class of investors known as *institutions.* Institutions may be major buyers of shares and private placements or provide the equity in leveraged leases. Their risk tolerance is low, so they become funders only of established operating companies or good mine development situations.

In addition to general funds, institutions have special financing niches. They will sometimes provide very long-term money, say, 15 years plus, for projects like coal mines supplying minemouth coal to power stations. Institutions may also be the source of funds for pollution-control bonds used in connection with a tailings project or a stack gas control investment. In general, they need to see a credit rating, but sometimes they will speculate on an emerging situation or act together with banks in a project financing.

6.6.3.12 Off Balance Sheet

Finally, some varieties of financing are designed to minimize the debt: equity ratio as calculated from the company's accounts. The debt portion of the company's capital structure may be disguised by intermediate entities that undertake the debt liability rather than the parent. The methods depend on accounting rules for consolidation, and it is becoming more difficult not to consolidate off-balance-sheet debt, for example, future lease obligations.

Table 6.6.5. Development Company Balance Sheet

	$000
Current assets	$3,250
Current liabilities	(1,050)
Working capital	$2,200
Investments	1,100
Mineral properties	18,000
Plant and equipment	10,000
Long-term debt	(15,000)
Shareholders equity	$16,300

The intermediate entities are generally owned less than 50% or may be trusts over which the parent ostensibly has no control. Sometimes, unbelievably complex ownership webs are used to this end and the financier and operating company are well advised to get full accounting, tax, and legal advice before proceeding. However, if the parent's capital structure is getting top heavy with debt, this approach may be necessary to raise further money or bypass existing financial covenant restrictions imposed by other lenders.

6.6.4 OPERATING MINE FINANCING

In addition to the financing techniques outlined in the foregoing, an operating company has to manage its ongoing payables and receivables. A typical balance sheet for an operating company is given in Table 6.6.6. This moves the financing more into the realm of the corporate treasurer rather than the mining engineer/company manager. A brief description follows showing how financing can be derived from these day-to-day payments.

6.6.4.1 Trade Financing/Letters of Credit

These are the familiar "net 10 days" for payment. A custom smelter gains trade credit by paying for concentrates two months after the month of shipment (Tinsley et al., 1985).

Inventory loans may be via a warehouse financing for 60 to 80% of good quality materials or work-in-progress. Legal security is handled in a variety of ways. Costs range to 2% per annum above a floating rate (e.g., prime).

Accounts receivable can be continuously assigned to a bank at a cost of 3 to 5% to cover the collection risks, for example, converting blister copper into salable form.

Letters of credit (LC) are bank undertakings to pay a given amount against presentation of specific documents (e.g., loading of concentrates into a ship). Various LC types should be examined.

Acceptances are created when a transaction has been completed and the payment process is underway. The promise of payment may be accepted and traded in the market at a discount.

A forfait is a variety of factoring import and export payment streams via bills of exchange usually guaranteed by the importer's bank (Bradbury, 1985). Put simply, it permits early payment while the goods are in transit.

Credit insurance is also important in trade finance and many government and private insurance sources are available, especially to cover political risks.

Banks are the main players in trade finance and letters of credit, and their advice should be sought on tailoring the best program.

6.6.4.2 Hedging

The mining industry has been too conservative when considering hedging. It is seen as a form of gambling. It is also perceived as altering the pure "metal" play underlying the company's share value. In fact, the opposite is true. Not hedging the imbalances in a mine's future income or past obligations is gambling with the company's financial position if not its very existence.

Hedge markets are available in many commodities, that is commodities that are fungible (viz., having the same character regardless of location). Metals, currency, interest rates, and stock market indices are the main varieties. Hedging may be physical, as on the London Metal Exchange (LME), or more financial in character with put and call options, warrants, and synthetic structures.

The need for a currency hedge arises where a borrowing has been incurred in, say, Swiss francs for a coal mine getting paid in US dollars, or where operating costs are in Australian dollars vs. revenue in US dollars. One should be careful to assess what the underlying revenue currency is, even though payment may be physically made, for example, in the Thai baht equivalent.

Currency hedges can be accomplished by formally purchasing forward contracts to match the net currency exposure, usually limited to 12 to 18 months, or by rearranging the loan obligation itself via back-to-back or parallel loans to shift the currency of the obligation, often out 8 to 10 years (Poole, 1985). A formal currency swap agreement may be negotiated between two parties directly or with a bank intermediary with various fees and reexchange arrangements at maturity. The currency swaps market is gigantic and is reaching the stage where it can be quoted directly off a trader's screen.

The interest rate obligation can also be swapped so that a floating interest obligation is converted to a fixed interest. This can also be overlain on a currency exchange.

Commodity hedging is more straightforward. Various exchanges provide a means to directly sell output (go short). A mine by definition is naturally "long" with its production. The main commodities exchanges are the LME, New York's Comex, and the Chicago exchanges. Others around the world sometimes mirror these contract conditions so that 24-hr trading is possible. If not, many metal traders maintain their own 24-hr "book" of long and short positions. The exchanges do not go out much further than 20 to 24 months, so hedging beyond this period requires either a principal to act as a buyer or an intermediary trader to construct the longer-term hedge synthetically. The outside limit is usually three to five years for otherwise exchange-traded metals.

Most companies do not like to hedge 100% of their production in the hope that they can take advantage of the price spikes that occur from time to time. Good rules of thumb for hedging are as follows:

1. Cover 100% of mine operating costs as far forward as possible on the downside production profile and be sure local currency costs are matched in that currency.
2. Cover loan repayments at least 50% by currency hedging if required. Change the percentage hedged progressively by rollovers and perhaps leave unhedged from time to time.
3. Cover forward price volatility with floor-price programs and put options designed to ensure a minimum cash position, after debt repayments and some exploration costs, remains each year.
4. Match debt obligation where possible by commodity-linked structures, e.g., gold loans, especially for volatile commodities.

6.6.5 MERGERS AND ACQUISITIONS

Finance plays a major role in mergers, acquisitions, takeovers, and divestitures. The process is initiated by an analysis of the underlying value or break up realization compared with the share market or balance-sheet valuation of the asset or equity. Investment analysts, merchant bankers, entrepreneurial companies, and strategic planning groups are continually sifting available information, such as annual reports or stock exchange filings, to see if value is not fully appreciated by the owners.

6.6.5.1 Management Buyouts

The share market may place little value in a conglomerate or a struggling unprofitable company. A parent company may not want to continue supporting a subsidiary due to an internal shift of emphasis. Management may be able to arrange high levels of debt, up to 90%, by getting rid of the "moribund" board or parent and by trimming and focusing product lines, or through improved marketing. Many conventions apply to the process but the keys are to provide a comprehensive business plan and the reason, frankly, why management have not been able to perform in the past.

Buyout funds exist to invest in this type of effort and their rewards are high and usually tied to earning a piece of the equity as well, usually 10 to 30%. Because of the high leverage, management's return can be very high or nothing.

6.6.5.2 Divestitures

Sometimes a mining division or an individual mine will be sold off by necessity since the parent is overloaded with debt or else the disposal is of a peripheral operation to what is viewed as the core business. One can either deal with a short list of potential buyers, or one can let a friendly investment banker earn his keep by privately arranging the sale or by a tender process.

The sale of a company takes longer because of the due diligence to ensure no skeletons remain in the corporate closet. An asset sale is often quicker. Sometimes the seller has to help the buyer with financing or provide for term payments. The latter needs very careful analysis, particularly if the buyer is overly dependent on the project it has thereby just purchased.

6.6.5.3 Reconstructions

Mines with excessive debt or technical problems often present opportunities for refinancing and turnaround by a new party. A company in bankruptcy/receivership may also be a candidate for the financier because the entry price may be very low. In general the financier in these circumstances needs especially strong legal and financial analysis support and the ability to renegotiate with past lenders and investors and the ability to bridge the credibility gap if new technology and management are to be applied.

6.6.6 INFORMATION REQUIREMENTS

The information required at one stage of financing can be drastically different from another phase, and each source of funding has its own conventions and idiosyncrasies.

6.6.6.1 Stock Exchange

Each stock exchange has its own rules and regulations for prospectuses. They are usually organized as follows:

Summary/use of proceeds
Technical review (independently checked; see Chapter 6.2)
Qualifications of directors/management
Legal review
Financial statements (audited)
Subscription form

In most cases, a lawyer should be part of the process to ensure compliance with the regulations. The technical review needs to cover (Affleck and Stevenson, 1985; Gentry and O'Neil, 1984):

Property description/tenure
Location/access
History
Geology
Reserves
Conclusion
Recommendations/budgets

6.6.6.2 Placements

Private placements very often require only an information memorandum, which may have little independent technical and financial audit data.

At the exploration stage, the geologist's review and recommendation may be sufficient. Some sources of private placement may simply conduct their own due diligence, and no formal report is required.

6.6.6.3 Bankable Document

The bankable document is a somewhat mythical volume that is satisfactory to bankers or major debt providers. It will inevitably contain a detailed independent technical review of the project (Emerson, 1985; Schreiber, 1985) covering:

Reserve estimation
Run-of-mine/mill-feed reserve
Mining
Processing
Marketing

The independent consultant should also comment on the appropriate risk levels and conduct sensitivity analyses accordingly. Detailed capital and operating cost workups supported by actual quotes and preliminary designed will be incorporated into the base case financial pro-forma cash flow projections.

The bankable document should state why alternatives were rejected over the chosen course but not provide all the backup testing and calculations. Project financing requires the project to stand on its own financially once it is built; therefore, it requires the most comprehensive review of feasibility. While checklists are useful, the complexity in present day minerals project analysis, marketing, and financing means that financing mixes and risk off-sets should also be analyzed in the bankable presentation and presented with a comprehensive series of cash flow projections reflecting these factors (Tinsley, 1985).

The providers of funds are no less human or warm than the people in the minerals industry and will be able to provide valuable guidance if approached correctly and in a timely manner. Knowledge of the different sources of funding will either eliminate (and thus save the time for preparation and approach) or open up new vistas for finance from the gleam in the geologist's eye to the time when the mine has been built and is happily producing from nature's storehouse.

Table 6.6.6. Operating Company Balance Sheet

	$000
Current assets	$15,800
Current liabilities	(12,500)
Working capital	$13,300
investments	13,200
Mineral properties	22,000
Net plant and equipment	56,000
Long-term debt	(32,000)
Shareholders equity	$72,500

Section 7 Mine Development

SCOTT G. BRITTON, ASSOCIATE EDITOR
BRADLEY A. BRASFIELD, SECTION COORDINATOR

Chapter 7.0
GENERAL PRINCIPLES

MIKE TRACY AND BRADLEY A. BRASFIELD

This section of the *Handbook* deals with general principles to be evaluated in the development of a mining operation. It addresses the major issues that must be examined to fully evaluate a mining venture. Of course, one of the main topics to be evaluated is mine planning, which is covered in more detail in other sections (13, 17) of the *Handbook* and should be referenced in mine development projects. The topics to be discussed in this introduction include equipment and supplies, infrastructure, utilities, and project management.

In any of the aspects mentioned, the current existing conditions at or near the mine site must be evaluated. This will include assessment of current use of utilities, infrastructure, housing, equipment suppliers, etc., as well as anticipated growth, both in the supply aspect of these systems as well as projected usage on these systems. After full assessment of both these aspects, an evaluation must be made as to the requirements the project will place on these items. Assessment must be made as to any upgrades required to bring the project on line, what impact the project will have on existing or expanded systems, and anticipated future growth impacts on support systems not only of the project but of other surrounding industry and urban development.

The general manager of any operating company must address all aspects of any project development. In mine development, additional topics not discussed include market analysis and financial analysis. The market must be assessed as to current pricing levels, projected pricing levels, projected consumption demands, projected supply, potential market penetration of the project, projected sales price of the product of the mining operation, projected cycles in the market, etc. In financial analysis, all of the items discussed in this section must be used as well as market information, cost of capital for the corporation, strategic planning of the corporation, and evaluation of the numerous financial indicators available for such projects. Details of financial analysis are covered in Sections 2 and 6.

Of course, one of the main considerations in the development of any mining project is the evaluation of the project in light of the strategic goals and plans of the parent organization. A detailed analysis must be made as to whether the project fits the needs and goals of the organization before preceding into the actual development stage.

The topics discussed in the chapters of this section are the areas that are under the primary control of management, namely, personnel and machinery and the expenditure of money on both.

7.0.1.1 Equipment and Supply Selection

The equipment to be used in the mining operation will be dictated primarily by the mining plan. However, latitude remains as to the actual equipment supplier selected, as long as the specifications required due to physical parameters dictated by the mining plan are still met. An evaluation must be made of all of the heavy equipment concerning items such as price, availability, product support, local vendor capabilities, etc. It is worth the time in large operations to visit other similar operations prior to the selection of equipment in order to gain the experience of others pertaining to specific pieces of equipment.

Product support is very important in the selection of any equipment. This will dictate the maintenance staffing requirements as well as capital expenditures on such things as shops and tools. Depending on the size of the project, the equipment supplier in many cases will make specific concessions as to product support for the particular project. Additionally, all local vendors are not created equal. Some vendors supply very little support while others supply very significant, support in both parts and supply availability as well as the supply of contract maintenance personnel and offsite component rebuild. If located in a remote location, another consideration is integrated infrastructure in regards to parts and supplies. An evaluation must be made on delivery of parts and supplies to the mining operation which may include use of the product transportation systems such as railroads, trucking, etc.

One of the main supply items of any mining operation is the source of fuel and lubricants. Care must be taken to evaluate all possible suppliers of such products in looking at price, supply capabilities, and evaluation of the product supplied by each vendor.

The supply of explosives is another area for evaluation. There are many legal restrictions on explosives manufacture and transportation all over the world. In many locations, the host country actually controls the movement of explosives through government regulations. In other countries, such as the United States, explosives are distributed by private corporations. An evaluation must be made of potential suppliers in regards to purchase price, delivery modes, and evaluation of specific products supplied by the supplier to determine if the products will meet the needs of the mining operation and how the products will be transported to the operation.

7.0.1.2 Infrastructure

One of the most important aspects of any mining operation in the development stage is to evaluate the availability and qualifications of the work force in an around the mining area. Evaluation of the qualifications of potential operators must be assessed, what training must be provided to these operators, what training facilities are available in the area, and if outside labor must be brought in for the more skilled jobs. Of course, the evaluation of such things as union vs. nonunion conditions and the salary levels of the work force must also be assessed to properly complete the financial analysis of the project.

In an ongoing operation, another large component of cost is parts and supplies. This must be addressed in the development stage of an operation. After the major equipment has been selected, the parts supply to service this equipment must be evaluated in light of such questions as point of sourcing and the transportation required to get these parts to the mining operation. Supplies must be evaluated in the same light.

The next area for evaluation in the development stages of an operation deals with the transportation of the actual product of the mining operation. Naturally, the location of the operation is predetermined by the geologic formation; however, potential markets must be identified and thereby dictate the two end points for the transportation system. All transportation systems should be evaluated including railroads, waterways, highways, potential use of conveyors, potential of pipelines, and any other transportation systems that may be available. This is normally a large portion during the development phase of a project and may vary in magnitude depending on the location of the project. In many of the more developed areas, existing transportation systems are available, and a simple discussion with the potential suppliers of this transportation will lead to the proper data needed to evaluate transportation systems and make the proper selection of the mode to be used. However, in the development of a new operation in a remote location, significant capital expenditures may be required for the transport system. In such case, substantial time and effort must be expended to evaluate each and every potential system as mentioned previously with close attention being paid to capital requirements, physical conditions existing in the area, longevity of the project, operating cost of the transportation system, governmental regulations on transportation systems, other potential users of transportation systems, etc. The decision-tree analysis is a good tool to use in selecting the alternative to put in place.

The final aspect to be considered under infrastructure is the topic of facilities. The size of the offices, shops, and warehouses will be dictated by the size of the operation, the compliment of equipment used in operations, the number of personnel required, and availability of existing facilities. In many remote locations, all of these facilities must be built to service each and every need of the operation. However, in many developed areas, existing office space may be used to reduce capital requirements of the project, and existing shop facilities and warehouse facilities may be utilized offsite for major-component rebuild or supply inventories.

7.0.1.3 Utilities

The installation of utilities is a very important aspect of any modern mining development project. Much of the heavy equipment utilized in large mining operations today is powered electrically. As such, electrical supply to the operation is extremely important and must be evaluated in great detail by personnel experienced in today's electrical technology. Involvement of the equipment suppliers is essential to establish the interaction of such equipment with electrical supply systems. Special attention must be paid to modern ac electrical equipment in surface operations and the higher horsepowers and resulting large power requirements in underground equipment.

Additionally, the mine planner must evaluate the water supply and sewage disposal systems to be established for the mining operations. Provisions must be made for potable water for the work force as well as water supplies for such items as steam cleaning of equipment. Also sewage disposal must be addressed for all the facilities on site as bathhouses, restrooms, etc.

7.0.1.4 Project Management

Project management is extremely important from the most minute activity up to the level of development of the overall large mining complex. The most widely used mathematical management tools are PERT (project evaluation and review technique) and CPM (critical path method). Computer software has made these techniques easy to use and available to almost all mining operations. This software can either be PC-based or mainframe-based, depending on the availability of hardware and the size, location, magnitude, and complexity of the development project being pursued.

Project management should be used throughout the design, construction, and exploitation phases of any mining project. This is imperative to control both cost and time of implementation of the project. Most of the software packages available today are easy to use and serve as a tool to control both the timing and cost factors involved in project management. It is also very important to staff this function with a competent individual who understands the process and who can keep the general managers informed of the current status of any phase of such projects. Coordination with the management information services department of the parent organization should result in a review of current software available and the development of a project management and control system best suited for the overall organization.

Chapter 7.1
LAND ACQUISITION

DONALD L. SCHAIBLE

7.1.1 INTRODUCTION TO LAND ACQUISITION

This chapter deals with the subject of land acquisition from a project engineering perspective. Therefore, the working definition of *land acquisition* as used in this context is

> *The activities and planning efforts that are intended to result in the acquisition of the required level of control over those parcels of property that are vital and necessary for the timely development of a particular mineral project.*

The subject is treated from the perspective of a project located in the United States. Many of the planning principles apply to projects in other countries, but specific legal considerations vary. The developer must make the necessary site-specific adjustments for these variations.

During discussion of the subject, references are made to various US governmental agencies, policies, laws, and regulations that may affect the developer. Likewise, there is some discussion of subject matter relative to land ownership, sources of land information, and forms of agreement. These references are included in this chapter as a convenience to the reader and to serve as background information only. For a more inclusive treatment of the subject of mineral law and land management, refer to Chapter 3.2; and for consideration of the role of land acquisition in project operating strategy, see Chapter 6.4.

Historically, land acquisition has not been considered an engineering function. Various methods of dealing with this activity have been used. Many project developers have assigned this function to their legal or real estate departments. Some have assigned the task to outside contractors or consultants. Still others have delegated the land acquisition activity to the person least busy at that particular time! All of these methods have been used successfully at one time or another. But, whatever method is chosen, the most successful land acquisition endeavors are usually the results of a team effort, characterized by the close involvement of the project engineer.

Land acquisition is fundamental to the success of any mineral development project. Indeed, there is no project without the legal right to affect the properties involved. Regulatory permits required for mining projects will not be granted unless the permittee can demonstrate a legal right to mine the properties. The value of the land and the underlying minerals is often the basis upon which project financing is extended.

Poorly planned acquisition activities can result in:

1. Acquiring less than the required property.
2. Acquiring more than required.
3. Paying too much.
4. Early acquisition (cash flow impact).
5. Late acquisition (project delays).
6. Acquisition by competitors.
7. Failure to acquire the required properties.

The first five results would have negative impacts on the financial feasibility of the project. Both of the last two items could result in total failure to develop the project. A well-conceived and coordinated land acquisition program can enhance the project economics and technical feasibility by avoiding, or minimizing, these negative impacts.

Given the pivotal importance of the activity, it is apparent that land acquisition demands careful planning and integration into the overall project development plan. This planning and integration is a function best handled, or at least coordinated, by the project engineer.

In this chapter, we will:

1. Discuss briefly the land ownership situation in the United States.
2. Identify the various levels of land control and the impacts on the project of each level.
3. Review the steps required to develop an orderly, efficient land acquisition plan, with particular emphasis on the role of the project engineer.
4. Discuss the potential roles of contractors and consultants in land acquisition.
5. Illustrate the land acquisition process in a case study of a hypothetical mining project.

7.1.2 LAND OWNERSHIP IN THE UNITED STATES

Land ownership in the United States resides with the federal government (*federal lands*), state governments (*state lands*), or with private individuals and business entities (*private lands*). The project engineer must be concerned with the distinct types of owners since the acquisition potential and procedures for a particular plot of land are largely determined by the ownership.

7.1.2.1 Federal Lands

The vast majority of federally owned acreage is contained in the western states. Acquisition for mineral development on these federal lands is primarily governed by the Mining Law of 1872 and the Mineral Lands Leasing Act of 1920.

Federal lands can be categorized as follows:

1. Public lands.
2. Reserved and withdrawn lands.
3. Acquired lands.
4. Severed lands.

The importance of distinguishing these categories to the project engineer is that the acquisition potential and the laws governing the acquisition vary for each category, as well as for different minerals within each category (again, see Chapter 3.2).

Public Lands (Public Domain): These lands were acquired by the United States through treaty or purchase from a foreign country. Both the surface and mineral rights belong to the United States, and the Mining Law of 1872 governs their acquisition by mineral developers. The mineral developer, upon the discovery of a valuable mineral deposit on public lands, may gain title to the land by staking a claim (*location*), demonstrating the presence of a valuable mineral deposit (*patenting*), and spending a specified minimum amount of money on development each year (assessment work). This process is referred to as acquisition by location. Additionally, the Mineral Land Leasing Act of 1920 specifies several commodities that may only be acquired by leasing. This list of commodities includes, among others, coal, oil, oil shale, and gas. The Common Varieties Act of 1954 further extended the “lease only” status to certain building materials (e.g., stone, sand, gravel, etc.). These “lease only” requirements apply to the specified minerals for both public lands and the other categories of federal land.

Reserved and Withdrawn Lands: Lands in these categories have been set aside by the federal government for special public use. Public uses include Indian reservations, military reservations and national parks, national monuments, and national forests. *Reserved lands* have been permanently set aside, while *withdrawn lands* have been set aside temporarily. The lands are not obtainable by location. Leases may or may not be issued on these lands depending upon the terms of their separation from the public domain.

Acquired Lands: These parcels have been acquired by the federal government from state governments or private owners. Since these lands are not part of the public domain, they are not available for acquisition or leasing except by special provision of the federal government.

Severed Lands: Severed lands are those lands for which the federal government has sold the surface rights while retaining the rights to any minerals underlying the surface. Mineral rights on severed lands may be acquired or leased depending on the site specific details of their severance.

7.1.2.2 State Lands

Lands owned by the various state governments may be owned in fee or the surface and minerals may have been severed. Most of the states have enacted laws governing the sale or leasing of these lands and mineral rights. Each state also has certain lands which have been set aside for public use, and they may or may not be available for mineral development.

Since mineral land laws and regulations vary considerably from state to state, the developer must become familiar with the situation in each state in which he/she is contemplating acquisition activities.

Acquisition procedures for state lands vary from state to state, but most include some form of prospecting permit that carries with it a priority to lease or purchase the permitted land. Some states have laws that loosely follow the federal government’s acquisition by location procedure.

7.1.2.3 Private Lands

Private land ownership, as with government-owned lands, may be in fee or consist of separate ownership of the surface and mineral rights. In some cases the mineral ownership may be further subdivided based upon the type of mineral or designations of specific lithologic units (as in the case of multiple coal seams).

Again, since state laws regarding the ownership and transfer of mineral rights may vary, the developer must be familiar with the laws of the particular state involved. It is not uncommon for the laws of a state to reflect considerations peculiar to the dominant mineral resource of that state. Texas, Oklahoma, and Louisiana, for example, are heavily influenced by the petroleum industry while Kentucky, West Virginia, and Pennsylvania are coal-oriented states. These influences often have an impact on the requirements for securing, and particularly for holding, mineral rights.

Acquisition activities on privately owned parcels may vary slightly depending on the nature of the owner. We will discuss the impact of dealing with private owners as opposed to corporate entities.

The term *private owners* includes not only individual persons but also trusts that may be land trusts in those jurisdictions that allow them, or estates administered by banks and/or trust companies. Private owners are generally subject to different influences and often possess different objectives from businesses. Since much of our mineral-bearing land occurs in rural settings, it is quite common for the individual owner to be a farmer or rancher. If a rancher or farmer is considering issuing a mineral lease, he/she will be very interested in the length of time the land is not available for agricultural production. The condition of the land when it reverts to him/her will also be an important consideration. Postmining agricultural productivity could become an issue to be addressed in the lease agreement.

If the project area is owned by a large number of private individuals, then the developer must be aware of the danger that he/she may drive prices up by settling too quickly with reluctant landowners. The developer must assume that all of the landowners in the project area will be knowledgeable of the terms and conditions of other purchases or lease agreements. It is generally desirable to acquire the most critical parcels first in this situation.

Corporate land owners of mineral properties quite often fall into one of the following categories:

1. Mining companies.
2. Transportation companies (railroads).
3. Forest products companies.

Corporate entities in the mining business routinely acquire prospects for development, and therefore, it is not uncommon to encounter them as landowners. Since mining companies are usually interested in developing the resource themselves, they may not be inclined to sell or lease to a competitor. There are, however, exceptions to this scenario. Occasionally, a mining company will decide to generate some cash by selling or leasing a property for which they have no immediate development plans. Another possibility for acquiring land from a mining company is by trade. If two mining companies each have partial holdings in several areas, they may be able to mutually benefit by a trade that will consolidate the positions of both parties. In these dealings, the developer may be sure that he/she is dealing with someone conversant in the mining industry and aware of the important issues involved in mineral-land acquisition.

Railroad companies and their subsidiaries control a vast acreage of mineral and surface rights, particularly in the western United States. Historically, the railroad companies have been prohibited from commercial exploitation of the minerals underlying these properties. Therefore, they have entered into lease agreements with mining companies in return for production royalties. Companies that own large tracts of land usually have a real estate management subsidiary handle mineral-land leases and sales. The mineral developer will be dealing with full-time land management professionals who will be working within the framework of company policy.

Another major class of corporate mineral land owners is the companies of the wood-products industry. This includes timber and paper companies. These companies typically will lease out mineral rights as long as the mining operations are compatible with their own use of the forest products. Often they will harvest the timber and/or pulpwood from the site just prior to mining operations. They are usually quite sensitive regarding the length of time the property is tied up by mining and also to the reclamation of surface mined lands to promote reforestation. They will sometimes require that a commitment to such reclamation be a part of the lease agreement.

7.1.3 FORMS OF LAND CONTROL AGREEMENTS

There are various forms of control by which a parcel of land may be held. These forms may be sorted according to the degree or level of control afforded by each. Three forms of agreements that will be discussed are (in ascending order of control):

1. Options.
2. Leases.
3. Purchases.

Often the acquisition project will feature two or all three of these forms of agreement and may address the control of the surface and mineral separately. The optimum level of control can usually be identified by a carefully conducted cost/benefit study. However, identifying the optimum level of control does not always mean that one can attain that level. When dealing with federal or state lands, for example, the level of control available is normally fixed by laws and regulations. Private lands, on the other hand, often offer a wide range of alternatives to the project developer and the landowner.

This discussion of these land agreements is predicated upon a "grass roots" project. If the land acquisition effort is focused on expansion, or continuation, of a mature project, certain of the comments contained herein will not pertain.

7.1.3.1 Options

During the exploration phase of a project, and prior to determining the full potential of a deposit, the developer often needs an agreement with the landowner to secure access and some level of control of the property. This agreement is required to give the developer the right to complete his/her assessment of the project, and also the exclusive (or first refusal) right to gain more complete control if and when the project is proven feasible. A common form of agreement for this purpose is the *option.*

An option agreement conveys the lowest level of control in that it gives the developer only temporary access to the property and usually restricts the developer's activity to exploration and data collection efforts only. The term of the option must be for a period of time sufficient to determine the feasibility of the project and to make the decision to proceed or abandon the project. The agreement should specify at least the general terms of a subsequent, more permanent agreement (lease or purchase) to be executed at the developer's option. In return for granting this temporary control and option, the landowner will usually receive compensation in the form of cash bonuses or rentals.

From the developer's viewpoint, the option allows time to conduct exploration programs and feasibility studies prior to committing large sums of money for acquisition. If the study results are positive, his/her investment in exploration programs and engineering studies is protected by the exclusivity provisions of the agreement. The landowner, on the other hand, receives some compensation during the time the land is off the market and the promise of more substantial revenues if the project moves forward. If the project does not become a reality, he/she still has the land.

7.1.3.2 Leases

The *mineral lease* is probably the most common form of agreement between developer and landowner in the mining industry. The lease agreement is often preferred by the developer over an outright purchase, because it requires less immediate cash outlay prior to the project becoming profitable. The landowner generally prefers this arrangement because he/she retains title to the property, and may resume possession at the expiration of the lease agreement.

The terms of the lease should have been defined to the highest degree possible and included in the option agreement. During the option agreement period, as the nature and economic potential of the deposit is further defined, the specific final terms of the mineral lease may be negotiated.

Whether negotiated prior to signing the option agreement or during the option period, the developer (lessee) should be sure that the following terms are addressed:

1. *Control*—The lessee needs adequate control of the property so that he/she has the flexibility required to conduct operations in the most efficient fashion.

2. *Term*—A long term provides the lessee with the assurance that he/she can maintain the lease and fully exploit the deposit through the downturns in the market that seemingly inevitably affect a commercial mining operation.

3. *Royalty*—A low primary royalty is obviously in the best interest of the lessee. In addition, he/she should attempt to keep the advance minimum royalties low. This is important in maintaining an attractive cash flow.

4. *Buy Out*—Often, if a very large mineral deposit is discovered, the project developer will desire to purchase the remaining term of the lease and assume title to the land after profitability is attained. If this is likely to occur, the lease should provide for an option to purchase.

5. *Termination*—The lessee should retain the right to terminate the lease upon adequate notice.

6. *Force Majeure*—The lessee requires protection in the event of an "act of God" or other disastrous occurrence beyond his/her control. He/she should be relieved of his/her commitments under the lease until such time as he/she is again able to perform. In many instances, it is recommended that events qualifying as force majeure be listed and also that the responsibilities of the parties during specific force majeure events be specified.

The landowner (lessor) will usually seek to have the following terms inserted in the lease agreement:

1. *Term*—The lessor will not want to tie up the property for an extended period of time due to the desire to accelerate the generation of revenues.

2. *Royalty*—The primary item of interest to the lessor will be the production royalty. He/she will attempt to maximize this payment. It may be based on a set rate per unit of production ($/ton), in which case it should be subject to adjustment for inflation to protect the purchasing power of the royalty dollar. Often the royalty rate will be a percentage of the realization from the sale of the mineral.

3. *Schedule*—The lessor will require diligent development to ensure that he/she begins to receive production royalty revenues at an early stage.

4. *Advance Royalty*—During the time when the developer is not producing the mineral commodity, the lessor will expect to receive advance, or minimum, royalty payments. These payments are intended to further prompt the lessee to put the project into production as soon as possible. Usually, these advance royalties will be recoverable from the production royalty.

5. *Reclamation*—The lessor will, if he/she anticipates the return of the property, probably insist upon a high standard of reclamation of the property. Although reclamation standards are generally prescribed by state and federal regulations, a private landowner may stipulate additional requirements in the lease agreement. This can be particularly likely in the case of prime agricultural or forest lands.

6. *Liability*—The lessor will want protection from third-party suits resulting from lessee's actions, and from such occurrences as increased taxes that may result of lessee's improvements to the property.

7. *Termination*—The landowner should insist on the right to terminate the agreement in the event of a breach by the lessee.

The lease agreement will also contain administrative provisions relative to record keeping, weighing and sampling, payment procedures, and remedies in the event of a disagreement.

7.1.3.3 Purchases

Total ownership is the highest level of control, and it is achieved by a *purchase* of the property. The purchaser in this case has the right to develop the property as desired within the framework and restrictions of all laws and zoning ordinances.

The advantages of total ownership all involve security and include:

1. *Access*—Total ownership is the most secure form of control. Uncertainties as to the ability to gain access are eliminated. Data collection programs may be performed at will. Technical planning for development may be conducted with confidence.

2. *Cost*—The cost of acquisition, once determined, is fixed and not subject to the whims of the marketplace. Financial planning may proceed with secure knowledge that little is likely to change.

Note: A variation of the ownership in fee situation involves a purchase of the property, with the seller retaining a production royalty. In this case, the advantage of an unchanging cost of acquisition will be negated by a royalty rate that is indexed for inflationary changes, or tied to the selling price of the commodity.

3. *Residual Value*—At the end of the primary project life, there may remain some quantity of unmined mineral. If the market value of this particular mineral has increased during the duration of the primary project, it may become a source of additional profits.

Disadvantages of total ownership include:

1. *Cash Flow*—The purchase involves an early commitment of cash, which has a greater impact on the project economics when considering the time value of money. Also there will be holding costs (property taxes) to be paid during the development period.

2. *Risk*—If some occurrence should make the project infeasible or less attractive (such as a sudden, drastic change in the market or regulatory actions), then the buyer may be "left holding the bag" until the project again becomes attractive.

In general, mining companies prefer to purchase only those properties upon which they will be constructing permanent facilities. The lands to be mined are more often acquired by leasing, at least initially.

7.1.4 ACQUISITION PLANNING

Land acquisition must be a team effort. The typical team will consist of field landmen, legal counsel, the project engineer, and a coordinator who has final responsibility.

The acquisition of land for a mineral development project is not a straightforward, simple procedure. Many activities must take place concurrently, and few if any are independent of all other activities. When dealing with private individuals, business representatives, or government administrators, personalities become intertwined with business issues to compound the intricacy of the procedure.

The land acquisition process can be greatly facilitated by the presence of a local populace that is friendly to the project. A generous dose of common sense and sensitivity to public relations will go a long way to secure this friendliness. This is particularly important to the development of a project in an area that is privately owned and does not have a significant history of mineral development.

In the face of initial local opposition, it becomes crucial to promote the positive effects to be enjoyed by the public. Issues such as new jobs, increased payrolls and taxes paid into the local economy should be highlighted for the public. Worker safety and environmental protection plans and requirements should be highlighted. The project engineering staff is the primary resource for the production of this information. The dissemination of the information will usually be made by the landmen who have day-to-day contact with the landowners.

The acquisition process is much enhanced if the public, and especially the local landowners in the project area, are aware of the benefits the project can bring to them as individuals and to the area as a whole. Care must be taken, however, that the competitive status of the project is not compromised by the release of sensitive information. The land acquisition coordinator with assistance from legal counsel should be involved in reviewing all information prior to release for the public. In short, mineral land acquisition planning is not an exact science, and certainly cannot be conducted in a vacuum.

The foregoing recommendations and cautions notwithstanding, a good acquisition plan that is integrated into the overall project development plan will play a key role in the success of the acquisition process. The acquisition plan must be flexible enough to adapt to events as they occur but still provide a framework which rigidly keeps the project objectives in the forefront.

A good acquisition plan accomplishes the following:

1. Identify the project area ownership.
2. Identify project land requirements.
3. Prioritize the acquisition of the parcels.
4. Determine the desired form of control.
5. Establish an acquisition budget.

The order in which these activities are listed is not necessarily the order in which they are accomplished. Rather, they are often advanced in steps on a concurrent basis. For example, the identification of the project land requirements must be done, in general terms, before the project ownership may be established. More precise definition of the land requirements may then be influenced by the results of the ownership search and be subject to change as the plans are developed. Similarly, establishment of an acquisition budget will be based on the desired form of control of each parcel, but the decision as to the desired level of control of an individual parcel may be based on information provided by the acquisition budgeting process. The entire process is a constantly evolving interactive network of information gathering, planning, and action.

7.1.4.1 Identifying the Project Area Ownership

When the overall project area has been determined, it is necessary to conduct an investigation to identify the owners of the properties involved. There are a number of sources of information from which to identify the landowners in the project area. If there are large federal land tracts involved, then the Bureau of Land Management (BLM) records are an excellent source. BLM maintains land offices in the western states as follows:

Office Location	Area of Record
Sacramento, CA	Northern California
Los Angeles, CA	Southern California
Phoenix, AZ	Arizona
Reno, NV	Nevada
Salt Lake City, UT	Utah
Santa Fe, NM	New Mexico, Texas, Oklahoma
Denver, CO	Colorado
Cheyenne, WY	Wyoming, Kansas, Nebraska
Billings, MT	Montana, North and South Dakota
Fairbanks, AK	Northern Alaska
Anchorage, AK	Southern Alaska

Information on federal lands in other states is available in the Washington, DC, office of the director of BLM.

The records in these offices are open to inspection by the public. Information on federally owned properties includes the category of ownership, any tracts that have been disposed of and the nature of such disposal, rights granted, patented mining claims, and other useful data.

Information on state lands must usually be obtained in the capital of the state of interest. State lands that were obtained from the federal government will be identified in the BLM record search. Actions relative to such lands subsequent to the transfer will be contained in the state land records. Since formats for land records vary from state to state, it is advisable to obtain assistance from state land management personnel when inspecting these records. The state records will normally contain similar types of data as the BLM records.

Information on the ownership of private lands is available from several sources. BLM and state records will indicate rights to federal and state lands that have been conveyed to private parties. More detail will be available at the office of the tax assessor of the counties involved. The names of individuals, or trustees who are paying the taxes will be available at this location. The most definitive source for current ownership by private parties will be the county recorders' files.

During investigation of the various sources of ownership information, the investigator needs to focus on the ownership, or other form of control, of the surface, mineral rights, structures and other easements or rights-of-way.

Surface control must be identified. The owner (or owners) of the surface may have issued leases to others for agricultural or other purposes. These leases may include all rights associated with surface ownership, or they may be only for a specified purpose. The surface rights may or may not automatically carry the rights to surface minable minerals. This must be determined by an investigation of the federal, state, or local regulations. In any regard, the controller of the surface must be contacted and legal arrangements made to secure access and rights to develop the properties.

Owners and lessees of those mineral rights that are separate from the surface estate must be identified. It is possible that multiple layers of leases and subleases exist, and it will be necessary to identify and locate all parties with interests in the mineral estate. Interests in all minerals should be identified, including minerals other than those that are the particular objective of the project planners. For example, it is common for oil or gas development to take place on land containing coal or lignite deposits. It is also common for the rights to these minerals to be severed and held by separate parties. Since the development of these minerals may be mutually exclusive, a determination must be made as to which rights are prime.

Owners of structures that exist on the properties must be identified. Homes, barns, fences, roads, pipelines, electrical transmission lines, telephone lines, etc., are examples of such structures. Often, but not always, the owners of buildings will be the owners or lessees of the surface. The market value of these structures should be estimated, preferably by an appraiser knowledgeable in the specific area.

Easements may have been conveyed to other parties for access roads, pipelines, transmission lines, drainage ditches, or utilities. These should be identified as prior rights and the holders of these rights established.

A useful tool for the acquisition process (and beyond) is a computerized property database. This database contains the legal description of the property, the size, ownership, assignments (leases or easements), and a description of all existing structures. Other remarks relative to the project are also committed to the database. These remarks include the purpose for which the parcel is required, the estimated amount of reserves contained, the parcel's priority relative to the viability of the project, its priority relative to the project schedule, and the status of the negotiations with the owner or lessee.

Computerization allows fast access to the current status of a particular parcel and allows the data to be sorted and retrieved according to various criteria such as priorities, size, reserves, proposed use, etc. This sorting and retrieving capability feature allows quick response to questions from the project planners and will facilitate the production of useful status reports. As progress is made on the acquisition, the database is updated. If a parcel is acquired, the terms of the acquisition will be included. Eventually, as the project becomes an operating entity, the information in the database becomes valuable for keeping track of property taxes, depletion of reserves, royalty payments and information relative to the status of regulatory permits and reclamation bonds.

All of the data gathered in the source investigations and included in the computer database should be presented in graphical form on a project land ownership map. This map will likely become the single most useful acquisition planning tool involved in the process. The land map should be available on the same scale as those maps that are used to present engineering plans for the mine and related facilities. The land map will show through the use of colors, symbols, and legend references each parcel of land that possesses unique ownership characteristics. If necessary, acetate overlays will facilitate showing all the data that are pertinent to the project. The acquisition process will be tracked on the land map. As each parcel is controlled, or otherwise changes in status, a notation will be made on the map. In effect, the land map becomes a visual representation of the computer database.

7.1.4.2 Identifying Project Land Requirements

The identification of land requirements is a direct function of the project engineering team. The procedure begins with the determination of the economic mineral resources available to the project. Preliminary exploration programs target a large area of potential interest. At this point, the land ownership identification effort may be started. The area of interest will usually be gradually decreased as the engineering studies zero in on the final targets.

The project planning efforts define the area to be mined, the sequence of mining, and other lands required to support the project.

These include areas required for the following purposes:

1. Mining.
2. Access.
3. Transportation.
4. Facilities.
5. Utilities.
6. Other miscellaneous requirements.

Mining areas include the actual portions of the mineral deposit that will be exploited during the mining operations. In the case of surface mining, the effect on the property is obvious. If underground operations are involved, the effects of subsidence must be anticipated and any required mitigating measures planned.

Access to the project area must be provided for both project personnel and for vendors delivering supplies and equipment to the project. The nearest public road is usually the beginning point. The mining plan identifies the location within the project area to which the access corridor must lead.

Transportation of the raw and finished products must be provided. This may include truck haulage roads, railroads, conveyor belts, aerial tramways, or pipelines. Corridors must be obtained to allow for the installation of these transportation facilities. Transportation routes must be provided both within the project area and for market access.

Facilities requirements include maintenance shops, offices, warehouses, bathhouses, equipment service facilities, outside storage, powder magazines, and processing plants including waste disposal areas. The preferred locations for these facilities will be determined by the project engineers.

Utilities include incoming electrical power, internal power distribution, water supply and distribution, sewage treatment and disposal, and communications lines.

Miscellaneous land requirements could include areas intended to provide a "buffer" between the active operations and the project's neighbors.

As these sites and areas are defined, they should be plotted on the land ownership map. In some instances, it may be desirable to adjust the location of a facility slightly to accommodate the land ownership situation. An example would be the relocation of a shop building in order to deal with a single landowner vs. dealing with two or more owners.

7.1.4.3 Prioritize Acquisition of the Parcels

The project engineering team is the only entity that can place the appropriate level of emphasis on the acquisition of each of the individual land parcels. During the process of creating the project plan, the engineers will determine both the strategic and chronological importance of the various parcels of land.

Strategic importance of a parcel of land is the measure of the economic impact on the project if the parcel is not acquired. A parcel may be strategically important due to the existence of particularly attractive mineral reserves or topographical suitability for the construction of mine structures, or it may provide access to a number of other parcels.

Examples of levels of strategic importance include:

Priority 1—This will include only those parcels that would constitute a fatal flaw to the project if they are not acquired. Priority 1 parcels will normally include the bulk of the mineral reserves properties.

Priority 2—These parcels represent very important, but non-fatal-flaw properties. The economic impact on the project without these parcels will be strongly negative, since alternatives will be much more costly, but the project will still be viable.

Priority 3—Parcels at this level of importance do not represent a threat to the viability of the project. Alternatives are available at similar costs.

Priority 4—The lowest priority. These parcels are not absolutely necessary and may only be desired as slight enhancements or for their "nuisance value" to the project.

Determination of the appropriate level of priority to place on an individual piece of property will often require an economic analysis in which the project economics are forecast with and without the property. Occasionally, this analysis will compare the acquisition of a particular property with the acquisition or use of an alternative property that could serve the same purpose.

Based on the results of the economic analyses, the project engineer should place one of the foregoing priority rankings on each parcel and enter these rankings into the land database and on the land ownership map. The reasons for a particularly high ranking should also be entered in the database.

The chronological importance of a parcel is a measure of the point in time, relative to the project schedule, at which it is desirable or imperative to have control of the property.

Examples of several levels of chronological priorities are listed below:

Priority 1—These parcels must be controlled prior to making the decision to spend any additional money on the project. The parcels are usually those that have a high strategic importance and thus serve to lower the level of risk to the project.

Priority 2—Before the project mining permits may be obtained, these properties must be acquired or otherwise controlled.

Priority 3—These properties are required before the commencement of construction and initial mining activities.

Priority 4—These low-priority parcels are required sometime later on during the project. They may provide for future expansion or extension of the project scope.

The project schedule and land database should reflect these priorities.

7.1.4.4 Identify the Required Level of Control

The project engineer should first determine, for each land parcel, the level of control that best fits the technical and economic needs of the project. Alternative levels of control to be considered are

1. Options to lease or to purchase (usually only considered in the early stages of development).
2. Outright ownership of surface and mineral in fee.
3. Lease of surface and/or mineral.
4. A combination of ownership and leasing.

Results of the project engineer's determination should be transferred to the land ownership map. The final determination will need to be done in conjunction with the landmen, legal counsel, and the acquisition coordinator. The landmen will, through their personal contacts with the landowners, know which forms of control the landowners prefer, and which forms they are not likely to accept. Legal counsel will determine the legal obligations that will be assumed for the various forms of control. The coordinator will consider the overall impact on the project and on the acquisition efforts for other parcels within the project area.

7.1.4.5 Prepare an Acquisition Budget

Preparation of an acquisition budget will involve all the members of the acquisition team. The landmen will appraise the value of the land surface and any structures located thereon. They will also know the landowners' expectations regarding price, bonus levels, and royalty rates. The lawyers will estimate the costs of document preparation, abstract searches, and legal representation. The project engineer will provide the estimates of the costs of various alternatives being considered. An example of such a calculation might be the comparison of the cost of acquiring a given parcel vs. the cost of mining around the parcel.

7.1.5 LAND ACQUISITION CONTRACTORS

At times, it may be preferable for the project developer to hire an independent land acquisition contractor or consultant. This will be true of projects in geographical areas in which the developer has little or no experience. Also a contractor may be preferred for "one-of-a-kind" projects, in which case the developer needs the expertise only once, and it does not make economic sense to hire full-time personnel for the task.

Selection of a contract landman should be based upon a record of proven performance that has been supported by references from other clients. This proven performance should preferably have been in the same general geographical vicinity and ideally on a similar mineral project. When these selection criteria are satisfied, the contract landman can usually be counted on to provide superior services to those that inexperienced in-house personnel could offer.

7.1.5.1 Services Available

Contractors may be hired to perform only a small portion or nearly the full gamut of activities required for the land acquisition program. Normally, however, project engineering services are not included.

A very common practice is to hire contract landmen who will make the landowner contacts, provide appraisals of the value of the property and structures, and make recommendations on forms of agreement. Occasionally, the landman contractor will also provide other assistance in the form of abstract searches and advice on leases and acquisition contracts.

7.1.5.2 Administering the Services of Land Acquisition Contractors

Although the administration of the activities and the contractual agreement with the contract landman will be the responsibility of the acquisition coordinator, it is important that the project engineer understand the relationship completely.

One of the most crucial decisions for the coordinator is to determine the level of authority to be bestowed upon the contractor. This authority may be measured by financial limitations or by the ability of the contractor to commit the project to some particular course of action. The coordinator may elect to provide the contractor with his limits of authority on an overall basis or set them on a parcel-by-parcel basis. The administration of the activities will require the coordinator to provide the contractor with information regarding the acquisition schedule and budget. Since much of this information will be prepared by the project engineer, the coordinator must provide a channel of communication for the exchange of data. The coordinator must insist that the contractor preserve the confidentiality of such data.

A regular system of reporting should be instituted whereby the contractor reports progress on either a regular periodic basis or on a milestone of accomplishment basis.

The coordinator will also oversee the payments made to the contractor. Some contracts specify a fee based on hours spent on the project, while others may provide for a commission type of payment.

7.1.6 CASE STUDY

The "Black Hole Project" is a hypothetical surface mining coal operation, the subject of a case study of a land acquisition project. The Acme Bituminous Co. (ABC) has developed a surface mining operation on approximately 15,000 acres (60.7 Mm^2) in the "Black Hole" area. The Black Hole mine commenced production in 1981 and currently produces 5 million tons (4.5 Mt) of coal annually for consumption at a mine-mouth power generating plant. The plant is owned and operated by the Kandleworth Home Electric Co. (KWH). The case study is a recitation of the history of the development of this fictitious project with emphasis on the land acquisition activities.

7.1.6.1 Black Hole Coal Deposit

In the late 1940s, oil drilling crews reported intersections of coalbeds near the surface in the Black Hole area. In the late 1950s, the state geological survey drilled several holes in a preliminary exploration program that indicated two persistent coalbeds correlatable over a wide area. The results of the drilling and preliminary estimates of the resource potential were published in Bulletin No. 1001, "Coal Resources of the Black Hole Deposit" in 1958. Bulletin No. 1001 referenced approximately 300 million tons (270 Mt) of potentially recoverable coal in two beds underlying 22,000 acres (89 Mm^2) in the Black Hole area.

The land overlying the coalbeds was predominantly privately owned. Small farming operations were conducted on some areas, and Timber Resources Eastern Establishment System (TREES) operated a forest products business on approximately 8000 acres (32.4 Mm^2) in the area of the coal deposit. The local county owned a 40-acre (1.8-Mm^2) tract including a garage that was used for storage of their highway maintenance equipment.

7.1.6.2 Predevelopment Period

In 1963, ABC began reconnaissance drilling on l-mi (1.6-km) centers in the Black Hole area. Their landmen secured landowner permission to enter the properties for drilling. This permission was generally granted in exchange for small sums of money and the promise to repair any damage to the surface that might occur during the road building and drilling operations. In some instances, the landowners requested that the drill site access roads be left in place for their later use during agricultural activities. As the results indicated the potential for commercial coal thicknesses, the landmen secured options to lease on several of the more promising areas. The legal form of these lease-option agreements was prepared by a local attorney who was retained to assist in the acquisition process.

In 1964, ABC hired a consultant to perform a prefeasibility study of the commercial potential for developing a coal mine and a power generating plant in the area. The study indicated that the project could become economically attractive if the price of oil were to increase by 40% above then current levels. During this study, the consultant identified the area of primary interest for mining and processing the coal, support facilities, and the power plant complex. The area of interest comprised approximately 20,000 acres (80.9 Mm^2). Using this initial "buy line," the landmen continued to acquire options to lease within the area. ABC held preliminary discussions with TREES regarding their coal properties and the possibility of leasing them for the project. A nonbinding agreement in principle was reached by the two parties.

By 1966, ABC decided to temporarily suspend its activities in the Black Hole area.

In 1973, the price of oil rose dramatically, and the Black Hole Project became potentially attractive. ABC reviewed all the previously generated information, and revised the cost estimates contained in the consultant's study to more accurately reflect the economics of the current time. This new forecast was sufficiently encouraging that ABC approached KWH with a proposal to develop a mine in the Black Hole reserves, serving a mine-mouth generating facility that KWH would build in an adjacent location. KWH expressed interest, negotiations were held, a coal supply agreement was executed, and the development period began.

7.1.6.3 Development Period

At this time ABC decided to form an acquisition team (the "A-Team"). The team leader was the Black Hole project manager. Other members included the local attorney, the ABC project engineer, and contractor landmen. The number of contractor landmen would vary as the acquisition workload increased or decreased. All the members had other responsibilities, but were expected to make land acquisition a high-priority project in their schedules.

ABC and KWH agreed that each company would be responsible for acquisition of the land required for their respective activities. They also agreed to coordinate their acquisition efforts so as to avoid competing for the same tracts, and to make the most efficient use of the lands acquired. The A-Team decided that its first assignment should be to develop the basis for the acquisition activities.

The first task of the team was to identify the land ownership within the project area. This information was primarily obtained from the county recorders' files. A map of the project area was prepared that included information vital to the acquisition effort. (the A-Map). Preparation of the A-Map was performed primarily by the project engineer with the assistance of the landmen. The map was prepared on a topographic base and included the following information:

1. Landowner property lines (surface and mineral).
2. Homes, barns or other structures.
3. Public roads.
4. Power lines.
5. Pipe lines.
6. Ponds, streams, and diversions.
7. Coal croplines and overburden depth contours.
8. Future mining areas with sequence of mining—preliminary.
9. Planned haul roads and access roads—preliminary.
10. Mine support facilities layout—preliminary.
11. Power plant site layout—preliminary.

A legend was prepared that matched a code number on the A-Map with the following information:

Item	Responsibility
Tract number	Project Manager
Surface owners name, address, and phone	Landmen and Attorney
Mineral owners name, address, and phone	Landmen and Attorney
Number of surface acres in the tract	Project Engineer
Number of coal-bearing acres in the tract	Project Engineer
Estimated tons of coal underlying the tract	Project Engineer
Estimated stripping ratio of the coal	Project Engineer

The second task for the A-Team was to identify the land requirements for the project. This was the responsibility of the project engineer. He used the preliminary mining plans as the basis for determining these requirements. The initial and future mining areas were identified in the mining plan. The locations and sizes of the areas required for support facilities such as offices, shops, warehouses, power lines, haul roads, etc., were selected. These areas were plotted on an acetate overlay of the A-Map. The areas were color coded according to their anticipated use and the acetate was titled the "Requirements Overlay."

The third task for the A-Team in determining the basis for the acquisition activities was to prioritize the acquisition of each tract. Two categories of priorities were to be addressed, namely, strategic and chronological priorities.

The project manager and the project engineer met to review the land requirements and rank the tracts according to their strategic importance to the project. The highest priority was assigned to those tracts that were absolutely necessary to the project. The second priority was assigned to those tracts that were very important to the project, but that would not constitute a fatal flaw if not acquired. The third priority was assigned to those tracts for which alternative areas could be acquired if necessary. Finally, the lowest priority was assigned to those tracts that would primarily constitute a convenience to the project and could be left unacquired if absolutely necessary. Each of the four priority levels was color coded and plotted on an acetate. This acetate was titled the "priority overlay."

The project engineer used the project development schedule to determine the date by which each of the tracts would be required. These dates, which represented the chronological priorities, were then plotted on the priority overlay.

Task number four for the A-Team in their acquisition planning was to determine which form of control would be optimum, and attainable, for each tract. The entire team was required for this effort. The project engineer listed the reason each of the tracts was required and the type of use that was anticipated. The landmen contributed their knowledge of the landowners' preferences regarding the type of agreement (option, lease, or purchase). The attorney then advised the team on the legal ramifications of each form of control relative to the anticipated use for which the project required the tract. The attorney also revised the lease-option form and prepared a standard form to be used for land purchases. The project manager subsequently made the decision as to which form of control should be sought for each tract.

The A-Team then convened to perform task number five, which was to estimate the acquisition costs. The landmen had performed a survey of each tract to determine the current use and the number and type of structures in place. They then made an appraisal of the value of the surface of the property including the value of the structures. The project engineer used the information on the coal reserves underlying each tract to make an estimate of the mineral value of each tract. Using all of this information, a consensus of opinion was then reached as to the most likely acquisition cost for each tract. The chronological priority information was used to forecast when each tract would be acquired. Finally, the project manager estimated the administrative and overhead costs that would be allocated to the A-Team's activities and prepared a schedule of expenditures for the acquisition effort. The result was the acquisition budget. Four months after the A-Team was organized, they had completed the first edition of their acquisition plan.

Beginning in 1974, ABC commenced the phase II drilling program on the Black Hole area. The drill holes were drilled on 1/4-mi (0.4-km) centers. Concurrently, an aerial survey was conducted and topographic maps were made of the area.

Prior to commencing this work, permission was required from the landowners for the access and control required to conduct the drilling and ground control survey activities. The project engineer provided the landmen with maps showing the drilling sites and the access roads that would be required for the drills and the survey crews. The project engineer also gave the landmen a description of the activities that would be conducted on each tract. Using these maps and descriptions, the landmen approached the landowners and negotiated the terms by which access was granted.

It was apparent at this early stage that the 8000 acres (32.4 Mm^2) that were owned by TREES would be required in order for the project to be feasible. TREES was interested in leasing to the project but had two primary concerns. The first concern related to the loss of revenue from their normal forest product operations during the time that the land was being mined. The second concern was the ability of ABC to return the timber land to its premining productivity levels.

The A-Team undertook the tasks of working with TREES to resolve its concerns and bring the properties to the project. The project engineer was the lead player in dealing with both of these matters. Working with the technical and financial personnel of TREES, he prepared an optimum mining plan by which the TREES property would be mined in a sequence that was compatible with its planned schedule for harvesting the timber. The revised sequence minimized the amount of time the land would be nonavailable for timber production. The project engineer then prepared an estimated schedule of production royalty payments that would be received by TREES. These plans and projections satisfied TREES concerns regarding the loss of timber revenues issue.

The concern regarding the postmining productivity of the land was addressed by a joint effort of the A-Team and the technical staff of TREES. Greenhouse-level studies were designed and conducted by the school of forestry of the state university. These studies were augmented by field studies on the Black Hole site. The results of these studies (which were completed in 1977) were sufficiently encouraging for TREES to commit their property to the project under the provisions of the standard Black Hole leasing agreement.

In 1975 at the conclusion of the phase II drilling program, ABC performed the final feasibility study on the Black Hole Project. KWH had refined their studies and submitted a revised fuel requirement schedule. In response, the project engineer had to change the initial mining areas from the previous studies, and to increase the maximum annual production requirements. All of these adjustments were also required to be compatible with the commitments that had been made to TREES. By this time, the drilling programs had identified 275 million tons (250 Mt) of commercially recoverable coal underlying an area of approximately 13,500 acres (54.6 Mm^2).

The changes in the mining plans and schedules made it necessary for the A-Team to revise the A-Map and the acquisition budget. The project engineer provided a new “buy line” for the acquisition plan and the A-Map and its overlays were revised accordingly. In addition to the 13,500 acres (54.6 Mm^2) of coal-bearing lands, the project engineer identified an additional 2500 acres (10.1 Mm^2) that would be required for access and support facilities. Based upon the revised “buy line” the landmen began acquisition of the newly identified tracts. Options on some tracts which were no longer included within the “buy line” were dropped.

In 1975, ABC began collecting environmental baseline data for the purpose of submitting a mining permit application. This data-collection effort was conducted over a two-year period, ending in 1977. Legal rights of access to the tracts required for the data collection efforts were negotiated and executed by the landmen.

During a similar period, the A-Team continued to acquire the required tracts according to the acquisition plan (with constant updates). The attorney and the landmen worked together to begin the process of “curing titles” for the tracts for which acquisition terms had been concluded. This process basically confirms, or identifies, the ownership of the tracts and provides the information required for royalty payment allocations.

Another major accomplishment of the team during this period was the development of a computerized land-management database. The system was developed to serve both the acquisition effort and the management of tracts after they had been leased or purchased.

The basic building block of the database system is the individual tract data base. Information compiled for the target tracts included the following:

Ownership Information	Tract Description
Name(s)	Legal description of the tract
Addresses	Surface acres
Telephone numbers	Coal acres
Percent of ownership	Coal tons
	Stripping ratio
	Current land use
	Structure inventory and values
	Postmining use
	Special reclamation requirements

The land-management database system was designed to be of use during the acquisition effort and also during the active mining phase of the project. During the acquisition process, the database management system was used for keeping a record of the acquisition status of each tract. Offers made by ABC were recorded, and counter offers from the landowner were also recorded. The status of the negotiations were thus monitored, and the next required activity was known. When lease or purchase agreements were executed, the conditions of the agreements were recorded in the database. These conditions included data on purchase price and payment terms (if applicable), bonuses, advance royalties and terms of recoupment, production royalties, taxes, length of the lease term, etc.

During the active mining phase of the operations, the database system was used for managing the leases and the purchased tracts. The system calculates payments required for taxes, advance royalties, rentals, production royalties, and the status of the recoupment of advance royalties. Routine correspondence with lessors such as requests for current addresses are automatically processed and printed by the system. The status of each tract in the mining plan area is monitored as the operation proceeds. The database is updated monthly to show the status of the following activities:

Clearing—acres (square meters) cleared
Topsoil removal—acres (square meters) stripped
Overburden stripping—cubic yards (cubic meters) removed
Coal removal—tons (tonnes) mined, in inventory, and remaining
Reclamation regrading—acres (square meters) graded
Topsoil replacement—acres (square meters) replaced
Revegetation—acres (square meters) initial seeding, acres (square meters) secondary seeding
Reclamation bond status—percentage released.

Reports on the status of each tract could be printed out routinely or upon special request of the landowner.

During 1978 and 1979, ABC performed the development drilling on 660-ft (200-m) centers in the initial mining areas and drilled closely spaced holes to define the limits of the cropline of the coal. This drilling information was required to make the detailed mine design and to plan the equipment specifications. Application was made to the state agency for a mining permit.

Land acquisition continued with concentration on the initial mining area. A situation arose during this time that required the A-Team to make an economic comparison of alternative courses of action. Prior to ABC securing leases in the area, a natural gas producer had completed a well on one of the tracts within the initial mining area. Production from the well was scheduled to continue for at least six years beyond the time when the tract was scheduled for mining. The owner of the well offered to sell the well to ABC for an amount that represented his estimate of the net present value of his projected profits. The ABC project engineer checked the well owner’s calculations of net present value of profits and basically concurred with his figures.

Then the project engineer made two alternate mining plans for the area in the vicinity of the well. In the first alternate plan, the mining operation would by-pass the well. This required leaving attractive coal reserves in the ground and also involved extra operating costs because of a loss of efficiency while mining around the well. The second alternate plan involved completely rescheduling the mining operations to delay the mining of the area around the well until the well had ceased to produce. The costs of the two alternate plans were estimated and compared with the costs involved in purchasing the well and mining through the area as originally planned. The comparison was made on a net present value basis, and showed that the offered purchase price of the well was less than the additional cost and the value of the coal that would be left unmined. Based on that analysis, the A-Team recommended that ABC negotiate with the owner of the well to purchase it and take it out of service shortly ahead of the time when the area was scheduled for the first mining activities. The ABC board of directors accepted the recommendation, and the agreement was executed.

In 1979, the state approved the Black Hole permit application. The approval was contingent upon the securing of the legal right to mine on all of the tracts within the permit area. The A-Team then continued to concentrate on leasing or purchasing the tracts within the initial mining area. This area was secured by the end of 1979, the permit was issued, and construction of the mine and facilities was commenced. Two years later, in 1981, ABC delivered the first coal from the Black Hole mine to the Kalcutta power plant of KWH. By mid-1982, both the mine and the power plant were operating at full commercial levels.

During this time, the A-Team continued its activities. Its efforts were required to choose between alternatives, schedule the acquisitions to be consistent with mining operations, and maintain the commitments to the lessors.

7.1.6.4 Case Study Summary

This study of the hypothetical Black Hole Project illustrates the value of planning land acquisition efforts and the need for close involvement of the project engineering personnel. The A-Team for the Black Hole Project was successful in their endeavors because they had a logical plan and the project engineers' participation ensured that the acquisition efforts were always consistent with the technical and financial goals of the project.

Chapter 7.2
PLANT SITING AND CONSTRUCTION

JOHN E. CAFFREY AND MARKUS J. LADD

7.2.1 PLANT SITE SELECTION

Selecting the optimum plant site location is an iterative process that requires the reduction of various geographic, technical, business, legal, and political considerations to economic terms. Once the lowest-cost location has been identified, then the incremental cost of alternative locations that are desirable for various technical, business, or political reasons can be determined.

One starts this process by assembling all of the known information concerning the project and general plant location. This information would include such items as the following:

Geographic Considerations

1. Topographic maps
2. Planimetric maps

Technical Considerations

1. Geologic maps
2. Ground stability
3. Mine(s) location(s)
4. Water sources
5. Utility sources
6. Transportation systems and capabilities
7. Climate data
8. Plant specifications
9. Refuse disposal requirements

Business Considerations

1. Competitive environment
2. Royalties
3. Tax laws
4. Materials availability
5. Contractor availability
6. Labor pool
7. Housing availability
8. Medical care availability

Legal Considerations

1. Property ownership
2. Surface rights
3. Regulatory requirements
4. Statutory requirements
5. Contractual requirements

Political Considerations

1. Development incentives
2. Environmental limitations
   a. Air
   b. Water
   c. Noise
   d. Subsidence
   e. Aesthetics
3. Employment rates
4. Business posture

As a general rule, it is most economical to have the plant located as close to the mine(s) as possible. This is especially true when run-of-mine material requires a high degree of concentration as transportation costs are normally reduced then. Following is a suggested process for the first iteration of the optimum plant site location.

7.2.1.1 Geographic Considerations

Using a topographic map as a base, and knowing the general plant area requirements, potential plant sites close to the mine(s) are identified. These potential sites should generally be on level ground and situated to maximize the natural advantages available. Flood plains, steeply sloping ground, and highly populated areas should normally be avoided. Surface features including railroads, rivers, streams, highways, roads, power lines, gas lines, and surface structures should be identified from planimetric maps and confirmed through onsite observation. There is no substitute for early and frequent field visits during the site selection process. Rough estimates of the total transportation costs from mine to plant and plant to market should be prepared at this point.

7.2.1.2 Technical Considerations

Using the topographic base maps that have been prepared, each potential plant site should be evaluated technically. Potential sites should be checked for geologic suitability, including proximity to future mining areas, soil and ground stability, and potential water availability. The sites of previous, present, and future mine works should also be located.

Water requirements, including quality and quantity, need to be determined and water sources and costs itemized. Other utility needs, such as electrical power, gas, sewage, and telephone, also need to be determined and estimated costs and lead times for these services established.

Alternative transportation systems from mine to plant and plant to market need to be evaluated for initial cost, operating cost, capacity, and reliability. A comparison of the cost of transportation alternatives for a hypothetical coal mine appears in Table 7.2.1.

Climatological data concerning prevailing wind direction, temperature, and precipitation should also be considered. Oftentimes, all of the potential sites fall under the same category, and site consideration based upon this parameter is not required. Sample precipitation frequencies (Table 7.2.2) and a map of maxima (Fig. 7.2.1) are provided.

Plant specifications should also be reviewed and alternatives considered in the event that one or more sites are eliminated unnecessarily due to falsely rigid physical constraints.

Lastly, the requirements for refuse, tailings, and wastewater disposal must be considered. Often, in the case of high-concentration processes, the disposal of tailings is a larger problem than product handling to the market. Requirements for disposal sites need to be evaluated on a life-of-reserve basis.

7.2.1.3 Business Considerations

Potential plant sites that meet necessary geographic and technical considerations can now be evaluated on a business basis. One's strengths and weaknesses compared to those of the competitors are very important. Transportation advantages to market can make the difference in winning a sale. How the sites rank with each other and the competition needs to be evaluated on a business basis. Parameters to be considered include contrac-

Table 7.2.1. Comparison of Transportation Alternatives

		Plant	Market A	Market B	Market C
Operating Costs, $/ton, destination					
Origin	*Mode*				
Mine	Belt	0.35	—	—	—
	Truck	2.10	—	—	—
	Slurry	0.30	—	—	—

tual requirements, royalties, wheelage, property taxes, income taxes, availability of contractors, quality of contractors, availability of labor, quality of labor, availability of materials, and quality of materials. The availability of community services, including school, housing, and medical care, needs to be determined. A final consideration that requires thorough evaluation is the availability of incentives from state and local governments, such as tax credits, municipal financing, and subsidized industrial development programs.

7.2.1.4 Legal Considerations

Potential plant sites that have been evaluated for their geologic, technical, and business characteristics now must be evaluated on legal issues. The starting points for these issues are the property maps showing ownership of surface, mineral, and surface rights for the target sites. Adverse property that is needed for the sites or access must be valued and rated for potential of acquisition. Statutory requirements such as zoning need to be researched as well.

The most significant legal requirements for most mining operations are environmental laws and regulations (see Chapters 3.4 and 7.3). Significant time, effort, and money are required for the preparation of environmental impact statements and regulatory plans. Prior to beginning the permitting process, one should evaluate potential sites for conflict with prohibitions concerning archeological areas, historic sites, endangered species presence, and wetlands protected areas. Statutory and regulatory requirements concerning employee health and safety and public safety may affect structural design requirements and certain construction activities such as blasting. Surface and groundwater protection requirements can be very stringent and should be reviewed as soon as possible for potentially fatal flaws.

7.2.1.5 Political Considerations

The prospective plant site list is in all probability quite short now, and those remaining need to be evaluated on a political basis. The attitude of local governments toward business is very important. One's success or failure often depends on the ability to operate in harmony with local governments and regulatory authorities. The limitation of sites must be assessed, especially concerning legal yet socially unacceptable levels of air, water, and noise pollution. For example, a residential suburban setting is probably not a good location for a copper smelter regardless of the strength of other considerations. Creating employment in high-unemployment areas and improving the tax base can be large assets to ensure continued community support (see Chapter 3.1).

In summary, it cannot be too strongly stressed that site selection is an iterative process. If potential sites are dismissed prematurely, the optimum site location may not be selected. It is important to test the economic valuation of various considerations for accuracy sensitivity. A poor plant location is a decision that must be suffered for the project life.

7.2.2 PLANT CONSTRUCTION

Once the general requirements and facilities for mining, transportation, run-of-mine storage, beneficiation, product storage, and product loading are defined and the general plant site selected, then preliminary engineering for the plant commences.

Reports and discussions concerning the objectives and parameters of the project lead to the preliminary engineering phase of construction. Preliminary engineering is the evaluation of

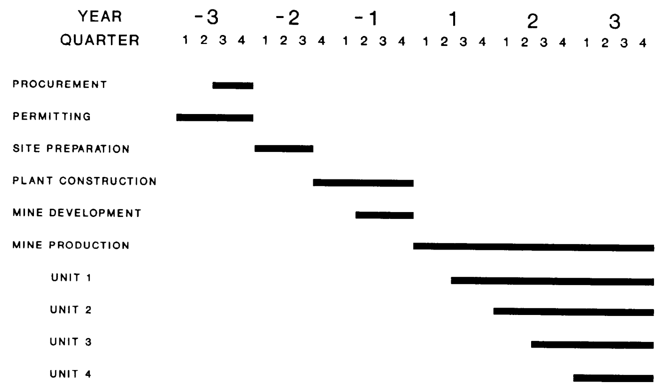

Fig. 7.2.2. Construction and development schedule, mine and plant complex.

potential alternatives leading to feasible solutions that meet the objectives and parameters of the project. Elements that are considered in this process include the following:

1. Local practices for mining, storage, transportation, beneficiation, and refuse disposal.
2. Competition analysis of neighboring operations including operating, transportation, and market advantages and disadvantages.
3. Identification and definition of key success factors.

During the preliminary engineering phase, it is very important that alternative solutions to project requirements are identified and evaluated. Potential alternative solutions are often best identified by a combination of internal engineering efforts and contracted engineering efforts. The former group normally has much greater knowledge of the specific objectives, requirements, and limitations of the project. The latter group, however, can apply a broader perspective to the problems and not be constrained by accepted parameters and assumptions made to date.

Refinement of the preliminary engineering ideas and plans becomes the preliminary design for the project, and a construction and development schedule is prepared (Fig. 7.2.2). The preliminary design usually includes the following:

1. Site selection and supporting documentation.
2. Preliminary facility layout.
3. Preliminary general specifications for plant and supporting infrastructure.
4. Estimated costs of construction and equipment.

The preliminary design becomes the basis for authorization to commit funds for construction and equipment purchase or, in the case of more complex projects, to commit funds for more refined engineering to bring the project feasibility and design within more accurate definition limits (i.e., ± 10%).

The preliminary design also becomes the basis for definitive design, specification preparation, and preparing invitation-to-bid packages for project design, or more commonly, turnkey project design and construction.

If the turnkey approach is selected, an invitation-to-bid package is prepared. Tables 7.2.3 through 7.2.5 outline typical sections of the package. These packages can vary dramatically in complexity, but almost all need to accomplish the following:

1. Ensure that the contractor understands the scope and intent of the project.
2. Ensure that the contractor understands that the preliminary design is a suggested approach, but that he will be held accountable for the feasibility of the design as bid and constructed.

3. Ensure that corporate objectives concerning areas such as discrimination, employment practices, safety, procurement, and insurance are met.

4. Provide sufficient detail in bid breakdown and supporting documentation so that proposals can be evaluated on an objective and professional basis.

5. Provide a schedule of construction that is recommended and the alternative schedule and cost thereof to meet current project completion goals.

During the invitation-to-bid package preparation time, considerable field effort is required to visit and evaluate potential contractors, visit similar installations to better define suggested equipment and specifications, and visit equipment manufacturers to learn as much as possible about the best available technology.

Consider, for example, the evolution during the mid-1960s of underground power centers for coal mines. Equipment was changing from primarily dc-driven to a mixture of ac- and dc-driven equipment. This combination required two electrical distribution systems and an outlay of $80,000 or more for the power center facilities. One company was offering a power center that provided both ac and dc power from one manageable unit using dry rather than fluid-filled transformers, and silicon rather than mercury arc rectifiers. This proprietary technology enabled the purchasers to obtain an ac/dc power center for $20,000 vs. the traditional $80,000 solution. The purchaser could not and did not reveal the proprietary technology to competing suppliers.

After the invitation-to-bid package has been prepared and qualified bidders determined, proposals are solicited from the bidders. The bids received must then be evaluated in an objective manner. Tabulation of the bids is a common method of evaluation and allows ready comparison of facilities, equipment, costs, and schedules. A contract is then drawn and awarded to the recommended supplier. At this time performance requirements are finalized and payment schedules prepared. Retainage or payment for work and/or equipment completed and received less a percentage, commonly 10 to 15%, is the most common method of encouraging performance. Bonding, a more conservative approach, is substantially more expensive, a cost that ultimately is borne by the purchaser.

Project management from the purchaser's viewpoint has the following principal requirements:

1. Ensure that work performed meets specifications.
2. Ensure that equipment delivered meets specifications.
3. Ensure that schedules are followed. Fig. 7.2.2 presents a typical construction and development schedule.
4. Ensure that, if modifications or changes are required to meet project requirements, they are cost effective and documented.
5. Ensure that record-keeping requirements for deliveries, safety, and work performed are adequate to support claims should disputes arise.
6. Verify that progress payments are appropriate.

Samples of a typical contractor's invoice and field inspector's log are shown in Tables 7.2.6 and 7.2.7. Above all, the project manager must ensure that the completed plant will achieve the objectives of the project.

Articles concerning current construction practices and methods may be found in many of the trade and professional journals. Following is a list of some of those that might be consulted:

Engineering News Record (ENR), McGraw-Hill, Inc.

Coal, Maclean Hunter.

Mining Engineering, Society for Mining, Metallurgy, and Exploration, Inc.

AMC Journal, American Mining Congress.

Engineering and Mining Journal (E&MJ), Maclean Hunter.

Chapter 7.3
ENVIRONMENTAL PROTECTION AND PERMITTING

DEAN K. HUNT

7.3.1 INTRODUCTION

7.3.1.1 Importance of Environmental Planning

The increasingly complex regulatory regime has brought environmental planning to the forefront of considerations integrated into the mine development process. In today's world, the integrity of any mining project often depends as much upon the soundness of measures proposed to mitigate environmental consequences, and the operator's ability to negotiate the regulatory maze he is confronted with in procuring required permits, as it does on the miner's traditional ability to extract and transport the mineral resource at the lowest cost.

As regulations for the protection of the environment from the impact of mining change and develop, they have brought with them changes in the methods of mining, in types and utilization of equipment, and in mineral processing and beneficiation techniques, along with changes in the procedures for planning and permitting the mining operation. The overall magnitude of the impact due to environmental restrictions has been dependent on the type of mineral involved, the geographical and topographical conditions at the mine, and the environmental requirements involved. Strict rules often mean not only that the mine will have to take additional measures such as preventing discharges of polluted water, but also that the operation may have to develop totally new concepts of mining in order to remain both in compliance and competitive.

Some examples of areas where changes in mining and related operations have been caused by environmental restrictions are

1. *Topsoil Removal.* Environmental regulations may require that topsoil be removed from the mineral reserve in a separate operation from the removal of other overburden horizons. Additional equipment and labor are needed to remove, segregate, and preserve topsoil.

2. *Runoff Control.* Runoff from mines must typically meet specified effluent limitations. Often, water treatment and sediment control facilities must be constructed prior to mining, and the mining layout and configuration must be designed to facilitate the control of runoff and the prevention of pollution of surrounding waters.

3. *Stream and Wetlands Protection.* Buffer zones to protect streams and wetlands are often required to prevent intrusion of mining into protected areas. Since the geologic location of mineral reserves can conflict with these surface features, difficult questions of stream relocation, wetlands preservation, and reserve loss can result.

4. *Blasting.* Restrictions on blasting limit the times of blasting as well as the blast design. Buffer zones around occupied dwellings and other protected structures are often imposed.

5. *Waste Disposal.* Historically, mine waste was often simply dumped at the nearest convenient location. Today virtually all mine waste must meet standards for the designed and controlled disposal of the waste material.

6. *Overburden Handling.* Overburden handling at one time was as simple as dumping the overburden material on the outslope or in a spoil pile. Most reclamation laws now require consideration of reclamation of the mined area in the handling of overburden.

7. *Processing and Beneficiation.* Discharge of water and air pollutants from processing and mineral beneficiation are today carefully controlled under a variety of environmental programs. Significant revisions have been required in these processes to ensure that the environment is protected and pollutional discharges minimized, while maximizing mineral recovery.

8. *Revegetation.* Revegetation of areas disturbed by mining was at one time left to mother nature. Today most reclamation laws require revegetation of mined areas and restoration of disturbed areas to an acceptable postmining land use.

The attitude that mining operations may be conducted without regard for the environmental consequences of these activities is as foreign to mining development in the United States today as perhaps the idea of environmental regulation itself likely was to miners at the turn of the century. Today every mining operation must contend with a broad range of laws and regulations dealing with a host of environmental concerns including water pollution, air pollution, waste disposal, mine reclamation, and other laws dealing with the protection of the environment.

Occasionally, these environmental programs will impose severe, even prohibitive restrictions on mining since mineral reserves cannot simply be moved to another location. Thus legislation such as the Endangered Species Act,[1] the Bald Eagle Protection Act,[2] the National Historic Preservation Act,[3] wetlands protection under the Clean Water Act,[4] and similar enactments can impose insolvable conflicts with the logical development of a mineral property.

Even where the development of a mineral reserve is not prohibited by environmental legislation, added environmental costs imposed on mineral production can have a direct and significant impact on the domestic industry's viability, particularly where foreign competitors are not subject to the same or similar economic burdens. Environmental regulation can have a dramatic adverse effect on the mineral reserve base. Mineral resources are fixed and finite. Recoverable reserves are that fraction of the resource base that can be mined economically. As environmental prohibitions place additional lands off limits to mining and increase the costs of mineral production, the economically minable fraction of the resource base is reduced.[5]

Nevertheless, our society has made it clear that environmental protection in the United States is an essential and important goal that will be achieved even at the expense of the development of some mineral reserves, and recognition of this basic fact must be included as an important aspect of all modern mine planning.

7.3.1.2 Compliance Strategy: The Continuous Nature of Environmental Planning

The environmental planning process must begin well before the commencement of mining activities and continue through the entire life of the mining project. Once underway, the future viability of a mining project can largely depend upon an effective compliance strategy that combines mineral recovery objectives with regulatory performance goals.

Careful planning at the permitting stage can help ensure that information is gathered in an efficient and effective manner,

1. References in this chapter are listed numerically.

that the application meets all of the minimum requirements for permit approval, that the mine planning is conducted in such a manner as to minimize redesign expenses imposed by regulatory agency review, and that the permit application is reviewed and approved on a timely basis. Failure to fully research permitting requirements and to effectively plan prepermit data gathering can significantly disrupt the start-up of the mining operation and potentially lead to the rejection of an insufficient application.

One of the most serious deficiencies encountered by many operators in the permitting process is to fail to adequately plan the time required to collect baseline data and to provide for public and agency review of the applications. As a practical matter, the preparation of the permit application should begin as soon as the decision is made to begin exploration and prospecting of a specific mineral reserve. Often geologic and hydrologic data can be collected at the same time that exploration drilling and other studies are being conducted to prove out the reserve. Other major tasks and activities that should take place during this early phase include:

1. Identification of the regulatory agencies that will be responsible for permitting the proposed mining operation.
2. Acquisition of all necessary permitting forms and copies of applicable regulations.
3. Identification of possible legal or technical restrictions that may make approval difficult or require special attention in the permitting process.
4. Identification of environmental resources information that will be required and the development of a plan and schedule for collection of the required baseline data.
5. Identification of any special requirements that will be imposed on the operations plan by the environmental protection and permitting regulations.
6. Consultation with regulatory agency personnel to solicit their early comments on the proposed operation and to involve them to the extent practical in the early planning process.

In practice, an operator's greatest aid in obtaining necessary permits will be open and regular discussions with the regulatory staffs involved. Although some agency staff may be hostile to mining, in most cases, government employees are helpful and will work cooperatively with an operator to ensure that applicable regulatory standards are met. Communication with the agencies involved and early planning are more and more becoming necessities if an operator is going to avoid unnecessary problems in the permitting process.

Obtaining necessary permits to open a mining operation, however, is only the first step in full compliance with the underlying regulatory requirements. It is the nature of mining that, as mineral recovery proceeds, changes in the mining operation will be proposed and implemented by the operations staff to improve efficiency and maximize mineral recovery. While such changes may be fully desirable from an operations viewpoint, it must be remembered that permits are generally issued based upon a specific plan for operations submitted to and approved by the regulatory agencies involved. Thus the modern mining engineer must remain ever vigilant to ensure that if operations are to be revised, the permits associated with those operations must also be revised and made consistent with the ongoing operations.

Another major factor that will mandate continued environmental planning throughout the life of most mining operations is the ever-changing nature of the regulatory programs involved. Environmental law is, in fact, a relatively new development, and as such, Congress, state legislatures, and regulatory agencies are in a seemingly never-ending process of reevaluating and revising the regulatory standards involved.

Mines are required to keep abreast of these changing requirements and to ensure that mining operations conform to all applicable standards. Again this can require revisions of the original permits and changes to the ongoing operations to ensure continued compliance with applicable requirements.

Thus it is clear that modern mine engineers must include a new set of skills in their arsenal of mine planning and design techniques. The best mining operation today is one that not only extracts the coal or mineral efficiently and profitably, but is one that is also conducted in full compliance with all permitting and environmental requirements while accomplishing its major objective.

For other discussion of environmental regulations and consequences, the reader is referred to Chapter 3.4.

7.3.2 SCOPING THE REGULATORY REQUIREMENTS

7.3.2.1 Identification of Applicable Regulatory Regimes

Mine permitting requirements in the United States can vary widely depending upon the type of mineral, the method of mining, property ownership, the state or locality in which the mine is to be located, the administrative structure and the laws and regulations of that state, the size and location of the mine or other facility, the type of operation planned, the type of support facilities that will be constructed, the environmental resources affected, and a variety of other factors. One of the confusing aspects of any effort to permit a new mining operation is the multiple levels of government and governmental agencies that may concern themselves with the operation.

As a practical matter, most mining operations are required to obtain at least one and often several permits from either a state or federal permitting authority. Typical permits that may be required for a particular mine could include, for example:

1. Mine reclamation permits.
2. Water quality and discharge permits.
3. Air quality permits.
4. Permits for the construction of dams and impoundments.
5. Waste disposal permits.
6. Waterway encroachment permits.
7. Water withdrawal and water rights permits.
8. Highway encroachment permits.
9. Mining licenses and mine safety permits and approvals.
10. Sanitary sewage permits.
11. Drinking water permits.

As can be seen by this listing, permitting requirements for a particular mine may be complex and varied. In order to simplify the permitting process, some states have attempted to develop a "one-stop" permitting process, designed to ease the burden of multiple permit applications. However, care must be exercised in relying on "one-stop" permit procedures, since there are often permits and approvals required that are not covered by the "one-stop" permit packages.

In identifying applicable permitting requirements, it is essential to understand the regulatory framework at each level of government—federal, state, and local—and to identify the applicable regulatory regimes and permit requirements at each level.

Under the United States Constitution,[6] the federal government has superior authority over any state or local governmental body. Thus, where the federal government determines to pass a law covering a specific area of environmental regulation, such as is the case with the federal Clean Water Act[7] and the federal Surface Mining Control and Reclamation Act,[8] states must either conform their state laws and regulations to the federal mandates or surrender regulatory control to the federal government. Similarly, where, as occasionally exists, an operator seeking a permit is caught between conflicting requirements of state and federal agencies, it is the federal agency and the federal permitting requirements that will prevail.

In any area where the federal government has not passed a law imposing specific regulation, or where the federal law leaves certain authorities and responsibilities to the states, the states retain the residual "police power" to enact appropriate laws to protect the general welfare.[9] This "police power" includes the authority to enact environmental legislation and regulate the environmental effects of mining operations.[10]

In environmental law today, most regulatory programs have evolved into two-level programs. Under this system, a federal agency will typically set minimum nationwide standards, but include provisions allowing the states to have direct regulatory responsibility under state laws that must be consistent with the federal requirements. Under the Clean Water Act (CWA), for example, the federal law imposes minimum standards for the review and issuance of National Pollution Discharge Elimination System (NPDES) permits.[11] Each state has the option, however, of developing an individual state program and receiving approval for the state to exercise NPDES authority within the state's boundaries. Where a state fails to adopt an NPDES permitting program, or where the state program fails to meet the minimum standards of the CWA, the federal Environmental Protection Agency (EPA) is required to assume responsibility for issuing NPDES permits for that state.[12]

Below the federal and state levels of government exist all city, county, and local levels of government. Local governmental bodies are generally considered to have limited authority to adopt environmental restrictions in areas where the federal or state governments have acted. Local governments do nevertheless retain significant land use planning authority through zoning laws, and these local laws can have major impacts on mineral development proposals.

The following discussion addresses the environmental regulatory regime from the perspective of the federal, state, and local governmental agencies involved.

7.3.2.2 Federal Regulatory Regime

The regulatory regime of the federal government will normally come directly into play in one of several circumstances:

1. Where the federal government is the permitting authority under an applicable federal law and there is no state program in effect. For example, the federal Office of Surface Mining Reclamation and Enforcement (OSMRE) will be the permitting authority for coal mining operations under SMCRA where there is no state program for the state in which the proposed coal mine is to be located;[13] and EPA will be the permitting authority for issuance of water discharge permits in states without NDPES authority.[14]

2. Where the federal government is required pursuant to federal law to be the permitting authority for the proposed mining activity. For example, EPA has responsibility for the issuance of Underground Injection Control (UIC) permits under the Safe Drinking Water Act.[15]

3. Where the federal government has permitting authority because there are federal lands involved. For example, the US Forest Service is the permitting authority for issuance of special use permits for any mining operations proposed within the boundaries of the National Forests.[16]

Whenever the federal government is the permitting authority, consideration of additional environmental requirements specifically applicable to federal activities will also necessarily be required. For example, the National Environmental Policy Act (NEPA)[17] requires that an Environmental Impact Statement (EIS) be prepared for every "major federal action" that may have a "significant impact" on the environment. Federal permitting actions have been found to be subject to the EIS requirements of NEPA for proposed mining operations. Where the permitting agency determines that the proposed permitting action is not a major federal action having a significant impact on the environment, a Finding of No Significant Impact (FONSI) will normally be issued with the permitting decision.

In addition to NEPA, the federal government is subject to a host of statutory mandates to protect particular environmental resources. Such mandates include, for example, the Endangered Species Act of 1973,[18] the Bald Eagle Protection Act of 1940,[19] the Fish and Wildlife Coordination Act of 1934,[20] the National Historic Preservation Act of 1966,[21] and the Archaeological and Historic Preservation Act of 1974.[22] Guidance on compliance with these requirements will typically be provided by the responsible federal permitting agency.

Additionally, one-third of the nation's land is owned by the federal government. Any activity on federal lands will necessarily have to comply with the requirements of the appropriate land managing agency.[23] Thus the US Forest Service, the Army Corps of Engineers, the Bureau of Land Management, and other federal agencies exercising jurisdiction over federal lands will play important roles in evaluating the impacts of proposed mining operations on public lands.

Both the Bureau of Land Management and the Forest Service, the two primary land management agencies, have programs for the review and approval of plans of operation for mining. These programs include review of proposed mining plans for their effect on the environmental resources, timber resources, wildlife, recreation, and other resources of the area, along with consideration of appropriate land use planning in effect for the area.

Typical of the broad scope of authority provided to a land management agency are the broad powers granted to the Bureau of Land Management to require specific actions by a mineral lessee on federal lands. The Mineral Leasing Act of 1920 (MLA), for example, controls leasing of federal coal, oil and gas, oils shale, and fertilizer and chemical minerals, and specifically empowers the Bureau of Land Management and the Secretary of the Interior to place conditions in leases to safeguard the "public welfare."[24] Similarly, the Federal Land Policy and Management Act of 1976 (FLPMA) provides the Secretary additional powers to impose lease conditions and requirements for environmental protection.[25] FLPMA contains one of the most sweeping empowerments in federal law:

"In managing the public lands the Secretary shall, by regulation or otherwise, take any action necessary to prevent unnecessary or undue degradation of the lands."[26]

The courts have been protective of the broad power of the federal government to impose lease conditions on federal lands because such conditions and stipulations are an "important mechanism for minimizing the environmental impacts" of mineral extraction.[27]

7.3.2.3 State Regulatory Regime

Despite the broad reach of the federal government, day-to-day mine permitting responsibilities typically rest primarily with the states. Pollution control was, during the first half of the 20th century, viewed as nearly exclusively a state responsibility. The first steps toward the federalization of environmental programs was during the late 1940s and 1950s, when Congress decided to allocate funds for federal research on air and water pollution and to implement measures to deal with some interstate pollution problems. During this period, mining activities were regulated almost exclusively by the states under state statutory and common law.

During the 1960s, however, the general public's perception was that the states had failed to deal adequately with environmental problems. First, many people felt that the standards of pollution control that were enacted by the states were not only insufficient, but also that industries were able to exercise political pressure on state and local governments to keep environmental regulation at a minimum. Secondly, states were faced with almost unprecedented population and industrial growth after World War II, which, in turn, led to an increase in the production of environmental pollutants.

Out of this general perception arose, throughout the 1970s, a comprehensive federal involvement in each area of major environmental concern. However, nearly all of these programs provided that the states would have the opportunity to assume the primary enforcement and permitting responsibility, provided the state program met the standards of and was as stringent as the federal program.

Today the actual permitting of mining operations under nearly all of the major federal environmental laws has been delegated to the states. For example, virtually all states have some form of approved air quality control program, most states with active coal mining operations have assumed primary responsibility for issuance of permits under SMCRA, and most states have assumed responsibility for issuance of NPDES permits under the Clean Water Act.

Depending upon one's view, this state/federal partnership can be seen as either dual regulation, or as a working partnership that forms a foundation for effective implementation of environmental laws. Under either view, it is clear that the mine operator today must normally look to the state first, and then to the local and federal governments to determine the applicable regulatory requirements and standards.

7.3.2.4 Local Requirements

The primary tool of local government in controlling mining development is through the local zoning authority.[28] Significant land-use issues are raised when mining operations are proposed for a particular tract of land. Conflicts between mining and other potentially competing uses are particularly apparent where the mine will be located near municipal and residential areas and where the mineral estate has been severed from the surface estate.

Where the state or federal government has created a regulatory regime for permitting the particular mining operations involved, local zoning may or may not be preempted by the superior state or federal law.[29] In Pennsylvania, for example, the state coal surface mining law specifically preempts all local ordinances purporting to regulate coal mining, "except with respect to local [zoning] ordinances."[30] Additionally, where federal lands are involved, local zoning may not be used to veto a federal program to develop the minerals on the federal lands.[31]

Where the local zoning authority has not been preempted, local governments may adopt ordinances controlling mining. Ordinances that would likely be permissible might include restricting mining in residential districts, providing regulations for the use of roads or highways, and conditioning the use of the land in certain districts.[32] Nevertheless, in practice, few local land-use planning controls and/or zoning restrictions have been developed to deal specifically with mining operations. In fact, in most rural areas, where mines would generally be located, there are no local land-use zoning restrictions at all.

7.3.3 PERMITTING PROCESS

7.3.3.1 Preparing the Permit Application

Permits today are one of the primary mechanisms for enforcement of environmental laws. The purpose of the permitting process is to ensure in advance of mining that the proposed operation will be in compliance with the applicable environmental standards. For the mining engineer, preparing the permit application is perhaps the most complex part of the permitting process. The application will usually identify the permittee, provide information on the proposed activity, and describe how the operation will be conducted in compliance with applicable regulatory requirements. The length of time and complexity of permit preparation can vary greatly depending on the type, location, and size of the proposed mine and the complexity of the applicable regulatory program.

The first step in preparing a permit application is to assemble the necessary permitting forms, guidelines, and the regulations that the permit must satisfy. The best source of the requirements normally is the state environmental and natural resources regulatory agencies. Personnel within these agencies are able to supply information on currently applicable permit requirements, premining data collection requirements, and appropriate forms and analyses.

State and federal permitting programs for mining have progressively become more complex and sophisticated. This is particularly true with respect to the collection of background information on the environment prior to mining, and to the analysis of the potential impacts of mining. Surface water and groundwater quality and discharge analysis, overburden analysis, and revegetation studies are several areas where current regulatory standards may require the mine operator to develop detailed plans, where historically little premining analysis may have been required.

Permit requests are initiated by filing a permit application on the form prescribed by the regulatory agency along with required narratives, maps, cross sections, and auxiliary forms. Typically, the application must be accompanied by a filing fee in an amount prescribed by law and specify whether the application is for a new permit, a revision of an existing permit, or for renewal of an existing permit.

The mine operator should verify that all applicable permitting requirements have been addressed. The key to a successful application is generally a demonstration that the proposed mining plan will be adequate to meet the permit's regulatory requirements. In addition to the potential need to obtain a mining and/or reclamation permit, permits and approvals may be required for safety, water discharges, air pollution control, zoning, transportation, etc.

7.3.3.2 Permitting Check List

Any permitting check list can only be representative of the types of information that are required for a specific permit application. Variations in type of mining, type of permit, state and location requirements, and site characteristics help assure that requirements for one permit will vary from those of another. The check list that follows provides a framework for understanding the scope and breadth of requirements that may be applied to a specific proposed operation.

A. *Applicant and Administrative Information.* The objective of the administrative section of a permit application is to provide the regulatory agency with information on the persons and companies responsible for the proposed mining operation and to address various criteria for permit approval related to the applicant and to the proposed mine generally. A check list of information that typically may be included in the administrative section of an application is as follows:

1. Name, address, and telephone number of the applicant and operator.
2. Officers, partners, directors, and major shareholders of the applicant.
3. Statement of the type of business entity applying for the permit.
4. Statement of current and previous permits held by the applicant.
5. Statement of the mine name.
6. Information on applicant's past violation history and any previous bond forfeitures or permit revocations or suspensions.
7. Proposed term for the permit.
8. Newspaper advertisement, proof of publication, and location where a copy of the application will be available for public inspection.

B. *Property and Right of Entry Information.* Although environmental agencies will not typically render decisions about a mine operator's property rights, many applications today require that the applicant describe the various property interests involved and the documents upon which the applicant relies to conduct mining on the property. Notice of the application and the right-to-file objections will be provided to other property owners potentially impacted by the mining operation. The following provides a check list of documents typically required relating to property and right of entry:

1. Names and addresses of the surface and mineral property owners.
2. Names and addresses of all lease holders.
3. Description of the documents that give the applicant the right to enter the property and conduct mining.
4. Map of the property boundaries.
5. Written consent of the surface owner, if required.

C. *Liability Insurance.* Nearly all mines are required by law to have liability insurance with an approved insurance carrier. Minimum coverage of $300,000 per occurrence and $500,000 aggregate for both bodily injury and property damage is typical. In some states, companies that meet minimum financial requirements may qualify to be self-insured. Information required related to liability insurance may typically include the following:

1. Personal injury and property damage insurance information.
2. A certificate of insurance from a licensed insurance carrier.
3. Where allowed, information for self-insurance approval.

D. *Hydrologic Information.* Surface water and groundwater information is typically required to allow identification of potentially impacted aquifers, surface waters, and water users in the area of the mine. Water quality and quantity data may be required. The following check list indicates the types of hydrologic data often required for a mining application:

1. Surface hydrology background water quantity and quality data.
2. Location of all streams, lakes, ponds, and springs.
3. Description of surface drainage systems.
4. Groundwater hydrology background water quantity and quality data.
5, Depth and horizontal extent of water table and aquifers.
6. Aquifer recharge and storage information.
7. Identification of water supplies potentially impacted by mining.
8. Climatological data.

E. *Information on Environmental Resources.* Collection of environmental data is often required for planning mining activities so that potential impacts on the environment may be identitied and minimized. The level of detail and extent of environmental resources data that will be required for a particular mine may vary significantly depending upon the type, location, and method of mining involved. The following check list indicates the types of environmental data that may be required for a new mining operation:

1. Information on surface water and groundwater resources potentially impacted by the proposed mine.
2. Information on archeological and historic sites around the mine area.
3. Information on fish and wildlife resources and their habitats in the area potentially impacted by mining.
4. Land-use information.
5. Map of buildings, cemeteries, and other structures near the mining operation.
6. Map of public roads near the mining operation.
7. Location of any gas or oil wells in or near the mine plan area.

F. *Soils and Geologic Information.* Minimum required geologic descriptions normally consist of a geologic cross section, drillhole logs, and physical characteristics of overburden strata. Soils information be required to allow identification of topsoil layers to be segregated and protected and to allow planning of the postmining reclamation. A check list of geologic and soils information frequently required with a mining application follows:

1. Map of premining topography.
2. Geology of the mining area.
3. Drillhole logs.
4. Chemical analysis of each stratum to be disturbed by mining.
5. Soil map and description of soils.
6. Location and extent of previous mine workings.

G. *Operations and Reclamation Plan.* A description of proposed mining operations and projected production methods is usually required for every permit application. The application generally contains a statement of the mining method, a statement of the engineering methods to be used for mineral extraction, a description of any mineral processing or beneficiation proposed to be used, and information pertaining to the design, modification, use, maintenance, and removal of mine facilities. Usually, the descriptions must demonstrate how the mining operation will be conducted to minimize the impacts upon the environment and comply with applicable regulatory requirements. The following check list is typical of the types of information that may be required for an operations and reclamation plan:

1. Plan for mining and methods to be used.
2. Size, sequence, and timing of the proposed mining operation.
3. Description of equipment to be used in the mining and processing operations.
4. Description of mine facilities.
5. Plan for overburden handling.
6. Plans for spoil and waste disposal.
7. Plans for all dams, embankments, and impoundments.
8. Plans for surface water and groundwater monitoring.
9. Description of water and air pollution control facilities.
10. Plan for blasting.
11. Plan for reclamation of the mine site, soil stabilization, grading, and revegetation.

H. *Environmental Mitigation Measures.* For each specific type of permit, a prediction of the environmental impacts of the proposed mining operation, along with plans for environmental mitigation measures that will be incorporated into the mine design, will usually be required to ensure that the anticipated impacts are within the regulatory limits. The following check list is typical of the types of information that may be required for specific environmental mitigation measures:

1. Prediction of environmental impacts of the proposed mining in relation to the requirements of the permit application.
2. Plans for mitigation of any prohibited impacts.
3. Analysis of the projected impacts of mining after application of mitigation and environmental protection measures.

I. *Transportation Plan.* Transportation to and from and within the mine site often has additional significant impacts on the public and the environment. Mining operations today are frequently required to submit a plan for the use of any public roads to transport mineral from the mine and designs for any transportation facilities constructed with the mine. The following list depicts the type of information often required for transportation facilities:

1. Plans for transportation routing, including the description of proposed routing over public roads.
2. Plans and approvals for relocation of any public roads.
3. Plans for roads to be constructed or used within the mining area.
4. Plans for conveyor systems and rail facilities to be constructed for the mining area.

J. *Bonding.* Prior to the issuance of a permit, many programs require that the operator post a bond to ensure the completion of measures required to protect the environment and to reclaim the land. The following depict the type of information often required in relation to bonding requirements:

1. Determination of the amount of bond required.
2. Description of the type of bond that will be provided upon permit approval, e.g., cash bond, surety bond, letter of credit, self-bond, etc.

K. *Confidential Information.* As permit applications and the permitting process become more complex, the risk of exposure of proprietary information related to the mineral reserve and proposed mining processes increases. Most regulatory programs provide a mechanism for the applicant to specially mark confidential information in order to prevent its disclosure to competing companies.

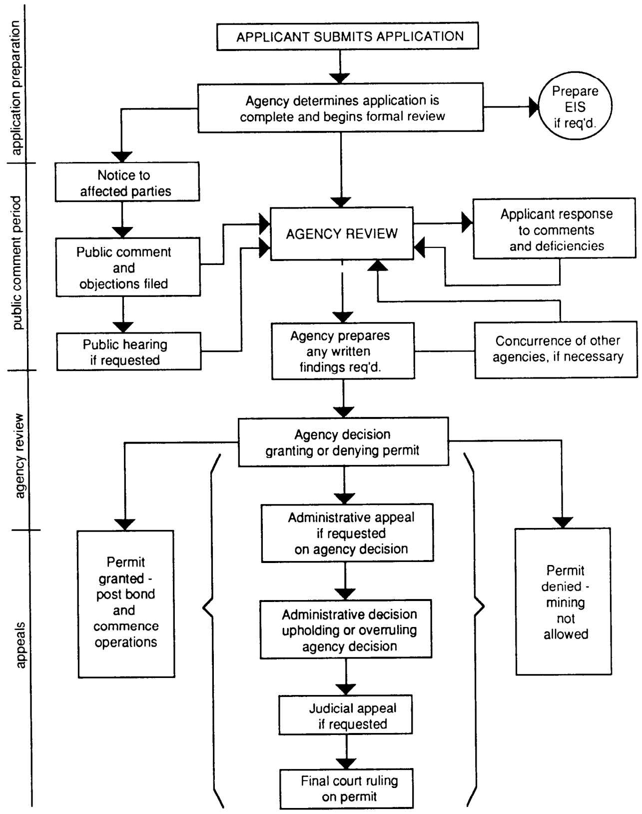

Fig. 7.3.1. Typical permitting process.

7.3.3.3 Agency and Public Review of Permit Applications

The processing of a permit application begins with the submission of a completed application for a new permit, permit revision, or permit renewal to the regulatory authority and ends with the final decision to approve or deny the application. A flow diagram for a typical permitting process is shown in Fig. 7.3.1.

Agency review begins when the applicant officially files the permit application. Once the agency determines that the application is complete, they begin the formal review process, notify affected parties, and begin a public comment period. In most cases, members of the public will be able to both submit written comments and request a hearing on the merits of the particular application. If the permit is granted, the operator may be required to post a bond. Upon approval of the bond, mining operations may commence.

Most agencies will conduct a detailed technical review of each application received to ensure that all applicable regulatory requirements are met. As part of this technical review, the applicant is notified of any deficiencies identified in the application as submitted and provided an opportunity to respond to the agency comments and to correct deficiencies. Failure to provide an adequate response or to correct any permit deficiency could result in denial of the application.

Where the permitting action involves an action by a federal agency, additional reviews may be required to ensure that the environmental impacts of the proposed activity are fully assessed under the applicable federal laws. For example, each federal permitting action will require consideration of the requirements of the National Environmental Policy Act. NEPA compliance will usually result in either the issuance of an environmental impact statement or a finding of no significant impact for the proposed activity.

7.3.3.4 Public Participation

Virtually all environmental laws require opportunity for public participation in the permitting process. Notice of the submittal of the permit application is usually advertised in a local newspaper, with information provided on the schedule for public comment, the availability of the application for public review, and the location where comments may be submitted and hearings requested.

People who have an interest that may be adversely affected have the right to submit comments and objections to the issuance of the permit during the public comment period. Requests for hearings or conferences on the application must also be submitted within the time provided for public comment.

Affected persons who filed comments on the application, and the applicant if the permit is denied, may appeal the agency's decision through an administrative or judicial hearing. In an administrative hearing, evidence will be accepted, and the administrative law judge or review panel will render a decision to uphold or overrule the agency determination. Additional appeals from a final administrative decision can be brought in appropriate state or federal courts if desired by an adversely affected party.

7.3.3.5 Permit Terms and Conditions

Each permit typically is issued for a specified term, with the permittee having the option of applying for a permit renewal prior to expiration. Once approved, the permit can conceptually be viewed as an agreement between the permittee and the regulatory authority to conduct the permitted activity in accordance with the terms and conditions of the permit and the regulatory program.

In addition to the general requirement that activities conducted under the permit be in compliance with the permit and regulatory requirements, a regulatory agency may also impose special conditions on the proposed mining operation to ensure compliance with specific requirements. Such conditions, unless appealed by the permit applicant, will have the force and effect of a regulation when applied to the particular mining operation.

Failure to conform mining operations to the terms and conditions of the permit can result in citizen complaints and/or enforcement action by the regulatory agency involved. If an operator continues in violation of an agency order or has developed a pattern of noncompliance, the more serious steps of permit suspension, revocation, and bond forfeiture are possible. Additionally, an operator with outstanding violations or a history of noncompliance may under some programs be denied the opportunity to receive approval of future permit applications.[33]

7.3.3.6 Overview of EPA's Permit Review Process

A typical permit review process is provided under the EPA's NPDES, RCRA, UIC, and PSD permit processes.[34] In each case, the permit process begins with the submission of an application for a permit, a permit modification, or the reissuance of a permit.[35] In some cases, however, EPA may decide to take action on its own initiative to require a change in a permit.

EPA may handle the permit request in either of two ways. First, it may tentatively decide to grant the request and issue a draft permit for public comment. Second, if it is clear that the application does not meet regulatory requirements, the application may be denied prior to preparation of a draft permit or public comment.

If the permit application is accepted for review, EPA will prepare a draft permit. Along with the preparation of the draft permit, EPA will also prepare a "statement of basis,"[36] a "fact sheet,"[37] and compile an "administrative record."[38] After the draft permit has been prepared, public notice and opportunity for public comment must be provided.[39] The minimum public comment period is 30 days after notice has been issued.[40]

When requested by public comment, and if there is a significant degree of public interest, a public hearing will be held.[41] A public hearing may also be held at the discretion of the local EPA administrator, when he or she determines that it would be helpful to the clarification of issues.[42]

After the close of the comment period,[43] EPA will complete its review for each individual permit requested and render a decision either issuing or denying the permit, or requesting additional information from the applicant.[44] The agency's final decision must be in writing, must include a response to comments,[45] must be based on the administrative record,[46] and must be sent to the applicant and each person who submitted written comment on the permit or requested a copy of the decision.[47]

Any person adversely affected by the decision who filed a timely comment or participated in a public hearing on the application may file an appeal of EPA's decision.[48] Appeals are taken on the formal record of the decision.[49]

The exact form of the appeal will depend upon the type of permit involved. EPA has both a conventional administrative review process,[50] and a special nonadversary panel hearing process that may be used for certain initial licensing decisions involving NPDES permits.[51] Fig. 7.3.2 depicts schematically EPA's conventional permitting procedures.

For RCRA hazardous waste permits, UIC permits, and PSD permits, a request for administrative review must be filed within 30 days after notice of the permitting decision, unless a longer time is allowed. The petition for review must include a statement of the reasons for review, including a demonstration that any issues being raised were raised during the public comment period. The petition must also show that the decision on the permit was based upon clearly erroneous findings of fact or conclusions of law or upon an exercise of discretion that is so important that it should be reconsidered.[52]

Once such an appeal has been filed, the petition for review will be referred to an administrative law judge who will establish a briefing and argument schedule and render a decision on the administrative appeal. Appeals from the administrative law judge can be made through judicial review.

The process of review for NPDES permits vary slightly from other EPA permit decision appeals. An appeal of a decision on an NPDES permit begins with the filing of a petition for review, stating the legal and factual issues involved and the basis for claiming error in the permitting decision. Except for "initial issuance" permits qualifying for the nonadversary panel review procedure, the NPDES review hearing will be a formal evidentiary hearing with formal procedural requirements for filings, service of notice, rules of evidence, etc., being followed.[53]

Again the petition for review will be referred to an administrative law judge who will render an administrative determination on the appeal. Subsequent appeal from the decision of the administrative law judge may be made to the Administrator[54] and then to judicial courts.

7.3.3.7 Overview of SMCRA's Permit Review Process

The permit review process for coal mining operations under SMCRA is similar to the EPA review process and begins with the submission of an application for a permit, permit modification, permit revision, or permit renewal.[55] Additionally, the surface coal mining permitting agency must also review existing permits and may require reasonable revisions of a permit during its term.[56]

The first step in permit review is to determine whether the application is administratively complete. An "administratively complete" application is one that addresses each requirement of the regulatory program under SMCRA and contains all information necessary to initiate processing and public review.[57]

Once the application is deemed administratively complete and accepted for technical review, the applicant will be notified to proceed with public advertisement of the application. The advertisement must be placed in a local newspaper of general circulation in the locality of the mine and be published at least once a week for four consecutive weeks.[58] A public comment period must then be provided that lasts a minimum of 30 days from the last date of advertisement.[59] When requested by public comment, an informal conference with the regulatory agency may be had.[60]

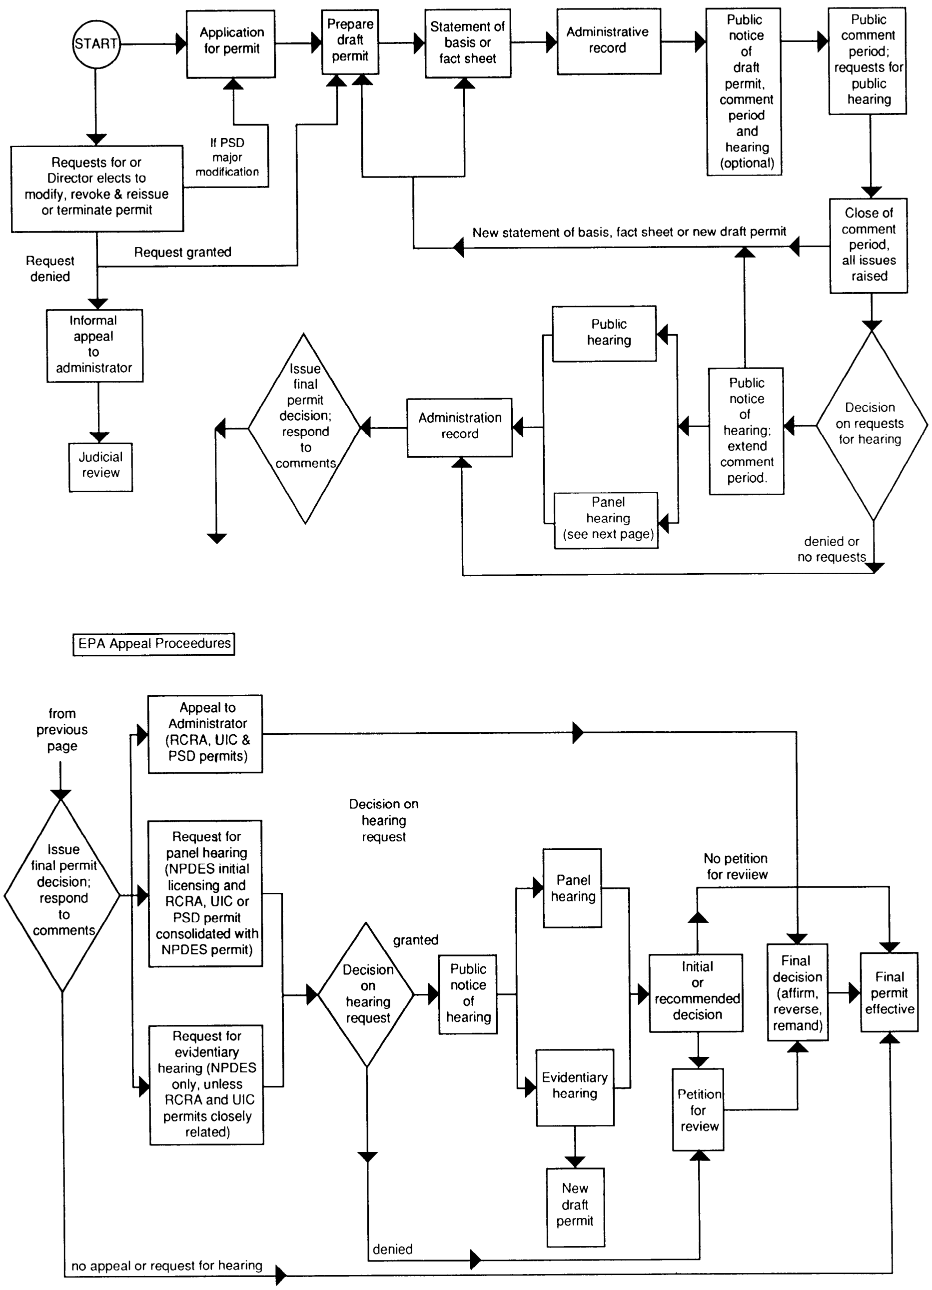

Fig. 7.3.2. Conventional EPA permitting procedures. *Source:* 40 CFR, Part 124, Appendix A.

After close of the comment period,[61] the permitting agency will complete its technical review and render a decision either issuing or denying the permit. The agency's final decision must be in writing, must include certain specific written findings,[62] and must be sent to the applicant, to each person who submitted written comment on the permit, and to local government offrcials.[63]

Any person adversely affected by the decision may file an administrative appeal of the agency's decision.[64] The appeal process is a conventional administrative review, which must be on the record and adjudicatory in nature.[65]

A request for administrative review must be filed within 30 days after notice of the permitting decision is provided to the applicant. Once the request is filed, the agency must schedule a hearing within 30 days of the request and must issue a final decision within 30 days after the close of the hearing record.[66] An appeal from the administrative hearing decision can be made to judicial courts.[67]

7.3.4 OVERVIEW OF SPECIFIC PERMITTING AND REGULATORY PROGRAMS

This segment discusses several of the major permitting and regulatory programs that control various aspects of mining and mining-related activities.

7.3.4.1 Water Pollution Control Programs

Water pollution from mining operations is generally associated with three major sources: ongoing mining operations, abandoned or orphaned mines, and processing and beneficiation plants. Control of these pollution sources is provided for, to varying degrees, under the federal Clean Water Act (CWA)[68] and associated state water quality control programs.

For mining operations, the backbone of the CWA lies in the requirements under Section 402 for obtaining National Pollution Discharge Elimination System (NPDES) permits.[69] Under the NPDES program, any operation that has a "point source"[70] discharge of "pollutants"[71] into "waters of the United States"[72] must obtain a permit and comply with specific requirements and standards.

The basic test of a point source is whether the discharge is a "discernible, confined and discrete conveyance."[73] In mining operations, point source discharges include pumped or gravity drainage from mines that pass through a pipe, ditch, or channel; discharges from ponds; discharges resulting from processing or beneficiation operations;[74] discharges from sanitary wastewater facilities; discharges from other treatment facilities associated with the mining operations; and channeled discharges from mining pits and surface work areas.[75]

Prior to permit issuance, applicants must demonstrate that they will comply with specific effluent limitations intended to protect the nation's waters. The effluent limitations applicable to any source are based on two factors. First, the source must comply with any technology based effluent limitations established for that industry.[76] Second, the discharge must conform to the water quality standards for the receiving stream and to the terms of any area or basin-wide water quality management plan.[77] Limits on the discharge of any toxic pollutants will also be incorporated in the permit if applicable.

Applicants for NPDES permit must submit data on the expected outfall location, the expected discharge dates, the expected flows, sources of pollution and treatment technologies, production, effluent characteristics, available technical evaluations of the wastewater treatment, and any other information the applicant wishes to have considered in the review process.[78] After review of the information submitted by the applicant and consideration of public comment, an NPDES permit containing specific effluent standards applicable to that discharge point may be issued. The permit will be issued for a specific term, with the permittee having the option of applying for reissuance of the permit prior to its expiration.[79]

Once an NPDES permit is obtained and site-specific discharge limits established, compliance with the requirements of the permit during its term constitute compliance with the CWA for enforcement purposes.[80]

An additional consideration under the CWA is the requirements applicable to "nonpoint" sources of pollution governed by Section 208 of the CWA.[81] Mine discharges not collected into a point source, such as unchannelled surface flows and discharges to groundwater, may be governed by a Section 208 plan for the region encompassing the proposed mine. Although Section 208 does not establish a permitting program, the requirements to collect and treat such unchannelled flows are often included in other permits for a mining facility.

7.3.4.2 Corps of Engineers' Section 404 and Section 10 Programs

A special category of permitting under the Clean Water Act (CWA) is the requirement to obtain a permit from the Corps of Engineers under Section 404 of the CWA for dredging and filling of waters and wetland areas.[82] Under Section 404, a permit must be obtained from the US Army Corps of Engineers before any dredge[83] or fill[84] activity can occur in waters of the United States.[85]

Special restrictions are imposed for any activities that are proposed to encroach upon a wetland area. The implementing regulations define a wetlands very broadly and can be extended to include swamps, marshes, bogs, and any other area possessing aquatic-type vegetative growth.[86] The Corps' decision whether to grant a permit for such activities is based upon an evaluation of the probable impacts of the proposed activity and its intended use on the public interest. A permit will be granted if, based upon an evaluation and balancing of the public interest, the District Engineer determines that issuance would not be contrary to the public interest, and that the proposed activity will comply with guidelines established by the EPA under Section 404(b)(l) of the CWA.[87]

Under Sections 404(b) and (c) of the CWA, EPA retains authority to develop guidelines for activities that will be allowed in wetlands and to veto any Corps of Engineers' permit that the EPA feels does not comply with the standards of the guidelines.[88] Before any permit can be issued under EPA guidelines, two general conditions must be met: (1) the applicant must demonstrate that there is no economic alternative to the proposed wetlands disturbance, and (2) measures must be taken to minimize and possibly to mitigate the damage.[89]

In addition to the Corps' permitting authority over dredge and fill activities under Section 404 of the CWA, the Corps also has permitting responsibilities under Sections 9 through 14 of the River and Harbor Act of 1899.[90] Section 9 prohibits the construction of any dam or dike across any navigable water of the United States without Congressional consent and a permit issued by the Corps.[91] Section 10 prohibits the unauthorized obstruction or alteration of any navigable water of the United States.[92] Section 11 allows the Corps to establish harbor lines and prohibit construction of piers, wharves, bulkheads, or other works channelward of the harbor lines. Section 14 provides the Corps with authority to allow temporary occupation or use of any sea wall, bulkhead, jetty, dike, levee, wharf, pier, or other work built by the United States.[93]

By far the most frequently encountered of the Corps' permitting requirements under the Rivers and Harbors Act is the requirement to obtain a Section 10 permit. Under Section 10, the Corps requires permits for any structure in or over any navigable water of the United States, for the excavating from or depositing of material in such waters, and for any other work[94] affecting the course, location, condition, or capacity of such waters.[95]

Each application for a Corps' permit must include a complete description of the proposed activity; the location, purpose, and need for the proposed activity; scheduling information; the names and addresses of adjoining property owners; the location and dimensions of adjacent structures; and a list of approvals required from other agencies. If the activity would involve dredging or the discharge of dredge material, the application would involve dredging or the discharge of dredge material, the method of dredging or disposal, and plans for the activity.[96]

Once the application is determined to be complete, the Corps will issue public notice and conduct a review of the permit application.[97] Permits for permanent structures will normally be issued for an indefinite duration with no expiration date. Permits for construction work, discharge of dredged or fill material, or other activity will normally be issued for a specific time period, with extensions of the permit possible upon approval of the District Engineer.[98]

7.3.4.3 Air Pollution Control Programs

Air pollution from mining activities can stem both from fugitive dust emissions from mine pits, haul roads, and transfer points, and emissions from processing and beneficiation plants. Regulatory control over these pollutants is based upon the requirements of the Clean Air Act (CAA)[99] and state and local laws, rules, and regulations that implement the programs established by the CAA.

The CAA establishes a complex system of interlocking regulations covering air pollutant emissions in all areas of the United States. Clean air areas[100] are governed by a detailed system of area classifications and air quality increments designed to prevent significant deterioration of air quality.[101] Dirty air areas[102] are governed by another set of rules intended to permit some industrial growth while moving toward attainment of acceptable air quality.[103]

Each new major source of air pollution must receive a permit from the state in which it is located.[104] In some cases, EPA retains permitting authority and will issue the permit itself. Additionally, some cities and counties have additional air pollution control requirements that must be met on a local basis.

To implement the CAA, each state develops a state implementation plan (SIP), which upon EPA approval,[105] sets forth the basic strategy by which the state will enforce air pollution standards to meet limitations for the ambient air quality.[106] Under SIPs, each new or modified "major source"[107] of air pollution must apply for a state permit and demonstrate how the source will meet "applicable portions of the control strategy" or how the course will be in accordance with "attainment or maintenance of a national standard."[108]

A review of typical requirements of state program SIPs indicates that most states provide the applicable state air pollution control agency with authority to control fugitive dust at mine sites. Possible control measures include application of water or other dust suppressants and control of dust on roads. Mineral processing is also typically the subject of discussion under most SIPs where mining operations will be located. These standards usually include limits on emissions from specific stationary sources of pollution by application of a variety of pollution control equipment designed to prevent uncontrolled emissions.

For clean air "attainment" areas, the prevention of significant deterioration (PSD) program establishes a detailed system of air classifications and air quality increments limiting the growth of "major emitting sources" or "major modifications."[109] Facilities that qualify as major sources in clean air areas are subject to PSD permitting requirements. An applicant for a PSD permit must demonstrate that it will meet all applicable standards including those applicable to ambient air quality and to the PSD increments.[110] Additionally, a source impact assessment is required to determine if emissions from the proposed source will impair visibility or adversely impact soils or vegetation.[111]

Approval or disapproval of a major source permit will depend primarily on the direct emissions of that source. However, when a new source will cause specific, well-defined, and reasonably quantifiable indirect or secondary emissions, these emissions must also be considered in the PSD increment evaluation and air quality impact assessments.[112]

In addition to standards imposed under the PSD program and under SIPs, the CAA also imposes performance standards on certain new sources of air pollution. These new source performance standards (NSPS) apply to particular categories of sources for which the EPA has established standards and for which construction is commenced after the date on which the EPA issues the proposal for the new standard.[113] These sources require permits regardless of the amount of their emissions, and include such mining-related activities as aluminum ore reduction, copper smelters, ferroalloy production, lead smelters, zinc processing, phosphate rock preparation, rock, gravel and sand quarrying, and certain coal preparation plants that process more than 200 tpd (180 t/day) of raw coa1.[114]

A final category of air emission covered under the CAA is the emission of certain hazardous pollutants. These hazardous air pollutants for which no national ambient air quality standards exist are regulated under the National Emission Standards for Hazardous Air Pollutants (NESHAP) program. NESHAPs apply to pollutants that the EPA believes may result in an increase in mortality or an increase in serious irreversible, or incapacitating irreversible, illness.[115]

NESHAPs are emission limitations that are applied like new source performance standards at both existing and new sources and cover such pollutants as asbestos, beryllium, mercury, and vinyl chloride.[116]

7.3.4.4 Hazardous and Solid Waste Programs

In 1976, Congress passed the Resource Conservation and Recovery Act of 1976 (RCRA).[117] RCRA established a federal program to control the environmental impacts of solid waste management (including mining waste), established minimum standards for solid waste disposal, and established programs to encourage resource conservation and recovery.[118] Included in RCRA is a complex program for the approval of state programs for the permitting and regulation of solid waste facilities, and a federal permitting program applicable to hazardous wastes.

Solid waste under RCRA is defined very broadly and includes "garbage, refuse . . . and other discarded material, including solid, liquid, semisolid, or contained gaseous material."[119] Even though mining wastes are classified as solid wastes under RCRA, Congress also adopted certain exemptions for mining waste from full regulation until studies could be completed by the EPA and determinations made with regard to the most appropriate approach to regulation of the mine waste (the Bevill amendment).[120] The EPA currently exempts 20 categories of waste under the Bevill amendment[121] and has ruled that five categories of mining waste should be regulated as hazardous wastes under RCRA.[122] Further, EPA's regulations list two other important exemptions from RCRA's hazardous waste permitting provisions. These include:

1. "Mining overburden returned to the mine site"[123] that is defined as "any material overlying an economic mineral deposit which is removed to gain access to that deposit and is then used for reclamation of a surface mine;"[124] and

2. Disposal of coal mine wastes or overburden for which a permit is issued or approved under SMCRA.[125]

Under these exemptions, certain mining operations are not required to obtain a hazardous waste disposal permit under RCRA. However, the exemptions do not prohibit EPA or the states from regulating mining waste disposal under nonhazardous solid waste management programs or mean that mining operations are totally exempt from RCRA. A state may regulate mining waste under state solid waste programs, and there are often materials used and discarded at a mine site or processing facility that will not fall within the exemptions. Such waste may include mine-site garbage, oil and machinery fluids, and any other material not generated as part of the mineral extraction and processing. Such materials must be disposed of in accord with state solid waste program requirements, and in accord with hazardous waste management requirements, if they exceed standards established by EPA for ignitability, corrositivity, EP toxicity, or reactivity.[126]

RCRA requires a permit for the "treatment," "storage," and "disposal" of any "hazardous waste."[127] If a hazardous waste management permit is required, the operator must submit a detailed permit application that demonstrates compliance with all of the specific performance and environmental protection standards established by the EPA.[128] Included among these requirements are detailed standards for facility construction and design, groundwater monitoring and protection, and waste material storage and treatment.[129] Once issued, compliance with the terms of the hazardous waste permit constitutes compliance for purposes of enforcement with RCRA.[130]

Requirements for nonhazardous solid waste disposal permits are determined on a state-by-state basis and depend upon the requirements of the particular state program. State program requirements for nonhazardous waste have varied greatly, both from state to state, and within individual states for different industry segments. However, under EPA's guidance, each state program will include minimum requirements for permitting, public participation, and environmental protection.[131] Under RCRA, EPA's guidelines are intended to achieve that level of protection necessary to ensure that there is "no reasonable probability of adverse effects on health or the environment from the disposal of solid waste."[132]

Most states have permitting programs and requirements to control mine-site development, operation, and reclamation. Often, where a state has a comprehensive program to specifically regulate and permit mining operations through a natural resources or mining agency, mine waste disposal is regulated under the specific mining permit and not under the solid waste disposal permit program. Under such programs, mine waste disposal considerations are included as part of the review of the mining permit.

7.3.4.5 SMCRA's Coal Mine Permitting Requirements

An exception to the EPA's extensive authority in the environmental area is the area governing the reclamation of coal mining operations under the federal Surface Mining Control and Reclamation Act (SMCRA).[133] Under SMCRA, the responsibility for regulating coal mine reclamation operations is delegated to the US Department of the Interior, Office of Surface Mining Reclamation and Enforcement (OSM). Under SMCRA, OSM developed minimum national standards creating a nationwide program for coal mine permitting applicable to both surface and underground mining operations.

As in many of the other environmental programs, each state is given the option of either developing a program that meets all of the federal standards and obtaining approval for a state "primary program" or having the federal government assume the primary responsibility.[134] Under state primacy, the state, not the federal government, takes the lead responsibility for issuing coal mining permits and enforcing coal mining regulatory requirements with federal oversight by OSM. In oversight, the role of OSM is that of an overseer, monitoring state programs to ensure continued compliance with the minimum federal standards.

On federal lands, on Indian lands, on lands within a state that chooses not to assume primacy, and where a state's primacy program has failed to meet the federal requirements and is rejected, OSM assumes directly the responsibility of issuing coal mining permits through a federal or Indian lands program.[135] Where a federal program exists, states will be preempted from issuing reclamation permits, but may still have other permitting responsibilities, such as the issuance of National Pollution Discharge Elimination System permits. In each case, before preparing an application, the operator should check with OSM and the state regulatory authority to ensure that the application will address the appropriate regulatory requirements.

The permit application under SMCRA must address the environmental impacts of the proposed coal mining operation, including detailed information on the type and method of coal mining and the engineering techniques and equipment to be used, background information and hydrologic data, a description of the geologic and physical characteristics of the coal and the mining area, a determination of the probable hydrologic consequences of the mining and reclamation, a complete operations and reclamation plan, and a demonstration that minimum performance standards for protection of the environment will be met.[136] Among the comprehensive environmental standards are requirements that all surface areas disturbed by mining, with limited exception, be returned to the approximate original contour, offsite impacts minimized, and the land be restored to as good or better condition as existed prior to mining.[137]

The reclamation plan must describe the condition of the land before mining, including its existing and potential land uses, its productivity, and its average yield or extent of cover. The plan also must specify the proposed postmining land use and describe in detail how this use will be achieved, including the mining techniques and equipment to be used.[138]

Once the SMCRA permit application has been approved, the permittee must post a bond covering the estimated cost for reclamation of the mined area.[139] Each permit is issued for a term of up to five years unless special conditions for a longer term are met. The permittee must commence mining within three years of permit issuance and may apply for renewal of the permit prior to the end of its term.[140]

7.3.4.6 Noncoal-mined Land Reclamation

There is no single nationwide program for the reclamation of noncoal mines like there is for coal mines under the federal Surface Mining Control and Reclamation Act. Rather, the reclamation standards that apply vary from state to state, and from mineral to mineral. As a general rule, most states regulate to some extent the reclamation of land affected by mining operations. These laws typically address the disposal of mine waste and the restoration of the area disturbed by mining, and typically require a state permit prior to commencement of mining.

To regulate the impacts of mining operations, most states supplement any requirements under state reclamation laws with application of the standards established under other programs such as the Clean Water Act and the Clean Air Act to ensure that the range of environmental impacts associated with mining are addressed.

7.3.4.7 Underground Injection Control Program

The underground injection control (UIC) program under the Safe Drinking Water Act[141] regulates any activity that uses a well to inject fluids into the earth.[142] Under the UIC program, any injection that will cause or allow movement of fluids into underground sources of drinking water is prohibited.[143]

The UIC program regulates underground injections by five classes of wells.[144] All owners or operators of any class of injection well must be authorized by either permit or by rule. All mine backfilling operations (active and those undergoing closure) are regulated by rule as Class V underground injection control (UIC) wells (backfilled mines are mines whose voids are filled with mine waste).[145] In situ oil shale and coal gasification retorts and wells used for solution mining and conventional mines, such as stope leaching, are also regulated as Class V wells. These activities are regulated by rule and a general performance standard that prohibits movement of the waste into underground sources of drinking water. Unless required by the state, no UIC permit is required for such Class V wells.[146] Nevertheless, injection that may cause a violation of primary drinking water regulations can result in either a closure action or a requirement that the facility obtain a UIC permit. Additional permits for underground injection may also be required at the state level.

Injection wells for in situ extraction of minerals such as copper, uranium, other metals, sulfur, and salt are regulated as Class III wells. Class III wells must be permitted, with the permit stipulating certain construction, operating, monitoring, and closure requirements to protect underground sources of drinking water.[147] Class I, II, and IV wells also require permits. Class I and IV wells are wells associated with hazardous waste management facilities. Class II wells are wells associated with oil and natural gas production.[148]

The UIC permit application must include information on the applicant, the principal products or services provided by the facility, other permits required for the facility, maps of the facility, and information on the proposed underground injection activity.[149] In addition to complying with the conditions of the permit, operators of UIC wells may also be required to comply with certain financial responsibility requirements for plugging and abandonment of the wells.[150]

7.3.4.8 Mine Safety and Health Act

The federal Mine Safety and Health Act of 1977 applies to almost all mining activities (Chapter 3.3).[151] It is not designed to be an environmental statute and does not impose broad permitting requirements on mine operators. Nevertheless, within the Mine Safety and Health Act's broad parameters are certain requirements for the mine operator to obtain premining approvals and to allow the Mine Safety and Health Administration (MSHA) to review certain mining plans prior to commencement of mining.

As a general rule, each mine operator must notify MSHA of the proposal to open a new mining operation, describe the type of mine or mines proposed, obtain an identification number for each mine, develop and implement mine safety training programs, and either incorporate mandatory safety standards into mine design or qualify for a modification of the standards. Plans for certain mine-related structures such as large impoundments and coal refuse embankments must be submitted to MSHA for approval prior to mining to demonstrate compliance with mandatory safety standards.[152]

7.3.4.9 Uranium Mill Tailings Radiation Control Act

Under the Uranium Mill Tailings Radiation Control Act of 1978 (UMTRCA),[153] the Nuclear Regulatory Commission (NRC), in conjunction with EPA,[154] has regulatory jurisdiction over the opening of any uranium processing facility.[155] The permitting requirements under UMTRCA are comprehensive and cover all aspects of the facility related to radioactive materials. Radioactivity standards and limits for disposal and cleanup of uranium mill tailings wastes are imposed as conditions of the permit.[156]

7.3.4.10 Areas Where No Mining is Allowed

A recent development in the area of environment regulation of mining is the establishment of areas that, because of their environmentally sensitive nature, are precluded from being disturbed by mining. As Congress continues to take steps to preserve natural resources, more and more land areas and in particular lands owned by the federal government may become off limits to mineral production.

Under the 1964 Wilderness Act alone, tens of millions of acres were set aside for study as areas from which any intrusion, including mining, may be permanently banned. Additionally, National Parks,[157] National Wildlife Refuges,[158] National System of Trails,[159] National Wilderness Areas,[160] and Wild and Scenic Rivers[161] for example, all can impose significant restrictions on mineral development. The US Forest Service as well is increasingly under pressure to restrict mining within the boundaries of the National Forests.[162]

Under SMCRA, certain areas are also deemed to be "Designated Unsuitable for Mining." SMCRA provides two ways an area can be declared off limits to coal mining. First, areas can be designated unsuitable for mining by Congress,[163] and second, a process is established by which the state or federal regulatory authority can designate additional areas unsuitable for mining because of the environmentally sensitive nature of the area.[164]

Areas designated by Congress as unsuitable for coal mining include lands within the boundaries of the National Parks, National Wildlife Refuges, National System of Trails, National Wilderness Areas, Wild and Scenic Rivers, National Recreation Areas, and National Forests,[165] and land that will adversely affect a publicly-owned park or a place on the National Register of Historic Places.[166] The Congressional designation also mandates that a buffer zone of area unsuitable for mining be created around publicly-owned parks (300 ft or 90 m), public road rights-of-way (100 ft or 30 m),[167] occupied dwellings (300 ft or 90 m),[168] public buildings (300 ft or 90 m),[169] and cemeteries (100 ft or 30 m).[170]

A discretionary designation as unsuitable for coal mining may be made for any area if the regulatory authority determines that the mine would be incompatible with existing state or local land-use plans or programs, or would adversely affect fragile or historic lands, renewable lands, or natural hazard lands. A designation as unsuitable for mining must be made if the regulatory authority determines that reclamation is not economically or technologically feasible. Designations under the discretionary criteria can be reversed if changing economics or technology make reclamation feasible in an area where it was not feasible before. However, first an applicant must go through a proceeding to "undesignate" the area.[171] Additionally, once a permit application has been submitted for an operation, a subsequent effort to have the area designated as unsuitable for mining will not prevent mining from continuing under the permit.

7.3.5 ENVIRONMENTAL AUDIT

7.3.5.1 Background

In conjunction with permitting, today's regulatory standards mandate some consideration of long-term environmental liabilities associated with most mining activities. Environmental audits are thus increasingly becoming a standard procedure for many mining companies.

Environmental audits have the potential to reveal sensitive environmental data, such as the presence of hazardous waste, the absence of required permits, environmental violations, environmental contamination, and the like; hence, there is occasionally reluctance on the part of mine management to complete a thorough audit. However, most of the information that could lead to environmental enforcement actions could be discovered by others under appropriate conditions, and many types of environmental problems could lead to mine closure if not properly addressed. Thus, as a rule, it is ultimately preferable for a company to take the appropriate steps to identify potential environmental issues and take corrective action prior to any regulatory enforcement action or offsite environmental damage.

Environmental laws are also increasingly acknowledging efforts to identify environmental issues as part of the normal due diligence review for a mining facility. For example, revisions to the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) officially recognize preacquisition property audits as a potential defense to Superfund liability.[172] Also, amendments to the Clean Water Act allow a variance in applicable effluent limitations for coal mines where there is a premining bad-water discharge.[173]

The following broad objectives can be stated for an environmental audit:

1. Evaluate the compliance status of all relevant facilities.
2. Ensure the existence of necessary permits, registrations, approvals, or certifications.
3. Identify current and pending or threatened regulatory, administrative, or judicial environmental actions and claims.
4. Identify postmining environmental liabilities.
5. Review the status of waste disposition, emissions, and discharges, past, present, and future.
6. Evaluate the personal exposure of employees, invitees, and the public.
7. Evaluate the potential for catastrophic incidents or releases.
8. Identify potential exposure of management and affiliated companies to liability.

7.3.5.2 Environmental Audit Check List

Based upon these broad objectives, a site "Environmental Audit Check List" can be prepared touching upon the major items that should be evaluated at a particular facility. The following outline provides an abbreviated review of major items that could appropriately be covered by an environmental audit for a mining facility. The outline is geared specifically to mining situations and the goal of providing a management framework within which a more detailed evaluation can be conducted of specific potential problem areas.

Permits:

1. Provide a list of all permits existing, applied for, and in preparation for the mine. Indicate the current status of each permit.
2. If the mine has NPDES permits, air permits, waste permits, water withdrawal permits, or other permits, include a listing of each applicable permit.
3. Are there any additional permits required for the facility but not already obtained?
4. Were any citizen protests or comments filed on any of the permits? If so, describe the issues raised.
5. What is the status of the bond on each permit? Indicate the amount of bonding liability under each permit.

Surface and Mineral Rights Information:

1. Is the surface property owned or controlled by the mining company?
2. Does the mine have a specific written agreement with each surface owner pertaining to and providing applicable rights to the surface?
3. If the mine is an underground mine, do the surface rights specifically include language that says the company has the right to subside?
4. Has the mine every received any complaints from a surface owner or any of the surrounding landowners? Indicate the nature of any complaint received.
5. With respect to mineral rights, has there ever been a claim made suggesting that the mining company does not have complete and full mineral rights?
6. Have any other entities been granted access rights to the property that may conflict with the rights to extract the mineral (e.g., oil wells, pipelines, utility easements, etc.)?

Ownership and Violation Information:

1. Is the mine permit held by any company not owned and controlled 100% by the operator?
2. Is the mine permit being held by an independent contractor?
3. Is the mine operation being conducted by any company not owned and controlled 100% by the permittee?
4. Is the mine being operated by an independent contractor? Give brief summary of applicable relation.
5. If the mine is permitted by or being operated by an independent contractor, has a review been completed of the contractor's violation history with regard to any other mines potentially affiliated with the contractor?
6. If the mine is permitted by or being operated by an entity only partially owned, has a review been completed of the contractor's violation history with regard to any other mines potentially affiliated with the other parties?
7. How is the relationship between mine personnel and the mine inspectors (excellent, good, poor)? If poor, please describe the problems encountered.
8. Have there been any citizen complaints filed on the mine? If so, please describe the complaints filed.

Information on Archaeological Sites, Cemeteries, etc.:

1. Within the permit area and adjacent areas, including the area over existing, past, and proposed underground workings, does the mine contain any of the following features?
   a. Federal lands? Indicate the type of federal land involved.
   b. Any archaeological or historical site that has been previously identified? Indicate the type of site involved.
   c. Public roads where there is not a specific written approval for mining through or under the public road by the agency that has jurisdiction over the road?
   d. Occupied dwellings where there is not a specific written waiver from the owner of the occupied dwelling?
   e. Any public buildings, schools, churches, community, or institutional buildings?
   f. Any public park?
   g. Any public or private cemeteries?

Hydrology:

1. Has the mine obtained all necessary water discharge permits?
2. Is the mineral being mined associated with potential pollutants, such as high sulfur-bearing strata?
3. Has the mine ever experienced any difficulties with poor-quality mine drainage? Briefly describe the situation encountered.
4. Does any of the mine water need to be treated to meet effluent limitations or other applicable standards?
5. Has any poor-quality mine drainage been observed on any part of the permit area, in any of the surrounding areas, whether associated with the mine or not?
6. Have any of the surrounding land owners or occupants ever complained about loss of water or the mine contaminating their water supplies?
7. Is the water used by surrounding landowners of poor quality? For example, is the water discolored, does it have a bad odor or bad taste, or are there other problems with water quality in the area?
8. Has the mine ever had any complaints about the water level in streams increasing or decreasing, or the fish population in streams increasing or decreasing?

9. Are there any in-stream treatment facilities or in-stream sediment ponds associated with the mine?

10. Are there any wetland areas, wet areas with cattails or similar aquatic vegetation that could be considered wetlands, within the vicinity of the mine?

Air Pollution:

1. Has the mine obtained all the necessary quality permits?

2. Have there been complaints about dust or air quality discharges from the mine?

3. Are mine haul trucks covered with tarps to minimize dust and to prevent material from falling off?

4. Is there a program for controlling dust and air pollution from the mine?

Explosives:

1. Has the mine had any complaints from land owners pertaining to blasting or the use of explosives?

2. Is the mine access limited due to topographic conditions or is it possible for local people to obtain unauthorized access to the mine site?

3. If it is possible for unauthorized persons to obtain access to the site, what measures are currently taken to control this access?

4. Are any personnel other than trained mine personnel allowed within the mine pit or the mine property in an area that may ever be subject to blasting?

Waste Disposal:

1. Does the operation include a facility for the disposal of mine waste?

2. Have there ever been any discolored or bad-quality water seeps from the waste pile?

3. Does the groundwater indicate any levels of pollution from the waste pile?

4. What is the worst-case chemical analysis for the waste material being disposed of at the mine?

5. Have there ever been any signs of slumping or instability of the waste pile?

6. Does the waste pile have any public roads, homes, or occupied dwellings, etc., downstream that could be affected by failure?

7. Is the waste pile routinely inspected and certified by a professional engineer to verify that it is being built in accordance with the approved plan?

8. Are there any abandoned mine waste piles within the vicinity of the mine, including the area overlying underground workings?

9. Do any of the abandoned mine waste piles show any signs of instability or poor mine drainage?

10. Does the disposal of any domestic or other nonmine waste occur within the property boundaries, including the disposal of garbage by mine or nonmine personnel?

11. Has a survey been done to determine whether there is any nonmine waste on the property? Are there any abandoned nonmine waste piles within the mine property?

12. What does the mine do with trash from the mine?

Impoundments:

1. Are there any large impoundments within the vicinity of the mine or included in the mine permit?

2. Are there any public roads, facilities, dwellings, or other such facilities downstream of an impoundment that could be affected by the impoundment's failure? If so, briefly describe.

3. Are all impoundments routinely inspected and certified by a professional engineer to verify that they are being built in accordance with the approved plans?

4. Have any of the impoundments ever experienced overtopping?

Backfilling and Slides:

1. Has the mine ever experienced a slide or instability of backfilled material or of outslope material?

2. Does the mine have an excess spoil fill? Does the mine have a durable rock fill? Were any of the fills constructed in a location where there was a stream or running water prior to mining?

3. If the mine is a surface mine, what is the maximum size pit and the size of the total pit currently open for the mine? How many cubic yards (cubic meters) of material would be required if the mine was closed today and the pit had to be backfilled?

4. What is the maximum amount of highwall currently open on the operation, including total length and height? How many cubic yards (cubic meters) of material would be required if the mine was closed today and the highwall had to be completely eliminated?

Subsidence:

1. Does the mine include longwall or pillar removal mining?

2. Has the mine ever identified any substance subsidence?

3. Have there ever been any complaints by surface owners about surface subsidence?

4. Does the mine have any significant problems with roof or floor control?

Mine Fires:

Have there ever been any mine fires, including outcrop fires, identified on the mine property?

Underground Injections:

1. Does the mine have any injection wells or pump any fluids or other material of any type underground?

2. If the mine is an underground mine, has an evaluation ever been completed to determine what will occur after the mine is closed and the mine workings become flooded? If yes, briefly describe the resulting conclusion.

Previously Mined Areas:

1. Does the area affected by the mine include a previously mined area?

2. Are there any of the following problems on the previously mined area?

a. Bad water drainage?

b. Unstable spoil?

c. Spoil on the outslope?

d. Refuse material on the outslope?

e. Unreclaimed areas where revegetation will be difficult?

f. Unreclaimed highwall?

Miscellaneous:

1. How close is the nearest house?

2. Have there been complaints about the use of roads in the area?

3. Has the mine ever received a closure or cessation order?

4. Are there cleaning or other chemical solvents located at the mine? Have all necessary forms been filed and provided in regard to "right to know" requirements for chemical exposure?

5. Have all transformers or other electrical equipment been checked for PCB contamination?

6. Is oil or fuel stored on the property? What type of facilities are provided for oil or fuel storage? Are there any underground storage tanks? Have all such tanks been tested?

7. Are there any oil or gas wells, or similar facilities on the property that could conflict with mining?

29. A number of cases have recognized the validity of local and state regulation, even where federal lands were involved. See, e.g., *Wallis v. Pan American Petroleum Corp.,* 384 U.S. 63, 67-72 (1966); *Texas Oil and Gas Corp. v. Phillips Petroleum Company,* 406 F.2d 1303 (10th Cir. 1969) *cert denied* 396 U.S. 829 (1969).
30. Pennsylvania Stat. Ann. Ti. 52, § 1396.17(a) (Purdon, 1982 Supp).
31. In the case of *Ventura County v. Gulf Oil Corporation,* 601 F.2d 1080 (9th Cir. 1979), *cert. denied* 48 U.S.L.W. 3622 (1980), Ventura County had designated the federal lands as "open space" under a zoning ordinance, a category that prohibited oil exploration and extraction unless a permit was granted. Gulf Oil Corp., which had a federal oil lease, refused to apply for the zoning permit. The US Court of Appeals ruled that the zoning ordinance conflicted with a major Congressionally sanctioned program and ruled that Gulf could not be required to obtain the local permit.
32. A total ban on mining within the confines of a municipality would likely be ruled improper, unless it can be shown that there are specific harms that may result from mining and that there are no alternative means that can minimize or prevent that harm. See, *e.g, Spillerdown v. Prewilt,* 21 Ill.2d 288, 171 N.E.2d 582 (1961) (ordinance prohibiting strip mining within village limits).
33. For example, under the federal Surface Mining Control and Reclamation Act (SMCRA), no coal mining permit may be issued to an applicant where information available to the regulatory agency indicates that any coal mining operation owned or controlled by the applicant is in violation of SMCRA or other law pertaining to air or water environmental protection, unless the violation is in the process of being corrected or is being appealed by the operator. 30 U.S.C. Section 1260(c)(1988).
34. EPA's procedures for issuing permits allow for the consolidation of the review of NPDES, RCRA, UIC, and PSD permits (except RCRA and UIC emergency permits). The procedures for processing each of these categories of permits are substantially identical and are contained in 40 C.F.R. Part 124 of the federal regulations.
35. The procedures for an NPDES permit are set forth in 40 C.F.R. Section 122.21, for a UIC permit in 40 C.F.R. Section 144.31, and for a RCRA permit in 40 C.F.R. Section 270.10 and 124.3.
36. 40 C.F.R. Section 124.7 (1989).
37. 40 C.F.R. Section 124.8 (1989).
38. 40 C.F.R. Section 124.9 (1989).
39. 40 C.F.R. 124.10 and 124.11 (1989).
40. 40 C.F.R. Section 124.10(b) (1989). EPA regulations require that all arguments and factual materials that a person wishes to be considered by the EPA in connection with a particular permit must be placed in the record by the close of the public comment period. 40 C.F.R. Section 124.13 (1989).
41. 40 C.F.R. 124.12 (1989).
42. *Id.* Where a public hearing is held, the comment period will be extended through the close of the hearing.
43. Although the EPA regulations do not specifically address it, it has been the custom of EPA to allow applicants time after the close of the public comment period to file responses to the comments submitted.
44. 40 C.F.R. Section 124.15 (1989).
45. 40 C.F.R. Section 124.17 (1989).
46. 40 C.F.R. Section 124.18 (1989).
47. *Id.*
48. 40 C.F.R. Sections 124.19 and 124.74 (1989).
49. 40 C.F.R. Section 124.18 (1989).
50. See 40 C.F.R. Section 124.19 and Section 124 Subpart E (1989).
51. See Appendix A to 40 C.F.R. Part 124. NPDES permits that involve "initial licensing" may be appealed in a special nonadversary panel hearing. The EPA regulations also provide that if such a hearing is granted for an NPDES permit, consolidated RCRA, UIC, or PSD permits may also be reexamined in the same proceeding.
52. 40 C.F.R. Section 124.19 (1989).
53. 40 C.F.R. Section 124.71–124.91 (1989).
54. 40 C.F.R. Section 124.91 (1989).
55. The procedures for permit review may vary among states based upon the specific organization and provisions of the state surface coal mining program. However, each state must meet the minimum federal standards in order to have an approved state program. 30 U.S.C. Section 1253.
56. 30 C.F.R. Section 774.11 (1988).
57. 30 C.F.R. Section 701.5 (1988).
58. 30 C.F.R. Section 773.13(a) (1988).
59. 30 C.F.R. Section 773.13(b) (1988).
60. 30 C.F.R. 773.13(c) (1988).
61. The permitting agency will typically notify the applicant of any deficiencies identified in the permit application and provide the applicant with an opportunity to respond to the deficiencies and any public comment.
62. 30 C.F.R. Section 773.15 (1988).
63. 30 C.F.R. Section 773.19 (1988).
64. 30 C.F.R. Section 775.11 (1988).
65. 30 C.F.R. Section 775.11(b) (1988).
66. 30 C.F.R. Section 775.11 (1988).
67. 30 C.F.R. Section 775.13 (1988).
68. 33 U.S.C. Section 1251 *et seq* (1988).
69. 33 U.S.C. Section 1342 (1988). See also, 40 C.F.R. Part 122 (1989).
70. A "point source" is defined as follows:

    Point source means any discernable, confined and discrete conveyance, including, but not limited to, any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, vessel or other floating craft from which pollutants are or may be discharged.

    33 U.S.C. Section 1362(14) (1988). Return flows from irrigated agriculture are not included in this definition. *Id.* See also, 40 C.F.R. Section 122.2 (1989).
71. *Pollutant* means dredged spoil, solid waste, incinerator residue,

filter backwash, sewage, garbage, sewage sludge, munitions, chemical wastes, biological materials, radioactive materials (except those regulated under the Atomic Energy Act of 1954, as amended [42 U.S.C. 2011 *et seq.* (1988)], heat wrecked or discarded equipment, rock, sand, cellar dirt and industrial, municipal, and agricultural waste discharged into water. It does not mean (a) sewage from vessels; or (b) water, gas, or other material [associated with oil and gas production.] 40 C.F.R. Section 122.2 (1989).

72. *Waters of the United States* or "waters of the U.S." means:
   (a) All waters which are currently used, were used in the past, or may be susceptible to use in interstate or foreign commerce, including all waters which are subject to the ebb and flow of the tide;
   (b) All interstate waters, including interstate "wetlands;"
   (c) All other waters such as interstate lakes, rivers, streams (including intermittent streams), mudflats, sandflats, "wetlands," sloughs, prairie potholes, wet meadows, playa lakes, or natural ponds the use, degradation, or destruction of which would affect or could affect interstate or foreign commerce including any such waters;
      (1) Which are or could be used by interstate or foreign travelers for recreational or other purpose
      (2) From which fish or shellfish are or could be taken and sold in interstate or foreign commerce; or
      (3) Which are used or could be used for industrial purposes by industries in interstate commerce;
   (d) All impoundments of water otherwise defined as waters of the United States under this definition;
   (e) Tributaries of waters identified in paragraphs (a) through (d) of this definition;
   (f) The territorial sea; and
   (g) "Wetlands" adjacent to waters (other than waters that are themselves wetlands) identified in paragraphs (a) through (f) of this definition. 40 C.F.R. Section 122.2 (1989).
73. See 40 C.F.R. Section 122.2 (1989).
74. A processing plant that is a "closed system" is not necessarily exempt from NPDES requirements unless the system can be guaranteed *never* to discharge water. *Sierra Club v. Abston Const. Co.,* 620 F.2d 41, 45 (5th Cir. 1980).
75. The case law has supported findings that mining can constitute a point source. *United States v. Earth Sciences, Inc.,* 599 F.2d 368 (10th Cir. 1979) (gold mining); and see also, *Sierra Club v. Abston Const. Co.,* 620 F.2d 41 (5th Cir. 1980).
76. Effluent limitations consist of numerical limits on the amount of pollutants that may be discharged by a facility, regardless of the location or condition of the receiving stream. 33 U.S.C. 1311, 1314, 1316, and 1317 (1988). See EPA Effluent Guidelines and Standards for Mineral Mining and Processing, 40 C.F.R. Part 436 (1989).; EPA Effluent Guidelines and Standards for Ore Mining and Dressing, 40 C.F.R. Part 438 (1989).; EPA Effluent Guidelines and Standards for Ore Mining Point Sources, 40 C.F.R. Part 434 (1989).; EPA Effluent Guidelines for Non-ferrous Metals, 40 C.F.R. Part 421 (1988).; and EPA Effluent Guidelines and Standards for Phosphate Manufacturing, 40 C.F.R. Part 422 (1988).
77. 33 U.S.C. Sections 1311, 1312, and 1342 (1988).
78. 40 C.F.R. Section 122.21(h) and (k) (1989).
79. 40 C.F.R. Section 122.41 (1989).
80. 33 U.S.C. Section 1342(k) (1988).
81. 33 U.S.C. Section 1288 (1988).
82. 33 U.S.C. Section 1344 (1988).
83. The EPA and the Corps define dredged material as "material that is excavated or dredged from waters of the United States." 33 C.F.R. Section 323.2(j) (1989).; 40 C.F.R. Section 232.2 (1989).
84. The dividing line between the Section 404 Corps' permit and the NPDES permit program is based on the type of material to be placed or discharged into the water. If the material is dredged or fill material, Section 404 applies. If the discharge consists of any other pollutant, the NPDES program applies.
85. The Corps regulations for issuing dredged and fill permits are contained in 33 C.F.R. Parts 320–323 (1989). States may be granted authority to issue Section 404 permits by the EPA for some waters of the United States. The Corps always retains jurisdiction over waters presently used, or susceptible to use, as a means to transport interstate commerce, including tidal waters and adjacent wetlands.
86. 33 C.F.R. Section 323.2 (1989).
87. 33 C.F.R. Section 320.4(a) (1989).
88. 42 U.S.C. Section 1344(b) and (c) (1988).
89. 40 C.F.R. Section 230.10 (1989).
90. 33 U.S.C. Sections 401–408 (1988).
91. See 33 C.F.R. Part 321 (1989).
92. See 33 C.F.R. Part 322 (1989).
93. Instead of a permit, the Corps will issue a real estate instrument for such activities.
94. The term "work" includes dredging or disposal of dredged material, excavation, filling, or other modification of a navigable water. 33 C.F.R. Section 322.2(c) (1989).
95. 33 C.F.R. Part 322 (1989).
96. 33 C.F.R. Section 325.1 (1989).
97. 33 C.F.R. Section 325.3 (1989).
98. 33 C.F.R. Section 325.6 (1989).
99. 42 U.S.C. Sections 7401 *et seq* (1988).
100. Areas that have air quality better than the national ambient air quality standards are known as "attainment areas." 42 U.S.C. Section 7407 (1988).
101. 42 U.S.C. Sections 7470–7491 (1988).
102. Areas which do not meet the ambient air quality standards are defined as "non-attainment areas." 42 U.S.C. Section 7407 (1988).
103. 42 U.S.C. Sections 7501–7508 (1988); and see 40 C.F.R. Part 50 (1989).
104. In making a decision as to whether a facility is a "major" source or not, EPA has determined to exclude the consideration of fugitive dust emissions from surface coal mines. This exclusion is significant because it means that few coal mines would be classified as major sources and thus subject to the CAA major source permitting requirements. See 54 Federal Register 48870 (November 28, 1989).
105. See 40 C.F.R. Part 52 (1988).
106. 42 U.S.C. Section 7410 (1988); 40 C.F.R. Part 51 (1989).
107. A "major stationary source" means:
   (1) Any stationary source of air pollutants which emits, or has the potential to emit, 100 tons/year or more of any pollutant subject to regulation under the Clean Air Act; or
   (2) Any physical change that would occur at a stationary source not qualifying under paragraph (1) above as a major stationary source, if the change would constitute a major stationary source by itself. 40 C.F.R. Part 51, Appendix S (1989).
108. 40 C.F.R. Section 51.18 (1989).
109. 42 U.S.C. Section 7470–7491 (1988). A "major emitting facility" and "major modification" are defined in 42 U.S.C. Section 7479 (1988).; and in EPA's regulations at 40 C.F.R.Section 51.24(b) (1989) and 52.2 l(b) (1988). As discussed earlier, EPA has excluded fugitive dust emissions from surface coal mines from the determination of whether a facility is a major facility for purposes of PSD permitting. See 54 Federal Register 48870 (November 28, 1989).
110. 42 U.S.C. Section 7475 (1988).
111. 40 C.F.R. Section 51.24, (1989); 40 C.F.R. Section 52.21 (1988).
112. 40 C.F.R. Section 51.24 (1989); 40 C.F.R. Section 52.21 (1988).
113. 42 U.S.C. Section 7411 (1988).
114. See 40 C.F.R. Part 60 (1989).
115. 42 U.S.C. Section 7412 (1988).
116. 40 C.F.R. Sections 61.01–61.71 (1989).
117. 42 U.S.C. Section 6901 *et seq* (1988). A companion law to RCRA is the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), also referred to as the "Superfund Act," which establishes a program to deal with releases and potential releases of hazardous substances, including hazardous wastes. CERCLA sets up a program for remedial measures and enforcement at existing sites, but is not a regulatory program and does not contain permitting requirements.
118. 42 U.S.C. Section 6902 (1988).
119. 42 U.S.C. Section 6903(27) (1988); 40 C.F.R. Section 2561.2 (1988). The definition of solid waste specifically refers to waste from "mining operations." *Id.*
120. 42 U.S.C. Section 6982(f) (1988). This exemption is commonly referred to as the Bevill amendment after Rep. Tom Bevill (Ala).

EPA initially interpreted the Bevill Amendment to apply to all solid waste from the exploration, mining, milling, smelting, and refining of ores and minerals. 45 Federal Register 76118 (Nov. 19, 1980). The list of waste excluded has since been reduced to 15 categories. The mining waste study was to include, among other things, the sources and volume of discarded material per year, present disposal practices, potential dangers from surface runoff or leachate, and estimates of air pollution by dust. *Id.*

121. Currently, five types of mining waste resulting from the extraction, beneficiation, and processing of ores and minerals are excluded from the hazardous waste permitting and regulatory requirements. These are:
(1) Slag from primary copper processing.
(2) Slag from primary lead processing.
(3) Red and brown muds from bauxite refining.
(4) Phosphogypsum from phosphoric acid production.
(5) Slag from elemental phosphorous production.
See 54 F.R. 36592 (Sept. 1, 1989). Also, 15 types of mining waste are being studied by EPA and are conditionally excluded from hazardous waste permitting and regulatory requirements. These include:
(1) Treated residue from roasting/leaching of chrome ore.
(2) Gasifier ash from coal gasification.
(3) Process wastewater from coal gasification.
(4) Calcium sulfate wastewater treatment plant sludge from primary copper processing.
(5) Slag tailings from primary copper processing.
(6) Fluorogypsum from hydrofluoric acid production.
(7) Process wastewater from hydrofluoric acid production.
(8) Air pollution control dust/sludge from iron blast furnaces.
(9) Iron blast furnace slag.
(10) Process wastewater from primary magnesium production by the anhydrous process.
(11) Process wastewater from phosphoric acid production.
(12) Basic oxygen furnace and open hearth furnace air pollution control dust/sludge from carbon steel production.
(13) Basic oxygen furnace and open hearth furnace slag from carbon steel production.
(14) Chloride process waste solids from titanium tetrachloride production.
(15) Slag from primary zinc processing.
55 F.R. 2322 (Jan. 23, 1990).

122. The five categories of mining wastes that have been ruled to be subject to the hazardous waste program requirements include:
(1) Furnace off-gas solids from elemental phosphorus production.
(2) Process wastewater from primary lead processing.
(3) Air pollution control dust/sludge from lightweight aggregate production.
(4) Sulfate process waste acids from titanium dioxide production.
(5) Sulfate process waste solids from titanium dioxide production.
55 Federal Register 2322 (Jan. 23, 1990.)

123. 40 C.F.R. 261.4(b) (3) (1989).
124. 40 C.F.R. Section 260.10 (1989).
125. 42 U.S.C. Section 6905(c) (2) (1988). The exemption for SMCRA permits was added to RCRA in May 1980. Solid Waste Disposal Act Amendments of 1980, P.L. 96-482 (1980).
126. 40 C.F.R. Part 261 (1989). Even if a waste is classified as a hazardous waste under RCRA, it may still be exempt from the hazardous waste program requirements if it falls within the small quantity exemption (40 C.F.R. Section 261.5), if the waste will be stored for a short period of time (40 C.F.R. Section 262.34), or if the material will be beneficially used, reused, recycled, or reclaimed.
127. The terms "treatment," "storage," "disposal," and "hazardous waste" are defined in 40 C.F.R. Section 270.2 (1989).
128. 40 C.F.R. Part 270 (1989).
129. 40 C.F.R. Section 122 *et seq* (1989).
130. 40 C.F.R. Section 270.4 (1989).
131. Subtitle D of RCRA provides guidance and federal financial assistance for the development of state and regional solid waste management plans and implementation of state solid waste programs. Although RCRA does not give EPA authority to enforce a permitting program for specific nonhazardous wastes, EPA still has authority to develop guidelines for implementation by the states which provide guidance on the development of such programs. 42 U.S.C. Section 6941 (1988).
132. 42 U.S.C. Section 6944(a) (1988).
133. 30 U.S.C. Section 1201 *et seq.*, P.L. 95-87 (1988).
134. Although SMCRA was passed by Congress in 1977, the permitting requirements of the federal law became applicable in a state when that state's permanent regulatory program was adopted and approved by the OSM. In states that chose not to develop a state permanent regulatory program, the permitting requirements of SMCRA became applicable upon the promulgation of a federal program by OSM. All states with potential for coal mining currently have either an approved state program or a federal program under SMCRA.
135. Indian programs are operated in conjunction with the individual Indian tribe involved.
136. 30 U.S.C. Sections 1257, 1258, 1260 (1988); See also 30 C.F.R. Parts 773–785 (1988).
137. 30 U.S.C. Sections 1265, 1266 (1988); See also 30 C.F.R. Parts 816, 817 (1988).
138. 30 U.S.C. Sections 1257, 1258, 1260 (1988); See also 30 C.F.R. Parts 773–785 (1988).
139. 30 C.F.R. Part 800 (1988).
140. 30 C.F.R. Section 773.19 (1988).
141. 42 U.S.C. 300(f) *et seq* (1988).
142. See 40 C.F.R. Section 122.32 and 40 C.F.R. Part 144 (1989).
143. 40 C.F.R. Section 122.34 (1989). The definition of "underground source of drinking water" includes "an aquifer or its portion:
(i) which supplies any public water system; or
(ii) which contains a sufficient quantity of groundwater to supply a public water system; and
(A) currently supplies drinking water for human consumption. . . ." 40 C.F.R. Section 146.3.
144. 40 C.F.R. Sections 144.3 and 144.6 (1989).
145. Coal processing wastewater injection wells have generally been interpreted to be Class V wells and allowed by rule unless there would be a potential for contamination of an underground source of drinking water (USDW). See *Re: Robin Reed; John and Helen Newsome v. US EPA et al.*, Civ. No. 84-3511 (6th Cir., 1984). In that case, EPA agreed to review all existing coal processing wastewater injection wells in Kentucky and take enforcement action against any wells causing a violation of primary drinking water standards for a USDW.
146. 40 C.F.R. Section 144.24 (1989).
147. 40 CFR Section 144.31 (1989).
148. See 40 C.F.R. Section 144.6 (1989).
149. 40 C.F.R. Section 144.31 (1989).
150. 40 C.F.R. Section 144.51 (1989).
151. 30 U.S.C. 802 *et seq* (1988).
152. 30 C.F.R. Parts 55–57, 70, 71, 74, 75, 77, 90 (1989).
153. P.L. 95-604, as amended (1978). Incorporated in the Atomic Energy Act of 1954, 42 U.S.C. 2022 (1988).
154. EPA's regulations containing health and environmental protection standards for uranium mill tailings are provided at 40 C.F.R. Part 192 (1989).
155. Wastes from the processing of uranium ores are regulated by the NRC under the Atomic Energy Act of 1954. 42 U.S.C. Section 2011 *et seq* (1988).
156. 40 C.F.R. Section 192.12 (1989).
157. The National Parks and Recreation Act of 1978, 16 U.S.C. §§ 1 *et seq.* (1982), establishes the National Park Service (NPS) within the US Department of the Interior and gives the NPS authority over National Park Lands.
158. The National Wildlife Refuge System Administration Act of 1966 allows the US Fish and Wildlife Service to establish and administer National Wildlife Refuges. 15 U.S.C. §§ 330 *et seq* (1982).
159. The National Trails System Act provides for the establishment and administration of national trails. 16 U.S.C. §§ 1241 *et seq* (1982).
160. The Wilderness Act establishes wilderness areas that are required to be preserved in their natural state. 16 U.S.C. §§ 1131 *et seq* (1982).
161. The Wild and Scenic Rivers Act provides that construction that would have a direct, adverse effect on the values for which a

national wild and scenic river was established can be prohibited. 16 U.S.C. §§ 1271 *et seq* (1982).

162. See 16 U.S.C. §§ 472 *et seq* (1982).
163. The Congressional designation does not apply to mines that were existing on Aug. 3, 1977 or which had valid existing rights to conduct the mining as of Aug. 3, 1977. 30 U.S.C. § 1272 (1988); see also 30 C.F.R. Part 761 (1988).
164. *Id*.
165. Mining may nevertheless be permitted within the National Forest if the mine is determined to be "compatible" with certain aspects of the National Forest and either: (1) the mine is an underground mine, or (2) the mining is west of the 100th meridian and is approved as meeting certain criteria by the Secretary of the Agriculture. However, no mining is allowed within the boundaries of the Custer National Forest. 30 U.S.C. § 1272(e) (1988).
166. Exceptions are allowed to the exception for parks and Historic Places if the mining is approved jointly by the regulatory authority and the federal, state, or local agency with jurisdiction over the park or place. 30 U.S.C.; § 1272(e) (1988).
167. Exceptions are allowed (1) where the mine access or haulage roads join the right-of-way line, and (2) after public notice, if the agency with jurisdiction over the road makes a written finding that the interests of the affected public landowners will be protected. 30 U.S.C. § 1272(e) (1988).
168. Exception is allowed if the owner of the occupied dwelling provides a signed written waiver consenting to mining closer than 300 ft (90 m). 30 U.S.C. § 1272(e) (1988).
169. Public buildings include schools, churches, community, and institutional buildings. 30 U.S.C. § 1272(e) (1988).

Chapter 7.4
IMPOUNDMENTS AND DAMS

PAUL D. NESBITT

The planning and design of impoundments in conjunction with mining projects takes into account many engineering and environmental considerations. Under the environmental scrutiny of today, any new major facility will come under public review. Whether the public itself is involved in an item-by-item review, the regulatory agencies will ensure that a careful review will take place.

Initial efforts need to focus on determining the exact use and purpose of the impoundment. Commonly, impoundments in conjunction with mining projects are used for sediment control, fine slurry settling ponds, and freshwater sources. There are other purposes, but those named are the most common. Based upon the proposed use of the facility, the design standards employed may vary. As with any design, it is not possible to design a structure without knowing the end use. A clear definitive statement of the end use coupled with referral to such goals as the design/permitting/construction process proceeds will ensure a usable and functioning end product.

For fundamental coverage of soil mechanics, see Chapter 10.1; and for related topics, see various chapters of Sections 10 and 12 (e.g., Chapter 12.1, Water and Sediment Control Systems).

7.4.1 PRELIMINARY STUDIES

In the preliminary study phase, the site must be examined from all aspects, using as much existing information as possible. It is important for the designer of an impoundment to study *all* available information.

Using the stated end use of the project, certain design considerations may appear. Obviously, if the purpose of the impoundment is to settle out fines, either slurry or sediment, then the volume and consistency of such fines must be examined. Obviously, the finer the slurry/sediment is, the longer the detention time must be in order to achieve the desired settling rate and subsequent water quality. If the purpose of the impoundment is for water supply, then the quantities of the water needed must be determined.

US Geological Survey (USGS) topographic maps then can be utilized to determine if the volumes that were estimated to be necessary in the impoundment can be achieved on the potential sites. It should be emphasized that these maps are used for planning purposes only. Coupled with these, many areas of the country also have geologic quadrangles that map the type and extent of the geology of a region. Also published in many regions are soil surveys. All these items need to be analyzed to see if there are any environmental or physical factors present that would impact on the functioning impoundment.

Today more than ever, the designer is faced with a massive amount of regulations and regulatory agencies to deal with in any project. A survey of the agencies that might govern minimum design or performance standards for such a facility needs to be made immediately. All the regulations that apply should be indexed. Obviously, the most stringent regulations for any aspect of a project need to be followed. The agencies could include, but are not limited to, the Office of Surface Mining (OSM), the Mine Safety and Health Administration (MSHA), the US Fish and Wildlife Service, and the Environmental Protection Agency (EPA) (all federal) as well as the state surface mining agencies, the state water agency, and any other agency that might impact this project. It is always helpful to meet with the agencies, clearly state intentions of the project, and ask for their input at the beginning of the process rather than after the design is complete. Any stumbling blocks that they might reveal can be addressed prior to work proceeding past the point where such items need to be utilized in the design/construct process.

Several recent additions to the regulatory list should be pointed out. It is normal now to require such items as fish and wildlife surveys, vegetative surveys, archeological surveys, and an inventory of wetlands. If any negative findings of these agencies' requirements are uncovered, it is easier to deal with in the beginning of the project rather than after an exhaustive amount of work is completed.

Using USGS topographic maps for crude volume calculations, preliminary hydrologic studies can proceed. The design storms that are proposed from the agencies, or more stringent design storms if desired by the designer and/or client, need to be identified. It should be noted that the design storm is specified for facilities given a possible chance of failure. If the client wishes, the designer can demonstrate by statistics what the probabilities are that the capacity of a particular impoundment hydrologic system will be exceeded within a certain time frame. Obviously, the longer the facility is proposed to be in service, the greater is the statistical chance of this happening. Also, based on a hazard classification for the structure, the greater the potential for loss of property and/or life in case of a failure, the greater the margin of safety that needs to be built in to the project. However, the design standards should be arrived at after a review of the minimum regulatory standards and the owner's specifications.

From the preliminary hydrologic studies, design flows for both mid-range storms and the maximum design storms can be arrived at. Computer programs are readily available for such computations.

7.4.2 HYDROLOGY

7.4.2.1 Introduction

The primary emphasis of mining hydrology is placed on storm water hydrology. The entire hydrologic cycle is depicted in Fig. 7.4.1, where the boxes represent storages and the arrows represent flow. Fig. 7.4.2 indicates the parameters related to storm water hydrology that need to be addressed in the analysis of any single precipitation event.

Hydrographs are developed using the unit hydrograph approach. A *unit hydrograph* is a graph depicting the quantity of runoff resulting from a unit of rainfall excess occurring at a uniform rate, uniformly distributed over a watershed in a specified duration of time, plotted against time. This approach is empirical and is based on several assumptions:

1. Uniform distribution of rainfall excess over the watershed.

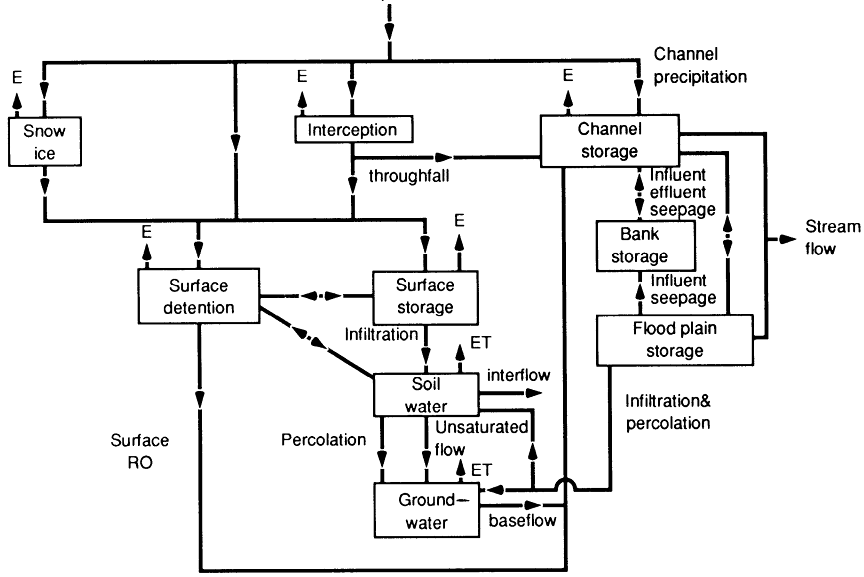

Fig. 7.4.1. Hydrologic cycle.

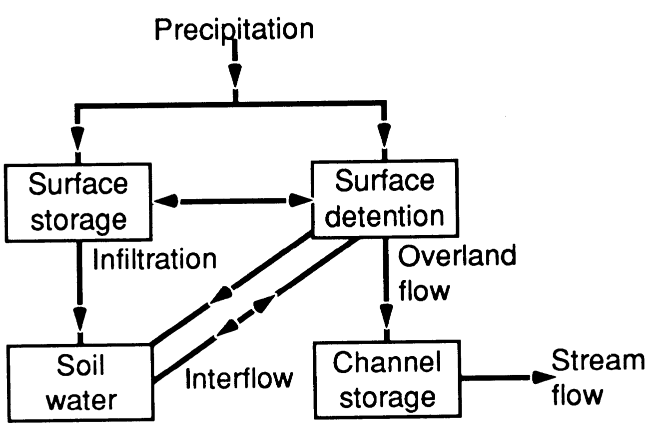

Fig. 7.4.2. Storm water hydrology.

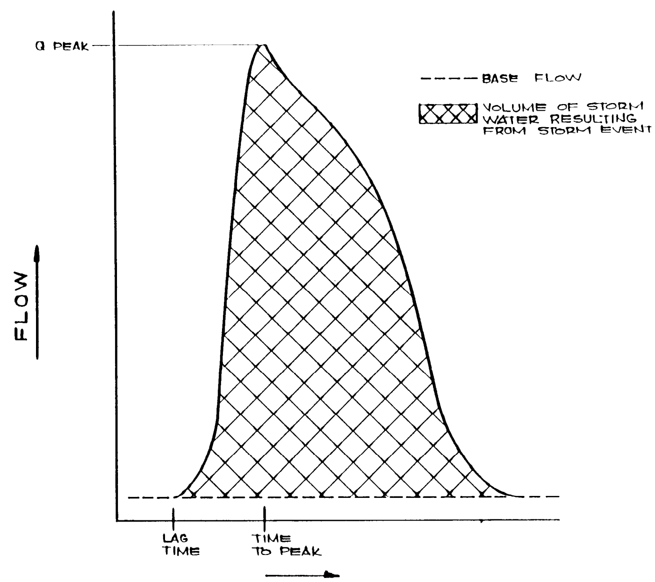

Fig. 7.4.3. Typical hydrograph.

2. Uniform rate of rainfall excess.
3. Superposition or linearity.

The last assumption states that the unit hydrograph reflects all basin characteristics to the degree that the runoff rate is proportional to the runoff volume for a rainfall excess of a given duration (Barfield et al., 1981). Fig. 7.4.3 is a typical hydrograph resulting from a storm event.

7.4.2.2 Design Considerations

If the impoundment is for sediment control or settling fine coal particles out of a slurry, then adequate volume must be available for this purpose. Using the best estimating techniques, such volumes must be estimated.

Any design storm must be specified utilizing both the duration of the storm and the return occurrence of the event. For example, the 10-yr/24-hr storm event is the amount (inches or millimeters) of rainfall that fall in a 24-hr period every 10 years. These numbers are statistical derivations and published by various agencies.

Under regulations, a dam must "contain or treat a precipitation event ('design event') to be based on regional diversity, terrain, climate, and other site specific conditions." Effluent limitation may vary depending on the size of the design storm. At present, during base flow conditions, the 35 to 70-mg/L (0.35 to 0.70-lb/1000 gal) total suspended solids effluent limitation must be met by all dams. If a structure is sized to the 10-yr/24-hr precipitation event, effluent limits for flows caused by rainfall events change to 0.5 mg/L (0.005 lb/1000 gal) settleable solids, and a pH from 6 to 9 is required. Only the pH standard applies during events larger than the 10-yr/24-hr storm. If a dam is

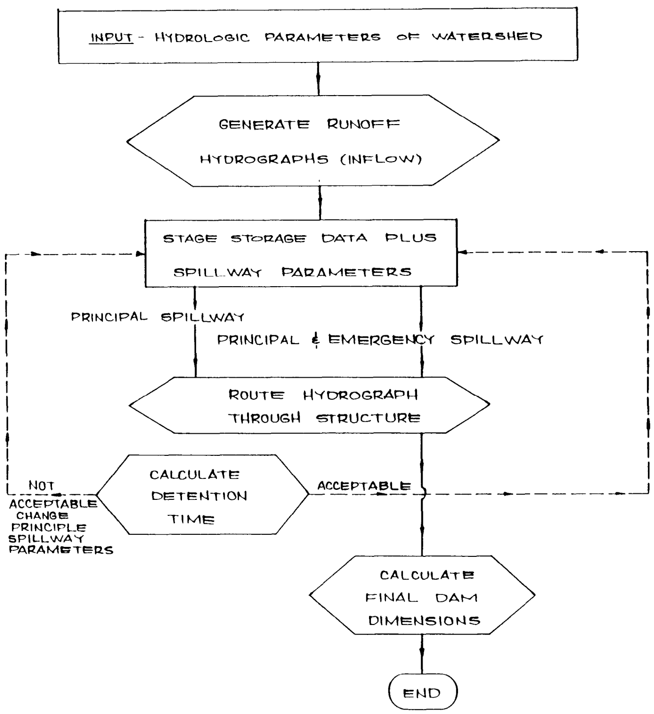

Fig. 7.4.4. Design flow chart.

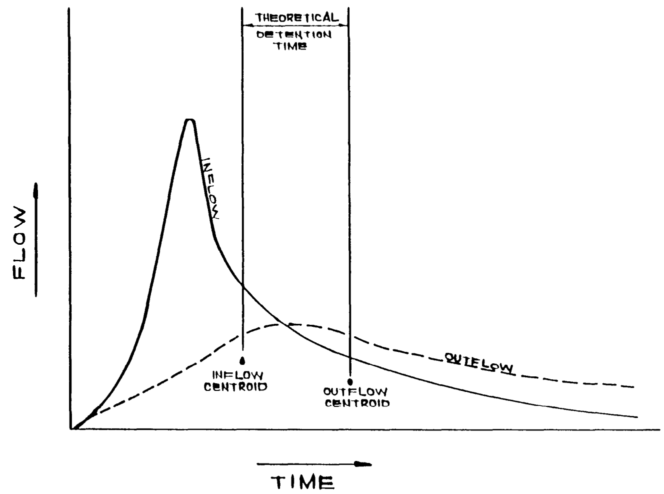

Fig. 7.4.5. Theoretical detention time.

sized to a smaller storm, the EPA effluent limitation of 35- to 70-mg/L (0.35- to 0.70-lb/1000 gal) total suspended solids will still be in effect during any precipitation event.

The design event, typically a 10-yr/24-hr storm event, is analyzed for the principal spillway. (The design procedure is outlined in Fig. 7.4.4.) This event is routed through the dam and the flood crest determined. The emergency spillway invert is set at this crest elevation. This is done in order to prevent flow through the emergency spillway during the principal spillway design event.

The combined principal and emergency spillways are required by the regulations to safely pass a larger storm, typically a 25-yr/24-hr precipitation event. This storm is routed through these spillways and the flood crest determined. To calculate the top of dam elevation, free board is added to the flood crest elevation, typically 1 ft (0.3 m), and a percentage of the dam height (the difference in elevation between the upstream toe of the dam and the emergency spillway crest) is added for settlement, typically 5%. The difference in elevation between the upstream toe of the dam and top of the dam is referred to herein as the total embankment height.

Fig. 7.4.5 illustrates the definition of *theoretical detention time.* This time is defined as the time difference between the centroid of the inflow hydrograph and the centroid of the outflow hydrograph for the design event. The greater the detention time, the better the effluent quality will be. Care must be taken to prevent short-circuiting that would invalidate detention time calculations.

Once a dam exceeds a certain height or reservoir storage, the design criteria become more severe. Also several other government agencies, such as MSHA or the state water division, may want to review the design.

There are many available numerical procedures for flood routing hydrographs through reservoirs. Computer models are modified numerical adaptations of the graphical Puls method (Warsaw et al, 198 1). This method solves the continuity equation in the form,

$$S_2 - S_1 = \frac{(I_2 + I_1)\,t}{2} - \frac{(O_2 + O_1)\,t}{2} \qquad (7.4.1)$$

where S is storage, I is inflow rate, O is outflow rate, and T is time interval over which flow rates are averaged.

This equation states that the net change in storage, be it positive or negative, is the difference between the volume entering the pond and the volume leaving the pond over any given time period. All routing procedures, graphical or numerical, are nothing more than solutions to this equation over a small period of time.

7.4.2.3 Types of Spillways

Three different spillway systems can be utilized. The first system is a trickle tube-emergency spillway system (Fig. 7.4.6). This consists of a single pipe running through the dam embankment. The invert of this pipe is set at the sediment pool elevation. An emergency spillway should be used in conjunction with the trickle tube, and can either be cut in soil or rock or be a lined channel.

The next system is a riser-emergency spillway system (Fig. 7.4.7). This consists of a vertical pipe in the pool connecting to a smaller pipe that runs under the dam. The same emergency spillway installed with the trickle tube should be installed with the riser.

A combination trickle tube, riser, and emergency spillway system (Fig. 7.4.8) can be utilized in order to increase detention times while bringing down the height of the dam.

The methodology used to compare the data generated by the reservoir routing program is relatively straightforward. To explain the rationale involved, a discussion of the hydraulics involved is essential.

Several different types of flow are possible through the spillway systems analyzed. In the riser-principal spillway systems, the following types of flow are possible:

1. Weir controlled.
2. Orifice controlled (riser).
3. Orifice controlled (principal spillway).
4. Pipe flow controlled.

At very low heads, the riser crest acts as a weir and weir flow controls. As the head increases, the inlet begins to act like an

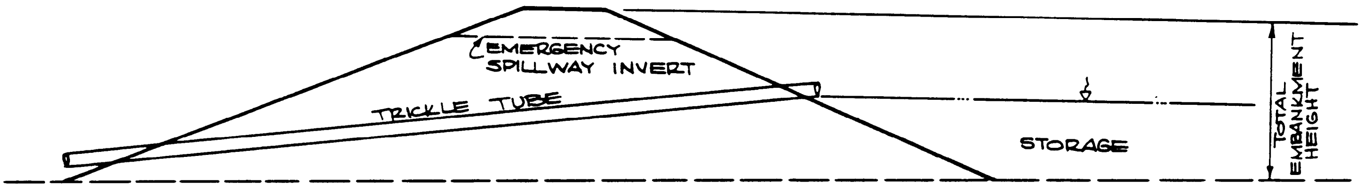

Fig. 7.4.6. Trickle tube—emergency spillway dam.

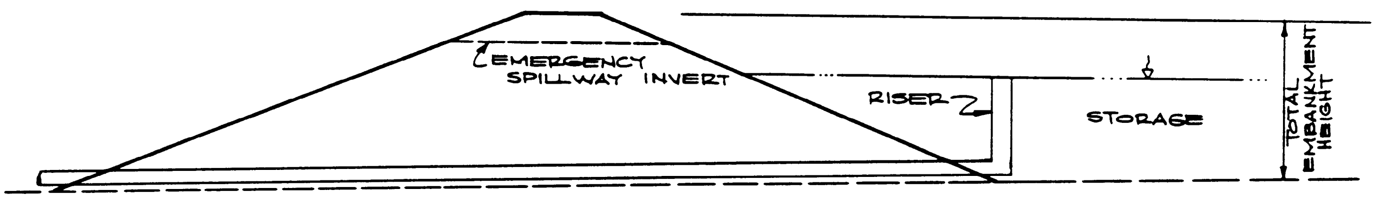

Fig. 7.4.7. Riser—emergency spillway dam.

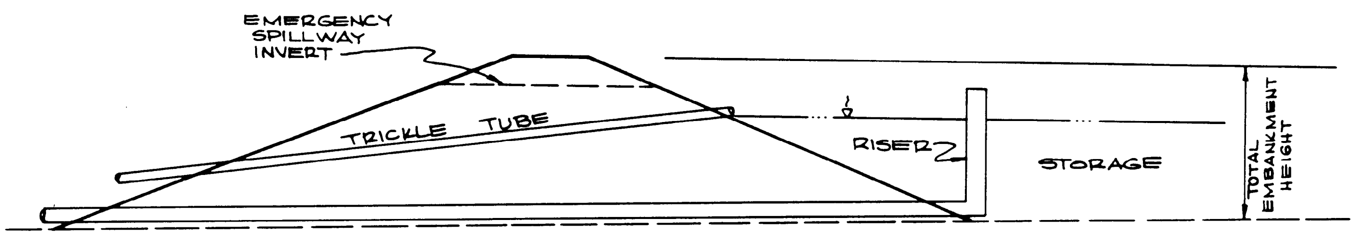

Fig. 7.4.8. Combination trickle tube—riser emergency spillway dam.

orifice with the riser crest still controlling the flow. When the head and flow rate reach a certain point, the principal spillway controls the orifice flow through the system. As the head continues to increase, the principal spillway pipe begins to flow full, and pipe flow will control. In order to determine which type of flow is controlling at any one point in the routing procedure, the flow rates for each control are calculated. The control allowing the smallest flow controls the system.

Flows possible in the trickle system are:

1. Weir controlled.
2. Orifice controlled.
3. Pipe flow controlled

The behavior for this system is similar to that of the riser-principal spillway system. Flow transitions occur from weir flow to orifice flow to pipe flow, depending on the amount of head available at any certain time. The controlling flow at any one point in the routing procedure is determined by computing the flow rates for each control. The one allowing the smallest flow controls the system.

When analyzing the combined trickle tube and riser-principal spillway systems, the same procedures outlined previously are used. Since the pipe systems are not dependent upon each other, flow-rate calculations for the two systems are done independently and their outflows added to find the total outflow at any point in the routing procedure.

In most cases, weir flow is sustained for a comparatively short amount of time in all systems. Orifice flow controlled by the riser is also relatively short term. Orifice flow and pipe flow, controlled by the principal spillway and trickle tube, are responsible for the majority of flow out of the dam. Since the trickle tube and principal spillway are controlling most of the flow out of the dam, results will emphasize comparison of these two entities. Therefore systems with the same size pipe controlling outflow are compared to see how different types of systems affect detention time.

Typically, the detention time for the trickle tube system is the longest of any of the systems. Detention times for the riser-principal spillway systems varied little with the size of the riser and are much lower than that of the trickle tube. As the riser diameter increases, a slight decrease in detention time occurs. This is due to the increased weir and orifice capacity of the larger riser. Since the riser controls flow for just a short period to time, very little change is detected in detention time.

When combining a trickle tube with a riser-principal spillway system, effects on a detention time can be predicted. By adding a riser-principal system to a trickle tube system, the flow rate from the dam would increase thereby decreasing detention time from the trickle tube system. Detention time for the riser-principal spillway system would increase with the addition of a trickle tube below the riser elevation. This would allow the initially slower trickle tube flow rate to control until the water surface reached the riser elevation. The centroid of the outflow hydrograph would be shifted to the right and detention time increased.

7.4.2.4 Hydrographs

Any hydrograph represents the response of a watershed to a particular storm event. Fig. 7.4.3 is such a hydrograph. The hydrograph graphically represents the flow at a particular spot in the watershed plotted against a time axis.

The base flow of the stream is represented in Fig. 7.4.3 as a dashed line. The lag time is the time the watershed takes to respond to a certain storm event, that is, the time it takes after a storm event before flow resulting from the storm occurs. Of course, lag time depends upon many factors including but not limited to soil moistures, types and extent of vegetations, topography, soil types, geography, etc.

The area under the curve but above the base flow represents the volume of the storm that ran off as surface water. The response of a watershed can then be estimated by examining the hydrograph for lag time, time to peak, the maximum flow, and the quantity of water discharged.

7.4.3 EMBANKMENT DESIGN

The design of the embankment itself and the configuration of the spillway system is the basis for implementing the information obtained by the hydrologic analysis. We discuss here the various materials and design considerations that need to be taken into account.

7.4.3.1 Construction Materials

Generally, the materials to be utilized in the construction should be taken from an area adjacent to the embankment itself in order to achieve the best economics possible. These materials may either be earth or rock. Additionally, in conjunction with many mining projects, the reject material from mineral or coal processing may be utilized to construct the embankment. In this case, it is very important to obtain representative samples of the material to be utilized, and to analyze not only their physical characteristics but also the potential environmental dangers that could result from utilization of the materials.

An exploration plan must be undertaken in order to determine the characteristics of the material so that the designer can utilize these characteristics in his/her analysis. Both disturbed and undisturbed samples should be taken in the soil exploration phase. The undisturbed sample can be utilized to classify materials "in place," and the disturbed samples can be utilized to determine the common characteristics that could be achieved during the construction process.

As in any program, the exploration phase must be documented well. Survey controls should be utilized to locate the exact placement of the samples. Any drilling and/or classification that is to be done should have logs prepared that detail at a minimum the following information:

1. Job name, boring. Sample number, sample location. Surface elevation.
2. Degree of saturation, observations.
3. Complete classification of the material, whether it be soil or rock.
4. All samples correctly and completely labeled immediately after taking.

In the exploration phase, care should be taken to totally classify the types of material that can be utilized. Many variations of a design can be prepared, depending upon the type of material to be utilized. If adequate descriptions of the materials are available to the designer, he/she can evaluate the most effective combination to utilize in his/her design. It is possible that additional sampling might have to take place after the designer completes his/her evaluation.

In evaluating the sources, the haul distance, access, location of groundwater, and the moisture content of the materials must be considered.

7.4.3.2 Foundation

Drilling must take place in the area that the dam is to be constructed in order to determine the foundation requirements for the embankment. The underlying rock needs to be pressure tested to make sure there are no cracks or fissures that would allow water to seep under the embankment. At times, by moving the embankment a small distance, such cracks can be avoided. A small amount of analysis and testing at this point will insure a proper working embankment.

The soils underlying the proposed embankment must also be analyzed as to their permeability and makeup. The size of the cutoff trench to be utilized will be determined by this analysis. Fig. 7.4.9 is a common cross section showing the normal design of such a cutoff trench. This cutoff trench insures that the seepage under the embankment will be kept to a minimum.

7.4.3.3 Embankment

The materials to be utilized in the embankment should have been classified during the exploration phase detailed previously. The embankment can be constructed of earth materials, rock materials, mine reject material, or possibly even concrete. For the purpose of this discussion, it is assumed that a concrete embankment would not be utilized.

The materials to be utilized in a rock fill dam should be strong, hard, durable, and relatively dense. Gradation limitations are not restrictive for such an embankment. The materials placed on the upstream and downstream slopes of such an embankment must be capable of resisting weathering. Usually, it is most economical if the materials to be utilized in the rock fill dam are taken from the area to be inundated by the reservoir.

If the material to be used to construct the embankment consists of earth fill, the natural materials and their ability to be utilized or compacted in the construction process will be examined. Since these types of embankments usually have various zones within them, the material may need to be separated. This requires close control during the construction process. As shown in Fig. 7.4.10, seepage control through the embankment, or making sure that the saturated zone stays small, is important. This is achieved by placing drains into the embankment or impervious cores to greatly decrease the amount of seepage through the embankment itself. The placement of these drains and cores is not done lightly by the designer. It is important in the construction process to insure that these are accurately placed.

7.4.3.4 Spillways

Spillways are designed based upon the anticipated flows as analyzed by the hydrologist. If the spillways are to be cut into the natural rocks and soils, care must be exercised to insure that the fracture systems in the rock structures would not cause the area to be unstable. If the spillways are to be cut into earth materials, the natural slopes adjacent to this spillway need to be studied with great care.

It must determined whether the spillway needs to be lined or not. The need for lining is determined by the geology of the region and the velocity of the spillway discharge. Obviously, materials that will slake over time need to be lined. In fact, it may be cheaper to line the channel with either concrete or asphalt initially rather than worry about the long-term maintenance of such a channel.

During the embankment design process, decisions need to be made as to the materials to be utilized, to what degree they need to be worked during the construction process, the place-

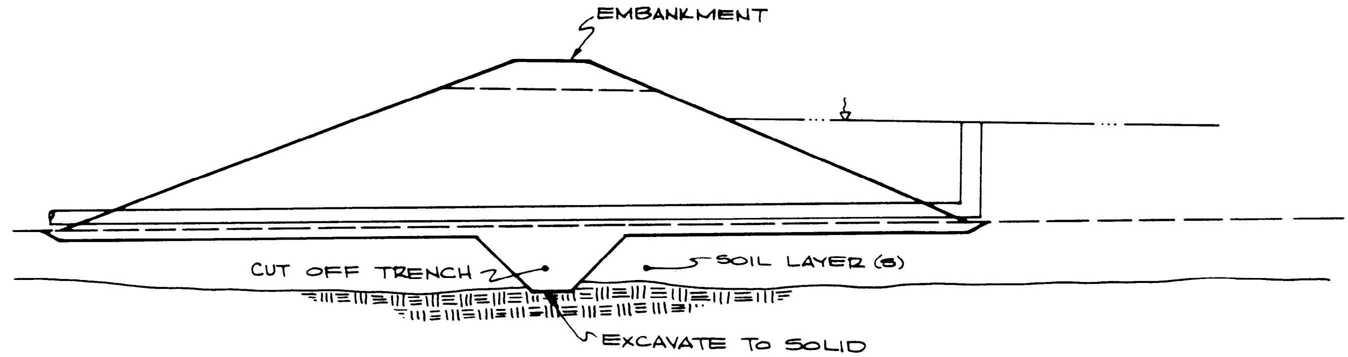

Fig. 7.4.9. Cutoff trench.

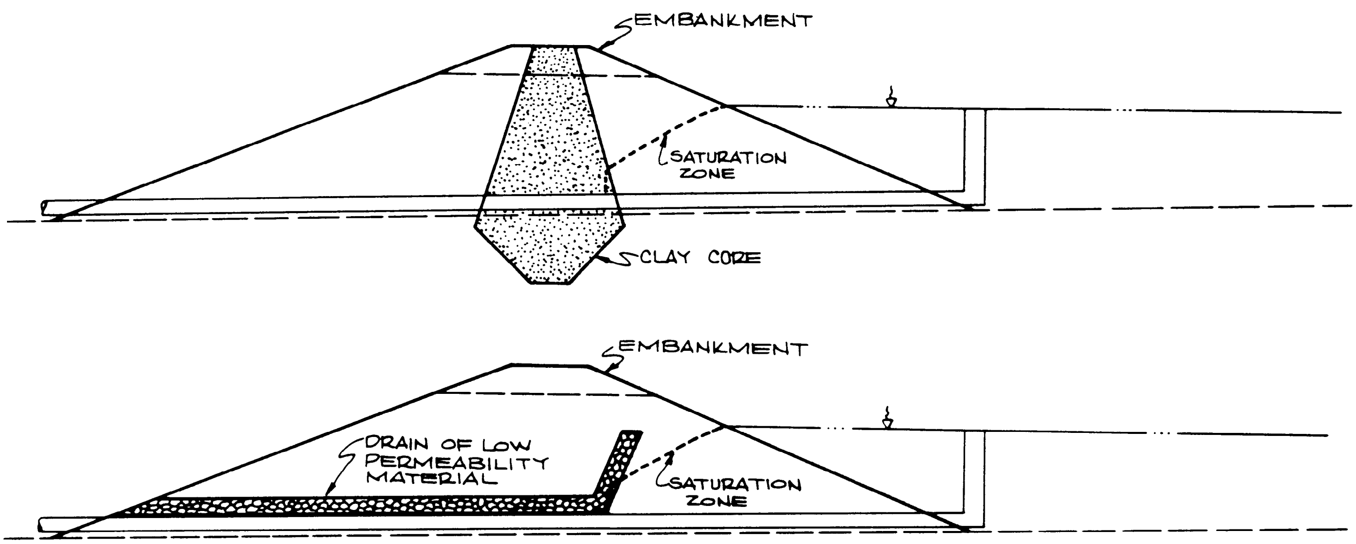

Fig. 7.4.10. Seepage control.

ment of the embankment to insure its proper functioning, and the materials to be utilized in the spillway construction.

7.4.4 CONSTRUCTION

The best studies, planning, and engineering design processes will be totally invalidated by poor construction practices. A definitive quality control and quality assurance plan must be prepared and adhered to during construction practice.

7.4.4.1 Quality Control/Assurance

Quality control and quality assurance are often confused. These terms, as defined by the Canadian Standards Association, are as follows:

1. *Quality control:* those actions that provide a means to measure and regulate the characteristics of an item or service to contractual and regulatory requirements.

2. *Quality assurance:* a planned and systematic pattern of all means and actions designed to provide adequate confidence that items or services meet contractual requirements and will perform satisfactorily in service.

What this means to the designer of an impoundment is that the quality assurance plan must be prepared along with the design that will systematically map out the actions that need to be taken to insure that the impoundment is properly constructed. The quality control program is then the program that carries out those actions and institutes the controls that are designed in the quality assurance program. A quality assurance program must be developed in order for a quality control program to be effective.

The person onsite observing the construction practices should be someone who realizes the consequences of deviations from the plan. Often, during the construction process, items are encountered that will necessitate a change in the construction practice. All such changes need to be noted. The usefulness of daily inspection logs and either pictures or videotaping of the construction cannot be emphasized enough.

7.4.4.2 Construction Practices

The following identify several different aspects of construction that need to be emphasized.

Survey Controls: During the design process, mapping was accomplished using either aerial or ground methods. Regardless of which method was utilized, permanent points that can be recovered both for horizontal and vertical needs should be placed in areas where construction processes will not disturb them. These survey points, or bench marks, should be referenced on the drawings. Multiple bench marks should be placed so that, if some are disturbed, the others can be utilized to replace one of the points. From that point onward, all actions at the scene of the construction should be referenced to these points. A baseline should be established in such a way that a single person using tapes or hand levels could reestablish approximate locations of any actions. All this information should be entered in the daily log for later reference.

The topography of a region is mapped and is critical to the design of an impoundment. The amount of material to be stored behind the impoundment changes as the topography is changed. Often during the construction of an impoundment, it is planned that excavation take place in the impoundment pool itself. While this excavation is taking place, a greater or lesser amount of material than planned may be taken. After the area is excavated and regraded, another survey needs to take place so that the designer can examine the topography of the pool to make sure that it does meet the minimum storage standard required. Also it is possible that if a greater storage area is behind the dam than planned, then additional regulatory and design requirements may be instituted. This needs to be examined as the construction process proceeds.

As construction proceeds and quality control tests take place, as will be described later, these need to be referenced in the daily log, along with their specified location. If a test fails, the location should be noted and a retesting noted at the same location at a later date. One cannot emphasize enough that this material must be organized and taken in a systematic manner.

Material Quality Control: All materials that are utilized in the construction of an impoundment should have specifications for that material. Obviously, in the design process, materials that are onsite to be utilized will be analyzed. Any soils, rocks, etc., that will be utilized have been tested. It is important that the test be representative of the type of materials to be encountered. If the inspector notes that new materials have been encountered, it is important to do new tests on this material. All of the design processes assume certain parameters. If these parameters are not achieved, the design process is voided.

Often the embankments will be constructed of earth materials, and compaction is specified. It is important that compaction testing be performed often and documented well. Prior to placing the material, the ability of the material to be compacted should be analyzed using laboratory tests, which are referred to as the proctor curves and modified proctor curves. What these curves represent is the ability of a material to be compacted. Fig. 7.4.11 represents these curves.

Note that when a material has very little moisture within it, it can be compacted only poorly. As the moisture content rises, the ability of the material to compact increases. Ultimately, it reaches a maximum compaction ability, and as more moisture is added, the ability for it to compact decreases. The top of the curve is called the "100% proctor," and it is normal practice for designers to specify that the material compacted reach a given percentage of the proctor.

Since construction practices take place in the environment, the moisture present will vary depending on the season and the weather. The moisture content of the material to be compacted has to be checked often to make sure that it does meet the degree of compaction specified. Also present in Fig. 7.4.11 is a curve that illustrates the conductivity of a material in relationship to moisture content as it is compacted. Note that the conductivity is much less, meaning that less seepage would occur, as compaction is achieved on the "wet" side of the proctor curve. Less seepage through an embankment is desirable; therefore, construction practice should try to achieve the desired compaction by utilizing the wet side of the curve.

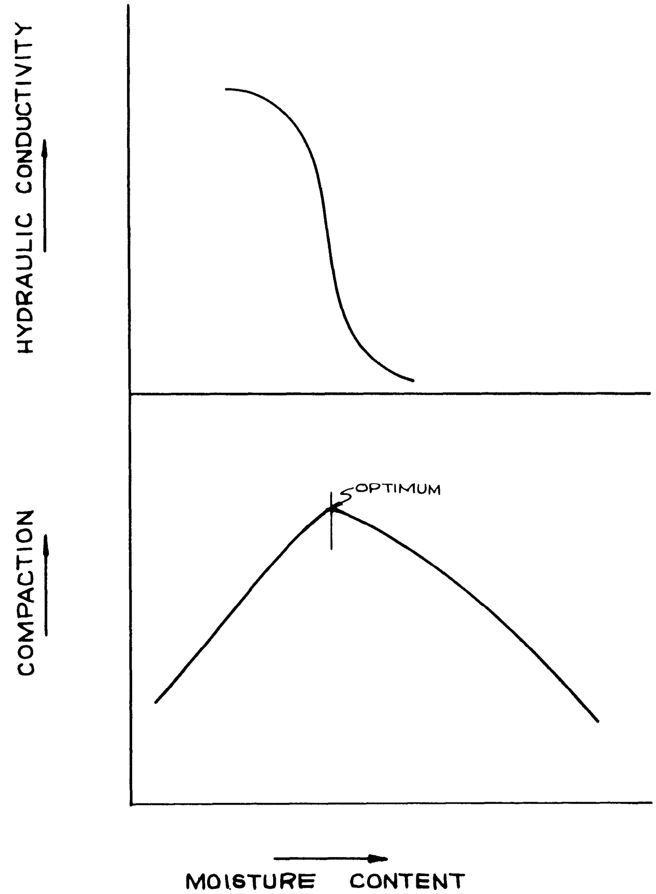

Fig. 7.4.11. Proctor curve.

Compaction testing can be achieved using many methods, but the most convenient and modern would be testing using nuclear density instruments. These are readily available from manufacturers. This allows for instantaneous readouts concerning compaction and moisture contents. Other methodologies such as the balloon or sand cone methods are available, but results generally take hours to achieve.

Piezometers: As construction proceeds, the installation of piezometers may be specified. These are for the protection of the owner and tell him where the saturated zone within the embankment lies. As mentioned previously, it is desired that the seepage remain low. There will be some degree of saturation within the embankment, and the designer allows for this. After construction and during the inspection process, the saturated zone needs to be checked against the design standards. Care should be taken during the construction process to insure that these piezometers are placed in the proper locations, and that any compaction around them does not damage the piezometer.

Cutoff Trenches: Normally, an impoundment is placed on top of a valley floor where soils have accumulated. It is possible that as the permanent pool establishes itself within the impoundment, water will seep into the soil layer and under the impoundment itself. To insure that this does not happen, a cutoff trench needs to be constructed. Fig. 7.4.9 shows such a cutoff; it is a cross section of an embankment illustrating the cutoff trench. Construction equipment should be utilized to excavate as deep as possible in this area and material compacted back in the void. This will insure that seepage under the embankment does not occur.

Anti-Seep Collars: Anti-seep collars may be specified along the pipe. The purpose of anti-seep collars is to prevent seepage along the interface between the material in the dam and the pipe itself. Because of fears of the damaging pipe, maximum compaction may not be achieved. Additionally, if bedding materials are placed around the pipe, at time the permeability of the bedding material is less than the embankment itself, it provides an easy route for seepage to occur. It is of utmost importance that these anti-seep collars be installed and that as much compaction as possible be achieved around the pipe. Normally, this is achieved by either hand compacting or using a mechanical compactor commonly referred to as a "jumping jack." Large compaction equipment should not be utilized around a pipe itself.

In summary, construction practices are extremely critical. Experienced personnel should be utilized to monitor the construction to insure that the assumptions used in the design are met in the construction process.

7.4.5 INSPECTION

After an impoundment is constructed and placed into service, the long-term maintenance of such a facility is of concern to the designer. Periodic inspections are mandated by regulations, but in the best interest of both the owner of the facility and the engineer in charge of operation of the facility, periodic inspections should be made. As with construction quality control, the inspector should be someone who is knowledgeable as to what impact various deviations from approved plans could make on the functioning of an impoundment. Following is a discussion of various aspects of inspection.

Short Circuiting: In the design of the impoundment, the designer assumes the principle of last-in/last-out. In other words, the inflow into the impoundment will flow out of the impoundment only after the rest of the volume of the impoundment is displaced. Obviously, in real life, this does not happen. Short circuiting is a phenomena that occurs where a path of flow exists through the impoundment. There will be areas of the impoundment where water is stagnant and is standing, and there will be other areas where flow through the impoundment occurs almost as if it was a stream flowing in another body of water. This is very simple to check for.

If a nontoxic dye is placed in the upstream inflow, any areas where short circuiting may appear can be easily seen in the surface of the impoundment. In addition, the length of time it takes for the dye to appear in the outflow can be noted. In a low-flow situation with an impoundment that should have had a two-day retention time, the author has observed dye flowing through a facility within 2 min.

There are several aspects within the design process that will minimize short circuiting. Obviously, the inflow must be placed as far away from the outflow as possible. In addition, barriers can be constructed in the impoundment either using wood or fabric material. Filter cloth can also be utilized to diffuse the flow. This forces the water to seek paths other than a straight path through the impoundment to the outflow.

Phreatic Surface: The *phreatic surface* within the impoundment is the surface area at the junction between the unsaturated and saturated zones. Since there is no material that is totally impermeable, the water stored behind an impoundment will force water through whatever structure is constructed. As noted in a previous section, the permeability of the material is the key factor. Designs will be prepared in order to make sure that the phreatic surface or saturated zones remain at a minimum within the embankment itself. The strength of a material is closely related to whether the material is saturated or not. Obviously, the material is weaker when saturated; therefore, if the phreatic surface is higher than the embankment, the factor of safety for failure is lowered. It is safe to say that most failures of embankments and slopes are connected to a higher saturated zone, or greater zone than was anticipated from the design.

There are several ways to insure that the phreatic surface does not rise within an embankment. It was noted in 7.4.4.2, that piezometers need to placed in the embankment itself. These piezometers need to be checked for the water surface, or the phreatic surface, and these comparisons made with design assumptions. If the water is higher than the design assumption, then the design needs to be verified to ensure that the embankment has a factor of safety that might be desired by the regulatory agencies or the owner.

Vegetation: It is extremely worthwhile to step back from the embankment during the inspection process and observe the vegetation growing on the outslopes of the embankment and downstream of the embankment. The vegetation that is growing in a saturated area will be different from that growing in an unsaturated area. Since the phreatic surface tends to assume a constant elevation (since water seeks its own level), a different type of vegetation can be noted at a specific point on the embankment. Usually in spring, because of the moisture, the saturated zones will be greener. Later on, in fall, the vegetation will be taller and a different type of species. This is important because normally it is not anticipated that the phreatic surface will actually outcrop on the downslope side of the embankment. Such observations could represent the saturated zone appearing on the downslope of the dam. When this is observed, it must be noted and reacted to immediately.

Walking downstream, it is important to notice the types of vegetation as well. If the cutoff trench is not constructed properly, water may seep through the soil layer next to the surface underneath the embankment and rise to the surface some distance downstream from the embankment itself. If water is observed coming upward out of the ground, it would be wise to check its source. Obviously, it cannot assumed that it is always from the embankment, but if it occurs immediately downstream from the impoundment, this needs to be investigated. Again, the use of dyes or tracers to verify the source of the water is the easiest way to verify this aspect.

Spillways: Spillways are designed for specific flows given normal functioning. Obviously, any restriction to the operation of the spillway impacts on the amount of water that can flow through a spillway.

Emergency spillways are often cut into rock. If the rock is friable and weathers easily, such as occurs with certain shales, this rock through the years might fall and restrict the flow in the emergency spillway. Obviously, if the slopes are unstable next to the emergency spillway, a slide may occur and partially or totally block the emergency spillway.

Examination of the principal spillway pipes is of utmost importance as well. In a riser-type design, brush and debris often may clog the inlet into the spillway system. This needs to be noted and removed from the inlet. Often a boat must be kept adjacent to the embankment in the designs where the spillway barrel may be in the middle of the embankment itself.

Pipes must be inspected to insure that if the inlet and outlets are not protected by headwalls, machinery and/or persons have not bent the ends of the pipe inward. When corrugated metal is used, often the ends can become bent downward. This, in turn, reduces the cross section available for flow and will restrict the amount of flow through the pipe.

Sediment Load: Any impoundment will have a certain amount of fines settle out in the pool. Obviously, in the case of a sediment pond, this is the reason for the embankment being constructed in the first place. In other areas, any inflow will be carrying suspended solids and settleable solids, and they will be deposited in the pool. In the design process, there is allowed a certain amount of load for this. If the volume allotted for this sediment is exceeded, the hydrology of the design is invalidated. Inspections must be made to examine the volume of the sediment placed in the embankment itself and the embankment cleaned out if necessary.

All of the foregoing items need to be inspected in order to insure that the quality control achieved in the design and construction process is not invalidated due to improper operation of the impoundment itself.

Section 8 Mine Exploitation

SCOTT G. BRITTON, ASSOCIATE EDITOR AND SECTION COORDINATOR

Chapter 8.0
INTRODUCTION

SCOTT G. BRITTON

Mine exploitation is a broad subject whose focus is the technical skills or efforts needed for the extraction of mineral from a known ore body. Mine exploitation can be considered the very core of the mining engineering discipline. It begins at the conclusion of the exploration and development stages of mining and ends when the ore body is exhausted and the mine (or mines) closes and is reclaimed.

Section 8 on mine exploitation is comprised of seven chapters: (1) classification of mining methods, (2) mine surveying and mapping, 3) systems engineering, (4) computer methods, (5) labor relations and training, (6) management and administration, and (7) mine closure, sealing, and abandonment.

Each chapter focuses its efforts towards providing detailed and useful information for the engineer on basic mine exploitation principles. The information can be applied to a broad range of mining problems without regard to mineral type or mining method.

The first chapter, classification of mining methods, is a rational and systematic approach to the organization of mine exploitation methods. A unique tree structure of mining elements is presented in support of the engineering-operations interface of mining. The reader is able to clarify the engineering problems he/she faces while obtaining a broader understanding of the relationship of these problems to the overall mining process. Prior problems or elements contributing to the current problem(s) can be readily identified, and the reader as well gains some insight into problems downstream of the current problem.

The second chapter concentrates on mine surveying practices, particularily on aerial mapping practices. Traditional mine surveying receives less emphasis in favor of emerging aerial surveying techniques. The reader will be able to understand all opportunities to use aerial mapping as well as the elements needed to manage such a program or the results of such a program.

The third chapter covers the diverse elements of mine systems engineering. This subject area encompasses the principles of industrial engineering as they are applied and refined for mining operations. The reader benefits from a discussion on improving operating functions through systematic study and refinement.

The fourth chapter covers the use of computer models to manage the exploitation function of a new or existing mining operation. The reader obtains a thorough discussion of the advantages and disadvantages of using the computer in mine exploitation applications. Specifications for computer use, as well as detailed examples, are provided.

The fifth chapter discusses the impact of improving the human element of mine exploitation through labor relations and training. Specific discussions of labor-management practices and the use of training as a means of improving the labor element are presented for the reader.

Management and administration is the sixth chapter in the exploitation section. The discussions in this chapter cover the structure and purposes of a variety of management systems used in mining operations today. Specific position descriptions, responsibilities, and authorities are covered within the confines of the chapter. The reader will obtain a complete understanding of the structure of the mining business and why it exists as it does.

The final discussion of the mine exploitation section is one covering the closure, sealing, and abandonment of a mining operation. The authors have compiled and presented current information on the legal, engineering, and public relations process for closing and abandoning a mining operation. The reader derives specific regulatory authority for closing activities on a federal and state basis. He/she is able to plan and budget the closing process as well as determine all related public relations elements needed for successful mine closure.

In reviewing the entire mine exploitation section, the efforts of the authors have been to provide the reader with hands-on information of interest for today's mining engineer.

Chapter 8.1
MINING METHODS CLASSIFICATION SYSTEM

L. ADLER AND S.D. THOMPSON

8.1.1 INTRODUCTION

The purpose of a classification system for mining methods is to provide an initial guideline for the preliminary selection of a suitable method or methods. Its significance is great as this choice impinges on all future mine design decisions and, in turn, on safety, economy, and the environment.

The choice of a mining method assumes a previous but cursory knowledge of the methods themselves. It also assumes a brief understanding of ground control and of excavating and bulk handling equipment. In the formal mine design procedure, the choice of mining methods immediately follows ground control and equipment studies, and feeds directly into the crucial *milestone diagram* where regions of the property are delineated as to prospective mining methods (Lineberry and Adler, 1987). This step in turn just precedes the subjective, complex, and critical *layout and sequencing study*.

To develop the proposed classification system adopted here, many existing ones, domestic and foreign, were examined and incorporated to varying degrees. The result is deemed more systematic, inclusive, and understandable than its predecessors (see references, e.g., Stoces, 1966).

Subsequent sections (13, 16, 17, 21, 23) elaborate on the selection and comparison of mining methods.

8.1.2 BACKGROUND

8.1.2.1 Input Statement

A comprehensive statement has been developed to provide a rapid checklist of the many important input parameters (Adler and Thompson, 1987). The three major areas are (1) natural conditions, (2) company capabilities, and (3) public policy (Table 8.1.1). Those parameters appearing early are generally the most important. Natural conditions, which are almost invariant, require that a dual thrust be maintained concerning resource potentials and engineering capabilities. An additional basic distinction occurs between geography and geology. For company capabilities, fiscal, engineering, and management resources must be recognized. This includes the scale of investment, profitability, and personnel skills and experience. Public policy must be considered, particularly as to governmental regulations (especially safety and health and environmental), tax laws, and contract status. Some of the latter input factors are held in abeyance until near the end of the investigation, and then considered as modifying factors. This organization duplicates but tightens others (Hartman, 1987a).

Table 8.1.1 Input Statement Categories

Primary Categories (Dependency)	Secondary Categories
Natural conditions (invariant)	Geography Geology economic engineering
Company capabilities (variant)	Business administration Monetary aspects Management aspects
Public policy (semi-variant)	Regulations Taxes Contracts Incentives
State of art (mining engineering)	Salient distinctions *Total Systems* (design/control), *Encumbered (and Regulated) Space* *Full Spectrum Practice* (manage/evaluate) Professionalism

8.1.2.2 Spatial Description

Most mineral deposits have been geometrically characterized as to an idealized shape, inclination, size, and depth. Complex or composite bodies are then composed of these elements.

Ideal shapes are either tabular or massive, with chimneys (or pipes) being subordinated. Tabular deposits extend at least hundreds of feet (meters) along two dimensions, and substantially less along a minor dimension. Massive bodies are approximately unidimensional (cubic or spherical), being at least hundreds of feet (meters) in three dimensions. A modification is recommended later to achieve closure with tabular deposits. For tabular deposits, the inclination (attitude or dip) and thickness are crucial. Inclinations range from flat to steep (Table 8.1.2) (Hamrin, 1980; Popov, 1971a).

In surface mining, the inclination limits the advantageous possibility of being able to cast waste material nearby, as opposed to hauling it a distance and then storing it. For flat deposits, especially when fairly shallow (see the following), an area can be successively opened up and the waste then be cast into the previously mined-out strips, a substantial economic advantage. Casting in its normal sense is not restricted to the use of rotating excavators; broadly, it means relatively short-distance hauling of waste, which can also be done with mobile loaders and/or trucks or with mobile bridge conveyors. For steeper (and deeper) deposits, stable pit slopes become important (Table 8.1.3) (Hartman, 1987b; Popov, 1971b). Where the deposit inclination exceeds that of the stable slope, both the hanging wall and footwall must be excavated and the increased waste then handled and placed.

Table 8.1.2 Tabular Deposits Classified by Attitude and Related to Bulk Handling and Rock Strength

Class	Attitude or Dip	Bulk Handling Mode	Rock Strength
Flat	≤ 20°	Use mobile equipment (and conveyors)	Weak rock (surficial)
Inclined	20–45°	Use slushers (also metal plate can vibrate—as gravity slides)	Average rock
Steep	≥ 45°	Gravity flow of bulk solids	Strong rock (at depth)

Table 8.1.3 Surface Pit Slopes Related to Rock Strength and Time

Rock	Maximum Pit Slope Short Term	Maximum Pit Slope Long Term
Strong	40–45°(– 70°)[a]	18–20°
Average	30–40°	15–18°
Weak (soils too)	15–30°	10–15°

[a]Note: Infrequently up to 70°

Table 8.1.4 Underground Deposits Classified by Thickness

Class	Deposit Thickness Coal	Deposit Thickness Ore	Comments
Tabular			
Thin	3–4 ft (0.9–1.2 m)	3–6 ft (0.9–1.8 m)	Low profile or narrow mine equipment
Medium	4–8 ft (1.2–2.4 m)	6–15 ft (1.8–4.6 m)	Post and stulls ≤ 10 ft (3.1 m)
Thick	8–15 ft (2.4–4.6 m) pillar problems	15–50 ft (4.6–15.3 m) can cave (steep dip)	Small surface equipment Crib problems
Massive	≥ 15ft (4.6 m)	≥ 50 ft (5.3 m)	Pillar problems or poor recovery Benching necessary Caving considered

Table 8.1.5 Deposits Classified by Depth

Class	Deposit Depth: Underground (a measure of overburden pressure) Coal	Ore	Surface
Shallow	≤ 200 ft (61 m) slope entries possible	≤ 1000 ft (305 m)	≤ 200 ft (61 m)
Moderate	400–800 ft (122–244 m) pillar problems	1000–1500 ft (305–457 m)	200–1000 ft (61–305 m)
Deep	≥ 3000 ft (915 m) bumps,burst,closure	≥ 6000 ft (1830 m)	≥ 1000–3000 ft (305–915 m) open pit

For both surface and underground mining methods, the inclination cutoff values nearly coincide (one for pit slopes, the other for face bulk handling mechanisms, whether mechanical or by gravity). While not identical, they are close enough to use similar values (20º and 45º; see Table 8.1.2).

The thickness of a tabular deposit is also important (Table 8.1.4), with reference primarily to underground work (Popov, 1971c). When several (≥ 3) benches are required, the deposit tends to be treated as massive. Primarily in flat underground deposits, thickness governs the possible equipment height (low profile), and in steep ones its narrowness. Also, in underground mining, the deposit thickness becomes a support problem, especially if effective pillars become so massive that recovery is compromised. When the upper limit of any of these concerns is reached (e.g., benching, equipment size, and pillar bulk), closure with massive deposits occurs for all practical purposes. Pillar size vs. recovery can dictate caving.

Finally, the depth below the ground surface is important (Table 8.1.5) (Popov, 1971d; Stefanko, 1983). For surface deposits, even flat ones, this can obviate casting and require increased waste haulage and expanded dump sites. For underground mining, earth pressures usually increase with depth, consequently raising the support needs. The ground surface location above a deposit must be clearly identified to evaluate other parameters (see 8.1.2.1, Input Statement).

Table 8.1.6 Deposit Classified by Geometry and Type

Geometric Class	Deposit Type	Comments
Tabular	Alluvium (placer)	Near surface—weak
Flat & Inclined	Coal (folded too)	Weak country rock—an erosion surface
	Evaporites (domes too)	
	Sedimentary	Good country rock, thicker
	Metamorphic (folded too)	
Steep	Veins	Can be weakened or rehealed (gouge and alteration)
Massive	Igneous (magmatic)	Strong
	Disseminated ores	Can be weakened

Table 8.1.7 Rocks Classified by Strength

Class	Compressive Strength	Examples
Weak	≤ 6000 psi (41.3 MPa)	Coal, weathered rock, alluvium
Moderate	6000–20,000 psi (41.3–137.9 MPa)	Shale, sandstone, limestone, schist
		Evaporites, disseminated deposit
Strong	20,000–30,000 psi (137.9–206.8 MPa)	Metamorphic, igneous, veins, marble, slate
Very strong	≥ 30,000 psi (206.8 MPa)	Quartzite, basalt, diabase

8.1.2.3 Correlating Deposit Types

The inclination (dip), discussed previously, can be roughly related to the deposit type (Table 8.1.6). Rocks can also be related to strength (Table 8.1.7) (Hartman, 1987c). The strength of the deposit and its envelope of country rock can then be related to its type (Table 8.1.8). For determining pit slopes, (surface mining) and support requirements (underground mining), these relationships become important. Some variations are noted, especially for veins and disseminated deposits. Near the ground surface, a typical geologic column occurs (Table 8.1.9). It involves weathering, jointing, the water table, and stress relief.

8.1.3 CLASSIFYING SURFACE MINING METHODS

8.1.3.1 Depth Related to Inclination

The surface mining classification, although based on the crucial ability to cast waste material rather than to haul it, has other features. These are primarily based on the depth of the

Table 8.1.8 Deposits Related to Geometry, Genesis, and Strength (In Order of Induration)

Deposits Type	Geometry	Genesis	Strength and Stiffness, Deposit/Country Rock	Examples
Alluvium (placers)	Tabular-flat	Surface-stream action deposition (fans, deltas, meanders, braids)	Poor/poor	Sand and gravel Precious metals and stones (tin)
Erosion surface (swamps)	Tabular-flat and thin (possible folding)	Swamps (possible dynamic metamorphism)	Poor/poor to good	Coal
Disseminated	Massive	Underground channels, and multi-faceted advance	Poor/poor	Hydrothermal ores (porphyry coppers and sulfides)
Vein (can be rehealed)	Tabular-inclined (pipes, chimney shoots)	Major underground channels (fissures) gouge, alteration (reheal)	Poor to good/good	Hydrothermal ores (above)
Evaporites	Tabular-flat-thick	Interior drainage	Good/good	Salt, phosphates
Sedimentary (bedded)	Tabular-flat-thick	Shallow seas	Good/good	Limestone, sandstone
Metamorphic	Tabular-flat-thick	Dynamic and/or thermal	Good/good	Marble, slate
Igneous (magnetic)	Massive	Plutonic emplacement	Good/good	Granite, basalt, diabase

Table 8.1.9 Normal Sequence of Near-surface Geologic Column (Related to Ground Water and Rock Stress)

Rock Column	Ground Water	Rock Stress
Ground surface		
Soil (alluvium) mantle	NA	NA
Blocky & seam rock		
Decomposed rock (weathered)	Water table	Stress relief zone
Jointed fresh rock		
Tight rock	—	Constrained zone

NA—not applicable

deposit being a function of its inclination. Flat seams tend to be shallow, and casting is possible; steep and massive deposits trend to depth. From this a number of relationships result.

8.1.3.2 Depth Related to Excavating Technique and Stripping Ratio

Because of the effects of weathering and stress release (Table 8.1.9), excavating becomes more difficult and expensive with depth, following a continuum from hydraulic action and scooping through to blasting (Hartman, 1987d).

As a matter of definition, the stripping ratio (ratio of waste to mineral) usually increases with depth. However, the relatively inexpensive handling of waste near the surface by casting tends to mitigate this increase, permitting higher ratios. The use of mobile, cross-pit, high-angle conveying allows greater pit depths and, along with the mineral value, also influences this ratio.

8.1.3.3 Surface Mining Classification System

Based on the foregoing factors, a surface mining classification has been developed (Table 8.1.10). The classification incorporates information dependent on the intrinsic characteristics of the geometry of the deposit. Quarrying appears to be anomalous because of (1) relatively steeper pit slopes, (2) specialized means of excavating and handling, and (3) less critical amount of overburden. Glory hole mining or its equivalent is making a comeback in very deep open pits using inclined hoisting.

In contrast to the underground classification, the surface one is not formed into a matrix. This is because depth and therefore excavating technique, waste handling, and stripping ratio are all functionally related to the deposit geometry, particularly the seam inclination. No preceding classification recognizes this relationship (Hartman, 1987e; Lewis and Clark, 1964a; Morrison and Russell, 1973; Stout, 1980; Thomas 1973a).

8.1.4 CLASSIFYING UNDERGROUND MINING METHODS

8.1.4.1 General

Normally, two major independent parameters will be considered that form a matrix, unlike for surface methods. These two parameters are (1) the basic deposit geometry, as for surface methods, and (2) the support requirement necessary to mine stable stopes, or to produce caving, a ground control problem (Boshkov and Wright, 1973; Hamrin, 1980; Hartman, 1987f; Lewis and Clark, 1964b; Thomas, 1973b).

8.1.4.2 Deposit Geometry

The deposit geometry employs the same cutoff points for tabular deposits as in the surface classification, but as noted for different reasons. Flat deposits require machine handling of the bulk solid at or near the face; steep ones can exploit gravity (Table 8.1.2), with an intermediate inclination recognized. If stopes are developed on-strike in steep seams, as "large tunnel sections," a new descriptive term, or "step room" (Hamrin, 1980), machine handling can still be used. The resulting stepped configuration causes either dilution or decreased recovery, or

Table 8.1.10 Classification of Surface Mining Methods

Shape, Attitude (Dip)	Deposit Characteristics	Stripping Ratio	Excavation: Waste Handling	Excavation: Excavation	Mining Method
Tabular					
Flat	Near surface	Low	Onsite	Hydraulic, scoop, dig	Placers—hydrosluicing, dredging, solution—at depth
	Shallow	Moderate	Cast	Scoop, dig, light blast	Open cast (strip)—area, contour, mountain top
Inclined		Moderate (remove hanging wall)	Need highwall	Auger	Auger
	Moderate		Haul (to waste dump)	Blast	Open pit
	Deep	High (remove both hanging wall and footwalls)	Haul (to waste dump)		Open pit
				Saw, jet pierce (joints)	Quarry
Massive	Full range	Depends on depth	Haul (to waste dump)		Open pit Glory hole

Note: In situ mining is always possible.

Table 8.1.11 Structural Components Located and Described for Underground Mining

Component (time dependent)	Location & (Material)	Loaded by	Supported by	Comments
Roof (can deteriorate, slough, slake—dry and crumble)	Back and hanging wall (envelope)	Main roof—all esp. overburden (cap rock)	Pillars and fill, also arched (1/5)	Spans ≈ 10 ft (3 m) for coal to 100 ft (30.5 m) for rock
		Immediate roof—body	Artificial supports can remove	Spans ≈ 10 ft (3.1 m) (stand up time)
Pillars & walls (can deteriorate—slough, slake)	Sides, deposit and waste (horses-mainly deposit)	All—esp. overburden	Floor	Critical: 1) stiffness: [slenderness ratio: ≈ 10/1 (coal) to 1/3 (rock)] 2) strength [material] 3) % recovery
Floor (can settle and heave)	Footwall (envelope)	All—through pillar watch water	Country rock can be compacted, removed, drained	Critical: 1) stiffness 2) strength (bearing capacity esp. if water) 3) heave (deep-seated)
Fill (for permanent stability)	Crushed waste, sand, water	All—esp. as pillars are removed	Footwall and floor	Good mainly to support hanging wall. Requires greater than angle of slide and confinement
Artificial support (limited time)	External: Timber (props, sets, cribs, stulls, posts) Concrete gunite (mesh)	Mainly immediate roof	Floor	Deterioration (chemical and stress)
	Internal: Bolts (headers), trusses, cables, grout, cementation	Mainly immediate roof	Anchorage in roof, etc.	Anchorage a concern

both. Since this face can also be benched (≤ 3), stope mining simply reproduces tunneling.

8.1.4.3 Ground Control

Ground control requires knowledge of the structure (opening), material (rock), and loads (pressures). The structural components (Table 8.1.11) are detailed for the strength and deposits (Tables 8.1.5 and Table 8.1.7). The roof, pillars, and fill are of primary concern.

Main Roof: The main roof (sometimes the hanging wall) is distinguished from the immediate roof by being the critical load-transferring element between the overburden and pillars. The immediate roof can be removed (mined out) or supported artificially and lightly. The main roof is defined as the first close-in, competent (strong) seam. If it is only marginally competent, heavy artificial support may keep it stable; if not, then caving can be expected. For a flat seam, the vertical (perpendicular) loads on the main roof are largely due to the overburden and its own body load. Horizontal (tangential) loads or pressures will tend to be uniformly distributed, resulting in a low stress concentration. If bed separation occurs above the main roof, this stress uniformity is enhanced; but at depth, overburden loading tends to decrease separation. Body loads are invariant, while edge loads particularly those due to the overburden can be shifted (pressure arching). The main roof is often sufficiently thick so that it can be arched ($\leq$ 1/5) to increase stability. For coal, stable spans usually are 3 m, while for rock they are generally less than 30 m.

For an inclined seam the main roof is the hanging wall, and the results are similar to a flat seam. Pressures perpendicular to it are more significant then tangential ones, and bed separation due to gravity is less likely.

Pillars: Pillars serve to support the main roof and its loads, primarily the overburden acting over a tributary area. Pillar material consists mainly of the seam itself and sometimes of waste horses in it. Pillars must not only be sufficiently strong but also must be sufficiently stiff, a frequently overlooked requirement. If pillars are not adequately stiff, but still adequately strong, the roof will collapse about the still free-standing pillars, especially when differential pillar (and floor) deflection occurs. The minimum slenderness ratio for pillars to avoid this crippling is inversely proportional to the recovery. The mining of flat, thick seams of coal dramatically reflects this relationship and is a factor in classifying seam thicknesses (Table 8.1.4). For massive deposits, even in strong rock, this makes free-standing pillars of doubtful value. Upper slenderness ratios range from about 10/1 for coal to 1/3 for rock. Continuous vertical pillars are used to separate vertical stopes in hard rock that employ steep, tabular stoping methods. Even with stable ground, these are usually filled soon after mining for long-term stability. When massive deposits along with their cap rock are weak, caving is necessitated, usually performed as horizontal lifts or as block caving. Caving always requires a sufficient span ($\geq$ 30 ft or 9 m), good draw control, and also risks dilution and/or poor recovery. Soft or nonuniform floors (footwalls) act the same as do soft and irregular pillars.

Fill: Fill, often a sandy slurry consisting of crushed waste, cement, and water, can be readily introduced into confined (plugged), inclined, and steep tabular stopes. When drained and dried, this hardened slurry provides permanent resistance to ground movement, especially for the walls or pillars. It is widely used in all but the caving methods. It is either run in progressively as a stope is mined out or done all at once at the end of stope mining. Because of settlement and shrinkage away from a flat back, it is marginally useful for flat deposits.

When timbering is densely placed, especially with square sets, it rivals pillars. It, too, is usually filled as stoping progresses (overhand mining). These relationships are summarized (Table 8.1.12) and lead into the formal classification.

8.1.4.4 Underground Mining Classification System

Based on an understanding of bulk handling and ground control, the underground classification system closely follows earlier ones (Table 8.1.13). The primary difference is that sometimes shrinkage stoping is considered self-supported rather than supported. However, although the broken mineral provides a working floor, it is still supporting the hanging wall (roof). On the other hand when the stope is drawn empty, it remains substantially self-supported until fill is introduced. The disadvantages of the shrinkage method are unique: (1) an uncertain working floor, (2) dilution due to plucking and falls, (3) possibly adverse chemical effects, and (4) tying up about two-thirds of the mineral until the stope is drawn.

Vertical crater retreat (VCR) mining is included in the classification between sublevel and shrinkage stoping (Hamrin, 1980).

8.1.5 OTHER FACTORS

While subordinated, there are additional factors that must be closely evaluated. These deal with the broad impacts on the environment, health and safety, costs, output rate, and others. They are usually evaluated on a relative basis although numbers may also be employed (Table 8.1.14) (Bohskov and Wright, 1973; Hartman, 1987g).

In addition, innovation is always occurring and some is currently of proven value. These include rapid excavation, methane drainage, underground gasification, and retorting (Hartman, 1987h). Some methods are being automated and even robotized.

8.1.6 CONCLUSIONS

Existing mining methods classifications were used and modified whenever possible. However, for surface mining the classification was drastically reworked for greater effectiveness, based on the relationships of the inclination of tabular deposits to depth, so that casting could be emphasized.

Earlier underground classifications were largely retained but now structured to underscore mechanical vs. gravity handling. It also emphasized an understanding of the roof, pillar, and fill aspects of ground control to assist in the stope support evaluation.

Chapter 8.2
MINE SURVEYING AND AERIAL MAPPING

BERNARD W. SOLOMON, JAMES MORGAN, SCOTT G. BRITTON, AND CHARLES O. FRUSH (deceased)

Mine surveying is as basic to prudent mining operations as is the employment of skilled labor to win minerals from the earth. The technical expertise needed to accomplish this task varies with the complexity of the mining operation (whether underground or surface, the size of the mining method, etc.) and the desires of mine management to comply with regulations and good mining practice. This chapter looks at two major components of mine surveying. The first is *operational surveying,* whose objective is to tie active mining efforts to spatial and physical control points. The second is *exploratory surveying,* which primarily focuses on aerial surveying, and whose major objective is to locate and define spatial and physical control points prior to commencing mining operations. Exploratory surveying can be done either in new areas or as support for expansion projects.

To accomplish reviews of these two components of mine surveying requires separate discussions in this chapter. The first reviews fundamental operational surveying techniques generally found at operating mines. This discussion is necessarily short because of the ready availability of instructional information elsewhere.

The second segment discusses the relatively new and emerging practice of aerial mapping techniques used for exploratory mapping and base surveying control points. Aerial mapping is the least expensive and best means for large-scale surveying. The use of aerial mapping was pioneered by the US Geological Survey and has been quickly adopted by the mining industry for nearly all major projects.

8.2.1 UNDERGROUND AND SURFACE MINE SURVEYING*

SCOTT G. BRITTON AND CHARLES O. FRUSH (deceased)

Mine surveying practices at underground and surface mines are based on plane surveying methods dating back to the time of the ancient Egyptians. These practices were refined and improved as new equipment was developed and the demand for accuracy increased.

It is not the goal here to completely and fully discuss the principles of mine surveying— there are many texts now available to the reader that address this subject more extensively than this *Handbook* can in the space available. However, the practice of mine surveying is evolving as new instruments and technology are introduced. Therefore, it is important the reader be aware of advancements in this area of mine engineering.

Of major importance in the field of mine surveying is the introduction and use of computer and laser technology for common surveying practices. Theodolites and electric distance-measuring (EDM) instruments are rapidly replacing the transit and tape measures. Computers with plotters and CAD (computer-aided design) capabilities are replacing the old manual methods of planimetering and contouring. These advancements have not fully displaced all older methods, but their use is becoming more commonplace as the technology becomes more cost competitive, better accuracy is demanded, and more personnel are trained to use such technology.

8.2.1.1 Uniqueness of Mine Surveying

The functions of the *mine surveyor* are to (1) provide a network of points of accurately known position, covering the entire mine property, (2) obtain the required data for the preparation of useful maps and sections, (3) provide position and directional control for the guidance of the operations, (4) measure the progress of the work, (6) measure the movement of rock masses, and (5) make miscellaneous surveys as needed.

Mining properties range from very small to extremely large, and from those involving only surface operations to those involving extensive underground workings. Active mines undergo constant change, necessitating continual updating of the surveys. The differences in the character of the deposits, the scale of mining, and the mining methods result in large differences in the surveyor's activities and techniques, but many of the problems involved are common to most mines.

The surface work of the mine surveyor is very similar to that of the plane surveyor in that control points are established by triangulation, trilateration, and traversing. Detail is taken by direct measurement, by stadia, and by aerial photography. The equipment used, the techniques, and the methods of processing the resulting data are likewise very similar. However, underground work is quite different:

1. The lines of sight frequently must be carried through constricted openings, often involving short lines of sight and awkward setups.
2. The lighting generally is poor, requiring illumination of the backsights and foresights, and the crosshairs.
3. The ambient conditions often are difficult, including falling water, high temperatures, poor visibility, and heavy traffic through the area being surveyed.
4. The surrounding rock may be unstable, resulting in movement or loss of the surveying stations, as well as hazard to the surveyors.
5. The points to be measured often are difficult or impossible to reach.
6. Steep vertical sights often are necessary, requiring the use of special equipment.
7. Many working levels commonly are involved, requiring the transfer of position and orientation to each with a high level of precision.

Because of these uniquenesses, this segment concentrates on surveying problems peculiar to the mine surveyor, chiefly in underground work.

8.2.1.2 Mine Coordinate System

A system of coordinates is essential for all permanent mining operations. It is very desirable that all mining operations in a given area be tied into the same system, as this minimizes problems of boundaries and connections. Wherever possible, this system should be tied into and made part of the state or regional

* Segments 8.2.1.1 through 8.2.1.9 are based on the original chapter by Charles O. Frush in the *SME Mining Engineering Handbook* (Cummins and Given, 1973).

grid system. It is desirable to orient the coordinate grid on a true-north line and to position the origin of the coordinates so that all of the work will be in the "northeast" quadrant, making the north and east coordinates always positive. This can be done by subtracting suitable constant values from the north and east coordinates of the regional system. The residual values are of more convenient magnitude and can be used as the local mine coordinates.

If the long axis of the mineralization is not generally north-south or east-west, it may be useful to establish a secondary coordinate system oriented parallel to the long axis. This makes it possible to depict the mine workings more conveniently on the working maps.

Commonly the elevations will be based on sea level, as taken from established stations. In most cases, all the mine workings will be above sea level so that all the elevations will be positive. If this is not the case, a different reference elevation may be necessary. Frequently, this is chosen so as to be above any possible mine working, making all elevations have a negative sign. This can be ignored if the measurements are considered to be "down" from the plane instead of "up."

Most mining operations are concentrated within relatively small surface areas. Thus it is possible to ignore most of the problems introduced by the curvature of the earth and by the convergence of the meridians, except in the most precise work. A level surface is considered to be a plane, and the meridians are considered to be parallel and perpendicular to the lines of latitude. These simplifying assumptions are entirely satisfactory for compact mining operations, but may not be adequate for distances exceeding several miles. In such cases, the principles of geodesy must be invoked.

8.2.1.3 Underground Traversing

The traverse is of paramount importance in underground surveying. Since mine workings provide the only access to a given point, all lines must be carried through them. If these workings are narrow and tortuous, the traversing will be difficult and less accurate. However, modern mechanized mining commonly requires more space, making surveying operations easier. Even so, traversing is the only practical means of carrying line and grade to the headings.

Stations: Underground traverse stations should be located in the back or on the roof, behind the working faces wherever possible. This prevents their being disturbed or destroyed by current mining operations. The positions of these stations should be selected with care so as to afford convenience in setting up under them and good lines of sight in all directions. A variety of means is available for their establishment.

Plug and Spad—A short hole is drilled into the rock at the desired location. A wooden plug then is driven into the hole, with a tight fit. A hook then is inserted into the plug, from which the plumb bob is to be hung. Specially designed hooks, called spads, are available from surveying equipment suppliers. These are recommended for their durability and ease of recognition. The size of the hole and of the plug is immaterial. Stub-blast drillholes can be used, or the hole can be made with a small star drill or electric hand drill for softer rock. In any case, the spad should be oriented as nearly as possible along the line of sight.

Simple Spads—Sometimes it is necessary to set stations in timber sets. Such stations are to be avoided wherever possible because of their impermanence and the ease with which the timber can be dislodged or shifted, thus destroying the line. Where they must be used, however, the spad, driven into the wood, makes an excellent temporary station.

Sometimes the spad can be driven directly into a crack on the rock, or the rock itself, if it is sufficiently soft. Such stations are rarely permanent enough to justify their use for important points.

Power-driven Studs—Some types of rock will accept and hold permanently a threaded hardened steel stud driven into place with an explosive charge by some variety of stud gun. A threaded hook to serve as a spad then can be attached to make the permanent station. In good rock such a station will be very durable, but the studs cannot be used in hard siliceous rock or in soft crumbly material. However, they work very well in steel-lined mine openings, as the stud can be driven directly into steel webs, flanges, or liner plate to make an exceptionally permanent installation.

Adhesive Stations—The use of durable, quick-setting, adhesive plastic cements, such as the epoxies, simplifies the establishment of underground survey stations in difficult places. The surface is cleaned and dried before application of the adhesive. The spad or hook is embedded before it has hardened completely.

Clamps—Clamps to support the hook may be useful when the line is being carried through an opening supported by steel sets. This technique is particularly useful when the line must be established in a specified position. The clamps can be removed and reset as required. The design of the clamps depends on the conditions.

Station Identification: Each station should be identified by a permanent marker. This can be of metal, usually brass or plastic. If of metal, the tag should not be in contact with the spad, particularly in wet or damp locations, as galvanic action can cause accelerated corrosion that will destroy the station. A wide variety of tags in different sizes, shapes, and compositions is available. Monel metal strips marked with a portable embossing tool make excellent tags.

Various systems of nomenclature for identifying the stations have been devised and are in use. Each has certain advantages. Some of the principal systems of nomenclature are as follows.

Sequential—This system gives each succeeding station a sequential number, regardless of where it may be located. It is best adapted to one-time surveys. An index of stations, showing the name, location, and coordinates of each, should be kept.

Position-coded Sequential—This system incorporates a code related to the station position. The complexity of the code is a function of the complexity of the workings and of the need. A simple example would be "4-N-172," which could indicate the 172nd station in the north part of the 4th level. Variations can easily be devised to identify specific entries, levels, drifts, or crosscuts on each level.

Position-coded Distance—This system names each point according to its distance from a reference point in the working in which it is located. Thus "22N-327L" could indicate a point in the 22nd entry north of the starting point approximately 327 ft (99.6 m) left of the intersection with the reference line.

Each system has numerous variations, which depend on the complexity of the mine and the purpose of the survey. The method adopted should be clear and easy to learn and use.

Station Occupation and Use:

Elevations—Elevations are carried to the stations either by differential leveling or by slope-distance traversing. For stations set in the ground or floor, the elevation is considered to be that of the point on which the level rod would rest. The elevation of points set in the back (roof) is considered to be that which the inverted rod would contact—the lowest point of the hook or spad. When traversing to the point, the horizontal crosshair is set on the top of the nail or the bottom of the spad and the vertical angle measured to that point. Often it will be difficult or inconvenient to sight directly to the spad. In such cases, the crosshair may be set on some other easily identifiable point on the plumb bob string and the distance up or down to it measured. This measurement is known as the *height of station* HS. If the line of sight passes over the station, HS is considered to be positive; if it passes under, negative. (This convention is that employed by several widely used computer programs for reducing survey notes. It may have to be modified to fit others.)

Setting Up Under a Station—In setting up under an underground station, it is convenient to first hang a plumb bob from it, slightly higher than the expected top of the transit. The telescope of the transit is set to the horizontal position, perpendicular to the vertical axis of the instrument. The legs then are positioned conveniently so that each is on solid footing, and their length is adjusted to bring the head directly under the plumb bob. The plate is leveled and shifted laterally as necessary to bring the vertical axis of the instrument directly under the point of the bob. Usually, it will be necessary to readjust the length of the legs, or their position, before a satisfactory setup can be obtained. The instrument is correctly set when the plate is level and the vertical axis is directly under the point.

Occasionally, it may be necessary to set up in extremely difficult locations where the previously described technique cannot be used. In such cases, it may be necessary to replace the tripod with a bracket that can be fastened to a post, or a stull or column to achieve the requisite position for the transit. Once in position, the adjustments proceed as before.

Setting up over a station is identical to the similar operation on the surface.

The *height of instrument* HI is measured as the distance from the point to horizontal axis of the telescope. The sign is positive if the instrument is over the point, negative if it is under it.

Illumination—Typically, mine surveying must be done in the dark, the only illumination coming from the cap lamps carried by the surveyors (and any stationary lighting in the vicinity). In such cases, it is necessary to illuminate the backsights, foresights, crosshairs, and the horizontal and vertical circles.

To illuminate the crosshairs on the standard mining transit, the beam of the cap lamp is directed so that a small part of the light enters the objective lens at an angle. The internal reflections make the crosshairs easily visible. The horizontal and vertical scales are illuminated directly by the lamp, holding it for maximum clarity.

Modern instruments also use internally illuminated horizontal and vertical circles and crosshairs. Light enters through an aperture on the side, passing along an intricate path through the glass circles and the vernier through a small telescope to the eye of the observer. A small mirror can be rotated to direct part of the beam onto the crosshairs. Auxiliary bulbs, mounting on the instrument, and a battery pack can be used as the illumination source if the surveyor so desires. Some instruments now have LED displays and readouts, making accurate reading easier.

Several techniques are used for illuminated the sights:

1. The chainman's cap lamp can be held behind the junction of the plumb bob and its string, directed at an angle toward the telescope so as not to blind the observer. The instrument man uses the light as a sighting point, seeing the string and the bob as a shadow against the light. This is a preferred method.

2. The chainman holds his lamp as before, but places a translucent paper or screen between it and the string. This provides a larger, but less bright, target for the instrument man, who puts his crosshair on the shadow.

3. Various kinds of self-illuminating sights can be used. One easily fabricated type is made from an ordinary two-cell flashlight, a piece of string and a bead. A hole is drilled in the center of the flashlight lens to receive the end of the string, which is knotted in place. The bead is slipped over the string and can be slid up or down as required. In use, the flashlight illuminates the lower side of the bead, to which the measurements are made.

Double-angle Traverses: Double-angle traverses are used to extend the network of control points in mines, both surface and underground. Where greater precision is required the angle should be observed more than two times, but always an even number. Double-centered instruments commonly are used, but pointing-type theodolites often are seen.

With the conventional mining transit, the zero points of the inner and outer horizontal circles are brought into exact coincidence. The telescope, in the erect position, then is centered on the backsight. The upper motion then is released and the telescope rotated to the foresight, the crosshair being brought to exact position with the tangent screw. The angle from the backsight then is read in a clockwise direction ("angle right") and the vertical angle is recorded. With the upper motion remaining clamped to the lower, the telescope then is rotated to the inverted position and, with the lower motion loosened, again is centered on the backsight. The lower motion is clamped, the hairline set exactly with the tangent screw, the upper motion loosened, and the telescope turned to the foresight and set. The doubled angle then is read from the horizontal circle and recorded, as is the vertical circle. The distance from the horizontal axis of the telescope to the foresight point is read and recorded, as is the HI and the HS. The instrument then is ready to be moved to the foresight station, unless there are other points to be observed from the same station.

The technique with the pointing-type theodolite is basically the same, except that there is only one horizontal circle instead of two. With the telescope erect, the crosshair is set on the backsight and the horizontal scale is read and recorded. The telescope then is pointed at the foresight and the horizontal scale read and recorded. The difference is the observed horizontal angle. The vertical angle to the foresight also is read and recorded. The telescope then is inverted and the process repeated. The two horizontal angles are averaged, eliminating any slight instrumental errors, as are the vertical angles. The inclined distance to the foresight and the HI and the HS are read as before.

If the traverse is carried in a loop back to the point of beginning, it is said to be "closed." It also may be closed by terminating it on another known point of equal accuracy. Closed traverses should produce the expected coordinates and azimuths within the desired degree of precision, as determined by the care and skill used in the field work, the applied corrections and the calculations. Any acceptable discrepancies can be distributed among the various courses by any of several means. Closed traverses should be done on a regular basis (i.e., monthly) to ensure rapid error correction within any one traverse.

Traverses that do not close back on their starting point or on other known points are said to be "open," meaning that there is no automatic check on the validity of the work. Such traverses can be checked in approximate fashion by using a protractor and a scale to plot the observed angles and the horizontal distances. If the coordinates of the plotted points check the calculated coordinates, within normal plotting accuracy, it may be assumed that the calculations are essentially correct.

Azimuth Traverses: By *azimuth traverse* is meant that procedure by which the instrument always is kept oriented on map north so that the pointings to the foresights also are the forward azimuths. The angles are not doubled, so azimuth traverses are of lesser precision. However, they are very useful for controlling the advance of mine workings between periods of advancing the main network with the double-angle traverse.

The traverse is started at a point on a line of known azimuth. The horizontal circle is set on the azimuth of the line from the backsight to the occupied station. The backsight is observed with the telescope in the inverted position. The telescope then is plunged to the erect position, the upper motion is loosened, and the instrument is rotated to the foresight. The observed reading on the horizontal scale also is the forward azimuth of the line from the station to the foresight. The vertical angle is read, as are the slope distance, the HI and the HS.

The calculations in an azimuth traverse also are simplified in that the azimuth already is known.

Compass Traverses: Ordinary surface compass traverses are very similar in theory to the azimuth traverse. The compass in the transit may be used to provide orientation, or an instrument such as the Brunton compass may be used to find the bearings and vertical angles. The calculations are identical with those of the azimuth traverse. The accuracy of the method depends on the constancy of the ambient magnetic field and on the accuracy with which the instrument can be read. Unless there are local magnetic influences, the ambient magnetic field will remain sufficiently constant for this technique to be useful for many applications requiring low to moderate accuracy.

Underground, however, there are likely to be many disturbing magnetic fields. These may result from the proximity of steel pipe and rails, machinery, power lines, and perhaps magnetic minerals in the ore and country rock. The possibility of the existence of such influence restricts the utility of the simple compass traverse as described.

These extraneous magnetic influences can be canceled out if the compass is held in the same position while both backsights and foresights are taken. The difference between the foresight and the backsight is the *horizontal angle*. This can be used in the ordinary traverse calculation to carry the bearings forward and to obtain coordinates. However, the greater difficulty in obtaining exact angles, as compared with the transit survey, introduces greater uncertainty into the results.

Distance Measurement in Traversing:

Steel Tapes—The standard device for measuring distance in surface or underground traverses is the steel tape. In mine surveying, the distances commonly are measured along the line of sight from the horizontal axis of the telescope to the sighting point. This is known as “slope chaining.” The technique is preferred to horizontal chaining because of the frequent steeply inclined lines of sight and because of its higher accuracy.

The tapes used are limited to 200 ft (60 m) in length for underground use, partly because of the frequently limited lines of sight but chiefly by the problem of compensating for sag in the longer unsupported lengths. The required pull becomes excessive as the length becomes great and the accuracy of the work diminishes as errors in the applied tension increase. The preferred tape is graduated to 0.01 ft (3mm) along its entire length. The tape should be carried on a reel for safety and convenience, and should be carefully cleaned and oiled after each use, particularly if it has become wet or dirty.

Ordinary traversing work seldom requires corrections for temperature or precise control of the pull. These factors must be taken into consideration for very precise work, such as in determining the exact length of a base line for triangulation. The tapes used for such work should be checked against tapes that have been calibrated by the National Bureau of Standards.

Subtense Bar—The subtense bar is a device for the indirect measurement of distances by measuring the horizontal angle subtended by the sighting points at the ends of a horizontal bar. Knowledge of the exact length between the marks and of the angle permits the distance to be calculated as the product of the cotangent of half the subtended angle and half the bar length. A typical bar is 7 ft (2 m) long in extended position, the sighting points being fastened to invar wires under spring tension. A theodolite is used to measure the subtended angles to the nearest second.

The accuracy of the determination is very high for intermediate distances up to perhaps 400 ft (120 m) per reading, but diminishes with increasing distance. The bar has the advantage of making it possible to determine the length of an inaccessible course and permits the measurement to be done by an individual, should this be necessary. With it, a theodolite, three tripods, and a set of targets, one person could run a traverse by himself, although this is not desirable.

The subtense bar is not widely used underground, but could be employed to advantage where the openings are wide enough to accommodate the bar and straight enough to provide a convenient length of sight.

The distances obtained with the subtense bar are horizontal distances, since the subtended angle is measured in the horizontal plane.

Electronic Distance Measuring Devices—The development and widespread availability of electronic devices for the direct measurement of distance has evolved rapidly (8.2.1.10). The apparatus best adapted to mine surveying problems is light in weight, easily portable, utilizes a beam of infrared or visible light reflected to the transmitter by a suitable reflector, and produces a distance reading directly without the need for data conversion by the operator. The equipment emits a narrow carrier beam, modulated at a succession of frequencies. Comparison of the phase difference of the outgoing and returning signals provides the basis for the distance determination. Corrections for air density and temperature and index constants for the transmitter and reflector must be supplied by the user. The equipment is made to be mounted on the same tribrachs or mountings used by theodolites, so that the horizontal and vertical angles can be determined from the same setup.

For short distances, up to perhaps several hundred feet (tens of meters), the reflectors can consist of simple reflecting tape or inexpensive plastic reflectors. These are useful in monitoring the position of inaccessible walls or back, as in large underground rooms.

For longer lines, it is necessary to use corner prisms set up over or under the desired point. These prisms have the property of reflecting a light beam back along the incident path, no matter what the angle of incidence may be within the acceptable range.

The distance measured is the inclined point-to-point distance. The error is a fixed quantity, essentially unrelated to the distance, except as the temperature and density of the intervening air may vary. The height of transmitter and height of reflector are essential data in work involving elevations.

The greatest application of electronic distance measuring devices is in surface work, where their long range and high accuracy make it possible to carry traverses rapidly over long distances. They make trilateration possible as a substitute for, or an adjunct to triangulation.

In underground surveying, it appears that their greatest application will be in measuring the movement of rock masses on the periphery of large excavations, and for traversing in mines where long lines of sight are involved.

Detail: In addition to establishing the point-to-point traverse, the surveyor frequently must locate the boundaries of the mine workings, the position of important structures, and other detail. Methods for doing so include the following.

Angle and Distance Measurements—The instrument is set up under or over a station and backsighted on a suitable neighboring station. The upper motion is released and the instrument pointed at successive significant points, to which slope distances are measured and recorded, as are the horizontal and vertical angles. The accuracy required is a function of the purpose of the work and of the scale to which the data is to be plotted. For most work, it is sufficient to read the horizontal angle to the nearest 15′ and the distance to the nearest 0.1 ft (30 mm). If elevations are not required, it often is possible to measure horizontally and thus ignore the vertical angle.

Ordinary detail taken in this fashion is best plotted by use of a protractor and scale. The more important points can be treated as points on the traverse, the coordinates computed, and the points plotted by the coordinates. This type of plotting is easily done when the coordinates are calculated by use of the digital computer.

Lefts-and-Rights—This technique requires that a tape be stretched from the instrument station to the foresight. Significant points are located by measuring the distance perpendicular to the tape and noting the distance along the tape at which the measurement is made. The technique is best adapted to rather narrow workings, as otherwise failure to measure perpendicularly may result in noticeable errors in the resultant plot. Measurements of this type usually are made at waist level for convenience and because this corresponds to the usual maximum width of the drift.

Plotting is done by laying a scale along the indicated line and marking off the taped distances. The scale then is held perpendicularly to the line and the corresponding widths plotted.

Stadia—The use of the stadia board as a means of obtaining detail is not appropriate to narrow workings, particularly if of a rounded cross section. However, it is useful in the larger workings, such as stopes and rooms where it is necessary to obtain not only the periphery, but also numerous points on the back and on the floor. When used, the length of the stadia board must be chosen to fit within the available vertical height. The board is held vertically over or under the point, the horizontal crosshair of the transit brought to a convenient number, usually the HI, and the vertical angle read. The lower crosshair then is moved slightly to an even marking or fraction and the intercept of the upper crosshair noted. The difference gives the stadia interval. The horizontal angle, vertical angle, and stadia interval are noted as the basis for subsequent reduction to horizontal distance, vertical distance, and elevation. This information then may be plotted with protractor and scale. If coordinates are desired, it is better to process the raw information with a suitable computer program, regarding the point as a point on the traverse, but the same calculation can easily be done by hand if necessary.

Range Finder—The range finder is not widely used in underground mines, but under the proper conditions, it is a very useful instrument. Its chief application is in obtaining cross sections of large stopes or rooms.

The range-finder instrument is similar in many respects to those used by the military. It is binocular in character, each line of sight being reflected to a prism or mirror at opposite ends of a horizontal tube and from there to the target. The mechanical adjustment required to bring the images into coincidence is used to provide a numerical indication of the distance.

In use, the range finder is positioned at the desired point along a line, backsighted, and the proper horizontal angle turned to obtain the desired orientation of the vertical plane passing perpendicularly through the center of the tube. A point of light is directed onto the stope wall, upon which the range finder is focused. The inclined distance is read directly from the instrument, as is the vertical angle. This information is used to plot the profile of the stope or room on the cross section with a protractor and a scale.

Steeply Inclined Lines: Occasionally traverse lines must be carried through openings so steeply inclined that the telescope cannot be raised or depressed enough to see the sighting point. Or perhaps it may be necessary to position the transit in a specific location where some obstruction interferes with the line of sight. In such cases, auxiliary equipment must be used, the type depending on the instrument used.

Side Telescope—The side telescope is used with the conventional mining transit, which is equipped with projecting threads at each end of the horizontal axis to receive the side telescope and its counterweight. The side telescope clears the base of the transit so that sights of any inclination are readily made. It is similar in construction to the main telescope, and its crosshairs are adjustable in the same manner. It is essential only that the horizontal hair remain on a point as the instrument is swung from side to side. A vertical adjustment permits the horizontal hair to be made coincident with the horizontal hair of the main telescope. If the situation permits both erect and inverted observations, the averages of the horizontal and vertical angles are the correct values, and no other calculations are needed. Minor maladjustments of the instrument also are compensated for in this case. If direct and inverted observations cannot be made, the instrument must be in excellent adjustment and the effects of convergence and offset of the line-of-sight must be eliminated from the observed horizontal angles through the application of calculated corrections.

Top Telescope—Most mining transits are equipped to use the auxiliary telescope as either a side or a top telescope. Another set of projecting threads extends above and below the main telescope for the attachment of the auxiliary telescope and the counterweight. The adjusting screws readily permit the vertical crosshair to be made coincident with the vertical crosshair of the main telescope. The top telescope can be used in the erect position to see past the instrument base, but not in the inverted one. Therefore, the angles cannot be doubled in the usual way and the effects of minor maladjustments in the instrument cannot be eliminated by manipulation. The effects of offset and convergence of the line-of-sight must be eliminated from the observed vertical angles by the application of calculated corrections.

Pentaprism—The widely used modern theodolites are not designed to permit use of the auxiliary telescope. The same function is served by the use of a pentaprism clamped to the objective end of the telescope, balanced by a counterweight at the eyepiece eye. The pentaprism is a five-sided prism, so cut that an emerging ray of light is offset exactly 90º from the entering ray. The prism is mounted in a tube which permits 360º of rotation about the telescope axis. In use, it is rotated until the vertical crosshair stays on a point as the telescope is rotated about its horizontal axis. The bent line of sight permits the user to see points that normally would be obscured by the base of the instrument. The telescope can be used in the erect and inverted positions by rotating the prism 180°. This has no effect on the angle of bending since the prism bends the light rays 90°, regardless of the direction in which it is pointed. The horizontal angles so measured are correct, but the vertical angles must be corrected for the 90º bend and for the offset.

Side Telescope Calculations: The line of sight through the side telescope will lie in a plane with the line through the main telescope but offset from it, and the lines may converge or diverge. If the averages of the erect and inverted sightings cannot be determined, it will become necessary to find the amount of offset from the line through the main telescope at the instrument and the amount and direction of convergence.

This is done by setting the instrument over a point and reading the intersections of the two vertical crosshairs on scales placed at known distances from the instrument. The offset at the instrument and the divergence then can be determined through the use of similar triangles.

Example 8.2.1.1. Assume that the following data were obtained:

Distance from instrument to scale, in.	Scale reading, main telescope, in.	Scale reading, side telescope, in.
99.86	4.01	8.56
198.57	1.53	6.59

Let x be the offset. Then

$$\frac{(6.59 - 1.53 - x)}{198.57} = \frac{(8.56 - 4.01 - x)}{99.86}$$

from which $x = 4.034$ in. or 0.336 ft offset.
Let alpha be the angle of divergence. Then

$$\text{Alpha} = \arctan \frac{(6.59 - 1.53) - (8.56 - 4.01)}{(12)(198.57 - 99.86)}$$

$$= \arctan(0.0004305541)$$

From which alpha = 0° 01′ 28.8″, angle of divergence.
(Conversion factor: 1 ft = 12 in. = 0.3048 m)

If the side telescope is used for the foresight, with the instrument erect and the auxiliary telescope on the right, then the observed angle will be too small by the sum of the angle subtended by the offset and the angle of divergence. The angle subtended by the offset is computed as the arctangent of the offset divided by the horizontal distance from the instrument to the point. If the instrument were inverted the observed angle would be too great by this sum.

Similarly, if the side telescope in the erect position is used for the backsight, with the main telescope used for the foresight, the observed horizontal angle is too large by this sum.

The correct horizontal angle must be determined before calculating the coordinates of the foresight.

Top Telescope Corrections—Theoffset and the angle of divergence for the top telescope are determined in similar fashion, but using the horizontal crosshairs of the two telescopes. The calculations are similar to those of the side telescope, except that the slope distance is used in determining the angle subtended by the offset. Up angles must be increased by the sum of the angle of divergence and the angle subtended by the offset. Down angles must be diminished by this sum.

Pentaprism Calculations—The determination of the offset and the divergence, if any, for the pentaprism is similar in principle to the technique used for the side telescope but is slightly more difficult to perform. Set the instrument up on level ground, and two other tripods on line, with the tripod heads as nearly as possible on a level line passing through the telescope, the nearer tripod being slightly lower than the farther one. Place a scale on each tripod, level and perpendicular to the line of sight. Measure the distance from the instrument to each scale. Turn the telescope at right angles to this line, attach the pentaprism and level the telescope. Rotate the prism so that the intercept of the vertical crosshair and the horizontal crosshair touch the top edge of the nearer scale. Read the scale. Repeat on the more distant scale. Next invert the telescope and relevel it. Make a similar set of readings. The calculations required to obtain the divergence and the offset are illustrated with these data.

Example 8.2.1.2. See Fig. 8.2.1.1.

OA = 15 ft	D = 10.97″	F = 10.14″
OB = 31 ft	C = 1.20″	E = 0.38″
	9.77	9.76

Diff. = 0.01″

Let alpha be the angle of divergence between the true line and the bent line.

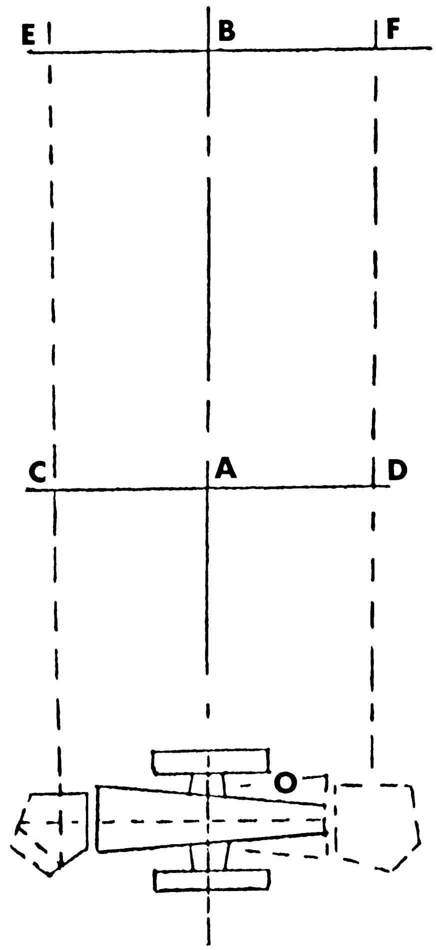

Fig. 8.2.1.1 Divergence and offset-calculations (see Example 8.2.1.1).

$$\text{Tan alpha} = \frac{-0.001}{(12(31 - 15)(2))} = -0.00002604$$

Therefore, alpha is 0° 0′ 05.4″converging.
Let x be the offset:

$$\frac{(9.76 - 9.77)}{(31 - 15)} = \frac{(9.77 - x)}{(15 - 0)}$$

Therefore, $x = 4.89$ in.
(Conversion factor: 1 ft = 12 in. = 0.3048 m)

If the line of sight in the field work is to a point lower than the instrument it will be necessary to add 90º for the bend and to subtract the sum of the divergence and the angle subtended by the offset. If the point is above the instrument it will be necessary to subtract 90º for the bend and to add the sum of the divergence and the angle subtended by the offset. The angle subtended by the offset is the arctangent of the offset divided by the inclined distance.

Calculation of Traverses: Traverse calculations, like most other mine surveying computations, are most conveniently done in the mine engineering office where calculating facilities are readily available. The equipment for such an office is described under a different heading. Such calculations as must be done in the field are greatly facilitated by the use of a pocket electronic calculator that generates trigonometric functions and utilizes several levels of storage registers.

All traverse calculations should be carefully made and recorded. The use of conventional formats for all manual calculations will help minimize errors and will facilitate checking.

Manual Reduction of Data—The averaged values of the field observations are copied into the calculation book or onto the calculation page. Care should be taken to put the data into the proper sequence, so that the foresight of the first line becomes the station of the next. If several foresights were taken from the same station, care must be taken to ensure that the right station coordinates are used in determining the coordinates of each foresight point, and that the right coordinates are used in carrying the traverse forward. It is very helpful to leave at least three blank lines between each line of data to facilitate the calculation of the azimuths, as shown in Table 8.2.1.1.

The first line of data pertains to the starting station. The azimuth shown is that from the backsight to the station and the coordinates are those of the station itself. The remaining spaces are not used. The subsequent lines are those of the successive traverse courses.

The azimuth is carried forward by adding the angle right to the previous azimuth and subtracting 180° from the sum. This compensates for the fact that the azimuth of the line from the station to the backsight is 180° different from that of the line from the backsight to the station as indicated on the previous line. If the difference is greater than 360°, subtract 360°. If the sum of the previous azimuth and the angle right is less than 180°, add 360° and then subtract the 180°, or simply add 180° to the sum. The result is the new azimuth.

If the new azimuth is greater than 9° and 90° or less, the forward line is in the northeast quadrant, so that the sine and the cosine of the bearing both have a positive sign. If the sum is between 90° and 180°, the forward line is in the southeast quadrant. The sine of the bearing will be positive, the cosine, negative. If the sum is between 180° and 270°, the forward line will be in the southwest quadrant so that both the sine and the cosine are negative. If the sum is between 270° and 360°, the forward line will be in the northwest quadrant. The sine will be positive, the cosine negative. Since the cosine of the bearing is used to determine the latitude and the sine is used to determine the departure, it is very important to determine and apply the correct sign to each.

The horizontal distance is computed by multiplying the slope distance by the cosine of the vertical angle; the vertical distance is obtained by multiplying the slope distance by the sine of the vertical angle. The cosine will always have a positive sign. The sine will be positive if the forward line is inclined upward, negative if inclined downward from the horizontal. However, if theodolites are used that have 0° at the zenith and 90° at the horizontal, it is more convenient to use the vertical angles as recorded but to multiply the slope distance by the sine of the vertical angle to get the horizontal distance and by the cosine to get the vertical distance. Angles greater than 90° have negative cosines, but the sine remains positive to 180°.

Multiplying the horizontal distance, which is always positive, by the cosine of the bearing, with the proper sign, gives the latitude of the foresight point. Multiplying by the sine gives the departure. Careful attention to the sign of each is required.

Adding, with due attention to sign, the latitude to the north coordinate of the station will produce the north coordinate of the foresight. Similarly, adding, with corresponding attention to sign, the departure to the east coordinate of the station will give the east coordinate of the foresight point.

The elevation of the foresight point is obtained by taking the elevation of the station, adding the height of instrument, adding (with due attention to sign) the vertical distance, and subtracting the height of the station. This convention works equally well on surface and underground points if it be remembered that the HI and HS are considered to be positive if the line of sight passes over them, negative if it passes under.

It is very desirable to record the trigonometric functions obtained by calculator or standard tables. This saves much time in subsequent checking of the calculations. Clarity is achieved and space is saved by writing these values on the calculation form immediately over the corresponding product, as shown in the example in Table 8.2.1.1.

Computer Reduction of Data—Much time and money can be saved and many errors avoided if the traverse calculations are done with the aid of a computer or with a programmable calculator. Greater accuracy will also be achieved. The ideal situation is for the surveyor to have access to a time-sharing terminal as this not only limits errors to those associated with typing in the data, but also permits immediate return of the results. The cost of time-sharing service is small and is trivial compared to the benefits obtained for any but the smallest mines, or those having poor telephone service.

Many of the programs needed by the mine surveyor can be obtained readily from the companies supplying the service. Others are available from the literature, the US Bureau of Mines, or other agencies. Often the user will wish to modify them somewhat, or devise his own, to better meet his particular needs.

Adjustment of Closed Traverses—The strongest type of closed traverse is one that ties in to one or more known stations and closes back on its point of origin. The tie into the known stations confirms that the azimuths and the quality of the closure into these and into the initial station indicates the quality of the work. The traverse that closed only on itself is almost as strong, but the one that closes only on previously accepted points is no stronger than the quality of the work by which the coordinates of such points were established. High-quality work requires meticulous care in closing the traverse and in eliminating the minor discrepancies that creep in in spite of the best of care in the field work and the calculations.

When closing a traverse on the initial point, it is necessary to occupy the initial point again and to turn the angle back to the original backsight. This provides a check on the quality of the angles-right that were observed. The closing error should be less than the product of the inherent error to be expected in each angle multiplied by the square root of the number of angles involved. In this case, the closing error may be distributed equally among all the angles. If the closing error is greater than this, but could still be acceptable, then it may be possible that it can be attributed to one or two difficult setups. The surveyor may have justification for placing all or most of the correction in these angles, but even so there may be uncertainty as to the quality of this judgment and its effects on the resulting coordinates of all the stations in the loop.

This uncertainty can be minimized, and the cost of correcting obvious errors can be reduced if the outgoing and returning lines of the traverse are made to cross at one or more common stations. It is usually preferable not to have the outgoing and returning lines have all common points, however, as this may result in the making and accepting of identical errors which would not be detected. The loops thus created can be considered as smaller closed traverses and any errors frequently can be localized in one or more loops, in which case additional field work may be indicated.

When the angles have been suitably adjusted so that no closure error remains, the traverse is then calculated. If this is done manually, the work is carried through the determination of the latitudes and departures before further adjustment can

begin. For a traverse closing back on its initial point, the sum of the latitudes should be zero and the sum of the departures zero. The linear discrepancy is calculated as the square root of the sum of the squares of the latitude and departure discrepancies. If the ratio of this length to the total distance traveled is smaller than that ratio that has previously been determined to be acceptable, it is appropriate to distribute the discrepancies among the various lines in proportion to their length, remembering that the incremental discrepancy corrections must all be applied in the same direction. The correction in latitude or departure for each side is calculated as:

$$\text{Correction} = \frac{\text{closure in latitude or departure}}{\text{total length of traverse}} \times \text{length of side} \tag{8.2.1.1}$$

This approach is known as the *compass rule* and is the one most commonly used.

8.2.1.4 Transferring Meridian Underground

All the underground workings of a mine must be referenced with respect to the same meridian and coordinates. This is easily done if the mine is serviced with a slope so that a traverse can be carried to each level. If it is not, other methods must be used.

Two-Shaft Method: This technique is useful when the level is accessed by two vertical shafts or raises straight enough to allow one wire to be hung in each without contact with the sides or fixtures. Piano wire is ideal for this purpose, as it combines great strength with small diameter. A heavy bob is attached to each wire. The bob may be immersed in water or oil to minimize oscillation of the wire. Care must be taken to insure that the wires hang free and that they are not excessively disturbed by air currents or falling water.

A traverse is then run to each wire from known points on the surface or on adjacent levels and elevations carried to a fixed point on or immediately adjacent to the wire. The coordinates of each wire are obtained and, by calculation, the length and azimuth of the line connecting them.

A convenient permanent station is then established on the new level, as is a permanent backsight. From this station is run a traverse to each of the wires. Arbitrary coordinates are assigned to the station, and an azimuth is assigned to the line from the backsight to the first instrument station. The coordinates of each wire are then calculated, and the bearing and distance of the line between them. The distance should be the same as previously determined, but the bearing of the calculated line will be off. The amount and direction of the discrepancy is determined, and the correction is applied to the azimuth of the assumed backsight line, making it now correct. The traverse is recalculated on the basis of the new bearing, obtaining new coordinates for the wires.

These new coordinates still differ from the true coordinates. If all the work has been well done, the differences will be the same for both wires. If they are not, the work must be redone correctly. These differences are used to correct the assumed coordinates of the initial station on the new level, after which the traverses again are recalculated. The coordinates thus obtained for each wire are identical with the true coordinates, and the coordinates of all the traverse points will be correct with respect to the mine coordinate system.

The elevation for the new level is obtained by careful taping down the vertical shaft.

Shaft Plumbing: When only one vertical shaft is available, the meridian must be carried through it. This is much more difficult because of the much shorter base line involved. Correspondingly greater care must be used. For important work it will be necessary to repeat the work a number of times to obtain the necessary precision.

Hanging the Wires—The wires should be piano wire of small diameter and should be kept on small reels for safe, easy handling. It is convenient to have the wires pass through a movable notch or aperture for easy exact positioning of the upper end. Heavy bobs are attached to the lower end to stretch the wire close to its elastic limit. These bobs may be immersed in water or oil to damp out any tendency to swing pendulum-fashion and thus bring the wire to rest more quickly. Vibration or oscillation of the wires about different nodes and planes will continue. Heavy bobs reduce the resulting difficulty of observation.

Care must be taken to insure that each wire hangs free in the shaft, touching neither the wall nor any fixture. Efforts should also be made to minimize the effect of falling water and strong air currents. If the surrounding rock contains large amounts of magnetic minerals, it may be necessary to use bronze wires to prevent attractive forces that could displace the wires slightly and warp the plane.

For deep shafts, those in excess of 3000 ft (900 m), the effect of other forces in distorting the plane may become noticeable. Gravitational attraction between the bobs and nearby masses or voids becomes increasingly important with depth because the increasing length of the wire reduces the restoring effect of gravity for a given lateral attraction. However, this problem has been eliminated by the introduction of the modern gyro-theodolite, as have most other problems associated with shaft plumbing if this equipment can be used.

Coplaning—This technique is used to put the transit and both wires into the same vertical plane. The transit is set up fairly close to the nearest wire and focused on the more distant one. Then, without turning the telescope on its vertical axis, the scope is focused on the nearer wire. The offset from the crosshair will show the operator which direction to shift the instrument to put the wire on the hair. The instrument is shifted bodily on its plate, releveled, and the process repeated until both wires coincide with the vertical crosshair. No difficulty will be experienced by the near wire obscuring the far one since the near wire will not be visible when the telescope is focused on the far one.

The point where the vertical axis of the instrument intersects the ground is then marked at the horizontal angle from a traverse station used as a backsight to the plane of the wires, is read and recorded, as are the distances to each wire and the vertical angles. The transit is then moved to the backsight station and the traverse carried forward to the temporary station just vacated.

The coplaning process is most easily done on the level from which the wires are suspended, as there is virtually no swing or vibration to interfere with the observations. Further down the shaft, however, difficulty will be experienced in bringing the wires to rest, particularly in the presence of falling water or air currents. Under such conditions it is better to use the Weisbach technique.

Weisbach Triangulation—This technique requires that the transit be set up close to, but not on, the plane of the wires, and as near the closer wire as conveniently possible. The angle subtended by the two wires should be less than 1º. The mean position of each wire must be established if they are moving or vibrating and the horizontal angle between these mean positions measured. The distances between the wires and from each wire to the transit are measured to the nearest thousandth of a foot (three-tenths of a millimeter), but accuracy to within 0.01 ft (3 mm) is sufficient for all normal work. The intersection of the vertical axis of the instrument with the ground surface is carefully marked.

With this information, the angle subtended at the far wire by the near wire and the transit can be calculated by the law of sines. In the range from 0° to 1°, the sine is a linear function of the angle, to 8 decimal places. Thus one may substitute the angle for the sine and solve for the unknown angle directly. If one knows the azimuth of the plane of the wires, it is a simple matter to obtain the azimuth of the line from the far wire to the transit. Knowing the coordinates of the far wire and the horizontal distance to the transit, the coordinates of the temporary station occupied by the transit are easily determined. The traverse from the temporary station to two permanent stations on the level is then carried forward and the task of establishing the meridian and the coordinate system on the new level is done.

The precision required in this work is a function of the accuracy demanded. For short levels, it may be sufficient to estimate the mean position of the wires, particularly if they are moving only over a short range, and to double the angles. The greater the distance between the wires, the more satisfactory this will be. For higher accuracy or for carrying long lines, greater care will be required. For maximum accuracy with the ordinary mining transit, both the interior and the exterior angles subtended by the wires should be read six times, three times erect, three times inverted; and the mean position of the wire must be determined much more carefully.

This can be done by placing a scale behind each wire, perpendicular to each line of sight. For very precise work, there should be another scale parallel to each line of sight. The observer notes a series of extreme positions for each wire, on both sides of the mean. The average is calculated and this average scale reading used for subsequent pointings of the telescope for the angular observations.

The work can be checked by moving the transit to the other side of the plane of the wires and repeating the work.

Triangulation—Sometimes it is impossible either to coplane or to use the Weisbach technique because of space or other limitations. In these cases, it is necessary to use triangulation to carry the azimuth forward from the plane of the wires. The transit is set up at a convenient point such that the triangle formed by the transit and the two wires is approximately equilateral. The distances between the wires and between each wire and the transit are carefully measured and recorded. The mean position of each wire is determined, and the angle subtended at the transit by the two wires is measured. Knowing the three distances, the cosine law can be used to find each of the angles of the triangle, and the observed angle can be compared with the calculated one as a means of estimating the quality of the work. The traverse can be carried forward from the wires through the temporary point to the two or more permanent points on the level as before, thus satisfying the requirements.

The triangulation technique is considered inferior to the Weisbach technique because of the greater inherent errors arising from difficulty in obtaining accurate distances and the role these distances play in the calculations. However, its accuracy can be improved by establishing a quadrangle, of which the wires form two of the corners, and the other two are instrument positions, permanently located. At each station the angles between the wires and between the wires and the other station are measured. The distance between the two stations is also obtained. This information, plus the known distance between the wires, allows the various unknown angles and distances to be calculated and checked. From this, the azimuth of the line between the two setup points can be determined accurately, as can their coordinates.

Use of Multiple Wires—More than two wires may be hung in the shaft. The measurements between them at depth can be used to confirm the fact that none are displaced by contact with the walls or timber. Additional planes of known azimuth are established from which the meridian can be taken and checked by methods already described and by others.

Gyro-Theodolite: The gyro-theodolite is a revolutionary instrument that simplifies the task of carrying azimuth into underground mines. It is a lightweight, self-contained apparatus giving results of great accuracy in a short time. It does not require the use of a shaft, nor does it interfere with normal mine operations if there is an unused heading of sufficient length to a backsight line. It is operated by one instrument person and a recorder. Similar units are supplied by several manufacturers.

The basic unit consists of a very precise gyroscope suspended by a short thin metallic band. The gyro is housed in a metal case that mounts on top of a theodolite. Power is supplied by a portable battery activating a converter supplying alternating current to the gyro motor. The position of the gyro is observed through an illuminated eyepiece. The gyro is clamped in position while being moved and brought up to speed.

When the rapidly revolving gyro is uncaged, its axis is horizontal and pointed toward some particular spot on the celestial sphere. The earth on which the tripod stands, however, is revolving. This, with gravity, produces a force on the gyro, to which it reacts by swinging its north end toward north. The momentum of the gyro causes it to overswing and thus to oscillate about the astronomical north line. The techniques of observation vary somewhat among the different types of instruments, but the basic approach is to find the mean position of the swing from a series of observations.

The physics of the gyro do not permit the theodolite to be used in the erect and inverted positions in order to average out any maladjustments. Consequently, these must be determined by setting up the instrument on a line of known azimuth, obtaining the angle from that line to astronomical north as indicated by the gyro, and using the difference as the correction factor. This work is commonly done on the surface before taking the equipment underground. It is important that this calibration be done within 200 to 300 ft (60 to 90 m) east or west of the point where it is to be used if calculations for the convergence of the meridians are to be avoided.

Mine coordinate systems are commonly regarded as exiting on plane surfaces, with the north-south and east-west lines being everywhere straight and at right angles. In reality, this is not true, except close to the equator. The convergence of the meridians in the temperate latitudes is perceptible to the gyro along east-west lines exceeding several hundred feet (meters) and must be compensated for either by manipulation or by calculation if the full available precision of the unit is to be achieved.

Having determined the correction constant to be used, the surveyor takes the equipment underground to the place where the azimuth is to be determined. Setting up under one permanent point he backsights another, preferably several hundred feet (meters) away. He then brings the gyro up to speed, uncages it, and proceeds to find the exact angle between his line and true north. Applying his correction, he now has the true azimuth of his fixed line. He will normally repeat the operation from the other end as a check.

It must always be remembered that when the gyro is revolving at full speed, it has stored in it a very large amount of kinetic energy. If the theodolite is revolved rapidly beyond the limits of free travel, a force will be exerted on the gyro that will cause its axis to rise out of the horizontal plane. Serious damage to the equipment may result. In extreme cases, there may even be some hazard for the operator. Therefore, the greatest of care is required. In spite of this, however, the gyro-theodolite is a rugged instrument and, when not in operation, can be handled like any other surveying instrument.

Coordinates can be brought down to the new level by means of a single wire hung in the shaft. The elevation is brought down by vertical taping. Small oscillations of the wire will not result in any error affecting normal mining operations. If greater precision is required, however, the laser can be used to establish a fixed vertical line.

Use of the Laser in Shaft Plumbing: Modern surveying in both mining and tunneling makes extensive use of the laser to extend the line of sight (8.2.1.10). In shaft plumbing, it is useful in transferring the meridian.

The helium-neon laser is a device which emits a beam of coherent red light. With simple optics, this beam can be narrowed into a slim pencil of intense light with only minor divergence. Such a beam is capable of traveling thousands of feet (meters) without loss of usable intensity. Further, commonly used laser units emit light beams containing only a few milliwatts of energy; these beams are too weak to cause permanent injury to any one looking directly into it momentarily.

If such a unit is mounted so that it projects its beam straight down a shaft onto a mirror of liquid mercury having an undisturbed surface, and the beam returns to the point of origin, it is apparent that such a beam will be truly vertical, being perpendicular to a level surface. Two such beams would define a vertical plane. By measuring to one of the beams at the surface and again underground, the coordinates could be transferred to any depth within its range.

Problems arise from density variations in the air, falling water disturbing the mercury surface, and, conceivably, from unequal masses near the mercury mirrors producing slight differences in the level surfaces. Also, it is difficult to define a sufficiently narrow point of light or shadow to define the plane accurately.

Air density variations, due to moving air currents and changing temperature and humidities, produce wavering of the light beam. Any disturbance of the mercury surface produces excessive wavering. Techniques for the successful use of laser surveying have been developed and are available from the manufacturer.

8.2.1.5 Triangulation and Trilateration

Triangulation and trilateration are surface surveying techniques for extending precise control over large areas at relatively low cost. Typical mining applications include the establishing of primary control points over the mining area and local control points within the operating areas. This control is in the form of a network of points characterized by triangles and quadrilaterals.

Triangulation is much the older of these techniques, having become feasible with the development of accurate optical instruments for the measurement of horizontal angles. Trilateration did not become a practical field technique for the measurement of large triangles until the fairly recent advent of electronic devices capable of very accurate measurement of line-of-sight distances. It is now becoming widely used.

Triangulation: The first step in the creation of a triangulation network is to establish a baseline of precisely known length and orientation, the ends of which are permanent stations in the network. Often permanent stations established by the government geodetic survey agency can be used; otherwise, it is necessary to establish a new base line, measuring the distance between the ends with very great care. Other permanent stations then are established to the sides in convenient positions to build up the desired network of triangles. The triangles should have no angles less than approximately 30° or larger than 120°. If possible the triangles should form quadrilaterals, the corners of which are all mutually intervisible, since a network of quadrilaterals is much stronger than a network consisting only of triangles.

Each corner of the triangle or quadrilateral is then occupied in succession for the measurement of the angles. If at all possible a modern theodolite should be used, graduated to seconds, as this produces much better work at lower cost than does the ordinary transit. If the transit must be used, it is necessary to increase the precision of the measurement by repetition. Six repetitions will determine the angle to ± 10″; 12 will reduce the uncertainty to ± 5″, at the expense of a much longer time for observation. The nature of the job will determine how much precision is required. Most mine surveys will not require or benefit from angular precision greater than 1″, which is readily obtainable with the theodolite.

It is always desirable to measure both the interior and the exterior angles, the sum of which should be 360°, plus or minus no more than the inherent uncertainty in the measurement of each angle multiplied by the square root of the number of angles. This test should be made before leaving the station.

Calculations—Each triangle should be solved using the following steps:

1. Balance the quadrilaterals to comply with the geometric requirements. Each can be divided into four overlapping triangles consisting of two quad sides and a diagonal. The interior angles of each triangle must total 180°. The diagonals cross each other, creating equal opposite angles. Thus, the sums of the remaining angles in the smaller triangles so created must also be equal. Lastly, the sum of all the interior angles of the quadrilateral must be 360°. Adjustment of the angles to meet these conditions does not necessarily produce exactly correct angles, but if the theodolite was used for the initial measurements, the discrepancies will be trivial for most applications.

2. Using the corrected angles, work out the azimuth of each of the lines, starting from the known line, going around each triangle, and coming back to the known line with no discrepancy.

3. Use the sine law to find the lengths of the unknown sides, starting with the known side:

$$\frac{\text{Sine A}}{\text{Side a}} = \frac{\text{Sine B}}{\text{Side b}} = \frac{\text{Sine C}}{\text{Side c}} \tag{8.2.1.2}$$

where side a is opposite angle A, b opposite angle B, etc.

4. Compute the latitude and departure of each line from its length and azimuth.

5. Determine the coordinates of the unknown point by adding the latitude to the north coordinate of the known point, the departure to the east coordinate. The coordinates of the unknown point should be determined twice, using each side line. If the work has been well done, using eight-place trigonometric tables, the coordinates thus determined should ordinarily check within about 0.02 ft (6 mm).

6. If a quadrilateral is involved an additional check is available. Compute the coordinates of each unknown corner, using a triangle based on the known line. Then compute the coordinates of one of the corners from the coordinates of a known station and the computed coordinates of the other unknown station. If these check, it is proof that the field work and the calculations were all well done.

If the project is so extensive or requires such precision that the foregoing steps are not sufficiently precise, the user should use the more elaborate methods of balancing described in texts on plane surveying and geodesy.

Trilateration: Trilateration, as the term is used here, requires the use of a properly calibrated electronic distance-measuring instrument and accessories. This will commonly involve a laser or infrared carrier-beam transmitting unit and one or more cube-corner reflecting prisms as a means of determining vertical angles accurately. The transmitting unit and reflectors are used with standard surveying tripods and tribrachs interchangeably with theodolites and targets. Time will be saved if several reflecting units and tripods are available so that one can be set on each point to be observed from a given station. Two-way radio transmitters are a most useful accessory for rapid communication.

In practice the transmitter and the reflectors are set up and centered over the points. The height of the emitted beam and of the reflecting point should both be read and the vertical angle determined. Using an altimeter, the elevation of the transmitter station should be obtained, as well as the air temperature, and corresponding adjustments made to the equipment. The transmitter is then pointed at the reflector and adjusted for maximum return signal. The distance is then measured by proper manipulation of the controls. This measured inclined distance is corrected by application of the calibration constants for the emitter and the reflector. Each line should be measured several times and the average used.

Calculations—The coordinates of each point are found as follows:

1. Reduce the inclined distances to the corresponding horizontal distances using the proper vertical angle.
2. Use the cosine law to solve for each of the internal angles of each triangle.
3. Work out the azimuth of each line and the latitude and departure of the unknown points.
4. Add a latitude and departure of each line to the north and east coordinates of the known end to get the coordinates of the unknown point. Each unknown should be computed from at least two known points and the coordinates should check closely.

Trigonometric Leveling: With suitable care the levels of the new stations can be approximated quite closely by trigonometric leveling. The vertical angles forward and backward from each station to the others in a triangle are measured with the theodolite. The height of instrument is measured each time, as is the height of the sighting point. The difference in vertical elevation between the instrument and the sighting point is determined from the inclined or horizontal distance and the vertical angle. From this and the HI and HS measurements the elevation of the new point is obtained. If the work is properly done, there will be two forward and two backward lines converging on the same point. The elevations indicated by these lines should agree closely, the average being used as a close approximation of the true elevation of the new point.

8.2.1.6 Field Notes

The importance of taking legible field notes and of keeping comprehensive notebooks cannot be overemphasized. The surveyor's work is commonly varied, involving many aspects of an operation that may have a long life. His measurements may be the only record of an original situation that is later affected by subsequent mining operations. It is frequently necessary to consult old notes for any of many different reasons. Hence the importance of making the notes taken so clear and explicit that others, years hence, will have no difficulty in reading them and in knowing exactly what was done. Completed notebooks should be preserved.

Different organizations utilize different means of taking and keeping notes. Some use hard-bound notebooks; others prefer loose-leaf pages that can be filed according to the level or section to which they pertain. The format of the data recorded also varies somewhat. The important thing is that notes for each job record the nature of the work, the place, the date, the people involved, the equipment used, and the conditions under which the work was done. The data kept must be clear, complete, and consistent. They should be accompanied by a neat sketch showing the situation. References should be made to related notes that may pertain to the same work or problem. No erasures should be made; errors should be canceled by being crossed-out and the data reentered on a new line. The data should be taken with a sharp, medium-hard pencil, and care should be taken to avoid smudging as far as possible. A table of contents should be kept in the front of the notebook, listing all the work.

8.2.1.7 Calculations

The mine surveyor should develop the habit of making all his calculations in a bound workbook, except for those that are required in loose-leaf form for convenient filing. As these books become filled, they should be indexed and filed for easy back reference.

Each page should be captioned with the name of the calculation, the purpose, the situation to which it refers, the name of the person doing the calculation, and the date. If the work involves computer printouts or calculator tapes, it is wise to attach these in appropriate fashion. The goal is to facilitate the work, to be meticulously accurate, and to leave a record so complete that subsequent readers will have no difficulty in understanding what was done and in checking the work. Neatness and clarity are essential attributes of a good calculation book.

8.2.1.8 Maps and Sections

Formerly all mine maps were hand-drawn. Now, however, with the ever-increasing use of computer graphics, many maps are produced by plotters. Even so, there is continual need for updating maps manually. One of the best practices is to put the grid and all permanent detail on mylar sheets or other high-quality translucent stock. This then can easily be reproduced or copied on paper or vellum. Secondary tracings made in this way can be completed in various ways to accentuate certain types of detail and can themselves serve as masters for subsequent families of tracings and prints.

Great care should always be taken in laying out the original grids to make sure that the horizontal and vertical lines are exactly perpendicular and that the lines are exactly spaced. Only if this is correctly done can the subsequent work be plotted properly.

Each map should be numbered and the master tracing indexed and filed for easy reference and recovery. Storage should be in a fireproof vault. Very important maps should also be microfilmed and the films stored in a different location for greater security. Working copies are easily reproduced or copied as needed.

8.2.1.9 Computer Calculations

A wide variety of computer programs for solving surveying problems is available from computer manufacturers, computer service organizations, and proprietary sources. A similar variety is available for use with the smaller desk-top stored-program calculators. These programs are easy to use, fast, and accurate, and make obsolete the calculation of traverses and other routine problems by manual means except in emergencies. Programs of this kind should be used as much as possible to reduce errors and increase productivity.

8.2.1.10 Innovations in Instrumentation

New technology has kept pace with the surveying profession as well as other aspects of mining. Surveying accuracy, distance, and recording features have been enhanced with the introduction of both electronic and laser technology. These features are especially useful on surface projects such as refuse piles, roads, ponds, plants, land and property traversing, and pipelines.

Electrical transits, capable of high degrees of accuracy, are now readily available for use in rugged environments. These transits carry batteries for improving optical prism angles and often combine with straightforward numerical keypads for transit control. Keyboard commands give the operator access to on-board software designed to provide the broadest range of capabilities within cost limits. The software can include selection of angles, slope distance, horizontal angles, height measurement, missing line measurement, remote elevation measurement, northing and easting, and setting-out functions. These transits very often carry RS-232 output ports to interface with office computers.

Electronic distance measuring instruments (EDMs) are electronic instruments that either attach to the transit (or theodolite) or stand alone for one purpose, and that is to measure the horizontal distance between two stations with remarkable accuracy (8.2.1.3). Using infrared light beams, one type of attachable EDM instrument bounces the light between stations and measures the time required to send and receive the signal. Another type of EDM is free standing and uses the principle of phase difference comparison between the emitted-to-received modulated light beam of a xenon gas lamp. From either application, distance can be reduced to a high degree of accuracy. The EDM is usually battery operated and is designed for at least 4 to 6 hr of continuous work.

Laser based technology is widely accepted for high-precision work such as vertical shaft sinking or driving inclined or horizontal slopes or tunnels. Lasers are also being used as intermediate sight instruments for face advances up to 1000 ft (300 m). An infrared laser beam is projected from a preconstructed, battery-operated tube hung from a string attached to a station and driving spad. The tube and battery are considered permissible, and a magnetic switch is used to turn the beam on and off.

8.2.2 AERIAL MAPPING

BERNARD W. SOLOMON

The purpose of this chapter segment is to assist engineers in the development and acquisition of aerial mapping and mapping control surveying services. It further covers geodetic, monumented, vertical, and horizontal control networks required of new field development and expansion or routine development of mapping for operations such as disposal site development, coal storage monitoring, design and construction of surface support systems, etc.

This segment is concluded by an appendix that discusses contract specifications for aerial mapping.

8.2.2.1 Aerial Camera Types and Evaluation Criteria

There are three types of camera systems currently used in aerial mapping production:

1. Older type cameras with metrogen lens or planigon conversions.
2. Newer precision cameras with planigon lens.
3. Image motion precision cameras that limit motion distortion under low altitude and limited light conditions.

Camera manufacturers in each category include:

1. Fairchild K17 and T11 series (T-12 is a planigon conversion).
2. Wild RC 8, 10, & 10A; Zeiss RMK 15/23, RMKA 15/23; Jena MRB.
3. Wild RC 20; Zeiss RMKA 15/23 IMC; Jena LMK.

Older type cameras are cameras with metrogen lens developed, manufactured, and modified during the 1930s, 40s, and 50s. They have limited aperture and shutter characteristics, which limit their ability to produce quality imagery over the entire photograph. This is due to shutter-design lens distortion and lens resolution qualities. The shutter design causes uneven lighting characteristics over the negative area. These cameras should not be used for high-quality mapping requirements. Even cameras that have been retrofitted with new planigon lens still have resolution and shutter limitations that make them inferior as compared to current-day-technology cameras.

The newer precision cameras manufactured since the 1960s have the f 5.6 aperture lens and even newer f 4 aperture lens. They have superior distortion and resolution characteristics as well as effective shutter designs. These cameras are better suited for quality mapping than their predecessors. Lens distortion is reduced to a minimum, and resolution is increased to provide extremely sharp photography translating to more accurate maps. The new shutter designs also provide even lighting distribution over the negative that enhances image quality.

Image motion cameras are the newest generation in camera development. They have been designed to reduce the image motion inherent in aerial photography because of the forward motion of the aircraft camera platform. Though this camera has the ability to produce better quality imagery under very low-altitude and limited-light conditions, it is doubtful that the quality is noticeably enhanced over the f 4 lens cameras under good lighting conditions.

Regardless of the camera system that is used, the camera should meet the following minimum standards as reported in camera calibration reports, issued by the USGS Calibration Laboratory, under the following headings.

Focal Length: 153 + 3 mm (6-in. lens).

Radial Distortion: No reading shall exceed 10; one-half of all readings shall be less than 6.

Area-weighted Average Resolution: Minimum 70.

Model Flatness: The highest plus reading and highest minus reading combined shall not exceed 24; no reading shall exceed 15.

Fiducials: Cameras are equipped with at least 4 and a maximum of 8; only 4 are required for the newer analytic control programs.

Aerial cameras are also designed with different focal lengths for various applications. Longer focal lengths such as 8¼, 12, 24 in. (210, 304, 610 mm), etc., are designed to reduce terrain distortion when only photo imagery is desired. Also the super wide angle, 3½-in. (89-mm) lens can be used by some mapping instruments for topography generation. This camera configuration should only be used in flat to rolling terrain and where there exists a limited number of tall structures. This is due to the large distortion effect this lens has on any vertical feature such as steep grades and tall structures.

8.2.2.2 Film Types and Uses

Should the user require other film uses beside basic mapping, the following film types and basic characteristics are provided.

Black and White Film: Black and white (Kodak 2405) Double X Aerographic film is the most popular film medium in the industry and is used for both mapping and photointerpretation projects.

Color Film: Color film (Kodak 2445) can be processed as either a positive or negative and is used for cosmetic and photointerpretation reasons where black and white photography will not suffice. It is a matter of dispute among stereo compilers whether or not color photography assists or hinders the stereo mapping process. Color photography requires better lighting conditions for exposure, and along with color processing and material costs, makes color photography more expensive to provide.

Infrared Film: In addition to color and black and white photography, two other film types are available. They are used basically for photointerpretive purposes. Color infrared (IR) films (Kodak 2424) are used mainly in vegetation and timbering types of photo interpretation projects and also can be processed for mapping purposes.

Black and white IR is also useful in determining shallow or minor water areas and swamp type conditions, in that water appears very black in the imagery.

Image Motion Photography: Two other types of black and white film, with finer-grained emulsion characteristics, are used in mapping in conjunction with the new image motion cameras. They are Plus X and Panatomic X films.

8.2.2.3 Photo-scale to Map-scale Ratios

In the competitive commercial world of aerial mapping, it is common—more so in the United States than in any other country—to stretch the vertical resolving limits of the stereo compilation equipment by flying higher in order to be more competitive. This is done, with disregard to the resultant decrease in map accuracies, in the interest of cost savings.

There are two primary factors in determining the proper photo-scale to map-scale ratio. One factor is the vertical resolving power of the stereo plotting instrument and the other is the ability to properly discern the physical features of the planimetric detail to be shown on the map. Because photogrammetry is a visual science, the better the stereo operator can see the ground and its features, then the more accurately the details can be measured and plotted. A camera is similar to the human eye (in the respect that the closer it is to an object, the better it sees the object), thus lower-altitude photography will produce more accurate and more detailed maps.

Certain constraints should be adhered to when using current technology optic train stereo plotters and aerial cameras with 6-in. (150-mm) nominal focal length for aerial mapping work. Basic map accuracy standards can be readily achieved if the following limitations are observed.

For horizontal accuracy and detail completeness, the ratio between the photo scale and map scale should not exceed five or six diameters. Example: 1 in. = 100 ft mapping equals 1 in. = 500 ft or 1 in. = 600 ft photography (1 mm = 1.2 m mapping equals 1 mm = 6.0 m or 1 mm = 7.2 m photography.) A smaller physical feature can be more readily seen and accurately measured by a smaller ratio.

For contours and vertical measurements, a C (contour) factor of 1500 to 2000 is recommended. This ratio is a factor of aircraft altitude. The altitude of an aircraft can be determined by multiplying the photo scale times six. The correct contour interval is determined by dividing the aircraft altitude by the C factor. Example: photoscale = 1 in. = 300 ft × 6 = 1800 ft, which is the altitude, divided by 1800 C factor = 1 ft contour.

The basic photo scale to contour convention involves the following:

l-ft (0.3-m) contours: 1 in. = 250 ft to 1 in. = 300 ft scale photography (1 mm = 3.0 m to 1 mm = 3.6 m).

2-ft (0.6-m) contours: 1 in. = 500 ft to 1 in. = 600 ft scale photography (1 mm = 6.0 m to 1 mm = 7.2 m)

5-ft (1.5-m) contours: 1 in. = 1000 ft to 1 in. = 1200 ft scale photography (1 mm = 12.0 m to 1 mm = 14.4 m).

Where minimum planimetric features exist in the project area, photography as high as 1 in. = 1500 ft (1 mm = 18 m) could be used for 5-ft (1.5-m) contours.

8.2.2.4 Seasonal Affects on Aerial Mapping

Photogrammetry is the science of vision and film imagery. Precision measurements require sharp and distinct images. Therefore, any impediments to sharp images, such as shadows, obstructions, poor light, and parallax, will cause accuracy problems wherever they occur.

Let us review the problems, one at a time, to understand their impact on accuracy. Such an understanding can lead to preplanning to minimize the negative effects to the overall project.

Shadows are a direct result of sun angle. The lower the sun angle, the longer the shadows and the deeper are their intensity. Unfortunately, the best sun angle occurs (June 22) during the foliage time of the year where deciduous trees and plants exist. Therefore, photography must be obtained as soon after leaf fall or just before foliage regrows to receive the best sun angles. Since the sun angle is already quite low when the leaves fall, the best time of year for good results is in the spring.

When the sun angle is lowest (December 22) or when it drops below 30º to the horizon, there is limited residual light for good sharp photography. During this period, shadows are extremely deep so features and ground surfaces in wooded areas cannot be seen properly. Shadows are a definite problem, for example, in rough terrain, where large buildings exist, in evergreen forested areas, etc.

Obstructions are another problem in attaining sharp, clear imagery. They include such things as foliated trees and plants, evergreen trees, snow, weeds, brush, buildings, overpasses, etc. Obstructions such as ground foliage and oak tree stands is another reason that spring photography is better. Rain, snow, and wind action better defoliates and compacts foliage obstructions during the winter months. Depending on map details and accuracy requirements, a certain amount of field survey completion may be required due to such obstructions.

In conclusion, close scrutiny of the aerial photos will provide a good idea of map accuracy and completeness. If ground features on the photo cannot be seen for any of the foregoing reasons, the chances are neither can the stereo compilation technician see them. Such areas would thus be prime places for field inspection and checking.

8.2.2.5 Control Placement Procedures

Ground control is required to scale and level each stereo model that comprises a project. The ground control for each stereo model within a project must be tied to the same horizontal and vertical network. As with good surveying practices, it is recommended that all circuits (vertical and horizontal) begin and end on different benchmarks and monuments. Ground control can be preestablished and pretargeted prior to flight or run after the flight to photo-identifiable points. Pretargeting is more positive and accurate, but properly identified physical features can be just as accurate and usually established with less cost and planning effort.

There are two types of control procedures. One is conventional full-model control that requires the field survey crew to occupy each of the numerous points in each stereo model. The other is analytical control that requires a limited number of points to be occupied in each group of models by the field survey crew. By using these limited number of points and specialized office instruments and computer programs, the values of the remaining required points can be computed.

Each stereo model is made up of the overlap area created by two adjacent stereo photos; the size of the area is basically 6.3 in. (160 mm) wide (perpendicular to the line of flight) and 3.6 in. (90 mm) long (parallel to the line of flight). This rectangle location is controlled by the nadir (center) point of each photo. The model lays between the nadir points of adjacent photos and 3.15 in. (80 mm) (perpendicular to the flight line) on each side of the nadir points. Photo control for each model must fall within these limits. The minimum points per model are as follows.

Vertical control requires four points per stereo model. They must be located as close to the model corners as possible. When adjacent stereo models are involved, it is recommended that two points controlling the adjacent edges of each model be visible in each model. In multiple model projects, the addition of two extra points per extra model edge placement requirement is met.

Horizontal control requires a minimum of three points in each single model project and two additional points in each additional model of the project. These points can be located in any portion of the model area but should be as far apart as possible. By locating the points along model edges, the points can be used for adjacent models so that if one model requires three points, two models will only require four points, and so forth.

The location of photo control points within each model is flexible to some degree. If points are not obtainable at a certain location, it may be possible to relocate the point without harm to its value to the model. Such movement should be performed only by a qualified person.

Preproject planning with the objective of deciding whether or not to pretarget or use photo-identifiable points is important. Photo-identifiable points are more efficient in areas where such points exist and can be readily identified. A project would not be recommended for this procedure if it were in a heavily forested area where one tree looks similar to another on the photo. Also one would not hope to find points in large open grasslands or agriculture areas where no distinguishable features exist. Such areas would require pretargeting. Pretargeting is also recommended for existing ground control that is in or adjacent to the project area.

Photo-identifiable horizontal points must be sharp features, such as intersecting white lines, sidewalk intersections, utility poles, etc. Vertical control points can be less distinct, but must be in relatively flat or in gently sloping areas, such as center of road intersections, edges of pavement, opposite poles, etc.

Misidentification is the most significant problem of photo-identifiable points. This means the survey crew has not located the exact point that the photogrammetrist intended. This requires skill on the part of the crew to occupy points only that they believe will not be misinterpreted by the stereo compiler who has not been to the site.

For instance, for horizontal points, if one utility pole in a long line of poles is being located, care must be exercised so that the correct pole is selected. Also, if it appears the pole has been freshly set, advise the photogrammetrist since it could have been relocated since the photo was taken.

For vertical points, in selecting the center of an intersection, if it so happens that at that point there is a deep pothole, do not locate the point at the bottom of the pothole. Obtain the elevation of the point at the average normal pavement surface adjacent to the pothole.

8.2.2.6 Targeting for Photo Control

Although pretargeting is the most positive and accurate procedure, it is not without drawbacks. The procedure is more expensive since additional employee-hours are involved to set and monitor the points prior to the flight and to retrieve the targets after the flight. Targets are subject to wind, vandalism, and other disturbances that can render them unusable unless they are monitored just prior to the flight.

Target materials can be large plastic sheeting, paper, cloth, wood, lime, rock dust, etc. Aluminum foil or any other reflective material should not be used. The best colors are white in contrasting areas of grass, black top, forest floors, etc., and black for contrasting areas such as dry earth, etc. Fluorescent orange should not be used in grass areas for black and white photography since this color is in the same grey spectrum as grass.

The best shapes for control are chevrons, Ts, and crosses. Circles can be used if the point is only for vertical control. When targeting to locate a feature such as a manhole, the best approach is to outline the feature with a 6- to 12-in. (150- to 300-mm) outline, depending on the photo scale.

The following information on target sizes and shapes will be of assistance:

Negative Scale	Thickness of Leg	Length of Legs
1 in. = 150 ft to 1 in. = 300 ft (1 mm = 1.8 to 3.6 m)	1 ft (0.3 m)	2 to 3 ft. (0.6 to 0.9 m)
1 in. = 350 ft to 1 in. = 500 ft (1 mm = 4.2 to 6.0 m)	1 ft (0.3 m)	3 to 4 ft (0.9 to 1.2 m)
1 in. = 500 ft to 1 in. = 800 ft (1 mm = 6.0 to 9.6 m)	2 ft (0.6 m)	4 to 5 ft (1.2 to 1.5 m)
1 in. = 1000 ft to 1 in. = 1200 ft (1 mm = 12.0 to 14.4 m)	2.5 ft (0.8 m)	8 to 10 ft (2.4 to 3.0 m)
over 1 in. = 1200 ft (1 mm = 14.4 m)		

Target leg length should be 1% of photo scale, and the width of each leg should be 30 to 36 in. (760 to 1080 mm).

1. The targets are placed so that the point being targeted is at the center intersection of the panels, with the exception of the

L or chevron panel. On the L or chevron panel, the point being marked is the intersection of the inside edges of the material.

2. Plastic flagging materials should be avoided for paneling purposes in grazing areas. Grazing animals eat certain types of plastic flagging.

3. In wooded areas, the length of the target panels should be doubled.

4. Any panel being used as a vertical target must be placed in a relatively flat or gently sloping area.

8.2.2.7 Ground Control Surveying Procedures

Photogrammetric ground control is accomplished with standard surveying equipment and procedures. It involves the systematic completion of both horizontal and vertical networks that provide scale and elevation points to strategic locations for the stereoscopic model scale and leveling.

Horizontal scale can be accomplished by measured horizontal distances between chosen control points or the establishment of coordinates using various accepted procedures. Closed traverse coordinate control is the preferred procedure. Coordinate networks can be established by conventional traverse, triangulation, inertial guidance, or satellite positioning (GPS) instrumentation.

Vertical control can be established by differential leveling, vertical angle, barometric, inertial guidance, or satellite positioning instrumentation.

Both vertical and horizontal networks can be tied to existing state plane coordinate systems and NGS vertical datums or independent arbitrary systems. It is very important that each total project is based on only one network or datum and that the correct equipment and procedures are used that yield the required accuracy of the map scale and contour interval.

Accuracy requirements for aerial mapping ground control are as follows:

1. Horizontal control is to be accurate to $^1/_{100}$ of the map scale.

2. Vertical control is to be accurate to $^1/_{10}$ of the contour interval.

Both of these accuracies can normally be achieved by third-order, class-one procedures.

8.2.2.8 Stereoscopic Compilation

There are three basic generations of stereoscopic (aerial mapping) equipment. They are (1) the anaglyphic analog (Kelsh type), (2) the optic train analog, and (3) the analytic. Although types 2 and 3 are the rule in most mapping firms and other mapping-related organizations, there are still a few type-1 instruments in use today. The following contour factor and scale ratio for each instrument type will better assure accurate mapping, even though many maps are being prepared from higher factor and ratio photography:

Type	Scale Ratio	Vertical Factor
1	4× to 5×	1200 to 1500
2	5× to 6×	1500 to 1800
3	6× to 7×	2000 to 2800

All stereo mapping instruments require periodic recalibration. Any prudent, quality-control-conscious mapper will make recalibration checks by both internal personnel and manufacturer personnel a routine matter. Internal checks should be made monthly, and manufacturer checks should be made every three years, or when internal checks indicate the instrument needs professional checking.

Normal map-scale to contour-interval ratios fall into the following basic convention:

Photo Scale	Map Scale	Contour Interval
1 in. = 200 ft to 1 in. = 300 ft (1 mm = 2.4 to 3.6 m)	1 in. = 20 to 50 ft (1 mm = 0.24 to 0.60 m)	1 ft (0.3 m)
1 in. = 500 ft to 1 in. = 600 ft (1 mm = 6.0 to 7.2 m)	1 in. = 100 ft (1 mm = 1.2 m)	2 ft (0.6 m)
1 in. = 1000 ft to 1 in. = 1200 ft (1 mm = 12.0 to 14.4 m)	1 in. = 200 ft (1 mm = 2.4 m)	5 ft (1.5 m)
1 in. = 2000 ft to 1 in. = 2400 ft (1 mm = 24.0 to 28.8 m)	1 in. = 400 ft (1 mm = 4.8 m)	10 ft (3.0 m)

Due to user needs, it is not uncommon for variations of the foregoing to be used. It is wise to remember that the photo-to-map conventional plotting ratio determines the map accuracy, and any enlargement or reduction of the nominal plotting scale will affect the size of the map but will not change the accuracy.

The basic scale and contour interval accepted standards follow. Although these are taken from the US Department of Transportation's *Guidelines for Aerial Mapping,* they are very close to and considered by some users to be "national map accuracy standards."

1. *Contours.* Ninety percent of the elevations determined from the solid-line contours of the topographic maps shall have an accuracy with respect to true elevation of one-half contour interval or better, and the remaining 10% of such elevations shall not be in error by more than one contour interval. This accuracy shall apply only to the contours that are on each map. Thus, in each particular area where the intermediate contours have been omitted because of the steepness of the ground slopes, and only the index contours are delineated on the maps, the accuracy stipulations apply to the contour interval of the index contours. Wherever the intermediate contours are not omitted, the accuracies are applicable to the contour interval specified for the topographic maps. In densely wooded areas where heavy brush or tree cover fully obscures the ground, and the contours are shown as dashed lines,* they shall be plotted from the stereoscopic model, while making full use of spot elevations measured photogrammetrically in places where the ground is visible.

* Author's Note: Dashed contour lines are used to indicate the contour placement is the best judgment of the map compiler and the foregoing accuracies may not apply.

2. *Coordinate Grid Lines.* The plotted position of each plane coordinate grid line shall not vary by more than $^1/_{100}$ in. (0.25 mm) from true grid value on each map manuscript.

3. *Horizontal Control.* Each horizontal control point shall be plotted on the map manuscript within the coordinate grid in which it should lie to an accuracy of $^1/_{100}$ in. (0.25 mm) of its true position as expressed by the plane coordinates for the point.

4. *Planimetric Features.* Ninety percent of all planimetric features that are well-defined on the photographs shall be plotted so that their position on the finished maps shall be accurate to within at least $^1/_{40}$ in. (0.64 mm) of their true coordinate position, and none of the features shall be misplaced on the finished map by more than $^1/_{20}$ in. (1.27 mm) from their true coordinate position.

5. *Spot Elevation.* Ninety percent of all spot elevations placed on the maps shall be accurate to one-quarter of the contour interval, and the remaining 10% shall not exceed one-half the contour interval.

8.2.2.9 Graphics and Drafting

Graphics or the finished map presentation comes in many forms. They include (1) pencil manuscript, (2) ink drafted, (3) scribe drafted, (4) laser or electrostatic drafted, and (5) digital formatted. The current media can be paper, vellum, mylar, tapes, or floppy disks.

Descriptions are as follows:

1. *Pencil Manuscript.* The end product is usually on one- or two-sided, matte-finished mylar and is in pencil or ballpoint ink. The graphics are the freehand result of the stereo operator, with little or no attempt at finish drafted quality.

2. *Ink Drafted.* Usually entails drafting with cartographic ink equipment on mylar with mechanical lettering and the finished qualities of a skilled cartographic draftsperson.

3. *Scribe Drafting.* Presents the same type of finished drawing as ink drafted, with the exception that all line weights are standardized by the designated scribe points and cutters. Scribing insures standard line weights, regardless of the drafter. Also scribe line work then becomes a photographic image and is part of the reverse side of the mylar emulsion, rather than ink being applied to the emulsion surface.

4. *Laser or electrostatic drafted.* These are the most recent generation of plotters. The laser plotter provides a solid line image, while the electrostatic plotter provides a screened line image of various dot density, depending on the plotter design.

5. *Digital Data.* These data are provided in user software language. It is the responsibility of the user to clearly designate the exact design language or standard interchange format that their software requires.

8.2.2.10 Digital Mapping

With the advent of computer-aided drafting (CAD) came a new need for aerial mapping output. Due to various advanced data collection systems that are available for stereo plotters, it is now possible to provide maps in digital form for computer-aided drafting and design (CADD) requirements.

A popular characteristic is the ability to layer features. This permits the land features to be stored in separate layers so the CAD user can display or plot individual features in an overlay fashion. Coding of lines for different line weights, symbols, and colors can also be provided. Digital mapping data can be structured for both the mainframe or personal computer (PC) systems.

Since there are many more types of host systems available than collection systems, it is necessary to do file conversions. Although there are some good conversion software available for the more prevalent systems, file conversion is a very real problem that needs to be resolved prior to starting into a digital mapping project. File structure differences between mainframe and PC systems can also present problems between collection and use systems. A sample disk or tape for trial use on the intended system is recommended.

File structures can also be designed to include 2D, Z and one-half D (2D tagged Z), or 3D data. The differences are as follows:

1. 2D files will provide feature data with X and Y values only. This will provide only the ability to recreate lines, but will give no intelligence for vertical data.

2. 2 and one-half D or 2D tagged Z will provide files with both vertical and horizontal intelligence, but the vertical intelligence will be limited to visual numeric titles for all contours and spot elevations.

3. 3D will provide feature data with X, Y, and Z intelligence so the database can be used directly for such things as earthwork volume computations and grade design information with available CAD software.

It should be noted that 3D file structures can be burdensome to PC systems and should be carefully considered. A successful alternate would be to use 2D tagged Z files and to upgrade small areas of use to 3D by windowing and enhancing the data on the user system.

8.2.2.11 Field Completion and Checking Procedures

There are many reasons that ground features can be obscured from view on an aerial photo. These include foliage, shadows, overhanging structures, etc. All these conditions cause the stereo instrument operators to use their best judgment or leave out data altogether. This causes the need for field completion and field checking.

The field completion is accomplished by using field surveying techniques and locating the missing features by coordinate and elevation to be plotted on the final map. This works best when accomplished after the map is complete. The use of autorecording "total station" surveying equipment and "digital terrain model" software has greatly improved both the cost and accuracy of this procedure.

Since errors or omissions can occur in any science, it is prudent to field check all maps before they are relied upon for engineering and constructions computations. It is wise to assume that any map that is not checked is wrong.

Field checking for physical features includes the establishment of a traverse to the features to be checked to obtain true coordinate positions. Checking for contours includes the establishment of a cross section to locate each contour that crosses as perpendicular as possible to at least 10 contours.

All control checks must start and end on control points that were established for the original mapping.

Field checking and field completion are normally options in any mapping project and must be requested. This practice is due to the normal requirement of a nonbiased checking procedure.

8.2.2.12 Volumes

Utilizing aerial mapping for volume determination is a proven and reliable procedure, relied on by many. The two basic methods that are employed are (1) the horizontal slice using an equal planes computation, and (2) the vertical slice using an end area computation.

The horizontal slice is used more often in that it involves the preparation of a contour map normally required as an end product. With current equipment and technology, the stereo plotter is enhanced with a digital collection device attached to a small computer which reduces human error. Each contour is compiled by conventional means, and the digital collection system collects and stores the area of each contour slice as it is completed. A simple program then computes the volume of the pile. A base computation is then required to provide quantitative values to the underside of the pile that is not visible by aerial photography. The procedure requires the digital input from a base contour map or base map with grid elevation points. Care must be exercised to guarantee both the contours produced in the quantity collection phase and the base map are on the same datum and grid system.

One- and two-foot (0.3-and 0.6-m) contours are recommended for accuracy requirements of valuable material such as coal and limestone. One-foot (0.3-m) contours should be used in gentle slope areas, limiting 2-ft (0.6-m) contours to steep slopes.

The vertical slice procedure differs only in that the computations are done by an average end area method based in elevation data obtained by cross sections. If the cross-sectional method is employed, the closeness of sections impacts the accuracy. Ten-foot (3-m) intervals between cross sections plus added sections at major breaks provide more reliable results than using sections with greater intervals.

A cross-sectional collection system replaces the quantitizer of the horizontal procedure, but all other automated aspects should remain the same including the base map treatment.

Both procedures yield basically the same accuracies when properly constrained.

To eliminate one major cause of discrepancy in comparing repetitive volume studies of the same pile, it is important to include all material that exists above the base in each inventory. It is normal for material to exist beyond the toe of slope in any material storage area. Mostly this material is considered unusable. If this material is ignored in one inventory and the pile enlarges to cover it in the next inventory, there will exist a quantity error when comparing the aerial volumes to those obtained by other sources such as scale readings, production reports, etc.

Aerial inventory procedures have been proven to be reliable within 2% on the average pile configuration. The accuracy is affected by the ratio of volume to pile surface. Piles that have a large surface and a shallow depth provide a lesser accuracy percentage than compact piles of greater depth.

The vertical slice procedure does not produce a contour map, and an additional step must be accomplished. This would include the compilation of a map by conventional aerial methods or using the cross section data with digital terrain model (DTM) software to create a topo map.

8.2.2.13 Ortho Photography

Ortho photography is the product of a procedure that corrects the distortions that exist in all aerial photography. These distortions exist due to the instability of the camera platform (aircraft), the terrain relief, and the angle of the light rays entering the camera lens.

The ortho instrumentation attached to a stereo plotting instrument is designed to semi-automatically relieve these distortions. The equipment is monitored by a stereo operator as it transfers the photo image from the original aerial negative to a new negative. The function of the equipment is to rectify the image in this transfer process so as to reposition it orthographically in its correct plane position. The resulting negative now has the total image restored to its correct coordinate position to "national map accuracy standards" (see 8.2.2.8).

The negative can now be processed to either a paper or mylar media in positive form. Photo scales can be adjusted by enlargers and copy cameras to any desired scale.

Since the photo has been rectified to the accuracy of a map, contours can be applied by drafting in ink on the mylar, creating a black line or by a positive overlay method creating a white contour. Since both black and white images occur on a photo, some problems of contour legibility will exist with either procedure. A third process involving an overlay lab procedure will produce a black contour with a white halo so the contour can be seen in either condition.

Two other shortcomings of the process are as follows:

1. The rectified negative is not as sharp as the original negative since it has gone through a duplicating process.

2. The procedure involves the transfer of only one of the two images making up the stereo model. This causes the displacement of the top of any building or feature that projects above the earth's surface. Due to such lean, features that are hidden by such lean will not be seen on the final photo, and there will be edge match inconsistencies due to the lean along model ties.

8.2.2.14 Cross Sectioning and Profiling

Automated cross-section and profile collection, by aerial mapping procedures, is a common practice. The stereo instrument is equipped with hardware and software systems that lock the stereo instrument on a given section. The equipment is designed to automatically collect and store the station, offset, and elevations that are input by the operator. The station is manually inserted, the offset is automatically inserted by digital scalers, and the elevation is automatically inserted once it is manually observed by the operator.

The accuracy of the data is twice that of a contour map and greatly reduces the task and human error possibilities over manual compilation from a topo map.

The output can be a magnetic tape or disk with the cross-sectional data, a hard copy printout of the section value, offset distance and elevation, or a hard copy plot that would be digitally plotted by a mechanical plotting device to any desired horizontal and vertical scale.

8.2.2.15 Photo Lab Products

The photo lab is an important attribute to the aerial mapping science since it provides many useful byproducts. Some of the user products are as follows:

1. Contact prints are 9 × 9-in. (229 × 229-mm) direct reproductions of the original negatives and can be provided in color or black and white depending on the negative.

2. Photo indexes are composites of the 9 × 9-in. (229 × 229-mm) contact prints that are reduced to one-third or one-quarter of their size so they can fit on one normal sheet size for use in identifying the location of any one print in a project.

3. Photo enlargements are direct enlargements of the original aerial negative to attain a large feature scale of the area. This can be done on a simple enlarger that will also correct for tip and tilt distortions introduced into the photo by aircraft instability.

4. Direct positives are reproductions of original drawings made on a vacuum frame to eliminate any distortions such as those created by standard print machines.

5. Mosaics are a composite of either aerial photos or drawings.

All of the foregoing products can be produced on either resin-coated waterproof paper (RC paper) or mylar. Mylar material is convenient for photo use in that it can be reproduced on a standard print machine.

8.2.2.16 Project Cost Factors

Photogrammetry has the ability to accurately map large tracts of land more cost- and time-effectively than any other procedure.

Cost is the predominant question when it comes to planning a project and one that is asked usually before definitive data is gathered.

The cost is related to the project as a unique entity, and it is difficult to respond to a project fee request without detailed information about the site. Since photogrammetry has a number of fixed procedures that have tightly controlled parameters, cost evaluations must address some of the following questions:

1. The number of miles from the project to the aircraft base.
2. The scale and contour interval of the map to be produced.
3. The size and shape of the tract of land.
4. The location of existing ground control to the site.
5. The road pattern or open areas available for field survey crew mobility.

6. The relief and its specific elevation differences and complexity.

7. The amount of cultural features, on the site, to be shown on the map.

8. Whether or not the map is to be field checked to verify compliance with the national map accuracy standards.

9. Whether the map is to be field completed to verify non-photo visible features.

These are a majority, but not all, of the factors that individually and significantly impact cost. Since the answers to all of these questions cannot be the same for each site, the cost cannot be the same by any evaluation criteria.

Basic cost rules are functions of scale and contour intervals. Basic map scales and contour intervals are

1 in. = 400 ft (1 mm = 48 m scale) with 10-ft (3-mm) contours

1 in. = 200 ft (1 mm = 2.4 m) scale with 5-ft (1.5-m) contours

1 in. = 100 ft (1 mm = 1.2 m) scale with 2-ft (0.6-m) contours

1 in. = 50 ft (1 mm = 0.6 m) scale with l- and 2-ft (0.3-and 0.6-m) contours

As the scale and contour interval decreases, the cost increases at the rate of over double the preceding category.

Minimal project sizes can be equated as follows. If the project would take three days in the field to collect the necessary data to construct a map by standard survey methods, then it has reached the area where it can probably be done as cheaply by aerial methods.

APPENDIX A. CONTRACT SPECIFICATIONS FOR AERIAL SURVEYING

JAMES MORGAN

This segment generalizes the basic criteria needed to establish or implement a successful aerial mapping project. It contains specifications for both managing a project and evaluating the results of a project. These specifications were extracted from a series of general contracting guidelines from generic public sources.

8.2.2.A1 General

1.01 Definitions:

a. The contracting officer is the official representative of the client.

b. The contractor is that firm, company, or organization to which the mapping or service contract has been let.

1.02 General Mapping Specifications:

a. The contractor will supply the contracting officer with a sample format of each map and/or overlay type showing the placement and content of all border information for approval prior to final map and/or overlay production.

b. All deliverable maps and/or overlays shall contain the following statement:

This map/overlay is correlated to the State Plane Coordinate System, 1983 North American Datum or the local mine control network, whichever applies.

c. All lettering on all deliverable maps and/or overlays shall be done by mechanical means only—freehand lettering will not be accepted.

8.2.2.A2 Aerial Photography

2.01 Project Area and Contract Map:

The location, size, and boundaries of the areas to be mapped should be outlined on a USGS 7½-in. (190-mm) quadrangle.

2.02 Conditions During Photography:

Vertical photography should be flown during the period when deciduous trees are barren, between the hours of 10:00 am and 2:30 pm Eastern Standard Time, and when the sun angle or elevation is not less than 30° above the horizon.

Photography will not be undertaken when the ground is obscured by snow, haze, fog, or dust; when streams are not within their normal banks; or when the clouds or cloud shadows will appear on more than 5% of the area in any one photograph. Photographic targets should be used to mark horizontal control points for aerial triangulation and control of base map compilation.

2.03 Scale of Aerial Photography Negatives:

The altitude above average ground elevation for aerial photography should be such that negatives will be at the scale specified in the following schedule:

Map Scale	Contour Intervals	Max. Negative Scale[a]
1″ = 400′ (1 mm = 4.8 m)	10′ – 20′ (3–6 m)	1″ = 2000′ (1 mm = 2.4 m)
1″ = 200′ (1 mm = 2.4 m)	5′ – 10′ (1.5–3 m)	1″ = 1200′ (1 mm = 14.4 m)
1″ = 100′ (1 mm = 1.2 m)	2′ – 5′ (0.6–l.5 m)	1″ = 600′ (1 mm = 7.2 m)
1″ = 50′ (1 mm = 0.6 m)	1′ – 2′ (0.3–0.6 m)	1″ = 300′ (1 mm = 3.6 m)

[a]Depending on the type of stereo plotters and 'C' Factor.

Negatives deviating from the following scales by more than 5% may be rejected.

2.04 Flight Plan:

The contractor's flight plan shall be drawn on a copy of the 7½-in. (190-mm) quadrangle. Each flight line will be flown continuously across the project area. The principal points of the first two and the last two exposures of each flight strip should fall outside the boundaries of the area to be mapped. All side boundaries should be covered by a minimum of 25% of the photo image format.

2.05 Endlap:

Photography used in the development of orthophoto maps should have an endlap of approximately 80% to ensure that one photograph will cover each map (based on neat image of 25 × 25 in. or 635 × 635 mm).

2.06 Sidelap:

Sidelap should be no less than 25% for topographic mapping.

2.07 Crab:

Crab in excess of 3° may cause rejection of a flight line or any portion thereof in which the excess crab occurs.

2.08 Tilt:

Tilt of the camera from verticality at the instant of exposure should not exceed 3°, nor should it exceed 5° between successive exposure stations. Average tilt over the entire project should not exceed 1°.

2.09 Aerial Camera:

A US Geological Survey (USGS) camera calibration report no more than four years old should be required for each camera used to obtain aerial photography.

a. Camera and lens.

The aerial camera should be a precision aerial mapping camera equipped with a low-distortion, high-resolution lens with the following characteristics:

1. Focal length, 153 + 3.0 mm Universal Aviogon, Pleogon A, or equivalent.
2. Usable angular field, at least 90°.
3. The following table lists the minimum acceptable radial and tangential resolution cycles line pairs per millimeter (measured with type V-F stectroscopic emulsion on micro flat glass plates exposed at maximum lens aperture):

0	7.5	15	22.5	30	35	40
57	57	48	48	40	34	14

b. Filter.

An appropriate glass filter with a metallic antivignetting coating should be used.

c. Shutter speed and efficiency.

1. The camera shall be equipped with a between-the-lens shutter of variable speed. The range of speed settings shall be such that in conjunction with flight height and aircraft speed, the camera will produce negatives that will result in high definition photographs. The shutter should also have a speed of $^{1}/_{200}$ sec or slower for laboratory testing.
2. The effective exposure time and the efficiency of the shutter as mounted in the camera will be measured at maximum

aperture, and the shutter shall have a minimum efficiency of 70% at a speed of $^1/_{200}$ sec.

3. This test shall be made in accordance with "Method I," American National Standard PH3-48-1972 (R1978).

d. Platen flatness and identification.

Cameras shall be equipped with an approved means of flattening the film at the instant of exposure. Data markers that protrude inside the focal plane frame should not exceed 0.25 in. (6.33 mm) in height and 1.0 in. (25.4 mm) in length and shall not obscure any part of the fiducial mark or reduce the usable image area.

e. Fiducial marks.

1. Each camera body shall be equipped with means of recording eight fiducial marks on each exposure, the marks to be located in each corner of the format and at the center of each side.

2. All fiducial marks and other marks intended for precise measuring shall be clear and well defined on the negative and shall be of such a form that the standard deviation of repeated readings of the coordinates of each mark made on a comparator shall not exceed 2µm.

f. Stereomodel flatness.

The deviation from flatness (elevation discrepancy at photography scale) at measured points should not exceed + $^1/_{5000}$ of the focal length of nominal 6-in. (153 + 3.0 mm) cameras. If elevation discrepancies exceed this value, the camera should not be used.

2.10 Aerial Film:

The black and white aerial film should be a fine-grained, high-speed photographic emulsion on a dimensionally stable base.

8.2.2.A3 Horizontal and Vertical Control

3.01 General:

Sufficient horizontal and, if applicable, vertical control surveys shall be established by the contractor for all photogrammetric mapping purposes. Prior to the establishment of the necessary basic horizontal and vertical control, the contractor shall make a thorough search of the project area for existing control of second order Class II accuracy or better, as established by the National Geodetic Survey (NGS, formerly the United States Coast and Geodetic Survey [CGS]). Additional control points established by the contractor will be monumented with permanent monuments as described in subsegment 3.05.

3.02 Horizontal Control Surveys:

All basic horizontal control shall be established by triangulation, traverse, or Global Position System (GPS) (see subsegment 3.08). The traverse error of closure of base control shall not be greater than one part in 10,000, and the allowable angular error shall not exceed 5 sec per angle.

3.03 Vertical Control Surveys:

All basic vertical control shall be extended from existing NGS or local mine datum bench marks and referenced to the National Geodetic Vertical Datum 1929 Adjustment. The vertical control survey shall be established according to NGS standards and procedures, and the survey shall be of third-order accuracy or higher.

3.04 Photo Control Contact Prints:

Control points will be pinpricked and symbolized on the face of the appropriate aerial photograph, and the locations will be precisely described on the back of the photo.

3.05 Permanent Monuments:

A permanent monument is defined as a shaft of concrete, metal, or precast concrete with metal reinforcement in or on which a survey disk or cap is imbedded or affixed, and which is capable of being detected by commonly used magnetic or electronic locators; is buried or driven nearly vertically in the earth in such a way so as to possess horizontal stability; and is extended below the normal frost line or a minimum depth of 30 in. (750 mm) below the ground surface unless a subsurface obstruction dictates a lesser depth. A survey disk or cap with a stem set flush in a drillhole in bedrock, rock outcrop, or concrete structure shall also be defined as a permanent monument. Monuments shall be ½-in.(13-mm) inside diameter or greater iron pipes, ½-in. (13-mm) diameter or greater solid metal rods, or 4 × 4 in. (100 × 100 mm) or greater concrete shafts. If iron pipes or rods are used without concrete, they must be flush with or below the ground surface. Iron pipes or rods projecting 1 in. (25 mm) or more above the ground surface shall be encased in concrete from the disk or cap to 8 in. (200 mm) below the ground surface. The disk or cap of each monument established by the contractor shall be stamped with the name and a sequential number obtained from the traverse. In the event that both vertical and horizontal control are to be established along the same route the vertical control should be established on horizontal control monuments that are accessible; no additional vertical control permanent monuments will be required along such routes.

3.06 Survey Records:

a. Field notebooks and data collector printouts.

Field notebooks shall be carefully and neatly prepared, identified, indexed, and preserved. All data regarding the establishment and extension of horizontal and vertical control, including descriptions of all established and recovered monuments, shall be recorded. Where existing control points are recovered by the contractor in extending the basic control required by the contract, the field notebooks should contain:

(1) Information as to the general condition of the recovered mark

(2) Original description

(3) Exact letter and numbers stamped on (not cast in) the mark

(4) Amended description, if applicable

(5) Additional tie data, if any

(6) Sketch of the location to facilitate future recovery

b. Computations.

All computations and adjustments of control data shall be referenced to the field notebooks by book and page number.

c. Control diagram.

This diagram will indicate all horizontal and vertical control pertinent to this project and will be shown on a copy of the index of deliverable maps. This schematic diagram shall show all existing and established control points properly identified in their approximate location. It will also show all traverse lines with their designations, including the beginning and ending points.

d. Control Data.

The contractor shall provide the information listed below for all monumented control points established and/or recovered:

1. Information on control points established by the contractor. This information shall be collected on monument description cards and shall include the following information:

(a) Designation of station.

(b) Date of establishment.

(c) Horizontal and/or vertical control data.

(d) A complete description of the nature and location of the point to include a "to reach" description referenced to nearby landmarks (e.g., proceed from the intersection of Aker Road [SR 1010] and Stagecoach Road [SR 1012] . . .; proceed from US 64 bridge over Neuse River . . .) and identified by field survey ties (bearing and distance) to three or more definable photo image points in the immediate vicinity.

(e) The location of each marked horizontal control point, symbolized on the face of the appropriate photograph by a triangle and annotated on the back with reference to its station designation as in (a).

3.07 Feet/Meter Conversions:

The US Survey Foot (1 meter = 3.2808333333 feet) shall be used in all conversions of State Plane Coordinates from meters to feet or feet to meters. All final control data shall be in feet, and the datum used (e.g., NAD 83) will be noted on any sheets bearing coordinates.

3.08 Global Positioning System (GPS):

GPS satellite surveying is a three-dimensional measurement system based on observations of the radio signals of NAVSTAR Global Positioning System. The GPS observations are processed to determine station positions in cartesian coordinates (X,Y,Z), which can be converted to geodetic coordinates (latitude, longitude, and height-above-reference ellipsoid). When using GPS to establish control surveys, the contractor shall adhere to the specifications for "traditional" surveys delineated in this section; additionally, the contractor shall follow the specifications for second-order surveys in the "Geometric Geodetic Survey Standards and Specifications for Geodetic Surveys Using GPS Relative Positioning Techniques" as incorporated into the Federal Geodetic Control Committee's (FGCC) Standards and Specifications for Geodetic Control Networks. Reduced GPS data submitted to the contracting officer should include baseline vector components in the cartesian system (X,Y,Z), variance-covariance data (or variance-correlations), number of observations available/used in the solution, and standard deviation of the "range" residuals. When the "single" baseline processing method (two-station solution) is employed, this data will be provided for all possible baselines dependent and independent. For example, if there were three receivers used during an observing session, three baselines will be processed; if there were four receivers, six baselines will be processed; and so on. When the "session" processing method (three or more station combined solution using all data from each observing session) is used, *r*-1 independent base line solutions will be provided where *r* is equal to the number of receivers collecting data simultaneously during an observing session. When the "network" processing method (two or more sessions combined solution using all data from each observing session) is used, *s*-1 independent baseline solutions will be provided where *s* is the total number of stations in the network solution. All digital data submitted will contain adjusted coordinates whenever they appear (latitude, longitude, ellipsoid height). The adjusted coordinates must be the result of a three-dimensional, least-squares, minimally constrained adjustment in the reference system for the satellite ephemerides (WGS 72 or WGS 84).

a. General Requirements for a GPS Survey:

1. The monumented point for a proposed GPS station must be in a location suitable for occupation with a survey tripod, stand, or tribrach. Monumented points located on vertical surfaces such as bridge abutment walls, building walls, and retraining walls, etc., are not suitable GPS stations. If it becomes necessary to connect the GPS survey to a station that is not acceptable for direct occupation, a permanent offset station should be established and monumented and tied to the existing network station using traditional surveying methods.

2. All GPS points must be established in pairs. Only one coordinate position will be established; the second position will be used as an azimuth mark.

3. All stations established using GPS will be monumented using permanent markers as detailed in subsegment 3.05.

4. The antenna must be located where there are no obstructions overhead.

5. The antenna should be located where there will be minimum radio interference. Areas with radio interference for the 1227.6 and 1575.42 Mhz frequencies, medium-frequency radar and high-power transmission antennas; high-voltage power lines and transformers, microwave relay towers, and excessive noise from automotive ignition systems must be avoided.

6. The antenna should be positioned at a height so as to avoid ground reflection of the satellite signal.

7. The antenna must not be placed near metal structures.

8. The antenna phase center will be plumbed over the survey point using an optical plummet, collimator or similar instrument. The plumbing for antennas set up on tripods shall be checked with a plumb bob at least once during the survey. This check is for the purpose of determining gross plumb errors of 0.4 in. (10 mm) or more. When back-to-back sessions are observed and an antenna occupies the same station for both sessions, the tripod will be reset and replumbed between sessions.

9. The receiver assembly, antenna, and other equipment must be protected at all times from theft, vandalism, and other types of disturbances.

10. All GPS receivers should have a signal input port for an external frequency standard.

11. Receivers must have the capability to track a minimum of four GPS satellites simultaneously.

12. The "master" receiver will occupy two or more local first- or second-order NGS or NCGS marks during a project. Some vertical data must be obtained via GPS to obtain a model of the geoid in the project area; therefore, a minimum of two vertical control monuments must be occupied.

8.2.2.A4 Analytical Triangulation

Fully Analytical Aerial Triangulation (FAAT) can be used to extend the horizontal ground control subject to the requirements stated in the following. Techniques of high-to-low aerial triangulation may be used, but shall not exceed a two-times ratio. Drop points established from FAAT performed on 1″ = 2000′ (1 mm = 24 m) photography may be used for scaling of 1″ = 1200′ (1 mm = 14.4 m) aerial photography. These drop points may be used in the production of maps from the 1″ = 1200′ (1 mm = 14.4 m) photography. Maps produced from 1″ = 500′ (1 mm = 6 m) photography may be produced from drop points established by FAAT on 1″ = 1000′ (1 mm = 12 m) aerial photography. The FAAT on 1″ = 1000′ (1 mm = 12 m) photography must use horizontal control established from the second order horizontal control points indicated on the control map. FAAT may not be used with aerial photography at scales smaller than 1″ = 2000′ (1 mm = 24 m). Maps at a scale of 1″ = 400′ (1 mm = 4.8 m) can be developed from FAAT performed on 1″ = 2000′(1 mm = 24 m) aerial photography. Maps at a scale of 1″= 200′ (1 mm = 2.4 m) can be developed from FAAT performed on 1″ = 1200′ (1 mm = 14.4 m) photography or using passpoints and drop points established from FAAT performed on 1″ = 2000′ (1 mm = 24 m) aerial photography. Maps at a scale of 1″ = 100′ (1 mm = 1.2 m) can be developed using analytical triangulation blocks on 1″ = 600′ (1 mm = 7.2 m) aerial photography or using passpoints and drop points established from an analytical triangulation block performed on 1″ = 1200′ (1 mm = 14.4 m) photography.

4.01 Nominal Scales for Triangulation:

Aerial triangulation may be used for horizontal scaling to produce maps of 1″ = 400′ (1 mm = 4.8 m), 1″ = 200' (1 mm = 2.4 m), and 1″ = 100′ (1 mm = 1.2 m). The nominal scale of the mapping photographs will be 1″ = 2000′ (1 mm = 24 m) for 1″ = 400′ (1 mm = 4.8 m) maps, 1″ = 1200′ (1 mm = 14.4 m) for 1″ = 200′ (1 mm = 2.4 m) maps, 1″ = 600′ (1 mm

= 7.2 m) for 1″ = 100′ (1 mm = 1.2 m) maps, and 1″ = 300′ (1 mm = 3.6 m) for 1″ = 50′ (1 mm = 0.6 m) maps.

4.02 Ground Coordinate Systems:

All ground positions determined by aerial triangulation will be in the State Plane Coordinate System or local mine datum whichever pertains. Elevations of monumented positions will be used in FAAT computations when they are available. If these elevations are not available, spot elevations derived from USGS 7½-in. (190-mm) quadrangle maps may be used.

4.03 Standards:

a. Positional accuracy.

The root-mean-square error (vector of both northing and easting coordinate errors) of passpoints established by aerial triangulation shall not exceed $^1/_{50}$ of the denominator of the finished map scale.

b. Elevation accuracy.

The elevation accuracy of passpoints does not have to meet the required accuracy for topographic mapping.

4.04 Passpoints:

a. General requirements.

Passpoint locations will be manually selected by reviewing the control photographs with a pocket stereoscope or other suitable stereo-viewing device. Selected passpoints shall be located, symbolized, and labeled on the image side of the control photographs. All selected passpoint locations will lie on unobscured level ground whenever topographic conditions permit.

b. Distribution of passpoints for fully analytical aerial triangulation.

Individual frames will carry a minimum of nine passpoints, with the exception of end frames of flight lines that will carry a minimum of six passpoints. One (1) point will lie near the corner of each neat model, and one point will lie near the nadir position of each neat model. It is recognized that deviation from the ideal distribution may be necessary for those photographs covering bodies of water or areas of heavy ground cover. Tie points between strips will occur with a frequency of at least one per frame. As a general rule, wing passpoints within lines of flight will also serve as tie points between strips.

4.05 Drop Points:

Drop points used to control lower altitude flights for direct compilation from photographs of larger scale will be located and labeled on the control photographs. These points should be marked, measured, and carried as extra passpoints in the aerial triangulation of the higher altitude photography.

4.06 Checkpoints:

Checkpoints are horizontal control points that have been established by ground control procedures throughout the block for accuracy checking purposes and should not be used in the analytical adjustment.

4.07 Diapositives:

a. Materials used.

All diapositives will be printed from original aerial photography negatives (i.e., not from duplicate negatives). Glass diapositives will conform to Kodak Ultra Flat Glass specifications for aerographic positive plates.

b. Printing and processing.

The printing and processing of all diapositives including development, fixation, washing, and drying must produce diapositives free from defects. Extreme care should be exercised to prevent lint from collecting on both the original negatives and the diapositives.

4.08 Point Marking:

a. General requirements.

All point marking (pugging) will be performed on the diapositives. Under no circumstances should any marking be performed on the original negatives. As a general rule targets will be marked, except targets which are exceptionally well defined on the diapositives.

b. Fully analytical aerial triangulation with mono-comparator.

All passpoints, checkpoints, and drop points (if any) should be marked stereoscopically on every frame with a Wild PUG point transfer instrument or equipment of equal or greater capability .

4.09 Aerial Triangulation Computations:

a. Computations will include ground control data, triangulated ground point residuals, triangulated ground points, and corrections applied to ground control.

b. Computed coordinates of all control points, passpoints, checkpoints, and drop points will be labeled on a computer printout with their field and/or computer designations.

The printout should include project name, date of computations, the name of the analytical program that was used to perform the computations, and the block or subblock designations. Root-mean-square (rms) error summaries should be given for bundle adjustment photographic measurement residuals or strip tie point residuals and misclosures at control points. All FAAT computations should be delivered to the contracting officer for review prior to any stereo compilation.

c. Narrative.

The report must include a brief narrative, including descriptions of laboratory equipment, procedures, and computer programs used. Of particular importance is a listing of field control points not used in the survey, any codes used in the computations, and a full description of significant misfits encountered at control points.

8.2.2.A5 Preparation of Base Maps

5.01 General:

The contractor should produce base maps in strict accordance with accepted stereophotogrammetric procedures, as published by the American Society for Photogrammetry and Remote Sensing, for each map scale. The maps (whether drawn, cartographic, or photographic image, orthophoto base maps) shall be compiled for each area at a scale equal to or larger than the scale required. Map compilation scales for the areas to be mapped will be limited to an approximate five-time enlargement over the scale of the aerial photography for each respective area. Example: a photo scale of 1″ = 2000′ (1 mm = 24 m) is the maximum scale allowed for a compilation scale of 1″ = 400′ (1 mm = 4.8 m). Only precision stereoplotting instruments of recognized proven accuracy shall be used in compilation work.

a. Coordinate grid ticks.

The plotted position of each plane coordinate grid tick shall not vary by more than 0.01 in. (0.25 mm) from true grid value on each manuscript map. These manuscript maps are used in scaling the stereo model to ground control. This is not to imply that the grid ticks plotted on the finished base maps (cartographic, orthophoto, or digital) are accurate to 0.01 in. (0.25 mm).

b. Horizontal control.

Horizontal control points and monuments shall be plotted to an accuracy of 0.01 in. (0.25 mm) of their true position as expressed by the plane coordinates for the control points.

c. Planimetric features.

Ninety percent of all planimetric features shall be plotted so their positions on the finished map will be accurate to within $^1/_{40}$-in. (0.64 mm) of their true coordinate positions; and none of the features shall be displaced on the finished map by more than $^1/_{30}$-in. (0.84 mm) from its true coordinate position.

5.02 Grid Lines and Values:

Grid line intersections of the State Plane Coordinate System are to be plotted at 5-in. (127-mm) intervals. These grid line intersections ½-in. (13 mm) in length, shall be shown throughout the neat image area. The State Plane Coordinates of the grid lines shall be printed in the margin along the image area border at the west (left) and north (top) sides of the map.

5.03 Match Notes:

"Match Notes" indicate the map numbers of the adjoining maps. These notes will be placed in the margin outside the image area.

5.04 Index of Deliverable Maps:

An index of maps to be delivered shall be prepared on a reproducible, polyester-based material (matte both sides) having a minimum thickness of 0.004 in. (0.10 mm). This map will show the individual map boundary outlines, map numbers, and existing and established monumented ground control.

8.2.2.A6 Orthophoto Base Maps

6.01 Final Orthophoto Base Maps:

Final orthophoto base maps shall be prepared by differential rectification. Mosaicking should not be permitted in the development of the orthophoto base maps. The outside edge dimensions of all orthophoto base maps shall be 30 in. (762 mm) high by 42 in. (1067 mm) long. The neat image area shall be 25 × 25 in. (635 × 635 mm) and the limit of the imagery shall extend 1½ in. (38 mm) beyond the neat image area on all sides of the maps. All ground level features on the final orthophoto maps should not be displaced from their State Plane Coordinate positions by more than $^1/_{30}$ in. (0.84 mm). When adjacent maps are aligned by grid ticks, imagery will not be misaligned by more than $^1/_{30}$ in. (0.84 mm), and on the majority of the maps, the imagery will be expected to exceed this accuracy.

6.02 Compilation:

Each stereo model to be scanned should be free of residual parallax and shall be leveled and scaled to plotted control. Ninety percent of all ground level features should be located so their positions on the finished map are accurate to within $^1/_{40}$ in. (0.64 mm) of their true coordinate positions. None of the features should be displaced on the finished map by more than $^1/_{30}$ in. (0.84 mm) from their true coordinate positions. Each stereo model should be scanned with a slit width compatible with the terrain and at a speed which achieves a good photo image and the accuracy referred to above. The Contractor should develop an orthophoto negative at least a two-times enlargement of the original aerial film negative.

6.03 Orthophoto Negatives:

For purposes of these specifications, "original orthophoto negatives" are defined as those negatives made directly from the diapositives used in the stereocompilation. The negatives should be free of scan lines, double exposures, out-of-focus images, mismatched imagery and inconsistencies in tone and density from one negative to an adjacent negative that may interfere with the interpretability of ground features or that are aesthetically objectionable. Original orthophoto negatives should not be cut in the process of mosaicking or for any reason. The corner grid positions of the neat image area of each orthophoto negative should be located and marked by pugging, pin pricking, or permanent ink; a minimum of two corner grid positions should be labeled with their State Plane Coordinates, outside of the image area.

6.04 Orthophoto Positives:

One unscreened reproducible positive of each formatted orthophoto map printed from the original orthophoto negative should be provided on polyester material with a minimum thickness of 0.004 in. (0.10 mm). All positives must be right-reading. Grid ticks on the positives will appear as white lines. The orthophoto positives shall be free of chemical stains; scratches; dust marks; and streaks, stains, and blemishes of any kind. Tone and density of the imagery shall be consistent from one map to the adjacent map. The photographic emulsion of the orthophoto positives shall be on the back side of the maps. Labeling such as match notes and map number shall be on the front side of the maps.

6.05 Border Data:

The following should be shown on all orthophoto maps: (1) title of map, (2) north arrow, (3) map number, (4) scale, (5) horizontal datum, (6) accuracy statement, (7) date of aerial photography, (8) name of mapping contractor, (9) match notes, (10) grid ticks, and (11) grid coordinate values (north coordinate values labeled across the west side of map and east coordinate values labeled across the north side of map).

8.2.2.A7 Topographic Maps

7.01 General:

A *topographic map* is an orthophoto or cartographic base map upon which contour lines and points of spot elevation have been depicted to show vertical datum changes in elevation of the ground surface. Elevations are normally based on the National Geodetic Vertical Datum, 1929 Adjustment. The topographic information may be depicted on an overlay which is registered to a base map.

7.02 Compilation:

The topographic map manuscripts may be compiled utilizing the techniques of Fully Analytical Aerial Triangulation (FAAT). For aerial photography at scales of either 1″ = 1200′ (1 mm = 14.4 m) or 1″ = 600′ (1 mm = 7.2 m), vertical ground control must be established in order to utilize FAAT, and no high-to-low bridging may be employed to obtain vertical control at these scales. When using FAAT for extension of vertical control, field positions should be established at a minimum of one point in every other stereo model along each flight line. Additional criteria include:

a. Contour lines.

Contour lines should be shown at a vertical interval of 2 ft (0.6 m) on 1″ = 100′ (1 mm = 1.2 m) scale topographic maps and at a vertical interval of 4 ft or 5 ft on 1″ = 200′ (1 mm = 2.4 m) maps. Every fifth contour line will be an index contour, indicated by a line heavier than that used for the intermediate contours. Index contours will be labeled inside a break in the contour line at a frequency that will permit ease of interpretation and that is aesthetically acceptable. All contour lines will be solid and unbroken except where they pass through dense ground cover, in which case dashed lines will be used. In those areas where vegetation prohibits accurate plotting of contour elevations, the contour line elevations will be interpolated as accurately as possible from spot elevations measured photogrammetrically in places where the ground is visible.

b. Spot elevations.

Spot elevations will be determined by photogrammetric procedures from the aerial photography that was used to produce the contour lines. The spot elevations will be placed on topographic maps at water levels of lakes, reservoirs, and ponds; hilltops; saddles; bottoms of depressions; intersections of principal streets and highways; and ends of bridges. Where contour lines are more than 1 in. (25 mm) apart, additional spot elevations can be shown to more accurately portray the slope of the land in such areas.

c. Accuracy requirements.

Vertical ground elevations generated from FAAT shall be third-order accuracy or higher.

d. Planimetric features.

The names of cities, towns, villages, rivers, major lakes, airports, streets, roads, railroads, and highways will be labeled on the topographic map to aid in orientation of the user.

e. Grid lines.

Grid lines at 5-in. (127-mm) intervals, running continuously across the topographic map, will be utilized rather than grid ticks and will constitute the outer boundaries of the map neat image area. Grid lines will appear as black lines on the finished (positive) topographic map.

f. Accuracy statement.

The following accuracy statement shall appear on each topographic map:

"Map complied by stereophotogrammetric methods in accordance with National Map Accuracy Standards."

g. Horizontal and vertical datum.

A note will be placed in the border of the map that will read as follows:

(Indicate proper zone) Zone 1983 North American Datum Vertical Datum 1929 Adjustment

h. Border data.

The following data shall be shown on the topographic map: map title, north arrow, grid coordinate values (labeled on all sides of map), match notes, horizontal and vertical datum, map scale, contour interval, map number, name of mapping contractor, date of aerial photography, accuracy statement, and map legend.

Chapter 8.3
SYSTEMS ENGINEERING

STANLEY C. SUBOLESKI, ROBERT E. CAMERON, AND ERIC K. ALBERT

8.3.1 INTRODUCTION

As Mutmansky (1973) has noted,

"The terms 'systems engineering,' 'systems analysis,' and 'operations research,' common in today's technical literature, often are interchanged because of their similar meaning. However, some differences exist . . ."

He then defines each term as follows. *Systems engineering* is the conception, planning, design, and engineering of any system of interacting elements so that the objective of the system is automatically optimized. Thus systems engineering normally is concerned with systems not yet activated. *Systems analysis* may be described as a scientific method of making decisions based on a quantitative or other objective evaluation of all action alternatives. It is very similar to systems engineering, but usually is not considered to be restricted to problems of design prior to use. While the previous two disciplines are somewhat vague and can encompass a great variety of engineering functions, *operations research* can be more specifically defined as the application of mathematical models to the problem of optimizing the objective of any predefined system.

Mutmansky further listed the techniques of operations research. This is largely reproduced as Table 8.3.1.

The techniques of operations research and systems engineering most widely used in practice within the mining industry are as follows:

1. Stochastic simulation.
2. Linear programming.
3. Network analysis/CPM (critical path method)/PERT (project evaluation and review technique).
4. Optimum pit limit techniques.
5. Nonstochastic modeling or simulation.
6. Structural/regression models.
7. Control charts.
8. Mixed-integer programming.

This chapter covers the principles of these systems used most widely in practice, along with applications and limitations of each. Examples of applications are also included in appropriate chapters of this *Handbook,* for example, 8.4 (Computer Methods), 9.4 (Cycles and Systems), and 12.6 (Monitoring, Control, and Communications).

8.3.1.1 General Method of Solution

Scientific problem solving comprises the following general steps:

1. Definition of the problem.
2. Construction of a model of the system.
3. Gathering data.
4. Testing of the model under known conditions.
5. Solution of the problem using the model.
6. Implementing the solution.

Often systems engineering problems are ill-defined or of such complexity that classical methods of solution cannot readily be applied. Direct optimization may not be possible; aid for making intelligent decisions may be the best that can be hoped for.

8.3.2 DATA COLLECTION

Often the most difficult part of systems engineering is the collection of data. Data are of four types (Manula, 1979):

1. *Static data* that do not change with time and space, e.g., length, weight, and capacity of a vehicle.
2. *Kinematic data* that deal with the motion of objects in time and space, e.g., speeds of trucks, shuttle cars, locomotives, etc.
3. *Dynamic data* that may change over time but do not necessarily involve space, e.g., methane emission, airflow rates in ventilation, etc.
4. *Statistical data* that deal with factors that follow no predictable pattern but can be studied using probability and statistical theory and by particular arrangement of measurements.

The most difficult problem lies in collecting statistical data. These problems concern determining:

1. What method to use.
2. When enough samples have been collected.
3. Whether to alter the raw data.
4. How to validate the data.

8.3.2.1 Collection Method

Generally the method of collection of kinematic or statistical data involves time studies or work sampling. The latter (also known as a "ratio-delay" study) is a sampling technique used to study elements that occur infrequently, thus making continuous observation impractical. Here the machines are observed at random intervals over a long period of time, and the percentage of time that the infrequent event (such as a specific type of breakdown) occurs is determined statistically.

Note that often historical records, such as breakdown reports, can be used to collect these data as well. At times, these records may be of doubtful accuracy, and work sampling may be used to validate the data.

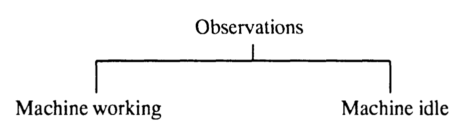
2	59.39			62.52					End @ 134′	Finish Cut
										Clean Up ⅔ Car

Time Studies: *Time studies* are used to collect data on events that occur frequently enough that continuous, direct observations are practical. Time study forms for collecting and processing data for cable reel shuttle cars behind a loading machine (or continuous miner) in a room and pillar mine are shown in Tables 8.3.2 through 8.3.4. The hauling pattern and terminology are shown in the mining plan (Fig. 8.3.1). Tables 8.3.5 through 8.3.7 illustrate the completed calculation of rates, speeds, and capacities for the cut shown.

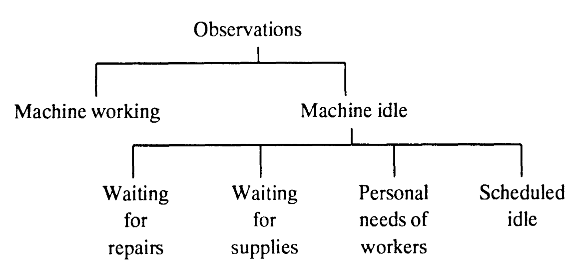
If the user is gathering data for a model, these data may be sufficient. However, if the purpose is to analyze the actual expenditure of time, then a summary sheet is ordinarily prepared showing the amount of time spent in various major time categories. In addition to a form showing the division of time, a second observation form is often used to help the user understand the special conditions encountered, as well as the qualitative factors at the production face.

An example of a very basic summary form is shown in Table 8.3.8. Fig. 8.3.2 shows a section observation and summary form, and Table 8.3.9 illustrates a summary form with additional section information that might be used as a supplement to the first two forms. Ordinarily, the time study would also include a map of the production section, showing the location of the loader and the dump, the routes of the load-haul-dumps (LHDs), trucks, or shuttle cars, and any other pertinent information helpful to the user of the time study.

Work Sampling: The simplest type of *work sampling* study is that of determining whether a given machine is idle or working. In such a case, the observations aim at detecting one of two possibilities only:



This simple model can be extended to determine the cause of the stoppage of the machine:



The objectives to be reached by the study will therefore determine the design of the recording sheet used in work sampling, as can be seen from Figs. 8.3.3 and 8.3.4.

							Last Car In Cut-⅔ Car

8.3.2.2 Number of Samples

For time study elements, it is seldom necessary to calculate the minimum number of samples needed since these are usually exceeded. This can be checked using several formulas based on normal distributions (i.e., the central limit theorem), large sample sizes, and the concept of confidence limits. One such formula, based on 95% confidence limits, is

$$N = [40\ (s/\bar{x})]^2 \tag{8.3.1}$$

where N is sample size needed, $\bar{x}$ is sample mean, S is sample standard deviation, and $S/\bar{x}$ is the coefficient of variation (the standard deviation expressed as a percentage of the mean). For 99% confidence limits, this becomes

$$N = [60\ (s/\bar{x})]^2 \tag{8.3.2}$$

The standard deviation of the sample may be calculated from the formula for sample variance:

$$S^2 = \frac{\Sigma\ (x_i - \bar{x})^2}{n - 1} \text{ or } S^2 = \frac{\Sigma\ x_i^2 - [(\Sigma x_i)^2/n]}{n - 1} \tag{8.3.3}$$

or may be estimated approximately as the range R divided by 4, or

$$S = R/4 \tag{8.3.4}$$

In general,

$$\sqrt{N} = \frac{t}{e}\left(\frac{S}{\bar{x}}\right) \tag{8.3.5}$$

where t is the number of standard deviations corresponding to the desired confidence limits (for 95%, t = 2; for 99%, t = 3), and e is the percentage error from the mean desired or allowed.

The chart shown in Fig. 8.3.5 may be used in lieu of the formula.

Work Sampling: In work sampling, the number of samples is more critical (Manula, 1979). Here the number of samples is based on the binomial distribution and its approximation of the normal distribution. The technique is to first take a (large) number of preliminary observations and determine the percentage of time the event being studied occurs. Then using the nomogram in Fig. 8.3.6, and the error desired, the final number of observations needed may be read.

Example 8.3.1. (Manula, 1979). Suppose a study is conducted to determine the downtime on a machine. Assume that some 100 observations were recorded as a preliminary study, and that these showed the machine to be idle in 25% of the cases (p = 25). In order to determine the value of n at the 95% confidence level with a ± 5 % margin of error, about 310 observa-

tions are needed (Fig. 8.3.6). Note that a 10% error requires 75 observations.

8.3.3 ANALYTICAL TECHNIQUES

Analytical techniques are defined here as those methods that do not result in optimization as a *direct* result of calculations. In general, these methods tend to have less restrictive conditions and are able more realistically to approximate a greater number of operational problems. *Stochastic simulation* is the most widely used technique of this type today. Other methods used fairly widely are control charts, nonstochastic models and statistical (usually regression) models. The application of each of these is covered in the sections following.

8.3.3.1 Statistical (Linear Regression) Models

Linear regression analysis has become one of the most widely used statistical tools for analyzing multifactor data. It is appealing because it provides a conceptually simple method for investigating functional relationships among variables. The standard approach in regression analysis is to use sample data to compute an estimate of the proposed relationship, and then evaluate the fit using statistics such as t, F, and R^2 (Chatterjee and Prince, 1977).

For example, in mining, productivity depends to some degree on the dimensions of the mining plan, the seam thickness, top and bottom conditions, equipment performance characteristics, and possibly other physical factors. If equations could be developed to predict productivities in advance of mining based on these simple measurements, the problems of mine planning, design, and economic justification would be greatly simplified.

Thus the solution would be proposed as a linear equation of the form,

$$Prod = A_1 + A_2 * THICK + A_3 * TOP + A_4 * BOTTOM, \text{ etc.} \qquad (8.3.6)$$

where A_1 is a constant, and A_2, A_3, etc., are the coefficients determined from the regression analysis; *THICK, TOP, BOTTOM,* etc., are the values for the thickness, top condition, bottom condition, etc., for the mine being evaluated; and *Prod* is the resultant productivity. Data would then be collected on these factors and the resultant production from as many operations as possible. Regression analysis would then be conducted to find the linear coefficients that best fit the data, that is, minimize the sum of squares error.

Serious regression analysis cannot be undertaken without the aid of computer programs, many of which are now available for personal computers. The role of the engineer is then to insure that the problem is adequately stated (i.e., that the significant independent variables are included), and that no serious errors mar the analysis. Likely error sources are:

1. Nonlinear relationships between the independent and dependent variables.
2. Outliers which significantly alter the regression results.
3. Collinearity among independent variables.
4. Autocorrelation within one or more independent variables.
5. In general, any nonrandomness in residuals caused by problems in the underlying model or data.

Often a secondary problem is to then choose an equation with the fewest number of independent variables to adequately explain the variation in the dependent variable. This involves both tests of significance and judgment on the part of the model builder. In addition to standard techniques of selection, such as forward and backward stepwise regression, several computer packages also offer the user information about all combinations of the variables, so that he may apply his practical knowledge as much as possible. For a more complete discussion, see Chatterjee and Prince (1977) or Draper and Smith (1966). Regression models have these general uses:

1. Description and model building: to help in the understanding of complex processes or interactions.
2. Estimation and prediction: to predict future values.
3. Control: to determine the change in independent variables needed to obtain a specified value of the dependent variable.

8.3.3.2 Control Charts

SQC or *statistical quality control* charts are used fairly widely in the mining industry to measure and control product quality. The primary purpose of a statistical control chart is to determine whether or not a stable system exists, that is, whether or not the system is regularly meeting statistical expectations or is in a state of statistical control. A second use is as the basis for making real-time decisions. Corrective action may be taken on the basis of the following:

1. Point outside the control limits.
2. Run of seven or more observations in a continuous trend (up or down).
3. Run of seven or more observations, all of which are either above or below the central line.

Two major types of statistical quality control charts are used. These are charts for means and charts for ranges. They are usually used together and are often constructed on the same page. An example of a control chart form used by Ford Motor Co. is shown in Fig. 8.3.7. (Anon., 1987).

Control Charts for Means: With a control chart for means, the vertical scale is the observed value of $\bar{X}$, and the horizontal scale indicates the time at which the sample was taken. A solid line is drawn through the standard mean, and two parallel dashed lines are drawn above and below the solid line, indicating the statistical control limits. If the observed $\bar{X}$ lies between the dashed lines, and no strong trends are evident, the production process is in control, and no action is required. If the point or points indicate the process is out of control, an attempt is made to find the factor that is causing these extreme observations. In Example 8.3.2, discussed later, the process was out of control on the fifth day.

Control Chart for Ranges: A second control chart to record dispersion is usually kept simultaneously with the chart for means. The dispersion is most often measured by the sample range R. If $\bar{R}$ is the expected range, then the control limits are $D_L\bar{R}$ and $D_U\bar{R}$, the lower and upper control limits, respectively. These multipliers are usually computed to give a 1% chance of the sample range being less than D_L or exceeding D_U (i.e., a 0.5 and 99.5 percentile of the sampling distribution of the statistic R).

Construction of Control Charts—Control charts are based on the central limit theorem and are usually constructed at the $3s$ limits.

To construct a control limit for means, a small number (n = 5 is typical) of samples is taken at close time intervals when the process is in control. Each five samples forms a subgroup, and N (N = 20 to 25 is typical) subgroups are collected.

When m and s are not known, the usual case, they must be estimated by sampling to establish the control limits.

Let i equal the sample (subgroup) number, i = 1,2,3. . . .N, x_i equal to the mean of the ith sample, and R_i equals the range of the ith sample. Then the

$$\textit{grand mean} = \overset{*}{x} = \frac{\sum_{i=1}^{N} \bar{x}_i}{N} \tag{8.3.7}$$

and

Table 8.3.7. Processed Data from Tables 8.3.3 and 8.3.4

SAMPLE CALCULATIONS:
1. TRAVEL LOADED: (ARR DUMP − LV CP LDD)
or 18.38 − 17.10 = 1.28 MIN
2. TRAVEL EMPTY: (ARR CP EMPTY − LEAVE DUMP)
or 20.46 − 19.60 = 0.86 MIN
FOR SPEEDS DIVIDE DISTANCE TO DUMP BY TRAVEL TIME:
335 FT ÷ 1.28 MIN = 262 FT/MIN

$$\textit{expected range} = \bar{R} = \frac{\sum_{i=1}^{N} R_i}{N} \tag{8.3.8}$$

are calculated. These are then used to construct the control charts. For the control chart for mean (**$\bar{x}$-chart**):

$$\text{Centerline} = \overset{*}{x} \tag{8.3.9}$$

$$\text{Upper control limit} = \overset{*}{x} + A_2\bar{R} \tag{8.3.10}$$

$$\text{Lower control limit} = \overset{*}{x} - A_2\bar{R} \tag{8.3.11}$$

For the control chart for ranges (R-chart):

$$\text{Centerline} = \bar{R} \tag{8.3.12}$$

$$\text{Lower control limit} = D_3\bar{R} \tag{8.3.13}$$

$$\text{Upper control limit} = D_4\bar{R} \tag{8.3.14}$$

Values for A_2, D_3, and D_4 are shown in Table 8.3.10.

It should be noted that:

1. "Out-of-control" readings should be excluded in calculating control limits.
2. A control chart assumes "normality" of data; other techniques are available for nonnormal data.
3. Charts and limits should be updated at regular intervals as more experience is accumulated.

The control limits on the mean define the *capability* of the process. Capability can then be compared with the *requirements* to determine if these can be met when the process is operating in statistical control.

Example 8.3.2. (Buffa, 1972). A study is undertaken to determine the time required to perform a certain repetitive task. Among other data gathered for the work measurement study are

100 stopwatch readings of the actual time required for the task. Table 8.3.11 shows these 100 readings in minutes, divided into the subsamples of $n = 5$ by which they were gathered. Each subgroup of five readings was taken at random times in the order of the sample numbers as shown.

Solution. Table 8.3.12 shows the sample means for each of the 20 samples, the grand mean of which is $\bar{\bar{x}} = 2.01$ min. Table 8.3.13 shows the range in minutes for each of the 20 samples, and the average of the ranges is calculated as $\bar{R} = 0.43$ minutes. The preliminary control limits for the $\bar{X}$ chart are then calculated as follows (the value of $A_2 = 0.58$ is obtained from Table 8.3.10:

$$UCL = \dot{x} + A_2\bar{R}$$
$$= 2.01 + (0.58 \times 0.43) = 2.26 \text{ min}$$
$$LCL = \dot{x} - A_2\bar{R}$$
$$= 2.01 - (0.58 \times 0.43) = 1.76 \text{ min}$$

These preliminary control limits and the preliminary centerline for the grand mean are plotted in Fig. 8.3.8a together with the 20 sample means shown in Table 8.3.12. The chart seems to indicate that there is a stable data generating system with the exception of sample No. 18 that falls below the lower control limit line. An investigation reveals the fact that the operator had been following a nonstandard method at that time because of a material shortage. Since it was not in control and an assignable cause was determined, sample No. 18 was eliminated from the data, and new revised grand mean and control limits computed as shown. The elimination of sample No. 18 also affects $\bar{R}$, which enters into the calculation of revised control limits. The control limits for the R chart are determined in a similar way:

$$UCL_R = D_4\bar{R}$$
$$= 2.115 \times 0.43 = 0.91 \text{ min}$$
$$LCL_R = D_3\bar{R}$$
$$= 0 \times 0.43 = 0$$

Fig. 8.3.8b shows the preliminary control limits for the R chart as just calculated. The centerline for the R chart is the average of the sample ranges, $\bar{R} = 0.43$ min. The 20 sample ranges are shown in Table 8.3.5, and we see throughout the 20 samples that variability within the samples remained stable within the control limits. Nevertheless, since sample No. 18 has been eliminated on the basis of the $\bar{X}$ chart, it must also be eliminated to calculate revised control limits for the R chart. The revised centerlines and control limits for the two charts of Figs. 8.3.8a and 8.3.8b now represent reasonable standards for comparison of future samples. The basic calculations for determining the control limits and centerlines for $\bar{X}$ and R charts remain the same, regardless of the variable being measured.

8.3.3.3 Mathematical Models of Loading and Hauling

Deterministic models of loading and hauling in underground or surface mines can be used to predict *changes* in these systems

Fig. 8.3.2. Time study observation and summary form.

with considerable accuracy. Prediction of absolute productive capability depends not only on the loading and hauling capacity but also the equipment and manning availability, as well as other factors which are largely a function of management and mining conditions.

Underground Mining: In room and pillar operations using either a loader and trucks, loader (which may be a continuous miner) and shuttle cars, or LHD units, the haulage system is usually as shown in Fig. 8.3.9. (Note that if the haulage vehicles can pass in a roadway, the haul distances are always equal.) As noted previously, management variability makes it difficult to predict the production that may be expected from a given plan and set of equipment. However, the production *rate* may be predicted readily for any given cut (or series of cuts) if average values of elemental operations are used. If it is assumed that the loader will complete any maneuver during the time the shuttle cars and trucks are changing out, the loader cycle time will consist of only five elements (Prelaz et al., 1964):

1. *Loading* (*TLT*). The time spent in loading a cut. Loading time begins at the instant the shuttle car (or truck) arrives at the back of the loader, and ends when the car is fully loaded.

2. *Changeout Time* (*COT*). The time spent waiting for the cars to travel over the common changeout distance. For systems with sufficiently wide entries, this may equal zero, equal the loader maneuver time, or equal the spot time of a truck.

3. *Waiting on a Shuttle Car* (*WSC*). The time during which a loaded car has cleared the change point and an empty car is not available at the change point.

4. *Tramming* (*TT*). Traveling from the face of one cut to the face of another, including all delays, such as hanging cables or changing ventilation controls.

5. *Waiting on a Place* (*WC*). Waiting because the next support operation has not completed preparation of the face for the loader.

Note that a sixth factor, *In Cut Delays* (*ICD*) may need to be added if the loader cannot complete maneuvers between cars. Measured individual *ICD* times should be decreased by the changeout time(s) before adding them to the cycle time. To predict total production, *Abnormal Delays* and *Fixed Delays* (Unavailable Time) must be accounted for. As noted earlier, these are site specific and, to a large extent, a function of management.

Fixed delays include:
Travel In and Out
Lunch
Scheduled Machinery Servicing
Prepare to Mine
Prepare to Leave

Thus, if Abnormal and In Cut Delays are disregarded, the loader cycle time for a cut may be stated as follows:

$$LCT = TLT + COT + WCS + TT + WC \qquad (8.3.15)$$

To calculate these terms, the following are used:

$$TLT = TONS \div LR \qquad (8.3.16)$$

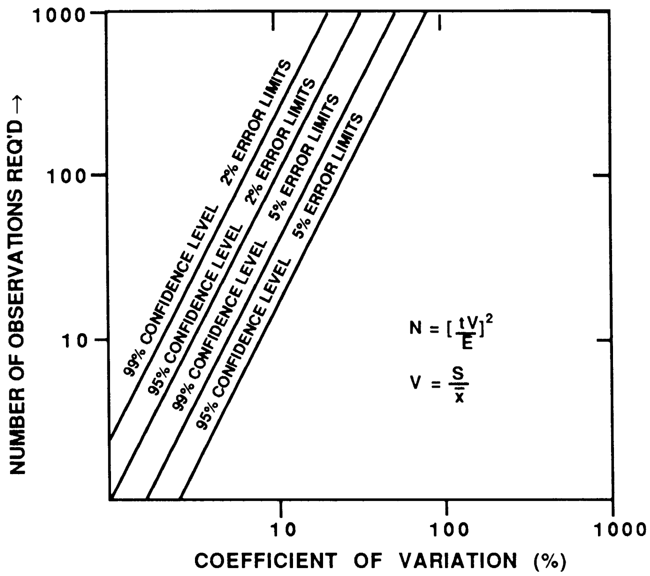

Fig. 8.3.5 Logarithmic plot of the relative dispersion to determine sample size (Manula, 1979).

$$COT = (n - 1)(O + I) \qquad (8.3.17)$$

$$W = TL + DT + TE - (N - 1)(L + O + I) \qquad (8.3.18)$$

$$WSC = \left[\frac{n - 1}{N}\right] W \qquad (8.3.19)$$

$$TT = (TD \times TR) + TC \qquad (8.3.20)$$

where *TONS* = tons in the cut, *LR* = loading rate (or mining rate), *COT* = changeout time, *O* = time to travel from the loader to the change point, *I* = time to travel from the change point to the loader, *L* = time to load one shuttle car, *n* = number of shuttle-car loads in the cut, N = number of shuttle cars used in the analysis (in this case = 2), [ ] = denotes the enclosed value should be truncated to an integer value (i.e., [3.83] = 3), *TE* = time to travel from the dump to the change point, *TL* = time to travel from the change point to the dump, *TR* = tram rate of the loader, *TC* = nontram delay time encountered which during tramming, and *W* = wait time for a shuttle car to reach the change point.

Note that it is also assumed that all haulage units have the same payload and speed characteristics.

While this equation may be used to quickly predict the production from a cut, it does not include the Wait on Place time that depends on the relative speeds of the support operations (i.e., "bottleneck" delays) and thus affects the overall production from a system. In addition, with a deterministic model, the effects of randomness are lost, and any waiting that may occur at the discharge change point, usually minor, is ignored.

Application—In ore mines or with long hauls in general, the speeds must either be time studied or estimated from rimpull-speed-gradeability curves (Chapter 13.1.2.). Table 8.3.14 lists average speeds for LHD units in underground mines. For short hauls (< 500 ft or < 150 m) or when electric-powered vehicles are used, Table 8.3.15 may be used to estimate speeds in firm, dry roadways. LHDs, trucks, and ram-type cars must usually turn at the change point and dump as part of their haul cycle. In coal mines, the "turn-car" time for battery cars in good conditions is 0.15 to 0.25 min per event.

Loading rates for front-end loaders may be calculated from cycle-time charts (Chapter 13.3). LHD loading times will vary with the material being loaded and the condition of the shot. A study of LHDs in underground lead mines (Bullock, 1975) showed an average load time of 1.16 min, including nonhaulage face delays. Stevens and Acuna (1982) note a range of 0.25 min for single-pass loads in good condition to 2 min for three-pass loads in poor conditions. Coal-mine loading machines typically load at 10 to 15 tpm (9 to 14 t/m), except for cleanup cars, which average 2 to 4 tpm (1.8 to 3.6 t/m). Continuous miners can load at similar rates but usually perform closer to their mining rate, which typically range from 5 to 10 tons/min (4.5 to 9 t/m), except for cleanup rates of 2 to 4 tpm (1.8 to 3.6 t/m).

Dump times are typically 30 sec for LHDs and trucks and 30 to 45 sec for chain-bed shuttle cars with unrestricted dumping. Turn and spot times must be added to these where appropriate. Table 8.3.16 shows recommended load and dump times for LHDs.

Payloads for trucks must be determined case by case, based upon the opening dimensions, material density, and truck dimensions. LHD payloads likewise must be estimated for specific cases. Table 8.3.17 lists rated payloads and dimensions for some LHD units. Fig. 8.3.10 shows the results of a study of payloads for shuttle cars with 48-in. (122-cm) conveyors in 15 coal mines. In general, ram-dump cars will have payloads 20 to 40% larger than this. Payloads for shuttle cars with wider conveyors should be increased proportionately.

Example 8.3.3. The following example illustrates the application of the cycle time model in coal. It is desired to calculate the expected miner cycle time for a cut assuming the vent tubing advances, etc., can be accomplished during haulage delays to the miner. Data regarding the cut and equipment are as follows:

seam thickness *H*	5.5 ft (1.6 m)
entry width *W*	18 ft (5.5 m)
cut depth *D*	18 ft (5.5 m)
coal density *d*	85 lb/ft^3 (1362 kg/m^3)
number of cars in use *N*	2
shuttle car payload *SCP*	5.0 ton (4.5 t)
loading rate *LR*	6 tpm (5.4 t/min)
average car speeds *SE SL*	300 fpm (91 m/min)
change out distance *CPD*	100 ft (30 m)
haul distance *HD*	300 ft (91 m)
dump time *DT*	0.7 min
tram time *TT*	20 min

Solution.

$$TONS = 18 \times 8 \times 5.5 \times 85/2000 = 75.7 \text{ ton/cut}$$
$$L = 5/6 = 0.83 \text{ min}$$
$$TLT = 75.7/6 = 12.6 \text{ min}$$
$$I = COD/SL = 100/300 = 0.33 \text{ min}$$
$$O = COD/SE = 100/300 = 0.33 \text{ min}$$
$$N = TONS/SCP = 75.7/5 = 15.1, \text{ say } 15$$
$$COT = (N - 1)(O + I) = 14(0.67) = 9.38 \text{ min}$$
$$TE = HD/SE = 300/300 = 100 \text{ min}$$
$$TL = HD/SL = 100 \text{ min}$$
$$WSC = \left[\frac{15 - 1}{2}\right](1.0 + 0.7 + 1.0 - ((2 - 1)(0.33 + 0.33 + 0.83))$$
$$= (7)(1.2) = 8.40 \text{ min}$$

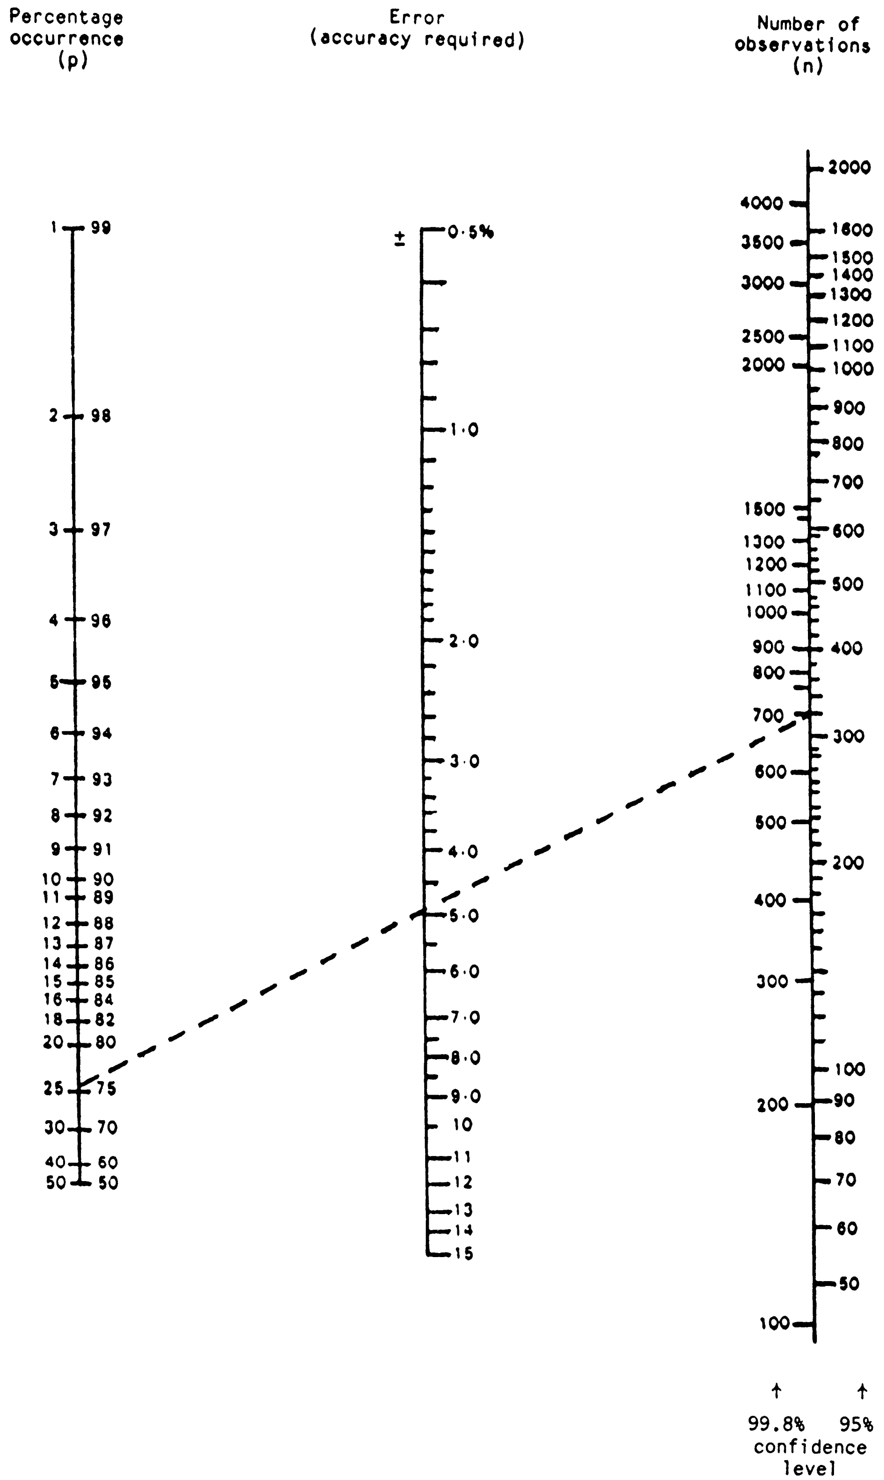

Fig. 8.3.6. Nomogram for determining number of observations (Manula, 1979).

$$LCT = 12.6 + 9.38 + 8.40 + TT$$
$$= 30.38 \text{ min}$$

Surface Mining: The previous model is applicable to analysis of truck-shovel operations in surface mining, with the following change in terms: I = spot time of the truck, and O = time to clear the loader area such that the next truck to be loaded may spot.

The model may be used to estimate average production rates from a cut just as in underground cuts. Alternatively, the number of trucks needed to insure the loader does not wait may be solved for. Since

$$W = O = TL + DT + TE - (N - 1)(L + O + I) \tag{8.3.21}$$

then

$$N = 1 + [(TL + DT + TE) / (L + O + I)] \tag{8.3.22}$$

Care must be taken if a single dump is used by trucks from several loaders (faces) since dump congestion may affect the dump time. In this case, simulation may be necessary.

8.3.4 STOCHASTIC MODELS

Stochastic models as related to mine systems engineering are generally viewed as discrete event Monte Carlo simulations, although the notion of stochastic models also include topics such as Markovian processes, dynamic programming, and other nondeterministic theories. Monte Carlo simulations are based on the utilization of Monte Carlo sampling for the duplication of mine systems containing stochastic or probabilistic elements. The technique was proposed by Von Neumann and Ulan in the 1940s and has become almost synonymous with the term simulation for systems engineering, although many simulations may not employ the method. The Monte Carlo approach is one in which the stochastic or probabilistic elements of a system are randomly determined through the use of randomized streams of variates that duplicate the expected probabilistic distribution of those elements.

The underlying assumption for employing Monte Carlo techniques is that the average or expected performance of a mining system that consists of many interacting stochastic variables can

be approximated through determining the average performance of repeated solutions of the system using randomly selected discrete values for each probabilistic variable that conforms to predefined probabilistic distributions. For example, the average performance of a shovel loading an 80-ton (72-t) truck can be approximated using Monte Carlo simulation techniques by randomly determining 100 load times that are variates of the probabilistic distribution inferred through time studies and performance statistics. Problems with using Monte Carlo simulation occur when there are too little data to adequately determine

Monte Carlo simulation enjoys popularity because of its ease of approximating solutions of highly complex interrelated stochastic systems. In the area of queueing models and waiting-line theory, the addition of interacting stochastic variable rapidly increases the mathematical complexity of the solution that results in an analyst's inability to derive a direct solution to the problem. As a result, Monte Carlo simulation techniques are generally utilized to accurately model the interaction of the probabilistic elements.

Monte Carlo simulation is a generic term used to denote any duplication of the dynamic behavior of a system through the use of a randomized stream of variates whether it be the simulation of financial risks within a mining venture, the probabilistic nature of chemical reactions, the modeling of failure criteria of a rock mass, or the interaction of trucks and shovels in an open pit. In applying Monte Carlo techniques, mine systems engineering usually looks at it from a narrower perspective of discrete simulation involving queues, waiting lines, or wait states. *Discrete simulation* is the branch of simulation that embodies a world view where all changes of a mining system can be described at discrete points in time such as an arrival of a truck at a shovel, the dumping to a bucket of ore into a truck, or the arrival of a surge of coal at a belt transfer point. In contrast, the term *continuous simulation* refers to the branch of simulation in which changes of a system are best described by defining a set of differential equations such as modeling the response of an electrical system to a ground fault.

Typical terminology used in model formulation of discrete change simulations involving the possible formation of wait states or queues (Shannon, 1975) includes the following.

1. Entity: An item which flows through the simulation. These can be trucks, shovels, ore cars, computers, maintenance personnel, or any other item within the simulation. They can also become available.

2. Attribute: A modification or characteristic of an entity. A truck might be characterized by its size, model, serial number, color, or maintenance records. These all would be attributes of the truck.

3. Activity: Time-dependent action within the simulation such as the activity of loading a truck, driving the truck from the pit to the crusher, or dumping the truck.

4. Event: A discrete change in the state of the system. The arrival of a truck at the crusher would be an event since the system changes states, that is, one of the trucks is no longer traveling. Events usually mark the beginning and ending of activities.

5. Process: A time-ordered sequence of events that may involve several activities. The cycle of a truck being loaded, driving to the crusher, dumping its load, and driving back to the shovel could be defined as a process.

The development of discrete simulation models involves the engagement of entities or items in a system in a manner which duplicates the functionality of the models and behavior of the system. Three primary modeling approaches are generally employed and according to Shannon (1975) include:

Table 8.3.17. LHD Vehicle Capacities and Sizes

Rated Payload Capacities				Operator Height		Overall Width		Approx. Turn Radius	
m^3	yd^3	t	tons	mm	in.	mm	in.	m	ft

1. Activity-oriented modeling.
2. Event-oriented modeling.
3. Process-oriented modeling.

Activity-oriented computer simulation involves representing the system as a set of activities. Entities within simulation engage activities and prescribe the conditions in which activities either start or end (Pritsker, 1985). Activities are initiated when a set of conditions is satisfied and therefore require the entire list of activities be evaluated when time is advanced. This type of simulation modeling is generally viewed as inefficient for most types of simulation work and is usually presented in most simulation texts for academic reasons. Pritsker (1985) gives a set of conditions in which the activity-oriented modeling framework should be considered. This approach would involve describing the activities in which entities are engaged and the set of conditions that cause a start or stop of the activity. Activities are initiated or terminated when a set of conditions is met.

The second major type of computer simulation involves representing the mining system as a set of events. *Event-oriented simulation* views the system from a perspective that the entire logic of a system can be represented as a set of time-ordered events. State changes within a system occur only at discrete points in time that are defined as events. The concept of activities occur in event-oriented simulation, but only as the abstraction that defines the point in time when events (the stop or start of the activities) take place.

For example, a truck-shovel cycle can be defined as a set of arrivals and departures of the truck. Every change of this system happens in conjunction with either an arrival or departure of a truck to or from some discrete point within the system. A queue at the shovel can only expand when a truck arrives, the next truck can only be loaded if the previous truck departs for the crusher or dump, and a truck can dump its load only after it arrives at its dumping point.

Process-oriented simulation models the flow of entities through the system. The distinction between event-oriented and process-oriented approaches is somewhat unclear since the notion of a process is defined as a sequence of events associated with the behavior description of the system. The main differentiation usually developed by general-purpose simulation languages is whether the events are directly defined and actually logically scheduled by the modeler (event-oriented simulation), or the events are logically implied through a process description and the simulation language translates the process into an appropriate sequence of events and handles the scheduling of the events in the sequence.

Process or event simulation approach is usually recommended by simulation experts and can be found applicable to a variety of mining problems. These areas include performance optimization (queuing problems), production scheduling and sequencing optimization, equipment selection, and production control.

It should be understood, however, that computer simulation itself is not a direct optimization technique. Simulation only provides a predictive model of the system. The analyst uses the predictive model as a tool for investigating alternative solutions and their economic impacts to the company. Optimization is a matter of selecting the best alternative within the framework of the alternatives explored.

There are a number of generic computer packages available to assist with problem definition and simulation for some of these optimizational areas. For example, there exist generic truck-shovel simulators, belt capacity simulators, and rail haulage simulators. These packages typically allow a user to input descriptions of a specific system and then provide a prediction of the operational characteristics of that system.

Several general-purpose simulation computer languages exist to aid in the development of stochastic simulations when an existing modeling package proves to be unavailable or inadequate. These include languages such as SLAM II, Simscript, GPSS, GASP IV, SIMAN, and DYNAMO to name just a few. Most of these languages are designed to limit the amount of code that a user must generate in order to simulate discrete processes or events and are usually better suited for model development than general purpose programming languages such as FORTRAN or C.

The design philosophy of simulation languages recognizes that if a system is modeled as parallel processes, a set of ordered events, or as a group of interrelated activities, certain generic operations must be done regardless of whether the simulation involves a small maintenance shop or the entire truck fleet of a large open pit mining operation. These generic operations include keeping track of time, accumulation of operational statistics, queue or idle time management, and the generation of the random variates of the defined probabilistic distributions. The advantage of the general-purpose simulation languages is that the codes to accomplish these tasks are generated for the user.

8.3.5 PIT LIMIT OPTIMIZATION

Optimum pit limit techniques or the delineation of recoverable ore reserves is an important area of application of systems engineering. Feasibility analyses, long-range planning, and the assessment of capital exposure and corporate risk can be significantly impacted by the results of the optimum pit limit determination. It is becoming increasingly necessary for companies to base even initial engineering studies of a mineral deposit on good estimates of the size shape and extent of a potential ore reserve (see 13.1.1 and 13.2.1).

The ultimate pit limit problem can be defined simply as determining the ultimate or final mining limits of a mineral deposit such that some set standard of maximum value or profitability is obtained from its extraction. By most pit optimization techniques, the *standard of profitability* is defined as maximizing the difference between the profit obtained from extracted ores and the cost incurred in removing associated waste materials. The standard most generally is set using a single period (life of mine) production schedule technique where profitability or lack of during subsets of that single period are ignored.

The use of advanced mathematical techniques in designing ultimate pit limits has become more practical in recent years due to the extension of various pit optimization methods along with advances in automated computational technologies. Optimization techniques can be briefly classified into five categories:

1. Heuristic techniques.
2. Dynamic programming.
3. Linear programming (integer programming).
4. Network flow theory.
5. Graph theory.

Heuristic optimization techniques have been one of the most widely used methods for ultimate pit limit analysis; however, these methods many times fail to generate true optimal designs. The most common heuristic technique used is the moving cone algorithm. *Dynamic programming* generates good results in two dimensions; however, three-dimensional extensions produce erratic results. The last three techniques—linear programming, network flow theory, and graph theory—actually employ the same problem formulation. Network theory and graph theory are alternate solution techniques for the linear programming problem.

The moving cone method (Pana, 1965; Pana and Carlson, 1966) is one of the most widely accepted techniques in the design of ultimate pit limits because of its rapid execution speed and easy conceptualization. Programming logic included in the method is patterned after conventional cross-sectional methods. It utilizes a break-even stripping ratio as the basic optimization criterion. The main difference from manual techniques is that it uses a 3D moving cone concept for removal increments instead of vertical sections to generate the final pit geometry.

A pit is generated and analyzed by constructing an upward cone and moving its vertex from one ore block to another. The cone shape is defined such that it conforms with pit slope design constraints in the various areas of the deposit. The computer is employed in generating 3D conical configurations and in the calculation of net value of each cone by summing the values of all ore and waste blocks enclosed within the cone. Finally, a 3D pit limit is obtained by removing the frustrums of all cones with net positive value.

From the point of view of finding a mutual support between overlapping cones, the moving cone method is significantly restrictive due to a large amount of computational effort required (Barnes, 1982). Indeed, the determination of a mutual support between overlapping cones is not usually required by most implementations of the moving cone algorithm. The method usually terminates after cones having their vertices located on all positive ore blocks have been evaluated. For this reason, the heuristic moving cone method many times fails to generate true ultimate pit limits.

In attempts to consider the mutual support between cones, more efficient techniques applying sophisticated mathematical programming or systems analysis concepts have been developed.

The original dynamic programming algorithm was demonstrated in the design of the optimal configuration of blocks to be removed in a two-dimensional (2D) cross section by Lerchs and Grossmann (1965). Given a 2D cross section of a block model and the defined slope constraints, the algorithm proceeds by calculating the column sum of original block value for each block. This column sum value represents a cumulative value realized in extracting a single vertical column from the top of the block model to each individual block. Next, column-by-column starting from any end column of the cross section, a pit value representing the maximum value of the potential 2D pit is computed for each block. This pit value is calculated from the column sum value of the block and the predetermined pit value of an overlying block in the previous column. This new value is the maximum possible contribution of the starting end column to the column containing that block to any feasible 2D pit that contains the block on its contour. An arrow (or pointer) is used to indicate the overlying block that provides the maximum value to the calculation of the pit value of a particular block. The ultimate pit limit is then determined by tracing back the arrows from the block in the uppermost level that has the maximum pit value. Fig. 8.3.11 shows an example of the 2D dynamic programming method.

The dynamic programming approach as originally defined by Lerchs and Grossmann is able to generate the optimal pit contours in given 2D cross sections. A final 3D pit geometry is then determined by merging the geometry determined by multiple cross sections through the pit. A true optimum may not be obtained by the assemblage of these 2D cross sections, and typically one finds that the final limits may also violate maximum allowable pit slopes.

In the past several years, many attempts have been made to extend the original 2D algorithm concepts to the design of truly optimum 3D ultimate pit limits. The algorithms developed by Johnson and Mickle (1970), Johnson and Sharp (1971), Barnes (1982), and Koenigsberg (1982) are still close to the original 2D algorithm, except they also consider block value information from adjacent cross sections. These 3D approaches are restricted in that the pit slopes must be consistent throughout the block model. The configuration of the generated pit generated with the algorithms may still fail to follow the general pit slope constraints, and a process called pit reaming is usually required as a final stage to correct inconsistencies. In contrast to other pit limit generation techniques, the dynamic programming algo-

Fig. 8.3.11. Ultimate pit limit problem formulated and solved by using the 2D dynamic programming algorithm.

rithms do not utilize a cone generation routine for obtaining the set of overlying blocks. Thus the method may yield final pit limits that are far from optimal.

The ultimate pit limit problem can be formulated as a simple zero-one integer programming problem with the following structure:

$$\max Z = \sum_{n=1}^{N} C_n X_n \qquad (8.3.23)$$

Subject to:
$$-X_t + X_n \leq 0 \text{ for all } n = 1 \text{ to } N \qquad (8.3.24)$$
$$X_t, X_n \text{ integer}$$

where N is total number of blocks, X_t is an overlying block that must be removed before mining block n, and C_n is cost or profit associated with mining block n.

The computer time required to generate the solution of this *integer programming* problem is proportional to the number of block sequence constraints. The sequence constraints required for each block amounts to one constraint equation for each overlying block that must be removed as defined by the pit slope constraints before that particular block can be mined. This means that unless the block model is fairly small, the integer zero-one programming technique cannot be practically applied due to the large amount of computer resources required for model description and resolution. However, this large binary integer programming problem may be transformed into an equivalent bipartite network flow problem that can be solved by highly efficient solution algorithms.

The *network flow* model for determining ultimate pit limits is based on the network theory of maximum flow and minimum cut. The solution technique was originally developed by Johnson (1968). The problem is formulated such that the nodes in the network are equated to blocks in a 3D block model, and arcs are generated to represent the required pit slope constraints for feasible mining sequences. That is, each node is defined as an indicator variable X_n of the integer programming problem. Network arcs connect positive valued nodes (potential ore) to overlying negative valued nodes (waste) that must be removed in order to mine the ore node. These arcs therefore represent the precedence constraints.

The basic network formulation has been shown by both Johnson (1968) and Barnes (1982) to be a bipartite network that can be easily solved by maximum flow theory. The basic set up procedure of the network is graphically shown in Fig. 8.3.12 with these constraints:

1. All positive-valued blocks (potential ore) are set up on the left side of the network and connected to an imaginary source node.
2. All negative-valued blocks (waste blocks) are set up on the right side of the network and connected to an imaginary sink node.
3. Arcs are drawn from each positive block to every waste block that must be mined prior to mining the positive valued block. In 3D space, this insures that pit slope geometry and constraints are maintained.
4. The arc capacity from the imaginary source node to each positive node (ore block) is equated to the financial return of mining and processing the block.
5. The arc capacity of the waste blocks to the imaginary sink is equated to the cost of extraction and removal of the block.
6. The arc capacity of the connections between the positive blocks and overlying the waste blocks is set to infinity.

A bipartite network of this nature can be effectively solved by one of several maximum flow algorithms. The ultimate pit ends up being defined as the removal of all blocks connected by arcs that belong to the maximum flow or minimum cut. If a labeling algorithm is used, this simply means that all labeled blocks in the final iteration are mined.

This approach to the generation of the ultimate pit can be shown to produce a truly optimal solution. The method does require significant computational resources and employs somewhat hard to understand mathematical techniques. Hanson (1986) presents a modification of the method to reduce the required computational resources by assigning priority to flow allocation.

The application of *graph theory* for designing pit limits was creatively introduced by Lerchs and Grossmann (1965). The algorithm formulates the zero-one integer programming problem into network tree. The vertices are equated to mining blocks, and the imposed directed arcs represent pit slope constraints. These directed arcs indicate the relationship between waste

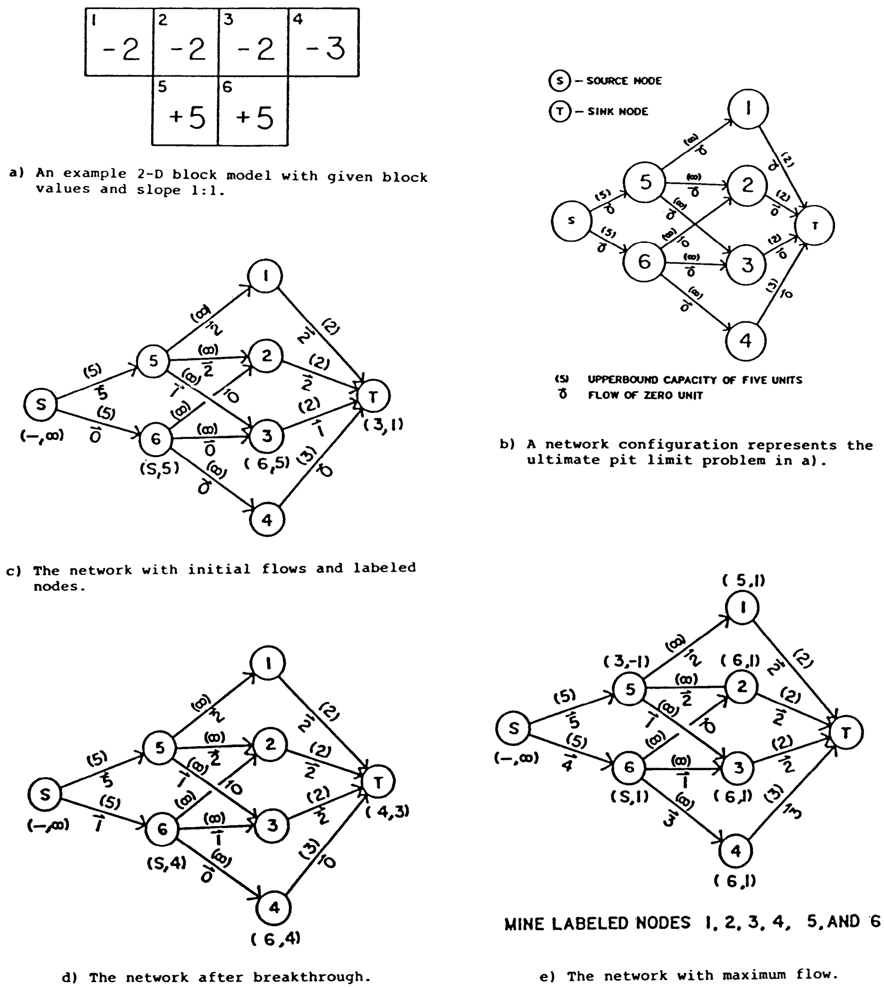

Fig. 8.3.12. Ultimate pit limit problem formulated as the network flow problem and solved by the labeling algorithm.

blocks that must be removed before mining a particular ore block. Since any feasible pit contour is obtained by a closure of a graph, Lerchs and Grossmann recognized that the ultimate pit is a problem of determining the closure of a graph with a maximum total mass.

This algorithm begins by classifying each vertex into either a positive or a negative mode category corresponding to its block value (positive = potential ore and negative = waste). Directed arcs are generated that represent the slope constraints from a positive node to its overlying negative node. In general, the algorithm starts constructing the initial graph tree from the blocks in the uppermost level of the block mode and proceeds down level by level. The initial tree is constructed by having a set of dummy arcs connecting the referential dummy node to all vertices. The tree will then be transformed into successive trees following set rules. The transformation process proceeds until no further transformation is possible. The algorithm terminates in a finite number of iterations. The graph method is shown in Fig. 8.3.13.

The directed graph problem can be transformed into a network flow problem due to the special structure of the network flow programming model (Lerchs and Grossmann, 1965). Barnes (1982) shows the graph concept is mathematically equivalent to the network flow programming concept previously discussed.

The graph algorithm has been shown to be a practical method for determining the true ultimate pit limit with variable pit slopes in 3D. The main drawback of the technique is that in its original form, it requires large quantities of computing resources to determine maximum graph closure. Many researchers have looked at techniques to reduce the computer resources required. These include bounding techniques (Rychkum and Chen, 1979), limiting the number of directed arcs (Whittle, 1987), and the modified tree algorithm (Huttagosol, 1988: Huttagosol and Cameron, 1989).

8.3.6 LINEAR PROGRAMMING

Linear programming (LP) is considered one of the most powerful tools in operations research. The technique is a mathematical structure for the analysis of normative, linear models formulated to allocate limited resources such as manpower, haulage capacities, or contract constraints among various activities (ore production) competing for those resources in a manner to achieve the most desirable result. The "most desirable result"

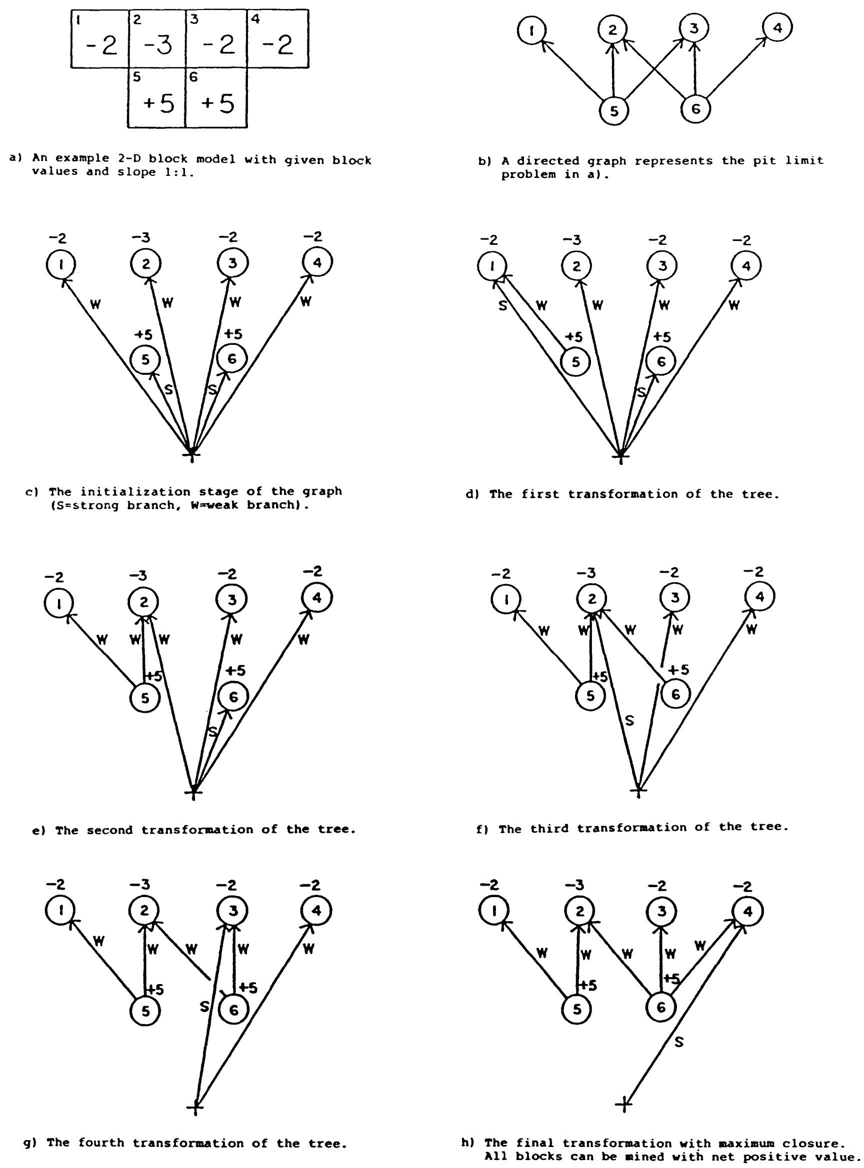

Fig. 8.3.13. Ultimate pit limit problem formulated and solved by using the directed graph algorithm.

typically is defined as the allocation scheme with maximum profits or minimum production costs per salable unit and is understood to be the objective for optimization.

Utilization of LP technique requires that all mathematical functions within the modeled system be linear. Both the objective function (maximizing profits or minimizing productin costs) and the limited resources (constraints) are expressed by linear equations. Hence problems are stated typically in a general mathematical form shown in Eqs. 8.3.25 and 8.3.26, in which n is the number of decision variables and m is the number of constraint equations.

$$\text{Max } Z = \sum_{i=1}^{n} c_i x_i \qquad (8.3.25)$$

Subject to:

$$\sum_{i=1}^{n} a_{ki} x_i \leq b_k \qquad k = 1, \ldots, m \qquad (8.3.26)$$

$$x_i \geq 0 \qquad i = 1, \ldots, n$$

$$b_k \geq 0 \qquad k = 1, \ldots, m$$

The solution technique used in linear programming to set production levels of competing activities is called the *simplex tech-*

nique. The simplex technique commonly imposes two fundamental requirements with respect to the structure of the system being analyzed:

1. All variables can assume any real nonnegative value.
2. All relationships are continuously linear.

The first condition states that variables are not restricted to whole values. A variable must be able to assume any value within the positive number space. If the quantity of labor for a certain mining section is to be determined, this assumption makes it equally valid for the solution to be either 4.3567 or 5.0 employee-hours of labor. Should it be necessary to limit a solution strictly to whole or integer numbers, then linear programming in its basic form is inappropriate and a mixed linear integer programming analysis should be considered.

The solution space is strictly limited to the positive number system by the first condition. In many cases it makes little sense to discuss negative activities or production. (Ore may be produced from a mine; however, rarely are we able to mine a negative quantity of ore!) When it is physically possible that a variable can assume a negative value, this restriction does not hinder the use of linear programming since any number, positive or negative, can be expressed as the algebraic difference of two nonnegative numbers. For example, when working with inventories it is possible to buy and sell goods. A positive number usually represents the quantity to buy while a negative number usually represents the selling or the consumption of inventory. However, if two separate variables are used, one positive number can quantify the amount to buy, and another positive variable can represent the quantity of inventory to sell.

The second condition is necessary for the simplex solution method to work. Implied in this condition by the term linear are proportionality and additivity assumptions over the entire range of the mathematically defined system being analyzed. Proportionality states that every increment of production utilizes an equal increment of the available resources. This is important since this restriction precludes equations that may take into account the economies of scale. The additivity property mathematically states that there are no cross-product terms that arise between activities. Given any activity level, the total usage of a resource is equal to the sum of the individual activities if considered separately. This precludes the use of LP where the marketability of one product is dependent of the production of another product.

Continuously linear conditions prohibit the use of functions that are stepwise or undefined at any point within the solution space. This restriction makes it more complicated to accurately model incremental production facilities typically represented by discontinuous functions.

Problem formulation for linear programming (LP) can be illustrated by the following highly simplified example.

Example 8.3.4. A small mine produces ore from two working stopes. The ore in stope A yields a profit of \$4.30/ton (\$4.74/t) and contains 0.36% arsenic. The ore in stope B yields a profit of \$5.00/ton (\$5.51/t) and contains 0.65% arsenic. The smelter requires that the average arsenic content of ore shipped cannot exceed 0.50% and the mine haulage system makes it impossible to haul more than 400 tons/shift (360t/shift). The objective of the problem is to maximize the profit per shift.

Solution. The decision that must be made is setting the quantity (or activity level) of ore to be produced from stopes A and B resulting in maximum profits. Two variables X_1 and X_2 can be defined: X_1 = tons/shift produced from stope A. X_2 = tons/shift produced from stope B.

Hence the following equation can be written to represent the objective of our linear programming analysis:

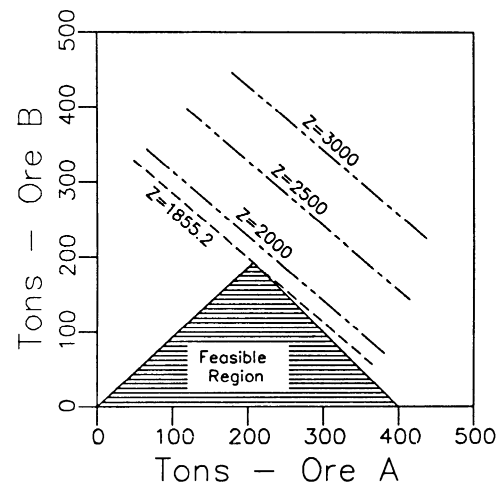

Fig. 8.3.14. Graphical solution of Ex. 8.3.4.

$$\text{Max } Z = 4.30X_1 + 5.00X_2 \tag{8.3.27}$$

The problem also has two constraints that bound the solution space. These constraints are a limited haulage capacity and a limit on the average arsenic content. In linear programming terminology these two constraints are considered the limiting resources. The mathematical form of the haulage constraint is easy to derive and can be expressed as

$$X_1 + X_2 \leq 400 \tag{8.3.28}$$

The average arsenic constraint requires a maximum average amount and can be expressed in mathematical terms as:

$$0.36X_1 + 0.65X_2 \leq 0.5(X_1 + X_2) \tag{8.3.29}$$

A little algebraic manipulation is needed to get the equation into the form specified in Eq. 8.3.26. Rearranging the terms, the arsenic constraint can be specified,

$$-0.14X_1 + 0.15X_2 \leq 0 \tag{8.3.30}$$

The result is the following formal mathematical formulation for the example linear programming problem:

$$\begin{array}{llrl}
\text{Max Z} & = & 4.30X_1 + 5.00X_2 & \text{objective function} \\
\text{Subject to:} & & X_1 + \quad X_2 \leq 400 & \text{haulage} \\
 & & -0.14X_1 + 0.15X_2 \leq \quad 0 & \text{arsenic} \\
 & & X_1 \geq \quad 0 & \\
 & & X_2 \geq \quad 0 &
\end{array}$$

The optimal solution of this highly simplified example can be easily seen by a quick 2D graphical analysis as shown in Fig. 8.3.14 since there are only two decision variables of interest. This figure shows that a maximum profit of 1855.20 can be obtained if 206.9 tons (187.7 t) of ore from stope A and 193.1 tons (175.2 t) of ore from stope B are produced. It illustrates the feasible solution space along with contours of equal and increasing values for the objective function (Z contour lines).

An important feature to note in the graphical solution is that the optimal solution lies on one of the extreme corner points of the feasible region as defined by the constraints. Formal proof that this will be true for any LP problem is shown by Wehl

(1934). Should the coefficients of the variables in the objective function change such that the optimal Z contour is parallel to a boundary of the feasible region, the optimal solution will be nonunique. However, one of the optimal solutions will still correspond to a comer of the feasible region.

Since the system of equations is also required to be continuously linear, the feasible region is guaranteed to be convex (Hillier and Lieberman, 1986). Convexity of the space and the linearity of the Z contours mandates that every corner will have at least one adjacent comer whose corresponding Z value is greater unless it is the optimal corner point. Therefore, the simplex method is a simple search technique that uses the foregoing two properties. It begins the process by starting at the origin where the Z contour value is zero, looks for an adjacent corner where the Z value is better, and iterates until it can make no more improvements to the objective function.

The simplex algorithm is covered in most texts on linear programming or operations research (Hillier and Lieberman, 1986; Daellenbach and George, 1978) if the exact mathematical manipulations involved in this solution technique are of interest. Many computer programs are available for a small charge to solve LP problems and are easier to obtain and use than working through the algorithm by hand.

The mathematical form of linear programming problems previously expressed with Eqs. 8.3.25 and 8.3.26 does not contain provisions for ≥ or = constraints on the resources. Yet production contracts typically require use of these types of constraints. For example, a contract may require delivery of an exact tonnage with minimums set on the quality of the product. Most texts dealing with linear programming derive the necessary algebraic manipulations and modifications required to use the simplex algorithm to derive a solution when these types of constraints are present. Commercially available computer software designed to solve linear programming problems automatically performs these manipulations should ≥ or = constraints be present. Therefore, a general formulation for LP problems, shown in Eqs. 8.3.31 and 8.3.32, can be expressed:

$$\text{Max } Z = \sum_{i=1}^{n} c_i x_i \qquad (8.3.31)$$

$$\text{Subject to:} \quad \sum_{i=1}^{n} a_{ki} x_i \begin{Bmatrix} \leq \\ \geq \\ = \end{Bmatrix} b_k \qquad k = 1, \ldots, m \qquad (8.3.32)$$

$$x_i \geq 0 \qquad i = 1, \ldots, n$$

$$b_k \geq 0 \qquad k = 1, \ldots, m$$

Example 8.3.5. The previous example can be modified slightly to illustrate problem formulation when dealing with the more general form. For example, assume that the silver in the ore in stope A averages 6 oz/ton (188 g/t), the silver in the ore in stope B averages 3.5 oz/ton (109 g/t), and the following two additional contractual constraints are imposed:

1. Tonnage in stope A must equal 200 tons/shift (180 t/shift):

$$X_1 = 200.$$

2. Average silver must be at least 4 oz/ton (125 g/t):

$$6X_1 + 3.5X_2 \geq 4.0(X_1 + X_2)$$

Solution. The modified mathematical formulation of the problem becomes:

$$\text{Max } Z = 4.30X_1 + 5.00X_2 \qquad \text{Objective Function} \qquad (8.3.33)$$

$$\text{Subject to:} \quad X_1 + X_2 \leq 400 \text{ haulage} \qquad (8.3.34)$$

$$-0.14X_1 + 0.15X_2 \leq 0 \text{ arsenic} \qquad (8.3.35)$$

$$X_1 = 200 \text{ tonnage} \qquad (8.3.36)$$

$$2X_1 - 0.5X_2 \geq 0 \text{ silver} \qquad (8.3.37)$$

$$X_1 \geq 0$$

$$X_2 \geq 0$$

The optimal solution of the modified example results in a maximum profit of 1793.50 by producing 200.0 tons (181.4 t) of ore A and 186.7 tons (169.4 t) of ore B. This problem can also be solved with most commercially available linear programming packages.

Simplex methods derive a solution to an associated problem simultaneously while finding the optimum resource allocations of the original problem. The related problem whose solution is obtained by solving the original problem is defined as the *dual* while the original problem is usually referred to as the *primal.* This concept of duality is a very powerful and useful advantage of utilizing linear programming techniques to solve resource allocations problems.

The secondary problem solved (the dual) when dealing with resource allocation is one which deals with the pricing of the scarce resources. The dual give the imputed value of the scarce resources within the problem; that is, the maximum price a company could pay for additional amounts is greater than the incremental profit derived by its use.

Included in most linear programming packages is the ability to display or print the solution to the dual problem. The dual solution of Example 8.3.5 gives the following:

Constraint	**Dual Value**
Haulage	0.00
Arsenic	33.33
Tonnage	8.97
Silver	0.00

The interpretation of the dual for resource allocation problems is that the dual values represent the maximum amount a company should pay to acquire an additional unit of each constraint. Haulage and silver constraints have dual values equal to zero. This is because the optimal solution does not utilize all of the existing capacity for the resources (i.e., 386.7 tons, or 350.8 t, of the 400-tons, or 362.9-t, haulage capacity is being used, and the silver content averages 4.79 oz/ton, or 150 g/t, in contrast to a minimum requirement of 4.0 oz/ton, 125 g/t). Therefore, a company should not be willing to spend any money on increased capacities for these two constraints since, in essence, any more capacity would also go to waste. The dual value for the tonnage in stope A is 8.97. This indicates that if the maximum tonnage mined from stope A can be increased 1 unit, an additional $8.97 can be obtained in profit (notice that increasing production in stope A also will allow additional tonnage to be mined in stope B at optimum performance of the system). The dual value of the arsenic content is 33.33. Interpretation of the dual for average content is a little more complex since the dual value reflects increasing the right-hand side of the final arsenic equation used in the linear program by one unit. Accordingly, that means that the equation,

$$-0.14X_1 + 0.15X_2 \leq 0 \qquad (8.3.38)$$

must go to

$$-0.14X_1 + 0.15X_2 \leq 1 \qquad (8.3.39)$$

or that the original arsenic equation must look like:

$$0.36X_1 + 0.65X_2 \leq 0.50(X_1 + X_2) + 1 \qquad (8.3.40)$$

With the assumed production constraints in the hypothetical problem of about 400 tons (360 t), increased profits of $33.33 can be expected for each 1/400th increase in the average arsenic content. If the average allowable arsenic content is raised to 0.5025, then an additional $33.33 could be expected as a profit if operating the mine at optimum levels. This means additional profit can be realized in the operation if penalty costs to the mine of increasing the arsenic content to that level is less than $33.33 additional profit gained.

Two other analyses that are also given by the simplex solution of the problem concern the sensitivity of the solution of its input parameters. These include what are called *objective row ranges* or *cost coefficients* and *right-hand-side ranges* analyses. The first is simply an indication of how stable the solution is in respect to changes in the coefficients of the objective function, while the second gives an indication of how far one can increase or decrease the value of the constraints before it becomes a fruitless exercise.

Simplex techniques usually express the objective row ranges as minimum and maximum values. In the previous example, the simplex gives:

Objective Row Ranges

Variable	Minimum	Maximum
X_1	None	None
X_2	0	None

This indicates that the coefficient of X_1 could be changed to anything, and the optimal operating point (ore in stope A = 200 tons, or 181.4 t, and ore in stope B = 186.7 tons, or 169.4 t) would not change. Profitability would change; however, the optimal operating point does not. This is not surprising since one of the constraints requires that production in stope A must equal 200 tons (181.4 t) regardless of its profit or loss. Likewise, the previous table shows that the profit coefficient of ore produced from stope B can be anything positive and the optimal operating point would not change. Notice that should the profit coefficient go negative (the company loses money by mining ore in stope B), then the optimal production rates will change. Typically, in real problems, these maximum and minimum coefficients tend to be within a few cents of the given parameters so that careful evaluation may have to be made on the appropriateness of the estimates utilized.

The right-hand-side range analysis is also expressed in terms of the maximums and minimums for the constraints of the problem. As before, they give an indication of how well estimates must be made. Another use of these values is to determine how far one of the constraints can be moved.

Example 8.3.6. To illustrate this concept, the simplex solution of Example 8.3.5 yields a right-hand-side range (RHS) printout as follows:

Right-Hand-Side Range Analysis

Constraints	Dual Value	RHS	Minimum	Maximum
Haulage	0.00	400.00	386.7	None
Arsenic	33.33	0.00	– 28.0	2.0
Tonnage	8.96	200.00	0.0	206.9
Silver	0.00	0.00	None	306.7

Solution. In this problem, haulage and silver have no dual value, so the right-hand-side range analysis indicates how far the RHS can be moved before the constraints would have a dual value; that is, it really indicates how much unutilized resource exists. Arsenic that has a dual value of $33.33 has a minimum RHS of –28.0 and a maximum RHS of 2. Once again referring to the original formulation of the constraint, a value of 1 equates to approximately $^1/_{400}$th of a percentage change in the allowable content. A maximum increase of profit can be realized if the arsenic constraint is increased from 0 to 2 or 2/400th of a percentage yielding increased profits of $66.66. The tonnage produced from stope A is constrained to equal 200 tons (181.4 t). The RHS analysis shows that if this tonnage constraint could be increased to 206.9 tons (187.7 t), increased profits of $8.96 ($9.88/t) for each ton would be realized. The RHS analysis shows that once the constraint exceeds 206.9 tons (187.7 t), the additional increase will not net additional profit. Likewise decreases of the constraints can be examined. They are handled the same as increases with the exception that the profit is being decreased by the dual value amount for each unit of decrease of the constraint.

8.3.7 MIXED INTEGER LINEAR PROGRAMMING

Mixed integer linear programming is a technique very similar to linear programming in its general mathematical form, with the exception that some or all of the variables used in the system can be defined such that they only assume whole or integer values. While the technique is still labeled by most texts as a special linear programming method, the introduction of integral constraints to one or more variables make it actually a nonlinear optimization technique (Beightler et al., 1979). Typical mixed linear integer problems are stated in a mathematical form almost identical to linear programming problems, with the exception that the nonnegativity condition for the integer variable are replaced by the requirement that the variables assume finite integer values, as shown in Eqs. 8.3.41 and 8.3.42:

$$\text{Max} \qquad Z = \sum_{i=1}^{n} c_i x_i \qquad (8.3.41)$$

$$\text{Subject to:} \quad \sum_{i=1}^{n} a_{ki} x_i \begin{Bmatrix} \leq \\ \geq \\ = \end{Bmatrix} b_k \qquad k = 1, \ldots, m \qquad (8.3.42)$$

$$x_i \geq 0 \qquad i = 1, \ldots, \bar{n}$$

$$x_i \text{ integer} \qquad i = \bar{n} + 1, \ldots, n$$

$$b_k \geq 0 \qquad k = 1, \ldots, m$$

The technique is useful in mining analyses since it allows one to accurately model production rates expressed in terms of the number of cars or labor in terms of employee-shifts. Once again, referring to the previous simplified example (i.e., Example 8.3.5), assume that the production in stopes A and B combined must be hoisted in a 7-ton (6.3-t) skip. A third variable that can only assume integer values can be introduced into the problem

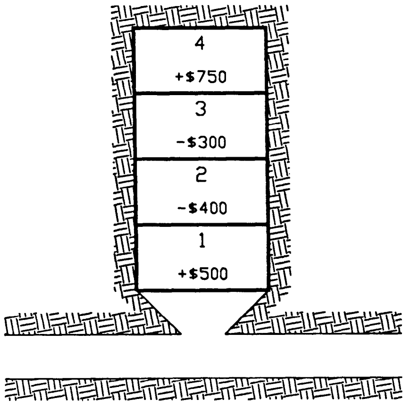

Fig. 8.3.15. Small ore stope with block values

to generate a production constraint that forces the total ore produced to some multiple of 7 tons (6.3 t). The new constraint added to the problem is shown in Eq. 8.3.43.

$$X_1 + X_2 = 7X_3 \tag{8.3.43}$$

where X_3 must assume an integer value of 1, 2, 3, ... *n*.

Rearranging the terms in Eq. 8.3.43 to standard mathematical form, the complete problem formulation then becomes:

$$\text{Max } Z = 4.30X_1 + 5.00X_2 \qquad \text{Objective Function} \tag{8.3.44}$$

$$\begin{aligned}
\text{Subject to:}\quad & X_1 + X_2 \le 400 \text{ haulage} && (8.3.45)\\
& X_1 + X_2 - 7X_3 = 0 \text{ haulage} && (8.3.46)\\
& -0.14_1 + 0.15X_2 \le 0 \text{ arsenic} && (8.3.47)\\
& X_1 = 200 \text{ tonnage} && (8.3.48)\\
& 2X_1 - 0.5X_2 \ge 0 \text{ silver} && (8.3.49)\\
& X_1 \ge 0 &&\\
& X_1 \ge 0 &&\\
& X_3 \text{ integer} &&
\end{aligned}$$

Mixed integer linear programming is used very frequently for scheduling and sequencing problems involving ordering restrictions such as modeling the production of an ore body where ore or waste must be exposed before it can be extracted. With such ordering restrictions, one typically formulates the problem with the introduction of variables that may take on only values of zero or one. This special case of mixed integer linear programming is referred to by most analysts as integer 0-l programming when all integer variables can only assume a value of either 0 or 1. In general, more efficient solution techniques can be applied to 1-1 problems; however, in practice, the general mixed integer linear programming algorithms are often used on these types of problems.

Example 8.3.7. To illustrate the use of mixed integer programming as applied to sequencing problems, assume that a small stope has four ore blocks (Fig. 8.3.15). The monetary value at the bottom of each block indicates either the profit or cost associated with mining and processing each block. In order to mine block 4 in this stope, blocks 1 through 3 must first be removed. If the objective of the problem is to determine the blocks to be mined that maximizes the total profit obtained from this stope, then four decision variables can be defined: X_1 through X_4. Each variable will assume a value of 0 if the block is to be left while it assumes a value of 1 if it is to be mined.

Solution. The following equation can be written to represent the objective of this problem:

$$\text{Max } Z = 500X_1 - 400X_2 - 300X_3 + 750X_4 \tag{8.3.50}$$

Constraints can be written requiring that if block 1 is not mined, then block 2 cannot be mined, and likewise, if block 2 is not mined, then block 3 and 4 are also left. This is accomplished by requiring that each 0-l variable be less than or equal to the 0-l variable representing the preceding block in the sequence:

$$X_1 \le X_2 \le X_3 \le X_4 \tag{8.3.51}$$

This results in the following integer programming formulation:

$$\text{Max } Z = 500X_1 - 400X_2 - 300X_3 + 750X_4 \tag{8.3.52}$$

$$\begin{aligned}
\text{Subject to:}\quad & X_1 - X_2 \le 0\\
& X_2 - X_3 \le 0\\
& X_3 - X_4 \le 0\\
& 0 \le X_1 \le 1\\
& 0 \le X_2 \le 1\\
& 0 \le X_3 \le 1\\
& 0 \le X_4 \le 1\\
& X_1, X_2, X_3, X_4 \text{ integer}
\end{aligned}$$

8.3.8 CPM/PERT

The *critical path method* (CPM) and the *program evaluation and review technique* (PERT) are two prominent procedures developed to aid in successful management of large-scale projects. These two techniques were first introduced in the late 1950s as methods for project management. PERT was developed by the US Navy to coordinate the work of many private contractors, while CPM was developed by the E.I. du Pont de Nemours Co. In recent years, these terms have been used to reference the network approach to project management in a very broad sense with little regard to the actual formal procedures represented by the original techniques.

Successful project management requires good planning, scheduling, and coordinating of numerous interrelated activities. Both CPM and PERT were developed with those goals in mind. These techniques answer the question of what is the minimum duration required for a given project, given proper management and sufficient resources.

While CPM and PERT are not direct optimization techniques, they provide a manager with information to aid project planning and control. These methods help resourceful managers deal with resource balancing and utilization in a manner that better sequences and schedules the use of a scarce resource. In addition, CPM and PERT may be used on an ongoing basis throughout the life of a project to help reduce total project duration, to allocate project funds, to optimally place purchasing requests, and to help allocate project or company resources involved in a project.

Project management as defined by CPM and PERT consists of three primary steps:

1. List and sequence project tasks.
2. Estimate task duration.
3. Evaluate the project.

The fundamental and common characteristic of CPM and

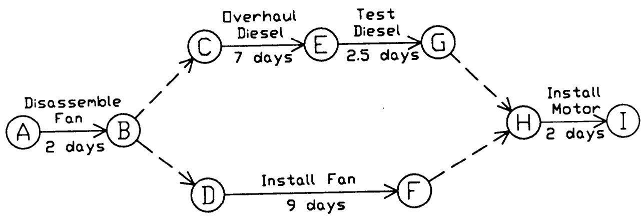

Fig. 8.3.16. Initial CPM network of a simplied fan move.

PERT is the use of a network to graphically illustrate both tasks and their sequence involved in completing a project. The project as a whole must be a set of well-defined tasks, which, in CPM/PERT terminology, are called *activities.* These activities or tasks are ordered such that they must be completed in some set sequence, and they are defined as the branches of the CPM/PERT network. The nodes of the network represents what is termed an *event,* which is defined as the point in time when all activities leading into that node are completed. Another component typically used with CPM/PERT networks is the incorporation of *dummy branches.* These are branches or dummy activities used to indicate interdependencies that cannot be represented correctly solely with the conventional activity and event structure and are useful when doing hand solutions of the network for creating parallel activities or merging several parallel activities. A highly simplified example is illustrated in Fig. 8.3.16 that represents a project where a diesel-powered mine fan is being moved to another site, and the diesel engine is overhauled in the process.

Step two involves the estimation of task duration. This is where CPM and PERT diverge. CPM takes a deterministic approach to the determination of task duration while PERT incorporates uncertainty into task duration.

8.3.8.1 CPM

CPM techniques utilize a deterministic approach to the determination of task duration. In step two, this simply involves estimating the time required to complete each task and using this assigned value.

Proceeding, the third step of evaluating the project involves determining the minimum duration of the project. The key to this step is to recognize that the minimum duration of the project is defined as the sequence of activities that yields the longest path or critical path through the network.

The estimated task durations found in the second step are used to calculate quantities for each node of the network called earliest and latest time. The *earliest time* is defined as the time at which the event will occur if all of the predecessor activities are started as early as possible and can be calculated on a forward pass through the network. Mathematically, the earliest time for any node j (ET_j) can be defined as:

$$ET_j = \max\ (EF_{i_k}, \text{ for all } i_k) \tag{8.3.53}$$

where (i_k) is a task ending at node j, EF_{i_k} is the earliest finish time of task i_k, and $EF_{i_k} = ET_i$ + task duration of task i_k.

The *latest time* for a node or event is the latest possible time that the event can occur without delaying the completion of the project and can be calculated from the earliest times on a backward pass through the network. Mathematically, the latest time for any node i (LT_i) can be defined as:

$$LT_i = \min\ (LS_{i_k}, \text{ for all } i_k) \tag{8.3.54}$$

where i_k is a task starting at node i, LS_{i_k} is the latest start time of task i_k, and $LS_{i_k} = LT_j$ – task duration of task i_k.

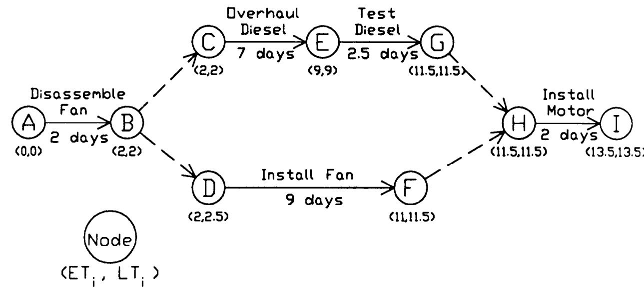

Fig. 8.3.17. Solved CPM network of a simplified fan move.

Once the earliest and latest times have been determined for each node or event in the network, the *critical path* is then defined as those tasks for which the earliest time is equal to the latest time. The critical path or paths (there may be more than one critical path within a network) represents the series of tasks or activities in which no delay in their start or finish can be tolerated without delaying the project as a whole.

Other nodes that are not considered critical have what is termed float or slack time. This *float time* is the difference between latest and earliest times and represents flexibility of task initiation by a project manager. A project manager can use float or slack time to delay initiation of various project tasks in order to better schedule manpower, equipment, or other company resources without delaying project completion.

A CPM analysis of the example illustrated in Fig. 8.3.16 yields the solution shown in Fig. 8.3.17. The figure shows the critical path by heavy lines, with the earliest and latest times of each node indicated.

8.3.8.2 PERT

The PERT technique utilizes a probabilistic approach to task duration. This approach is called the three-estimate approach. CPM assumes that task durations are known with certainty, while PERT in contrast accounts for the possible uncertainty in the activity duration by defining all task durations as a random variable conforming to a probabilistic distribution.

Each task or activity in a PERT analysis requires three estimates for its duration. These estimates include a "most likely" (usually denoted as *m),* an "optimistic" or minimum (denoted by *a),* and a "pessimistic" or maximum (denoted by *b).* PERT then assumes a beta distribution where the expected completion time t_e is approximated as,

$$t_e = \frac{1}{3}\left[2m + \frac{1}{2}(a + b)\right] \tag{8.3.55}$$

Next PERT requires that a variance is calculated for each task duration. This value for the beta distribution is approximated as

$$\sigma^2 = \left[\frac{1}{6}(b - a)\right]^2 \tag{8.3.56}$$

The third step of PERT, that of project evaluation, involves once again determining the minimum duration of the project. The expected values of the task durations t_e found in the second step are the values utilized. The process is then to use the t_e values to determine the critical path of the project, identically as with the CPM technique.

After the critical path has been determined, the probabilistic information is used to give a probabilisitic description of the

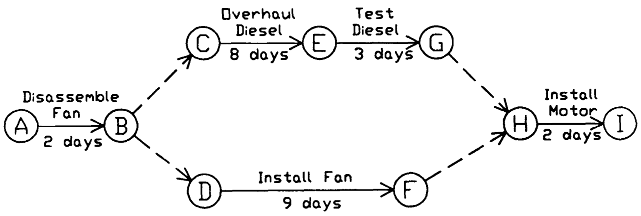

Fig. 8.3.18. Initial PERT network of a simplified fan move.

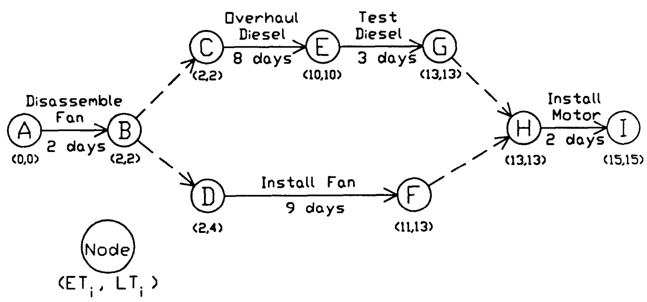

Fig. 8.3.19. Solved PERT network of a simplified fan move.

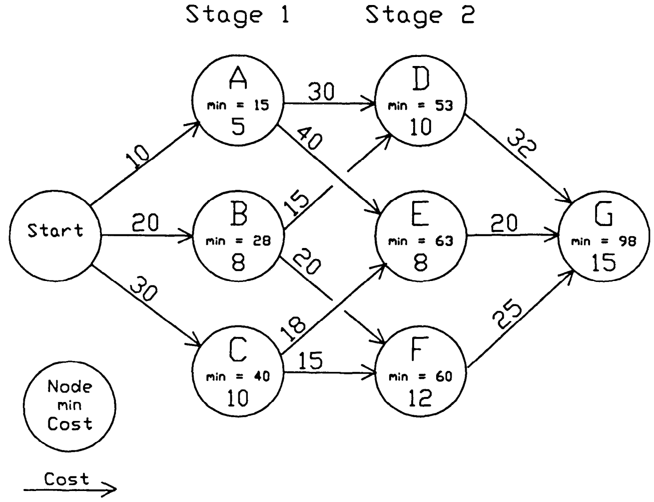

Fig. 8.3.20. Example dynamic programming network.

project completion time. Since any path through the network represents a sum of random variables, and PERT assumes that these random variables are statistically independent, the sum of the variances along each path represents the variance of the path. The critical path represents the project duration so that its mean and variance therefore reflect those of the project as whole. The central limit theorem then implies that such a sum is approximately normal so that, given the mean and variance, it is then possible to find the probability that the project completion time will be less than any given value. Likewise, the same technique can be used to find the probability that any given subevent within the project will be completed before some specific time.

Example 8.3.8. Assume that the following are the estimated time durations for each task using the PERT three-estimate approach of the original project illustrated in the network shown in Fig. 8.3.18.

	Duration				
Task	m	a	b	t_e	σ_e^2
Disassemble fan	2	2	2	2	0
Overhaul diesel	7	6	14	8	16/9
Install fan	9	8	10	9	1/9
Test diesel	2.5	2	6	3	4/9
Install motor	2	2	2	2	0

Solution. The resulting task durations denoted by the calculation of t_e are then used to determine the critical path as shown in Fig. 8.3.18 and yield the solution illustrated in Fig. 8.3.19. The total project duration according to the PERT analysis is increased to 15 days. The next step in a PERT analysis is to determine the expected variance along the critical path. This is simply the sum of the variance terms associated with each activity which lies on the critical path. Numerically, the value is 20/9.

Since the sum of independent ransom variables tend to approximate a normal distribution, the area under curve from negative infinity to some given time duration represents the probability that the project will be completed in that time or less. This is provided that the variability of noncritical paths is ignored. In the previous example (Example 8.3.8), this indicates that there is a 50% probability of completing the task in less than 15 days (mean value), a 90% probability of completing the project in less than 17.45 days (mean + 1.645 standard deviations), and a 95% chance of completing in less than 17.9 days (mean + 1.940 standard deviations).

8.3.9 DYNAMIC PROGRAMMING

Dynamic programming does not have a standard mathematical formulation in which a generalized algorithm can be applied to derive a solution, such as the simplex method for linear programming problems. Instead, *dynamic programming* is a systematic procedure for building and analyzing mathematical relationships that describe the operational characteristics of sequences of interacting decisions, taking into account the interrelationship of multistage systems. Beightler et al. (1979) refers to dynamic programming as conditional or partial optimization schemes.

The most common examples of dynamic programming techniques involve serial multistage systems. These involve a series of decisions in which it is necessary to determine which combination of decisions maximizes the operational performance of the entire system. Dynamic programming recognizes that solutions to this sort of multistage problems do not require total knowledge of every possible path to the states in each stage. Instead, the concept looks at how to get to the current state from the previous stage at a maximum profit or minimum cost.

Dynamic programming as applied to serial multistage systems can be illustrated by a simple network-type decision problem. Assume that a mine is interested in building an overland conveyor system that will be made up of five different belts. It is planned to build four transfer stations, for each of which there are several different site alternatives available along the planned route. The resulting network along with associated costs is shown in Fig. 8.3.20.

The dynamic programming concept simply recognizes that determining the minimum cost of building the belt system to any given node does not require investigating every possible route to that node. It requires only that the cost of the belt link from a predecessor site and the cost of the transfer station be added to the known minimum cost of reaching each predecessor node in

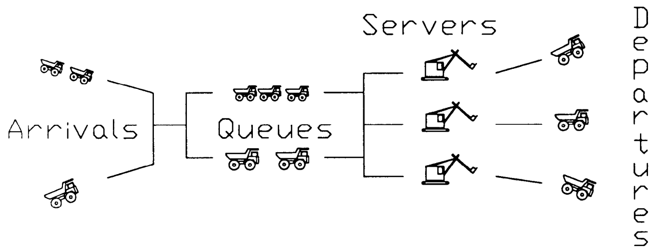

Fig. 8.3.21. Major components of typical queuing models.

the previous stage. The minimum cost of reaching a given site is then the minimum of all possible ways of getting to that state from the previous stage. Thus only partial paths need be examined to determine an optimal value. For example, the minimum cost of constructing the system node G in Fig. 8.3.20 is found by:

$$\text{Min} \begin{cases} \text{Minimum Cost to D} + 32 + 15 \\ \text{Minimum Cost to E} + 20 + 15 \\ \text{Minimum Cost to F} + 25 + 15 \end{cases}$$

In a very small network, such as that illustrated, the computational saving over investigating through complete enumeration many times are minimal. However, in many multistage networks, the computational requirements can soar very rapidly. For example, if the previous belt system had 10 links instead of 5, and there were 10 alternative sites for each of the transfer stations, then exhaustive enumeration would result in 10^9 total paths. The dynamic programming approach would evaluate only approximately 810 partial paths (Beightler et al., 1979).

8.3.10 QUEUING THEORY

Queuing theory is a branch of mine systems engineering that involves the mathematical analysis of waiting lines or queues. The theory primarily deals with the formal mathematical description of the waiting lines that form behind service facilities. In particular, queuing theory is used to determine the crucial characteristics of a waiting line such as average queue length, average waiting time, and average idle time of the service facility, given that both waiting-line formation and service times are stochastic processes. The theory itself is not a direct optimization technique. It only deals with providing a description of the waiting line. The description of the queue provided by the mathematical model is used as input for optimal decision making by an analyst.

Queuing problems tend to deal ultimately with trying to determine the optimum number of servers, efficiency of the servers, and required number of service facilities. In mining, the classic example of a queuing problem is trucks waiting in line to be loaded in a truck-shovel mining operation. With these problems the goal is to evaluate the optimum arrangement of trucks and shovels or to try to assist in the selection of trucks and shovels.

There are four major components common to most queuing models, as illustrated in Fig. 8.3.21. These include:

1. Arrivals.
2. Queue(s) or waiting lines.
3. Service facilities.
4. Departures.

Arrivals may originate from one or several different sources and are usually randomly spaced over time, conforming to some sort of probability distribution. These distributions are usually defined by time studies of an operation. Once an arrival takes place, it is either serviced by one of the servers, or if all servers are busy, it is placed in line (or in one of several lines). Here the arrival waits until its turn for service. The service facilities may be one shovel or several serving a single or multiple lines. The amount of time required for service (e.g., filling a 200-ton, or 180-t, truck) is also somewhat randomly distributed conforming to some sort of probability distribution. When service is completed, the arrival then departs from the system.

The nature of the queues is one of the controllable aspects of any queuing system. For example, a waiting line might be a first-come-first-serve queue; it might be subject to some sort of priority arrangement; or it might be possible for arrival to switch between queues, balk (leave if length is excessive), or renege (leave after joining a queue). The overall performance of a system can sometimes be improved by simply changing how the queues are handled.

The waiting line optimization problem is one of determining the number of service facilities and queue priorities or rules such that a minimum cost is obtained by a company. A company incurs cost if it has servers (such as a shovel) idle. A company also incurs a cost if it has too many customers (trucks) waiting on the shovel. Thus the optimization problem becomes one of minimizing the total cost to the company.

Most mining applications of waiting-line theory tends to be highly complex. Accurate modeling of most mining situations results in complex queuing models that have no direct analytic solution. Usually, even the more complex cyclic queuing models are simple approximations of the actual queue and tend to serve only as a first approximation to the behavior of the system. As a result, stochastic simulation techniques are generally employed as the practical choice of representing the true features of a waiting line or queue. Those interested in the mathematical formulation of these simple queuing models should refer to Daellenbath and George (1978), Panico (1969), or Hillier and Lieberman (1986).

8.3.11 ARTIFICIAL INTELLIGENCE

Artificial intelligence (AI) can be generally defined as “the development of computer systems to perform cognitive tasks that are, at present, more appropriately performed by humans” (Rich, 1983). Four broad AI categories can be identified. These are (1) natural language understanding, (2) machine vision and scene recognition, (3) robotics, and (4) expert systems. AI has its roots in the development of modern computational equipment in the 1950s and so is a very young and emerging area.

Natural language understanding is aimed at creating computers that can recognize continuous speech, and subsequently determine the deep meaning of what is spoken. Speech recognition has developed rapidly, and much progress has been made in this area. However, universal and continuous speech recognition (i.e., speaker and language independent) has not been achieved to date. Natural language understanding is still in its infancy. While much research has been done to advance this area, machines that can truly understand unbounded discourse are far from reality.

Machine vision attempts to duplicate both the ability to record a scene and to incorporate the complex scene processing of human vision. his includes such tasks as depth perception, motion cues, and scene recognition. All these visual tasks come naturally to humans, but represent very complex mechanisms that are not yet fully understood. While there are many general similarities between eyes and cameras, these are largely along the lines of physical optics. Research into how the eye actually works began with Helmholz in the 1880s. However, many questions remain unanswered. We still do not fully understand the retina and the action of neural processes behind the primary visual receptors. Beyond this, we have no firm understanding of how our brains construct an image from the retinal information. Recent work on edge detection models of the retina has proved of value, but only in a limited way. From the standpoint of applications, machine vision holds much promise for mining. Anywhere that human vision is essential to operation could potentially be replaced or improved by machine vision. Coupled with robotics, machines could be designed to operate remotely and in hazardous situations unrestricted by considerations of human safety.

Robotics, while somewhat more familiar to the general public through the media, is nevertheless distinct from that popular view. Robotics is the attempt to provide machines with much the same freedom of motion and mechanical interaction with the environment as is shown by humans. This includes tactile sensory feedback (such as pressure, temperature, and texture), balance, position sensing, and adaptation to obstacles of travel (collision avoidance). Simple robots are widely in use in well-controlled applications (such as assembly line work). Where more complex situations are found and adaptation is needed, robots are still being developed. While machine vision would solve the problem of scene recognition and understanding, robotics seeks to provide mechanical devices capable of responding to the information obtained from the visual processing of the environment. The average person thinks little of driving a car, but this is a tremendously complex problem for a machine. Recent development of an Autonomous Land Vehicle (ALV) shows some promise for the future, but this system is capable of navigating only well-constructed test roads. Again, much work is needed to advance robotics to levels approaching human performance.

The last area is *expert systems.* An expert system is, in effect, a computer counterpart to a human expert in a particular field (Rolston, 1988). Both the knowledge of the expert and the rules of problem solving are captured in an expert system. The role of the expert system is to gather facts about a problem in a directed manner, much as an expert would do, so that only those facts that are pertinent to the analysis are obtained. The expert system then "reasons" to a certain conclusion. This could be a simple statement concluding that the evidence submitted is indicative of an identifiable state of affairs, or that some facts are inconsistent with known parameters. The conclusion is based on the responses provided and the rules present in the rule base. Depending on the "shell" (software that implements the expert system), the entire reasoning process can be traced and inquiries can be made as to why the expert system provided a particular recommendation and what changes in facts or parameters will influence the outcome. This is much like the use of sensitivity analysis in numerical studies. The decision-making process can deal with both certain and uncertain information, thus imitating the reasoning process of a human expert. If uncertainty is included in the reasoning process, then it is possible that the result is a list of ranked conclusions rather than one value for an assertion.

Some examples of expert systems in earth sciences and engineering are worthy of note. An expert system was developed in 1987 to address issues related to natural resource management by researchers at Texas A & M University (Folse and Loh, 1987). GEOTOX, an expert system to analyze hazardous waste disposal sites, was developed at Lehigh University in 1986 (Wilson et al., 1987). The Environmental Protection Agency developed in 1986 an expert system to process effluent discharge permits. This system automatically adjusts the analysis based on the individual states' permit requirements. Prospector, developed by Science Research Associates, is an expert system which duplicated the "common sense" of a field geologist and a prospector (Duda et al., 1979). Its focus was to aid in locating mineral deposits. Other examples of expert systems in mining include blasting round design, ventilation, network analysis, maintenance and diagnostics of underground machinery, electrical system faults, and mining permit evaluation (Albert, 1989a).

Artificial intelligence remains a rapidly developing research field encompassing first computer science and subsequently many related disciplines. While some practical applications have emerged (such as expert systems), most of the fundamental goals of AI research have yet to be realized. Clearly, the nature of mechanized equipment, including that used in mining, will benefit greatly from advances in this area.

Other discussion of artificial intelligence may be found in Chapter 22.2 of this *Handbook.*

8.3.12 EXAMPLE OF A STOCHASTIC MODEL

A *deterministic model* is one in which a given set of inputs always produces the same set of outputs. However, in studying real-world systems, certain measurements or outcomes can only be described by an observed or expected distribution of outcomes—a random quantity. Generally, whenever a model includes random variables, it is considered to be a *stochastic model* (see 8.3.4) (Hillier and Lieberman, 1986).

Simply stated, the term *random* means without plan or order. Thus a random variable cannot be described by an equation, since the ordered rules of mathematics precludes this very situation. Instead, a random variable can be characterized by its distribution—an expression of the probability density for the observed set of outcomes (Emshoff and Sisson, 1970). Despite having constructed such a distribution, this only provides the probability of outcomes, not an explicit prediction of individual outcomes. Indeed, computer algorithms (systems of equations) to generate random numbers are actually pseudorandom.

In constructing stochastic models, variables in the system are recognized (or chosen explicitly) as stochastic. For example, virtually any task involving human labor will demonstrate a random variation that can be described by a distribution (Maisel and Gnugoli, 1972). Time study data plotted as a frequency distribution (or histogram) will almost always have this characteristic.

The goal of modeling is primarily to reflect the essential attributes of a system in a mathematical expression, thus duplicating the behavior of the system without constructing or altering the "real-world" counterpart. Of course, one is not restricted to known physical systems in the construction of a model. In either case, the behavior of the system is the result of the interaction of the entities of the system through the variables that represent the state of nature of each entity. The model is said to simulate the system of interest.

An important issue involved with modeling of any sort is the level of abstraction. A model with a high level of abstraction is one which includes only major and essential variables. Conversely, a model constructed with a low level of abstraction includes all of the major details of a system and many less important ones as well. It is usually the case that a model with a low level of abstraction can provide more detailed (and therefore more accurate) reflection of the modeled system. However, merely including more detail in a model does not guarantee a more accurate or even more realistic simulation.

Example 8.3.9. To illustrate these concepts and demonstrate a practical approach to stochastic modeling, consider a shovel-

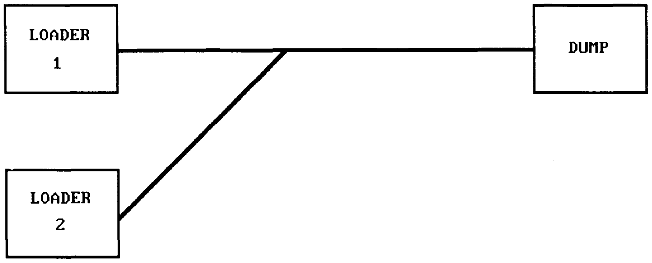

Fig. 8.3.22. Truck/shovel haulage diagram.

truck haulage system operating as in Fig. 8.3.22. At a high level of abstraction, this system embodies the load and haul deterministic model of the previous segment (8.3.4). Viewing this system as a collection of variables (in the load-haul-dump equation), the following time relationship for a truck is derived (Albert, 1979):

$$TCT_{\text{truck}} = LTT + TL + DT + TE + ST \qquad (8.3.57)$$

where TCT_{truck} = total cycle time for one truck load, from beginning of loading to next, LTT = total time to load a truck by shovel, TL = travel loaded time to dump, DT = dumping time, TE = travel empty time, and ST = spot time for truck before loading.

Note that no provision for mechanical delays is explicitly included, and any waiting time is considered separately.

Solution. To simplify the expression further, the variables TL, DT, TE, and ST are lumped together into one variable, namely, TA (truck away time from loader). The model is now formed with only two distributions: one for the load time of the truck and one for the away time of a truck (the time from the dispatch event to the return of the truck for loading again). Now assume that each of these distributions is normally distributed for the sake of demonstration (in real life, they usually are not).

To create the simulation, consider that there are two loaders and six trucks. The mean time to load a truck is 4 min with a standard deviation of 1 min, and the away time of a truck is 16 min with a standard deviation of 2 min. As indicated, the times will be modeled with a normal distribution. Every instance in the model that a time is needed for either a loading time or an away time, the following equation is employed:

$$Ts = MeanTime + (NDRD * StdDev) \qquad (8.3.58)$$

where Ts = time sample for this event, $MeanTime$ = mean time for event, $NDRD$ = normally distributed, random number sample (mean= 0, standard deviation = 1), and $StdDev$ = standard deviation of time for event.

The model proceeds from event to event, creating an event-oriented simulation. This means that the time clock in the model will jump from each loading event to the next based on the times sampled for each sequential event.

The procedure to determine an particular sampled time (the time to load a truck or the time a truck is away from the loader) is to substitute the distribution parameters in the equation, obtain a normally distributed random number *(NDRD)*, and apply the equation. The normally distributed random number stream is created by adapting the uniform random function supplied in the programming language environment.

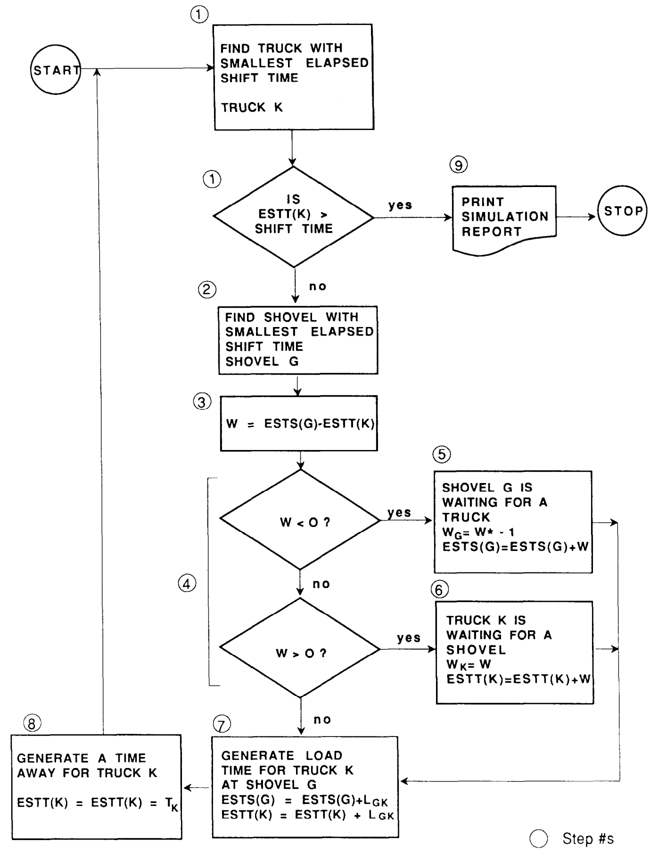

Fig. 8.3.23. Flow diagram for event model.

Fig. 8.3.23 shows a flowchart for the simulation model. It has been generalized to any number of trucks and loaders, so it is not explicitly limited to the two loaders and six trucks used for this demonstration. Refer to the flowchart for the steps described in the following that are a procedural definition of the model.

Next define the following:

M = number of shovels in the system.
N = number of trucks in the system.
$ESTS(i)$ = elapsed shift time of shovel i.
$ESTT(i)$ = elapsed shift time of truck i.
ST = ending time for simulation end.

To perform the simulation, the steps below are executed (Ramani and Albert, 1985). These steps correspond to the labels on Fig. 8.3.23.

1. Choose the truck with the smallest elapsed shift time. Let it be the Kth truck.

If $ESTT(K) \geq ST$ THEN GO TO step 9

2. Choose the shovel with the smallest elapsed shift time. Let it be the Gth shovel.

3. Calculate W as follows:

$$W = ESTS(G) - ESTT(K) \qquad (8.3.59)$$

4. If $W < 0$ GO TO step 5 [Shovel waited for a truck]
If $W \geq 0$ GO TO step 6 [Truck waited for a shovel]
If $W = 0$ GO TO step 7 [No waiting—exact match]

5. Shovel G was waiting for a truck to become available to load. Therefore, W is the waiting time of the shovel.

Update the event time for shovel G:

$$ESTS(G) = ESTS(G) + W \tag{8.3.60}$$

GO TO step 7

6. Truck K was waiting for a loader to become available. Therefore, W is the waiting time for truck K.

Update the event time for truck K:

$$ESTT(K) = ESTT(K) + W \tag{8.3.61}$$

GO TO step 7

7. Generate a load time for truck K at the Gth shovel. Call this time L_{GK}.

Update the status of the shovel and truck by the load time:

$$ESTS(G) = ESTS(G) + L_{GK} \tag{8.3.62}$$

$$ESTT(K) = ESTT(K) + L_{GK} \tag{8.3.63}$$

8. Generate an away time for truck K. Call this T_K.

Update the status of the truck:

$$ESTT(K) = ESTT(K) + L_{GK} \tag{8.3.64}$$

GO TO step 1

9. Produce end of simulation report since the time threshold has been equalled or exceeded by the time of the next event.

Table 8.3.18 is a listing of a program written in Microsoft™ Quick BASIC to perform the simulation just described. Applying the information for time distributions and costs, Table 8.3.19 presents the summary report from running the model.

Chapter 8.4
COMPUTER METHODS

KHOSROW BADIOZAMANI

8.4.1 INTRODUCTION

To provide a description of computer methods used in mining, one must first define the area of interest. The extension of computer usage to the many facets of mining is too numerous and complex to be described in a short chapter. Today computers are used in all areas of mining, from exploration and drilling to mine planning and mine design, mine operation, reclamation, surveying, maintenance, inventory control, accounting, payroll, and marketing, to name a few. For computer applications in mining, the reader is referred to the appropriate sections and chapters of this *Handbook.*

In this chapter, concentration is on the scientific and technical aspects of mining and only on major topics. The plan is to examine the what, where, how, and when aspects of computer usage, that is, what a computer is used for, where it is used, how it is used, and when it should be used. Then the concepts, advantages, and disadvantages of computer usage are expanded to provide a better understanding of the details involved in its usage. In addition, an attempt is made to provide some guidelines on how to select a system of hardware and software. It is understood that rapid changes in the state-of-the-art of hardware and software technology make it difficult to establish long-lasting selection criteria; however, the main ideas and concepts should stand the test of time and provide useful and general guidelines.

8.4.1.1 Where Computers Are Used

Computers are used for storage, retrieval, and analysis of geologic data plus design, simulation, and monitoring of mine plans and mining operations.

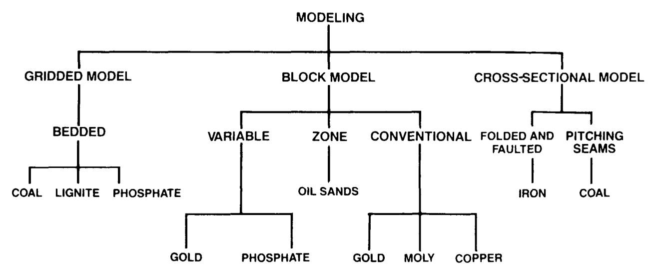
The majority of effort in computerization has been concentrated in the areas of storage, retrieval, and modeling. Early efforts were concentrated on automating manual methods to reduce error and increase efficiency. As the user's acceptance of the automated methods has increased, along with the complexity of ore bodies, the need for more sophisticated techniques has moved computer usage to a new frontier. Geostatistics and complex mathematical modeling provide ore-reserve approximation techniques and simulation approaches that are basically impractical to perform manually.

Blind application of computers to all situations, however, is not advisable. Computers should only be used where they provide an immediate or long-range advantage. For situations with little data and only one time evaluation or calculation, it may be easier and less costly to use manual methods. It should be remembered that computers are another tool in the engineer's tool kit. They have their place and can be useful if used properly and can complicate the situation if not.

8.4.1.2 How Computers Are Used

Computer applications vary with the type of mineral deposit and the complexity of the ore body. The basic ore body modeling concept, however, remains the same even though the method of compositing varies from one type of deposit to another. Table

Table 8.4.1. Decision Tree



8.4.1 provides a simple look at the classification of modeling based on the type of commodity, stratabound vs. disseminated type of deposits, and the locale of mining, that is, surface or underground. From this table, it is obvious that to provide a complete explanation for all available options is not practical within the space allotted to this *Handbook.* As a result, except for conditions common to all deposits and types of mining, our discussion will concentrate on the stratabound type of deposits and mostly on surface applications.

8.4.1.3 Basic Concepts in Use of Computers

The main objective of computer application is to simplify the process of data collection, retrieval, analysis, and modeling. In addition, computer modeling removes the possibility of an undetected error in calculation and allows evaluation of more alternatives in a shorter period of time than is possible by the manual approach. As a result, computer modeling will assist in achieving the ultimate goal of mine planning, which is to provide the "best" strategy for developing and mining a deposit. The best may not necessarily be the optimum and will be dependent on the goals set by each corporation. The reason is that to obtain an optimum solution, one may need to spend a great deal of computer resources, and at the end the optimum solution may not be practical.

As easier deposits are exhausted and the need for designing more complex mine plans become commonplace, computers can assist in reducing tedious tasks and allow the specialist to concentrate on his/her area of expertise, which is mine design.

Computers can be regarded simply as devices that are fed raw information. These raw data are processed, analyzed, and modeled, and the result is an output in the form of reports, maps, and graphs. In other words, the operation is based on three simple activities: input, processing, and output (Fig.8.4.1). The main task is to make sure that the correct information is contained in the input and the right type of process is selected to assure correct results as output.

A major benefit of computerization is compulsory collection of all data in advance of modeling. This process in actuality forces many users to collect all data, maps, and information from various individuals involved in the project in one area rather than having them scattered in different file cabinets and drawers.

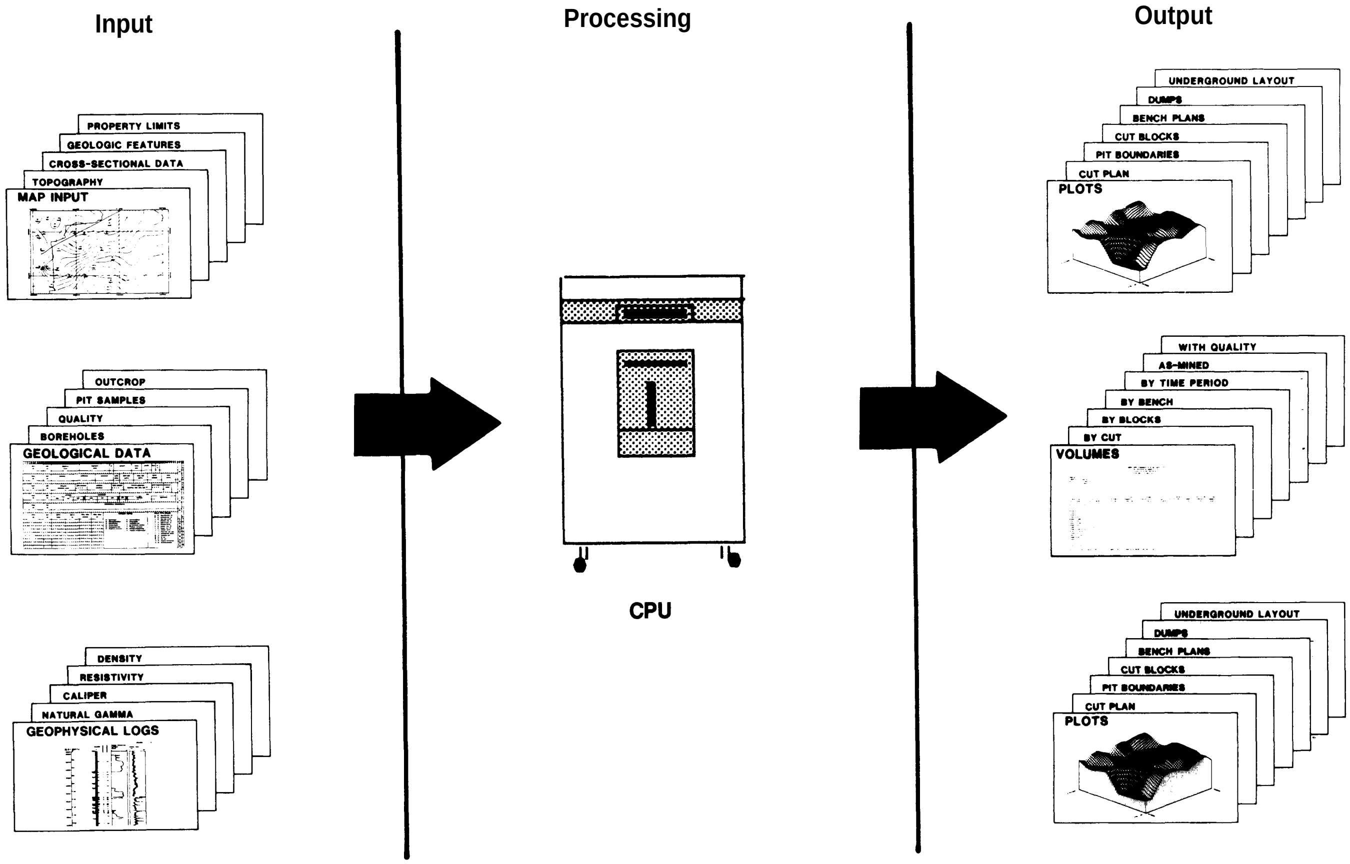


Fig. 8.4.1. Stages of computer processing.

The initial collection and input of data into computers forces purging of invalid and incorrect data or simply forces cleansing of information before use. In fact, a sign of a well-designed system is its ability to assist users in differentiating between valid and invalid data by processing the information before permitting its transfer to the database.

8.4.2 RESOURCE MODELING

8.4.2.1 Data Acquisition

Resource modeling starts with the gathering of information, that is, drillers' data, core-hole information, geophysical logs, topographic maps, cross sections, and survey data. In some cases, detailed drillhole information is not available, and only previously generated structures or isopach maps are provided.

The initial task is to organize the data in appropriate categories, because each set of data is handled differently. Drillhole information is either transferred to preprinted forms or it is directly entered into the computer using formatted screens.

Even though it is possible for the geologist to input data directly into the computer, if more than 50 to 100 drillholes need to be processed, it is advantageous to have data entry clerks enter the data. After all the information is entered, the geologist can check the results for inconsistencies or possible data-entry errors.

As mentioned earlier, a good system provides automatic checking of the data as much as possible. In the following pages, for the sake of demonstration, examples from EAGLES, a comprehensive geologic and mine planning system developed at Morrison-Knudsen Co., are presented. There are many other systems available on the market that are suitable for modeling and mine planning of various types of deposits. These models vary in their scope and the range of mining options they cover. Their functions mainly reflect the area of expertise of the primary developers and the type of mining the model was intended for. One should examine the functionality of a system carefully to ensure that it can adequately perform the functions specified. A detailed discussion of the hardware and software selection is provided at the end of this chapter to assist readers in the selection process.

8.4.2.2 Minimum Data Requirements and Database Concepts

To analyze and model a property, one has to have a minimum set of data. The basic data consist of a set of information that defines drillhole location and geologic as well as assay or analytic data. As a minimum, the database should contain:

1. Drillhole name, collar elevation, X-coordinate, Y-coordinate, drillhole deviation, seam/unit ID, seam/unit top intercept, seam/unit bottom intercept, grade/assay, analytic/quality, lithology/rock type.

2. Additional information, such as property name, driller's logs, geophysical logs, special codes for geologic conditions, water table, and many other such items of information may be also added to the database.

A database may be set up with two different concepts in mind. The first is to set up a database as a repository for all the information. In this type of database, in addition to items specified previously, information such as lithologic characteristics, mineralogical, petrographic, and alteration descriptions are also stored. To accomplish this, a number of text fields are assigned to the descriptions and narrative information provided by the drillers or geologists.

The second type of database is mainly set up for mapping and modeling. Such a database does not contain much text or narrative information, and only data pertinent to modeling will be coded and entered into the database. The majority of available commercial modeling systems are of this type, where they provide for storage of data pertinent to modeling. The advantage of this type of database is that it minimizes the disk space required, and by reducing the size of the database it will expedite updating and retrieval of the data.

A separate database contains property boundaries, physical structures, pipelines, power lines, and so on. This type of data is normally available in the form of maps or survey information. Map data needs to be digitized.

8.4.2.3 Digital Map Data

To transfer plotted information to the computer, a map is positioned on the digitizer tablet, and after initialization the data are digitized. If the X and Y (easting and northing) scales are the same, two separate points digitized on the map can establish the scale. However, if the X and Y scales are different, three points are required to establish the scale. The points digitized for the initialization process should be at the extremities of the map to assure correct scale and to compensate automatically for the stretch or shrinkage in the map. Paper maps stretch and shrink depending on the moisture content in the air; therefore, providing a map scale directly to the system may result in error.

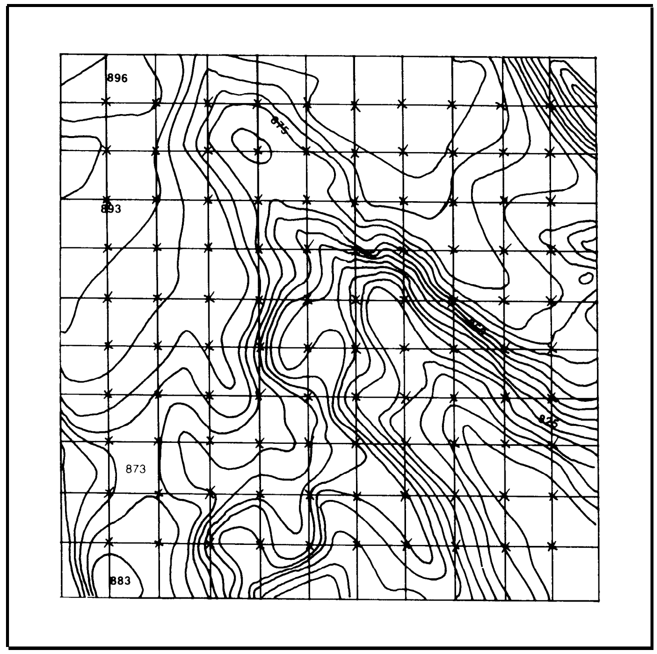
Following establishment of the scale, each individual line is traced either in a continuous or in a point mode. Most systems allow editing capability during digitization or immediately after. Data can be stored as individual files or they can be directly input into a database and tagged with identifiers.

Survey data is regularly provided in a digital form by photogrammetric companies or by survey crews through a total station or survey notes. These data can be added to the system by automatic reading of the digital tapes or by direct input of the data via formatted screens.

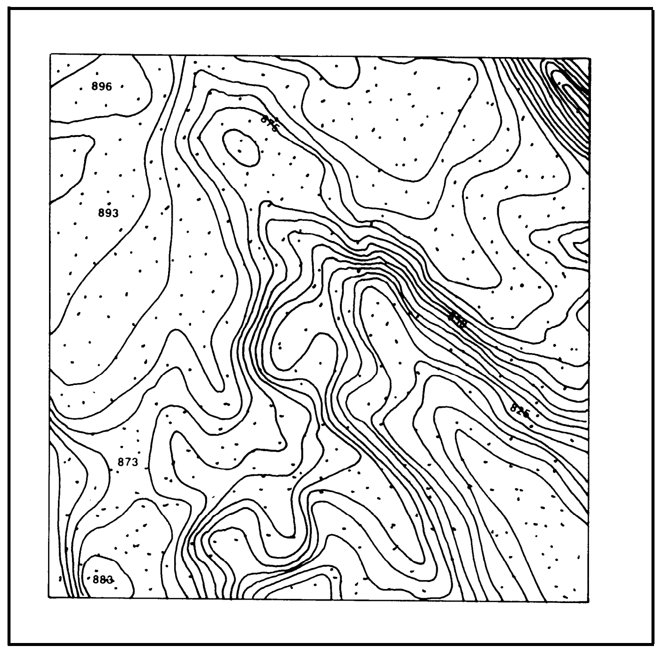
Photogrammetric companies can provide topographic data in digital or map form. Digital data are provided in one of two forms: (1) in rows and columns at a given interval, that is, on a grid pattern; or (2) as a set of irregularly spaced data depicting breaks in elevation taken throughout the region of interest (Fig. 8.4.2). Irregularly spaced data may be provided by way of cross sections parallel to Y (northing) or X (easting) and points taken at the break points greater than specified elevation difference (Fig. 8.4.3).

Each set of data provided by any of the foregoing methods has its advantages and disadvantages. The gridded data is the simplest to handle, because all that needs to be done to it is to read it and store it in the desired format. As long as the same grid increment or multiples of it are used throughout the operation, there is no problem. As soon as a smaller grid interval becomes necessary, however, the data has to be regridded. As a general rule, the accuracy of the regridded data is less than original data, and the grids may be off by a substantial amount from the actual. The difference between the estimated and actual surface elevation is a function of changes in topography, that is, the more rugged the terrain the more deviation from the actual.

The irregularly spaced data option eliminates this problem and allows generation of grids of any size. Grids generated by



Gridded Pattern

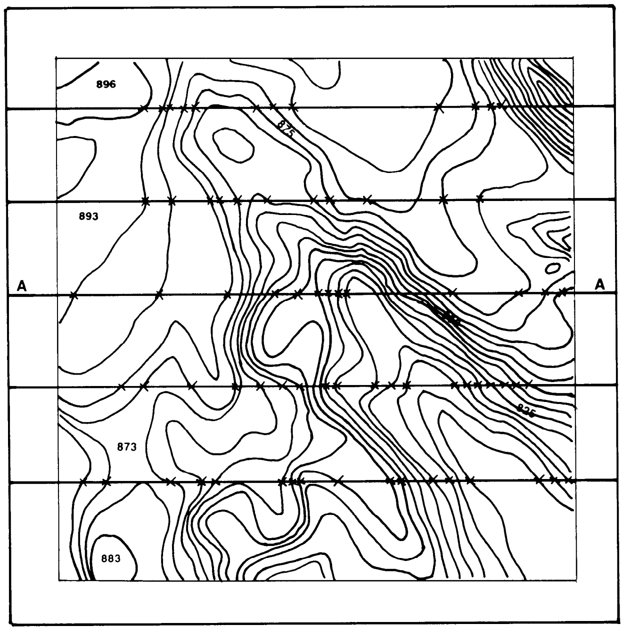


Irregular Pattern

Fig. 8.4.2. Digital sampling of topographic data.

this method represent the actual elevations as closely as possible, the main reason being that during sampling, all major breaks in the topography are picked. The gridding process uses this data to arrive at a value for each node. The main problem with the irregularly spaced data option is the enormous number of data points sampled and the tremendous amount of processing required to generate a gridded surface from this data.

The cross-sectional method is a cross between the two other options (Fig. 8.4.3). It provides the number of data at the break



CROSS-SECTIONAL PATTERN

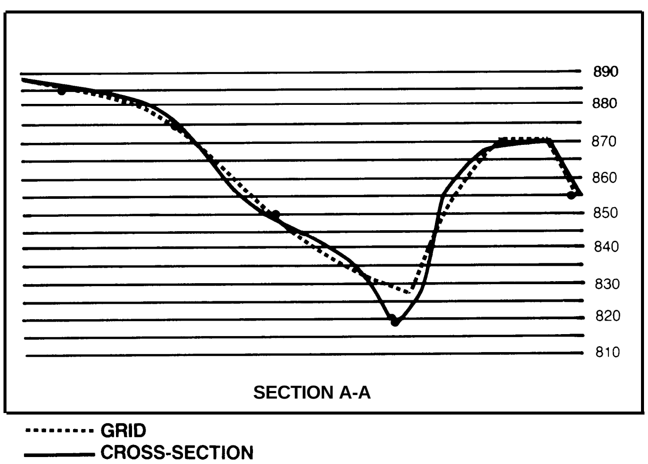


Fig. 8.4.3. Cross-sectional sampling of topographic data.

points in one direction, but it is set at regular intervals in the other direction. The processing requirement is not as intense as the irregularly spaced option, but it is more than gridded data. The accuracy factor, however, is not as good as the irregularly spaced option, because it lacks the necessary detail in one direction. For this reason, the cross-sectional data are not as useful as the other two. If the possibility of regridding is minimal, then the gridded data provide the best and fastest result. In particular, if the initial grid is generated at small enough increments, then larger grid increments can be generated without losing accuracy. If gridding increments are to be changed on a regular basis, or a suitable grid interval cannot be decided upon, then the irregularly spaced option is a better choice. Experience shows that a 100-ft (30-m) grid increment is a satisfactory increment for most operations in the United States, Canada, and most other parts of the world.

8.4.2.4 Geologic Modeling

The most important task in any modeling process is collection and editing of the data. The reason for emphasis on the need for thorough data checking and validation is to minimize wasted time and effort during the modeling process. Discovery of an erroneous data point during the modeling stage is a very costly and time-consuming endeavor because the entire process of data checking, retrieval, and modeling has to be repeated again. If the problem is not discovered on time, it may result in inaccurate interpretation and improper decision, with grave consequences. Following the completion of data entry, checking, and editing, the modeling task begins.

Geologic modeling, in essence, is reconstruction of the three-dimensional geologic picture of a deposit from a handful of sample data. The process combines the power of imagination with mathematical formulations to arrive at a satisfactorily reconstructed model. There are numerous approaches to the problem. In the following pages, the major approaches to the process are described.

To model a property, three pieces of information—the topography, the geologic and assay data, and the properties or other physical information—are required. The data may be obtained through any of the previously mentioned processes.

8.4.3 DATA INPUT

8.4.3.1 Topography

Topographic data are obtained either through photogrammetric means or digitization of existing maps. If data are available from photogrammetric services, the tape provided is loaded into the system, and through usage of a translation program, it is translated into a specific required format.

If the provided information is in the form of irregularly spaced data, it is passed through a gridding program with desired grid increments specified. The resultant grid then is used in the subsequent operations, and the raw data are stored on tape for possible later use. Cross-sectional data may or may not need any processing, depending on the capability of the system. EAGLES provides cross-sectional, gridded, and variable block modeling techniques, and their usage is dependent on the type of deposit and the degree of pitch of the strata. For steeply dipping deposits or for very complex geology, a cross-sectional modeling approach is more appropriate. The cross sections can be used at any time to generate a gridded surface. This data then can be used in the subsequent operations. At the end of this process, a model of the topography is developed for the area of interest.

8.4.3.2 Geologic Input

Geologic data-input requirements vary depending on the commodity of interest, the complexity of the geologic conditions, and the size of the property. As a general rule, the more complex the geology, the more information is required. Also a coal deposit normally requires more data than, say, a gold deposit. In addition to basic information such as the ones specified, quality data for proximate and ultimate analysis, washability, ash-fusion temperatures, and trace-element analyses are regularly provided for coal. Other commodities such as phosphate may require information for the processing plant as well. Regardless of the type of commodity, the data input deserves a great deal of attention. The input determines the usefulness of the model. Companies usually assign their most junior geologists or engineers to this important task and as a result spend a great amount of time rectifying the resulting problems during or after modeling.

Data Verification: After loading the data into the database, various reports should be generated and reviewed for accuracy of input and for elimination of invalid data. Statistical tables showing the range of data and the mean and standard deviations for each field can assist in data verification. It is useful to display the number and the X,Y locations of the drillholes that contain the maximum and minimum values for each field. These reports and statistical tables should be reviewed carefully to ensure that the data extremes are valid.

Another verification method is to generate a contour map of the data and look for "bull's eyes" on the map. They invariably point to the error in the data, that is, either input error or assignment of the wrong X and Y location to the hole. All errors should be corrected in the database, and new reports generated. The process should be repeated as long as erroneous data are found.

Use of Database: The database should contain data in their raw form and without any regard to mining criteria or minability of any unit. Many companies allow their interpretation of the minability of the units to determine which ones will be entered into the database. This practice is unwise, and as mining and economic conditions change, the database becomes useless, resulting in another round of data input. The preferred method is to keep data in the database in their rawest form possible but allow the retrieval programs to combine and sort the data, based on the economic criteria specified at the time of retrieval. This simple concept will ensure the longevity of the database while providing the possibility of unlimited mining and economic combination alternatives throughout the life of the project.

Correlation: Bedded deposits require extensive amounts of time to correlate individual units across the property. This process is not only very time-consuming but repetitive. The geologist has to analyze each drillhole in conjunction with all other holes and for all units down-hole. An on-line correlation program with direct access to the database can save many man-months of efforts. The concept is simple but somewhat hard to implement. EAGLES allows the user to select a set of cross sections from a plan-view location map of the area. Sections can be defined either by a traverse line and an area of influence to either side of the line or by selecting individual drillholes. Following the selection process, all drillholes will be retrieved from the database, and the geologist can examine any of the sections by recalling that section. In addition, geophysical logs for each hole can be displayed, along with the stratigraphic logs, to assist in the correlation process. A comprehensive set of commands provide full correlation capability right on the graphic terminal. Key holes can be set up as the guiding holes for the rest of the data. Modified drillholes will be updated directly into the database, therefore providing an up-to-the minute set of data to all users.

8.4.4 DATA RETRIEVAL

8.4.4.1 Retrieval Process: How and What to Include

A good retrieval system is essential to a good geologic system. Not so obvious is the fact that a strong retrieval system can simplify, and at the same time, enhance the geologist's task. It can simplify a task because the geologist does not have to decide on the details of what should be included in the database; instead, concentration will be on actual data input and correlation. It will enhance the geologist's capability because it will allow retrieval of data in any set of combinations desired. Many factors such as economic conditions, minability of the thin units, and geologic factors such as erosion or pinching seams can be specified at the retrieval time for alternative evaluation. The retrieval process normally is customized for the type of commodity being modeled.

8.4.4.2 Coal

For coal deposits, structural and thickness data are retrieved and modeled first, to delineate the extent of the deposit and its spatial distribution. If borehole deviation or pitching seam data are available, the necessary correction is made to provide for a true-thickness calculation. However, a true-thickness calculation is not necessary if the model is going to be used for volumetric calculation. A majority of the volumetric programs calculate the in-place or as-mined volumes directly from the model.

Following or concurrent with retrieval and modeling of physical data, quality data are also retrieved and modeled. Samples usually need to be combined for a given seam or range of seams. If washability data are available, washability tables are generated to determine the appropriate specific gravity of wash. Quality data for desired specific gravities are retrieved and modeled. Reduction and dilution factors may be incorporated in the data at this time, or they may be postponed and applied to the gridded model at the time of mining. Reduction and dilution can be on a percentage basis or based on a specified thickness from top and/or bottom of each seam. Cumulative information may be necessary if seams are too thin or the parting is less than a given thickness that can be mined separately.

The retrieval system provides for selection of raw or washed data and for conversion of as-received data to dry basis and back. It should be able to use any of the three moisture data in the database, that is, sample moisture, equilibrium moisture, or air-dry moisture for these calculations.

8.4.4.3 Noncoal

For nonstratabound deposits and for disseminated ore bodies, physical data retrieval is combined with retrieval and compositing of the assay data for each mineral and for a given bench height. Correction for borehole deviation, if applicable for dipping seams, is made at this time. Compositing of samples is necessary for various reasons. The sample size, length, and weight of sample vary among drillholes, and to arrive at a common size for a given interval, samples are composited. Depending on the deposit, it is necessary to combine samples into common weight segments representing a segment of ore body for volume or grade calculation. The compositing process is the same for various commodities; however, depending on the type of deposit, care should be taken not to composite among dissimilar geologic zones.

Provided that the sample length and associated assay values are available, compositing is accomplished by summing the products of sample lengths and corresponding assay values, then dividing this sum by the total of sample lengths, to arrive at a weighted average (Barnes, 1980a). The composite interval is usually determined by the bench height at the time of mining. For example, if samples are taken at 10-ft (3-m) intervals, and a 35-ft (11-m) bench is required, then the first three samples and half of the fourth are used to arrive at the composite value for that bench (Fig. 8.4.4). This assumes that the entire bench is part of the same geologic unit. Extreme care should be taken to avoid compositing of dissimilar data. Barnes (1980) suggests the term *draped composite* for a compositing process that uses a surface or multiple surfaces to initiate the compositing. This process allows the use of the surface of the mineralized zone as the starting point for compositing rather than an arbitrary

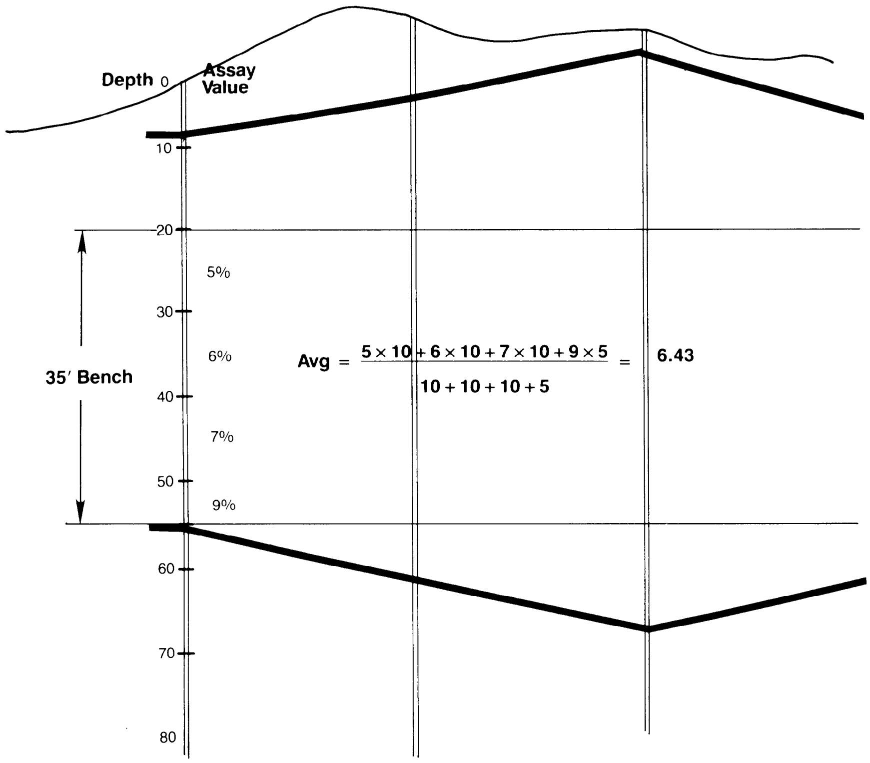

Fig. 8.4.4. Bench compositing.

elevation, resulting in a more accurate representation of the mineralized zone.

Badiozamani et al., (1988a, 1988b) have developed a new compositing and variable-zone modeling process to deal specifically with the problem of inclusion of geologic and depositional environment in the compositing and modeling process. The model was developed to handle complex geology and the variation in ore content of deltaic tar sand deposits. However, the same modeling process can be applied to other mineral deposits. with only minor modification to the compositing routine.

Variable Zone Compositing: This compositing process starts with first definition of depositional environment and correlation of geologic units across the property. The groups and formations are identified, and each group or formation is further divided into their depositional subunits or so-called zones. For example, a group may be divided into marine, transitional, and continental zones. If additional information is available, each of these zones may be further divided into subzones. For instance, a transitional zone may be divided into delta plain, delta front, and prodelta subzones. By using the depositional environment to arrive at the subzones, advantage is taken of the available geologic knowledge to limit the grade estimation across the property to only comparable units. In essence, we take advantage of other parameters contributing to grade variation such as porosity and permeability, especially when secondary mineralization is involved.

Following identification of the zones, the combination of each unique lithology and depositional facies is identified. We refer to this unique combination as *material type* (MT), which is used as the basic unit for interpolation and compositing between the drillholes. For example, a channel sand and a point bar sand constitute two different material types. During modeling, regardless of the algorithm used, only similar material types are used for interpolation within each subzone.

In addition to material type, a zone may be divided into smaller subzones by using sudden grade variation down-hole as another criterion for control of lateral interpolation. Figs. 8.4.5 and 8.4.6 depict the effect of zone, subzone, material type, and grade variations on defining each interpolation region. Fig. 8.4.5 shows the entire region being divided into zones one, two, and three. Then each one of these zones is further divided into four material types. Fig. 8.4.6 shows how each of these material types is subsequently divided into a number of subzones as a result of grade variations of more than 3%.

As indicated previously, this process allows inclusion of maximum geologic and depositional control into interpolation process. After zone and subzone designation, and prior to interpolation, grade and other values need to be assigned to each subzone. Generally, the sample intervals do not coincide with the top and bottom of each subzone, or multiple samples may be available for each subzone. If the subzone and the sample intervals coincide, the value of the sample interval is assigned to the subzone. However, if there is more than one sample per subzone, the samples are composited and the composite value is assigned to the subzone. Composite value may be weight averaged by thickness of the samples or, where there is a noticeable difference in the density of the samples, by the product of the thickness and density. The weight averaging is performed only for those values that are reported as weight percentage such as grade, and not for the values that are reported as volume percent such as porosity.

8.4.5 MODELING AND RESERVE ESTIMATION

8.4.5.1 Modeling Selection

The modeling process starts with results of data retrieval or compositing. Modeling choices are extensive and depend on the type of deposit, the commodity being modeled, the value of interest, the complexity of the geologic deposit, and the user's

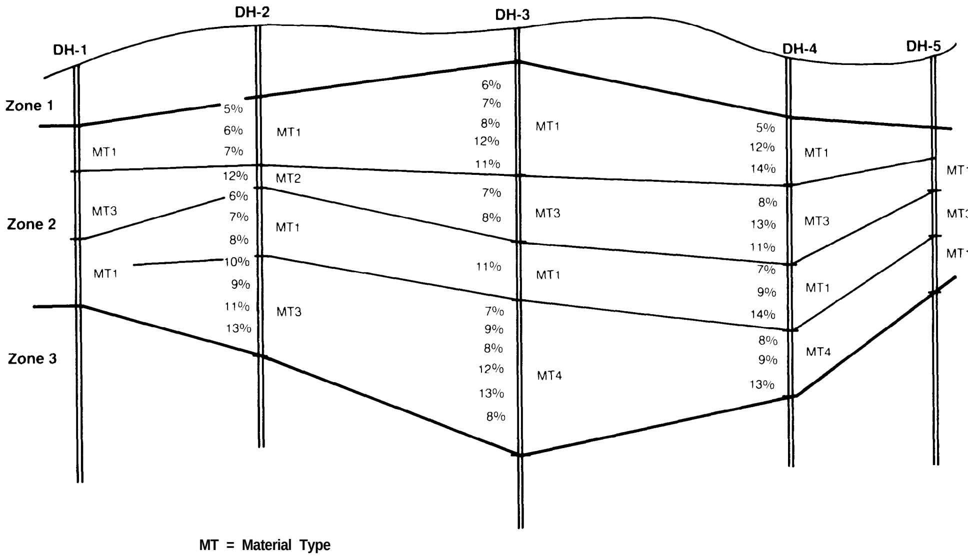

Fig. 8.4.5. Zone and subzone designation based on material type.

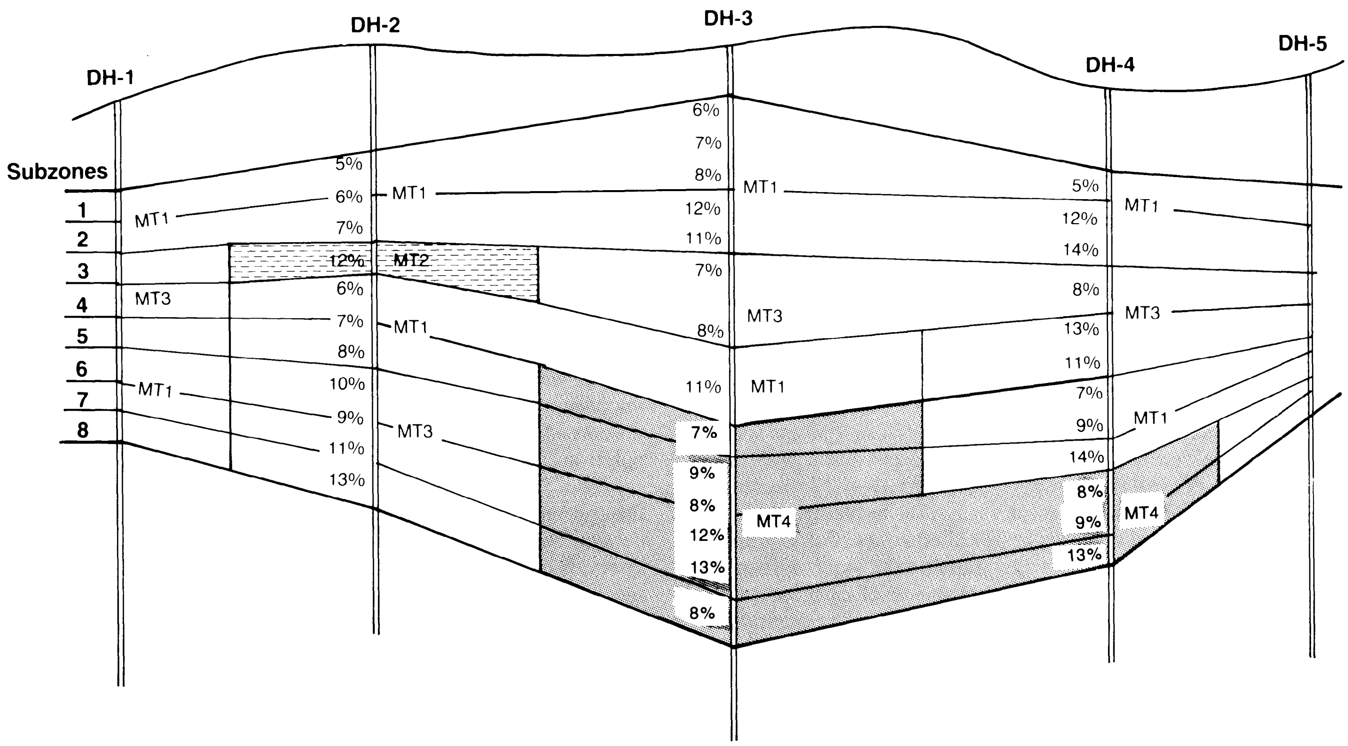

Fig. 8.4.6. Subzone designation based on material type and grade variation.

acceptance and familiarity with various modeling techniques. There are essentially three major modeling concepts and a few other approaches that do not meet the strict definition of modeling. For example, polygonal estimation should not be regarded as a modeling process. The three major modeling processes are the gridded model, block model, and cross-sectional model. Each of these models is used for specific conditions and specific mining operations. The gridded model is normally used for bedded deposits such coal, phosphate, sulfur, limestone, oil shale, and tar sand. The block model is usually used for disseminated deposits such as porphyry copper, uranium, gold, and other nonstratabound deposits. The cross-sectional model is commonly used for complex folded and faulted or steeply dipping deposits. Block modeling techniques have been applied to steeply dipping deposits; however, by using the block model, one loses control over the structural position of the units in a block. If it is important to maintain the structural integrity of the unit, then the cross-sectional modeling technique should be used.

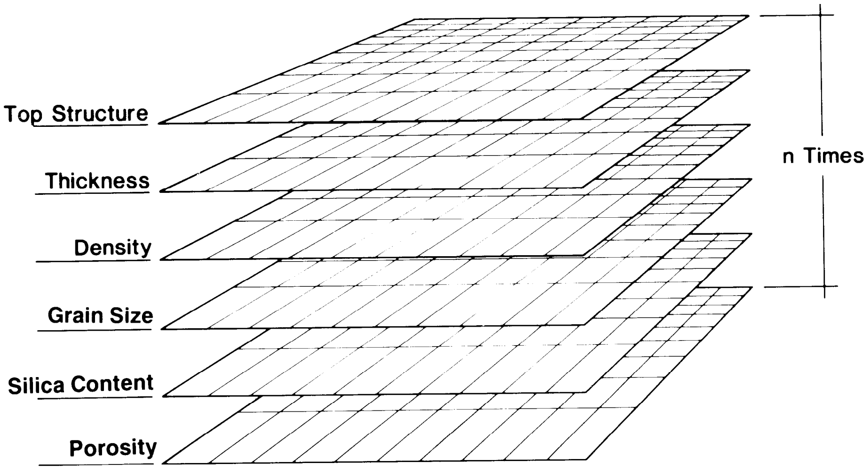

Fig. 8.4.7. Gridded model.

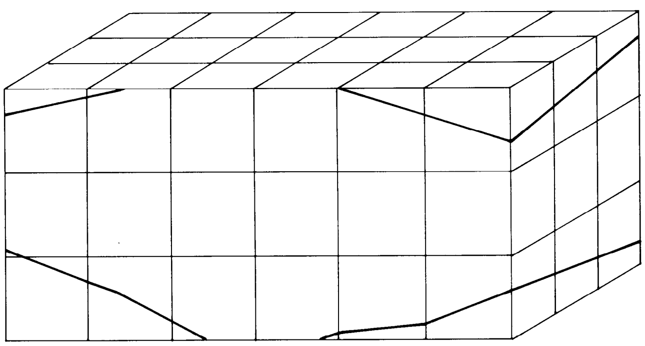

Fig. 8.4.8. Conventional block model with fixed blocks.

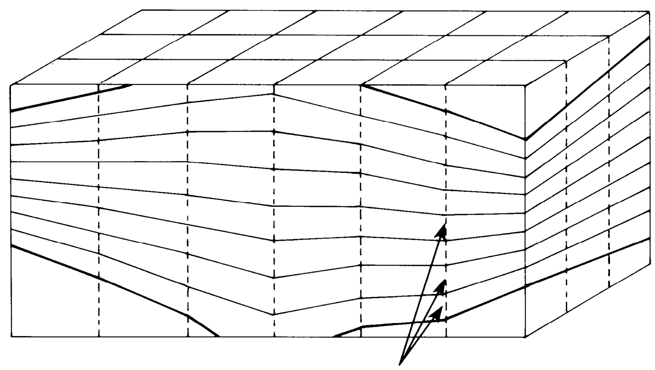

Fig. 8.4.9. Modified block model with variable thickness blocks.

8.4.5.2 Gridded Model

The *gridded model* is a set of two-dimensional matrices, each representing a surface or a value. These surfaces or values are each the result of interpolation from a set of irregularly spaced data to a fixed grid or matrix (Fig. 8.4.7). The major advantage of using a matrix or a grid is ease of use and manipulation of the data. Structures, thicknesses, and other values stacked on top of each other can be easily added, subtracted, multiplied, divided, or logically compared to arrive at other sets of data. For example, the bottom structure of a seam can be subtracted from its top structure to obtain the seam thickness, or the top structure of the first seam can be subtracted from the topography grid to obtain an overburden thickness. Another advantage of the gridded model is a reduction of required space (by two-thirds) by eliminating the need for X and Y coordinates. Given a matrix and the coordinates of its starting position along with the X and Y increments, the location of any other point on the matrix can be easily calculated. This is a very significant reduction of disk space, especially when numerous seams are involved, and each seam may have as many as 20 or more other attributes associated with it.

In a gridded model, only the units of interest are modeled, which means that the model need not necessarily be contiguous. This is the major difference between the gridded model and the block model.

8.4.5.3 Block Model

A *block model* is the collection of a series of blocks of given X, Y, and Z dimensions stacked on top of one another, which represent a model of a property to a given depth (Fig. 8.4.8). Each block is identified by the X, Y, and Z coordinate at the center of the block and contains the percentage values for each item of interest. For example, in a porphyry copper deposit, a block may contain, in addition to the percentage copper, the percentage of zinc, lead, waste, and air, totaling 100%.

There are two other variations to the conventional block-modeling technique called variable block model (VBM) and variable zone model (VZM). In a variable block-model, the X and Y dimensions are fixed and the Z dimension is variable to better approximate the geologic variability of the deposit (Banfield and Wolff, 1979). However, even though the Z dimension may change from block to block, they form rectangular blocks of different size (Fig. 8.4.9). In the variable zone model the Z dimension may vary for each side of the block, resulting in blocks of trapezohedron shapes (Fig. 8.4.10).

8.4.5.4 Cross-sectional Model

A *cross-sectional* model is a collection of parallel or nonparallel sections, dissecting the property of interest. These sections contain the geologic structures of the deposit along the section lines. A model is built basically by connecting sections to one another, by linear interpolation and assuming a gradual change from one section to the next; or by extending each section halfway to the next, reflecting an abrupt change in the deposit. The grade or quality data may be assigned to polygons formed by the top and bottom structures of each seam and the lines halfway between the two adjacent drillholes on the section (Fig. 8.4.11). Another way of assigning grades to these sections is to generate

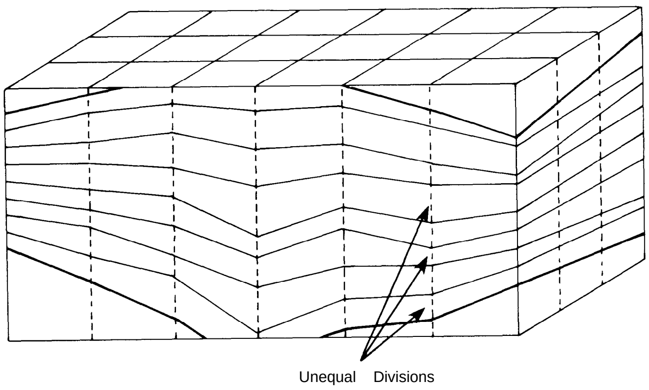

Fig. 8.4.10. Variable zone model with variable thickness subzone blocks.

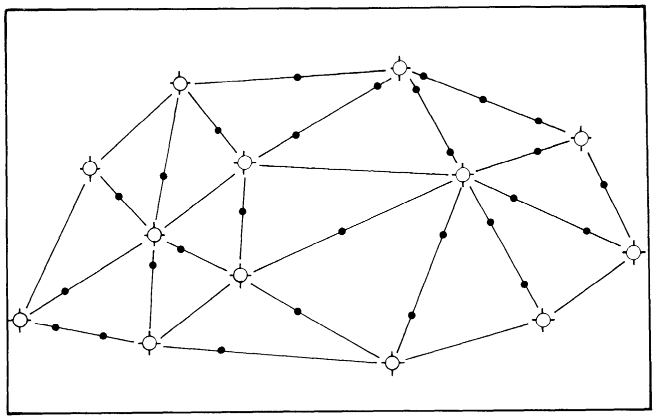

Fig. 8.4.13. Division of triangle sides into contour intervals.

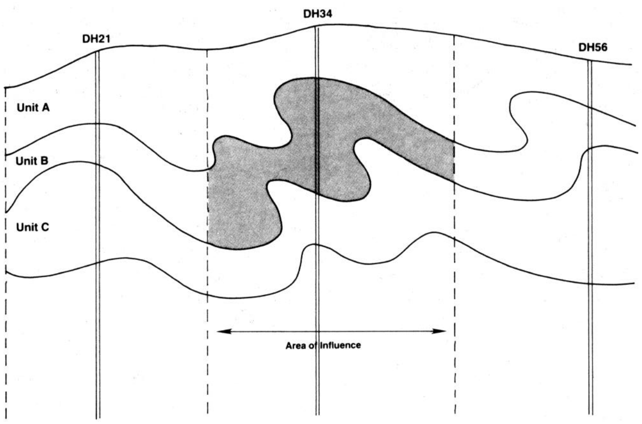

Fig. 8.4.11. Grade assignment using structure and drillhole area of influence.

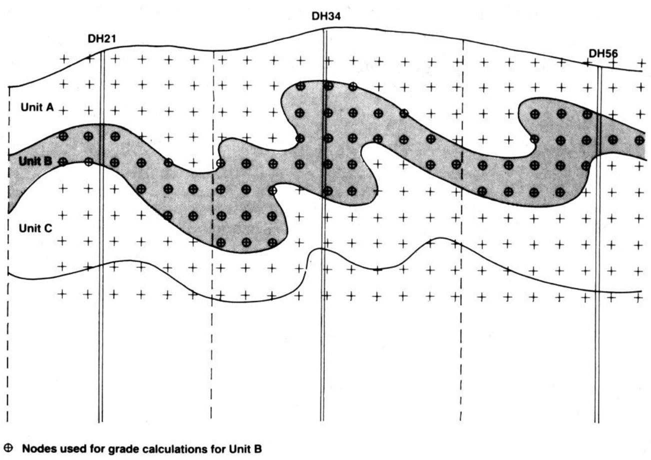

Fig. 8.4.12. Grade assignment using gridded assays.

a gridded model of the grade or other quality data, and then to use the values that fall within the area of influence of each drillhole to calculate the desired grade or quality (Fig. 8.4.12).

8.4.5.5 Estimation Process

The estimation process is common to all models discussed previously. It involves the application of a series of mathematical algorithms to interpolate and extrapolate from a set of irregularly spaced data to a grid node or the center of a block. Estimation techniques vary from a simple triangulation, to polygonal approximation—where an area of influence is assigned to each drillhole—to a much more complex algorithms such as trend-surface analysis, Fourier series, and geostatistics.

The estimation process is nothing new to geologists and engineers. They have been using manual methods, starting at a corner of the property and connecting the three closest holes with straight lines to form a triangle. Then they linearly divide the length of each side into equal units between the values of the two vertices to arrive at desired increments. This process is then repeated over and over again for the next closest hole that forms a triangle with one of the sides of the existing triangle, until all the holes are used and a triangulation network is established. The computer industry started initially by mimicking the manual methods and has built on the same concepts by adding an array of mathematical techniques, which more closely approximate the actual reserve.

Given a set of irregularly spaced data, the user has to develop the model of the deposit in order to be able to calculate the reserve. As mentioned earlier, when performed manually, one uses only three holes at a time. However, using computers, more than three holes at a time can be used to arrive at an estimate for a node. The method used routinely by many companies is to use a circular search radius and as many as 24 holes for estimation. Let us look at few estimation techniques and see the difference in approach by evaluating the pros and cons of each method.

8.4.5.6 Triangulation

One of the earliest methods of estimation was *triangulation.* It is based on generation of a network of triangles connecting all the control points together. The assumption in this type of estimation is that every three points form a plane from which given any X, Y point falling on that plane, a Z value can be estimated, by using the equation of the plane. Triangulation has been used for many applications, but mainly it has been used in finite element calculations and in geodetic surveys. More recently they are being popularized by some companies for quick modeling and contouring. As shown in Fig. 8.4.13, following completion of the network, each side of the triangle is divided into a fixed

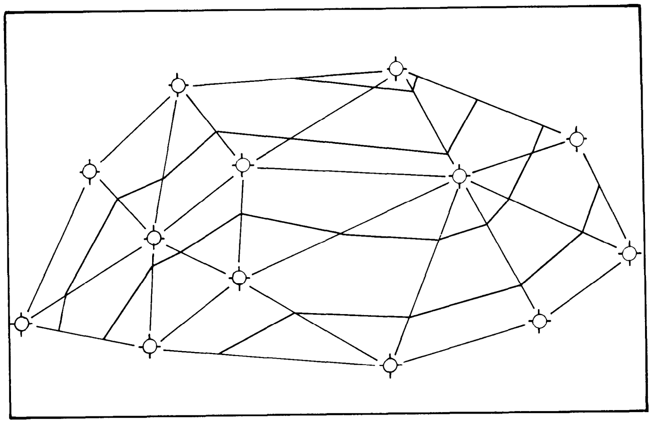

Fig. 8.4.14. Contour generation by triangulation.

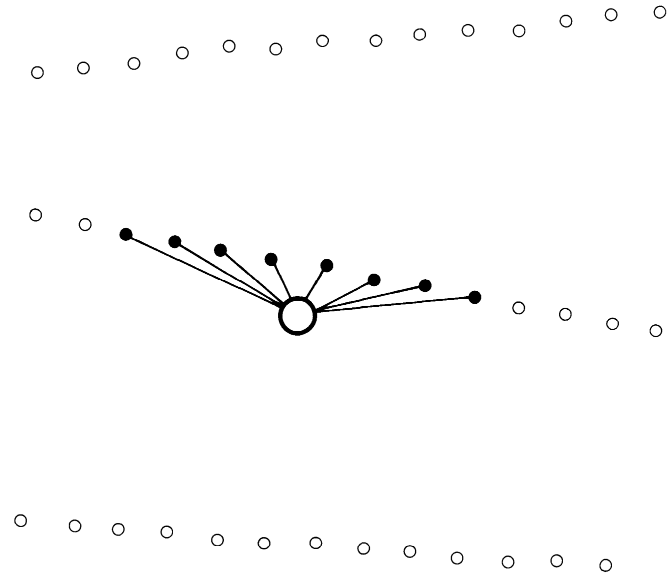

Fig. 8.4.15. Improper data selection (modified after Jones, 1986).

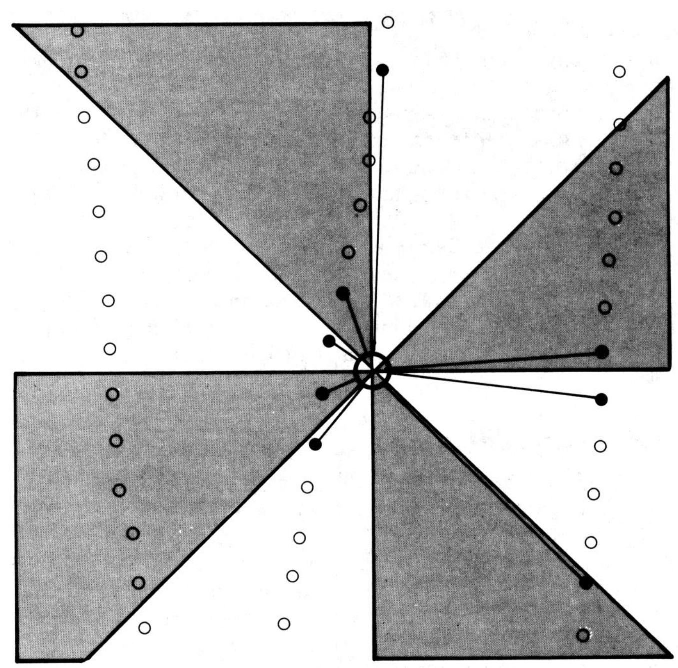

Fig. 8.4.16. Proper data selection using octants (after Jones, 1986).

number of specified elevations, which then can be connected and elevation contours generated (Fig. 8.4.14). It is obvious that in the absence of a standard technique, various triangulation networks can be generated from the same set of control points, resulting in totally different-looking contour maps. Early attempts at solving this problem were not successful, and trial and error attempts were too costly, resulting in complete abandonment of the algorithm (Davis, 1986). Recent development of algorithms (Gold et al., 1977; McCullagh and Ross, 1980; Watson 1981; Bowyer 1981), that ensure almost optimum triangles (referred to as Delaunay triangles) with as equiangular triangles as possible, has revived interest in the triangulation method again.

Davis (1986) provides a good description of the methodology of generating Delaunay triangle networks. Advocates of triangulation techniques refer to the ease of generation of contour maps without gridding, the fact that it will fit a surface more tightly than a square grid, and other inherent mathematical properties of triangulation as the main advantages of this technique. However, along with any advantage, there is a disadvantage. Triangulation suffers from lack of surface manipulation capability, especially where deviated holes are present (Jones et al., 1986).

8.4.5.7 Grid Generation

Initial problems with triangulation and the lack of consistency in contour generation by this method resulted in development of gridding techniques. Using the gridding process, generation of contour maps became a much more consistent process, because instead of using the original values, one could use a set of regularly spaced estimated data for each node. To arrive at the estimated value for each node, two steps are necessary: first, selection of data surrounding a grid node and, second, the estimation process itself.

8.4.5.8 Selection of Control Points

To estimate the value of data for a given grid node, one may use the closest data points to the node. However, this approach may result in selection of data from only one set of drillholes or samples, especially if seismic line information is being used (Fig. 8.4.15) (Jones et al., 1986). To reduce the bias, many programs now require selection of data from within a specified search radius and limit the number of data to one to three points from each quadrant, sextant, or octant (Fig. 8.4.16). The search radius limits the number of data points to be selected for evaluation, therefore minimizing the computer search time. In addition, the reduced number of drillholes reduces the node calculation time. The more recent programs automatically adjust the search radius to further eliminate unnecessary processing time. The initial radius is set to a small window, and if the desired number of control points are found, the estimation process will take place. If in the first pass, the desired number of points are not found, then a pre-set increment is added to the original radius and search continues. This concept is specifically useful where there is an uneven distribution of data, for example, a cluster of data

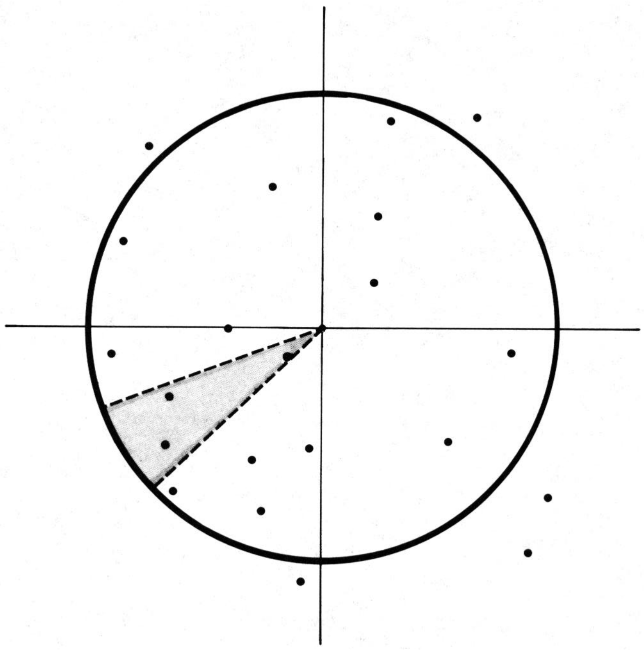

Fig. 8.4.17. Shadow effect concept.

in the active mining area and dispersed information in the rest of the area.

In selecting the points for estimation, it is important to ensure proper representation of data from all directions. By selecting data from all octants, the estimated value more appropriately represents the actual condition. Some programs use the concept of *shadow effect,* to further reduce biased contribution from one direction (Fig. 8.4.17). The shadow effect is specified as a cone around each point, so that any other point falling within the specified cone will not be used in estimation. This is based on the concept that any point falling in the shadow of the previous point should not contribute much to the estimated value.

8.4.5.9 Grid Estimation

Grid estimation is accomplished in one of two ways: (1) by individual node calculation or (2) by fitting a function to the data and then estimating the grid node from the function.

The individual node estimation consists of calculating the average contribution from all the samples to the node by some weight function. The concept is that the data points farther away from the node have lesser effect on the node than the closer ones, resulting in inverse distance functions. The only question, then, is how should the distance be weighted. The linear inverse distance assumes a one to one relationship, in other words, a point 50 units away has 10 times less effect than the one 5 units away. In many situations, it is more appropriate to diminish the effect of the control points at a faster rate. As a result, weight functions of higher degrees are used. For example, an inverse squared distance will reduce the contribution of the control points by the square of the distance. Some software companies provide deterministic, as well as statistical, weight functions. Statistical weight functions are more applicable in situations where an individual sample's contribution to the estimation is not significant by itself. An example is the sulfur distribution in a coal seam, where a high sample value should not be weighted heavily because it may be the result of a nugget in the sample. Under such circumstances, the general trend of the data is more meaningful than an individual sample value.

The functional estimation process fits planes, polynomials of various degrees, or other functions to the data first, and then uses this calculated function to estimate the value of interest at the grid node. The main advantage of fitting a function to the data is generation of a grid that preserves the trend of the data. Grid nodes form continuous and smooth transition from node to node but may have values that are higher or lower than the actual data points. The same advantages may be looked upon as major disadvantages of surface fitting, that is, they normally obscure the sharp variations in the data, and oftentimes they project beyond the limits of the data, to much higher or lower values than the actual data permits, especially at the edges of the property.

Trend surface analysis has been used in *geologic modeling* for many years (Whitten, 1963; Krumbein and Graybill, 1965; Harbaugh and Merriam, 1968; Whitten, 1970; Agterberg, 1974; Davis, 1973, 1986). As Davis points out, the trend analysis is a mathematical method of separating map data into two components, (1) that of a regional nature and (2) local fluctuations. The regional and local trend separation concept has been used by geologists, geophysicists, and petrologists for many years on a manual basis. They have, for example, considered the regional dip of a formation vs. the local structural variations. For a detailed review of usage and application of trend surface analysis, refer to Krumbein and Graybill (1965) or a more recent explanation by Davis (1986).

In trend surface analysis, linear, quadratic, or higher-order polynomials are used with the intent to minimize the squared deviation from the trend. The lower the degree of the polynomial, the lesser the degree of variations from the straight line. For example, the linear model only will display straight-line fitting through the data, whereas the quadratic fit will display the harmonics (Fig. 8.4.18), and cubic fit will even display smaller variations in the trend. The residual data, if gridded, represent the local trends in the data.

The main disadvantage of polynomial fitting is the so-called edge effect at the property boundary, where data are scarce and limited to one side only. Under these conditions the estimated grids display a high degree of deviation from actual.

8.4.5.10 Kriging

Under previous topics, we reviewed the application of trending or deterministic functions (polynomials) to the estimation process. In this segment, we evaluate the concept of Matheronian geostatistics, which is the study of regionalized variables. Regionalized variables are variables which their magnitude is a function of their neighboring values and their position in the three-dimensional space. The previous methods use classical statistics, which are based on random variables and the probability of independent events (Barnes, 1980b). To have an unbiased evaluation means that samples should have been collected in a totally random fashion. Unfortunately, many drilling activities are controlled by physical and practical considerations, which violates the random sample assumption.

Matheronian geostatistics, or simply geostatistics, is the science of regionalized variables as defined by Matheron (1963). The key assumption in geostatistics is that the data display a stationary behavior. Stationarity means that the distribution of the difference for a given parameter, between two sample points, is the same over the entire deposit, and it depends only on the distance and direction of the sample points. In other words, there is no trend in the data.

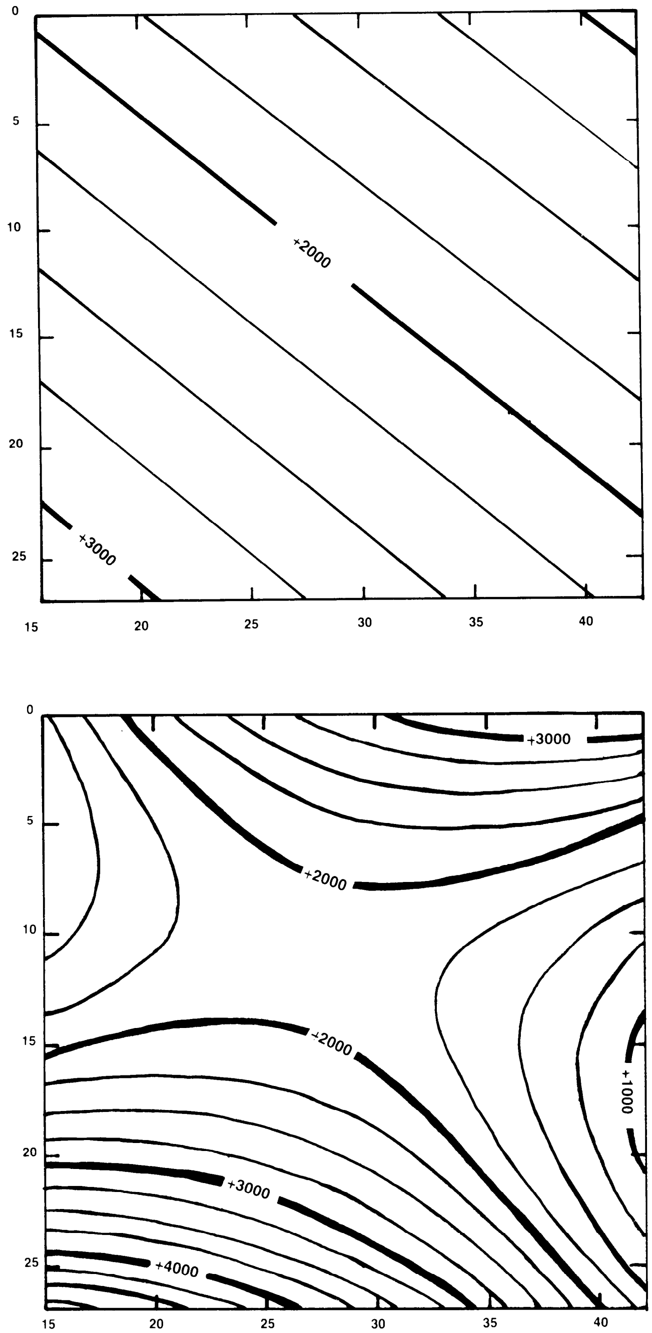

Fig. 8.4.18. First and second degree surface trends (modified after Davis, Wiley, (c) 1986).

It is an intuitive concept that the closer the samples, the less variation in the data, except for a totally randomly distributed deposit. If samples are fully random in their distribution, then we are better off using the standard statistical techniques. However, if there is a correlation between the samples and their spatial position, then geostatistics not only can provide the estimated value for the block, but it can provide us with an estimate of how good our block estimation is. For a discussion of elements of *kriging* and geostatistics, see David (1977), Royle (1980), Clark (1980), Journel (1978), Agterberg (1974), Barnes (1980a), and Davis (1986). Geostatistics provides a formalized and mathematical approach to geologists' long-used methodology for calculating the direction of rapid change. For a more detailed discussion of geostatistics, refer to Chapter 5.6 of the *Handbook.*

8.4.5.11 Grid Modification

To develop a complete model of a deposit, grid or block generation the process is repeated for all units and their associated grade or chemical analysis. Normally, for a single unit with thickness and structures, as many as 15 other kinds of chemical or grade information may be modeled. Depending on the complexity of the deposit, the generated structure grids may crossover each other. The crossover normally occurs because all drillholes do not contain information for all units. Lack of information may be caused by missing data, pinching units, nondepositional, and shallow drillholes where they do not penetrate all units. To eliminate the crossover problem or to incorporate some of the geologist's knowledge of the deposit into the model, a series of tools are made available to modify the generated surfaces and grids. These include arithmetic, logical, and comparative operations. For example, Fig. 8.4.19 shows drillhole 5 penetrating an erosional channel (paleo-erosion). To model such a unit, it is better to allow the straight interpolation across the channel and then to modify or blank the generated grid within the channel area. Grid modification programs are also used to obtain other grids from existing ones. For example, an isopach map can be generated by subtracting the bottom structure from the top structure, or a ratio map can be generated by summing up all the waste units and dividing it by the sum of all the ore units.

8.4.5.12 Block or Grid Size Selection

Selection of appropriate block size or grid spacing is crucial in generation of representative models. It is a balancing act between generating grids that are not too far apart so that they mask variations in the data, or too small a spacing that requires extensive computer time and resources, or too many blocks or grids that exceed the program limits. The grid-spacing selection is more an art than a science; however, a few comments may assist the novice user in a better selection process. As a rule of thumb, the best results are generated when each grid cell contains only one drillhole. This is more easily said than done, because the data are not usually distributed evenly. As a matter of fact, one usually faces the extreme variation of the cluster of closely drilled data in one end of the property and highly scattered data at the other.

The second rule of thumb is to adjust the grid spacing to the type of usage. For example, for a cursory evaluation, a large grid spacing will be acceptable, whereas a detailed mine plan requires a dense grid spacing. A dense grid spacing does not necessarily have to be generated from the original data. If there is not sufficient data to warrant generation of a tight grid from original data, a useful approach would be to generate the initial grid from control points at a larger grid spacing and then regrid it to a smaller spacing at a fraction of the central processing unit (CPU) resources necessary to do so otherwise.

8.4.6 MAPPING AND RESERVE CALCULATION

8.4.6.1 Mapping

Initial contouring programs followed the manual method by using triangulation and then dividing each side of these triangles into desired multiples of the contour interval based on the values

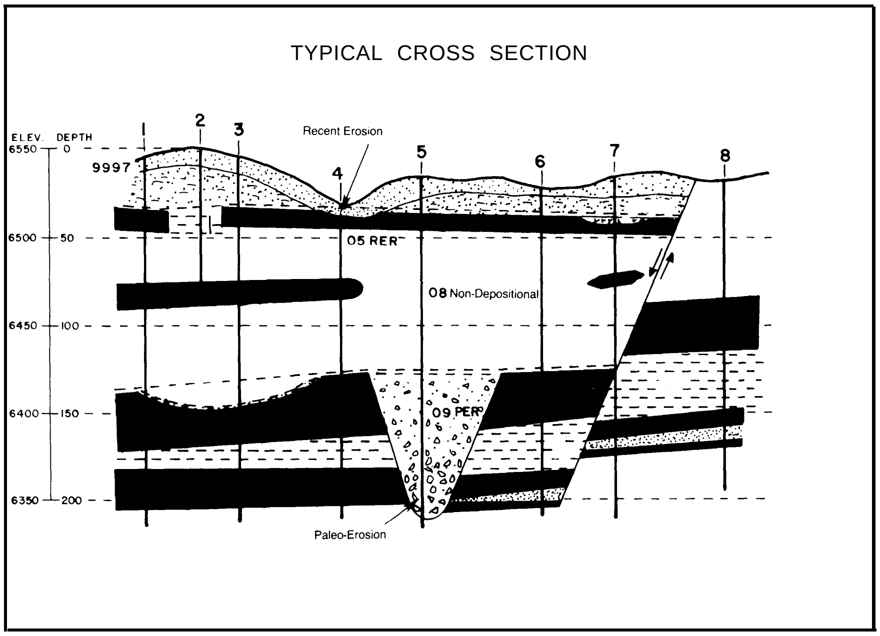

Fig. 8.4.19. Modeling erosional or nondepositional units.

at each vertex. Connection of equal values throughout the area would then generate a contour map. Problems with generation of appropriate triangles resulted in discontinuation of triangulation approach and precipitated gridding techniques. More than three adjacent drillholes are usually used for grid generation. Generated grids are then used for contouring. To generate smooth contours that are appealing to the eye, most contouring programs process the data a second time, where the initial grids and the original control points are used together to calculate newly weighted values at each node. One approach uses values from one or two rows and columns surrounding a node of interest and recalculates a new weighted average value for the node. The process is repeated for all subsequent nodes. Smoothed contours generated by these programs, while more pleasing, may in actuality be less accurate than the initially generated contours.

Once a map is generated and plotted, it must be checked thoroughly for possible problems resulting from modeling or mapping. The maps should be checked for accuracy, to ensure that the correct search radius and grid spacing was selected to generate contours that match the data. In addition, the extrapolated areas need to be evaluated for validity of extrapolation. The undesirable contours may have resulted from incorrect data input, inappropriate grid spacing, improper search radius, unsuitable algorithm, or a combination of the above.

Extrapolation may be contained by providing the cropline or other natural and ownership limits. The newer programs provide on-line editing and modifying capabilities. The geologist can correct or enhance the contour map based on his/her knowledge of the depositional environment, which is not quantifiable. For example, the geologist's knowledge of a sand bar channel can be used to elongate the contours parallel to a paleoshoreline. At the present time, unquantifiable data cannot be provided to the mapping program, but incorporation of expert systems in the future may make this possible.

Lack of data may result in blank regions; these areas need to be evaluated. If the blank areas are out of the region of interest, no action is necessary. However, if they are within the areas of interest, either the search radius should be increased or a new drilling program should be scheduled to fill in the gap in the data. If neither of these are possible or desirable, then the areas can be updated by one of the following actions:

1. Use of outcrop or other information that may not have been incorporated in the database.

2. Use of on-line interactive graphics update capabilities and geologist's interpretative ability.

3. Use of grid extension capabilities by slope or gradient modification.

The final map should include all localized geologic features and physical information such as paleo-channels, fault lines, burn areas, limits of lenticular units, weathered zones, and property, section, or mined-out areas. Almost all mapping packages include a capability for plotting property boundaries along with control point locations, names, and the associated Z values over the contour map. Most of these packages also allow for plotting of various drillhole symbols representing core holes, open holes, oil wells, gas wells, environmental holes, hydrological wells or others.

8.4.6.2 Reserve Calculation

The reserve calculation is the simplest and yet the most elusive part of any mining computer program. It is the simplest because it is a multiplication and summation process. It is elusive because to calculate an accurate reserve, there are many intricate points that need to be considered. Reserves can be calculated by various techniques, that is, by a simple polygonal method where the area of influence around each drillhole is multiplied by the thickness of the unit or the percentage grade. This method of volume calculation is not very accurate, and it is only used when an order-of-magnitude calculation is intended or when very dense drilling is available. Another method of reserve calculation is double-end area calculation from cross sections. This is the same process as the manual method; only a digitizer is used to expedite the calculation. An automatic cross-sectional calculation approach is used for steeply dipping deposits, which is basically the most accurate volumetric method for such deposits. The third method is again a duplication of the manual process where a planimeter is replaced by a digitizer tablet. Here the

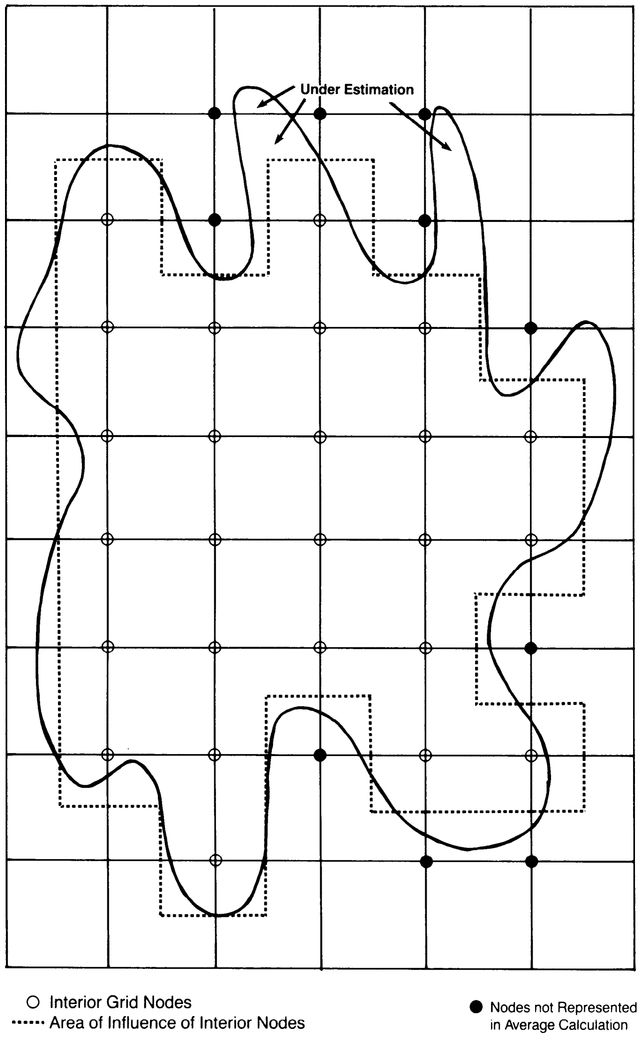

Fig. 8.4.20. Effect of irregular boundary on volumetric calculations.

isopach maps of the ore and waste are placed on a digitizer, and each contour level is traced separately to determine the area of influence under the contour. The volumetric program uses the contour thickness value and the area traced by the digitizer to calculate the volume. If tonnage calculations are required, then a density factor is used to convert the volumes to tons. This type of calculation is equivalent to the manual approach at a much faster speed, however, the computerized version automatically accumulates the results for each unit thickness and provides a final report.

Introduction of grids opened a whole new approach to volumetrics. Using grids, the volumetric program adds the values of all the nodes falling within the digitized area and calculates an average value which, when multiplied by the area, will result in desired volume. This process is fine for flat-lying or uniform deposits and boundaries that are smooth. In situations where the digitized boundary is an irregular shape, the result of the volumetric calculation varies as a function of irregularity. The higher the degree of irregularity the less accurate the result, because many nodes close to the boundary, but not falling within it, will be excluded from the average calculation (Fig. 8.4.20). It should be noted that the volume inaccuracy is also dependent on the grid spacing. As a result, volumetric programs should

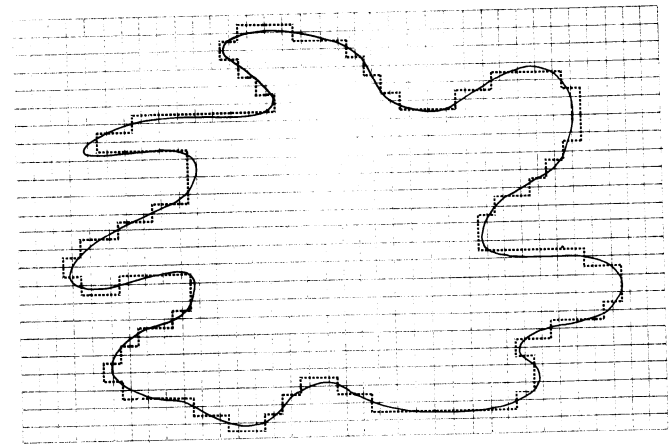

Fig. 8.4.21. Increase of volumetric calculation accuracy using smaller grid size.

provide automatic regridding of the data to smaller grids, at user's option, during the volumetric calculation (Fig. 8.4.21). The smaller the grid spacing, the better the precision of calculation, provided the original data warrants the smaller spacing.

The more advanced version of reserve calculation programs assign an area of influence, that is, a small rectangle equal to the grid spacing to each grid node and then will intersect each one of these rectangles with the property boundary (Fig. 8.4.22). The resulting area is multiplied by the value of the grid and summed up to provide the volumetric result:

$$V = \sum_{i=1}^{n} A_i * T_i \tag{8.4.1}$$

where i is the individual grid node, A is the intersection of the digitized boundary and the area of each rectangular grid, and T is thickness at each grid node.

This is the most accurate approach to in situ volumetric calculations; however, it requires much more CPU and it takes longer to calculate. This approach is fine if a thickness grid is used, but if the program is to calculate the thickness from subtraction of two structure grids, then the problem is somewhat more complex. Fig. 8.4.23 shows a cross section of a deposit with topography and top and bottom structures of two seams. Vertical lines represent the location of the grid nodes. Subtracting the top structure of the first seam from the topography at each grid node will result in a waste grid above the first seam as shown in Fig. 8.4.23. Direct subtraction of one node from the other will result in a series of nodes with positive and negative values. Since the negative thicknesses are not valid, the remaining positive grids result in an overburden thickness grid that is not representative of the pinching portion of the unit. There are two ways to resolve this problem. First, the volumetric program may be set up such that it will automatically extend the area of influence of each grid at the edge of the pinch out by half the grid spacing (Fig. 8.4.24). The second approach is to replace all the negative values with zeros. In essence, this will have the same effect as the previous method. The only disadvantage of these two approaches is that grid spacing will play an important role in the final result, that is, the larger the grid spacing the lower the accuracy of calculation. In other words, these approaches assume that the pinching always occurs halfway between the positive and zero or negative grid nodes.

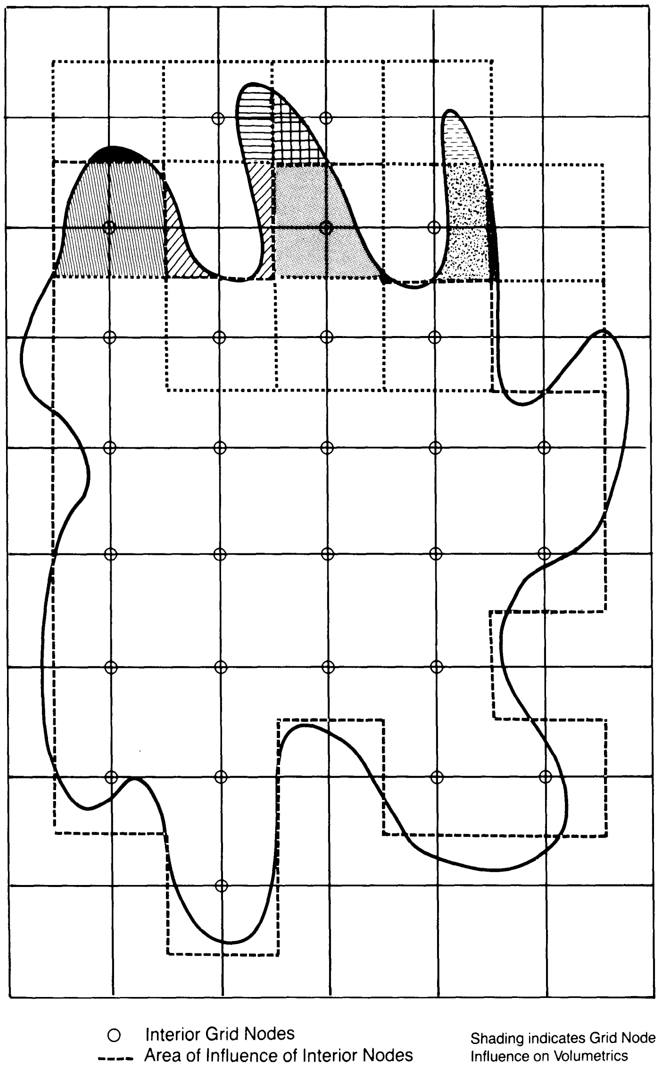

Fig. 8.4.22. Volumetric calculations using actual area of influence.

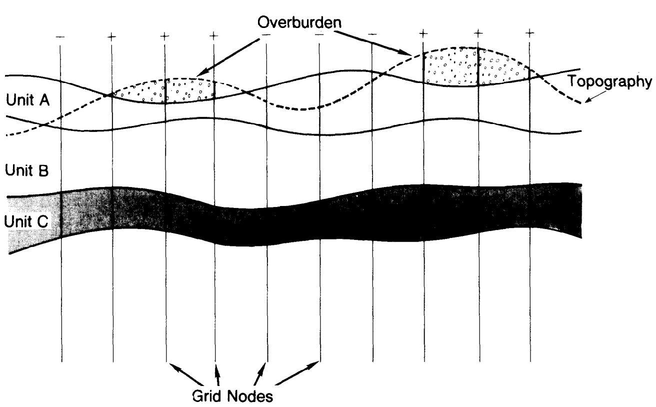

Fig. 8.4.23. Representation of computer generated waste above first seam.

To alleviate the foregoing problem and to improve the accuracy, volumetric programs are designed to request the degree of accuracy desired from the user. If the volumetric is for bulk

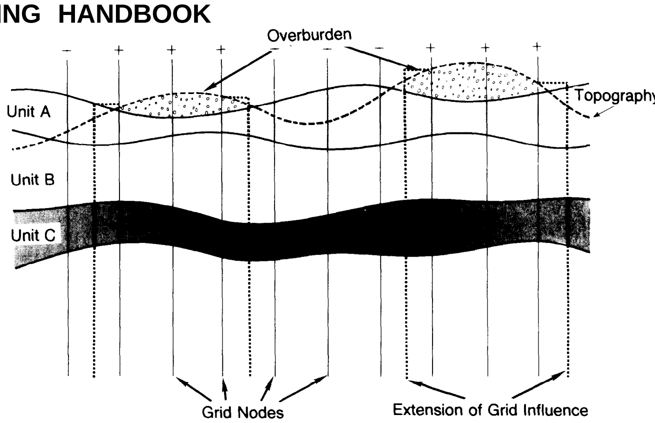

Fig. 8.4.24. Result of grid extension on volumetric calculation.

estimate, then the lower accuracy level is used with a much faster response. However, if higher degrees of accuracies are desired, then the program automatically divides the grid spacing into smaller units, depending on the level of accuracy requested. In essence, the higher the degree of accuracy, the smaller the integration steps. It should be noted that the higher the level of accuracy, the longer it will take to obtain the result.

Computerized volumetric calculations are superior to manual methods in many respects. For one, the calculation speed is much greater, even when the highest degree of accuracy is used, which will result in high levels of CPU usage. In addition, computerized volumetrics provide different accuracy levels and speed, as well as minimizing the calculation error compared to the manual method. Using the geologic model of the deposit, one can calculate and generate a cumulative report for the entire property by merely digitizing the areas of interest. The programs can additionally accommodate dilution, reduction, or minimum thickness considerations in a coal mining operation, or recovery and processing factors in other types of mining. Concurrent with volumetrics, one can also generate individual as well as cumulative seam ratios.

8.4.7 MINE PLANNING

At the end of the modeling process, depending on the number of units or depth of mining considered, tremendous amounts of information and files may have been generated. To simplify access to the latest data available for the property of interest, all the information is combined in a three-dimensional model of the deposit. This model includes the topography, topsoil, structures, thicknesses, grade or analytic data, property, and crop boundaries, fault zones, and other pertinent data all in one place. By collecting all the data in one area and assigning a code to the project or property, the subsequent users will be relieved from bookkeeping chores and can concentrate on the analysis and usage of the data. Data for reclamation, processing, and other factors for each unit may also be added to the list. The volumetric factors may include items such as the unit densities, swell and compaction factors, angle of repose, and abrasion factor.

Mine planning is a complex and involved process. Each mining process is to some degree unique and dependent on the mine location, mine management's experience, economic conditions, and local, state, and federal government regulations. In effect, the uniqueness of a plan is based more on the specific sequence of mining and the equipment used. The entire process can, however, be summarized in a simple statement, that is, the best and the most economical method possible to extract the ore.

In other words, it is the optimum mining process that can result in maximum profit. Given this assignment, the task becomes clear. In order to maximize the profit, one needs to minimize the cost, increase the ore recovery, or a combination of the two. To minimize the cost or maximize the ore recovery, one must be able to evaluate multiple alternatives in a short period of time and have the ability to modify the assumptions used, based on new sets of information. Computer mine planning is the best way to accomplish both objectives, that is, to allow evaluation of multiple alternatives in a short period of time and to be able to change the assumptions quickly.

Computer applications to mining can be categorized under two broad headings. The first includes programs that provide basic analysis of the data and allow a design generation analogous to the manual method. The second consists of programs that provide simulation and optimization capabilities beyond the reach of the manual approach. These two are not always distinct and separate processes; rather they may be integrated in the same program with options to use them or not. Because of the complexity and variation of approach, it is difficult to describe a general system. Instead, major concepts will be provided from EAGLES, and wherever possible there will be discussions of other variations. For discussion of other methods and mining operations, see Pana and Davey (1973), Manula et al. (1977), Mooney et al. (1979), Banfield and Wolff (1979), McMorran (1982), McBride (1988), and Badiozamani (1988b).

Mine planning in EAGLES follows the conventional path for both surface and underground operations. Surface mine planning starts with the definition of the pit boundary and proceeds with the pit slope specifications to the location of safety benches, haulage routes, bench heights, and continues with cut or block generation, mining scenarios, as-mined volumetric calculations, equipment selection and specification, working schedules, production scheduling, plus haulage and other equipment simulations. Underground mine planning starts with building a library of room and pillar or longwall panels (if coal), or stoping designs (if noncoal). These panels will form the basic building blocks from which the entire mine layout is built. Following the layout design, the events follow the path of sequencing, equipment and crew assignment, simulation, and volumetric calculation (Badiozamani et al., 1988c)

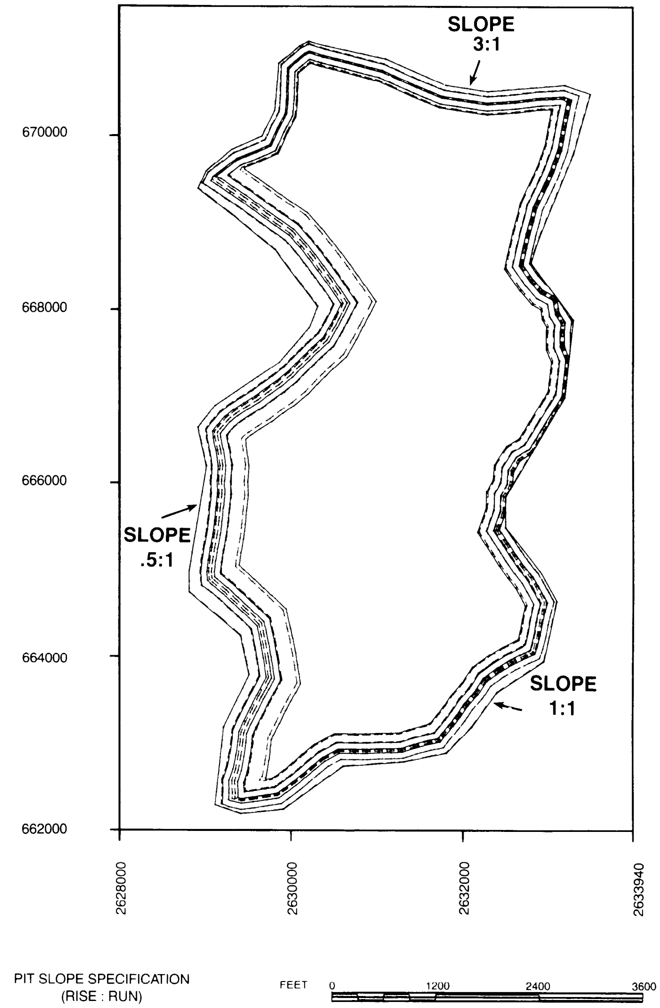

Fig. 8.4.25. Final pit configuration after pit slope specification. Conversion factor: 1 ft = 0.3048 m.

8.4.7.1 Surface Mine Planning

For general coverage of the topic, refer to Chapters 13.1 and 13.2.

Pit Limit Specification: The pit limit can be either generated manually or by computer, given specific criteria. In the manual method, the engineer uses the digitizer or interactive graphic programs to define the pit limits. The pit limit may be a combination of crop boundaries, property line, and the plan-view limit of the ore body. The computer generated limits may be based on volumetric or economics ratio, or limits defined by floating cone algorithm. Using this boundary as the ultimate limit of the pit, one then proceeds to define the pit angles for each lift. The pit angles around the ultimate pit boundary may vary based on geotechnical considerations and the competency of the rocks. Fig. 8.4.25 shows the final result of an interactive graphics screen where the user defines the angles around the pit boundary by specifying the starting and the ending points for each segment. The program then requests the desired angle in degrees or rise to run. The process is continued until the pit angles for all the segments around the pit are defined. The same angles can be applied to all the subsequent benches, or a different set of angles can be defined for any or all benches. The interactive graphic capability allows the engineer to examine and refine the design criteria as the process proceeds. In a matter of minutes, a series of options can be evaluated. By the end of this process, the final configuration of a pit—complete with sloped walls, benches, and haul roads to the bottom of the pit—is generated. This configuration contains the total material, ore and waste, that is to be removed from the pit.

Cut Generation: Results of overall pit configuration are passed to the next program where the actual mining cuts and blocks are defined. Cut definition is based on the type of mining and the type of equipment to be used. In open-cast mining, a dragline, truck-shovel, dozer-shovel, or combination of these are used. Consequently, the width of cuts to be removed in successive advances of the mine is a function of the size of the equipment. The direction of mining and the size of the cuts have considerable influence on the amount of material to be removed at a given time and therefore on the economics of the mine. An interactive graphic program, again, simplifies the generation of multiple alternatives in a short period of time. Fig. 8.4.26 demonstrates the cut generation capability of EAGLES. Other systems may provide different approaches than the one being described here. Simply by specifying two end points of a line, a direction, and cut width, the program generates the entire cut pattern in less than a minute. The cuts can be set up to follow the starting pattern or to be straightened up as they proceed from one end

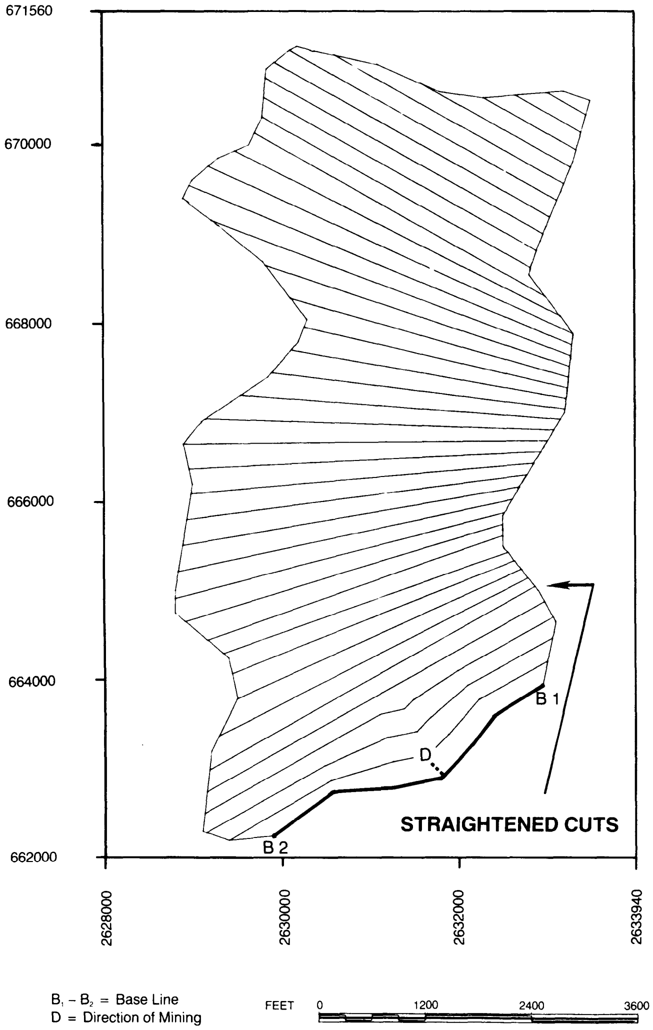

Fig. 8.4.26. Automatic straightening cut generation.

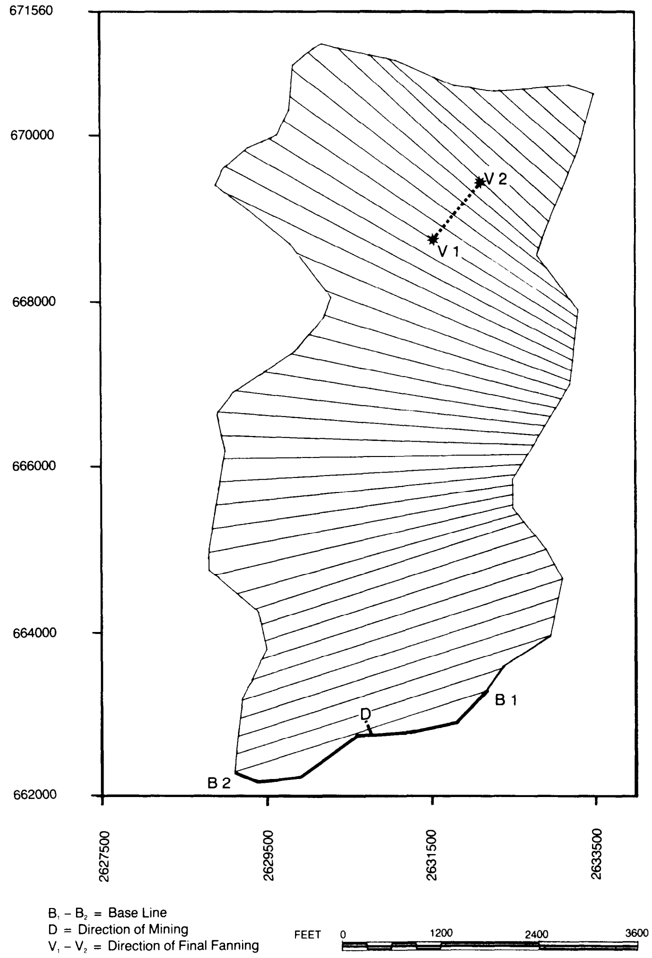

Fig. 8.4.27. Computer-generated fan cuts.

to the other (Fig. 8.4.26). In addition, using a minimum or maximum cut-width specification, cuts can be fanned (Fig. 8.4.27). Changes to the cut pattern or direction of advance is easily accomplished by using the edit function. A range of cuts specifies the limits of modification and eliminates those cuts from the screen (Fig. 8.4.28). New cuts are then designed as before with all the previous functions being available for new cut generation (Fig. 8.4.29).

Upon completion of the cut design, the cuts are projected from one unit to the next, using the specified angles and the benching configuration defined in the previous stage. Each cut is divided into a number of blocks (Fig. 8.4.30), which will form the smallest units to be assigned a volume and grade. Blocks are three-dimensional units defined by cut width, block length, and bench height or stratigraphic units (Fig. 8.4.31). In computerized mining, the block generation is necessary to reduce computation time and space requirements. Otherwise, angle projections, wall intersections, and all calculations have to be repeated each time. Block definition and block generation reduce this process to one time only, and thereafter, it will be mostly straight arithmetic operations.

Mining Scenarios: The preceding steps prepare a three-dimensional model of the deposit with all the associated grades, quality, and analytical information interpolated to each block. These blocks then form the basis for all subsequent volumetric calculation, scheduling, and production sequencing. It should be noted that, unlike the block modeling process, the volumetric or grade calculation in EAGLES is not only based on summation of blocks, but the block values are interpolated to the segments being mined, regardless of their geometric configuration. In other words, the intersection of the pit plane, the bench, the cuts, and the blocks will determine the geometric configuration to be used in volumetric and grade calculations (Fig. 8.4.32).

Mining scenarios are alternate plans to evaluate the most desirable mine plan. These alternatives will consider the effects of different rates of mining from each bench, the trade-offs between a truck-shovel and, for example, a dragline operation. Effects of combining smaller waste zones into the ore zone or thinner ore zones into waste are considered and their merits evaluated. In coal operations, conditional mining scenarios based on variations in the quality parameters can be considered as well. For instance, conditions can be specified, where, if the sulfur content is greater than 1% and the caloric value is less than 4000 Btu (6200 kJ), then that block will be designated as low-grade coal or waste. Or if seam A is less than 2 ft (0.6 m), and seam B is greater than 6 ft (1.8 m), and the thickness of the waste material between the two is less than 2 ft (0.6 m), then A, B, and the waste in between will be considered as ore and will be mined

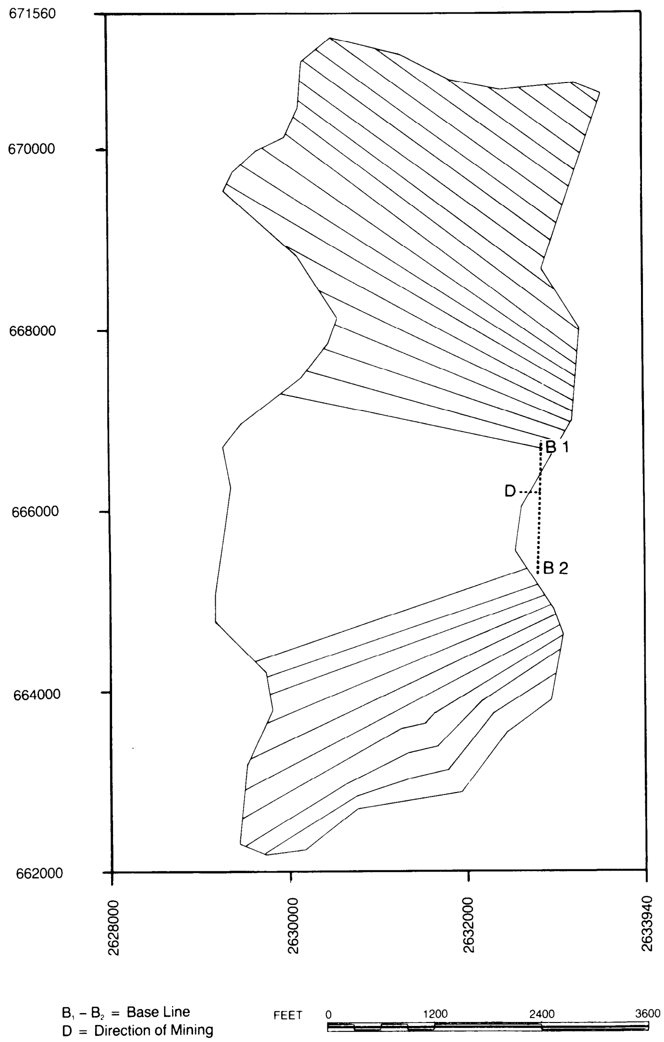

Fig. 8.4.28. Specification of range of cuts for editing.

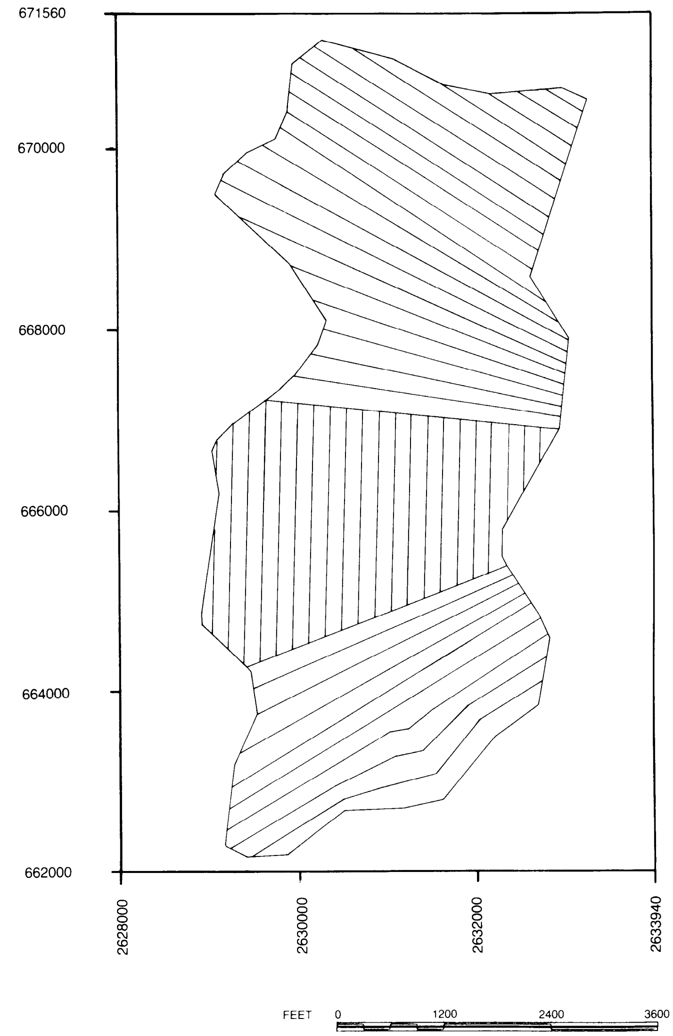

Fig. 8.4.29. Final cut plan after modification.

as one unit. However, if the waste thickness in between is greater than 2 ft (0.6 m), the A seam will be considered as waste along with the waste in between the two seams. These changes in conditional simulations provide a quick answer to different scenarios that an engineer can evaluate readily.

At this point, a bench can be considered as a unit, or it can be divided into smaller units or lifts. A minimum and maximum bench height specification guarantees the division of each bench into the appropriate number of lifts. To generate a new lift, the remaining portion should be equal to or greater than the minimum lift height specified; otherwise, a new lift is not created, and the extra height is kept with the previous lift. The minimum height specification is based on the assumption that stripping equipment cannot operate efficiently on lifts smaller than the minimum height.

Bench specification for advance stripping (benching across the cuts), for operation within a cut (benching within a cut), and for evaluation of different bench heights is also provided. The bench-height specification at this stage has a different purpose than the one specified during pit limit designation. During pit limit specification, the bench-height designation establishes the individual volumetric and reporting units; that is, the volumetric for benches specified at that stage will be always reported as a unit, even though many of them may be combined to form a single bench during mining scenario evaluations. On the other hand, during mining scenario specification, the benches are combined to form a single unit for a specific operation such as dragline bench. When reporting the volume and quality for this bench, each original bench is reported separately along with the total for the combined benches. Prestripping bench configuration is specified by the maximum separation desired for each bench. These separations are defined in multiple of cut widths for the across the cut option and in multiple of block lengths for within a cut. This configuration is used during scheduling to ensure appropriate spacing between the working benches for proper operation (Fig. 8.4.33).

Working Schedule: Operation of a mine depends on the scheduled operating shifts, the number of hours per shift, the equipment fleet, the assignment of each piece of equipment to a given bench, scheduled downtime, holidays, and many other items. These items and data are provided to the mining programs prior to production scheduling. Initially, the number of shifts per day that a mine is planning to operate, the hours that each shift will be operating, the number of days in a year that the

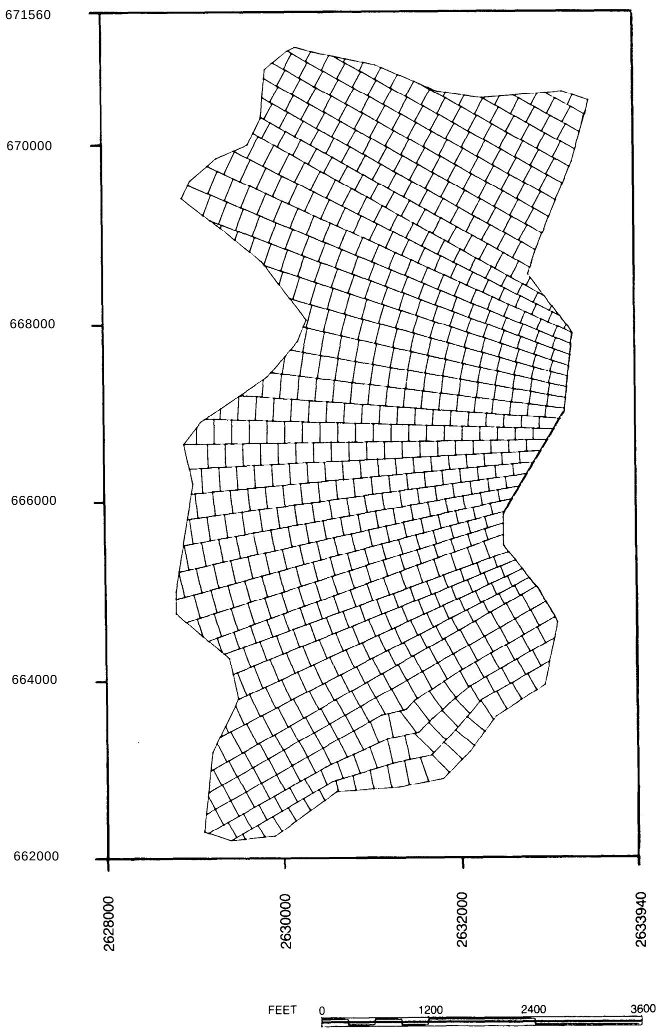

Fig. 8.4.30. Final block generation.

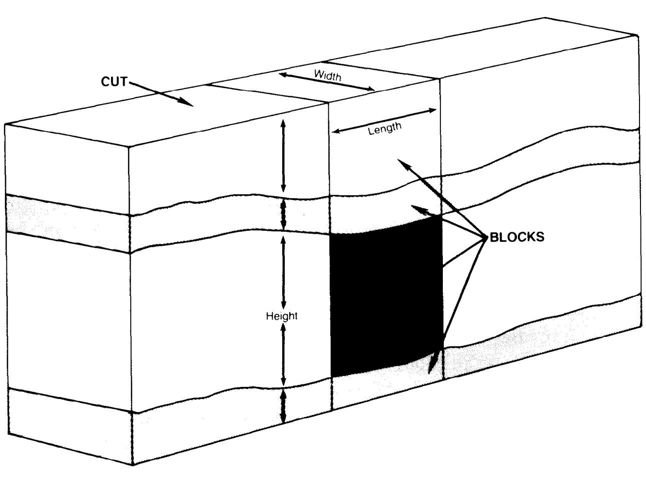

Fig. 8.4.31. Block definition in 3D.

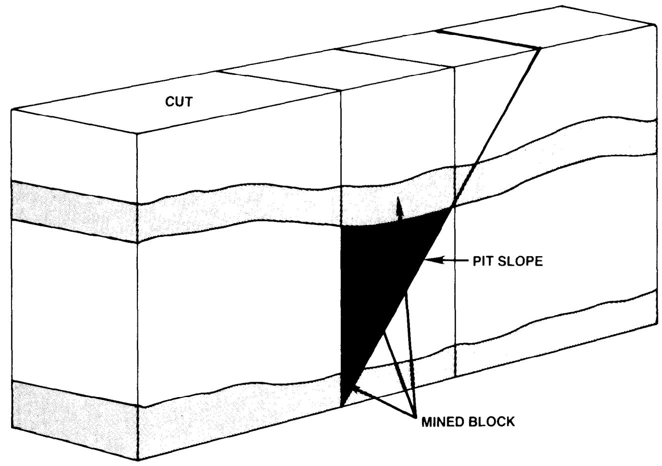

Fig. 8.4.32. Volumetric block definition.

mine will be in production, and the scheduled vacations and holidays will be defined. The schedule can be assigned to any given bench or a series of benches. In addition, the number of Saturdays and Sundays that the mine will be in operation is defined for any given bench desired. These data form the operating calendar for the mine. Following the scheduled days and shifts, the individual equipment units are assigned to a given bench or benches. Also the scheduled downtimes are incorporated in the plan. This information is then used by a production scheduling program to calculate the rate of mining, the tonnage and yardage removed during each shift and throughout the year, and the status of each bench at the end of any given period.

If any overtime is scheduled, the shift differential pay for the overtime and Saturdays and Sundays needs to be specified. The shift differential pay is used to calculate overtime payment schedule.

Production Scheduling: Production targets in a mine may be based on tonnage of coal or ore produced, yardage of waste removed, production capacity of a specific piece of equipment, and the quality or recovery of a product. In each one of these cases the production calculations will be dictated by that specific item. For example, if the production target is based on tonnage of ore produced on a monthly basis, then the program will proceed based on the scheduled shifts per day and number of hours per shift during a given month and will report the tonnage, the yardage, and the stripping ratio for each bench, plus the cumulative values. The calculation is performed by summing the tonnage and yardage for each block along each cut according to the direction of mining specified by the engineer. When the desired target is reached, the total tonnage, yardage, ratio, and weighted quality will be reported for that period and the process repeats for the next period until the entire mine area is covered. In addition, the location of the mined-out area is recorded for each bench so it can be plotted on a plan-view map.

The program uses the mining and benching scenarios established during mine block specification. The calculation at this stage is only a summation and reporting process, according to the factors specified. If the production schedule is based on a specific equipment, then the program uses that equipment's mining rate and scheduled hours to establish the removal process. The operation schedule for this equipment determines the schedule for the rest of the fleet. This is especially applicable to the use of a dragline. Because of the large amount of capital associated with a dragline, mine managers will try to maximize its operation, thus making the remaining equipment subservient to it.

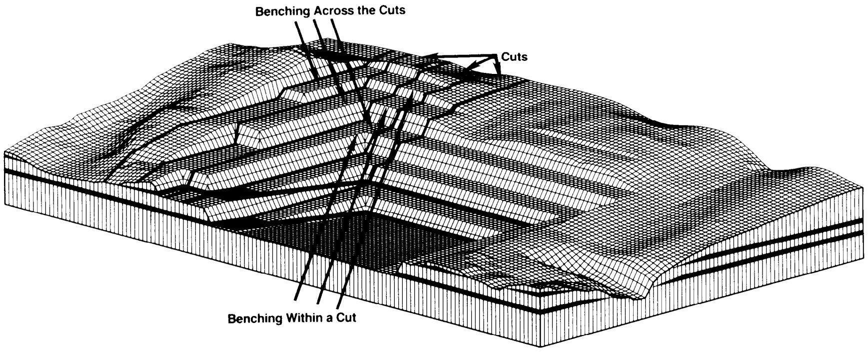

Fig. 8.4.33. Bench specification both within and across the cuts.

In some deposits, such as lignites, the tonnage or the yardage mined is not as important as the millions of Btu (kilocalories) delivered to the plant. As a result, the production target is based on the millions of Btu required. Consequently, the type and number of equipment items selected is tied to the tonnage of lignite that can produce the desired Btu (Badiozamani and Price, 1983).

Production schedules can be defined for long- or short-term operations. Even though the process is similar on the surface, there are many differences in detail. In long-range planning, the main objective is to meet the overall production targets and maximize the life of the mine. In short-range scheduling, the engineer is concerned with the day-to-day operation; and his main goal is to meet specified production targets, maximize the equipment usage, and minimize the cost. The two objectives are not necessarily contradictory, but their emphasis is different. The latter is concerned with using available equipment, moving available equipment to the most critical location to eliminate bottle necks, balancing mining from various pits to meet the grade or quality balance, and minimizing the effect of equipment downtime. The former is concerned with the type of equipment that best suits the long-range planning based on the geological and geotechnical conditions, location and distribution of ore, the balancing and minimizing the rehandled material, location of spoil piles to minimize the cost of reclamation, and so on.

Many procedures and programs have been written to optimize mining operations and sequencing (Lerchs and Grossman, 1965; Lipkewich and Borgman, 1969; Johnson and Mickle, 1970; Reibell, 1971; Manula and Venkatarman, 1973; Davis et al., 1973; Rogado, 1974; Lemieux, 1979). These optimization programs have had more success in hard-rock mining than any other type of mining. The major lack of success may be attributed to three factors. First, many of these programs are limited or restricted in capability so that an engineer does not have the full range of options or flexibility to direct the outcome. Second, the more sophisticated programs are too complex for an engineer without adequate knowledge of operations research and computing to be able to use them. Finally, up to now, the programs did not provide proper interactive graphic tools to help the engineer visualize the sequence of operation and see the effect of a decision on an ongoing basis. With the introduction of PCs and graphics workstations, many of the visualization problems are being resolved. An example of this type of program is provided by Gershon (1988) where he uses a heuristic approach and the concept of a ranked positional weight to arrive at the optimum mining sequence.

As mentioned at the beginning of this segment, computerized optimization, specially for soft-rock mining, may not be ideal or practical. As a result many operations prefer engineer-assisted "optimization" programs where an engineer can evaluate multiple alternatives in a short period of time to arrive at the desired outcome. An example is EAGLES' short-range production sequencing program where an engineer uses an interactive graphic terminal to arrive at the desired sequence. This system is especially useful when one desires to blend various grades of product to obtain a given product. The interactive nature of operation allows the user to select individual blocks, cuts, or benches to be mined. The program marks each unit specified and automatically displays the tonnage, yardage, and quality or grade at the bottom of screen. As the process continues, the results are reported cumulatively. If any of the items exceed the desired target value, the engineer can "un-mine" any sequence and reenter a new sequence. This approach is very useful in an actual mining operation where a quick decision is required to change the mining operation to alleviate a short-term problem in the pit.

Run-of-Mine Volumetric: At this stage, a run-of-mine volumetric is based on the blocks generated by the combination of cuts, benches, block cuts, pit slope, and any other specified haul roads or safety benches. The volumetric programs then use the information for each block and the sequence specified by the engineer, or from simulation, to arrive at the total volumes and tonnages. The program reports in situ as well as run-of-mine data. The data are reported for each seam, each bench, and each cut within the area of interest. Also, if there were any thin-coal units that were considered waste, coal tonnages that did not meet high-grade coal specifications, or burden that was included as ore; they will be reported separately as such for each seam. In addition, quality information for each seam as well as cumulative ratio and product recovery through the processing plant or wash plant is reported. The detailed data are then summed up and reported in the cumulative section at the end of each cut (Table 8.4.2). The cut information is repeated for each weekly, monthly, or yearly period.

8.4.7.2 Underground Mine Planning

General coverage of the topic is contained in Chapters 17.1 and 17.3.

To initiate an underground mine plan, it is desirable to have a computer program that allows freedom of choice to a designer, that is, to start a plan from ground zero or to build upon previously developed panels or layouts. A selection menu provides option for designing a panel, copying panels, or developing a layout. The system then directs the designer's actions according to his selection. For example, if the plan is to start from scratch, then one is asked for general mine-wide information such as property boundaries, location of shafts, markers, etc. In the case of panel design, the system moves to the panel design screen and continues from there.

Design of the Mine Plan: The design phase of the mine planning effort usually has two phases. In the first phase, the panels to be used are designed or copied from an existing plan,

and in the second phase a layout is generated. The concept of the *panel* as an object means that each panel can be constructed, saved, copied, and modified as many times as required. These objects inherit properties of the parent objects; that is, they maintain the original characteristics of the panel such as heading, crosscut, and pillar configurations, unless modified by the user. The collection of panels for a project is called the *panel library.* Each panel can be placed on the layout or mine plan as many times as required.

Panel Design: Polygons for room and pillar mining using conventional equipment may be designed in three ways. Each method utilizes pillar configuration parameters such as heading and crosscut widths and pillar dimensions to calculate placement within the polygon. Room and pillar mining is chosen as an example because it is the most popular underground method and because it lends itself readily to computer design.

The first method involves a combination of keyboard output and graphical design, using information on overall panel length, width, heading and crosscut widths, and rectangular pillar dimensions to generate a *default* rectangular panel. The generated panel may be sized to the exact length and width indicated, fitting as many full pillars into the panel as possible, or may be automatically adjusted to fit the proper number of headings and crosscuts into the panel.

The second method involves building a panel using only the graphics cursor, in a *free-form* manner. This is particularly useful when irregular shaped polygons must be constructed to meet special circumstances. The panels will be generated to fit as many pillars into the panel as possible.

The third method requires the user to input *exact dimensions* for the panel. This method is very useful for situations where a prespecific panel configuration is established for certain regions of the country, for example coal mines in the Illinois No. 6 seams.

Note that although individual polygons each have their own dimensions and pillar configurations, these polygons may be joined at any angle to form the collection of polygons called a panel (Figure 8.4.34). The panel *object* can then itself be copied and modified as needed.

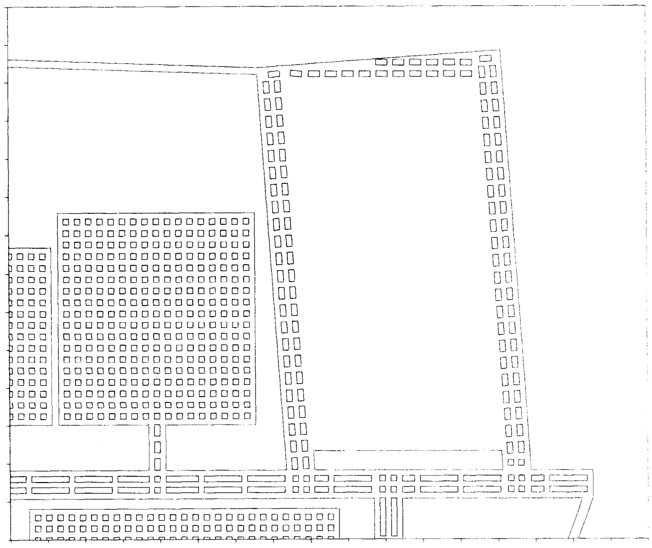

Fig. 8.4.34. Generation of room and pillar or longwall panels.

Panels in longwall mining, another popular underground method, typically consist of many separate polygons, each with its own characteristics. Graphically designing each polygon would be quite tedious, as would entering coordinates into the system. A simple interactive menu requires only that the user supply the dimensions of the longwall block, pillar configurations for the gateroads and back, and the dimensions of the barrier pillar. From these dimensions, the system generates the configuration of the longwall panel (Fig. 8.4.34). The panel itself may then be modified using interactive graphics. It should be noted that this automatic capability includes options for angling the longwall block entry to allow more room for start-up operations, and designating areas for start-up and finishing. These areas will have lower production rates than main longwalling operations.

In each case, the pillars are generated as rectangles according to the input pillar configuration information. The user may modify individual pillars by deleting, cutting, extending, or moving them. In addition, any pillar may be moved to any location within the panel polygon. This allows the user to compensate for local conditions by interactively changing the pillars in that area.

Such localized operations would be quite time-consuming when building chevron or herringbone pillar configurations. To meet these requirements, the program provides the ability to use the first row of pillars in a polygon as a template. All options for modifying pillars (e.g., cutting, shifting, moving) can be applied during the design of the pillar template. Once the first row has been designed, the same configuration will be replicated throughout the rest of the polygon (Fig. 8.4.35). Users can always then modify individual pillars as required. Note that some of the pillars have been modified for local mining conditions.

When panel design has been completed, the results are placed in the panel library. This library is available to the design of the current project and can also be used, through a utility program, in other projects concurrently. Panels may be added to or deleted from the library at any time. The library of panel objects can save considerable amounts of design time and can ensure a high degree of uniformity among various mine design projects.

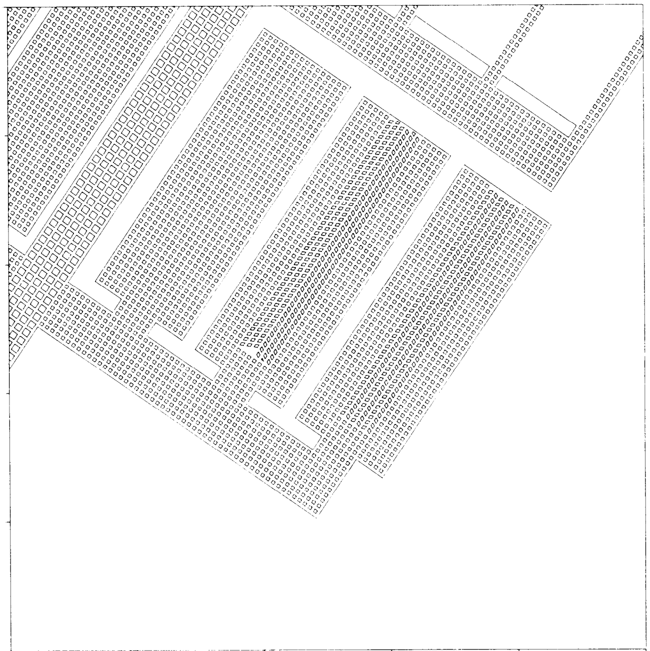

Fig. 8.4.35. Generation of chevron pattern or modified pillars.

Layout Design: The layout is usually entered by combining the digitizing of an existing mine plan with interactive graphics design. The graphics design capabilities indicated in the panel design is largely transferred to the layout design phase as well.

Any submain can be designed in default rectangular form, as a freeform polygon, or can be entered using map coordinates. The same pillar generation and modification capabilities of the panel design phase are present in the layout design phase as well.

The basic steps in layout design follow an intuitive pattern. Initially, basic mains and submains are designed; then panels from the panel library are *snapped* or placed on the layout so they are connected to the submains. Once a panel is selected from the library, it can be placed on the layout as many times as desired, at any orientation to the other polygons on the layout. Additional submains can be added and the process repeated. It should be noted that submains themselves can be copied to other locations on the layout, so that the mine design can be quickly created, cloned, or modified (Fig. 8.4.36).

The layout design phase also contains significant additional capabilities. Any submain can be extended automatically to a specified distance of a boundary feature such as a river, railroad, or inhabited area. This feature allows the designer to be sure that his layout meets required safety criteria.

Once designed, submains can be lengthened or shortened as required. An important feature is that longwall panels can be adjusted in either length or width by adjusting the size of the longwall block. This allows a generalized longwall panel to be used in many different areas of the layout. Once the longwall panel is placed, its dimensions can be adjusted to meet local layout conditions.

Existing Operations: Frequently, alternative mine plans are to be developed for operations already in progress. To accomplish this, the initial step is to digitize the relevant portions of the current mine plan, using specialized digitizing routines. These routines require only that the outside boundaries of each polygon be digitized. Pillar configuration information is entered using an interactive menu system, and the pillars are automatically generated. If desired, individual pillars can also be digitized to reflect specialized conditions.

Another important capability is the use of surveyed information to mark progress on the mine plan. The survey information input can be direct from a total station or by using a forms-driven survey system. The survey data then available for generation of month-end reports or can be plotted on the layout maps.

Sequencing: Sequencing combines the *who*—what mining systems and crews will be working—the *what*—what areas of the mine plan are to be mined and in what order—the *when*—at what times will these crews be working—and the *how fast*—at what rates of advance will the mining systems be moving.

In order to develop the sequence, the system must have the following:

1. The mining systems and crews that will be working.

2. The calendar showing the working schedule for each system. The calendar system contains all information on shift lengths and schedules, scheduled holidays, time off, partial shifts, etc. As such, it reflects the actual work patterns for each crew.

3. The advance rates for each mining system. Advance rates are given in tons recovered or distance traveled each shift. These advance rates may be used interchangeably anywhere in the sequence for any crew.

4. The "relative sequence" showing what polygons will be mined and in what order. The relative sequence would be the actual sequence if only one crew were used. When multiple crews are introduced, the relative sequence provides information on the general order in which areas may be mined.

5. Mining options, such as minimum and maximum mining thickness, and leaving coal roofs and floors. These affect both the rates of mining and the recovered tonnage and quality.

6. Production delays that are required by the nature of the mining systems used. For example, a longwall crew may be required to spend a considerable amount of time setting up before longwalling can begin. These delays must be accounted for by the sequencing system.

To facilitate the entry of this information, a combination of forms-driven screens and graphic inputs are used. The objective is to provide the maximum flexibility of input while minimizing the amount of typing and work on the part of the engineer. Even a complicated sequence can be entered in a short period of time. An expert system is used to ensure that no area of the mine can start production until all required development to reach that area has been completed. Data from the geologic model concerning ore body thicknesses, quality parameters, etc., is automatically included in the calculations. Once the sequence has been completely generated, the engineer can now review the results via an animated sequencing and determine if the sequence meets his requirements.

Feed Back: One key feedback mechanism found in the system is the *animated sequence* feature. This shows the advance by calendar month for all crews and can be generated for any time period in the sequence. The animation demonstrates which crews are working at what particular times and easily identifies delays that may be able removed by revising the sequence, the production rates, or crew schedules. This type of visual feedback is very important because it utilizes the pattern recognition skills of an experienced engineer to determine the occurrence and nature of problems that would be very difficult to determine by simple reports or static plots. For example, delays in finishing longwall development activities can easily be located because the longwall crews will be idle after they have finished their scheduled activities.

Other feedback mechanisms include hard-copy plots of the sequence, showing the areas mined by each crew in a time period, and a production report giving the raw and recovered tonnages

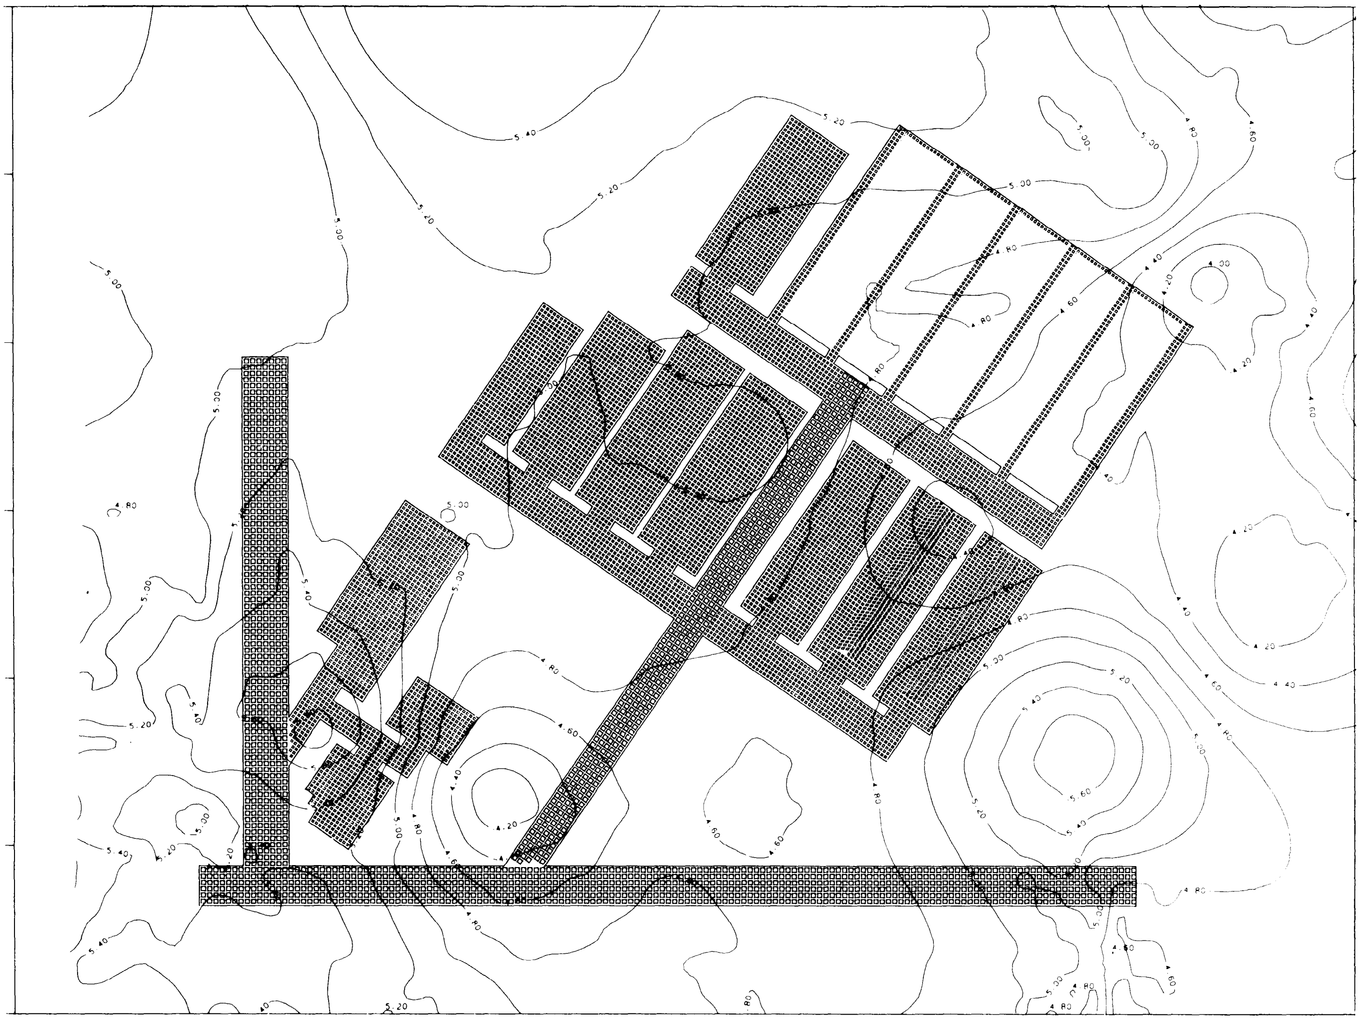

Fig. 8.4.36. Final layout design with superimposed contours.

and quality parameters for selected time periods (month, quarter, year, etc.). In addition, a crew utilization report provides a Gantt chart of crew activities, showing periods of inactivity that may be modified if necessary. With these tools, the engineer can now modify the sequence to more closely meet his requirements. For example, the quality produced in a time period may not meet contractual requirements. This may require higher production from an area of higher quality. One or more crews may be having long periods of inactivity, suggesting that they be shifted to other areas or furloughed.

Finally, the engineer can use current production information to update the sequence and develop projections from this date forward. All production plans are affected by outside events, such as production that occurs too rapidly or too slowly, equipment breakdowns, changes in marketing requirements, etc. The ability to play *what if* games with a sequence, based on currently available knowledge, is a major requisite of any mine planning system.

8.4.8 MINE OPERATIONS

Mine operation programs provide the capability for maintaining records of actual mining operations. These programs can form a set of sophisticated tools for day-to-day monitoring of operations, personnel, equipment, production, and maintenance. In this segment, emphasis will be on the EAGLES' operation system and its application to surface mining, mainly for production, equipment, surveying, and personnel. There will be no discussion of items such as maintenance and inventory.

The system is organized around three databases, that is, daily production, equipment operation, and volumetric (Fig. 8.4.37). It allows daily monitoring of the mine and enables the exchange of data between the planning department and operations. By use of this system, deviations from a plan can be quickly identified and necessary action taken to bring the operation in-line with the plan or to change the plan to reflect the actual operational conditions.

Another function of this system is to allow the resident engineer at the mine to update the plan and the topographic maps to reflect the latest mining advance, the position of equipment, and the location of the pit. Prestripping and reclamation progress is also monitored and mapped. The result of all these activities can be reported on daily, weekly, and monthly reports and maps.

8.4.8.1 Surveying

Surveying systems in recent years have improved to the point where survey data can be captured in the field and transmitted

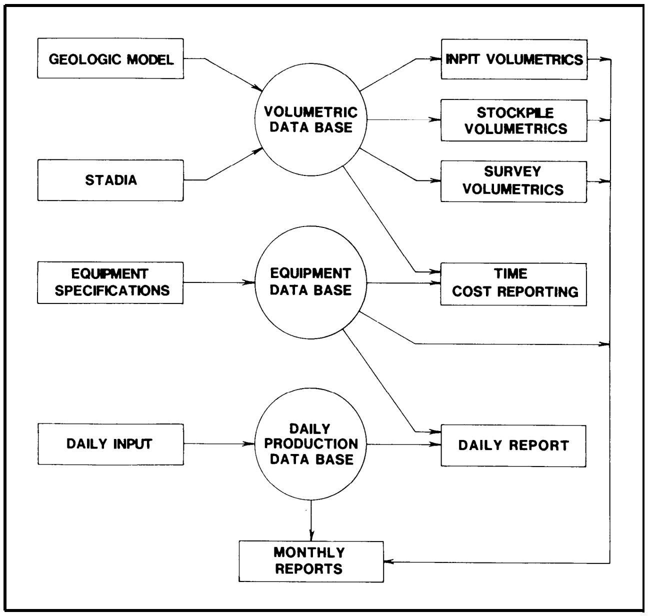

Fig. 8.4.37. Schematic of mine operations monitoring system.

electronically to the computer (Chapter 8.2). The *total station* has eliminated many tedious surveying tasks. Despite the introduction of total stations, many mines still are using the more traditional surveying methods of stadia and chaining. To facilitate and provide for all diverse situations, an interactive screen-driven menu assists the users at the mine site to capture information from any source and incorporate it into the database (Fig. 8.4.38). Following data entry, the coordinates of each survey point are calculated using the information provided for gun site, back site, and each shot point. The program also provides for loop closure and automatic adjustments. Input errors occur especially during the manual input so the program provides for graceful error recovery procedure; and to ensure data input accuracy, it generates a plot of the survey points.

Four types of data are tagged specifically for later volumetric calculations: toe, crest, highwall, and floor. These data are also used to combine the location of the crest of a bench in previous period with the present one to delineate the area mined during this period. One may graphically join these to form a boundary for volumetrics.

Stockpile surveys are captured in the same manner; however, these data are identified separately to allow special interpolation routines for volumetrics. The special interpolation routines are necessary to capture abrupt changes in the stockpile or account for the central pipe. Stockpile volumetrics require special handling because the survey information from the previous period is used to generate a grid of the stockpile surface. The same process is used for the survey data from the latest period. The resulting surfaces are subtracted from one another to determine the relative change during the period. A positive change will indicate an addition to the stockpile, and a negative volume is indicative of extraction. If the total volume of stockpile is required rather than the relative change, then the original ground survey must be available, and therefore the system always retains a copy of the original surface. The same process is followed for maintaining a dump inventory.

8.4.8.2 Mine Production

To keep track of a mining operation, four activities have to be monitored separately: (1) waste production, (2) ore production, (3) reclamation activities, and (4) monthly mapping updates. Waste production is based on the truck counts from the pit, and the volume is calculated from survey data. Ore production is also monitored by truck count, but the weights from the weighing station are also entered into the database to compare with tonnage calculated from the plan. As a general rule, tonnages calculated through multiplication of the mined-out area, times the thickness of the ore, times the density of the ore, never match the tonnage reported by weighing. The sources of discrepancies are numerous. For one, in normal mining operations, the equipment removing the ore is not capable of removing it to the exact interface of the ore and waste. As a result, in certain areas a portion of the ore is left behind, and in other areas a portion of the waste is added to the ore. This mixing of ore and waste, usually referred to as reduction and dilution, contributes to discrepancy between the two measurements. The second source of discrepancy is from the inaccuracy introduced by using only one density value for the entire unit. Experience has shown that coal density varies from sample to sample, and even though an average density is fine for approximating the overall tonnage throughout the mine, it will not compare favorably against localized direct measurements by each truck. The third possible source is from the lack of ability to account accurately for the fractures and gaps in the ore deposit while using the areal extent.

Information gathered from various activities is recorded in a database and is used to update the topographic map from the pit, reclamation, or dump-site survey data. This process eliminates the need for end-of-the-month aerial surveys of the pit except for once or twice a year.

Equipment operating hours, scheduled and unscheduled downtimes, delays, maintenance hours, and other data are re-

corded for each piece of equipment and stored in the equipment database. This information can be used by the operation manager to evaluate the merits of one type of equipment vs. the others, or to check the production variations for different shifts and even for various seasons. The information, once generated, will be useful in developing production rates for the coming year's planning.

Drilling and blasting information is collected for the drilling pattern, the amount of explosives used, the number of holes drilled, and the depth of holes drilled. The summary report provides information with respect to the amount of explosives used for a given period and the drilling footage. Also, drilling data from the blastholes and the ore-waste interface can be passed to the geologic database for incorporation into the modeling. These data are used later as an added control point for interpolation during revisions to the geologic model.

Personnel records contain information with regards to hiring dates, absenteeism, seniority, and other necessary records. These data are available to the foreman to use for assigning appropriate jobs to the crew quickly and effectively. The result of all such information can be reported on a daily, weekly, or monthly basis.

8.4.9 HARDWARE AND SOFTWARE SELECTION

8.4.9.1 Selection Steps

Proper selection of hardware and software play an essential role in acceptance, usage, and satisfaction of computerized systems by the users. Unfortunately, many software packages are impressive and user-friendly on the surface, but on a more thorough evaluation fall short of expectations. To avoid pitfalls and assist the reader in the selection criteria, the following procedure is provided. It should be noted, however, that the computer industry is the fastest growing industry, and some of the generalizations presented may not stand the test of time.

Software and not hardware should be the primary focus of selecting a computerized system. Hardware costs have been dropping steadily, and if the present trend continues, future hardware will be even less expensive. Many companies overlook the long-term and hidden costs associated with new software. For example, for software to get widespread acceptance among users, the computing department has to spend a long time assisting the users and providing free demonstrations and training before expecting user support for their effort. The user's acceptance and willingness to use the system is essential for successful implementation of any system. The computing department should concentrate on the ease-of-use and applicability of software to the user's need. Also those in charge should select the most suitable computer that can accomplish the task, rather than trying to fit software to existing hardware. By trying to retrofit the software to existing hardware, one may spend more than the cost of new hardware while attempting to make the new software work on the existing hardware.

The following approach is recommended to hardware and software selection:

1. Define project scope specifications.
2. Establish a user committee.
3. Define objectives.
4. Define the system.
5. Write a request for proposal (RFP) for the system.
6. Select a short list of candidates.
7. Arrange for demonstration and testing.
8. Score and make final selection.
9. Select hardware.
10. Negotiate a contract.
11. Install hardware and software.
12. Train operating personnel.
13. Implement cooperative projects.
14. Evaluate and provide advance training.

8.4.9.2 Define Project Scope Specifications

The first step in system acquisition is project scope specification. This task involves defining the scope of the project as far as the type of system to be acquired, the overall company needs, and the extent of computerization. If this is the first large system the company is acquiring, questions such as centralized system vs. a distributed computing environment should be decided on. Also it is advantageous to determine which department and the person in that department who will be responsible for maintaining support for the rest of the company. If multiple mines are involved, the method of access by the users in those mines should be decided on at this time.

In essence, project scope should answer who the users are, where the machine will be located, what the system will be used for, how it will serve the users, and who will be responsible for supporting it throughout the company.

8.4.9.3 Establish a User Committee

The next step is to assemble a representative user committee from all the interested departments. This kind of representation ensures participation from all interested parties and at the same time can define their needs by direct participation. A major advantage of early participation by user departments is their involvement in the project, which will make them party to the new development. This will help in breaking the barrier to entry and acceptance instead of being perceived as another concept that is being pushed on them by management. Care should be taken to draft interested and enthusiastic participants rather than the skeptical and ill-informed.

The initial task of this committee is to select a group of three to five individuals who will be responsible for assembling all the input from other users and will draft the final RFP. This group will also participate in demonstration and testing of the products by the short-listed companies. At least one senior geologist, a senior mining engineer, a computer specialist, and a representative from management is recommended.

8.4.9.4 Define Objectives

The committee has to develop a precise and definitive mission objective. This objective must state the reason for computerization and what exactly the system has to be able to provide. For example, the objective may state, "To obtain an interactive, graphic oriented, geologic, and mine planning system to simplify operation, enhance productivity, and improve accuracy. The system should handle shallow as well as steeply dipping seams. The software should have been in use for more than five years and should have at least five installed bases similar to the planned operation."

8.4.9.5 Define the System

System definition provides a detailed description of all the required functions as well as desirable ones. In this study, every area of interest is defined and detailed. For each section, performance criteria have to be defined. For example, for a geologic database, the details may include having the capability of entering borehole names with up to 10 alphanumeric fields, X and Y coordinates with up to 12 numeric fields, surface elevation, lati-

Table 8.4.3. System Selection Weight Factor Example

Geologic Model's General Requirements	Weight Factor
On-line help capability	6
Menu-driven screens	8
Relational database	10
Screen, card, tape input	7
Auto validation process	5
Optional requirements	
Ability to custom design reports	3
Ability to handle English and metric	4
Total	350

Other modules of the system are given similar weight factors and the overall system may be summarized as follows:

Digital terrain modeling	150
Geologic modeling	350
Mapping and contouring	230
Grid manipulation	160
Volumetric calculation	210
Mine planning	400
Total system	1500

tude and longitude, geophysical logs, and hole-deviation information in azimuth and degree. In addition, there should be ability to input data either directly from screen or via card or tape punch. Log date, logger's name, date drilled, and date capped may be defined as desirable items. Other general information may be included for systems operation such as computational speed, input screens, relational database, and range checking requirements.

8.4.9.6 Write a Request for Proposal for the System

Following compilation of the entire set of detailed-functional requirements and system definition, an RFP is prepared and copies distributed to all possible candidates for bidding. This document should contain the objective definition, the detailed system definition, along with a schedule of events and deadlines for RFP submittal plus decision dates. The RFP should also include a short description of the company's primary functions, the overall objective, and location of each mining operation.

8.4.9.7 Select a Short List of Candidates

To compile a short list of the companies that meet specified software requirements, an unbiased weighing system should be developed. The weighing system can be a range of numbers from one to ten for each item, one being the lowest, and ten the highest. The required functions have a much higher weight than the desirable ones. Each function shall be divided into small components and its usefulness to the overall system ranked accordingly. Table 8.4.3 provides an example of weight factors for a geologic and surface mine planning system.

Functional requirements and associated weight factors should be listed and distributed to all members of the selection committee. Copies of received RFPs are also given to each panelist to evaluate and rate each proposal according to the functional requirements and the established weight functions. The result of the committee's evaluation is then summarized and the top three to five respondents selected for further evaluation. It is a good idea to establish the minimum number of points required for a software vendor to make the short list ahead of time. If too many companies make the short list in the first pass, then only the top-ranking companies will be selected, and the lower-ranked ones will be eliminated from further consideration. The short list participants should be notified of the final selection and specific dates set up for actual testing and demonstration. All the other respondents should be thanked for their participation and notified of not making the short list.

8.4.9.8 Arrange for Demonstration and Testing

Arrangements should be made for each company on the short list to demonstrate their software. It is recommended practice to visit all the companies on the short list and to participate in a live demonstration. The reason for this is to allow the selection committee to meet with each vendor, and while evaluating their product to evaluate their staff as well. The number of people available for support, the stability of the company, the length of time that the main support and programming staff have been with the company, and their mode of operation are of primary importance. These items will provide valuable insight to the suitability of the company and its capability to provide training, future support, and the speed by which they will be able to correct software problems.

Companies that look good on paper may not be as impressive in a live demonstration. It is advisable to have a representative set of data which can be given to each company a few days in advance of the visit. This is to eliminate the time necessary to load and convert the data to the vendor's computer system. However, the test data should not be given to contenders too much in advance because they may use it to acquaint themselves with the data, thus obscuring the actual time required to model a property.

The main idea in the collection of test data should not be to discredit the software under investigation, but rather to find out how many of the operations can be automated with each specific software. It is impossible to find on-the-shelf systems that will satisfy 100% of a company's needs. A software satisfying 70 to 90% of a company's requirements is more than satisfactory. The remaining requirements have to be contracted out. As a result, software houses that are willing to modify their software or provide companion programs to satisfy the remaining needs should be sought.

During the visit and demonstration, a similar weighing document will help to rate the companies on their performance. The testing process should include additional items such as competency of the demonstration staff, the ability of the company to respond to questions, the documentation availability and completeness, the length of time to complete the test, and other items of importance to each company.

8.4.9.9 Score and Make Final Selection

Upon completion of the testing process, the result of the evaluation is tabulated and the highest-rated company normally should be selected as the finalist. However, as it is the case with any scoring system, it is usually very difficult to look at the scores alone. There are other factors that cannot be quantified, and care should be taken to somehow consider such factors. For example, the working relation with the vendor's staff may become an issue of concern. The scoring system is fine to quantify the overall performance of the system, but the committee's judgment should also be taken into consideration.

The final vendor should be notified of the decision and the others should be thanked for their participation, and if necessary a debriefing session should be set up to explain why they were not selected. The strengths and weaknesses of their system should be explained in a short meeting.

8.4.9.10 Select Hardware

Hardware selection has become both easier and harder at the same time. It is easier because mining software is available on most major hardware platforms. It is harder because of the availability of too many options. The choices are no longer limited to mainframe and minis but to mainframe, minis, personal computers (PCs), micros, and workstations. At the same time, the number of vendors of hardware has increased extensively. The user not only has to consider the machine type but has to look at the viability of a vendor 10 and 20 years down the road. One has to consider longevity of a vendor and availability of the equipment, consistent with rapidly changing hardware and software technology from the same vendor in the future. The selection of hardware based on equipment capability is also becoming more difficult. Micros have the advantage of cost, ease of use, and user acceptance; however, they do not have the processing power of workstations or larger machines. Workstations provide the power necessary for large computations and interactive graphics, but they have not been in the market long. As a result, not enough software is available for them yet. This problem will most probably be eliminated within a few years.

Software consumes a major portion of a system's cost; therefore, during hardware selection, in addition to capability, the number of users and aggregate cost of software plays a major role in the final decision. If the number of users is small, or if the majority of the users are not in a central location, then PCs or workstations may be more appropriate. However, if there are more than five to ten users in one location, then it is more cost effective to have a central mini or mainframe system.

If possible, the final hardware selection should be based on the recommendation of the vendor. It is important to select hardware that best suits the capability of the software. Some vendors may provide software on many different platforms, but even these vendors have a preferred hardware platform. This reference is based either on the machine that the original software was developed on or the one that they are presently concentrating their development efforts.

With reduction in the cost of workstations, if possible, it is recommended to have a smaller central unit with a number of distributed workstations. Such an arrangement serves two purposes. First, provides a central repository for the entire company, and second, it permits distribution of the processing load. The distributed processing will aid in increased productivity and better utilization of the resources; it will eliminates bottlenecks and transfers the load to the users' sites.

8.4.9.11 Negotiate a Contract

Contract negotiation is as important as the selection process. Among items to be included in the negotiations are training, warranty period, maintenance support, frequency of maintenance release, the unscheduled release in case of emergency, and the availability of source code. The contract should clearly specify the conditions under which the source code will become available to the company in case the vendor decides to stop maintenance or they become insolvent. Some companies prefer having the source code in an escrow account. This arrangement is satisfactory as long as there is a mechanism to ensure that the escrow account always has the latest workable version of the software, a task not easily accomplished. The reason for uncertainty lies in the fact that, as a rule, a bank where the software is kept does not have either the facility or the technical knowledge to test and ensure the workability of the software provided them.

8.4.9.12 Install Hardware and Software

Coordination among the hardware vendor, the software vendor, and the company is the main concern during installation. There are great numbers of items that need to be considered before installation. The location of the hardware has to be identified, and proper wiring for electrical outlets, appropriate electricity such as three-phase 220-V lines, air conditioning, raised floor, patch panel for user terminals, and so on, have to be clearly established and installed before the equipment's arrival. Shipping date for the hardware sets the date for installation. It is advisable to have a member of the software vendor on hand to assist in testing and acceptance of the hardware. Also the software vendor should schedule installation of software concurrent or immediately after hardware installation.

8.4.9.13 Train Operating Personnel

As a general rule, companies do not spend as much time on training as necessary. To have a successful installation, a great amount of time should be devoted to staff training. The payoffs of well-planned training is enormous, and assignment of a certain number of users to the initial training is essential. It is advantageous to have a preliminary training course so that the users will become acquainted with the overall system in a short time. Then they should be given a project to complete using the new system. One of two approaches may be taken at this stage. The first is, after initial training, to let users struggle with the new system on their own, which is usually not very productive, especially if they have to meet a project deadline. A second approach and a much more appropriate one, is to have the users work on a project while a representative of the software vendor is present. The vendor's staff should not perform the tasks; rather he/she should assist in using the correct application programs and keeping the users from taking a wrong turn. Even though the second method is costlier at the start, it will pay for itself in increased productivity and user acceptance in the long run. User acceptance of the system cannot be overemphasized. It makes the difference between a system that will be used extensively and a system that will be forgotten in few years.

8.4.9.14 Implement Cooperative Projects

The best strategy for successful implementation of a new hardware and software system of the magnitude discussed previously is a three-step process. The first step is to have initial training for a limited number of users. These users may be referred to as *super-users,* for lack of a better term. After the initial training, the software company should be asked to complete a project in the client's office, where the super-users will participate as assistants. During this process, the super-users gain first-hand knowledge of the usage of the system and the speed with which a project can be completed using the software. At the same time, they will gain valuable lessons in using the total package at once rather than at a later date when they have forgotten the lessons from the training. In the third stage, the roles are reversed—that is, the super-users perform a project while a member of the software company monitors their usage of the software and interjects guidance when necessary.

At the completion of cooperative project implementation, the super-users are ready to train other members of the company by conducting similar training and cooperative projects throughout the company. The payoff of such a plan is very high, because it can contribute right from the beginning to the correct usage of the software. In addition, the super-users are available at any time to assist new users and to distribute the new technology to the rest of the staff. This approach will reduce the need for continuous dependence on the software vendor as well.

8.4.9.15 Evaluate and Provide Advance Training

To complete the process, a review and advance training session should be set up for the super-users and others, three to six months following the system usage. After six months of usage, the users are more confident of their ability and can question the software vendor on specifics of their applications. The software vendor should be ready to respond to the users' questions. At the same time, they may provide advanced training plus shortcuts to accomplish the more difficult tasks. As mentioned before, on-the-shelf software cannot usually satisfy all the requirements of a company. Additional requirements that the existing software cannot provide may be discussed, and new development can be initiated during the advanced training session. It is a much better approach to wait for at least six months of usage before modifications and additional capabilities are requested. There is a tendency to overreact to functions provided by a software that are different from the standard procedures in a company. Users usually want to maintain familiar routines and resist any changes in approach. However, if they are given the opportunity to use the system as is for a period of time and make their recommendations for change after usage, then they will have a more objective viewpoint. This procedure will eliminate unnecessary modifications and additional cost to the company.

Chapter 8.5
LABOR RELATIONS AND TRAINING

JOSEPH W.R. LAWSON II AND FREDERICK H. RICHARD

8.5.1 MANAGEMENT'S LABOR RELATIONS RESPONSIBILITIES IN LABOR NEGOTIATIONS

8.5.1.1 Employer's "Good Faith" Bargaining Requirements.

Once the status of a bargaining representative for employees is established, the National Labor Relations Act imposes a duty on both the employer and the bargaining representative to bargain "in good faith." Specifically, Section 8(d) states:

"For the purposes of this section, to bargain collectively is the performance of the mutual obligation of the employer and the representative of the employees to meet at reasonable times and confer in good faith with respect to wages, hours, and other terms and conditions of employment, or the negotiation of an agreement, or any question arising thereunder, and the execution of a written contract incorporating any agreement reached if requested by either party, but such obligation does not compel either party to agree to a proposal or require the making of a concession." (Anon., 1959.)

In addition, under Section 8(b)(3), it is an unfair labor practice for a labor organization "to refuse to bargain collectively with an employer, provided it is the representative of his employees. . . ."

What constitutes "good faith" on the part of the employer or the union is difficult to define; indeed, the National Labor Relations Board (NLRB) has described the test of good faith as a fluctuating one, "dependent in part upon how a reasonable man might be expected to react to the bargaining attitude displayed by those across the table" (Anon., 1959).

8.5.1.2 "Good Faith"–What Does it Mean to the NLRB?

Although it is difficult to establish a precise definition of the term "good faith," the basic requirement of good faith bargaining is that both the union and the employer must negotiate with the view of *trying to reach an agreement.* The bargaining obligation is not satisfied merely by going through the notions without actually seeking to adjust differences. In order to determine whether the conduct of the union and employer meets this general requirement, the Board and the courts look to all the relevant facts of the case; the "totality of conduct" of the parties is the standard for testing the quality of the negotiations.

8.5.1.3 "Good Faith Bargaining" Factors

In examining the conduct of a union or an employer, the Board and the courts look to the following, among others, to ascertain whether the parties have bargained in "good faith:"

1. Whether concessions have been made.
2. Whether an adamant position has been taken.
3. What proposals and demands have been made, and when they have been made.
4. Whether counter-proposals have been made.
5. The sufficiency of the company offer.
6. Whether there has been discussion of proposals.
7. The duration of negotiations.
8. Whether there have been inconsistent positions taken.
9. Whether there has been withdrawal of offers or concessions.
10. Whether the employer is willing to take a position on economic issues.
11. Whether either party has attempted to delay the negotiations.
12. Whether either party has used evasive tactics.
13. Whether the employer has made any unilateral changes in working conditions.
14. Whether the employer has attempted to deal directly with the employees rather than with the union.
15. Whether negotiators have been given sufficient authority to carry on meaningful negotiations.

Any one of these factors alone does not constitute "bad faith" in itself. However, if many of them are present, the bargaining will be deemed to be "in bad faith."

8.5.1.4 Management Guidelines in Dealing Directly with Employees During Labor Negotiations

Once the representative status of a union is established, the employer is required to deal with the employees through the union rather than dealing with the union through the employees. Thus any attempts by the employer to bypass the union representative may be held to be evidence of bad faith.

The Board has condemned employer attempts to deal directly with employees in order to *undermine* a certified union bargaining agent. Examples of conduct that the Board has found objectionable are:

1. Offering the employees a wage raise if they will disavow the union.
2. Seeking individual contracts with employees after having recognized a union.
3. Making speeches or statements to employees demonstrating anti-union sentiments.

It should be noted that the employer is free to communicate with his employees both during contract negotiations and during the term of the collective bargaining agreement, so long as his communications do not undermine the employees' bargaining agent. For example, an employer is free to tell his employees about the proposals he has made to the union during contract negotiations, and he may even attempt to convince them of their fairness, so long as his conduct does not amount to an attempt to *bypass the representative.*

The Supreme Court, in *NLRB v. Wooster Division of the Borg- Warner Corp.,* 356 U.S. 342, 42 LRRM 2038 (1958), clarified an employer's duty to bargain "in good faith." The Court divided lawful subjects of bargaining into two groups: mandatory subjects and nonmandatory (permissive) subjects. The Court read Section 8(a)(5) and Section 8(d) in combination and stated

". . . these provisions establish the obligation of the employer and the representative of its employees to bargain with each other in good faith with respect to "wages, hours, and other terms and conditions of employment. . . ." The duty is limited to those subjects, and within that area neither party is legally obligated to yield. . . . As to other matters, however, each party is free to bargain or not to bargain, and to agree or not to agree."

8.5.1.5 Mandatory Subjects of Bargaining

An employer must bargain with the union about "rates of pay, wages, hours, and other terms and conditions of employment." This duty encompasses such topics as bonuses, pension plans, profit-sharing plans, stock purchase plans, merit wage increases, and company meals, discounts, and services.

Mandatory subjects of bargaining are not only topics that an employer is compelled by law to negotiate in good faith, but also include topics where an employer is barred from *unilateral action.* An employer never has a legal duty to concede a mandatory subject during bargaining, but he must bargain over these topics until an agreement is reached or the parties come to an impasse. Refusal to bargain about a mandatory subject prior to *impasse* is a Section 8(a)(5) violation.

Mandatory subjects of bargaining include:

1. *Wage Compensation for Services*
   - Wages
   - Salaries
   - Incentive pay or bonus
   - Shift premiums
   - Overtime premiums
   - Premium pay for work on Sundays and holidays
   - Merit pay increases
   - Equity pay adjustments
   - Cost of living adjustments (COLAs)
   - Premium payments for undesirable schedules of work
   - Red-circle pay
   - Longevity pay or premiums
   - Pay for training
2. *Wage Compensation for Nonworked Time*
   - Holidays
   - Vacations
   - Jury duty pay
   - Funeral or bereavement pay
   - Call-in or call-back pay
   - Report-in pay or daily/weekly minimum pay
   - Stand-by pay
   - Travel pay
   - Pay for time spent on union business
   - Pay for time spent on safety matters
   - Severance pay
   - Pay for lost wages due to contract violation
3. *Non wage Benefits*
   - Holiday bonuses or "gifts"
   - Pension benefits for current employees when they retire
   - Profit-sharing plans
   - Stock purchase or bonus plans
   - Employer-provided or employer-reimbursed housing, meals, and services
   - Medical, life, sickness and accident, dental and vision plans
   - Legal services plans
   - Discounts on company products
   - Leaves of absence (paid or unpaid)
   - Clothing and tool allowances or benefits
   - Company-provided or employer-reimbursed transportation
   - Tuition reimbursement programs
4. *Working Conditions on the Job*
   - Hours of work and work schedules
   - Rest and lunch periods
   - Plant rules of conduct
   - Grievance procedures and arbitration
   - Promotions, transfers, layoffs, recalls, etc.
   - Work loads
   - Discharge and discipline
   - Safety and safety rules
   - Probationary and trial periods
   - Testing of employees, including use of lie detectors
   - Job-required clothing or equipment
   - Job duties
   - Job qualifications and certification requirements
   - Workplace facilities and conveniences
   - Seniority accumulation (loss and application)
   - Work assignments
5. *Management Rights and Union-Management Rights*
   - Subcontracting
   - Management rights clause
   - Effects on employees of plant closure, relocation, sale, etc.
   - Union shop or other union security agreement (unless state law prohibits)
   - Dues checkoff clauses
   - Bargaining unit work
   - No-strike clause
   - Union hiring halls
   - Nondiscrimination clauses
   - Waiver or "zipper" clauses
   - "Most favored nation" clause
   - Arrangements for labor contract negotiations

8.5.1.6 Non-mandatory Subjects of Bargaining

Nonmandatory or "permissive" subjects of bargaining are all legal topics that fall outside the phrase "rates of pay, wages, hours, and other terms and conditions of employment." The law permits, but does not compel, an employer to bargain about these topics. Some of these topics include industry promotion funds, settlement of charges, union labels, and internal union affairs. An employer may never insist to the point of impasse on a permissive subject of bargaining. Insistence on a permissive subject of bargaining is a Section 8(a)(5) violation. (Anon., 1957)

Nonmandatory subjects of bargaining include:

- Definition of bargaining unit
- Conditions affecting supervisors
- Formal parties to the collective bargaining agreement
- Performance bonds
- Legal liability or indemnification clauses
- Identity of either party's bargaining representatives
- Internal union affairs including contract ratification procedures
- Union label
- Industry promotion funds
- Settlement of unfair labor practice charges
- Multi-employer or multilevel negotiations
- Pension benefits for persons presently retired
- Interest arbitration
- Recording or transcribing of negotiations
- Closed shop (illegal)
- Hot cargo clauses (illegal)
- Clauses which are racially or sexually discriminatory (illegal)
- Union shop clauses (in states with right-to-work law)
- Strike insurance or mutual aid plans (MAPs)

8.5.1.7. NLRB's Concept of "Good Faith" and "Bad Faith" Bargaining

In determining whether an unlawful refusal to bargain has occurred, the Board and the courts normally probe the conduct of the parties for evidence of their subjective "good faith." In some situations, the Board will find a "per se" violation of Section 8(a)(5). A "per se" violation occurs when an employer refuses to discuss a mandatory subject of bargaining, insists until impasse on a permissive or illegal subject of bargaining, or makes unilateral changes in proper subjects of bargaining. (Anon., 1957)

What is said by management to employees and actions taken toward them during labor negotiations will be considered by the NLRB to be the acts and opinions of the company. Every supervisor and member of a management team must realize that any word or action by them may give rise to an unfair labor practice charge by the union.

The following few ground rules are offered to help understand the areas of permitted and prohibited conduct by supervisors and all members of management (Anon., 1979). By no means are these statements to be considered complete on the subject. Any questions which arise as to proper legal conduct should be referred to a labor attorney.

What Management Cannot Do or Say.

1. Management cannot bargain individually with employees on even minor matters pertaining to wages, benefits, and working conditions.
2. Management cannot threaten to close or move, or to drastically reduce operations, to avoid the union.
3. Management cannot threaten to discharge employees who engage in union activity.
4. Management cannot threaten, coerce, or in any way intimidate employees in their right to engage in union activity.
5. Management cannot spy on meetings.
6. Management cannot promise employees a pay increase, a promotion, betterment, benefits, or special favors not previously offered to the union in negotiations.
7. Management cannot call individuals or small groups of employees in the bargaining unit in to supervisors' or management offices to make anti-union speeches.
8. Management cannot make false statements about the union or its position on issues in negotiations.
9. Management cannot make a statement or hint that the company will not negotiate in good faith, or that management does not want a contract, or that management will never sign a contract.
10. Management cannot show favoritism between pro-union and anti-union employees.

The TIPS model is an easy and effective way to remember the foregoing things a manager cannot do (Fig. 8.5.1).

Threats

Interrogation

Promises

Spying

Fig. 8.5.1. TIPS: what a manager cannot do.

What Management Can Do and Say.

1. Management can tell or describe to employees the company's position in negotiations and the reasons for it. It must always be completely *accurate and factual.*
2. Management can talk with employees about the status of negotiations and answer any questions they may have on any issues.
3. Management can enforce company rules fairly and impartially in accordance with past practice and published rules.
4. Management can tell employees the company will comply in good faith with all legal requirements in any future dealings with the union.
5. Management can continue to manage its business and supervise its people in all departments according to past and present company operating procedures and performance standards.
6. Management can handle employee complaints and problems on the job without going through any union "shop steward" or union grievance procedure. This will continue to be the supervisor's responsibility in all bargaining unit departments and classifications.
7. Management can tell employees that the company plans to keep operating to serve its customers during labor negotiations and during any union strike if a strike ever took place.

8.5.1.8 Management Guidelines on Making Unilateral Changes in Wages, Benefits, and Working Conditions

Once a collective bargaining relationship is established, an employer is not free to change his policy regarding such things as sick leave, wage increases, vacation time, or any other term or condition of employment without negotiating with the union about them.

Unilateral action by an employer during bargaining that affects the wages, hours, or working conditions of employees is normally indicative of bad faith on the part of the employer. However, the continuation of wage scales already in effect or the implementation of increases already promised to employees is not unlawful.

There are, however, limited circumstances when an employer may institute unilateral changes while a collective bargaining relationship exists. These circumstances exist when the union has waived its right to bargain about a particular subject or where an impasse in bargaining has been reached.

8.5.1.9 Recommended Ground Rules for Labor Negotiations

1. Negotiations are divided into two phases: (a) contract language and noneconomic issues, and (b) economic and money issues. The first area of discussion between the parties is limited to contract language and noneconomic items.
2. In advancing contract proposals and language, both parties have the right during negotiations to substitute proposals for those included in the first draft and to add to or delete proposals as negotiations proceed and the problems arising therefrom become apparent.
3. Both parties present demands or counterproposals in writing whenever possible. There is no tentative agreement reached on anything not reduced to written form, read aloud to

both sides, and agreed upon as the understanding between the parties. As complete articles and paragraphs of each article are agreed upon verbally, they are retyped with copies provided each party, proofread, and then initialed and dated by both the union and the company. These are filed together pending total tentative agreement on the entire contract.

4. As proposals and counterproposals are considered and tentatively agreed to by the parties, it is understood that such tentative agreement will become final only after total agreement on all parts of the contract is reached by the negotiating team for each side, and after approval by the company's board of directors, and after ratification by the local union and the international union, if required.

5. During all negotiating sessions, both parties equally share in the cost of meeting room expenses.

6. Should an employee be asked to serve on the union negotiating committee, and if such negotiating session is held during the employee's scheduled work shift, the employee may be excused to serve on the union negotiating committee. Such excused time will be noncompensable by the company.

7. Both parties agree to meet with each other at reasonable and convenient times for the purpose of negotiating in good faith.

8.5.2 PROGRESSIVE DISCIPLINE: DISCHARGE RESPONSIBILITIES

8.5.2.1 Progressive Discipline

The role of a supervisor is to counsel effectively with an employee and obtain the best possible job performance and job behavior. To the extent that behavior is not consistent with desired work requirements, it is the obligation of each supervisor to counsel with each employee to obtain this maximum job performance. As these discussions take place, each meeting should be documented.

The first verbal discussion with an employee about a job-related problem is not necessarily a formal "write up." However, you may want to write yourself a note and/or route to personnel file. The purpose of this is to "jog" your memory as to when this conversation took place and what was said. If the problem continues, the verbal discussion should be confirmed with a written correction notice. This notice should spell out the inappropriate behavior and a detail of your concerns about corrective action. It is suggested giving the employee a copy of this notice.

If the inappropriate job behavior continues, further progressive discipline should be exercised. With each continuing application of discipline, a confirmation in writing must be made. The number of corrective steps and resulting documentation depends upon the severity of the questionable work performance and the steps outlined in your discipline procedure.

When the time comes to implement a discharge, in most cases, it means that management failed in its counseling efforts with the employee. Accordingly, when the discharge decision is ultimately communicated to the employee, it should not be a surprise, for the last discussion prior to the discharge should have warned of the pending consequences.

Each termination should be fully documented. The exact reasons for separation should be noted on the separation form. It is suggested that the employee sign his separation form, along with you, to verify the information stated. The original separation notice is to be returned to the employee's personnel file and a copy should be given to the employee. See Fig. 8.5.2 for a summary of the discipline process.

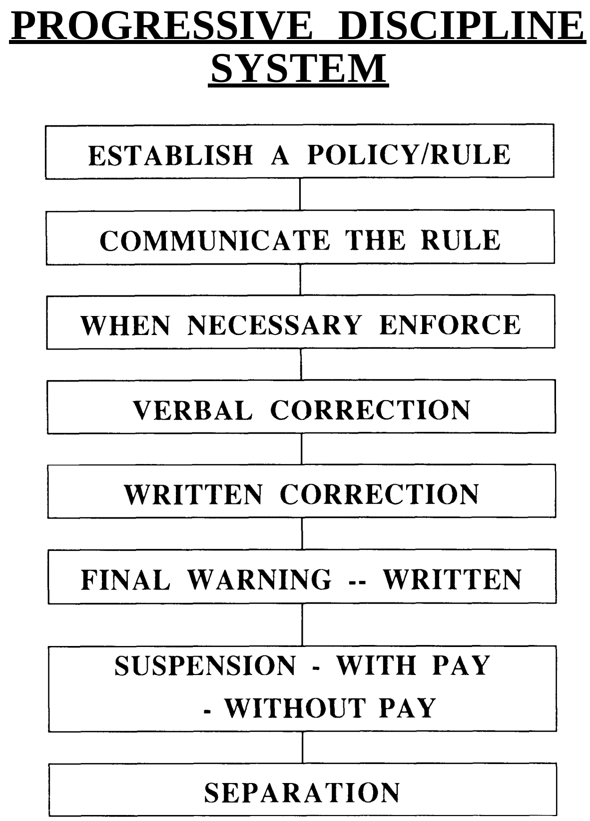

Fig. 8.5.2. Summary of the discipline process.

8.5.2.2 Eight Steps on Correcting an Employee Properly

1. Never criticize, correct, or reprimand your employee before others. Employee discipline and correction are a private matter.

2. Never try to correct or reprimand an employee when tensions are high.

3. Listen. Listen quietly to your employee's point of view of what happened. He/she may see the situation more clearly than you do. Even if he has a distorted view, let him get it off his chest.

4. Share the blame if necessary. Accept your part of the responsibility for the mistake. Perhaps you did not give your employee adequate training or preparation. Or maybe you did not forewarn him/her that this type of problem or situation might arise. Your becoming a "center" with him helps ease the load and assures him that he is not alone.

5. Discuss the problem rather than the employee. Be concerned with correcting a mistake because it is a mistake. Do not focus on the person or his/her personality. To all of us, our person and personality are usually sacred ground.

6. Deal with "why" as well as "how." Many supervisors tell employees what they are doing wrong, but not why they should do something another way. Explain your recommendations fully. Make certain that you and the employee are shooting as the same target with the same kind of gun.

7. Find a better way. A correction or disciplinary interview is not a success unless there is agreement on a better way. No one likes to be told flatly that he/she is doing something wrong. He/she will dislike it even more if he/she is left up in the air

with no solution to his/her problem. Through free give-and-take, try to settle on an approach that you both agree will be better.

8. Finish your correcting and disciplinary interview on a high note. End on a note of optimism and confidence. Don't let your employee feel you have less confidence in him/her because the problem arose (Anon., 1988).

8.5.2.3 How to Avoid Firing Mistakes: A Supervisor's Checklist

When an employee continues to pay no attention to rules and disciplinary action where an offense is repeated, or misconduct is serious enough for discharge on the first offense, decisive action must be taken. However, most discharges can be planned so careful consideration is given to all circumstances.

To help guide you through this area, we suggest you stop and carefully review the following checklist before any employee is ever discharged. Chronic rule violators who continue to menace efficient operations must be dealt with accordingly. On the other hand, every employee represents an investment in time and money—**our employees are our most valuable asset!** Ask yourself these questions, before you fire an employee:

1. Has the policy or rule been properly communicated to the employee?
2. Have I been objective and treated this employee the same as another would be treated for the same offense?
3. Have I accumulated all of the facts accurately?
4. If it is a repeated offense, has the employee been properly reprimanded in the past and have written corrections been issued?
5. Is the employee guilty by his/her own actions or by association with another employee?
6. Is the employee involved in "protected concerted activity," complaining about a job-related problem involving another employee(s)?
7. Am I taking action against the employee because he/she has "challenged my authority"?
8. Does the punishment fit the offense?
9. Was the employee's guilt supported by direct objective evidence, as opposed to just suspicion?
10. Has a top management official reviewed the facts and approved the discharge, or should I suspend the employee first to review all facts?

Remember, this recommended checklist is not very helpful after a discharge. If there is any question about facts or reasons for discharge, suspend the employee instead of firing, during an investigation of the facts (Anon., 1988).

8.5.3 MINE MANAGEMENT GUIDELINES FOR HANDLING WORK STOPPAGES

A misconception held by many is that the National Labor Relations Act only protects employee efforts in organizing, supporting, or joining labor organizations. Employers and employees are often unaware that many other kinds of group actions by employees are also protected by the NLRA, regardless of the presence or absence of any union activity.

The idea that employee group action is protected from employer retaliation emanates from Section 7 of the National Labor Relations Act, which provides in part that employees shall have the right "to engage in . . . concerted activities for . . . mutual aid or protection," 29 U.S.C. Section 157. It is this same Section 7 that affords employees the right to freely engage in union activity. The significance of this is that protected, group employee action is *not* of lesser significance, but is instead afforded the full panoply of rights and remedies granted to employee union activity.

Perhaps the most appropriate way to address group employee activity is to consider it as being a form of union activity. It can be said that, for its duration, protected, concerted activity is in essence *de facto* union activity, in that it is, for that instant, an attempt to bargain collectively over wages, hours, or other conditions of employment.

In order for employee group action to be protected, it must be *both* protected activity *and* corrected activity. Not all employee group activity is protected, concerted activity in that one of the necessary elements will be absent. If it is clearly protected activity, that is reasonable and reasonably related to wages, hours, and conditions of employment, but is not *group* activity, then it is *not* protected, concerted activity. Conversely, if it is clearly group action, but is *unrelated* to wages, hours, and conditions of employment, or irresponsible in its conduct, it is *not protected, concerted activity.*

If the task of determining whether or not particular employee actions are protected and concerted activities seems at times complex, the reader probably has a good grasp of its complexities. At times protected, concerted activity is clearly recognizable—at times it is vague—at times it is only a legal invention.

Nevertheless, following a formula similar to the one proposed hereafter will simply, or at least structure your determination:

1. Determine if the actions are protected
   - Is the object legitimate?
   - Is the conduct permissible?
2. Determine if the actions are concerted
3. If the actions are not clearly concerted
   - Is the employee acting, by admission, on behalf of other employees?

   Or, if not,
   - Do any facts suggest such a representative capacity?
4. Determine if the acts of the sort in which "groupness" is implied by law.

8.5.3.1 How to Handle Protected Concerted Activity

Section 7 of the Act declares that employees have the "right to engage in mutual aid or protection" for themselves through concerted activities on your premises during work time and nonworking time. If your employees engage in protected concerted activity:

- You should meet with them and listen to their complaints about wages, benefits, or working conditions. Tell them you are concerned about their job satisfaction—that you are interested in their well-being—and, that you do want to listen to their complaint, concern, or problems. You have the right to listen to (not negotiate with) them *individually* or in *small group meetings.*
- You should ask "leaders" of employees engaged in concerted activity on a one-to-one basis, *why* they feel the way they do about the particular complaint or problem and, *what* they are asking for in terms of improvements or solutions to these complaints or problems.
- You must not discipline or discharge any employee for engaging in protected concerted activity. This includes verbal warnings, written warnings, or disciplinary suspensions.
- You must not *threaten, coerce, or intimidate* any employee for engaging in protected concerted activity. You are prohibited by Section 8(a)(l) of the National Labor Relations Act from intimidating, coercing, or restraining employees in the exercise of their right guaranteed in Section 7 including the right to

engage in protected concerted activity for their mutual aid or protection.

- You should not commit yourself or agree to making any changes in wages, hours, benefits, or working conditions or to reinstate any discharged employees while the employees are engaged in a work stoppage, strike, sit down, or slow down. Do not let yourself be "blackmailed" by employee threats, ultimatums, deadlines. Make every effort to persuade the unhappy, dissatisfied employees of your sincere and genuine interest in removing any cause of their job dissatisfactions, but you will need time to look into the matter carefully and in depth.

8.5.3.2 If Concerted Activity Does Occur: How to Operate With New Replacements

Employees may refuse to "clock in" and report to work or fail to continue performing their assigned job duties during scheduled work time. If this protected concerted activity occurs, you have the right to inform them of a deadline by which they must report to work and continue their job duties or else they will be subjected to being *replaced with other (new)* employees. The NLRB permits management to hire a *permanent replacement* for any person who engages in any economic strike (a work stoppage involving wages, hours, and working conditions) or any employee engaged in concerted activity even though the activity is "protected." *You cannot discharge or suspend any employee for engaging in protected concerted activity.* But you do have the place to *replace* the employee *permanently* with a new employee yet to be hired.

Your deadline for reporting to work or continuing work must be communicated by a bulletin board notice, mailgram, or letter to the employees' homes as well as verbally to individuals or in small group meetings on the premises. (Caution: it is extremely important that all verbal and written communications from management to employees engaged in concerted activity be screened and approved by a labor relations consultant or labor attorney. The communications must be free of any threats, coercion, or intimidation as a result of their protected concerted activity.)

You may use properly worded advertisements in your local newspaper or on radio and TV to announce permanent job vacancies that are created by employees who are refusing to perform scheduled work by withholding their services. Such advertisements should include a statement to the effect that there presently exists a work stoppage involving several employees. The advertisement may list positive statements about your wages, excellent benefits, and good working conditions to attract as many qualified applicants as possible.

It is recommended that your advertisement include a brief "application for employment" and a telephone number that will be manned during the evening and on weekends. Thus interested applications may "mail in" an application or call for further information without taking time off from their job or coming onto your premises.

Your response to a striking employee or employees will depend, to some extent, on the cause of the strike. If the strike or work stoppage is to protest conduct by the employer that is found to be in violation of the National Labor Relations Act the strikers are said to be unfair labor practice strikers and may not be replaced. If the employees are on strike in support of such bargaining demands as wages, working conditions, or recognition, the strikers are considered to be economic strikers and may be replaced.

8.5.3.3 Document Carefully

To protect yourself from ever-present danger of an Unfair Labor Practice (ULP) charge, you must have a detailed record of every incident involving the work stoppage, sit down, or refusal to perform assigned duties. A conscientious person should be assigned the responsibility for maintaining a "Daily Strike Log" to record every incident, either major or minor. This log should include the following information:

1. Names and job classifications of employees engaged in the concerted activity.
2. Date, time of day, and location of activity taking place.
3. Type of concerted activity.
4. Description of any verbal threats (verbatim if possible) or strike misconduct with the identity of individuals involved—perpetrator, recipient, and witnesses. Take written, signed, and dated statements from recipients of misconduct.

Document all "permanent replacements" for employees engaged in concerted activity. This would include:

1. Name of new employee hired as permanent replacement for the employee engaged in the protected concerted activity, date of employment, first day worked, shift, rate of pay, immediate supervisor.
2. A notation indicating that the new employee has been told that he/she is being hired as a replacement for an individual engaged in the concerted activity. Place a copy of this permanent replacement notice in the new employee's personnel file and a copy in the personnel file of the replaced employee who is engaging in the concerted activity. You need only tell the new employee he/she is being hired as a permanent activity. Do not pinpoint a specific named individual because, while this activity is going on, you may have to shift employees around to cover protection and service needs. You may then wait until the striking employee wants to return to work to determine who specifically has replaced him/her.

8.5.3.4 When Employees Call In or Report Back to Work

When the employees who are engaged in the concerted activity call in by telephone or report in at the end of the work stoppage, wanting their job back, if they have been permanently replaced, tell them so. There is no need to disclose the name of the new person hired as their replacement.

If the replaced employee makes an unconditional offer to return to work, then you are required to place them on a "Preferential Recall" list for the next available position in which they are qualified. *They must be recalled before you hire additional employees off the street.* To provide documentation, you are required to record their name, date of unconditional offer to return to work, and former job classification. You cannot refuse to take them back unless the employee that was permanently replaced finds substantially equivalent employment elsewhere, quits, or resigns, or you abolish their former job for business or economic reasons. Otherwise, should the replacement employee leave the job, the employee replaced must be offered the job now available.

You may hire new employees to replace employees engaged in a work stoppage, strike, or refusal to perform assigned duties at the current hourly or salary rate for that particular job classification. You *cannot* promise new employees who are hired as permanent replacements more pay, benefits, or better working conditions, or to actually give any of these to them in order to induce them to come to work as new replacements.

8.5.3.5 Ground Rules for Managers and Supervisors During Protected Concerted Activity Work Stoppage

What we say to employee strikers and the actions taken toward them during a strike situation will be considered by the NLRB to be the acts and opinions of the company. Every supervisor and member of the management team must realize that any careless word or action by them may give rise to an unfair labor practice charge by the union. We must all prevent this from happening.

The following few ground rules will help you know and understand the areas of permitted and prohibited conduct by supervisors and all members of management. By no means are these statements to be considered complete on the subject. Any questions which arise as to proper legal conduct will be referred to a labor attorney.

8.5.3.6 What Management Cannot Do or Say

1. Management cannot bargain individually with employees on even minor matters.
2. Management cannot threaten to close or move, or to drastically reduce operations.
3. Management cannot threaten, coerce, or in any way intimidate strikers in their right to strike.
4. Management cannot visit strikers' homes to persuade them to return to work.
5. Management cannot take pictures (photographs or videofilm) of *peaceful picketing* or distribution of handbills when it takes place off company property.
6. Management cannot promise strikers anything to try and solicit them to stop striking and return to work.

8.5.3.7 What Management Can Do and Say

1. Management can tell employees we plan to keep operating to serve our customers—strike or no strike.
2. Management can tell employees that federal law gives them the right to strike or not to strike, and we will respect that right.
3. Management can tell employees that federal law gives our company the right to hire a permanent replacement for anyone who engages in an economic strike.
4. Management can enforce company rules fairly and impartially in accordance with past practice published rules.
5. Management can speak to strikers on the picket line so long as no promises or threats are made to solicit them to give up the strike, abandon the union, and come back to work.
6. Management can permanently replace an economic striker unless he has made an unconditional offer to return to work before the time he was replaced with another person.
7. Management can refuse to reinstate an economic striker if he has committed strike misconduct, made threats to other employees, damaged personal or company property, or used force to prevent other employees from crossing a picket line.

8.5.4 HANDLING A WILDCAT STRIKE

8.5.4.1 What to Do Before and During a Wildcat Strike

There is a major difference between a wildcat strike and one that is authorized by the union to enforce demands after a collective bargaining agreement expires. The wildcat is in violation of the no-strike clause of an existing labor contract. MANAGEMENT CAN ASSERT CONSIDERABLE PRESSURE, including discipline up to and including discharge, to put an end to this kind of work stoppage.

1. When a supervisor senses that a WILDCAT STRIKE IS IMMINENT (because of employees' grumblings and hesitation in response to an unpopular management decision for example), the supervisor should immediately alert his immediate supervisor and/or superintendent. The manager will often take over direction of the situation. In many cases, it will be desirable to have the supervisor do the talking to the rebellious rank-and-filers whom he knows and with whom he deals every day. The labor consultant or labor attorney should be called immediately and possibly the union should be called immediately either by the company itself, its labor consultant, or labor attorney.
2. The supervisor SHOULD GET HOLD OF THE UNION STEWARD and advise him of his obligation to tell the employees that the strike violates the contract and subjects them to extreme penalties; that the grievance procedure established under the contract must be invoked to settle their gripes.
3. Supervisors should KEEP AN EYE ON LOCKER AREAS, water coolers, and time clocks where wildcatters are apt to congregate at the outset of their stoppage. All-out efforts should be made to snuff out wildcats at the start.
4. If employees have no reasonable excuse for being off the job, a supervisor should ASK THEM TO RETURN TO WORK and use the established grievance procedure. (Should be in employee handbook or posted on bulletin board.)
5. The supervisor should WARN THE EMPLOYEES that refusal to work violates the contract and subjects them to discipline, perhaps discharge. Supervisors should not leave it to the union steward alone to get the employees back to work. However, the supervisor should not guarantee that if the wildcatters go back all will be forgiven. Supervisors SHOULD BE SILENT ON THIS, not committing the employer before getting explicit instructions on this point.
6. Employees should be reminded that they will NOT BE PAID for time not worked.
7. Supervisors should ASK EMPLOYEES WHY THEY HAVE STOPPED WORK, but they should not "negotiate" a settlement of the grievance or discuss it in any way, until the employees are back on the job.
8. Supervisors must be instructed to be sure to observe the efforts made—or not made—by the stewards and other union officials to end the stoppage.
9. Supervisors should TRY TO PREVENT THE STRIKE FROM SPREADING. Discouraging wildcatters from standing around in idle groups may help. Supervisors in adjacent areas should be advised about the situation at once.
10. It is essential for supervisors to record, accurately and with all relevant detail, all of the facts involved in a wildcat. Each supervisor should try to have a witness with him, if possible, to corroborate what was done and said. An accurate written record can help sustain company disciplinary decisions before an arbitrator; buttress a possible damage suit in court. Corroboration adds that much more. It should be impressed on supervisors that they are the management men immediately on the scene. Supervisors, specifically, should observe and record:

A. WHO STOPPED WORK: WHO STOPPED FIRST (AN INDICATOR OF LEADERSHIP OF THE STRIKE)?
B. WHO WERE THE STRIKE LEADERS?
C. DETAILS OF WHAT HAPPENED, WHEN, AND WHERE.

D. DETAILS OF WHAT WAS HEARD AND OBSERVED: WHAT THE SUPERVISOR SAID, AND TO WHOM.

E. WHO THE WITNESSES ARE.

11. Ask the following questions of every wildcatter as he leaves the job:

"WHERE ARE YOU GOING?"

"WHY ARE YOU DOING THIS?"

"WHO TOLD YOU TO TAKE THIS ACTION?"

12. Get pictures of picket line, work stoppage or slow down, and picket signs.

13. Advise local union and international union officers by telephone, confirmed by wire, confirmation of delivery, that illegal stoppage exists and that positive and affirmative action be taken to halt the stoppage. Please be advised that the local and international union will be held responsible for losses incurred should positive and affirmation action not be taken!

14. NEVER AGREE TO NEGOTIATE THE END OF A "WILDCAT." Agree only to discuss an existing grievance after employees are back to work.

15. Different levels of discipline are acceptable according to degrees of guilt; however, all in each level must receive the same discipline.

16. When in doubt as to appropriate discipline to give wildcat striker—suspend the striker pending a review of the facts and circumstances surrounding the work stoppage and final documentation.

8.5.5 TRAINING AND DEVELOPING HUMAN RESOURCES

8.5.5.1 Today's Training Scene

Training and developing employees and managers is becoming a number one priority in today's workplace. The employer no longer has the option to train or not to train—the question simply is how much and when? The mining industry will experience this need as automation increasingly makes an impact in the workplace and new jobs and employees are required. As the mining labor supply gets smaller, it will be necessary to keep and develop the resources that the industry has. In this segment, the topics to be covered are the people to train, when to train, how to train, how to plan for training, and how to evaluate training.

The training field today is getting more sophisticated and professional. There are more training materials of various types available than ever before. There are better equipped trainers. These developments in turn provide more tools to meet individual training needs.

Professional and business conditions have led to the era of the lifelong learner. Workers will have to continue to learn all of their lives or become obsolete. For example, it is said that the productive work life of an engineer after graduating from college is four to six months before he or she has to start learning new things. This lifelong learning has to be deliberate, planned, and continuous.

8.5.5.2 People to Train

The first step in preparing to train people is to have a clear understanding of the people to be trained. The better the understanding, the more effective the training can be planned and conducted. In most cases, training centers on the adult learner. The adult learner is mature and a different breed. He or she is different from the child (for a comparison of how adults and children learn, see Table 8.5.1). One cannot teach adults in the same way that children have been taught in the past.

Table 8.5.1. Comparison of Child and Adult Learning

	Children	Adults
Concept of learner	Dependent	Self-directed
Role of learner	To be built upon	To be used as a resource
Readiness to learn	Curriculum	Develops from own motivation
Orientation	Subject	Life centered
Motivation	External	Internal
Climate	Low trust formal	Trust mutual respect
Planning	By teacher	Mutually
Diagnosis of needs	Teacher	Mutually
Setting of objectives	Teacher	Mutually
Designing learning plans	Teacher	Learning contracts
Activities	Transmittal	Various techniques
Evaluation	By teacher	By learner

Who is the adult learner? The adult learner can be characterized as follows:

- The **adult** has his or her own set of values, needs, beliefs, attitudes, self-concepts, and past experiences that are brought to the training session.
- The **adult** comes to learn what he or she wants.
- The **adult** comes to learn when he or she wants.
- The **adult** chooses what he or she is going to learn.
- The **adult** has his or her goals for life set.
- The **adult** wants his or her needs met in the learning experience.
- The **adult** is somewhat of a neglected learner when treated as a child.
- The **adult** has limited time for learning.

These factors all affect the working place and the training that takes place there. They must be taken into account when seeking to train a person.

The other part of understanding the individual to be trained is looking at the training and what the individual's needs are at present. Training involves either a new employee or a current employee. New employees come to the training eager to learn because it will mean being able to do the job for which they have been hired. It will mean new skills. What do they want to learn? They want to learn about the company, how to do their job, and how the workplace operates.

Present employees come to the training experience either reluctantly or eagerly. They will be reluctant if they cannot see the advantage of the training, or if they have been sent because of something they have done. They will be eager if they can see the need and the advantages of the training.

What do today's employees want to learn? The American Society of Training and Development and the US Department of Labor recently conducted a study of what employees want to learn in the workplace, of the skills they need to do their job (Carnevale et al., 1989). Today's employee wants and needs these key basic skills:

1. *Learning to Learn*—The ability to learn new skills.
2. *Listening*—The ability to really hear what others are saying.

3. *Oral Communication*—The ability to communicate effectively orally.

4. *Problem Solving*—The ability to solve problems on one's own.

5. *Creative Thinking*—The ability to come up with new ideas.

6. *Self-Esteem* —The ability to feel good about one's self.

7. *Goal Setting*—The ability to set realistic goals.

8. *Personal and Career Goals*—The ability to set clear goals.

9. *Interpersonal Skills*—The ability to relate effectively to others.

10. *Team Work*—The ability to work on a team.

11. *Negotiation —The* ability to build consensus.

12. *Organizational Effectiveness*—The ability to understand the direction the organization is headed.

13. *Leadership*—The ability to assume responsibility.

In planning for training, it is important to have a thorough understanding of the person to be trained and his/her needs. One can then plan the training more effectively.

8.5.5.3 When Does Training Occur?

When are the best times to train? Here are some key times when training can be most effective:

1. When an employee is new.
2. When a promotion is coming or given.
3. When jobs are restructured.
4. When there is a slowdown or shutdown.
5. When the quality of the work needs improvement.
6. When it has been planned.

8.5.5.4 Types of Training

Training in the workplace involves several types of training.

1. Cross Training: Cross training is training persons to do a number of jobs within the company so that they can be shifted from job to job as needed. As fewer people are required in the mining industry, this will become more viable.

2. Retraining: Training of present employees for a new job when their jobs have become obsolete or the procedure for doing the job has been changed.

3. Employee Training: Training designed specifically for the employees. This may include technical safety or human relations skills. It may be done on site, or they may be sent to a seminar or workshop. It focuses on what they need to do the job effectively.

4. Required Training: This is training that is mandated by the federal or state government for the mining industry. An example is training on hazardous materials mandated by the Occupational Safety and Health Administration.

5. Technical Training: Training focuses on the technical skills needed to do the job effectively. It is usually very structured and "hands on."

6. Management Training: Training focuses on the key skills that a person needs to manage people effectively in today's workplace.

7. Executive Development: Specific training for executives to learn to develop their skills to work as team and to manage the organization more effectively.

8.5.5.5 Planning for Training

It is extremely important that training be planned. If not, it may not achieve the stated objectives. If a *helter-skelter* approach is used, the training may end up getting no where, and no one will increase his or her skill level.

The first step in planning for training is to do a training needs assessment. The purpose of the assessment is to determine the present and future training needs of the organization. When these data are gathered, a training gap usually emerges; then plans can be made to bridge that gap. The training needs assessment provides a sense of direction; it points the trainer in the right direction.

How is a training needs assessment conducted? The following steps are suggested:

Step 1. Determine the training needs of the organization.

What kinds of training are needed for the organization to operate at top efficiency? Here one needs to look at the organization as a whole and what kinds of management training, employee training, safety training, and technical training are needed at present. In this way, a complete picture is obtained.

Step 2. Assess present training.

Now that the idea is before management, the next step is to look at what is being done at present. What kinds of training are being offered? How is it being done? Who is doing it? The process normally will turn up a gap between the *real* and the *ideal*

Step 3. What is the present skill level of the people?

Then it is time to look at what is available. What training do the people have, and what training do they need to do the job more effectively? Very likely one will again discover the difference between what is available and what is needed.

Step 4. Bringing the data together.

Now it is time to bring all of the data together and discover the training gaps. At this point, there is a comparison of the ideal with the real, what is needed?, what is available?, and what is needed to bridge the gap. Regarding training needs, conclusions can then be drawn.

With the assessment done for the organization, a master training plan can be developed. The elements in the master plan are (1) the training mission statement, (2) training goals, (3) training strategy, (4) training plan, and (5) an implementation plan.

The *training mission* is the purpose or reason for doing the training. It is what needs to be achieved in providing training for human resources. Take this example of a training mission statement:

"The training mission of XYZ Coal Co. is to provide the finest training available for our most valuable assets, our human resources. We will keep these skills up-to-date so that we are able to perform at top efficiency."

Note how this statement sets both tone and direction for the company.

Training goals are developed next. They are taken from the mission statement. They are the specific objectives to strive for in conducting training in an organization. They are the overall guides that will be aimed for in training. Based on the mission statement, the next step is the training goals of XYZ Coal Co., which are

1. To provide the finest training available.
2. To provide training for the most valuable assets, human resources.
3. To keep the employees' skills up-to-date.
4. To train to perform at top efficiency.

Once the training mission and training goals are developed, a *training strategy is needed.* The strategy is how to do it. It is how to carry out the mission and to accomplish the goals. The training strategy of XYZ Coal Co. is

"Our training strategy at XYZ Coal Co. is to provide our training in-house. We will provide all the training needs to do the job effectively. Training will be planned according to the goals of the company and the needs of the individuals. We will seek constantly to bridge our training gap."

The training strategy is followed by a *training plan.* The training plan outlines the kinds of training that will be included in the process of meeting the strategy, the mission, and the goals. It will outline the kinds of seminars that will be held, the kinds of *hands-on* training that will be conducted, and the kind of individual instruction that will take place. This plan will be reviewed annually as the needs change.

The training plan of XYZ Coal Co. consists of the following:

1. Conduct one seminar for managers each month.
2. Develop technical training guides and train supervisors to use them.
3. Develop an orientation program for all new employees.

As can be seen, XYZ Coal Co. has pinpointed specific areas to focus on.

All this leads to implementation. An *implementation plan* is needed of the exact time that the training will be delivered and who will deliver it. In implementing a training plan, it is good to follow it as closely as possible. XYZ Coal Co. also has an implementation plan.

The implementation plan for XYZ Coal Co. contains these elements:

1. January: Management Seminar: Identify elements of employee orientation training program.

2. February: Management Seminar: Begin writing orientation program; assign persons to develop technical manual.

In addition to the organization plan, individual training plans for the persons in the organization may be developed. This allows focusing the individual's training where it will do the most good. It will show that the individual's training needs are taken seriously. The *training gap analysis* is a method of determining the individual's training needs. An example of a training gap analysis is included in Table 8.5.2.

Table 8.5.2. Training Gap Analysis, Employee

Employees' present skill

↓ ↓ ↓

Training gap

↑ ↑ ↑

Skills needed to do job now and in the future

Training gap analysis

The training gap analysis is a tool for planning training and retraining of managers and supervisors. The training gap is the distance between the present level of training and the desired level to do the job effectively now and in the future. The training gap analysis helps you identify the areas in which you as an employer need to provide training to develop and preserve your human resources.

Name ______________________________

Position ______________________________

Step 1. Developing a job description

The job description outlines the duties of the job and the skills necessary to perform it. This is the foundation of the training gap analysis.

Step 2. Identify present skills

What skills does the employee have now that meet the requirements of the job description. Identify technical and human relations. If you do not have one, now is the time to develop one.

Human relations—interpersonal skills

Technical skills—list particular skills for the job

Step 3. Skills needed to do job effectively now

What skills are needed to do the job now. Identify human relations and technical skills. Look at the job description and list in step two.

Human Relations and Management Skills	Technical Skills

Step 4. Identify training gap

What skills does the employee need training to bridge the gap—Compare step two and three.

Step 5. Future skills needs

What skills will employee need in the next five years to stay current.

Step 6. Your plan to bridge the gap

To bridge the gap, the following training will be provided for this person.

A. In-house training

Type	Date	Trainer

B. Seminars away from site

Seminar	Date

C. One-on-one coaching and counseling

Person Providing	Date

D. Reading and self-study

The other part of planning for training is planning to conduct the individual sessions. Here are some suggestions on how to plan a training session:

1. Master all the material in advance.
2. Plan sequence of training. The following guidelines are helpful:
   a. Start the sequence with materials that are familiar to the trainee.
   b. Proceed from simple to complex.
   c. Place easily learned tasks early in the sequence.
   d. Don't overload one learning time, keep it focused.
   e. Provide adequate practice time between sequences.
   f. Put most complex skills late in sequence.
   g. Plan training so one segment builds on another.
3. Plan training schedules—when and how long?
4. Gather all materials.

The last piece of planning for training is the evaluation of training resources. There are many kinds of training resources on the market, and the following criteria are suggestions for evaluating packaged training:

1. Will this training resource help meet the training mission?
2. Will this training resource help meet the training strategy?
3. Are the skills taught applicable to the workplace transferrable from the classroom?
4. Will this material be understandable to all employees?
5. Can this material be used more than once if it is purchased?

Careful evaluation of the material will permit a more effective job to be done in training. Also unusable or unused materials will collect on the shelf.

Next, how does one evaluate trainers? The following questions will help in evaluating a potential trainer:

1. What is the person's training style?

2. What do others say about this trainer (references)?
3. What kinds of evaluations does this person get?
4. Has the person conducted this seminar before?

8.5.5.6 Methods of Training

There are several ways the training can be delivered and take place within the organization. Each has strengths in certain situations. Each has its limitations. The methods of training are as follows:

1. Self-Instruction: Self-instruction occurs when the employee takes the material and goes through it him or herself. Here the worker may take the material while at the workplace and take it home to study on his or her own time. This type of material may be a workbook, video tape series, computer-based training, or an audio tape series. Here the individual takes responsibility for learning the material and may be asked to pass a written or hands-on test when he/she feels confident with it. The advantage of this is that the instruction can be individualized and it can be self-directed. The disadvantage is that the employee does not receive feedback from the instructor as the learning process takes place.

2. Mentor: Here an older or more experienced employee takes the new employee under his/her wing and trains the person to do the job. The advantage of this is that it is “hands-on” training, and the person can learn the job effectively. The caution or disadvantage here is that the training done by the mentor must be carried out in the way that the company wants its people trained. If the training is done wrong, it is worse than no training at all. Be sure to check the mentor out before turning him/her loose.

3. On-the-Job Training: This is hands-on training. The person normally does not go to any formal sessions but does it all by simply working in the actual work situation. The advantage of this is that the person learns by doing. The disadvantage to it is that the person may not know the reason behind what he/she is doing.

4. Seminar: A seminar is a formalized training setting that can take place onsite or offsite. It ranges from one day to several days and may cover a variety of subjects or one subject. The advantage of this type of training is that it can provide more professional instruction. The disadvantage is that it may not cover the material in the way the employer considers useful, and the person may come back to the work situation frustrated because what he/she has learned is not applicable.

8.5.5.7 Proposed Training Method

Now we need to look at a proposed method of training. There are many methods available, but the most effective method of training is behavior modeling.

Before looking at how behavior modeling works, some background would be helpful. Behavior modeling first appeared as a method of instruction in the 1970s. It is based on the work of psychologist Albert Bandura. He concluded that people learn best by imitating other’s behavior (modeling) and receiving an immediate observable reward. B.F. Skinner expanded this into reinforcement theory. Skinner says positive consequences produce positive results, and negative consequences produce negative results. It has been adopted by many corporations today and is the theory behind a great deal of current training material (Zemke, 1978).

Behavior modeling is based on the principle that if a person sees a task being done correctly, and then has it explained as to why it is being done that way, it will transfer to the workplace more effectively. He/she will not only know how to do it but why it must be done a particular way.

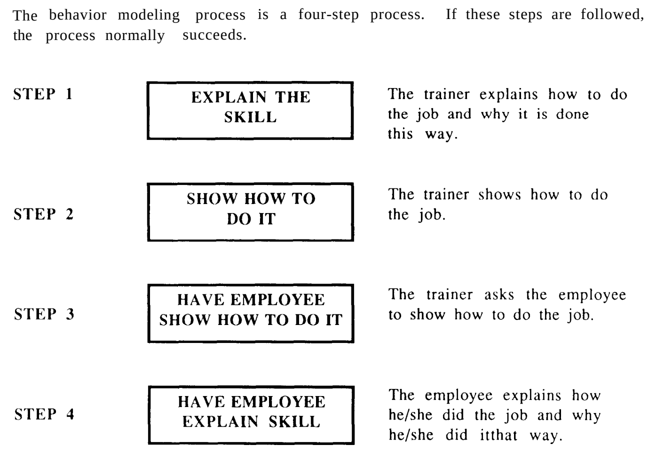

Fig. 8.5.3. Behavior modeling.

Behavior modeling works like this. The trainer does the task and then explains to the person what he/she has done and why he/she has done it that way. Then the trainer asks the employee to perform the task, explaining how to do it and why. The trainer gives feedback as to how the task went. He/she may repeat this process several times until the person has the skill down effectively. This method is highly effective in settings where tasks are taught as *hands on* (Fig. 8.5.3).

Four tools are helpful in supporting behavior modeling. They include coaching, positive reinforcement, counseling, and feedback. (See Figs. 8.5.4 through 8.5.7 for models of coaching, positive reinforcement, counseling, and feedback.)

8.5.5.8 Training Evaluation and Record Keeping

The last part of the training process is evaluation and record keeping. It is very important to keep good training records. The person responsible needs to know what he/she has done and the individuals trained. Record keeping is a simple process that can be done by hand. A sample form appears in Table 8.5.3.

Also there are many computerized training record programs that can be purchased. These make it easier to keep training records by entering each time.

To complete the training process evaluation needs, there are two methods of evaluation that may be used. One method is oral evaluation. Here each of the trainees is interviewed separately; he/she is asked how it went and what the good points and bad points were. Alternatively, this also can be done in a group with all persons sharing their evaluations together.

The second method of evaluation is written. In this method, an individualized form is created or use is made of a prepared one. If the form is especially designed, one should ensure that appropriate data are obtained. It should be custom designed to get the kind of feedback that is helpful both in evaluating the training and in designing future training experiences. A sample evaluation form appears in Table 8.5.4.

The ultimate evaluation of training is successful transfer to the workplace. One can evaluate transfer by observation. The transfer process works as diagrammed as Fig. 8.5.8.

How do skills transfer to the workplace? Skill transfer takes place through observation, imitation, practice, and adaptation. The employee learns the skill by watching someone else perform the task. Then he/she performs the task and practices it. Finally, If an employee has problems during the training process, the coaching technique is a way to plan how to overcome the problem. In the coaching session, the employee and supervisor work together to solve the training problem.

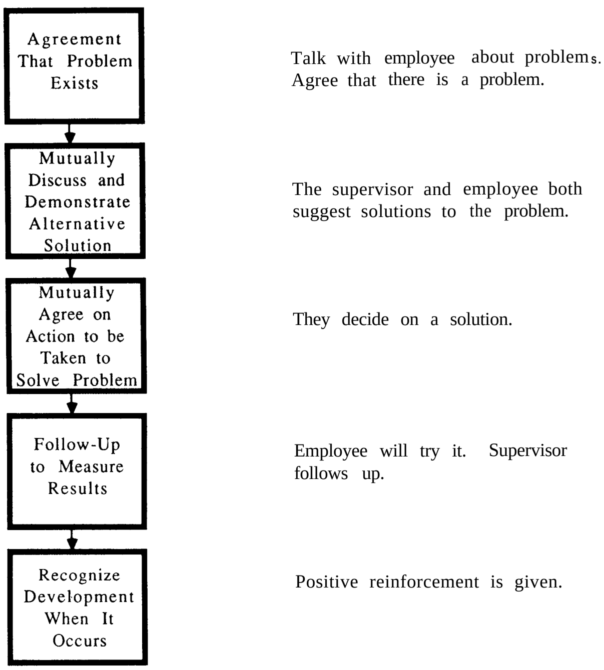

Fig. 8.5.4. Steps in coaching technique.

Positive reinforcement is a powerful tool for management to use during training. It produces the desired behavior, and the employee feels good about what he/she has learned. Positive reinforcement is rewarding the employee with praise when he/she does it right.

STEPS IN POSITIVE REINFORCEMENT - This is how the process works:

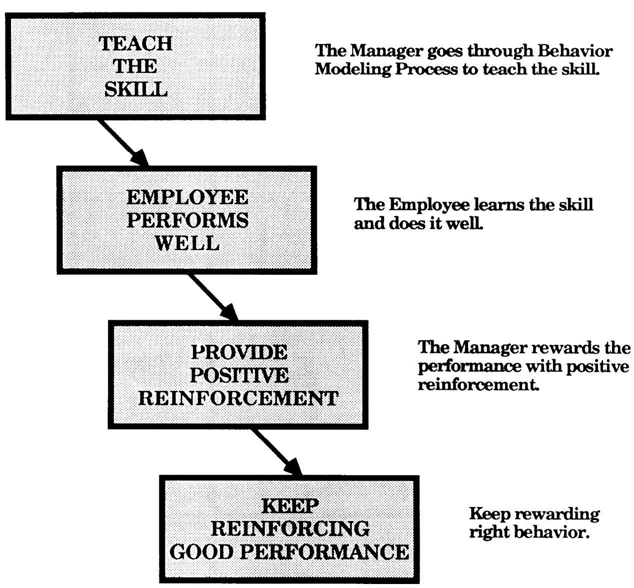

Fig. 8.5.5. Positive reinforcement during training.

During the training process, the employee may experience one or more of the symptoms below. If he/she does, the supervisor should sit down and have a counseling session.

AN EMPLOYEE NEEDS COUNSELING WHEN

1. There is failure/frustration.
2. There is discouragement about progress.
3. There is lack of confidence to do the job.
4. There are personal problems preventing adequate performance.
5. There is a bad attitude toward the job.

COUNSELING CHAIN - If the problem is not treated, the process looks like this:

The following guidelines are offered to assist during the counseling session.

1. State the problem -- Get person to acknowledge it.
2. Listen to the problem.
3. Generate solutions to the problem that are acceptable to both parties
4. Agree on a solution.
5. Implement solution.

Fig. 8.5.6. Counseling.

Feedback is of utmost importance during the training process. The following guidelines are offered for good feedback.

1.	***Give frequent feedback:***	Do it all of the time
2.	***Feedback on the behavior:***	Let the person know his/her behavior is correct.
3.	***Reflect the feelings of the worker:***	Be sensitive to problems with the new skill.
4.	***Perception Checking:***	How does the person feel about the progress being made?
5.	***Give timely feedback:***	Give it when the situation occurs. Don't wait several days.

Fig. 8.5.7. Feedback.

the skill becomes truly his/hers when adaptation is made. This happens when the person makes some adaptations to make it fit him/her. For example, the left-handed person adapts a right-handed procedure to fit his/her need.

Table 8.5.3. Training Record

Name	Training	Given	Date	Recommendations

OBSERVATION
Watching someone else do it.
The employee watches the task performed through the Behavior Modeling Process.

IMITATION
Does it like the one watched.
The employee does the task in the last steps of the Behavior Modeling.

PRACTICE
Repeats until it becomes habitual.
The employee performs the task until it becomes comfortable on the job.

ADAPTATION
Individual modifies and adapts to suit self and situation
The employee makes it his/her own. He/She adapts the skill to his style of doing things.

Table 8.5.4. Evaluation of Training

Give us your evaluation of this seminar:

1. What did you like about this seminar?

2. What would you have done different?

3. On a scale of 1–10, with 1 being poor and 10 being excellent, How would you rate the instructor?

4. Additional comments

Please evaluate the seminar on the following aspects:

Chapter 8.6
MANAGEMENT AND ADMINISTRATION

MILTON H. WARD AND SCOTT G. BRITTON

8.6.1 INTRODUCTION

Management is defined by the well-known business consultant Peter Drucker (1954) as "taking action to make the desired results come to pass." More formal descriptions, however, include "management is the conscious process by which individual and group actions are coordinated to accomplish organizational goals" (Duncan, 1983), or ". . . the attainment of organizational goals in an effective and efficient manner through planning, organizing, leading, and controlling organizational resources" (Daft, 1988).

These ideas indicate a relatively straightforward process, but in reality, managing even a small mining operation may involve a complex series of activities—not necessarily related to the actual mining of ore. These activities involve developing all encompassing plans, controls, and task assignments; allocating scarce resources; managing conflict; and reacting to the unexpected. The following discussion outlines methods for addressing and handling the variety of tasks found in the mining business. However, the reader should keep in mind that, in many instances, no ready-made solution exists. Success requires the manager to utilize guidelines and information contained herein, as well as a willingness to call on his own ingenuity and the experience and talents of his colleagues and employees.

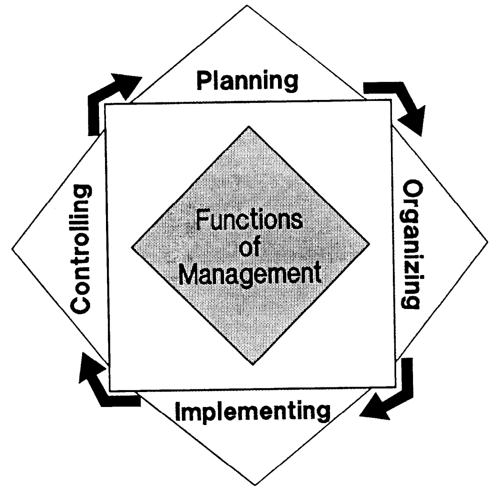

Fig. 8.6.1. The functions of management.

8.6.1.1 Evolution

Management has been practiced since the dawn of civilization, and it can be credited as the catalyst that fostered many of our social and physical accomplishments. Construction of the pyramids of Egypt and the building of our industrial society are often given as examples of well-organized management systems. No doubt, this is correct, but today the demands of society and industry placed on the participants, worker and manager, are changing and tasks are not as repetitive; therefore, even more attention must be given to management and organization.

The Industrial Revolution of the 18th century stimulated the earliest formal interest in management (Flippo, 1978). This interest occurred because better direction was needed as large numbers of workers were brought together to utilize the equipment and machinery of a separate owner, all supposedly working toward a common goal. In time, management began to develop as a recognizable and structured field of study. The analytical approach of scientific management has been credited to an engineer, Frederic Taylor (1911), who practiced from the late 1800s through the early 1900s. Taylor believed waste could be reduced by applying scientific principles to the problems of management. Specifically, his thesis stated that management was a process in which the scientific method of studying operations aided in formulating answers to business problems. His experiments and improvements undertaken for employers supported this position. Subsequently, the idea was espoused by a host of management contributors, including the famous French mining engineer and executive, Henri Fayol (1916). Fayol developed a broader theory of general management that focused on the fundamental functions of planning, organizing, implementing, coordinating, and controlling. Later, in the 1920s and 1930s, a variety of concepts was set forth with emphasis placed on the human factors of management. Another management pioneer, Mayo (1933) a clinical psychologist at Harvard Business School, was given credit for championing this effort that fostered concern for others (the employee) thereby yielding worker effectiveness, reducing labor unrest, and satisfying the human needs of the employee. An amalgamation of portions of these and ideas of other management thinkers make up what we currently consider the functions of management that are shown in Fig. 8.6.1.

8.6.1.2 Management Commitment

An untold number of writings and studies has explored the question of management plans, structure, controls, and other elements of this field, all with the objective of encouraging one to take appropriate action to obtain the desired results. The mining business is replete with risks and unknown conditions; therefore, it is also imperative that management be committed to formulating contingency programs and be prepared to implement these in a prompt manner. If the contingency plan fails, then the quest for a solution, and if necessary formulation of another plan, should be pursued until the desired objective is reached. A commitment to this "success philosophy" should permeate the entire organization—from president to shift boss—all in an effort to achieve the stated goals. Be assured that the mining business will always have problems, and when challenging objectives are attained, management is managing. Success depends on many factors, and these will be reviewed. Key among the initial decisions of the newly created business is the form of the entity.

8.6.2 LEGAL FORM

The typical mining enterprise is now conducted in the corporate form, although many of the earlier companies in our industry transacted business as an individual proprietorship or part-

Table 8.6.1. Comparison of Legal Forms

Pros	Cons
Proprietorship	
Fewer Regulations	Death terminates business
Less reporting	Only owner can act
Quick decision making	Unlimited personal liability
Less risk by others' actions	Equity capital is limited
Owner's total assets recognized	Profits taxed as income
Single taxation	Fewer tax privileges
Partnership	
Fewer regulations than corporations	Unlimited personal liability
Less reporting than corporations	Joint and several liability
Every partner can act	Dissolution by partner's death
Eliminates one tier of taxation	Profits taxed as income
All partners agree to new partner	
Owners' total assets recognized	
Corporation	
Limited personal liability	Owner's personal assets not considered
Unrestricted transfer of stock	No restriction on share ownership
Legal entity that can act	Desires of majority rules
Unlimited owners	Ownership separate from management
Ready access to public trading	Must qualify in state
Survives death of investors	Many governmental restrictions
	More onerous taxation

nership. The most appropriate form for any organization is that which best meets the objectives of the owners, and owners often have a wide disparity of goals. Tax provisions usually influence this choice, but unfortunately, in recent years, US tax laws have changed frequently—and in many instances in a manner that totally circumvents the planned objectives of the organizational form selected. A tabulation of the pros and cons of each form is shown in Table 8.6.1.

8.6.2.1 Individual Proprietorship

As the name *individual proprietorship* indicates, this form is often suitable for the sole proprietor. It is by far the simplest and most common, and it allows the owner to function as owner and worker, as well as an owner that can employ unlimited workers. The primary disadvantage of the proprietorship is that the business terminates on death of the principal, liability is unlimited, and financing and growth can be restricted.

8.6.2.2 Partnership

Formation of a *partnership* takes place when two or more individuals agree to combine their property, labor, and/or capital to function in an activity in which they have a community of interests. Here each partner is to be a principal owner as distinguished from a mere agent, clerk, or creditor, and each is to share in profits and losses because of this relationship. Some would say a partnership is nothing more than a proprietorship with several owners; and while partnerships do have many of the legal characteristics of proprietorships, compared to the corporate form, they eliminate one tier of taxation.

One of the major disadvantages of a partnership is the unlimited personal liability for obligations of the business. This characteristic led to the *limited partnership*, which is a statutory form that allows the investor to limit his liability to the amount invested in the partnership. If this and other protection are to be obtained, scrupulous adherence and compliance with statutes is a necessity. There must be one partner, the general partner, who accepts the risks of the enterprise in this situation, and the limited partners are passive participants who should not exercise control. Another attractive feature of the limited partnership is the assignability of the interest of the limited partners without dissolution of the entity. Use of this form of business has increased in recent years, primarily because the limited partnership eliminates one layer of taxation, and it can be marketed on a public exchange, traded, and operated quite similarly to a corporation.

8.6.2.3 Corporation

As noted earlier, today the *corporate form* is most common for larger businesses and has many attractive features, generally including limited liability of shareholders, unrestricted transferability of ownership by sale of stock certificates, and an unlimited number of owners. As with other forms, often the advantages of a particular entity lead to disadvantages. Among the drawbacks of a corporation are limited credit available (only that justified by the corporation's assets—not total assets of the investors), and taxation requirements are more onerous—especially the double taxation that requires payment of taxes by the entity and then additional payment by the individual investor.

A corporation is most suitable for the large and rapidly growing enterprise, and this is currently the most common form for mining companies. As noted earlier, tax advantages have fostered a revival of partnerships in recent years, but this form remains secondary to the corporate mode. These three entity structures (sole proprietorships, partnerships, and corporations) are the basic forms, although variations of these can be designed to fit the needs of a particular investor or situation. To be most effective, these needs should be identified in the planning stage of the business.

8.6.2.4 Formation Mechanics

The mechanics for establishing the business entity are influenced by the form (proprietorship, partnership, or corporation) and domicile of the enterprise. Regulations are set forth by local, state, and federal governments, and provisions of all these bodies must be followed. Here also, requirements are affected by the type or entity, whether the enterprise is marketed publicly or privately, and how widely traded.

The pros and cons of proprietorships have been listed, and while simplicity of formation and ease of operation are advantages, this structure is rarely selected for a growing business. Exposure to liability, restrictions to funding, and limited life are usually justifications for rejecting. Partnerships may be less onerous and can fill special needs, but since they are often designed to meet a particular situation, they too are infrequently selected for the growth-minded company.

As noted, the corporate form is the most common structure chosen in the mining business, and the manner in which this entity is legally established is well defined. A corporation is created through the joint act of the state and individuals whereby the government grants the privilege of incorporation. The legal concept of a corporation consists in the offer and acceptance of a charter, which is a written instrument that sets forth the terms

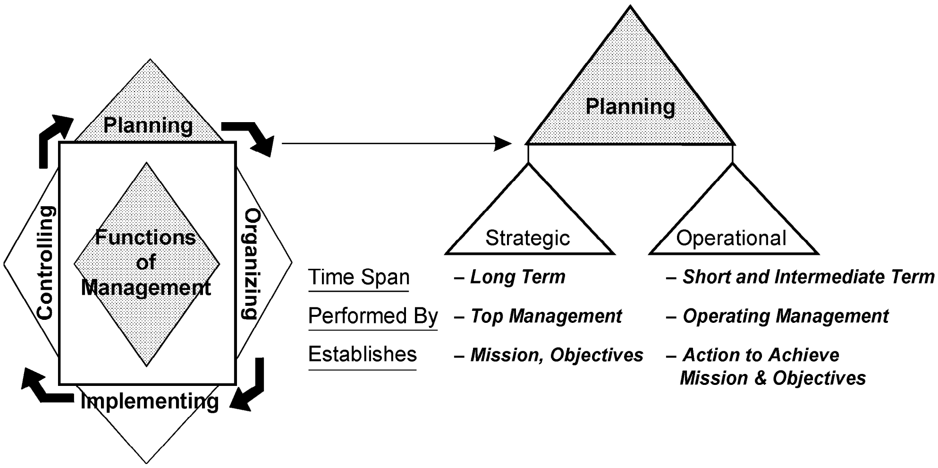

Fig. 8.6.2. Planning—key function of management.

and conditions upon which the stock permits one to exercise the franchise created in the charter. Briefly stated, the steps of incorporation are:

1. Principals arrive at an agreement as to nature and scope of business and broad outline of capitalization and distribution of securities.
2. Select and clear corporate name.
3. Select corporate directors and officers.
4. Describe role of directors and intent with regard to meetings.
5. Note amount and par value of stock.
6. Select the resident agent.
7. Submit the appropriate information from the foregoing and file for a certificate of incorporation with state (secretary of state) and local offices (county clerk of the county wherein the corporation will have its principal office).
8. A few states require a preliminary agreement of association.
9. Prepare bylaws.
10. Obtain any necessary authority for issuance of stock and/or other securities under local blue-sky law.
11. Obtain from law stationer, corporate seal, stock ledger, minute book, and stock certificates.
12. Hold organization meetings.

If public trading of the stock is planned, there will be additional filing requirements with regard to listing on a public stock exchange and a host of related issues. While it is relatively simple to form a corporation by completing standard forms, if the enterprise is to be sold to the public, the complexity increases, and the advice of a competent attorney early in the formation stages can be most valuable.

8.6.3 PLANNING

Planning is the process by which profitable growth is sought and attained in a changing and uncertain world. As shown in Fig. 8.6.2, planning is divided into two major segments, often classified as strategic or operational: *strategic planning* is the broadest, highest level, and longest term effort concerned with defining the objectives of the firm—where the firm wants to go and how it will get there. The other segment, *operational planning,* often relates to the activities of the organization that concern the near term, but its primary focus is controlling the actions to achieve the stated objectives.

Planning may also be further described as long-range, intermediate-range and short-range. The distinctions result from the time frame covered, individuals involved, and activities incorporated in each type. Needless to say, these many classifications of planning may be confusing, because they often overlap, and definitions may vary from company to company.

8.6.3.1 Strategic Planning

Strategic planning involves an assessment of strengths and weaknesses that must be undertaken in order to direct future action. A review of past activities and experience should determine the following:

1. Can management operate in foreign environments?
2. Is the company to be an explorer, developer, and/or operator?
3. Is the enterprise knowledgeable in transportation and marketing?
4. Does it have in-house financial and legal personnel?
5. Is it generating positive cash flow?
6. How large or limited is the borrowing capacity?
7. A host of other key factors.

If the potential business of the company requires new skills, then this inadequacy should be recognized and action plans (called appraisals) formulated to eliminate or minimize these weaknesses. Such appraisals can significantly alter the direction of an enterprise and are the key determinants of restructuring programs implemented by a major segment of American business in recent years. Such reviews have suggested divestment of ill-fitting businesses and have guided many companies back to the core business from which they started.

Appraisal of markets and products starts with the customer. During a strategic planning session, typical questions posed include:

1. Who is the customer, and what are his needs?
2. Where are the customers located, and what type products are or will be in demand?
3. How much of the market do we control, and how can we capture more? Is the demand for our commodity or product expected to change significantly?
4. If markets change, will this influence our divestment or acquisition policies?

Assessment of these and other key factors make up the mission, objectives, and strategies of the mining enterprise and are a part of the total strategic planning process and action flow shown in Fig. 8.6.3.

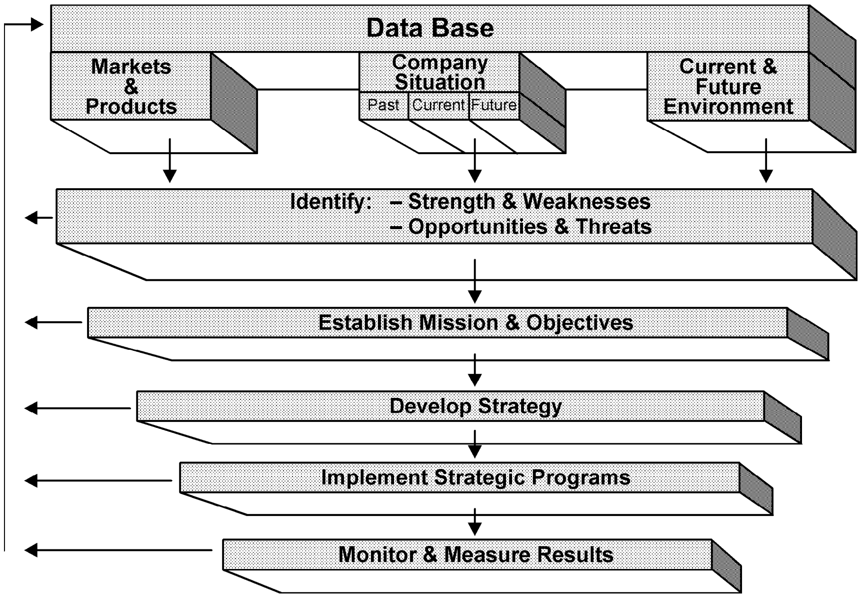

Fig. 8.6.3. Strategic planning—action flow.

8.6.3.2 Mission

The efforts of any organization, be it military, religious, or business, can be better marshaled and directed if they are committed to a guiding principle known as the *mission.* The company's mission statement articulates this principle and outlines the nature of the enterprise's activities and businesses that it will pursue. The mission or justification for the organization's existence should be shared with those involved in attaining the desired results. Someone, ideally top management, must ask and answer: what is our business, and what should it be? Typically, this utilizes steps in the foregoing assessment relative to where the company is, the status of its markets and products, and an appraisal of the firm's strengths and weaknesses.

Many companies prefer not to state their mission precisely, but one can be assured that the goal exists—whether noted in public documents or only etched in the mind of the chief executive officer (CEO).

Cyprus Minerals Co.'s goal that was noted in a recent annual report (Anon., 1989) may serve as an example of the mission statement:

"Cyprus Minerals' goal is to be a premier mining and minerals company. Cyprus aims to profitably grow internally and through acquisitions to increase shareholder value. Cyprus seeks to be a low-cost producer, a technologically superior mining and processing company, a reliable customer-oriented supplier, an effective marketer of quality mineral products and a safe and fair employer. "

Fulfilling the mission of the mining company requires continual success in many areas—profits, debt repayment, discovery of ore bodies, and exploitation of reserves—all with a regard for the constituency of the company. These achievements do not come easily, but they must be pursued and assessment must utilize meaningful measuring sticks.

8.6.3.3 Objectives

In the parlance of strategic planning, objectives are the longer-term goals of the enterprise. Webster defines *objectives* as "something toward which effort is directed, that is, an aim or end of action." This is how the term is used in this writing. Specifically, objectives are the longer-term aims of the natural resource company. Typically, such objectives last for years and relate to the broad issues of growth, profitability, stability, and image—all factors that the company seeks in order to fulfill its mission.

As noted, objectives should be written and distributed to members of the management team to aid in decision making and give direction to operations of the firm. Usually financial objectives speak to the desired growth rate, dividends paid, debt level, and return on investment. Each major segment of the company should formulate its objectives and run its business accordingly. As an example, exploration objectives over the next five years could include maintaining a portfolio of ten new prospects, four advanced-stage prospects, and ongoing definition drilling on two projects—all with the objective of finding an additional gold ore body within a three- to five-year span. Specific objectives of different departments should be tailored to those activities in which their performance and results significantly affect the prosperity of the business. This requires a determination of what is to be measured and what is the yardstick for measuring.

Objectives may be identified and formulated by middle- and senior-level management, but since these guide key action of the enterprise, top management must participate. The CEO or president must not only review and give approval but should also be the person to communicate objectives to all involved. Top management's task is to solicit support of all today for action that will influence results tomorrow.

8.6.3.4 Strategy

Company strategies are made up of action plans and programs necessary to achieve the overall important objectives of the enterprise (Steiner, 1969). *Strategy* is often simply defined as "the action taken to achieve the company's purposes" (Cannon, 1968). Frequently the words strategy and tactics are used synonymously, but in other instances, *tactics* are the more detailed actions taken to attain the strategy. Here we speak only of strategy, and it is indeed action- and results-oriented.

Development and implementation of strategy require identifying the goals of the organization, the activities to be considered, and selecting the most likely action that will yield the expected results. Additionally, responsibilities must be assigned, an allocation of resources determined, and a schedule for completion established. The entire program should be monitored and the results measured by predetermined guidelines.

As an example, consider strategy development to achieve the exploration objectives. As mentioned previously, a company must weigh a number of factors: whether the area of exploration offers the possibility of being a district, region, or country, whether a full geological/exploration staff is to be employed or a portion of the work handled by consultants, and whether drilling is to be undertaken by the company or by contractors. After review, the preferred strategy is selected, responsibility assigned, and work commenced. In many instances, decision making is delayed while newly identified objectives are investigated. In this instance, the review might suggest joint venturing with an exploration company that is seeking a partner. Further study could lead to selection of a totally different option that requires less time and is more cost effective.

8.6.3.4 Operational Planning

Operational planning, as noted earlier, is one of the key functions of management for directing and controlling activities so that the objectives of the enterprise can be attained. While the time frame of action can be long or moderate, most actions involve short-term or in many instances day-to-day tasks. Often unit or departmental programs are classified as operational planning, and typically annual budgets and rolling forecasts may fit this classification. Again the key factor that makes operational planning different from strategic planning is that operational planning is involved with the tasks on a day-to-day basis that are necessary to influence the company's long-term objectives.

8.6.3.5 Long-range Plans

Long-range plans can set the direction of the enterprise and may be analogous to strategic planning. These plans focus on the mission, objectives, and strategies of the company, but also influence and guide intermediate- and short-range operational planning (Steiner, 1963). They are developed, monitored, and, when required, altered by top management. However, since they direct major investments and action, all for an extended period, only infrequent changes are made to these plans. As an example, these can focus on the commodity to be produced, and whether the company will be a miner, processor, and/or smelter of the commodity. They also consider where the entity will operate and with whom. Additionally, long-range plans may also be quite operational in nature. Mine development plans of major ore bodies often consider programs that may not be implemented for decades, and similarly, it is not unusual for financial schemes to extend for at least a decade. The point is that long-range plans, as the words indicate, look to the long-term, regardless of whether the plans are strategic or operational.

8.6.3.6 Intermediate-range Plans

This type of planning provides the means for achieving the mission and long-term goals. The plans, depending on the company's definition of short-term planning, usually have an outlook of two to five years. In the mining business, the definition of *intermediate-range* may cover that time period required to develop and bring into production a deposit that has recently been discovered. Here the term intermediate will depend on the size of deposit, method of mining (underground or surface), degree of processing, and other key parameters of the deposit. If the mine is already in operation, this planning may focus on that period required to plan, develop, and bring into production an expansion of existing operations. At any rate, such planning is often viewed as that ranging from two to five years.

8.6.3.7 Short-range Plans

Short-range plans cover a span of one year or less. Ideally, these would be geared to long-term and intermediate-term programs as well as the overall strategic plan. Here investment funds, revenues, production, and activities can be budgeted with a more reliable degree of accuracy and can be measured on quarterly or more frequent bases.

Summarizing the planning function, as in describing its multifaceted types, objectives, and methods, is no mean task. Definitions are often confusing with several terms used for identical activities. This is because objectives, goals, and tasks may be words that mean the same thing in one organization or writing, while totally different in another organization or writing. The preceding description should clarify the verbage, but more importantly it should aid in leading the organization toward its long-term objectives. This is the purpose of planning—not only to establish the plan, but to assign responsibility and cause the appropriate action to be taken. The best designed plan will be ineffective if it does not generate action and the desired results. Numerous methods of motivating the staff and management to achieve such results are utilized, including the commonly applied practice of management by objectives, an approach that will be described later in this writing.

8.6.4 ORGANIZATIONAL STRUCTURE

8.6.4.1 Method of Design

Design of the organizational structure should focus on enterprise objectives and how the structure can best assist in achieving these objectives. The mining company must be concerned with minimizing capital requirements, but also effectively finding the ore body and efficiently mining, processing, and transporting the mineral product to the customer. How best can this be done? Many organizational design factors come into play—including size of entity, functions required, span of control, reporting relationship, and minimizing duplication while maximizing communication and flexibility. The broader question of the type of structure must be addressed. Which of the forms in Fig. 8.6.4. should be followed?

Should we use functional, divisional, matrix, or a combination of these. Within this issue is the question of how much staff and the relationship of staff to line. Additionally, top management must decide whether the available personnel and the nature of the business suggests a heavy emphasis to centralization or decentralization. This array of questions, large number of issues, and new terms indicates that structure design may be a difficult and complex task, and it may. But paramount to good design is a clear understanding of the strategy and tasks to be achieved and then designing a structure to accomplish these tasks. Chandler (1962), an expert in organizational design, strongly advocates "strategy before structure." Clearly, it pays to know what you want to do, before you start doing it. Success also depends on getting the proper person in the proper position. Many would say that after design, the requirements for each position should be established, and if qualified personnel are not available, they should be recruited and hired. In reality, this is not necessarily the practice. Often such positions are assigned to whomever is available within the organization. While this practice can be criticized, to some extent it has merit—especially if the one assigned is underutilized in his current role; has the proper attitude, desire, basic skills; and is willing to be trained.

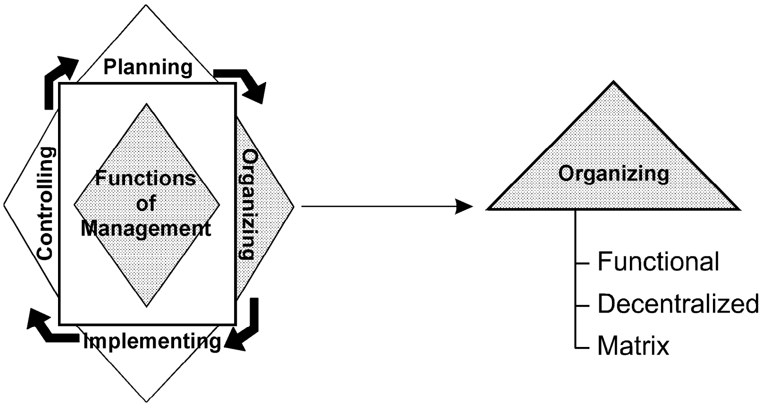

Fig. 8.6.4. Organizing—key function of management.

The key to organizational design is creativity with flexibility. Flexibility is important not only for maximizing performance but also so that one will feel free to redesign organizational structure as frequently as required. Proper design is an organic process in which organizational goals and needs change and management must change the structure to meet the new demands of the enterprise.

8.6.4.2 Centralization - Decentralization

Whether an enterprise is organized on a centralized or decentralized basis depends on where most decisions are made. In centralized organizations, the key decision making takes place where top management is located. Many would say centralization weakens middle management and restricts a manager's development, but others would note that it most effectively conveys the true philosophy and intent of top management. Critics of centralization believe that decision making can be learned, and if one (a younger inexperienced manager) is not exposed to or allowed to make decisions, then his experience will be limited. Decentralization usually moves the administrative and support systems from headquarters to regions, districts, or branches. Decentralization of most activities is almost a necessity for large foreign operations and is frequently used in the larger domestic company. Often, even when decentralization is followed, the policy-making, planning, and financing activities remain with headquarters.

Management's preference for centralization or decentralization changes from time to time and from one CEO to another. Several decades ago, there was a strong shift to decentralization in American industry. This was then followed by a shift back to centralization, with creation of staff specialists and control from headquarters. Recently, hard times in the natural-resource industry have fostered a retrenchment effort with trimming of central staffs, and lean simplified organizations are back in vogue. Proponents of decentralization believe that its advantages far outweigh its shortcomings and that it serves industry best under any condition. Its advantages are thought to

1. Allow daily decision making at the lowest level and thereby aid in development of personnel.
2. Raise morale to a peak if the manager is part of the decision-making process.
3. Enable managers at the work location, who are supposedly best qualified, to make decisions and take action.

8.6.4.3 Matrix

Structures that follow the *matrix mode* are often thought of as temporary because they are frequently created to solve a particular problem. Commonly, the use involves technical organizations in which specialists (mine development, mining engineers, mechanical engineers, geologists, etc.) are brought together to complete a particular project (e.g., an underground machine shop). The organizational structure for this special project team in a smaller company could be as shown in Fig. 8.6.5.

Here the project manager is responsible for the overall program. He/she is assigned personnel from other functional departments to complete this special task, and when the job is finished the personnel return to their former duties, or move on to another project. The next project may have a totally different group of specialists and a new project manager.

Some organizations use the matrix system as a permanent structure with the project manager giving full-time effort to a continuing variety of projects. As an example, this position (project manager) could be responsible for corporate growth and his/her teams made up of personnel from different departments depending on the activity under consideration. Here the project manager could be responsible for several growth projects at any time, with teams dismantled as projects are completed.

The matrix structure allows special projects to utilize the best personnel available for the tasks at hand; it minimizes the number of specialists required in the company, puts them to maximum use, and allows jobs that are often deferred or set aside by the busy functional manager to be completed by the special project manager. This practice, however, is not without problems. Such planning sets the stage for conflict between the functional and project managers since the functional officer may feel that his authority is being preempted. Similarly, matrix planning can create a problem for the specialist since he is often working for two superiors, and there may be questions of loyalty, time allocation, and priority. Also personnel directly involved in the project may be concerned about job security. What job do they return to when the project is completed? Will someone have taken their place in the functional line while they are on assignment? Will their relationship with their functional superior be damaged because of the new job? These questions must be addressed, and senior management should give comfort to all involved so that they will strive eagerly to assist with the project to attain a common goal for the enterprise.

8.6.4.4 Line And Staff

The two structural classifications common to most organizations are line and staff. *Line activities* follow the primary functions of the company and normally include operations, sales, finance, and exploration. *Staff activities* are separate from the primary line, but interface with this group. Staff types are com-

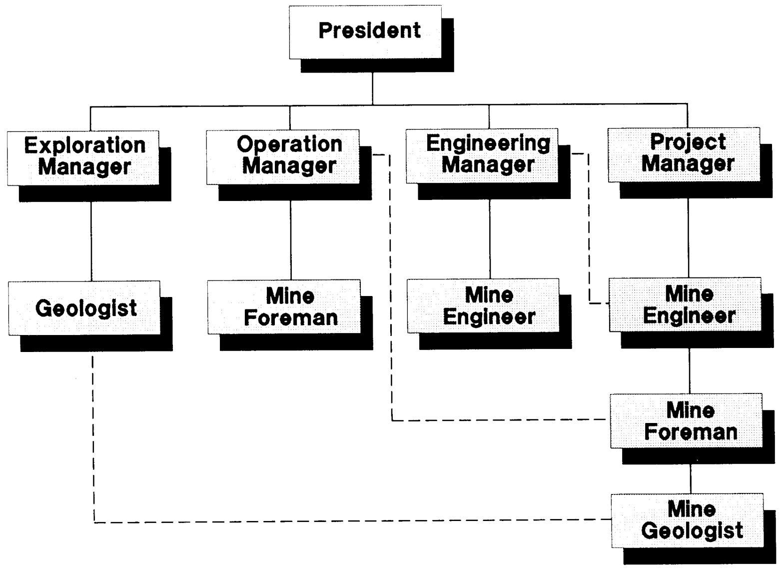

Fig. 8.6.5. Matrix organization.

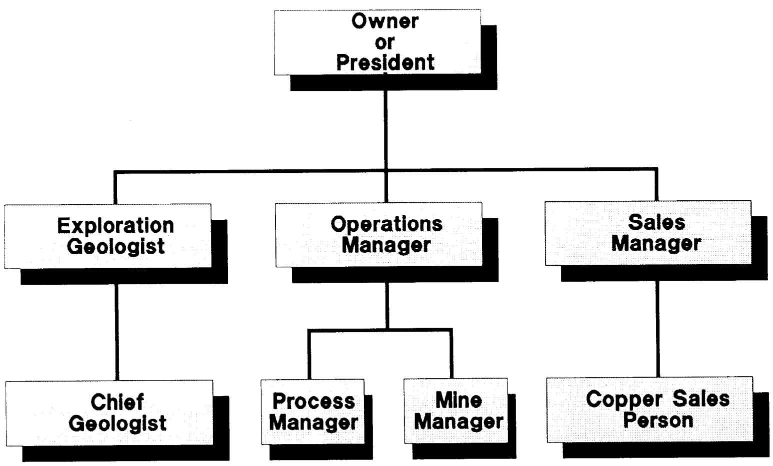

Fig. 8.6.6. Line organization.

monly classified as general and specialized, where general staff serves the needs and duties of a senior officer, as an example, assistant to the president. Specialized staff, on the other hand, commonly concentrate on the more specific part of the business and include cost control engineers and marketing research specialists. The simplified organizational chart in Fig. 8.6.6. illustrates the line tasks. Addition of staff personnel to this structure would show the positions listed in Fig. 8.6.7.

Utilization of staff specialists requires a clear understanding of these duties. Typically, staff personnel lack rights of command, but rather advise and recommend. Cost control engineers collect and analyze data and suggest methods for reducing cost but do not direct action to capture the savings. Similarly, market research staff personnel identify and develop programs that may yield higher revenues but do not implement the new ideas. This practice is often followed in an effort to maintain integration of the line, prevent confusion, and fix responsibility. In a situation such as this, the effective staff person strives to work with and support line personnel rather than take over line duties or impair the activity. As an example, the surveyor picks his time for installing grade or locations points to minimize interruption of production. Similarly, in the spirit of cooperation, the wise grade-control engineer follows the principle of giving prompt advice on dilution to low levels in the line rather than directing the problem to higher levels, that is, to the supervisor of his counterpart .

It is inevitable that from time-to-time conflicts will develop between line and staff. These conflicts occur because objectives of the two groups are perceived as being different. The foreman wants to maximize production while the grade-control engineer's objective is to maximize quality of output. However, conflicts can be reduced by educating all involved with the overall objectives of the mine, and then noting the importance of the line and staff groups working together to achieve joint goals. Occasionally, better appreciation of the tasks of each can be gained by rotating the advisors into line roles and the operating personnel into staff positions.

Clearly, the best solution to conflict is for the participants to solve their own differences, and this approach should be fostered. If a solution cannot be reached, then the supervisors of these personnel should interject themselves into the fray to reach a compromise. Conflicts will develop, but if handled properly and promptly, the impact will be minimal—and, in the process, the enterprise should reap the efficiency and performance that can flow from the advice of the staff specialist.

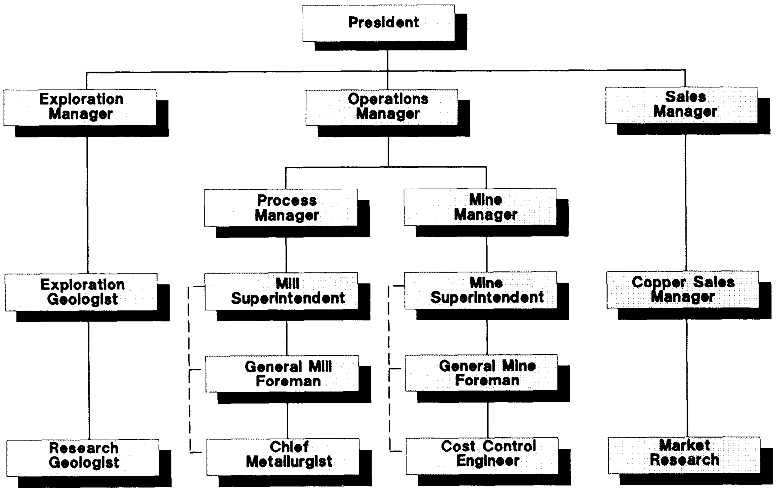

Fig. 8.6.7. Combination of line and staff organization.

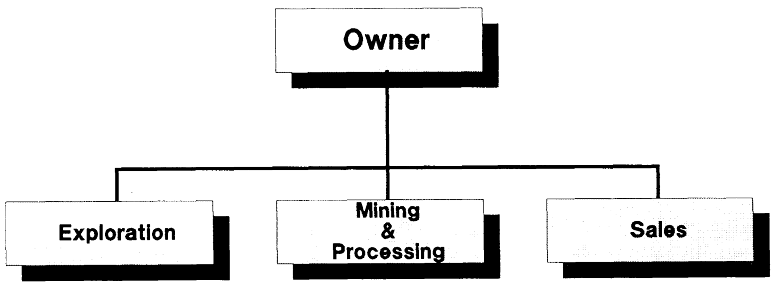

Fig. 8.6.8. Simplified organization.

8.6.4.5 Organizational Size

Normally, the small operation can function satisfactorily without the heavy hierarchy of the typical large institution. The small entity requires no president or CEO or other sophisticated structure. The owner directs some of the functions and actually performs others. Jobs may be combined and often only one person is responsible for financing, accounting, and sales. Initially, part-time personnel may be employed, but eventually, full-time employees are retained. A typical simple structure for the small start-up company is shown in Fig. 8.6.8.

Changes take place as the enterprise grows, and many specialized skills are required. Therefore, there is merit in reviewing the differences in structure and organizational responsibilities associated with size. Governmental agencies and industry associations often precisely describe small, medium, and large entities by the number of employees, dollars of turnover, geographical span, or variety of products. Obviously, the definition of size is a relative statement, and herein the number of personnel involved in the business has been selected as the distinguishing feature, with small being any organization that has less than 100 employees, medium the firm with up to 500 employees, and large the enterprise that contains more than 500 personnel. Often the classification can be better defined by the more sophisticated manner in which the business is organized and managed.

In today's business environment, most moderate-sized companies in the mining industry have chosen to follow an organizational form that includes a presidential, vice presidential, and managerial structure. This organizational form mirrors the large corporation, provides management ego satisfaction, and allows corporate and operating officers to carry the title of their counterparts in larger organizations.

The transition from the small to medium-sized company typically involves a flat management structure that is aligned with functional activities. These might include the structure shown in Fig. 8.6.9. Any complex, hierarchical structure should be avoided since a multi-layered organization can be confusing and costly. Most operating personnel believe that optimal management involves a broad span, and where possible decentralized decision making is preferred. Here "span" refers to "span of control," a term that indicates the number of subordinates reporting to a particular supervisor. As an example, the president in the chart in Fig. 8.6.9 has a span of seven individuals, that is, seven managers performing functions and reporting directly to him. Span limits are often selected arbitrarily. They depend on the superior, the subordinate, and the complexity of the tasks being performed. These like the structure can also change with time.

The middle-sized organization can usually justify management for each functional area, while the large company has a clear-cut assignment of responsibilities, usually with a vice president for each functional area.

The foregoing are hypothetical organizations; however, it is apparent from the actual examples shown in Figs. 8.6.10 and 8.6.11 that the structures described incorporate the key functions. But, as noted at the beginning of this part, organizational structure is an organic process, and while these designs are appropriate for the companies shown at the time of this writing, changes will be made as the organizations change. It has been stated that "The shelf life of any organization's design is probably less than a year" (Sheridan, 1989), and this comment is grounded on the fact that markets, needs, and personnel change—all of which may call for a new structure. Interestingly and supportive

of this statement is that the submittor of the organization in Fig. 8.6.11 said that a vice president-operations would probably be added as the company developed additional mines.

8.6.5 FUNCTIONS

8.6.5.1 General

Development and growth of the mining organization often evolve through several stages. Typically, the first stage has a dominant focus on exploration. The initial deposit must be discovered or acquired before self-sustaining funds can be generated, and therefore finding this ore body is of paramount importance. Once in hand, the deposit must be developed, and this requires skills of engineers and operators. Concurrent with, if not before development, come financing, marketing, and many staff and line functions required in the mining business. A brief consolidation of these plus all activities for the mining entity is depicted in Fig. 8.6.12.

8.6.5.2 Exploration

The explorationist must have excellent geological and exploration skills and properly apply these if the mining company is to find ore bodies allowing commencement of operations. Unfortunately, successful exploration requires not only technical skills and good judgment but persistence, long-term funding, and a modicum of luck. The search for a viable deposit is the riskiest and most uncertain challenge facing company management. Statistics show that the odds of success are overwhelmingly negative, with reports indicating that only one out of every 1500 prospects will make a mine. Therefore, the key actors in this facet of the business must have access to and the strong support of top management. Ideally, the person responsible for exploration reports directly to the chief executive officer and works in concert with him. It is imperative that there be agreement about the target commodity, geographical area of interest, budget level, and manner in which the exploration program is to be pursued. For further discussion of exploration management, see Chapter 4.6.

8.6.5.3 Engineering

This facet of the organization typically includes surveying, structural, mechanical, and electrical engineering; mine planning; cost estimating; and other related engineering tasks. Larger companies will have full-time specialists in these areas, while smaller mines will contract or retain certain skills on an as-needed basis. Usually, mine planning and engineering include full-time personnel since this group is involved in all stages of the operation, such as ore reserve computation, predevelopment, development, and operational planning, as well as grade control and production statistics. Selection of the mining method is a critical decision, and where possible, the choice should be designed with flexibility in mind. Unfortunately, ground conditions, water flow, and ore deposition cannot be predicted with precision. Former President Herbert Hoover (1909), a renowned mining engineer, described the situation well:

"The mining engineer's works, on the other hand, depend at all times on many elements which, from the nature of things, must remain unknown. No mine is laid bare to study and resolve in advance. We have to deal with conditions buried in the earth. Especially in metal mines we cannot know, when our works are initiated, what the size, mineralization, or surroundings of the ore bodies will be. We must plunge into them and learn—and repent."

In his excellent book on mining management, Sloan (1983) supports this theme and makes the point that in many areas, mining and mining management are different from that of other industries. One should therefore recognize that mining management systems as well as the work of the mining engineer need to be tailored to our industry.

8.6.5.4 Operations

This usually contains the largest group of workers and can encompass predevelopment, construction, mining, milling, and smelting. Obviously, the makeup of the organization depends on the size of the company and its span of activities. Even the smallest operation commonly has a mining and milling/processing department. These managers may handle their own engineering, construction, and production functions, or they may be limited to only production responsibilities. Here the term mining describes the tasks of development, which includes prestripping (if an open pit) or excavating access and mine openings used in extraction (if an underground mine), and the drilling, blasting, loading, and transporting of ore. Milling or ore dressing describes the process of crushing, grinding, and treatment of the ore such that its valuable constituents are concentrated in a more valuable salable form. Smelting and refining are further stages of processing that change the form of the product, that is, copper concentrates to copper metal.

The operations manager, superintendent, and front-line supervisor must not only have technical expertise but should also be schooled in human relation skills, management techniques, and company policy. Production output and efficiency are influenced by the layout and choice of equipment, but equally by marshaling and motivating the work force. Training incentives and other methods for obtaining commitment of the worker have been emphasized in recent years with gratifying results.

8.6.5.5 Taxes

As noted at the beginning of this chapter, taxes play an important role in the form of the entity, and they also influence the manner in which the business is managed (e.g., see Chapter 2.4). When a mine is determined operational, its method of depreciation and amortization, its depletion rate, and whether costs are expensed or capitalized all affect the amount and timing of profitability. Taxes, as mine development and operations, will be greatly influenced by preplanning.

Many small firms retain consultants to advise, organize, and administer their taxes, and even the largest fully staffed companies frequently call on experts to advise and assist in special tax situations.

8.6.5.6 Marketing, Sales, and Transportation

The purpose of any business is to satisfy the customer since the customer's satisfaction determines whether the enterprise will continue to exist. Marketing skills are necessary for mining companies because competition and customer demands require both an anticipatory and reactive supplier. Therefore, this task encompasses sales, customer research, product planning and diversification, advertising, warehousing, and transportation—all to capture and hold the customer, and thereby justify production. Senior management must be sensitive to these needs and espouse a philosophy tailored to meet the customer's requirements.

Marketing can be a staff or line function, or a combination of the two, and there are a number of successful companies that follow each approach. Traditionally, in the mining industry, this function has not been given the attention and support of top management that it deserves. This attitude is changing as the marketplace becomes a world arena and competition intensifies. Cycles of our business, especially the lengthy down-portion of the cycle, have caused management to attempt to differentiate a portion of the commodities produced in an effort to create a specialty demand that will be countercyclical. Differentiation methods include further processing or modifying the output, or providing cheaper transportation to capture an advantage. The marketing manager is the executive responsible for the marketing task and the individual who should be seeking approaches that will lower costs or make the mine's output more attractive to the customer. It has been noted that mining industry products often are the most important and costly raw material of a manufacturing company, and the customer's chief executive officer may take direct charge of purchasing certain high-cost raw materials (Boyd, 1973). This often urges the top officer of the mining enterprise to deal directly with and indeed build a business and social relationship with the customer. Such practice may be a necessity for the new miner attempting to break into a market. A major effort to gain market share is often pursued at this stage—including granting of discounts on materials sold. In mining, the direct and administrative expenses of moving supplies to, and products from, the mine are one of the major cost items. It is therefore necessary to establish a traffic person or group responsible for finding the lowest-cost method for transporting and receiving incoming supplies and raw materials and shipping the product produced. This requires a professional manager experienced and capable of dealing with transportation companies.

Most commodities and mining products now compete in the world market, and low-cost transportation can be the key to profitability. Experienced assistance is a requisite for this task, especially for low-value, high-bulk minerals and products. Its importance is apparent when one notes that for some materials, freight costs to move the material exceed the value at the mine site. Therefore, swaps of ores, concentrates, and metals are practiced, such that a competitor may deliver for the company in one market while the company may deliver for the competitor in another market—all which can significantly reduce costs. Similar cooperation in using transportation systems jointly, whereby a back haul is identified to eliminate the return of empty vessels can also reduce transportation costs.

8.6.5.7 Human Resources

The term *human resource department* is a relatively new one for the mining industry. Over the years, the activities encompassed herein have often been listed as labor relations, employee relations, and personnel functions. Briefly stated, the human resources department is the department that deals with all the people activities and today this can also include public relations. Traditionally, labor relations has been the primary function of this department, especially where large and powerful unions are in place. This can be a very important and difficult task. In the early years of the union movement, as labor fought for its rights, confrontation was inevitable. This often created an uncooperative atmosphere that adversely affected labor-management relations and therefore hampered productivity and efficiency, which in turn resulted in higher production costs. The union's increased demands not only raised costs but occasionally led to strikes. Unions realized that their most powerful weapon for obtaining the ear of management and achieving their demands was the strike. This is indeed a costly activity, and one that management should strive to avoid. Experience has shown that the best method for preventing such confrontations is to treat the employee so well that the need for a union is eliminated. Achieving or maintaining the goal of a nonunion mine requires a sensitive responsive human resource department and supportive top management.

The human resource management structure for all sizes of companies, but especially the moderate- and large-sized entities, requires close attention and assignment of responsibility to operations. The individual selected to handle mine-site activities is often backed up by a coordinating and monitoring staff position at corporate headquarters. Benefits and work rules may be developed and implemented at the job site, but they should be critiqued and guided by the corporate officer to assure appropriateness and elimination of conflict with established company-wide practices.

8.6.5.8 Safety and Environment

Generally, mining operations of even modest size have assigned a person or persons to be responsible for safety and, with the emphasis now placed on the environment, this area is also receiving constant attention. Both sectors merit professionally trained personnel, with the authority to summarily cease an activity or breach of procedures that may endanger life or violate regulatory guidelines. Governmental regulations and their administration have evolved to the point where it is expensive and embarrassing to the company if citations are issued. The responsible enterprise places protection and safety of its personnel first. This practice not only minimizes suffering to the employee and his family, but it is cost effective. Ideally, personnel responsible for these functions should report to top management, not only to assure that authority is given those involved, but also to show the entire organization that top management is committed to safety and protection of its employees and the environment. Historically, the safety engineer has been located at the mine and has reported to mine personnel, with oversight from a safety director at headquarters. Environmental activities, in many operations, if monitored at all, were handled by an occasional visit from a headquarters person. In recent decades, most mining organizations view these tasks so important that such site personnel report through a matrix structure to safety and environmental directors located in the corporate office.

8.6.6 TOP MANAGEMENT

8.6.6.1 Chairman of the Board

The person carrying this lofty title is viewed as holding the highest authority in any corporate entity. This is because the board of directors is responsible for hiring and retaining top management. The person that greatly influences board action is its chairman. The chairman is charged with handling board meetings and related activities, and also serves as the board's spokesman. He is selected by the board and represents the board to management, the public, and shareholders. A review of practice shows that while this is an important position, it is not as influential, nor as critical to the success of the company, as the chief executive officer (CEO) (Townsend, 1984; Geneen, 1984). However, frequently the chairman also serves as CEO, and this position then carries maximum clout.

8.6.6.2 Chief Executive Officer

This position description has evolved over time, as have the words that describe the top decision maker. In the proprietorship, "owner" is still used, while in a partnership "managing partner" is quite fitting. Chairman, CEO, president, or manager is the title given the key person in corporations, and today it is not uncommon for any of these terms to be used regardless of the legal structure—whether proprietorship, partnership, or corporation.

The CEO, subject to the board of directors, usually has general control, authority, and responsibility for the corporation. Clearly, this is the most important role in the organization, and therefore it is critical that the best possible person be selected for this job. Here the position description considers not only the typical requirements of managing the corporation but also the special present needs, skills, and vision that will insure future success for the enterprise. Business, financial, and operating talents are necessities, but equally important is the ability to select, train, and motivate the management team and work force. This is a changing role, and Table 8.6.2 contains a tabulation of the knowledge and skills expected for the year 2000 compared with those of today. As business demands increase, more attention will be given to strategy formulation, human resource management, and international economics and politics.

8.6.6.3 President

Frequently the president of the corporation is also its CEO, and it is not unusual for the president to be the CEO and chairman. However, in today's complex business environment, and especially in a larger corporation, there is often both a CEO and a president. Typically, the president performs the functions delegated to him by the CEO, and this usually involves the day-to-day operations of the business. In a situation such as this, commonly the chairman carries the title chairman and chief executive officer, and the president has the title of president and chief operating officer (COO).

8.6.6.4 Board of Directors

The function of directors varies from entity to entity, depending on the needs and expectations of the enterprise (Drucker, 1972). Their duties can include:

1. Selection of top officers and decision makers.
2. Approval of long-range direction of the enterprise.
3. Determining company objectives and philosophy.
4. Fixing responsibility.
5. Determining executive compensation.
6. Approval of annual operating plans.
7. Attention to public affairs.

Generally, these and other duties are classified under three broad headings: legal requirements, assisting management, and acting as trustees for the owners.

Frequently, the new enterprise and especially the small company, because of limited resources, can gain from a board of directors that has specialized skills. Ideally, it would have one director with experience in the following:

1. Banking.
2. Engineering and construction.
3. Finance and accounting.
4. Legal requirements.

8.6.6.5 Shareholders

Shareholders own the company and are represented by the board of directors. Investors have bought company shares with the objective of obtaining profits, and in fact, increasing profits and rate of return on their investment. In earlier years, management's attention to shareholder interest tended to ebb and wane, depending on the tenor of the times. In recent years, because of reporting requirements, the risk of takeovers, and the attention given by the press, there has been a shift back to serving the interest of the shareholder.

Identifying methods for fulfilling the needs of the shareholder is a challenge that alert management will pursue. Earnings per share is commonly the measuring stick for assessing performance, and its movement will influence share prices. Without doubt, management's expression of a desire to enhance shareholder value has merit and can aid in raising share prices, but action and results must follow if credence is given to this position. The key factor is earnings growth, but responses to provide growth in stock value can also include share buybacks, paying higher dividends, recommending stock splits, and other creative mechanisms.

8.6.7 IMPLEMENTING

8.6.7.1 Description

It is worth repeating that the basic and key functions of management are planning, organizing, implementing, and controlling. The activity that is described as *implementing* is often termed directing, leading, or decision making. Any or all descriptions could fit, but "implementing" is selected because the dictionary specifically defines this as "carrying out" or "accomplishing," and that is the step shown in Fig. 8.6.13 that is required in this stage of the management continuum. All the key activities of management are critical, but little ore is going to be hoisted and processed if well-thought-out plans are not transmitted into action, or implemented. This facet of the process is often the most difficult, and therefore it has received great study and attention. Detailed analysis of leadership, motivation, training, and incentive programs are all pursued in an effort to attain the desired results that flow from proper implementation of well-crafted plans. Traditionally, the mining company has directed adequate if not excessive attention to the mining method or processing flowsheet, while sometimes giving insufficient thought to the overall motivation of the worker and individual employee.

Most are familiar with Maslow's hierarchy of needs shown in Fig. 8.6.14, but in earlier years, only thoughtful management (or, ironically, organized labor) acted to provide a response to some of the needs of the worker (Silber, 1974). Today, however, practically every organization realizes that most if not all these considerations should receive attention. Proper action by management will not only improve performance but can eliminate the justification for a workers' union. Holding and motivating employees require programs that speak to Maslow's entire hierarchy, from physiological to self-actualization.

8.6.7.2 Leadership

President Dwight Eisenhower reportedly said that "leadership is the art of getting someone else to do something you want done because he wants to do it." Leadership is indeed often identified as the key factor that stimulates implementation of action programs, and as noted, action is the critical element. *Leadership* by definition is the capacity to direct or influence others. In any organization, mine included, the leader must have the ability to convey the objectives of the company and to inspire employees to commit to high performance. Leaders may use many incentives, ranging from instilling fear of job loss to providing an opportunity for advancement or profit sharing.

All these approaches have been and, in fact, are still used in mining, but experience shows that in today's environment, positive, encouraging, participative efforts yield the most favorable results. The leader sets the tone, but all managers in the organization should be involved. If the enthusiasm and commitment of the top person can be expanded to other members of the company, then success is more likely.

8.6.7.3 Management By Objective

Like many other management practices, *management by objective* (MBO) was outlined by Drucker (1973) as a method of joint (manager-subordinate) goal setting, measurement of results, and motivation. MBO programs vary from company to company, but all urge employees to concentrate on specific objectives while pursuing ongoing activities of the organization. MBO involves agreement between the manager and his subordinate about the task to be accomplished, action to be taken, time

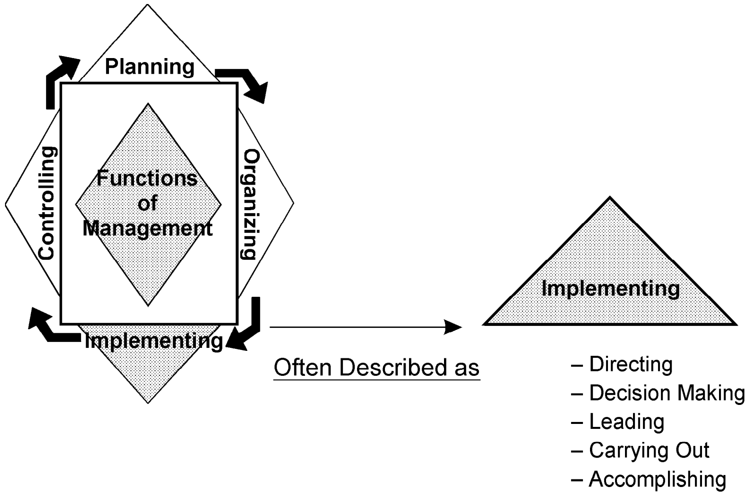

Fig. 8.6.13. Implementing—key function of management.

Fig. 8.6.14. Maslow's hierarchy of needs.

Table 8.6.3. Management By Objectives—Advantages and Problems

Management By Objectives (MBO)	
Advantages	Problems
Emphasizes enterprise's objectives	Developing and maintaining monitoring system
Develops commitment	Reluctance to share authority
Motivates employees	Tendency to focus on mechanics rather than results
Improves quality & output	Time-consuming
Enhances communications	Requires excessive paperwork
Fosters morale	
Aids control	

frame for completion, and method for measuring progress. Such programs have value but require a significant amount of planning, explanation, administration, and commitment. Often this practice, because of its complexity when first implemented, is introduced to one sector or department, such as engineering, and in time is then expanded to other areas such as the mine, mill, and other departments. Typically, the program eventually covers all corporate-wide activities.

MBO is now accepted practice in a large number of North American and foreign operations and, while companies may not have a formalized program, most would recognize both its advantages and associated problems that are shown in Table 8.6.3.

Without doubt, the last requirement in this table, that is, excessive paperwork, is a valid point—MBO does demand an exceptional amount of time, record keeping, and paperwork. Its total benefits, however, by far outweigh the disadvantages of the program. Ideally, it is a system that incorporates and guides individual, department, and division efforts toward the mission of the company, by integrating the objectives and tasks of top, middle, and front-line management. At the minimum, it produces an improvement in the planning and performance of those participating. In an overall sense, MBO can be viewed as an activity that transcends and supports a broader list of the elements of good management, such as planning, organizing, motivating, implementing, controlling, and coordinating.

8.6.7.4 Compensation

Typically, this term, *compensation*, is defined as the benefits provided an employee for services performed. More specifically, it can be described as base pay, variable pay based on individual or group performance, and lastly additional benefits that are tied directly to the job. *Base pay* is influenced by demands of the job and the ability and aptitudes required to perform the tasks assigned. Additionally, competition for employment and location of the work site also affect this amount. Normally, the base pay rate considers all these factors, and job analysis and job evaluation are the formal steps undertaken to numerically quantify the value of the job.

The objectives of variable pay are to increase performance, output, or sales. This form of pay is often termed *bonus* and is based on performance above a fixed level. It is not unusual in underground hard-rock mines for the bonus to range from 10 to 100% or more of base pay, with the higher amounts being awarded to only a limited number or small percentage of the participants.

Additional benefits to that noted are *fringe benefits* which include pensions, insurance, vacations, holiday pay, and other related payments. This form of compensation, similar to the base rate, is often influenced by competition or union practices. Fringe benefit costs vary but can range from 25 to 40% of base pay.

The greatest variance in compensation in the mining industry is in the variable pay or bonus sector of the hourly worker. In some industry branches or types of work (surface, nonmetallics), bonus may not be paid; while in other operations (underground, metallics), the miner may make an excellent bonus. Arguments can be made that all workers should participate, or not participate, in an incentive compensation program, and cases for either situation have been made. Frequently, the location of the work site influences this decision. It is most difficult to refuse to pay a bonus if the local competition has an incentive system. Without doubt, a well-designed bonus program can dramatically improve output and productivity. A difficult problem with such programs is that of establishing a fair assessment of the work required for the pay awarded. This is a challenge, but the incentive value of such a program far outweighs its problems. Studies have shown that the motivational force is greatest if the reward is highly valued, goals can be attained, and one expects the award to be properly allocated. Ideally, the incentive program would be based on the performance of each individual directly involved in a given task and not be dependent on the actions of others. Such a program is often difficult to design, but an effort should be made to minimize the participants grouped in any particular bonus pool. The mining industry is replete with examples of effective, fair, reward systems, but unfortunately, there are many instances of unsatisfactory programs that over or under incent the worker. However, even with such problems, most believe the benefits of such systems are worth pursuing.

The foregoing comments refer primarily to hourly workers, but the same compensation philosophy applies to the staff and executive personnel of the organization. The units of measurement should consider not only specific accomplishments, such as production of the mine or mill, but also overall profitability of the enterprise. The measuring sticks of performance may be different, but the results can be the same—most positive.

Record keeping and paperwork for incentive programs can frequently be time-consuming and complex. Therefore, a constant effort should be made to simplify the program so the participant knows how he is performing and what reward can be expected. Programs of this type are not low cost, but shareholders have consistently supported hourly and executive compensation programs if they are based on performance.

8.6.8 CONTROLLING

8.6.8.1 Controlling

This is often viewed as the last of the four key functions of management, and as reported earlier, this activity follows planning, organizing, and implementing. *Control* is the manner in which an organization influences and monitors activities in an effort to achieve or redirect action to attain planned goals. The control system requires the tasks shown in Fig. 8.6.15.

Performance standards vary from activity to activity and department to department, and are often incorporated in the formal plan or department budget. As an example, if next year's mine plan calls for a production increase from 4000 to 5000 tpd (3600 to 4500 t/day), while at the same time increasing productivity from 8 to 10 tons (7 to 9 t)/employee-shift, these goals should be used as the basis for the standards. If standards are not being achieved as the year progresses, deliberate action must be taken to pull or push the area of shortfall back on schedule. The properly designed plan contains specific measuring sticks or factors that are monitored to determine progress. Daily, weekly, and monthly reports containing the tonnage and grade produced from each stope, section, and mine level, along with the work force involved in such production activities provide the basic performance numbers. These data are recorded, certain statistics computed, and the information reported for comparative purposes, as shown in Table 8.6.4.

Ideally, a simple comparison of actual to expected results will indicate whether corrective action is necessary. If daily mine production is experiencing a shortfall, that is, 3800 tpd (3450 t/day) rather than the budgeted 4500 tpd (4080 t/day), then additional workplaces must be activated. Implementing such changes may appear to be a minor task, but in practice this may be most difficult. Are required resources, extra workplaces, equipment, and manpower available to commence mining in the new production area? Sensitivity to this possible need and adequate preplanning or contingency planning will allow corrective action to be taken in an expeditious manner. This simple example of a control procedure used for monitoring and adjusting to a production shortfall must be developed for the entire operation, and it is performed more effectively if standards are identified in the planning stage.

8.6.8.2 Budgeting

A key element of the control process is the formal budget—either a period or rolling budget. Here, *period budget* describes a process that remains essentially fixed or unchanged for the period under review, possibly a year, while the *rolling budget* is modified on a more frequent basis. Obviously, the rolling forecast represents more current information, and therefore comparisons with actual performance show less variation. Either budget, period or rolling, may utilize a short-term forecast of one year and a mid-term budget of three to five years. If term forecasting is followed, then the one-year plan is often updated at mid-year, and the mid-term (three- to five-year) budget is updated on an annual basis. Rolling forecasts, on the other hand, are normally updated quarterly for one year into the future. Traditionally, most mining companies use term planning and budgeting, but there is merit in the more frequent updating and assessment of forecasts, and recognition of this value is causing increased use of rolling forecasts. The primary disadvantage is that the rolling forecast requires additional analysis, action, and paperwork. However, it should yield a better measuring stick and better performance.

Proper planning requires budgeting of all critical activities including exploration, operations, and sales. These inputs form the foundation of the financial budget, along with project revenues, costs, and profits. Typical performance standards for certain activities of the business are monitored monthly.

8.6.8.3 Establishment of Performance Standards

Performance standards must be defined in a manner that is clear to those involved—conceptually, numerically, and in time. The standard of performance is not articulated only as "raising overall mine production," but more specifically as "raising overall mine production of ore by 25% by the end of next year." Often an even more detailed breakdown of the appropriate factors is

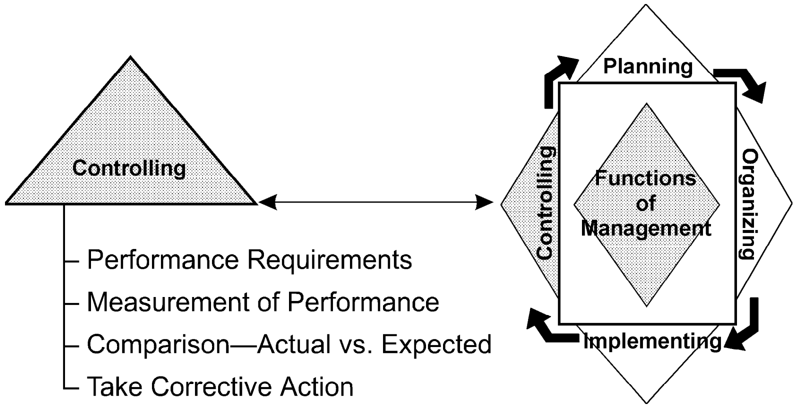

Fig. 8.6.15. Controlling—key function of management.

Table 8.6.4. Control Data—Mill Operations

	Current Mtd	% of Plan	Plan Mtd	Current Ytd	% of Plan	Plan Ytd
Feed dry tons	114,604.000	97.5	117,600.000	713,530.300	94.9	751,800.000
Feed dry tons/day	4,093.000	97.5	4,200.000	3,986.200	94.9	4,200.000
Feed leach ratio	0.010	10.0	0.100	0.010	10.0	0.100
CIP feed ratio	0.215	109.1	0.197	0.198	98.1	0.202
CIP recovery	90.350	99.3	91.000	90.744	99.7	91.000
CIP tails oz/ton	0.019	105.6	0.018	0.019	105.6	0.018
CIP liquor, ppm	0.029	72.5	0.040	0.029	72.5	0.040
Rec. CIP, Au/oz	22,237.650	104.0	21,377.832	128,463.240	91.6	140,216.786
Mill equip. available	95.000	98.5	96.500	95.978	99.5	96.500
Total mill available	94.500	99.5	95.000	94.334	99.3	95.000

established. Mine production may be defined as tons of ore, at or above the required ore cutoff grade delivered to the mill stockpile. The desired production increase of 25% must consider an increase of 25% above a specific level or point in time, say, the average of last year, last quarter, or the last month of last year. These numbers can be quite different depending on whether production is increasing, decreasing or static during the base period.

8.6.8.4 Measurement of Performance

Every key activity in the operation must have *measures of performance* if the activity is to be properly quantified and assessed. Development, construction, mining, and processing are typical functions that are reported in detail on a frequent, often daily, basis. However, other activities such as exploration and research and development are analyzed on a longer-term basis. Generally, the measures for ore processing are relatively standard, focusing on tons of ore milled, percentage recovery, pounds of reagents consumed, and dollars per unit for the cost factors of production. These particular measures are often monitored, not only on a daily basis, but also by shift. Obviously, this reporting requires constant attention and measuring schemes that provided the information desired. However, such data are also required for daily process control, so little additional expense or effort is involved in accumulating this information. These are excellent quantitative measures, and their value will be illustrated in the next section, but control can also be exerted by on-the-spot personal assessment. Personal contact shows an interest in the task, and also allows an immediate assessment so that prompt suggestions or corrective responses can be given if required.

8.6.8.5 Comparison

Actual to expected comparisons serve as the motivator for corrective action, should such action be necessary. Reporting of the comparison between actual and expected results is usually through a variance report. This document frequently contains columnar numbers of actual, planned, and the variance or difference between the two. The report concentrates on the performance results to be controlled including quantity (tons), quality (grade), time (per day or month) and costs (per unit or total). If the variation between actual and expected is significant, an explanation of the cause is justified. Reports, and the appropriate variances, commonly compare the month and quarter with that budgeted, as well as the month and quarter for the previous year. This comparison is helpful in determining differences, trends, and whether immediate action is required, or it indicates whether the situation only requires monitoring for the near term. After studying the variation report, management must determine what action, if any, should be taken.

8.6.8.6 Corrective Action

The primary objective of the control process is to indicate whether corrective action is necessary for a particular program, and if so, whether action must be taken immediately or later. If the degree of variation is just a minor or short-term aberration, no action is required. Experience has shown, however, that if there is a period of significant variation, or a strong negative trend, there can be merit in responding quickly. As an example, if the ore grade is lower than forecast for a given month, then an investigation should be undertaken to determine the cause. One may choose to defer immediate action, assuming that the low grade of one month or one period will be offset by a higher grade the next period. After all, it is the average grade that counts. This assumption may be correct, and the situation may improve. Unfortunately, however, valuable time, production, and profits can be lost if the cause of the low grade is dilution from poor drilling control, caving of waste, or errors of location in the deposit. Prudence would say, identify the cause of the problem as rapidly as possible and formulate a program to get back on budget. Finding the cause is not always easy, and developing a program for correcting the problem may be quite time-consuming and costly. Therefore, it is best to initiate promptly the required changes.

The second phase of corrective action is to determine why the variance developed and what can be done to prevent a recurrence. This review, as well as the search for a solution to get back on schedule, may show that the original plan was faulty. If this is the case, management must decide whether it is better to change the plan or provide additional resources to achieve the original goal. This has been a rather lengthy example of the control cycle, but it illustrates a system that is commonly applied and that most companies believe has merit.

When the company and operations are small and contain few mines and a relatively small number of personnel, the foregoing control system alone may be adequate. But as the enterprise grows, additional mines are developed, and personnel and staff increase, policies and procedures are a necessity. Here policy is defined as a general guideline, allowing one to use discretion in its application. Procedures, on the other hand, tell the user exactly what to do in certain situations. These, plus more sophisticated and more specific control procedures, are utilized and, as might be expected, the complexity of the task may influence the complexity of the system.

8.6.8.7 Communication

Narrowly defined, *communication* is the act of transmitting information, but more broadly described, it is a giving and exchanging of signals or messages. For our purposes, exchanging is emphasized. We not only need to exchange or share information, but we want the message to be understood. The objective is to motivate or influence the attitude of our constituencies, and this can be better accomplished if the intent of the communication is understood. Management deals or makes contact with a variety of individuals and groups, and the methods and tools of communication should be adapted to the particular need or relationship. Management information, as most information, flows downward, upward, and horizontally, and leaders of the organization must develop the channels for establishing this flow. The mix of downward communication is abundant compared with that flowing upward. Normally, the mission, objectives, plans, procedures, practices, and training information are communicated down through the organization. Upward communication, which should be encouraged, is often formalized. Examples include financial and accounting information, complaints and grievances, suggestions, problem, reporting, and exceptions. While upward communication is desired, it often meets with resistance because lower levels of management are reluctant to pass along negative reports, or employees are fearful that their comments will be misinterpreted. Poor morale, efforts to unionize, unsafe working conditions, and discontent can develop in the mine that has faulty communication.

Management must continually foster an environment conducive to good information flow, and should assure lower levels in the organization that their comments will be objectively received and acted on. Horizontal, the third form of communication, is the lateral transmitting of information among peers and departments. This contact is effective in keeping colleagues informed, coordinating task forces, and advising staff departments of the plans and actions of the enterprise. Examples of downward communication in a mining company include approval of the mine production program for the upcoming year, the budget for the period, and more specifically blueprints for developing and producing from a portion of the mine. Some of this information passes through several levels of management in the organization, and when this is the case it is important that the transmitted data and information be clearly presented, and where possible be self-explanatory. This can best be assured if those involved in the proposed program can make inputs into the plan when it is being formulated. Both special discussions held with the user to aid in understanding and personal contact associated with a feedback system (suggestion box, etc.) should yield better results. Personal contact with the worker is a job responsibility and a necessity for mining supervisors, superintendents, and managers. The frequency of contact with the worker varies inversely with the level of the job, but there is value in all, from the shift boss to the CEO, visiting the operation on a regular basis. This attitude and action has coined a new management term: “management by wandering around.” Under this concept, management at all levels talks directly with employees to determine first hand what is going on from the workers’ perspective, and it gives an opportunity for management to explain the organization’s plans and intent. The objective of this practice is to develop a more committed, motivated employee.

Much of the foregoing concentrates on management’s relationship with the employee, and this is appropriate, especially if the company wants to build loyalty and improve productivity. Attention has been directed to the worker because case studies of many companies show that this approach can minimize the involvement of unions, raise morale, and yield outstanding results.

The effect of communication in the directing or implementing phase of management has been reviewed, and this area can be dramatically influenced by communication. However, planning, organizing, and controlling, as well as all management activities, are affected by communications. Strategic plans, budgets, and all reports convey information and are communication devices. These approaches are often supplemented by a formal management information system.

8.6.8.8 Management Information System

The need increases for prompt, quality information as business becomes more complex and competitive. For many years, the *management information system* (MIS) effort focused on dispersing accounting and financial information to senior management. Over time, the system expanded, and today most organizations’ management information is collected and dispersed to different levels of management. The variety and type of data as well as the recipient and user have changed dramatically. Practically all departments can be served by this group. Information dispersed might be data on absenteeism or employee turnover for the human resources department, detailed production information on stopes, levels, and shifts for the mining department, and feet (meters) of hole drilled and costs per foot (meter) for the exploration group. The primary purpose of this information is to allow control and good communications but also to provide data for decision making.

Collection and dispersion of these data can involve the use of existing reports, summarizing of existing information, or generation of new information. Initially, in the mining business, the data were collected by hand and either rearranged or used directly as base data, and then transmitted to the manager. Today computers can store, rearrange, compute additional information, and automatically provide the findings directly to the user. Computer systems allow "real time" capability which enables the user to make requests and then immediately receive a response to his/her queries. As an example, if the quality of coal coming from a given mine is not as expected, the user can ask for a readout of the ash, Btu, and quantity coming from each section. These data can give an idea of the problem area and suggest a correction.

Designing the MIS requires a determination of the data to be used, how these will be collected and stored, the method for converting raw data into useful information, and the manner in which it will be transmitted to the user. Objectives of the system include gathering and communicating useful information, but equally important is accomplishing this in a timely manner. A properly designed system can be of immeasurable value to all levels in the organization.

The MIS acts as a service department with the task of providing information of value. The information needs of the complex mining enterprise are many, and when we think of a MIS product, a detailed computer printout may come to mind. In actual practice, the product may, and probably should be, a sheet of readily readable technical or economic information, or a simple collection of articles from the daily business press that affects the company. The purpose of this output, and indeed, MIS, is to provide information that will influence management decisions and performance of the enterprise.

8.6.9 CONSULTANTS AND ADVISORS

Samuel Johnson said, "The next best thing to knowing something is knowing where to find it." Clearly, quality advice is worth seeking, and in many instances, it is a legal necessity. Specialists can include the outside auditor who checks the accounting records, consultant who verifies ore reserves, and investment bankers who provide due diligence for the new stock issue. While involvement of some of these may be mandatory, use of others is discretionary. Discretion is the byword. Best and most effective contributions are forthcoming only from the outside professional that understands the needs, philosophy, objectives, and integrity of the organization's management.

External auditors are legally required to ensure that the bookkeeping records are correct and that financial statements present a true and fair picture of the business. Comfort with company information evolves over time as the outside auditor considers data and reports prepared by internal accountants, and as the outside expert performs spot checks to assure accuracy. The auditor not only urges full disclosure but where necessary suggests policy changes. It is the responsibility of auditors to pass on their findings and recommendations to top management, board committees, and the board of directors. Additional benefits of experts include well-presented financial and accounting information that reduces criticism and shareholder lawsuits—all being undertaken to develop and protect the investor. Such specialists and consultants are plentiful and can be used frequently, and in fact public accounting services often make up a significant portion of outside charges. Financial exposure and stock exchange requirements prompt the use of the public accounting firm.

Outside legal advisors also provide critical services, especially when forming the corporation, commencing operations, obtaining environmental permits or resolving legal disputes. In-house attorneys may handle these activities, but it is often advantageous to retain experts in each specific area. This practice provides knowledgeable advice that can be called on only when required.

Outside technical advisors such as geologists, engineers, and consulting firms have their place and can pay their way, even though this may involve duplication of in-house skills. Normally, the independent professional geologist or engineer is viewed by top management and outside investors as being objective and having broader, more varied experience. Examinations and reports of these experts are usually required to satisfy financing or lending institutions, and if such advisors are to be involved, it is worthwhile having them on board early enough to influence the methods utilized. Specialists in the environmental, governmental, and political arenas are justified in the same manner.

Today's complex and confusing rules, regulations, and laws of practically every facet of business require special expertise, and this has fostered an increasing use of advisors and consultants. In the past, it was thought economical to call on these professional skills only when absolutely required, but current practice is to retain such talents so that they can be utilized on a regular basis. At one time, the use of consultants was eschewed, especially in the technical and operating area. Management was reluctant to admit that it did not have the skills to handle many of the mining, processing, and operating tasks encountered in running a mine. Thoughtful analysis should allow one to conclude that in special cases, these activities, similar to certain accounting and legal sectors, can justify outside experts. Traditionally, staff personnel claimed that taking a consultant into confidence allowed the expert to obtain company secrets. Another criticism is that the expert only obtains opinions and plans of the company, dresses these up, and resubmits them to top management. To some extent, this is a valid criticism; however, the wise manager will make sure that much more is obtained from than given to any advisor.

Favorable results are most likely if management selects a highly qualified consultant, clearly outlines the assignment, regularly monitors progress, and gives this outsider complete support. Establishing these guidelines is important, but the most critical act is the initial decision to retain an advisor or consultant. Recognizing the need and value of an outside advisor requires sensitivity and confidence, and can often be the factor that assures success.

8.6.10 MANAGEMENT PHILOSOPHY

8.6.10.1 Characteristics

Much has been written about the attributes of the successful enterprise, and as might be expected, surveys and studies frequently find a host of similar characteristics. Among these are

1. Action oriented: All levels of supervision and management are inculcated with a desire to act, change things, initiate new programs, and solve problems.

2. People dedicated: Attention is directed toward all levels of employees, regardless of the job. In order to maximize productivity, the entire work force must understand the required tasks and be dedicated to improving performance.

3. Simple in form: All activities of the company are kept as simple as possible. Headquarters staff should be lean and policies and procedures minimal. Every function needs to be scrutinized to determine whether it can be eliminated or simplified.

4. Committed to improvements and innovation: Competition is becoming more severe and global, and improvement in operations must be initiated if the business is to remain competitive and survive.

5. In contact with customer: Unfortunately, most mining companies produce a commodity product with little opportunity to differentiate. Therefore, much creativity is required to main-

tain the competitive edge. Contact with the customer offers the opportunity to hear his likes and dislikes, so that a purer or improved commodity can be produced. Typically, one obtains new business by lowering prices, but providing an available inventory, giving excellent shipping options, or extended payment terms may also be of value in retaining or acquiring customers.

6. Emphasizing the need for profitability: Accountability for profit and loss should be pushed down to the manager who has hands-on control over marketing and production. Additionally, there is merit in having a portion of the compensation of every employee tied to overall performance and profitability of the company.

7. Flexible: There is nothing permanent except change, and therefore the successful organization attempts to anticipate change and respond appropriately. Metal prices, politics, labor policies, and operating conditions change, and alert management must be willing to minimize the disadvantages and capitalize on the opportunities presented.

The foregoing attributes of the successful enterprise are most important, and few would argue that they are not worthy guidelines. Interestingly, few mining companies follow all of the suggested practices. No doubt, a portion of the inaction is caused by uncertainty of how the union will react to the changes. Also there is concern whether any compensation program based on profitability will work well when prices are low and profits unsatisfactory. Additionally, past practices, especially those involving relationships with customers, have a pattern of receiving little attention. Typically the manager has concentrated on production and allowed the commodity to sell itself. This philosophy is changing, and it is now apparent that the mining company must be more responsive to the customer if it is to retain its sales base. Last of the attributes listed previously and foremost in drawing criticism to the mining industry over the years has been its lack of flexibility. No doubt, this as well as the other reasons for not following the suggested principles have a basis, but the benefits of change are so overwhelming that any risk is miniscule compared to what may be gained by remaining flexible. The survivors of the last decade have not only exhibited flexibility but also creativity, and if these characteristics are retained mining will indeed remain a viable industry.

Chapter 8.7
MINE CLOSURE, SEALING, AND ABANDONMENT

THOMAS A. GRAY AND RICHARD E. GRAY

8.7.1 INTRODUCTION

All mines will eventually close. When a mine permanently stops operating due to economic conditions, the depletion of reserves, or any other reason, the following activities generally occur:

1. Underground mine openings are sealed.
2. Surface facilities are removed.
3. Surface mines and the surface areas of underground mines are reclaimed.

Only after these activities are completed can the mining company abandon the site. However, even after the mine is abandoned, specific postmining liabilities rest with the mining company. This chapter presents aspects of the closure, sealing, and abandonment activities.

8.7.1.1 Definitions

To enable the reader to interpret this chapter, the following definitions are provided.

Closure: The act of closing or the condition of being closed, such as the closing of a mine. There are different degrees of closure: permanent, temporary, and semi-permanent. In this chapter, it is considered that the closing of a mine is permanent. Mines that are not open for production but that could be reopened should be considered as temporarily or semi-permanently closed.

Sealing: The securing of mine entries, drifts, adits, slopes, shafts, and boreholes with suitable materials to protect against fires, gas, and water emissions and for the safety of the public (Foreman, 1971; Thrush, 1968).

Abandonment: The act of abandoning and relinquishment of a mining claim or intention to mine; a voluntary surrender of the claim or mine to the next party. This differs from forfeiture that can be considered the involuntary surrender of a mine by neglect (Thrush, 1968).

8.7.1.2 Regulatory Requirements

In the United States, federal, state, and local governments have issued regulations that must be followed during the closure of a mine. Because regulations may change, a summary of only the existing federal regulations is presented in this chapter. Federal agencies that regulate mine closure activities are the Mine Safety and Health Administration (MSHA), Environmental Protection Agency (EPA), Office of Surface Mining Reclamation and Enforcement (OSMRE), US Geological Survey (USGS), Bureau of Land Management (BLM), US Forest Service (USFS), National Park Service (NPS), and Bureau of Indian Affairs (BIA) (Anon., 1980a). MSHA regulations are applicable for health and safety standards and apply to all coal and noncoal mines. EPA's water discharge effluent limitations apply also to all coal and noncoal mines. OSMRE reclamation regulations apply only to nonanthracite coal mines. Pennsylvania anthracite mining regulations apply to all anthracite coal mining by OSMRE reference. Since the other agencies (USGS, BLM, USFS, NPS, and BIA) have jurisdiction only in federal lands, their regulations are not presented. If applicable to a specific mine, these agencies should be contacted directly.

A brief synopsis of the applicable federal regulations appears in Tables 8.7.1, 8.7.2, and 8.7.3.

Individual states have different rules and regulations that must be followed during the closure of mines. All states must follow the federal OSMRE regulations as they apply to coal mines. OSMRE regulations allow states to request primacy in self-regulating these rules and regulations. Most states with coal mining activities have passed their own regulations that closely resemble the federal OSMRE regulations, thus regulating their coal mining industry. Individual state health and safety rules may differ from the MSHA rules and must be considered in addition to the MSHA regulations when closing a mine.

Local government may enact rules covering topics such as (1) zoning (which could affect the selected postmining land uses) and (2) land value assessment (for taxation). It is suggested that engineers involved with a mine closure contact their local and state regulatory agencies to determine if any local regulations apply.

8.7.2 MINE CLOSURE PRACTICES

8.7.2.1 Surface Mines

The closure of all new surface mines must be planned prior to the beginning of operation. A reclamation plan must be included with all new permit submittals. This planning is also important in evaluating the economic justification for the mining operation. A substantial amount of money can be saved if the most appropriate reclamation or closure procedures are thoroughly considered and carried out as planned.

Unless an alternative plan is approved at the closure of a surface mine, the mine site must be regraded to approximately the original contours. Backfilling should remain as close as possible to the active mining area, not only to reduce haulage distances but also to save on reclamation costs in the event that the surface mine must be closed and regraded due to economic conditions prior to its planned closure.

Reclamation planning and closure methods vary among types of surface mines. Some different methods are discussed briefly here.

Open Pit Mines: *Open pit mining* is defined as "the mining of ores (primarily referring to metalliferous ores) by surface mining methods where waste or overburden is first removed, and the mineral is broken and loaded" (Thrush, 1968).

At the present time, the closure of open pit mines is controversial. Currently, there are no federal regulations covering the closure of open pit mines. The operators must contact local and state agencies to determine what requirements must be followed at those governmental levels. According to Dohm (Crawford and Hustrulid, 1979), the increased environmental awareness (of open pit mining) definitely indicates that proper production planning and scheduling can minimize the costs associated with mine reclamation. The items most effectively handled by efficient planning are (1) returning ground contours to approximate premine conditions by blending in the new grades with the surrounding topography, (2) minimizing surface depressions to the greatest extent possible, and (3) revegetating all disturbed areas.

Table 8.7.1. Federal Regulations Applicable to Mine Closure, Sealing, and Abandonment, Mine Safety and Health Administration, *Code of Federal Regulations,* Chap. 30

Regulation	Paragraph	Description
Part 57—Metal and Non-Metal Underground Mines—Safety and Health Standards	57.1000	When any mine is closed, the person in charge shall notify the nearest subdistrict office and indicate whether the closure is temporary or permanent.
Part 75—Underground Coal Mines. Mandatory Safety Standards	75.1204	Within 60 days of (a mine's) permanent closure or abandonment, mine operators must file a copy of the mine map, revised and supplemented to the date of closure, with the Secretary of the Interior. The map must be certified by a registered surveyor or registered engineer.
	75.1204-1	The notice of mine closure and copies of the mine map must be filed with the Coal Mine Safety District office.
	75.1711	Mine openings declared inactive or permanently closed or abandoned for more than 90 days shall be sealed.
	75.1711-1	Shaft openings to be sealed shall be capped or filled. Filling shall be for the entire length of the shaft with the first (lower) 50 ft (15 m) being filled with incombustible material. Caps shall consist of 6-in. (152-mm) thick concrete or equivalent and equipped with a vent pipe (2 in. or 50 mm in diameter, and 15 ft or 5 m above the surface).
	75.1711-2	Slope or drift openings shall be sealed with solid, incombustible material for a distance of at least 25 ft (8 m) into the opening.
Part 77—Surface Coal Mines and Surface Work Areas of Underground Coal Mines—Mandatory Safety Standards	77.215.4	MSHA's District Manager shall be notified in writing when a refuse pile is to be abandoned. If a hazard is determined to be present, a plan for abandonment shall be submitted by the operator and approved by the District Manager. The plan shall include a schedule for its implementation and describe provisions to prevent burning and future impoundment of water and provide for major slope stability.
	77.216-5	Prior to a mine's abandonment, an abandonment plan for water, sediment, or slurry impounding structures shall be submitted by the operator and owner and approved by MSHA's District Manager. The plan shall include a schedule, a provision to preclude future impounding, and provide for slope stability.

Table 8.7.2. Federal Regulations Applicable to Mine Closure, Sealing, and Abandonment, Office of Surface Mining Reclamation and Enforcement, *Code of Federal Regulations,* Chap. 30

Regulation	Paragraph	Description
Part 715—General Performance Standards	715.13	All disturbed areas shall be restored in a timely manner to conditions that are capable of supporting the uses the lands were capable of before mining or to higher or better uses.
	715.14	Postmining graded slopes must approximate the premining natural slopes (approximate original contours). Certain exceptions, such as for mountaintop removal or leaving permanent impoundments, may be approved.
	715.15	The permittee must plan and conduct reclamation operations to minimize disturbance to the prevailing hydrologic balance in order to prevent long-term adverse changes in the hydrologic balance. Changes in water quality and quantity, both surface and groundwater, shall not affect the postmining land use. If pollution can be controlled only by treatment, the permittee shall operate and maintain the necessary water treatment facilities for as long as treatment is required. Groundwater recharge capacity shall be restored to approximate premining recharge capacity. The permittee shall be responsible for monitoring to ensure conformance.
	715.18	All dams shall be removed and the disturbed area regraded, revegetated, and stabilized unless the regulatory authority approves retention of such dams as part of the postmining land use plan.
	715.20	The permittee shall establish on all land that has been disturbed a diverse, effective, and permanent vegetative cover of species native to the area or species that will support the postmining land use.
Part 717—Underground Mining—General Performance Standards	717.14	Upon completion of the underground mining, road cuts and mine entry area cuts shall be regraded to approximate original contours.
	717.17	The permittee must plan and conduct reclamation operations to minimize disturbance to the prevailing hydrologic balance in order to prevent long-term adverse changes in the hydrologic balance. Changes in

Table 8.7.2.—cont.

Regulation	Paragraph	Description
		water quality and quantity, both surface and groundwater, shall not affect the postmining land use. If pollution can be controlled only by treatment, the permittee shall operate and maintain the necessary water treatment facilities for as long as treatment is required. Groundwater recharge capacity shall be restored to approximate premining recharge capacity. The permittee shall be responsible for monitoring to ensure conformance.
	717.18	All dams shall be removed and the disturbed area regraded, revegetated, and stabilized unless the regulatory authority approves retention of such dams as part of the postmining land use plan.
	717.20	The permittee shall establish on all land that has been disturbed by mining operations a diverse, effective, and permanent vegetative cover capable of self-regeneration and plant succession and adequate to control soil erosion. Introduced species may be substituted for native species if approved by the regulatory authority.
Part 780—Surface Mining Permit Applications—Minimum Requirement for Reclamation and Operation Plan	780.18	Each permit application shall contain a plan for reclamation of the lands within the permit area. This plan is to be followed during the closure of a mine.
	780.20	Each permit application shall include a plan that includes steps to be taken during reclamation to minimize disturbance to the hydrologic balance within the permit area and adjacent areas, to prevent material damage outside the permit area, to meet federal and state water quality laws and regulations, and to protect the rights of present water users.
	780.23	Included in the reclamation plan shall be a description of the proposed postmining land use, including a discussion of its utility and capacity to support alternative uses and the relationship of the proposed use to existing land use policies and plans.
	780.25	Each reclamation plan shall include timetables and plans to remove ponds, impoundments, banks, dams, and embankments, if appropriate.
Part 784—Underground Mining Permit Applications—Minimum Requirements for Reclamation and Operation Plan	784.13	Each permit application shall contain a plan for reclamation of the lands within the permit area. This plan is to be followed during the closure of a mine.
	784.14	Each permit application shall include a plan that includes steps to be taken during reclamation to minimize disturbance to the hydrologic balance within the permit area and adjacent areas, to prevent material damage outside the permit area, to meet federal and state water quality laws and regulations, and to protect the rights of present water users.
	784.15	Included in the reclamation plan shall be a description of the proposed postmining land use, including a discussion of its utility and capacity to support alternative uses and the relationship of the proposed use to existing land use policies and plans.
	784.16	Each reclamation plan shall include timetables and plans to remove ponds, impoundments, banks, dams, and embankments, if appropriate.
Part 800—Bond and Insurance Requirements—For Surface Coal Mining and Reclamation Operations Under Regulatory Programs	800.13	Performance bond liability shall be for the duration of the mining and reclamation operation and until successful revegetation or until achievement of reclamation.
	800.14	The amount of bond shall be sufficient to assure completion of the reclamation plan by the regulatory authority in the event of forfeiture.
	800.17	The period of bond liability shall last until all reclamation, restoration, and abatement work has been completed.
	800.40	The applicant may file an application for release of all or part of a performance bond after the applicant has completed any part of the reclamation activities. A newspaper advertisement stating that a bond release has been requested shall be placed by the operator. The advertisement shall run once a week for four weeks in a local newspaper of general circulation.
		The regulatory authority may release all or part of a bond when it is satisfied that all reclamation or a phase of reclamation is accomplished.
Part 816—Surface Mining Activities—Permanent Program Performance Standards	816.11	Signs and markers identifying the mine and permit numbers shall be retained and maintained until after the release of all bonds for the permit area.
	816.13	When no longer needed for monitoring or other purposes, each exploration hole, other drilled holes, and other exposed underground openings shall be capped, sealed, backfilled, or otherwise properly managed.

Table 8.7.2.—cont.

Regulation	Paragraph	Description
	816.49	A permanent impoundment of water may be created if it is designed for permanent use, will not result in the diminution of quality and quantity of water utilized by adjacent landowners, and will be suitable for approved postmining land use.
	816.132	Persons who cease surface mining activities shall close, backfill, or otherwise permanently reclaim all affected areas. All underground openings, equipment, structures, or other facilities not required for monitoring, unless approved as suitable for postmining land use, shall be removed and the affected area shall be reclaimed.
	816.133	All disturbed areas shall be restored in a timely manner to conditions capable of supporting the uses they were capable of supporting before mining or to higher or better uses.
	816.150	A road not to be retained for use under an approved postmining land use shall be reclaimed immediately after its use for mining and reclamation operations ceases.
Part 817—Underground Mining Activities—Permanent Program Performance Standards	817.15	When no longer needed for monitoring or other purposes, each shaft, drift, adit, tunnel, exploration hole, entry way, or other opening shall be capped, sealed, backfilled, or otherwise properly managed.
	817.48	A permanent impoundment of water may be created if it is designed for permanent use, will not result in the diminution of quality and quantity of water utilized by adjacent landowners, and will be suitable for approved postmining land use.
	817.56	Before abandoning a permit area or seeking bond release, the operator shall ensure that all temporary erosion and sedimentation control structures are removed and reclaimed and that all permanent sedimentation ponds, diversions, impoundments, and treatment facilities meet the requirements of the *Code of Federal Regulations,* Chap. 30, Pt. 817.
	817.132	Persons who cease underground mining activities shall close, backfill, or otherwise permanently reclaim all affected areas. All underground openings, equipment, structures or, other facilities not required for monitoring, unless approved as suitable for postmining land use, shall be removed and the affected area shall be reclaimed.
	817.133	All disturbed areas shall be restored in a timely manner to conditions capable of supporting the uses they were capable of supporting before mining or to higher or better uses.
	817.150	A road not to be retained for use under an approved postmining land use shall be reclaimed immediately after its use for mining and reclamation operations ceases.

Table 8.7.3. Federal Regulations Applicable to Mine Closure, Sealing, and Abandonment, Environmental Protection Agency, *Code of Federal Regulations,* Chap. 40

Regulation	Paragraph	Description
Part 401 —General Provisions	401.12	Requires achievement of effluent limitation for point sources. It is generally the view of the EPA that the effluent limitations apply until the point source is eliminated.
Part 434—Coal Mine Point Source Category	434	Provides effluent limitations for point discharges of various categories of coal mines, coal preparation plants, and associated areas.
Part 430—Mineral Mining and Processing Point Source Category	436	Provides effluent limitation for point discharges of various categories of mineral mining.

Open pit mines often may be temporarily closed since the selling price of the commodity being produced can fluctuate greatly. Past mining methods called for mine overburden to be totally removed and placed in a designed disposal site. Backfilling the pit with the previously disposed waste rock is not normally done as it would be economically disastrous to the mining company. Backfilling of the extreme low areas to eliminate any ponded water may, however, be appropriate. Grading and vegetating pit slopes is also important for ground stabilization reasons.

Quarries: *Quarries* are defined as "open or surface workings, usually for the extraction of building stone, slate, limestone, etc." (Thrush, 1968). Quarries normally sell most of the material mined and therefore leave little waste material for filling in the excavation.

The closure practices employed to achieve effective abandonment include regrading to eliminate hazardous highwalls and revegetation. Steep highwalls can sometimes be removed by "shooting down the highwall." This method (Fig. 8.7.1) can inexpensively reduce the grade and effectively remove a highwall. The regraded area could then be covered with soil and revegetated.

Novel ideas on reclamation are being developed by the the quarry industry. Because many sites are located near urban

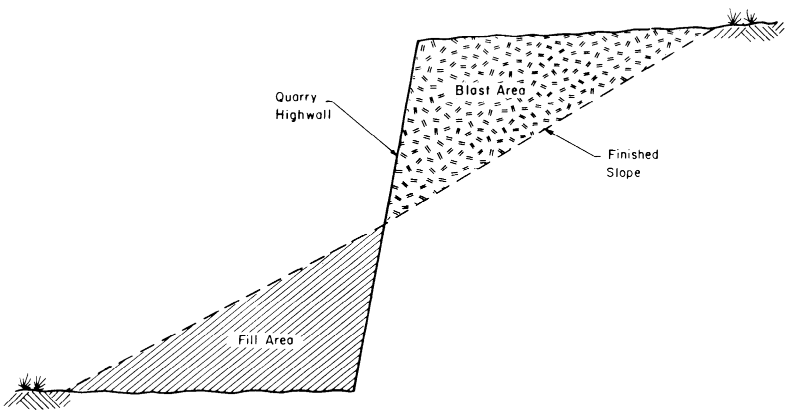

Fig. 8.7.1. Typical section—shooting down the highwall.

areas, landscape architects have become involved with mine planning to integrate the quarry site with existing communities (Culbertson et al., 1988). Three-dimensional simulation by computers is becoming increasingly popular. The view of postmining land is important in areas of high public visibility. In areas close to large population centers, some quarry sites have planned the reclamation to include a lake surrounded by a housing project in the lower parts of the quarry, thus increasing the postmining land value.

Surface Coal Mines: A reclamation plan must be approved prior to the opening of a *surface coal mine.* This plan must be followed when the mine is closed. It is standard practice to submit a reclamation schedule to regulatory agencies within a few months after a decision is made to close a mine permanently. Normally, the backfilling of cuts and the restoration of the surface is required.

Placer Mines: The term *placer* is applied to deposits of sand, gravel, and other detrital or residual material containing a valuable mineral that accumulated through weathering and mechanical concentrating processes (Wells, 1969).

Currently, there are no federal regulations that apply to the closure of placer mines. It is recommended that regulatory agencies be contacted to determine if the project site is subject to any new regulations. Most areas in the United States that are subject to placer mining are on federal or state lands. Reclamation and closure practices for each placer mine site should be discussed and agreed upon prior to leasing the property.

8.7.2.2 Mine Facility Removal

In accordance with mine reclamation regulations, all associated facilities must be removed unless they serve a useful purpose in the postmining land use. These facilities include buildings, material handling systems (conveyors, rail lines, transfer stations, storage bins, docks, etc.), electrical lines, transformers, substations, pipelines, roadways, drainage ponds, and drainage channels. Waste disposal areas must be reclaimed, and any hazardous material must be removed from the site and disposed of at a hazardous waste disposal facility. The following sections discuss certain aspects of removing these facilities.

Demolition and Salvage of Structures: A complete inventory of all available equipment, parts, and supplies should be made as soon as a decision to close a mine is made. From this list, the dispensing of each reusable or salable item can be chosen. Some items could be sent to another mine that is owned by the company. Attempts to sell the remaining items of value should be made. Items can be sold:

1. To a salvage company (usually at “scrap prices”).
2. Individually, grouped by bid, or grouped by negotiated price.
3. By public or private auction (auctioneer fees normally range from 5 to 10% of the sale)

For removal of buildings and other structures, a demolition and disposal contractor should be hired. A specialist in this type of work is likely to be less expensive than a mining company performing the removal itself. If enough materials such as copper and steel are salvageable, the contractor may do the project at no cost or even pay the mining company for the salvage rights. The mining company should develop a demolition specification to be agreed to by the contractor. A sample demolition specification, as used by the West Virginia Dept. of Energy on an abandoned mine site demolition project, follows (Anon., 1988a).

“DEMOLITION: Demolition of existing structures shall be performed using standard construction equipment wherever practical. Demolition operations shall be performed with the utmost care not to endanger life or property. The contractor shall be responsible for analyzing all of the structures to be razed so that demolition operations are performed in a manner which results in a total and safe collapse of the structures while maintaining the safety of construction laborers, equipment operators, and vehicular traffic along all public roads.

DEBRIS REMOVAL: All concrete, concrete block and timber, remnants, metal scrap, equipment, and other debris shall be removed from the project area. All foundations are to be completely removed, and the areas regraded to the final ground surfaces shown on the plans, or to the approximate original ground surface.

DEBRIS DISPOSAL: All concrete, concrete block, timber, metal scrap, structural remnants, equipment, garbage and demolition debris shall become the property of the contractor and shall be salvaged or buried within proposed embankment. Onsite burial of noncombustible materials in an approved area is permissible provided a minimum of 2 ft (0.6 m) of natural soil fill is placed over the buried material and provided that the concentration of debris to be buried in any one area is not excessive.

REGRADING: All areas where structures, foundations, equipment, etc., have been demolished and removed shall be regraded. The approximate limits of regrading are shown on the drawings. The slopes shall be regraded to form stable, uniform slopes which conform to the natural slopes in the area and promote proper drainage of surface runoff into natural drainage ways. Upon completion of regrading, the slopes shall be revegetated.”

Waste Disposal Areas: Mine wastes that are placed in dry disposal areas can be closed after the site is graded for proper

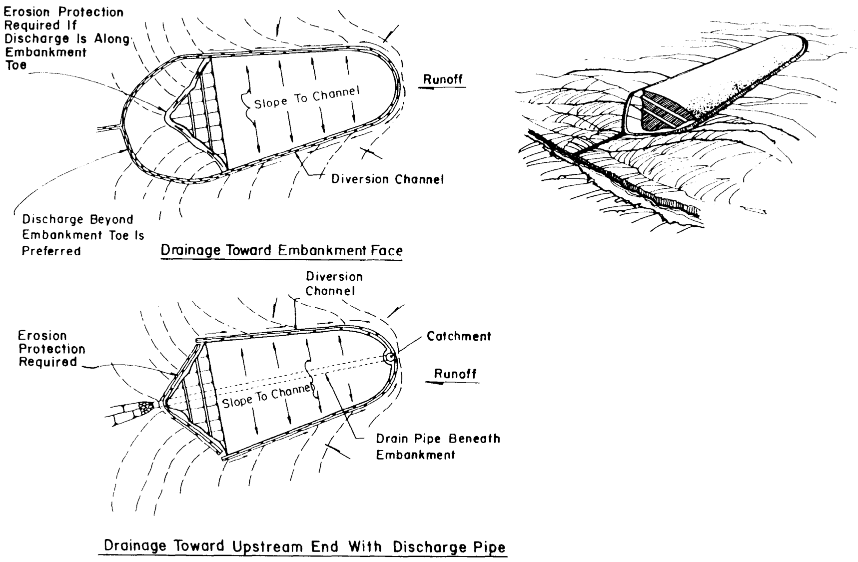

Fig. 8.7.2. Typical final drainage pattern, valley fill disposal site (Anon., 1973).

drainage, covered with soil, and revegetated. Because most waste sites consist of elevated piles, the piles must be left with stable slopes to reduce the potential for sliding. The final grading should be done in a manner that reduces water infiltration into the disposal site so that the potential for toxic leachate generation and surface erosion can be minimized. Fig. 8.7.2 shows a typical layout and grading pattern for a valley fill disposal site. The following two paragraphs are excerpted from the US Department of the Interior's *Engineering and Design Manual for Coal Refuse Disposal Facilities* (Anon., 1975a):

"The final grading of the coarse (dry) refuse would take on a convex or ridgelike configuration with some precipitation running over the first terrace of the refuse slope. However, the bulk of the surface runoff from the crest would flow into diversion ditches around the fill."

"In the instance of an elevated ridge or valley-dump type of facility, the final grading and drainage plan of the crest will have a concave configuration with subsurface drain inlets placed at low point(s). All surface runoff will thus be directed away from the edge of the slope face."

Toxic leachate from waste piles must be eliminated prior to final abandonment of a site. If this is not possible, then a means to treat the water discharge to meet EPA standards must be maintained until the standards can be met and the discharge point eliminated from the EPA's list of point discharges.

Slurry waste disposal impoundments normally are closed by breaching the embankment, letting the material solidify through drying, regrading the surface to drain, covering with soil, and revegetating. Some slurry disposal areas have recently been successfully reclaimed as wetlands (Nawrot et al., 1987). This approach provides new habitat for wildlife and, if appropriate, can reduce closure costs.

Utilities and Roadways: Unless included for a postmining use or for postmining maintenance, electrical facilities such as power lines, substations, and pipelines should be removed during the closure of a mine. Electrical power lines and substations can sometimes be sold to local utilities or other local industries but must remain in service until electrical power is no longer needed at the mine site.

Aboveground pipelines should be dismantled, removed from the site, or buried on site. Underground pipelines can sometimes be capped and abandoned in place unless local regulations specifically require their removal.

Roadways are to be removed and revegetated when they are no longer needed. This can be accomplished by scarifying the surface and regrading to blend the mine roadway into the surrounding landscape. Topsoil may be required to cover the road base material. However, most regulatory agencies will allow roadways to remain if the landowner requests their use for access and to promote the postmining utilization of the property. Roadways can also be used for access to the property during postmining maintenance activities until the reclamation bond is released.

Drainage Facilities: Sedimentation control ponds and ditches should remain active and be maintained for a few years after the mine is closed until the revegetation of the site can successfully control erosion. After their use for erosion and sedimentation control, ponds and ditches can be removed by regrading them to contours that match the surrounding landscape.

Removal of Hazardous Materials: During the operation and particularly during the closure of a mine, the mining company's liabilities with regard to hazardous substances under the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Compensation and Liability Act (Superfund) must be considered (see Chapter 3.4). Although there are a few exceptions, most mining wastes are not currently considered hazardous by the EPA.

Haller (1987) reports that, "the law (Superfund) provides that the owners and operators of mining sites, together with those who transport hazardous substances to such sites, can be held jointly and severally liable for the cost of cleaning up the site." If a site becomes listed by the EPA as a Superfund site, a cleanup agreement will have to be negotiated between the mining company (or whoever is deemed liable) and EPA.

To close and abandon a mine site that is not listed on the Superfund list is more common. During the closure operation, the mine operator must investigate the site to determine whether there are any hazardous substances on site. Engineers experienced with performing environmental assessments of properties should be retained to make this determination. Hazardous substances most commonly found include asbestos used as building and pipe insulation, PCBs used in electrical devices, and solvents used as cleaners. Areas that had been used as trash disposal areas during the mine operation should have the soil sampled to verify if any hazardous materials leached into the ground.

If contamination is found, a study should be performed by a qualified engineer to verify the degree of contamination. Any potentially contaminated soils must be adequately sampled to determine whether any action is required or if the soils can be left in place. If the levels of contamination are relatively high, then removal and offsite disposal or onsite treatment of the soils may be required. If hazardous substances are required to be transported offsite, a licensed hazardous waste contractor should be hired to remove the material from the site and transport it to a licensed hazardous waste disposal site. The owner should verify that the contractor and proposed disposal area are currently meeting all regulatory requirements, because if the wastes are spilled enroute to the disposal site or disposed of improperly, the owner may still be held responsible.

8.7.2.3 Underground Mines

Equipment Salvage: Prior to the closure of a mine, the operator should decide whether some equipment (parts, supplies, etc.) could be economically removed from the mine and sold or used elsewhere by the operator. An inventory of available equipment and materials should be made. To assess whether a salvage operation is economical or not, a cost estimate for the removal of each piece of equipment should be made and compared with its resale value. According to Brezovec and Heges (1986), difficult-to-move equipment, such as a coal mine longwall unit, is normally abandoned at a lower cost than the cost to recover the machinery unless, of course, a sure buyer has been found. Mobile equipment such as trucks and continuous miners can generally be sold for more than the cost of removing them. Underground cables that contain a large quantity of copper often are salvagable.

As stated in the previous section, some equipment that may contain hazardous materials must be either decontaminated or removed and disposed of at a hazardous waste disposal site. Inside mines, hazardous materials are generally limited to electrical equipment that contains PCBs.

Hydrology Analysis: Prior to designing any mine seals, the hydrology of the mine must be considered. OSMRE regulations require the completion of a hydrology analysis before permitting any new coal mines. These regulations have essentially prevented up-dip mining in acid-producing coal seams where the mine opening is at a lower elevation than the mine reserves. These regulations were adopted to minimize the impact of postmining water discharge.

A hydrology analysis is required to determine if a hydraulic head will be placed on the mine seal after closure. A crude method of calculating the hydraulic head is to subtract the mine opening elevation from the highest elevation of coal extraction. This method may be acceptable to some regulatory agencies, but it does not consider the potential for additional hydraulic head due to groundwater above the mine. Consideration of the potential hydraulic head associated with groundwater can, however, be very complex. To predict groundwater impacts accurately, hydrogeologists utilize information such as well records, geology, and surface topography to model the groundwater. Groundwater monitoring wells or piezometers may be necessary to monitor the groundwater levels in the mine's vicinity.

Ventilation Planning: During the closure of an underground mine, the shutdown of the mine's ventilation system must be well planned, particularly in gassy mines with water conditions. The ventilation shutdown plan needs to be reviewed on a mine-by-mine basis. The engineer must plan for the systematic shutdown of the system to keep all of the active work areas ventilated and safe from harmful or explosive gases. Regulatory agencies will often require this ventilation plan prior to permitting the closure activities.

For the final sealing of mine openings, again primarily for gassy mines, ventilation must also be considered. During the filling of shafts, some MSHA districts require remote testing for gas the entire length of the shaft. When a gas problem is found, all work must stop until the gas dissipates.

To seal drift, slope, or adit openings in gassy mines that are accessible, a temporary stopping can be erected beyond the work zone. Ventilation tubing can be extended to near the work area and connected to a fan to blow fresh air into the opening.

8.7.2.4 Revegetation

Revegetation of the surface areas of the mine must be accomplished in accordance with the mine's permit. There is much published information available to assist the engineer in formalizing these procedures for a particular mine. Sources of information include local universities with agricultural and/or mining departments, government agricultural agencies, and the US Bureau of Mines.

References by Williams and Schuman (1987), Lyle (1987), and Vogel (1987) are helpful manuals that can be used for mine revegetation planning.

8.7.3 SEALING OF UNDERGROUND OPENINGS

Previously, mine sealing was generally performed only as a safety precaution. Mining regulations now require sealing to be performed during closure. According to Utah's *Shaft Abandonment Guidelines* (Anon., 1987), the following parameters should be considered in sealing shafts.

1. Eliminate any danger to the health and safety of the general public.
2. Control release of hazardous, acid/toxic-forming materials or gases to the atmosphere.
3. Control the movement of underground water or hydrologic communication.

Before a sealing method is selected, the degree of mine closure must be determined. Potential future geologic or economic value, historic value, hazards, and costs must be considered. The different degrees of mine seals can be considered as follows (Anon., 1980b).

Permanent: A safeguard that would completely seal off abandoned workings and would preclude the rehabilitation and future access to the mine. This would be the case if all the ore reserve has been mined or economics dictate that future profitable operation is not deemed probable.

Temporary: Seals that prevent deliberate or accidental entry into a working while preserving the general condition of the opening for future use. If there is some potential future value that can be gained by maintaining an opening to the mine, then this type of closure method should be used. Methods employed are fencing around shafts, glory holes, adits, or drifts; locked doors for adits, drifts, or slopes; and concrete covers for shafts.

Semi-Permanent: A system of seals that completely seals or otherwise blocks an opening while maintaining the general integrity of the opening. Future access to the workings may be desirable. This method should be employed when there is future economic value, but by employing only the temporary method of closing the opening, a threat to the public may exist such as emission of radon or other gases.

As discussed earlier in this section, a hydrogeologic study must be done prior to selecting a seal type. This study will determine if a hydraulic head could build up behind the seal and estimate what it would be. The estimated hydraulic head must be used in seal design calculations.

Permanent seal types available as described in a Bureau of Mines publication (Adams and Lipscomb, 1984) are as follows.

Dry Seal: A dry seal is constructed by placing suitable material such as cement blocks in mine openings to prevent the entrance of air and water into the mine. A dry seal is suitable for openings where there is little or no flow and little danger of a hydraulic head developing.

Wet Seals: A wet seal prevents the entrance of air into a mine while allowing the mine discharge to flow through the seal. Seals of this type are constructed with a water trap similar to traps used in sinks and drains.

Hydraulic Seals: Construction of a hydraulic seal involves placing a plug in a mine entrance that is discharging water. The plug stops the discharge, and the resultant flooding excludes air from the mine and retards the oxidation of sulfide minerals.

8.7.3.1 Boreholes

Temporary seals on boreholes can consist of a locked cap over a protruding casing. When boreholes are no longer required for mine operation or monitoring purposes, a drilling contractor is usually hired to seal the opening. To permanently seal a borehole, the surface casing and protective cap should be removed to a few feet (meters) below the proposed final surface elevation. A plug must be installed in competent strata as close to the borehole and mine roof interception as possible, either remotely by the drilling contractor or from inside the mine if the location of the plug is accessible. The borehole can then be sealed by filling with a nonshrink cement grout. A pour pipe extending to the bottom of the hole should be utilized when placing the cement grout to assure uniform placement of the grout and eliminate voids. The Pennsylvania Dept. of Environmental Resources (Anon., 1988b) guidelines indicate that grout should be placed to within 2 ft (0.6 m) of the surface, with the remainder being filled with dirt to blend into the surrounding area. Other methods employed are plugging the borehole with a bentonite gel or if the borehole is known to have a grouted casing, a plug at the top and bottom and the remainder being filled with inert material may be sufficient. Fig. 8.7.3 shows two types of borehole plugs.

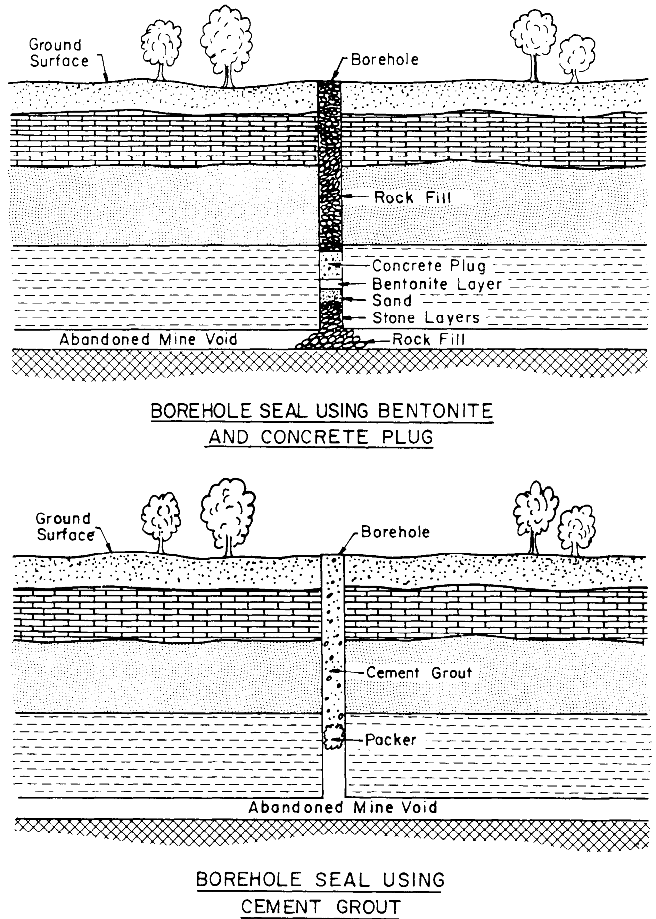

Fig. 8.7.3. Borehole seals (Anon., 1980a).

8.7.3.2 Shafts

For permanent mine closure, OSMRE requires shaft openings into coal mines to be either filled or capped. Filling shall be for the entire length of the shaft with the lower 50 ft (15 m) filled with incombustible material. Caps shall consist of 6-in. (120-mm) thick concrete or other equivalent means and be equipped with a vent pipe (2 in. or 50 mm in diameter, and 15 ft or 5 m above the surface).

Examples of shaft fill plans (where there are no expected hydrologic heads) are presented in Figs. 8.7.4 and 8.7.5. The following is a reprint of the *Shaft Abandonment Guidelines* from the Utah Dept. of Natural Resources (Anon., 1987).

"If there is no hydrologic involvement, small-sized fill material should be interspersed with large debris to allow for void filling. Any debris deposited in this manner should not create voids within the fill that could subside at a later date. Maximum compaction attained during placement is the goal of the selection of the type of backfill material."

"The backfill material selected must be free of acid/toxic-forming and combustible materials. No wood or metal debris should be considered for backfilling of shafts."

"Inorganic and organic silts and clays should be avoided as much as possible. Gravel/sand combinations are the best quality. The material shall be sized so as to minimize voids, i.e., uniformly graded or well-graded. Results of a sieve analysis and engineering soil characteristics shall be submitted to the Division with the reclamation plan about the backfill material."

"In the event of hydrologic movement, consideration must be given to the unique situation and will be handled specifically."

"Caps are recommended at the collar of shafts. A port should be included in the design to monitor the backfilled material. Maintenance of the shaft abandonment should also be included in the plan in the event more backfill may be needed."

To account for settlement in shaft backfill material, the State of Montana (Anon., 1988c) requires that, "shafts be backfilled to a finished elevation above the surrounding natural ground equal to 5% of the shaft depth or as directed by their engineer."

To ensure safety when filling in shafts, the following procedures should be utilized (Hoelle, 1988):

1. Remove surface structures surrounding the shaft.
2. Erect temporary protective fence around work area.
3. Place a sturdy barrier (wheel stop) around the shaft collar.
4. Place a steel cover over the shaft top during idle periods.
5. Monitor for hazardous gases.
6. Place a fence around the site after filling.

An example of a concrete cap used to seal an abandoned shaft is shown in Fig. 8.7.6. Inverted pyramid-shaped caps (or plugs) have also been used successfully to seal abandoned shafts. Dressel and Volosin (1985) describe this method in a US Bureau of Mines publication; it is depicted in Fig. 8.7.7.

If a hydraulic shaft seal is planned in an attempt to eliminate water discharges from a shaft, seals such as the ones shown in Figs. 8.7.8 and 8.7.9 can be designed. These hydraulic plugs must be designed using the same structural design methods as used to design a surface dam.

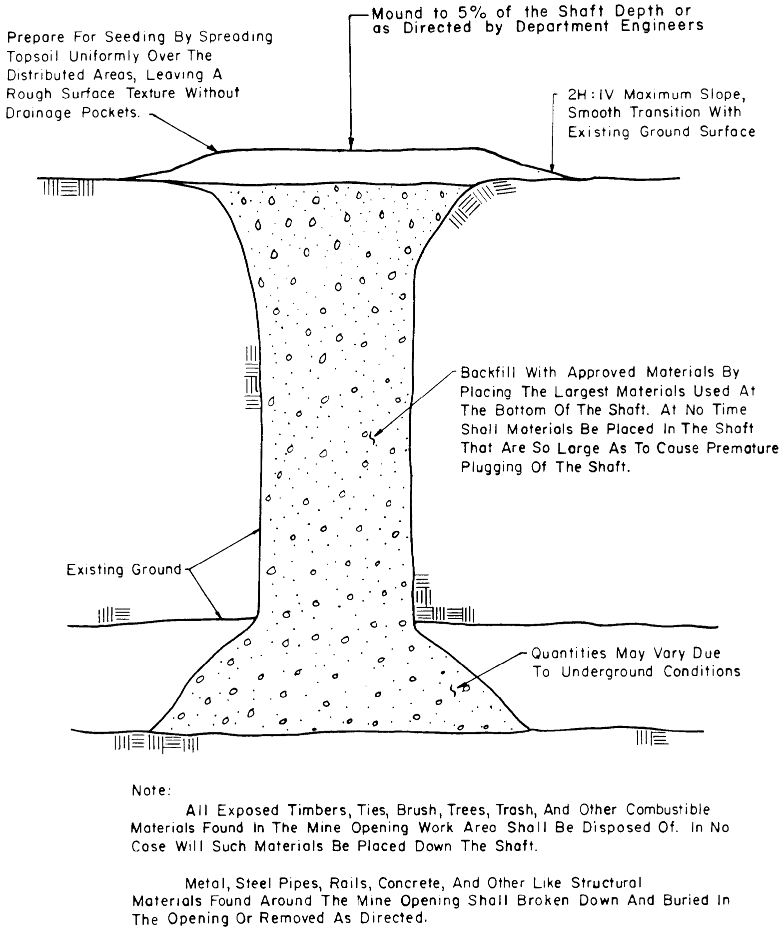

Fig. 8.7.4. Dry shaft seal (Anon., 1988c).

8.7.3.3 Slopes, Drifts, and Adits

Dry Seals: Dry seals can be used to close slopes, drifts, and adits when there is no hydraulic head anticipated at the mine opening. Several different methods can be employed. A method seldom used today is that of simply drilling and shooting down the roof and regrading the area. Fig. 8.7.10 depicts this sealing method. This cannot be done at coal mines because OSMRE requires the opening to be filled by at least 25 ft (8 m) of incombustible material. When the opening is accessible, a concrete wall is often constructed inside the 25-ft (8-m) zone and backfilled. Figs. 8.7.11 and 8.7.12 depict other typical dry seals.

Mine seals placed pneumatically like those depicted in Fig. 8.7.13 are also often used at remote locations (Roberts and Masullo, 1986). Aggregate can be pumped pneumatically through a pipeline from a location accessible to large equipment to the unaccessible mine opening that is to be sealed. If necessary, the aggregate can also be injected with a grout.

Wet Seals: Wet seals are constructed at locations where a hydraulic head is anticipated. A typical wet seal design is shown in Fig. 8.7.14. A variation of a wet seal that is meant to keep air from entering the mine is called an *air seal.* These are constructed at mines where an attempt is being made to limit the oxygen content of the mine atmosphere and thereby limit acidic water production. Fig. 8.7.15 depicts an air seal.

Hydraulic Seals: Current EPA regulations require that all mine water discharges be within acceptable limits. The limits vary according to mine type. After mine closure, mining companies have been required to continue to treat the mine discharge unless it meets the effluent discharge limitations. To eliminate treatment cost and to improve the environment, hydraulic seals have been designed and installed to act as dams and eliminate water discharge. Designing a hydraulic seal to withstand a head of water is not simple. There have been many designs used. Figs. 8.7.16 through 8.7.20 show various types. To be designed and constructed successfully, several design criteria should be met (Chekan, 1985):

1. The bulkhead should be designed to withstand the static forces of hydrostatic pressure rather than the dynamic forces of an explosion.

2. The bulkhead should be constructed from a material, such as concrete, that will resist deterioration by water.

3. The bulkhead should be constructed to be sufficiently thick and properly anchored, and the surrounding strata should be pressure grouted to minimize water seepage.

In addition to the general criteria listed, Chekan also reports that the following factors should be considered before designing and constructing a bulkhead to impound water at a coal mine:

1. The bulkhead should be located in competent ground that is not excessively fractured or broken, preferably in areas of stable ground. However, in most coal mines, ground movements such as roof convergence and floor heave are inevitable, and supplemental roof supports should be installed at the site.

2. The bulkhead, in most cases, should be designed to withstand the maximum hydrostatic pressure that can develop. Practical limits of potential inundation can be determined by plotting the expected mine pool elevations and corresponding ground

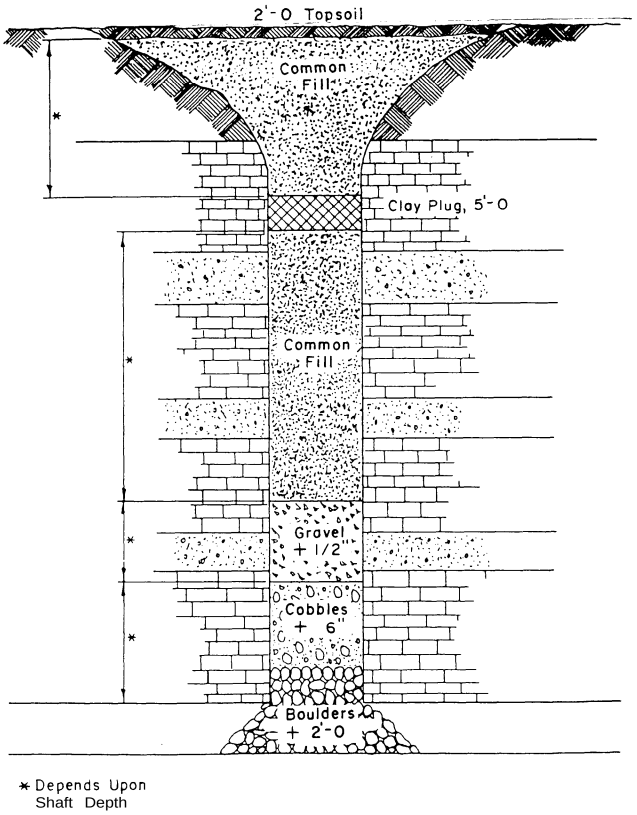

Fig. 8.7.5. Dry shaft seal (Anon., 1980b).

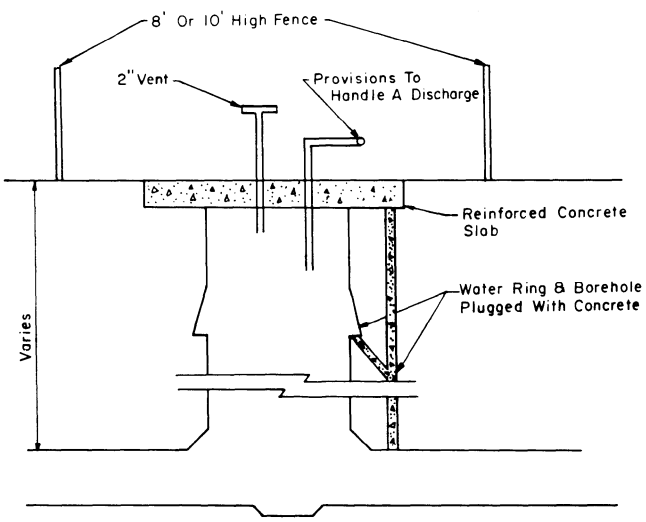

Fig. 8.7.6. Shaft seal using a concrete cap (Anon., 1985).

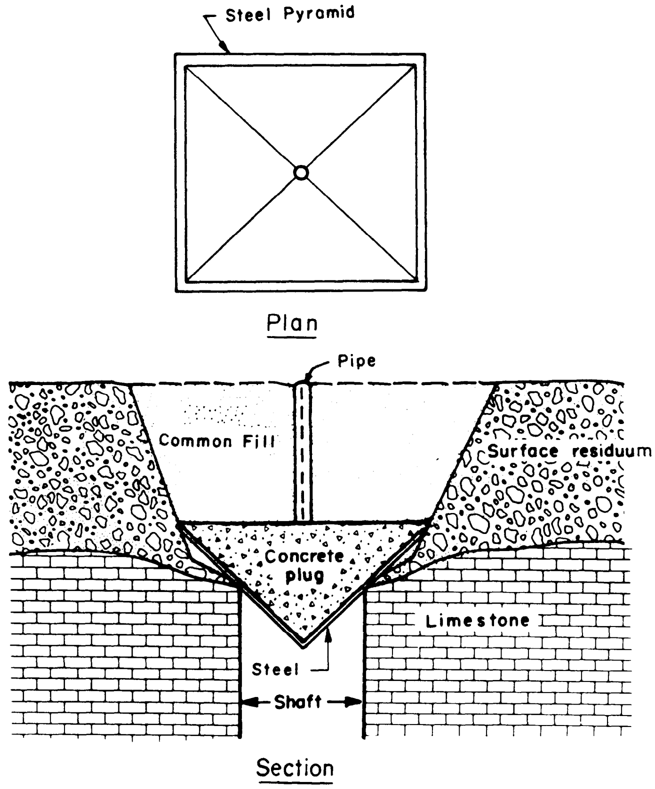

Fig. 8.7.7. Inverted pyramid shaft seal (Dressel and Volosin, 1985).

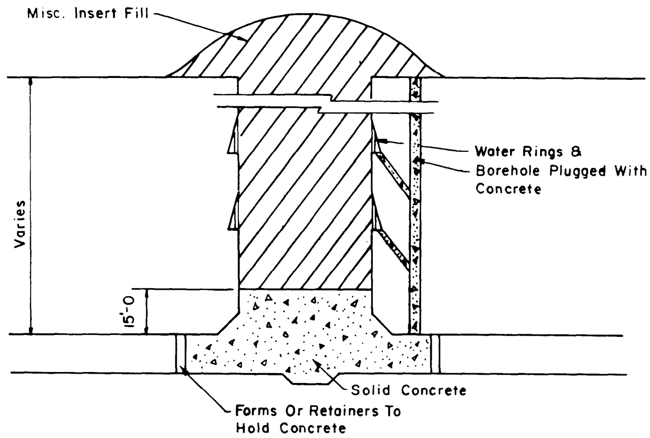

Fig. 8.7.8. Hydraulic shaft seal (Anon., 1985). Conversion factors: 1 in. = 25.4 mm, 1 ft = 0.3048 m.

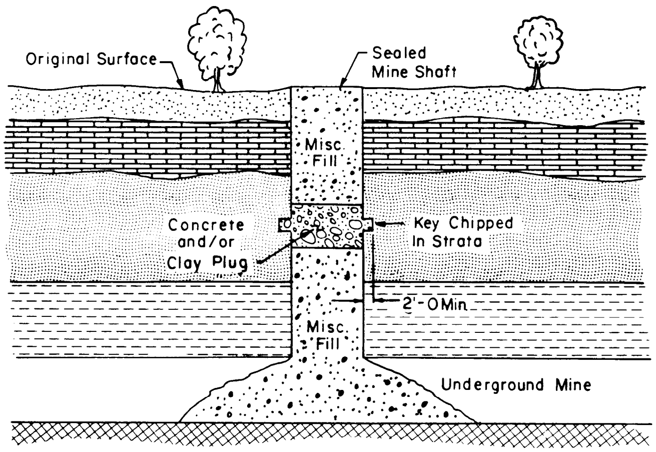
surface elevations on a coal contour map. Areas where excessive water heads may accumulate can then be projected. To convert water head H in feet to hydrostatic pressure P in psi, multiply the water head by 0.434, or $P = 0.434\ H$. In SI units, P in kPa = 9.82 H in meters.)

3. The concrete for constructing the bulkhead must be properly mixed and placed to achieve acceptable strengths upon curing.

4. Anchorage of the bulkhead to mine roof, ribs, and floor is important and depends on design as well as on strata type and condition. Some design methods rely on the strength of the concrete bearing against the irregularities in the rock surface to provide anchorage. Others require the excavation of trenches.

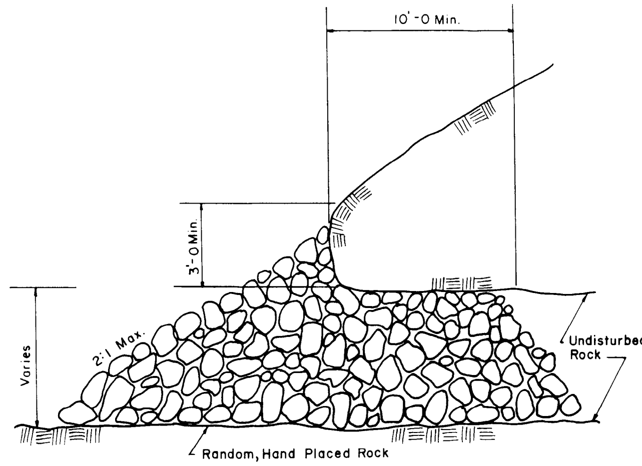
5. Adequate pressure grouting of the immediate strata surrounding the bulkhead is probably the most significant factor in the bulkhead's long-term performance. Deterioration of the anchoring strata by acid-water permeation is a major structural concern, especially if large pressures are anticipated over the life of the bulkhead.

At coal mines having drift entrances that are being sealed using hydraulic seals, it is important that the engineer consider



Conversion factor: 1 ft = 0.3048 m

Fig. 8.7.9. Hydraulic shaft seal (Anon., 1980a).



Conversion factor: 1 ft = 0.3048 m

Fig. 8.7.11. Dry seal of an adit or drift by backfilling rock (Anon., 1988c).

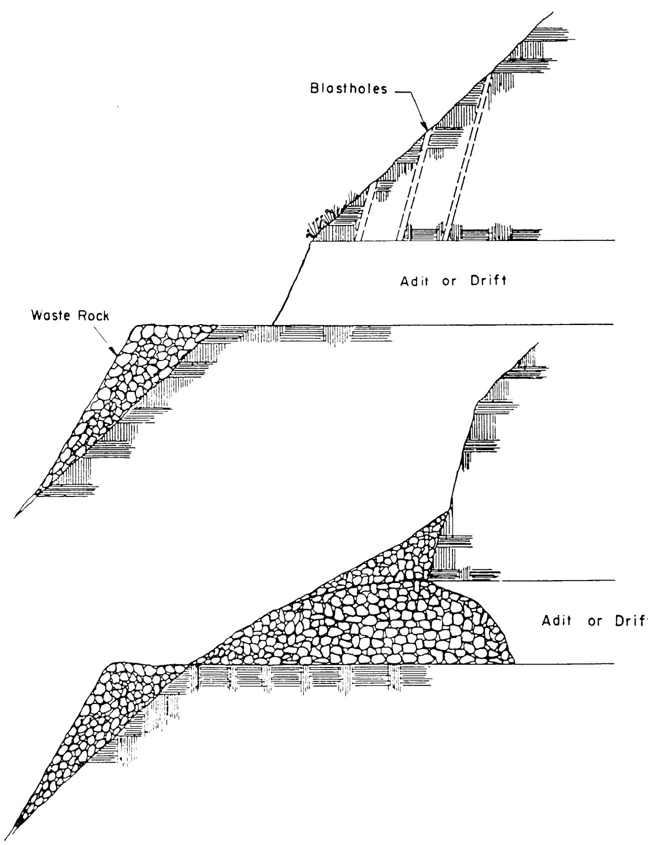


Fig. 8.7.10. Dry seal of an adit or drift by blasting (Anon., 1980a).

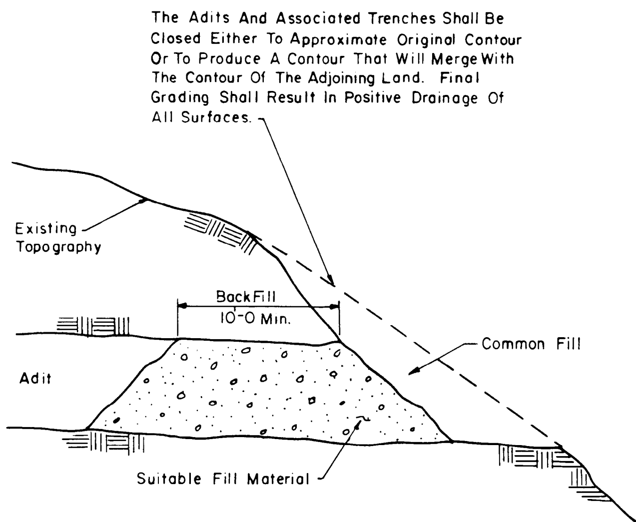

Conversion factor: 1 ft = 0.3048 m

Fig. 8.7.12. Dry seal of an adit or drift by backfilling (Anon., 1988c).

what maximum head the coal barriers along the outcrop can withstand without failing. The mine seal may be designed to withstand any water pressure, but the outcrop thickness or mine roof may be of such conditions to permit seepage or a "blowout." Failure could occur due to uplift of the rock strata above the coal barrier or due to lateral translation of the coal barrier.

8.7.4 ABANDONMENT

Only after the mine has been sealed and reclaimed can the mining company abandon the site. Items that must be considered prior to the mining company's legally abandoning the site include postmining land use, maintenance of the site, recovery of reclamation bond, and postmining liability.

8.7.4.1 Postmining Land Use

Permits for new mines require that the planned land use after the mine closes be identified. Normally, the land is returned to a similar premining use or an improved use. After closure of the mine and prior to completely abandoning the site, the mining company must prove to the regulatory agency's satisfaction that the land use is as it was planned to be.

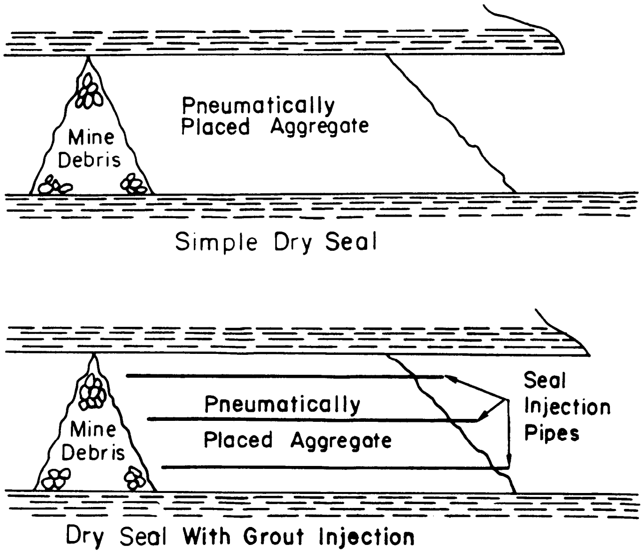

Fig. 8.7.13. Dry seal of an adit or drift by pneumatically placing aggregate (Roberts and Masullo, 1986; *permission: Coal Age*).

Alternative postmining land uses are often requested by mining companies. These alternate uses should be consistent with the land use planning of the local government. If the local land use planners support the alternative land use, no difficulty should be expected in obtaining approval from the mining regulatory agencies, as long as there are no detrimental environmental effects with an alternative use.

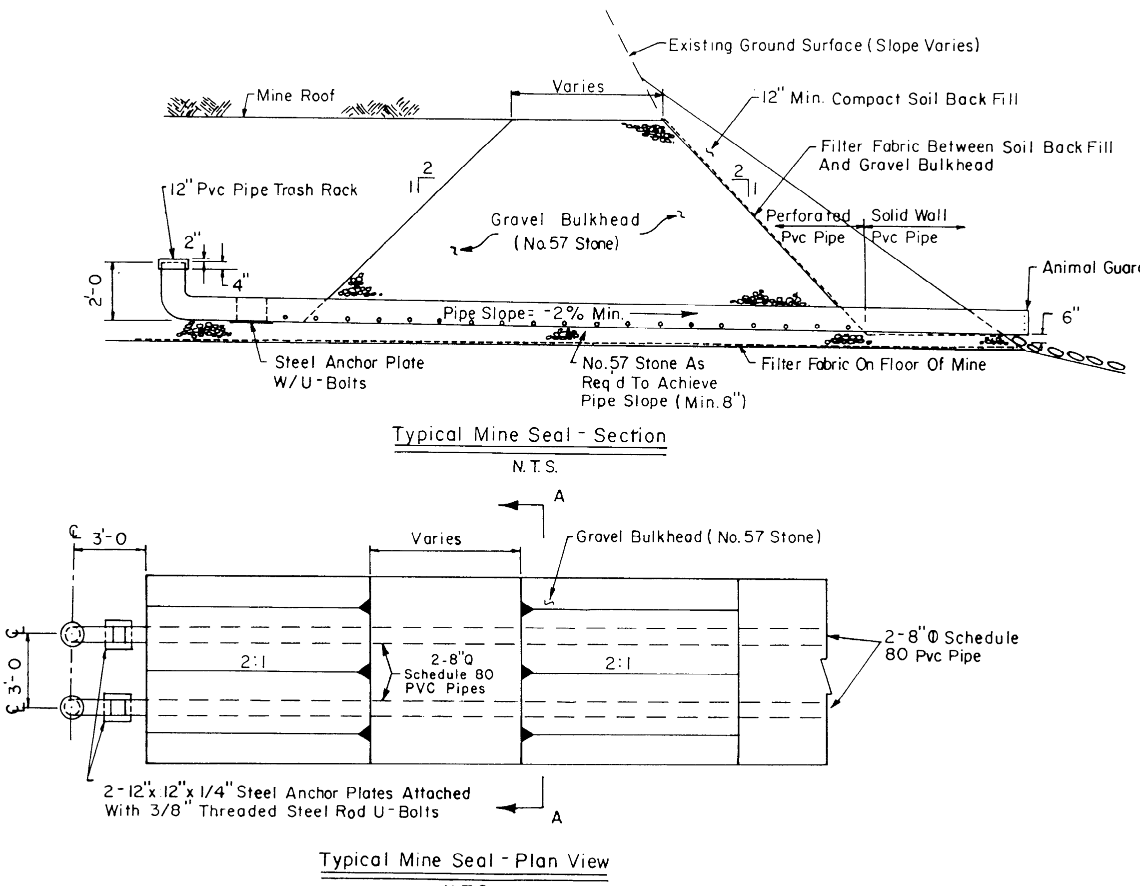
8.7.4.2 Maintenance

After reclaiming a mine site, there will probably be several years of maintenance activity required. This will include periodic inspections of the site to verify that the reclamation is effective. Inspection activities include

1. Verification that mine seals are effective.
2. Cleaning out of sediment and erosion control structures, primarily ponds and ditches.
3. Verification that water discharges are within the permitted effluent limits.
4. Regrading and reseeding of areas, as required.

8.7.4.3 Bond Release

To obtain an operating permit, most mines are required to post a reclamation performance bond that is to be used by a regulatory agency to reclaim an area in the event of forfeiture.



Conversion factors: 1 ft = 0.3048 m, 1 in. = 25.4 mm

Fig. 8.7.14. Wet seal of an adit or drift (Anon., 1988a).

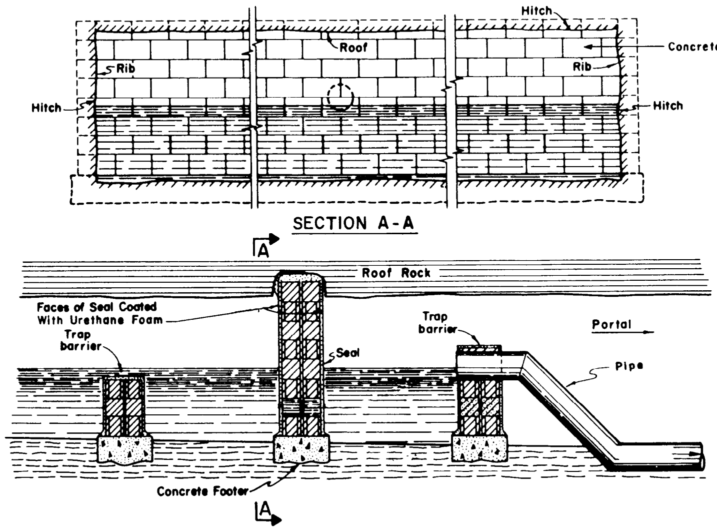


Fig. 8.7.15. Bureau of Mines air seal of an adit or drift (Moebs and Krickovic, 1970).

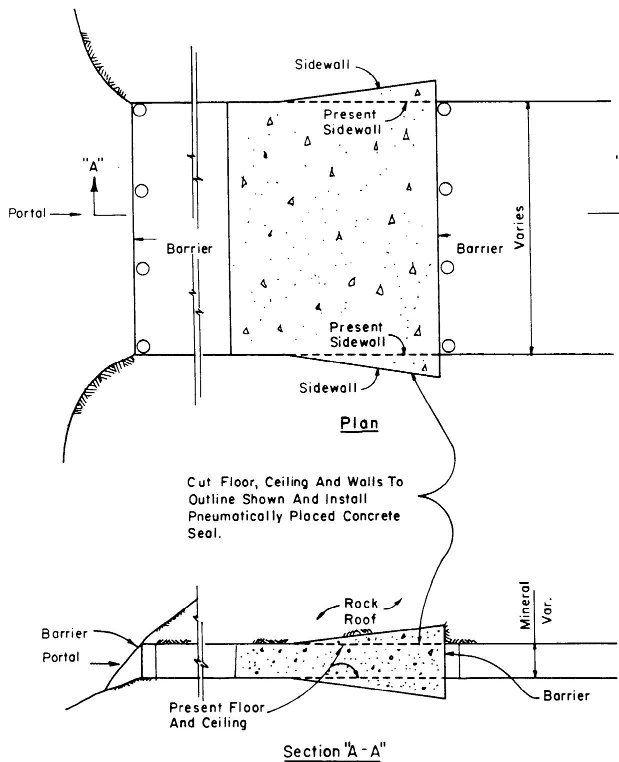

Fig. 8.7.16. Hydraulic seal of an adit or drift using gunite (Anon., 1973).

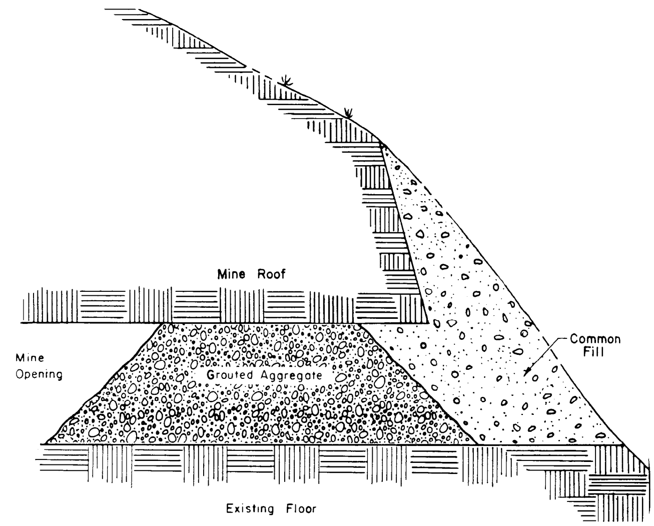

NOTE: Grout Roof Ribs and Floor if Needed

Fig. 8.7.17. Hydraulic seal of an adit or drift using grouted aggregate.

When a mining company has successfully reclaimed the closed mine (or a portion thereof), it may apply for the release of the applicable bond. OSMRE regulations for coal mines specify that the bond is not to be released until the reclamation activity has been completed and revegetation is successful. Verification that the revegetation is successful can often take several growing seasons.

Each regulatory agency may have its own procedure to obtain the release of a reclamation bond. An example of a bond release procedure (that can be considered typical) is the following procedure utilized by the Pennsylvania Dept. of Environmental Resources (Anon., 1985).

On completion of the appropriate stage of reclamation, the operator may file a completion report and request a bond release. Completion reports may be filed only when the appropriate stage of reclamation is completed. The completion report may be filed on either a designated portion or all of the permit area, as appropriate, and only at those times of the year which permit the Department to properly inspect the area.

Bond Release Procedure—Step 1. Action: The application must be examined for completeness, then logged and distributed for office and field review. (If the application is submitted during times of the year when an inspection cannot be made, the operator must be notified that the application is being held until the inspection can be made.)

A field inspection notice must be issued to the operator and the surface owner, agent, or lessee. The notice must be issued and received prior to the field inspection and within a reasonable time of the inspection so that the operator or landowner may participate in the inspection. Notice to the surface owner, or

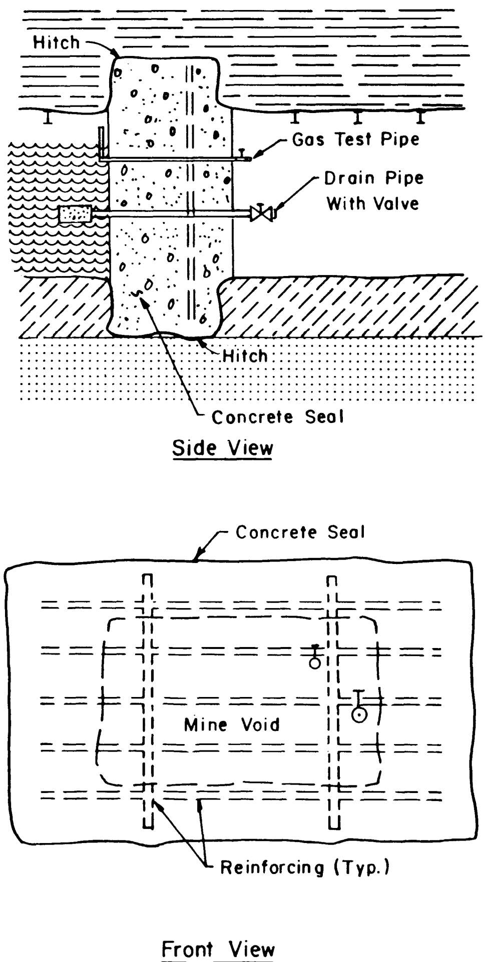

Fig. 8.7.18. Hydraulic seal of an adit or drift using a single concrete bulkhead (Garcia and Cassidy, 1938).

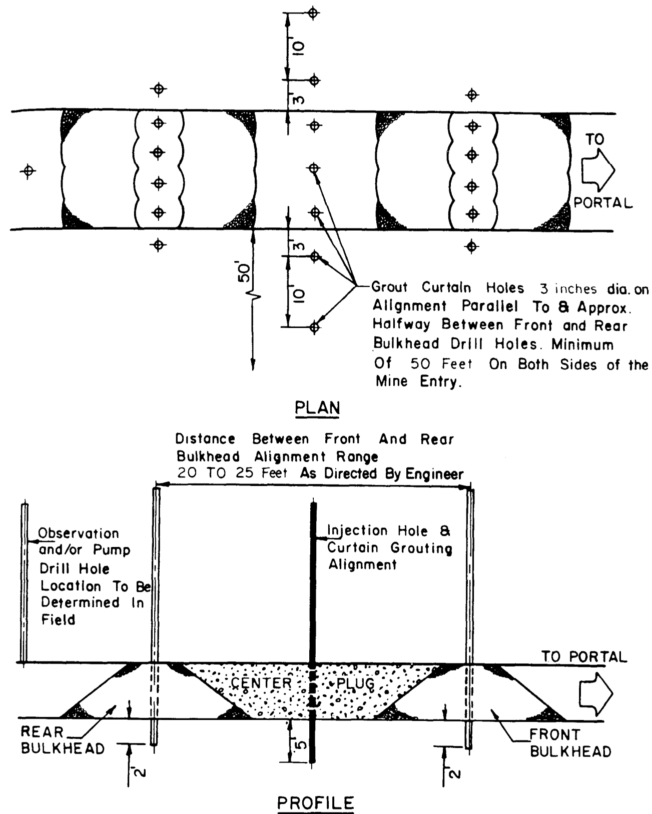

Fig. 8.7.19. Hydraulic seal of an adit or drift using a grout curtain with double bulkhead seal (Foreman and McLean, 1973). Conversion factor: 1 ft = 0.3048 m.

agent or lessee of the surface owner, will be based on the completion report.

Step 2. Action: Verify that the application, public notice advertisement and public notice letters are proper.

Step 3. Action: Field review of area. When possible, the field inspection should be scheduled at the same time as the monthly inspection and also documented as a monthly inspection.

Step 4. Action: Conduct an informal conference if requested.

Step 5. Action: Finalize review of the completion report and issue the final determination to the operator. A copy of the final determination must also be sent to the local municipality, each party that submitted written comments or objections, and each party that attended the informal conference. If a bond release is approved, the amount of bond release must be verified.

8.7.4.4 Postmining Liability

Even after the mine has closed and reclamation activities are completed, the mining company's liability may not end. Two primary potential problems are water treatment and subsidence. Each mine's development and operation plan and mining methods should be instituted so that they limit the mine's susceptibility to postclosure costs. The costs can be substantial and could affect the economic condition of the mining company.

Water Treatment: If there is water being discharged from the mine site that does not meet the effluent limitations of the current applicable regulations, treatment of the water discharge is required. This treatment may be necessary for many years or even perpetually. Because this cost can be great, future mining methods should include planning either to eliminate a postmining discharge or to assure that the discharge will meet the EPA effluent limitations. Metcalf and Eddy (Anon., 1979) and Reynolds (1982) can be used to assist engineers in the design of water treatment facilities. The US EPA (Anon., 1983) has also published a design manual on the neutralization of acid mine drainage.

Subsidence: OSMRE regulations require coal mine operators to "adopt measures consistent with known technology which prevent subsidence from causing material damage to the extent technologically and economically feasible, maximize mine stability, and maintain the value and reasonably foreseeable use of surface lands; or adopt mining technology which provides for planned subsidence in a predictable and controlled manner. Nothing in this part shall be construed to prohibit the standard method of room and pillar mining."

Although this regulation applies to coal mines only, underground mine operators of noncoal mines may want to do similar planning if they deem their specific situation warrants it. If subsidence does occur following mining and causes material damage to the surface, OSMRE regulations further require the operator to

"1. Correct any material damage resulting from subsidence caused to surface lands, to the extent technologically and economically feasible, by restoring the land to a condition capable

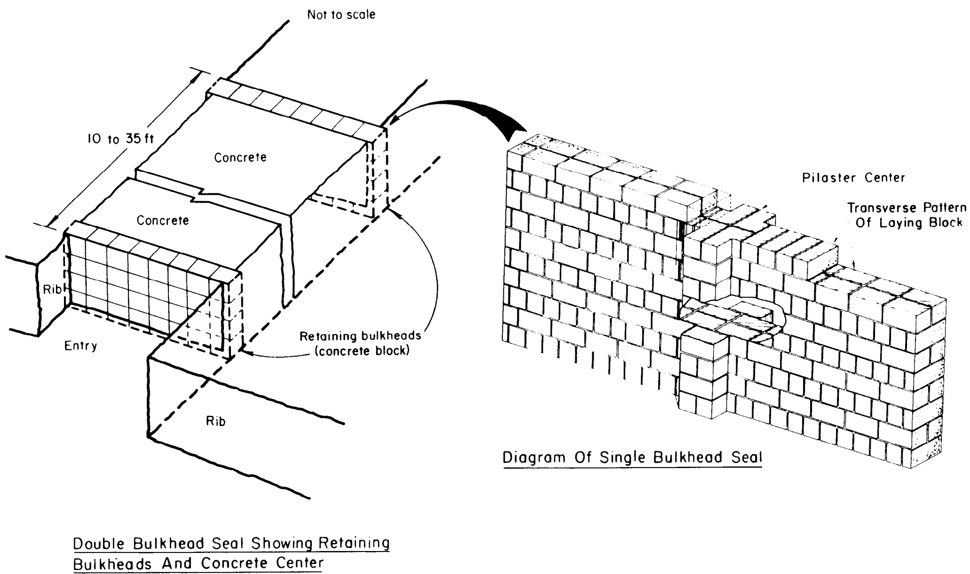

Fig. 8.7.20. Hydraulic seal of an adit or drift using a double bulkhead (Chekan, 1985). Conversion factor: 1 ft = 0.3048 m

of maintaining the value and reasonably foreseeable uses which it was capable of supporting before subsidence; and

"2. To the extent required under applicable provisions of state law, either correct material damage resulting from subsidence caused to any structures or facilities by repairing the damage or compensate the owner of such structures or facilities in the full amount of the diminution in value resulting from the subsidence. Repair of damage includes rehabilitation, restoration, or replacement of damaged structures or facilities. Compensation may be accomplished by the purchase prior to mining of a noncancellable, premium-prepaid insurance policy."

This liability to pay for subsidence-caused surface damage does not leave the mine operator after abandonment of the mine.

Subsidence-related underground coal mining is the inevitable result of high-extraction mining practices and the occasional (relatively infrequent) result of partial extraction mining practices. Mine operators can categorize various portions of their mine into the following:

Planned Subsidence—Represents lowering the ground surface in a manner predictable (within limits) as to areal extent, amount of subsidence, and amount of ground surface distortion as a result of appropriate mine design and mining procedures. Planned subsidence is the result of high-extraction technologies, such as longwall and pillar retreat in coal mines.

Unplanned Subsidence—Represents lowering of the ground surface in a manner that cannot be predicted as to areal extent, amount of subsidence, or amount of ground surface distortion, as a result of failure at mine level of the overburden support system (pillars/mine roof/mine floor) or as a result of the action of other unanticipated causes, such as the piping of unconsolidated sediments into the mine.

Planned Subsidence Prevention—Can be accomplished by utilizing a mining method that provides for permanent ground support. When the percentage extraction from a mine panel is low to moderate, the loads imposed upon pillars by the overburden are generally small in relation to the size of the pillars. In this situation, subsidence of the ground surface is virtually nil and will remain so over the long term.

In planned subsidence or planned subsidence prevention areas, the mining company should be confident that no long-term liability exists. In areas considered to have unplanned subsidence potential, subsidence may occur at an unpredictable time in the future. If any areas in this category exist in a mine being abandoned, and the company has some control over future land use, the company may wish to consider limiting land uses or requiring subsidence resistant designs for future building developments. Insurance against future claims could also be purchased.

Part III
Unit Operations of Mining

Section 9 Production Operations

MADAN M. SINGH, ASSOCIATE EDITOR
LEE W. SAPERSTEIN, SECTION COORDINATOR

Chapter 9.0
BASIC TASKS IN THE PRODUCTION CYCLE

LEE W. SAPERSTEIN

9.0.1.1 Application

At the heart of the mining process are a number of basic and fundamental tasks whose regular and repeated performance constitute the mining cycle. As will be discussed presently, these tasks are the basic components of the mining system. Section 9, Production Operations, provides the mine designer and engineer with an understanding of these tasks and with sufficient design principles to allow this person to create an efficient mine system. This section is meant to be an introduction and adjunct to subsequent sections that describe specific mining systems. However, sufficient design information is included here for the independent design of mine systems that may not be described elsewhere or for subsequent verification of existing designs.

For the purposes of this section, mining subsumes excavation; thus this material applies to any excavation process. Accordingly, this section is written in general enough terms to include both surface and underground mining. It may be used also for civil engineering excavations that often involve the same steps. Obviously, the actual procedures undertaken in any specific mining system will appear to be very different from those taken in any other system. This is certainly true when comparing surface with underground methods. Yet the fundamental principles are often the same. This segment is written to explicate the basics. Wherever appropriate, the section will suggest the differences between the application process to surface or to underground mining.

9.0.1.2 Unit Operations

The phrase, *unit operations,* is used often to describe the basic tasks of any systematic process. In mining, the unit operations of production are fragmentation, loading, and haulage; the auxiliary unit operations include site preparation, ground control, transportation of personnel and supplies, provision for pumping, ventilation, and power, as well as reclamation procedures not included in the other steps. Many synonyms exist for these tasks; for example, *penetration and fragmentation* are often referred to as drilling and blasting, loading as mucking, and haulage as transportation. In particular, loading and haulage are grouped in the term *materials handing.* In this section, drilling and mechanical breakage, such as ripping or continuous mining, is included in the chapter on “Rock Breakage: Mechanical;” blasting is included in the chapter on “Rock Breakage: Explosives;” and the last two production operations are included in the chapter on “Materials Handling: Loading and Haulage.” The ancillary unit operations are described in subsequent sections.

Unit operations are often recognized more easily than they are defined. Yet there are several distinctive characteristics: a unit operation defines a process and not the subject of that process; it is often an elemental step that does not divide easily into further substeps; consequently, it often is identified with a single machine or operator; finally, even though part of a cyclical process, it often can be performed continuously. This identification with process allows the same principles to apply to seemingly widely different circumstances: the calculation of tractive effort of a rubber-tired vehicle is the same for a large, diesel-electric haul truck as it is for a battery-powered scoop used in an underground coal mine; the determination of bucket size for a large stripping dragline is done with the same steps and principles as used to size an underground load-haul-dump (LHD) machine.

9.0.1.3 Mine Cycles

Should an observer stand in one place near the mine face—the point where excavation is underway—for a period of time, it will be seen that the unit operations are performed in an orderly rotation. When a period is complete, with at least one task being seen twice, then one cycle will have been performed and the face advanced by the dimension set in the fragmentation phase. Normally, the cycle is thought to begin with preparation for drilling. Over a number of cycles, the face will advance so as to define the mine's geometry.

The repetitive nature of the unit operations means that the design or sizing of the equipment can be adjusted so as to be specific to the task, and the training of the operator can also be as specific. With appropriate overall mine design, done so as to minimize moves of equipment between adjacent cycles, efficiencies of operation that are nearly as high as with a continuous operation can be obtained. In a well-designed mine, where each unit operation is sized so as to be compatible with the successive operation and equipment moves are kept to a minimum, the work effort continues as regularly as if it were a mechanical assembly.

Tables 9.0.1. and 9.0.2. are placed here to show ideal cycles for surface and underground mining. Within each table, comments are inserted to show where a particular operation may be omitted.

9.0.1.4 Task Integration

In striving for lowest cost and maximum productivity, the mine designer follows several simple maxims.

1. The productivity of each unit operation, measured in units of production per unit of time, is matched with all other operations linked by a particular cycle.

2. More than one machine is used, as in a fleet, if machines with less than the desired capacity are less expensive or more flexible than a single machine with the desired capacity.

3. Mine layout is made so as to minimize nonproductive movements of equipment.

4. Unit operations are linked wherever possible to provide for continuous flow of material, providing that the resulting operation is not more cumbersome or less reliable than the separate units. This linkage creates a fundamentally different mining system: one that is called continuous. These systems, called closed-connected when each component is physically linked to another, minimize the delays associated with changing the respective unit operations in and out of the face area. Unlike open-connected systems, however, a failure of any component will shut down the entire operation. Open-connected systems may be continuous, but do not have physical ties among the components. Descriptions of continuous systems are found in the respective chapters that describe applications.

The final chapter of this section, "Cycles and Systems," is included to help the mine designer assemble unit operations into an optimum system that has a cycle time coincident with or convenient to shift times or other working periods.

Table 9.0.1. Surface Mining Cycle

1. Install Erosion and Sediment Controls: this Step and Step 2 are performed only when mining new ground. Proceed to Step 3 if entering into a previously mined zone,
   a. Ditches, diversions, terraces, and down drains.
   b. Ponds.
2. Remove Topsoil
   a. Place in temporary, environmentally sound storage piles.
   b. Place directly onto restored mine land.
3. Prepare Drill Bench: if the material is sufficiently soft to not need blasting, then go to Step 6.
   a. Level bench with bulldozer.
   b. Inspect highwall for potential rockfalls and scale as necessary.
   c. Survey and lay out drillholes.
4. Drill Blastholes
5. Blast
   a. Load explosives into boreholes.
   b. Connect detonators so as to give desired firing order and times.
   c. Fire when safe to do so.
6. Load Fragmented Material: soft material will be fragmented by the cutting action of the loading machine.
   a. In quarry and open pit mining, loading will be into haulage conveyances.
   b. In large-scale area strip mining, the loading machine also performs the haulage (called casting in this case) function.
7. Haul Material
   a. Ore, coal, or other valuable material goes to subsequent processing.
   b. Waste goes to permanent storage.
      i. Off-site storage usually accompanies open pit mining.
      ii. Restored lands characterize strip mining.
   c. Haulage can be local, as with rubber-tired vehicles used in a gathering mode, or long distance.
   d. Haulage can be cyclical or continuous.
      i. Cyclical: trucks or load-and-carry vehicles.
      ii. Continuous: conveyor belts or pipelines.
8. Dispose of Waste or Overburden
   a. Overburden Storage.
      i. Waste piles.
      ii. Rebuild mine lands.
   b. Preparation Wastes.
      i. Waste disposal ponds.
      ii. Integrate into overburden storage.
9. Restore Topsoil
   a. Onto restored mine lands.
   b. Onto permanent waste piles.
10. Reclamation: may not be done with every cycle, but according to the season or when sufficient acreage has been restored to be efficient; in no case should restored lands be left uncovered.
    a. Revegetate.
       i. With temporary cover.
       ii. With permanent cover
    b. Maintenance until permanent succession is achieved.
    c. Remove temporary drainage controls
11. Return to Step 1.

Table 9.0.2. Underground Mining Cycle

(This table is intended for drill and blast cycles and not for continuous mining)

1. Enter Work Place After Previous Blast
   a. Check that ventilation has removed blasting fumes.
   b. Provide for dust suppression.
   c. Inspect back and ribs for loose material.
2. Install Initial Ground Support
   a. Scale, bar down, or otherwise remove loose material.
   b. Install temporary or initial ground support if it is not provided automatically by the loading machine.
3. Load Fragmented Material
   a. Onto gathering haulage.
   b. Directly onto main haulage.
4. Haul Material
   a. In gathering systems.
      i. Load-Haul-Dump
      ii. Truck
      iii. Shuttle Car
      iv. Gravity Transfer
   b. Main haulage.
      i. Truck
      ii. Train
      iii. Conveyor Belt
      iv. Pipeline
5. Install Permanent Ground Support If Needed
6. Extend Utilities If Needed
   a. Ventilation.
   b. Power (electricity or compressed air).
   c. Transportation.
7. Drill Blastholes
   a. Survey for line and grade; mark blasthole location.
   b. Drill holes.
8. Blast
   a. Load explosives into boreholes.
   b. Connect detonators so as to provide desired firing order and times.
   c. Blast when safe.
   d. Return to Step 1.

Chapter 9.1
ROCK BREAKAGE: MECHANICAL

M.C. Hood and F.F. Roxborough

9.1.1 INTRODUCTION

Almost exclusively, the methods that are used for rock excavation today employ either mechanical rock cutting tools or explosive charges. It is important, therefore, to have a good understanding of the advantages and the limitations of rock cutting with mechanical tools in order to assess both the potential for making significant technological advances using this approach and to develop a strategy for achieving these advances. Also, although many of the alternative methods for rock destruction, such as thermal or erosional, have been demonstrated as technically successful (i.e., it is possible to excavate rock using these methods), most of these techniques are impractical either because they are extremely energy intensive, or they are not cost-effective. Hence none of these alternative methods is likely to replace rock cutting with mechanical tools in the short-to-medium term (0 to 10 years). This is not to say that these other methods will not find application in rock breakage systems in this time frame. Indeed, it is most likely that the next generation of rock excavation systems will employ a hybrid cutting principle with mechanical tools assisted by one or more of these other breakage methods. Discussion of these topics occurs in the segments that follow. The main point is that future rock excavation systems are likely to continue to employ mechanical tools, and thus it is important to understand the processes of rock destruction caused by these tools.

Breaking rock by the penetration of a wedge is the basic mode of action used by virtually all rock excavation machines. There are only two essential types of mechanical rock cutting tools, *indenters* and *drag bits*. Tools in this latter category often are termed picks and these terms, drag bits and picks, are used interchangeably throughout this chapter. The distinction between the two types of tools is that an indenter breaks the rock by applying a force that is, predominantly, in a direction normal to the rock surface. In contrast, the main force applied to a sharp drag bit to effect rock breakage is in a direction approximately parallel to the rock surface. The loading geometries for both types of tools are illustrated in Fig. 9.1.1.

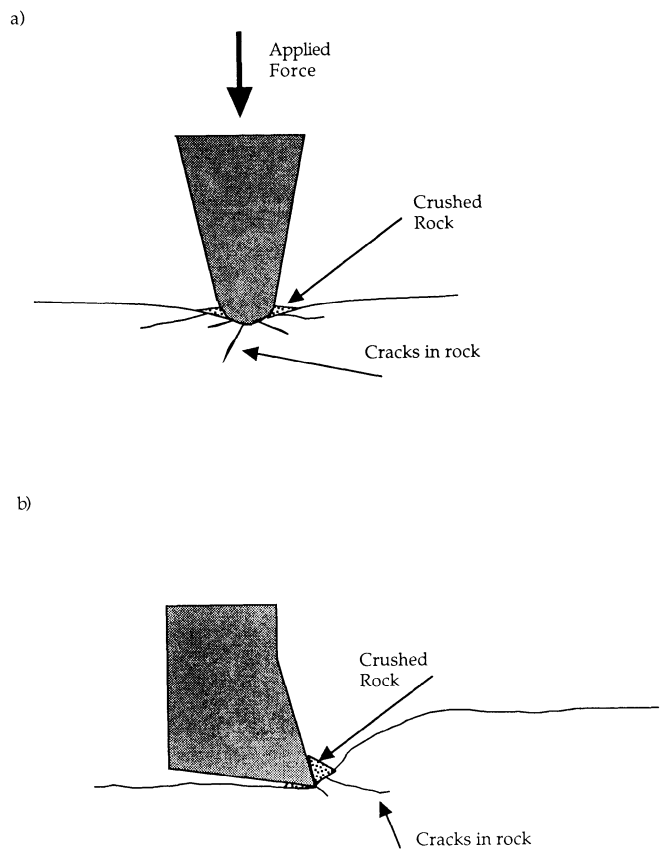

Fig. 9.1.1. Methods of rock loading by a) an indenter and b) a drag bit.

The great majority of the rock cutting tools employed today are indenters. Thus all types of roller cutters—disk cutters, rolling cone bits, etc.—break the rock in a indentation process. Similarly, all types of percussive tools, including percussion drillbits, down-hole drillbits, and high-energy impact bits, induce rock fracture by indentation. Only rotary drillbits and picks, such as those employed on coal excavation machines, break the rock by applying the main force in a direction parallel to the rock surface. Many of these various types of cutting tools are illustrated in Fig. 9.1.2.

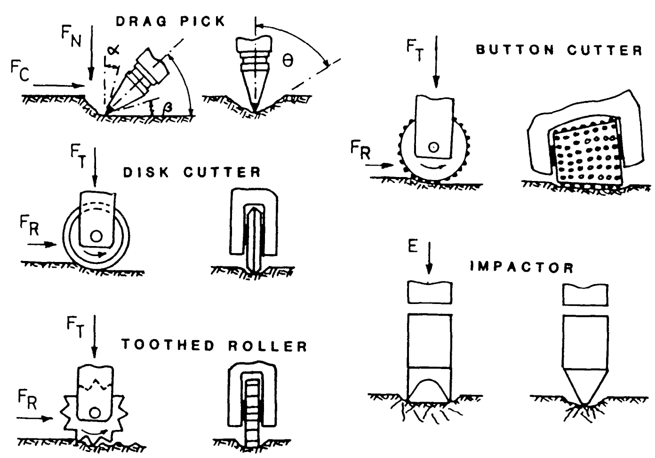

Fig. 9.1.2. Mechanical rock breaking tools.

Although indenters are more widely used than drag bits, they are less efficient; that is, an indenter requires more energy to excavate a given volume of rock than does a drag bit. This is because of the processes that lead to the formation of a major rock chip. The preponderance of the evidence points to the mode of propagation for the cracks that form the large rock chips as tensile fractures both for indenters and for drag bits. This, perhaps, is surprising because, as shown in Fig. 9.1.1, the load applied by an indenter is one of compression and that applied by a drag bit is one of shear. Details of the crack initiation and propagation processes for these two types of tools are given in the following. It is sufficient to note here that whereas a drag bit initiates a tensile fracture in the rock in a fairly direct manner, an indenter generates tensile stress in the rock by crushing a portion of the rock mass beneath the tool. This crushed material dilates and induces the tensile stresses that eventually lead to the development of a fracture in the surrounding intact rock.

Since drag bits are the more efficient type of cutting tool, it is fair to ask not only why are indenters used more widely than drag bits, but why are indenters used at all? The answer lies in the fact that the shear loading of rock by a drag bit induces bending, or tensile, stresses in the bit cutting edge. The material used for this cutting edge is brittle; generally, it is a cemented tungsten carbide. Because all brittle materials are weak in tension, this mode of loading stresses the tool in a dangerous manner that makes catastrophic failure of the bit more likely. The cutting edge of an indenter, on the other hand, can be mounted in the bit body in a manner such that this insert is loaded only, or mainly, in compression. This maximizes the strength of the tool material, which is the reason that this type of tool is widely used. Because of this limitation of tool strength, in practice today the use of drag bits is restricted to weak rock materials, such as coal or evaporites. An indentation type of tool generally is employed when drilling or cutting is carried out in any rocks stronger than these.

In fact, this discussion on the strength of the cutting tool materials really is the nub of the problem addressed in this section. Rock cutting has aptly been described as a contest between the strength of the tool and the strength of the rock. No single-strength value is appropriate for predicting the outcome of this contest. The strengths of both the rock material and the tool material depend on a number of factors, generally including:

1. Whether the material is loaded in tension or compression.
2. Whether uniaxial or multiaxial stresses are applied.
3. The sign and the magnitudes of all of the applied stresses.
4. The temperature of the material.

The reason for the higher breaking efficiency of the drag bit now is apparent. Most rocks behave as brittle materials. These materials are about an order of magnitude weaker in tension than they are in compression. Hence the energy spent by a drag bit will be low because the normal force acting on this tool is small, and thus only a small amount of work is done in rock compression by this tool. On the other hand, crushing or fine comminution of the rock requires a very large amount of energy. Since this work must be carried out in order to form rock chips with indenters, the work expended by these tools is large.

A major objective of the following discussion is to document laboratory and field experiences with various rock breaking methods in order to identify those parameters that most influence the efficiency of a breaking method.

Drills and mining machines deploy an array of one or other type of cutter on some form of powered cutting head such that a rock face is attacked by a multiplicity of cutters acting in concert. Most, but not all, cutting heads rotate about an axis disposed either parallel to or normal to the rock face. Rotary drills, continuous miners, roadheaders, shearers, bucket wheel excavators, and raise and tunnel borers all conform to this machine format. There are other machine formats such as ploughs and tractor rippers that use linear motion and external traction.

In all cases, however, rock breakage is effected by forcing a multiplicity of basically parallel and interacting wedges across a rock face to cut off a thin layer of rock. With rotary machines this process is continuous, with the cutter head moving incrementally forward as the rock is peeled off the face. It is an important feature of the machine cutting process that the wedges are made to cut, in effect, parallel to and at a relatively small depth into the exposed rock surface.

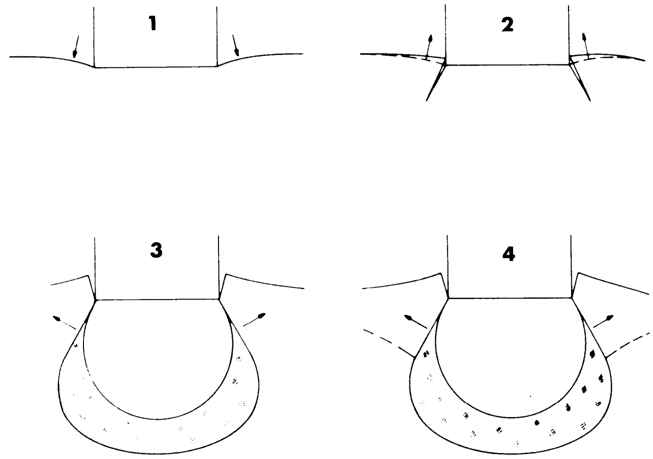

Fig. 9.1.3. Schematic representation of the failure mechanism of rock loaded by a flat-bottomed punch (after Wagner and Schumann, 1971).

These essential features have characterized machine mining from the outset of mechanization and probably will continue to dominate it for at least another generation. Research work on coal and rock cutting started with the advent of machine mining shortly after World War II and set itself the task of making the cutting process as efficient as possible. It did so by a stepwise approach to addressing the following key issues.

1. How is coal and rock broken by cutting tools operating both singly and in array?

2. What are the features of tool design and operation that characterize efficient cutting processes?

3. What are the consequences of departing from optimum design, if such exists?

4. What factors limit the application of mechanical cutting processes?

The segments that follow describe this work. For discussion of the more novel methods of rock penetration—applications as well as fundamentals—see Section 22 (e.g., Chapters 22.1, 22.3, 22.4, and 22.9).

9.1.2 ROCK:BIT INTERACTIONS

9.1.2.1 Indentation

Indentation with mechanical tools is the most widely used technique for drilling holes, ranging in diameter from a fraction of an inch (10 mm or so) to several feet (meters). With this method, the tool is placed in contact with the rock and a normal, or predominantly normal, stress is applied by the tool to the rock. The processes of fracture in brittle rock from indentation are described in this subsection.

Flat Bottomed Punches. The rock surface deforms elastically when the stress applied to a flat-bottomed indenter (punch) is at a low level (Fig. 9.1.3a). As the applied stress is increased, a Hertzian cone crack is initiated in the rock from the tool corners (Fig. 9.1.3b). As the stress continues to be increased intense comminution (crushing) of the rock takes place beneath the tool (Fig. 9.1.3c). Eventually, major fractures are initiated from the

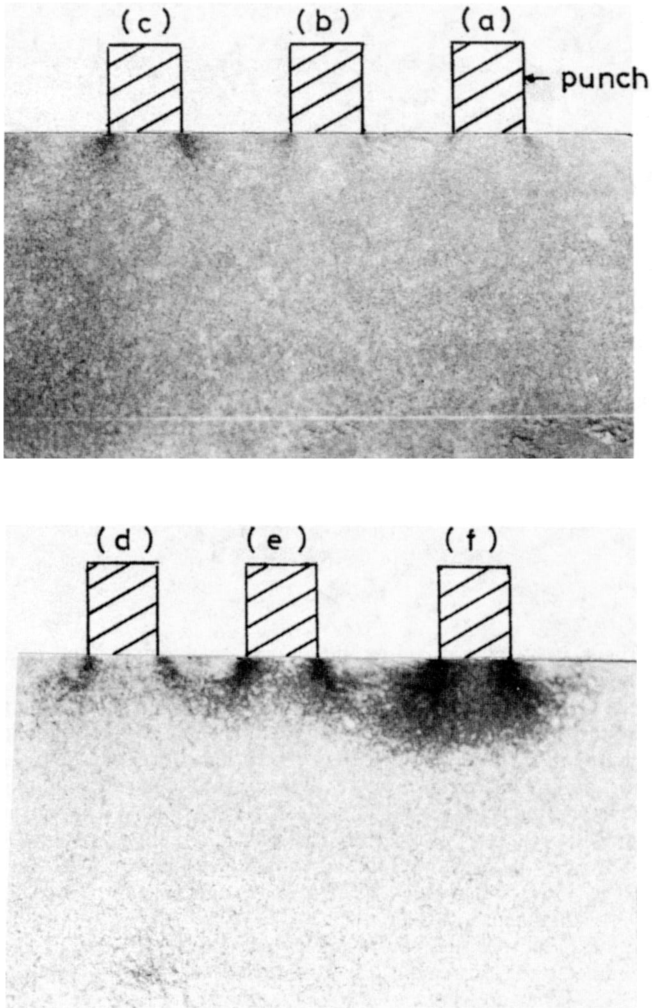

Fig. 9.1.4. Crack and microcrack development in a granite sample beneath a ½-in. (10-mm) diameter flat-bottomed punch (after Cook et al., 1984).

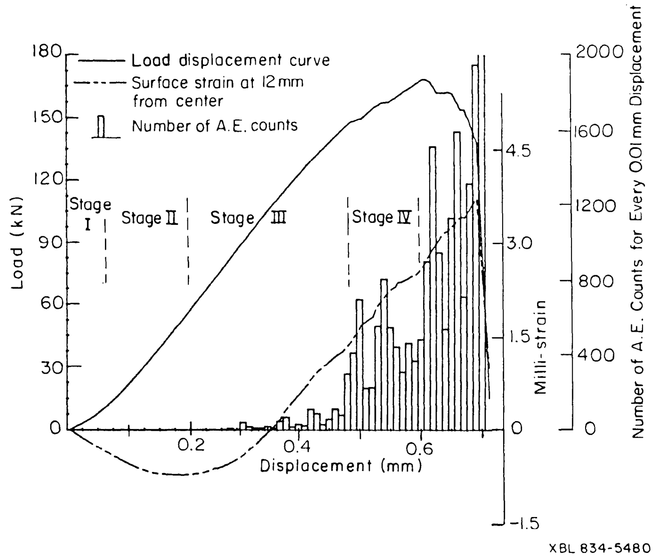

Fig. 9.1.5 Results from a typical loading cycle in granite with a ½-in. (10-mm) diameter punch, showing the punch load-displacement curve, the rock radial strain-punch displacement curve, and the number of AE events.

zone of crushed rock beneath the tool, and these propagate to the surface to form rock chips (Fig. 9.1.3d).

Cross sections through a granite sample loaded by a flat-bottomed punch are shown in Fig. 9.1.4. In this figure, the initiation of the Hertzian crack is evident in (a). As the punch load is progressively increased, the length of this crack increases in (b), (c), and (d). It is apparent from the width of the dark band indicating the crack in these photographs that this crack is surrounded by an intensely microcracked zone of rock. As the punch load is increased beyond (d), the microcracked region, indicated by the darkened region in (e) and (f), becomes much more extensive. This heavily microcracked region beneath the punch corresponds to the crushed zone in Figs. 9.1.3c and 9.1.3d.

A load-displacement curve, representative of these punch tests in granite, is given in Fig. 9.1.5. It is interesting to observe that this indentation load-displacement curve displays the same four characteristic regions observed in uniaxial or triaxial rock testing despite the obvious differences in the loading method. In Fig. 9.1.5, stage I loading corresponds to the closure of preexisting flaws in the rock. Stage II loading is the linear-elastic portion of the curve. In stage III, the rock has ceased to respond in an linear-elastic manner. In stage IV, the curve deviates substantially from linear-elastic behavior.

An understanding of the rock deformation during this loading process can be gained from inspection of the other curve and the bar chart plotted in Fig. 9.1.5. These show, respectively, values of the radial strain, measured by gages mounted on the rock surface, and the number of acoustic emission (AE) events. The energy that must be applied to extend a crack is much greater than the energy required to create new surface area on the faces of the crack. This difference is accounted for by (i) the energy consumed in the formation of the so-called process zone, this is a region where microfractures are generated in the rock ahead of the main crack, and (ii) the energy dissipated by heat and sound. The acoustic emission counts shown in Fig. 9.1.5 are measurements of the acoustic energy generated within the rock during the loading process. The number of AE counts shows the relative intensity of fracturing taking place within the rock as a function of the punch displacement.

The curve of the radial strain in Fig. 9.1.5 shows that during the initial loading, negative values of strain are observed. This indicates that the surface of the rock is in tension, corresponding to the elastic downward displacement of the rock surface shown in Fig. 9.1.3a. The maximum tensile strain takes place at the beginning of stage III on the loading curve. At this point, the Hertzian crack is initiated (Fig. 9.1.3b). As the punch load increases, this crack propagates, and the rock surface around the punch rebounds (Fig. 9.1.3b). This reduces the measured tensile radial strain. The punch continues to penetrate the rock and the radial Poisson expansion of the punch begins to exert a compressive stress in the rock at the surface. Consequently, the measured radial strain becomes positive, or compressive.

At the end of stage III loading, the rock damage has progressed to the point shown in Fig. 9.1.4e. It can be seen that the AE counts begin at some point during the stage III loading, roughly corresponding with the initiation of the Hertzian crack. The rate of fracture damage, as measured by these counts, remained at a low level until nearly the end of stage III when a sudden increase in fracturing activity can be seen. During stage

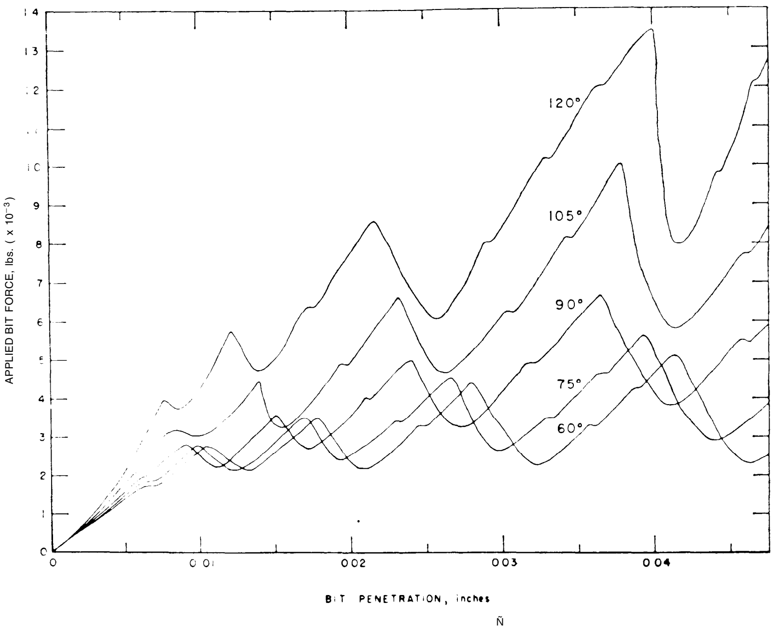

Fig. 9.1.6. Force indentation curves in Charcoal Gray Granite using a wedge indenter (after Reichmuth, 1963).

IV, an intense amount of microfracturing takes place beneath the punch (Fig. 9.1.4f), and this is reflected by the rapid increase in AE count activity. These experiments were conducted under displacement control in a stiff testing machine; consequently, it was possible to record information beyond the peak of the load-displacement curve until a rock chip formed at the surface. It can be seen that a quiescent period in AE activity took place immediately prior to the peak punch load. The AE counts were observed to increase dramatically immediately past this peak value, again indicating that major fracturing activity was taking place. Almost certainly this activity reflects the formation and propagation of the major crack (shown as a dashed line in Fig. 9.1.3d) that was to form the rock chips. The value of the measured, now compressive, strains increased in an approximately linear manner to a peak value at which point the developing crack forming the rock chip passed beneath the gage and relieved the strain.

One of the interesting findings from these indentation tests is that the stress necessary to cause the formation of rock chips decreases as the size of the punch increases (Wagner and Schumann, 1971; Cook et al., 1984). Cook and his coworkers attributed the reason for this measured change in strength with punch size to the size effect on rock strength.

Wedge Indenters: In practice, many indenters used for effecting rock breakage are wedge-shaped. Furthermore, the indenter is not pressed only once onto a pristine rock surface—usually the process is repeated many times. For example, a percussion drill bit repeatedly indents the bottom of the hole until the desired hole depth is achieved. This means that for the second loading (that is, after the formation of the first rock chips) and for all subsequent loadings, the stress applied to the intact rock to form new chips is transmitted from the indenter through a zone of crushed rock from the previous loadings. This results in an increase in the indenter (bit) force for each loading. One of the first investigators to study this phenomenon was Reichmuth (1963), and some of his results, using wedges with a variety of wedge included angles, are given in Fig. 9.1.6. Paul and Sikarskie (1965) developed a model to describe the locus of the peaks of the curves shown in this figure. This locus is the upper bound of the chipping force. The model, summarized below, sheds light on the mechanics of the rock breakage process.

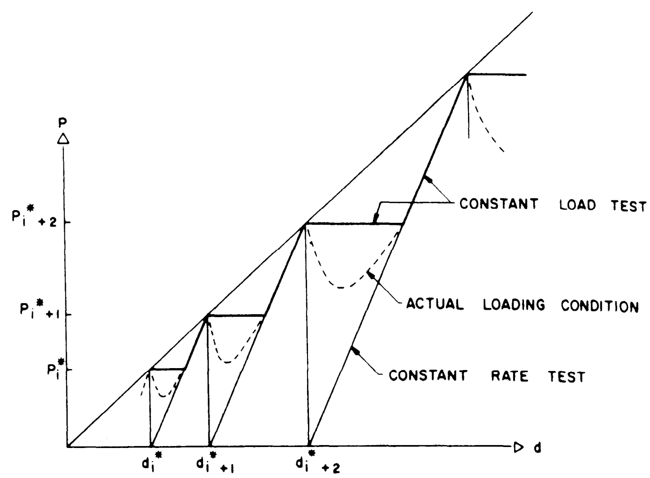

Fig. 9.1.7. Idealized loading cycles for a wedge indenter (after Paul and Sikarskie, 1965).

Paul and Sikarskie assume that the relationship between load and displacement during the loading cycle is linear and that the slope of this line, k, remains the same for the second and all successive cycles. Their model does not address the initial loading cycle. The locus describing the upper bound of the chipping force has a slope K^*. These parameters are illustrated in Fig. 9.1.7. In this figure it can be seen that the response of the loading curve between chipping cycles depends on the method of loading used. If the bit is pressed into the rock at a constant rate, then the bit force would be expected to fall to zero between cycles. On the other hand, if a constant force is applied to the bit, when a chip forms the loading system will cause the bit to advance rapidly into the rock while maintaining the load at the previous peak value. Most practical loading systems are closer to constant load than to constant displacement rate; however, these systems generally are unable to respond quickly enough to maintain the load constant immediately following the formation of a chip. Consequently the actual loading condition is more likely to be

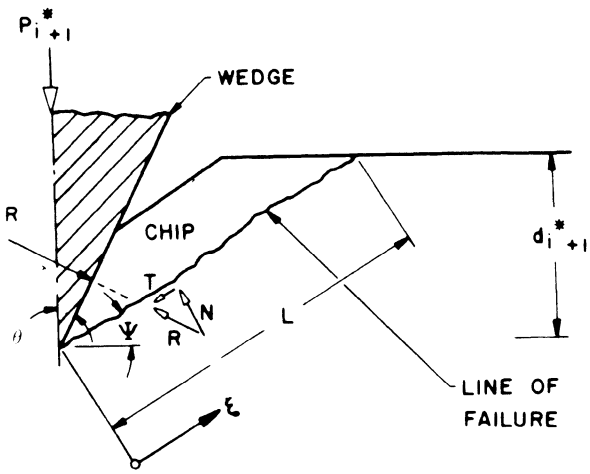

Fig. 9.1.8. Stresses acting along failure plane (after Paul and Sikarskie, 1965).

that illustrated by the dashed line in Fig. 9.1.7. It can be seen that this behavior is similar to that measured by Reichmuth (Fig. 9.1.6).

A diagram illustrating the physical representation of the breaking process is shown in Fig. 9.1.8a; the mathematical idealization is shown in Fig. 9.1.8b. The model assumes that failure along the fracture surface takes place when the Coulomb criterion is exceeded:

$$|\tau| - \mu\sigma = S_0 \tag{9.1.1}$$

where τ is the shear stress acting on the incipient fracture surface, σ is the normal stress acting on the incipient fracture surface, *m* is the coefficient of internal friction, and S_0 is the inherent shear strength of the rock.

The stresses acting along this failure plane are calculated by resolving the forces transmitted by the wedge to the rock in the manner shown in Fig. 9.1.8. When this is done and the failure criterion is applied, then the following relationship for K^* is derived:

$$K^* = \frac{P^*_{i+1}}{d^*_{i+1}} = 2C_0 \frac{\sin\theta\,(1 - \sin\phi)}{1 - \sin(\theta + \phi)} \tag{9.1.2}$$

where P^*_{i+1} is the wedge force at the formation of the 1 + *i th* chip, d^*_{i+1} is the wedge penetration at the formation of the 1 + *i th* chip, C_0 is the uniaxial compressive strength of the rock, *q* is the half-angle of the wedge, and ϕ is the angle of internal friction of the rock.

Since θ, ϕ, and C_0 are constant for a given wedge in a given rock type, this model predicts that K^* = constant; in other words, the locus of the upper bound of chipping is a straight line.

Also, substituting $P^*_{i+1} = k[d^*_{i+1} - d_i^*]$ into Eq. 9.1.2 yields

$$P^*_{i+1} = \frac{kK}{k - K} d_i^* \text{ and } d^*_{i+1} = \frac{k}{k - K} d_i^* \tag{9.1.3}$$

Hence k and d_i^* can be determined from one loading cycle. This permits the calculation of K^* as well as the loads and the displacements at all the succeeding points where chipping occurs.

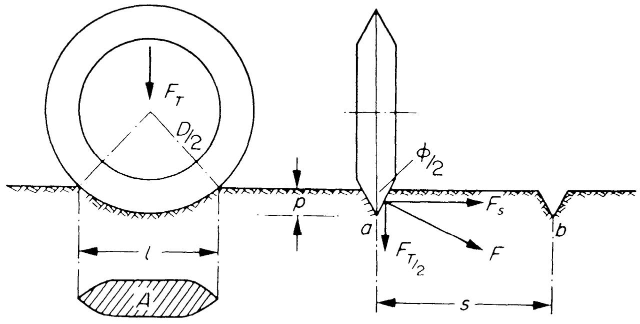

Fig. 9.1.9. Model for disk cutting (Roxborough and Phillips, 1975a).

This model overpredicts the force necessary for chipping. Recent work by Peng (1986) has shown that this problem can be overcome if an allowance is made for the effective decrease in rock strength caused by the increased area of contact between the wedge and the rock with each successive chipping cycle. Peng used a Weibull analysis to account for this effective change in rock strength. This approach yields

$$P^*_{i+1} = Kd^*_{i+1}((m - 1)/m) \tag{9.1.4}$$

where *m* is the Weibull parameter.

When m = ∞, this relationship is the same as Eq. 9.1.2. In general, however, when m < ∞, the locus of the force-displacement curve for the upper bound of chipping is not a straight line, and the model predicts that along this locus the force at any give, displacement is less than that obtained from Eq. 9.1.2. The value of m for a particular wedge in a particular rock type is obtained experimentally (Peng, 1986).

Models for Disk Cutters: Evans (1974) used essentially the same argument as Paul and Sikarskie in developing a model for rock breakage using disk cutters. Evans assumed that the cross section of a disk cutter is a wedge and derived the following relation:

$$\frac{F_T}{d} = 2\left(\frac{S_0 \cos\phi \sin(\theta + \phi_f)}{\sin^2\left(\frac{\pi}{4} - \frac{1}{2}(\theta + \phi_f + \phi)\right)}\right) \tag{9.1.5}$$

where F_T is the *thrust force on the disk* necessary to form a rock chip, *d* is the depth of cut, and ϕ_f is the friction angle between the wedge and the rock.

In a slightly rearranged form, this expression is the same as Eq. 9.1.2 with $F_T = P^*_{i+1}$ and with the term ϕ_f included to account for the friction between the wedge and the rock.

A different approach for predicting both this thrust force and the orthogonal force in the direction of cutting, the *disk rolling force,* was taken by other workers (Crow, 1975; Ozdemir et al., 1976; Roxborough and Phillips, 1975a; Roxborough and Phillips, 1975b). These researchers assumed a constant value for the indentation strength of a rock using a disk cutter. The area of the disk cutter in contact with the rock then can be calculated from considerations of the depth of rock penetration by the disk and the disk geometry. The product of this contact area at a given depth and the indentation strength then yields the thrust force acting on the disk. This approach as developed by Roxborough and Phillips (1975a, 1975b) is illustrated in Fig. 9.1.9.

The area of the disk in contact with the rock is

$$A = 2dL \tan \theta \qquad (9.1.6)$$

where L is the chord length of the disk in rock contact = $2\sqrt{Dd - d^2}$, d is the depth of disk penetration, D is the disk diameter, and q is the half-angle of disk.

Thus the thrust force F_T required to penetrate the rock to a depth d is

$$F_T = 4dC_0 \tan\theta \sqrt{Dd - d^2} \qquad (9.1.7)$$

Roxborough (1978) noted that for a free rolling disk the resultant force must pass through the center of rotation, in which case

$$\frac{F_T}{F_R} = \sqrt{\frac{D - d}{\mathrm{d}}} \qquad (9.1.8)$$

where F_R is the disk rolling force (Fig. 9.1.13)

Thus,

$$F_R = 4C_0 d^2 \tan \theta \qquad (9.1.9)$$

Eqs. 9.1.7 and 9.1.8 are plotted together with cutting force data collected by several workers in Fig. 9.1.10. It can be seen that the agreement between theory and these results is tolerable. What probably is more significant, however, is that the predicted trends in F_T and F_R with each of the disk variables are found to closely parallel measured trends. The implications are that the geometrical basis of the equations is correct but that the stress conditions applying over the disk contact area may be more complex that has been supposed.

Ozdemir et al. (1976) observed that the projected area of the disk in rock contact is given by Eq. 9.1.6 only when the disk is pressed in a quasi-static manner onto a plane surface. These authors argued that during the cutting operation, the contact area is only half of this value. In developing their model, these authors argued that the magnitude of F_T depends in part on the indentation strength of the rock and in part on that shear component of this force that causes chips to form between adjacent grooves. The following equations were derived:

$$F_T = \tan\theta \sqrt{Dd^3} \left[\frac{4C_0}{3} + 2S_0 \left(\frac{s}{d} - 2 \tan\theta\right)\right] \qquad (9.1.10)$$

$$F_R = \frac{\tan\theta \; [d^2C_0 + 4S_0\Phi(s - 2d \tan\theta)]}{D(\Phi - \sin\Phi \cos\Phi)} \qquad (9.1.11)$$

where Φ is arc $\cos\left(\frac{D - 2d}{D}\right)$ and s is the spacing between adjacent grooves.

Eqs. 9.1.10 and 9.1.11 are reported to agree reasonably well with measured data.

In contrast to this unified model of Ozdemir et al. (1976) Roxborough and Phillips (1975a) considered the interaction between disks as a separate issue to the initial disk penetration. They argued that F generated by an unrelieved disk would have the potential to shear off a rib of rock extending laterally from the disk if an adjacent groove was present. The maximum width of this rib would be determined by F_T. Accordingly, they proposed the simple model, illustrated in Fig. 9.1.9, from which they determined:

$$\frac{s}{d} = \frac{C_0}{S_0} \qquad (9.1.12)$$

Roxborough (1988) cites experimental data that accord reasonably well with Eq. 9.1.12. Other workers, notably Snowden et al. (1982), have published results that do not agree with this expression. Several workers have argued that this difficulty arises because these two models, by Ozdemir and his co-workers and Roxborough and Phillips, make the incorrect assumption that lateral breakage between grooves occurs because of shear failure. These workers argue that, on the basis of the observed failure surfaces as well as the knowledge that rock is stronger in shear than it is in tension, the chips between grooves are formed by tensile crack growth. Fenn (1985) points out that rock chips formed by multiple disks cutting adjacent grooves simultaneously are not different in appearance from chips cut by a single disk in a sequential manner. In the former case, it is apparent that a shear stress is not exerted along the fracture plane. This calls into question whether a shear failure criterion is appropriate for this fragmentation process.

Lindqvist and Ranman (1980) have developed a model for tensile failure caused by disk cutters. This model assumes that only a small fraction of the thrust force exerted by the disk is directed laterally, in other words, that most of this force is directed normally into the rock in a manner analogous to a flat-bottomed punch. The tensile stresses induce cracks that initially run parallel to the rock surface. If the spacing between grooves is sufficiently small, these tensile cracks will propagate between the grooves rather than up to the rock surface. Further, these authors argue that the elastic deformation of the surface will tend to cause the formation of chips with a convex upper surface (Fig. 9.1.11). This indeed is a feature of chip geometry that frequently is observed. Their predictive equation linking chip geometry with disk forces and rock properties is

$$F_T = \frac{2.09 \; T_0 D s^4}{16t^3(1 - \upsilon^2)} \qquad (9.1.13)$$

where T_0 is the rock tensile strength, υ is the Poisson's Ratio, and t is the chip thickness.

Results from experiments using multiple disks (i.e., more than one disk cutter on a single hub) cutting in granite are compared with theoretical values from this model in Fig. 9.1.12). The theory suggests that the spacing s is strongly influenced by the chip thickness, that is the groove depth, and this is often found to be the case in practice. Lindqvist and Ranman concede that the model relies on several tenuous assumptions, but they suggest that it constitutes a first simple expression for a tensile failure model for disk cutters.

These authors made other observations on chip formation, noting that a considerable quantity of crushed material is formed beneath the chip adjacent to the cutter. Also several fragments, 0.04 to 0.16 in. (1 to 4 mm) in size, were observed within about 0.4 in. (10 mm) of the disk. However, a clean single fracture with no debris was found over the rest of the distance between the disks.

Howarth (1980), Fenn (1985) and others report similar observations of a crushed zone and the associated crack development caused by disk cutters. For example, Fig. 9.1.13 shows carefully mapped crack distributions along with delineation of crushed zones taken from vertical rock sections by Fenn (1985).

The importance of the zone of crushed rock in indentation processes has long been recognized (Dalziel and Davies, 1964; Fairhurst and Deliac, 1986; Hartman, 1959; Maurer and Rinehart, 1960; Reichmuth, 1963) and as described before, Paul and

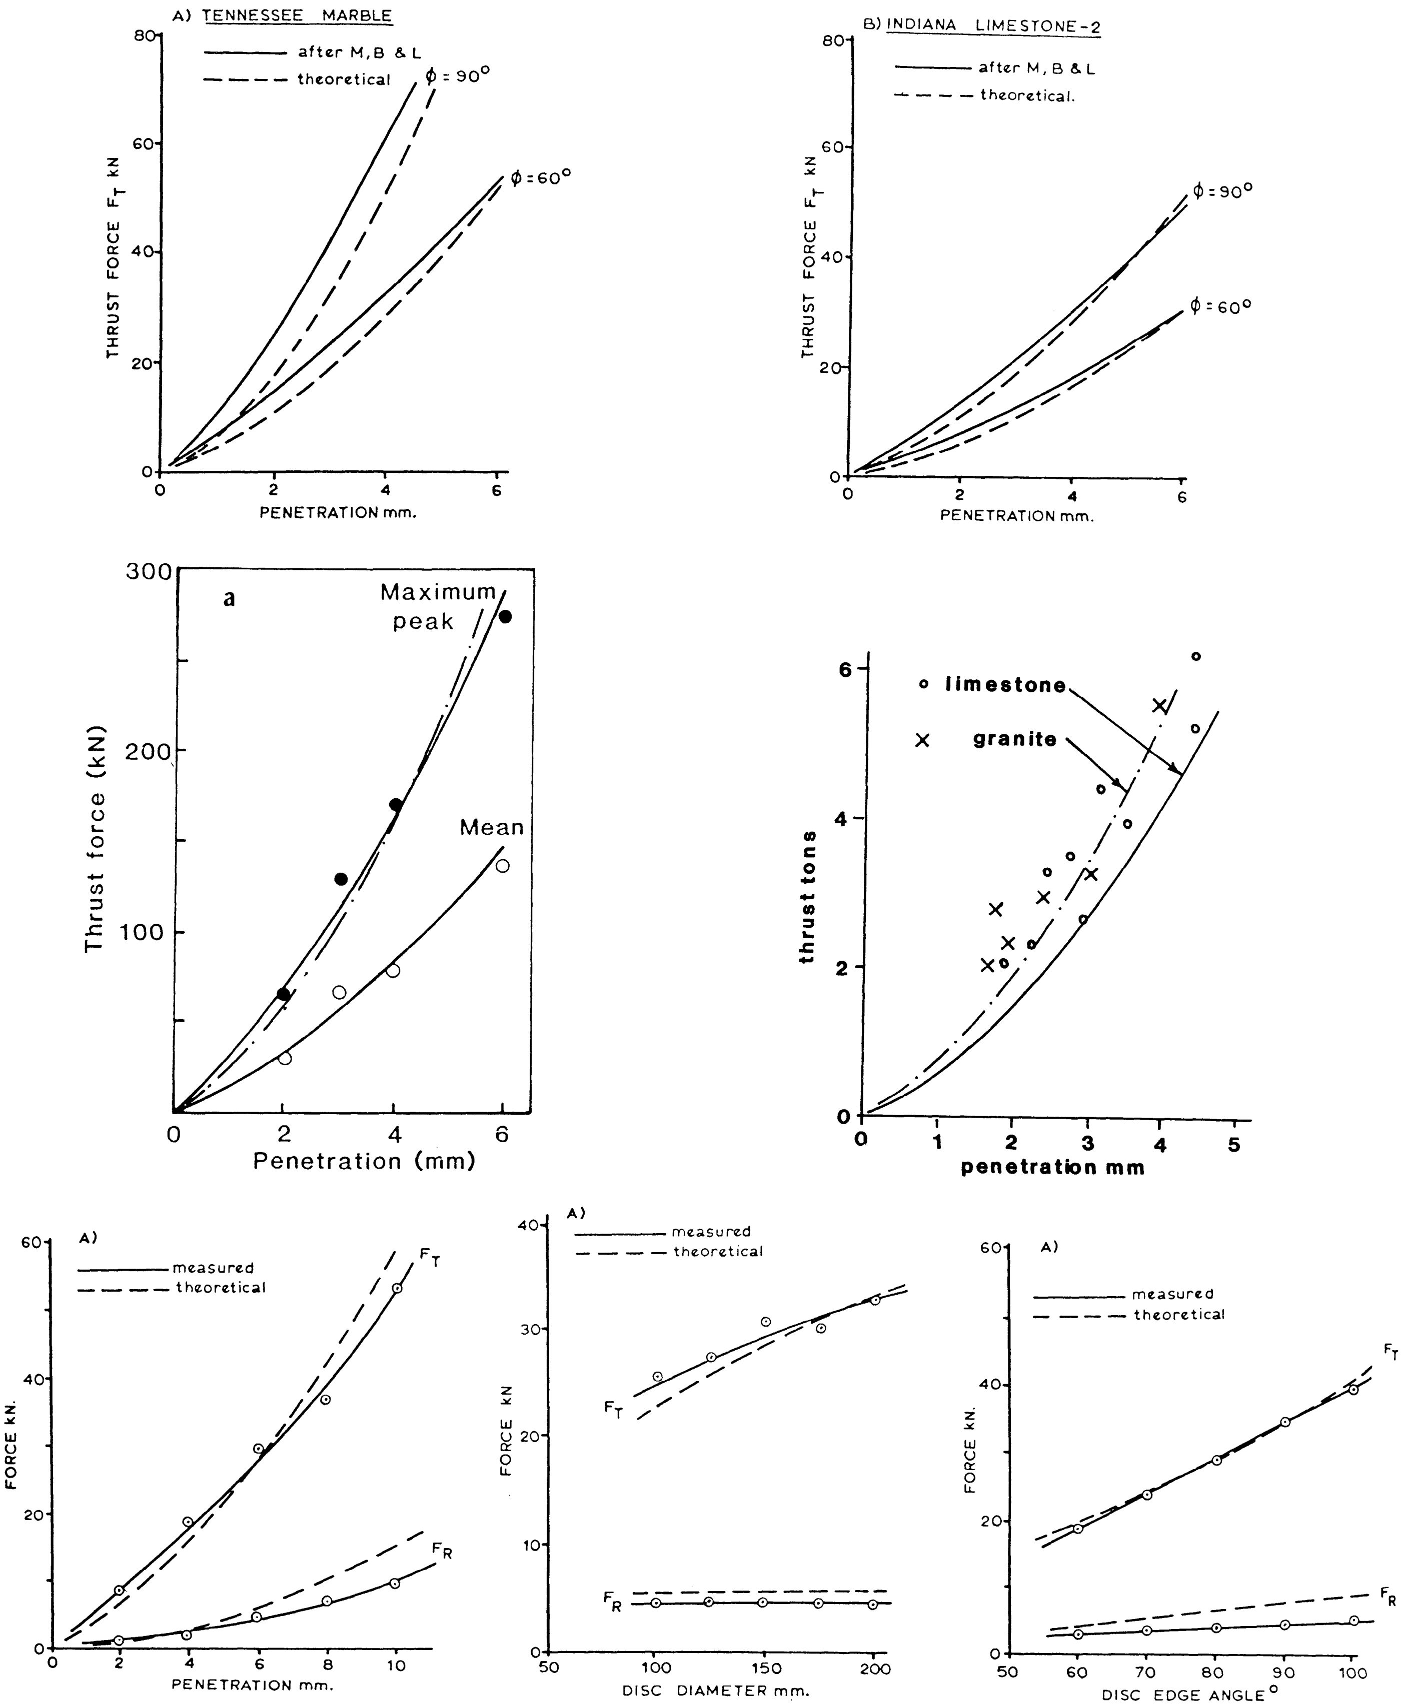

Fig. 9.1.10. Comparison of model for disk cutting developed by Roxborough and Phillips (1975a) with experimental data.

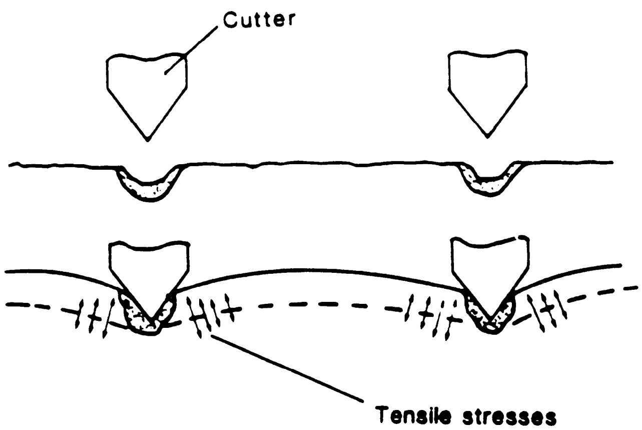

Fig. 9.1.11. Model for tensile chip formation by disk cutters (after Lindqvist and Ranman, 1980).

Sikarskie (1965). One of the first attempts to write the effects of a crushed zone into disk theory appears to come from Gaye and Stephens (198). They introduce the concept of "fragma" to describe the mass of broken material in the vicinity of the disk edge, arguing that the leading curved edge of a disk plows through the "fragma" like the bow of a boat through water. They argue further that the disk thrust force F_T required for breakage between parallel grooves arises from:

1. A component F_N corresponding to the buoyancy of the disk moving through the fragma.

$$F_N = \frac{C_0 \tan\theta}{7.5} \sqrt{Dd^3} \qquad (9.1.14)$$

2. A shear stress component $F_{N'}$ corresponding to the initial phase of the breakage process that generates the "vee" profile of the disk groove.

$$F_{N'} = \frac{sS_0 \tan\theta}{5} \sqrt{Dd} \qquad (9.1.15)$$

3. A tensile component $F_{N''}$ causing rupture of the rib of rock between the adjacent rib grooves.

$$F_{N''} = \frac{s^2 T_0 \tan\theta}{11} \sqrt{\frac{D}{d}} \qquad (9.1.16)$$

In addition, these authors calculate the rolling force acting on the cutter using the relation,

$$\frac{F_T}{F_R} = \frac{3}{4}\sqrt{\frac{D}{d}} \qquad (9.1.17)$$

The components for F_T are not additive, but they define the limiting conditions for the breakage process to proceed from one phase to the next. Gaye and Stephens draw on the observed change in performance with certain variables on a tunnel boring machine (TBM) to support the theory, and they suggest that controlled experiments should be used to test, and if necessary, to modify it.

Kutter and Sanio (1982) and Sanio (1985) have developed a model for disks taking into account the role of the crushed zone. They assume a dominantly tensile mode of failure. Their hypothesis is developed as follows (Fig. 9.1.14):

1. The high stress concentration at penetration causes a crushed zone around the edge of the disk.

2. Within the crushed zone, the stress will approximate the hydrostatic state causing tangential tensile stresses. When these stresses reach the tensile strength of the intact rock T_0, radial tensile cracks will develop.

3. One such crack will extend to the free rock surface forming a chip.

The theory is developed by assuming the crushed zone to be circular in shape. Its center is at the disk edge, and its radius is taken to be a constant fraction q of the penetration depth d.

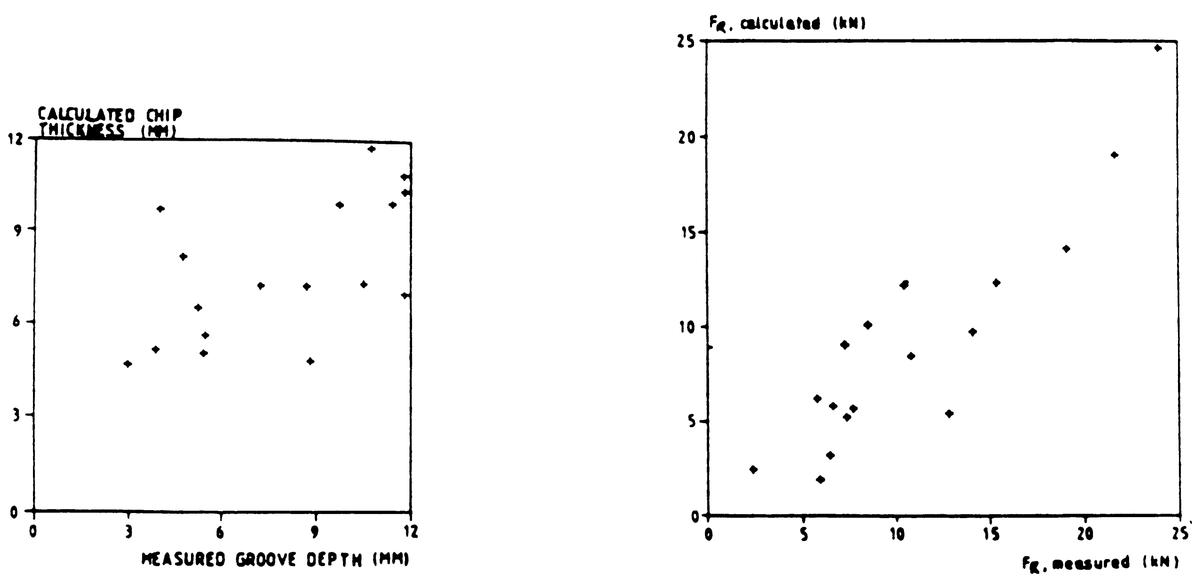

Fig. 9.1.12. Measured and predicted chip thicknesses and disk cutting forces (after Lindqvist and Ranman, 1980).

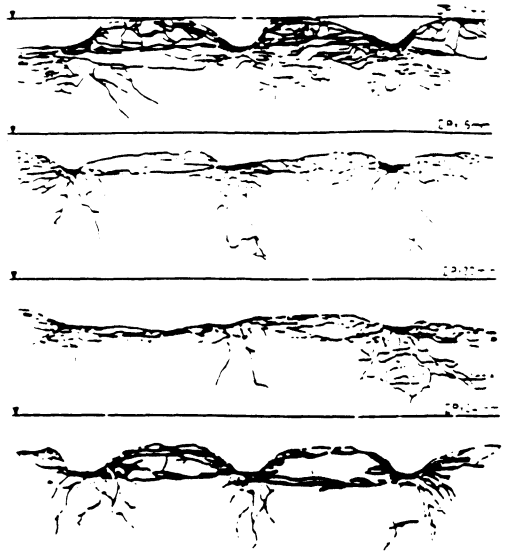

Fig. 9.1.13. Development of cracks by interacting disks (after Fenn, 1985).

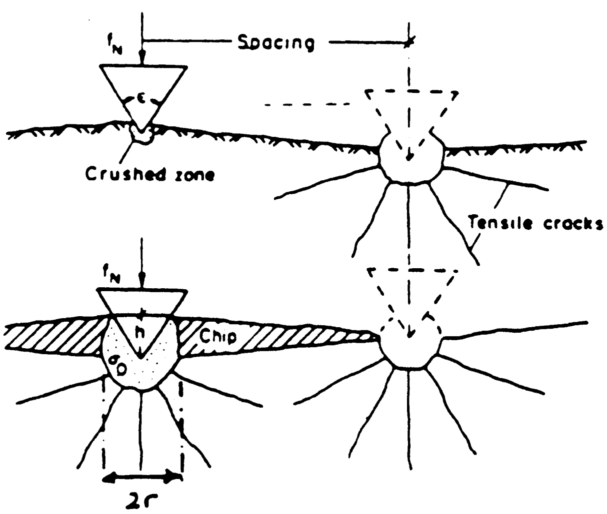

Fig. 9.1.14. Tensile breakage model for disks (Sanio, 1985).

Sanio introduces a critical stress intensity factor, or fracture toughness, K_c, adopting Ouchterlony's (1974) relation,

$$2\sigma_0 r = Kc\sqrt{a} \qquad (9.1.18)$$

where σ_0 is the hydrostatic pressure in the crushed zone, r is the radius of the crushed zone, and a is the crack length.

It is assumed that the crack length increases from zero at the leading edge of the disk to a maximum value of S, whereupon a chip is formed. This leads to the following equation:

$$F_T = \frac{2K_c \tan\theta}{3q}\sqrt{S(Dd - d^3)} \qquad (9.1.19)$$

Sanio calculates the cutter rolling force using,

$$\frac{F_T}{F_R} = \frac{5}{4}\sqrt{\frac{D}{d}} \qquad (9.1.20)$$

Sanio defines $\dfrac{K_c}{q} = S_K$ as a cutting constant that depends on the strength and defect structure of the rock as well as the number of radial cracks and the geometry of the crushed zone. This large number of variables precludes a theoretical determination of S_K. Sanio reports values for S_K in a single rock type ranging from 0.17 to 0.47, with a coefficient of variability of about 10% in each case, depending on the schistosity orientation. The Kutter-Sanio model has been tested by Sanio (1985) against experimental data using different disk cutter geometries in 14 different rock types with varying degrees of anisotropy. Sanio reports that the mean deviation between the measured and the predicted disk forces was less than 20%.

Indentation—Summary: In Paul and Sikarskie's model, the shear force acting along the fracture plane is assumed to be responsible for inducing rock failure. The magnitude of this force is determined by resolution of the force components acting on the wedge. From this argument, the force required to cause failure should be a function of the wedge included angle. Clearly from Fig. 9.1.6 this is the case. Also, when this included angle exceeds a critical angle, the ratio of the shear stress to the normal stress along the failure plane should fall below the Mohr-Coulomb criterion, and no failure should take place. A flat-bottomed punch simply is a wedge with an included angle of $\pi/2$; obviously, this exceeds the critical angle, yet failure does occur. It follows that, depending on the geometry of the indenter, more than one mechanism is causing rock failure.

Three processes have been identified during the loading operation with the flat-bottomed punch. First, Hertzian cracks are developed, then intense crushing of the rock beneath the punch takes place, and finally cracks initiating from this crushed zone develop to form rock chips. The second of these processes is associated with dilatation that causes tensile stresses to be induced in the intact rock surrounding the crushed region. Consequently the crack that forms the rock chip is initiated when this tensile stress exceeds the rock tensile strength.

It is likely that this rock failure mechanism also plays a role, perhaps even a substantial role, when wedges with smaller included angles are used to load the rock. It is fairly clear, for example, that the rock chips induced by wedge-shaped disk cutters on a boring machine are not shear cracks, because the surfaces of these cracks show none of the gouge damage usually associated with shear failure. Rather, these crack faces are clean and have the characteristics associated with tensile failure including, sometimes, a visible transition at the point where the crack length had grown sufficiently for the fracture to become unstable. Thus, while Paul and Sikarskie's model predicts that failure takes place as the result of an applied shear stress, and the Coulomb-Mohr criterion in a modified form seems adequate to predict the magnitude of the applied stress necessary to cause this failure, rock breakage takes place because a tensile fracture is initiated and propagated. This fracture is induced as a result of a combined loading: first, the tensile extension of preexisting flaws along the fracture plane and second, by tensile stresses induced by the crushed zone beneath the wedge. Korbin (1979) described this loading as a pressure bulb.

9.1.2.2 Drag Bits

The action of sharp drag bits is to cleave rock chips from the face (Fig. 9.1.15). Although a shear force is applied to the

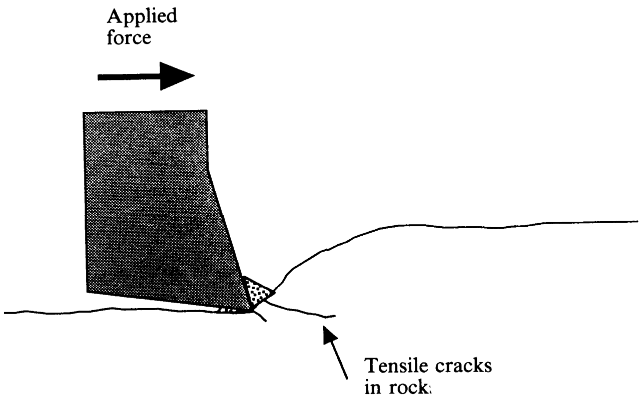

Fig. 9.1.15. Shear force applied to the rock by a drag bit inducing tensile crack growth in the rock.

rock by the bit the rock breaks as the result of tensile crack growth (Fig. 9.1.15).

Drag Bit Forces: From the outset of studies in rock cutting mechanics, attempts have been made to describe the action of cutter drag bits in mathematical terms. An early effort sought to borrow from the field of metal machining theory by adapting Merchant's (1944) continuous cutting (elastoplastic) model to the discontinuous (brittle, discrete chipping) regime of rock cutting. Thus Shuttleworth offered the equations:

$$F_C = \frac{S_0 dw \cos(\phi_f - \alpha)}{\sin\phi \cos(\phi + \phi_f - \alpha)} \qquad (9.1.21)$$

$$F_T = \frac{S_0 dw \sin(\phi_f - \alpha)}{\sin\phi \cos(\phi + \phi_f - \alpha)} \qquad (9.1.22)$$

where a is the tool rake angle, and w is the tool width.

A good qualitative and limited quantitative value was ascribed to the model in that it:

1. Indicated a linear increase in drag bit forces with depth of cut.
2. Described the monotonic decrease in forces with increasing rake angle.
3. Showed drag bit forces to increase linearly with rock strength, in this case specifically shear strength.

The model is limited, however, in the sense that it is a two-dimensional description of what in reality is a three-dimensional process. Furthermore, the observed chip failure patterns caused by wedge penetration into coal were argued to be essentially tensile, rather than shear, in character.

The first discretely rock cutting theory was proposed by Evans (1962). It arose from studies of the failure produced when a simple wedge was pushed into coal. The penetration rate was at a very slow rate, and photographs were taken at intervals during the process. Some crushing of coal was evident in the vicinity of the wedge surface, but the most interesting feature was a lengthy crack extending from the edge of the wedge that moved ahead into the unbroken coal.

The breakage pattern was even more revealing when the wedge was made to penetrate parallel to, and some distance in from, a free surface (Fig. 9.1.16). This was argued to be more representative of the practical cutting situation. Here the major, and often the only, crack occurred as a curved arc originating at the drag bit tip and emerging at the coal surface. This resulted in the formation of a large chip.

Evans argued such failure to be essentially tensile and considered the limiting equilibrium of the chip, assumed to be a circular arc, under the action of three principal forces and by invoking the minimum work hypothesis developed the equation,

$$F_C = \frac{2T_0 d \sin\theta}{1 - \sin\theta} \qquad (9.1.23)$$

where F_C is the tool cutting force, i.e., the force component in the direction of tool motion.

This model was for a symmetrical wedge that is untenable in practice and so it was adapted to the asymmetric geometry to give

$$F_C = \frac{2T_0 d \sin\frac{1}{2}\left(\frac{\pi}{2} - \alpha\right)}{1 - \sin\frac{1}{2}\left(\frac{\pi}{2} - \alpha\right)} \qquad (9.1.24)$$

It was found by experiment that this expression gave the right sort of variation of cutting force with wedge angle. Further studies of wedge penetration into different rocks showed the curved chip formation to dominate.

As an aside, the rock breakage patterns deliberately generated by stone masons from ancient times when dressing blocks of rock conform closely with those described by Evans, and the durability of the resulting rock surfaces lends support to the notion of a single dominant curved crack being the cause of breakage. Nevertheless, it was noticed that chip formation was not always curved but could be flat. Indeed, as the rake angle of a drag bit reduced, it was more likely that chips would tend to be pushed off as opposed to being prized off. Accordingly, Nishimatsu (1972) has proposed an alternative model by invoking a Coulomb-Mohr failure criterion along a plane leading to an equation for the generalized drag bit force *F:*

$$F = \frac{2S_0 dw \cos\phi}{(n + 1)\,[1 - \sin(\phi - \alpha + \phi_f)]} \qquad (9.1.25)$$

where n is the stress distribution factor.

The cutting (F_C) and normal (F_N) components are given as

$$F_C = F\cos(\phi_f - \alpha) \qquad (9.1.26)$$

$$F_N = F\sin(\phi_f - \alpha) \qquad (9.1.27)$$

As with the Shuttleworth and Evans models, this one also suggests a linear increase in drag bit force, with both cutting depth and rock strength and a monotonic reduction in force with increasing rake angle. In other words, the three models predict the same basic force trends for the principal cutting variables. Little confidence, however, can be attached to them in the quantitative sense although they may show tolerable agreement with the idealized two dimensional situations they represent. Another limitation is that the models all attempt to describe the simple wedge, and this shape is not common in practice.

In this latter context, Evans has proposed a model for pointed drag bits. For this, he postulates the rupture of rock by means of a circular hole having its axis parallel to the surface of a semi-infinite medium, which is subject to internal pressure (Fig. 9.1.17). Radial compressive stresses in the rock are accompanied by tensile hoop stresses to cause cracks to open up at the interface between the hole and the rock when the stress equals

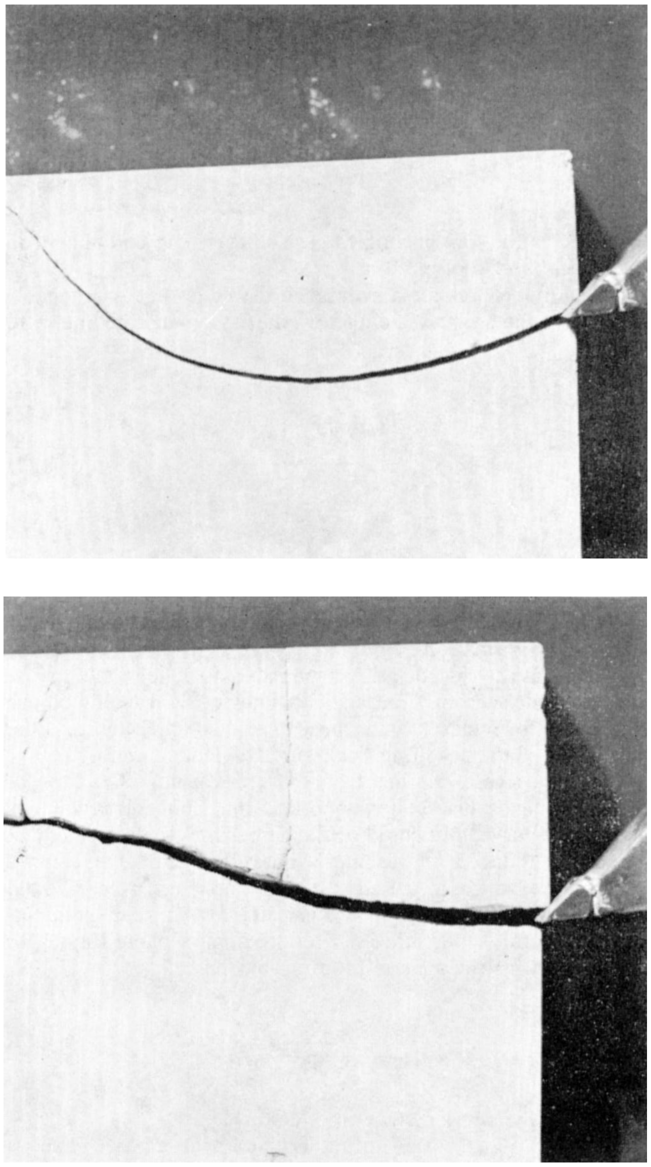

Fig. 9.1.16. Chip formation in coal by wedge penetration parallel to a free surface (after Evans, 1962).

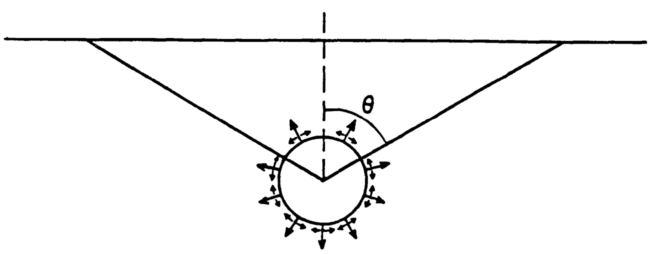

Fig. 9.1.17. Model for rock failure using pointed drag bits (after Evans and Hurt, 1979).

the tensile strength of the rock. Judging by the breakage patterns produced by pointed drag bits, a major crack will propagate to the unstressed surface to each side of the hole at an angle *q.*

The angle *q* is calculated by considering the limiting equilibrium of the half segment of the rock chip under the action of three forces. The value of *q* at which breakage takes place is argued to be that which minimizes the energy of radial displacement produced by a compressive stress *q*. This is calculated to be 60°, which is of the right order for the breakout angle found in practice.

Theoretical explanations of the effect of blunting on drag bit forces have been offered by Dalziel and Davies (1964). Employing Griffith's hypothesis, they suggested that the indentation force *F* required to penetrate a wedge presented normally into a rock surface would vary according to the radius of wedge tip r_1:

$$F\alpha\sqrt{r_1} \qquad (9.1.28)$$

Controlled coal cutting experiments with drag bits having artificially generated wear lands showed this relation to be valid, a plot of F against width of wear land yielding the exponent 0.52 ± 0.05.

Evans (1965) used this relation to adapt his tensile theory for wedge action to take account of drag bit blunting. He assumed that, for a wedge having an included angle of $2q$ with a wearflat $2b$ ground perpendicular to the wedge axis, the compressive force needed to initiate a tensile crack would be proportional to

$$F \alpha 2b^M \tag{9.1.29}$$

where M is a constant.

Evans went on to derive the equation,

$$F_C = 2T_0 d \left[\frac{\sin(\theta + \phi_f)}{2 \sin A \cos(A + \theta + \phi_f)} + 2^{(M-1)} \left(\frac{C_0}{T_0}\right)\left(\frac{b}{d}\right)^M \left(1 + \frac{\sin A \sin(\theta + \phi_f)}{\cos(A + \theta + \phi_f)}\right)\right] \tag{9.1.30}$$

Values for A in Eq. 9.1.30 are determined from

$$\frac{\cos(2A + \theta + \phi_f)}{1 - \cos 2A} = 2^{(M-1)} \left(\frac{C_0}{T_0}\right) \left(\frac{b}{d}\right)^M \cos(\theta + \phi_f) \tag{9.1.31}$$

The equation shows very good approximation to the experimental results of Dalziel and Davis when (C_0/T_0) is 6.25 and M is 0.67, whereas on theoretical grounds M should be 0.5 and (C_0/T_0) should be between 8 and 10.

The equation conforms with measured data in that progressive blunting does not have a proportionate effect on forces. It does not, however, provide any insight into the disproportionate increase in normal force over cutting force as wear proceeds.

Effect of the Principal Cutting Variables: Results from rock cutting experiments with picks have been reported from many laboratories worldwide. These cover a wide range of cutting conditions (pick shape, rock type, etc.). Inevitably, there are some conflicts of evidence, but some generalities do emerge that can be regarded as fundamental features of pick cutting.

Before describing these, some further definitions are required. Pick performances are usually defined in terms of mean and peak values of F_C and F_N. A further important performance parameter is, however, specific energy E_s, which relates cutting force to the amount of rock produced. It is defined as the work done per unit volume of rock excavated. There is also a wide variety of pick types characterized by shape (chisel, round bottom, v-front, v-bottom, pointed) and various attendant angles (rake, bottom clearance, side clearance, attack, v-front, v-bottom). Most of these have been studied, but the effects of those angles describing the more complex shapes appear to be of no more than marginal significance to the cutting process. Consequently, consideration of picks is confined to three essential shapes: the simple chisel, the round bottomed tool, and the pointed tool. These are illustrated, showing their principal geometric features, in Fig. 9.1.18.

The generalities of pick performance are now summarized with reference to Figs. 9.1.19 to 9.1.23.

1. Both F_c and F_N increase with d for all pick shapes. In most circumstances, the increase is approximately linear from or close to the origin (Fig. 9.1.19a). When using wide picks at depths much less than their width, the force increases may not be linear. Because it is largely irrelevant to the practical situation, this latter condition has not been studied in detail.

2. Specific energy varies inversely with depth of cut for all pick shapes (Fig. 9.1.19b). In other words, cutting efficiency improves with depth of cut. This arises from item 1, thus

$$E_s = \frac{F_C 1}{A * 1} = \frac{k_1 d}{k_2 d^2} = \frac{\text{constant}}{d} \tag{9.1.32}$$

3. Cutting and normal forces decrease monotonically with increasing rake angle (Fig. 9.1.19c). Most of the benefit to pick forces has been achieved at a rake angle of 20°, beyond which further marginal improvement is at an increasing penalty to pick strength and its potential to survive.

4. Increasing back clearance angle reduces pick forces up to about 5°, beyond which forces are independent of this angle (Fig. 9.1.19d).

5. Cutting speeds of up to 17 fps (5 m/s) and possibly someway beyond have no discernible affect on pick forces or specific energy.

6. Given that speed has no direct effect on pick forces and that cutting efficiency improves with cutting depth, it follows that for a given available power, greater production will be achieved by cutting slowly and deeply than at a faster and proportionately more shallow depth.

7. For a chisel-shaped pick, F_C and F_N increase linearly with pick width (Fig. 9.1.19e). The intercept on the ordinate is the force attributable to the production of breakout. In general, the breakout component appears to require about the same specific energy as the component of breakage corresponding to the area swept by the pick.

8. Pick forces increase approximately linearly with rock strength. Because of rock heterogeneity, it is difficult to say which of the strength parameters, if any, dominates the situation. Figs. 9.1.20a and 9.1.20b show the relation between, respectively, unconfined compressive and tensile strengths and pick cutting force. Both are substantially linear. These data come from controlled cutting experiments using rock samples from different geographic locations and vertical horizons in a single massive sandstone formation.

9. Further on the matter of rock strength, when a rock is saturated, it invariably leads to a reduction, often quite large, in mechanical strength. It might be expected, therefore, that saturation would correspondingly lead to a reduction in pick cutting forces. This is not necessarily found to be the case. What few data are available show pick forces to increase in saturated rock. The reasons are not fully understood but are believed to be due to pore water dissipating the high local stress concentrations normally associated with crack development.

10. For picks of different shape but having the same rake and clearance angles and operating at the same depth of cut, the pointed pick requires the least cutting and normal force. The chisel pick requires the highest forces with the round-nosed pick taking an intermediate position. However, because the chisel pick cuts a disproportionately larger volume of rock than the other two shapes, it cuts with the lowest specific energy and is thereby the most efficient shape. The pointed pick is the least efficient. Indeed, controlled laboratory tests, in whatever rock, invariably show the chisel-shaped pick to be the most efficient of all shapes. Shape features such as a ridged front, v-bottom, round bottom, side rake, and point are all less efficient than the simple chisel when operating at the same depth of cut. It is important, however, to stress the qualification "at the same depth of cut." The pointed pick because of its better penetrating capability (lower normal force) can, for a given available normal force, achieve a larger depth of cut than the chisel or other shapes. It can thereby operate more efficiently than the chisel by virtue of its ability to cut more deeply (Fig. 9.1.21).

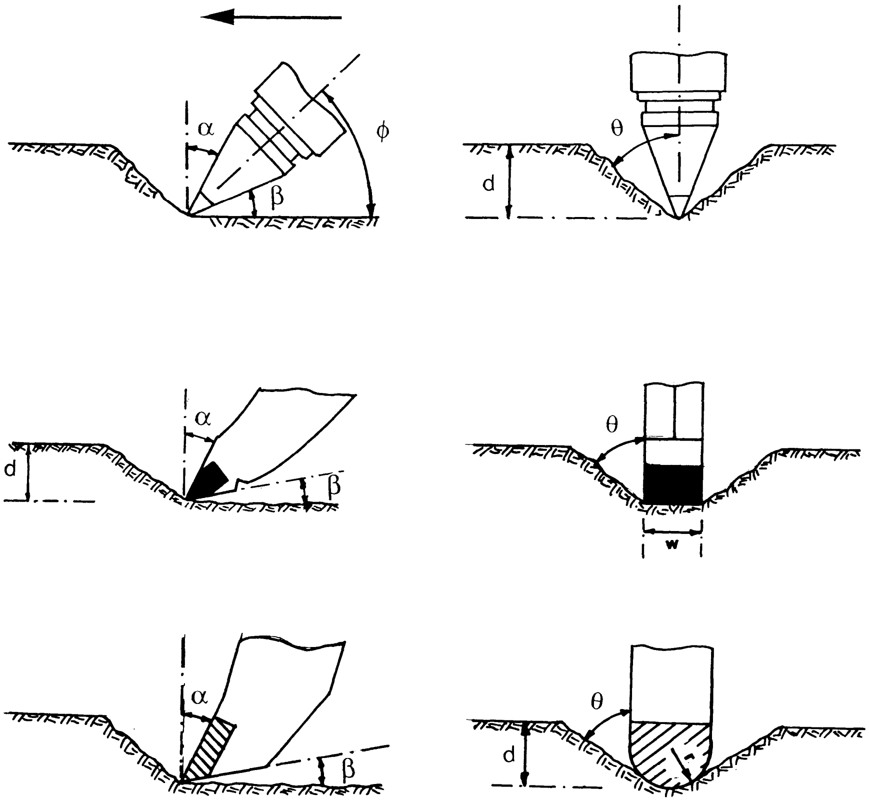

Fig. 9.1.18. Pick shapes.

11. There is strong evidence that the coarseness of the rock broken during cutting increases with cutting efficiency. The generality appears to be that, in a given rock, any combination of cutting variable that leads to an increase in cutting efficiency (reduction in specific energy) causes a corresponding increase in the coarseness of the product, and by inference (with some supporting experimental evidence) a reduction in the amount of potential airborne dust (Figs. 9.1.22 and 9.1.23).

12. Few data are available on the effects of pick rigidity. Some experiments using a stiff but compressible backing to the pick showed no discernible effect on cutting forces or specific energy. Energy stored by the compliant backing material on release produced no measurable beneficial or deleterious effect and was dissipated by propelling broken rock fragments away from the cutting edge at high velocity. An aspect of pick rigidity that appears not to have been studied to any significant extent is its effect on pick damage.

Drag Bit Interaction: Evans (1974) looked at the lateral breakage induced by both chisel and pointed drag bits as a quite separate issue to his forward breakage models. For chisel drag bits, he considered the geometry of the section of a cut made in a rock surface and assumed breakout to start from the corners of the cut and to propagate towards the surface, the lines of breakage making an angle *g* to the horizontal.

He considered unit extent of this model and the forces acting on section AOBC at breakage. This leads to an equation for breakout angle (π/2 − *g*):

$$\tan\gamma = \frac{1}{5}\left[\frac{w}{d} + \sqrt{\left(\frac{w}{d}\right)^2 + 20}\right] \qquad (9.1.33)$$

and thereafter the maximum separation between drag bits is derived from the simple geometric relation,

$$s = w + 2d\cot\gamma \qquad (9.1.34)$$

Eq. 9.1.33 yields values for *g* which are significantly larger (i.e., smaller breakout angle) than are commonly found in practice. However, the equation does indicate only a small variation in *g* over a wide but sensible practical range for both *w* and *d*. This is much in line with practical experience.

Evans and Hurt (1979) offered a solution for the spacing between pointed drag bits based on an extension of his pointed drag bit cutting theory. This considered the rupture of the rock between two parallel holes each being stressed by a drag bit (Fig. 9.1.24), which resulted in the equation

$$s = 2d\sqrt{3} \qquad (9.1.35)$$

The breakout angle caused by single pointed drag bit breakage (Fig. 9.1.17b) was determined to be a constant 60°. And two adjacent grooves at this angle that just meet at the rock surface are exactly defined by Eq. 9.1.35 (i.e., $\tan^{-1}\sqrt{3} = 60°$). This is the same result as obtained for breakout with chisel-shaped drag bits, thus suggesting that the breakage pattern for both chisel and pointed drag bits is essentially the same.

Studies on the interaction between adjacent parallel picks have been reported from several laboratories covering a range of rocks. The generalities that emerged from these studies are summarized.

1. Cutting with an array of picks involves each pick passing through the rock in sequence. Each pick thereby has the opportunity to exploit the relief provided by an adjacent groove produced by a preceding pick in the sequence.

2. There is an optimum spacing between adjacent picks in an array that is consistent with minimum specific energy. This optimum spacing increases with depth of cut, but because of

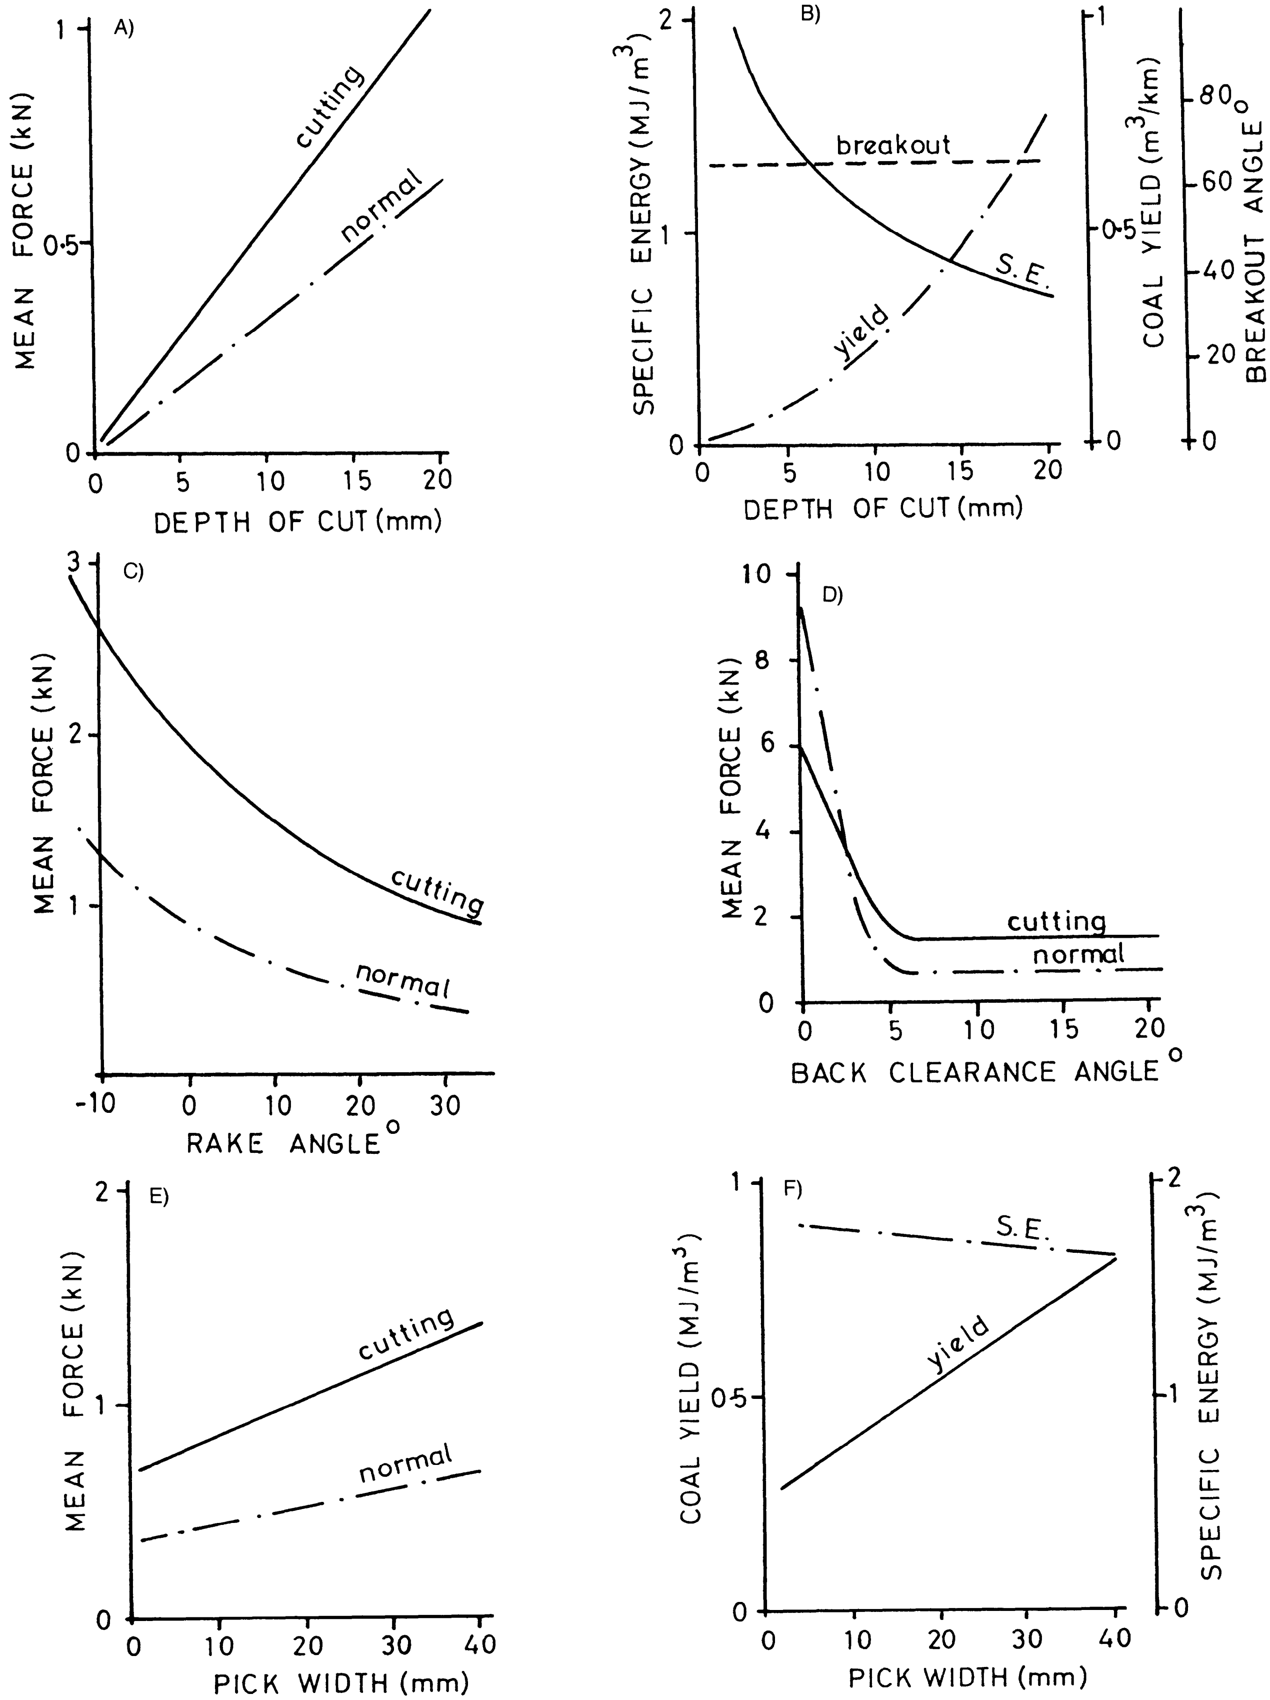

Fig. 9.1.19. Effect of principal cutting variables on pick performance.

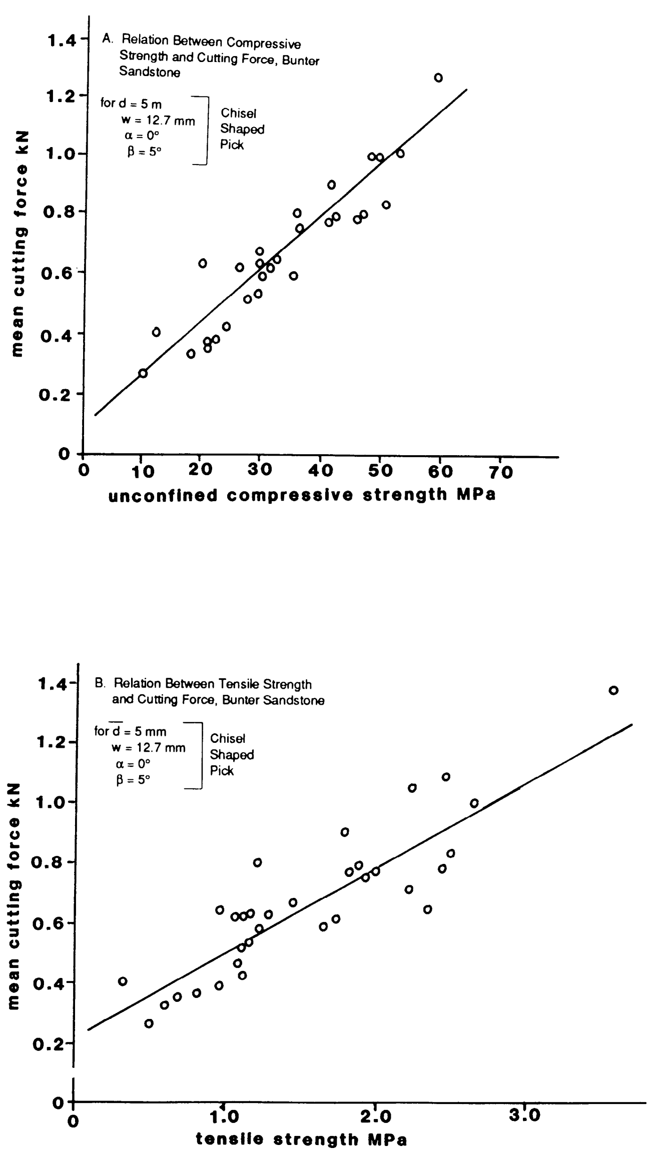

Fig. 9.1.20. Effect of rock strength on cutting force.

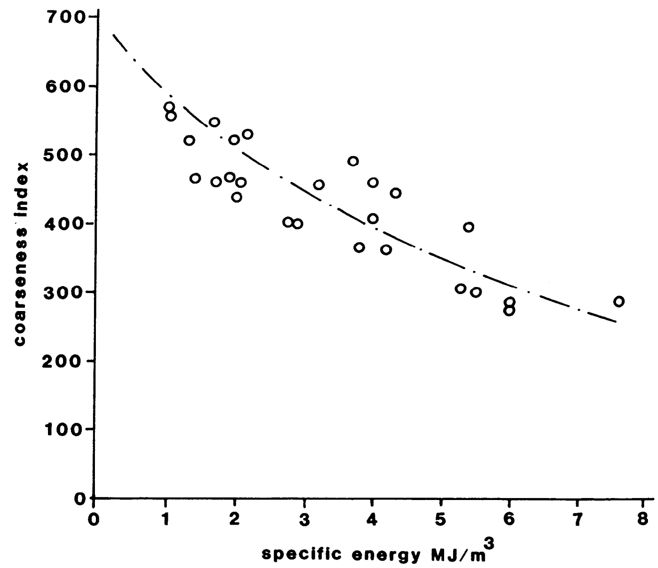

Fig. 9.1.22. Variation of product coarseness with cutting efficiency.

geometric consistency (as shown in Fig. 9.1.25), the optimum spacing can be expressed as a multiple of cutting depth. This is a singularity known as the spacing-depth ratio and its optimum value is found to be reasonably constant in a given rock.

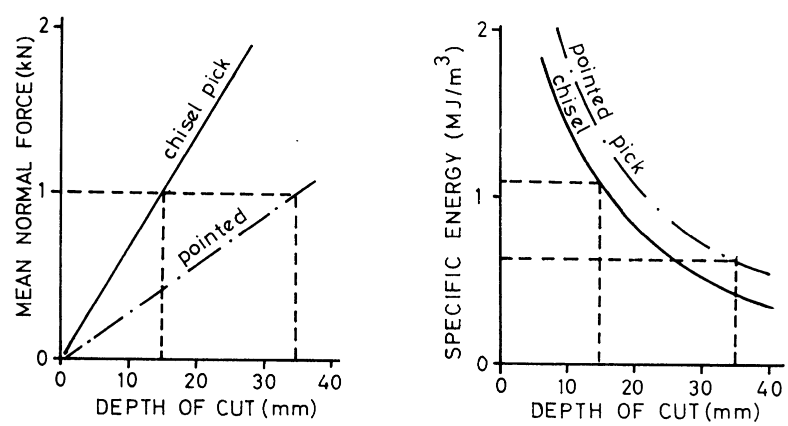
3. Values for optimum *s/d* ratio with pointed picks have been found to range from about 1.5 to 3.0, according to rock type. With chisel picks, the interaction between pick width and spacing has to be taken into account as illustrated by Fig. 9.1.26. Spacing refers essentially to the land of rock between adjacent cutters which for chisel picks is described by *s–w*. For pointed picks, where *w* is sensibly zero, *s–w* reduces to *s*.

4. It is commonly found that interaction between adjacent picks ceases when $(s-w/d) \leq 2 \tan g$. This defines any distance beyond the point where the breakout originating from adjacent picks meet at the rock surface.

5. It is also found that the optimum spacing is usually about one-half (i.e., = tan *g*) the limit of pick interaction.

6. At spacings less than the optimum, specific energy increases rapidly and reaches a maximum at zero spacing, that is, when a pick tracks in the same groove as the preceding pick. This situation is consistent with the implications of Eq. 9.1.32 as $d \rightarrow 0$.

Fig. 9.1.21. Relative performances of pointed and chisel picks.



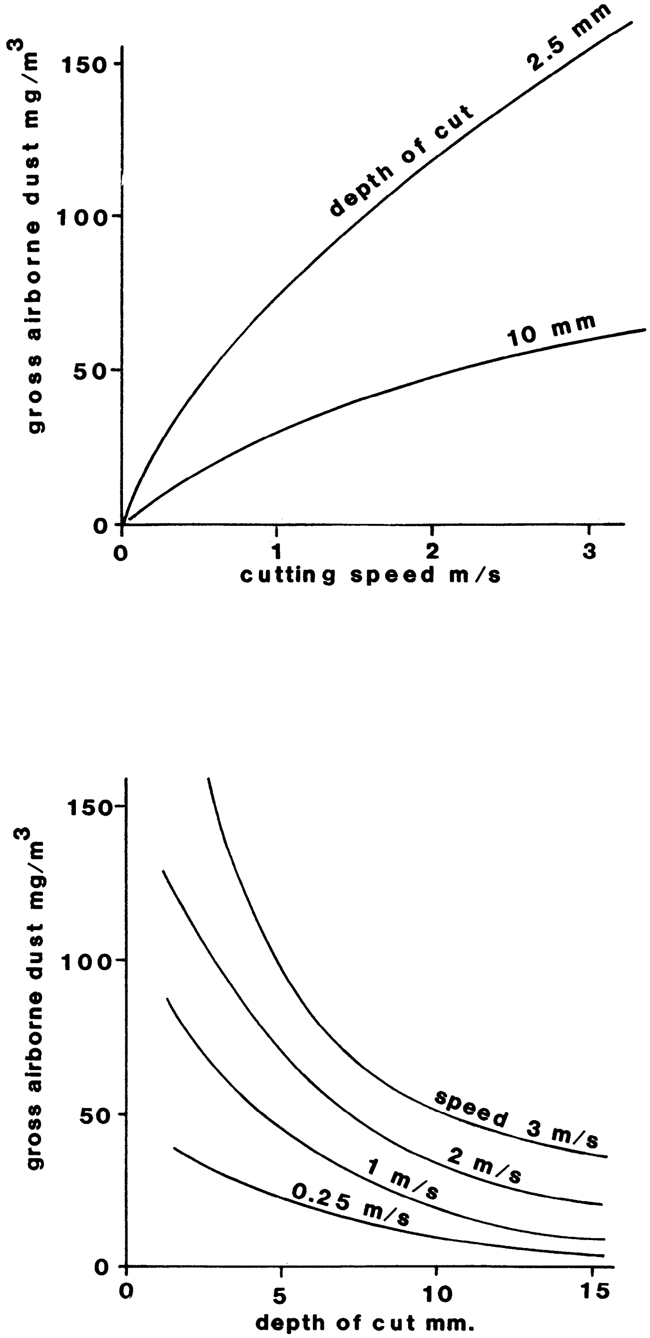


Fig. 9.1.23. Effect of depth of cut on dust generation.

7. Pick forces are at a minimum for $s = 0$ and increase approximately linearly as spacing increases, to reach a maximum equal to an unrelieved pick for $s \geq 2\ d\ \tan g$. Some typical force data expressed as a fraction of the unrelieved forces are shown in Fig. 9.1.27.

8. Practice commonly involves the following pick in an array overcutting (i.e., cutting deeper than) the preceding adjacent pick. This arises from a forward axial motion of a drum being superimposed on its rotational motion. It is thought that this and other associated factors such as variable cutting depth and cutting through generated surfaces can have little, if any, notable effect on the established principles.

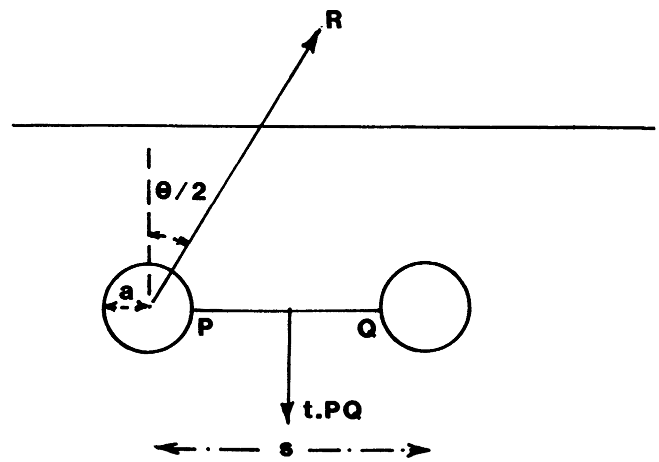

Fig. 9.1.24. Interaction of adjacent pointed drag bits.

9. Every excavation has at least one corner that defines the boundary of the cutting area, and some picks are required to cut in this region. Measurements show that the cutting force for corner cutting is typically two to three times higher than for cutting an unbounded surface. Normal force, however, appears not to increase in the same proportion and is between one and two times higher. The confinement of the corner inhibits rock breakage, and so the volume of rock cut is reduced. This leads to the specific energy for corner cutting picks to be typically three to four times higher than for face picks.

10. Situations can arise in practice where the achievable depth of cut is less than is required for effective pick interaction. This leads to a situation known as groove deepening where adjacent cutters, which fail to interact in a single pass, make repeated deepening passes in the same tracks. This does not, however, lead to breakthrough between adjacent grooves. There is a progressive loss of breakout as the grooves are deepened with no prospect for initiating interaction. Groove deepening is, in fact, a very inefficient process.

11. The cutting sequence of an array of picks should be arranged such that the first pick in the sequence is able to exploit any available free surface. Thereafter, the following picks should successively exploit the relief produced by the pick immediately preceding it. In this way, relief can be progressively carried through to the corner of the excavation. The cutting sequence should always end in the corner; it should never start there.

Comments on Drag Bit Theory: What has been described may not cover all drag bit cutting theories so far developed. They are, however, the theories that are most widely recognized and most frequently cited in the literature. They all have serious limitations. Some qualitative success can be claimed for each, but none provides an adequate quantitative description of the drag bit cutting process. The principal limitation is that all are two-dimensional and simplified descriptions of what in reality is a complex three-dimensional situation. Furthermore, each theory has its incongruities. For instance, Evans' tensile theory for wedges specifically excludes a normal force, and in his pointed drag bit theory F_C does not reduce to zero when q is 0°.

These deficiencies apart, the various theories do have some modest successes to their credit. They show the right sort of variation in drag bit forces with the main variables of rock strength, drag-bit geometry, cutting depth, drag-bit interaction and wear. Perhaps significantly, Evans' suite of theories, used collectively, shows that little if any difference can be expected between the performance of chisel and pointed drag bits that are

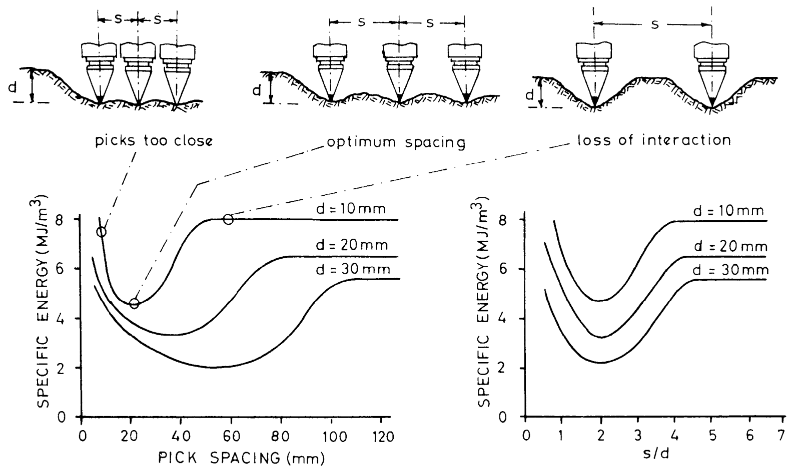

Fig. 9.1.25. Pick spacing and its effect on specific energy.

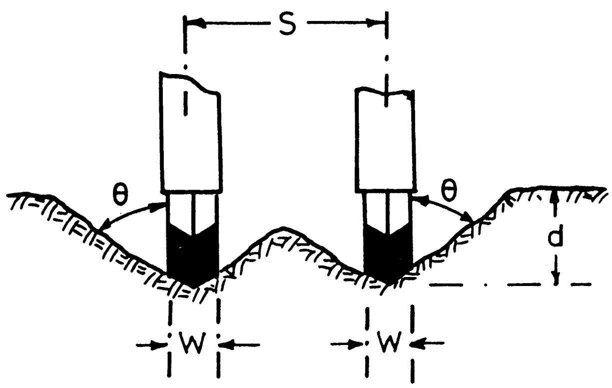

Fig. 9.1.26. interplay between pick width and spacing.

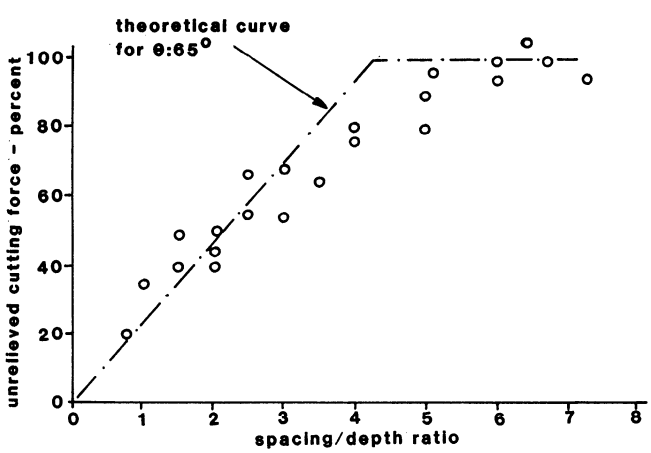

Fig. 9.1.27. Measured values for Bunter Sandstone.

optimally spaced. Such, by and large, is found to be the case in practice.

Practical Implications: Drag bits are an efficient means of breaking rock. Setting aside, for the moment, the question of their ability to survive in the hard-rock environment, they require substantially less energy than other mechanical cutters. They are also at least one order of magnitude more efficient than exotic devices such as water jets, jet piercing, and lasers. Research findings have now been largely assimilated by the industry into the design of mining machines, and significant benefits to machine performance have resulted.

There are two main problems to be solved before the present limits of drag bit application can be extended:

1. The development of new drag bit materials of substantially better wear resistance and strength than those presently available.

2. The ability of machines to provide sufficient thrust force to keep drag bits at an effective depth of cut as drag bit wear proceeds.

9.1.3 DRILLING

Rock excavation in the great majority of noncoal, underground mining operations is carried out using drill-and-blast techniques. About 85% of the holes drilled in underground mines are produced using conventional percussive drills. A small fraction of the holes are drilled with down-hole drills. The remaining, roughly 15%, of these holes are drilled with small diameter, rotary drills. Most of these small-diameter holes are drilled in coal mines for the emplacement of roof bolts. In surface mines, the vast majority of the rock is excavated by drill-and-blast methods. The machines used most commonly for excavating the blastholes in these mines are large-diameter rotary drills.

9.1.3.1 Drillbits

Percussive: Percussive drillbits break rock by indentation. The energy applied to the bit by the drilling machine causes the bit to strike the rock face at a velocity v. The peak stress σ_p induced in the rock by this impacting tool is given by

$$\sigma_p = \rho c v \tag{9.1.36}$$

where ρ is the density of the impacting body (490 lb/ft^3 or 7850 kg/m^3 for steel), and c is the compressional wave velocity of the impacting body (16,400 fps or 5000 m/s for steel).

Thus, for a steel projectile, $\sigma_p = 1{,}733v$ psi when v has units of feet per second, and $\sigma_p = 39.25v$ MPa when v has units of meters per second.

Two major types of percussive drillbit are available commercially; the brazed bit and the button bit. The brazed bit is made up from (either one or four) rectangular prisms of cemented tungsten carbide. These inserts are brazed into the end of the

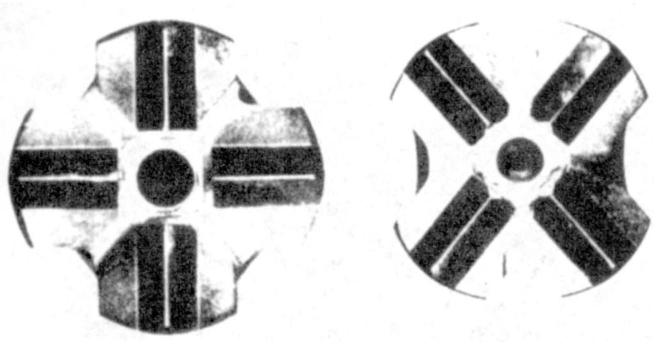

Fig. 9.1.28. Cross bit and X-bit (from Kurt, 1982, originally from Padley and Venables Ltd.).

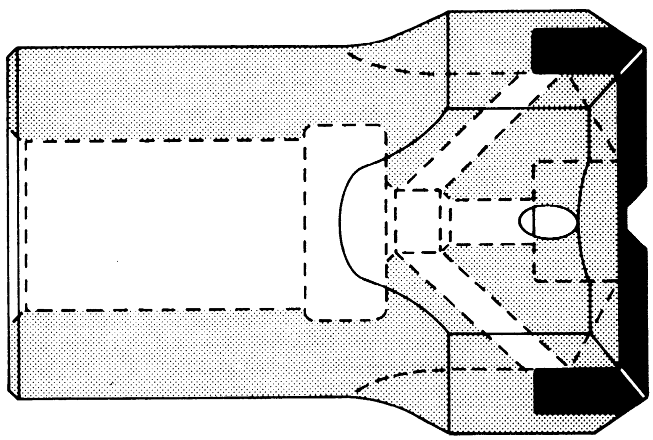

Fig. 9.1.29. Water flushing holes in bit (from Kurt, 1982).

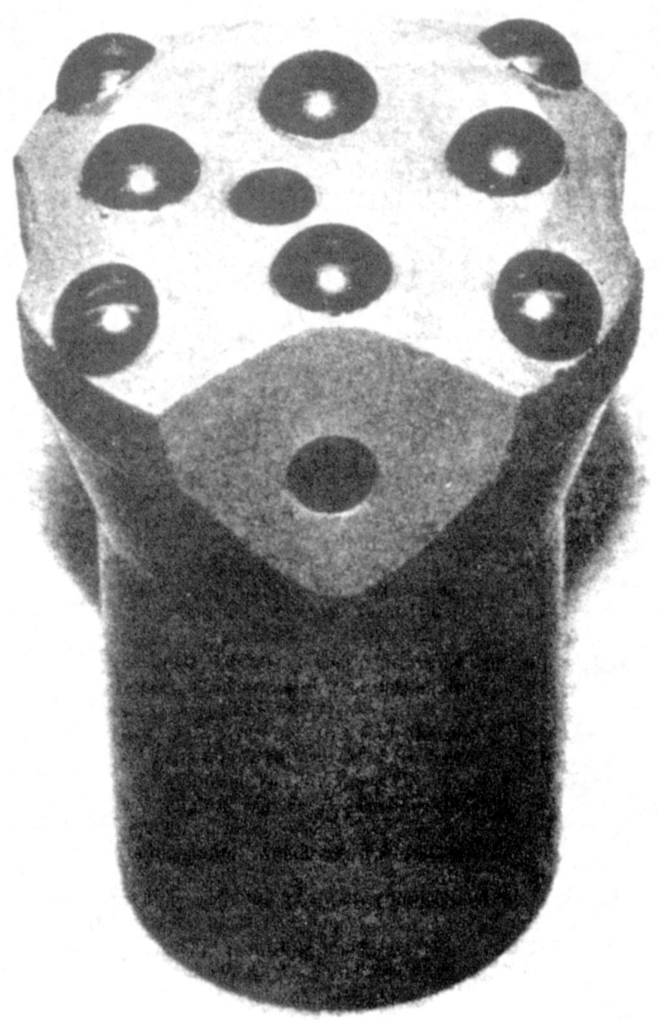

Fig. 9.1.30. Button bit (from Kurt, 1 982, originally from Ingersoll Rand Co.

steel drillbit. Two arrangements for mounting four inserts in these inserts in the bit are common; these are the crossbit, in which the inserts are mounted at 90° intervals around the bit face (Fig. 9.1.28a), and the X-bit where the angles between the inserts are 80° and 100° (Fig. 9.1.28b). The angle of the cutting edge of all these tungsten carbide inserts generally is 110°.

Drilled holes are provided in the bit body. The usual arrangement is for one center hole and four other holes located around the outside of the bit (Fig. 9.1.29). These provide the passages for conducting water to the bit face during the drilling operation. This water serves both to cool the bit inserts and to remove the broken rock debris from the region ahead of the bit. Adequate cooling is essential if the rate of bit wear is to be minimized (see 9.1.5). Continual removal of the rock debris as it is formed is essential if rapid penetration of the drillbit is to be achieved. This type of bit has the advantage that, when it becomes worn, it can be resharpened by grinding the tungsten carbide inserts.

Button bits also employ cemented tungsten carbide inserts to break the rock, but in this case the shape of these inserts is cylindrical. These cylinders are press-fitted into holes drilled into the end of the bit body, and the end of the inserts that project from the bit body is domed (Fig. 9.1.30). Because when the bit size is small, the space available for mounting the buttons is limited, button bits typically are found only in bit diameters greater than 2 in. (51 mm). The advantage that button bits have over brazed bits in the larger hole sizes is a more even distribution of cutting elements over the hole bottom. This tends to result in faster drilling rates. A disadvantage of button bits is that, generally, they cannot be resharpened.

In recent years, polycrystalline diamond compacts (PDC) have begun to find application as the cutting material in a number of different types of drillbits, including percussion button bits. Because the hardness of PDC is much greater than that of cemented tungsten carbide (WC), PDC is significantly more wear resistant than WC in rock excavation applications (see 9.1.5.2). However, PDC suffers from being substantially more susceptible to brittle fracture than WC. In some applications, where either by appropriate bit design or by limiting the classes of the rock types in which the bits are employed, PDC bits have been demonstrated to give superior performance to conventional WC bits. This improved performance generally is observed in terms of much increased rock excavation rates and dramatically improved bit life. The principal disadvantage of a PDC bit is that, at least at the present time, it is substantially more expensive (often by more than an order of magnitude) to produce than the equivalent WC bit.

In all PDC bits, a layer of polycrystalline diamond is diffusion-bonded to a cemented tungsten carbide backing material. The high-modulus (85×10^6 to 100×10^6 psi or 600 to 700

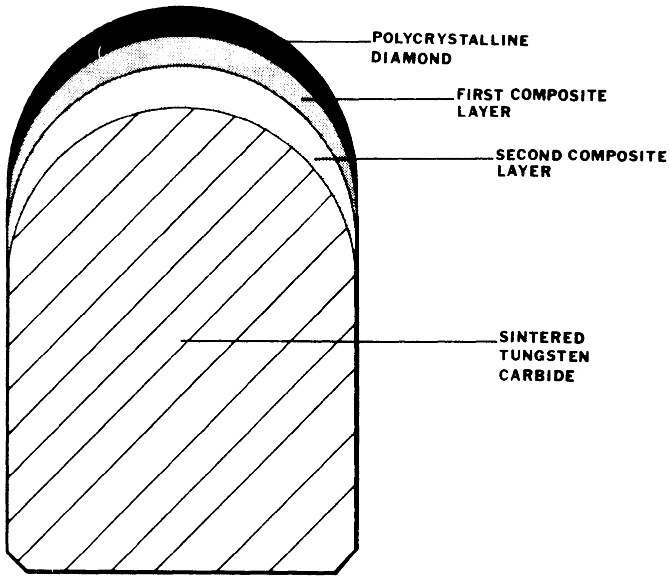

Fig. 9.1.31. Polycrystalline diamond button (from Sneddon and Hall, 1987).

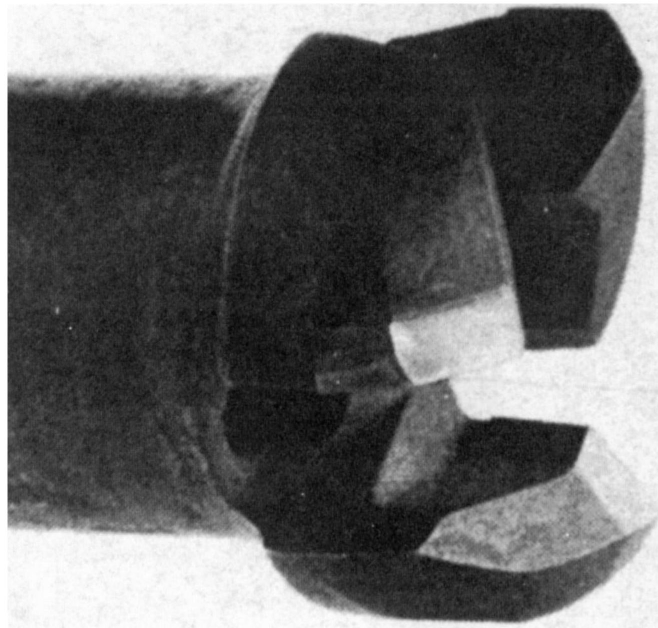

Fig. 9.1.32. Small-diameter rotary drag bit (from Rabia, 1985).

GPa) tungsten carbide provides a stiff mounting for, thereby minimizing the deflection of and thus the stresses induced in, the PDC layer. Until recently only simple shapes of PDC, typically thin cylinders about 0.04 in. (1 mm) thick and 0.5 in. (12.5 mm) in diameter, were manufactured. This material, when bonded onto the tungsten carbide substrate was used as the cutting surface of a drag bit. Today there are many sizes and variants on this shape for drag bit construction. The breakthrough in bit construction that allows PDC to be used on button bits was the development technology of fabricating PDC onto the hemispherical end of a tungsten carbide button, as opposed to the flat cylindrical shape. This breakthrough, by itself, apparently was insufficient. It was found that a single PDC layer was too brittle and resulted in premature failure of the button. The resolution to this problem was revealed in two patents (Hall, 1985; Hall et al., 1986) in which the button end was constructed from three layers of PDC and cemented carbide (Fig. 9.1.31). The layer immediately adjacent to the tungsten carbide substrate is mostly cemented carbide, the middle layer contains a greater proportion of PDC, and the outer layer has the highest volume of PDC and may be nearly identical in composition to the PDC used in drag bit cutters (Sneddon and Hall, 1987).

Field tests conducted with percussion button bits comparing standard WC bits with composite PDC buttons have shown that the latter produced an increase in bit life by about a factor of two and in drilling rate by 45% (Reinsvold et al., 1988). In these tests, the drilling costs were reduced by 33% using the PDC bits. Other advantages claimed by Sneddon and Hall (1987) for the use of these bits are the maintenance of a consistent hole diameter (because of low wear of the bit gage) and reduced wear of the other components of the drill rig (because a higher fraction of the input energy is transferred to the rock as opposed to being reflected into the rig).

Rotary: *Drag Bits*—Small diameter (2-in. or 51-mm) rotary drillbits typically are drag-type tools (Fig. 9.1.32). Again cemented tungsten carbide inserts are used for the cutting elements in these bits; these inserts are brazed into the steel bit body.

Research and development work has been conducted with rotary drills in small-diameter holes using polycrystalline diamond cutter drag bits as the cutting surfaces. The geometry of the individual cutters used on these bits is shown in Fig. 9.1.33. The main application for this type of bit is for drilling roof-bolt holes. The performance of these PDC bits has been shown frequently to be vastly superior to that of conventional WC bits. In abrasive rock formations, a PDC bit typically drills at a much faster rate, and its life often is more than an order of magnitude greater than that of an equivalent WC bit. Despite these advantages, PDC bits have not been adopted by industry for this small hole application. The reasons for this, apparently, are that the demonstrated advantages are not sufficient to overcome the cost disadvantage ($100 to $200 for a PDC bit compared with a few dollars for a WC bit) and the need for different torque and thrust requirements (a PDC bit requires high rotational speed and relatively low thrust). A PDC bit also requires more accurate control of torque and thrust in order to prevent premature bit failure.

These disadvantages have been addressed and, to a large extent, overcome for rotary drilling of large-diameter (6-in. or 150-mm) oil and gas wells using polycrystalline diamond cutter drag bits. In recent years, drillbits of the type shown in Fig. 9.1.34 fitted with a large number of PDC cutters have become increasingly popular for these applications. The rate of drilling achieved using these PDC bits often is considerably more than that obtainable with conventional roller cone bits (described in the following). Since the time spent actually drilling a well typically accounts for about a third of the total time spent by the rig on the hole, and since the cost of the rig while it is on the hole can be well in excess of $100,000/day, this improvement in drilling rate for this application can result in substantial cost savings. At the present time, the propensity of PDC cutters to fail in a brittle manner restricts the use of these bits in this oil and gas market to relatively weak, plastic rock formations such as shale. However, the range of rock types in which these bits can be applied is broadening as improvements in the quality of the cutter materials continue.

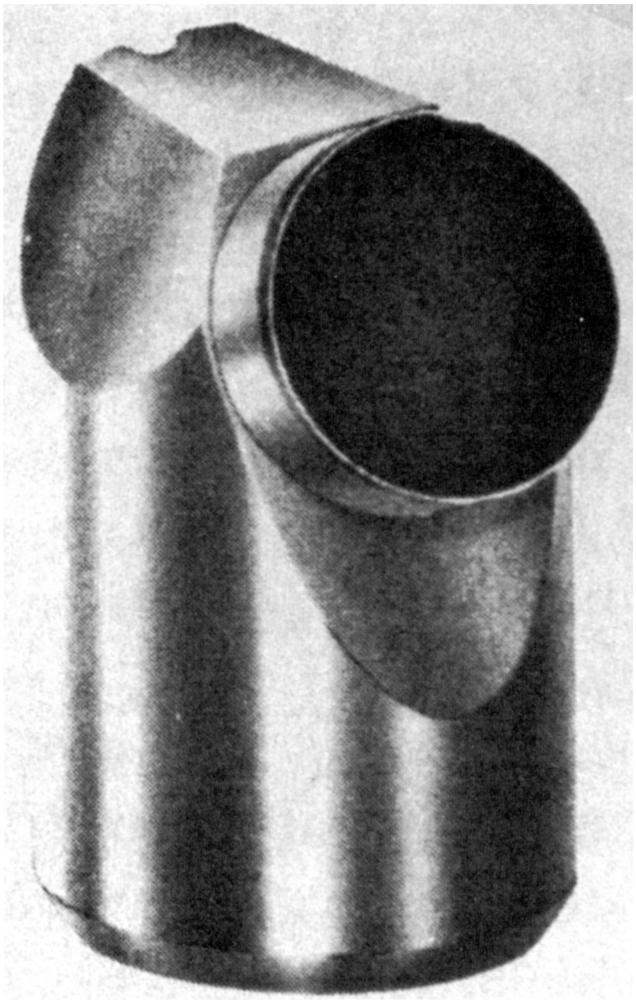

Fig. 9.1.33. Polycrystalline diamond drag bit cutter (from Bourgoyne et al., 1986, courtesy of Norton Christensen).

Fig. 9.1.34. Large diameter PDC rotary drill bit (from Bourgoyne et al., 1986, courtesy of Norton Christensen).

It is to be expected that PDC bits will find wider use in mining applications as the technology of manufacturing these tools improves, thereby reducing their tendency to fail in a brittle manner. As this market increases, the price of the tools should decrease. Lower bit prices undoubtedly would spur market interest in this new tool technology in the mining industry.

Surface-Set and Impregnated Diamond Bits—Both surface-set and impregnated diamond bits have diamonds embedded in a matrix material, such as bronze. This matrix material, in turn, is attached to the end of the drill pipe. Diagrams of this type of bit are shown in Fig. 9.1.35. The matrix of the surface set bits is selected to resist abrasion, and all of the diamonds in these bits are mounted to project from the matrix. Diamonds in the range 10 to 80/carat are used in these bits. They are arranged in the matrix in a manner that ensures overlap along the cutter path by many diamonds.

Impregnated bits, on the other hand, contain a diamond grit, typically 80 to 1000/carat, uniformly distributed throughout the matrix. In these bits, the matrix is designed to wear so that, as the diamonds on the surface become blunt, they are torn away from the matrix and new, sharp diamonds are exposed (Fig. 9.1.36).

In mining applications these bits generally are used for core drilling. The surface set bits are suitable for soft to medium-hard rock formations. The impregnated bits are used for drilling medium to very hard formations.

Roller Cone Bits—These bits usually consist of three cone elements mounted on rolling bearings. The rock is broken by indentation as the cutting elements that project from the surfaces of the cones are pressed, by a thrust force applied to the bit, into the rock surface on the hole bottom. A torque also is applied to the bit; this causes the cones to roll on their bearings and brings other cutting elements into contact with the rock face. The bits illustrated in Fig. 9.1.37 show both hardened steel teeth and cemented tungsten carbide buttons as the cutting elements. Both of these types of tool are used commonly today.

Also shown in this figure are nozzles directed at the rock face. A fluid, either compressed air or a drilling mud, is conducted down the center of the drill pipe and directed at high

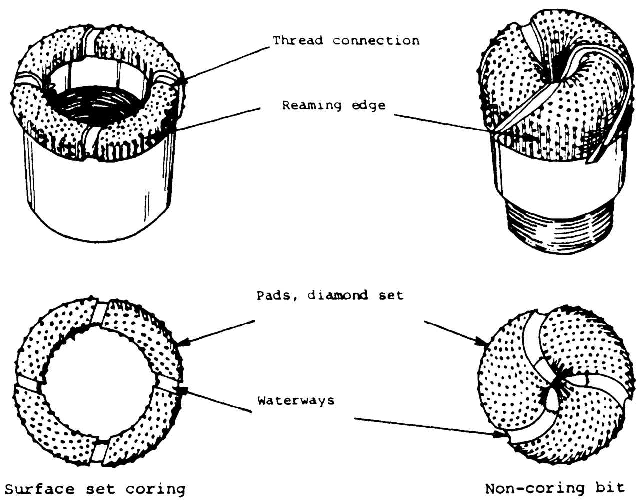

Fig. 9.1.35. Surface set and impregnated diamond rotary bits (from Sweet, 1984).

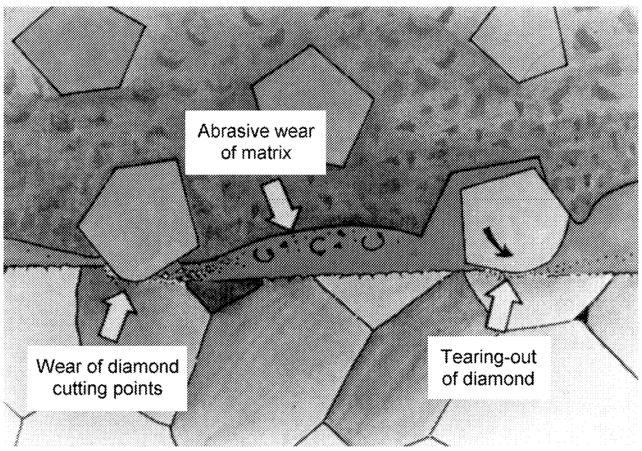

Fig. 9.1.36. Wear mechanisms of impregnated diamond bits (from Cooper, 1978).

velocity onto the face through these nozzles. This fluid serves at least three purposes. One is to cool the bearings. Another is to remove the rock fragments from the face as they are produced by the action of the cutting elements. The third is to transport this rock debris to the surface. The debris-laden fluid returns to the surface up the annulus between the drill pipe and the hole wall. In relatively shallow holes drilled in reasonably competent rock, compressed air is used as the drilling fluid. In deep wells, such as those drilled typically for oil and gas, it becomes necessary to provide a lining to the hole wall as the drilling proceeds to prevent the high in situ stresses from causing spalling of the wall rock. The drilling mud forms a cake on the hole wall and thus provides this immediate support. In most mining applications compressed air flushing is employed.

As shown in Fig. 9.1.37 each cone has two, three, or four rings of cutting elements. Considerable work has been conducted to optimize the pattern and the sequencing of the rock indentations caused by the cutting elements. This includes examining the spacing between the cutting elements in a row, the spacing between rows on an individual cone, and the interaction between

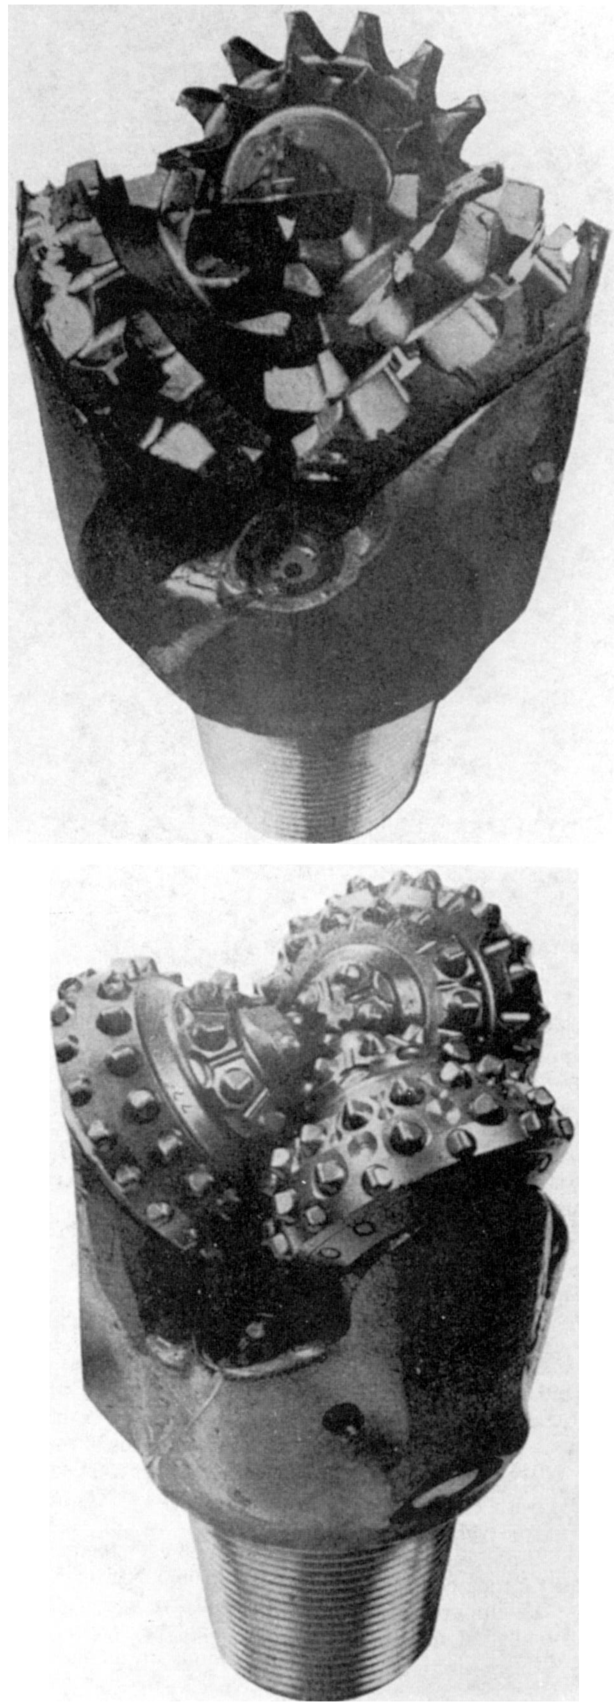

Fig. 9.1.37. Roller cone bits with a) milled steel teeth, and b) cemented tungsten carbide inserts (from Rabia, 1985, *courtesy:* Smith Tool Co.).

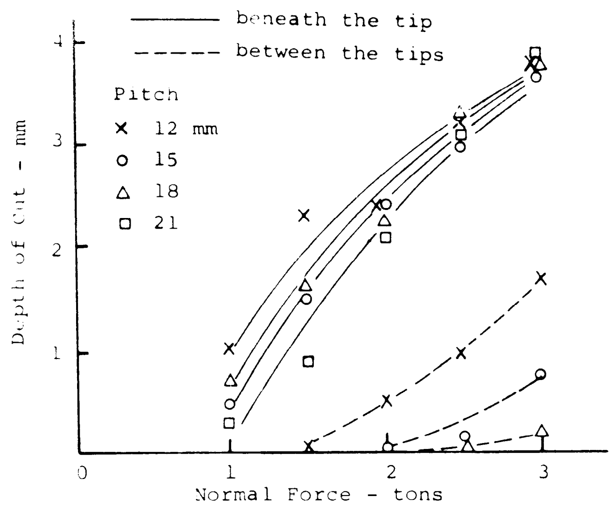

Fig. 9.1.38. Relation between thrust force and groove depth (after Takaoka et al., 1973).

cutting elements on different cones. One of the early reports in the literature on the performance of button cutters comes from Japan (Takaoka et al., 1973). These workers experimented with 7.9-in. (200-mm) diameter by 0.79-in. (20-mm) wide cutters fitted with 0.24-in. (6-mm) diameter buttons at pitches of 0.47, 0.59, 0.71, and 0.79 in. (12, 15, 18, and 20 mm). Their program involved experiments in two different type of rocks:

	Uniaxial Compressive Strength		Uniaxial Tensile Strength	
	psi	MPa	psi	MPa
Kofu Andesite	24,360	168	1,840	12.7
Sawairi Granite	19,900	137	1,320	9.1

The cutting rig applied thrust force F_T as an independent variable at levels of 1.0, 1.5, 2.0, 2.5, and 3.0 tons and measured rolling force F_R and groove geometry as dependent variables.

The observed effect of F_T on the depth of penetration is shown in Fig. 9.1.38. The authors, however, point to variations in penetration depth along the length of the groove and identify two characteristic measures of depth. As illustrated in Fig. 9.1.38a, one is a maximum, being the depth immediately beneath each button. The other is a minimum and occurs midway between adjacent buttons (i.e., at half pitch).

The results show that:

1. Maximum penetration d_1 increases with thrust force F_T at all values of pitch. The relation is generally of the form,

$$F_T \propto d_1^a \tag{9.1.37}$$

where $a > 1.0$.

2. For a given thrust force F_T, maximum penetration d_1 reduces with increasing button pitch. Takaoka, however, discounted the variation as insignificant on the grounds of the strongly opposing trend at minimum penetration d_0 and also similarly strong contrary evidence with toothed cutters.

3. Minimum penetration d_0 also increases with thrust force F_T. The relation appears to be of the form,

$$F_T \propto d_0^b \tag{9.1.38}$$

where $b < 1.0$.

4. Minimum penetration d_0 increases as button pitch s_1 decreases according to the following approximate relation:

$$F_T = A + Bd_0^c \tag{9.1.39}$$

where A and B are constants depending on button pitch and rock properties and with the exponent $c < 1.0$.

It is interesting to note the following values from Fig. 9.1.38. At pitch = 0.47 in. (12 mm), $p_0 = 0$ when d_1 = approximately 0.079 in. (2 mm); and at pitch = 0.59. in (15 mm), $d_0 = 0$ when d_1 = approximately 0.09 in. (2.3 m); pitch = 0.71 in. (18 mm), $d_o = 0$ when d_1 = approximately 0.079 in. (2 mm).

It can be deduced from these data that there is no interaction occurring between adjacent buttons when the pitch/penetration ratio exceeds about six. Takaoka made corresponding measurements of crater width (w) produced by the buttons. The results suggest that:

1. Maximum width w_1 increases with thrust force F_T in similar fashion to maximum depth d_1.
2. For a given thrust force, maximum width appears to increase only marginally with decreasing button pitch; and
3. Minimum width w_0 increases with thrust force in similar fashion to minimum depth and is clearly affected by button pitch.

Groove width was found to be linearly related to penetration depth and to be independent of button pitch. This implies the relation,

$$Q \propto d^2 \tag{9.1.40}$$

where Q is the volume of cut groove and d is the depth of cut groove

In a later study Savadis (1982) conducted similar work in other rock types and confirmed the validity of this expression.

Now, Takaoka's work implies:

$$Q \propto F_T^2 \tag{9.1.41}$$

and if Eqs. 9.1.40 and 9.1.41 are valid, it follows that

$$F_T \propto d \tag{9.1.42}$$

a relation which is clearly at variance with Fig. 9.1.38 and Eq. 9.1.37. So the probability is that 9.1.41 is, in fact,

$$Q \propto F_T^a \tag{9.1.43}$$

where $1 < a < 2$.

Takaoka and his coworkers also report values for rolling force F_R, which, as illustrated in Fig. 9.1.39, increase linearly with thrust force F_T. The peak F_T/F_R ratio ranges from about 10 to 15 according to thrust force and pitch and, thereby, according to penetration.

The method employed in practice to design these bits is to provide each cone with a row of cutting elements to cut the hole gage. These elements are known as the heel teeth, and the number of teeth per unit length of cut is greater along the gage than elsewhere across the rock face because of the difficulty, experienced in all machining operations, of removing material from a corner. The disposition of the cutting elements everywhere other than the gage row is such that the teeth intermesh. In other words, a goal of good bit design is to have the various cutting elements produce indentations across the entire rock face, while

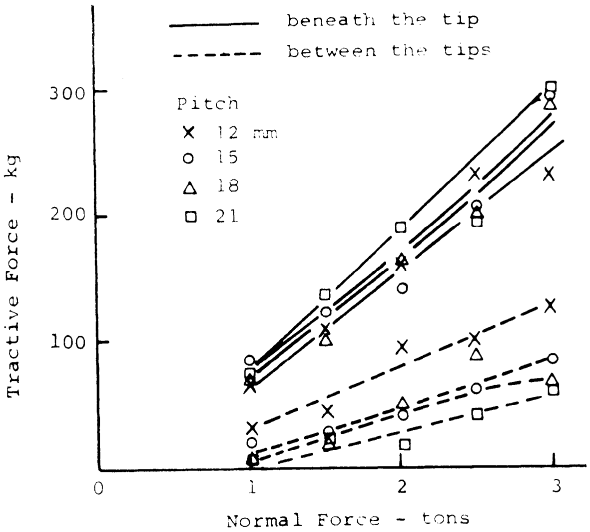

Fig. 9.1.39. Relation between normal and tractive forces (after Takaoka et al., 1973).

at the same time to ensure that no two elements track in the same indentation hole.

It is apparent that the maximum rate of advance per revolution of the drillbit is limited to the height of the tooth from the surface of the cone. The height of the steel teeth above this surface is greater than that of the buttons; consequently, steel-toothed bits would be expected to drill faster than button bits. This conclusion, however, must be qualified because in strong and/or abrasive rock types the steel teeth blunt rapidly and this reduces their effectiveness as indentation tools. Accordingly, their use is limited to relatively weak rock types and, indeed, in these formations, the rate of drilling is greater with steel-toothed bits.

The strength and abrasivity of the rock to be drilled has other influences on the design of roller cone bits. In very strong formations, it is important that the cones roll true, that is, without the cutting elements skidding across the rock face. This requirement arises because skidding in hard rocks results in rapid wear of the cutting elements. On the other hand, in rocks that are not excessively strong, the introduction of even a slight amount of skidding to the cutting elements causes significant reduction in the normal, or indentation, stress required to cause rock failure. An analysis to explain this phenomenon was provided by Hood (1977) who showed that a small shear force applied to an indenter pressing normally into an elastic surface caused considerable distortion to the stress field induced in the elastic material. This produces cracks in the elastic material ahead of the indenter at substantially lower levels of the normal stresses applied by the indenter. Two methods are used to introduce skidding of the cutting elements. One is to mount the cone with the cone apex away from the center of bit rotation. In Fig. 9.1.40a, the cone apex is at the center of rotation and thus the cone will roll true. In Fig. 9.1.40b, the cone has two angles; neither of these angles coincide with the center of bit rotation. Since the cone is constrained to rotate about the bit axis, the elements skid. This skidding action can be further increased by

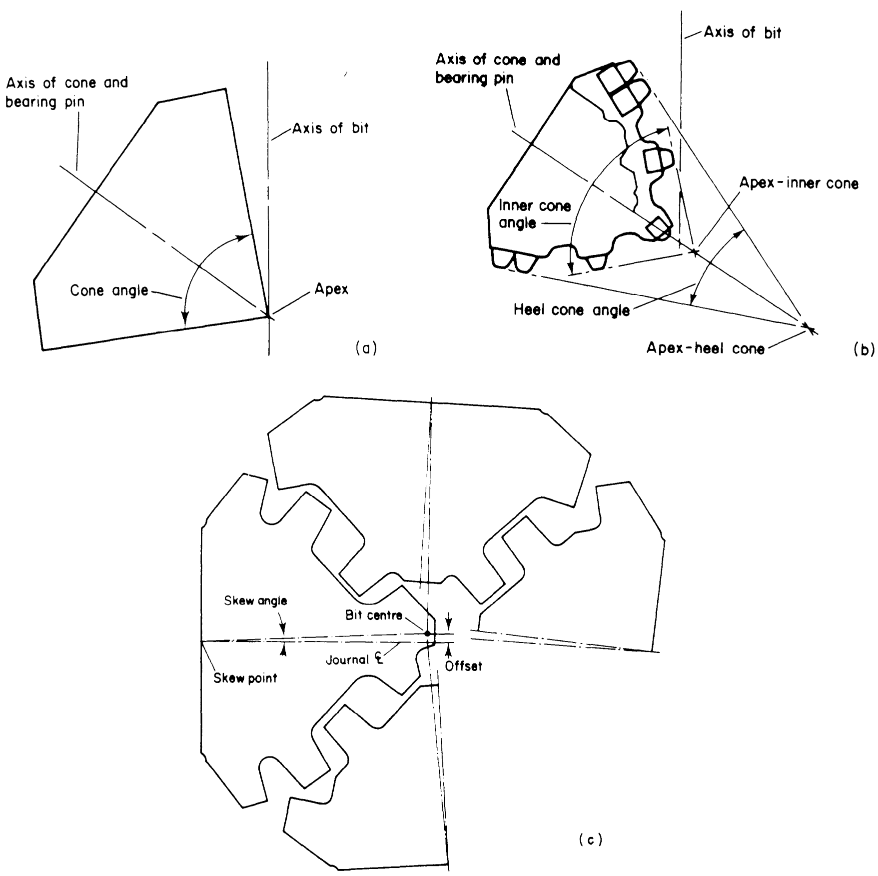

Fig. 9.1.40. Bit cones showing (a) the condition for true roll, (b) different cone apex angles, and c) cone offset angles (from Rabia, 1985).

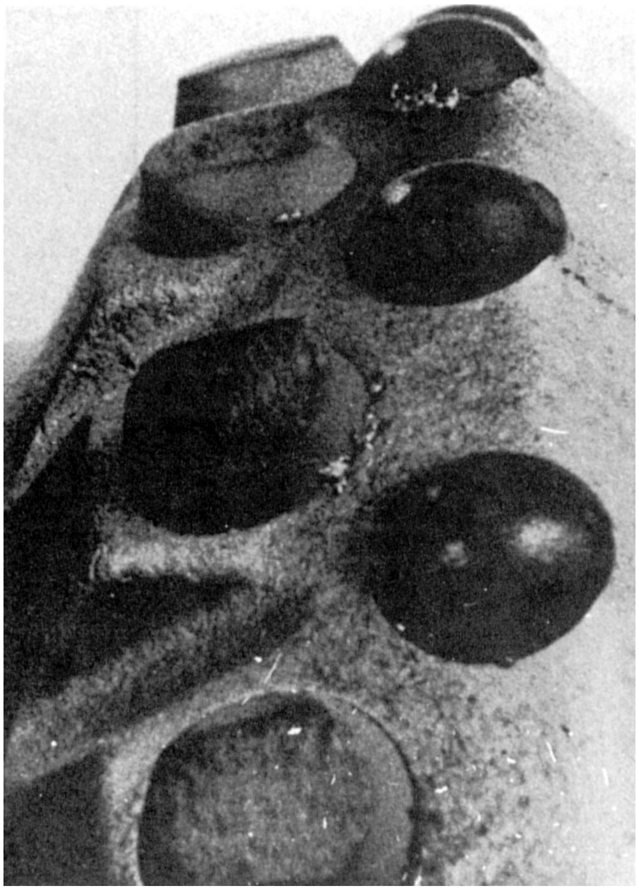

Fig. 9.1.41. Roller cone bit with PCD buttons in gage row (from Reinsvold et al., 1988).

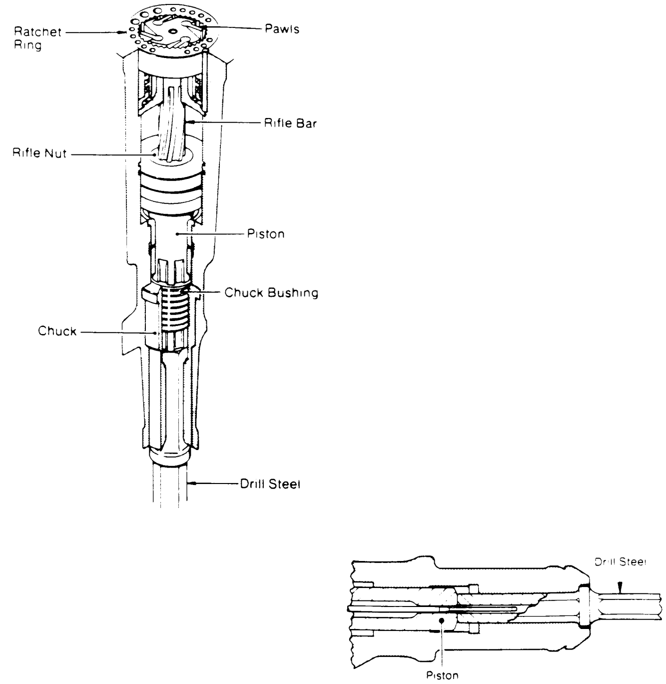

Fig. 9.1.42. Internal components of a percussive drill (from Kurt, 1982).

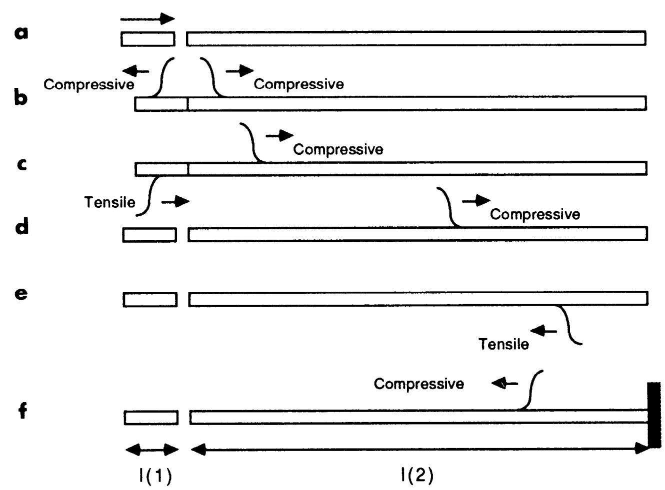

Fig. 9.1.43. Stress waves in piston and drill steel.

offsetting the centerlines of the cones from the center of bit rotation (Fig. 9.1.40c). An offset angle of 2° might be typical for bits used to drill medium-strength rock.

In strong rock, even when these inserts are mounted in cones that roll true, wear of the cemented tungsten carbide buttons remains one of the principal reasons for bit failure. The inserts that suffer the most damage are those on the heel row. Drilling experiments have shown that significant increases in bit life can be achieved when conventional WC buttons are replaced with PDC buttons in this heel row. An example of a bit with the gage row fitted with PDC buttons and with conventional WC buttons in the other rows is shown in Fig. 9.1.41. The wear of the WC inserts is apparent, whereas the PDC buttons remain, even in this heel row, in pristine condition. Again, although the technical advantages are recognized, because of the high cost of the PDC buttons, bits equipped with these buttons have not, to date, found widespread application in the mining industry.

The other principal cause of bit failure arises from deterioration of the bearings. Considerable improvements have been made in bearing technology over the past few decades. This has enabled the loads applied to the bits to be increased. Work currently is being conducted to determine the feasibility of replacing conventional rolling bearings with PDC face bearings (Sneddon and Hall, 1987). The advantages claimed for this new diamond bearing are lower friction and greater wear resistance. This could lead to the ability to apply greater loads to the bits, and thereby produce greater rates of penetration, and longer bit life.

9.1.3.2 Drilling Machines

Percussive: *Fundamental Considerations*—Fig. 9.1.42 shows the essential features of a percussion drill. A fluid, either compressed air or hydraulic fluid, causes the piston in the drill to reciprocate and to strike the drill steel in a repetitive manner (Fig. 9.1.42b). Energy is imparted to the rock through the drillbit by the compressive stress wave induced in the drill steel by this impacting action. When the piston strikes the steel (Fig. 9.1.43a), compressive stress waves are set up in both the piston and the drill steel (Fig. 9.1.43b). These waves travel, at velocity *c*, to the ends of the piston and the drill steel, respectively (Figs. 9.1.43c and d). Here they are reflected. The nature of these reflected

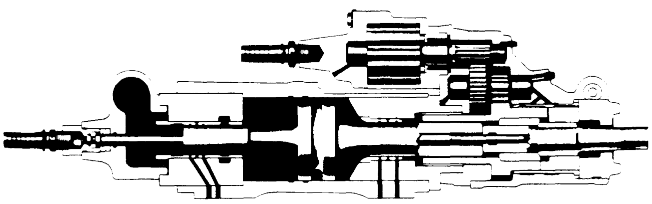

Fig. 9.1.44. Rotary-percussive drill (from Kurt, 1982).

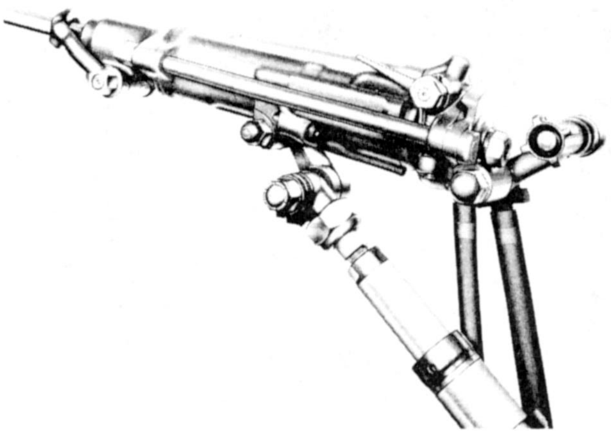

Fig. 9.1.45. Jackleg (from Kurt, 1982, *courtesy:* Ingersoll Rand Co.).

waves depends on the boundary conditions at these ends. For a bar with a free (i.e., unsupported) end, the compressive stress wave is reflected as a tensile wave (Figs. 9.1.43d and e), whereas for a bar with a fixed (i.e., rigid) end, the incident compressive wave is reflected as a compressive wave (Fig. 9.1.43f).

The end of the piston remote from the point of impact will always be a free end, and hence the wave reflected from this end will always be tensile (Fig. 9.1.43c). The end of the drill steel remote from the point of impact generally will be in contact with the rock. Because the rock deforms when the incident wave arrives at the drill steel:rock interface, this boundary is neither free nor fixed but some combination of these conditions. If all of the energy in the incident wave were employed either usefully in causing rock fracture or in frictional heating, then, obviously, there would be no reflected wave. In general, this is not the case, and some fraction of the energy is reflected. The nature of this reflected wave (tensile or compressive) depends on the extent of the contact between the drill steel and the rock and on the rock properties.

The piston remains in contact with the drill steel until a tensile wave arrives back at the piston-drill steel interface. This tensile wave causes these two bodies to separate (Figs. 9.1.43c and d). This terminates the compressive stress wave that has been set up in the other body. This enables the length and the duration of this stress pulse to be calculated. Consider the case where the piston has a length l_1, the drill steel length is l_2, and $l_1 < l_2$. Consider also the case where the diameters of the piston and the drill steel are the same; then the length of the compressive

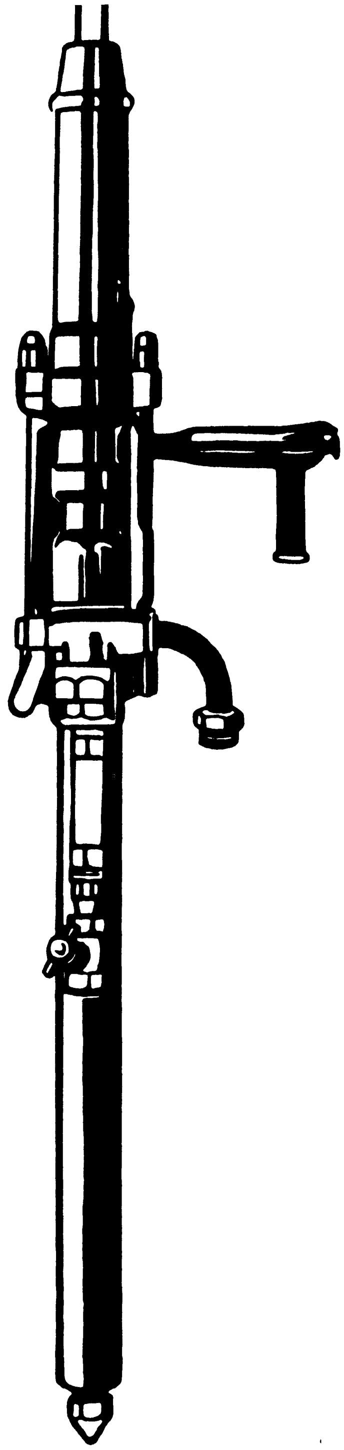

Fig. 9.1.46. Stoper (from Kurt, 1982, *courtesy:* Ingersoll Rand Co.).

wave set up in the drill steel is $2l_1$. The time t_s during which this pulse acts is given by

$$t_s = \frac{2l_1}{c} \tag{9.1.44}$$

Grantmyre and Hawkes (1975) observed that the yield strength of the steel used for the piston and the drill steel limits the stress that can be applied to the rock using the piston-type device. They noted that the maximum stress in the piston σ_h and in the drill steel σ_t are given by

$$\sigma_h = \rho c v \frac{A_t}{(A_t + A_h)} \qquad \sigma_t = \rho c v \frac{A_h}{(A_t + A_h)}$$

where A_t is the cross-sectional area of the drill steel, and A_h is the cross-sectional area of the piston.

Thus, for the case where $A_h = A_t$, $\sigma_h = \sigma_t = \rho c v/2 = 866.5v$ psi where v is given in feet per second (19.63v MPa where v is given in meters per second). In order to prevent damage to the drill steel or the piston, generally it is desirable to limit the stresses in these components to about 31,000 psi (212 MPa); thus the maximum piston velocity $v \approx 35.4$ fps (10.8 m/s). Grantmyre and Hawkes noted that, in some machines, appropriate design of the components has enabled piston velocities as high as $v \approx 50$ fps (15.25 m/s) to be used. This constraint applies only to hydraulic drills, because the piston velocities of pneumatic drills are a factor of 20 or more less than these limiting velocities.

Conventional Drills—An essential feature of any drill is that rotation of the bit takes place between successive impacts. This rotation is required because the effectiveness of the drilling process is impaired greatly by the cushioning effect of the crushed rock from the initial impact, if the bit is constrained to strike in the same part of the rock face. The rotation is achieved either using a mechanism internal to the drill, known as a rifle bar, or using an external motor. The rifle bar arrangement, shown in Fig. 9.1.42a, is an inclined spline and a ratchet. The rifle bar is held fixed by the ratchet mechanism, and the rifle nut in the head of the piston causes the piston to rotate on the return stroke. Since the piston is connected to the drill steel through the chuck nut and the chuck (Fig. 9.1.42a), this also causes the drill steel to rotate. The ratchet allows the rifle bar to rotate on the power stroke, and thus the piston and the drill steel do not rotate on this stroke.

An arrangement for independent rotation of the drill steel is shown in Fig. 9.1.44. Although independent rotation generally is regarded as advantageous because it provides control over the rotational speed and torque, it has the disadvantage of adding considerably to the weight of the drill. Consequently, this type of drill typically is used only on mechanized drill rigs.

It is important also that the drill is kept adequately lubricated during the drilling operation. This lubrication is achieved with pneumatic drills by placing an in-line oiler in the compressed air line immediately upstream of the drill. The air entrains oil as it passes through this oiler.

Drills may be either hand-held or machine-mounted. The pneumatic hand-held drills are the jackhammer (or sinker), the jackleg, and the stoper. Machine-mounted drills are known as drifters. A jackhammer is used for mine utility work, such as drilling anchor holes and holes for boulder breaking. It is also used for shaft sinking. A jackleg is a jackhammer with a pneumatic cylinder hinge-mounted to it. The cylinder is used to support the weight of the drill and to provide thrust to the drill during the drilling operation (Fig. 9.1.45). Jacklegs are used in small drifts and headings and in stopes. They are lightweight and versatile. Stopers are used for drilling upholes. They are jackhammers with a pneumatic cylinder rigidly attached to the drill (Fig. 9.1.46). The typical sizes and lengths of holes drilled by these machines are as follows:

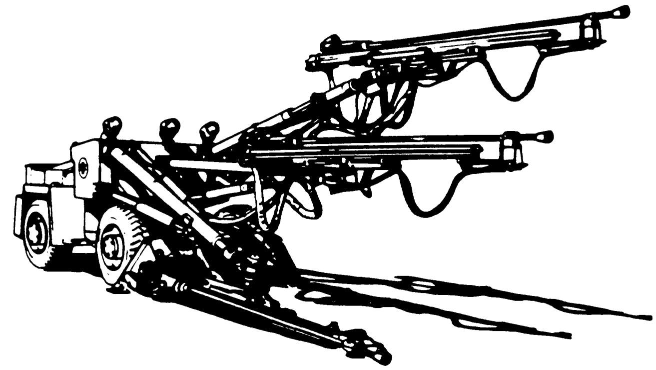

Fig. 9.1.47. Jumbo drill rig (from Roos, 1982, *courtesy:* of Gardner-Denver Co.).

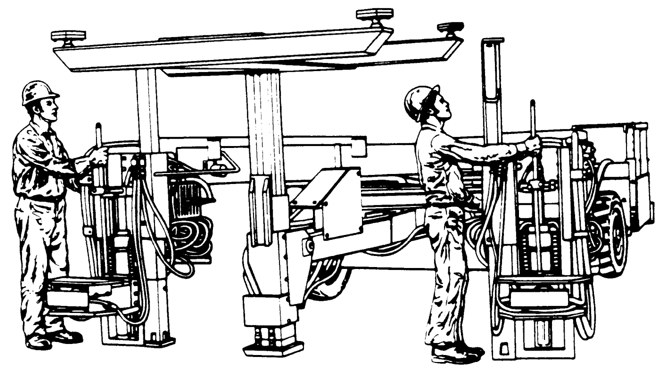

Fig. 9.1.48. Roofbolting drill rig (from Roos, 1982, *courtesy:* Gardner-Denver Co.).

	Typical Hole Sizes		Typical Hole Lengths	
	in.	mm	ft	m
Jackhammers	0.75–1.25	19–32	1–4	0.3–1.2
Jacklegs/Stopers	1.25–1.75	32–44	4–12	1.2–3.7
Drifters	1.50–2.25	38–57	4–100	1.2–30.5

Most of the drills in service today are pneumatic. These drills have the following advantages: low cost, traditional and well-established technology, simplicity of mechanical components, and, in many mines, an existing compressed air distribution system. However, these drills suffer from the disadvantages of having very low efficiency (often less than 5% of the input power to the compressor is delivered to the rock) and creating a poor environment for the machine operator (the drills are noisy and the drill exhaust generates a fog). These disadvantages are overcome to a large extent by hydraulic drills. The overall efficiency of a hydraulic drill is in the range 25 to 30%, the noise level of these machines is 8 to 10 decibels less than that of pneumatic drills, and no fog is generated. The principal disadvantages of hydraulic drills are that they are technically more sophisticated and the capital cost of the units is higher.

Hydraulic drills are finding application as hand-held units, but mostly they are found mounted on a drill jumbo. This term is applied to a self-propelled machine equipped with one or more arms fitted with drill rigs. Drill jumbos, such as that illustrated in Fig. 9.1.47, frequently are used for tunnel or developments drivage. Other configurations (Fig. 9.1.48) are used for drilling

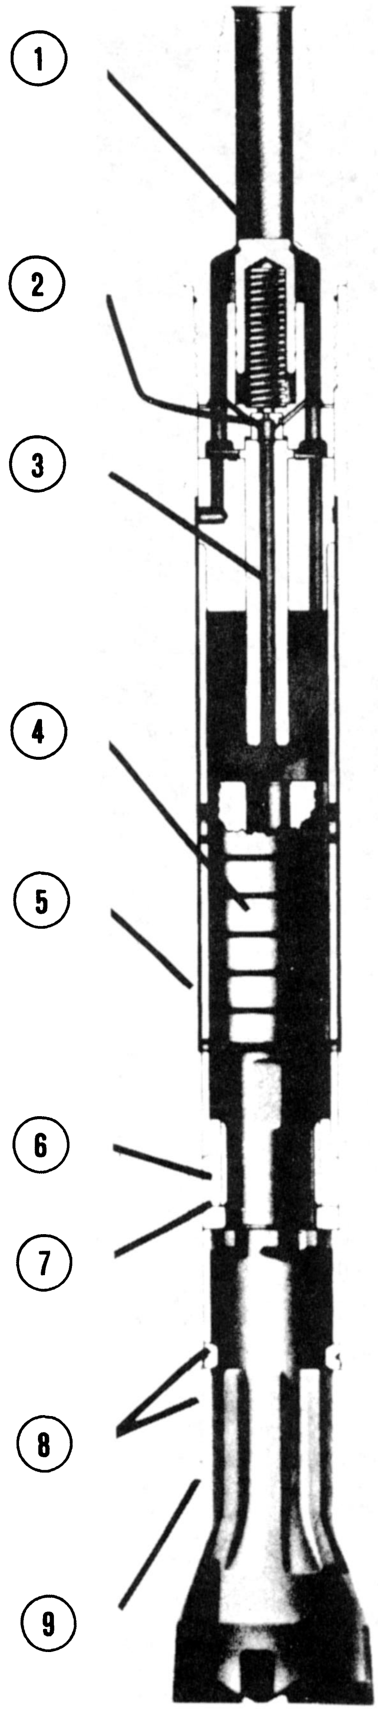

Fig. 9.1.49. Down-the-hole drill. (1) check valve; (2) air metering plug; (3) air distributor; (4) piston; (5) cylinder; (6) piston-stem bearing; (7) washer; (8) bit retaining ring; (9) splined chuck (from Anderson, 1984).

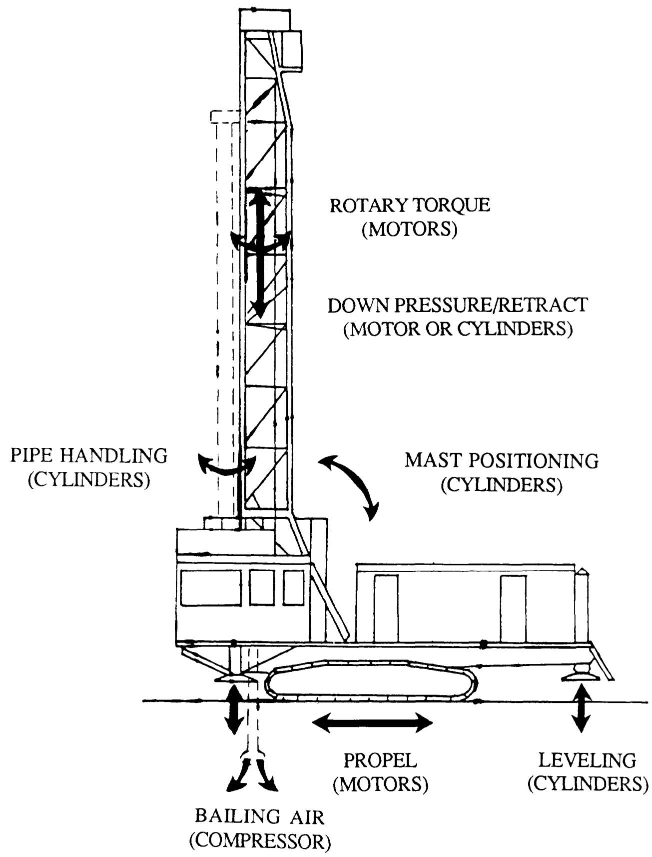

Fig. 9.1.50. Schematic of a surface rotary drill rig.

roof bolt holes, and yet other configurations are used for shaft sinking.

Down-the-Hole Drills—The previous discussion makes it clear that in a conventional percussive drill the mechanism that imparts energy to the rock remains outside the hole and this energy is transmitted in the hole through the drill rod(s) and the bit. As the name, down-hole (DTH) drill implies, with this percussive unit the mechanism for imparting energy to the rock is located in the hole. Fig. 9.1.49 shows the main features of a DTH drill. The piston in these drills is powered by compressed air. Holes 4 to 8 in. (100 to 200 mm) in diameter up to 500 ft (150 m) long can be drilled with a DTH drill (Anderson, 1982). This system eliminates energy transmission losses in the drill rods; thus a major advantage of a DTH drill is a constant penetration rate that is independent of hole depth.

Rotary Drills: Small-diameter rotary drills are used for drilling weaker rock types. These drills usually employ a rotary hydraulic motor to provide the drill torque, and a hydraulic cylinder to provide the thrust. They are mounted, in a similar manner to percussive drills, on drill jumbos for face drilling and for roof drilling.

Large-diameter holes in both underground and, more frequently, in surface mines typically are drilled with roller cone bits. The essential features of a rotary drill rig for a surface mining operation are shown in Fig. 9.1.50. These features include a motor as the rotary drive, a chain pull-down arrangement operated by hydraulic rams to provide thrust, a rod handling device, a compressor for flushing the rock debris from the hole bottom, hydraulic leveling jacks, a dust collection system, and a main motor, either diesel or electric.

9.1.4 EXCAVATION MACHINES

9.1.4.1 Tunneling and Boring

Coverage here is restricted to the fundamentals of rock excavation machines. For applications to rapid excavation techniques see Chapter 22.1.

Tunnel Boring Machines (TBM): This type of machine can be used to drive circular tunnels from 5.7 ft (1.75 m) to more than 36 ft (11 m) in diameter in rock types that range from weak, loosely consolidated to very strong and abrasive. In almost all cases breakage is effected by roller cutters mounted on the cutting head (Fig. 9.1.51). Because these cutters break the rock by indentation, these machines are characterized by very high thrust requirements. This thrust is provided by hydraulic rams that press the cutterhead into the rock face. The thrust reaction force is reacted through gripper pads that are pressed, again hydraulically, against the tunnel walls. The rock broken from the face by the cutters falls to the floor where it is scooped into buckets mounted around the gage of the cutterhead. This debris is lifted in the buckets to the tunnel crown, whereupon it is tipped onto a belt conveyor that runs through the center of the machine.

The most common type of cutting tool employed on these machines is the disk cutter. In some cases the cutting edge of this tool is a hardened steel surface (Fig. 9.1.52), and in other cases it is a row of cemented tungsten carbide buttons that are press-fitted into the disk rim. The most common cross section for a hardened steel disk cutter several years ago was a wedge (Fig. 9.1.53a). The disadvantage of this design is that the tool area presented to the face increases as 2 tan q (where q is the half angle of the wedge) as the cutters become worn. Thus, in order to maintain penetration rate as the cutters become blunted, it is necessary to increase both the machine thrust force and torque. The majority of disk cutters used today are "constant section" disks (Fig. 9.1.53b). Appreciable wear of these cutters can occur without causing a substantial increase in the surface area presented to the rock. Other cutter types include the kerf cutter, which is simply multiple disks mounted on the same hub (Fig. 9.1.54a), and the pineapple cutter, which is a frustrum with cemented tungsten carbide buttons press-fitted onto the surface (Fig. 9.1.54b).

A ranking of cutting efficiency of these tool types, in terms of specific energy, places the steel disk cutter as the most efficient, the disk-button cutter next, and the pineapple cutter as least efficient. However, the wear resistance, and therefore the capability of cutting strong abrasive formations, is the reverse of this efficiency ranking. Consequently, steel disks tend to be used for cutting weaker, less abrasive rocks, and pineapple cutters are used for machining the most abrasive and toughest formations.

Several other comments can be made about the cutting behavior of disk cutters. First, in contrast with drag bits, the efficiency of the rock breakage process does not decrease when disk cutters are used in a groove deepening (when multiple passes are

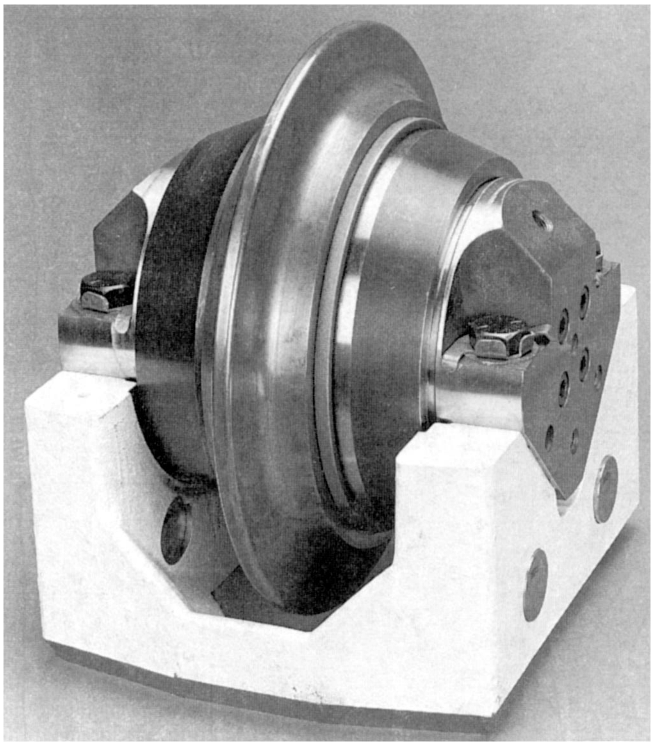

Fig. 9.1.52. Disk cutter (*courtesy:* Robbins Co.).

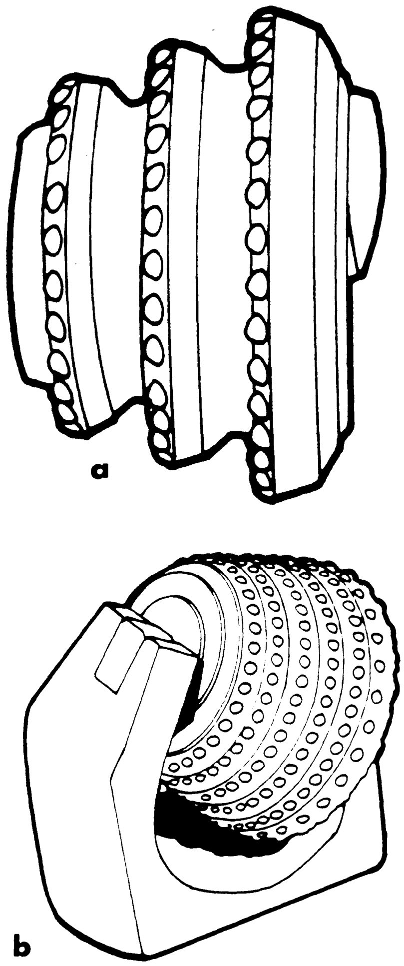

Fig. 9.1.54. (a) Kerf cutter (b) Pineapple cutter.

made by a tool taking a series of shallow cuts in a kerf before producing major rock chips) mode. This is fortunate because in practice, groove deepening is the cutting procedure most commonly employed with tunneling and with other boring machines. Second, similar to the findings for drag bits, an optimum spacing exists between an array of disk cutters working a rock face. The value of this optimum spacing depends on the depth of cut taken and on the rock type. However, whereas with drag bits an optimum *s/d* value of 2 to 3 is typical (Fig. 9.1.25), with disk cutters this value is more typically in the range 5 to 10. Third, the efficiency of the rock breakage process is independent of whether the grooves are cut simultaneously, with multiple disks on a single hub, or sequentially, with independent disks.

A factor crucial to cutter longevity, particularly in hard and abrasive formations, is whether the cutters roll true, that is without skidding, across the rock face. This factor was discussed in connection with tricone roller drillbits in the previous section. The two possible modes of disk cutter skidding are illustrated in Fig. 9.1.55a. The mode that Hood (1978) described as ploughing can apply to any type of roller cutter. In this case the cutter acts in part as roller cutter and in part as drag bit. This dragging or ploughing action can greatly exacerbate cutter wear. Problems with this type of wear occur frequently with cutters mounted near the center of the cutterhead. The spinning type of cutter skidding (Fig. 9.1.55b) occurs with kerf and pineapple cutters that are mounted on the head in a manner such that the cone apex of the cutter frustrum is not coincident with the axis of the cutter head. This type of skidding action also results in accelerated cutter wear in strong or abrasive rock types.

Over the past two decades full-face rock tunneling machines have become very widely used in civil construction applications. A principal advantage is that this type of machine represents a quasi-continuous excavation system, compared with the alternative, cyclic, drill-and-blast method. Hence the tunnel advance rates generally are much greater when a TBM is employed. For example, in a 12 ft (3.6 m) tunnel, typically the face will advance with drill-and-blast working by one blast round, say 10 ft (3 m), per shift. Thus on a 3-shift a day operation the tunnel advance is 30 ft (9 m). A TBM, in the same tunnel would be expected to

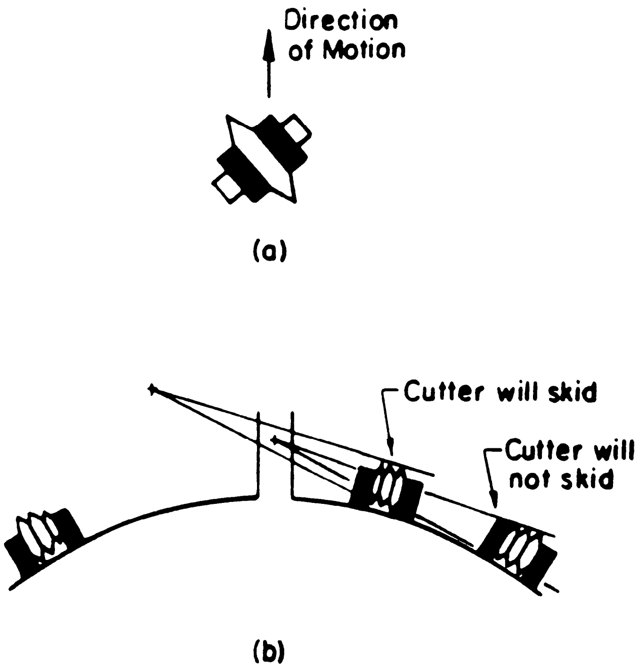

Fig. 9.1.55. (a) Ploughing mode and (b) spinning mode of cutter skidding.

advance about 33 ft (10 m) per shift, or 100 ft a day (30 m a day) on 3 shifts.

The disadvantages of this machine are:

1. High capital cost (several million dollars)
2. Tunnel cross section is necessarily circular
3. Large turning radius (typically 330 ft or 100 m)
4. Cumbersome initial machine and system installation. In practice this means that a minimum tunnel length of about 1.2 mi or 2 km is needed to justify the cost of machine setup (Handewith and Dahmen, 1982).

TBMs have not, as yet, found a wide market in the mining industry. The reasons for this probably are partly related to the initial capital cost and to the conservatism of the industry. It is more likely that the other constraints of this tunneling system—inflexibility of geometry, inability to turn the tunnel rapidly, and the requirement for long, relatively straight tunnels—are the main factors that have limited the interest of the mining community in this now well-established technological area.

Mobile Miner: The Robbins Company in Seattle has developed a new excavation machine, termed the “mobile miner” (Fig. 9.1.56) to overcome these limitations of conventional TBM systems in mining applications. The cutting head on this machine is a wheel with disk cutters mounted around the circumference. Only a portion of the rock face is contacted by the cutterwheel at any point in time; thus the number of cutters in contact with the face is small and consequently the reaction forces on the machine are less than for a TBM driving an equivalent size opening. This allows for a smaller, and therefore more maneuverable, machine than a TBM.

The cutterwheel is connected by a boom to the main body of the machine. The machine cuts by first anchoring the machine with staking jacks. The wheel then is rotated, and the cutters are sumped to the desired cut depth into the rock; this is effected with hydraulic sumping cylinders plunging the boom forward on one side of the heading. Hydraulic swing cylinders then traverse the boom across the width of the heading. Boyd (1987) observes that the cutting action of the disk cutters during this swing part of the cycle is similar to that experienced by gage cutters on a TBM. At this point the wheel is sumped again, and another cut is taken. These cycles are repeated until the sumping cylinders are fully extended (about 30 in. or 760 mm), at which point the staking jacks are retracted, the machine advances on its crawlers, and the process is repeated. The machine drives a tunnel that is rectangular with rounded corners (Fig. 9.1.57). This is advantageous both from a mining viewpoint, because it is maximizes the utility of the excavated opening and it is suitable

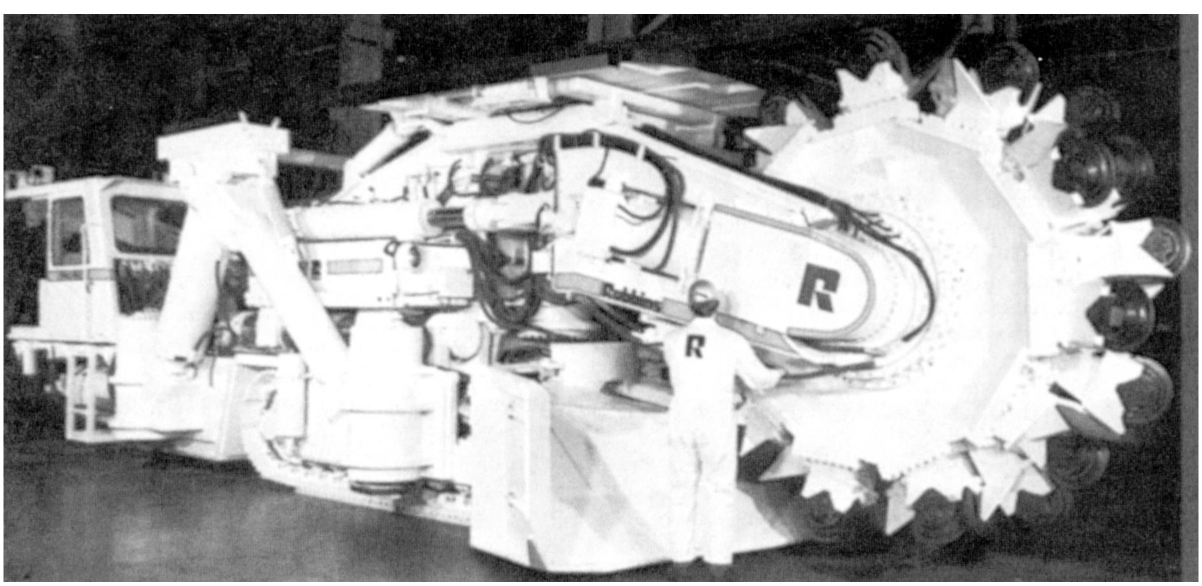

Fig. 9.1.56. Robbins Mobile Miner MM120-3001 (*courtesy:* Robbins Co.).

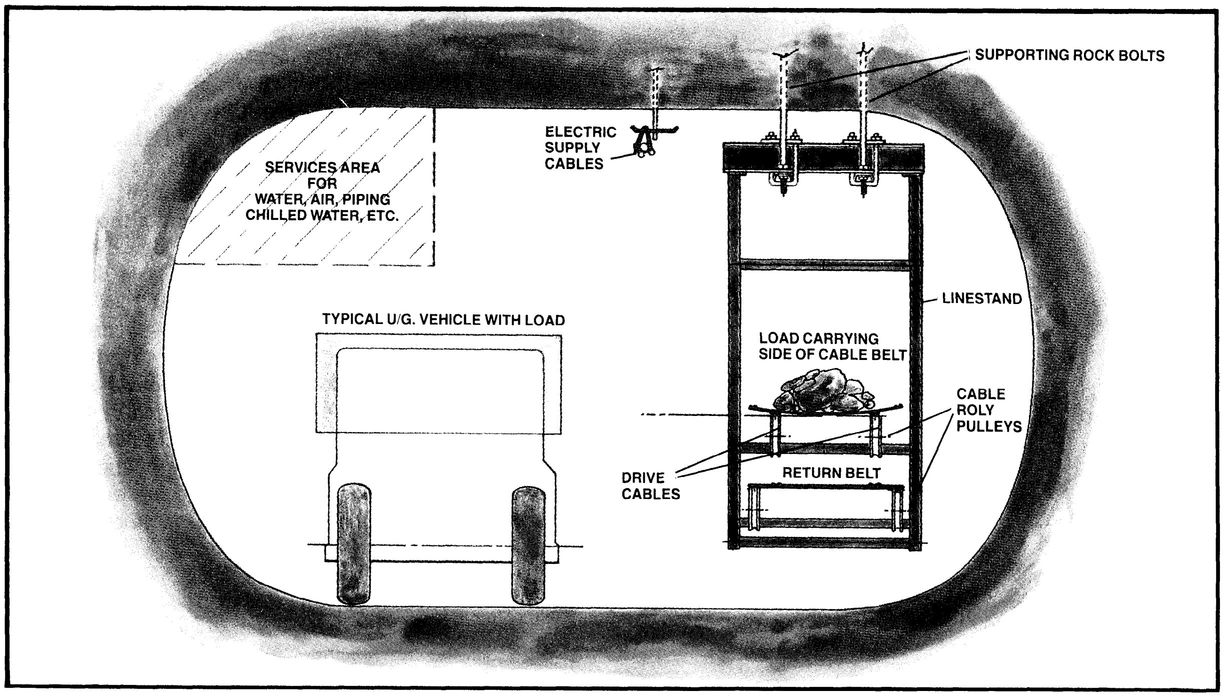

Fig. 9.1.57. Geometry of excavation cut by Mobile Miner (from Boyd, 1987).

for road transport, and from a rock mechanics viewpoint, because the rounded corners avoid the high stress concentrations usually associated with square or rectangular tunnels.

To date, only two machines of this configuration have been built. A prototype unit was tested in a quarry in Seattle. Subsequently, the first production machine was built and used to drive a decline in strong, abrasive quartzite at the Mount Isa mine in Australia. Although several problems were encountered with this first machine in the very difficult rock conditions into which it was placed, the results obtained were sufficiently encouraging that work to develop this machine concept is continuing. Another mobile miner has been ordered for use at Broken Hill Pty. mines.

Raise, Blindhole, and Shaft Borers: These machines use the same roller cutter technology described above, but they drive vertical or steeply inclined holes rather than tunnels.

Raise Borers—These machines are used to produce a circular excavation either between two existing levels in an underground mine or between the surface and an existing level in a mine. The principle of raise boring is shown in Fig. 9.1.58. First, the boring machine is set up on the upper level, and a small-diameter (of the order of 9 in. or 230 mm) pilot hole is drilled, usually with a tricone bit, down to the lower level. When this hole is completed, the drillbit is removed and replaced by a reamer head having a diameter with the same dimension as the desired excavation. Some type of roller cutters are mounted on the reamer head. This head then is rotated and pulled back up towards the machine. The rock debris falls by gravity into the lower excavation where it is removed.

These machines are very effective in driving raises, and they have become very popular, particularly in hard-rock underground mines. Frequently the direct costs of driving a raise, in terms of dollars per foot (dollars per meter), are reduced by using these machines. In addition, however, this raising system offers other significant advantages. One of these is improved safety—conventional drill-and-blast raising is notoriously dangerous. Another is improved excavation rates and improved productivity. Also the circular shape combined with the lack of blasting damage results in an excavation of greater strength and integrity than a hand-driven raise.

Blindhole Borers—A blindhole machine will produce a circular excavation without the need for a pilot hole. The machine is set up on a level in an underground mine, and a steeply inclined hole, generally several feet (meters) in diameter, is excavated upward from this level (Fig. 9.1.59). The purpose of this hole often is to make connection with a stope above the level. South Africa, in particular, makes extensive use of these machines in their gold mines.

Shaft Borers—This technique for large-hole drilling has been practiced for decades at the Nevada Test Site (NTS) and, in recent years, attention to mechanized shaft sinking for mining operations has increased. The experiences of drilling in the welded tuff found at the NTS are described in a paper by Lackey (1983), and these are summarized as follows. The uniaxial compressive strength of this tuff ranges from 4000 to 25,000 psi (28 to 170 MPa). The hole sizes drilled typically are 5.2 to 7.9 ft (1.6 to 2.4 m) in diameter and 1600 ft (490 m) deep. Hardened steel mill tooth, steel disk, kerf, or pineapple cutters are used depending on the rock strength.

Cuttings removal from the hole is achieved using either reverse circulation or dual-string circulation (Fig. 9.1.60). In both cases, air jets are injected into the upstream flow to help lift the cuttings. Efficient removal of the drill cuttings remains the single greatest limitation of blind shaft drilling (Pigott, 1985). It is apparent that the problem with cuttings removal is the large quantity of the rock debris, because of the large hole size, and that, unlike the situation for raise and blindhole boring, these cuttings must be lifted against gravity to the surface. According to Lackey (1983), the positioning of the fluid jets to clear the rock chips from the working face remains an empirically determined art.

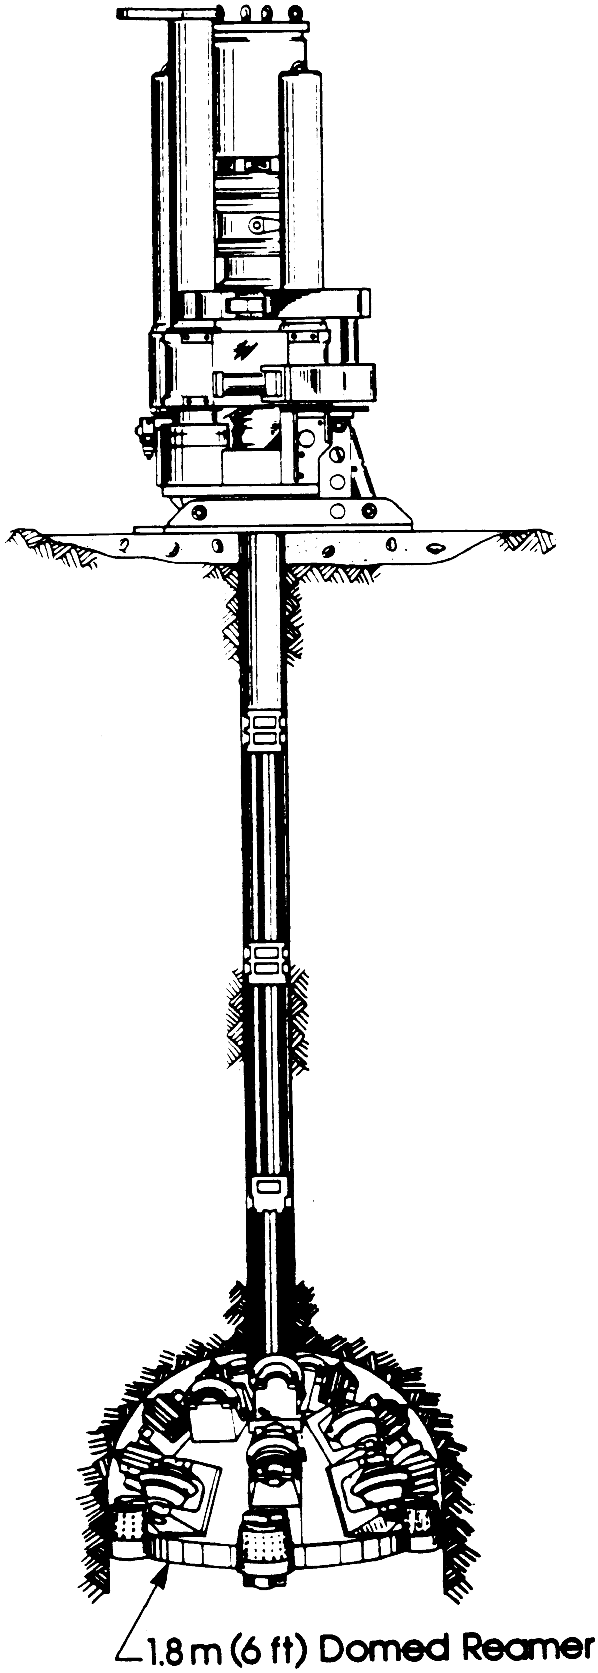

Fig. 9.1.58. Raise borer operation (from Home, 1982, *courtesy:* Robbins Co.).

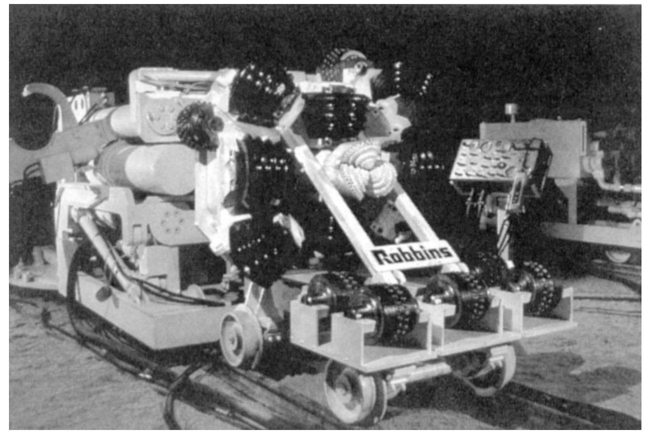

Fig. 9.1.59. Blindhole borer (*courtesy:* Robbins Co.).

The drilling machines used for these large holes are scaled up versions of standard oil field drilling systems. The right-hand diagram in Fig. 9.1.61 shows the down hole assembly, and the left-hand diagram shows the assembly, at the hole collar.

Drilling accuracy for these large holes is achieved either using the "plumb bob" effect or using a stinger in a predrilled pilot hole. The former approach uses gravity acting on the mass of the cutting head assembly to maintain the shaft vertical. Generally, less than 50% of the weight of the cutting head is applied as a thrust force to the cutters; the rest of this weight is reacted by a tensile force applied at the drilling mast and transmitted through the drill string. This large mass on a long string tends to maintain a vertical position. The latter approach employs a pilot hole, some 12 in. (300 mm) in diameter, drilled before the boring head is installed. A stinger on the boring head then is fitted into the pilot hole and this hole serves to guide the head. At the NTS, where no pilot holes are used, the accuracy of the drilled holes is reported to be somewhat more than 1 in 100. This accuracy probably is unacceptable for mine shafts where conveyances are to be employed. At an Australian gold mine, two holes were drilled successfully, one in an access shaft with an accuracy of greater than 1 in 160 over a length of 1050 ft (320 m), and the other in a ventilation shaft with an accuracy somewhat less than 1 in 130 over a length of 870 ft (264 m).

Shaft boring also was employed at a uranium mine in New Mexico. Here three large holes, one 10 ft (3 m) and the other two 6 ft (1.8 m) in diameter, were drilled to depths of 2243, 2188, and 2188 ft (684, 667, and 667 m), respectively. Subsequently, the plan called for underground connection to be made between these holes, and then the two smaller holes were to be reamed to a final diameter of 18 ft (5.5 m). The drilling rates in the 10-ft (3-m) hole were about 1 fph (0.3 m/h) and in the other two holes were 1.7 to 1.8 fph (0.52 to 0.55 m/h). The reported drilling accuracies were 1.03 ft in 2243 ft (0.314 m in 684 m); 1.33 ft in 2188 ft (0.405 m in 667 m); and 0.84 ft in 2188 ft (0.256 m in 667 m).

Roadheaders: A roadheader is a boom-type tunneling machine that uses drag bit cutting tools (Fig. 9.1.62). These machines are restricted to excavating relatively weak rock types, and their main use is for roadway drivage in coal mines. During the past three decades efforts have been devoted to increasing the cutting capability by increasing the installed power of these machines. This has resulted in increased machine size and mass (Fig. 9.1.63).

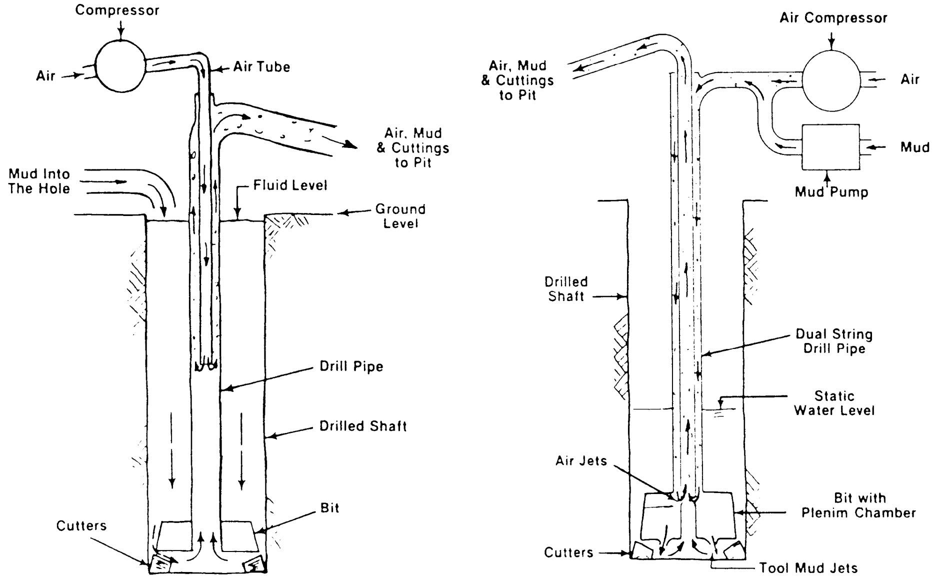

Fig. 9.1.60. Reverse circulation flushing (left) and dual string circulation (right) (from Lackey, 1983).

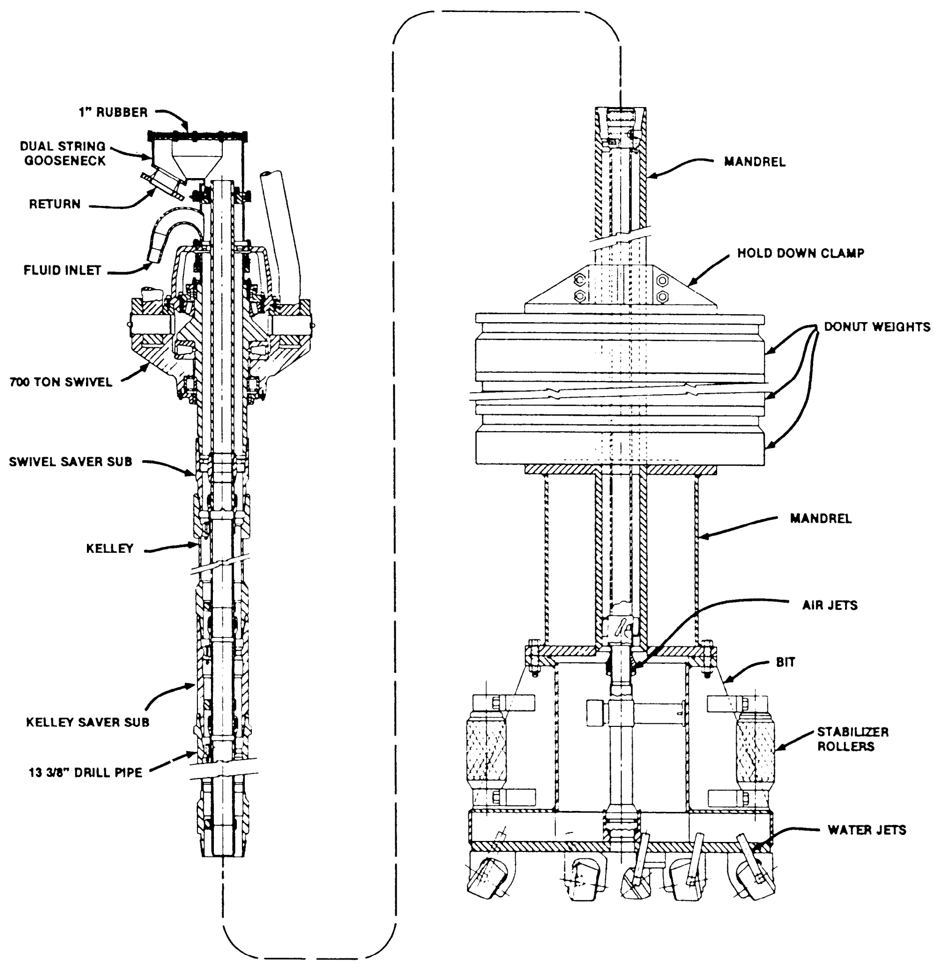

Fig. 9.1.61. Kelly and swivel together with the bottomhole assembly (from Lackey, 1983).

Roadheaders are track-mounted machines. Excavation is carried out by first sumping the cutting head into the face and then traversing the boom to cut the desired roadway profile. The broken rock deposited on the floor is loaded by a gathering arm arrangement onto an armored conveyor that runs through the center of the machine. This material then can be removed by shuttle cars.

In recent years the cutting capability of these machines has been enhanced by the addition of a water-jet-assisted cutting system. One of the direct benefits for this system, reported by Morris and Harrison (1985), is illustrated in Fig. 9.1.63. This shows that a 35-ton (32-t) machine, that normally would be restricted to cut in rocks with compressive strengths of the order of 12,000 to 14,000 psi (83 to 97 MPa), was capable of cutting in rock with compressive strengths in excess of 20,000 psi (140 MPa) when the machine was assisted with high-pressure water

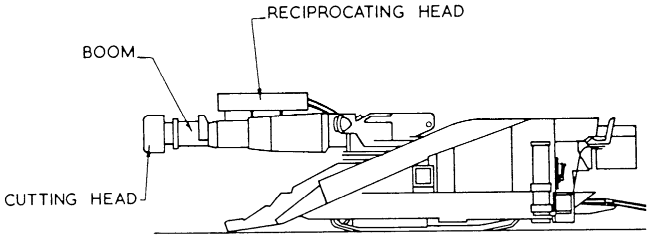

Fig. 9.1.62 The main components of a roadheader (from Morris and Harrison, 1985).

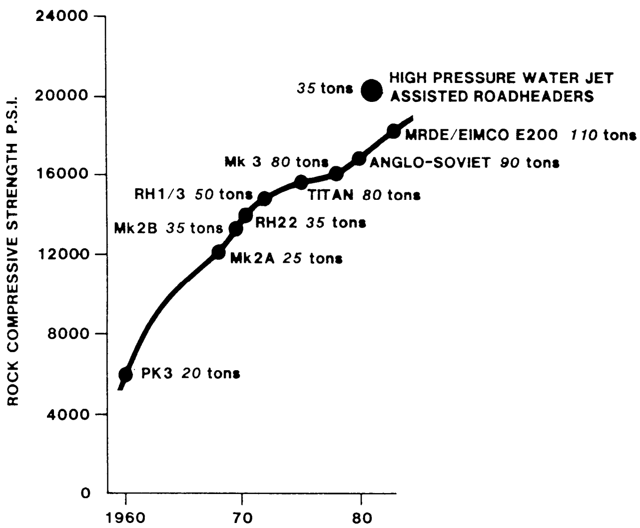

Fig. 9.1.63. Improvements in roadheader performance and the trend for increasing weight on these machines over time (from Morris and Harrison, 1985).

jets. At least two manufacturers now supply commercial water-jet-assisted roadheading machines.

9.1.4.2 Coal (and Other Weak Rock) Mining

Shearers: These machines, illustrated in Fig. (9.1.64), are used on longwall faces. Modern shearers are predominantly double-ended, ranging drum machines; that is, there is a cutting drum at both ends of the machine and these drums are mounted on hydraulically powered arms that are used to adjust the position of the drums to varying seam heights. The machine rides on skids on an armored steel face conveyor that extends the length of the face. The cutting tools are picks (drag bits). The drums are driven by an electric motor (or motors) through a gear train. The rotation of the drums serves both to cut and to load the rock onto the face conveyor. As with roadheaders the trend with these machines has been to increase the machine power and size. Today machines with an installed power of 1000 to 1340 hp (750 kW to 1.0 MW) are not uncommon.

The biggest operational problems with shearers are maintaining the cutting drums within the seam and the high dust production on the face. When the cutting drums are allowed to cut into adjacent strata, the rate of pick wear often rises dramatically, because these other rocks are generally stronger and more abrasive than the coal and evaporites normally cut by shearers. This results in increased downtime for pick changes, and often this is a substantial fraction of the overall machine downtime. Also, in coal mines particularly, cutting out of the coal seam can result in frictional sparking which can cause face ignitions of methane. Considerable work has been conducted to develop automatic steering for shearers to overcome this problem. The only commercial system for automatic steering that has been developed to date uses a signal obtained from the natural gamma radiation difference that exists between coal and many, but not all, rock types that lie adjacent to the coal seam. This signal is used to control the movement of the ranging arms and thereby to keep the cutting drums contained within the seam.

Numerous systems have been devised to control the dust levels on a longwall face. All of these remediate the dust problem, but to date, no universally accepted solution to this problem exists.

Continuous Miners: These machines (Fig. 9.1.65) also cut the rock with picks. These tools are mounted on a cutter drum some 10 to 13 ft (3 to 4 m) long. The drum, in turn, is mounted on a hydraulically powered arm that controls the vertical movement of the drum. The machine is track-mounted, and the cutting procedure is to sump by driving the machine into the face with the rotating drum raised to cut the top portion of the face. When the machine is fully sumped, generally to about one-half the diameter of the drum, the arm shears the drum down to the floor. Broken rock (coal or some other weak rock type) is dropped onto the floor during this cutting action. A gathering arm (Fig. 9.1.65), or some similar loading system, loads this broken material onto an armored conveyor that runs through the center of the machine. This product is transported from this conveyor with shuttle cars.

The problems with this machine relate not so much to the machine itself but rather to the mining system in which it works. Many of these machines are capable of mining at rates of the order of 12 tpm or 720 tph (655 t/h). However, in practice, the average production from continuous miners in US coal mines is of the order of 400 to 500 tons/shift (360 to 455 t/shift). This disparity between machine capability and actual productivity arises mainly because of the need to tram the machine frequently out from the heading in order to install roofbolts and because of the discontinuous transport system (i.e., shuttle cars). Work continues to find solutions to these problems.

9.1.5 LIMITATIONS ON THE USE OF MECHANICAL CUTTING TOOLS

9.1.5.1 Specific Energy and Specific Power

The theoretical minimum quantity of energy that must be supplied in a fragmentation process is the surface energy required for the new surface area of the fragments produced. In practice, with all materials including rocks, the quantity of energy actually necessary to effect fragmentation is much greater, often by orders of magnitude, than this theoretical minimum. The actual quantity of energy depends on the type of process employed and the nature of the rock. These factors are not independent.

A useful method for comparing the efficiencies of various rock breaking methods is to measure the quantity of energy required to excavate a unit volume of rock. This parameter, which actually is the inverse of breaking efficiency since a high energy value indicates a low efficiency, is termed the *specific energy.* As indicated previously, specific energy depends on both the breaking method employed and the rock type. This empirical parameter is the most useful measure available for predicting either the power requirements for a particular machine to exca-

vate at a given rate in a given rock type, or, alternatively, the rate of excavation that a particular machine might be expected to achieve in a given rock type. The following discussion, modified from Jaeger and Cook (1979), shows how this parameter can be used to make these predictions.

Cook and Joughin (1970) published data on the measured values of specific energy for a variety of breaking methods in one type of rock, a strong quartzite. They plotted these data as a function of the mean sizes of the rock fragments produced by each method. Their figure is replotted in Fig. 9.1.66. Several interesting points are illustrated in this diagram:

1. Points that lie above the line, points 1 and 2, represent methods for which the surface energy exceeds the average. Conversely, points that lie below the line, points 3 and 8, represent methods for which the surface energy is less than the average.

2. The estimated average value for surface energy of 5.78 hp-hr/ft^2 (167 kJ/m^2) is almost three orders of magnitude greater than a value for the work of fracture that might be measured in a laboratory test set up to determine this constant. This is not surprising. In a laboratory test to measure surface energy, a tensile crack is driven slowly through a rock sample. For the processes indicated in this figure, indentation loads were applied, and energy was lost through friction in the crushed material formed. More energy was lost to kinetic energy of the rock fragments. Furthermore, the values in the figure represent the energy input to the machines loading the rock. Thus the mechanical inefficiencies of the drills or cutting machines also help to account for this discrepancy between laboratory and field measurements.

3. The most efficient processes (i.e., those with the least specific energy values) are impact drive wedges and explosives, points 7 and 8. Both of these methods break the rock in tension. The next most efficient methods—percussive drilling, drag bit cutting (with blunt bits), and roller bit cutting, points 4, 5, and 6—are mechanical methods that all break the rock by indentation. The least efficient methods—flame jet piercing and high-pressure water jets, points 1 and 2—involve, respectively, thermal breaking and erosional processes.

Specific energy (hp-hr/ft^3 or MJ/m^3) is related to the rate of excavation R (ft^3/sec or m^3/s), and the power applied to the rock P (hp or MW) through:

$$E_s = \frac{3600\ P}{R} \text{ in English units, or} \tag{9.1.45}$$

$$E_s = \frac{P}{R} \text{ in SI units}$$

Considerable attention is given in the literature to specific energy. Although the quantity of energy consumed in rock breakage is considerable, most of this energy is expended in secondary breaking operations. Usually, in primary rock breaking processes, the direct energy cost is not the dominant cost factor. Thus it is pertinent to ask why much attention should be paid to this parameter. The answer is that while the energy cost often is not a limiting factor, the quantity of energy that can be (1) transferred up to the working face and (2) injected into the rock, frequently is the real limitation on the rate at which rock can be excavated.

Most primary rock breaking operations today involve the use of either mechanical tools or explosives. Even when explosives are employed, mechanical tools, in the form of drillbits, are used first to excavate the holes into which the explosive charges are placed. The popularity of mechanical tools lies in the fact that, relative to many of the alternative methods, the specific energy required for breakage with these tools is low. Consequently, for a given rate of rock excavation, the power needed at the working face also is relatively low. The disadvantage of using mechanical tools is that, in many rock types, they limit the rate of energy transfer (i.e., power) to the rock which, in turn, limits the rate of rock excavation. This limit on power arises because the rate of wear or fracture of the tool materials increases as the power transmitted through the tools to the rock is increased. In weak rocks where the specific energy requirement is low, this is not a constraint on rock excavation rates. Indeed, over the past few decades, the trend in excavation equipment has been continuously to increase the power supplied to the machine cutting head in order to enhance the cutting rate. This might be termed the "brute force" approach. However, in medium-strength and strong rocks, this option of increasing the cutting rate by increasing power is not available because this additional power results in unacceptably short tool life.

As noted above, only a small fraction of the energy applied to a mechanical tool is usefully expended in the creation of new fracture surfaces. Most of this energy is dissipated as heat. Therefore, one approach for increasing excavation rates or for extending the range of rock types in which mechanical tools might be employed would be to increase the proportion of the tool energy used for creating rock fractures. This could be termed the "smart" approach. A basic understanding of the basic principles of rock fragmentation induced by mechanical tools, given in the preceding sections, is necessary in order to develop a system utilizing the available power in a more productive manner.

An alternative approach would be to develop stronger tool materials, and work that is being carried out in this area shows some promise.

Many of the nonmechanical methods for rock breaking are associated with very high specific energies. In some cases, these energy requirements are severe enough that the energy cost for the rock excavation process would be prohibitive. Even when this is not the case, problems would likely be experienced either in transmitting sufficient power to the rock face, to maintain a reasonable rate of excavation, or in removal of the heat produced, from energy not expended in creating new rock surfaces.

One solution to these problems is to use a combination of methods to effect rock breakage. For example, a nonmechanical method can be used to preweaken the rock by cutting a series of kerfs in the face. A mechanical tool then might be employed to break out the majority of the rock. In this case, because only a small volume of the total rock excavated is removed by the nonmechanical method, Maurer (1980) suggested that a new term be introduced to define the energy requirements for breaking. This term he called the *specific kerfing energy* E_{ke}, which he defined as:

$$E_{ke} = \frac{\text{energy}}{\text{kerf area}} = \frac{\text{power}}{\text{kerf depth} \times \text{traverse speed}} \qquad (9.1.46)$$

where kerf area is the surface area on one side of the kerf.

Another technique, known as jet assisted cutting, uses water jets to assist the action of mechanical tools during the rock cutting operation. In this case the jets are not used to kerf the rock, but rather they act to continuously remove the crushed rock from beneath the tool. This substantially reduces the tool forces necessary to cut the rock because the cushioning effect of the crushed rock is eliminated allowing the tool to press more directly on the intact rock to form chips. Hybrid techniques using these approaches have been developed and, in fact, some of these methods show promise for achieving a substantial breakthrough in rock excavation technology. Some of these methods are reviewed elsewhere in this *Handbook*.

9.1.5.2 Factors that Affect Tool Life

Although some disk cutters and some roller cone bits continue to be manufactured from hardened steel, cemented tungsten carbide is by far the most widely used material for rock cutting tools today. A relatively new material, polycrystalline diamond compact, is finding increasing application for drag bits, particularly in drillbits (see 9.1.3.1). This material has the promise, as yet unfulfilled, of producing a major breakthrough in cutting technology.

The properties of tungsten carbide that make it the material of choice are high hardness combined with high (relative to other hard cutting materials) toughness. Hardness provides wear resistance. Toughness is a measure of resistance to brittle fracture. High toughness, therefore, minimizes the probability of inducing fractures that could lead to tool failure. Kenny (1971) notes that this definition of toughness is not synonymous with an absence of brittleness. Rubber and cemented tungsten carbides are examples of two materials that are both tough (i.e., resistant to fracture) and brittle when loaded in tension. In these cases, there is no distinction between strength and toughness. Polycrystalline diamond is much harder, and thus more wear resistant, but it is more susceptible to brittle fracture (i.e., it is less tough), than cemented tungsten carbide.

Wear Mechanisms: The four most significant wear processes for materials in general are identified by Rabinowicz (1965) as adhesive wear, abrasive wear, corrosive wear, and surface fatigue wear. These processes are described briefly in the following.

Adhesive Wear—When two surfaces are brought together, an attraction force is set up between the atoms on the surfaces of the two bodies. If the bodies then are separated, this attractive force attempts to pull material from one surface onto the other. Any material removed in this way is termed an adhesive wear fragment. Although this is the most common of all wear mechanisms, it is not the most important mechanism for rock cutting tools.

Abrasive Wear—This form of wear occurs either when a hard, rough surface slides against and plows grooves in a softer surface, or when abrasive particles are introduced between two surfaces and these particles abrade material from one or both surfaces. This is the most common and the most important wear mechanism for rock cutting tools. In this case, the rock debris formed by the tool constitutes the wear particles that abrade the tool.

Fortuitously, these two important wear processes, adhesive and abrasive wear, obey the same Holm-Archard relationship (Holm, 1946; Archard, 1953):

$$V = \frac{k_a P\, l}{H} \qquad (9.1.47)$$

where k_a is a wear coefficient, a constant dependent on whether the wear process is adhesive or abrasive; P is the applied load; l is the distance of sliding; and H is the hardness.

This expression shows the importance of hardness of the tool material to the wear process.

Corrosive Wear—This form of wear occurs when sliding takes place in a corrosive environment. This mechanism is not of great concern for rock cutting tools.

Surface Fatigue Wear—Repeated mechanical or thermal loading cycles can lead to the formation of fatigue cracks in the surface or subsurface of a material. These cracks eventually cause breakup of the surface with the formation of large fragments.

Cemented Tungsten Carbides: This tool material is manufactured by sintering powders of tungsten carbide and cobalt. The cobalt is a binder that is distributed throughout the body of the material in thin films between the tungsten carbide grains. It constitutes 5 to 15% by weight of the mix (for mining tools) and gives increased toughness to the material. The properties of the tool material are affected both by the cobalt content and by the size of the tungsten carbide and cobalt grains.

Cemented tungsten carbide is manufactured in a wide variety of sizes and shapes, depending on the rock cutting application. The larger the size of the carbide insert the lower its strength. The carbide is mounted into a (usually hardened) steel bit body. This mounting is achieved either with a braze joint or by press-fitting the carbide insert into a machined hole in the bit body. The hardness of the cemented tungsten carbides produced for

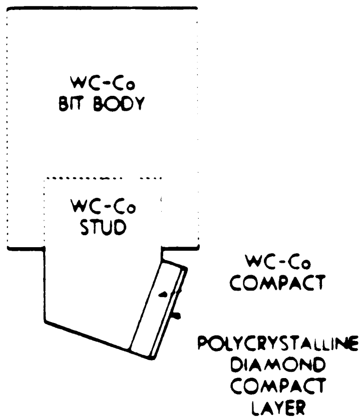

Fig. 9.1.67. Mounting of PDC onto a cemented tungsten carbide stud.

mining tools generally is in the range 1.45×10^6 to 2.175×10^6 psi or 10 to 15 GPa (Perrott, 1980).

Polycrystalline Diamond Compacts (PDC): These compacts are manufactured by sintering synthetic diamond crystals with a (mostly cobalt) binder. The binder acts to promote diamond bonding and, in contrast to the cemented carbides, it only plays a role in the mechanical behavior of the composite at high temperatures (Hibbs and Lee, 1978). After the sintering process, the binder forms roughly spherical inclusions rather than films between the grains, which means that hard bridges exist between the diamond grains. These boundaries are, however, very strong, and when fracture occurs it is as likely to propagate through the grain as along a grain boundary (loc. cit.).

The room-temperature hardness of polycrystalline diamond compacts is approximately 9.86×10^6 psi or 68 GPa (Lee and Hibbs, 1979). The importance of this additional hardness now is apparent. Provided that the dominant wear mechanisms for the cutting tools are adhesive, abrasive, or both, it can be seen from Eq. 9.1.47 that for a given loading situation, the wear rate (that is the volume of tool material removed per unit length of cut) of a PDC bit will be less than that of a cemented tungsten carbide bit by the ratio of the hardness of these two materials, or a factor of about five.

PDC, however, is more susceptible to brittle failure than cemented tungsten carbide (Glowka and Stone, 1984). Consequently, to give the required strength to the tool material, a PDC cutting insert is constructed by sintering a thin layer of polycrystalline diamonds onto one end of a short cylinder of cemented tungsten carbide. This carbide provides support to the diamond wafer. This cylinder, in turn, is attached, usually with a braze joint onto a (generally) cemented tungsten carbide stud (Fig. 9.1.67). These studs are then mounted, often by press-fitting, into the bit body (Fig. 9.1.34).

Tool Fracture and Wear: *Fracture*—Because cemented carbides and PDCs are brittle materials, they are approximately an order of magnitude stronger when loaded in compression than when loaded in tension. Furthermore, their strength, as for any brittle material, is enhanced dramatically when (even relatively small) compressive loads are applied to the body in directions orthogonal to the line of action of the main force. This is termed triaxial loading.

Consequently, bit designers aim to ensure that the bit geometry and the mode of loading will not cause tensile stresses to be applied to the bit. Also, where possible, they will mount cemented tungsten carbide inserts in a bit body in a manner such that triaxial compressive stresses are applied to the inserts. For example, when tungsten carbide button inserts are press-fitted into the bit body the hardened steel body applies a radial compressive stress to the inserts.

Despite these precautions, in many applications, one of the main reasons for replacing bits (both cemented tungsten carbide and PDC) in service is because the inserts fail in a brittle manner.

One of the main factors responsible for this type of failure is impact loading of the bits. An impact blow induces compressive stress waves in the bit insert. These are reflected back from free surfaces as tensile stress waves, which, because the material is very susceptible to tensile failure, can induce cracking in the insert. The magnitude of this tensile stress may be sufficient to initiate and propagate a crack to induce failure with a single blow. More typically, impact fatigue will take place. In this case the crack is extended incrementally by each loading cycle until eventually failure takes place. To prevent or to minimize this type of failure it is important to minimize impact loading to the cutting tools. This is most easily achieved through the use of a stiff drive to the cutting head.

Wear—The two processes considered to be of most importance for rock cutting tools are abrasive wear and surface fatigue wear. Abrasive wear can take place only if the hardness of the abrasive particles in the system is greater than, or at least of the same order as, the hardness of the cutting tool. In other words, if these particles are much softer than the cutting tool, abrasive wear will not take place. In rock cutting, the rock debris constitute the abrasive particles. One of the most common hard constituents of rock is quartz. The room temperature hardness of this mineral is only 1.595×10^6 psi (11 ± 0.3 GPa) (Perrott, 1980), generally less than that of cemented tungsten carbide and considerably less than that of PDCs.

It is recognized that the mechanisms of wear are different depending on the relative hardness of the abrasive particles and the material experiencing wear. When the hardnesses of these two materials are comparable, the particles are termed a "soft" abrasive (Richardson, 1968). On the other hand, when the hardness of the particles far exceeds that of the material of interest, the particles are termed a "hard" abrasive. According to Larsen-Basse (1980), quartz acts as a hard abrasive when the hardness of cemented tungsten carbide is less than about 1.566×10^6 psi (10.8 GPa); otherwise it acts as a soft abrasive. The rate of wear is found to be proportional to the applied load for both hard and soft abrasives. In other words Eq. 9.1.47 is correct, in terms of the applied load, for both types of abrasive. This is not the case for hardness. The wear rate is much greater (often an order of magnitude greater) when hard abrasives are used (Larsen-Basse, 1981). Thus Eq. 9.1.47 is correct, in terms of hardness, only for hard abrasives. An abrasive is considered hard, in general, when the ratio of the abrasive hardness to the materials' hardness is 1.2 or greater.

Hard abrasives with coarse (1.57-in. or 40-mm) particles act as micromechanical cutting tools, cratering and cutting grooves in the surface of a cemented carbide. These craters and grooves are much larger than the carbide grains, and the material from these damaged regions is easily removed (loc. cit.).

Soft abrasives cannot indent the surface; instead, damage to the tungsten carbide grains occurs through surface fatigue. Also these abrasives cause erosion and extrusion of the cobalt binder from the region around the grains close to the surface. Work by Brainard and Buckley (1979) showed that the removal of cobalt, even to shallow depths below the surface, greatly increases the wear rate of the carbide by allowing the tungsten carbide grains to be more easily plucked from the surface.

Although thermal fatigue has not been thoroughly investigated for rock cutting tools, it has been shown to be an important failure process in metal cutting (Bhatia et al., 1978), and probably it also is significant in rock cutting (Perrott, 1980).

From this discussion, it is apparent that rock particles would be expected to act only as a soft abrasive on cemented tungsten carbides. In consequence, it would be expected that abrasive wear of these rock cutting tools would not pose substantial difficulties, although thermal fatigue still might produce significant tool wear. In fact, however, for reasons discussed below, abrasive wear of cemented tungsten carbide rock cutting tools is a major problem.

Rock debris, with a relative hardness some six times less than that of diamond, would not be expected to cause abrasive wear of PDCs, and this indeed appears to be the case. In this material, each diamond grain acts like a single-crystal cutter. Failure of the material while cutting rock occurs through one of following processes (Hibbs et al., 1978):

1. The edges of individual crystals are crushed, and the broken material is removed in small pieces; alternatively, a large portion of an individual crystal is broken in a simple brittle fracture process.

2. By gross fracturing, either as a result of impact loading or crack formation from bending stresses caused by the rock pressing on the front face of the bit; in both cases, the fracture is transgranular indicating the high strength of the grain boundaries.

3. By the growth of pits that are formed initially by the removal of surface metallic inclusions during the tool shaping process.

4. From internal flaws, such as poorly bonded grains.

The factor that has been overlooked in the discussion thus far is the influence of temperature on the hardness of the tool materials. It is known that the temperature of a tool rises, usually to several hundred degrees Celsius or more, during rock cutting operations (see, for example, Hood, 1978; Whitbread, 1960). The hardness of both cemented tungsten carbide and diamond decreases dramatically with increasing temperature (Figs. 9.1.68 and 9.1.69). From Fig. 9.1.68, it is apparent that discrepancies exist in the literature regarding the hardness values of cemented tungsten carbide with temperature. Osburn (1969) attempted to explain these discrepancies in terms of different methods of sample preparation by the various investigators.

The hardness of quartz as a function of temperature also is given in Fig. 9.1.68. It can be seen that the hardness of this mineral decreases rapidly as the temperature increases from room temperature to 1063°F (573°C), at which point quartz experiences a phase change. The hardness then increases with temperature over approximately a 200°F (100°C) range before decreasing rapidly again.

The hardness of a diamond compact as measured using a Vickers diamond indenter (Lee and Hibbs, 1979) is given by the lower curve in Fig. 9.1.69. The upper curve in this figure, reproduced by Lee and Hibbs (1979), is taken from Loladze and Bockuchava (1972). The type of diamond tested for this upper curve is unknown. Lee and Hibbs (1979) observed that polycrystalline diamond compacts suffer gross thermal damage when they are heated above 1382°F (750°C). However, the main point of note is that at 1292°F (700°C), they measured the hardness of a PDC as 6.754×10^6 psi or 4750 kg/mm^2, or 47 GPa (since 1000 kg/mm^2 = 9.807 GPa).

In terms of damage caused to tools by thermal heating during rock cutting operations, drag bits present a much greater problem than roller cutters. This is because an individual element on a roller cutter heated by the rock breaking process, has the opportunity to cool as the cutter rotates to bring other cutting elements into contact with the rock. Typically, any one element will be heated by frictional contact with the rock for less than 10% of the time that the cutting machine is operating. A drag bit, on the other hand, frequently is in continuous contact with the rock while the machine is operating. Even when these bits are mounted on a rotating drum, such as a continuous miner, generally they are in contact with the rock for about half of the time that the machine is cutting. Hence they have far less opportunity to cool. For this reason, research efforts to model the temperatures generated by tools during the cutting operation have concentrated on drag bits. Analytical models for these drag bit temperatures have been proposed by Cook (1982) and Glowka and Stone (1983).

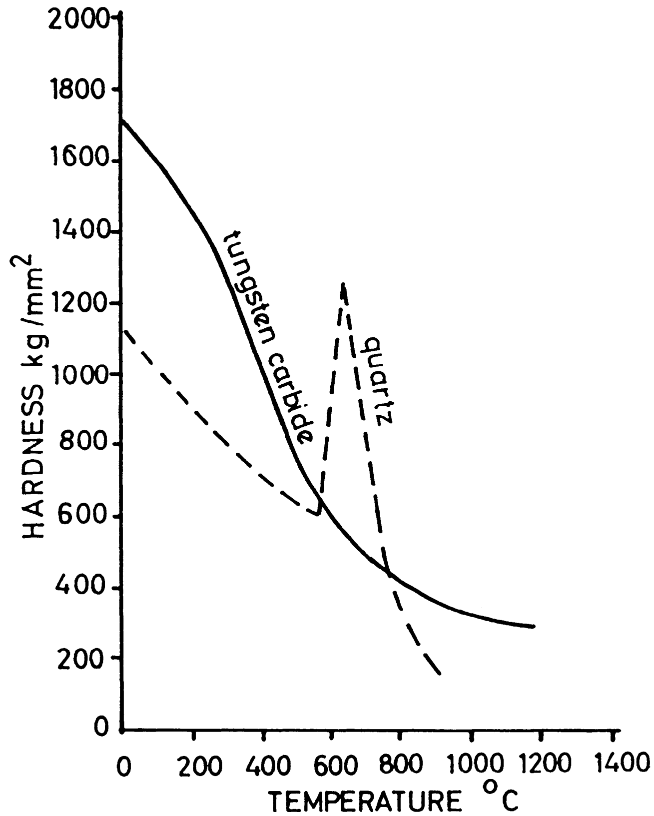

Fig. 9.1.68. Reported effects of temperature on the hardness of cemented tungsten carbide and quartz (after Osburn, 1969).

The latter authors used a laboratory study cutting in sandstone (Lee and Hibbs, 1979) in which it was shown that PDC wear rates accelerate when bit temperatures exceed 662°F (350°C). Glowka and Stone used their model to predict the maximum bit cutting force, μF_{cr}, that could be exerted on the bit without causing it to exceed this threshold temperature. In this expression, μ is taken as constant and is termed the coefficient of cutting friction, and F_{cr} is the critical weight-on-bit, (equivalent to the bit normal force). F_{cr} controls the depth of cut taken by the bit. Glowka and Stone correlated their calculated bit temperatures with measured bit wear rates and found the consistent pattern of constant bit wear rates (about 10^{-10}cm^3 of wear/cm of cut length) when bit temperatures were maintained below 350°C. Above this wearflat temperature, the bit wear rate accelerated rapidly, in some cases by as much as two orders of magnitude. Their results also showed that liquid cooling of the bits was an important factor in reducing bit temperatures. Glowka and Stone interpreted these results as support for the case that bit wear is correlated directly with reduced bit hardness at elevated

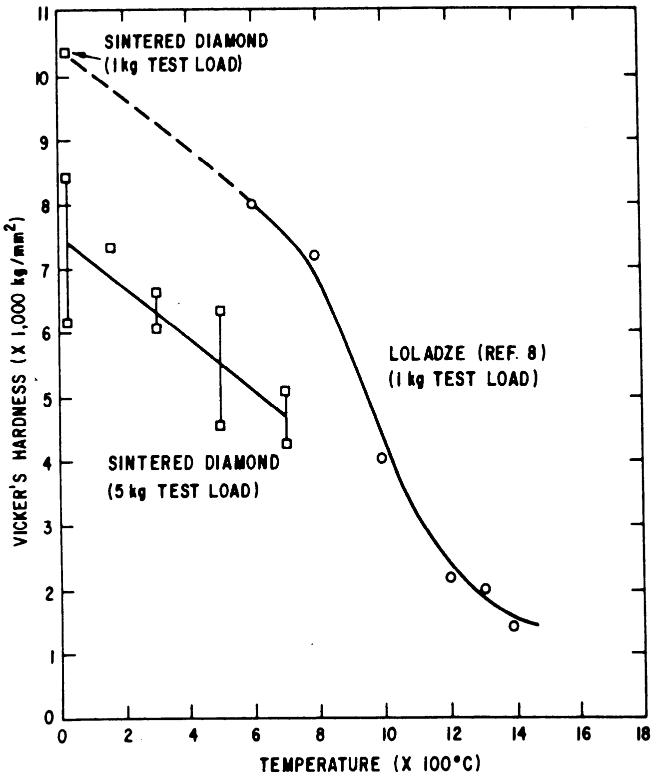

Fig. 9.1.69. The effect of temperature on the hardness of diamond (after Lee and Hibbs, 1979).

temperatures, and they recommended that the operating conditions for PDC bits should be such that bit wearflat temperatures are always maintained below 350°C. They used their model to determine the maximum forces that should be transmitted to a bit to ensure that this criterion is satisfied.

Perrott (1980) suggested that a lower bound for cutting tool wear could, in principle, be determined by calculating or measuring the temperature at the rock/tool interface during a cutting operation and by making the assumption that the abrasive rock particles and the tool are in thermal equilibrium. The hardnesses of the particles and the tool at this temperature then could be determined, and this would establish whether the particles were acting as hard or as soft abrasives. Similarly, an upper bound for wear could be determined by assuming that the abrasive particles remain at room temperature while the tool is heated by the cutting process. The author notes that the latter assumption is likely to be the more realistic one because the tool is continuously sliding over new abrasive particles.

Making this latter assumption Perrott proceeded to back calculate temperatures at the rock/tool interface during a cutting operation, using wear data published by other workers. The assumption was made that the tool wear rate accelerates when the ratio of the (room temperature) hardness of the abrasive to the (hot) hardness of the tool is 1.25 or greater. In other words, wherever these other investigators reported a transition in wear behavior from slight or moderate to severe, Perrott assumed that this change was caused by the abrasive particles starting to act as a hard abrasive. Using this approach, he calculated temperatures at the interface of 662 to 752°F (350 to 400°C) for results published by Latin (1961) and 392 to 482°F (200 to 250°C) for results published by Larsen-Basse and Koyangi (1978). Perrott noted that temperature measurements of rock bits during cutting operations confirm that temperatures of this magnitude commonly are generated at the rock/tool interface. In fact, work by Hood (1978) demonstrated that blunt drag bits cutting in strong abrasive rock can generate temperatures of 752°F (400°C) several millimeters back from this interface in the braze joint between the cemented tungsten carbide insert and the steel bit body. Calculations by Whillier (1976) demonstrated that with these temperatures in the braze joint the interface temperature was likely in excess of 1832°F (1000°C). These calculations were verified by Hood (1978) who found streaks of the WC-Co composite in the rock debris at the bottom of the groove machined by the bit. Since the cobalt binder melts at a temperature of 2723°F or 1495°C (Cook, 1981), this finding of thermal breakdown of the bit insert showed that the temperature generated at the bit/rock interface must have exceeded this value during the cutting operation.

In summary, temperature is the main factor that controls the wear rates of both cemented tungsten carbide and PDC bits. Above some critical temperature (this temperature value is not yet well established but probably is of the order of 392 to 662°F (200 to 350°C)), a WC-Co composite begins to wear rapidly because it sees quartz particles as hard abrasives. Although the wear mechanism of PDC bits is different, mainly microchipping rather than abrasive wear, this process also is temperature sensitive. The critical temperature below which it appears that these bits should be operated is 662°F (350°C). At temperatures in excess of 1382°F (750°C), a PDC tool fails catastrophically.

The temperatures generated at the bit wearflat is a function of the power applied to the tool. Thus one way to control these temperatures, and thus to control bit life, is to restrict this applied power. Unfortunately, this is not a satisfactory solution; the power to the tool can be reduced either by decreasing the cutting velocity of the tool or by reducing the depth of cut taken by the tool. Obviously, either of these steps causes a reduction in the rate of rock excavation, hardly a desirable option. Another approach is suggested by Glowka and Stone's finding that liquid cooling of the bit results in substantial reductions in bit temperatures.

Chapter 9.2
ROCK BREAKAGE: EXPLOSIVES

CHARLES H. DOWDING AND C.T. AIMONE

9.2.1 BLAST DESIGN

C.T. AIMONE

The application of explosives to the fragmentation of rock for mining or extractive purposes is often referred to as a science as well as an art. In early years, explosives development became a science as chemists strove to perfect stable yet powerful explosive mixtures for a variety of purposes. In recent years, the needs to minimize the costs of blasting and to control the environmental effects of noise and ground motions have brought about carefully engineered blast designs, aided by research. The research includes computer modeling, explosives formulation, high-speed photography, and development of new initiators. In addition, improved quality control in the manufacturing of explosive products and devices has evolved. Scientists and engineers, however, along with practicing blasters, continue to agonize over the ideal approach to optimizing the fracturing process. Systematic research in rock blasting has provided a good understanding of the many factors that influence fragmentation. Many of these factors involve site geology, explosives selection, timing for individual detonations, drilling pattern, and explosives loading characteristics. Parameter studies in blasting research are limited to two to three factors. The cumulative effects of these factors can only be obtained through costly trial-and-error blasts. As a result, obtaining precise control of these factors is a constant challenge. The art in blasting evolves from the skillful way in which the blaster uses an understanding of the influencing factors to maximize blasting efficiency.

Chapter 9.2 provides a basic understanding of the principles involved in the selection and application of commercial explosives to rock blasting in the mining industries and of the monitoring and control of blast effects. In 9.2.1, entitled blast design, the calculations and examples presented are to be used as guidelines and are representative of the many different methods of calculation and design. This chapter begins with a discussion of the chemical and physical properties of explosive mixtures. The following description of explosive products and initiating systems includes a discussion on comparative properties of explosives. An overview of important explosive thermodynamic properties is given with example calculations. Rock blasting practices are presented with fracture theory and the effects of geology. Aspects of safety in the transportation, storage, and handling of explosives are discussed. Blast-design procedures and examples applied to surface and underground mining are presented. Estimating drilling and blasting costs and an overview of recent advances in rock blasting conclude this portion of the chapter.

Throughout this segment, units of cubic centimeters (cm^3) are used for numerical examples that involve explosive quantities on a bulk or volumetric basis. Notwithstanding usage norms involving SI units, cm^3 is used extensively in the explosives industry to describe explosive properties. Density values appear in this text without units; however, for calculation purposes, the units are assumed to be g/cm^3.

Segment 9.2.2, monitoring and control of blast effects, summarizes vibration measurement and structural response associated with rock blasting. Experimental observations are included to demonstrate the effects of blasting on ground motion parameters. Blast design procedures to set safe criteria for the control of blast effects are exemplified. Blasting regulations and computerized monitoring instrumentation are also discussed.

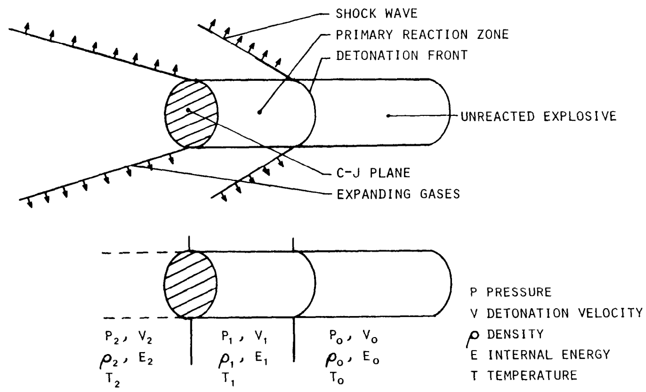

Fig. 9.2.1.1. The detonation process for cylindrical explosives.

9.2.1.1 Classification of Commercial Explosives

Detonation Theory: An *explosive,* or blasting agent, is a compound or a mixture of compounds, which, when initiated by heat, impact, friction, or shock, is capable of undergoing a rapid decomposition, releasing tremendous amounts of heat and gas. The decomposition is a self-propagating, exothermic reaction called an *explosion.* The stable end products are gases that are compressed, under elevated temperature, to very high pressures. It is the sudden rise in temperature and pressure from ambient conditions that results in a shock wave, or a *detonation*, traveling through the unreacted explosive. The velocity of detonations lies in the approximate range of 5000 to 30,000 fps (1500 to 9000 m/s), well above the speed of sound in the explosive material. *Deflagration* is the chemical burning of explosive ingredients at a rate well below the sonic velocity. It is associated with heat only and carries no shock. Deflagration occurs when less than ideal hole-loading conditions or explosive formulation are involved.

All commercial explosives are mixtures of carbon, hydrogen, oxygen, and nitrogen. The maximum energy release upon detonation occurs when the explosive mix is formulated for oxygen balance. An *oxygen-balanced mixture* is one in which there is no excess or deficiency in oxygen, such that the gaseous products formed are chiefly H_2O (water vapor), CO_2 (carbon dioxide), and N_2 (nitrogen). In actual blasting practice, small amounts of noxious gases such as NO (nitric oxide), CO (carbon monoxide), NH_4 (ammonia), CH_4 (methane), and solid carbon, are formed resulting in nonideal detonations and somewhat less than ideal pressures and energies. Commercial explosive formulation attempts to achieve an oxygen-balanced mixture.

The work done by chemical explosives in the fragmentation and displacement of rock depends on the shock energy as well as the energy of the expanding gases. Fig. 9.2.1.1 shows an

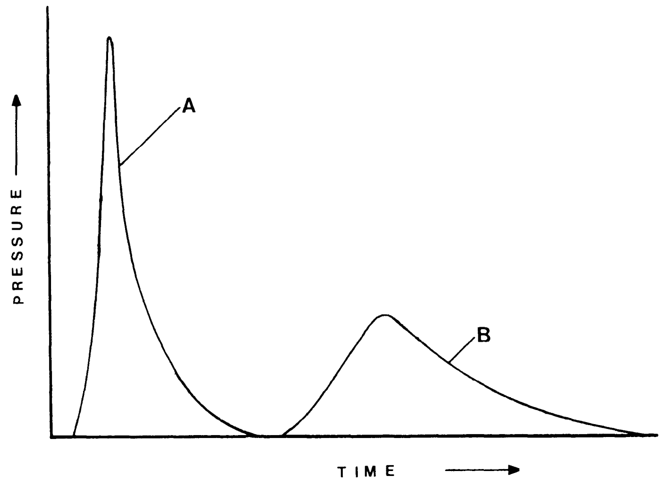

Fig. 9.2.1.2. Pressure pulse shapes for a high explosive (A) and a commercial explosive containing high gas volume (B).

idealized detonation wave traveling through a cylindrical explosive shape, producing an increase in pressure. The steady-state chemical reaction takes place behind the shock front within the reaction zone. At the end of this zone, a nonsteady-state region exists. It is created by a flow of expanding gases in a direction opposite to that of the traveling wave front. The boundary between the steady and nonsteady states is referred to as the *Chapman-Jouget (C-J) plane.* At this plane, the chemical reaction is complete, assuming an ideal detonation. It is at the C-J plane that all the thermodynamic properties of pressure P, velocity V, temperature T, internal energy E or heat of formation Q, and density r, are calculated. Fig. 9.2.1.2 shows generalized pressure waves produced from two detonations. The maximum pressure and duration of a wave pulse is directly proportional to the shock energy and gas pressure of the explosive, respectively. High explosives such as military explosives or highly sensitive commercial explosives are characterized by an intense shattering effect upon detonation (known as *brisance*). They liberate gaseous products very quickly. The distance between the shock front and the C-J plane is very short and results in a pressure pulse of high amplitude and short duration. The pressure pulse for less-sensitive commercial explosives shows a decreased pressure amplitude and a longer pulse length. In this case, the reaction is slower and the gas volume is greater.

Comparative Properties of Explosives: Explosives and blasting agents are characterized by various properties that indicate how they will perform under field conditions. These properties include fume class, density, water resistance, temperature effects, detonation velocity, detonation pressure, borehole pressure, sensitivity, and strength.

Fume Class—Fumes are noxious gases that are produced from the detonation of explosives. The production of these gases is most critical in underground and other confined workings. Many factors affect the volume of poisonous gas produced including oxygen balance and adverse loading of explosives. The *fume class* is a measure of the toxic gases in cubic feet per 0.44 lb (200 g) of unreacted explosive. Table 9.2.1.1 lists the current fume classifications as adopted by the Institute of Makers of Explosives (IME). The US Bureau of Mines (USBM) limits the volume of poisonous gases produced by permissible explosives (those used in underground coal and other gaseous mines) to 2.5 lb (1.14 kg).

Table 9.2.1.1. Standards for Fume Class

Class	Volume poisonous gas per 0.44 lb explosive, ft^3
1	0.16
2	0.16–0.33
3	0.33–0.67

Source: Dick et al., 1983.

Density—The *density* of an explosive is defined as the weight per unit volume or the specific gravity. Commercial explosives range in density from 0.5 to 1.7. Explosives with a density less than 1 will float in water. Therefore, in water-filled holes, an explosive with a density greater than 1 is required. For certain granular explosives such as dynamite, density correlates to the energy released in a given borehole volume. However, for water-based explosives, this is not the case, and often the reverse is true. Density is most useful in determining the *loading density LD* or the weight of explosives one can load per unit length of borehole (in pound per foot or kilogram per meter), and is calculated in English units as

$$LD = 0.3405\ \rho\ D^2 \tag{9.2.1.1}$$

where r is density, and D is explosive column diameter in in. Knowledge of loading density is required for blast-design calculations.

Water Resistance—The ability of an explosive to withstand exposure to water for long periods of time without loss of strength or ability to detonate defines the *water resistance.* A numerical rating is used based on the results of tests performed on the explosive. However, explosive manufacturers individually rate products based on a relative basis as good, fair, or poor rating. The presence of moisture in amounts greater than 5% dissolves chemical components in dry blasting agents and alters the composition of gases produced, contributing to the formation of noxious fumes and lower energy output. Gelled granular products have good water resistance, and certain water-based mixtures have an excellent rating.

Temperature Effects—Extreme low temperatures affect the stability as well as the performance of explosives. The sensitivity and detonation velocity are hampered for certain water-based explosives at low temperatures while dynamites can become dangerously unstable below freezing temperatures. Explosives manufacturers recommend the appropriate range of temperature for storage and use.

Detonation Velocity—The *detonation velocity* is the speed at which the detonation front moves through a column of explosives. For high explosives such as dynamite, the strength of an explosive increases with detonation rate. For dry blasting agents and water-based explosives, field loading conditions greatly affect detonation velocity. Such conditions include borehole diameter, density, confinement within the borehole, the presence of water, and other factors. The speed of detonation is important when blasting in hard, competent rock where a brisance effect is desired for good fragmentation.

For most explosives, there is a minimum diameter D_{min} below which detonation velocity increases nonlinearly with increasing borehole diameter (Fig. 9.2.1.3). Above D_{min}, the explosive has reached its steady-state velocity. At this point, all thermodynamic properties are at a maximum as the reaction front approaches a plane shock front. At diameters less than D_{min}, com-

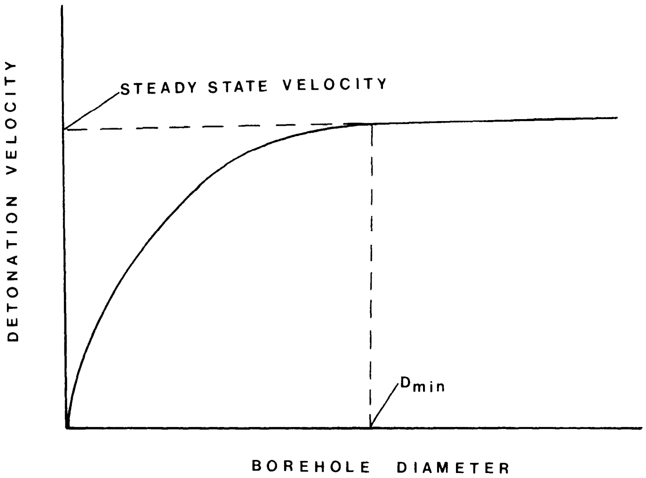

Fig. 9.2.1.3. Generalized relationship between detonation velocity and borehole diameter.

plete reactions do not take place, and less than ideal energy and pressure evolve from the slower detonation rates. This represents a loss in terms of dollars spent on explosive energy.

Detonation Pressure—The *detonation pressure* is the maximum theoretical pressure achieved within the reaction zone and measured at the C-J plane in a column of explosives. The actual pressure achieved is somewhat less than this maximum due to nonideal loading conditions always present in practice and due to certain explosive formulation. Most commercial explosives achieve pressures in the range of 0.29 to 3.48 × 10^6 psi (2 to 24 GPa). Although detonation pressure is related to the temperature of the reaction, a number of simplifying formulas are available for estimating detonation pressure for granular explosives based on detonation velocity and density, such as (in English units):

$$P = 3.37\,(10)^{-3}\,\rho\,V^2 \qquad (9.2.1.2)$$

where P is detonation pressure in psi, ρ is density, and V is detonation velocity in fps (Anon., 1987a).

Borehole Pressure—*Borehole pressure* is the maximum pressure exerted within the borehole upon completion of the explosive reaction measured behind the C-J plane. Such measurements cannot be made directly and are done during underwater tests performed for energy and strength determinations. With the use of hydrodynamic computer codes, theoretical calculations of borehole pressures are made. There is little agreement in the literature regarding specific estimates of actual borehole pressures. In general, pressures after detonation within the borehole are estimated to be less than 30% of the theoretical detonation pressure.

Sensitivity— The definition of explosive *sensitivity* is two-fold. It includes sensitivity against accidental detonations in addition to the ease by which explosives can be intentionally detonated. From the standpoint of safety and accidental detonations, the sensitivity of an explosive to shock, impact, friction, and heat determine its storage and handling characteristics. Standardized tests for high explosives have been adapted for commercial explosives that include the friction (pendulum), impact (fallhammer), and projectile tests, among others. These tests are explained by Meyer (1981).

The term properly used to define the propagating ability of an explosive is *sensitiveness.* In this respect, tests such as the No. 8 strength blasting cap test, air-gap test, and the minimum critical diameter test are used. The cap sensitivity test measures the minimum energy required for initiation and is used to classify explosives (e.g., cap sensitive vs. noncap sensitive products) or the ability to initiate an explosive directly with a standard cap. The No. 8 cap is an industry standard cap of specific dimensions and charge characteristics. The air-gap test measures the distance between the ends of adjacent cartridge explosives for which reliable initiation can be propagated from one cartridge to another. The *critical diameter* of an explosive is the smallest diameter at which an explosive will maintain a steady-state detonation. Below this critical diameter, explosives may deflagrate or "dead press." Dead pressing occurs when an explosive is densified to a point that no free oxygen is available to ensure the start or progression of detonation. Establishing the critical diameter of all explosives is an important explosive selection criteria.

Strength—The strength of an explosive is a measure of its ability to break rock. The terms "weight strength" and "bulk strength" were useful many years ago when explosives were primarily comprised of nitroglycerin cartridges, packaged in 50-lb (23-kg) boxes. In recent years, with the development of bulk blasting agents and less sensitive ingredients, new testing methods have been established to determine relative energies for all commercial products regardless of ingredients or packaging. The performance potential of an explosive is a function of the detonation velocity and density, as well as the volume of liberated gases and the heat of the reaction. A number of methods are used to establish this energy including the use of theoretical computer models and tests such as crater, ballistic mortar, and underwater tests. Of these methods, underwater tests give the best correlation to rock-breakage performance.

Underwater tests were developed to measure both the shock energy and the gas (bubble) energy released during the detonation of standard test samples. Cole (1948) describes the calculations involved while the test is detailed by Anon. (1987a) and Anon.(1977). These energy values have been useful in predicting the rock-breaking capabilities of explosives for comparative purposes.

Other terminology widely used by manufacturers is based on the theoretical heat of reaction determined by explosive formulation. *Absolute bulk strength* (ABS) in calories per cubic centimeter and *absolute weight strength* (AWS) in calories per gram are computed from the heat liberated during the detonation and formation of gaseous end products. Note ABS and AWS can be computed from one another if density is known, and it is the volumetric basis of reaction heat which correlates with energy. Most manufacturers of explosives will include either value with technical product literature.

A mixture of ammonium nitrate and fuel oil (ANFO) is by far the most widely used commercial blasting product. Depending on the proportions of the mix, the heat of reaction is approximately 850 cal/g. As a dry, free-running blasting agent, ANFO is capable of being loaded or packaged at varying densities. For a typical density of 0.85 and an AWS of 850 cal/g, the ABS = (850 cal/g) (0.85) = 723 cal/cm^3.

Other common strength terms are the *relative weight strength* (RWS) and *relative bulk strength* (RBS) in which the relative measure of energy available per unit weight or volume of an explosive is compared to an equal weight or volume of the standard commercial explosive ANFO. The RWS and RBS are computed as a percentage of that available from ANFO. In Ex. 9.2.1.1, explosives A and B have ABS values of 645 and 980 cal/cm^3 and densities of 0.8 and 1.25, respectively, and the RBS and RWS are computed.

Example 9.2.1.1. Determine the relative strengths of explosives A and B.

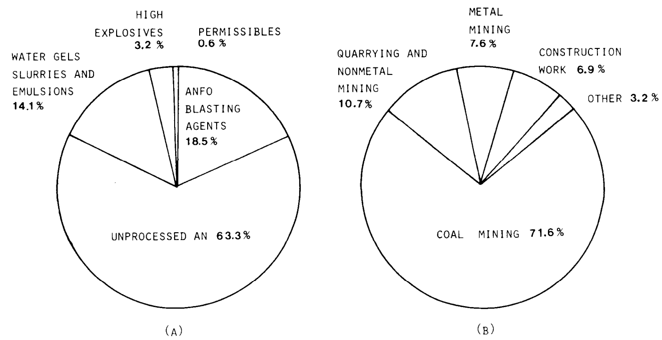

Fig. 9.2.1.4. Industrial explosives and blasting agents sold in the US for consumption in the US (A) by classification for 1988 and (B) by use for 1987 (Anon., 1989).

Solution. Relative bulk strength:

Explosive A

$[(645 \text{ cal/cm}^3)/(723 \text{ cal/cm}^3)]$ 100% = 89.2%

Explosive B

$[(980 \text{ cal/cm}^3)/(723 \text{ cal/cm}^3)]$ 100% = 135.5%

Relative weight strength:

Explosive A

$[(645 \text{ cal/cm}^3)/(0.8)\ (850 \text{ cal/cm}^3)]$ 100% = 94.9%

Explosive B

$[(980 \text{ cal/cm}^3)/(1.25)\ (850 \text{ cal/cm}^3)]$ 100% = 92.2%

The value of RBS and RWS of ANFO is 100%. It should be noted that based on a volumetric basis, explosive A is less powerful than ANFO while explosive B is more powerful than ANFO.

Commercial Explosive Products: There are a number of ways in which commercial explosives are classified. Often *military explosives,* referred to as high explosives (HE), are classified separately from industrial explosives. Examples of military explosives include TNT, PETN, RDX (cyclonite), Tetryl, and compositions such as A3, B, B4, C4, which are mixtures of RDX, TNT, and additives to provide a moldable consistency. These explosives are chiefly used in the weapons industry. However, small amounts of HE are added to commercial explosives to increase strength and sensitiveness. Many commercial or industrial explosives are classified as HE because they contain critical amounts of military explosives or nitroglycerin, and usually they are cap sensitive. Others, such as dry blasting agents, are not classified as HE, and require boosters or primers of HE for initiation.

Industrial explosives are classified as one of the following: nitroglycerin-based, dry blasting agents, water gels, emulsions, permissibles, primers, and boosters. Two-component explosives, a common category, actually contain mixtures or characteristics that fall in other classifications. Often the difference among these products is formulation; however, product packaging and consistency can also change a classification. The USBM (Anon., 1989) reported the relative consumption of these products as a percentage of total industrial explosive use and consumption by industry. These consumptions are shown in Fig. 9.2.1.4.

Explosive components are referred to as oxidizers, fuels, absorbants, thickeners, and stabilizers. *Oxidizers* contribute oxygen for oxygen balance, and include nitrated salts such as ammonium nitrate (AN), sodium nitrate (SN), and calcium nitrate (CN). *Fuels* include fuel oil, carbon, granular aluminum, TNT, black powder, or any carbonaceous material that produces heat. Many of these components are also referred to as sensitizers and can also act as absorbants. *Absorbants* are products, such as wood pulp, sawdust, cotton, and cellulose, that incorporate liquid explosive components such as nitroglycerin. *Stabilizers* include flame retardants, gelatins, densifiers, water, gum, emulsifying agents, and thickeners.

Nitroglycerin-based Explosives—Dynamite is a trade name introduced by Alfred Nobel. It is comprised primarily of a stable yet powerful mix of nitroglycerin (nitrostarch). Since its invention, a number of nitroglycerin (NG)-based products have been developed and are outlined in Table 9.2.1.2. The three basic types include granular, gelatin, and semigelatin, which are all considered HE. Gelatins and semigelatins contain nitrocotton that combines with NG to form a gel structure whose consistency is controlled by the percentage of nitrocellulose. Dynamites are packaged in cylindrical cartridges from $\frac{7}{8}$ in. (22 mm) in diameter and 8 to 24 in. (203 to 610 mm) in length. The quality of the waxed paper wrapping is important to water resistance, fume production, and the ease and safety of loading.

Straight dynamite derives its energy source from NG, SN, and AN, including absorbants such as wood pulp and flour that also act as combustibles. These dynamites come in varying weight strengths (40, 50, and 60% being the most common) which correspond to the weight percentage of NG contained in the formulation. Ditching dynamite (50% NG) is a commonly used product. These dynamites are characterized by high velocity and brisance, low flame temperature, and good water resistance; however, these dynamites are sensitive to shock and produce poor fume quality.

Ammonia dynamite (or "extra" dynamite) is a granular mix that contains a smaller quantity of NG mixed with AN and SN. Two varieties are available. The high-density, high-velocity product is available in weight strengths of 20 to 60%. They have poor water resistance and low explosion temperature. The low-density variety comes in either a high- or low-velocity series and a constant 65% weight strength.

Gelatin dynamites are either straight gelatin or ammonium (extra) gelatin. Each has similar mixtures as straight and ammonia (extra) dynamites with the addition of nitrocellulose for a gel consistency. Ammonia gelatins are commonly used as boosters and as primers to initiate cap insensitive explosives.

Blasting gelatin is one of the strongest commercial products, with 92 to 94% NG gelatinized with 6 to 8% nitrocellulose. As the most energetic product available, it primarily is used in the seismic industry, although some commercial products are used as primers and boosters.

Semigelatins are ammonia gelatin with a small amount of nitrocellulose and a 65% weight strength. They are also used as primers and boosters.

Dry Blasting Agents—Dry blasting agents are one form of a general category of blasting agents. A *blasting agent* is, by definition, a mixture of fuel and oxidizer. It is not classified as an explosive, and cannot be detonated with a No. 8 blasting cap. A *dry agent* is a granular, free-running mix of a solid oxidizer (usually AN), prilled into porous pellets onto which a liquid fuel oil or propellant is absorbed. ANFO is the most widely used blasting product, with approximately 94.5% industrial-grade ammonia nitrate and 5.5% No. 2 grade diesel fuel oil for a nearly oxygen-balanced mix. It is available in bulk form for onsite mixing of the AN and fuel or in 50-lb (23-kg) premixed bags as pourable forms. Waxed card board and woven polypropylene tubes of diameters required for various borehole sizes are available for wet hole conditions. Typical values of specific gravity range from 0.75 to 0.95.

The properties of dry blasting agents vary significantly with borehole diameter, density, confinement, particle size, water conditions, and size of primer used for initiation. Fig. 9.2.1.5 illustrates the effect of charge diameter on detonation velocity for ANFO and other selected explosives. The steady state detonation

Table 9.2.1.2. Basic Properties of Nitroglycerin-based Products

Explosive	Specific Gravity	Detonation Velocity, fps	Water Resistance	Fume Quality
Straight dynamite	1.3–1.4	9,000 to 19,000	Poor to Good	Poor
Extra dynamite	0.8–1.3	6,500 to 12,500	Poor to Fair	Fair to Good
Blasting gelatin	1.3	25,000	Excellent	Poor
Straight gelatin	1.3–1.7	11,000 to 25,000	Excellent	Poor to Good
Extra gelatin	1.3–1.5	16,000 to 20,000	Very good	Good to Very good
Semi-gelatin	0.9–1.3	10,500 to 12,000	Fair to Very good	Very good

Source: Dick et al., 1983. Conversion factor: 1 fps = 0.3048 m/s.

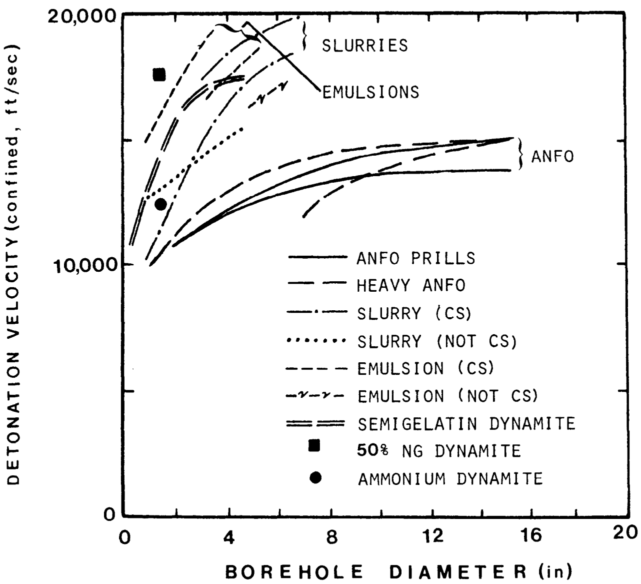

Fig. 9.2.1.5. Variation in detonation velocity with borehole diameter for selected commercial explosives. Conversion factors: 1 in. = 25.4 mm, 1 fps = 0.3048 m/s.

velocity of ANFO is over 15,000 fps (4500 m/s) and is achieved in borehole diameters greater than 15 in. (381 mm). The critical diameter of ANFO is between 2 and 4 in. (51 and 102 mm) and is a topic of controversy among blasters and, in particular, those who blast underground using small-diameter holes. The exact values of the critical diameter depends on the loading conditions; however, ANFO does not detonate reliably within the range cited above. Only explosive manufacturers can verify the minimum reliable diameter for initiation. The cost of ANFO ranges from as low as \$0.10/lb (\$0.22/kg) for bulk form to \$0.15 to \$0.18/lb (\$0.33 to \$0.40/kg) for package forms.

One form of dry blasting agent that is used in a variety of applications is referred to as a high-density (HD) ammonium nitrate agent. AN prills, crushed to a flakelike consistency, are mixed just prior to use with approximately 11% propellant (rocket fuel) such as nitromethane or nitroethane. The resulting product has a density higher than ANFO and generates more gas pressures based on the fuel used. The product is packaged in two components, often mixed in small batches for specialty uses such as secondary boulder breakage or removing tree stumps. Two-component blasting agents and explosive, however, can comprise a variety of mixtures for specialty blasting purposes including seismic exploration and are generally not used in large quantities.

Table 9.2.1.3. Typical Compositions of Some Slurries and Emulsion

Aluminum Sensitized Slurry	Water Gel Slurry
10% Aluminum	13% Amine nitrate
15% Water	15% Water
5% Ethylene glycol	5% Sodium nitrate
44% Ammonium nitrate	3% Ammonium perchlorate
25% Calcium nitrate	63% Ammonium nitrate
1% Guar gum	1% Guar gum
Explosives Sensitized Slurry	**Emulsion**
25% TNT, smokeless powder or nitrostarch	6% Wax/oil
	2% Emulsifier
25% Water	14% Water
15% Sodium nitrate	76% Ammonium nitrate
44% Ammonium nitrate	2% Hollow microballoons
1% Guar gum	

Aluminum in granular form can be added to ANFO to increase the heat or energy output. For increasing percentages of aluminum by weight up to 6%, a measurable increase in fragmentation energy is noted (Thornley and Funk, 1981). The cost of additional aluminum beyond 6% does not result in proportionally increased work output and, therefore, is not cost effective.

Wet Blasting Agents—Blasting agents that contain more than 5% water by weight are referred to as *wet blasting agents.* Within this category are water gels or slurries, emulsions, and heavy ANFO. The latter is a combination of prilled ANFO and emulsion. The development of wet blasting agents, led by slurries in the 1950s, came about in response to the disadvantages of ANFO in certain applications. These were the lack of water resistance and the low bulk strength due to low density. Typical compositions of water gels and emulsions are shown in Table 9.2.1.3. The critical diameter of wet blasting agents is often less than 1 in. (25 mm).

Three varieties of wet blasting agents are in common use in the mining industry.

1. *Slurries* (water gels) are a colloidal suspension of solid AN particles suspended in a liquid AN solution that is gelled, using cross-linking agents. The gels (guar gum) effectively surround the solid AN, rendering the oxidizer water resistant while thickening the explosive mix. Fuels and sensitizers such as TNT, nitrostarch, Composition B, ethyl alcohol, fuel oil, and glass bubbles (microspheres) are dissolved or added to the liquid phase. Granular aluminum, added as a sensitizer, increases weight and bulk strength. Up to 18% aluminum by weight has been found to provide increased energy output. In general, 20% water is used. Certain mixtures, containing high-explosive sensi-

tizers, are cap sensitive and hence should not be classified as a blasting agent, but rather as a slurry explosive.

Slurries are characterized by excellent water resistance, high density and bulk strength, good oxygen balance, confinement, and coupling within the borehole. The density of slurries ranges from 1.1 to 1.3, while detonation velocities vary from 13,500 to 20,000 fps (4115 to 6096 m/s), with borehole diameter as shown in Fig. 9.2.1.5. Detonation pressures range from 0.73 to 1.5 × 10^6 psi (5 to 10 GPa). Experiments performed by Bauer et al. (1984) show that decreasing explosive temperature decreases detonation velocity, while certain explosive diameters failed to detonate below 0°F (–17.8°C).

Products can be delivered for onsite mixing or premixed (only the gelling agent is added during hole loading) for bulk storage and loading. Plant-mixed slurries are packaged in polyethylene cylindrical bags in a variety of diameters and lengths. Onsite mixing has the advantage of varying explosive density and strength for hole loading conditions or for geological requirements. Prices range from $0.18lb ($0.40/kg) for bulk products to as high as $0.35/lb ($0.77/kg) for packaged slurries and those containing aluminum or other sensitizers.

2. *Emulsions* are a two-liquid phase containing microscopic droplets of aqueous nitrates of salts (chiefly AN) dispersed in fuel oil, wax, or paraffin using an emulsifying agent. The water-in-oil structure depends on entrapped air or microspheres for sensitivity, thereby eliminating the need for expensive explosive compounds. Microspheres, microscopic glass, or plastic air-filled bubbles and the AN droplets form the oxidizer, while the fuel oil exists as the oil phase. Emulsions provide high detonation pressures of 1.45 to 1.74 × 10^6 psi (10 to 12 GPa) with detonation velocities between 14,500 to 18,500 fps (4420 to 5640 m/s), as shown in Fig. 9.2.1.5. Densities range from 1.15 to 1.45. Emulsions have excellent water-resistant properties regardless of packaging, and they remain stable at low temperatures. The cost of emulsion products is within the range for slurries.

The excellent properties of emulsions are due to the intimate contact between the microscopic droplets and the continuous oil phase containing the fuel. Over time, the oil phase migrates, and droplets combine to form larger particles sizes whose bulk surface area is reduced. Less fuel is in contact with the oxidizer, and less than ideal explosive properties are achieved. Current research on emulsions will lead to formulations with longer shelf life.

Emulsions can be mixed onsite and pumped from bulk trucks. Premixed emulsions are available in plastic tubes in a variety of diameters and lengths. Depending on product diameter and sensitizers used, emulsions can be cap sensitive; however, the manufacturer must be consulted for primer requirements.

Certain site-mixed emulsions require heating the mixture prior to loading depending on the hydrocarbon used as the fuel. Waxes and paraffin require heating to fluidize the product for ease of loading while fuel oil can be pumped cold.

3. *Heavy ANFO*. Recent developments in explosives have produced a heavy ANFO product that is comprised of up to 45 to 50% ammonium nitrate emulsion mixed with prilled ANFO in an attempt to increase the bulk density of ANFO. The only fuel component is in the ANFO (or a liquid fuel), while the emulsion contains no solid fuel, making the mixture a "repumpable" consistency. The final product has improved strength and provides good water resistance in comparison to ANFO, with a price range between that of ANFO and emulsions. Research has shown, however, that the ability of emulsion to prevent ANFO from being dissolved in the presence of water, thereby reducing blasting efficiency, is questionable.

Bulk trucks for the loading of heavy ANFOs are designed to blend components prior to loading and provide loading of emulsion or ANFO alone, or a combination of the two, in varying proportions. Heavy ANFO products are also available in a variety of packages and sensitivities.

Permissibles—Permissible explosives are those made of special mixtures, which produce short-lived detonation flames, and do not ignite methane or fine coal dust within the air of underground coal mines. Salt (NaCl) is used in the mix to produce a quenching reaction. The USBM (Anon., 1961) developed criteria for permissible explosives and maintains a list of manufacturers supplying permissible products.

Primers and Boosters—A *primer* charge is an explosive ignited by an initiator, which, in turn, initiates a noncap-sensitive explosive or blasting agent. A primer contains cap-sensitive high explosive ingredients. Often cartridges of dynamites, highly sensitized slurries, or emulsions are used with blasting caps or detonating cord. Other primers are cast into specific shapes and weights, using TNT and PETN, designed with wells for initiator acceptance. Most primers are used in weights ranging from 12 oz (340 g) to over 5 lb (2.27 kg). An overview of explosive priming techniques is given by Dick et al. (1983).

Boosters are highly sensitized explosives or blasting agents, used either in bulk form or in packages of weights greater than those used for primers. Boosters are placed within the explosive column where additional breaking energy is required. Oftentimes, cartridge or plastic-bagged dynamites or sensitized wet blasting agents are used as primers as well as boosters. Boosters are often used near the bottom of the blasthole at the toe level as an additional charge for excessive toe burden distances. They are also placed within the explosive column adjacent to geological zones that are difficult to break or intermittently within the main explosive charge to ensure continuous detonation.

Initiators and Initiation Systems: *Initiators* are devices containing high explosives that, upon receiving an appropriate mechanical or electrical impulse, produce a detonation or burning action. Initiators are used as components within a system of explosives and other devices to start the detonation of all other components. Initiation systems are either electric or nonelectric, and include blasting caps, safety fuse, detonating cord, or nonelectric shock tubes. Certain primers, which are shape-cast or contained in plastic shells, are provided with wells for cap or cord insertion.

Electric blasting caps are the most commonly used method of initiation. Electrical energy (ac or dc) is sent through copper or iron legwires to heat an internal-connecting bridgewire. This heat, in turn, starts a chain reaction of explosives burning within the metal cap shell, through a powder delay train. This process detonates a high-explosive base charge, igniting a cap-sensitive explosive. They are manufactured with an instantaneous (no delay train) time of initiation, or time delays (in milliseconds) used in delayed blasting practices. Time delays with intervals of 25, 50, 100, 500, and 1000 ms are available for short- (ms) or long-period (LP) delays. Table 9.2.1.4 summarizes typical delay time intervals available for electric and nonelectric initiating systems. Short delays are used in surface blasting operations, while longer delays are used underground where blasting conditions are more confined. The use of time delays in blasting enhances fragmentation and the control of ground vibrations (see 9.2.2). In recent years, improvements have been made in the manufacturing of blasting caps that increase the accuracy in detonation time. The next generation of high-precision detonators will contain an electronic circuit instead of pyrotechnical delay elements. The integrated circuits will permit microsecond rather than millisecond timing accuracy and allow programmability for onsite selection of each cap detonation timing.

Ac power lines and capacitor-discharge dc power sources approved for blasting are used to energize caps. Precise calcula-

Table 9.2.1.4. Typical Delay Times for Electric and Nonelectric Delays

Short-Period Delays				Long-Period Delays	
Electric		Nonelectric			
Period	Delay time, ms	Period	Delay time, ms	Period	Delay time, sec
0	0	0	0	0	0
1	25	1	25	½	0.1
2	50	2	50	1	0.2
3	75	3	75	1½	0.3
4	100	4	100	2	0.4
5	150	5	125	2½	0.5
6	200	6	150	3	0.6
7	250	7	175	4	1.0
8	300	8	200	5	1.4
9	350	9	250	6	1.8
10	400	10	300	7	2.4
11	450	11	350	8	3.0

17	800			14	8.5
18	900			15	9.6
19	1000				

tions are needed to determine the entire blasting circuit resistance, including all accessory connecting wires. This is to ensure that the power source supplies the correct current to each cap in the circuit. Excellent source on blasting circuit calculations are provided in the *Blasters Handbook* (Anon., 1977) and *Handbook of Electric Blasting* (Anon., 1985a). Safe blasting practices dictate that precautions are used to avoid blasting in the vicinity of extraneous electricity such as stray current, static electricity, electrical storms, and radio frequency energy when using electric caps (Anon., 1974).

Nonelectric initiation systems include a cap similar to that of an electric cap, but they are connected to plastic tubing or a transmission line that carries an initiation (shock and heat) to initiate the cap. The energy source in the tubing is either a gas mixture or an internal coating of special explosive. Nonelectric tubing is not used in underground coal or gassy mines as it carries an open flame. The plastic tube itself does not detonate; therefore, the only noise source is the cap itself. Caps and tubes of varying lengths are connected with special connectors between holes to configure unique blast pattern arrays. Surface delay elements, when used in conjunction with in-hole delays, provide nearly infinite numbers of delays in blasting patterns. Delays are available in short and long periods as well as in-hole and surface delays. The advantage of nonelectric systems over electric systems is the ability to design blasts with a greater number of holes than traditional electric blasting. In addition, concerns about the effects of accidental detonations of electric caps due to stray currents are eliminated with the use of nonelectric systems.

Blasting Safety: Due to the fact that explosive materials are deemed hazardous, the sales, transport, storage, and use of explosives are regulated by a multitude of federal, state, and local agencies. In addition, safe blasting practices dictate that companies or agencies engaged in the use of explosives provide standard operating procedures (SOPs) for personnel that outline the acceptable safe and legal handling of hazardous materials. Depending on the situation under which explosives are being used, the blaster may be required to comply with a number of different codes as well as be tested for certification or license. The Bureau of Alcohol, Tobacco and Firearms of the US Department of Treasury (Anon., 1988c) regulates commerce in explosives importation, manufacturing, distribution, and storage. The US Department of Transportation (DOT) regulates the transport of explosives on highways, railroad, water, and in the air (Anon., 1988b). Of importance is the classification of explosives outlined in these regulations and the requirement of all shippers and manufacturers of packaged products for shipment to identify all explosives and their classification with standard labels. The following list outlines the classification defined by DOT and used in the commercial blasting industry:

Class A Explosives: Explosives that contain detonating materials or materials of maximum hazard: in general, these explosives, are cap-sensitive.

Class B Explosives: Explosives that carry a flammable hazard.

Class C Explosives: Explosives that contain components classified as either Class A or B but in limited quantities.

Blasting Agents: A mixture of fuel and oxidizer that is not defined as an explosive and cannot be detonated with a No. 8 test blasting cap.

Under the Department of Labor, the Mine Safety and Health Administration (MSHA) (Anon., 1988a), and the Occupational Safety and Health Administration (OSHA) (Anon., 1988) regulate the storage and use of explosives in certain mining activities and in general industry use, respectively. MSHA outlines safe blasting practices for surface and underground metal, nonmetal, sand and gravel, and underground coal mines. OSHA similarly outlines procedures for good practices to handle and load explosives in other industries. The Office of Surface Mining, Department of Interior (Anon., 1983), is concerned with the environmental effects and safety of explosives used in surface coal mines. These regulations restrict the quantities of explosive loading in the vicinity of dwellings to control noise, ground vibrations, and flyrock.

An excellent source of explosive safety information is the Institute of Makers of Explosives. The IME is an association of commercial explosive manufacturers concerned with safe and

Table 9.2.1.5. Thermodynamic Data for Selected Explosive Components and Gases

Explosive	Formula	Moles/ kg C	H	O	N	Enthalpy, kcal/ kg
Nitroglycerin	$C_3H_5O_9N_3$	13.21	22.02	39.62	13.21	– 392.0
Ammonium nitrate	$C_4O_3N_2$	—	49.97	34.48	24.99	–1091.0
TNT	$C_7H_5O_6N_3$	30.82	22.01	26.40	13.20	– 62.5
Diesel fuel	CH_2					+ 898.0

Gases	Formula	Heat Capacity Constants, cal/mole-°K a	b, 10^{-3}	c, 10^{-6}	Enthalpy, kcal/mole
Carbon dioxide	CO_2	6.85	8.53	–2.48	–94.05
Water (vapor)	H_2O	6.89	3.28	–0.34	–57.80

Source: Meyer, 1981.

proper practices in transport, storage, and use of their products. Its members are involved with legal affairs and regulatory monitoring of legislation affecting industry operations. A number of valuable publications are available from the IME (Anon., 1985 through 1987).

9.2.1.2 Explosive Thermochemistry

All explosives are mixtures of carbon, hydrogen, nitrogen, and oxygen, plus other components used for special purposes. In order to achieve maximum rock-breaking efficiency from an explosive, an oxygen-balanced mixture is formulated to ensure the formation of nonnoxious gases upon detonation. With an oxygen-balanced formula, it is assumed that optimum values of thermodynamic properties such as energy, temperature, and pressure are achieved, and that these values are not affected by changes in the reactants (explosive mixture). This is the case for ideal reactions. Unfortunately, commercial explosives are nonideal materials. Changes in the physical nature rather than the chemistry of the explosive mixture, such as particle size and borehole diameter, vary the rate of detonation and hence affect thermodynamic variables. Furthermore, many granular explosives, such as ANFO and nitroglycerin, do not completely react, whereas water-based blasting agents react more efficiently, releasing optimum energy as predicted by formulation.

It is possible, however, to estimate the thermodynamic properties of an explosive reaction, assuming an oxygen balance. The following calculations are made to illustrate the methods used to estimate explosive properties of interest. Although there are a number of methods available (Cook, 1958, 1974; Manon, 1976–1977; Meyer, 1981), the procedures selected herein are the least difficult to apply. Thermodynamic data used for these calculations are found in Table 9.2.1.5 and given by Meyer (1981).

Oxygen Balance: As explained in 9.2.1.1, an oxygen-balanced explosive formula is one in which the amount of oxygen O_2 is sufficient to form the desired detonation gases CO_2, H_2O, and N_2, but not noxious fumes such as CO, NO, and CH_4 (if the mix is oxygen deficient), or free oxygen (if the mix has an excess of oxygen). Oxygen balance for an explosive component or a mixture of components is usually reported in percentages or as moles of monatomic oxygen. It is computed using the mass balance relationship for a reaction of 1 kg of explosive, assuming the formation of ideal gaseous products. The computations are illustrated using nitroglycerin, TNT, and ANFO mixture.

Example 9.2.1.2. Find the oxygen balance for nitroglycerin, $C_3H_5O_9N_3$.

Solution. The mass-balance equation is

$$\begin{aligned} C_{13.21}H_{22.02}O_{39.62}N_{13.21} &\rightarrow 13.21\ CO_2 \\ &+ 22.02/2\ H_2O + 13.21/2\ N_2 \\ &+ (39.62/2 - 13.21 - 11.01/2)\ O_2 \end{aligned} \tag{9.2.1.2}$$

where subscripts denote mole numbers of each element in 1 kg. Oxygen in excess

$$\begin{aligned} &= +1.095 \text{ moles } O_2 \\ &= +2.19 \text{ moles O} \end{aligned}$$

Oxygen balance (OB)

$$\begin{aligned} &= \{[\text{O (excess)}]/\text{O (available)}\}\ (100\%) \\ &= 5.53\% \end{aligned}$$

With the exception of ammonium nitrate and nitroglycerin, most explosive components are oxygen deficient. Oxygen balance for TNT is given next in Ex. 9.2.1.3.

Example 9.2.1.3. Find the oxygen balance for TNT, $C_7H_5O_6N_3$.

Solution.

$$\begin{aligned} C_{30.82}H_{22.01}O_{26.4}N_{13.2} &\rightarrow 30.82\ CO_2 \\ &+ 22.02/2\ H_2O + 13.2/2\ N_2 + (26.4/2 \\ &- 30.82 - 22.01/4)\ O_2 = \\ &-42.25 \text{ moles O} \end{aligned} \tag{9.2.1.3}$$

Oxygen balance for an oxygen-deficient component is

$$\begin{aligned} &= \{\text{O (deficient)}/[\text{O (deficient)} - \text{O (required)}]\}\ (100\%) \\ &= -63.7\% \end{aligned}$$

Example 9.2.1.4. Find the oxygen balance for the mixture, ANFO.

Solution. For the mix of 94.5% AN, NH_4NO_3,

$$5.5\% \text{ FO, } CH_2 \text{ (approximate)}$$

For 1 kg of each component, the subscripted mole numbers are

$$\text{AN} \quad H_{49.97}O_{37.48}\,N_{24.99}$$
$$\text{FO} \quad C_{69.9}\,H_{139.86}$$

Mass balance for the mixture

Percentage of component in mixture	Mole contribution to each element			
	C	H	O	H
94.5% AN	—	47.22	35.42	23.62
5.5% FO	2.05	7.85	—	—
Total moles in 1 kg mix	2.05	55.07	35.42	23.62

$$C_{2.05}H_{54.91}O_{35.42}N_{23.62} \rightarrow 2.05\ CO_2$$
$$+\ 55.07/2\ H_2O + 23.62/2\ NO_2$$
$$+\ 1.89\ O_2 = +3.78 \text{ moles O}$$
$$\text{OB} = 10.7\% \tag{9.2.1.4}$$

Explosive Energy: Energy is expressed in terms of heat of formation (or enthalpy) for a reaction involving constant volume, given as kilocalories (kcal). It is computed as the sum of the heats of formation for the products minus the sum for the reactants. The reaction is based on 1 kg of explosive component or mixture (reactants). The enthalpies are given for the reactants in terms of kilocalorie per kilogram (calorie per gram or weight strength), and for the gaseous products, in terms of kcal/mole. Using the single component NG and the number of moles formed of the various gas products as shown in Eq. 9.2.1.3, Ex. 9.2.1.5 calculates energy.

Example 9.2.1.5. Energy (heat of formation) for nitroglycerin

Solution.

$$Q = [13.21 \text{ moles } (-94.05 \text{ kcal/mole}) + 11.01 \text{ moles}$$
$$(-57.8 \text{ kcal/mole})] - (-392.0 \text{ kcal})] =$$
$$-\,1487 \text{ kcal/kg of NG}$$

For mixtures, the enthalpy contribution of each component must be determined.

Example 9.2.1.6. Find the energy for ANFO.

Solution.

Net enthalpy

= [(– 1091 kcal/kg)(0.945 kg AN) + (898 kcal/kg)(0.055 kg FO)]

= –981.61 kcal

Energy, Q

= [2.05 mole (–94.05 kcal/mole) + 27.54 mole (–57.8 kcal/mole) – (–981.61 kcal)]

= –803.64 kcal/kg (9.2.1.5)

Explosion Temperature: The theoretical temperature can be calculated assuming that the detonation reaction takes place under an adiabatic condition, and that the reaction takes place as a constant pressure process from ambient temperature T_1. In this case, the temperature of the explosion T_2 is calculated by expressing the enthalpy of the products as a function of their temperature. The enthalpy Q is expressed in terms of T_1 and T_2 for n moles of product as

$$Q = n \int_{T_1}^{T_2} (C_p)\, dT \tag{9.2.1.6}$$

Expressing C_P, molal heat capacity, as a quadratic function of temperature, $C_P = a + bT + cT^2$, where a, b, and c are constants experimentally derived and available in standard chemistry hand books. Integrating Eq. 9.2.1.6, the heat of formation is

$$Q = n\,[a\,(T_2 - T_1) + b/2\,(T_2^2 - T_1^2) + c/3\,(T_2^3 - T_1^3)] \tag{9.2.1.7}$$

For a reaction involving more than one product, the enthalpy of each product is obtained in the form of Eq. 9.2.1.7. The sum of all products is set equal to the heat of formation of the reaction (based on 1 mole of explosive), and explosion temperature T_2 is determined.

The following example involving ANFO illustrates the calculations involved to compute explosion temperature. The constants for heat capacity of the products are given in Table 9.2.1.5.

Example 9.2.1.7. Find the temperature of ANFO detonation.

Solution.

Heat of formation based on cal/mole:

Component	Percentage	Atomic Mass, g/mole	Weighted Atomic Mass, g/mole
AN	94.5%	80	75.60
FO	5.5%	14	0.77
Total			76.37

mole/kg = (1000g/kg)/(76.37 g/mole) = 13.09 mole/kg

Enthalpy

= (–803.64 kcal/kg)/(13.09 mole/kg)

= –61,393 cal/mole (9.2.1.8)

From Eq. 9.2.1.5, for 13.09 moles of ANFO explosive, 1 mole of ANFO produces

$$0.157 \text{ mole } CO_2 + 2.104 \text{ moles } H_2O + 0.9 \text{ mole } N_2$$
$$+\ 0.144\ O_2 = 3.31 \text{ moles of gas products}$$

Substituting T_1 = 298°K in Eq. 9.2.1.7 for each gas product gives the following results:

$$CO_2 = .157\,[6.85\,(T_2 - 298) + 8.533/2\,(10^{-3})(T_2^2 - 298^2) - 2.48/3\,(10^{-6})(T_2^3 - 298^3)]$$

$$H_2O = 2.104\,[6.89\,(T_2 - 298) + 3.28/2\,(10^{-3})(T_2^2 - 298^2) - 0.34/3\,(10^{-6})(T_2^3 - 298^3)]$$

$$N_2 = 0.90\,[6.30\,(T_2 - 298) + 1.82/2\,(10^{-3})(T_2^2 - 298^2) - 0.35/3\,(10^{-6})(T_2^3 - 298^3)]$$

O_2 = 0.144 [6.13 (T_2 – 298) + 2.99/2 (10^{-3})(T_2^2 – 298^2) – 0.81/3 (10^{-6})(T_2^3 – 298^3)]

The sum is equal to –61,393 cal/mole, and the cubic form (Eq. 9.2.1.7) becomes

$$0 = 22.137\ T_2 + 0.00516\ T_2^2 - 5.13\ (10^{-7})\ T^3 - 68365$$

The solution to the cubic equation has three roots (determined graphically or solved numerically), one of which lies between reasonable values of 2000 to 5000°K. The graphical solution gives the explosion temperature for ANFO as 2204°K.

Detonation Pressure: The equation of state for explosive gases produced by detonations must define the temperature-pressure-volume relationships at high temperatures and pressures. Many equations of state for nonideal gas pressure calculations are proposed (Cook, 1958; Fickett and Davis, 1979; Mader, 1979; Johansson and Persson, 1970). These solutions require the use of large hydrodynamic computer codes and the knowledge of empirically derived constants from high-pressure experiments. A simple expression used to estimate pressure is the covolume equation of state:

$$P\,(V_e - \alpha) = n\,R\,T \qquad (9.2.1.9)$$

where V_e is specific volume of the explosive (inverse of r explosive density), T is explosion temperature in °K, n is the number of gas moles, and R is the gas constant, 82.06 cm^3-atm/mole-°K. Covolume a is a measure of the actual volume of gas molecules. Pressure is thus related to the inverse of P – a, or free volume. Experimental values of a are given by Cook (1958) as a function of r and approximated by,

$$\alpha = e^{-0.4\rho} \times 10^3\ cm^3/kg \qquad (9.2.1.10)$$

Example 9.2.1.8. Calculate the detonation pressure for ANFO.

Solution.

Given 1 kg of ANFO mixture,

n = 43.285 mole

T = 2204 °K

r = 0.85

a = 711.8 cm^3/kg (from Eq. 9.2.1.9)

V_e = (1000 g/kg)/(r) = 1176.5 cm^3/kg

$$\text{Pressure, } P = \frac{(43.285\text{ moles})(82.06\text{ cm}^3\text{-atm/mole-°K})(2204\text{°K})(14.7\text{ psi-atm})}{(1176.5\text{ cm}^3/\text{kg} - 711.8\text{ cm}^3/\text{kg})}$$

$$= 0.247 \times 10^6\ \text{psi (1.7 GPa)} \qquad (9.2.1.11)$$

For explosives that are not oxygen balanced such as TNT, experimental data for n are required and vary widely among experimentalists. Cook (1958) among others gives experimental data for TNT.

Example 9.2.1.9. Calculate the detonation pressure for TNT.

Solution.

Given 1 kg of TNT,

n = 23 moles

T = 4100°K

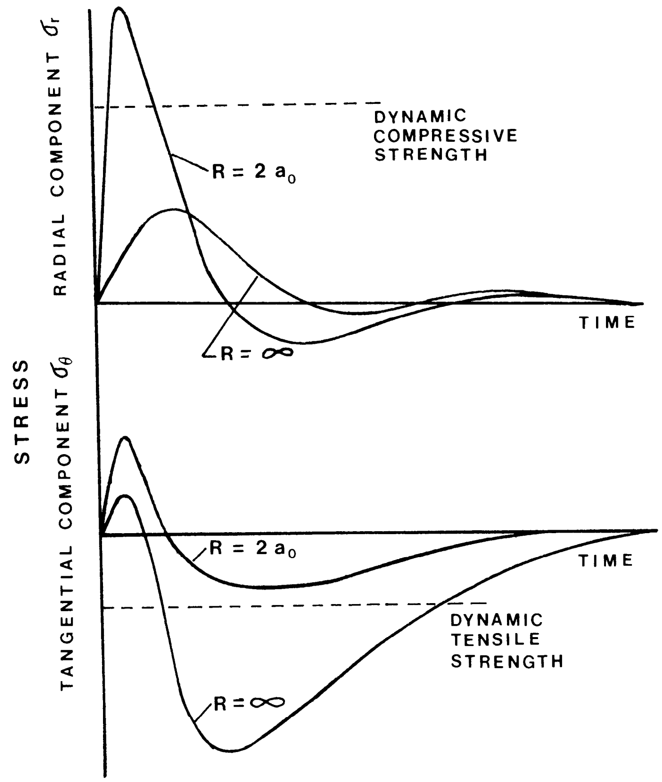

Fig. 9.2.1.6. Generalized stress vs. time for radial and tangential components of stress at two distances R from the borehole center (a_o = original borehole radius).

r = 1.59

P = 1.1 × 10^6 psi (7.57 GPa)

which agrees with experimental results.

9.2.1.3 Blasting Practices

The use of explosives to break rock requires the proper selection of explosives and blasting devices, the careful design of borehole patterns, loading characteristics, and delay blasting sequence, and the control of ground vibration, airblast, and flyrock. Efficient blast designs produce the desired particle size distributions and placement of muckpiles for ease of rock removal and handling.

Rock Breakage Using Explosives: There are a number of theories used to describe rock fragmentation by blasting (Winzer and Ritter, 1980; Anon., 1987a). Two broad areas of breakage mechanisms include (1) the role of stress waves generated from the explosive detonation (shock) force, and (2) the role of borehole pressures created by the detonation gas products.

Effect of Stress Waves—The theoretical treatment of explosively generated stress waves is given by Kutter and Fairhurst (1971), Rinehart (1975), and Mohanty (1985). Upon detonation within a borehole, a shock wave is generated and travels into the rock, quickly decaying in peak pressure amplitude and dispersing in shape as the wave travels away from the borehole. The cylindrically divergent wave carries both a radial and tangential stress component whose stress time histories are shown, idealized, in Fig. 9.2.1.6. The response of the rock adjacent to the borehole

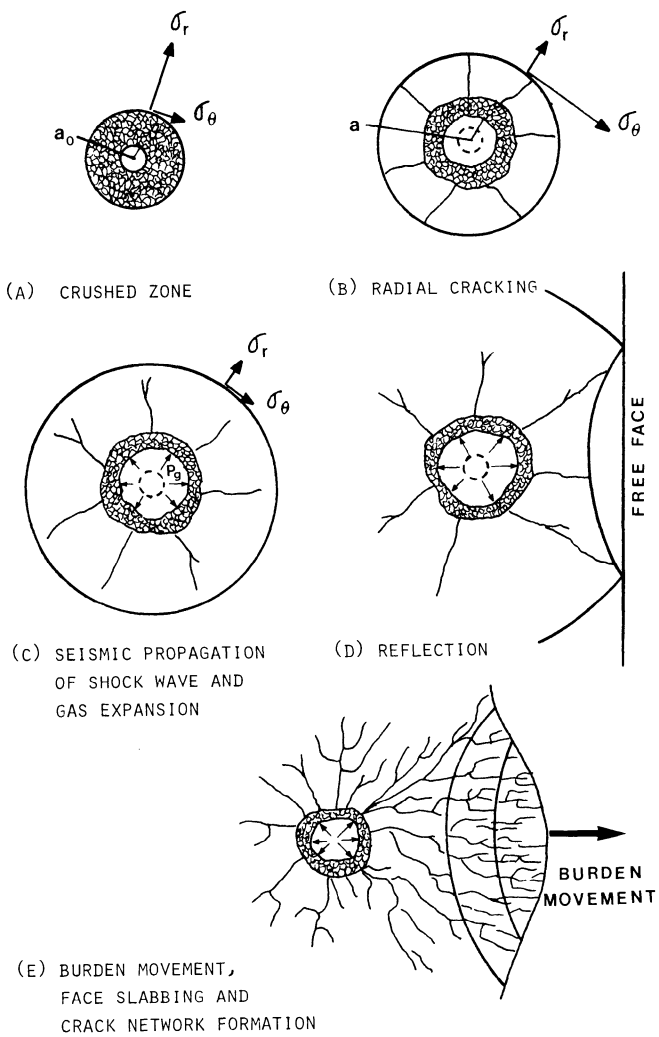

Fig. 9.2.1.7. Generalized plan view through detonating borehole showing sequence of events occurring in the rock mass, where a_0 and *a* are charge radius and expanded borehole radius, respectively, P_g is borehole pressure, s_q and s_r are tangential and radial stress components, respectively.

is shown in Fig. 9.2.1.7. Close in to the borehole, the radial component carries a high compressive stress exceeding the dynamic compressive strength of the rock. The rock experiences intense shearing in this zone. At greater distance from the borehole, this component attenuates below the rock strength, defining the end to the crushing zone. The tangential component carries a tensile phase that rapidly increases to a level greater than the dynamic tensile rock strength. The rock surrounding the borehole develops radial fractures as the rock fails in tension. Once the tensile tail of this component attenuates below the tensile strength, the fractures cease, and the wave travels radially away as an elastic sound wave.

Depending on the explosive and the rock strengths, characteristic degrees of rock damage occur at varying distances from the borehole. Experimental data for limits of the crushed and fractured zone distances are given for a variety of rock and explosive strengths (Siskind and Fumanti, 1974; Anon., 1987a). The crushed zone ranges from 2 to 4 borehole radii away from the center of the borehole, while the fracture zone averages 20 borehole radii away and extends to 50 radii away.

In the vicinity of free surfaces, such as the ground surface or a mining bench face, an enhancement of fracture patterns occurs. This is caused by the transition of the radial component from a compressive to a tensile pulse at the free face as the wave is reflected. The interaction of all waveforms produces intense fracturing within the rock mass between the borehole and free surfaces (e.g., burdens). Recording of crack development in polymeric materials with time-elapsed photoelastic techniques has been used to characterize fracture patterns and fragmentation for stress waves (Kutter and Fairhurst, 1971; Barker et al., 1978, 1978a). Multiple reflections of outgoing and reflected waves (primary and shear) occur while fracturing takes place, dictating flaw initiation sites. The resulting fragmentation, however, is highly dependent on inherent geological discontinuities that are absent in polymeric materials. In studying free-surface fracturing in limestone, Winzer and Ritter (1980) noted surface crack formation formed independently of radial crack development. Timed photography showed the effects of bedding and joint (inherent flaw) influence on face cracking during burden acceleration. Trapped waves reflecting in detached rock particles contributed to continued particle size reduction.

In competent dense rock, excellent fragmentation occurs when using explosives that produce high shock forces. NG-based explosives and highly sensitized blasting agents work well in these rocks.

Effects of Gas Pressures—Subsequent to detonation, gas products are formed, internally pressurizing the borehole and adjacent cracks. Some researchers believe these pressures, often referred to as borehole pressures, are sufficiently high to extend radial cracks (Porter and Fairhurst, 1970; Langefors and Kihlstrom, 1978) while others believe these pressures promote only heaving. Heaving assists in muckpile placement by opening internal surfaces preconditioned by stress waves (Kutter and Fairhurst, 1971). High-speed photography of blasting has shown additional fragmentation occurring during gas-driven heaving of rock thrown from the bench (Hagen, 1977; Chiappetta et al., 1983), while Winzer and Ritter (1980) believe stress waves trapped in detached blocks promote increased fragmentation. In general, explosives formulated with nitrates of ammonium or sodium produce large volumes of gas contributing to good heaving and throwing. Their use in well-bedded and jointed material such as sedimentary rock or highly altered ore, promote good fragmentation.

Effects of Geology on Blasting—Rock properties that influence blasting results are strength, density, sonic velocity, and structure. Rock structures are defined using the frequency and orientation of bedding planes, joints, and other naturally occurring fractures. Characteristic impedance, which is the product of density and velocity, is useful for matching an explosive to the intact rock specimen properties. Knowing the density and wave velocity of the rock, one selects an explosive with a similar impedance value. Often such decisions must also consider the effects of fracture frequency defining the competency of a rock.

The selection of explosive loading quantities and explosive type can be guided by rock-mass fracture data (Hoek and Bray, 1977). The decision to use a ripper, for example, rather than explosives for construction applications can be made with the help of empirical data provided by the equipment manufacturer using rock seismic velocity charts or rock fracture frequency and compressive rock data (Anon., 1987b). If explosives are selected, the orientation of borehole pattern and hole-loading characteristics are important to the blasting results. As shown in Fig. 9.2.1.8, hard rock layers require additional energy while soft clay seam intervals may not require loading. The placement of explosives within the holes can dictate muckpile movement and influence overall muckpile shape. The orientation of boreholes,

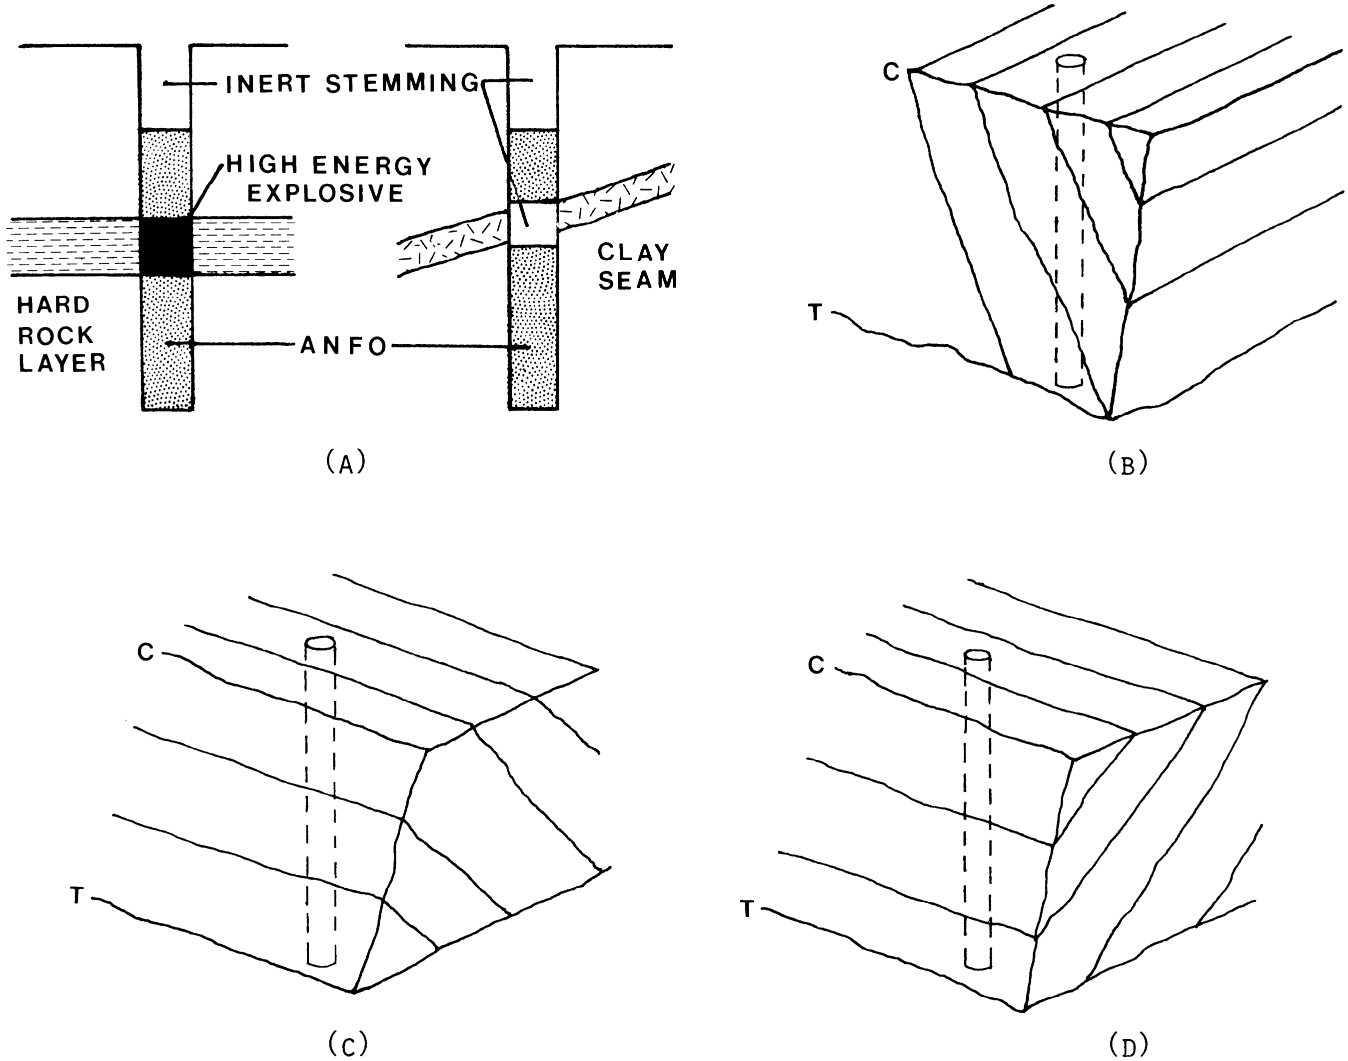

Fig. 9.2.1.8. Geological considerations in blasting: (A) explosive loading for geological variations; (B) blasting against the strike; (C) and (D) blasting with the strike, with the dip and against the dip, respectively (*C* = bench crest; *T* = bench toe).

pattern spacing, and orientation of free faces will determine the efficiency of open pit blasts (Ashby, 1980). Borehole spacing aligned with the joint strike can be widened for optimum fracture development, while shooting with the dip, rather than against, results in safer highwalls and requires the use of less explosive energy.

Surface Blast Design: Surface blast designs require the selection of hole spacing *S*, burden *B*, charge weight *W* or powder factor *PF*, top-hole stemming length *T*, and subgrade drilling depth *J*. Design parameters are shown in Fig. 9.2.1.9. Borehole patterns are drilled square ($S/B = 1$) or rectangular ($S/B \geq 1$) on center or offset (staggered). The sequence of hole initiation timing, *S/B* ratio, actual timing between charge detonations, and number of blasthole rows determine the shape of the broken rock pile as well as the degree of rock fragmentation.

An empirical approach is taken in blast design as blasting is a never-ending process of fine-tuning and modifications. This approach is necessary due to the many factors that cannot be controlled, such as geology and explosive loading conditions. Empirical relationships used in the design of blasting have been proposed by Ash (1963), Pugliese (1973), Van Ormer (1973), Hagen (1981), Dick et al. (1983), and many others. Borehole diameter and burden are perhaps the most important factors used in design. Burden values should be selected based on geology and explosive energy output. Usually hole diameter is set by the drill rig capacity, which is matched to the range of hole depths anticipated for the job. It is desirable to select a size that will provide an adequate powder factor (the ratio of explosive quantity used to the yield of rock breakage) for breakage while distributing the explosive evenly throughout the hole depth. Fragmentation and particle size distribution are a function of hole diameter and burden. The capacity of the excavation equipment dictates the required fragmentation. The charge length to charge diameter ratio for a cylindrical charge should be five or greater.

Ash (1963) has provided simple empirical formulas to compute burden, spacing, subgrade, and stem lengths using "K factors," shown in Table 9.2.1.6. Other rules of thumb are in agreement with the range of acceptable multiplying factors given by Ash. However, many relationships exist for stem length *T*. This is because the determination of *T* is essentially site specific. If too short a value of *T* is selected, air pressure can evolve

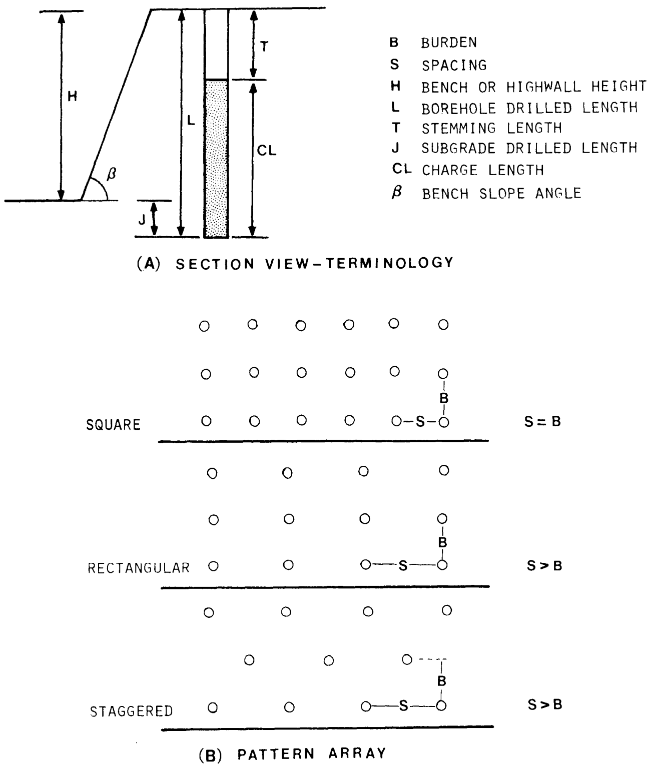

Fig. 9.2.1.9. Blasthole section view (A) showing terminology used in design and (B) pattern array for layout of holes.

Table 9.2.1.6. Selected Factors for First-Approximation Surface Blast Designs

		Using ANFO:
Burden	$B = K_B$	K_B = 22 for rock density < 2.7 g/cm^3
		= 30 for rock density > 2.7 g/cm^3
		Using slurry, dynamite or other high explosive:
		= 27 for rock density < 2.7 g/cm^3
		= 35 for rock density > 2.7 g/cm^3
Spacing	$S = K_S B$	K_S = 1 to 2, depending on initiation
Subgrade	$J = K_J B$	K_J = 0.2 to 0.5 (average 0.3)
Stemming	$T = K_T B$	K_T = 0.5 to 1.3 (average 0.7)

Source: Ash, 1963.

through the stem, disturbing nearby residents. If T is too long, rock breakage near the hole collar is poor. Recommendations for T (in feet) range from 1.2D to 2D (based on charge diameter in inches), or 0.5B to 1.3B. The lower range of these two relationships should be used with caution if airblast or flyrock is a problem.

Once the design parameters are established, the powder factor PF is computed as the quantity of explosives used divided by the volume yield of material blasted, or,

$$PF = \frac{(W \text{ lb})\ (27 \text{ ft}^3/\text{yd}^3)}{[(B)\ (S)\ (H)]\ \text{ft}^3} \qquad (9.2.1.12)$$

Powder factors range 0.25 to 2.5 lb/yd^3 (0.15 to 1.5 kg/m^3) for surface blasting but average 0.5 to 1 lb/yd^3 (0.3 to 0.6 kg/m^3). Higher powder factors result in fine fragmentation and are

Table 9.2.1.7. Typical Powder Factors Used in Rock Blasting

Excavation Method		Range in Powder Factors, lb/yd^3
Surface metal mining		0.6–1.0
Surface coal mining	60 yd^3 dragline	0.5–0.7
	30 yd^3 shovel	0.6–1.1
	17 yd^3 front-end loader	0.6–1.6
Coal mining blast casting		0.9–1.5
Quarrying		0.6–1.5
Construction	open excavations	0.25–0.8
	trenching	2.0–3.0

Conversion factor: 1 yd^3 = 0.7646 m^3, 1 lb/yd^3 = 0.5933 kg/m^3.

required for small capacity removal equipment such as front-end loaders. Higher powder factors result in coarser fragmentation and are typically used for rock removal using draglines and large shovels. Table 9.2.1.7 gives typical powder factor values for various surface blasting situations. Powder factor is often reported as the rock yield in tons per pound of explosive used.

Example 9.2.1.10. Determine the blast design for a copper porphyry open pit mine.

Given blasthole diameter D = 9.25 in., bench height H = 50 ft, rock density r = 2.55 (quartz monzonite), and explosive density r = 0.85.

Subdrilling is required and the nearest dwelling is 7 mi away.

Solution. The following values are obtained as a first approximation:

burden	B = 30 (9.25/12)	subdrilling	J = 0.3 B
	= 23 ft		= 7 ft
spacing S	= 1.3	collar stemming	T = 1.2 D
	= 30 ft		= 12 ft

Thus drilled length L = 57 ft and loaded hole length is 45 ft. The ratio of H/B is 2.17, and the ratio of charge length to diameter is 5.2. The maximum charge that can be loaded is

$$LD = 0.3405\ (0.85)\ (9.25 \text{ in.})^2 = 24.8 \text{ lb/ft}$$

$$W = 45 \text{ ft } (24.8 \text{ lb/ft}) = 1116 \text{ lb loaded/hole}$$

Powder factor and rock breakage yield per hole are

$$PF = \frac{(1116 \text{ lb})\ (27 \text{ ft}^3/\text{yd}^3)}{(32 \text{ ft})(40 \text{ ft})(50 \text{ ft})}$$

$$= 0.87 \text{ lb/yd}^3$$

$$\text{Volume} = 1280 \text{ yd}^3 \text{ of usable ore}$$

The yardage is computed assuming the subgrade material is shot but not removed until the lower bench level is blasted.

Many blast designs use decked charges formed by dividing the explosive column into two or more individual charges, initiated on the same or different time delays, separated by inert stemming material. Decking is employed to (1) conserve explosive use adjacent to weak rock zones, faults, or clay seams; (2) reduce the charge quantity detonated on one time delay, lowering ground vibrations; or (3) bring the powder column up higher in the hole to assure good breakage near the collar. Decked charges should be separated by stemming materials at a length beyond which two adjacent decks do not affect one another. If interdeck stemming is too small, the deck designed to initiate on the earlier time delay may prematurely initiate the second deck. This situation is referred to as *sympathetic detonation* and may lead to excessively high ground vibrations or flyrock. A rule of thumb for the design of interdeck stem length is to employ the hole radius dimension in feet.

The following example gives the design procedures for a blast design in which the explosive charge is limited to control ground vibrations.

Example 9.2.1.11. Using Ex. 9.2.1.10 and limiting W to 300 lb/delay, a modification to the previous design is required such that the powder factor is kept at 0.87 lb/yd^3, using 300-lb decks. Collar stem and subgrade drilling remain unchanged.

Solution. Charge length per deck, (300 lb)/(24.8 lb/ft) = 12 ft/deck.

If three decks are used, 36 ft of hole length is required, leaving 9 ft of interdeck stem length remaining between the decks, or 4.5 ft between two decks. Using the expression for powder factor, a new burden and spacing are computed:

$$PF = \frac{(3 \text{ decks})\ (300 \text{ lb/deck})\ (27 \text{ ft}^3/\text{yd}^3)}{(B)\ (1.3\ B)\ (50 \text{ ft})} = 0.87 \text{ lb/yd}^3$$

$$B^2 = 430 \text{ ft}^2$$

$$B = 21 \text{ ft}$$

$$S = 1.3\ (21 \text{ ft}) = 27 \text{ ft}$$

Thus total hole charge weight W=900 lb. Yield per hole is 1050 yd^3.

Hole Loading Practices—Safe loading practices are given by Dick et al. (1983) and Osen (1985). Recommended procedures include taking adequate precautions and using proper accessories during the hole-loading process. Keeping careful records summarizing blast design dimensions and loading quantities is essential to safety and economics.

Once drilled, all holes should be plugged or covered to prevent rocks and drill cuttings from filling the hole. Prior to loading, the driller's log should be checked for hole depths, subdrilling, and indications of hard or soft seams, voids, and the presence of water. The blaster must check each hole for any change in conditions prior to final design. This is to ensure that all safety precautions are considered. Abandoned holes must be filled with cuttings to prevent flyrock.

Transporting the blasting crew and explosives to the blasting site is done once the site has been identified with markers and the site cleared of all personnel not involved in hole loading. Initiators, cap-sensitive explosives, and noncap-sensitive agents must be transported in accordance with regulations in approved vehicles, carrying classification signs. Proper tools for loading include a cloth measuring tape, a wooden tamping pole, a pair of wire cutters and strippers, a mirror, grappling hooks, and a powder punch. If electric caps are to be used, an approved blasting multimeter or galvonometer must be used to check circuit resistance.

If the blastholes are filled with water, and a water-resistant explosive of a density greater than one is not used, the holes must be pumped or blown free of excess water. Plastic sleeves or hole liners, available to protect from water seeping back into the hole over a limited time period, minimize the desensitization of granular explosives and blasting agents.

In holes that are partially filled with water, a wet blasting agent recommended in wet-hole loading is used below the water level, while granular agents may be placed above. In this case, plastic tubes are slit along the axis for good coupling.

Once the delay sequence is designed, in-hole or surface delays are placed adjacent to respective holes. Each hole is then loaded after it is measured for correct depth. If primers are used for noncap-sensitive explosives, they are made up at the time of loading. Caps or detonating cords are inserted and wrapped around the primer in accordance with manufacturer's recommendations. A small amount of main charge is added to the hole bottom, then the primer carefully lowered. The main charge is poured (for free-running explosives) or carefully lowered (if packaged), while measuring the loading depth to ensure that each deck or column rises to the designed length (based on known loading density). Care must be taken not to overload holes. Any loading of charge that does not result in a measurable powder column rise must be stopped immediately. This situation may indicate a loss of explosive into cavities or open fractures. It may be necessary to plug the open hole section and stem a safe distance, continuing the loading with a separate deck. If this is not possible, a second primer and initiator may be placed at the charge top and the hole should be stemmed to the top.

The location of the primer for a single explosive column is a matter of choice. Primers can be placed at the toe, the middle, or near the top of a column of deck charge. In certain bedded rock, toe priming provides the best results, while some blasters feel middle priming works well. High-energy primers, if used too close to the collar stem base, can displace the stemming material, sending wasted energy into the air. Top priming should be used with care, particularly when collar stem lengths are short or the stemming is damp, to prevent flyrock and excessive air concussion. Multiple priming is often employed as an added safety measure in the event of explosive column cutoffs. Detonating cord downline cutoffs can occur in horizontally bedded rock formations as bedding units shift during the detonation of adjacent holes (Fig. 9.2.1.10). A second downline and primer near the explosive column top may prevent a misfire.

Initiating systems are also a matter of choice. Detonating cord is easy to use; however, cutoffs can occur if flyrock severs surface lines. High-grain core load detonating cord tends to promote the "rifling" of explosive energy through an open channel within the collar stem as the stem material compresses from the initiation shock force, as shown in Fig. 9.2.1.10. Angles between a branch and the line carrying the incoming detonation wave should be 90° or more, and connections should be made with slip-proof knots.

When using electric blasting caps, precautions must be made to monitor extraneous currents at the blast site. Always check the resistance of each cap before stemming the hole to ensure continuity. If the detonator is damaged, a second initiator can be placed in the hole. Once all cap, connecting, and firing line wires are joined, the resistance must be checked and compared to the calculated resistance for agreement. Nonelectric initiating systems are recommended when blasting in the vicinity of stray currents or to control air concussion. As nonelectric systems comprise surface and in-hole delays as well as tubing, the blaster must follow the manufacturer's recommended procedures for layout and connection.

Detonating cord downlines must be cut from the supply spool and held securely during hole loading. Should the cord slip into the hole during loading, a second primer and initiator must be immediately placed in the hole before loading is continued. Blasting cap legwires must also be held securely during loading, and care must be taken not to damage legwires.

Stemming material should provide a high degree of frictional resistance against the explosive detonation force moving upward from the charge base. In dry holes, drill cuttings work well;

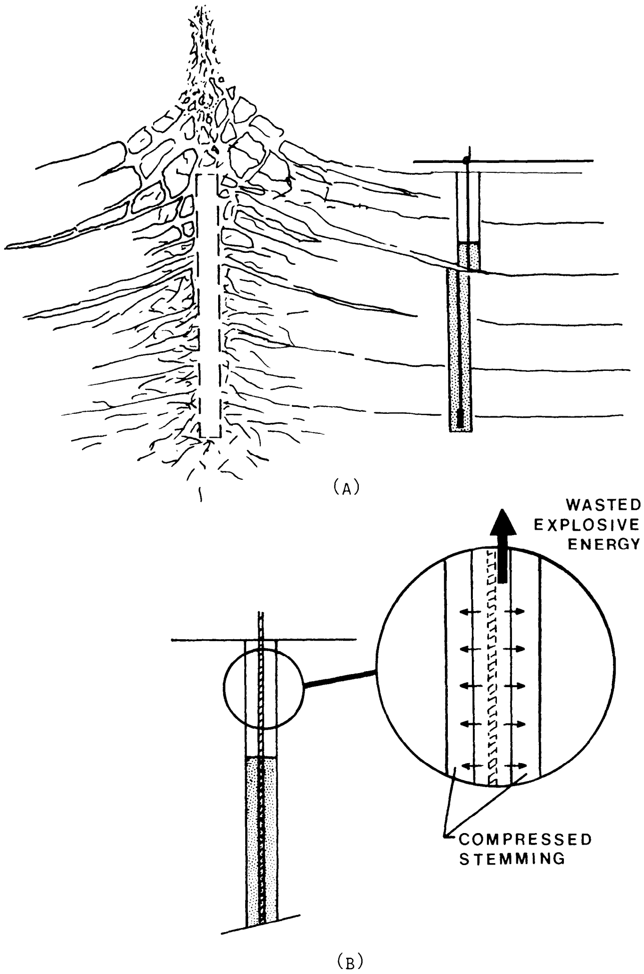

Fig. 9.2.1.10. (A) Detonating cord downline cutoff caused by shifting of horizontally bedded rock, and (B) stemming compression leading to a loss of explosive energy

however, when cuttings are wet, they provide little resistance. In this case, $^3/_8$-in. (9.53-mm) crushed stone is recommended.

Prior to shot initiation, the blast site and surrounding area must be cleared and all access to the blast site must be guarded. A sequence of audible sirens of a set code precedes the blast, with an "all clear" siren following the blast. During shot firing, all personnel must be adequately covered and fully protected from flyrock. A certain time period must pass before entering the blast site as both flyrock and noxious fumes may be present for an extended period of time after detonation.

If a misfire occurs, the charge should be flushed from the hole with water or air. If this is not possible, the cord, legwires, or tubing may be reconnected, if available, once continuity is established. If continuity is not established, the hole should be reprimed after the stemming is flushed out. In this case, care must be taken during initiation as excessive flyrock may result. In the case that it is not possible to use these approaches, qualified professional assistance must be sought. With the assistance of experts trained to handle misfires, the charge may be carefully dug out or a hole may be drilled adjacent to the unshot hole. The adjacent hole is then lightly loaded, and detonated, to lift the rock surrounding the unshot charge for removal. Under no circumstances should these attempts be made by unexperienced blasting personnel without consultation with their supervisors and experts in this field.

Surface Delay Blasting—Delay blasting techniques are employed to improve fragmentation, control of rock movement, overbreak, and to reduce ground vibrations. Delays are incorporated into the blast design using electric or nonelectric caps or delay connectors with detonating cord. The delay patterns used in design will determine the sequence of hole or deck initiations, thereby, dictate the overall direction of blasted rock movement and resulting fragmentation. Depending on the *S/B* ratio, the actual timing (in milliseconds) between detonating charges will determine muck pile displacement height and distance from the bench. Fig. 9.2.1.11 shows variations of timing patterns used for surface blasting. Depending on initiation sequence, an effective burden B_e and effective spacing S_e result as shown in Fig. 9.2.1.11. The effective spacing is the distance between holes in a row defined by adjacent time delays (e.g., delays by rows). Effective burden is the distance in the direction of resultant rock mass movement. The V and echelon (diagonal) patterns are used when rock placement is restricted. Designs using two free faces usually provide improved fragmentation and throw control over those using a single face.

The design of initiation timing for multiple-hole blasting is critical to the blasting effectiveness. If the interhole delay is too short, the movement of row burdens is restricted and fragmentation is poor. High ground vibrations result, and backbreak along the new highwall may persist, jeopardizing the stability of the slope. If interhole delays are too long, cutoffs of surface delays may occur. The minimum time for design is controlled by the stress wave travel distance (= 2 B_e) in order for radial cracking to begin to develop, contributing to the detachment of the rock mass in the vicinity of the hole. This detachment forms an internal free face (or relief) to which successive detonations will interact with the reflection of stress waves. The minimum timing is, therefore,

$$t = 2\ B_e\ /\ C_p \times 10^3 \tag{9.2.1.13}$$

where t is stress wave travel time in ms, B_e is effective burden or distance from the hole to the free face in feet, and C_p is velocity of sound for the rock in fps. The maximum timing is that at which the burden is fully detached and accelerating as gas pressures build. Research by Barker and Fourney (1978, 1978a), Winzer and Ritter (1980), and others, has shown that stress wave travel time is a fraction of the time required to develop radial cracks. Furthermore, studies using high-speed photography indicate that the burden moves within a timeframe which is between 2 to 10 times the wave travel time to the face. Hagen (1977) noted the time to burden movement ranges from 5 to 50 ms, and suggests an optimum range of timing for design between 1.5 to 2.5 ms/ft of B_e.

Timing studies have been performed to investigate resulting fragmentation and muck pile shapes. Reduced-scale research using a variation in delay ratios suggests improved fragmentation for timing between 11 to 17 ms/ft of B_e (Stagg and Nutting, 1987), while Bergmann et al. (1974) demonstrated improved fragmentation for *S/B* ratios of two at timing ratios of 1 ms/ft of B_e or greater.

Production-scale, multiple-row blasting has resulted in recommended timing to improve fragmentation. Andrews (1981) suggests delays of 1 to 5 ms/ft within rows and 2 to 15 ms/ft of B_e between rows (or on the echelon). Anderson et al. (1982) measured flyrock velocity, or gas venting, through the collar stemming to establish a 3.4 ms/ft of hole spacing and 8.4 ms/ft of B_e recommendation for optimum breakage and forward movement. Similar work in which muck pile profiles were

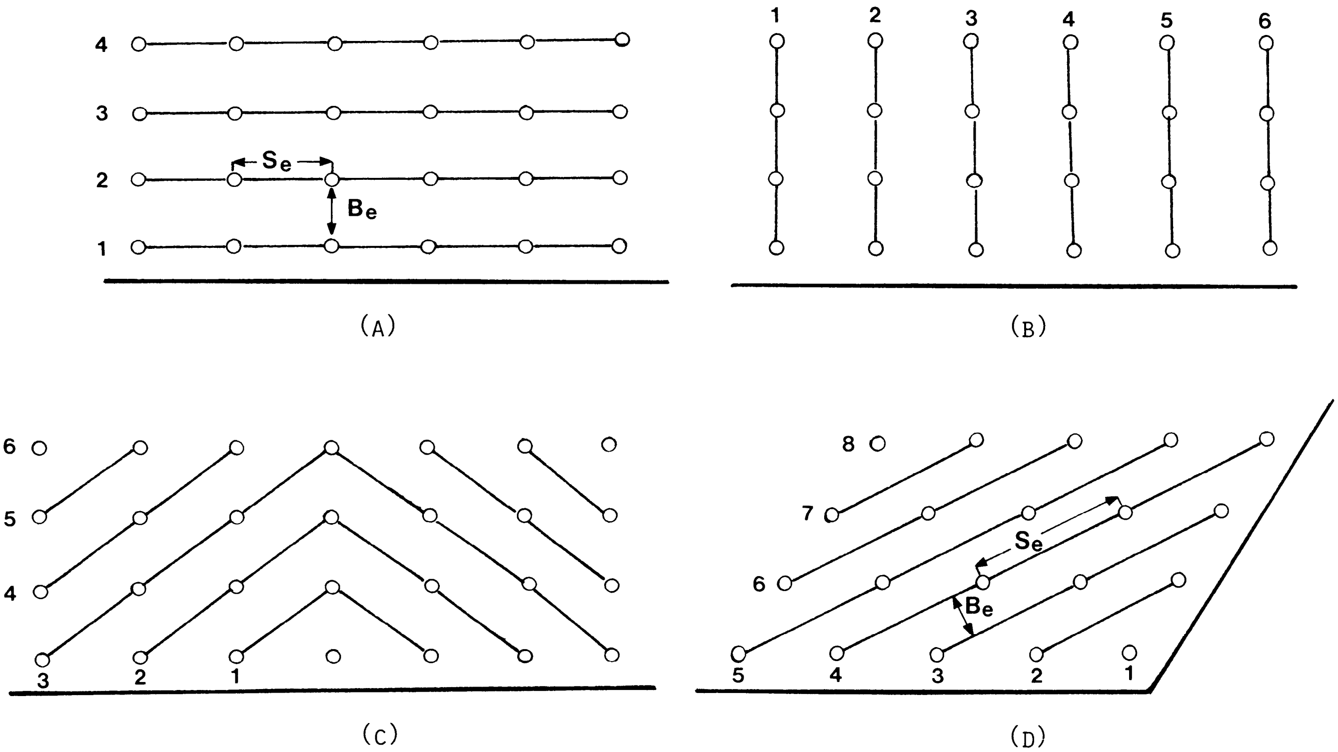

Fig. 9.2.1.11. Typical initiation patterns for surface blasting showing initiation by rows (A) parallel and (B) perpendicular to a single free face, (C) in a "V" configuration and, (D) echelon pattern using two free faces; B_e and S_e are effective burden and spacing, respectively.

mapped indicates that optimum forward throw and muck pile height reduction occur for delay ratios of 4.2 ms/ft of S_e and 10 ms/ft of B_e, while forward throw is minimized, resulting in high muck piles, with ratios of 1.5 to 2 ms/ft of S_e and 5 to 6 ms/ft of B_e (Winzer et al., 1981). Hagen (1977) has shown for single-row production shooting and *S/B* of 1.2 to 1.6 that timing ratios greater than 1.2 ms/ft of B_e are ideal. Hagen recommended 1.2 ms/ft of B_e for multiple-row production blasting in hard rock, while using high powder factors and short stem lengths. A 2.4 ms/ft of B_e was recommended for soft rock with long stem lengths and low powder factors. To control ground vibrations, Kopp (1987) recommended that a 1.3 ms/ft of *S* and 1.2 to 4.3 ms/ft of B_e be used.

The timing ratios cited are found to vary over a wide range. A great deal of research on the effects of initiation timing cannot be compared due to the lack of similar variables such as geology, scale, and explosive type. Winzer et al. (1983) recognized the need to qualify delay ratios, in a general way, based on existing fracture density. Competent dense rock requires lower delay ratios to achieve fine fragmentation, while weak fractured rock fragments best with higher delay ratios.

Underground Blast Design: Blasting rounds are used in the development of tunnels, shafts, raises, stopes, caving, and other underground openings. Powder factors range from 1.5 to over 10 lb/yd^3 (0.9 to 6 kg/m^3). The lower values are used in large open rooms in soft weak rock while the higher values are used in confined raises and shafts for hard competent rock.

Underground explosives should be selected for ease of handling and loading. Explosives with a fume class of 1 are required, and permissibles must be used in gassy mines. Wet and dry blasting agents as well as dynamites are used in a variety of blasting situations. The storage of explosives underground should be made for limited periods of time in the case of atmospheric conditions which present high humidity and temperatures. Cartons must be kept sealed until used, and a rigid system of stock rotation employed. Many loading procedures outlined in the segment on surface blast design also apply to underground loading. During blasted rock removal, a constant watch for unshot explosives must be made. Prior to drilling the subsequent round, the face must be closely inspected for evidence of unshot explosives from the previous round. The holes are then blown with compressed air to clear blockages and remove water from the holes.

For loading short holes using cartridge explosives, the charge is tamped with nonsparking poles. The cartridge containing the initiator should never be tamped, but rather pushed gently into the holes. In recent years, advances in hole loading have been made with the use of mechanized pneumatic and pumping machines. Pneumatic loading uses pressurized airstream flow to inject conventional cartridge as well as dry bulk explosives (Ljung, 1978; Smith, 1982; Russell, 1984; Day and Joyce, 1988). In loading dry bulk ANFO, care must be taken to adjust the pressure regulator such that the tank or line pressure remains below the level recommended by the manufacturer. Static electricity buildup is a problem with this method, and nonelectric or anti-static blasting caps must be used with pneumatically loaded ANFO. The success of loading bulk ANFO and wet blasting agents in upholes, using pressurized air and pumps, has allowed the application of large-diameter holes (6.5 in. or 165 mm) to stoping techniques and the development of the vertical crater retreat (VCR) method of stoping (Bauer, 1978; Lang, 1978).

Priming methods used in underground holes are a matter of choice. Large-diameter holes are primed at the base of the hole.

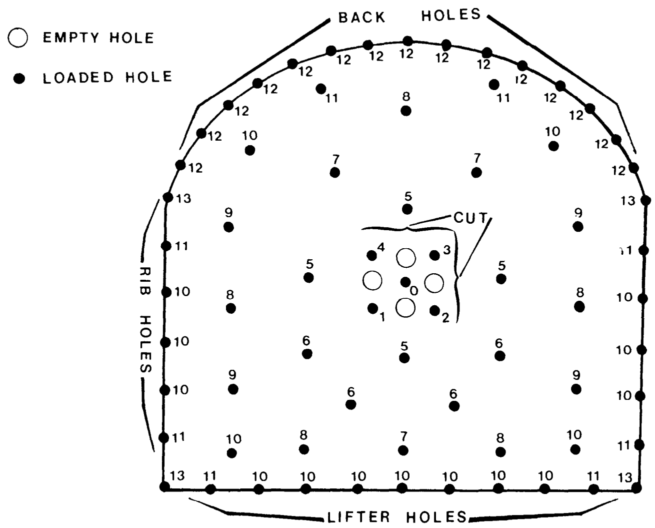

Fig. 9.2.1.12. Typical tunnel round showing drillhole terminology and an initiation sequence for delay timing; all holes between the cut and perimeter holes are referred to as relief holes.

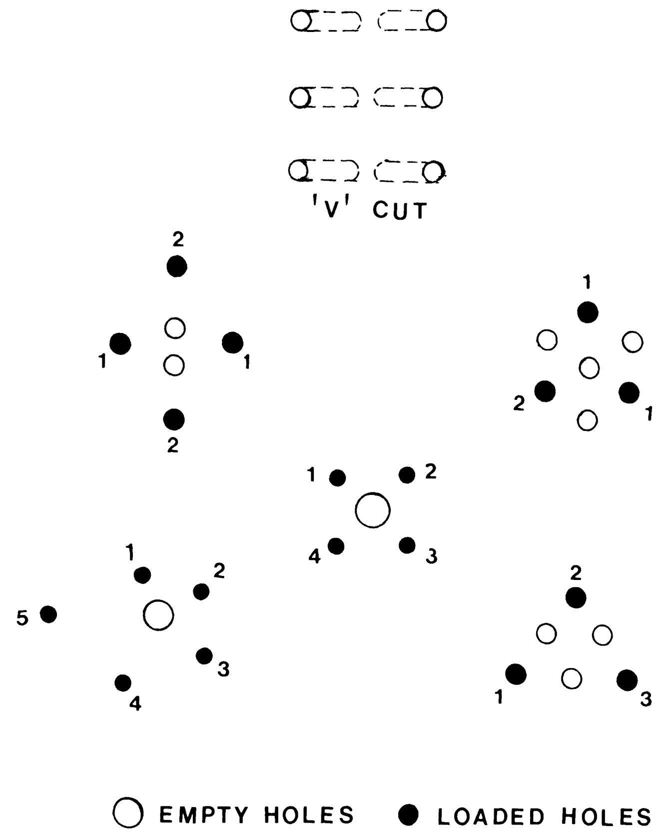

Fig. 9.2.1.13. Example of burn and V cuts used in underground blast designs.

Blasting caps are inserted with the exploding tip facing the line of charge. Small-diameter horizontal holes should be primed at the hole bottom to ensure maximum confinement. If the primer containing the initiator is placed at the hole collar, it could be expelled upon detonation if the stem length is too short. A misfire could result with unshot explosives remaining in the hole. If a misfire occurs, it should be handled as described in the segment on surface blasthole loading.

Post-shot procedures must include a safe waiting time for fumes to disperse from the working area. This time varies based on the explosive and rock type, as well as the ventilation system. Measurements should be taken to establish this safe time.

The design of underground blasting rounds is covered in detail by Langefors and Kihlstrom (1978), Gustafsson (1981), and Dick et al. (1983). Two types of blasting rounds are those with one free face and those with more than one free face. Single-face rounds are used in development openings (tunnels, shafts, raises) as well as in room and pillar, longwall, and shrinkage stoping methods of mining. All mining methods require single-face blast designs for development work. Multiple-face rounds are used in open stopes, sublevel caving, and large-diameter tunnels using benching methods. In many cases, multiple-face rounds are designed similar to surface blasting.

Single-Face Rounds—Names given to the various blastholes drilled within a round are shown in Fig. 9.2.1.12. *Cuts* refer to a group of holes, centrally located at the face and detonated on the first few delay intervals. The purpose of the cut is to provide initial relief to which the remaining holes break. Cuts comprise parallel holes, referred to as the burn cut, or angled holes, defined as V cuts. Various types of burn and V cuts are shown in Fig. 9.2.1.13. In the case of single free faces, the *burden* is defined as the distance, on the face, between each hole and adjacent relief. This relief can be provided by the empty holes in the cut, by the blasted and ejected cut itself, or by holes surrounding the cut as the delayed sequence of holes are initiated.

Langefors and Kihlstrom (1978) provide design criteria for the distance between loaded and empty holes to maximize breakage and advance of the face for the burn cut round. As a general rule, the burden between central empty holes and the nearest small-diameter loaded hole should be 0.7 times the area of the empty holes.

The location of the cut on the face will dictate the direction and distance of throw. In soft rock, such as coal or potash, a saw or cutter chain is used to produce a kerf cut near the floor, roof, or along the midsection of a face to serve as a plane of relief in addition to protecting the wall rock from backbreak.

Borehole patterns are selected based on rock type and size of the face. Drillhole alignment is critical for blasting results. If holes are incorrectly spaced, wallrock damage or poor fragmentation can occur. Bottom-hole deviation is defined as the offset distance measured at the hole bottom divided by the planned hole length and is given in percentage. Hole alignment is a function of hole size, total hole length, direction drilled and geology. Longhole deviations can be approximated by 0.015 times hole length in feet (0.05 times hole length in meters). Vertical, large-diameter down-holes can be drilled with little deviation. Small-diameter holes drilled within a fan or ring result in large deviations. When loading holes, deviations must be considered such that adequate hole bottom powder factors are used. If powder factors are too low, the advance per round, or pull, is poor. If holes are too close together, resulting in high powder factors, dead pressing of explosives may occur leading to bootlegs, or misfires. Sympathetic detonation could also occur, prematurely initiating adjacent holes simultaneously, and results with in-place fragmented rock and no displacement. This rock is referred to as "frozen" in place, and generally leads to no advancement of the face.

Empirical relationships available for spacing of holes and powder factors are given by Langefors and Kihlstrom (1978), Gustafsson (1981), and Holmberg (1982). Approximate relationships between total heading area and total hole area, powder factors, and approximate number of holes required based on geology and hole size are given. Such relationships are based on hard-rock blasting techniques used in Sweden and Austria. They are based on empirical data and cannot be expected to apply to each underground blasting situation in other types of rock.

Wilbur (1982) gives drillhole requirements for US tunnel projects and a generalized range of geology. The relationship for N, the number of blastholes per round based on tunnel area A in square feet, is approximated for soft or highly fractured rock (9.2.1.14) and for hard or massive rock (9.2.1.15) by

$$N = 0.124\ A + 10 \tag{9.2.1.14}$$

$$N = 0.158\ A + 28 \tag{9.2.1.15}$$

Gustafsson provides numerous design examples for relationships developed in Austrian tunnels. Design formulas are based on holes loaded with a nonuniform distribution of explosive charge or loading density. A heavy charge, loaded at the bottom one-third of the hole, and a column charge equal to one-half the bottom charge is used in tunnel blastholes. The burden in feet is equal to (hole depth − 1.3/2), and spacing in feet is 1.1 times the burden. Stemming length is one-half the burden depth.

Such relationships only serve as examples of the procedures to be taken in the design process. For each design situation, a trial-and-error approach is usually taken by experienced and qualified blasters.

Delays used are either short- (ms) or long- (sec) period electric or nonelectric delays. In general, long periods provide coarse fragmentation, and muck pile placement is high and close to the blasted face. These delays are necessary in tight headings such as raises where more time is necessary to displace rock for individual delays. Short-period delays generate finer fragmentation and a long, low muck pile profile.

Delay patterns and approximate hole spacings used for single-face blasting underground are shown in Fig. 9.2.1.14. Blast designs used for sinking shafts are similar to those used for tunnels. For full-face rounds, a burn cut or V cut is used. A bench round or sump cut, shown in Fig. 9.2.1.14, allows for dewatering during development. Powder factors range from 2 to 7 lb/yd^3 (1.20 to 4.2 kg/m^3). Hole diameters average 2 in. (50.8 mm) in tunnels, and diameters of 4 to 6 in. (101.6 to 152.4 mm) are used in stoping techniques.

Raises using short holes less than 120 ft (36.6 m) or long holes greater than 120 ft (36.6 m) are drilled 2 to 6.5 in. (50.8 to 165 mm) in diameter and loaded up or down from a horizontal drift. Drillhole deviations limit raise drilling to less than 148 ft (45 m). Drilling and loading upholes from below can be dangerous and time consuming. Down-hole drilling and loading is safer and provides a high productivity. This is usually done with a central large relief hole or using the vertical crater retreat (VCR) method. The VCR method has been adapted to drilling large-diameter down-holes, providing a safer and more efficient means of advancing raises from the bottom taking advantage of gravity, while equipment and men remain at the top sill.

The shrinkage stope method used for production can be adapted to VCR methods in large diameter (6.5 in. or 165 mm) holes. In this method, down-holes are drilled from an upper drift, plugged near the hole bottom, loaded, and shot using delays. The sequence is repeated several times, advancing the back of the undercut with horizontal slices. Each round is loaded with a charge length to diameter ratio of 6 or less with parallel hole spacing designed 20 times the hole diameter dimension. The advantage of this method used in shrinkage stoping is higher productivity, improved safety, good fragmentation, and cost per ton lower than traditional overhand shrinkage methods.

Multiple-Face Rounds— Underground blasting techniques using multiple faces are shown in Fig. 9.2.1.15. Benching, similar to surface methods, is employed for room and pillar and open stoping methods. Medium- to large-diameter holes, drilled either vertically using subdrilling or horizontally, are used.

Shrinkage stopes are blasted using either the overhand or blasthole shrinkage method. Hand-held jacklegs or stopers are used to drill small-diameter upholes or holes in an inclined back, as well as horizontal holes, using overhand or breasting methods, while working support is provided by the previously blasted muck pile.

Cut and fill mining methods excavate horizontal slices of ore working from the stope bottom upward. In this method, the ore is blasted and removed after each slice, then replaced with waste material usually comprising cemented mill tailings. Hydraulic filling provides a competent, even floor for the drilling of horizontal or vertical holes along the back using mechanized drilling equipment.

Sublevel or blasthole stoping methods include small-diameter hole ring and fan drilling techniques or large-diameter parallel holes drilled the entire stope length. Sublevel stopes are developed with small-diameter holes approximately 2 in. (51 mm) in diameter. Drilling efficiency is limited to 60 to 80 ft (18 to 25 m) for rings. Fan upholes, angled 45° to 88°, are drilled 45 to 65 ft (12 to 20 m) in length. Stope widths range 20 to 150 ft (6 to 46 m), and heights up to 250 ft (76 m) are common. An end pillar raise or a central slot raise is initially blasted from wall to wall to which successive slab rounds break. Fan or ring spacings along the drill drifts, or the burden distance between holes, vary 5 to 10 ft (1.5 to 3 m), and hole bottom, or toe, spacings between holes in a fan or ring range from 10 to 20 ft (3 to 6 m). Hagen (1988) recommends the use of staggered drilling patterns between fans or rings with a spacing 3.5 to 4 times the burden distance. The use of this ratio should minimize sympathetic detonation, improve fragmentation, lower ground vibrations, and provide a good distribution of explosive energy. ANFO or water gels are commonly used with powder factors ranging from 2 to 6 lb/yd^3 (1.2 to 3.6 kg/m^3). Short period electric or nonelectric blasting caps with delay intervals of 25 ms are generally used.

Large-diameter parallel holes 4 to 7 in. (102 to 178 mm) in diameter are often used to blast entire stopes without sublevels to heights of 250 ft (76 m). The vertical limits of the stope are defined by an upper drill drift or top sill and an undercut drift. The upper sill is developed to the width of the ore body. Down-the-hole (DTH) drilling equipment is used to drill down-holes 150 to 200 ft (45 to 65 m) in length. Two methods of production blasting include vertical slabbing to an open stope and crater blasting or VCR. Panel blasting requires a raise and slot to be developed in addition to an undercut fan beneath each slab round. A 0.32-lb/ton (0.15-kg/t) powder factor is typically used. The application of crater blasting in stope mining requires a minimum of development within the ore pillar. Its use depends on the size of the ore body and the stability of wallrock. The VCR method has been shown to reduce pillar damage and overbreak, resulting in less ore dilution. Drilling and blasting cycles were described previously under single-face shrinkage stopes. Spacings and burdens range 8 to 10 ft (2.4 to 3 m) square or staggered on a 7 × 9-ft (2.1 × 2.7-m) pattern for a typical drillhole diameter of 6.5 in. (165 mm). Charge weights per hole using ANFO or water gels vary from 10 to 20 lb (4.5 to 9 kg), and a vertical advance of 10 to 15 ft (3.0 to 4.6 m) is typical. A major drawback with the use of this method is the difficulty in keeping

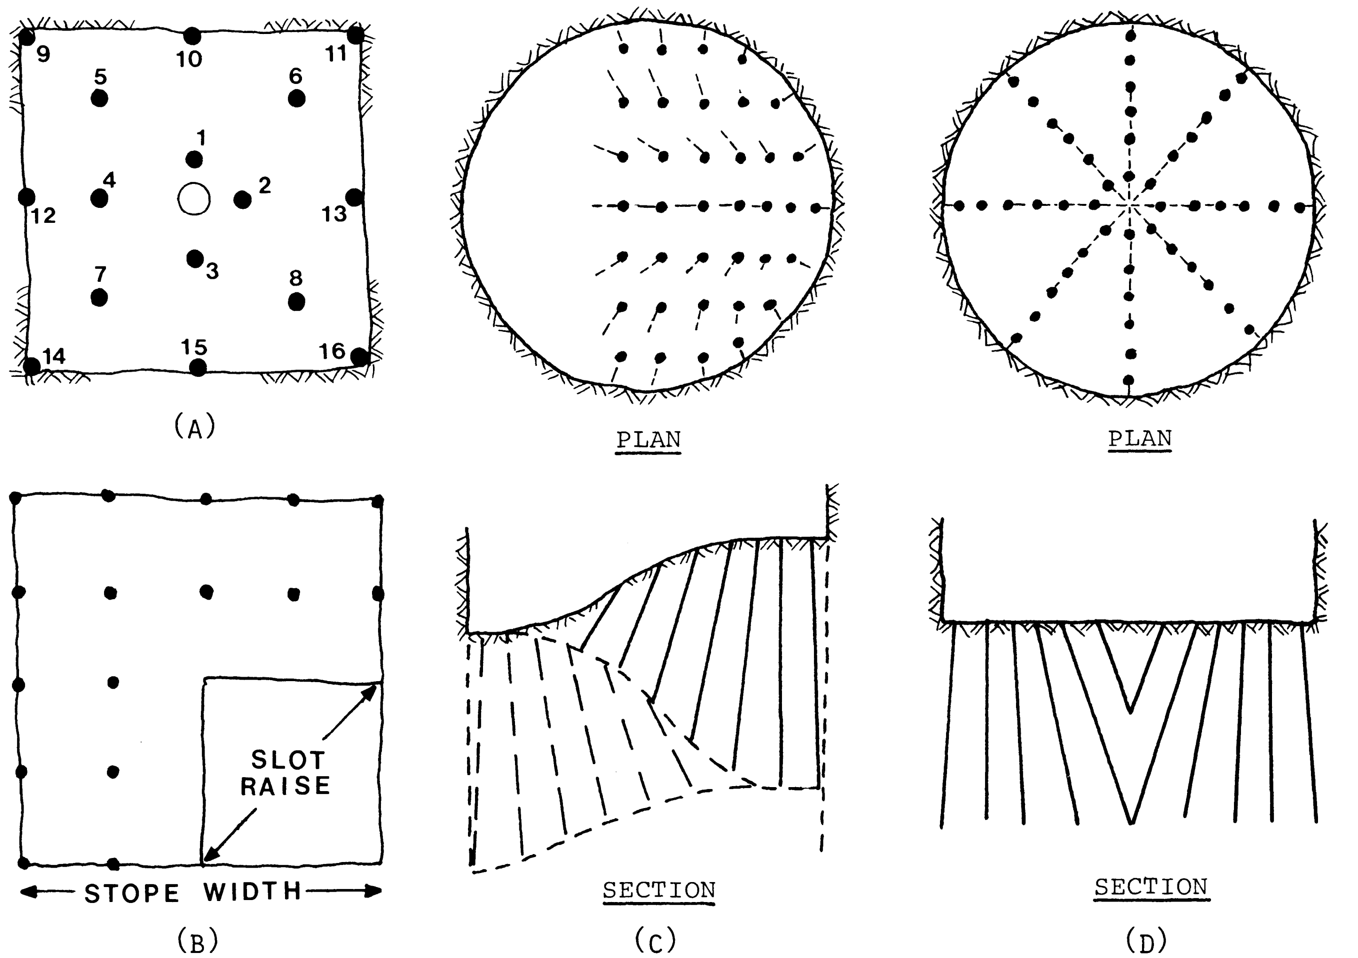

Fig. 9.2.1.14. Single face drilling patterns for (A) a long-hole raise, (B) drop raise for blasthole stopes (note: slot raise pattern similar to long-hole raise design), (C) shaft bench round, and (D) full face V shaft round.

holes open during blasting cycles in fractured and faulted ground.

Block and sublevel caving techniques are used at depths below which stoping methods become unstable or used for low-grade, fractured ore bodies. The sublevel caving method employs the use of fan drilling using long, small-diameter holes, between sublevels or drill drifts to undercut and blast the ore zone. An initial slot is developed at the wallrock, and vertical uphole fans are drilled in a diamond pattern from sublevels in sequence. Generally, eight holes, inclined 85° toward the slot, are drilled. Hole diameters average 2 in. (51 mm). Burdens and spacings vary from 4 to 6 ft (1.2 to 1.8 m) and 5 to 6 ft (1.5 to 1.8 m), respectively. Blasting is performed against broken waste rock as the wall rock caves. Powder factors range from 0.6 to 0.9 lb/ton (0.3 to 0.4 kg/t).

Block caving techniques require an initial development blast above the undercut level to start caving. Jumbos with 2- to 3-in. (51- to 76-mm) diameter holes drill fan rounds, oriented 45° to vertical and 15 to 38 ft (4.6 to 11.6 m) in length. Fan spacing is generally 5 ft (1.5 m). Secondary blasting is often required to dislodge oversize material or broken muck that has hung up within the raises. Bagged water gels are used in raises at a powder factor of 0.2 lb/ton (0.09 kg/t).

Controlled Blasting Techniques: *Controlled blasting* employs the use of reduced explosive quantities loaded into holes that are generally smaller in diameter and spaced closer than the main blast. The holes are often placed along the periphery of an excavation or round. This method is used to control overbreak, reduce fractures within remaining rock walls, and reduce ground vibrations. Such methods are variations of line drilling in which closely spaced, unloaded holes form a natural excavation line beyond which no rock is to be blasted. In general, hole diameters range from 2 to 3 in. (51 to 76 mm), and spacings range from 0.3 to 1 ft (0.1 to 0.3 m).

Two versions of line drilling used in surface blasting are presplitting and cushion blasting. *Presplitting* (or *preshearing)* uses a line of closely spaced loaded holes in the range of 2 to 4 in. (51 to 101.6 mm) in diameter and 2 to 4 ft (0.61 to 1.22 m) is spacing. They are drilled along the periphery of an excavation and initiated before the main blast is detonated. In this respect, an internal free face is formed, containing stress waves from successively detonated holes within the boundaries. Explosive charges range from 0.1 to 0.7 lb/ft (0.06 to 0.42 kg/m). Presplitting is often employed with trench blasting techniques.

Cushion blasting (also referred to as *smooth-wall* or *trim blasting)* is performed using hole sizes of 2 to 6 in. (51 to 152 mm) and loading from 0.1 to 1.5 lb/ft (0.06 to 0.89 kg/m). Hole spacings are generally set between 3 to 9 ft (0.9 to 2.74 m). In this method, explosive charges in cartridge form are decoupled

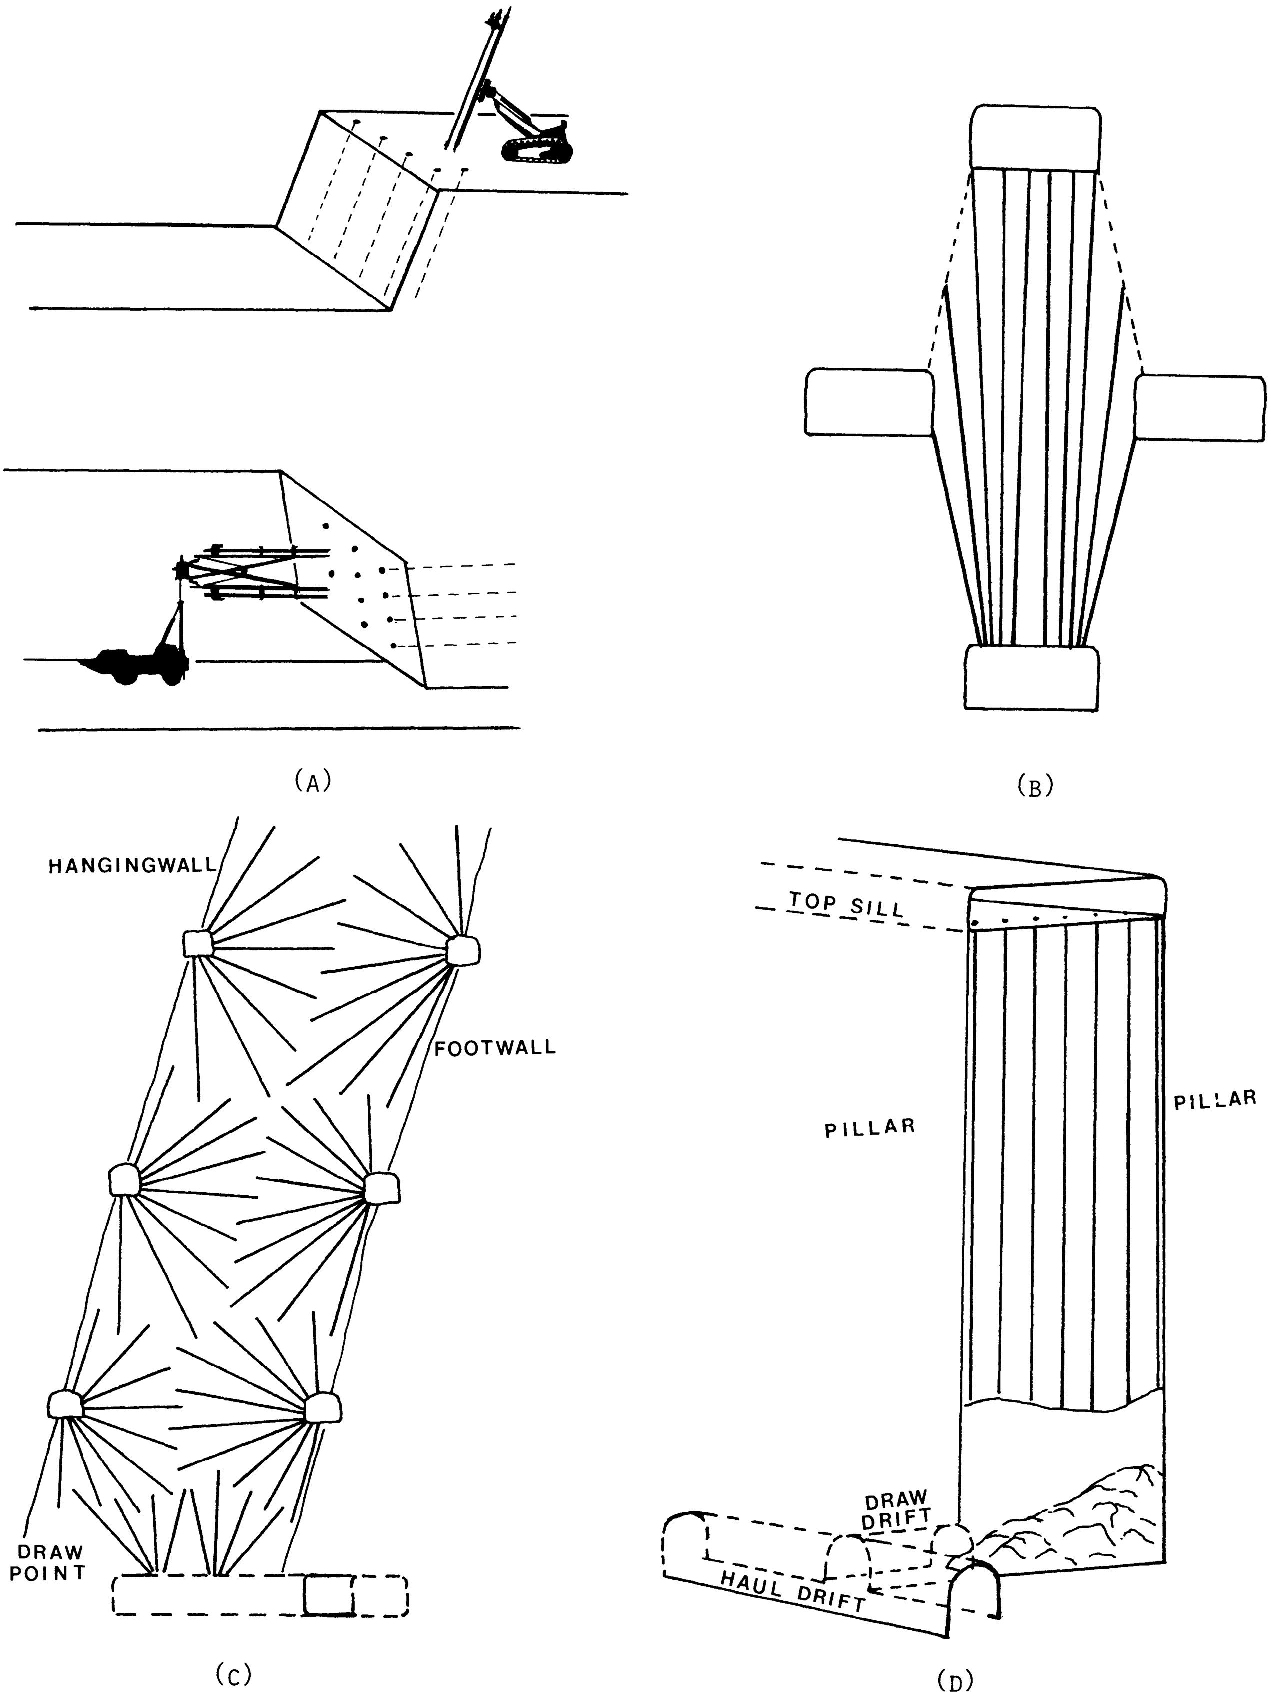

Fig. 9.2.1.15. Multiple face drilling patterns for (A) room and pillar, cut and fill, and shrinkage stoping methods; (B) sublevel caving; (C) sublevel stoping; and (D) long-hole stoping or vertical crater retreat methods.

from the borehole wall, intermittently spaced along the borehole length.

Smooth or trim blasting is the underground application of cushion blasting. For large-diameter blasting underground, an effective method of protecting pillars and stope walls is the decoupling of charges with air. Often a mixture of 50% ANFO and 50% polystyrene beads is used to lower the explosive energy in prefractured rock and for pillar protection. The use of spacers or plugs is used to distribute the charges, lowering the powder factor and eliminating the chance for charges to prematurely initiate adjacent holes designed for later initiation timing. Often the charge is placed in cardboard liners one-half the diameter of the borehole, filling the annular area with drill cuttings. Trim blastholes are shot after the main blast round is detonated.

9.2.1.4 Estimating Drilling and Blasting Costs

Drilling and blasting are unit operations required for development and production. The components of costs for drilling and blasting include labor, direct costs of operating equipment, and supplies. In surface mines, the basis of cost is computed per ton (tonne) of ore produced or per cubic yard (cubic meter) of material broken for removal. The costs are directly related to powder factor and depend on geology, type of explosives, and the size of the blastholes and excavating equipment. Underground costs are a function of mining method, level of mechanization, productivity, and operational cycle time. Development costs are given per foot (meter) of advance for tunnels and raises and are expensed over the ore block associated with development. Production drilling and blasting is computed per foot (meter) of hole drilled or per ton (tonne) of ore produced.

For equipment, such as a drill rig, the costs can be summarized with the following relationship:

$$\text{Drill cost, \$/ft} = \frac{(C_{own} + C_{op})\,BL\,(\text{hr}) + BC}{BL\,(\text{ft})} \qquad (9.2.1.16)$$

where C_{own} is cost per hour to own the rig, C_{op} is cost per hour to operate the rig, BL is bit life in hours or in feet, and BC is bit cost. The cost to own includes taxes, interest, insurance, amortization, and depreciation. The cost to operate includes labor, fuel, and parts and supplies, such as tires and drill steel. Labor costs, also applied to blasting costs, include base salary plus benefits. Benefits, which range from 30 to 40% of base salary, include insurance, health care, pension, and vacation. Incentive pay, as a percentage of base salary, is often provided when productivity increases over a predetermined average. Productivity is measured as feet (meters) drilled for the drill crew or loaded and shot per employee-shift for the blasting crew. Incentive pay is also provided for accurate underground drillhole alignment and depth.

Blasting costs comprise explosives, boosters and primers, initiation systems, and other expendables. Labor costs include the hours spent by the blasting crew to handle and transport explosives, load holes, detonate the shot, and take inventory and prepare paperwork. The cost of bulk loading and storage equipment is also included.

A comparison of drilling and blasting costs for various mining methods is shown in Table 9.2.1.8. Blasting costs are directly related to powder factor and the cost per pound of the main explosive charge. Labor costs can represent 5 to 40% of the total blasting costs, while the cost of expendable blasting accessories such as primers and initiators is generally less than 20% of total costs. Example cost calculations are given for the surface blast designs in Exs. 9.2.1.10 and 9.2.1.11.

Table 9.2.1.8. Comparison of Drilling and Blasting Costs for Various Mining Methods

Extraction Methods	Cost, $/yd^3
Metal mines and quarries	0.08–2.00
Construction	0.03–0.35
Tunneling	0.80–2.00
Longhole stoping	0.50–1.20
Vertical crater retreat mining	0.45–0.90
Cut and fill stoping	0.60–1.00
Shrinkage stoping	0.50–0.75

Conversion factor: $1 /yd^3 = $1.31 /m^3.
Source: Aimone, 1979.

Example 9.2.12. Using single-column loading from Ex. 9.2.1.10, estimate the drilling and blasting costs. The following cost data are used:

blasting:	ANFO	$ 0.12/lb	drilling:	$1.30/ft
	primer	1.50/ea		
	caps	1.30/ea		
	labor	16.00/hr		

A three-person blasting crew is assumed, and hourly wages include benefits. The unit drilling cost includes all costs to own and operate the rig, computed using Eq. 9.2.1.16.

Production data:

weekly production	150,000 tons
tonnage factor	2.4 tons/yd^3
yield/hole	1280 yd^3
holes/week required	50
yield/week	64,000 yd^3 or 153,600 tons

Solution.

1. Blasting cost

Explosives per hole:

ANFO 1114 lb @ $0.12/lb	$133.68	
Primer and cap	2.80	
Total per hole	$136.48	
Total per week, 50 × $136.48		$6824
Labor, 8 hr, 3 miners @ $ 16/hr		384
Total blasting per week		$7208
Total per yd^3		$0.113

2. Drilling cost

50 holes, 57 ft per hole @ $1.30/ft	$3705
Total per yd^3	$0.058

Example 9.2.1.13. Using three-deck loading from Ex. 9.2.1.11, estimate the drilling and blasting costs.

Production data:

yield per hole	1050 yd^3
holes per week	60
yield per week	63,000 yd^3 or 151,200 tons

Solution.

1. Blasting Cost

Explosives per hole:

ANFO, 900 lb @ $ 0.12/lb	$108.00	
3 primers and caps	8.40	
Total per hole	$116.40	
Total per week, 60 × $116.40		$6984

Labor, 9 hr, 3 miner, @ $ 16/hr	432
Total blasting per week	$7416
Total per yd^3	$0.118
2. Drilling cost	
60 holes, 57 ft per hole @ $1.30/ft	$4446
Total per yd^3	$0.071

Cost Comparison for Increase in Explosive Energy: The following example gives a cost comparison for two explosives of different energy levels. A design for explosive A, with a density of 0.85 and per-pound cost of $0.12, is compared with a design for explosive B, whose density is 1.3 and cost $0.20/lb. The design involves 4-in. (101.6-mm) diameter holes for a 150,000-yd^3 (114,690-m^3) excavation using 28-ft (8.53-m) long holes, 8-ft (2.44-m) collar stem, and 4-ft (1.22-m) subdrilling. The excavation subgrade is 24 ft (7.3 m) below current surface. Primer and cap costs are $2.80, while it is assumed that blasting labor is $4.00/hole, and drilling costs are $ 0.90/ft ($2.95/m).

Example 9.2.14. Cost comparison.

	Explosive A	**Explosive B**
explosive density	0.85	1.30
loading density	4.63 lb/ft	7.08 lb/ft
charge weight/hole	93 lb	142 lb
total blasting cost/hole	$17.96	$35.20
pattern ($B \times S$)	10 × 13 ft	12 × 17 ft
yield per hole	116 yd^3	181 yd^3
number of holes required	1293	829
powder factor	0.80 lb/yd^3	0.78 lb/yd^3
blasting cost	$0.155/yd^3	$0.194/yd^3
drilling cost	$0.217/yd^3	$0.139/yd^3
total costs	$0.372/yd^3	$0.334/yd^3

The higher cost of blasting with the higher-density explosive is offset with a lower drilling cost. With a higher-energy explosive, an expanded pattern is drilled with fewer holes. The overall cost savings is $5830.

Cost Comparison of Two Stoping Blasting Methods: Example 9.2.1.15 provides a cost comparison between conventional sublevel stope blasting (longhole stoping) and cratering techniques. Production costs are considered and development costs are not included.

Example 9.2.15. Cost comparison.

Production ore stopes are 250 ft (76 m) high, 420 ft (128 m) in length, and 35 ft (11 m) in width. Production is 1000 tpd (900 t/day), and stope production is 326,700 tons (296.4 kt). In longhole stoping, 2-in. (51-mm) drillholes are used to drill rings from sublevels with approximately 60 ft (18 m) of vertical separation. Eight holes are drilled per ring with an average hole depth of 35 ft (11 m). The crater method (VCR) uses 6.5-in. (165-mm) holes drilled vertically from the upper drill drift. A total labor cost of $18.75/hr or $150/employee-shift, is used. Drilling and blasting activities take place over 6.5 hr of the 8-hr shift.

Longhole stoping costs:

Drillhole size	2 in.
Explosive density	1.03
Explosive loading density	1.4 lb/ft
Powder factor	0.7 lb/ton
Explosive cost	$0.12/lb

Solution.

Blasting yield	
(1.4 lb/ft)/(0.7 lb/ton)	= 2 tons ore/ft of drillhole
Total stope drilling required	
326,700 tons/(2 tons/ft)	= 163,350 ft
Productivity and costs	
Drilling labor	
(35 ft/hr drill rate)(6.5 hr)	= 228 ft/employee-shift
($150/employee-shift)(228 ft/employee-shift)	= $0.66/ft
Drilling supplies and nonlabor costs	= $0.10/ft
Total drilling costs	= $0.76/ft = $0.38/ton
Blasting	
Explosives, (0.7 lb/ton)($0.12/lb)	= $0.084/ton
Primer and initiator	= $0.035/ton
Total blasting supplies	= $0.119/ton = $0.238/ft
Labor productivity	
(35 ft/hole)/(0.25 hr/hole loading time)	= 140 ft/employee-hr
(140 ft/employee-hr)(4 hr loading/shift)	= 560 ft/employee-shift
Labor cost	
($150/employee-shift)/(560 ft/employee-shift)	= 0.27/ft = $0.14/ton
Total blasting costs	= $0.51/ft = $0.25/ton
Total drilling and blasting costs	= $0.634/ton

VCR stoping costs:

Blasthole pattern	9 × 9 ft
Total VCR holes/stope	182
VCR drillhole length	220 ft
Total crater hole drilling	40,040 ft
VCR production	287,500 tons
Undercut development	39,200 tons
Explosive density	1.35
Explosive loading density	19.42 lb/ft
Explosive cost	$0.20/lb
Loading length-to-diameter	6
Charge weight per slab round	60 lb

Based on preliminary tests, a powder factor of 0.83 lb/ton (0.5 g/kg) is adequate to break 72 tons (65 t) for a 10-ft (3-m) retreat along the back. Total slab tonnage is 13,104 (11.9 kt). Rotary drilling cost, including labor, is $0.60/ft.

VCR blasting per 10-ft advance		
explosives		
(182 holes)(60 lb/hole)($0.20/lb)	$2184	
primer and initiator		
(182 holes)($2.50/hole)	455	
labor		
(54.6hr)(2 miners)($18.75/hr)	2048	
Total blasting costs	$2.57/ft	= $0.36/ton
VCR drilling per 10-ft advance		
($0.60/ft)(10 ft/hole)(182 holes)	$1092	= $0.083/ton
Total VCR drilling and blasting costs		= $0.443/ton

The costs to drill and blast the 39,200-ton (35.6 kt) undercut must be included. This is assumed to be a total cost of $0.634/ton as calculated for the smaller diameter hole. Thus the entire stope drilling and blasting cost is $0.466/ton. The application of VCR to stoping techniques for this example results in a 26% reduction in drilling and blasting costs over conventional long-hole stoping.

9.2.1.5 Research in Explosives Applications

Within the past two decades, advances have been made to improve the efficiency of explosives and rock blasting. These advances have been, in part, largely due to analytical and computational techniques of high-speed photography and computer modeling. These methods have brought about a greater understanding of the distribution of explosive energy during the rock fracturing process. Other areas of advancement include initiators and explosives formulation.

Much attention has been given to modeling the explosive fracture and fragmentation processes (Cunningham, 1987; Danell and Leung, 1987; Kuszmaul, 1987; Kirby et al., 1987; Paine et al., 1987; Exadaktylos et al., 1987; Crum and Stagg, 1989) and to modeling explosive detonations (Leiper and Plessis, 1987). With fracture and fragmentation modeling, the effects of variations in design parameters on blasting results are readily obtained without costly field trial and error attempts. The output from many codes show particle size distributions, radial fracture formation, muck pile profiles, and stress profiles or damage functions, plotted along a borehole axis for a hypothetical blast. The blast may include charges placed within a two- or three-dimensional rock mass. Thermodynamic characteristics of the explosives and time delays are also modeled. The usefulness of these models are, however, limited as they cannot completely take into account the variability of geology or hole-loading conditions in practice. Output from computer models must be field tested for validation.

Explosive performance, particularly in the areas of wet blasting agents and heavy ANFOs, has been extensively researched (Bauer et al., 1984; Lee, 1987; Van Ommeren, 1989). Explosive manufacturers are investigating ANFO/emulsion blends to increase shelf life and the number of times the mix can be repumped. One area of ongoing research is the formulation of a water-based replacement for dynamite or a non-nitroglycerin explosives with the energy of dynamite. Improvements in the performance of AN prills, with changes in particle sizes and the selective penetration of liquids, is being investigated.

High-speed photography (Anon., 1983a; Chiappetta et al., 1983), used to evaluate blast designs, initiator timing, and explosive performance, has led to new product development and a better understanding of blasting theory. Cinematography has been used to assist in the selection of optimum hole loading, stemming, spacings, and burdens for control of throw and muck pile placement. Optimum delay sequencing can be identified from photographic work, both underground and on the surface. Surface-cast blasting, a method used primarily in surface-coal mining, was perfected using high-speed photography (Burleson, 1988; Guiliani and Otuonye, 1989). Cast blasting, using angled or vertical holes in a limited number of rows, is performed with high-gas producing explosives, to "cast" the burden rock. In the case of blasting overburden wasterock, the material is thrown to the final spoil area to minimize equipment handling. In theory, the cost tradeoff between increased blasting costs and decreased material handling costs lowers overall operating costs.

The concept of air decking applied to surface blasting techniques has been made with the use of high-speed photography (Bussey and Borg, 1988). Air decking, developed 50 years ago, involves the use of a small, concentrated charge at the hole bottom and a rigid plug near the hole collar to hold a length of stemming. Between the plug and charge is a length of unloaded hole, or air deck. Its application to blast design greatly enhances fragmentation and controlled fracturing near the collar and throughout the hole length. Upon detonation, the shock wave generated at the hole bottom travels through the air deck, reflecting at the stem base, intensifying the shock energy within the rock at the hole collar with a minimum (limited) explosive charge. The air deck is effective in modifying the pressure pulse shape within this region by lowering the stress wave amplitude; however, the pulse is increased in duration. The stress wave amplitude remains at the level that promotes tensile fracturing. It is the increase in pulse duration or the time application of this tensile pulse that enhances fragmentation. Currently, the method is employed successfully for surface presplitting.

Two major advances have occurred in the area of initiators. These are the developments of precise pryotechnical delays for electric blasting caps and electronic integrated circuit delays. Timing errors are inherent to the design and manufacture of all standard electric blasting caps (Winzer, 1978). Such errors become critical when accurate timing is required for fragmentation and the control of ground vibrations. Precise pyrotechnical delay caps are now manufactured to provide an increase in accuracy on the order of milliseconds; however, they cost slightly more than standard caps.

Programmable blasting caps are being developed with millisecond accuracy (Worsey and Tyler, 1983; Wilson et al., 1987; Larsson et al., 1988). The caps comprise an integrated circuit, using a microprocessor to receive and distribute programmed information on detonation time, current required for detonation, and other coding to prevent access by unauthorized personnel. All forms of electrical hazards are eliminated with these caps, as a unique rate of current must be supplied to the caps before detonation can occur.

9.2.2 MONITORING AND CONTROL OF BLAST EFFECTS

CHARLES H. DOWDING

9.2.2.1 Introduction

Monitoring and control of blast effects near critical rock masses or constructed facilities depend upon two main considerations. First, shot designs must reduce the amount of explosives detonated at any instant and adjust the initiation sequence to reduce resulting ground and airborne disturbances. Second, the amount of explosives detonated per volume of rock and the shot pattern must be adjusted to ensure adequate fragmentation. Therefore, at the same time, the initiation sequence must be separated in time but not in space.

There is an optimum design which achieves both objectives of control of disturbances and production of adequate fragmentation. This optimum can be reached only through an understanding of the physics of rock mass and structural response to blast disturbance and the interaction between rock fragmentation and shot design. This segment summarizes the state of the art in vibration measurement and structural response to facilitate such an optimum blast design.

Furthermore, it is an effort to transfer advances in earthquake engineering and nuclear blast protective design to blast vibration monitoring and control while summarizing the most recent experimental observations of mining-induced ground motions and structural response. It is hoped that such a transfer and summary of the state of the art will mitigate several recent trends.

For one, there has been a general downward trend in regulatory limits on allowable blast-induced vibrations. In addition to new observations, this drift, in part, can be attributed to the tendency to take the limit of the last study and divide it in half "to be safe." Unfortunately, too many studies whose limits were divided were themselves only summaries of past work that had also divided past limits. The discussion here presents the background for original experiments conducted to determine safe blasting controls and therefore will allow the reader to set appropriate limits based upon the original past work within the framework of existing regulations.

Another trend is the misapplication of peak particle velocity limits that were determined for cosmetic cracking of residential structures. These limits have been applied to tunnel liners, radio towers, slabs-on-grade, and curing concrete. This segment draws attention to studies made to determine limits specifically for these and other cases. Where no studies exist, it presents methods based upon response spectra or ground strains that allow setting of appropriate criteria or limits.

Frequency of vibration and ground strain form the foundation for the presentation. The importance of frequency cannot be over estimated, as it is as critical as peak particle velocity in determining the response of aboveground structures. For below ground structures, frequency, in combination with propagation velocity, controls response. In both cases, cracking results from induced strains, where particle velocity is employed as an index of the strain level.

In addition, computerized monitoring instrumentation is described. Such computerization simultaneously increases monitoring efficiency as well as decreases costs, both original capital costs as well as those associated with record keeping. The latter labor-saving efficiency associated with automated record keeping continues to be undervalued by many mining operations.

9.2.2.2 Range of Blast Effects

Blast effects on surrounding earth materials and structures can be divided into the permanent and transient displacements. While the focus of this chapter is the transient displacements, effects of permanent displacements are presented as they are associated with significant transient effects at relatively small distances.

Permanent Degradation and Displacement of Adjacent Rock: Permanent effects, with the exception of fly rock, are only described within a few hundreds of feet (meters), and can be divided into degradation and displacement.

Degradation —Degradation is normally described by cracking intensity. Such blast-induced cracking has been observed experimentally to vary with hole diameter and rock type (Siskind and Fumanti, 1974; Holmberg and Persson, 1978). Small-hole-diameter construction blasting has induced cracking at distances of 3½ to 7 ft (1 to 2 m), and larger-hole-diameter mining blasts are capable of producing cracks at distances of 35 to 70 ft (10 to 20 m). Careful blast design can dramatically reduce these maximum distances.

Displacement— Displacement can be produced by either delayed gas pressures (those that accumulate during detonation) or by vibration-induced shaking. Delayed gas pressure have dislocated blocks as large as 1300 yd^3 (1000 m^3) during construction blasting (Dowding, 1985). Such movement is unusual, but is associated with isolated blocks, leakage of gas pressures along open joints, and poor shot design with large burdens. Vibratory or shaking-induced displacement is normally associated with unstable blocks in rock slopes and can occur wherever static factors of safety are low and ground motions produce permanent displacements that are greater than the first-order asperity wave length (Dowding and Gilbert, 1988). Gas pressure related displacement can occur out to several hundred feet (meters).

Fly Rock—Fly rock is a special case of permanent displacement of rock by explosive expulsion from the top of the blasthole. Rock has been observed to have been propelled as far as 330 to 3300 ft (100 to 1000 m) (Roth, 1979). Statistical studies have shown that the probability of these extreme events is quite low under normal circumstances, 1 in 10,000,000 at 2000 ft (600 m) (Lundborg, 1981). Since the probability increases with decreasing distance, blasting mats are required in any construction blasting in an urban environment to prevent all fly rock.

Soil Densification or Compaction—Another special case of permanent displacement is the vibratory densification of a nearby mass of loose, clean sand. The propensity for such densification is a function of the soil's density, mineralogy, and grain size distribution. Soils that are densifiable are loose sands, with less than 5% silt-size particles. These clean sands were densified out to distances of 70 ft (20 m) (Ivanov, 1967) after detonation of single, 11-lb (5-kg) charges within the loose sand mass itself. Soils that are either slightly cemented or contain more than 5% fines are a great deal less subject to vibratory densification from typical ground motions.

Transient Structural Response: Transient effects result from the vibratory nature of the ground and airborne disturbances that propagate outward from a blast. In this discussion, it is assumed that no permanent displacements are produced. Thus the only effects are those associated with the vibratory response of facilities in or on the rock or soil mass surrounding the blast. Transient means that the peak displacement is only temporary, lasts less than one-hundredth of a second, and the structure returns to its original position afterwards.

Transient structural effects can be arranged to reflect the expected distance from a blast. Beginning with the closest, transient effects are structural distortion, faulted or displaced cracks, falling objects, cosmetic cracking of wall coverings, excessive instrument and machinery response, human response, and micro disturbance.

The first four effects, those that relate to structural response, are normally grouped together for experimental observation as structural response, and do not normally occur when vibration levels are regulated to prevent cosmetic cracking.

Excessive structural response has been separated into three categories arranged below in the order of declining severity and increasing distance of occurrence (Northwood et al., 1963; Siskind et al., 1980b). Beginning with effects that occur closest to the blast, the categories are listed here.

1. MAJOR (Permanent Distortion). Resulting in serious weakening of the structure (e.g., large cracks or shifting of foundations or bearing walls, major settlement resulting in distortion or weakening of the superstructure, walls out of plumb).
2. MINOR (Displaced Cracks). Surficial, not affecting the strength of the structures (e.g., broken windows, loosened or fallen plaster), hairline cracks in masonry.
3. THRESHOLD (Cosmetic Cracking). Opening of old cracks and formation of new plaster cracks, dislodging of loose objects (e.g., loose bricks in chimneys).

These specific definitions of response should not be described collectively as "damage." To do so blurs the distinction between threshold or cosmetic cracking and major response or structural distress.

Regulation to Prevent Cosmetic Cracking of Residential Structures—Regulatory controls in North America are based on the occurrence of threshold cracking of plaster and gypsum wall board in residential structures (Siskind et al., 1980; Dowding, 1985). Observed cracking is cosmetic in nature and does not affect structural stability. These cosmetic cracks are hair-sized and are similar to cracks that occur during the natural aging of structures. In fact they are indistinguishable from those that result from natural aging. Control limits are based upon direct observations of test homes immediately before and immediately after blast events, to avoid confusion with the similar cracks that might occur from natural processes. These controls do not apply to engineered structures that are constructed of steel and concrete, buried structures, or adjacent rock.

Distinction of Blast-induced Cracking from Natural Cracking: Control of blast-induced transient effects to prevent threshold or cosmetic cracking reduces blast-induced displacement or strains in structures to or below that caused by every day human activities and changes in the weather (Stagg et al., 1984; Dowding, 1988). These cosmetic cracks in many cases are smaller than cracks caused by other natural or occupant initiated processes that are active in all constructed facilities. Thus blast-induced threshold cracks can be scientifically observed only with visual inspection immediately before and after each blast. Observations made under less stringently controlled conditions have little scientific merit because of the high probability of environmentally produced cracks occurring between or before visual inspections.

Multiple Origins of Cracks—Several institutional references (Anon., 1977; Anon., 1956; Thoenen and Windes, 1942) present excellent summaries of the multiple origins of cracks. Basically, cracks are found to be caused by the following:

1. Differential thermal expansion.
2. Structural overloading.
3. Chemical changes in mortar, bricks, plaster, and stucco.
4. Shrinkage and swelling of wood.
5. Fatigue and aging of wall coverings.

Table 9.2.2.1. Comparison of Strain Levels Induced by Household Activities, Daily Environmental Changes, and Blasting

Loading Phenomena	Site[a]	Microstrain Induced by Phenomena, μin/in.	Corresponding Blast Level[b]	
			in./sec	mm/s
Daily environmental changes	K_1	149	1.2	30.0
	K_2	385	3.0	76.0
Household activities				
Walking	S_2	9.1	0.03	0.8
Heel drops	S_2	16.0	0.03	0.8
Jumping	S_2	37.3	0.28	7.1
Door slams	S_1	48.8	0.50	12.7
Pounding nails	$S_{1,2}$	88.7	0.88	22.4

[a]K_1 and K_2 were placed across a tape joint between two sheets of gypsum wallboard.

[b]Blast equivalent based on envelope line of strain vs. ground vibration.

6. Differential foundation settlement.

Overtime, all of the causes listed are likely to crack walls, whether or not blasting occurs.

There are three important implications associated with the list above. Structures expand and contract preferentially along existing weaknesses (cracks). Seasonal expansion and contraction along these cracks will return patching and repainting to the original cracked state within several years. This persistent cracking is annoying to those owners who are unaware of the difficulty of patching existing cracks of any kind. Second, the distortion that caused the cracking also creates stress concentrations which may lower a wall-covering's resistance to vibration cracking; however, current regulatory limits already implicitly include these distortion effects as explained in 9.2.2.6. Third, these natural cracks continue to occur over time. Therefore, any postblast inspection at low vibration levels is likely to find new cracks from natural aging unless preblast inspection is conducted immediately before the blast.

Response of Structures to Everyday Activities: A comparison of strains produced by blast vibrations and everyday events with those needed to fail wall-covering materials gives perspective to the observation of cracking at low particle velocities. Table 9.2.2.1 compares strains from daily environmental changes (temperature and humidity) and household activities measured in the US Bureau of Mines test house (Stagg et al., 1984). The door was slammed adjacent to the wall on which the strains were measured.

It appears that in the course of daily life, an active family will produce strains in walls similar to those produced by blasting vibrations of 0.1 to 0.5 ips (2.5 to 12 mm/s). Most astonishing are the measurements in a wood-framed home of relatively enormous strains from daily changes in temperature and humidity. These alone are large enough to crack plaster.

Blast-induced Air Overpressures: Blast-induced air overpressures are the air pressure waves generated by explosions. The higher-frequency portion of the pressure wave is audible and is the sound that accompanies a blast; the lower-frequency portion is not audible, but excites structures and in turn causes a secondary and audible rattle within a structure.

Overpressure waves are of interest for three reasons. First, the audible portion produces direct noise. Second, the inaudible portion by itself or in combination with ground motion can produce structural motions that in turn produce noise. Third, they may crack windows; however, air-blast pressure alone would have to be unusually high for such cracking. Previous researchers (Kamperman and Nicholson, 1970; Borsky, 1965) have found that response noise within a structure (from blasting and sonic booms respectively) is the source of many complaints. It appears that structure and wall motions, which are induced by airblasts and sonic booms, rattle loose objects within the structure, which then startle the occupants.

Human Response: Humans are quite sensitive to motion and noise that accompany blast-induced ground and airborne disturbances. Therefore, human response is significant in the reporting of blast-induced cracking. Motion and noise from blasting can be startling and lead to a search for some physical manifestation of the startling phenomena. Many times, a previously unnoticed crack provides such confirmation of the event. Furthermore, if a person is worried and observes a crack that was not noticed before, the crack's perceived significance increases over one noticed in the absence of any startling activity. These concerns are real and in the mind of the observer are sincere.

In typical mining situations, significant blast-induced inaudible air overpressure and audible noise immediately follows the ground motion and intensifies human response. Both the ground and airborne disturbances excite walls, rattle dishes, and together tend to produce more noise inside a structure than outside. Thus both the audible noise as well as the wall rattle produced by inaudible pressures contribute to human response. To complicate matters even more, inaudible air overpressures can vibrate walls to produce audible noise at large distances, which are inaccurately reported by occupants as ground motions.

9.2.2.3 Character of Blast Excitation and Structural Response

As shown in Fig. 9.2.2.1, both the ground and airborne disturbances (upper-four time histories) produce structure response (lower-four time histories). Because of the importance of frequency, the full wave form or time history should be recorded. When a critical location is known, blast response is best described by the strain at that location. Alternatively, particle velocity (that shown in Fig. 9.2.2.1) can be measured outside the structure of concern, as many recent cracking studies have correlated cracking with excitation particle velocity measured in the ground.

Ground Motion: *Ground motion* can be described by three mutually perpendicular components labeled L (longitudinal), T (transverse), and V (vertical) (Fig. 9.2.2.1). The L and T directions are oriented in the horizontal plane with L directed along the line between the blast and recording transducer. When a study focuses upon structural response, axes can be labeled H1, H2, and V, with H1 and H2 oriented parallel to the structure's principal axis.

Variation of peak motions in each component (L, V, and T in Fig. 9.2.2.1) has led to difficulty in determining which is more important. Horizontal motions seem to control the horizontal response of walls, and superstructures and vertical motions seem to control the vertical response of floors. In an absolute sense, the peak ground motion is actually the maximum vector sum of the three components, which usually occurs at the largest peak of the three components, the dashed line in Fig. 9.2.2.1. This true maximum vector sum is not the FALSE maximum vector sum calculated with the maxima for each component (dots in Fig. 9.2.2.1) no matter their time of occurrence. The FALSE maximum vector sum may be as much as 40% greater than the

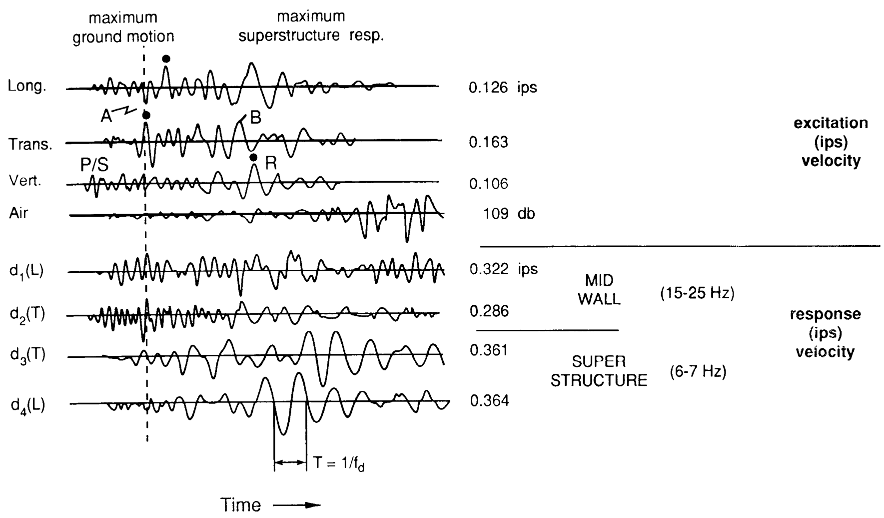

Fig. 9.2.2.1. Comparison of blast excitation by ground and airborne disturbances and residential structure response of walls and superstructure. Measurements were made some 2000 ft (600 m) from a typical surface coal mining blast. (After Dowding, 1988). Conversion factor: 1 ips = 25.4 mm/s.

TRUE maximum vector sum, which is normally 5 to 10% greater than the maximum, single component peak.

In general, experimental observations of threshold or cosmetic cracking, which form the basis of blasting controls in North America, have been correlated with the maximum single component regardless of direction. Therefore, use of the FALSE maximum vector sum, for control, provides a large, unaccounted for, factor of safety.

Two wave types are produced by blasting, *body* and *surface*, and are illustrated by the ground motion in Fig. 9.2.2.1 measured some 2000 ft (600 m) from a typical surface coal mining blast. Body waves travel through earth materials, whereas surface waves travel along surfaces and interfaces of earth materials. The most important surface wave is the Rayleigh, denoted R on the vertical trace in Fig. 9.2.2.1. Body waves can be further subdivided into compressive (compression/tension) or soundlike waves, and distortional or shear waves, denoted as P/S on the vertical trace in Fig. 9.2.2.1. Explosions produce predominantly body waves at small distances. These body waves propagate outward in a spherical manner until they intersect a boundary such as another rock layer, soil, or the ground surface. At this intersection, shear and surface waves are produced. Rayleigh surface waves become important at larger transmission distances as illustrated in the vertical trace by the relatively larger "R" amplitude compared to the "P/S" amplitude.

Sinusoidal Approximation—Typical blast vibrations, no matter the wave type, can be approximated as sinusoidally varying in either time or distance along the radial or longitudinal line as shown by the time variations in Figs. 9.2.2.2a and b. This approximation is useful because it makes calculations for strain and acceleration from particle velocity much simpler than that for an irregular pulse. Ground motion from a blast is similar to the motion of cork caused by a passing water wave. Displacement of the cork from its at rest position is similar to the displacement u of a particle in the ground from its at rest position. Similarly, the cork's velocity $\dot{u}$ as it bobs up and down is analogous to that of a particle in the ground, hence the term *particle velocity.*

The water wave that excites the cork can be described by its wave length g, the distance between wave crests; the wave speed or propagation velocity c at which it travels outward from the stone's impact; and the frequency f or the number of times the cork bobs up and down in one second. Frequency f is equal to $1/T$ or the reciprocal of the period or time it takes the cork to complete one cycle of motion. Frequency is measured in cycles per second or hertz, H_3. Propagation velocity c should not be confused with particle velocity $\dot{u}$, as c is the speed with which the water wave passes by the cork, and $\dot{u}$ is the speed at which the cork moves up and down while the wave passes. Blast vibration waves also can be described by their wavelength, propagation velocity, and frequency in the same fashion as the water wave.

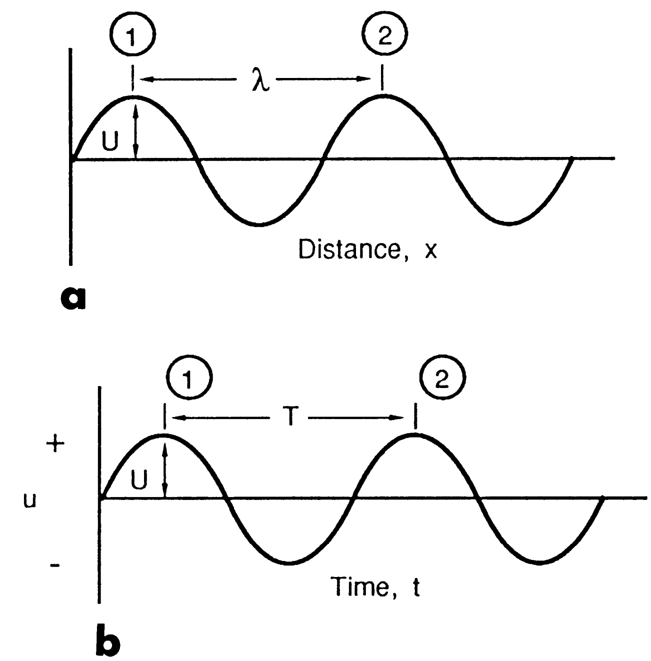

Fig. 9.2.2.2. Sinusoidal approximations: (a) sinusoidal displacement at a fixed point (x = constant); (b) sinusoidal displacement at one instant (t = constant). (Dowding, 1985).

Kinemetric Relationships of Ground Motion—The general form for the sinusoidal approximation is best understood by beginning with the equation for sinusoidal displacement u:

$$u = U \sin(2\pi f t) \qquad (9.2.2.1)$$

where U is maximum displacement, f is frequency, and t is time.

The relationship between the maximum particle displacement u_{max}, particle velocity $\dot{u}_{max}$, and acceleration $\ddot{u}_{max}$, is also greatly simplified by the sinusoidal approximation and is found through differentiation with respect to time of Eq. 9.2.2.1, as shown, whenever the sin/cos function maximizes at 1:

$$\begin{aligned} u_{max} &= U \\ \dot{u}_{max} &= U\, 2\pi f = 2\pi f u_{max} \\ \ddot{u}_{max} &= U\, 4\pi^2 f^2 = 2\ \pi f \dot{u}_{max} \end{aligned} \tag{9.2.2.2}$$

Usually, acceleration is normalized (divided) by gravitational acceleration, 386.4 in./sec^2 (9814 mm/s^2). Therefore, an acceleration of 79 in./sec^2 (2000 mm/s^2) is

$$\frac{2000}{9814} = \frac{79}{386} = 0.2\ g$$

or two-tenths that of gravity.

Kinematic relations between particle displacement, velocity, and acceleration for complex wave forms are exactly related through integration or differentiation of any of the wave forms. For instance, an acceleration time history can be integrated once for a velocity time history, which in turn can be integrated for a displacement time history. Even though a particle velocity record can be differentiated to find acceleration, it is not recommended, as the procedure is sensitive to small changes in the slope of the velocity time history. Further discussion of the inaccuracies of differentiation and integration can be found in Dowding (1985) and in texts devoted to interpretation of time histories (e.g., Hudson, 1979).

Transient Nature of Blast Motions—Great care should be taken not to confuse the effects of steady-state, single-frequency motions with those of transient, blast motions. Most vibration studies conducted by personnel trained in mechanical and electrical engineering and geophysics implicitly assume that the motions are continuous (last many cycles) and steady state (have constant frequency and amplitude). As can be seen in Fig. 9.2.2.1, blast-induced motions last only one or two cycles at a relatively constant amplitude and frequency. Such conditions are not similar enough to steady state motions to allow specific application of steady state approximations such as resonance.

Estimation of Dominant Frequency—Adoption of frequency-based vibration criteria has made the estimation and calculation of the dominant frequency an important concern. Dominant frequency can be estimated through visual inspection of the time history or calculated with Fourier frequency spectra or, alternatively, response spectra.

The accuracy or difficulty of visually estimating the dominant frequency depends upon the complexity of the time history. The easiest type of time history record for frequency estimation is one with a single dominant pulse like that shown in the inset in Fig. 9.2.2.3. This dominant frequency can be determined through the hand measurement of the time of the two zero crossings on either side of the peak. The difference between these times is one-half of the period, which is the inverse of twice the frequency of the dominant peak as shown in the figure.

As shown in Fig. 9.2.2.3, the relatively large explosions produced by surface coal mining, when measured at typically distant structures, tend to produce vibrations with lower principal frequencies than those of construction blasts. Construction blasts involve smaller explosions, but the typically small distances between a structure and a blast as well as rock-to-rock transmission paths tend to produce the highest frequencies. Such high-frequency motions associated with construction blasts have less potential for cracking adjacent structures (Dowding, 1985).

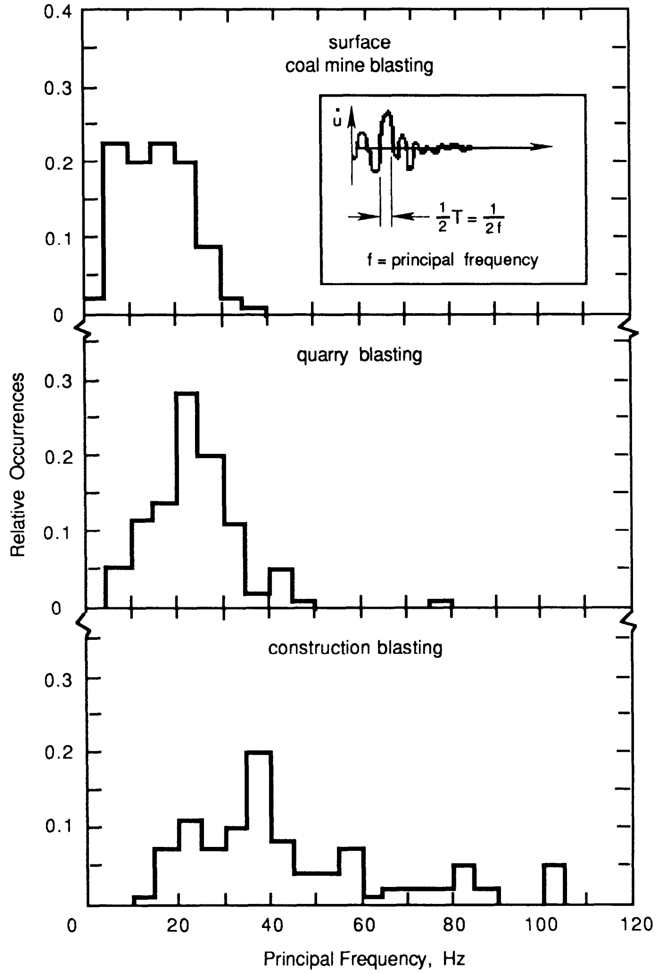

Fig. 9.2.2.3. Dominant frequency histograms at nearest structures categorized by industry. Dominant frequency is defined in the inset. (After Siskind et al., 1980b.)

The most difficult type of record to interpret is that which contains nearly equal peaks at two dominant frequencies such as that in Fig. 9.2.2.1. The two dominant frequencies are the initial 15- to 20-Hz portion (peak A) and the later 5- to 10-Hz portion (peak B). As can be seen in the figure, the initial portion produces the highest wall response while the second produces the greatest superstructure response. For the best frequency correlation of both types of response, both frequencies should be calculated.

The best computational approach to determining the dominant frequency involves the response spectrum. The response spectrum is preferred over the Fourier frequency spectrum because it can be related to structural strains (Dowding, 1985). A compromise approach is to calculate the dominant frequency associated with each peak by the zero crossing approach described above.

Since many time histories do not contain as broad a range of dominant frequencies as that in Fig. 9.2.2.1, most approaches require only the calculation of the frequency associated with the maximum particle velocity for blasts that produce small particle velocities. The more complex frequency analyses are employed only when peak particle velocities approach control limits.

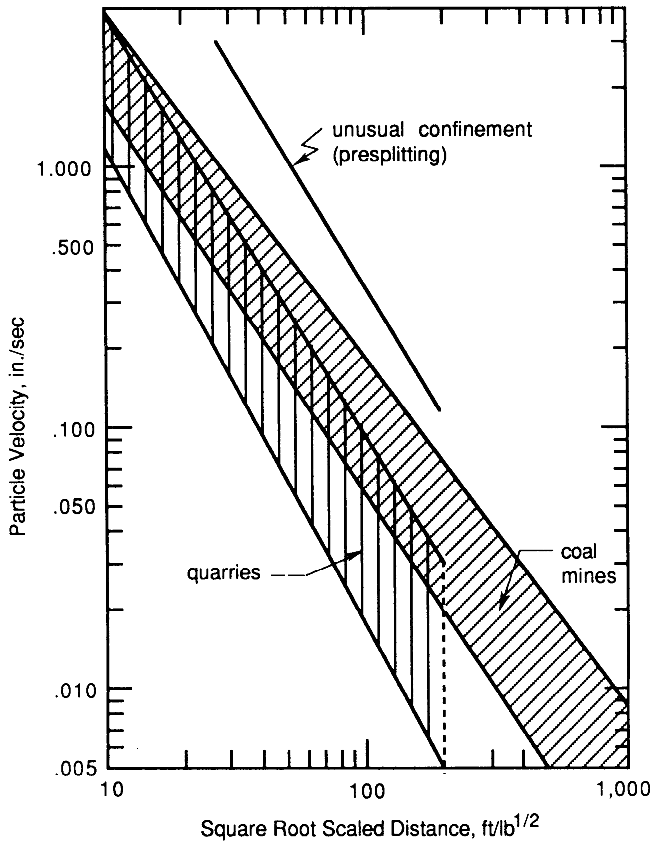

Fig. 9.2.2.4. Attenuation relationships showing scatter from geological and blast design effects as well as high expected velocities from confined shots, such as presplitting. (After Siskind et al., 1980b). Conversion factors: 1 ips = 25.4 mm/s, 1 ft/lb$^{1/2}$ = 0.8197 m/kg$^{1/2}$.

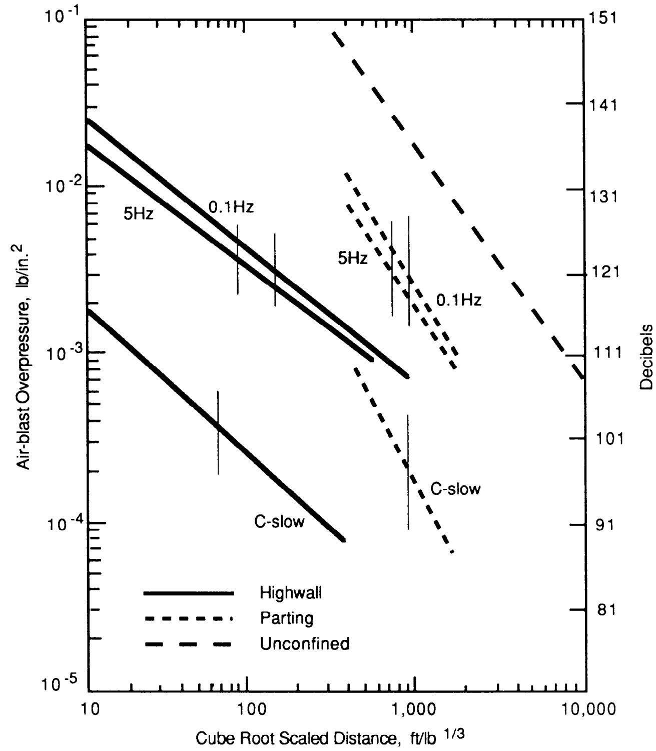

Fig. 9.2.2.5. Attenuation relationships for air overpressures produced by confined (highwall) and partially confined (parting) surface coal mining blasts, as well as unconfined blasts. (Siskind et al., 1980a). Conversion factors: 1 lb/in.^{2} = 6.894 kPa, 1 ft/lb$^{1/3}$ = 0.8759 m/kg$^{1/3}$.

Propagation Effects—Ground motions always decreased with increasing distance. Effects of constructive and destructive interference and geology are included within the scatter of data about the mean trend of the decay in amplitude with distance. While this scatter is large, the associated decay with distance is observed in all blast-vibration studies. Typical examples of this decay are shown in Fig. 9.2.2.4 where maximum particle velocity is plotted as a function of square-root scaled distance from the blast.

Square-root scaling, or plotting peak particle velocity as a function of the distance R divided by the *square root* of the charge weight, $R/W^{1/2}$, is more traditional than the cube-root scaling, which incorporates energy considerations (Hendron, 1977). Both square- or cube-root scaling can be employed to compare field data and to predict the attenuation or decay of peak particle velocity; however, square-root scaling is more popular.

Several square-root attenuation relationships employed in the United States are shown in Fig. 9.2.2.4. They are banded to reflect scatter, which is typical of blasting operations. Curve P should be used for presplitting, cratering, and beginning new bench levels. It is also the basis for Office of Surface Mining (OSM) regulations for conservative shot design when monitoring instruments are not employed.

Dominant frequencies also tend to decline with increasing distance and with increasing importance of surface waves. At larger distances typical for mining, higher frequency body waves begin to have relatively lower peak amplitudes than the lower frequency surface waves, as shown in Fig. 9.2.2.1. Since lower frequencies can elicit greater structural response (Medearis, 1976) as shown in 9.2.2.5, OSM scaled-distance limits decline with increasing absolute distance.

Blast-Induced Air Overpressures: Just as with ground motions, blast-induced air overpressure waves can be described with time histories as shown in Fig. 9.2.2.1. The higher frequency portion of the pressure wave is audible sound. While the lower frequency portion is not audible, it excites structures, which in turn causes a secondary and audible rattle within the structure. The air-blast excitation of the walls is shown by comparing the last one-quarter of the time histories of air blast and wall response in Fig. 9.2.2.1. Unlike ground motions, air overpressures can be described completely with only one transducer, since at any one point air pressure is equal in all three orthogonal directions.

Propagation Effects—Propagation of blast-induced air overpressures has been studied by numerous investigators and is generally reported with cube-root rather than square-root scaled distances. Peak pressures are reported in terms of decibels (dB), which are defined as

$$\mathrm{dB} = 20 \log_{10}\left(\frac{P}{P_o}\right) \qquad (9.3.2.3)$$

where P is the measured peak sound pressure and P_o is a reference pressure of 2.9×10^{-9} psi ($20 \times 10^{-6}(P_a)$).

Fig. 9.2.2.5 summarizes the effect of two important instrumentation and shot variables. First, the effect of the weighting scales is dramatically evident. C weighting greatly reduces the recorded peak pressure at any scaled distance. This does not mean the peak is reduced by changing instruments, but rather that the C weighting system does not respond to the low-frequency pressure pulses. These low-frequency pressure peaks excite structures and occupants whether or not they are sensed by the measurement instruments. The other (5- and 0.1-Hz) labels denote the lower-frequency bounds of the recording capabilities of the "linear" systems.

Second, the effect of venting caused by inadequate stemming can be observed in Fig. 9.2.2.5 from the higher average pressures produced by the parting shots at any scaled distance. Parting shots are detonated in thin rock layers between coal strata in surface mines. Consequently, there is less hole height available for stemming, and these shots many times eject the stemming and thereby produce abnormally high air overpressures. The unconfined relationship should be used for demolition of structures after modification for effects of weather and ground reflection.

Various effects of the wind have been reported and should be added to the average relations presented in Fig. 9.2.2.5. Wiss and Linehan's (1978) study of air overpressures produced by surface coal mining showed that in moderate winds the typical 7.7-dB reduction for each doubling of distance is reduced by

$$7.7 - 1.6\ V_{\mathrm{mph}} \cos\theta \text{ dB} \qquad (9.2.2.4)$$

where V_{mph} is wind velocity in miles per hour and q is the angle between the line connecting the blast and transducer and the wind direction.

An air-temperature inversion causes the sound pressure wave to be refracted back to the ground and at times to be amplified at small, 16-acre (65 km^2) sized locations. Such an inversion occurs when the normal decrease in temperature with altitude is reversed because of the presence of a warmer upper layer. Schomer et al. (1976) has shown that for propagation distances of 2 to 40 miles (3 to 60 km), inversions produce zones of intensification of up to three times the average, attenuated or low air overpressures *at those distances*, with an average increase of 1.8 times (5.1 dB). At distances less than 2 miles (3 km), where high air overpressures are likely to occur, his measurements show no inversion effects.

Structural Strains vs. Particle Velocity: While particle velocity is the traditional measurement of choice, structural strains control cracking. They should be measured directly from relative displacements on structures or within rock masses when critical locations are known, and can be obtained with a variety of strain and relative displacement gages (Stagg et al., 1984). Unfortunately, these critical locations may be either unknown or too many in number to economically measure. Therefore, some means of estimation is necessary.

Ground motion and air overpressure time histories can be employed to calculate the relative displacement of structural components with a knowledge of the responding structure's dynamic response characteristics (Dowding, 1985). These relative displacements can in turn be employed to calculate strains. The accuracy of these estimates is limited by the degree to which the structure behaves as a single degree of freedom system and the accuracy of the estimate of the dynamic response characteristics.

Appropriate Measurement of Particle Velocity: While any of the three kinemetric descriptors (displacement, velocity, or acceleration) could be employed to describe ground motion, particle velocity is the most preferable. It has the best correlation with scientific observation of blast-induced cracking, which forms the basis of vibration control. Furthermore, it can be integrated to calculate displacement. If acceleration is desired, it should be measured directly to avoid differentiation of the particle velocity time history.

The location for measurement varies throughout the world. In North America, the excitation or ground motion is measured on the ground adjacent to the structure of interest. In Europe, the excitation motion is measured on the structure's foundation. The difference stems from historical precedent and location of transducers during scientific observation of cracking rather than difference in philosophy. In North America, many times it is impossible to place transducers on adjacent property owned by a party not involved in the project. Furthermore, if it is desired to describe the excitation motions, then they should be measured outside of and not on the structure. If it is desired to measure structural response motions then they should be measured on the most responsive structural members, which are not the basement or foundation walls because of the restraint provided by the ground.

Time histories of the three components of motion should be measured because of the importance of excitation frequency. Recording of peak motions will not yield information about the dominant frequency and time history details that control structural response. Peak motions and dominant frequency can be employed to describe low-level, non-critical motions. Therefore, machines employed to monitor critical motions (type I in 9.2.2.4) should be capable of recording time histories of selected critical motions. Machines that record only peak motions (type II in 9.2.2.4) can be employed with those that record time histories to provide redundant measurement where frequency content does not vary widely.

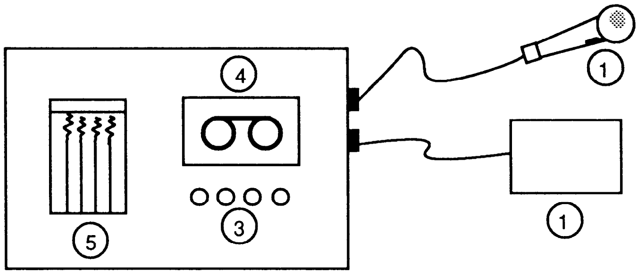
9.2.2.4 Measurement Instruments and Their Deployment

This segment describes characteristics of instruments that measure the ground motions (acceleration, velocity, displacement) and air blast (air overpressure). Since there are many excellent sources for information on instruments, the principal characteristics of available systems will be summarized rather than exhaustively reviewed. The most complete single reference for detailed instrumentation information that is updated periodically is the *Shock and Vibration Handbook* (Harris and Crede, 1976). Specific information on blast vibration monitors is contained in specific publications by the US Bureau of Mines and the Office of Surface Mining (i.e., Rosenthal and Morlock, 1987).

An idealized, field-portable blast monitoring system operating on a 12-V battery is illustrated in Fig. 9.2.2.6. It consists of transducers (1) that convert physical motion or pressure to an electrical current, which is transmitted through cables (2) to an amplifying system (3); and a magnetic tape, paper or computer digital, recorder (4) that preserves the relative time variation of the original signal for eventual permanent, hard-copy reproduction by a pen recorder or light-beam galvanometric recorder or dot matrix printer (5). As one can imagine, there is an almost endless variety of configurations of these five basic components. However, the best involve micro processors (computers) for data acquisition, storage and reproduction.

Transducers: Transducers are one of the weaker links in the measurement system because they must translate kinemetric motions or pressures to electrical signals. The remaining components transform electrical signals or light beams and are not restricted by mechanical displacement. The main characteristics of transducers that affect their performance are sensitivity and frequency response.

Sensitivity of an instrument is the ratio of its electrical output to its kinemetric displacement, velocity, and acceleration or overpressure for energy-converting transducers (i.e., do not require



1. Velocity (3 orthogonal) and sound pressure transducers
2. Cables
3. Amplifier
4. Recorder (tape, disk, or memory)
5. Light beam oscilloscope or dot matrix printer

Fig. 9.2.2.6. Idealized, field portable blast monitoring system that shows the schematic relationship of the five principal components. (Dowding, 1985).

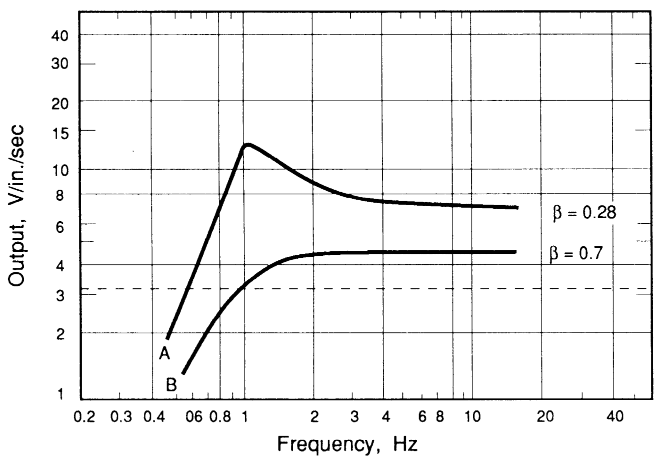


Fig. 9.2.2.7. Example response spectra of a velocity transducer with differing percentages of damping. With 70% of critical damping, this system is ± 3 dB (± 30%) down 1 Hz. (Dowding, 1985.) Conversion factor: 1 ips = 25.4 mm/s.

an energy source). Since allowable limits are specified in terms of ground particle velocity, all blast monitors come equipped with velocity gages.

Frequency response is the frequency range over which the electrical output is constant with a constant mechanical motion. This constancy is normally expressed in terms of decibels. For instance, linear within 3 dB between 5 and 200 Hz means that the transducer produces a voltage output that is constant within 30% between 5 and 200 Hz. Generally, it is better to look at the transducer's response spectra (such as those shown in Fig. 9.2.2.7) to determine the frequencies where this difference occurs. For example, the difference occurs at low frequencies for the velocity transducers in the figure. The importance of the frequency response of air overpressure transducers was discussed in 9.2.2.3.

Transducer Attachment—One of the most critical aspects of vibration monitoring is the mounting of the transducers in the field. The importance of mounting is a function of the particle acceleration of the wave train being monitored. The type of mounting on a horizontal surface is the least critical when the vertical maximum particle accelerations are less than 0.3 g. In this range, the possibilities of rocking the transducer or the transducer package are small, and the transducer may be placed upon a horizontal measurement surface without a device to supply a holding force. When the maximum particle accelerations fall between 0.3 and 1.0 g, the transducer or transducer package should be buried completely when the measurement surface consists of soil (Johnson, 1962). When the measurement surface consists of rock, asphalt, or concrete, the transducers should be fastened to the measurement surface with either double-sided tape, epoxy, or quick-setting cement (Hydrocal or other gypsum-based cements set within 15 to 30 min). If these methods are unsatisfactory, or accelerations exceed 1.0 g, only cement or bolts are sufficient to hold the transducer to a hard surface.

All transducers mounted on vertical surfaces should be bolted in place. Air overpressure transducers should be placed at least 3 ft (1 m) aboveground, pointed downward (to prevent rain damage) and fitted with a windscreen to reduce wind excitation-induced false events.

Digital, Tape, and Hard-Copy Recorders: Microprocessor (computer) or digital recording systems now dominate technical recording because of the ease of computer linkage. The signal is sampled at a certain rate, say, 1000 times/sec, and each sample is converted to a single magnitude. This magnitude and its associated time are then stored in computer memory. Digital recording has several advantages. It is very accurate, as variation in the speed of the tape, if it is used, has no effect, and records can be directly accessed by a computer. Details of the digitization process are discussed elsewhere (Dowding, 1985).

Of those blast-monitoring systems with tape recorders, most employ compact FM cassettes. Many of the systems involve separate record and reproduction modules to reduce the complexity of recording. Care should be exercised to determine the exact details of the system before purchasing, as tape recorder performance varies at low temperature.

A permanent record or "hard copy" of the vibration time history is usually made on photographic film, floppy disk or battery-powered memory chips or paper. Almost all present film-based recorders employ special field-developable, ultraviolet light sensitive paper in combination with light-beam galvanometers to record high frequency motions. The newest generation recorder employs dot matrix printers and/or floppy disks with microcomputers. Unfortunately, those monitors that print after a vibration event may not be recording another event while printing. If multiple shots are likely, this reset time should be determined. Furthermore, printer behavior in cold weather is variable and should also be investigated.

Most recorders can be bought as either single- or multichannel units. A four-channel unit is necessary in blast monitoring to record simultaneously the three components of the ground motion (L, V, and T) and the air blast. The present trend in vibration equipment is to include a signal-conditioning amplifier in the recorder to allow flexible amplification of the signals.

Frequency analysis of records requires a time history and thus some form of permanent record. Instruments recording only peak particle velocities will not allow a frequency analysis. Sending records through the mail for interpretation, results in a delay of five days, and sometimes up to a month. Systems with light sensitive paper or dot matrix printers allow immediate interpretation of frequency without additional costly equipment.

Calibration: It is obvious that the entire vibration measurement system should be calibrated, as it is futile to record data if they cannot be exploited because of a lack of reference. Manufacturers supply calibration curves with their instruments that are similar to the response spectra for transducers shown in Fig. 9.2.2.7. Recalibration or checking requires special vibrating platforms where frequency and displacement are controlled, and, in the field, a calibrating circuit to pulse the magnetic core of the geophone (Stagg and Engler, 1980).

Number of Instruments: While the obvious irreducible number of instruments for each blast is one, two would provide a more thorough documentation of the spatial distribution of effects. If only one instrument is employed, then it should be located at the nearest or most critical receiver. This single type I instrument should record time histories of the three axes of particle velocity as well as air over-pressure. Since it must monitor continuously, it must trigger (begin recording) automatically, and be capable of monitoring even while printing or communicating results. When blasting will occur at more than one general location (i.e., involve nearest structures separated by hundreds of feet or meters), then two and four are the irreducible and optimum number of instruments, respectively. The third should be a spare to insure continuous coverage in case of failure.

The second and fourth instruments in the situations described here may provide a smaller level of service and will be termed type II. They must at least continuously record the peak particle velocity in one axis and may or may not measure air overpressure. The best axis is the vertical, since no horizontal direction decision is required and surface waves usually involve a significant vertical component regardless of the direction of the maximum horizontal component, These instruments should be located at a greater distance than the nearest structure to monitor a large area.

The third or spare instrument can be either type I or II. Where air overpressures will be problematic or frequencies critical, the spare should be type I. This spare instrument can also be employed to monitor sites where complaints develop. This public relations work is essential in North America where lawsuits arise even when all blast effects comply with regulatory guidelines.

This approach describes the least number of instruments. Applicable regulations and mining schedules may require a larger number.

Instrument Deployment During Test Blasts: When blasting projects begin, when geological conditions change radially, or when new initiation systems are introduced, test blasts should be conducted to minimize the number of instruments necessary to monitor production blasts. These tests are conducted to produce project-specific attenuation relations for both air overpressures and ground motion. Such relations vary from project to project because of changes in geology and blasting practices. Additionally, the test blasts allow the determination of the frequency content of motions at different scaled and absolute distances. Frequency is important in estimating structural response through response spectrum analyses.

The attenuation relation is not solely a site property. Although it is dependent upon geology, it is also heavily dependent upon the blast geometry and timing. For instance, with the same charge per delay, a blast with a larger burden will produce an attenuation relation with a similar slope or decay with distance, but with a larger intercept. Furthermore, differing initiation timing will produce changes in the time history, both length and frequency content.

During test blasts, a minimum of four instruments should be deployed to measure peak particle velocity at widely differing scaled distances for the same blast. Therefore, for any one blast design, parameters and initiation sequence are constant, and the resulting attenuation relationship shows only the effect of distance, direction, and/or geology. Seismographs and/or transducers should be placed along a single line with constant geology to determine best the attenuation relationship, or at all critical structures to determine the effects of direction and variable geology. Ideally, the linear orientation should be along a path with constant thickness of soil and not cross any large geologic discontinuities such as faults. If geology changes radically, then two such attenuation lines are necessary, but not necessarily with each blast.

A number of approaches to blast design for vibration control are now available that employ a single-delay, single-hole test blast and a number of instruments to record the attenuation and frequency change around the site. These single-time histories are then synthesized to reproduce the additive time history effects of multiple delay, multiple hole blasts at the differing instrument sites. Such synthesis of time histories to guide blast design has met with variable success, but does not replace monitoring of blast effects at critical structures during production blasting.

9.2.2.5 Evaluation of Measurements

Documentation of blast effects involves two radically differing endeavors: measurement of ground and air disturbances as well as observation of cosmetic cracking. Measurement can now be accomplished remotely with computers to eliminate completely human interaction, whereas scientific observation must involve meticulous human inspection immediately before and after a blast. While the focus of this section is instrumental monitoring, the alleged appearance of cracking by neighboring property owners is nonetheless a very serious consideration.

Principal problems in the evaluation of measured effects involve (1) accounting for geologic and weather effects on the overall attenuation with a small number of instruments and (2) incorporating structural response and frequency effects. Principal problems with the observation of blast-induced cracking involve (1) separating blast-induced from environmentally and human-induced cracking and (2) reducing the enormous amounts of time necessary for direct observation. Observational problem are normally overcome by employing instrumentationally measurable blasting controls at low enough levels to prevent the threshold of cosmetic cracking to even old, degraded structures and eliminating observation altogether. Otherwise blast-induced cracking can be observed only with immediate before and after blast inspection. The remainder of this discussion concentrates on the instrumentation approach and calculation of structural response.

Structural Response and Frequency Effects: Structures respond to both ground and airborne disturbance, as shown by the bottom four time histories in Fig. 9.2.2.1. Walls respond more to the higher frequency (15 to 20 Hz) waves in the early portion of the ground motion, while the superstructure or overall skeleton of the structure responds more to the last or lower frequency (5 to 10 Hz) portion. Walls are again excited by the arrival of the air pressure wave. Structural response can be calculated from the ground motions if the natural frequency and damping of structural components are known or estimated.

Langan (1980) has shown that measured structural response has a higher correlation coefficient with calculated single degree of freedom (SDF) response than with peak ground motion. Therefore, structural motions can be estimated more accurately by assuming that they are proportional to response spectrum values at the particular structure's natural frequency than by assuming that they are proportional to the peak ground motion. This improved correlation is largely a result of the consideration of frequency in the response spectrum, which is calculated from SDF response.

Origin of the SDF Model—One of the critical structural response factors is the amount of differential displacement (δ in Fig. 9.2.2.8) that occurs between or along structural members because it is proportional to strain, which, in turn, causes crack-

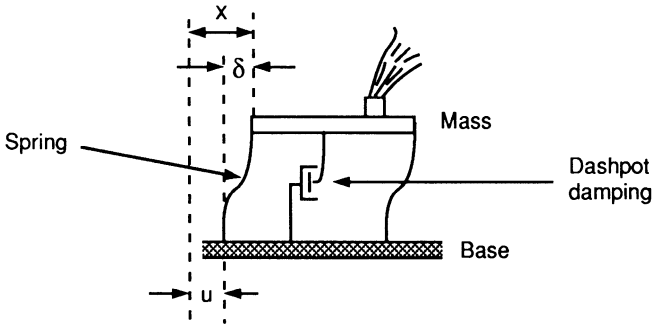

Fig. 9.2.2.8. Single degree of freedom model of house that shows relative displacements of the walls δ, and the analogy between model mass and roof mass, model stiffness, and wall stiffness. (Dowding, 1985.)

ing. Such displacements can be computed with a mathematical idealization of the SDF model shown in Fig. 9.2.2.8.

It is necessary to simplify a structure so that computations are practical. The fundamental characteristics of a structure that govern its behavior under vibratory or dynamic loading are (1) the masses of the main components (analogous to floor and roof masses), (2) the spring stiffnesses of the main components (analogous to wall stiffness), and (3) the amount of damping or energy dissipation (analogous to differential movement in cracks, joints, and connections). Behavior of one- or two-story buildings is directly analogous to the behavior of an SDF system when movement in only one direction is considered. When multistoried structures are considered, it is necessary to model the structure as multidegree-of-freedom systems. However, even such a system may be idealized as a single-degree-of-freedom system to calculate the fundamental mode of response.

If a structure's damped natural frequency f_d and its fraction of critical damping b are known, values of dynamic properties, f_d and b, can be accurately measured from a free vibration time history of the building response. These measured parameters automatically account for the factors that are difficult to quantify, such as the degree of fixity of the columns and the damping coefficient. As shown in Fig. 9.2.2.1, these parameters can be measured from the structure's free response. Time between peaks is the period, $T = 1/f_d$, and the decay of free oscillation is proportional to the damping, b.

Estimation of Dynamic Response Properties—The fundamental natural frequency f_d of the superstructure of any tall building can be estimated from compilations of work in earthquake engineering (Newmark and Hall, 1982):

$$f_d = \frac{1}{0.1N} \tag{9.3.2.5}$$

where N is the number of stories. Substitution of 1 and 2 for residential structures for N yields f values of 10 and 5 Hz for one- and two-story structures, which compares favorably with the results of actual measurements.

Damping b is a function of building construction and to some extent the intensity of vibration. Thus it cannot be simplified as easily as the natural frequency. Measurement reveals a wide range of damping for residential structures with an average of 5% (Dowding et al., 1981). This value is also appropriate for initial estimates involving taller engineered structures. Further details for engineered structures can be found in Newmark and Hall (1982).

Conversion factor: 1 ft = 0.3048 m.

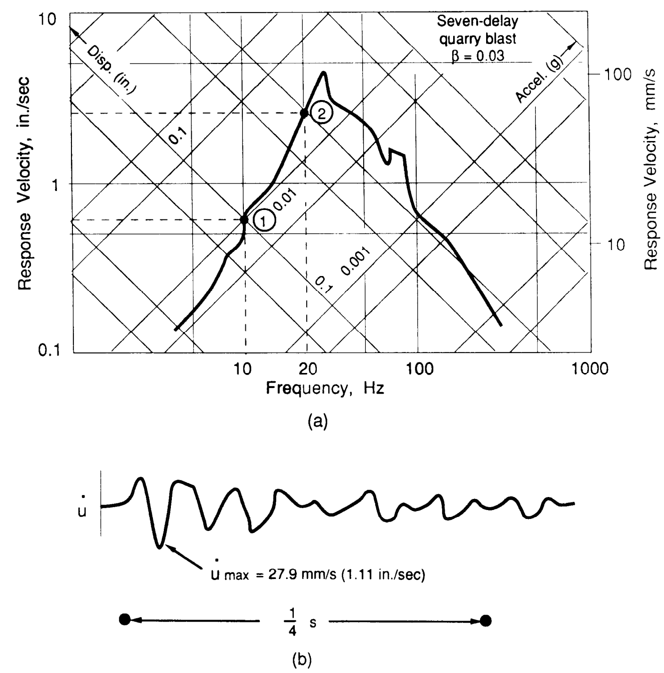

Fig. 9.2.2.9. Construction of pseudovelocity response spectrum: (a) response spectra; (b) associated excitation time history. The time history is operated upon by the single degree of freedom (SDF) equation to produce a computed relative displacement (δ), which is then multiplied by the circular natural frequency ($2\pi f$; or $2\pi 10$ for point (1)) to produce the pseudo response velocity. (Dowding, 1985).

Walls and floors vibrate independently of the superstructure and have their own, but similar, fundamental frequencies of vibration that range between 12 and 20 Hz with an average value of 15 Hz (Dowding et al., 1981). Floors tend to have lower natural frequencies in office buildings with large floor spans, but are similar to wall natural frequencies in residential structures.

Dynamic response properties of some tall, unique structures cannot be estimated with the l/0.1 N equation. Field-measured natural frequencies for these types of structures are given in Table 9.2.2.2.

Response Spectrum—The pseudovelocity response spectrum of a single ground motion, such as that of a seven-delay quarry blast in Fig. 9.2.2.9, is generated from the relative displacement δ_{max} values of a number of different SDF systems when excited by that motion. Consider two different components of the same structure, the 10-Hz superstructure and the 20-Hz wall. If the ground motions, $\dot{u}(t)$ in Fig. 9.2.2.9b, of the seven-delay quarry blast are processed twice by the SDF response equation with

f = 10 and 20 Hz and b held constant at 3%, two δ_{max} values will result.

The first computation is made with the 10-Hz system, which has a circular natural frequency of

$$p = 2\pi(f) = 2\pi(10) \quad (9.2.2.6)$$

and results in an SDF equation computed

$$\delta_{max} = 0.25 \text{ mm } (0.01 \text{ in.}) \quad (9.2.2.7)$$

This δ_{max} is then converted to pseudovelocity, PV as

$$PV_{10} = p\delta_{max} = 2\pi(10)(0.25)$$
$$= 15.7 \text{ mm/s } (0.62 \text{ ips}) \quad (9.2.2.8)$$

and is plotted as point 1 in Fig. 9.2.2.9a. The same computation is then repeated for the 20-Hz system.

$$p = 2\pi(20)$$
$$\delta_{max} = 0.5 \text{ mm } (0.02 \text{ in.})$$
$$PV_{20} = 2\pi(20)(0.5) = 63.5 \text{ mm/s } (2.5 \text{ ips})$$

and PV_{20} is plotted as point 2 in Fig. 9.2.2.9a. If the same ground motion time history in Fig. 9.2.2.9b is processed a number of times for a variety offs with b constant, the resulting pseudovelocities will form the solid line in Fig. 9.2.2.9a.

Fourier Spectra DO NOT Directly Predict Response—With increasing use of computers, calculation of various spectra from time histories have become commonplace. The two most common are the Fourier frequency and pseudovelocity response spectra. Although they are essentially different in meaning and typical use, they are similar for undamped response where the maximum motion occurs near the end of the time history (Dowding, 1985; Hudson, 1979). Since response spectra are calculated for damped response and peaks normally occur in the middle as well as the beginning of the time history, the two spectra are not usually the same.

Only the pseudovelocity response spectrum can be employed to calculate directly structural response. Because of the similarity of Fourier and response spectra, either can be employed to determine the dominant frequency in the ground motion.

Case Histories Demonstrate Importance of Response Spectrum Analysis: Fig. 9.2.2.10 compares time histories and response spectra from the longitudinal components of an urban construction blast and a surface coal mine blast. Although the peak particle velocities are similar: 0.15 ips (3.8 mm/s) for the construction blast A; and 0.13 ips (3.3 mm/s) for the surface mining blast B; the response spectra differ radically. This difference is greatest in the range of natural frequencies of residential structures and their components, 5 to 20 Hz. In this range the surface mining motions produce response velocities that are 10 times greater than the construction blast.

Surface Mine Blast—Surface mining induced ground motion was produced by a multiple row blast. Some sixty 83-ft (25-m) deep, 15-in. (380-mm) diameter, holes were arranged in a four-row pattern. The burden between rows was 20 ft (6.1 m) and the hole spacing was 25 ft (7.6 m). Each hole contained four decks (or charges that are detonated at intervals separated by at least 17 ms). The ammonium nitrate-fuel oil (ANFO) charge weight per deck ranged from 100 to 130 lb (45 to 60 kg). Therefore, the largest charge per delay was 130 lb (60 kg), and the total charge was 27,700 lb (12,600 kg).

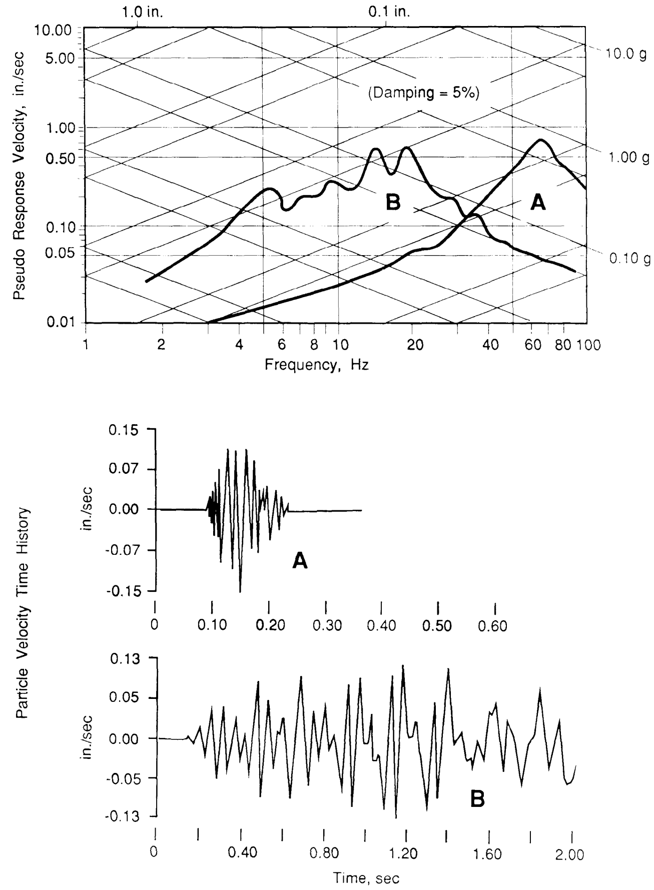

Fig. 9.2.2.10. Comparison of time histories spectra from construction and surface mining blasts respectively lasting 0.15 and 2.0 sec. Even though the particle velocities are approximately equal, responses in the 5 to 20 Hz frequency range differ greatly. Conversion factor: 1 ips = 25.4 mm/s.

Geology between the blast and the transducer, located at the nearest residence, consisted of sedimentary rock with 10 to 30 ft (3 to 10 m) of overlying silty glacial till. A small, 33-ft (10-m) deep, gully was located some 1300 ft (400 m) north of and between the blast and transducer. Soil depth at the transducer was 10 to 15 ft (3 to 4 m). Some 2750 ft (825 m) separated the shot from the transducer, where the longitudinal velocity time history in Fig. 9.2.2.10 with a peak of 0.13 ips (3.3 mm/s) was recorded. The accompanying transverse and vertical peak particle velocities were 0.18 and 0.09 ips (4.6 and 2.3 mm/s) with dominant frequencies between 11 and 13 Hz. Other similarly designed shots with distances between 1900 and 2700 ft (580 and 825 m) produced peak particle velocities between 0.17 and 0.23 ips (4.3 and 5.8 mm/s) with dominant frequencies between 13 and 17 Hz.

These particle velocities are high at 2700 ft (825 m) according to scaled distance relationships. These greater than normal particle velocities may be a result of unusual confinement (too large a burden) or delay overlap. For instance, if two delays had overlapped to add, then the maximum charge per delay would have doubled and the square-root scaled distance would have declined by 30%. Particle velocities measured at smaller scaled distances were closer to expected levels.

Urban Construction Blast—Construction blast-induced motion was produced by a much smaller shot than the surface mining example. Some five 12-ft (3.6-m) deep, 1.5-in. (38-mm) diameter holes were arranged in a single row. Each hole was charged with a stick gelatin dynamite and initiated separately with a constant 25 ms between each delay. The burdens and hole spacings were small, approximately 2 to 3 ft (0.6 to 0.9 m). The total charge was 20 lb (9 kg), and the maximum charge per delay was 5 lb (2.3 kg).

The structure of concern, a historic theater, and the recording transducers were located some 50 ft (15 m) away. Rock being fragmented consisted of granitized biotite schist. This shot produced peak particle velocity in the L, T, and V axes of 0.15, 0.16, and 0.28 ips (3.8, 4.1, and 7.1 mm/s), respectively, with dominant frequencies between 75 and 125 Hz.

Because these dominant frequencies were so high compared to the natural frequencies of the theater's structural components, their response was less than the peak excitation particle velocity. The transducer recording the excitation motions was located in the basement because there was no stable location outside as rock was being removed immediately adjacent to the theater's wall. Another vertical axis transducer was placed at the mid span of the theater's balcony, whose left most support was immediately above the transducer measuring the excitation motions. The peak vertical particle velocity of the theater's balcony was only 0.14 ips (3.6 mm/sec), approximately half of the peak excitation motion in that axis.

Restrained Structures and Rock Masses: Capacity for free response allows aboveground structures such as homes and rock pinnacles to amplify selectively incoming ground motions. On the other hand, buried or restrained structures such as pipelines and rock masses cannot respond freely. Regardless whether response is restrained or free, cracks are initiated by strains in either case. Whereas strains in a freely responding structure are proportional to the relative displacement between the ground and the superstructure as shown in Fig. 9.2.2.11, strains in a restrained structure such as pipelines will usually be those of the surrounding ground and can be approximated as those produced by plane wave propagation and are

$$\epsilon = \frac{\dot{u}}{c_c} \text{ and } \gamma = \frac{\dot{u}}{c_s} \qquad (9.2.2.9)$$

where ϵ and γ are axial and shear strains, c_c and c_s are compressive and shear wave propagation velocities, and $\dot{u}$ are maximum compressive and shear wave particle velocities, respectively (Dowding, 1985). For cases involving one critical location along a pipeline, the pipe strains should be measured directly on the metal (Dowding et al., 1990). For cases involving tunnel and/or cavern liners critical strains can be estimated through calculation of the relative flexibility of the rock and liner (Hendron and Fernandez, 1983).

9.2.2.6 Controlling Blast Effects

Direct regulation or specification of effects, rather than design, is the most effective control from a regulatory viewpoint because effects are so dependent upon details of the shot geometry and initiation sequence. Such dependency renders control impossible by simple regulatory specification of two- or three-shot design parameters. For instance, consider control by specification of the maximum charge weight detonated per instant at given distances from the nearest structure. Even with such detailed specification, intended vibration limits at the structure may be exceeded because of poor choice in the location of holes and/or their relative time of initiation. Discussion of shot design is presented earlier in this chapter (segment 9.2.1).

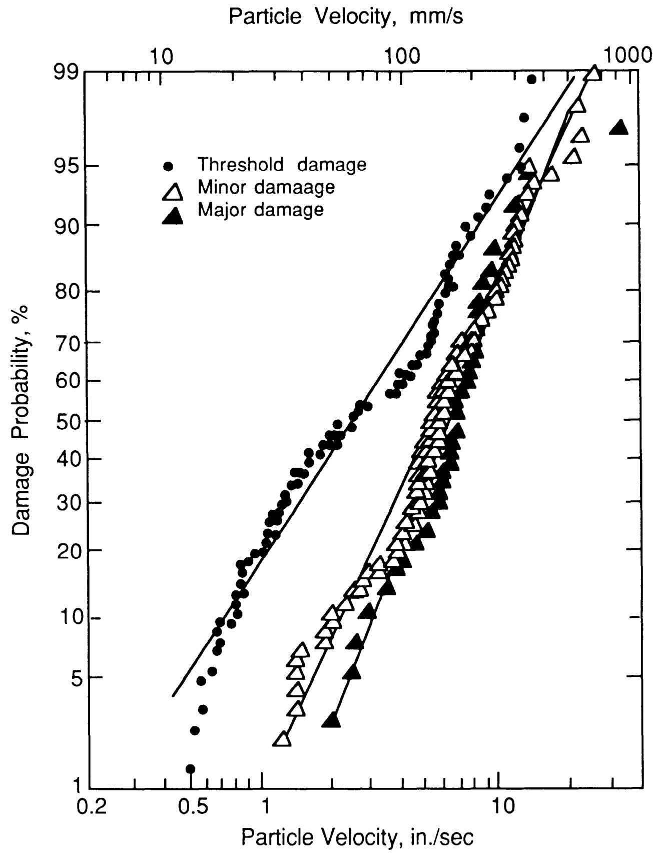

Fig. 9.2.2.11. Probability analysis of worldwide blast cracking data. (Siskind et al., 1980b.) Threshold damage is the occurrence of hair-sized, cosmetic cracks similar to those caused by natural, environmentally induced expansion and contraction.

Present regulatory control limits in many countries are below those levels at which cosmetic cracking may appear. There are two principal reasons for such tight restrictions. First, regulatory limits are influenced heavily by human response to blast-induced vibration and noise. Since humans are approximately 10 times more sensitive than structures to vibration, low regulatory limits are understandable. Second, many regulations appear to have been adopted without the documented, scientific experimentation necessary to determine the vibration levels that cause cracking.

Statistical Analysis of Data with Pre- and Post-Blast Inspection: Unmeasurables in observation can be taken into account indirectly by considering the appearance of cosmetic cracks as a probabilistic event. In order to investigate the effects of certain data sets on the overall conclusions, the probability computations of cracking at given particle velocity levels have been made several times (Siskind et al., 1980b, 1981). All of these studies involve both immediate pre- and post-blast inspection of walls in residential structures, many of which were old, distorted, and whose walls were covered with plaster. Definitions of the observed cracking in each study are described in 9.2.2.2.

Data from various sets of observations were analyzed with cracking points and the assumption that every cracking point excludes the possibility of noncracking at a higher particle velocity (Siskind et al., 1980b, p.55). If the probability of cracking is calculated as the percentage of points at lower levels of velocity, the result is the log-normal scaled plot of the probability of

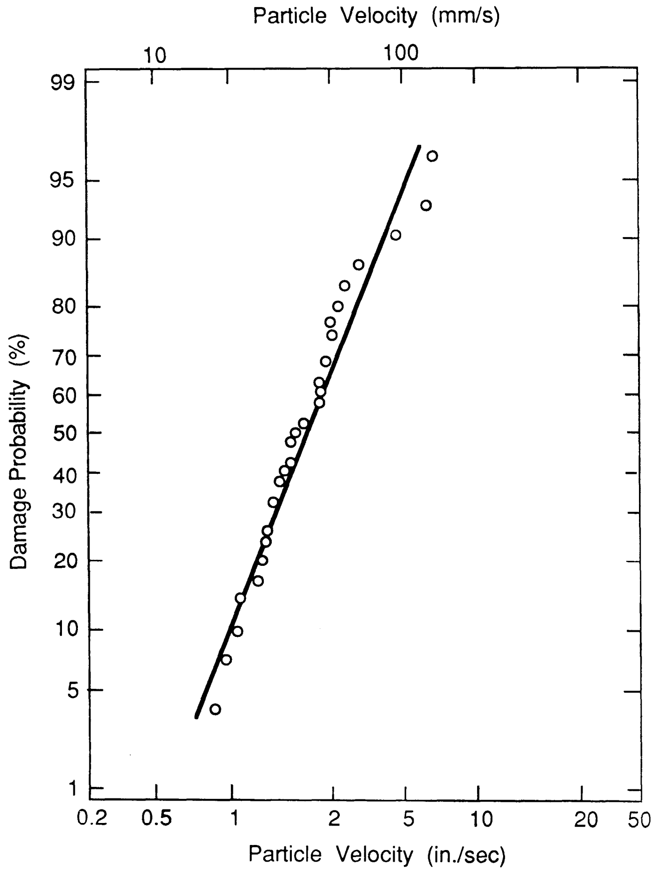

Fig. 9.2.2.12. Probability analysis of blast-induced threshold cracks observed by US Bureau of Mines. (Siskind, 1981.)

cracking vs. particle velocity in Fig. 9.2.2.11. This approach seems conservative as low particle velocity observations do not count noncracking at higher levels.

According to Fig. 9.2.2.11, there appears to be a lower limit of particle velocity of 0.5 ips (12 mm/s) below which no cosmetic or threshold cracking (extension of hairline cracks) has been observed from blasting anywhere in the world. This observation includes the data with unusually low frequencies that were collected by Dvorak (1962). His data are those that tend to populate the lower region of Fig. 9.2.2.11. High-frequency data (> 40 Hz) show that a 5% probability of minor cracking does not occur until particle velocities reach 3 ips (75 mm/s) (Siskind et al., 1980b).

Admissibility of Dvorak's data has been questioned because of the absence of time histories; some of the other studies, such as that by Langefors et al. (1958), are also plagued by the same lack of time histories. To resolve this difficulty, only the new US Bureau of Mines observations have been included in a recomputation of probabilities in Fig. 9.2.2.12. The observations include low frequency motions associated with surface mining. Again there is a particle velocity, 0.79 ips (20 mm/s), below which no blast-induced cracking was observed.

Comparison of Blast and Environmental Effects: Crack width changes from ground motions less than 1 ips (25 mm/s) are less than those caused by the passage of weekly weather fronts (Dowding, 1988). This conclusion was reached after measuring the displacement response of a poorly built, nonengineered house to surface coal mining vibrations for some 8 months. Displacements were measured at ten different wall positions that included cracked and untracked wall covering. Weather and blast-induced crack displacements across the most dynamically responsive wall covering crack are compared in Fig. 9.2.2.13. The continuous and highly cyclical curve is that of displacements produced by environmental change. The small circles are the maximum, zero-to-peak, dynamic displacements recorded by the same gage. Even though the maximum recorded particle velocity was as high as 0.95 ips (24 mm/s), the maximum weather induced displacements were three times that produced by blasting. On other gages, weather changes produced displacements that were 10 times greater than those produced by blasting.

Special Considerations: The statistically determined control limits are too low for basement walls and engineered structures. They were based on response of residential structures and the lower limit cases involving cracking of above ground plaster or gypsum wall board wall coverings in older, distorted structures.

Engineered Structures—Concrete is a good deal stronger than plaster. Therefore, engineered structures constructed of concrete can withstand maximum particle velocities of at least 4 ips (100 mm/s) without cracking (Crawford and Ward, 1965). Furthermore, buried structures such as pipelines and tunnel linings are not free to respond, as were the above ground residential structures whose response provides the data from which most limits are chosen. Therefore underground structures are able to withstand even greater excitation motions (Dowding, 1985).

Specific engineered structures should be analyzed in terms of the strain that can be withstood by critical elements and the strain should be measured. This approach is particularly appropriate for singular structures with isolated portions nearer to the blast source.

Fatigue or Repeated Events—Since current regulatory limits are so low as to restrain blast-induced displacements below those caused by the passage of weekly weather fronts, the question of repeated events becomes moot. Weather by itself over the years produces greater repeated event effects than does blasting.

A repeated event experiment conducted at the US Bureau of Mines test house (Stagg et al., 1984), confirms the low level of current regulatory controls with respect to fatigue cracking. The test house was framed in wood with paper-backed gypsum board interior walls. When continuously vibrated at an equivalent ground particle velocity of 0.5 ips (12 mm/s), no response was observed until 52,000 cycles, when a taped joint between sheets of gypsum board cracked. These taped joints are the weakest and most compliant zones in a house with paper-backed gypsum board walls.

Rock Mass Displacement and Cracking—Cracking in rock immediately adjacent to a blast can be controlled by limiting the particle velocities to 27 ips (700 mm/s) in the volume of rock to be protected (Holmberg and Persson, 1978).

Rock displacement by forces produced by delayed gas pressure cannot be controlled by specifying an allowable particle velocity. Fortunately, these displacements occur only very close to a blast, within 100 to 165 ft (30 to 50 m), and are associated with blocks that are unconstrained by other surrounding rock.

Sliding instability of individual rock blocks must be evaluated on a case by case basis. Each block must have an adequate factor of safety to prevent static failure (Dowding and Gilbert, 1988).

Frequency Based Control with Dominant Frequency: Fig. 9.2.2.14 shows the limit adopted by the US Office of Surface Mining that is based on a suggested, but not rigorously validated, proposal by the US Bureau of Mines (Siskind et al., 1980a). Corner 1 represents the lowest particle velocity at which USBM

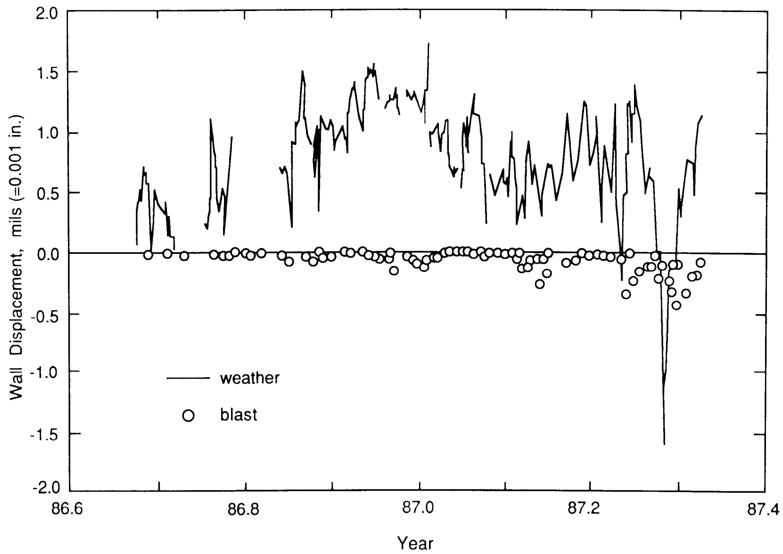

Fig. 9.2.2.13. Comparison of displacements produced by weather-induced changes in humidity and temperature (continuous line) with those produced by surface coal mine induced ground motions (O's). Conversion factor: 1 mil = 0.0254 mm.

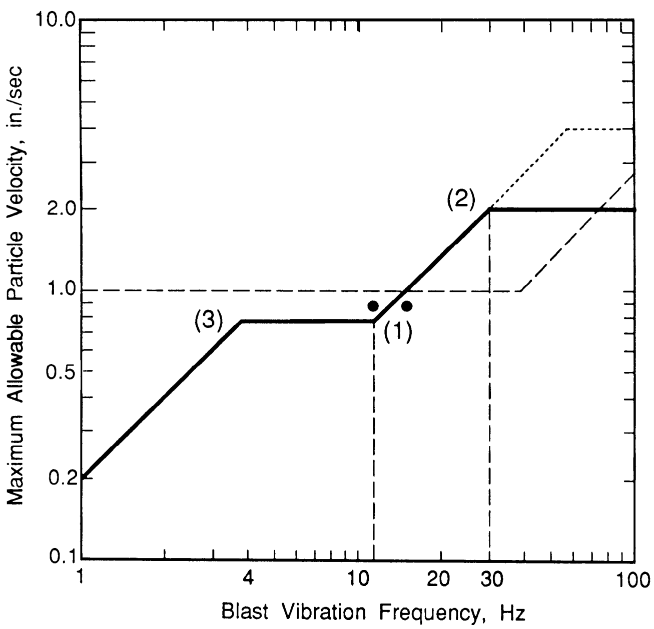

Fig. 9.2.2.14. Frequency-based blast vibration control limit to protect residential structures modified by US Office of Surface Mining from US Bureau of Mines suggestion (Federal Register, Vol. 48, No. 46, 1983). Corner 1 is verified. Dotted line has been employed safely for close construction blasting near engineered structures. Dashed line has been employed safely for construction blasting in urban areas near older homes and historic buildings. Conversion factor: 1 ips = 25.4 mm/s.

personnel have observed cosmetic cracking. Neither of the corners 2 and 3 have been confirmed.

Dominant frequency that is consistent with Fig. 9.2.2.14 is that associated with the peaks in the time history with amplitudes greater than 50% of the peak or maximum particle velocity. The frequency of these peaks were calculated from the zero crossing method as shown in the inset for Fig. 9.2.2.3. Determining frequency from that associated with the peak particle velocity is a good first approximation and eliminates the need for sophisticated Fourier or, alternatively, response spectra analysis. Response spectrum analyses are the most precise approach to account for the frequency effects of structural response and should be employed in singular cases where an exacting analysis is required.

Table 9.2.2.3. Air Overpressure Control Limits as a Function of Instrument Frequency Weighting

Lower frequency limit of measuring system, in Hz (–3 dB)	Maximum level, in dB
0.1 Hz or lower—flat response[a]	134 peak
2 Hz or lower—flat response	133 peak
6 Hz or lower—flat response	129 peak
C-weighted—slow response[a]	105 peak dBC

[a]Only when approved by the regulatory authority.

Regulatory Compliance for Air Overpressure: Although broken glass is normally associated with excessive air blast overpressures, limits in the United States are based upon wall response necessary to produce wall strains equivalent to those produced by surface coal mining-induced ground motions with peak particle velocity of 0.75 ips (19 mm/s). These limits are presented in Table 9.2.2.3. If a wall strain level equivalent to that produced by 1.0 ips (25 mm/s) particle velocity (measured in the ground) were chosen, the allowable overpressure would increase by 3 dB. Most cases of broken glass are reported to have been observed at air overpressures of 136 to 140 dB (as measured with a linear transducer).

Because of the different sound weighting scales that might be employed by monitoring instruments, the recommended levels in Table 9.2.2.3 differ by instrument system. Since structures are most sensitive to low frequency motions and the greatest air pressures occur at these inaudible frequencies, A-weighted scales cannot be employed at all. Since C-weighted scales are the least sensitive at low frequencies, their use requires the most restrictive limits.

Chapter 9.3
MATERIALS HANDLING: LOADING AND HAULAGE

RICHARD J. SWEIGARD

9.3.1 INTRODUCTION

The combined tasks of loading and haulage are the foundation of the mining industry. In the simplest scenario, a loading device is used to load fragmented ore into a unit conveyance, which carries the ore to a facility where it will be beneficiated. In the past, the loader has been as primitive as a laborer equipped with a shovel and the conveyance, a mule-driven cart. Although loading and haulage as performed today encompass much more, the basic operations are still the same. In addition to the loading and haulage of the mineral commodity to be exploited, many operations require loading and haulage of large volumes of waste material to expose the economic deposit. Some loading and haulage operations, such as disposal of mill tailings or replacement of topsoil at strip mines, are ancillary to the actual production cycle; however, the same principles are applicable.

The loader and conveyance must be selected to suit the needs of the operation. The mining industry is accustomed to dealing with large volumes of material. Some of the largest earthmoving machines in existence are employed in surface coal mines, where a single machine may excavate in excess of 25 million yd^3 (19 Mm^3) of material per year. Although small volumes are the exception, more selective operations result in a reduction of the total volume of material to be moved and employ much smaller loading machines, since the point of attack is very specific.

In general terms, the material most commonly handled by the mining industry is rock that has been fragmented either by mechanical or explosive methods. This rock can be an ore containing an economic mineral; it can be the salable mineral product itself in a fairly undiluted form, such as coal, phosphate, and industrial minerals; or it can be waste rock that must be excavated to expose the economic mineral deposit. Some of the physical properties that affect the handling of materials are abrasion, adhesion, cohesion, angle of repose, compressibility, bulk density, particle density, friability, moisture content, hygroscopicity, fragment size, fragment shape, and void ratio. Fragment size is determined primarily by the method of fragmentation. Although any material will have some in situ moisture content, this property may be altered during the materials handling process. The remainder of the properties listed are inherent to specific materials and must be considered in the design or selection of a materials handling system.

In selecting equipment for loading and haulage, it is necessary initially to determine the production requirements of the system. Generally, these requirements are given in units of weight or volume per unit of time. Typical units vary for different operations. For example, the production of coal loading machines may be given in terms of the amount produced per minute, hour, or shift while the production of large overburden stripping machines may be given in cubic yards (cubic meters)/hour, but the overall production requirement is reported usually in millions of cubic yards (cubic meters)/year.

Once the production requirements are known, various combinations of equipment and sequences of operations can be developed that are designed to produce the required volume of material. This step assumes a knowledge of the production capacity for each specific component of the proposed loading and haulage system. The production capacity of any loading or haulage component can be described, in general terms, by the volume of material it can handle at any instant (capacity) and the time required to complete one cycle of operation, or in other words, the time it takes for that volume of material to move completely through that component of the system (production rate). Of course, this simple volume and cycle time formulation must be modified to account for varying job conditions and the knowledge that mechanical systems do not always perform at peak efficiency.

The simplest materials handling systems involve a discrete volume of material produced by a single machine with a well-defined cycle time. Systems become more complex when multiple machines are needed to satisfy production requirements, continuous flows of material are produced by loading or haulage equipment, or it is necessary to provide storage within the system to accommodate surges by various components.

Engineering judgment is a necessity in developing initial loading and haulage plans, since it is impossible to evaluate every conceivable system that would potentially satisfy the production requirements. The selection of a loading and haulage system, then, is based upon safety considerations and an economic evaluation aimed at meeting the production requirements at a minimum cost per unit of production.

A straightforward or deterministic approach is taken to production calculations in this chapter of the *Handbook.* In the next segment (9.3.2), equipment used for loading and haulage are classified according to the type of function they perform and the manner in which they operate. In the following segment (9.3.3), a generalized equipment selection process is described, and in the last (9.3.4), production calculation steps are described for each class or subclass of equipment. Although the descriptions are fairly specific for particular types of equipment, the same formulation may apply to several varieties of equipment as noted at the beginning of each segment. A caution is in order to alert the reader that the deterministic approach to loading and haulage production calculations may be misleading if various uncertainties are misunderstood or ignored. The reader is, therefore, also referred to Chapter 9.4, Cycles and Systems, where these uncertainties are given due consideration.

9.3.2 EQUIPMENT CLASSIFICATION

To discuss loading and haulage it is necessary to address specific types of equipment or groups of equipment with common characteristics. This requires some system for classifying or grouping the various types of equipment. A few general classifications have been proposed in materials handling texts (Carson, 1961; Apple, 1963). Adler and Lineberry (1986) presented a comprehensive classification system for all mining and reclamation equipment. Atkinson (1971) presented an equipment application scheme for surface mining that classified equipment for each unit operation as either continuous or noncontinuous.

A slightly different classification system is presented here to satisfy the particular objectives of this portion of the *Handbook.* Those objectives are to provide the basic selection principles while maintaining some measure of generality. This should facilitate the preliminary design of loading and haulage systems, al-

Table 9.3.1. Classification of Loading and Haulage Equipment

	Load		Haul		Combined	
	No tramming	Minimal tramming	Nonfixed path	Fixed path	Mobile	Fixed-base
Discrete unit	Loading shovel Backhoe Hydraulic front shovel	Front-end loader (FEL)	Truck Shuttle car*	Rail Skip hoist Slusher Aerial tramway	Tractor scraper Dozer Load-haul-dump (LHD)	Dragline Stripping shovel
Continuous flow	Bucket wheel excavator (BWE) Bucket chain excavator Dredge Continuous miner		Bulk solids	Fluid transport		
			Belt conveyor Screw conveyor Chain conveyor	Slurry pipeline Pneumatic transport	This category is not characterized by single machines. Rather, continuous loaders and haulers are placed in series to create a continuous flow of material, e.g., longwall shearer and chain conveyor, BWE and belt conveyor, auger head and screw conveyor. Therefore, production capacity of the combined system is the smaller production capacity of the two components.	

*Electrically powered shuttle cars do not follow a fixed path, but are constrained by the trailing cable and cable reel location (except with battery-powered cars).

though more detailed equipment information will be needed for final selection. The classification system used here is not intended to be a comprehensive classification of all mining equipment; rather, it addresses only loading and haulage equipment.

The classification system used in this section is outlined in Table 9.3.1. The two primary distinctions in this system are the type of function that the machine performs (i.e., loading, haulage, or a combination of loading and haulage) and the form that the material has in the process (i.e., either discrete units or a continuous flow of material).

The distinction between discrete units of material and a continuous material flow is an important one from the standpoint of production capacity calculations. All the production calculations for loading and haulage equipment that treat the material as discrete units can be characterized by a cycle. These cycles are sequences of constituent operations that the machine performs in loading or hauling one complete unit of material. Estimating the cycle time, then, is the key to determining the production capacity of this equipment type. The output of the continuous flow operation is characterized typically by the cross-sectional area of the material flow multiplied by the speed at which the material is traveling.

Presented in matrix format (see Table 9.3.1), the two primary means of classification result in six separate categories of equipment. As noted in the table, the category of combined loading and haulage equipment utilizing continuous flow is not characterized readily by any one piece of machinery, but requires separate continuous flow loading and haulage units to be operated in series. The other categories are subdivided, as necessary, to describe major distinctions in the manner that the primary function is performed. For example, as stated previously, all loading and haulage equipment that deal with discrete units of material can be described in terms of a cycle time. However, these categories can be subdivided into one group that does not require the machine to travel during its cycle and another group that requires translocation as part of its cycle. Travel time, then, can become a major component of the overall cycle time for this class of equipment. Likewise, haulage machinery can be subdivided into one group that always travels a fixed path, such as a rail car, and another group that is not confined to a fixed path, such as a truck. Even in this example, however, the path is not totally unrestricted since trucks must typically follow prepared haul roads. Finally, in the case of continuous flow haulage systems, a distinction is made between bulk solids conveyors and fluid transport due to the large differences in the production formulations.

9.3.3 EQUIPMENT SELECTION PROCESS

Before a generalized selection process is described, it is necessary to define several fundamental terms that are independent of specific equipment types. These terms are as follows.

1. *Production:* Total volume or weight of material to be handled in a specific operation. It can refer to either the economic mineral to be produced or to the waste material. Mineral production is given most frequently in units of weight while waste rock is often expressed in units of volume. It is common, for example, to refer to total annual production.

2. *Production rate:* The theoretical production volume or weight of a machine per unit of time. It is usually expressed on an hourly basis but can be given for other units of time such as a shift or a day.

3. *Productivity:* The actual production per unit of time when all efficiency and other management factors are considered. It can also be referred to as a net production rate, or production per unit of labor and time (e.g., tons/employee-shift).

4. *Efficiency:* The percentage of the estimated production rate that is actually handled by a machine. Reductions in production rate can be related to the machine itself, personnel, or job conditions. The efficiency factor can be expressed as the average number of minutes worked at full production in one hour divided by 60 minutes (Anon., 1975).

5. *Availability:* That portion of the scheduled operating time that a machine is mechanically ready to work (Anon., 1976).

6. *Utility:* That portion of the available time that a machine is actually working (Anon., 1976).

7. *Capacity:* Refers to the volume of material that a loading or haulage unit can hold at any point in time (e.g., volume of a loading machine bucket or a truck bed). Capacity can be classified according to the following two types:

a. Struck capacity: The volume of material in a loading or haulage unit when it is filled to the top, but with no material above the sides or carried on any external attachments such as bucket teeth (Peurifoy, 1956).

b. Heaped capacity: The maximum volume of material that a loading or haulage unit can handle when the material is heaped above the sides. While the struck capacity is a constant for any unit, the heaped capacity is a function of the material properties and the shape of the unit (Peurifoy, 1956).

8. *Rated capacity:* The load that a machine can carry in terms of weight. Most machines are designed to carry a particular weight rather than volume. Therefore, the volume of material handled will be dependent upon the density of the material and will vary with density for a given machine while the maximum weight is a constant and is a function of the strength of the machine components.

9. *Swell factor:* The fractional increase in material volume that occurs when it is fragmented and removed from its natural state (bank volume) and deposited in a loosened state (loose volume). It can be expressed as either a decimal fraction or as a percentage.

10. *Bucket fill factor:* An adjustment to the capacity of a loading machine bucket. It is expressed generally as a decimal and corrects the capacity of the bucket to the actual volume of material it moves by taking into consideration the material heaping characteristics, the angle of repose, and the skill of the operator in filling the bucket (Anon., 1976).

11. *Cycle:* As mining is described generally as a *cycle of unit operations* (Chapter 9.4), so each unit operation is generally cyclical in nature. The unit operations of loading and haulage can be divided into an orderly rotation of steps or suboperations. For example, the most common components of a discrete unit haulage cycle are load, haul, dump, and return. From an equipment selection or production planning standpoint, the duration of each component is of primary importance. The sum of the time durations for one complete cycle is called the *cycle time.*

The objective of the *equipment selection process* for loading and haulage is quite simple. It is to select a single machine or combination of machines that is capable of moving a specified amount of material over a known distance within a given period of time. While minimization of cost may be stated as a goal, most designs are based upon a minimum acceptable rate of return so that estimated costs must not exceed those that would result in a rate of return less than the established minimum. Following is a generalized step-by-step selection process. This is presented as a preface to the more machine-specific production calculations given in the next subsection. The basic steps are as follows.

1. *Determine required production:* The total production requirement can be affected by a number of factors that are external to a particular mine. These factors include sales projections, contracts, amount of available reserves, and other operations of the company in question. Based upon consideration of these factors, management must make a decision concerning the total amount of mineral to be produced. Production requirements are stated generally for an entire year.

The total annual production requirement for the mine must then be converted into daily or hourly production rates for each operation. Production rates for specific operations within the mining cycle will be affected by such factors as percentage recovery, ore grade, and stripping ratio in the case of surface operations. For example, as the stripping ratio increases in a surface coal mine, the overburden removal rate must increase proportionally to maintain the same coal production rate. Therefore, loading and haulage production rates must be determined for the mineral commodity and for waste rock when its removal is necessary for mineral extraction.

2. *Determine reach or haul path:* Fixed-base equipment load at one location and then swing in an arc to dump at a second location. The maximum horizontal distance over which a machine can either load or dump is referred to as its *reach.* The geometry of the deposit to be excavated is the primary factor in determining the required reach of a machine.

Haul path refers to the distance and grade over which mobile equipment must travel. For both mobile haulers and combined mobile loader-hauler, units there is some distance to be traversed between the loading point and the dumping point. However, this distance is not necessarily represented by a straight line. In underground operations, the haul path is constrained mainly by the geometry of the mine openings, but can also be affected by such factors as ventilation and power availability. Topography is the primary consideration in determining surface haul paths. However, property boundaries and legal right-of-ways may also be involved.

3. *Calculate cycle time:* The cycle time for a unit operation can be divided into two primary components. The first component consists of those tasks that have a relatively constant duration from one application to the next. This includes such tasks as turning, spotting, dumping, and loading. Estimates of the time required for each of these fixed components of the cycle are generally available from equipment manufacturers. These estimates are based upon experience and are given for specific equipment models operating over a range of job conditions. The variable component of the cycle time is associated with the travel time for mobile equipment and the swing time for fixed-base equipment. Swing time is controlled primarily by the swing angle. Travel time for mobile equipment is much more variable. It is dependent not only upon the haul distance but also the geometry of the haul path and the speed of the vehicle, which is itself a function of available power, total resistance, and load.

4. *Calculate capacity:* The general relationship between production rate, cycle time, and capacity is quite simple and can be stated as

$$\text{production rate} = \text{capacity} \times (\text{no. of cycles/unit time}) \tag{9.3.1}$$

When all efficiency factors are considered,

$$\text{productivity} = \text{production rate} \times \text{efficiency factors} \tag{9.3.2}$$

The calculation of required capacity is rather straightforward once production requirements have been established and estimates have been made for cycle times and all efficiency factors. It is important to remember, however, that machines must be designed to handle a specified weight rather than a particular volume. Therefore, it is necessary to consider the rated capacity of a machine along with the density of the material to be certain that the required production can be achieved with the equipment selected.

5. *Iterate to improve productivity:* In step 3 above, certain assumptions had to be made about the class of machinery to be used so that a cycle time could be estimated based upon the determined haul path. The capacity calculated in step 4 may not be achievable with the class of machinery assumed in step 3. This would then require an adjustment in the cycle time, which would in turn require a further refinement in the design capacity. Several iterations may be necessary before a satisfactory solution is achieved. There can be, however, more than one equipment solution to the loading and haulage problem. Knowing that

production rate is directly proportional to capacity and inversely proportional to cycle time, the engineer may perform several iterations of this process in order to produce a number of loading and haulage alternatives for cost comparison.

6. *Calculate fleet size:* Up to this point, the discussion of equipment selection has assumed either a single loader-hauler unit or a single loader paired with a single haulage unit. However, it may not be possible or desirable to supply the entire required capacity in this manner. Although there is an economy of scale (i.e., the unit cost of material handled tends to decrease as the capacity of the machine increases), this gain must be weighed against the uncertainty associated with the availability of a single machine. Whereas a fleet can continue to produce when one machine is unavailable, a single-machine operation is idled when the machine is mechanically unavailable. Various algorithms exist for calculating the probability of any number of machines being available at a point in time for a given fleet size (Anon., 1979). The total number of machines needed to satisfy the production requirement can then be determined using a probabilistic cumulative availability.

7. *Iterate to reduce owning and operating costs:* The technical phase of the selection process will most likely identify a number of feasible loading and haulage system alternatives. These alternatives may include a single machine, a pair of machines working in tandem, or a fleet of machines. A cost comparison should be performed to evaluate the total cost per unit of production considering differences in capital costs, operating costs, and the estimated life of the equipment. An additional step beyond traditional engineering economic analysis involves computer simulation of the various systems under consideration. Simulation attempts to deal with many of the assumptions that are inherent in the deterministic equipment selection algorithms and to provide production and cost estimates that are less approximate. These techniques not only facilitate a straightforward comparison of alternatives but also assist in identifying potential changes in the system design that can result in better alternatives. This subject is the primary focus of Chapter 9.4.

9.3.4 LOADING AND HAULAGE PRODUCTION CALCULATIONS

The subject of production calculations has been addressed extensively by various authors and equipment manufacturers. Several of these earlier works are referenced extensively in the following segment. Also, rather than repeating similar steps in each group of calculations, the reader is referenced to the preceding or following discussion to a type of calculation that is similar.

For additional applications coverage, refer to Chapters 13.3 and 17.2.

9.3.4.1 Production Capacity of Discrete Unit Loaders

Discrete unit loaders can be divided into two classes: those that require no tramming and those that require minimal tramming. Discrete unit loaders that require no tramming include backhoes, hydraulic excavators, mining (or loading) shovels, and small draglines that are used to load-haulage vehicles. Those that require minimal tramming include front-end loaders (FELs) and load-haul-dumps (LHDs). The segment dealing with loaders that require no tramming is extracted from the *Caterpillar Performance Handbook* (Anon., 1990), and the subsection on loaders requiring minimal tramming is from Haley (1973).

Loaders That Require No Tramming. The hydraulic excavator (Fig. 9.3.1) is typical of discrete unit loaders that do not require tramming. As with any other piece of materials handling equipment, hydraulic excavator earthmoving production is dependent on average bucket payload, average cycle time, and job efficiency. If an estimator can accurately predict excavator cycle time and bucket payload, a machine's earthmoving production can be derived from the following formulas:

$$\text{yd}^3\,(\text{m}^3)/\text{60-min hr} = \text{cycles}/(\text{60-min hr} \times \text{avg. bucket payload in yd}^3\,(\text{m}^3) \tag{9.3.3}$$

$$\text{yd}^3\,(\text{m}^3)/\text{60-min hr} = \frac{\text{60-min/hr}}{\text{cycle time} - \text{min}} \times \text{avg. bucket payload in yd}^3\,(\text{m}^3) \tag{9.3.4}$$

$$\text{avg. bucket payload} = \text{heaped bucket capacity} \times \text{bucket fill factor} \tag{9.3.5}$$

$$\text{actual yd}^3\,(\text{m}^3)/\text{hr} = \text{yd}^3(\text{m}^3)/\text{60-min hr} \times \text{job efficiency factor} \tag{9.3.6}$$

Bucket Payload—An excavator's bucket payload (actual amount of material in the bucket on each digging cycle) is dependent on bucket size, shape, curl force, and certain soil characteristics (e.g., the fill factor for that soil). Fill factors for several types of material are listed in Table 9.3.2.

$$\text{average bucket payload} = \text{heaped bucket capacity} \times \text{bucket fill factor} \tag{9.3.7}$$

Estimating Cycle Time—The digging cycle of the excavator is composed of four segments:

1. load bucket
2. swing loaded
3. dump bucket
4. swing empty

Total excavator cycle time is dependent on machine size (small machines can cycle faster than large machines) and job conditions. With excellent job conditions, the excavator can cycle quickly. As job conditions become more severe (tougher digging, deeper trench, more obstacles, etc.), the excavator slows down accordingly. As the soil gets harder to dig, it takes longer to fill the bucket. As the trench gets deeper and spoil pile larger, the bucket has to travel farther and the upper structure has to swing farther on each digging cycle, and so on.

Spoil pile or truck location also affects cycle time. If a truck is located on the floor of the excavation beside material being moved, 10- to 17-sec cycles are practical. The other extreme would be a truck or spoil pile located above the excavator 180° from the excavation.

The cycle time estimating chart (Fig. 9.3.2) outlines the range of total cycle time that can be expected as job conditions range from excellent to severe. Many variables affect how fast the excavator is able to work. The chart defines the range of cycle times frequently experienced with a machine and provides a guide to what is an "easy" or a "hard" job. The estimator can then evaluate the conditions of the job and use the cycle time estimating chart to select the appropriate range. A practical method of further calibrating the chart is to observe excavators working in the field and correlate measured cycle time to job conditions, operator ability, etc.

Fig. 9.3.1. Hydraulic excavator front shovel (*courtesy:* Caterpillar Inc.).

Table 9.3.2. Bucket Fill Factors

Material	Fill Factor Range (Percent of heaped bucket capacity), %
Moist loam or sandy clay	100–100
Sand and gravel	95–110
Hard, tough clay	80–90
Rock—well blasted	60–75
Rock—poorly blasted	40–50

Source: Anon., 1988.

The same factors must be considered in production calculations for loading shovels, backhoes, and small draglines used for loading. Example 9.3.1 illustrates the selection of loading shovels for an open-pit mine (Anon., 1979).

Example 9.3.1. Select the bucket size for a fleet on mining shovels at an iron ore operation given the following assumptions about the operation.

Daily required capacity/machine (3 machines)	32,700 tpd
Estimated daily operating time	17.02 hours
Diggability rating	very hard digging
Estimated work cycle	37 seconds
Material bulk weight	6000 lb/yd^3
Swell factor	0.60
Dipper fill factor	0.80

Solution. Conventional double backup loading planned; therefore, a standard boom length is satisfactory.

$$\text{Shovel cycles per day} = \frac{\text{operating hr} \times 3600}{\text{work cycle in sec}} = \frac{17.02 \times 3600}{37} = 1656 \text{ cycles/day}$$

Required material.

$$\text{Tonnage per cycle} = \frac{\text{daily tonnage}}{\text{no. of cycles}} = \frac{32{,}700}{1656} = 19.8 \text{ tons or } 39{,}600 \text{ lb}$$

$$\text{Dipper size} = \frac{\text{tonnage per cycle} \times 2000}{\text{bank density in lb/yd}^3 \times \text{swell factor} \times \text{dipper fill factor}} = \frac{39{,}600}{6000 \times 0.6 \times 0.8} = 13.8, \text{ say } 14 \text{ yd}^3$$

Loaders That Require Minimal Tramming: The output of a front-end loader (Fig. 9.3.3) or similar discrete unit loader requiring tramming is the product of the mass of material delivered per cycle × cycles per hour. Cycle times vary in accordance with job conditions and loader stability.

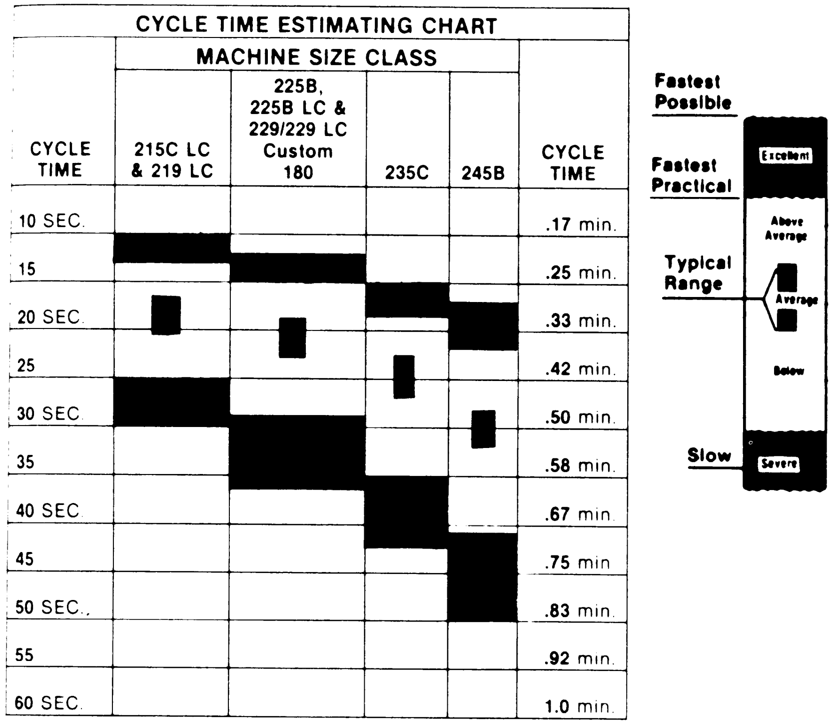
Material delivered per cycle reflects bucket size, carry characteristics (bucket fill factor), and weight of the material. A common error is assuming that a full-rated load will be delivered each cycle. In all cases, the density of the material in the loose state should be determined in lb/ft^3 (kg/m^3). Weighing a known sample volume by some means is recommended.

Rated (maximum) hourly production (lb or kg) = rated bucket size (yd^3 or m^3) × carry factor × material wt (lb/ft^3 or kg/m^3) × cycles per hr (9.3.8).

For longer periods, an overall efficiency factor also should be applied.

Bucket Size—Bucket capacities are determined in a manner similar to their determination in the previous section for nontramming loaders.

Loader Cycle Times—Loader cycle time is made up of load, haul, dump, and return. In any stockpile or bank work, these maneuvers require four reversals to direction. In loading trucks



CYCLE TIME -vs- JOB CONDITION DESCRIPTION

– Easy digging (unpacked earth, sand, gravel, ditch cleaning, etc.). Digging to less than 40% of machine's maximum depth capability. Swing angle less than 30°. Dump onto spoil pile or truck in excavation. No obstructions. Good operator.

– Medium digging (packed earth, tough dry clay, soil with less than 25% rock content). Depth to 50% of machine's maximum capability. Swing angle to 60°. Large dump target. Few obstructions.

– Medium to hard digging (hard packed soil with up to 50% rock content). Depth to 70% of machine's maximum capability. Swing angle to 90°. Loading trucks with truck spotted close to excavator.

– Hard digging (shot rock or tough soil with up to 75% rock content). Depth to 90% of machine's maximum capability. Swing angle to 120°. Shored trench. Small dump target. Working over pipe crew.

– Toughest digging (sandstone, caliche, shale, certain limestones, hard frost). Over 90% of machine's maximum depth capability. Swing over 120° Loading bucket in man box. Dump into small target requiring maximum excavator reach. People and obstructions in the work area.

Fig. 9.3.2. Cycle-time estimating chart for Caterpillar hydraulic excavators based upon machine size class and job conditions (*courtesy;* Caterpillar Inc.).

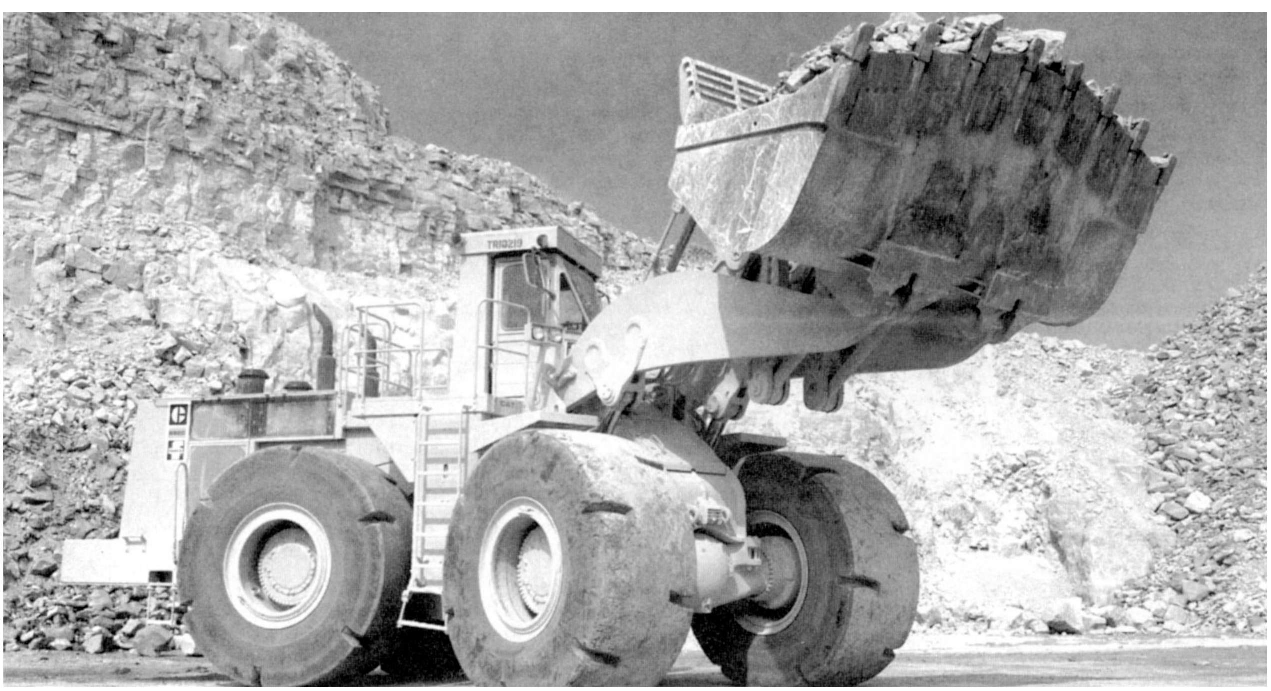


Fig. 9.3.3. Front-end wheel loader (*courtesy:* Caterpillar, Inc.).

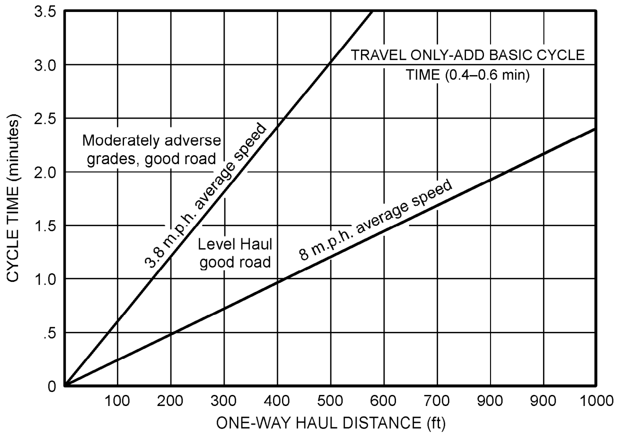

Fig. 9.3.4. Example of wheel loader haul and return estimating chart (Haley, 1973). Conversion factors: 1 ft = 0.3048 in., 1 mph = 1.609 km/h.

from a stockpile, the distance traveled is held to a minimum. Depending on the operator, material, truck size, and underfoot conditions, cycle time segments will vary upward from the following:

	Cycle time (min)
Load	0.06
Haul	0.15
Dump	0.05
Return	0.14
Total	0.40

On other than truck-loading applications, extended hauls usually are involved. Regardless of haul length, the turns and reversals of truck loading or basic maneuvers must be completed. Fig. 9.3.4 is an example of a guide for estimating load-and-carry cycle times. (Caution: the basic cycle time, usually 0.4 to 0.6 min, must be added.)

9.3.4.2 Production Capacity of Continuous Flow Loaders

Bucket wheel excavators (BWEs) are probably the predominant type of equipment in this class, but it also includes bucket chain excavators and bucket dredges.

The theoretical output of a BWE, as reported by Ramani et al. (1980), is based on the bucket size and the number of bucket discharges per minute. If I is nominal bucket capacity in yd^3 (m^3), Z is number of buckets in the wheel, V_1 is cutting speed of the wheel in ft/sec (m/s) and D is diameter of the wheel in ft (m), then

$$S_s = V_1 \times Z/\pi D \qquad (9.3.9)$$

where S_s = number of bucket discharges per second

$$Q_t = I \times S_s \times 3600 \qquad (9.3.10)$$

and Q_t = theoretical capacity of the excavator in yd^3/hr (m^3/h).

As can be seen from these equations, the number of bucket dischargers is dependent on the peripheral speed. The peripheral speed of a bucket wheel is limited by the ability of the wheel to discharge its bucket content on the chute against the counteracting centrifugal force. In theory, the maximum peripheral speed must be such that the bucket discharge will be ensured.

Mathematically,

$$M \times g = M \times V_1^2/R \qquad (9.3.11)$$

where M is mass of material in the bucket, lb (kg), R is in radius of the wheel in ft (m), and g is acceleration due to gravity, ft/sec^2(m/s^2), which yields the following expression:

$$V_1 = \sqrt{g \times R} = V_{\max} \qquad (9.3.12)$$

Practical values of speed lie between 0.4 to 0.6 $V_{\max}$. To keep the wear on the bucket's cutting knives or teeth at a minimum, speeds do not exceed 17 fps (5 m/s). The peripheral speed selected will also depend greatly on the nature of material to be excavated. In principle, however, a higher peripheral speed will be decided upon if hard material is to be cut, in which case maximum output may not be attained. Based on a constant output, the doubling of the peripheral speed will halve the amount of material excavated by each bucket; thus cutting performance will be reduced.

Yet another factor that affects the output of a BWE is the bucket filling capacity. It has been found that, in hard ground, bucket filling is around 30 to 40% of the nominal capacity. The relationship between digging resistance and the hourly capacity of the BWE is

$$Q_1/Q_2 = k_2^2/k_1^2 \qquad (9.3.13)$$

where Q_1 is BWE hourly capacity in yd^3 (m^3) in soil with specific cutting resistance k_1, and Q_2 is BWE hourly capacity in yd^3 (m^3) in soil with specific cutting resistance k_2. Thus, the actual capacity of the BWE in any soil is given by

$$Q_a = I \times B_f \times S_s \times 3600 \qquad (9.3.14)$$

where B_f is bucket filling capacity in the soil expressed as a fraction of the nominal bucket capacity, S_s is number of bucket discharges per second, and Q_a is actual capacity of the BWE in yd^3/hr (m^3/h). In soils with high cutting resistance, higher cutting speeds with lower bucket filling will result in a very small Q_a as compared to Q_t. The ratio may be as small as 0.2. One can visualize that in hard soils the excavating operation of the BWE has changed to a milling operation.

Example 9.3.2. A bucket wheel excavator has eight buckets with a nominal capacity of 2 m^3/bucket. The wheel has a diameter of 15 m and operates at a speed of 0.4 m/s. In a material with a digging resistance of 25 kg/cm, the BWE is producing 400 m^3/h. If the speed of the bucket does not change, what would be the bucket-fill factor (i.e., fraction of nominal bucket capacity) for the buckets when cutting a material with a digging resistance of 45 kg/cm?

Solution. The production rate in the new material can be determined as follows (Eq. 9.3.13):

$$Q_2 = Q\,\frac{k_1^2}{k_2^2} = 400\,\frac{25^2}{45^2} = 123.5 \text{ m}^3/\text{h}$$

The production rate can also be expressed as

$$Q = I \times B_f \times S_s \times 3600$$

Table 9.3.3. Bench Height/Wheel Diameter Factor for BWE Power Requirement Calculation

Height/diameter ratio	0.1	0.2	0.3	0.4	0.5	0.6	0.67	0.7	
Value of C									
English Units ($\times 10^4$)		3.06	2.57	2.30	2.11	1.96	1.85	1.78	1.74
SI Units		295	248	222	203	189	178	171	168

Source: Ramani et al., 1980.

Solving for B_f,

$$B_f = \frac{Q}{I \times S_s \times 3600}$$

but, $S_s = \dfrac{VZ}{\pi D}$, therefore,

$$B_f = \frac{Q}{I \times \dfrac{V \times Z}{\pi D} \times 3600} = \frac{123.5}{2 \times \dfrac{0.4 \times 8}{\pi \times 15} \times 3600}$$

$$= 0.252 \text{ or } 25.2\%$$

The required cutting power depends on the type of ground, the cross-sectional area and the shape of the slice cut, the configuration and sharpness of the cutter blades, the shape of the teeth, and the cutting speed. Hard ground requires a high specific cutting force, high cutting speeds, and additional cutting blades between the buckets. Reducing the output and the rate of swing decreases the slice cross section and increases the specific cutting force for a given wheel drive rating. This will be clear from the following expression (Rasper, 1964):

$$N_G = \frac{K}{\eta \times C}\sqrt{Q \times S \times R} \tag{9.3.15}$$

where N_G is power required for cutting in hp(kW), Q is actual digging capacity in yd^3/hr (m^3/h), S is number of bucket discharges per min, R is radius of the cutting wheel in ft (m), C is a constant depending on the bench height/wheel diameter ratio (for the cutting height = 2/3 wheel diameter, its value is 171), η is efficiency of the wheel drive, and k is specific cutting force in lb/ft (kg/cm).

The change in the value of C with a change in the height/diameter ratio can be observed in Table 9.3.3 (Rasper, 1964).

9.3.4.3. Carrying Capacity of Discrete Unit Haulers

Discrete unit haulers fall into two categories: those that follow a fixed path and those that are free to move about in any direction. The nonfixed-path haulers are characterized primarily by trucks. Electric shuttle cars (nonbattery) can also be included in this category, even though their travel is restricted by a trailing cable. The cycle time calculations presented in this segment emphasize gradeability and engine performance, which are issues relating particularly to truck haulage. Three references are excerpted extensively in this segment: Peurifoy (1956), the Bucyrus-Erie Open Pit Training Program (Anon., 1979), and Bishop (1972). The fixed-path production calculations address primarily rail haulage, Bise (1986) is referenced in this segment.

Fig. 9.3.5. Typical rear-dump mine haul truck (*courtesy:* Caterpillar Inc.).

Mobile Haulers (Nonfixed Path): The productive capacity of a truck (Fig. 9.3.5) or wagon, as discussed by Peurifoy (1956), depends on the size of its load and the number of trips it can make in an hour. The size of the load can be determined from the specifications furnished by the manufacturer. The number of trips per hour will depend on the weight of the vehicle, the horsepower of the engine, the haul distance, and the condition of the haul road.

Bucyrus-Erie Co. (Anon., 1979) describes three different ways in which this productivity can be calculated with each method having a distinct meaning or use:

1. *Theoretical Productivity:* The tons (kilograms) or cubic yards (cubic meters) per hour produced by an operating unit if no delays were encountered. This indicates 100% potential, which is rarely, if ever achieved.

$$\text{tons (kg) per hr, tph (kph)} = \frac{60}{\text{(cycle time)}} \times \text{(truck rating)} \tag{9.3.16}$$

$$\text{bank yd}^3\ (\text{m}^3) \text{ per hr, bcy/hr (bcm/hr)} = \frac{60 \times \text{(truck rating)}}{\text{(cycle time)} \times \text{(swell factor)} \times \text{(density)}} \tag{9.3.17}$$

2. *Average Productivity:* The tons (kilograms) or cubic yards (cubic meters) per hour produced by an operating unit, taking into account fixed and variable delays. This rate should be applied to the desired period of time (shift, day, etc.) to estimate total production:

Table 9.3.4. Turning-Spotting-Dumping Time (min)

Operating conditions	Bottom-dump tractor-trailer	Rear-dump	Side-dump semitrailer
Favorable	0.3	1.0	0.7
Average	0.6	1.3	1.0
Unfavorable	1.5	1.5–2.0	1.5

Source: Bishop, 1972.

$$\text{tph (kph)} = \frac{(U - D) \times 60 \times E \times TR}{U \times C} \quad (9.3.18)$$

$$\text{bcy/hr (bcm/h)} = \frac{(U - D) \times 60 \times E \times TR}{U \times C \times SF \times M} \quad (9.3.19)$$

where U is unit of time (say, 8 hr), D fixed delays (hr), E is job efficiency (adjusts for variable delays), TR is truck rating (tons or kg), C is cycle time (min), M is material density (tons/bank yd^3 or kg/bank m^3), and SF is swell factor.

3. *Peak Productivity per Hour:* The tons (kilograms) or cubic yards (cubic meters) per hour produced by an operating unit taking into account variable delays only. This rate would be used to determine the number of haulage units to be assigned to a shovel to achieve a given required production.

$$\text{tph (kph)} = \frac{60 \times \text{(job efficiency)} \times \text{(truck rating)}}{\text{(cycle time)}} \quad (9.3.20)$$

$$\text{bcy/hr (bcm/hr)} = \frac{60 \times \text{(job efficiency)} \times \text{(truck rating)}}{\text{(cycle time)} \times \text{(swell factor)} \times \text{(density)}} \quad (9.3.21)$$

Haulage Cycle Time—The information in this segment, taken from Bishop (1972), is intended as a guide in the determination of the time required by the vehicle for its complete haulage cycle, including loading, hauling, dumping, returning, and spotting times.

1. **Loading Time:** There are several methods for determining the number of shovel, dragline, or loader passes per load and the resulting load time. One of the more simple and reasonably accurate methods is as follows:

Weight per yd^3 (m^3) of material (loose) = weight in bank × swell factor (9.3.22)

No. tons (kg) per pass = bucket capacity (yd^3 or m^3) × fill factor × loose weight per yd^3 (t) or m^3 (kg) (9.3.23)

No. passes per load = rate capacity of haulage unit (tons or kg) /ton (kg) per pass (9.3.24)

Load time (min) = no. passes × excavator cycle time (min) (9.3.25)

The answer to the number of passes is rounded off to the next largest whole number, and generally the potential excess load is ignored in the production study. Three passes are generally considered to be the minimum, and five passes are optimal for most types of operations. Care should be taken to insure that the same units are used for both vehicle rating and bucket loading purposes in the above computation.

2. **Turn, Spot, and Dump Time:** Turning, spotting, and dumping time depends upon the type of unit and the specific operating conditions. As a guide, average values for the different types of haulage units under the indicated conditions are shown in Table 9.3.4.

Table 9.3.5. Spot at Loading Machine (min)

Operating conditions	Bottom-dump tractor-trailer	Rear-dump	Side-dump semitrailer
Favorable	0.15	0.15	0.15
Average	0.50	0.30	0.50
Unfavorable	1.00	0.50	1.00

Source: Bishop, 1972.

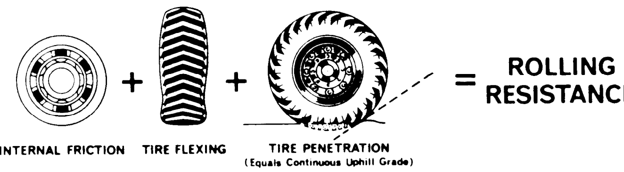

Fig. 9.3.6. Rolling resistance created by tire penetration, tire flexing, and internal resistance in final drive set. Indicated as pounds pull per ton of vehicle weight (Bishop, 1972). Conversion factor: 1 lb/ton = 0.5 g/kg.

3. **Spot Time at Loading Position:** The spotting time at the loading position also depends upon the type of haulage unit and the operating conditions. The average values are given in Table 9.3.5.

Haphazard spotting at the shovel is one of the most common and wasteful malpractices of the shovel cycle. Cutting a 30° arc from the swing out and return (only $^1/_{12}$ of the full 360° circle) will increase shovel production by approximately 15%. If the haulage unit is spotted for loading on a 180° swing when the job could be planned for 90°, nearly one-third of the possible production is lost.

In addition, accurate spotting of trucks at a correct angle and in the same relative position considerably improves the operator's timing and speeds up shovel operation. Trucks always should spot on the same radius to save racking the dipper in and out. This should line up as closely as possible with the radius of dipper as it leaves the bank.

4. **Haul Time:** *Gradeability* can be defined as the ability of a vehicle to negotiate a given grade, taking into account both grade and rolling resistance. The sum of these two values is expressed as "total resistance in percent of vehicle weight."

Grade resistance is defined as the rimpull or tractive effort required to overcome gravity in propelling a vehicle up an incline. It amounts to 20 lb/ton (10 g/kg) or 1% of unit weight for each percent of grade. For example, a 5% grade would offer a resistance of 100 lb (50 g) for each ton (kg) of vehicle weight.

Rolling resistance is the amount of rimpull or tractive effort required to overcome the retarding effect between the tires and the ground. It includes the resistance caused by the tire penetration into the ground, by the flexing of the tires under the load, and (to a degree) by the friction in the wheel bearings (Fig. 9.3.6). It is normally expressed as pounds pull per ton of vehicle weight, or as a percentage of vehicle weight. For example, a common value used to cover a well-maintained, smooth, hard, dry dirt and gravel road is 40 lb/ton (20 g/kg), or 2%.

Rimpull is discussed by Peurifoy (1956). It is a term used to designate the tractive force between the rubber tires of driving wheels and the surface on which they travel. If the coefficient of traction is high enough to eliminate tire slippage, the maximum rimpull is a function of the power of the engine and the gear ratios between the engine and the driving wheels. If the driving

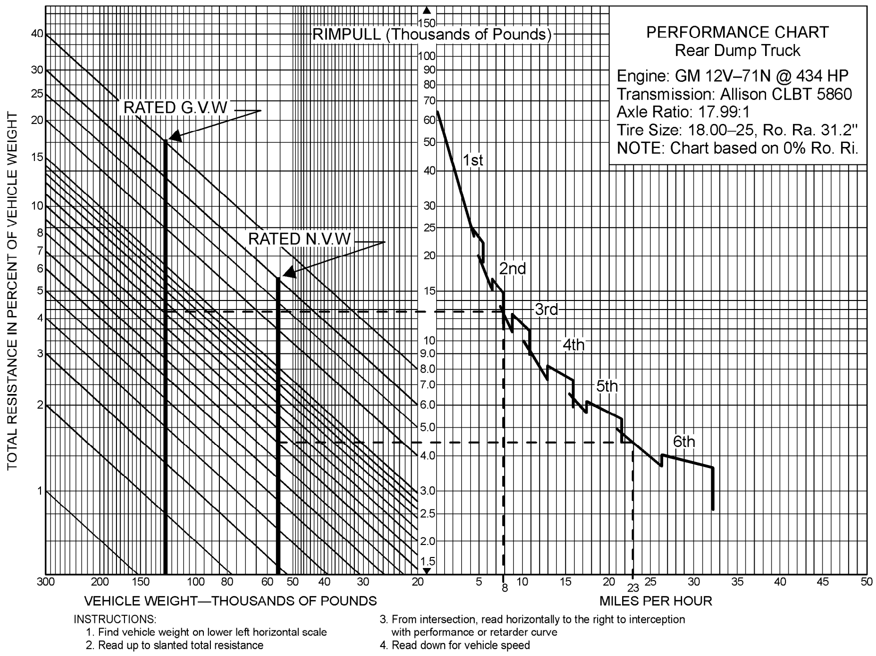

Fig. 9.3.7. Typical performance chart covering a 35-ton capacity rear-dump truck equipped with 434-hp engine, 6-speed powershift transmission, and 18.00-25 (32) tires (Bishop, 1972). Conversion factors: 1 lb = 0.4536 kg, 1 mph = 1.609 km/h.

wheels slip on the haul surface, the maximum effective rimpull will be equal to the total pressure between the tires and the surface multiplied by the coefficient of traction. Rimpull is expressed in pounds (kilograms).

If the rimpull of a vehicle is not known, it may be determined from the formula

$$\text{rimpull (lb)} = \frac{375 \times \text{hp} \times \text{efficiency}}{\text{speed (mph)}} \qquad (9.3.26)$$

or

$$\text{rimpull (kg)} = \frac{383 \times \text{power (kW)} \times \text{efficiency}}{\text{speed(km/h)}} \qquad (9.3.26a)$$

In computing the pull that a tractor can exert on a towed load, it is necessary to deduct from the rimpull of the tractor the tractive force required to overcome the rolling resistance plus any grade resistance for the tractor.

Bishop (1972), however, states that the use of this alone will not measure the performance or gradeability of the vehicle. To achieve this, one must have engine performance, gear ratios, tire data, weights, etc. This information is not normally available, so the engineer, in order to determine the speed a vehicle will negotiate a particular grade having a certain rolling resistance (total resistance), will have to refer to the vehicle manufacturer's performance chart. Fig. 9.3.7, showing a representative performance chart, has been marked to show the possible speed of the loaded vehicle operating on an adverse 8% grade having a 2% rolling resistance (10% total resistance). It will be noted when following a path of dotted (---) lines that the loaded unit can climb the 8% grade at a speed of 8 mph (12.9 km/h) in 2nd gear lock-up. To illustrate possible empty vehicle performance, the chart has been marked to show operation on a 6% grade with a 2% rolling resistance (8% total resistance). It will be noted that the empty unit can negotiate this grade at a speed of 23.5 mph (37.8 km/h) in 6th gear converter.

Most haulage units today are fitted with an auxiliary braking arrangement usually referred to as a "retarder." This is a device designed to serve as a brake working through the drive line to hold back the vehicle on downgrade haul roads. The use of the retarder saves the regular service brake for normal or emergency stops and reduces brake maintenance costs. Fig. 9.3.8, showing a representative retarder chart, has been marked to show the downgrade retarding ability of the loaded vehicle on an 8% grade, having a 2% rolling resistance. In this case, however, the rolling resistance serves to hold the vehicle back and thus, the total grade resistance would be 8% – 2% = 6%.

Following the dotted (---) lines in a similar manner to that of the performance chart, it is noted that the retarder has the capability of holding the loaded vehicle to a maximum speed of about 24 mph (38.6 km/hr). This, undoubtedly, is too fast for a normal 8% haul, but by shifting back to 4th gear, a slower speed of about 18 mph (29 km/h) can be achieved. As a further example, the chart has been marked to show that the retarder has the capability of controlling the empty vehicle on a 15% grade at speeds up to a maximum of 24 mph (38.6 km/h).

Having selected a transmission gear or range from the performance charts, it is necessary to modify the indicated road speeds through the use of a speed factor to reflect an average rather than a maximum speed. Table 9.3.6 shows the factors required to establish these average travel speeds over various lengths of haul.

A unit having a "stick shift" transmission and clutch cannot accelerate as rapidly as one with the torque convertor and full powershift transmission. As a result, the lower speed factors, at least up to 1500 ft (450 m) distances, should be considered.

To determine the average travel speed, multiply the maximum attainable speed as indicated in the performance chart by the factor shown, unless safety or other considerations impose lower limits.

Knowing the average travel speed from the above, the travel time can be calculated by means of the following formula:

$$\text{Travel time in minutes} = \frac{\text{distance in feet}}{\text{speed in mph} \times 88} \qquad (9.3.27)$$

or

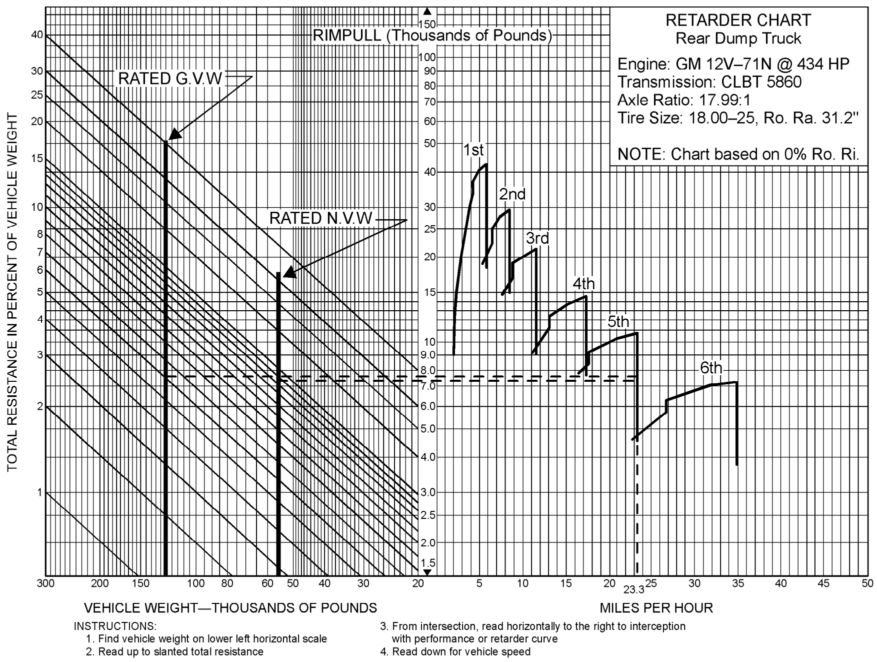

Fig. 9.3.8. Typical retarder chart covering a 35-ton capacity rear-dump truck equipped with 434-hp engine, 6-speed power-shift transmission, and 18.00-25 (32) tires (Bishop, 1972). Conversion factors: 1 lb = 0.4536 kg, 1 mph = 1.609 km/h.

Table 9.3.6. Speed Factors

Length of haul road section: ft	Length of haul road section: m	Short, level hauls 500–1000 ft (150–300 m) total length	Unit starting from stop	Unit in motion when entering haul road section
0–350	0–110	0.20	0.25–0.50	0.50–2.00
350–750	107–229	0.30	0.35–0.60	0.60–0.75
750–1500	229–457	0.40	0.50–0.65	0.70–0.80
1500–2500	457–762		0.60–0.70	0.75–0.80
2500–3500	762–1067		0.65–0.75	0.80–0.85
Over 3500	over 1067		0.70–0.85	0.80–0.90

Source: Bishop, 1972.

$$\text{Travel time in minutes} = \frac{\text{distance in meters}}{\text{speed in km/h} \times 16.7} \qquad (9.3.27a)$$

5. **Return Time:** Return time of the hauling unit is often governed by job conditions and safety precautions, rather than by the performance ability of the unit. If no grade conditions or operating hazards are present, these factors apply to the top speed empty:

	Under 500 ft (150 m)	Over 500 ft (150 m)
Favorable	0.65	0.85
Average	0.60	0.80
Unfavorable	0.55	0.75

If complicated grade conditions are present, use the high factors in Table 9.3.6.

Example 9.3.3. (Anon., 1975). An operator is determining which of two possible haul roads should be used:

1. The first alternative is a level roadway, 6000 ft (1830 m) long with a rolling resistance factor of 120 lb/ton and a coefficient of traction of 0.45.

2. The second alternative is a 3000-ft (914-m) roadway with a 5% adverse grade on the haul, and a rolling resistance factor of 200 lb/ton and coefficient of traction of 0.40.

The hauling unit is an off-highway truck with a gross vehicle weight of 130,000 lb; with 81,000 lb on the rear wheels when loaded to rated capacity.

Solution. Fig. 9.3.9 gives the appropriate rimpull curve for an off-highway truck and may be used where needed. Fig. 9.3.10 is the travel time.

Alternative 1:

Rolling resistance factor	= 120 lb/ton
	= 6% (20 lb/ton= 1%)
Grade resistance on haul	= 0%
Grade resistance on return	= 0%
Effective grade on haul	= 6% + 0%
	= 6%
Effective grade on return	= 6% = –0%
	= 6%

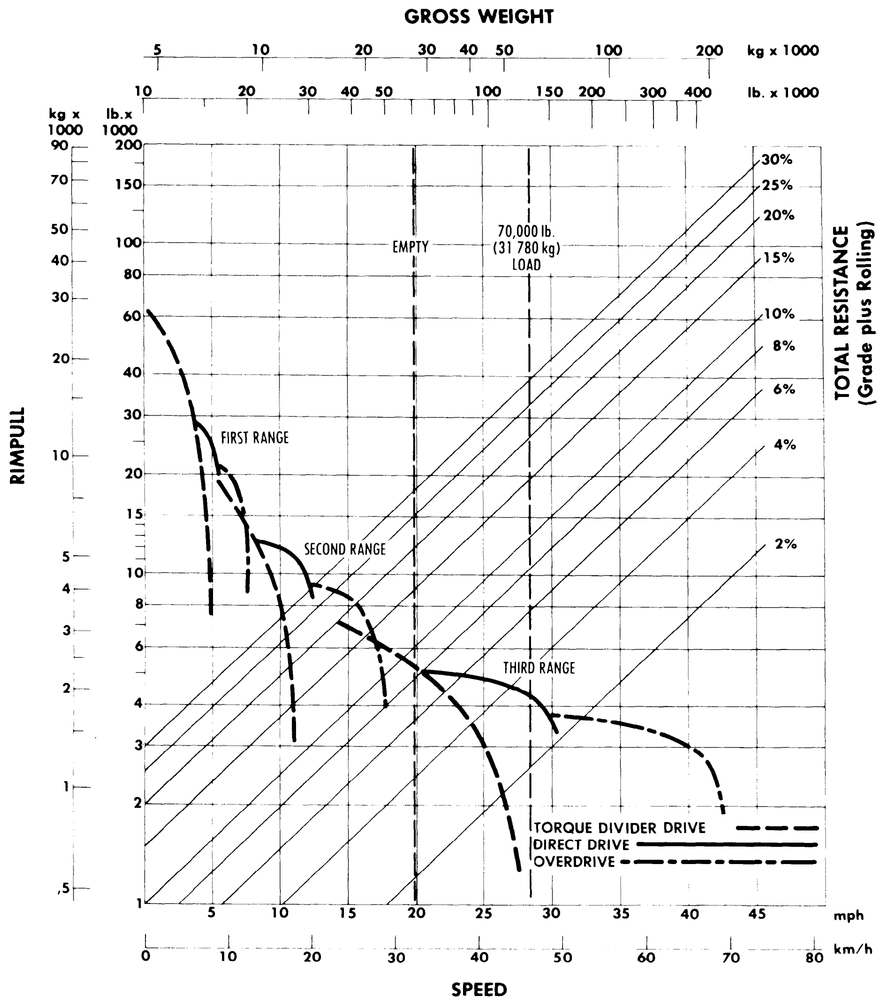

Fig. 9.3.9. Rimpull curve for off-highway truck used in Ex. 9.3.3. (*courtesy:* Caterpillar Inc.).

Gross vehicle weight = 130,000 lb
Power required = 130,000 lb × 6% = 7800 lb
Power available = 8000 lb at 16 mph (Fig. 9.3.9)
Power usable = 81,000 (weight on drive wheels) × 0.45 (coefficient of traction) = 36,450 lb
Vehicle will be able to haul under the given conditions

Haul time	4.70 min (Fig. 9.3.10)
Return time +	2.40 min (Fig. 9.3.10)
	7.10 min

Alternative 2:

Rolling resistance factor	= 200 lb/ton
	= 10% (20 lb/ton = 1%)
Grade resistance on haul	= 5%
Grade resistance on return	= −5%
Effective grade on haul	= 10% + 5% = 15%
Effective grade on return	= 10% − 5% = 5%
a) Gross vehicle weight	= 130,000 lb
Power required on the haul	= 130,000 lb × 15% = 19,500 lb
Power required on the return	= 130,000 lb × 5% = 6500 lb
Power available	= 20,000 lb at 7 mph (Fig. 9.3.9)

Power usable = 81,000 lb (weight on drive wheels) × .40 (coefficient of traction)= 32,400 lb
Vehicle will be able to haul under the given conditions

b) Haul time	5.50 min (Fig. 9.3.10)
Return time +	1.30 min (Fig. 9.3.10)
	6.80 min

Regardless of which path is used, the load, dump, and manuever times will remain the same. Therefore, the total of haul and return times will determine the path taken. It takes 0.3 minutes/cycle longer on the first alternative than on the second, which means that the contractor should choose the second to maximize production.

Discrete Unit Haulers With Fixed Paths: Productive capacity has the same form as mobile haulers with nonfixed paths, i.e.,

$$\text{Productivity} = \frac{(\text{rated capacity of hauler})\,(\text{efficiency factors})}{(\text{cycle time})} \tag{9.3.28}$$

The determination of cycle times involves quite specific calculations that are unique for each type of hauler. Rail haulage was addressed by Bise (1986), and portions of that discussion are included here to illustrate the selection of discrete unit haulers with fixed paths. Skip hoists are another type of discrete unit hauler that travel a fixed path (see Chapter 17.5).

The selection of mine locomotives for rail haulage centers on the weight and horsepower of the prime mover. Fig. 9.3.11

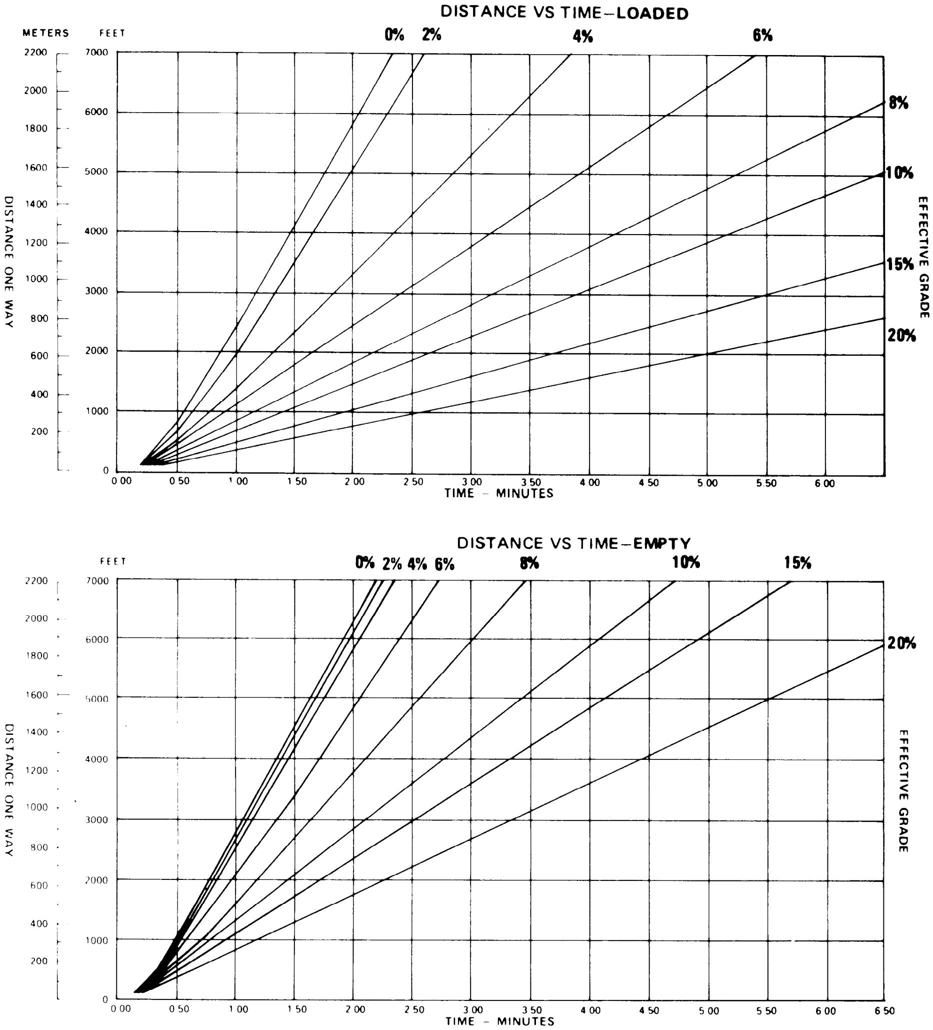

Fig. 9.3.10. Travel time curves for off-highway truck used in Ex. 9.3.3. (*courtesy:* Caterpillar, Inc.).

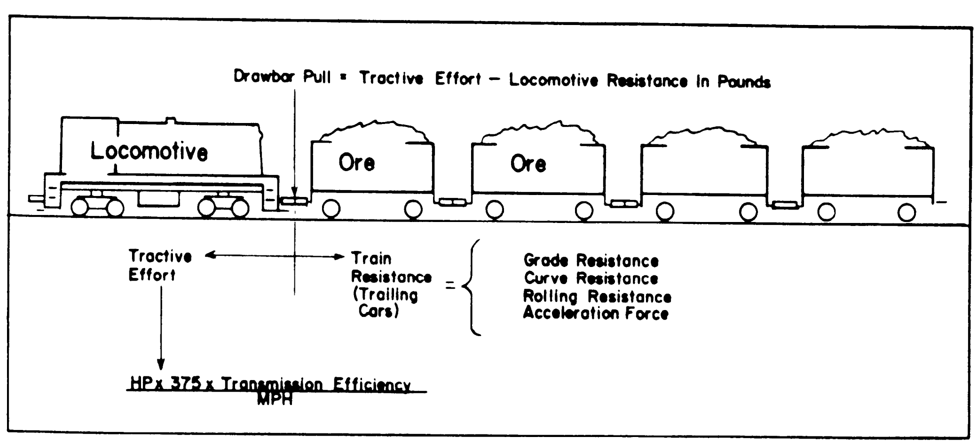

Fig. 9.3.11. Accelerating and resisting forces in railroad design (Brauns, 1973).

shows the relationship between a mine locomotive and its trailing loads. The *tractive effort,* exerted by the locomotive at the rim of its driving wheels, is a function of its weight and its ability to adhere to the track. *Adhesive values* for locomotives represent the portions of the prime mover's weight available to haul the trip. *Drawbar pull* is that portion of the locomotive's tractive effort that remains after the locomotive's resistance has been subtracted.

The locomotive's horsepower can be determined from the following relationship:

$$\text{power (hp)} = \frac{(TE)\,(V)}{(375)\,(E)} \tag{9.3.29}$$

$$\text{power (kw)} = \frac{(TE)\,(V)}{(383)\,(E)} \tag{9.3.29a}$$

where TE is the available tractive effort in lb (kg), V is the velocity in mph (km/h), and E is the transmission efficiency.

To move a trip, a mine locomotive must be capable of overcoming the following resistance for both itself and the mine cars: (1) rolling resistance, (2) curve resistance, (3) grade resistance, and (4) acceleration or deceleration.

The *rolling resistance* of the entire train is equal to the weight of the locomotive and mine cars (including the payload, if any) multiplied by a frictional coefficient. When roller bearings are used, the coefficient is 20 lb/ton (10 g/kg) of weight; the coefficient for plain bearings is 30 lb/ton (15 g/kg) of weight.

Curve resistance is a function of the radius of curvature and gage of the track, wheel base and diameter, speed, and load. It is often ignored because, in a properly installed system, it accounts for less than 1 lb/ton (0.5 g/kg) per degree of curve for that part of the train on the curve.

On a 1% grade, a ton (kilogram) must be raised 1 ft (m) for every 100 ft (m) that the train advances, making the grade resistance 20 lb/ton (10 g/kg) for each 1% of grade.

Tractive effort is also required to accelerate or decelerate. In mine locomotive calculations, it is assumed that it takes 100 lb (50 g) to accelerate each ton (kilogram) of the train's weight to achieve an acceleration rate of 1 mph/sec (1.6 km/h/s). Normally, mine locomotives accelerate between 0.1 (0.16) and 0.2 (0.32) mph/sec (km/h/s); therefore, the acceleration resistance is usually between 10 and 20 lb/ton (g/kg). Naturally, when the trip is decelerating, it can be analyzed in a similar manner.

9.3.4.4 Carrying Capacity of Continuous Flow Bulk Solids Conveyors

Two major types of continuous-flow bulk solids conveyors are addressed below: belt conveyors and screw conveyors. The carrying capacity of chain conveyors can be analyzed in much the same manner as belt conveyors. The calculations outlined in this segment are extracted from Brook (1971).

Belt Conveyers: The carrying capacity of the belt depends on how the material can be piled up on the belt width. As the belt is continuously passing over sets of supporting idlers, the material is slightly disturbed all the time and tends to spread out on the belt. The carrying capacity of the conveyor is given by the equation,

$$T = a\,b\,v \tag{9.3.30}$$

where T is carrying capacity, a is average cross-sectional area of material, b is bulk density, and v is speed of the conveyor belt.

For a belt of width W, the value of the area a varies approximately between $W^2/10$ and $W^2/12$, depending on the nature of the material. The value of cross-sectional area given by $W^2/10$ represents a high loading, but in some cases this should be considered, especially if it is possible to load the belt at this intensity by flood feeding, when finding the greatest force acting on the belting.

Example 9.3.4 (Brook, 1971). A belt 0.9 m wide conveys material of bulk density 1.35 t/m^3 at a speed of 1.75 m/s. What is the carrying capacity?

Solution. Referring to Eq. 9.3.30 and assuming $a = W^2/11$, then

$$T = \frac{(0.9)^2}{11}\ \text{m}^2 \times 1.35\ \text{t/m}^3 \times 1.75\ \text{m}$$

$$= \frac{0.81}{11} \times 1.35 \times 1.75\ \text{m}^2\ \frac{\text{t}}{\text{m}^3}\ \frac{\text{m}}{\text{s}}$$

$$= 0.1735\ \text{t/s}$$

$$= 0.1735\ \text{t/s} \times \frac{3600\ \text{s}}{1\ \text{hr}} = 625\ \text{t/h}$$

The speed of the belt is limited mainly by the accuracy of alignment possible. At fast speeds, any slight wandering of the belt is difficult to correct by the slight forward angling of the outer wing idler rollers, which depicts the angling greatly exaggerated, or by the angling of complete sets of idlers to try to counteract misalignments.

The belt strength affects the maximum force which can be taken by the belt, and the value of the maximum force depends on the power required and the drivehead frictional grip. The power required by a belt conveyor can be divided into three components:

1. Power for the empty belt, W_e.
2. Power to convey the material, W_m.
3. Power to raise the material, W_r.

The total power required, at the belt, is then $W_T = W_e + W_m \pm W_r$.

The value of W_r is written "plus or minus" as if the material is being lowered. This helps to run the belt, and the power requirement for this is thus negative. The power as calculated here is the power required at the driving drum of the conveyor, and so the motor power required will be greater because of power losses in the gearing at the drivehead.

Assuming an efficiency of 90% for this gearing, the motor power is then given by

$$W = W_T/0.9 \tag{9.3.31}$$

The power required to drive the empty belt depends on the total force required to move the empty belt and on the belt speed.

The force required

$$N_e = \text{total weight on idlers} \times \text{friction coefficient} = M_i g \mu_e \tag{9.3.32}$$

The friction coefficient of ball bearing idlers is very low, and a value of 0.03 is generally used. The total weight on the idlers depends on the mass of two lengths of belt and the mass of the idlers themselves. This is conveniently expressed as mass per unit length, and the value is the total for both strands of the conveyor and the associated idlers. The weight on the idlers for a conveyor of length l is then given by $m_i lg$ where m_i is the mass per unit length. The actual value of the mass per unit length can be obtained from manufacturer's data and varies with the design of conveyor. Belts that are to carry dense materials require close spacing of idlers, and this increases the weight on the idler bearings. The value of l, the length of the conveyor, is increased by l_x = 148 ft (45 m) to allow for end pulley friction, so that

$$N_e = m_i\,(l + l_x) g \mu_e \tag{9.3.33}$$

and the power required is

$$W_e = N_e v \tag{9.3.34}$$

or

$$W_e = m_i(l + l_x)g\mu_e v \tag{9.3.35}$$

The power required to convey the material can be calculated in a similar fashion:

$$W_m = m_m l\, g\mu_m v \tag{9.3.36}$$

The value of m_m, the mass of material per unit length, is obtained from

$$m_m = \frac{T}{v} \tag{9.3.37}$$

Substituting this in the formula for W_m gives

$$W_m = \frac{T}{v}\, l\, g\mu_m v \tag{9.3.38}$$

or

$$W_m = T\, l\, g\mu_m \tag{9.3.39}$$

The value of the friction coefficient μ_m is again 0.03 for well-maintained conveyors, but this is sometimes raised to 0.04 if the conditions are unfavorable. The simple length l is used and not $l + l_x$.

The power required to raise the material at the rate T through height h is obtained directly as

$$W_r = T\, g\, h \tag{9.3.40}$$

The effective belt tension, or the tension difference at the drivehead, can then be found from the total belt power W_t:

$$W_t = W_e + W_m \pm W_r \tag{9.3.41}$$

Effective tension $P_e = W_T/v$

The maximum tension P_1 is obtained from the formula $P_e = P_1 - P_2$. The value of P_2 is assumed to be just sufficient to prevent slip, and for no slip to occur:

$$\frac{P_1}{P_2} = e^{\mu\theta} = n \tag{9.3.42}$$

Slip is avoided in practice by using a value of n less than that possible by assuming a low value for m, the value of q being fixed by the arrangement of the drum or drums at the drivehead. The angle q is about 250° for a single-drum drive and 400° to 450° for a two-drum drive. The value of μ is assumed to be 0.25 for a rubber-covered conveyor belting on a steel drum and 0.35 for rubber on a lagged drum, the corresponding values for PVC-covered belting being 0.2 and 0.28, respectively.

For no slip, $P_1/P_2 = n$ at the limiting conditions, and therefore

$$P_2 = P_1/n, \text{ and } P_1 - P_2 = P_1/n = P_1(n - 1)/n$$

so that

$$P_1 = \frac{n}{n - 1} P_e \tag{9.3.43}$$

Screw Conveyors: The capacity of such a conveyor is

$$T = a\, b\, v \tag{9.3.44}$$

where a is the average cross section of material passing, and is given approximately by

$$a = \frac{k\pi d^2}{4} \tag{9.3.45}$$

where d is the diameter of trough and k is the loading factor.

The average speed of the material is v and is equal to about one pitch of the screw per revolution of the helix, despite the erratic mode of movement. For most types of conveyor, the pitch p is equal to the diameter d, so that if the rotary speed of the screw is n, usually measured in rev/sec or rev/min, the velocity v is given by $v = n\, p$, or approximately, $n\, d$.

The size of screw conveyors ranges from about 6 in. (150 mm) diameter to 30 in. (750 mm) diameter, and the value the loading factor k varies from 15 to 45% depending on the type of material to be conveyed. The rotary speed n varies between 50 and 100 rev/min.

Although a combination of smooth helix and a rough trough is the best for effective axial movement, the actual friction coefficients will be near to each other for material against the helix, and the material on the floor of the trough, where often a bed of small particles of the material builds up. To estimate the power required, the power to move the material can be calculated, and then multiplied by three to allow for paddle friction, bearing friction, etc., and the efficiency of the driving gear allowed for by dividing by 75%:

$$\text{Force required to move material} = \frac{T\, g\, l\, \mu}{v} \tag{9.3.46}$$

where T is the capacity, v is the speed of material, l is the conveyor length, and m is the friction coefficient. The motor power required is then

$$W = \frac{3\,(T\, g\, l\, \mu\, v)}{v\,(0.75)} = \frac{3\, T\, g\, l\, \mu}{0.75} \tag{9.3.47}$$

9.3.4.5 Carrying Capacity of Continuous Flow Fluid Transport

The carrying capacity of any hydraulic transport system is addressed by Brook (1971) and can be expressed as

$$T = a\, s\, v \tag{9.3.48}$$

where a is average cross-sectional area of solids, s is solids density, and v is fluid velocity.

If the volumetric concentration of solids is c, and the full area of the pipe of flume is A, then $c = a/A$. Strictly speaking c is the actual concentration, and not the delivered concentration, but unless the speed is very low and near to the speed that may cause blockage of the system, these two concentrations can be considered equal.

The velocity required for fluid transport is rather greater than the velocity required to cause the solids to "float" in an upward stream of fluid, and a useful practical guide is

$$v = K\sqrt{d\left(\frac{s - r}{r}\right)} \qquad (9.3.49)$$

where K is a constant dependent upon the particle size, d is the pipe diameter, s is the solids density, and r is the fluid density.

For pipe sizes above about 20 in. (0.5 m), the value of d should be kept as 20 in. (0.5 m).

For both suction and pressure systems, a pressure difference of $p = p_i - p_o$ must be overcome, where p_i is inlet pressure and p_o outlet pressure. The pressure difference may be due to fluid friction on the conduit walls, sliding friction of the solids is on the conduit walls, increase in potential energy of both fluid and solids, and may be affected by the conditions at inlet or outlet.

The power required is given by

$$W = p\,A\,v = pQ \qquad (9.3.50)$$

where $Q = Av$, which is the total volumetric flow.

This is the power required in the fluid, and if the pressure is generated by a pump or a fan (compressor), the power of the driving motor will also depend on the pump or fan efficiency, which is often about 75%, so that a typical value of overall efficiency of pump and motor is about 66.7%.

The four main components of the pressure differences are

1. Pressure due to fluid friction on walls.
2. Pressure due to sliding friction of solids.
3. Pressure required to increase potential energy of fluid and solids.
4. Pressure required to increase kinetic energy of fluid and solids.

Some of these components may be neglected in particular circumstances, but they may be important in other cases. Energy is also involved when temperature changes are considered, particularly with pneumatic transport, but in most cases temperature can be ignored.

The pressure difference to be overcome by the fluid is thus

$$p = p_f + p_s + p_p + p_k \qquad (9.3.51)$$

Comprised of these components:

1. pressure due to fluid friction:

$$p_f = \frac{fl}{m} \cdot \frac{rv^2}{2} \qquad (9.3.52)$$

where f is friction coefficient, l is conduit equivalent length, and m is hydraulic mean radius.

2. pressure due to sliding friction:

$$p_s = \mu\,k\,c\,l_h\,g(s - r) \qquad (9.4.53)$$

where m is coefficient of friction of the solids on the conduit, k is portion of weight actually touching the walls ($0.1 \le k \le 1.0$), and $l_h = l \cos q$ (q is pipe slope angle).

3. pressure to increase potential energy:

$$p_p = g\,h\,[r + c(s - r)] \qquad (9.3.54)$$

where h is increase in elevation over l.

4. pressure to increase kinetic energy:

$$p_k = \frac{v^2}{2}\,[r + c(s - r)] \qquad (9.3.55)$$

5. overall pressure difference:

$$p = p_i - p_o$$

where p_i is intake pressure and p_o is discharge pressure.

9.3.4.6 Production Capacity of Discrete Unit Combined Loader-haulers

Discrete unit combined loader-haulers can be further divided into mobile equipment and fixed-based equipment. Mobile equipment includes wheel tractor scrapers (Fig. 9.3.12) and both rubber-tired and track dozers. Fixed-base equipment includes draglines and stripping shovels that excavate material and place it in a final destination without moving the base of the machine.

Mobile Equipment: The hourly production of mobile equipment has been addressed by Caterpillar Inc. (Anon., 1975) and can be estimated using the following relation:

$$\begin{aligned} \text{production/hr} &= \frac{\text{loads}}{\text{cycle}} + \frac{\text{cycles}}{\text{hr}} \\ &\times \text{(job efficiency factor)} \\ &\times \text{(correction factors)} \end{aligned} \qquad (9.3.56)$$

Although the machine will change from one example to another, the following steps for estimating production will be the same.

1. *Machine Capacity.* The first step is to determine the machine capacity. This is expressed as "THE LOAD" per cycle. How much will the unit carry on each cycle? This will depend on the size of the bowl of the scraper. For this step, only the rated capacity of the scraper is needed. This can be found on the specification sheets.

2. *Cycle Time.* Next, calculate the cycle time of the machine. All cycle times have four parts: load, haul, dump, and return. By finding the cycle time, the number of cycles completed per hour can be determined.

a. *Load Time:* For wheel tractor scrapers, it normally ranges from 0.6 to 1.0 min depending upon bowl capacity, size of pusher, job conditions, single or tandem power, etc.

b. *Dump Time:* Maneuvering and dumping averages from 0.6 to 0.8 min.

c. *Haul Time:* Haul time will depend on weight carried, power available, tractive effort, effective grade, conditions of haul road, and distance moved.

Fig. 9.3.13 is a graph similar to those in the *Caterpillar Performance Handbook* (Anon., 1990). It is used to figure the travel time one-way with a loaded wheel tractor scraper of a particular size.

If the effective grade is known, Fig. 9.3.13 can be used.

effective grade = rolling resistance (%) + grade resistance (%). (9.3.57)

d. *Return Time:* When the unit returns, two things will be different from the haul. First, it will be empty, or weigh less. Second, it will have an opposite grade affect.

Fig. 9.3.12. Typical wheel tractor scraper (*courtesy:* Caterpillar, Inc.).

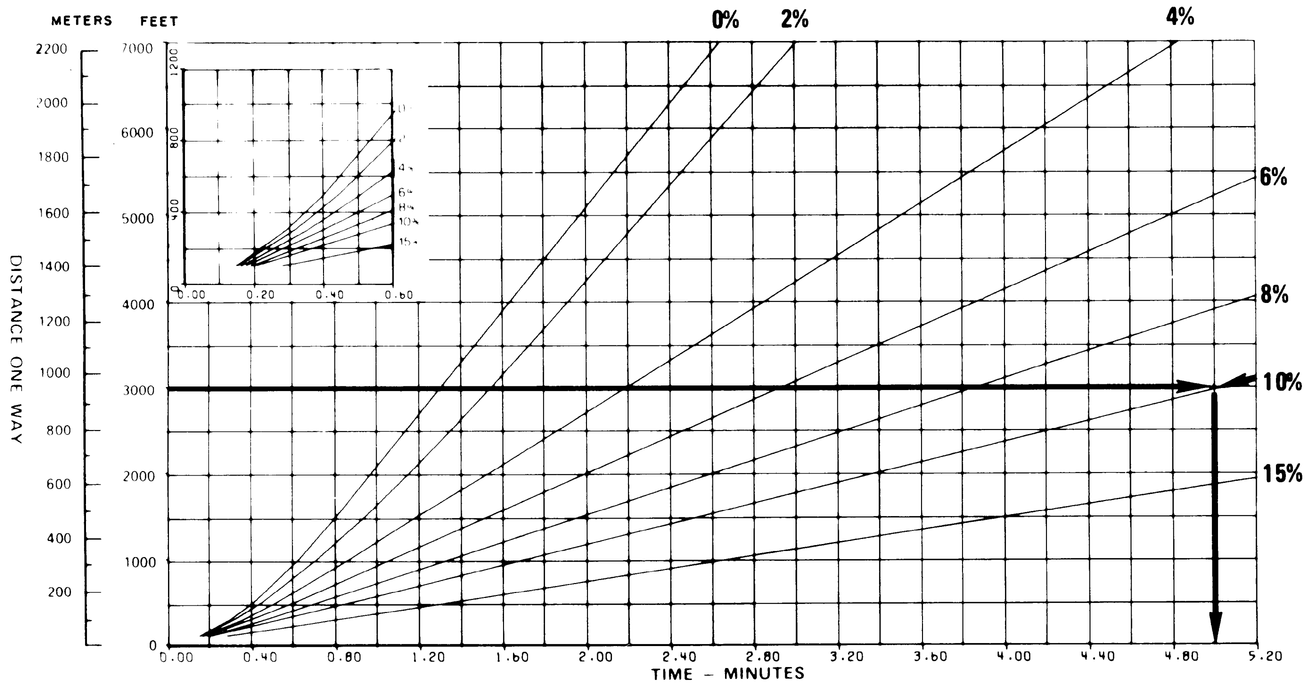

Fig. 9.3.13. Example of one-way travel time curve for a loaded wheel tractor scraper as a function of distance and effective grade (*courtesy:* Caterpillar, Inc.).

Retarder and Brake Performance—When operating on steep downgrades, wheel tractor scrapers may have to limit their operating speed for safety reasons. Operating speeds need to be limited in order that the braking or retarding capabilities of the machine are not exceeded. This will affect travel time. The maximum safe sustainable speed can be obtained by using performance curves like the one in Fig. 9.3.14.

To determine maximum safe speed: Read from gross vehicle weight down to the percentage effective grade. From this weight-effective grade point, read horizontally to the curve with the highest obtainable speed range, then down to maximum descent speed brakes can safely handle without exceeding cooling capacity.

Once the maximum safe speed is found, the travel time for the segment can be calculated using the formula,

$$\text{time (min)} = \frac{\text{distance (ft)}}{\text{speed (mph)} \times 88} \qquad (9.3.58)$$

or

$$\text{time (min)} = \frac{\text{distance (m)}}{\text{speed (km/h)} \times 16.7} \qquad (9.3.58a)$$

3. *Job Factors.* The last step is to consider the job efficiency

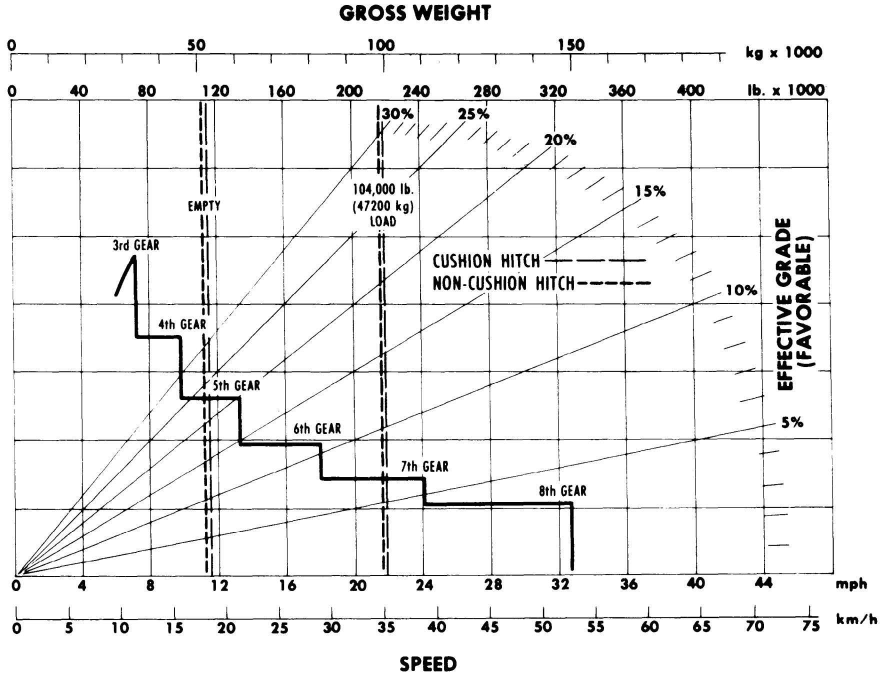

Fig. 9.3.14. Sample performance curve for determining maximum safe sustainable speed for wheel tractor-scraper when operating on a downgrade (*courtesy:* Caterpillar, Inc.).

and any correction factors. These factors could be based on operator proficiency, production methods, weather, traffic, acts of God, etc. A contractor's ability to determine and apply these correction factors under his particular conditions will, to a large extent, determine his degree of success in the earthmoving business.

To find the final hourly production, the estimated amount would be multiplied by any correction factor relating to the job. Correction factors for bulldozer production can be determined from Table 9.3.7 and Fig. 9.3.15. These correction factors can be applied to production estimates, such as those found in Fig. 9.3.16, for different sizes of dozers and types of blades.

Example 9.3.5. Estimate the hourly production of a track-type tractor fitted with a universal (8U) blade to doze anthracite coal from a stockpile 200 ft down a 5% grade to a conveyor hopper. The operator is average and operates an average of 50 min/hr.

Solution. Use Fig. 9.3.16 for estimating.

1 yd^3/hr (m^3/h) = 525 (Fig. 9.3.16) correction factors:

0.75 average operation (Table 9.3.7)
1.20 loose stockpile (Table 9.3.7)
0.83 job efficiency (Table 9.3.7)
1.20 light material U-blade (Table 9.3.7)
1.10 grade correction (Fig. 9.3.15)

estimated hourly production
= (525 lyd^3/hr) x (0.75) x (1.20) × (0.83) x (1.20) × (1.10) = 517.5 lyd^3/hr

Assuming anthracite weighs 2000 lb/lyd^3 estimated hourly production will equal 517.5 tph.

Fixed-Base Equipment: Capacities of stripping shovels and draglines (Fig. 9.3.17) are calculated generally on the basis of annual overburden yardage, as outlined in the Bucyrus-Erie Surface Mining Supervisory Training Program (Anon., 1976):

$$Y = \frac{BC \times Q \times A \times U \times B}{C \times (1 + S)} \tag{9.3.59}$$

Table 9.3.7. Correction Factors for Bulldozer Production

Job Condition Corrections:	Track-type tractor	Wheel-type tractor
Operator—Excellent	1.00	1.00
Average	0.75	0.60
Poor	0–0.60	0–0.50
Material—		
Type— Loose stockpile	1.20	1.20
Hard to cut; frozen—		
with tilt cylinder	0.80	0.75
without tilt cylinder	0.70	—
cable controlled blade	0.60	—
Hard to drift: "dead" (dry, non-cohesive material or very sticky material)	0.80	0.80
Rock, ripped or blasted	0.60–0.80	—
Slot Dozing	1.20	1.20
Side by side dozing	1.15–1.25	1.15–1.25
Visibility—Dust, rain, snow, fog or darkness	0.80	0.70
Job efficiency—50 min/hr	0.84	0.84
40 min/hr	0.67	0.67
Direct drive transmission (0.1 min. fixed time)	0.80	—
**Bulldozer*—Angling (A) blade	0.50–0.75	—
Cushioned (C) blade	0.50–0.75	0.50–0.75
DS narrow gage	0.90	—
Light material U-blade (coal)	1.20	1.20
Blade bowl (stockpiles)	1.30	1.30
Grades—See following graph.		

*Note: Angling blades and cushion blades are not considered production dozing tools. Depending on job conditions, the A-blade and C-blade will average 50–75% of straight blade production.

Source: Anon., 1975.

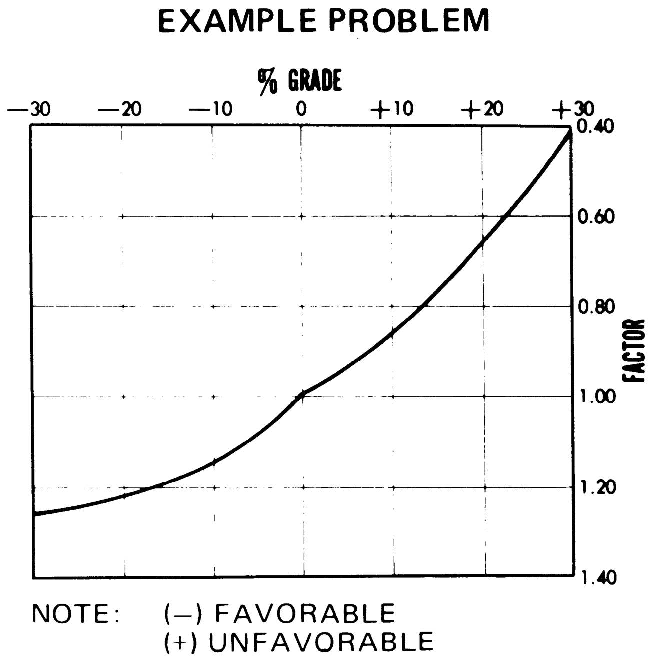

Fig. 9.3.15. Correction curve for adjusting bulldozer production when operating on a grade (*courtesy:* Caterpillar, Inc.).

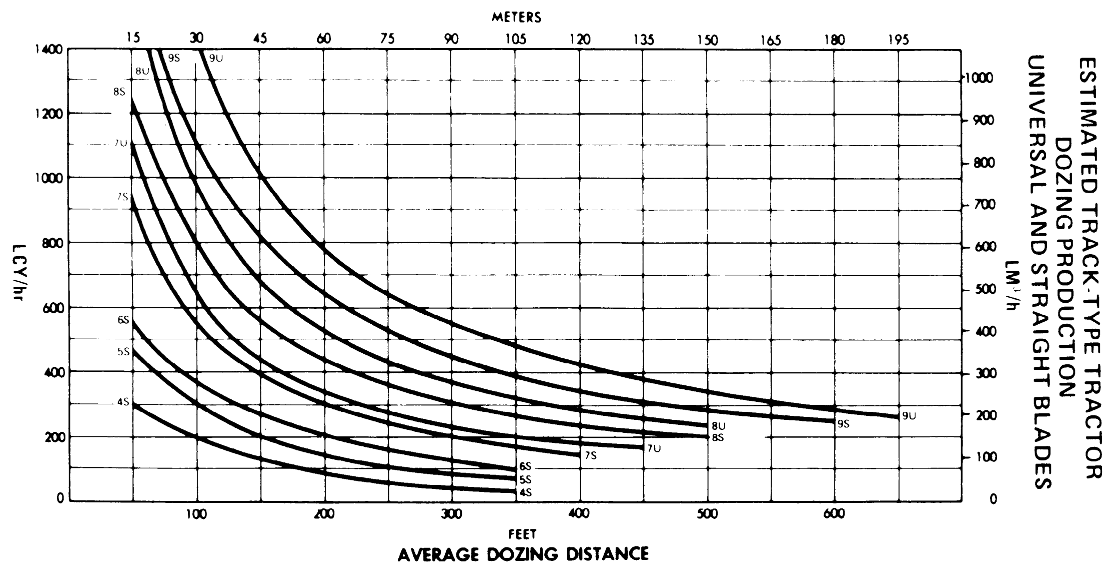
where Y is annual overburden stripping requirement in bank yd^3 (m^3), BC is bucket capacity in yd^3 (m^3), C is cycle time in sec, S is swell factor expressed as percentage, O is dragline scheduled yearly operating time sec, A is dragline availability as a percentage, U is dragline utility expressed as a percentage, and B is bucket fill factor expressed as a percentage.

The cycle *time* refers to the length of time that is taken between commencing to dump one bucket load to commencing to dump the subsequent load. In other words, it is the time for one complete cyclic operation. For this calculation, however, this should not be a design figure or theoretical maximum; rather, it should be the overall average cycle time that can be expected over a period of years. The time should also include all the unrecorded delays inherent in the operation including all inefficiencies in motors, operators, occasional poor digging, etc. Typical values of dragline cycle time range between 58 to 68 sec.

When the material has been loaded into the bucket, a similar increase in material volume is experienced. This is comparable to the swell in in situ overburden volume that occurs in the spoil pile itself. Thus the rated bucket capacity must be adjusted by the swell to correctly express the equivalent in situ bank volume. Swell factors in the 20 to 35% range are common.

The *bucket fill factor* is another adjustment to the rated bucket capacity. This adjustment corrects the rated cubic yards (cubic meters) to the actual volume, which is dependent on the material heaping qualities, the angle of repose, and the consistency with which the operator completely fills the bucket. Although it is theoretically possible to have a bucket fill factor greater than 100%, usual actual values for draglines are in the 80 to 95% range.



*Note: This graph gives the estimated track-type tractor dozer production using universal (U) and straight (S) blades. It is based on the following conditions:

a. 100% efficiency (60-minute hour).
b. Power shift machines with 0.05 fixed times.
c. Machine cuts for 50 ft, then drifts blade load to dump over a high wall.
d. Soil density (weight) of 2300 lb/lyd^3 (3000 lb/byd^3), material swell 30%, load factor 0.76.
e. Coefficient of traction 0.5 or better.
f. Hydraulic controlled blades used.

Fig. 9.3.16. Production curve for estimating track-type tractor dozer production based upon dozing distance, machine class, and type of blade (*courtesy:* Caterpillar, Inc.).

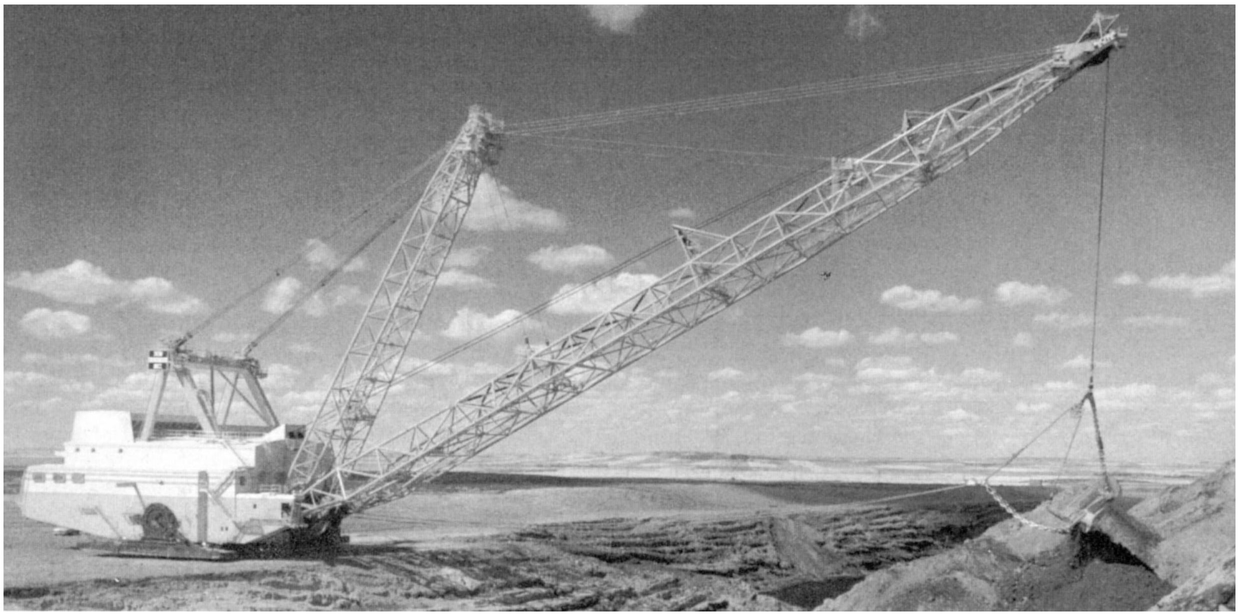


Fig. 9.3.17. Typical large walking dragline (*courtesy:* Bucyrus-Erie Co.).

The *scheduled operating time* makes allowance for periods of time when the dragline will not be operated. For some operations, this will be 100%, that is, the dragline is always scheduled to work, even on holidays such as Christmas Day, etc. These operations are probably in the minority today although, in general, operators tend to work their stripping equipment more continuously than, say, the loading equipment. A scheduled operating time for draglines of 90% or better is usually attained at most properties.

The *availability* is the part of the scheduled hours, expressed as a percentage, that the machine is electrically and mechanically ready to work. Thus this is the total time the operator has available in which to strip overburden. A 90% machine availability can be attained, although a more usual figure would be 80%.

Finally, the *utility* is the part of the machine available time that the machine is actually stripping. The types of delay the utility allows for are those other than mechanical and electrical, such as lunch, loss of electric power, waiting for blasting, etc. This factor varies from mine to mine, but values in the low 90s can regularly be attained at well-organized properties.

The primary dimensions required for dragline selection are

1. Dragline reach.
2. Cut depth capability.
3. Stacking height.
4. Bucket capacity.

The first three factors are dependent on the stripping method with associated overburden cut depth, coal thickness, proposed pit width, etc. The fourth factor is controlled by the proposed production rate, which then dictates the required stripping rate.

An additional requirement is introduced when multiple draglines are proposed. This requirement is the balancing of production between the machines to ensure a continuous and orderly operation.

There are two main methods to obtain the required dragline dimensions, these being by using graphs or by computation. Both use the "cut diagram" or simple range diagram for either actual measurement or derivation.

Fig. 9.3.18 illustrates a typical cross section through a pit. The overburden is dug from the area cut A and is deposited in

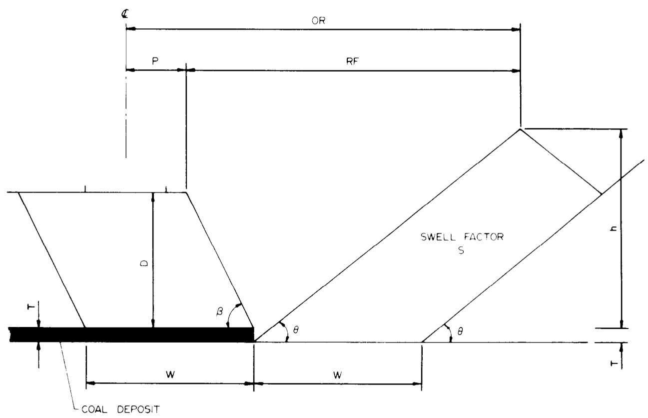

Fig. 9.3.18. Simple side-casting dragline range diagram showing relevant geometrical parameters (*courtesy:* Bucyrus-Erie Co.).

the area spoil A. As before, this diagram is a view perpendicular to the direction that the dragline is working and is thus a simple range diagram. By considering it to be a slice of uniform thickness, areas on the diagram become directly proportional to the relative volumes. Thus for a swell factor of 25%, the area marked spoil A should be 25% larger than the area marked cut A. Using this technique, the actual conditions in the field can be graphically or mathematically represented.

The graphical method utilizes a precisely drawn scaled diagram similar to Fig. 9.3.18. Then by direct measurement, the required dragline dimensions can be found. This method is long and laborious, especially when a number of different combinations of bank heights, coal thicknesses, pit widths, etc., are to be analyzed. However, it does find excellent application for the more complex mining methods.

The computational method is performed by deriving the mathematical relationship that describes the particular stripping method. In this relationship, factors such as bank height, coal thickness, spoil pile angle of repose, etc., can be considered as variables. Thus the effect of changing one or more of these factors can be readily calculated.

Sometimes, for the most common stripping methods, these relationships are computed over a wide range of values and are then presented in graphical or tabular form. These graphs or tables then provide good quick first-order results for the given situation.

Fig. 9.3.18 illustrates a pit cross section with the relevant geometrical parameters labeled. It should be noted that this particular cross section illustrates an operation that spoils just up to the coal. The spoil pile toe does not ride up the coal side. Other cross sections can be treated in a similar manner.

The parameters used in the analysis are

b = Highwall slope with the horizontal in degrees
q = Spoil pile slope with the horizontal in degrees
D = Overburden depth, *OR* = Dragline operating radius
P = Dragline positioning, *RF* = Dragline reach factor
S = Spoil pile swell factor, expressed as a decimal fraction
W = Pit width
h = Height of the spoil pile peak above the top surface of the coal
T = Coal thickness

Basically, this method equates the area of the cut slice with the area of the spoil slice, adjusted for swell, which is equivalent to equating the appropriate yardage because of the assumed unit cross-sectional thickness.

The reach factor is given by the following equation:

$$RF = \frac{D(1 + S)}{\tan\theta} + \frac{W}{4} + \frac{D}{tan\beta} - \frac{t}{\tan\theta} \qquad (9.3.60)$$

where t is the height the spoil toe is allowed to ride up the coal face.

The dragline reach factor is the horizontal distance between the bench crest and the spoil pile peak. The dragline operating radius can be found from the relation,

$$\text{operating radius} = \text{position} + \text{reach factor}. \qquad (9.3.61)$$

The required dragline digging depth is the dimension $\boldsymbol{D}$ or the total depth of overburden between the bench floor and the coal surface.

Finally, the required dragline stacking height is given by

$$\text{stacking height} = h - D \qquad (9.3.62)$$

which is the height the spoil pile exceeds the height of the cut above the coal surface, where

$$h = \frac{RF - D\cot\beta}{\cot\theta} - T \qquad (9.3.63)$$

Example 9.3.6. Consider an operation with the following parameters:

b = 1:3 (highwall slope)
q = 1.25:1 (spoil pile slope)
D = 90 ft (27 m) (overburden depth)
S = 25% (swell factor)
W = 120 ft (37 m) (pit width)
T = 5 ft (2 m) (coal thickness)
t = 0 ft (0 m) (spoil pile toe just touches the coal)

Solution. The first calculation is to determine the dragline reach factor. Using Eq. 9.3.60,

$$RF = \frac{90\ (1 + 0.25)}{4/5} + \frac{120}{4} + \frac{90}{3/1} - \frac{0}{4/5}$$
$$= 140.63 + 30.00 + 30.00 - 0$$
$$RF = 200.63, \text{ say } 200 \text{ ft}$$

The second calculation is to determine the stacking height.

$$\text{stacking height} = h - D$$

where h is the height of the spoil pile peak above the top surface of the coal.

In order to make this calculation, h must first be determined using Eq. 9.3.63:

$$h = \frac{200.63 - 90\ (l/3)}{5/4} - 5$$
$$= 136.50 - 5$$
$$= 131.50 \text{ ft}$$

Therefore the stacking height is given by

$$131.50 - 90.0 = 41.5 \text{ ft}$$

This is seen to be a very moderate requirement compared with the reach factor of 200 ft (61 m). This is usually the case for the standard stripping methods, and only in the more complex systems does the stacking height directly affect the dragline selection.

Before a machine can be selected, certain adjustments must be made to the parameters to make them readily comparable to the machine design criteria.

The actual capacity of the bucket is of secondary importance when considering forces and loads on the boom, etc. The result is the designer uses a term *maximum suspended load* (MSL) when considering the business end of a dragline, which specifies the maximum allowable weight of the loaded bucket plus rigging that the machine is designed to support, and is calculated as follows:

$$MSL = \text{rated bucket capacity (bucket weight/yd}^3 \text{ or m}^3 + \text{material weight/yd}^3 \text{ or m}^3) \qquad (9.3.64)$$

This means the actual rated capacity of the bucket is not significant compared with its overall loaded weight. Thus not only the bucket's own weight is involved, but also the weight of the material being stripped, which varies with overburden type.

The weight of the bucket itself is usually expressed in terms of pounds (kilograms) per cubic yard (cubic meter) of rated capacity. This figure can vary from 1500 to 2100 lb/yd^3 (890 to 1250 kg/m^3) depending on the bucket size and class of service. Larger buckets tend to weigh more per unit of volume than smaller ones because of a nonlinear increase in the component's mass. Similarly a heavyduty bucket will weigh more than a medium- or light-duty at the same rated capacity. An average figure often taken for "ball-park" estimate is 2000 lb/yd^3 (1187 kg/m^3) of rated capacity.

A convenient method of machine selection is given in Fig. 9.3.19. This is a chart of several machines plotted on a graph of reach factor against maximum suspended load.

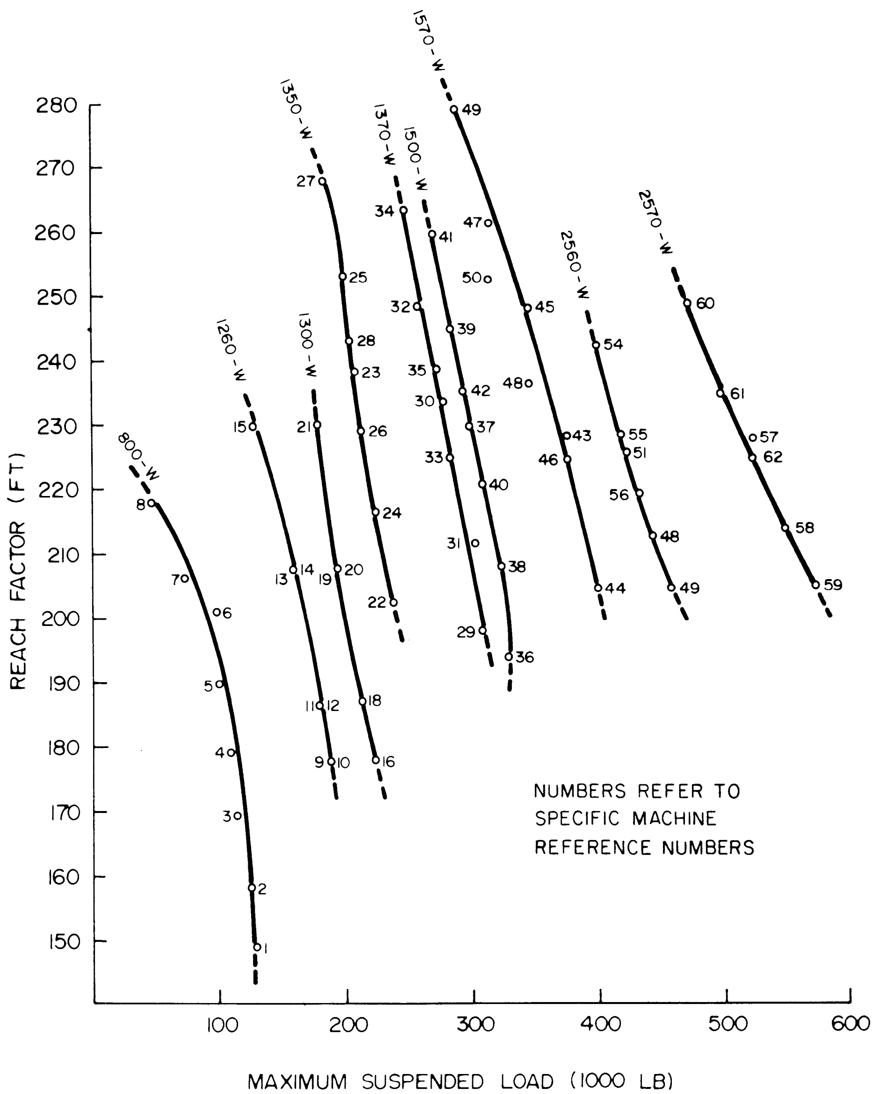

Fig. 9.3.19. Dragline standard machine selection chart (*courtesy:* Bucyrus-Erie Co.). Conversion factors: 1 ft = 0.3048 m, 1 lb = 0.4536 kg.

It is necessary to choose a dragline that meets both the reach factor and maximum suspended load criteria.

Chapter 9.4
CYCLES AND SYSTEMS

JON C. YINGLING

9.4.1 INTRODUCTION

Though mine production unit operations must be matched to the characteristics of the site at hand–sufficient power must be available at the excavator's cutterhead for effective fragmentation, haulage vehicles must be matched to the physical characteristics of the roadways, bucket design must be matched to the handling characteristics of the material being excavated, etc.—the process of design is not finished when equipment is identified that satisfies these requirements. How the unit operations will work together must be considered.

The integration of the unit operations discussed in previous chapters of this section into a system that can execute the production cycle efficiently requires great attention, both in initial design of the system and in managing its day-to-day operations. Some of the important decision areas are as follows:

1. *Scheduling and sequencing unit operations executed in parallel* (i.e., simultaneously) so that any one operation seldom results in excessive delay in execution of another.

2. *Balancing production capacity of unit operations* (e.g., sizing a truck fleet to match a loading shovel or a conveyor network to match the output of multiple production sections). A good solution to this problem is often much more involved than simply matching either the peak or the average material production capacities of the different unit operations.

3. *Assessment of systems level design effects on availability.* Overall, mine production systems tend to be highly interdependent and serial in nature. Failure of one unit operation may cause production in a number of other dependent operations to cease. Buffer storage capacity in transportation systems and use of fleet operations to perform a task (a number of smaller machines instead of one large one) are sometimes appropriate approaches to improving overall availability and, accordingly, the long-term rate of production output from these systems.

4. *Assessment of working-section layout effects on the performance of the production system.* For instance, entry layout and cut sequence in room and pillar mines influence the total nonproductive time spent moving equipment between the working places, the lengths of haulage runs, and tradeoffs between haulage distances and downtime due to extension of the section belts.

5. *Real-time operations control strategies,* such as the rules used to dispatch pooled truck fleets to service multiple loading operations at a surface mine.

Mine production systems engineering aims at evaluating the many alternative designs and operational strategies that can be developed for a given application. It serves as a vehicle for identifying good, perhaps optimum, choices. It views the unit operations collectively as integrated systems rather than independent operations. The interfacing and interaction of the unit operations is explicitly considered. It evaluates performance in terms with overall relevance to mine management rather than in terms only locally relevant to the unit.

Though some general rules of "good practice" can be stated (see 9.0.1.4) and should always be considered, these rules are not highly prescriptive of the detailed design and control of these systems. Production systems engineering is primarily a collection of techniques, that, if properly applied, can give good answers to often rather complicated questions. The tremendous incentives for efficiency of mine production systems are powerful motivations for routine application of these techniques. At the many operations where profit margins are low, these incentives are often demands.

Consistent with the scope of Section 9, this chapter focuses on topics of mine production systems engineering relevant to systems-level aspects of equipment selection and utilization. Specifically, the following three technologies are treated in some detail:

1. *Simulation of mine production systems.* This technology has taken a major role in detailed analysis of the performance of these systems. It uniquely can capture the stochastic (i.e., random) and dynamic character of these systems in models with little abstraction. Simulation models can be constructed to address any of the issues listed above.

2. *Fleet dynamics and dispatch strategies.* Addressed here are approaches for real time control of mine production systems involving fleet operations. These approaches are based on heuristic strategies, although the heuristics themselves sometimes employ solutions to rather sophisticated mathematical models. (The adjective "heuristic" is used in this chapter to refer to decision rules that arise from one's intuition regarding approaches that *appear* appropriate for design or control of a system. The general performance of these rules cannot be characterized by deductive mathematical reasoning, and they lack complete theoretical foundation. However, they often provide a very useful and practical basis for decision making.) In the case of truck dispatch, this technology has been proven to utilize equipment more effectively.

3. *Stochastic process models of mine production systems.* Though simulation techniques can be used to model the performance of mining systems involving stochastic elements (e.g., truck queues at a loader, material flows on a conveyor network), a more detailed mathematical analysis using the theory of stochastic processes can sometimes lead to a concise analytical model. Relative to simulation models of the same process, these models can greatly simplify comparisons of system design and control alternatives and can thereby lead to stronger conclusions. They can be very useful in cases where the level of abstraction required to establish the model is not excessive.

Other aspects of production systems engineering that are broader in scope and longer term in nature, such as mine development planning and production scheduling, are discussed from the perspective of mine exploitation in Chapters 8.3 and 8.4. Moreover, consistent with the theme of Section 9, the perspective of this chapter is general. Numerous other discussions of mine production systems engineering can be found throughout this *Handbook,* addressing specific application areas, including the examples listed.

9.4.2 GENERAL CONCEPTS AND TERMINOLOGY

A vocabulary that helps one to characterize these systems and to understand the tools that may be used in predicting and analyzing their performance follows.

A *system* is a collection of components on which *processes* operate, causing the components to interact for some objective purpose. Typically, the degree to which intended purposes of the system being met are assessed in terms of one or more *performance measures,* e.g., "production rate," "tons per employee-hour," or "cost per cubic meter of material moved." The options that management have in design and control of the system are expressed in terms of a set of *decision variables.* For example, in designing a materials handling system, management may be able to specify the number and size of trucks in its fleet or the width and speed of its belt conveyors. The natural objective of management is to specify the decision variables so that system performance in terms of the appropriate performance measures is good, preferably "optimum."

Production systems engineering relies extensively on the use of mathematical/logical *system models.* System models are established using knowledge of the performance of individual unit operations and the rules for interaction among these operations. The model should attempt to capture the essence of system performance and should adequately portray changes in performance as values of the decision variables are changed.

An appropriate balance must always be sought with respect to the level of detail incorporated in the model. Too much detail unnecessarily consumes the analyst's time. It may also hamper the tractability of obtaining a solution to the model or realizing extended analytical objectives such as mathematical optimization. Conversely, too little detail may result in a model that is an abstraction of little relevance to the problem at hand.

The immediate utility of the model is that it enables examination and evaluation of alternative values of the decision variables. One can readily discern good options from bad ones. This typically is done at a fraction of the cost of experimenting with the real world system. The model provides considerable opportunity for both thoroughness and creativity on the part of the designer or analyst.

It is sometimes possible to explore by mathematical techniques *all* possible specifications of the decision variables and to select the one that results in the best values for the performance measure(s). If one can accomplish this, *optimization* has been achieved. However, one often must be content at considering a limited number of alternatives and, therefore, has little assurance that the optimum solution has been found. The term optimization is frequently misused, referring to studies where the analyst simply selected the best from a few alternative designs that were examined rather than attempting comprehensive exploration of the range of the decision variables.

The *scope* of the models, that is, the extent of the real world system that one attempts to represent explicitly in the system models, is an issue of considerable importance. One should attempt to keep the scope as small as possible consistent with the objectives in studying the system. For example, face operations might be the focus without special concern for outby transportation or vice versa. One stands a much better chance in arriving at a good, useful solution with small, focused problems.

Scope is delineated by *system bounds,* partitioning the system under study from its environment. The internal workings of the system, within the system bounds, are said to be *endogenous* (endogenous variables, endogenous events), whereas external impacts on the system are termed *exogenous.* Typically, many transactions occur across the system bounds, both outputs from the system to the environment and exogenous inputs from the environment to the system. It is always assumed that the system outputs in no way determine the exogenous inputs.

To clarify the issue of scope and system bounds, consider a belt network in an underground coal mine where shuttle cars are used for face transportation. Assume that spillage problems have been occurring at transfer points because of insufficient belt capacity for handling situations where peak loads from several

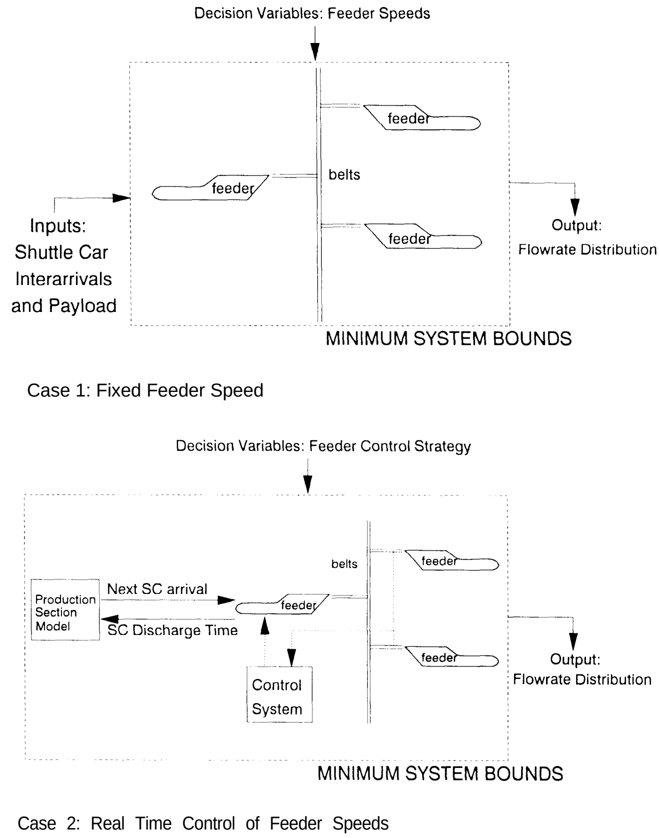

Fig. 9.4.1. Contrast of minimum system bounds for two approaches to control belt spillage

production sections are superimposed. One wishes to adjust speeds of the section feeders to reduce the incidence and extent of such problems. One approach might be just to reduce speeds permanently somewhat from current levels, spreading the discrete loads of material from the shuttle car into longer, thinner layers on the belt. Another might be to install belt load sensors, a data transmission network, and some type of intelligent control system to reduce speeds only on an "as needed" basis to prevent spills. Minimal system bounds (i.e., system bounds that keep the overall scope of the model as small as possible) will be contrasted for rigorous system models that one might construct to study these two alternative approaches to control of the system.

In the first case, one could set the system bounds at the section feeder, including the conveyor network in the model but excluding face operations. One would need to input shuttle car interarrival times and loads exogenously to the model, but these inputs would in no way be influenced by outputs of the system model for a given, fixed feeder speed.

For a rigorous model of the second case, however, one would have to broaden the model's boundaries relative to the first case, explicitly incorporating the face operations in some fashion. The reason for this is that feeder speed would be varied with time by the control system in response to circumstances on the belt network. When feeder speed changes, the discharge time of any shuttle car currently unloading is affected. This, in turn, influences subsequent interarrival times. The face operations and the belt network are intimately coupled here and, if rigor is desired, should not be modeled independently (Fig. 9.4.1).

The *state* of a system is defined in the model by the value of a collection of variables sufficient to characterize system operation and performance. *Static models* are solved for a single value of the state variables. *Dynamic models* are solved to obtain a trace of how the state variables change over time or, perhaps, over space or through a series of stages.

The first test for sufficiency of state variables is that one should be able to ascertain performance measures of interest with respect to making comparisons among alternatives. For example, consider a surface mine haulage system where trucks wait in line to be loaded by a shovel, travel to the dump site, dump (without having to wait in line), and return to the load site. One might be interested in analyzing the rate of production of this system for a given size of truck fleet. For this purpose, state might be characterized at any point in time by the number of trucks waiting to be loaded, the status of the loader (idle/busy), and the number of trucks in the process of dumping (ignoring equipment breakdowns). The stated performance variable as well as others that might also be of interest, such as average haul cycle times, average truck delay times, etc., can obviously be inferred from knowledge of how these variables change through time.

For dynamic models, such as the example just noted, a second test of sufficiency is also required. One must be capable of generating the subsequent state of the system given the current value of the state variables, exogenous inputs, and the known functional relationships among the system components. If one can do this, such a system is referred to as possessing the *Markovian property*. Specifically, this property states that the subsequent state of the system depends on the prior history of the process only through the present state. The next state may be generated from the model input using known relations describing single-step transitions. This criterion, in conjunction with the ability to infer performance variables of interest, provides a test to determine whether a given definition of state variables for the system is insufficient, sufficient, or superfluous.

With *discrete-event* dynamic models, the state variables only change at a countable number of points in time. A plot of the state variables vs. time appears as a step function. Using the state variables mentioned previously, the truck haulage system might be modeled as a discrete event system. *Events* are those occurrences at discrete points of time that result in the state changes. For example, arrival of a truck to the loading site changes the number of trucks waiting to be loaded and may change the status of the loader unit from idle to busy. Fig. 9.4.2 shows a plot of the state variables “queue length” and “loader status” vs. time for this system.

With *continuous* dynamic models, the state variables change continuously with respect to time. An example where a continuous model might be used would be in sizing the capacity of a mine drainage sump so that pumping can be shifted to off-peak periods to reduce power costs. The level of the sump, a state variable, would change continuously with respect to time as a function of inflow and outflow rates. As will be noted in the following with respect to a discussion of conveyor network modeling, sometimes one can convert from a continuous to a discrete model by making an appropriate selection of state variables. In general, discrete-event systems are easier to model than continuous systems. Some real world systems may require that a mixed discrete/continuous representation be used.

Stochastic models are used where the exogenous input to the model is random in nature. Note that this input is characterized in the form of some appropriate type of probability distribution (e.g., a distribution fitted to dump cycle times obtained in a time study of haulage operations). The input distributions are known, both their form (e.g., normal, exponential, gamma) and appropriate parameters. The modeling effort is to see, for a given specification of the decision variables, how the system responds

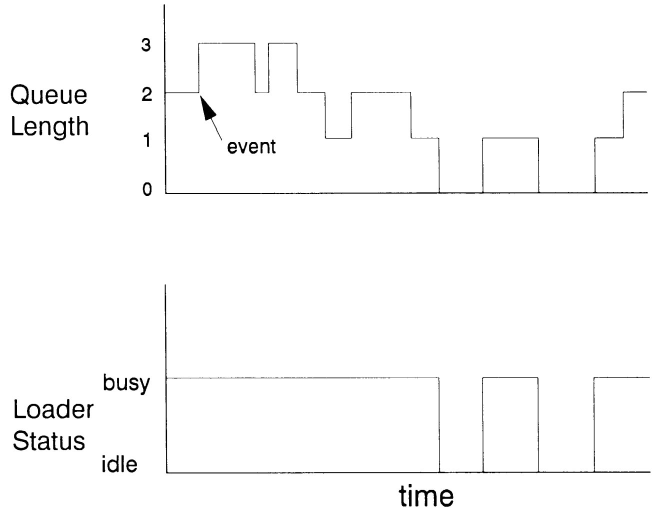

Fig. 9.4.2. Plot of state variables vs. time for a discrete-event dynamic model.

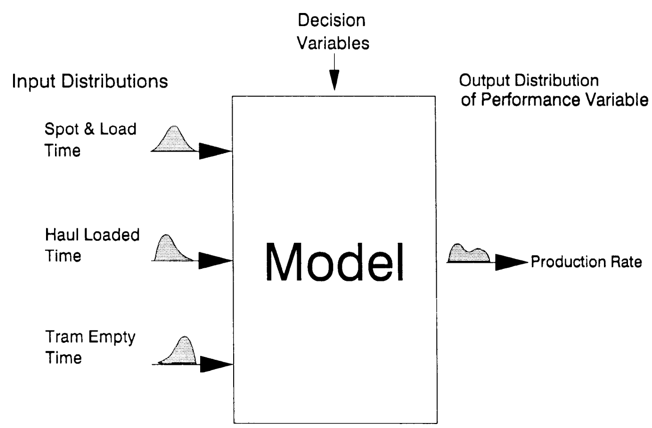

Fig. 9.4.3. Output from a stochastic model of production system performance.

to this input. Such response will also be stochastic in nature (Fig. 9.4.3). By modeling, one attempts to infer or deduce the distribution of the response, or important properties of this distribution, such as mean levels of the performance variables.

If, on the other hand, the input is not stochastic, the model is *deterministic*. In general, deterministic situations are easier to model and analyze.

Many times, mean levels of input variables are inserted into a mathematical expression that represents performance of the system such as the equations given for cycle calculations for haulage systems in Chapter 9.3. For example, one might insert mean trip times, mean spotting times, mean loading cycle times, mean dipper fill ratio, truck volume, and long-term average unit availability into a mathematical equation representing the production rate of a truck/loader system. Note, however, that probability theory provides no guarantee that the resulting answer would represent the mean level of the performance variable. Such approaches, when randomness is significant, only provide approximations. *It is an expressed role of the techniques discussed in this chapter to eliminate the errors inherent in such approaches*

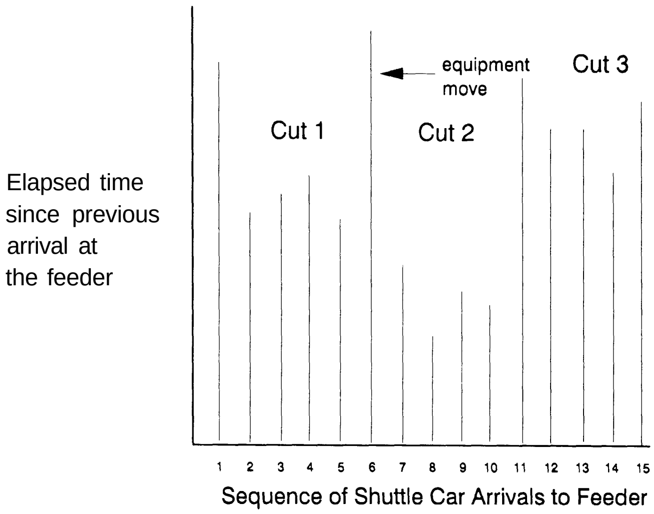

Fig. 9.4.4. Nonstationary input distribution required to describe shuttle car arrivals to the feeder.

and establish more accurate and meaningful performance predictions.

A model where the exogenous input and internal relationships do not vary systematically over time may yield what is called a *steady-state* solution. All static models are steady state. Such a solution represents an equilibrium behavior reflecting long-term performance of the system. A requirement for a stochastic model to provide a steady-state solution is that the parameters of the input distributions are held constant.

Note that if the the foregoing condition is not true, the input is said to be *nonstationary* and the *transient* behavior of the system must be studied. Although one might think that study of transient behavior is more difficult than steady state, often the reverse is true. In simulation of production systems, particular short periods of interest in analysis of transient behavior can often be defined. For instance, performance of a rail transport system might be studied only during the hour around shift changes when demands on the system are at their peak (assuming both men and ore are being transported simultaneously). The model might appropriately focus on transient behavior for this interval of time.

Input distributions to many mining models are nonstationary. For instance, the input to the belt network model discussed previously would systematically change as the mining machine proceeds through its cut sequence. The time between consecutive shuttle car arrivals should reflect this underlying cycle. When cuts are close to the feeder, interarrival times will be small. When cuts are far from the feeder, they will be large. If rigor is desired, interarrivals should not be taken as independent draws from a probability distribution since the influence of cut sequence on the sequence of interarrivals will be lost (Fig. 9.4.4).

The concepts previously discussed are useful in characterizing a system, selecting an appropriate modeling technique, determining the proper structure of the model, and in assessing the output or results produced by the model. The chapter continues with an overview of techniques that may be employed for detailed performance analysis of integrated systems of mine unit operations.

9.4.3 SIMULATION OF MINE PRODUCTION SYSTEMS

Discrete-event and *continuous simulation* are the modeling techniques that have been most widely applied in mine production systems engineering for the detailed analysis of equipment interaction. There are several good reasons for this. Most importantly, these approaches can readily accommodate the strong dynamic and stochastic character of these systems. Further, great levels of detail can readily be incorporated in simulation models. If properly carried out, such detail can insure valid representations of the real system without undesirable abstractions.

The technique is also one of the easiest to learn. The main prerequisites are a modest degree of computer literacy and a reasonably strong background in probability and statistics. Constructing the models is usually a conceptually easy process (though perhaps time consuming in some cases). Analysis of the output in proper scientific fashion is the more technically difficult issue.

9.4.3.1 Nature of Simulation Models

Simulation models are distinguished from other systems models in that the basis for model construction and solution is the *run*. A run is used to generate an artificial history of the process, specifying how state variables change either through time or through a sequence of stages. These histories, in whole or in part, provide information useful to the analysis of system performance.

To understand what is meant by a run and why the idea is so useful in constructing many types of process models, the following example will be considered. A number of boxes of different sizes, shapes, and weights are to be loaded on a cargo plane. The center of gravity of the boxes is of concern and some loading pattern that locates the center of gravity in a position acceptable for stable flying needs to be identified.

Generating a candidate loading pattern in a single step is a mentally forbidding task. However, if the task is broken into a sequence of stages, it becomes much less intimidating. For instance, a candidate loading pattern might be generated step by step using a three-dimensional graphics package, putting one box alongside or on top of others as one would if the boxes were being physically stacked. This is an example of using a run to construct a candidate solution to the model. In this example, only the terminal state of the run is of interest; but in many cases the entire history of the process evolution is of value.

The advantage of this approach to systems modeling is that it is often quite easy to specify the mechanics of the run. One can readily express rules for stacking boxes one atop the others. Given these rules, one can arrive at a candidate loading pattern by building up the pattern sequentially. However, given a collection of boxes of assorted weights, sizes, and shapes, a feasible loading pattern could not be deduced in a single step. In short, the mechanism of a run can generate information useful to the solution of a problem when attempts to summarize system behavior, via deductive mathematical analysis, cannot be made fruitful. However, as will be seen later in this chapter, the information provided by a run is often of weaker nature than that which might be obtained if analytical techniques can be applied to the problem.

Note that many models called simulations are misnamed. For example, one often says that a chemical process, a coal preparation flowsheet, or a mine ventilation network has been simulated. However, if steady state flows through the system are

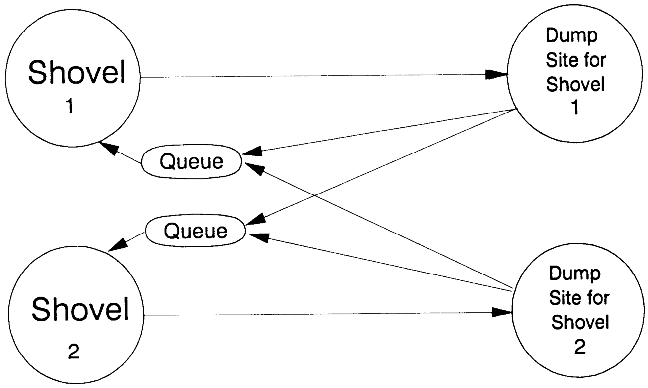

Fig. 9.4.5. System structure for truck haulage example.

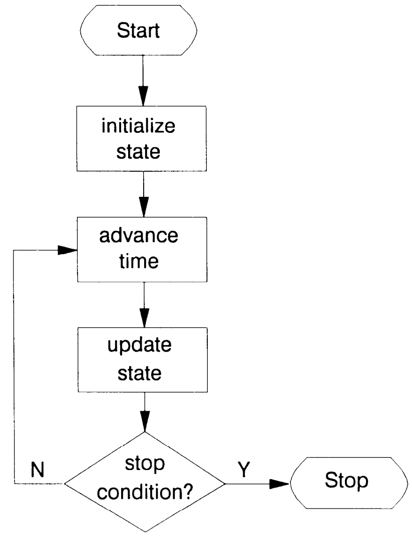

Fig. 9.4.6. Mechanism of a simulation model.

being computed, one is really solving a model expressed as a system of equations in each of these cases. A run has not been executed, generating an artificial history of system behavior. This misnomer arises from the fact that many of the equation-solving techniques used for these models are similar to the run mechanism.

9.4.3.2 How Simulation Models Are Structured
